FIELD FORMS

USGS Field Form 1. Basin Characterization

[Fill out one form for each site. Items in **bold** are required for NAWQA national data aggregation. Circle units of measure where appropriate. Abbreviations in parentheses refer to parameter codes in NWIS or the NAWQA data dictionary file]

1. Study Unit (SUID): __ __ __ __
2. Site type (SITYPE): BFS IFS SYN
3. **Station ID (C001 or STAID): _____**
4. HUC code (C020): _____
5. Station name (C900):_____

6. Reference location: longitude (C010): _____ latitude (C009): _____
   elevation (meters above NGVD) (C016): _____

7. State FIPS code (C007):_____
8. County FIPS code (C008): _____
9. State (STATE): _____
10. County (COUNTY):_____
11. Township (TWN): _____ 12. Range (RANGE): _____ 13. Section (SEC): _____

14. Quad topographic sheets covering basin (QUAD):

Quad name	Scale	Year

15. File name(s) and path where these data can be found:
_____

16. Contact person for site and basin data: _____

17. Total drainage area (C808): _____ square kilometers square miles
Contributing drainage area (C809): _____
18. Drainage area method (DRAREAMD): map year _____
Computation method list (circle one): manual vector raster
Source-map-scale list (circle one): 1:24k 1:48k 1:100k 1:250k
19. Average annual runoff (RUNOFF): _____ centimeters inches
20. Average annual runoff method (RUNOFFMD): GAGE WTGAGE REFERENCE OTHER _____
21. Length of record for average annual runoff: Beginning year (BYRUNOFF) _____
Ending year (EYRUNOFF) _____
22. Average annual air temperature (TEMP): _____ °C
23. Average annual air temperature method (TEMPMD): THIESSEN NEIGHBOR ISOHYET REFERENCE AVG KRIG OTHER _____
24. Length of record for average annual air temperature:
Beginning year (BYTEMP) _____
Ending year (EYTEMP) _____
25. Average annual precipitation (PRECIP): _____ centimeters
26. Average annual precipitation method (PRECIPMD): THIESSEN NEIGHBOR ISOHYET REFERENCE AVG KRIG OTHER _____
27. Length of record for average annual precipitation:
Beginning year (BYPRECIP) _____
Ending year (EYPRECIP) _____

28. Average annual Class A pan evaporation (EVAPAN): _____ centimeters inches
29. Average annual evaporation method (EVAPANMD): THIESSEN NEIGHBOR ISOHYET REFERENCE AVG KRIG OTHER _____
30. Length of record for average annual Class A pan evaporation:
    Beginning year (BYEVAPAN): _____ Ending year (EYEVAPAN): _____

31. Basin length (BLENG): _____ kilometers miles
32. Basin length method (BLENGMD): map year _____
    Computation-method list (circle one): manual vector raster
    Source-map-scale list (circle one): 1:24k 1:48k 1:100k 1:250k
33. Minimum elevation in the basin (MNELEV):_____ meters above NGVD (above datum > 0.0; below datum < 0.0)
34. Minimum elevation method (MNELEVMD): map year _____
    Computation-method list (circle one): manual vector raster
    Source-map-scale list (circle one): 1:24k 1:48k 1:100k 1:250k
35. Maximum elevation in the basin (MXELEV): _____meters above NGVD (above datum > 0.0; below datum < 0.0)
36. Maximum elevation method (MXELEVMD): map year _____
    Computation-method list (circle one): manual vector raster
    Source-map-scale list (circle one): 1:24k 1:48k 1:100k 1:250k
37. Basin relief ratio (RELRAT): _____
38. Drainage shape (DRNSHAPE): _____
39. Stream length (SLENG): _____ kilometers (> 0.0)
40. Stream length method (SLENGMD): map year _____
    Computation-method list (circle one): manual vector raster
    Source-map-scale list (circle one): 1:24k 1:48k 1:100k 1:250k
41. Cumulative perennial stream length (PSLENG): _____ kilometers (> 0.0)
42. Cumulative perennial stream length method (PSLENGMD): map year _____
    Computation-method list (circle one): manual vector raster
    Source-map-scale list (circle one): 1:24k 1:48k 1:100k 1:250k
43. Drainage density (DRNDENS): _____ $kilometers^{-1}$
44. Drainage texture (DRNTEX): _____ contours/kilometer (> 0.00)
45. Entire stream gradient (SLOPE): _____ meters/kilometer
46. Estimated flow characteristics:
    Beginning period of record (QBDATE): _____ Ending period of record (QEDATE): _____

Recurrence interval (in years)	Peak flow (m^3/s ft^3/s)		Flood volume (m^3 ft^3)		7-day low flow (m^3/s ft^3/s)	
1	_____	(QP1)				
2	_____	(QP2)	_____	(QV2)	_____	(Q7L2)
5	_____	(QP5)	_____	(QV5)	_____	(Q7L5)
10	_____	(QP10)	_____	(QV10)	_____	(Q7L10)
25	_____	(QP25)	_____	(QV25)	_____	(Q7L25)
50	_____	(QP50)	_____	(QV50)	_____	(Q7L50)
100	_____	(QP100)	_____	(QV100)	_____	(Q7L100)

47. Method(s) for estimating streamflow characteristics, such as from gaging-station data or list references if State or regional equations were used (FLOWMD):

_____

USGS Field Form 2. Segment Characterization

[Fill out one form for each site. Items in **bold** are required for NAWQA national data aggregation. Circle units of measure where appropriate. Abbreviations in parentheses refer to parameter codes in the NAWQA data dictionary]

1. Study Unit (SUID): __ __ __ __ **2. Station ID (C001 or STAID):** _____

3. Station name (C900): _____

4. EPA RF3 segment code (SEGCODE): _____

5. Location of segment boundaries (degrees, minutes, seconds):
Upstream end: latitude (USLAT) _____ longitude (USLONG) _____
Downstream end: latitude (DSLAT) _____ longitude (DSLONG) _____

6. Segment boundary location method (LOCMD): map year _____
Computation-method list (circle one): manual field GIS-vector GIS-raster
Source-map-scale list (circle one): 1:24k 1:48k 1:100k 1:250k

7. Segment length (SEGLENG): _____ kilometers meters miles feet

8. Segment length method (SEGLENMD): map year _____
Computation-method list (circle one): manual field GIS-vector GIS-raster
Source-map-scale list (circle one): 1:24k 1:48k 1:100k 1:250k

9. Curvilinear channel length and distance to reference locations (upstream is negative, downstream is positive):
Upstream end (USDIST): _____ kilometers meters miles feet
Downstream end (DSDIST): _____ kilometers meters miles feet
Total curvilinear channel length (SEGCUR): _____ kilometers meters miles feet

10. Curvilinear channel length method (SEGCURMD): map year _____
Computation-method list (circle one): manual field GIS-vector GIS-raster
Source-map-scale list (circle one): 1:24k 1:48k 1:100k 1:250k

11. Upstream and downstream elevation above NGVD:
Upstream end (USELEV): _____ meters feet
Downstream end (DSELEV): _____ meters feet

12. Elevation method (SELEVMD): map year _____
Computation-method list (circle one): manual field GIS-vector GIS-raster

8.1 Introduction

8.1.1 History of the USLE (Universal Soil Loss Equation)

Conservation of soil and water requires both knowledge of the factors affecting these resources, and methods for controlling those factors to preserve those resources. Over the years, field, plot and small watershed studies have provided much valuable information regarding the complex factors and interactions involved in the environmental operations of land use and farming. These studies are the basis of the Universal Soil Loss Equation (USLE), which is a conservation planning tool that has been demonstrated to do a reasonably good job of estimating erosion for many disturbed-land uses. Predicting soil loss associated with modern land use is based on guidelines developed from research information in combination with additional experience from many sources. Information from empirical experiments and physically-based principles both assist in effective conservation planning.

The process of pulling together research results and experiences from agricultural practices began with Hugh Hammond Bennett (Helms, 2008), who was undoubtedly the most influential soil conservationist in the US. His early efforts led to his recognition as the 'father of soil conservation'. Bennett's early preaching against the menace of soil erosion led to Congressional action in 1929 establishing ten experimental stations, primarily in the cultivated agricultural areas of the US (Meyer & Moldenhauer, 1985; Renard, 1985). Later expansion of the research programmes included a large number of plots, crops, and management conditions that ultimately resulted in over 10,000 plot-years of data, collected over seven decades. Most of the plots involved the familiar dimensions 6.0 ft (1.8 m) wide by 72.6 ft (22.1 m) long, or a plot 35 ft (10.7 m) long used for some rainfall simulator studies. These plots simplified the computing of runoff and erosion on a per unit area basis (0.01 acre for the 6 × 72.6 ft or nominally 40 m^2 for the 1.8 × 22.1 m). Typical plot configurations were described in Brakensiek *et al.* (1979) and Laflen and Moldenhauer (2003).

In 1954, the National Runoff and Soil Loss Data Center was established by the US Department of Agriculture – Agricultural Research Service (USDA-ARS) at Purdue University in West Lafayette, Indiana. The Center was established to provide a central location for compiling and analysing soil erosion data collected from studies throughout the US. The Center, under the direction of W.H. Wischmeier, was responsible

Handbook of Erosion Modelling, 1st edition. Edited by R.P.C. Morgan and M.A. Nearing.

for summarizing and analysing the more than 10,000 plot-years of soil erosion and runoff data mentioned above, which resulted in the USLE (Wischmeier & Smith, 1965, 1978).

It has now been more than 50 years since the first releases of erosion prediction technology based on what have become widely known as the factors affecting sheet and rill erosion and, ultimately combining those in the USLE. Table 1 in Laflen and Moldenhauer (2003) gives an excellent synopsis of the published chronology of soil erosion prediction technology in the US.

The USLE and its predecessors were meant as field-level conservation planning rather than research tools, and were therefore structured to be 'user friendly' for USDA programmes in the Soil Conservation Service (SCS) (now the Natural Resources Conservation Service (NRCS)), and designed for tailoring erosion-control practices to the needs of specific fields and farms. The USLE was a 'paper-based' model where factors were found in printed tables and charts, and calculations were done by hand.

> "Had digital computers been available in the 1940s when erosion became recognized as a national problem, current prediction methods might more closely mimic the theory contained in Ellison's classic paper (1947) than the current empiricisms of the USLE." (Renard, 1985: 5)

What follows is a description of the evolution of the USLE–RUSLE effort, beginning with the improvements over the USLE leading to the RUSLE1 computer program and publication of the USDA Agriculture Handbook No. 703 (Renard *et al.*, 1997). We will then describe the development of RUSLE2, leading to its release in 2004 and its continuing documentation. The final section of this chapter will examine continuing and possible future developments of the technology.

8.1.2 USLE/RUSLE factor values

The fundamental concept in establishing factor values in the USLE was the Unit Plot. This conceptual plot was composed of a land parcel 72.6 feet (22.1 m) in length with a 9% slope, maintained in a continuous, regularly tilled fallow condition with up-and-down hill tillage, thereby representing a condition very near the worst-case management. Such a plot was used as a base condition to which all other topographic, cropping, management and conservation practices were compared. Data from plots with different slopes, lengths and crops were adjusted to the unit plot, and compared across locations to establish reliable factor values. Benchmark soil erodibility and other terms (rainfall, slope length, slope steepness, cover-management and the support practice factors) used in the USLE/RUSLE have evolved over the years from data derived for varied conditions. Few if any unit plots were ever actually developed, but the concept was used to determine how the conditions of actual plots related to the unit plot.

The USLE soil loss equation is:

$$A = R\,K\,L\,S\,C\,P \qquad (8.1)$$

where A is the computed soil loss per unit area, expressed in the units selected for K and for the period selected for R (in common practice these are usually selected such that they compute A, soil loss in US tons per acre per year); R, the rainfall and runoff factor, is the number of rainfall erosion index units, plus a factor for runoff from snowmelt or applied water where such runoff is significant; K, the soil erodibility factor, is the soil loss rate per rainfall erosion index unit for the specified soil under Unit Plot conditions; L and S are the slope length and steepness factors in relation to the conditions on a unit plot; C, the cover and management factor, is the ratio of soil loss from an area with specified cover and management to that from an identical area under the tilled continuous fallow Unit Plot conditions (C thus ranges from a value of zero for completely non-erodible conditions, to a value of 1.0 for the worst-case Unit Plot conditions); and P, the support practice factor, is the ratio of soil loss with a support practice like contouring, stripcropping, or terracing to that with straight-row farming up and down slope.

Because the USLE was based on empirical erosion data collected from relatively small plots or subwatersheds on relatively uniform hillslopes, the resulting erosion estimates were limited to similar situations. In essence, these results did not

include any impact (either erosion or deposition) of the concentrated flow channels that form in the natural swales at the bottom of the roughly planar hillslopes, and certainly did not address classical gullying processes that often occur at steep boundaries such as headcuts and sidewall sloughing.

Use of the plot data to establish values for the factors above began with an analysis of rainfall erosivity by correlating the erosion measured under Unit Plot conditions with a whole series of measured rainfall values. A very strong correlation was found between this worst-case erosion and a combination of two rainfall factors, namely the total storm energy E and the maximum storm 30-minute intensity, or I_{30} (Wischmeier, 1959). The R factor was then calculated by summing over the calendar year the $E \cdot I_{30}$ values for all storms of over 12 mm (0.5 in.) or with more than 6.5 mm (0.25 in.) falling in 15 minutes, and taking the average of those annual values over all years of record. The soil erodibility (K) values were then determined for Unit Plot conditions ($C = P = LS = 1.0$) solving for K using measured A and R values. With the K values in hand, the values for C, P and LS could be determined by replicated plot studies on similar soils using different management practices or topographies.

Techniques for determining factor values to insert in the USLE (Equation (8.1)) were first presented for general use in the USDA's Agriculture Handbook No. 282 (Wischmeier & Smith, 1965). As use of this technology expanded and new studies were carried out to fill gaps and address weaknesses, new data were incorporated into the USLE, resulting in the second and most widely known release of the USLE technology in the USDA's Agriculture Handbook No. 537 (AH537) (Wischmeier & Smith, 1978). The values for the USLE factors as presented in AH537 were generally created to represent an average annual basis, although the form of the relationship does not demand that. The exception to this was the C factor, which was recognized as changing substantially through the year, leading to the cropping-period approach presented in AH537.

Following the release of AH537, the USLE became very widely used, both within the US and internationally. Perhaps its most common use was as one of the primary tools of the USDA Soil Conservation Service for conservation planning on agricultural lands. As use of the USLE expanded and it was applied in other situations, like disturbed forest lands (Dissmeyer & Foster, 1981, 1984), limitations of the technology became apparent. At the same time, continuing soil erosion research on both natural plots and under simulated rainfall led to improved understanding of the physical processes involved in hillslope sheet and rill erosion. Recognized limitations and advancements in erosion science pointed to the need for updating the USLE.

8.2 RUSLE

8.2.1 RUSLE1 development

In 1985, scientists and engineers from the USDA-ARS and the USDA Soil Conservation Service and affiliated academics with expertise in soil erosion assembled in West Lafayette, Indiana. At that workshop, two important decisions evolved, including the need to (1) develop technology to replace the USLE with a physically-based model (subsequently called the Water Erosion Prediction Project or WEPP); and (2) to computerize and update the 1978 version of the USLE with an improved model, subsequently called the Revised USLE or RUSLE. All subsequent material in this chapter is directed to a description and analysis of the various portions of the RUSLE effort, including both RUSLE1 and RUSLE2.

The first version of RUSLE1, a software program designed to operate in a DOS-based computer environment, was released in 1997. RUSLE1 was supported by USDA-ARS through Agriculture Handbook No. 703 (AH703) (Renard *et al.*, 1997). The computer system soil erosion model described therein was a major conversion of the factor approach presented in AH537. Perhaps the most significant change was the subfactor approach to the calculation of the cover-management factor C, thereby allowing use of RUSLE1 for any land use that could be adequately addressed by these subfactors. This broke the previous bonds of the

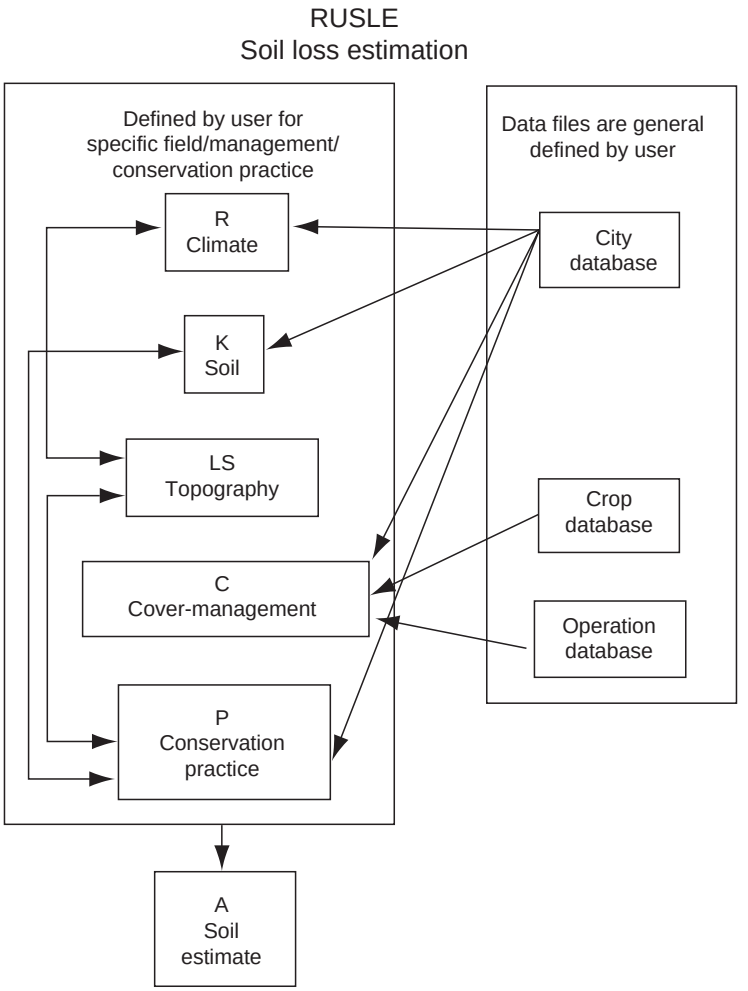

Fig. 8.1 RUSLE1 software flow chart (from AH703).

USLE to agricultural settings, as described in some detail below. The new AH703 development took an appreciable amount of effort involving scientists and engineers with experience in areas of knowledge representing each factor. It also involved a significant amount of testing by SCS-NRCS personnel in various locations, each having specific expertise in the crops, soils and climates involved. The DOS program developed for the 1997 RUSLE1 version permitted English unit calculations only. To input or output metric units required hand conversions of individual factor values using conversion factors (Foster *et al.*, 1981) which were included in Appendix B of AH703.

Another change in the RUSLE1 approach was to begin grouping the expanded list of required user inputs into a crude database, defined as shown in Fig. 8.1. This allowed for saving and re-use of sets of inputs corresponding to, for example, a specific location. In addition to the computerization of the model, every USLE factor underwent significant changes in moving to RUSLE1. These changes are generally described in the paragraphs that follow.

(i) Rainfall erosivity factor (*R*) The most common way of presenting rainfall erosivity information in the US has been through the use of isoerodent maps, allowing the reader to interpolate the corresponding *R* value for a specific location. The isoerodent maps in AH703 were calculated using the same criteria as in AH537, namely summing the storm kinetic energy times the maximum 30-minute intensity for storms larger than 0.5 in (12 mm), unless at least 0.25 in (6.5 mm) fell in 15 min. These calculations were computed for all non-snow storms within a period of *N* years. Normally at least 22 years of storms were included for the calculations (see AH537 for details), but longer periods are advisable when the coefficient of variation of annual precipitation is large. A total of 181 key precipitation locations with 15-min data were used for the map in AH537, and a few additional locations to fill in gaps were added to produce Figure 2.1 in AH703. AH537 included very little erosivity information for the western US, with only 11 western station isoerodent values used to estimate the two-year 6-h precipitation amount. A power relationship developed by Wischmeier (1974) to fit those values provided some measure of the expected erosivity, but the results were not thought to be very accurate, or to reflect adequately the known intermontane climate variability. Through an agreement between Oregon State University, USDA-ARS, USDA-SCS and the National Weather Service, data from 713 stations with 15-min measurement intervals were used to calculate *EI* values, and thereby to construct new isoerodent maps for the western US in AH703, although all storms were included in the western erosivity calculations (excluding snow). Analysis of these records showed that 225 precipitation-measuring locations had records longer than 12 years and precipitation resolutions of 0.01 in. (0.25 mm). Values of the coefficient of determination (R^2) in excess of 0.8 were obtained with the model $EI_{15} = b(EI_{60})$. Values of the regression parameter *b* ranged from 1.08 to 3.16, varying widely among climate zones.

To supplement this work, 1082 hourly stations were used to calculate EI_{60}. Of these stations, 790 had record lengths of 20 years or longer. These data were adjusted to a 15-min measurement interval using the cited correction. *R* factors were also adjusted to equivalent break-point data using the Weiss (1964) relationship $R = 1.0667\ (R_{15})$. The isoerodent map was prepared by hand contouring on large-scale maps, reflecting the major topographic influences in mountain and range topography. The newer isoerodent maps (Figures 2-2, 2-3 and 2-4 of AH703) were thus felt to be a significant improvement over those in AH537.

In addition, seasonal *EI* distributions were developed for 84 climate zones in the western US (Fig. 2-7, AH703). The distributions were developed for calculating the time-varying *C* factor in RUSLE1, building on the crop growth stage approach found in AH537.

City database files were then developed in RUSLE1 to provide the climatic data needed for erosion calculations. This included the *R*-factor value, the *EI* distribution values for 24 bimonthly periods, and the 10-yr frequency storm maximum *EI* that was needed for calculating the *P* factor credit for contour farming. Maps of these values were calculated for precipitation gauge locations and are presented in Figures 2-9 to 2-12 in AH703.

Two additional modifications to the classical USLE *R*-factor approach were included in RUSLE1 to address specific geographical needs. In areas with very low relief and high rainfall intensities (such as in the Mississippi River delta), research has found that runoff ponds to substantial depths before running off, and that this ponded water absorbs some of the raindrop impact that could cause detachment (Mutchler, 1970). Based on these data, RUSLE1 included a term to adjust downwards the erosivity experienced by the soil, based on slope steepness and rainfall erosivity (taken as a surrogate for intensity). The other modification to the *R* factor was for frozen and thawing soils, encountered in the Pacific Northwest (Northwest Wheat and Range Region (Austin, 1981)), and in some of the southern plains of Canada. In these cases, a soil with much weakened structure exposed to even a low-erosivity event will experience high erosion rates, so an

alternative means of selecting an equivalent *R* value for these conditions was included in RUSLE1.

(ii) Soil erodibility factor (*K*) The soil erodibility factor (*K*) represents the effect of soil properties and soil profile characteristics on soil loss (see Chapter 2 in Renard *et al.*, 1997). In a practical sense, *K* is a lumped parameter representing an integrated annual average of the soil and profile reaction to erosion and hydrological processes. The processes consist of soil detachment and transport by raindrop impact and surface flow, deposition due to topography and tillage roughness and rain infiltration into the soil profile.

The best erodibility factors are obtained from long-term direct soil-loss measurement on natural plots. Rainfall simulation data has also been used, but is recognized as being less accurate (Römkens, 1985). Only inherent soil properties are considered determinants of the USLE soil erodibility factor, which means that soil erodibility must be measured under the Unit Plot conditions described earlier. The minimum adequacy of the observation period for soil erodibility was usually taken as two years, but longer periods provide better results due to the likelihood of experiencing a broader range of climatic and soil conditions. Most of the plots used in measuring soil erodibility were in the Midwestern cropping areas of the US (see Table 3.1 in Renard *et al.*, 1997).

In most cases, US RUSLE1 users will have little trouble in selecting specific *K* values, because NRCS has identified values for most major soil mapping units. Site-specific values can be obtained from the widely available NRCS soil surveys, or directly from USDA soil databases. If such data are not available, the erodibility nomograph (Fig. 8.2), based on a relationship fitting the data as described above, is the most commonly used tool to estimate *K*, although there are some soils where it does not apply, and one of the site-specific relationships for specific soils (Renard *et al.*, 1997: 75) may be a better choice in the US. Users should contact their NRCS state soil scientist or other local soil specialist to certify the value to be used for their location. In other areas of the world, users may have to resort to soil sampling and the use of Fig. 8.2.

(iii) Topography factors (*LS*) There are more questions and concerns about the *LS* topographic factor than for any other term in RUSLE. The primary reason for these concerns is that the choice of slope length involves substantial judgment; different users choose different slope lengths for similar situations. The two primary questions here are what hillslope (downslope runoff path) to use to represent an area, and how then to define that hillslope in terms of specific length and steepness values. The first question is really one of policy rather than science (do we choose the worst-case hillslope, or the median slope, or some other?), while the second question is a more technical yet qualitative one of how to define where runoff begins, the path it takes down the slope and when it reaches a concentrated flow channel, thus ending the hillslope. The attention given to slope length is not always warranted because soil loss is often less sensitive to slope length than to any other USLE/RUSLE factor. For typical slope conditions, a 10% error in slope length results in a 5% error in computed soil loss. In contrast, soil loss is much more sensitive to changes in slope steepness than to errors in slope length. In the USLE, for example, a 10% error in slope steepness will usually give about a 20% error in computed soil loss. RUSLE has a more linear slope steepness relationship than did the USLE. Improvements in the relationship for steep slopes mean that computed soil loss for slopes less than 20% are similar in RUSLE and USLE, but on steep slopes, computed soil loss in RUSLE is just over half that predicted by the USLE, whose relationship did not include data for steep slopes. In addition, RUSLE makes more explicit the reliance of the length relationship on the susceptibility of the soil to rilling, which may be influenced by the slope steepness, soil characteristics, and management impacts. Finally, RUSLE includes a slope relationship specifically for the frozen soil region of the Northwest Wheat and Range Region (Austin

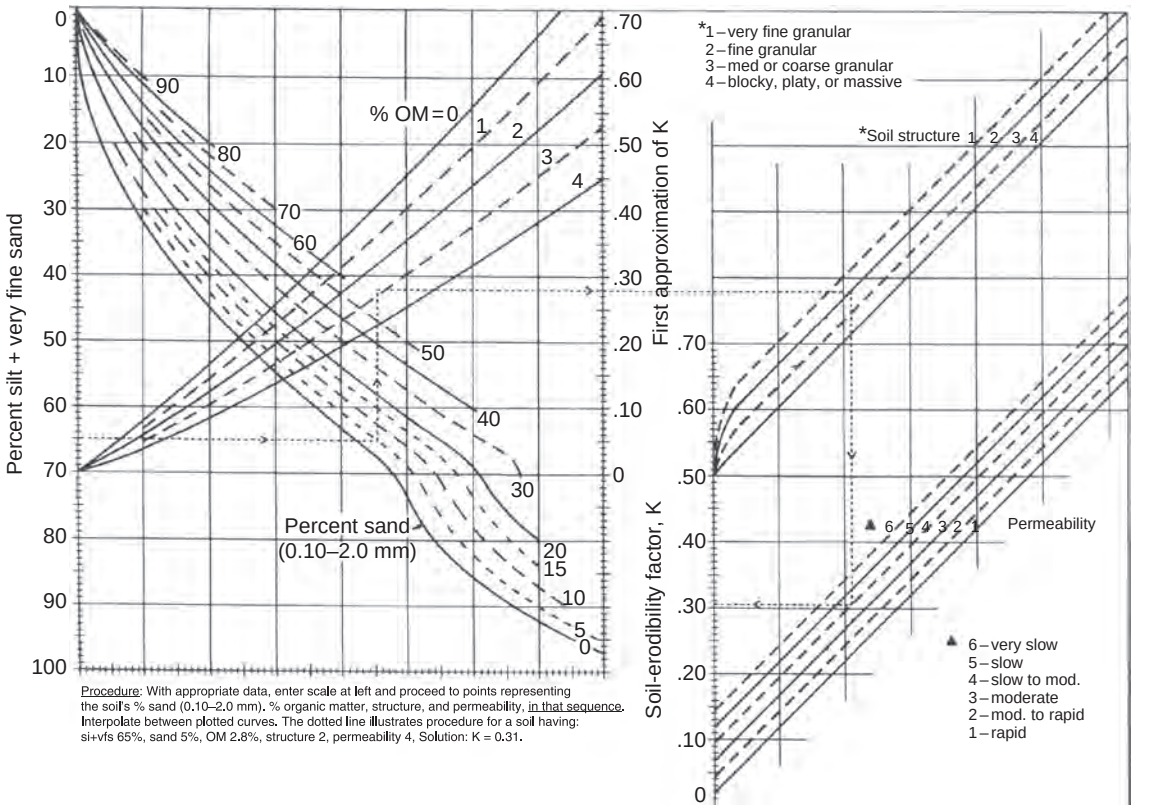

Fig. 8.2 The soil erodibility nomograph that gives *K* in US Customary Units (see Wischmeier & Smith, 1978).

1981). Detailed information on the selection of slope calculations is given in AH703 Chapter 4.

The difficulty in defining slope length is, however, substantial enough to have served as the primary impediment for employing GIS-based systems in using RUSLE. The topographic data available to populate GIS databases generally does not have the spatial resolution necessary to pick out the small concentrated flow channels commonly found at the bottom of a USLE/RUSLE hillslope. As a result, slope lengths computed using these data are almost always far too long. In fact, most attempts to use GIS with USLE/RUSLE recognize this and simply cut off the slope lengths at some arbitrary value. This poor resolution also causes the GIS system to miss the flat floodplains often found at the bottom of a hillslope, where substantial deposition may occur. This may change as higher-resolution topographic data (such as those collected using Lidar) become available, although how best to use these extensive datasets must still be decided.

In using the USLE, the slope length was defined as beginning at the top of the hillslope where runoff starts, and extending down to where the sheet and rill flow reaches either a concentrated flow channel or a depositional area. This limit of the depositional area was required because such deposition rarely occurred on the plots used to collect USLE data. Deposition can be caused by anything that slows the runoff and causes sediment to deposit, such as an increase in roughness caused by a management change (e.g. a strip of dense vegetation), or a decrease in slope grade.

In RUSLE1, this definition was expanded slightly to include areas of deposition caused by management changes on the hillslope, which was accomplished by including some of the more process-based routines used in CREAMS (Foster *et al.*, 1980).

Slope length factor (L) Plot data used to derive slope length (L) show that erosion for slope length λ (ft) varies as:

$$L = (\lambda/72.6)^m \qquad (8.2)$$

where 72.6 = the RUSLE unit plot length (ft) and m is a variable slope length exponent. The slope length λ is the horizontal projection. The value for m can be found from $m = \beta/(1 + \beta)$, where the slope-length exponent β is related to the ratio of rill erosion (caused by overland flow) to inter-rill erosion (principally caused by raindrop impact). The ratio of rill to inter-rill erosion when the soil is susceptible to both rill and inter-rill erosion is:

$$\beta = (\sin\theta/0.0896)/[3.0(\sin\theta)^{0.8} + 0.56] \qquad (8.3)$$

where θ is the slope angle. For a value of β, the slope-length exponent m is calculated using the relation above. When runoff, soil, cover, and management conditions indicate that the soil is highly susceptible to rill erosion, the exponent should be increased (see AH703, Chapter 4). These conditions are expected, for example, for steep, freshly prepared construction slopes. In such cases where the soil is highly susceptible to rilling, AH703 recommended doubling the value of β resulting from Equation (8.3). When conditions favour more inter-rill and less rill erosion, as in cases of consolidated soils like those found in no-till agriculture, m should be decreased by halving the β value. A low rill to inter-rill erosion ratio is typical of conditions on rangelands. With thawing, and cultivated soils dominated by surface flow, a constant value of 0.5 should be used (McCool *et al.*, 1989, 1993). In RUSLE1 the choice between these alternatives was made by selecting a general land-use category; in RUSLE2 the program automatically and continuously adjusts the m value based on slope steepness, soil type and management impacts.

Slope steepness factor (S) Soil loss increases more with steepness than with slope length. In RUSLE, the slope steepness has changed from that used by the USLE, and is evaluated with the relationship (McCool *et al.*, 1987):

$$S = 10.8 \sin\theta + 0.03 \quad S<9\% \qquad (8.4)$$

$$S = 16.8 \sin\theta - 0.50 \quad S>9\% \qquad (8.5)$$

The relationship is based on the assumption that runoff is not a function of slope steepness for slopes greater than 9%. Slope effect on runoff and erosion as a result of mechanical disturbance, cover and vegetation is considered in the cover-management (C) or support practice factor (P). For slopes shorter than 4.6 m (15 ft), use:

$$S = 3.0 (\sin\theta)^{0.8} + 0.56 \qquad (8.6)$$

Equation (8.6) applies to conditions where the water drains freely from the slope end. For the slope steepness factor above, it is assumed that rill erosion is insignificant on slopes shorter than 4.6 m (15 ft), and that inter-rill erosion is independent of slope length.

When freshly tilled soil is thawing, in a weakened state and primarily subjected to surface flow, use the following (McCool *et al.*, 1993):

$$S = 10.8 \sin\theta + 0.03 \quad S<9\% \qquad (8.7)$$

$$S = (\sin\theta/0.0896)^{0.6} \quad S>9\% \qquad (8.8)$$

In most practical applications, a single plane or uniform slope can be a poor representation of the hillslope topography, and erosion can vary greatly between concave or convex slopes of equal average steepness. Users are cautioned and encouraged to use the complex slope calculations, because differences can be significant when contrasted with a uniform plane.

Actual selection of the hillslope used to represent a field can be a complicated choice, and is best done through examples rather than verbiage. Additional detail and guidance for field measurement of the *LS* factor for varying field scenarios is given in AH703.

Cover-management Factor (C) The cover-management factor, *C*, is possibly the most important of the RUSLE/USLE factors because it represents the most readily managed condition for reducing erosion. In the USLE, the *C* factor was described as providing a measure of how erosion from the current condition compares with that for the Unit Plot condition, which is considered as nearly worst-case. The individual values of *C* vary between 0 for a completely non-erodible condition, to a value somewhat greater than 1.0. Values greater than 1.0 imply conditions more erodible than those normally experienced under Unit Plot conditions, which can occur for conditions with very extensive tillage (e.g. roto-tilling), leaving a very smooth surface that produces much runoff and makes the soil especially susceptible to erosion. *C* values are weighted average soil-loss ratios (SLRs), each of which represents the ratio of soil loss under current conditions for a short period of time to the expected soil loss under Unit Plot conditions during that same period. The SLRs vary throughout the year as soil and cover conditions change with soil disturbance and plant growth. The *C* value then represents the average of the time-varying SLR values, each weighted by the portion of rainfall erosivity during that same time period.

In contrast to the tables of *C* factors presented in AH282 and AH537, RUSLE1 uses a subfactor method to compute SLRs as a function of five factors:

$$C = PLU \cdot CC \cdot SC \cdot SR \cdot SM \qquad (8.9)$$

where *C* is the overall cover-management factor, *PLU* is the prior landuse subfactor, *CC* is the canopy cover subfactor, *SC* is the surface cover subfactor, *SR* is the surface roughness subfactor, and *SM* is the soil moisture subfactor (used only in the Northwest Wheat and Range Region area (Austin, 1981), otherwise unity). Expanded details for evaluating *C* factors are presented in AH703.

Although ground cover is known to affect erosion more than the other subfactors, it is wrong to give it exclusive attention without considering within-soil effects such as those associated with root mass and tillage. A 30% surface cover after planting is the criterion frequently used for conservation tillage; the USLE relationships predict that this 30% cover will reduce soil loss by about 72%. By comparison, the soil loss for a freshly ploughed meadow is reduced by about 75% from that for Unit Plot conditions, showing that within-soil effects can have a substantial impact. Although the effects are not as pronounced, the impacts of canopy cover and surface roughness can also provide substantial benefits, especially in the absence of surface cover.

The structure of Equation (8.9) implies that the effects of subfactors in reducing erosion are multiplicative. For example, if there is a canopy cover that reduces erosion by 45% from Unit Plot conditions, this means that $CC = 0.55$. If there is also enough surface cover to reduce erosion by 60% from Unit Plot conditions ($SC = 0.4$), then assuming all other factors are under Unit Plot conditions ($PLU = SR = SM = 1.0$), the overall factor value would be $C = 0.55 \times 0.4 = 0.22$, or a 78% reduction in erosion from Unit Plot conditions.

The subfactor approach in RUSLE1 was designed to break the dependence of the USLE structure on specific land-use data. Without this break, calculations would require separate complete and expensive datasets for each possible combination of land uses. The subfactor analytical approach was carried out under the basic assumption that the erosion impact of various factors such as surface cover and roughness is really independent of the type of land management controlling that factor. For example, the impact of covering the surface with straw mulch and of growing grass should be relatively independent of whether this is done as part of normal agricultural field operations or to control erosion on construction sites. Under this assumption, we start with the relationships to estimate erosion

based on the parameters that control the subfactors for surface cover, biomass and roots in the soil, surface roughness, vegetative canopy cover, and soil moisture. Once those relationships are developed using field data, if the RUSLE1 program can model the effect of any field management operation on those parameters (soil, vegetation, biomass), it should be able to model the resulting erosion.

The subfactor approach and the equations controlling it are described in great detail in AH703. What follows is a brief introduction to the subfactors included in RUSLE1.

Prior land-use subfactor (PLU) The *PLU* subfactor is calculated in RUSLE as the product of soil consolidation and soil biomass effects:

$$PLU = C_f \cdot C_b \cdot \exp\text{-}[(c_{ur} \cdot B_{ur}) + (c_{us} \cdot B_{us}/C_f^{cuf})] \quad (8.10)$$

where *PLU* is the prior land-use subfactor (ranging from 0 to 1), C_f is a surface-soil-consolidation factor, C_b represents the relative effectiveness of subsurface residue in consolidation, B_{ur} is the mass density of live and dead roots in the upper 100 mm (lb acre^{-1} in^{-1}), B_{us} is the mass density of incorporated surface residue in the upper 100 mm of soil (lb acre^{-1} in^{-1}), C_{uf} represents the soil consolidation impact on the effectiveness of incorporated residue, and c_{ur} and c_{us} are calibration coefficients indicating subsurface residue impacts.

The B_u variables calculate the impact on erosion rates of live and dead roots and incorporated residue. The effectiveness of such materials can take two forms. Firstly, roots and residue can control erosion directly by physically binding soil particles together and acting as mechanical barriers to soil and water movement. Secondly, roots and residue exude binding agents and serve as a food source for micro-organisms that produce other organic binding agents. These serve to increase soil aggregation and thereby reduce susceptibility to erosion. The RUSLE software keeps track of the biomass in each layer, continuously adjusting the rootmass and subsurface residue to account for residue additions or losses by decomposition.

Canopy cover subfactor (CC) The canopy-cover subfactor indicates the effectiveness of the vegetative canopy in reducing the energy of rainfall striking the soil surface. Although most of the rainfall intercepted by canopy eventually reaches the soil surface, it usually does so with much less energy than rainfall directly striking the ground. The intercepted drops fracture into smaller drops, or drip from leaf edges, or travel down crop stems to the ground. The canopy-cover effect is given as:

$$CC = 1 - F_c \cdot \exp(-0.1 \cdot H) \quad (8.11)$$

where *CC* is the canopy-cover subfactor ranging from 0 to 1, F_c is the fraction of land surface covered by canopy, and H (ft) is the distance that raindrops fall after striking the canopy.

Surface cover subfactor (SC) Surface cover affects erosion by reducing the transport capacity of runoff, by causing deposition in ponded areas, and by decreasing the surface area susceptible to raindrop impact. This is perhaps the single most important factor in lowering SLR values. Surface cover includes crop residue, rocks, cryptogams, and other non-erodible and non-mobile material in direct contact with the soil surface. The effect of surface cover on soil erosion is given as:

$$SC = \exp[-b \cdot S_p (0.24 / R_u)^{0.08}] \quad (8.12)$$

where *SC* is the surface cover subfactor, b is a coefficient, S_p is the percentage of land area covered by surface cover, and R_u is the surface roughness, as will be defined later.

Land area percentage covered by residue can be estimated from residue weight by the relationship of Gregory (1982):

$$S_p = [1 - \exp(-\alpha \cdot B_s)] \cdot 100 \quad (8.13)$$

where S_p is percentage residue cover, α is the ratio of the area covered by a piece of residue to its

mass (acre lb^{-1}), and B_s is the dry weight of crop residue on the surface (lb ac^{-1}). If more than one type of residue is present, the resulting total surface area cover is calculated as:

$$S_p = \{1 - \exp[-\Sigma (\alpha_i \cdot B_{si})]\} \cdot 100 \qquad (8.14)$$

where α_i is the ratio of area covered to the mass of that residue for each type encountered. The summation is for each type of residue, as each residue type may have a unique α_i value.

Surface roughness subfactor (SR) Surface roughness has been shown to affect soil erosion directly, and also to affect it indirectly through the impact of residue effectiveness as controlled by the *b* value in Equation (8.12). The surface roughness subfactor is a function of the surface random roughness, which is defined as the standard deviation of surface elevations across the slope, when changes due to land slope or non-random tillage marks (such as dead furrows, traffic marks, and/or disk marks) are removed from consideration. A rough surface has many depressions and barriers. During a precipitation event, these trap water and sediment, causing rough surfaces to erode at lower rates than do smooth surfaces under similar conditions. Increasing surface roughness decreases transport capacity and runoff detachment by reducing flow velocity.

Roughness and cloddiness of soils also affect the degree and rate of soil sealing from raindrop impact. Soils that are left rough and cloddy typically have greater infiltration rates. Soils that are finely pulverized are usually smooth, seal rapidly, and have low infiltration rates. RUSLE assumes that roughness decreases with the time since tillage by the relationship:

$$D_r = \exp[\ ½(-0.14\ P_t) + 1/2(-0.012 \cdot EI_t)] \qquad (8.15)$$

where D_r is the dimensionless roughness decay coefficient, P_t is the total inches of rainfall since the most recent soil-disturbing surface operation, and EI_t is the total *EI* amount since that operation.

If the initial roughness is defined as R_i, then surface roughness just before a new tillage operation (R_u) can be defined as:

$$R_u = 0.24 + [D_r (R_i - 0.24)] \qquad (8.16)$$

where R_u is in inches. Since many field operations affect only a portion of the surface, R_u is also the roughness of that field portion left undisturbed by the current operation.

For that surface portion affected by the field operation, the resulting roughness has been found to be a function of subsurface biomass present in the top 4 in. of soil. The relationship is:

$$R_a = 0.24 + (R_t - 0.24) \{0.8\ [1 - \exp\ (-0.0012\ B_u)] + 0.2\} \qquad (8.17)$$

where R_a is the roughness after biomass adjustment (in.), R_t is the original roughness based on the assumption of ample subsurface biomass such as is found with high-yielding US-type corn, and B_u is total subsurface biomass density in the top inch of soil (lb ac^{-1} in^{-1}), with $B_u = B_{ur} + B_{us}$ as used in Equation (8.10).

The adjusted tillage roughness is then combined with that of the undisturbed portion of the surface as follows:

$$R_n = R_a F_d + R_u F_u \qquad (8.18)$$

where R_n is the net roughness following the field operation (in.) and F_d and F_u are respectively the fractions of the surface disturbed and undisturbed, such that their sum equals one.

Similarly, the roughness decay coefficient must be adjusted to reflect that only a portion of the field is disturbed using the relation:

$$D_e = D_r F_u + 1.0 F_d \qquad (8.19)$$

where D_e is the equivalent roughness decay coefficient. RUSLE then reorganizes the relationships described above to calculate the R_t, P_t and EI_t values corresponding to the equivalent roughness decay coefficients, under the assumption of a constant EI_t/P_t ratio. If a site is clean-tilled and left without human intervention, two things will happen: (1) the tillage roughness will decrease as defined previously; and (2) as time passes, vegetation will tend towards its climax

community, with attendant roughness caused by protruding roots, soil pushing up around old basal areas, rocks, and so on. RUSLE assumes that the formation of this vegetative roughness follows a typical sigmoidal growth curve, increasing from the minimum roughness (r_{min} with a default of 0.24 in.) to the total roughness when soil is consolidated (r_{max}) over the time required for consolidation (t_{con}).

Once the current roughness R_u has been defined based on the tillage roughness and all the roughness decay calculations described above, the surface roughness subfactor for this time period is then:

$$SR = \exp\left[-0.66\,(R_u - 0.24)\right] \qquad (8.20)$$

Soil moisture subfactor (SM) In non-irrigated portions of the Northwest Wheat and Range Region (NWRR; Austin, 1981), soil moisture during critical crop periods depends upon crop rotation and management. In such cases, the addition of a soil-moisture subfactor (*SM*) is suggested. *SM* reflects dry fall conditions and increasing soil moisture over winter. The soil moisture decrease during the growing season depends upon crop rooting depth and soil depth, and the soil moisture replenishment during the winter and spring depends upon precipitation amount and soil depth. Research to make such a correction is needed. In most instances this factor is assumed to be unity, which means that there is no substantial impact of soil moisture extraction by the vegetation on erosion. This assumption of $SM = 1.0$ is probably valid for all areas except those experiencing erosion caused by light rains on frozen-thawing soils.

(iv) Conservation practice factor (*P*) It is not always clear how the conservation practice factor (*P*) differs from the cover management factor (*C*), because both are meant to indicate the impact of management practices on erosion. In general terms, the basic difference is that the *C* factor reflects the positive impact over the larger portion of the management area, through factors like vegetation, biomass on the surface or within the soil, and roughness. The *P* factor is generally seen as reflecting the positive impacts of management through the control of runoff, with special emphasis on how the management changes the direction and speed of that runoff, but also reflecting to some degree management practices that control the amount of runoff. Traditionally the *P* factor has been used to reflect the impact of agricultural practices such as the various forms of strip-cropping (buffer strips, filter strips, rotational strip-cropping), terraces, contour tillage, and subsurface drainage. In other land uses, *P* would reflect the impact of analogous practices, such as filter strips for water quality control, or the use of diversions on construction sites. RUSLE1 brought to the USLE structure a subfactor approach for the *P* factor as well as the *C* factor, with separate subfactors for contouring, strips, terraces, and subsurface drainage. As with the *C* factor, these subfactor values are multiplied together to give the overall *P* factor.

Contouring subfactor Data on the effect of contouring show a tremendous amount of scatter, but there are some trends, as shown in Figure 6-2 of AH703. These indicate that higher ridges give more benefit than lower ridges, that contouring is more effective for areas with lower rainfall intensities, and that the effectiveness reaches a peak at about 9% slope, losing effectiveness at lower slopes due to less inherent erosion, and at higher slopes due to potential breakover of the ridges by ponded runoff. In addition, contouring is most effective when the ridges are perfectly on the contour, with its impact decreasing rapidly as the furrows have more grade.

RUSLE1 fits the scattered contouring data with a series of equations used to describe the base contouring *P* value for different slope steepnesses. It then adjusts these for climate and storm intensity using a runoff scaling factor based on the 10-year storm *EI* compared with a value for the central part of the US, and finally adjusts the results based on the contour furrow grade, using the relationship (AH703 eqn. 6-11):

$$P_g = P_o + (1 - P_o)(s_f / s_l)^{1/2} \qquad (8.21)$$

where P_g is the P factor for off-grade contouring, P_o is the P factor for on-grade contouring calculated using the sequence described above, s_f is the grade along the contour furrow, and s_l is the slope grade.

As reflected in the data summarized in tables in AH537, contouring tends to lose effectiveness on very long slopes, as runoff tends to build up behind the contour ridges and cause breakover of the ridges, which can be assumed to make the lower contour ridges ineffective. RUSLE estimates the maximum slope length over which contouring is effective (called the 'critical slope length' in AH703) using a variation on a relationship developed by Foster *et al.* (1982) for mulch stability. Once again, this relationship depends on slope steepness and runoff, and it is calibrated against the critical slope lengths shown in the tables in AH537. RUSLE then gives *P*-factor credit (i.e. reduces the erosion estimate) for the area upslope of the critical length, but not for the downslope area.

Strip-cropping subfactor The impact of management on runoff and its ability to carry sediment is probably the single factor that has changed most in the USLE/RUSLE evolutionary process. As described above, this has included substantial changes in how the hillslope is defined. RUSLE1 included a process-based approach to estimating the amount of deposition caused by changes in management and the resulting slowing of runoff. This started with the definition of a slope segment as being a portion of the topography with constant soil, management, and steepness. The approach taken was a simplified version of the CREAMS approach (Foster *et al.*, 1980), which looks at four possible cases for each slope segment, where a segment is defined: (1) where there is no runoff leaving the segment, so all incoming sediment is deposited; (2) where there is erosion throughout the segment; (3) where there is deposition throughout the segment; and (4) where deposition occurs at the top of the segment and erosion at the bottom. These four cases are examined by calculating the increase in transport capacity within the segment, and comparing that with the amount of additional sediment added by erosion within the segment. This requires estimation of a runoff rate, which in RUSLE1 is based on the ten-year *EI* storm erosivity.

The impact of the deposited sediment on the *P* factor is somewhat subjective, as the *P* factor is meant primarily as a measure of soil resource conservation, while the primary effect of deposition is on sediment delivery. Because sediment deposition does not preserve the soil resource as much as preventing erosion in the first place, RUSLE1 does not give as much conservation credit for practices that cause sediment deposition as for practices that prevent soil erosion. RUSLE1 gives credit for deposition that occurs based on its location on the slope, using the relationship:

$$B = M\,(1 - x^{1.5}) \tag{8.22}$$

where B is the benefit, M is the mass of sediment deposited, and x is the location of the deposition as a fraction of the total distance downslope. This benefit is calculated into the P factor as:

$$P_s = (g_p - B)/g_p \tag{8.23}$$

where P_s is the P factor for strip-cropping, and g_p is the potential sediment load that would occur if there was no deposition.

Terracing subfactor Within RUSLE, terraces (or diversions on construction sites) provide two benefits: (1) they break the hillslope profile into a combination of multiple shorter profiles, thereby reducing erosion; and (2) they cause some deposition to occur up on the hillslope, thereby providing some benefit in conserving the soil resource. The first of these benefits is taken into account through the *LS* topographic factor described above. For the second benefit, RUSLE uses sediment yield data collected on watersheds with terraces to estimate the amount of sediment deposition that will take place, then gives that a credit benefit identical to that described above for the benefit of deposition in strip-cropping.

Subsurface drainage subfactor There are some data that suggest subsurface drainage can be effective in reducing erosion, presumably by reducing soil moisture and thereby decreasing runoff during a storm event (Formanek *et al.*, 1987; Bengtson & Sabbage, 1988). These data show substantial scatter, but indicate an average erosion reduction of about 40% for a subfactor $P = 0.6$.

Sediment delivery estimate As the first step in the evolution from the USLE, RUSLE1 is still primarily geared towards planning based on soil conservation. In spite of this, using the techniques described above for strip-cropping, it does provide a crude sediment delivery estimate. This is done by using a value of $B = M$ in Equation (8.22), providing the ratio of sediment delivered over sediment eroded, or essentially a sediment delivery ratio. Multiplying this P factor for sediment delivery by the other factors then provides the hillslope sediment delivery for evaluating off-site impacts.

8.2.2 RUSLE1 program implementation

The RUSLE1 computer code was written in the C programming language. Chapter 7 in AH703 included a fairly detailed description of the RUSLE1 program layout and operation. This was deemed necessary because as dissemination of and training in RUSLE1 proceeded, it quickly became apparent that a program with this level of complexity could not be assumed to be intuitive to a first-time user. Part of this complexity was inherent in the level of input information required from the user, while an additional portion was due to the program structure. This structure was based on the USLE 'paper' implementation, and hid nothing from the user.

8.2.3 RUSLE1 implementation history and experience

Perhaps the two primary lessons learned from the USDA-NRCS implementation of RUSLE1 were: (1) the importance of an iterative feedback process in developing the program; and (2) the sheer scale of the effort necessary to implement such a model on the national scale. Although these lessons were partially due to the specifics of the situation, they are also broad enough to be instructive to other individuals and groups within or outside the US who are implementing a program like RUSLE. One of the key elements in the development of the RUSLE1 computer program was the close contact between the program developers and a variety of user representatives. Although the development began with defined user requirements, these underwent substantial changes as the program was presented to users through a variety of feedback and training sessions, involving a mixture of skilled and novice users. Only through that iterative feedback process did the program begin to meet the true user needs, as these needs often only became apparent when users were exposed to the program. Based on the RUSLE experience, it simply does not work to introduce a new model under the presumed process of setting initial user requirements and declaring success once those are met.

Although the RUSLE1 computer program itself was first deemed ready for full review and delivery in 1991, the process of developing the database information necessary to allow full implementation took an additional 4–5 years. This included a strong collaborative research effort sponsored by USDA-NRCS and carried out by researchers at North Carolina A&T University, Alcorn State University, and Alabama A&M University to collect the data required for the vegetation descriptions, including especially time-varying data on vegetative canopy cover, rootmass and biomass.

Substantial effort also went into determining exactly how the program would be implemented in the USDA-NRCS field offices, with special attention paid to consistency of results across political boundaries, and consistency of use patterns. One of the important concepts developed during this period was the development of *C*-Factor Zones, which recognized that climatic differences rather than political boundaries controlled the possible management scenarios, leading to shared management descriptions across state lines. National, state and regional NRCS

personnel developed the required management descriptions to describe the bulk of schemes used in these areas, which in turn defined the operation and vegetation descriptions that had to be developed. In other words, broad implementation required both local expertise and substantial cooperation and oversight.

In spite of all the work that needed to be done and all the decisions that needed to be made (and remade!), full NRCS implementation of RUSLE1 began in 1993, using version 1.04 of the program, which is the version represented and documented in far more detail in AH703. This was actively used for conservation planning throughout the US, and for the Conservation Compliance portion of NRCS responsibilities associated with the 1985 and 1990 US Farm Bills.

8.2.4 Science problems with RUSLE1

As the USLE came into general use, it quickly became apparent that the impact of management on erosion could vary greatly among periods within a year or among years within a rotation. This was recognized by the later USLE methods, with AH537 using a time-varying SLR based on cropping periods. RUSLE1 carried this further, using a daily time-step for the *C*-factor calculations, and also for some of the *P*-factor calculations. However, due to user requirements that the structure of RUSLE1 reflect that of a 'paper implementation' of the USLE, this was not carried to its logical extreme. The time-varying values of each of the individual factors were aggregated over the year, and the resulting annual values were multiplied as shown in Equation (8.1). Unfortunately, this aggregated approach is not correct, as the sum of products is not equal to the product of sums, which can be seen in the simple calculation $(2 + 3) \times (4 + 5) = 45 \neq (2 \times 4) + (3 \times 5) = 23$. Clearly, the proper approach was to take any time-varying values and multiply these for each day or period, then add the daily products to get the total erosion. This was recognized as a problem early in RUSLE1 development, but it could not be dealt with while retaining the 'paper implementation' capability. Calculations showed that the erosion results could vary by up to 30% between the two approaches.

8.2.5 RUSLE1 program weaknesses

In addition to the weaknesses inherent in the RUSLE1 science development, some more general weaknesses in the program operation became apparent during implementation.

The first program weakness was that the RUSLE1 structure was based on science rather than on how the user saw things. For example, one parameter used in the *LS* calculations is the soil texture, which affects the susceptibility of the soil to develop rills, thereby impacting the *LS* β value (Equation (8.2)). In spite of this, the user will clearly think of texture as a soil property, and not as something related to topography. This is one of many examples in RUSLE1 where there was a need to approach things more from the user's viewpoint, and not from the modelling viewpoint.

Another weakness of the RUSLE1 approach is that any user could change any database value. Although NRCS had put substantial effort into developing specific databases for climates and vegetations, any user could change the values, either intentionally or by accident. This resulted in many implementation headaches, such that two users using the same inputs would get very different results because one of the underlying database files had been modified.

Finally, the DOS-based interface used in RUSLE1 was already dated at the time of its delivery, and users repeatedly asked for a Windows®-based or similar graphical user interface, with which they were becoming increasingly familiar.

8.3 RUSLE2

As RUSLE1 developed, it quickly became apparent that there were some scientific weaknesses with the approach taken that were primarily caused by its close linkage to the methodology used in the USLE. In addition, through the training and implementation process, some lessons were learned about how the general program

could be improved. Work began to address these issues in 1996, culminating in the release of a first RUSLE2 version in 2001 and the beginning of a US-wide NRCS implementation with actual distribution of the program to the field offices beginning in 2004. Based on some of the lessons learned in RUSLE1 implementation, this included a much earlier push to begin establishing the required databases, as well as to begin the iterative process of developing and modifying the program based on user feedback.

A primary change in the RUSLE2 implementation of the USLE relationships could be described as downplaying the importance of the individual factors. In the original USLE concept, these factors (except perhaps for C and P) were generally considered to be independent. This was clearly no longer the case in RUSLE1, as exemplified by the dependence of the β term in the LS relationship (Equation (8.3)) on various soil and management factors, which also impact the K and LS values. The factor-based RUSLE1 implementation caused both science and user problems. Inconsistent values could be entered in the various factors (a science error) and the program required the user to jump back and forth between factors in order to enter relevant and related data.

Implementation of RUSLE1 also made clear many places where the science was not specifically in error, but could be greatly enhanced. The most obvious of these was in full implementation within RUSLE2 of the CREAMS (Foster *et al.*, 1980) sediment transport and deposition approach, allowing the definition of the RUSLE2 hillslope to include depositional zones all the way down to the concentrated flow channel, and making RUSLE2 much more applicable to water quality problems. Other places where it was thought that the science could be enhanced by smaller improvements were many, especially in reducing the need for user selection of values by developing ways for the program to calculate needed values from information already available in databases. For example, in RUSLE1 the user needed to describe in several places the susceptibility of the soil to rilling; but this would vary with time, and can be estimated using parameters such as the soil texture, slope steepness, and management parameters already calculated within RUSLE2.

As with RUSLE1, many scientists and engineers were involved in producing and delivering the RUSLE2 technology, including those involved in data collection and preparation for analysis. Most of these individuals are acknowledged in the references for the corresponding documents.

8.3.1 General approach to RUSLE2 science problems

The following summary brings up to date earlier and more extensive summaries of science improvements in RUSLE2 (Foster *et al.* 2000, 2003; USDA-ARS, 2008a,b). In this treatment, distinctions are drawn between RUSLE2 and RUSLE1 version 1.04, as documented in AH703. Some of the science enhancements in RUSLE2 exist in later versions of RUSLE1, specifically in RUSLE1.05 and RUSLE1.06, which were developed with the support of the US Department of Interior Office of Surface Mining (Foster *et al.*, 2003).

RUSLE2 retains the conceptual use of the USLE factors, makes computations that are based on soil loss estimates referenced to unit plot conditions, and uses ratios to adjust predictions to other conditions. However, RUSLE2 goes beyond the USLE. It uses process-based equations derived from fundamental erosion science and professional judgment to make RUSLE2 applicable to situations beyond the scope of USLE or RUSLE1. As scientific approaches improved, RUSLE2 was calibrated to reproduce the core SLRs for different cropping systems and crop growth stages listed in Table 5 of Agriculture Handbook 537 (Wischmeier & Smith, 1978). This calibration ensured that RUSLE2 erosion estimates for common situations would be similar to the established and accepted values that have been used for decades in the US for conservation compliance assessment.

A major change in RUSLE2 was the de-emphasis of the USLE factors, and the organization of information into 'objects'. This object-oriented

organization applies to both the computer programming and the way that data are input by the user. The RUSLE2 developers made an effort to group and consolidate information needed by RUSLE2 into objects or descriptions that reflected how users think about the USLE factors. In the example mentioned above, with RUSLE1 the user had to use soil-related information not only in determining the *K* factor, but also in determining the *LS* factor, where the user chose among soil classes differing in their relative susceptibility to rill or inter-rill erosion (Table 4-5, Renard *et al*., 1997). In RUSLE2, all soil-related information is included in a soil description, and all management information is contained in a management description. RUSLE2 combines these descriptions with the topographic description to define another description, that of a hillslope profile object, and extracts the information it needs from the descriptions to make erosion computations based on climate information contained in a location description.

Databases are maintained at the object level. Objects may contain other objects and subobjects. For example, a management object is composed of the dates of occurrence of operation objects (like tillage, planting, or other soil-disturbing operations) and vegetation objects. Vegetation objects contain descriptions of growth patterns, and canopy and residue characteristics needed by RUSLE2 to compute the vegetation's influence on erosion. RUSLE2 does not simulate the growth of vegetation, but rather takes the information contained in the vegetation description and accounts for its effect on the *L*, *C* and *P* factors through numerous influences on variables tracked or calculated internally by RUSLE2, including soil biomass, surface residue cover, surface roughness, canopy cover, Manning's roughness, and the runoff curve number. In the USLE, all the factors were independent of each other; the *K*, *L*, *S* and *P* factors were annual constants, while the *R* and *C* factors were broken down into crop growth phases. In RUSLE1, the *R*, *K* and *C* factors varied among 24 half-month periods but remained largely independent of each other, although the *LS* and ground-cover effects varied with the ratio of rill to inter-rill erosion, which in turn varied with soil texture, slope steepness and cover-management variables. In RUSLE2, all factors except *S* vary on a daily basis, and there are numerous interactions among the factors (USDA-ARS, 2008a). Annual averages of the RUSLE2 factors can be calculated, but the products of these averages will not equal the average annual erosion predicted by RUSLE2.

A major improvement in RUSLE2 is that the user can now define any number of steepness, soil, or management breaks along the slope, and the program will accordingly break the slope into segments representing each combination, and complete the calculations on those. RUSLE2 overcame limitations in describing complex hillslopes that existed in USLE and RUSLE1 by conceiving of hillslopes as being composed of three layers: topography, soil, and management. Each of these layers can be segmented independently to represent any complex one-dimensional hillslope situation. RUSLE2 then defines slope segments as each unique combination of topography, soil, and management layers. Because of the inclusion of deposition routines that were not part of the USLE or RUSLE1, RUSLE2 applies to hillslopes that include concave areas where sediment deposition occurs. Also, channels at the slope bottom, terraces with channels within hillslopes, impoundments, and sediment basins may all be described. These features allow RUSLE2 to compute sediment deposition and fine-particle enrichment of delivered sediment using process-based equations. Currently RUSLE2 does not simulate erosion in channels.

This ability to consider slope segments has also enabled RUSLE2 to deal nicely with the application of terraces or diversions as a management alternative. From a USLE/RUSLE perspective, the terrace channel becomes the concentrated flow channel defining the bottom of an upper hillslope profile, while the top of the terrace itself defines the beginning of a new lower profile. Within RUSLE2 this is handled automatically, defining not only the profiles, but allowing the user to specify the type of concentrated flow

channel transferring water down from the terrace/diversion to the hillslope bottom. This channel can currently be modelled to cause deposition, but cannot currently be modelled as experiencing erosion. The ability to easily add or remove terraces for the hillslope description is important because it allows these to be approached as another management alternative, rather than requiring redefinition by the user of the hillslope profile itself.

(i) Changes in the climate description The climate data required to calculate soil loss in RUSLE2 are monthly averages for precipitation, temperature and erosivity, plus the desired location's ten-year 24-h precipitation amount ($P_{10y,24h}$). Climate description changes from RUSLE1 to RUSLE2 include: specification of $P_{10y,24h}$ rather than the ten-year *EI* event; updating the underlying record to the period from 1960 to 1989 (1960 to 1999 in many cases); and development of the erosivity density concept. Specification of monthly average precipitation and monthly average erosivity density is the preferred way of describing monthly erosivity in RUSLE2, and these values are contained in all the NRCS location climate files (USDA-NRCS, 2008). Erosivity density is defined as the amount of rainfall erosivity per unit of precipitation. Erosivity density has units of energy per unit area per unit time (e.g. MJ ha^{-1} h^{-1}), and when multiplied by the depth of precipitation over an interval (event, day, month, year) yields the appropriate average erosivity value. Using erosivity density has several advantages over directly calculated rainfall erosivity: (1) because it is the ratio of storm erosivity to storm precipitation, missing data have less impact on monthly means; (2) a shorter period of record is needed to arrive at a stable value of this ratio than a stable absolute value of erosivity; (3) because erosivity density was found to be relatively independent of elevation up to 3000 m, it was possible to interpolate a smoothly-varying erosivity density surface for the entire nation, making it possible to calculate erosivity for each county (common use in the US) or each precipitation zone (USDA-ARS, 2008a,b). The effect of elevation on erosivity was reflected by defining precipitation zones within counties of 11 mountainous western US states. The erosivity density approach allows geographically consistent erosion predictions needed for a conservation/erosion planning tool, and maximizes information that can be extracted from available 15-min precipitation data.

(ii) Changes in the soil description Changes in the soil description and *K*-factor computations include the development of a modified nomograph for highly disturbed soils, the development of new routines to describe time-variation in the *K* factor based on location temperature and precipitation data, and the ability to reflect the impact of subsurface drainage by specifying a soil hydrological class. RUSLE2 contains equations representing both the standard nomograph (Fig. 8.2) and a modified nomograph that applies to disturbed soils such as construction sites or reclaimed mine soils. The modified nomograph is the same as the standard nomograph for fine granular soils ($S = 2$), but the structural trend in erodibility is reversed in the modified nomograph, so that erodibility decreases as structure varies from very fine granular to massive. In the modified nomograph, the labels for class 1 and 3 structures would be exchanged and the line for class 4 structure would be to the left of all structure lines shown in Fig. 8.2. The modified nomograph is recommended for highly disturbed lands such as reclaimed mined land and construction sites, whereas the standard nomograph is recommended for agricultural soils because of its empirical support. For equivalent soil properties, both the standard and modified nomograph return a base *K* factor for Columbia, MO, which is a reference location and the centre of the RUSLE2 domain.

RUSLE1 included a time-varying *K* factor that was based on a few data points collected in the central US that indicated a time-varying change in Unit Plot erosion from storms with similar erosivity. New relationships in RUSLE2 capture the effect of temperature and precipitation on the likelihood of runoff and hence the *K*

factor. For example, during cool and wet periods, higher antecedent soil water is likely to increase runoff and soil erosion, thus K should be higher. Similarly, increased temperature is expected to increase evapotranspiration, leading to lower antecedent soil moisture, lower runoff, and reduced K values. Relationships in RUSLE2 capture the main effects of seasonal variation in K at each location based on the ratio of temperature and precipitation values at each location to the average annual values at the reference location (Columbia, MO). For identical soil descriptions, these adjustments will increase the annual effective K at locations that are cooler and wetter than Columbia, MO, while average K values will be lower than the nomograph value at locations that are hotter and drier than Columbia, MO.

In RUSLE2, inclusion of the CREAMS (Foster *et al.*, 1980) sediment transport and deposition relationships requires knowledge of the sediment size distribution at the point of detachment, so the diameter, specific gravity, and primary particle composition of each of five size classes is calculated as a function of soil clay using equations similar to those in CREAMS (Foster *et al.*, 1985). The effect of drainage on runoff and sediment transport is discussed below with regard to the P factor.

(iii) Changes to the topographic description Whereas the rill to inter-rill erosion ratio in RUSLE1 was selected by the user, in RUSLE2 this ratio is calculated internally based on soil texture, prior land use (soil biomass and soil consolidation) effects, ground cover and slope steepness. This ratio determines the slope length exponent, m, in Equation (8.2), which controls the sensitivity of sheet and rill erosion to slope length. Instead of using Equation (8.3), the ratio of rill to inter-rill erosion in RUSLE2 is computed from (USDA-ARS, 2008a):

$$\beta = \left(\frac{K_r}{K_i}\right)\left(\frac{c_{pr}}{c_{pi}}\right)\left(\frac{\exp(-b_r f_g)}{\exp(-0.025 f_g)}\right)\left(\frac{s/0.0896}{3s^{0.8}+0.56}\right) \quad (8.24)$$

where the ratio K_r/K_i is the inherent rill to inter-rill soil erodibility ratio computed as a function of soil texture (as discussed in the text following Equation (8.3)); the term c_{pr}/c_{pi} reflects the effect of prior land use on the rill to inter-rill erosion ratio; the ratio $\exp(-b_r f_g)/\exp(-0.025 f_g)$ reflects how ground cover affects rill erosion more than it affects inter-rill erosion, b_r and 0.025 are coefficients ($\%^{-1}$) that express the relative effectiveness of ground cover for reducing rill erosion and inter-rill erosion, and f_g is ground cover expressed as a percentage. The last term is the same as Equation (8.3). Equation (8.24) shows how RUSLE2 takes the information stored in the topographic, management, and soil objects and uses it to calculate needed coefficients, thus reducing the need for users to specify unfamiliar parameters. The fact that the rill to inter-rill erosion ratio, as calculated from Equation (8.24), is independent of slope length (when it really is not) illustrates the price that RUSLE2 pays for the ability to retain the simple and familiar USLE equation structure.

Complex slopes can be represented in RUSLE2 to provide a better approximation of topography. A broad range of process-based routines allows for calculation of deposition caused by either management or topographic changes. This means that, for RUSLE2, the hillslope is defined as from where runoff begins until it enters a concentrated flow channel, which is the same definition as for WEPP.

(iv) Changes to the management description One significant change from RUSLE1 to RUSLE2 was the grouping of field operations and vegetations into a separate management object or description. Management objects comprise descriptions of field operations (their dates of occurrence, and their effects on surface cover and surface roughness) with vegetation descriptions whose growth is begun by the operation (if any) and the yield expected for that vegetation, and the amount and type of external residue added to the surface if a mulching operation. Management descriptions result in daily tracking of an extensive suite of variables that affect sheet and rill erosion, including canopy cover, standing residue,

surface residue, surface roughness, ridge height, and the depth distribution of buried residue and soil biomass. Some of these, like standing stubble and ridge height, are variables that did not exist as USLE or RUSLE1 subfactors, but even the more familiar variables have received new and more detailed treatment in RUSLE2. In addition to surface and standing residue, RUSLE2 tracks dead biomass in 24 2.5-cm-thick soil layers in the soil profile. By default, standing residue decays at a rate that is a fraction of that of the surface residue, buried residue, or dead roots, which all decay at a rate controlled by climatic and residue variables using the same relationships as in RUSLE1. Mechanical tillage operations are described much more fully in RUSLE2 database files than in RUSLE1, in terms of the impact they have on flattening standing residues, disturbing the soil, or affecting the growth of vegetation. Soil disturbance is described in terms of the fraction of the soil disturbed, the intensity and depth of soil disturbance, the creation of ridges and random roughness, and the effect on burying, redistributing, or re-surfacing residues.

In a vegetation description, users define the base crop yield, the time course of canopy and root mass development (a 'growth chart'), and the characteristics of the residue produced when the crop dies. RUSLE2 uses this information once a 'begin growth' operation in a management description calls for that vegetation. The growth of the vegetation in RUSLE2 is independent of the location's climate data, so it must be properly described by the user for the situation being analysed. Several 'wizards' are available in the RUSLE2 interface to help users to develop vegetation descriptions, to define canopy/biomass relationships, canopy shape and intercepted raindrop fall height, and yield/flow retardance relationships. A new portion of the program specifically designed to help the database developer and program user properly to account for residue and root production in perennial vegetation systems is being developed, and is discussed subsequently.

One key feature added to the vegetation/operation/management descriptions in RUSLE2 is the ability of the user to vary crop yield. Vegetation is described for a specific assumed base yield, but when the vegetation is actually used within a management regime, the user can specify a higher or lower yield value. The vegetation description includes how the biomass varies with yield, allowing adjustment of all of the vegetation parameters by the program.

(v) Changes to the support practice factor

Whereas the RUSLE1 user selects a cover management condition that, together with the soil hydrological group, defines a 'runoff index' analogous to the runoff curve number (*CN*), RUSLE2 calculates a *CN* internally as a function of soil hydraulic class, soil biomass, soil consolidation, soil roughness, and soil residue cover, thus reflecting the combined effects of soil, management and climate. RUSLE2 calculates runoff for the $P_{10y,24h}$ rainfall event every day. It also calculates sheet and rill erosion for this index event, and uses process-based equations to determine sediment transport, deposition, and fines enrichment. 'Infiltration' is calculated on slope segments with a low *CN* as the difference between $P_{10y,24h}$ precipitation depth and the 'initial abstraction', taken as 0.2 times the 'maximum retention' parameter, a transform of the *CN* (USDA-ARS, 2008a). The RUSLE2 equations for sediment transport capacity and deposition, and robust simplifications of the equations used in CREAMS, give RUSLE2 the ability to reflect the effects of spatial variation of soil erodibility, slope steepness, and cover management along a slope on detachment, transport and deposition. This approach results in estimates of the long-term average sediment production, erosion rate, transport capacity, deposition, and sediment characteristics along the slope, as well as the sediment amount and characteristics of sediment leaving the slope (Foster *et al.*, 2000). In fact, RUSLE2 goes further than other 'process-based' models, in that it approximates backwater effects when it determines the effectiveness of dense narrow vegetative buffers on sediment trapping (USDA-ARS, 2008a). RUSLE2 also includes the ability to approximate the effect of simple impoundments and channels on sediment delivery and fines enrichment.

8.3.2 RUSLE2 implementation and lessons learned

(i) RUSLE2 websites There are two 'official' RUSLE2 web sites: an ARS site, http://www.ars.usda.gov/Research/docs.htm?docid=6010, and an NRCS site, http://fargo.nserl.purdue.edu/rusle2_dataweb/RUSLE2_Index.htm. Both sites offer the same model, but with different databases, permission (access) levels, and templates. The ARS site provides a minimal database and access levels that allow scientists and engineers to see and change more parameters. The NRCS site includes much more extensive databases, and templates including a wide variety of additional tools, but the permissions for database manipulation are more restricted. The USDA-NRCS website is the single national point of delivery for the NRCS-approved RUSLE2 management templates and database components. Both websites contain documentation and training materials.

The NRCS website is remotely maintained and kept current by the NRCS database manager, who posts frequent database updates, revised soils data in RUSLE2 format, and updates to the 24,000+ management templates. Although the current version installer is posted for downloading and installation by private sector users, the NRCS has recently begun using an automatic software installation process for new releases of RUSLE2. This minimizes the amount of support time necessary to remove and install RUSLE2 on NRCS field office computers.

(ii) RUSLE2 interface: plasticity and security An internal NRCS oversight and evaluation review of RUSLE1 implementation uncovered significant differences in soil loss estimates from RUSLE1 across county lines in adjacent states and regions due to a lack of consistent RUSLE1 databases within NRCS. With this past experience in mind, RUSLE2 was implemented with a hierarchical approach that allows users to see and change only those factors they fully understand. In RUSLE1, any user could change any parameter, sometimes leading to a very unlikely combination of inputs that gave them the output they desired. In RUSLE2 inappropriate changes are controlled by three mechanisms. The first is the user interface, which is very user-configurable. This allows more complicated inputs or outputs to be removed from the visible set, simplifying the model to a degree matching the user's interests and abilities. Since in the RUSLE2 calculation engine a parameter that is not needed is not calculated, removing unnecessary parameters also accelerates calculations. The second control mechanism is called access control, which limits what the user is allowed to see or edit. Access must be granted to the user by a higher-level user, providing a very flexible control structure that can be modified as a user is trained and needs greater control over the program. The third control mechanism is protection of specific records or groups of records within the database. For example, records created by a user with a high access level can only be edited and re-saved by a user with that access level or a higher one in the same access chain. Other users can edit the record, but can only save it as another record, over which they can exert control. As a result, once NRCS creates and locks a record, they can distribute it with the confidence that it cannot be modified by less knowledgeable users.

(iii) RUSLE2 database development and management RUSLE2 is supported by databases that store factor data and data entered by users. The climatic data are held in a location/climate description stored in the database, as are the soil data in their own separate description. These can then be accessed for re-use simply by calling for them by name. The most extreme example of this approach is in the management descriptions. A management description is a list of the field operations and associated dates, including what vegetation is planted or residue added (if any). These field operation, vegetation, and residue descriptions are each stored in their own named database descriptions for potential re-use by other managements, which in turn can also be stored.

Database development began in early 2000 with the designation of a USDA-NRCS National Database Manager or 'czar' who was given the

task of expanding the initial minimal core vegetation and operation descriptions for NRCS use on cropland and pastureland, as well as assisting with the development of detailed climate descriptions, and directing and managing the importing of soils data for all available soil surveys. Working with many colleagues, the database czar populated a single nationally-coordinated database of climate, soils, operations, vegetations, residue and support practice descriptions. For consistency, field office users were 'locked out' of editing the data in these parts of the database.

Because the national database was vast, it was organized into sections that could be downloaded from the NRCS website for use in local conservation planning. Soils data were organized by state and county or soil survey area. Thus, only the soils data that a particular field office or user needed would be contained in the local database, although another soils description could be imported as needed. Climate data were organized by state for use in the same way. Management records were organized by Crop Management Zones (CMZs), 75 regions of the country with similar crops and tillage systems.

Climate records. Climate data were populated for the entire US, including Alaska, Hawaii and the Pacific islands, Puerto Rico and the Virgin Islands. The effort included extraction of the monthly parameters from the national 1960–1989 dataset (1960–1999 in some cases), with calculation of monthly *EI* values for stations with recording intervals of 15 min or shorter. These data were smoothed using several routines and visual inspection to provide a relatively smooth erosivity density 'surface', which was then used to provide point values or, more commonly, an average value over a county.

Soil records. Creation of soil descriptions in RUSLE2 was eased by making direct use of the NRCS NASIS/SURGO soil database and tools, available online at http://soils.usda.gov/technical/nasis/. This is based on an NRCS soils expert (usually the State Agronomist) downloading from NASIS all of the necessary soil descriptions, then running those through a RUSLE2 utility that extracts the necessary information, tests it for consistency, and puts it into the required RUSLE2 format. Most RUSLE2 soils databases include some generic soil descriptions based on soil texture, and these are often more appropriate for use with highly disturbed and mixed soils like those on construction sites and mine reclamation projects.

Management records. The RUSLE1 experience used the approach of organizing the US by *C* factor or *EI* distribution zones in order to develop and coordinate the issuance of *C*-factor sets for common single crop and crop rotation scenarios. With RUSLE2 implementation, this cropping region concept was built upon with the creation of 75 Crop Management Zones (CMZs), in which common crops and tillage systems were described in detail and saved as 'locked' RUSLE2 management templates. CMZs are zones in which the climate and other factors thought to control management are assumed to be constant and unaffected by political boundaries. In other words, within a CMZ the crops are likely to be grown with very similar planting and harvest dates, as well as similar tillage systems, and so on. For example, one CMZ representing the central Corn Belt stretches east from the southeastern corner of Nebraska and northwestern corner of Kansas through northern Missouri, and across central Illinois, Indiana and Ohio. Another CMZ stretches south along the eastern side of the Appalachian range from Maryland into Alabama.

With national coordination, this effort involved significant coordination among NRCS state agronomists in setting typical dates of operations and creating these management templates to represent the typical tillage systems used in growing the important crops in each CMZ. Once a set of crop management template descriptions was created by a CMZ coordinator, it was submitted to the database manager for inclusion in the national NRCS RUSLE2 database. Each CMZ set was contained in a separate RUSLE2 export file so it could be imported into the local RUSLE2 database in each field office located within the boundaries of that CMZ. This provided a starting point for field offices as they implemented RUSLE2, and also provided consistency in the use of RUSLE2 since the locked management templates were based on typical

dates and typical tillage systems used in the CMZ. Internally, the vegetations, operations and residues used by these managements all came from the same national NRCS RUSLE2 database. Users could copy templates into a local management file and change or edit the tillage system details, yields, crops and dates of operations to tailor them for use locally in specific runs, whereas the locked templates remained unedited for future use.

(iv) RUSLE2 database status Although the data developed for RUSLE1 (especially the vegetation and operation descriptions) proved invaluable in the NRCS database development efforts, development of the RUSLE2 database was still a tremendous effort. The USDA-NRCS, with initial guidance from ARS and aided by university and other cooperators, has compiled a database that includes (as of 21 July 2008): (1) 105 residues, describing how much cover each provides and how fast it decomposes; (2) 917 vegetations, from asparagus to zucchini, with each describing how the vegetation grows in terms of providing canopy cover and biomass; (3) 438 field operations, describing what happens to the soil, residue and vegetation as a result of the operation; (4) 10,976 climate descriptions; (5) 1,048,659 soil component descriptions, representing 649,032 soil map units in 3100 soil survey areas; (6) 467 special descriptions describing saved descriptions of strip-cropping, contouring, terracing, and sediment control basin practices; and (7) 26,361 managements for 75 CMZs, describing how the field operations, vegetations and residues fit together into management schemes.

8.3.3 Implementation needs and training requirements

(i) Preliminary training Initial RUSLE2 training was conducted by NRCS with assistance from the RUSLE2 development team in regional testing sessions during the period from 1999 to 2000. A minimal database, which included generic soils and only a few major crops and operations, was used for testing RUSLE2. As the training sessions progressed, it became clear that there were several background requirements that would be required of the trainees prior to full-scale training, including:

- enough background in the underlying USLE/RUSLE science to allow the trainee to understand the conceptual approach, the use of the inputs, and the meaning of the results; and
- a general understanding of how the computer program organizes information and reflects the 'conceptual model' behind RUSLE. This was enhanced by the flexibility of the program in developing very simple user interface templates, which allowed the program to be introduced at a rather basic level.

In addition, a fuller database adequately reflecting the broad range of situations that users would need to address was required for full-scale training.

(ii) NRCS RUSLE2 training Beginning in the summer of 2001, USDA-NRCS conducted regional 'train the trainer' sessions for NRCS state and area agronomists and others with erosion prediction responsibilities. These sessions were conducted by the NRCS Water Erosion cooperating scientist, national database manager, and the RUSLE2 development team. Training focused on the erosion science on which RUSLE2 is based, how to navigate the user interface, how the database structure is organized, the content of records in the various parts of the database, and hands-on experience in creating management scenarios and making simple RUSLE2 runs. One or two individuals from each state attended and began learning the model as well as learning how to train field office employees within their states. Each of these trainers then went back and conducted a series of 1–2 day RUSLE2 model training sessions to allow field office staff to develop sufficient skills such that they could make soil loss estimates using a relatively simple user template.

The regional 'train the trainer' sessions proved very valuable not only to the NRCS state personnel but also to the RUSLE2 development team, in that several NRCS user needs were identified that eventually led to enhancements and modifications

to the RUSLE2 user interface. One enhancement was the development of a rotation builder module to allow creation of multi-year and multi-crop rotations from concatenation of single-year management scenarios. This also allows rapid substitution of individual tillage system years as treatment alternatives are explored during conservation planning with producers. NRCS users also expressed a need to group RUSLE2 runs for these different alternative treatments into a 'worksheet screen', and to assemble the worksheets for multiple fields within RUSLE2, thereby representing an entire farm. This need was addressed through the development of the 'plan view' in the interface. As states began to conduct field office training sessions, an NRCS User Guide for the RUSLE2 interface was developed and distributed. Additional 'how to' guides and references were prepared for specific tasks, such as importing and exporting database components, importing soils data from NASIS soils descriptions, installing new versions, and performing database updates.

As implementation and use of RUSLE2 expanded, and as NRCS and private sector users gained experience in the model, regional advanced RUSLE2 training sessions were conducted in all regions of the US. These sessions built on the initial training and provided more in-depth training, resulting in a deeper understanding of operations, vegetations, and support practice records, of modelling erosion and sediment deposition on complex slopes, of database management, of more complex screen views, and of organizing outputs and dealing with complex management scenarios. Additionally, as users became more sophisticated, more complicated screen views and printing templates that included more detailed outputs and analysis were developed and released.

(iii) Day-to-day support A significant amount of day-to-day support was provided to states and field offices by the NRCS water erosion cooperating scientist and the national database manager during the implementation years of 2001 through to the present. This was provided through a combination of telephone and e-mail support, and direct computer-to-computer sharing of software applications. Several 1–3 hour training sessions were conducted via this latter method to provide training to multiple states on new enhancements and timely topics. Support personnel also processed hundreds or even thousands of individual requests for additional vegetations, operations and support practices, as RUSLE2 use expanded across the US.

As various other applications were being developed, access to the 24,000 + RUSLE2 crop management templates became necessary. A common file exchange format was used so that these files could be exported and utilized by the Wind Erosion Prediction System (WEPS) model (Hagen, 1996). Several other applications have used this file exchange format to utilize all subsets of the RUSLE2 management templates.

8.3.4 Most significant application enhancements

RUSLE2 includes a user convenience called the 'worksheet view' that allows comparisons or combinations of a series of hillslope profiles, each of which represents a single RUSLE2 erosion/delivery calculation. For example, the management alternative worksheet uses a single climate, soil and topographic description, but below that shows a table of management alternatives and resulting erosion and sediment delivery (Plate 4). Each line in the table represents a single RUSLE2 calculation, and all lines share the common climate, soil and topography. The idea is that each worksheet in this case represents a field, with a list of likely management options and resulting erosion values. A group of worksheets can then be combined/compared in a 'plan', which can represent a farm, with each worksheet representing a field within that farm or land parcel. Within the worksheet, the user can control which management alternatives are brought into the plan for each field, allowing for comparison of all the alternatives. Once the planning decision is made, yes/no toggles can be set to display only the scenarios representing the 'before' and 'after' management

alternatives. Thus they provide documentation of the 'before' and 'after' soil losses.

As indicated earlier, a feature added to the RUSLE2 program that greatly eased the database development effort was the inclusion of the Rotation Builder. This allowed the management scenarios to be developed as single crops, allowing the user within the program to 'paste' these together into the desired sequence. For example, the long growing seasons in the southeast US allows for multiple vegetable crops to be grown in sequence, resulting in a huge number of permutations requiring a large number of database descriptions. The Rotation Builder allows for limiting the descriptions to the single vegetations, which the RUSLE2 user can then combine within the program run as desired. If a specific combination is used frequently, the program allows users to save the combination as a single management, allowing for easy re-use.

Another RUSLE2 enhancement, developed with the support of the Wisconsin Department of Natural Resources and Dane County Land Conservation, is that the erosion and sediment delivery no longer need to be summed for the year. Conservationists working on construction sites are often interested in what happens only during some accounting period, over which the site operator is liable for erosion and sediment control. For example, the Wisconsin project defined a successful management plan as that which would keep the total sediment delivered from the site under 11 Mg ha^{-1} (5 US t ac^{-1}) during the period from the time of first soil disturbance until either placement of some non-erodible cover, or 60 days of growth of a permanent perennial vegetation. RUSLE2 allows for flexible definition of the accounting period, and of the target that must be achieved.

RUSLE2 also allows for printing a report describing the inputs and outputs of a RUSLE2 calculation. The form of the report is user-configurable, allowing users to define what they would like to see and in what form in a Microsoft Word® document. The resulting document can then be locked so that the user cannot change the results, and the associated RUSLE2 inputs can be saved into the document, allowing for a regulator to inspect the underlying information.

8.3.5 NRCS tools added to the NRCS RUSLE2 interface

Several additional calculations have been added to the NRCS RUSLE2 interface. The most prominent of these is calculation of the Soil Conditioning Index (SCI) (USDA-NRCS, 2002, examined by Zobeck *et al.*, 2007), which provides a rough estimate of whether a specific location/management/soil combination will tend to cause an increase or decrease in soil organic matter. One component of the SCI that has also proved useful is the Soil Tillage Intensity Rating (STIR), which makes use of the tillage type, tillage depth, operation speed, and percentage surface disturbance as a rough estimate of the soil disturbance cause by the operation. The STIR value is used as a criterion for NRCS's National Residue Management Practice Standards (available for download at http://www.nrcs.usda.gov/Technical/Standards/nhcp.html, accessed 3 September 2008). The STIR and SCI calculations have no impact on the RUSLE2 erosion/delivery calculations, but make use of the management operation and erosion results.

NRCS has added a calculation of management fuel usage based on the sequence of operations to the RUSLE2 interface. Several state phosphorus index calculations have also been added to the interface. Other tools were added to the NRCS RUSLE2 interface to compute a Nitrogen Leaching Index and an Energy and Fuel Use Calculator based on the tillage operations. Examples of the SCI and the Fuel Use Calculator results are shown in Plate 4.

8.3.6 Future of the technology

The science supporting RUSLE2 continues to advance and will be incorporated into future releases of the model. Two active areas of research include (1) residue production in perennial systems, and (2) ephemeral gully erosion estimation.

In most USDA erosion models (e.g. WEPP, WEPS, RUSLE1), residue production occurs only during senescence of a crop and is calculated from the decline in live biomass. This is equivalent to the assumption that there is no dead biomass production during periods of increasing biomass, and no additional growth after the peak biomass is reached. This is probably a reasonable and acceptable assumption for the treatment of annual crops. However, in perennial vegetation and in mixed stands where different components mature at different times, death and growth usually occur simultaneously. A new type of vegetation description is being developed for RUSLE2 in which residue production is more continuous, based on the assumption that live biomass has an effective life span. In the absence of forage harvest or biomass removal, the daily change in live biomass amount is calculated as the difference between new growth and the death of old growth. Live biomass that is not harvested is added to a dead biomass pool after its lifespan is reached, thereby providing the soil the benefits of additional residue cover. Users input monthly potential growth patterns and shoot and root life-spans, and RUSLE2 calculates corresponding residue production patterns. Growth patterns are altered in response to management operations involving biomass removal. Daily changes in residue biomass are then calculated as the difference between death and decomposition or residue harvest. RUSLE2's new routines will simplify the creation of vegetation descriptions for perennial systems, providing more realistic estimates of residue creation throughout the year, and thereby improving runoff and erosion estimation for pastures, hay fields, and other systems dominated by perennial vegetation.

To predict average annual ephemeral gully erosion is challenging because there is no existing long-term database of ephemeral gully erosion rates comparable to the plot database underlying the USLE, which in turn underlies RUSLE. Ephemeral gully erosion is a process inherently driven by larger-than-average runoff events (see Chapter 19). Many process-based models have developed climate-generators (e.g. CREAMS: Knisel, 1980) that reproduce the stochasticity of weather. Applying these long-term weather records to an ideal runoff and erosion model would create a distribution of runoff and erosion events. Taking the monthly means of this population of ephemeral gully erosion events would represent the long-term average values needed to complement RUSLE2 sheet and rill erosion estimates and to estimate long-term average ephemeral gully erosion. The RUSLE2 developers proposed that modelling the correct storm amount and sequence of storms could reproduce the mean values. Toward this end, techniques to predict a sequence of index storms for any combination of soil and management anywhere within the continental US (and elsewhere, with appropriate calibration) have been developed, and require only RUSLE2 climate and profile-level information. The results approximate the mean monthly runoff, annual runoff event frequency, and a gamma distribution function scale parameter that characterizes 30-year stochastic runoff predictions generated using the AnnAGNPS (annualized Agricultural Non-Point Source) model (Bingner & Theurer, 2001).

By taking the largest in a series of runoff events as a 6-month return period event, and scaling the magnitudes of the periodic runoff events proportional to the long-term average disaggregated daily runoff amounts on event days, these parameters allow estimation of the date and size of a series of index runoff events that are proposed as the basis for an ephemeral gully calculation capability within RUSLE2. Index event RUSLE2 hillslope runoff, sediment yield, and sediment size distribution will be coupled with a physically-based ephemeral gully erosion model, possibly that used in CREAMS, to predict annual average ephemeral gully erosion.

8.3.7 RUSLE2 examples

RUSLE2 is so flexible that it is very difficult to decide which capabilities to show in a few examples, and in which form to display those. In narrowing the possibilities, it was decided to concentrate on three examples. The first example

is included especially to dispel the notion that RUSLE2 is difficult and complicated to use. The other examples represent two common uses of RUSLE2. The second example compares management alternatives on a single field, as would probably be done by a conservation planner working with an agricultural producer. The third example demonstrates planning to meet a specific sediment delivery target on a construction site. In both of these latter cases the figure will appear relatively complex, but this complexity was added so that specific features could be highlighted.

(i) Example 1. Very simple view One of the complaints sometimes lodged against RUSLE2 is that it is too complex and difficult for a novice user. As described in the sections above, the complexity the user sees in RUSLE2 is totally controlled by what the user asks to see and how they ask to see it. The calculations are exactly the same for a simple view (Plate 5) as for a more complex one, except that fewer calculations may be needed because fewer outputs are requested. The user views are completely user-configurable, so there is an infinite number of possible views, not just some pre-specified simple, medium and complex views. The RUSLE2 screen capture (Plate 5) shows one of the simpler views, which could be used by someone with a minimal understanding of soil erosion. In order to get an erosion and sediment delivery result, the user need only select a location (climate), a soil, and a management from pre-existing lists in the database. They then enter a slope length and steepness (which assumes a uniform slope), and can immediately see the resulting erosion and sediment delivery. If desired, this view also allows the user to select from pre-defined contour or cross-slope tillage systems, to put in pre-defined vegetated barriers on or at the bottom of the slope, or to see what happens if pre-defined terrace systems are installed. If the trainer or program supplier believes that even these few conservation practices will not be understood by the target user, even these entries associated with Step 5 in the view above may be easily removed.

In this access level and view, the user has no way of directly modifying any of the inputs except slope length and steepness. Everything else must be selected from pre-defined descriptions in the database, presumably placed there by someone with the training and knowledge to do so. Most users are not long satisfied with so little flexibility. For example, they may want to be able to see the impact of a complex slope shape rather than being forced to assume a uniform slope. This increased power comes at the cost of increased complexity, as the user must now be faced with a user template allowing them to enter length and steepness values for the slope segments. This constant desire for more power and flexibility results in what the RUSLE2 development team calls 'template creep', which is the tendency of user templates to become increasingly complex over time in order to provide additional power. The RUSLE2 complexity that some users complain of is not built into the RUSLE2 program, but rather exists because other users who developed that user template thought those entries and outputs were necessary.

Finally, notice that Plate 5 shows the inputs and results in metric units, while the values shown in Plate 4 were in Imperial units. This demonstrates some of the additional flexibility of the RUSLE2 interface, which allows for any desired mixing and matching of units, and also for selecting the desired units within a system (e.g. cm or mm for height).

(ii) Example 2. Agricultural conservation planning The RUSLE2 screen capture shown earlier in Plate 4 presents the results of conservation planning on a hypothetical field. In this view the field is defined as having a single climate, soil, and uniform slope. Each line in the table then represents a single RUSLE2 erosion calculation, using the climate, soil and topography defined above, and combining it with a unique combination of contouring, terraces and cropping sequence to yield erosion, fuel use, and Soil Conditioning Index (SCI) results. In order from the top of the table, the lines represent: (1) corn with moldboard ploughing in the fall and disking in the spring,

tilled and planted up-and-down the slope; (2) the same tillage, but close to the contour; (3) the same as (2), but with a single terrace in the middle of the slope; (4) fall chisel ploughing up-and-down the slope; (5) fall chisel ploughing, but close to the contour; and (6) fall strip tillage, where in the fall only a narrow strip is disturbed in knifing in nitrogen. The results for each line show the planner not only the erosion and sediment yield associated with each alternative, but also the estimated fuel cost and the SCI value for that option, with values > 0 indicating a net increase in soil organic carbon over time. These generally show the expected results, with the reduced tillage option resulting in the lowest erosion, fuel cost, and highest SCI values.

The graphs shown in Plate 4 indicate some of RUSLE2's capability in graphically representing results. In this case the graphs are of the percentage of soil surface covered by crop residue, with the graph on the left for the fall moldboard plough scenario, and that on the right for the strip till management. In addition, although it is not displayed here, the crop yields for each of the management alternatives can be set by the user, if it is thought that the management sequence has an effect on those.

(iii) Example 3. Construction site sediment control As described above, although the RUSLE2 calculations for estimating erosion and sediment yield for construction sites are no different from those for agricultural settings, the RUSLE2 flexibility allows for a substantially different look and feel, which makes it easier to use in construction settings. Several of these differences are shown in Plate 6.

One primary difference seen here is that for construction sites the primary output of interest is not the soil erosion on the hillslope, but rather the sediment delivery to the receiving channel, representing the off-site impact. In fact, it is often comparison of this value to some defined standard rather than comparison of average annual soil loss with the soil loss tolerance (*T*) (Johnson, 1987) that indicates the success or failure of a construction plan.

Another difference is the look and feel of the screen itself, including especially the visible icons and the text. These can be things as trivial as using a bulldozer icon instead of a tractor to represent field operations, or as substantial as completely different text shown on the screen for the same parameter, reflecting differences in terminology. For example, in agricultural settings we generally speak of crops and of crop residues added to the surface, while in construction settings we would use the more generic vegetation and surface cover materials, including synthetic blankets and added mulches as well as residues from the vegetation grown on the site.

Another difference mentioned above is the ability of RUSLE2 to aggregate results not only on an average annual basis, but over a user-defined accounting period. For example, in the situation shown here, the accounting period is defined as beginning from the time of the first soil disturbance until either the application of some non-erodible permanent material (e.g. pavement, sod, or landscaping materials) or 60 days of growth of perennial vegetation, with days whose average temperature falls below 35°F not counted. In Plate 6, the two bottommost results in the lower left-hand corner indicate whether the system meets the definition of the accounting period, and a green or red colour in the rectangle indicates whether the system did or did not meet the allowable sediment delivery threshold, in this case set by the regulatory body as a total of no more than 5 Mg ha^{-1} (2 US t ac^{-1}) over the entire accounting period.

Users indicated that for construction site use – unlike for agricultural use – there would be little need for the capability to save and re-use management descriptions, as the timing of field operations would vary tremendously due to many factors. Because of this, the view in Plate 6 shows the management scenario description (dates and descriptions of field operations) directly within the general RUSLE2 profile view, rather than named and stored as a separate database record.

These users also indicated a need to define complex slope topography, as they wanted to be able to account for the deposition occurring on

the flatter portion at the bottom of an S-shaped slope: thus the complexity of Step 3 in Plate 6, which in the previous views was shown simply as single uniform slope length and steepness. The slope schematic in the upper-right corner of the view displays this complexity. The upper (management) layer of this schematic shows a management break about 55 ft (16.8 m) down the slope. This is caused by the selection in Step 5 of a pre-defined strip-barrier system, which in this case puts a single 20-ft strip of poor stand cool-season grass at the bottom of the slope. In addition, Step 5 sets that the runoff from the bottom of the slope feeds to a sediment basin, which is pre-defined as having an 80% settling efficiency for a silt loam soil that has not experienced previous deposition. This last clause is important because any deposition occurring before the runoff hits the sediment basin will cause the coarse material to settle out, thereby reducing the actual efficiency of the basin. In the specific case shown here, there will be deposition at the bottom of the slope caused by both the decreased slope steepness and the grass strip, so the basin will not provide 80% efficiency. If they had so desired, the users could have added additional complexity to the view to show where the deposition actually occurred, but this was not deemed worthwhile.

8.4 Summary

Soil erosion has long been recognized as a serious problem. Considerable efforts have been expended to address this problem, beginning in Missouri in 1923 and supported by the US Congress in a 1929 appropriation that initiated intensive soil erosion research. Early efforts to preserve soil and prevent erosion through the work of pioneers like H.H. Bennett led to an early period of plot scale conservation research at sites representing the ten major farming regions in the US. The 6 ft (1.8 m) wide by 72.6 ft (22.1 m) long (0.01 acre, 40 m^2) research plots were constructed to represent various crops and rotations. Primary measurements included precipitation, runoff and soil loss (erosion). The results from this research, in combination with additional crops and cultural practices data, ultimately provided a repository of data widely used by engineers and scientists to evaluate conservation practices. These data were the foundation of the empirical erosion prediction technologies and ultimately the Universal Soil Loss Equation (USLE).

The USLE was developed at Purdue University under the direction of Walter Wischmeier, with able assistance from Dwight Smith, and was published in 1965 and 1978 in two handbooks (AH282 and AH537). The handbooks became widely accepted for conservation farming (and especially soil erosion by water) in the US. In the early 1980s a program to develop technology to replace the USLE was initiated. The computer-based RUSLE (Revised Universal Soil Loss Equation) model was published in 1997. RUSLE incorporated significant advances over the USLE and permitted application of soil erosion estimation for a greater variety of crops and management practices beyond those in the original USLE database.

RUSLE was subsequently revised to include advanced scientific and interface technology and subsequently delivered as RUSLE2, along with expanded databases and more control over the parameters that specific users could see and change. The USDA-NRCS has accepted responsibility for the underlying databases within the US, which include descriptions of climates, vegetations and soils, along with extensive files describing common management practices. RUSLE2 is widely recognized as a major advance in erosion prediction and conservation technology, and provides a very flexible tool allowing resource conservationists, managers and developers to compare a broad range of management alternatives in deciding on an optimum resource use.

ABSTRACT

Wischmeier, W. H., and Smith, D.D. 1978. Predicting rainfall erosion losses—a guide to conservation planning. U.S. Department of Agriculture, Agriculture Handbook No. 537.

The Universal Soil Loss Equation (USLE) enables planners to predict the average rate of soil erosion for each feasible alternative combination of crop system and management practices in association with a specified soil type, rainfall pattern, and topography. When these predicted losses are compared with given soil loss tolerances, they provide specific guidelines for effecting erosion control within specified limits. The equation groups the numerous interrelated physical and management parameters that influence erosion rate under six major factors whose site-specific values can be expressed numerically. A half century of erosion research in many States has supplied information from which at least approximate values of the USLE factors can be obtained for specified farm fields or other small erosion prone areas throughout the United States. Tables and charts presented in this handbook make this information readily available for field use. Significant limitations in the available data are identified.

The USLE is an erosion model designed to compute longtime average soil losses from sheet and rill erosion under specified conditions. It is also useful for construction sites and other nonagricultural conditions, but it does not predict deposition and does not compute sediment yields from gully, streambank, and streambed erosion.

Keywords: Conservation practices, conservation tillage, construction sites, crop canopy, crop sequence, delivery ratios, erosion factors, erosion index, erosion prediction, erosion tolerances, erosivity, gross erosion, minimum tillage, no-till, rainfall characteristics, rainfall data, residue mulch, runoff, sediment, sediment delivery, slope effect, water quality, soil erodibility.

PREDICTING RAINFALL EROSION LOSSES— A GUIDE TO CONSERVATION PLANNING

Walter H. Wischmeier and Dwight D. Smith[1]

PURPOSE OF HANDBOOK

Scientific planning for soil and water conservation requires knowledge of the relations between those factors that cause loss of soil and water and those that help to reduce such losses. Controlled studies on field plots and small watersheds have supplied much valuable information regarding these complex factor interrelations. But the greatest possible benefits from such research can be realized only when the findings are converted to sound practice on the numerous farms and other erosion prone areas throughout the country. Specific guidelines are needed for selecting the control practices best suited to the particular needs of each site.

The soil loss prediction procedure presented in this handbook provides such guidelines. The procedure methodically combines research information from many sources to develop design data for each conservation plan. Widespread field experience for more than two decades has proved it highly valuable as a conservation planning guide.

The procedure is founded on an empirical soil loss equation that is believed to be applicable wherever numerical values of its factors are available. Research has supplied information from which at least approximate values of the equation's factors can be obtained for specific farm fields or other small land areas throughout most of the United States. Tables and charts presented in this handbook make this information readily available for field use.

This revision of the 1965 handbook (*64*) updates the content and incorporates new material that has been available informally or from scattered research reports in professional journals. Some of the original charts and tables are revised to conform with additional research findings, and new ones are developed to extend the usefulness of the soil loss equation. In some instances, expanding a table or chart sufficiently to meet the needs for widespread field application required projection of empirical factor relationships appreciably beyond the physical limits of the data from which the relationships were derived. Estimates obtained in this manner are the best information available for the conditions they represent. However, the instances are identified in the discussions of the specific erosion factors, tables, and charts. Major research needs are suggested by these discussions and were recently summarized in an available publication by Stewart and others (*42*).

HISTORY OF SOIL LOSS EQUATIONS

Developing equations to calculate field soil loss began about 1940 in the Corn Belt. The soil loss estimating procedure developed in that region between 1940 and 1956 has been generally referred to as the slope-practice method. Zingg (*64*)[2] published an equation in 1940 relating soil loss rate to length and percentage of slope. The following year, Smith (*38, 39*) added crop and conservation practice factors and the concept of a specific soil loss limit, to develop a graphical method for

[1] Retired. Former research statistician (water management), Science and Education Administration (SEA), and professor emeritus, agricultural engineering, Purdue University, West Lafayette, Ind.; and agricultural engineer, SEA, Beltsville, Md.

[2] Numbers in parentheses refer to References p. 48.

determining conservation practices on Shelby and associated soils of the Midwest. Browning and associates (*6*) added soil and management factors and prepared a set of tables to simplify field use of the equation in Iowa. Research scientists and operations personnel of the Soil Conservation Service (SCS) in the North Central States worked together in developing the slope-practice equation for use throughout the Corn Belt.

A national committee met in Ohio in 1946 to adapt the Corn Belt equation to cropland in other regions. This committee reappraised the Corn Belt factor values and added a rainfall factor. The resulting formula, generally known as the Musgrave Equation (*31*), has been widely used for estimating gross erosion from watersheds in flood abatement programs. A graphical solution of the equation was published in 1952 (*19*) and used by the SCS in the Northeastern States.

The soil loss equation presented in this handbook has become known as the Universal Soil Loss Equation (USLE). Regardless of whether the designation is fully accurate, the name does distinguish this equation from the *regionally* based soil loss equations. The USLE was developed at the National Runoff and Soil Loss Data Center established in 1954 by the Science and Education Administration (formerly Agricultural Research Service) in cooperation with Purdue University. Federal-State cooperative research projects at 49 locations[3] contributed more than 10,000 plot-years of basic runoff and soil loss data to this center for summarizing and overall statistical analyses. After 1960, rainfall simulators (*23*) operating from Indiana, Georgia, Minnesota, and Nebraska were used on field plots in 16 states to fill some of the gaps in the data needed for factor evaluation.

Analyses of this large assembly of basic data provided several major improvements for the soil loss equation (*53*): (a) a rainfall erosion index evaluated from local rainfall characteristics; (b) a quantitative soil erodibility factor that is evaluated directly from soil property data and is independent of topography and rainfall differences; (c) a method of evaluating cropping and management effects in relation to local climatic conditions; and (d) a method of accounting for effects of interactions between crop system, productivity level, tillage practices, and residue management.

Developments since 1965 have expanded the use of the soil loss equation by providing techniques for estimating site values of its factors for additional land uses, climatic conditions, and management practices. These have included a soil erodibility nomograph for farmland and construction areas (*58*); topographic factors for irregular slopes (*12, 55*); cover factors for range and woodland (*57*); cover and management effects of conservation tillage practices (*54*); erosion prediction on construction areas (*61, 24, 25*); estimated erosion index values for the Western States and Hawaii (*5, 21, 55*); soil erodibility factors for benchmark Hawaii soils (*9*); and improved design and evaluation of erosion control support practices (*17, 36*).

Research is continuing with emphasis on obtaining a better understanding of the basic principles and processes of water erosion and sedimentation and development of fundamental models capable of predicting specific-storm soil losses and deposition by overland flow (*10, 11, 22, 26, 32*). The fundamental models have been helpful for understanding the factors in the field soil loss equation and for interpreting the plot data.

SOIL LOSS TOLERANCES

The term "soil loss tolerance" denotes the maximum level of soil erosion that will permit a high level of crop productivity to be sustained economically and indefinitely.

---

[3] The data were contributed by Federal-State cooperative research projects at the following locations: Batesville, Ark.; Tifton and Watkinsville, Ga.; Dixon Springs, Joliet, and Urbana, Ill.; Lafayette, Ind.; Clarinda, Castana, Beaconsfield, Independence, and Seymour, Iowa; Hays, Kans.; Baton Rouge, La.; Presque Isle, Maine; Benton Harbor and East Lansing, Mich.; Morris, Minn.; Holly Springs and State College, Miss.; Bethany and McCredie, Mo.; Hastings, Nebr.; Beemerville, Marlboro, and New Brunswick, N.J.; Ithaca, Geneva, and Marcellus, N.Y.; Statesville and Raleigh, N.C.; Coshocton and Zanesville, Ohio; Cherokee and Guthrie, Okla.; State College, Pa.; Clemson and Spartanburg, S.C.; Madison, S.Dak.; Knoxville and Greeneville, Tenn.; Temple and Tyler, Tex.; Blacksburg, Va.; Pullman, Wash.; LaCrosse, Madison, and Owen, Wis.; and Mayaguez, P.R.

The major purpose of the soil loss equation is to guide methodical decisionmaking in conservation planning on a site basis. The equation enables the planner to predict the average rate of soil erosion for each of various alternative combinations of crop system, management techniques, and control practices on any particular site. When these predicted losses can be compared with a soil loss tolerance for that site, they provide specific guidelines for effecting erosion control within the specified limits. Any cropping and management combination for which the predicted erosion rate is less than the tolerance may be expected to provide satisfactory erosion control. From the satisfactory alternatives indicated by this procedure, the one best suited to a particular farm or other enterprise may then be selected.

Soil loss tolerances ranging from 5 to 2 t/A/year for the soils of the United States were derived by soil scientists, agronomists, geologists, soil conservationists, and Federal and State research leaders at six regional workshops in 1961 and 1962. Factors considered in defining these limits included soil depth, physical properties and other characteristics affecting root development, gully prevention, on-field sediment problems, seeding losses, soil organic matter reduction, and plant nutrient losses. A deep, medium-textured, moderately permeable soil that has subsoil characteristics favorable for plant growth has a greater tolerance than soils with shallow root zones or high percentages of shale at the surface. Widespread experience has shown these soil loss tolerances to be feasible and generally adequate for sustaining high productivity levels indefinitely. Some soils with deep favorable root zones may exceed the 5-t tolerance without loss of sustained productivity.

Soil loss limits are sometimes established primarily for water quality control. The criteria for defining field soil loss limits for this purpose are not the same as those for tolerances designed to preserve cropland productivity. Soil depth is not relevant for offsite sediment control, and uniform limits on erosion rates will allow a range in the quantities of sediment per unit area that are delivered to a river. Soil material eroded from a field slope may be deposited in the field boundaries, in terrace channels, in depressional areas, or on flat or vegetated areas traversed by the overland flow before it reaches a river. The erosion damages the cropland on which it occurs, but sediment deposited near its place of origin is not directly relevant for water quality control.

If the soil loss tolerance designed for sustained cropland productivity fails to attain the desired water quality standard, flexible limits that consider other factors should be developed rather than uniformly lowering the soil loss tolerance. These factors include distance of the field from a major waterway, the sediment transport characteristics of the intervening area, sediment composition, needs of the particular body of water being protected, and the probable magnitude of fluctuations in sediment loads (*42*). Limits of sediment yield would provide more uniform water quality control than lowering the limits on soil movement from field slopes. They would also require fewer restrictions on crop system selection for fields from which only small percentages of the eroded soil become off-farm sediment.

SOIL LOSS EQUATION

The erosion rate at a given site is determined by the particular way in which the levels on numerous physical and management variables are combined at that site. Physical measurements of soil loss for each of the large number of possible combinations in which the levels of these variable factors can occur under field conditions would not be feasible. Soil loss equations were developed to enable conservation planners to project limited erosion data to the many localities and conditions that have not been directly represented in the research.

The USLE is an erosion model designed to predict the longtime average soil losses in runoff from specific field areas in specified cropping and management systems. Widespread field use has substantiated its usefulness and validity for this purpose. It is also applicable for such nonagricultural conditions as construction sites.

With appropriate selection of its factor values, the equation will compute the average soil loss for a multicrop system, for a particular crop year in a rotation, or for a particular cropstage period within a crop year. It computes the soil loss for a given

site as the product of six major factors whose most likely values at a particular location can be expressed numerically. Erosion variables reflected by these factors vary considerably about their means from storm to storm, but effects of the random fluctuations tend to average out over extended periods. Because of the unpredictable short-time fluctuations in the levels of influential variables, however, present soil loss equations are substantially less accurate for prediction of specific events than for prediction of longtime averages.

The soil loss equation is

$$A = R K L S C P \qquad (1)$$

where

A is the computed soil loss per unit area, expressed in the units selected for **K** and for the period selected for **R**. In practice, these are usually so selected that they compute **A** in tons per acre per year, but other units can be selected.

R, the rainfall and runoff factor, is the number of rainfall erosion index units, plus a factor for runoff from snowmelt or applied water where such runoff is significant.

K, the soil erodibility factor, is the soil loss rate per erosion index unit for a specified soil as measured on a unit plot, which is defined as a 72.6-ft length of uniform 9-percent slope continuously in clean-tilled fallow.

L, the slope-length factor, is the ratio of soil loss from the field slope length to that from a 72.6-ft length under identical conditions.

S, the slope-steepness factor, is the ratio of soil loss from the field slope gradient to that from a 9-percent slope under otherwise identical conditions.

C, the cover and management factor, is the ratio of soil loss from an area with specified cover and management to that from an identical area in tilled continuous fallow.

P, the support practice factor, is the ratio of soil loss with a support practice like contouring, stripcropping, or terracing to that with straight-row farming up and down the slope.

The soil loss equation and factor evaluation charts were initially developed in terms of the English units commonly used in the United States. The factor definitions are interdependent, and direct conversion of acres, tons, inches, and feet to metric units would not produce the kind of integers that would be desirable for an expression of the equation in that system. Therefore, only the English units are used in the initial presentation of the equation and factor evaluation materials, and their counterparts in metric units are given in the Appendix under **Conversion to Metric System.**

Numerical values for each of the six factors were derived from analyses of the assembled research data and from National Weather Service precipitation records. For most conditions in the United States, the approximate values of the factors for any particular site may be obtained from charts and tables in this handbook. Localities or countries where the rainfall characteristics, soil types, topographic features, or farm practices are substantially beyond the range of present U.S. data will find these charts and tables incomplete and perhaps inaccurate for their conditions. However, they will provide guidelines that can reduce the amount of local research needed to develop comparable charts and tables for their conditions.

The subsection on **Predicting Cropland Soil Losses**, page 40 illustrates how to select factor values from the tables and charts. Readers who have had no experience with the soil loss equation may wish to read that section first. After they have referred to the tables and figures and located the values used in the sample, they may move readily to the intervening detailed discussions of the equation's factors.

The soil loss prediction procedure is more valuable as a guide for selection of practices if the user has a general knowledge of the principles and factor interrelations on which the equation is based. Therefore, the significance of each factor is discussed before presenting the reference table or chart from which local values may be obtained. Limitations of the data available for evaluation of some of the factors are also pointed out.

RAINFALL AND RUNOFF FACTOR (R)

Rills and sediment deposits observed after an unusually intense storm have sometimes led to the conclusion that the significant erosion is associated with only a few storms, or that it is solely a function of peak intensities. However, more than 30 years of measurements in many States have shown that this is not the case (*51*). The data show that a rainfall factor used to estimate average annual soil loss must include the cumulative effects of the many moderate-sized storms, as well as the effects of the occasional severe ones.

The numerical value used for **R** in the soil loss equation must quantify the raindrop impact effect and must also provide relative information on the amount and rate of runoff likely to be associated with the rain. The rainfall erosion index derived by Wischmeier (*49*) appears to meet these requirements better than any other of the many rainfall parameters and groups of parameters tested against the assembled plot data. The local value of this index generally equals **R** for the soil loss equation and may be obtained directly from the map in figure 1. However, the index does not include the erosive forces of runoff from thaw, snowmelt, or irrigation. A procedure for evaluating **R** for locations where this type of runoff is significant will be given under the topic **R Values for Thaw and Snowmelt.**

Rainfall Erosion Index

The research data indicate that when factors other than rainfall are held constant, storm soil losses from cultivated fields are directly proportional to a rainstorm parameter identified as the **EI** (defined below) (*49*). The relation of soil loss to this parameter is linear, and its individual storm values are directly additive. The sum of the storm **EI** values for a given period is a numerical measure of the erosive potential of the rainfall within that period. The average annual total of the storm **EI** values in a particular locality is the rainfall erosion index for that locality. Because of apparent cyclical patterns in rainfall data (*33*), the published rainfall erosion index values were based on 22-year station rainfall records.

Rain showers of less than one-half inch and separated from other rain periods by more than 6 hours were omitted from the erosion index computations, unless as much as 0.25 in of rain fell in 15 min. Exploratory analyses showed that the **EI** values for such rains are usually too small for practical significance and that, collectively, they have little effect on monthly percentages of the annual **EI.** The cost of abstracting and analyzing 4,000 location-years of rainfall-intensity data was greatly reduced by adopting the 0.5-in threshold value.

EI Parameter

By definition, the value of **EI** for a given rainstorm equals the product, total storm energy (**E**) times the maximum 30-min intensity ($\mathbf{I}_{30}$), where **E** is in hundreds of foot-tons per acre and $\mathbf{I}_{30}$ is in inches per hour (in/h). **EI** is an abbreviation for energy-times-intensity, and the term should not be considered simply an energy parameter. The data show that rainfall energy, itself, is not a good indicator of erosive potential. The storm energy indicates the volume of rainfall and runoff, but a long, slow rain may have the same **E** value as a shorter rain at much higher intensity. Raindrop erosion increases with intensity. The $\mathbf{I}_{30}$ component indicates the prolonged-peak rates of detachment and runoff. The product term, **EI,** is a statistical interaction term that reflects how total energy and peak inensity are combined in each particular storm. Technically, it indicates how particle detachment is combined with transport capacity.

The energy of a rainstorm is a function of the amount of rain and of all the storm's component intensities. Median raindrop size increases with rain intensity (*62*), and terminal velocities of free-falling waterdrops increase with increased dropsize (*13*). Since the energy of a given mass in motion is proportional to velocity-squared, rainfall energy is directly related to rain intensity. The relationship is expressed by the equation,

$$\mathbf{E} = 916 + 331 \log_{10} \mathbf{I}, \qquad (2)$$

where **E** is kinetic energy in foot-tons per acre-inch and **I** is intensity in inches per hour (*62*). A limit of 3 in/h is imposed on **I** by the finding that median dropsize does not continue to increase when intensities exceed 3 in/h (*7, 15*). The energy

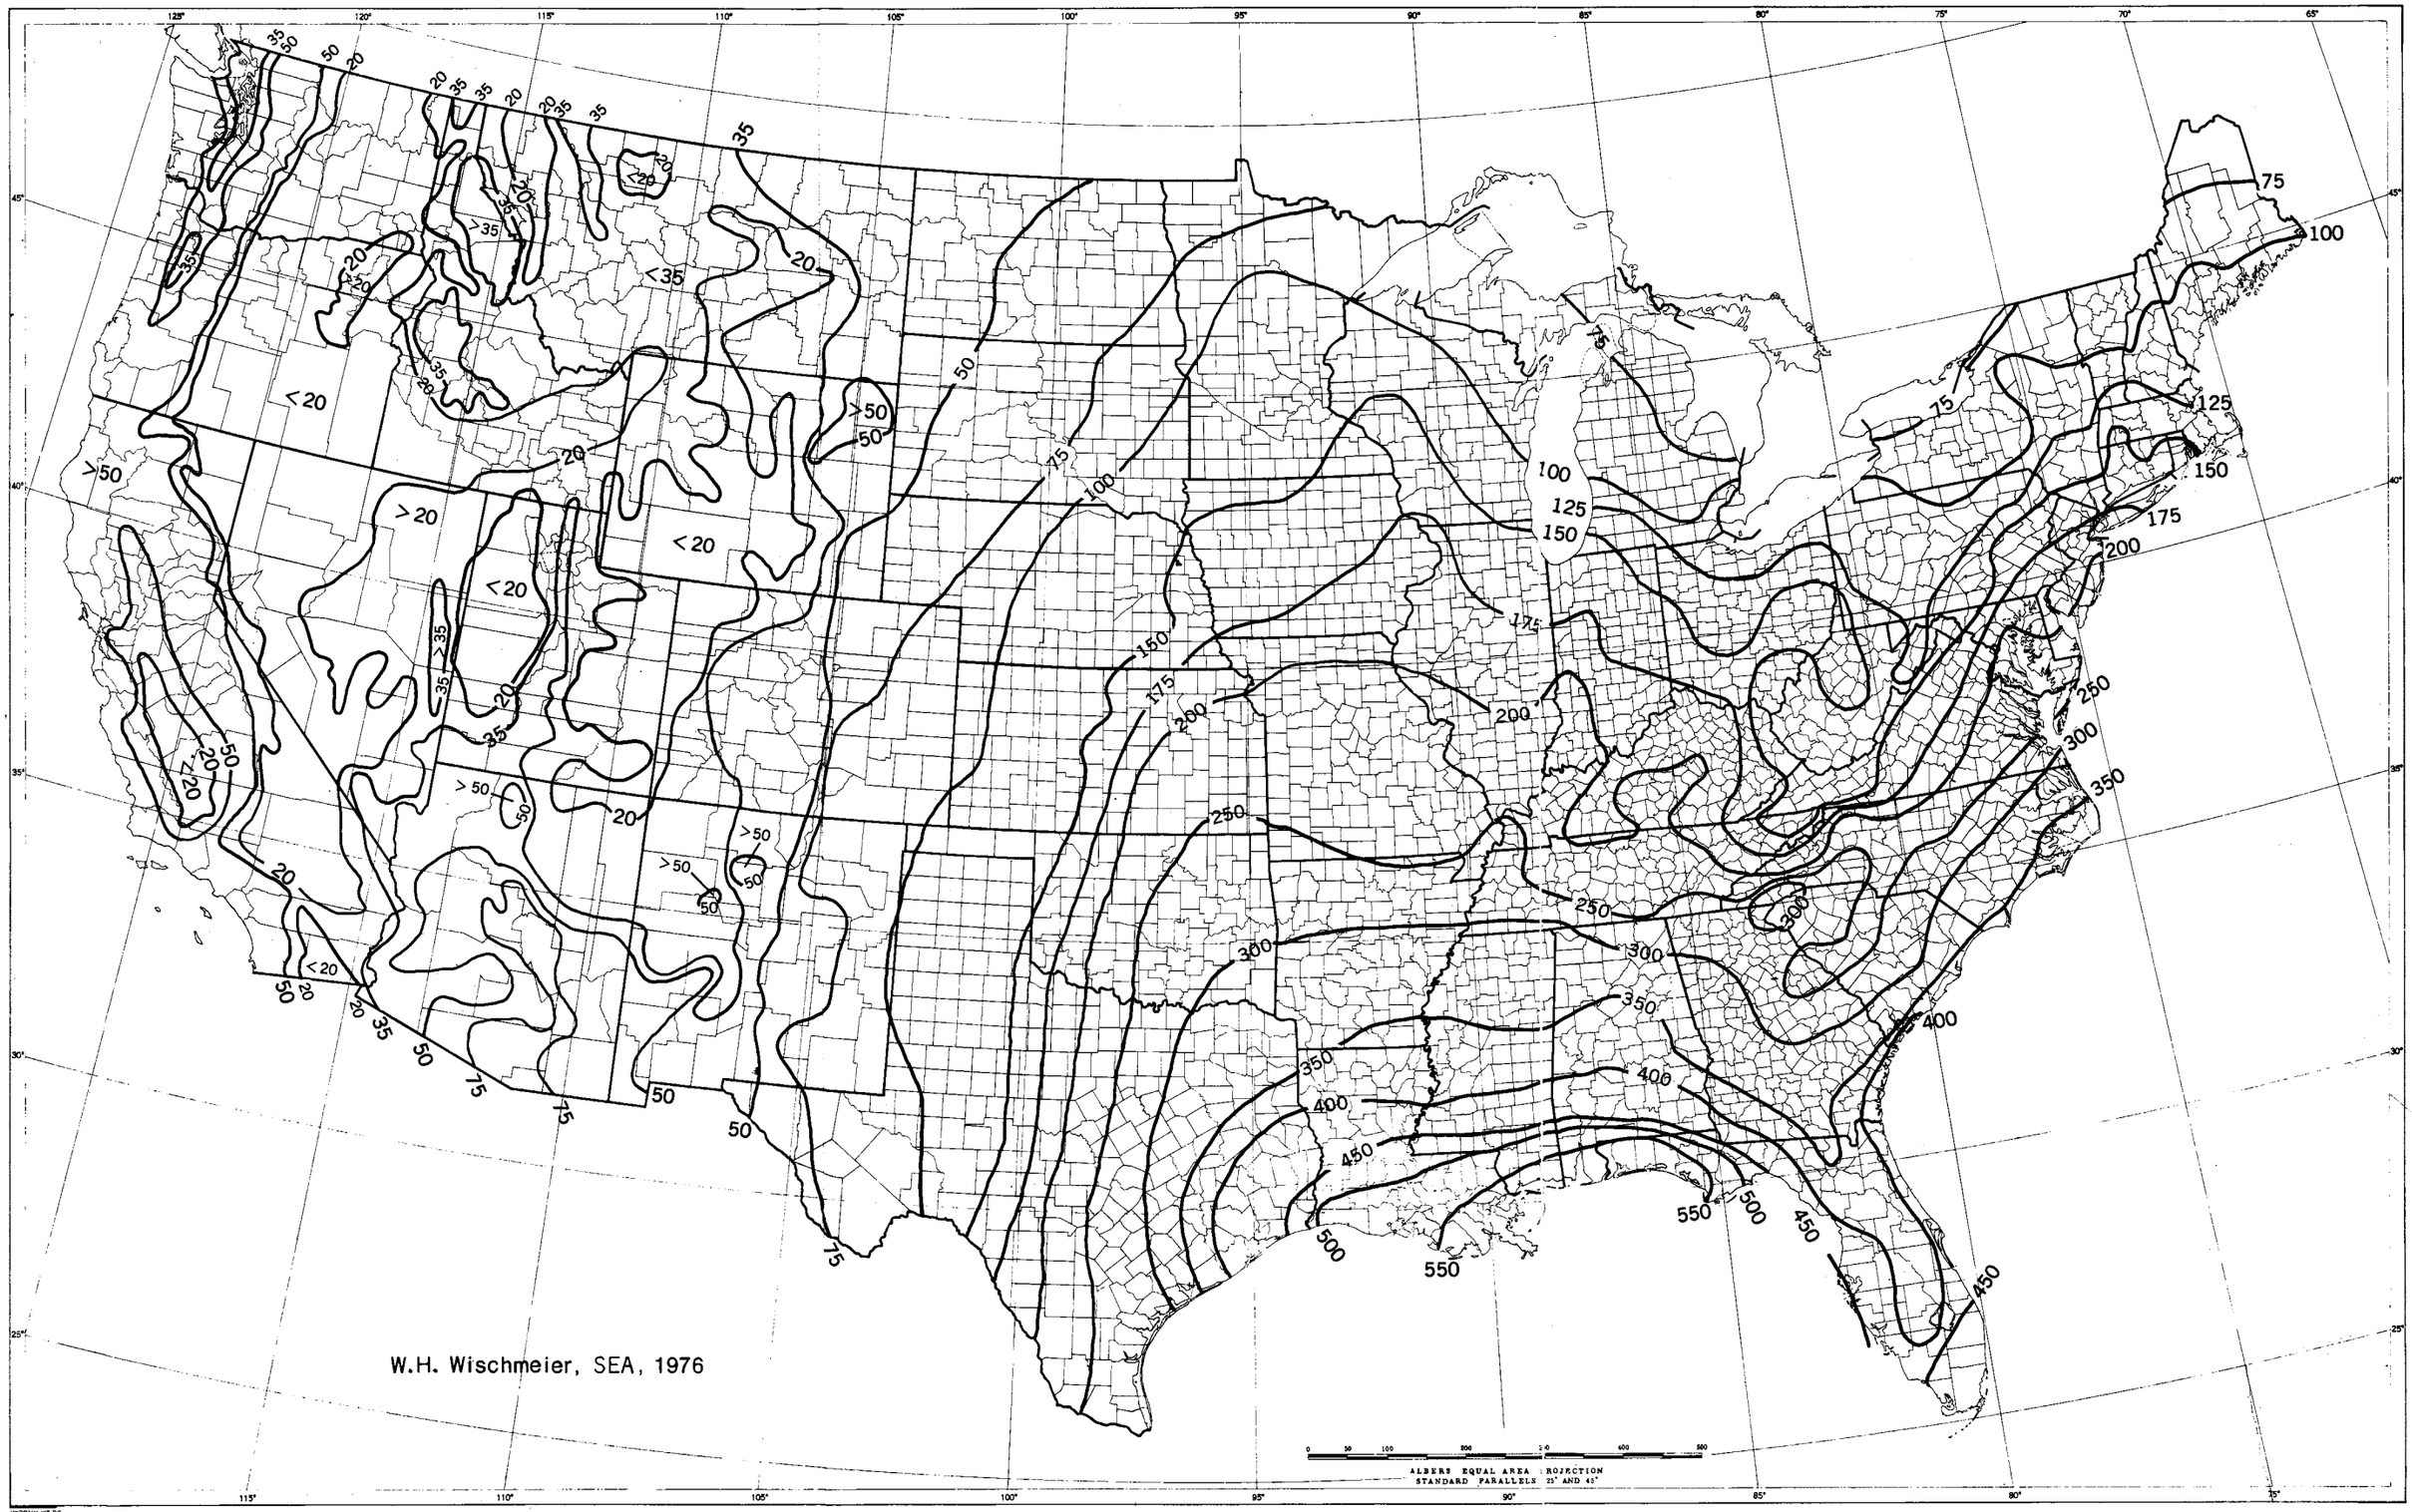

FIGURE 1.—Average annual values of the rainfall erosion index.

of a rainstorm is computed from recording-rain gage data. The storm is divided into successive increments of essentially uniform intensity, and a rainfall energy-intensity table derived from the above formula (app., table 19) is used to compute the energy for each increment. (Because the energy equation and energy-intensity table have been frequently published with energy expressed in foot-tons per acre-inch, this unit was retained in table 19. However, for computation of **EI** values, storm energy is expressed in hundreds of foot-tons per acre. Therefore, energies computed by the published formula or table 19 must be divided by 100 before multiplying by I_{30} to compute **EI**.)

Isoerodent Maps

Local values of the rainfall erosion index may be taken directly from the isoerodent maps, figures 1 and 2. The plotted lines on the maps are called isoerodents because they connect points of equal rainfall erosivity. Erosion index values for locations between the lines are obtained by linear interpolation.

The isoerodent map in the original version of this handbook (*64*) was developed from 22-year station rainfall records by computing the **EI** value for each storm that met the previously defined threshold criteria. Isoerodents were then located between these point values with the help of published rainfall intensity-frequency data (*47*) and topographic maps. The 11 Western States were omitted from the initial map because the rainfall patterns in this mountainous region are sporadic and not enough long-term, recording-rain gage records were available to establish paths of equal erosion index values.

The isoerodent map was extended to the Pacific Coast in 1976 by use of an estimating procedure. Results of investigations at the Runoff and Soil Loss Data Center at Purdue University showed that the known erosion index values in the Western Plains and North Central States could be approximated with reasonable accuracy by the quantity $27.38\ P^{2.17}$, where **P** is the 2-year, 6-h rainfall amount (*55*). This relationship was used with National Weather Service isopluvial maps to approximate erosion index values for the Western States. The resulting isoerodents are compatible with the few point values that had been established within the 11 Western States and can provide helpful guides for conservation planning on a site basis. However, they are less precise than those computed for the 37-State area, where more data were available and rainfall patterns are less eratic. Also, linear interpolations between the lines will not always be accurate in mountain regions because values of the erosion index may change rather abruptly with elevation changes. The point values that were computed directly from long-term station rainfall records in the Western States are included in table 7, as reference points.

Figure 2 was developed by computing the erosion index for first-order weather stations in Hawaii and deriving the relation of these values to National Weather Service intensity-frequency data for the five major islands. When the present short-term, rainfall-intensity records have been sufficiently lengthened, more point values of the index should be computed by the standard procedure.

Figure 1 shows that local, average-annual values of the erosion index in the 48 conterminous States range from less than 50 to more than 500. The erosion index measures the combined effect of rainfall and its associated runoff. If the soil and topography were exactly the same everywhere, average annual soil losses from plots maintained in continuous fallow would differ in direct proportion to the erosion index values. However, this potential difference is partially offset by differences in soil, topography, vegetative cover, and residues. On fertile soils in the high rainfall areas of the Southern States, good vegetal cover protects the soil surface throughout most of the year and heavy plant residues may provide excellent cover also during the dormant season. In the regions where the erosion index is extremely low, rainfall is seldom adequate for establishing annual meadows and the cover provided by other crops is often for relatively short periods. Hence, serious soil erosion hazards exist in semiarid regions as well as in humid.

Frequency Distribution

The isoerodent maps present 22-year-average annual values of **EI** for the delineated areas. However, both the annual and the maximum-storm values at a particular location vary from year to year. Analysis of 181 station rainfall records showed that they tend to follow log-normal frequency distributions that are usually well defined by continu-

ous records of from 20 to 25 years (*49*). Tables of specific probabilities of annual and maximum-storm **EI** values at the 181 locations are presented in the appendix (tables 17 and 18).

R Values for Thaw and Snowmelt

The standard rainfall erosion index estimates the erosive forces of the rainfall and its directly associated runoff. In the Pacific Northwest, as much as 90 percent of the erosion on the steeply rolling wheatland has been estimated to derive from runoff associated with surface thaws and snowmelt. This type of erosion is not accounted for by the rainfall erosion index but is considered either predominant or appreciable in much of the Northwest and in portions of the central Western States. A linear precipitation relationship would not account for peak losses in early spring because as the winter progresses, the soil becomes increasingly more erodible as the soil moisture profile is being filled, the surface structure is being broken down by repeated freezing and thawing, and puddling and surface sealing are taking place. Additional research of the erosion processes and means of control under these conditions is urgently needed.

In the meantime, the early spring erosion by runoff from snowmelt, thaw, or light rain on frozen soil may be included in the soil loss computations by adding a subfactor, $\mathbf{R}_s$, to the location's erosion index to obtain **R**. Investigations of limited data indicated that an estimate of $\mathbf{R}_s$ may be obtained by taking 1.5 times the local December-through-March precipitation, measured as inches of water. For example, a location in the North-

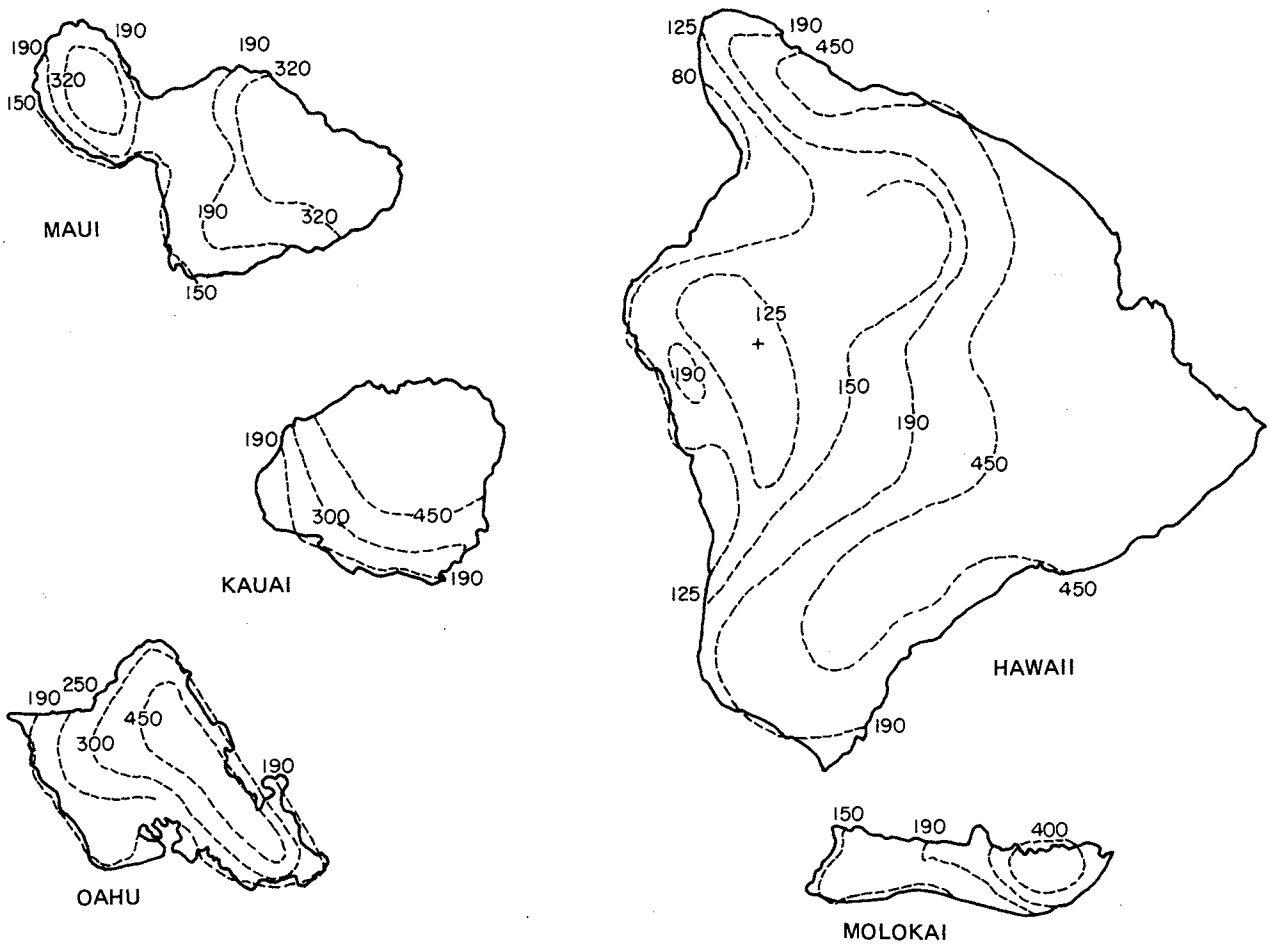

FIGURE 2.—Estimated average annual values of the rainfall erosion index in Hawaii.

west that has an erosion index of 20 (fig. 1) and averages 12 in of precipitation between December 1 and March 31 would have an estimated average annual **R** of 1.5(12) + 20, or 38.

This type of runoff may also be a significant factor in the northern tier of Central and Eastern States. Where experience indicates this to be the case, it should be included in **R** and also in the erosion index distribution curves as illustrated on page 27.

SOIL ERODIBILITY FACTOR (K)

The meaning of the term "soil erodibility" is distinctly different from that of the term "soil erosion." The rate of soil erosion, **A**, in the soil loss equation, may be influenced more by land slope, rainstorm characteristics, cover, and management than by inherent properties of the soil. However, some soils erode more readily than others even when all other factors are the same. This difference, caused by properties of the soil itself, is referred to as the soil erodibility. Several early attempts were made to determine criteria for scientific classifications of soils according to erodibility (*6, 18, 28, 35*), but classifications used for erosion prediction were only relative rankings.

Differences in the natural susceptibilities of soils to erosion are difficult to quantify from field observations. Even a soil with a relatively low erodibility factor may show signs of serious erosion when it occurs on long or steep slopes or in localities with numerous high-intensity rainstorms. A soil with a high natural erodibility factor, on the other hand, may show little evidence of actual erosion under gentle rainfall when it occurs on short and gentle slopes, or when the best possible management is practiced. The effects of rainfall differences, slope, cover, and management are accounted for in the prediction equation by the symbols **R, L, S, C,** and **P**. Therefore, the soil erodibility factor, **K**, must be evaluated independently of the effects of the other factors.

Definition of Factor K

The soil erodibility factor, **K**, in the USLE is a quantitative value experimentally determined. For a particular soil, it is the rate of soil loss per erosion index unit as measured on a "unit" plot, which has been arbitrarily defined as follows:

A unit plot is 72.6 ft long, with a uniform lengthwise slope of 9 percent, in continuous fallow, tilled up and down the slope. Continuous fallow, for this purpose, is land that has been tilled and kept free of vegetation for more than 2 years. During the period of soil loss measurements, the plot is plowed and placed in conventional corn seedbed condition each spring and is tilled as needed to prevent vegetative growth and severe surface crusting. When all of these conditions are met, **L, S, C,** and **P** each equal 1.0, and **K** equals **A/EI**.

The 72.6 ft length and 9 percent steepness were selected as base values for **L, S,** and **K** because they are the predominant slope length and about the average gradient on which past erosion measurements in the United States had been made. The designated management provides a condition that nearly eliminates effects of cover, management, and land use residual and that can be duplicated on any cropland.

Direct measurements of **K** on well-replicated, unit plots as described reflect the combined effects of all the soil properties that significantly influence the ease with which a particular soil is eroded by rainfall and runoff if not protected. However, **K** is an average value for a given soil, and direct measurement of the factor requires soil loss measurements for a representative range of storm sizes and antecedent soil conditions. (See **Individual Storm Soil Losses** under **APPLYING THE SOIL LOSS EQUATION**.) To evaluate **K** for soils that do not usually occur on a 9-percent slope, soil loss data from plots that meet all the other specified conditions are adjusted to this base by **S**.

Values of K for Specific Soils

Representative values of **K** for most of the soil types and texture classes can be obtained from tables prepared by soil scientists using the latest available research information. These tables are available from the Regional Technical Service Centers or State offices of SCS. Values for the exact

TABLE 1.—*Computed* **K** *values for soils on erosion research stations*

Soil	Source of data	Computed K
Dunkirk silt loam	Geneva, N.Y.	[1]0.69

[1] Evaluated from continuous follow. All others were computed from rowcrop data.

soil conditions at a specific site can be computed by use of the soil erodibility nomograph presented in the next subsection.

Usually a soil type becomes less erodible with decrease in silt fraction, regardless of whether the corresponding increase is in the sand fraction or the clay fraction. Overall, organic matter content ranked next to particle-size distribution as an indicator of erodibility. However, a soil's erodibility is a function of complex interactions of a substantial number of its physical and chemical properties and often varies within a standard texture class.

Values of **K** determined for 23 major soils on which erosion plot studies under natural rain were conducted since 1930 are listed in table 1. Seven of these values are from continuous fallow. The others are from row crops averaging 20 plot-years of record and grown in systems for which the cropping effect had been measured in other studies. Other soils on which valuable erosion studies have been conducted[4] were not included in the table because of uncertainties involved in adjustments of the data for effects of cropping and management.

Direct measurement of the erodibility factor is both costly and time consuming and has been feasible only for a few major soil types. To achieve a better understanding of how and to what extent each of various properties of a soil affects its erodibility, an interregional study was initiated in 1961. The study included the use of field-plot rainfall simulators in at least a dozen States to obtain comparative data on numerous soils, laboratory determinations of physical and chemical properties, and operation of additional fallow plots under natural rain. Several empirical erodibility equations were reported (*3, 60*). A soil erodibility nomograph for farmland and construction sites (*58*) provided a more generally applicable working tool. Approximate **K** values for 10 benchmark soils in Hawaii are listed in table 2.

[4] See footnote 3, p. 2.

Soil Erodibility Nomograph

The soil loss data show that very fine sand (0.05-0.10 mm) is comparable in erodibility to silt-sized particles and that mechanical-analysis data are much more valuable when expressed by an interaction term that describes the proportions in which the sand, silt, and clay fractions are combined in the soil. When mechanical analysis data based on the standard USDA classification are used for the nomograph in figure 3, the percentage of very fine sand (0.1-0.05 mm) must first be transferred from the sand fraction to the silt fraction. The mechanical analysis data are then effectively described by a particle-size parameter **M**, which equals percent silt (0.1-0.002 mm) times the quantity 100-minus-percent-clay. Where the silt fraction does not exceed 70 percent, erodibility varies approximately as the 1.14 power of this parameter, but prediction accuracy is improved by adding information on organic matter content, soil structure, and profile permeability class.

For soils containing less than 70 percent silt and very fine sand, the nomograph (fig. 3) solves the equation:

$$100\,K = 2.1\,M^{1.14}\,(10^{-4})\,(12 - a) + 3.25\,(b - 2) + 2.5\,(c - 3) \quad (3)$$

where

M = the particle-size parameter defined above,
a = percent organic matter,
b = the soil-structure code used in soil classification, and
c = the profile-permeability class.

The intersection of the selected percent-silt and percent-sand lines computes the value of **M** on the unidentified horizontal scale of the nomograph. (Percent clay enters into the computation as 100 minus the percentages of sand and silt.)

The data indicate a change in the relation of **M** to erodibility when the silt and very fine sand fraction exceeds about 70 percent. This change was empirically reflected by inflections in the percent-sand curves at that point but has not been described by a numerical equation.

Readers who would like more detail regarding the data and relationships underlying the nomograph equation may obtain this from journal articles (*58*, 60).

Nomograph Solution

With appropriate data, enter the scale at the left and proceed to points representing the soil's percent sand (0.10-2.0 mm), percent organic matter, structure code, and permeability class as illustrated by the dotted line on the nomograph. The horizontal and vertical moves must be made in the listed sequence. Use linear interpolations between plotted lines. The structure code and permeability classes are defined on the nomograph for reference.

Many agricultural soils have both fine granular topsoil and moderate permeability. For these soils, **K** may be read from the scale labeled "first approximation of **K**," and the second block of the graph is not needed. For all other soils, however, the procedure must be completed to the soil erodibility scale in the second half of the graph.

The mechanical analysis, organic matter, and structure data are those for the topsoil. For evaluation of **K** for desurfaced subsoil horizons, they pertain to the upper 6 in of the new soil profile. The permeability class is the profile permeability. Coarse fragments are excluded when determining percentages of sand, silt, and clay. If substantial, they may have a permanent mulch effect which can be evaluated from the upper curve of the chart on mulch and canopy effects (p. 19, fig. 6) and applied to the number obtained from the nomograph solution.

Confidence Limits

In tests against measured **K** values ranging from 0.03 to 0.69, 65 percent of the nomograph solutions differed from the measured **K** values by less than 0.02, and 95 percent of them by less than 0.04. Limited data available in 1971 for mechanically exposed **B** and **C** subsoil horizons indicated about comparable accuracy for these conditions. However, more recent data taken on desurfaced high-clay subsoils showed the nomograph solution to lack the desired sensitivity to differences in erodibilities of these soil horizons. For such soils the content of free iron and aluminum oxides ranks next to particle-size distribution as an indicator of erodibility (*37*). Some high-clay soils form what has been called irreversible aggregates on the surface when tilled. These behave like larger primary particles.

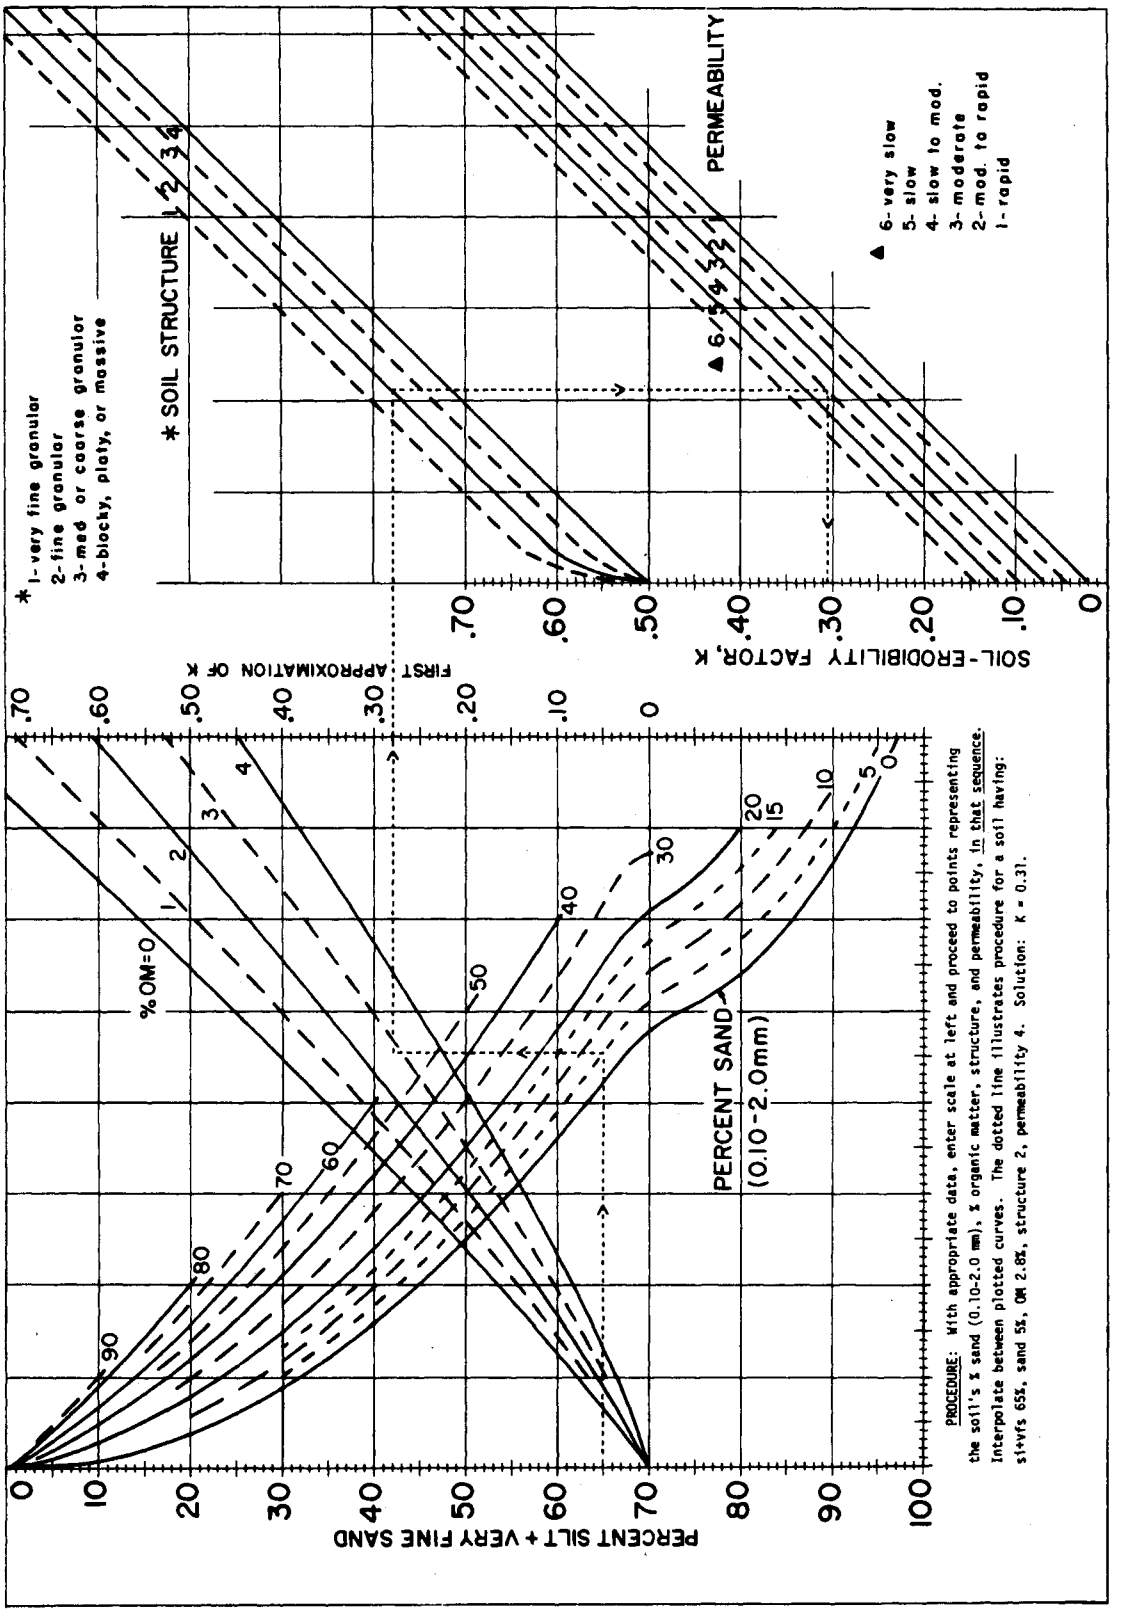

FIGURE 3.—The soil-erodibility nomograph. Where the silt fraction does not exceed 70 percent, the equation is $100\ K = 2.1\ M^{1.14}\ (10^{-4})\ (12 - a) + 3.25\ (b - 2) + 2.5\ (c - 3)$ where M = (percent si + vfs) (100 — percent c), a = percent organic matter, b = structure code, and c = profile permeability class.

TOPOGRAPHIC FACTOR (LS)

Both the length and the steepness of the land slope substantially affect the rate of soil erosion by water. The two effects have been evaluated separately in research and are represented in the soil loss equation by **L** and **S**, respectively. In field applications, however, considering the two as a single topographic factor, **LS**, is more convenient.

Slope-Effect Chart

LS is the expected ratio of soil loss per unit area from a field slope to that from a 72.6-ft length of uniform 9-percent slope under otherwise identical conditions. This ratio for specified combinations of field slope length and uniform gradient may be obtained directly from the slope-effect chart (fig. 4). Enter on the horizontal axis with the field slope length, move vertically to the appropriate percent-slope curve, and read **LS** on the scale at the left. For example, the **LS** factor for a 300-ft length of 10-percent slope is 2.4. Those who prefer a table may use table 3 and interpolate between listed values.

To compute soil loss from slopes that are appreciably convex, concave, or complex, the chart **LS** values need to be adjusted as indicated in the section **LS Values for Irregular Slopes.** Figure 4 and table 3 assume slopes that have essentially uniform gradient. The chart and table were derived by the equation

$$LS = (\lambda/72.6)^m \ (65.41 \sin^2 \theta + 4.56 \sin \theta + 0.065) \quad (4)$$

where λ = slope length in feet;
θ = angle of slope; and
m = 0.5 if the percent slope is 5 or more, 0.4 on slopes of 3.5 to 4.5 percent, 0.3 on slopes of 1 to 3 percent, and 0.2 on uniform gradients of less than 1 percent.

The basis for this equation is given in the subsection discussing the individual effects of slope length and steepness. However, the relationships expressed by the equation were derived from data obtained on cropland, under natural rainfall, on slopes ranging from 3 to 18 percent in steepness and about 30 to 300 ft in length. How far beyond these ranges in slope characteristics the relationships derived from the data continue to be accurate has not been determined by direct soil loss measurements.

The Palouse Region of the Northwest represents

[1] $LS = (\lambda/72.6)^m \ (65.41 \sin^2 \theta + 4.56 \sin \theta + 0.065)$ where λ = slope length in feet; **m** = 0.2 for gradients < 1 percent, 0.3 for 1 to 3 percent slopes, 0.4 for 3.5 to 4.5 percent slopes, 0.5 for 5 percent slopes and steeper; and θ = angle of slope. (For other combinations of length and gradient, interpolate between adjacent values or see fig. 4.)

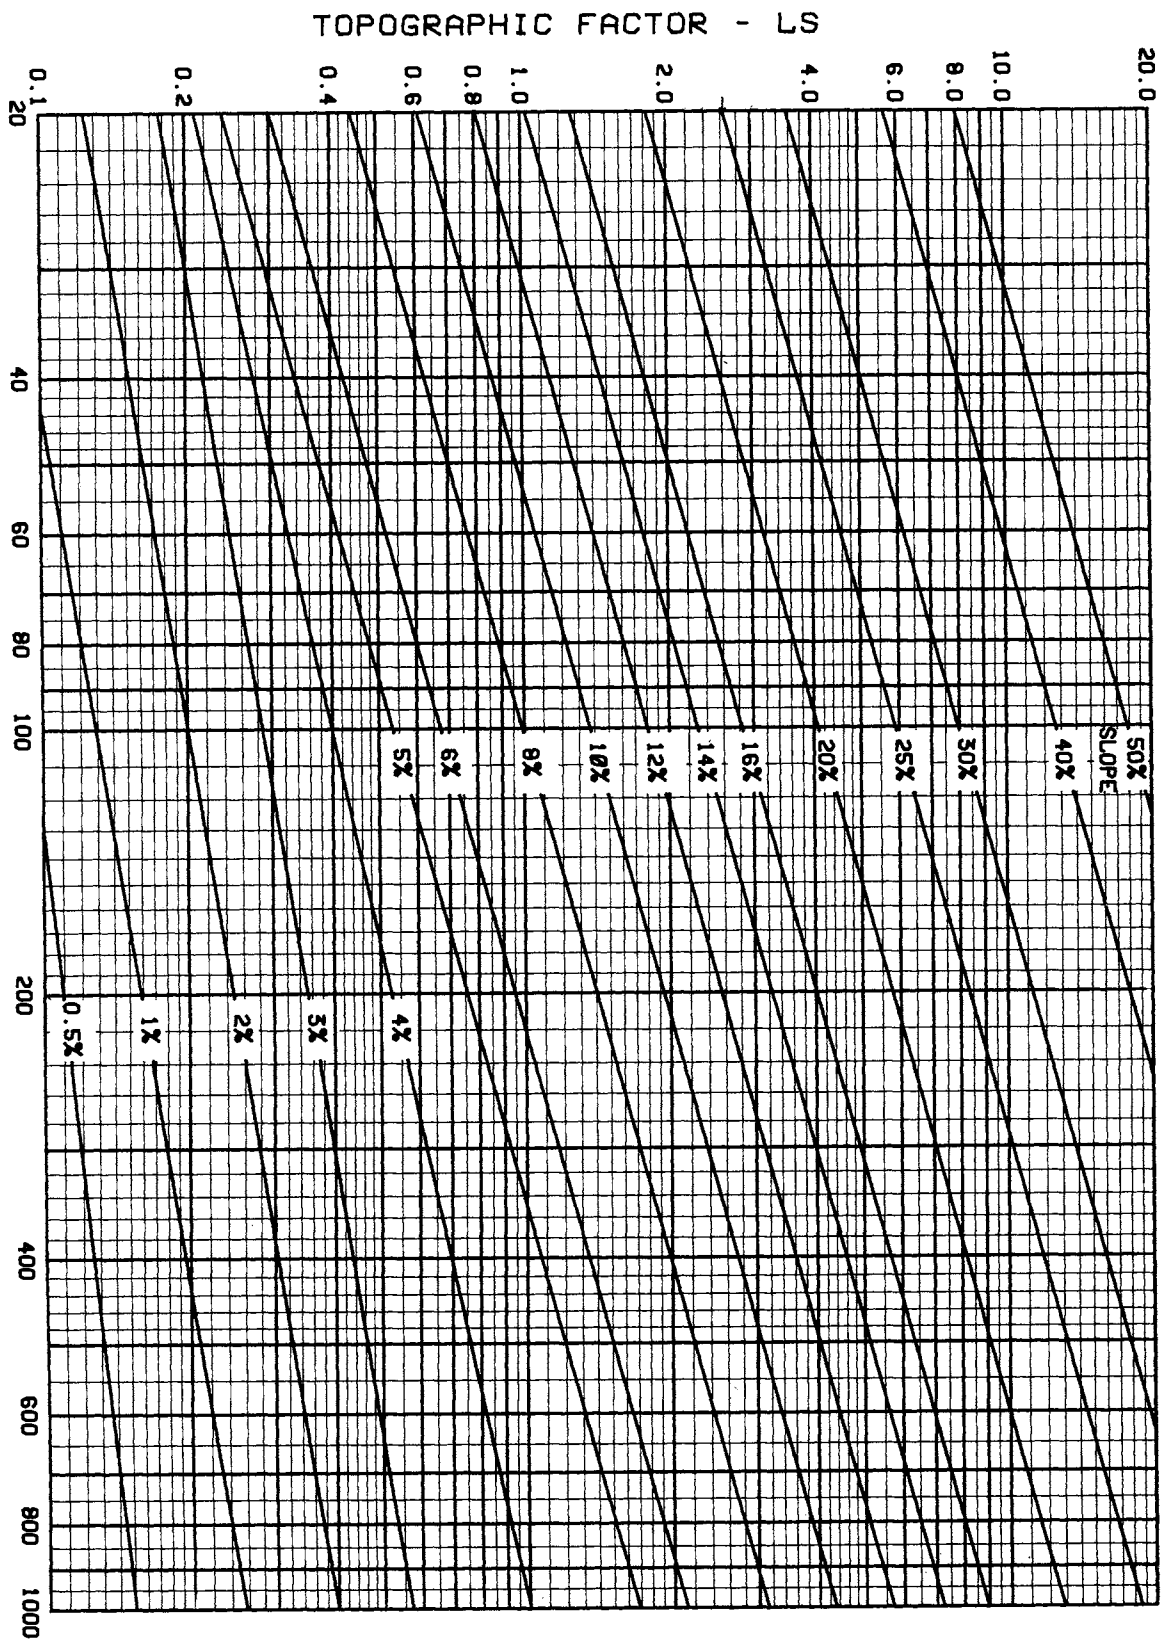

FIGURE 4.—Slope-effect chart (topographic factor, LS). $LS = (\lambda/72.6)^m$ $(65.41 \sin^2\theta + 4.56 \sin\theta + 0.065)$ where λ = slope length in feet; θ = angle of slope; and $m = 0.2$ for gradients < 1 percent, 0.3 for 1 to 3 percent slopes, 0.4 for 3.5 to 4.5 percent slopes, and 0.5 for slopes of 5 percent or steeper.

a different situation. The rainfall erosion index is quite low because most of the rain comes as small drops and at low intensities. But many of the cropland slopes are long or steep, and substantial erosion occurs because of runoff from snowmelt or light rains over saturated soil surfaces. Limited erosion data from this region, mostly observational, strongly indicate that for this type of runoff (not accompanied by raindrop impact) the effects of percent and length of slope are of lower magnitude than indicated by the humid region data. Investigations designed to develop a more accurate **LS** equation for this region are underway at Pullman, Wash. (*21*). In the meantime, the researchers are temporarily recommending using a modified equation which computes **LS** values that are close to those that would be calculated by the equation given above if $\sin^{1.5}\theta$ were substituted for $\sin^{2}\theta$ and the length-exponent, **m**, were assumed to equal 0.3. Intuitively, these changes seem reasonable for the conditions under which about 90 percent of the erosion in this region occurs.

Slope-Length Effect

Slope length is defined as the distance from the point of origin of overland flow to the point where either the slope gradient decreases enough that deposition begins, or the runoff water enters a well-defined channel that may be part of a drainage network or a constructed channel (*40*). A change in land cover or a substantial change in gradient along a slope does not begin a new slope length for purposes of soil loss estimation.

The effect of slope length on annual *runoff* per unit area of cropland may generally be assumed negligible. In some of the studies runoff per unit area was slightly lower on the longer slopes during the growing season and slightly higher during the dormant season, but the differences were relatively small and neither of the relationships was consistent (*52*).

However, the *soil loss* per unit area generally increases substantially as slope length increases. The greater accumulation of runoff on the longer slopes increases its detachment and transport capacities.

The plot data showed average soil loss per unit area to be proportional to a power of slope length. Because **L** is the ratio of field soil loss to the corresponding loss from 72.6-ft slope length, its value may be expressed as $\mathbf{L} = (\lambda/72.6)^{\mathbf{m}}$, where λ is the field slope length in feet, and **m** assumes approximately the values given in the **LS** equation in the preceding section. These are average values of **m** and are subject to some variability caused by interaction effects which are not now quantitatively predictable.

The existing field plot data do not establish a general value greater than 0.5 for **m** on slopes steeper than 10 percent, as was suggested in 1965 (*64*). Although apparent values up to 0.9 were observed in some of the data (*63*), the higher values appear to have been related to soil, crop, and management variables rather than to greater slope steepness. However, basic modeling work has suggested that **m** may appreciably exceed 0.5 on steep slopes that are highly susceptible to rilling, like some construction slopes (*10*). Additional research data are greatly needed to quantify the significant interaction effects so that specific site values of **m** can be more precisely computed. Subdividing erosion between interrill (or sheet) erosion and rill erosion, being done in recent modeling work (*10, 11, 22*), promises to be quite helpful for solving this problem.

Some observations have indicated that the values of the length exponent that were derived from the plot data may overestimate soil loss when applied to lengths in the range of a quarter of a mile or more. This is logical because slopes of such lengths would rarely have a constant gradient along their entire length, and the slope irregularities would affect the amount of soil movement to the foot of the slope. By the definition of slope length quoted earlier, such slopes would usually consist of several lengths, between points where deposition occurs.

Slope length is difficult to determine for long slopes with an average gradient of less than 1 percent, unless they are precisely formed with a land leveler. On flat slopes, reflecting both the erosion and the deposition accurately by a length factor may not be possible. However, on a nearly zero-percent slope, increased length would have minor effect on runoff velocity, and the greater depths of accumulated runoff water would cushion the raindrop impact. An exponent of 0.2 for gradients of less than 1 percent is compatible with the

scarce data available for such slopes and was used to derive figure 4 and table 3.

Distribution of Length Effect

LS values from figure 4 or table 3 predict the *average* erosion over the entire slope. But this erosion is not evenly distributed over the entire length. The rate of soil loss per unit of area increases as the m^{th} power of the distance from the top of the slope, where **m** is the length exponent in the preceding equation.

An equation by Foster and Wischmeier (*12*) estimates the relative amounts of soil loss from successive segments of a slope under conditions where there is no deposition by overland flow. When the gradient is essentially uniform and the segments are of equal length, the procedure can be shortened (*55*). Table 4, derived by this procedure, shows the proportionate amounts of soil detachment from successive equal-length segments of a uniform slope.

Table 4 is entered with the total number of equal-length segments, and the fraction of the soil loss for each segment is read beneath the applicable value of **m**. For example, three equal-length segments of a uniform 6-percent slope would be expected to produce 19, 35, and 46 percent, respectively, of the loss from the entire slope.

TABLE 4.—*Estimated relative soil losses from successive equal-length segments of a uniform slope*[1]

Number of segments	Sequence number of segment	Fraction of soil loss		
		m = 0.5	m = 0.4	m = 0.3
2	1	0.35	0.38	0.41
	2	.65	.62	.59
3	1	.19	.22	.24
	2	.35	.35	.35
	3	.46	.43	.41
4	1	.12	.14	.17
	2	.23	.24	.24
	3	.30	.29	.28
	4	.35	.33	.31
5	1	.09	.11	.12
	2	.16	.17	.18
	3	.21	.21	.21
	4	.25	.24	.23
	5	.28	.27	.25

[1] Derived by the formula:

$$\text{Soil loss fraction} = \frac{i^{m+1} - (i-1)^{m+1}}{N^{m+1}}$$

where **i** = segment sequence number; **m** = slope-length exponent (0.5 for slopes $\geq$ 5 percent, 0.4 for 4 percent slopes, and 0.3 for 3 percent or less); and **N** = number of equal-length segments into which the slope was divided.

Four segments would produce 12, 23, 30, and 35 percent, respectively. Segment No. 1 is always at the top of the slope.

Percent Slope

Runoff from cropland generally increases with increased slope gradient, but the relationship is influenced by such factors as type of crop, surface roughness, and profile saturation. In the natural rain slope-effect studies, the logarithm of runoff from row crops was linearly and directly proportional to percent slope. With good meadow sod and with smooth bare surfaces, the relationship was insignificant. The effect of slope on runoff decreased in extremely wet periods.

Soil loss increases much more rapidly than runoff as slopes steepen. The slope-steepness factor, **S**, in the soil loss equation is evaluated by the equation

$$S = 65.41 \sin^2 \theta + 4.56 \sin \theta + 0.065 \qquad (5)$$

where θ is the angle of slope.

This equation was used to develop the slope-effect chart. The values reflect the average effect of slope steepness on soil loss in the plot studies. The relation of percent slope to soil loss is believed to to be influenced by interactions with soil properties and surface conditions, but the interaction effects have not been quantified by research data. Neither are data available to define the limits on the equation's applicability.

This equation can be derived from the formerly published equation for **S**. Expressing the factor as a function of the sine of the angle of slope rather than the tangent is more accurate because raindrop-impact forces along the surface and runoff shear stress are functions of the sine. Substituting 100 sin θ for percent slope, which is 100 tan θ, does not significantly affect the initial statistical derivation or the equation's solutions for slopes of less than 20 percent. But as slopes become steeper, the difference between the sine and the tangent becomes appreciable and projections far beyond the range of the plot data become more realistic. The numerator was divided by the constant denominator for simplification.

Irregular Slopes

Soil loss is also affected by the shape of a slope. Many field slopes either steepen toward the lower end (convex slope) or flatten toward the lower end (concave slope). Use of the average gradient to enter figure 4 or table 3 would underestimate soil movement to the foot of a convex slope and would overestimate it for concave slopes. Irregular slopes can usually be divided into segments that have nearly uniform gradient, but the segments cannot be evaluated as independent slopes when runoff flows from one segment to the next.

However, where two simplifying assumptions can be accepted, **LS** for irregular slopes can be routinely derived by combining selected values from the slope-effect chart and table 4 (*55*). The assumptions are that (1) the changes in gradient are not sufficient to cause upslope deposition, and (2) the irregular slope can be divided into a small number of equal-length segments in such a manner that the gradient within each segment for practical purposes can be considered uniform.

After dividing the convex, concave, or complex slope into equal-length segments as defined earlier, the procedure is as follows: List the segment gradients in the order in which they occur on the slope, beginning at the upper end. Enter the slope-effect chart with the total slope length and read **LS** for each of the listed gradients. Multiply these by the corrresponding factors from table 4 and add the products to obtain **LS** for the entire slope. The following tabulation illustrates the procedure for a 400-ft convex slope on which the upper third has a gradient of 5 percent; the middle third, 10 percent; and the lower third, 15 percent:

Segment	*Percent slope*	*Table 3*	*Table 4*	*Product*
1	5	1.07	0.19	0.203
2	10	2.74	.35	.959
3	15	5.12	.46	2.355
				LS = 3.517

For the concave slope of the same length, with the segment gradients in reverse order, the values in the third column would be listed in reverse order. The products would then be 0.973, 0.959, and 0.492, giving a sum of 2.42 for **LS.**

Research has not defined just how much gradient change is needed under various conditions for deposition of soil particles of various sizes to begin, but depositional areas can be determined by observation. When the slope breaks are sharp enough to cause deposition, the procedure can be used to estimate **LS** for slope segments above and below the depositional area. However, it will not predict the total sediment moved from such an interrupted slope because it does not predict the amount of deposition.

Changes in Soil Type or Cover Along the Slope

The procedure for irregular slopes can include evaluation of changes in soil type within a slope length (*55*). The products of values selected from table 3 or figure 4 and table 4 to evaluate **LS** for irregular slopes are multiplied by the respective values of **K** before summing. To illustrate, assume the **K** values for the soils in the three segments of the convex slope in the preceding example were 0.27, 0.32, and 0.37, respectively. The average **KLS** for the slope would be obtained as follows:

Segment No.	*Table 3*	*Table 4*	K	*Product*
1	1.07	0.19	0.27	0.055
2	2.74	.35	.32	.307
3	5.12	.46	.37	.871
				KLS = 1.233

Within limits, the procedure can be further extended to account for changes in cover along the slope length by adding a column of segment **C** values. However, it is not applicable for situations where a practice change along the slope causes deposition. For example, a grass buffer strip across the foot of a slope on which substantial erosion is occurring induces deposition. The amount of this deposition is a function of transport relationships (*10*) and cannot be predicted by the USLE.

Equation for Soil Detachment on Successive Segments of a Slope

This procedure is founded on an equation (*12*) that can be applied also when the slope segments are not of equal length. Concepts underlying this equation include the following:

Sediment load at a location on a slope is controlled either by the transport capacity of the runoff and rainfall or by the amount of detached soil material available for transport. When the amount of detached material exceeds the transport capacity, deposition occurs and the sediment load is determined primarily by the transport capacity of the runoff at that location. Where upslope detachment has not equaled the transport capacity, sediment load at a given location is a function of erosion characteristics of the upslope area and can be computed by the USLE. Soil loss from a given segment of the slope can then be computed as the difference between the sediment loads at the lower and upper ends of the segment.

Foster and Wischmeier (12) present a procedure for using this equation to evaluate **LS** for irregular slopes and to account for the effects of the soil or coverage changes along a slope, so long as the changes do not cause deposition to occur.

COVER AND MANAGEMENT FACTOR (C)

Cover and management effects cannot be independently evaluated because their combined effect is influenced by many significant interrelations. Almost any crop can be grown continuously, or it can be grown in rotations. Crop sequence influences the length of time between successive crop canopies, and it also influences the benefits obtained from residual effects of crops and management. The erosion control effectiveness of meadow sod turned under before a row crop depends on the type and quality of the meadow and on the length of time elapsed since the sod was turned under. Seedbeds can be clean tilled, or they can be protected by prior crop residues. They can be left rough, with much available capacity for surface storage and reduction of runoff velocity, or they can be smoothed by secondary tillage.

Crop residues can be removed, left on the surface, incorporated near the surface, or plowed under. When left on the surface, they can be chopped or dragged down, or they can be allowed to remain as left by the harvesting operation. The effectiveness of crop residue management will depend on the amount of residue available. This, in turn, depends on the amount and distribution of rainfall, on the fertility level, and on the management decisions made by the farmer.

The canopy protection of crops not only depends on the type of vegetation, the stand, and the quality of growth, but it also varies greatly in different months or seasons. Therefore, the overall erosion-reducing effectiveness of a crop depends largely on how much of the erosive rain occurs during those periods when the crop and management practices provide the least protection.

Definition of Factor C

Factor **C** in the soil loss equation is the ratio of soil loss from land cropped under specified conditions to the corresponding loss from clean-tilled, continuous fallow. This factor measures the combined effect of all the interrelated cover and management variables.

The loss that would occur on a particular field if it were continuously in fallow condition is computed by the product of **RKLS** in the soil loss equation. Actual loss from the cropped field is usually much less than this amount. Just how much less depends on the particular combination of cover, crop sequence, and management practices. It also depends on the particular stage of growth and development of the vegetal cover at the time of the rain. **C** adjusts the soil loss estimate to suit these conditions.

The correspondence of periods of expected highly erosive rainfall with periods of poor or good plant cover differs between regions or locations. Therefore, the value of **C** for a particular cropping system will not be the same in all parts of the country. Deriving the appropriate **C** values for a given locality requires knowledge of how the erosive rainfall in that locality is likely to be distributed through the 12 months of the year and

how much erosion control protection the growing plants, crop residues, and selected management practices will provide at the time when erosive rains are most likely to occur. A procedure is presented for deriving local values of **C** on the basis of available weather records and research data that reflect effects of crops and management in successive segments of a rotation cycle. The cropping and weather data needed for this purpose appear in reference form in the subsections entitled, **Soil Loss Ratios** and **Erosion Index Distribution Data.**

Cropstage Periods

The change in effectiveness of plant cover within the crop year is gradual. For practical purposes, the year is divided into a series of cropstage periods defined so that cover and management effects may be considered approximately uniform within each period.

Initially, five periods were used, with the seedling and establishment periods defined as the first and second months after crop seeding (*50*). Because of the existing ranges in soil fertility, row spacing, plant population, and general growing conditions, however, soil loss prediction accuracy is improved when the cropstage periods are defined according to percentage of canopy cover rather than for uniform time periods. The lengths of the respective periods will then vary with crop, climate, and management and will be determined by conditions in a particular geographic area.

The soil loss ratios presented in the next subsection for computation of **C** were evaluated for six cropstage periods defined as follows:

Period F (rough fallow)—Inversion plowing to secondary tillage.

Period SB (seedbed)—Secondary tillage for seedbed preparation until the crop has developed 10 percent canopy cover.

Period 1 (establishment)—End of *SB* until crop has developed a 50 percent canopy cover. (Exception: period 1 for cotton ends at 35 percent canopy cover.)

Period 2 (development)—End of period 1 until canopy cover reaches 75 percent. (60 percent for cotton.)

Period 3 (maturing crop)—End of period 2 until crop harvest. This period was evaluated for three levels of final crop canopy.

Period 4 (residue or stubble)—Harvest to plowing or new seeding.

Quantitative Evaluations of Crop and Management Effects

More than 10,000 plot-years of runoff and soil loss data from natural rain,[5] and additional data from a large number of erosion studies under simulated rainfall, were analyzed to obtain empirical measurements of the effects of cropping system and management on soil loss at successive stages of crop establishment and development. Soil losses measured on the cropped plots were compared with corresponding losses from clean-tilled, continuous fallow to determine the soil loss reductions ascribable to effects of the crop system and management. The reductions were then analyzed to identify and evaluate influential subfactors, interactions, and correlations. Mathematical relationships observed for one crop or geographic region were tested against data from other research sites for consistency. Those found compatible with all the relevant data were used to compute soil loss reductions to be expected from conditions not directly represented in the overall plot studies.

The value of **C** on a particular field is determined by many variables, one of which is weather. Major variables that can be influenced by management decisions include crop canopy, residue mulch, incorporated residues, tillage, land use residual, and their interactions. Each of these effects may be treated as a subfactor whose numerical value is the ratio of soil loss with the effect to corresponding loss without it (*57*). **C** is the product of all the pertinent subfactors.

Crop Canopy

Leaves and branches that do not directly contact the soil have little effect on amount and velocity of runoff from prolonged rains, but they reduce the effective rainfall energy by intercepting falling raindrops. Waterdrops falling from the canopy may regain appreciable velocity but usually less than the terminal velocities of free-falling

[5] See footnote 3, p. 2.

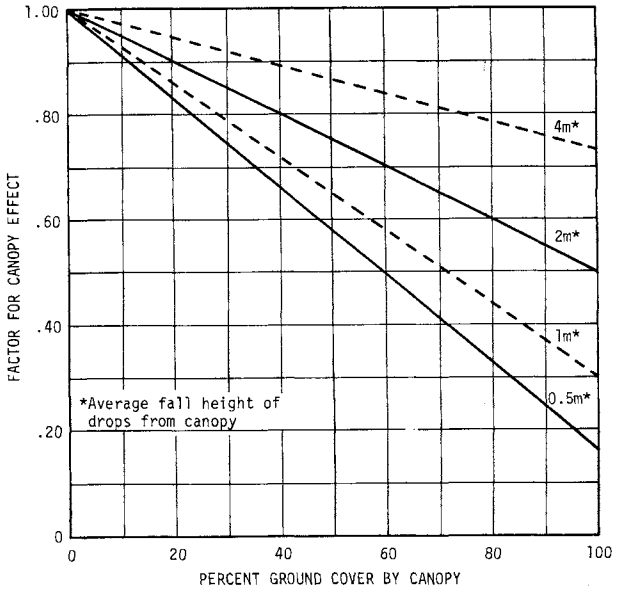

FIGURE 5.—Influence of vegetative canopy on effective EI values. Canopy factor is a subfactor of C.

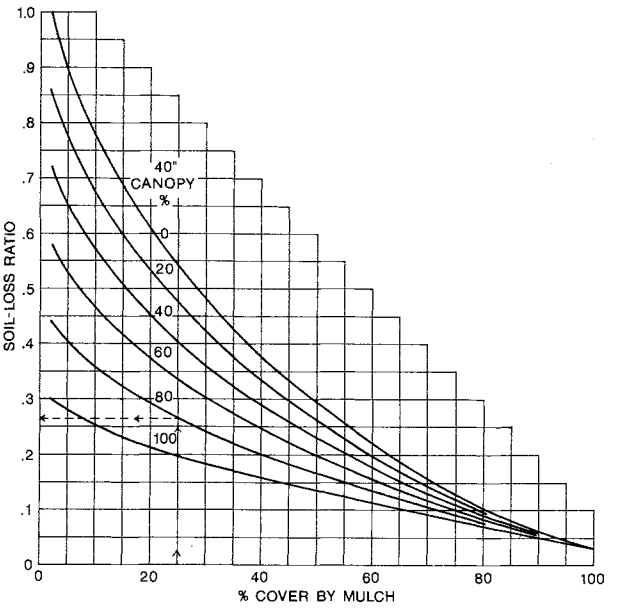

FIGURE 6.—Combined mulch and canopy effects when average fall distance of drops from canopy to the ground is about 40 inches (1 m).

raindrops. The amount by which energy expended at the soil surface is reduced depends on the height and density of the canopy. The subfactor for canopy effect can be estimated for specified conditions by reference to figure 5.

Residue Mulch

Residue mulches and stems from close-growing vegetation are more effective than equivalent percentages of canopy cover. Mulches intercept falling raindrops so near the surface that the drops regain no fall velocity, and they also obstruct runoff flow and thereby reduce its velocity and transport capacity. Measurements of the effectiveness of several types and rates of mulch have been published (*1, 2, 20, 27, 43*). Average subfactors for specific percentages of surface cover by plant materials at the soil surface are given by the upper curve of figure 6. Guides for estimating percent cover are given in the appendix.

If the cover includes both canopy and mulch, the two are not fully additive; the impact energy of drops striking the mulch is dissipated at that point regardless of whether canopy interception has reduced its velocity. The expected effects of mulch and canopy combinations have been computed and are given in figures 6 and 7. Figure 6 applies to corn, sorghum, and cotton in the maturing stage. Figure 7 applies to small grain, soybeans, potatoes, and the establishment period for taller row crops. Enter either figure 6 or 7 along the horizontal scale, move vertically to the appro-

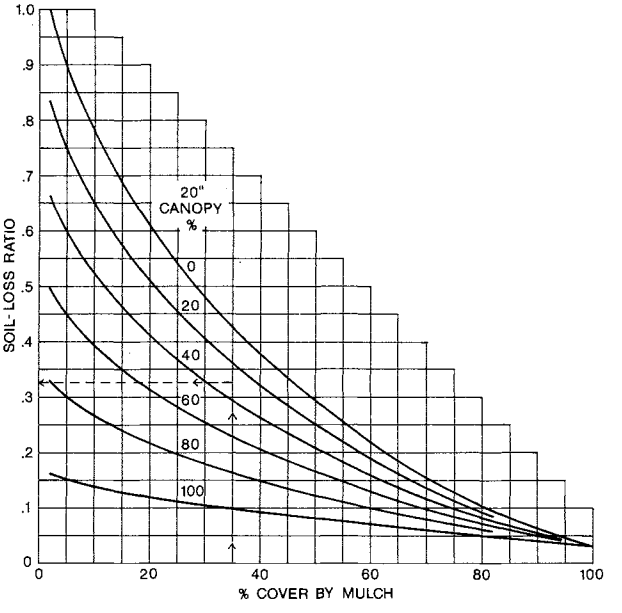

FIGURE 7.—Combined mulch and canopy effects when average fall distance of drops from canopy to the ground is about 20 inches (0.5 m).

priate percent-canopy curve, and read at the left the soil loss ratio from cover effect. This ratio is a subfactor that may be combined with other pertinent subfactors to account for the cropstage soil loss of table 5 or to estimate others.

Incorporated Residues

The plot data indicate that, at least during the seedbed and establishment periods, the erosion-reducing effectivensss of residues mixed into the upper few inches of soil by shallow tillage is appreciably greater than the residual effect of long-term annual incorporation with a moldboard plow. However, the incorporated residues are less effective than if left on the surface.

Tillage

The type, frequency, and timing of tillage operations influence porosity, roughness, cloddiness, compaction, and microtopography. These, in turn, affect water intake, surface storage, runoff velocity, and soil detachability, all of which are factors in potential erosion. These effects are highly correlated with cropland residual effects.

Land Use Residuals

These include effects of plant roots; long-term residue incorporation by plowing; changes in soil structure, detachability, density, organic matter content, and biological activity; and probably other factors. The residual effects are most apparent during seedbed and establishment periods.

Some residual effect will be apparent on nearly any cropland, but the magnitude of its erosion-reducing effectiveness will differ substantially with crops and practices. Tillage and land use residuals are influenced by so many factor interrelations that development of charts like those for canopy and mulch has not been feasible. However, apparent values of these subfactors for some situations were derived from the data and used for expansion of the soil loss ratio table to include conditions somewhat different from those directly represented in the plot studies.

Plowing residues down is far less effective than leaving them on the surface but better than burning them or removing them from the land. After several years of turning the crop residues under with a moldboard plow before row crop seeding in plot studies under natural rainfall, both runoff and soil loss from the row crops were much less than from similar plots from which cornstalks and grain straw were removed at harvesttimes (*52*, *54*, *59*).

Short periods of rough fallow in a rotation will usually lose much less soil than the basic, clean-tilled, continuous fallow conditions for which **C** = 1. This is largely because of residual effects and is also partly because of the roughness and cloddiness.

The most pronounced residual effect is that from long-term sod or forest. The effect of a grass-and-legume rotation meadow turned under diminishes gradually over about 2 years. In general, the erosion-reducing effectiveness of sod residual (from grass or grass-and-legume meadows) in the plot studies was directly proportional to hay yields. Site values of the subfactor for sod residuals in rotations can be obtained from soil loss ratio table 5-D. The effectiveness of virgin sod and of long periods of alfalfa in which grass became well established was longer lasting. Mixtures of grasses and legumes were more effective than legumes alone.

Residual effectiveness of winter cover crops plowed under in spring depends largely on the type and quality of the crop and its development stage at the time it is plowed under. The effectiveness of grass-and-legume catch crops turned under in spring was less and of shorter duration than that of full-year rotation meadows. Covers such as vetch and ryegrass seeded between corn or cotton rows before harvest and turned under in April were effective in reducing erosion during the winter and showed some residual effect in the following seedbed and establishment periods. Small grain seeded alone in corn or cotton residues showed no residual effect under the next crop. Small grain or vetch on fall-plowed seedbed and turned at spring planting time lost more soil than adjacent plots with undisturbed cotton residues on the surface.

Soil Loss Ratios

Factor **C** is usually given in terms of its average annual value for a particular combination of crop system, management, and rainfall pattern. To derive site values of **C**, soil loss ratios for the indi-

vidual cropstage periods must be combined with erosion-index distribution data, as demonstrated later. Ratios of soil losses in each cropstage period of specified cropping and management systems to corresponding losses from the basic long-term fallow condition were derived from analysis of about a quarter million plot soil loss observations. The ratios are given in table 5 as percentages.

The observed soil loss ratios for given conditions often varied substantially from year to year because of influences of unpredictable random variables and experimental error. The percentages listed in table 5 are the best available averages for the specified conditions. To make the table inclusive enough for general field use, expected ratios had to be computed for cover, residue, and management combinations that were not directly represented in the plot data. This was done by using empirical relationships of soil losses to the subfactors and interactions discussed in the preceding subsection. The user should recognize that the tabulated percentages are subject to appreciable experimental error and could be improved through additional research. However, because of the large volume of data considered in developing the table, the listed values should be near enough to the true averages to provide highly valuable planning and monitoring guidelines. A ratio derived locally from 1-year rainfall simulator tests on a few plots would not necessarily represent the true average for that locality more accurately. Small samples are more subject to bias by random variables and experimental error than larger samples.

Table for Cropland

Table 5, with its supplements 5A, B, C, and D, replaces tables 2, 3, and 4 in the 1965 edition. The supplements had to be separated from the main table to accommodate changes in format requirements. The ratios are expressed as percentages in the tables to eliminate decimal points.

More than half the lines in table 5 are for conditions associated with conservation tillage practices (65), which were not included in the 1965 edition. Also, it provides a direct means of crediting effects of faster and more complete canopy development by improved fertility, closer row spacing, and greater plant population. Because the table includes several times as many specific conditions as the table in the 1965 edition and defines applicable field conditions more accurately, some simplicity has been sacrificed. However, it is not intended for direct use by each field technician or farmer.

Table 5 as presented here is designed to provide the details needed by a trained agronomist to develop simple handbook tables of **C** values for conditions in specific climatic areas. It is designed for use of the revised definitions of cropstage periods given in the preceding section. The agronomist will first determine, for the particular climatic area, the number of weeks normally required for the crop canopies to attain 10, 50, and 75 percent surface cover, respectively. The table will then be used as illustrated in the next major section. Linear interpolation between ratios listed in the table is recommended where appropriate.

Semiarid Regions

Water erosion is a serious problem also in subhumid and semiarid regions. Inadequate moisture and periodic droughts reduce the periods when growing plants provide good soil cover and limit the quantities of plant residue produced. Erosive rainstorms are not uncommon, and they are usually concentrated within the season when cropland is least protected. Because of the difficulty of establishing rotation meadows and the competition for available soil moisture, sod-based rotations are often impractical. One of the most important opportunities for a higher level of soil and moisture conservation is through proper management of available residues. The effects of mulch-tillage practices in these areas can be evaluated from lines 129 to 158 of table 5 and item 12 of 5-B.

Erosion Index Distribution Data

The rainfall factor, **R**, in the soil loss equation does not completely describe the effects of local differences in rainfall pattern on soil erosion. The erosion control effectiveness of a cropping system on a particular field depends, in part, on how the year's erosive rainfall is distributed among the six cropstage periods of each crop included in the system. Therefore, expected monthly distribution

Footnotes for table 5.

[1] Symbols: B, soybeans; C, corn; conv till, plow, disk and horrow for seedbed; cot, cotton; F, rough fallow; fld cult, field cultivator; G, small grain; GS, grain sorghum; M, gross and legume meadow, at least 1 full year; pl, plant; RdL, crop residues left on field; RdR, crop residues removed; SB, seedbed period; sprg, spring; TP, plowed with moldboard; WC, winter cover crop; —, insignificant or an unlikely combination of variables.

[2] Dry weight per acre after winter loss and reductions by grazing or partial removal: 4,500 lbs represents 100 to 125 bu corn; 3,400 lbs, 75 to 99 bu; 2,600 lbs, 60 to 74 bu; and 2,000 lbs, 40 to 59 bu; with normal 30-percent winter lass. For RdR or fall-plow practices, these four productivity levels are indicated by HP, GP, FP and LP, respectively (high, good, fair, and low productivity). In lines 79 to 102, this column indicates dry weight of the winter-cover crop.

[3] Percentage of soil surface covered by plant residue mulch *after* crop seeding. The difference between spring residue and that on the surface after crop seeding is reflected in the soil loss ratios as residues mixed with the topsoil.

[4] The soil loss ratios, given as percentages, assume thot the indicoted crop sequence and practices are followed consistently. One-year deviotions from normal practices do not have the effect of a permanent change. Linear interpolation between lines is recommended when justified by field conditions.

[5] Cropstage periods are as defined on p. 18. The three columns for cropstage 3 are for 80, 90, and 96 to 100 percent canopy cover at maturity.

[6] Column 4L is for all residues left on field. Corn stalks partially stonding as left by some mechanical pickers. If stalks are shredded and spread by picker, select ratio from table 5-C. When residues are reduced by grazing, take ratio from lower spring-residue line.

[7] Period 4 values in lines 9 to 12 are for corn stubble (stover removed).

[8] Inversion plowed, no secondary tillage. For this practice, residues must be left and incorporated.

[9] Soil surface and chopped residues of *matured* preceding crop undisturbed except in narrow slots in which seeds are planted.

[10] Top of old row ridge sliced off, throwing residues and some soil into furrow areas. Reridging assumed to occur near end of cropstage 1.

[11] Where lower soil loss rotios ore listed for rows on the contour, this reduction is in addition to the standard field contouring credit. The *P* value for contouring is used with these reduced loss ratios.

[12] Field-average percent cover; probably about three-fourths of percent cover on undisturbed strips.

[13] If again seeded to WC crop in corn stubble, evaluate winter period as a winter grain seeding (lines 132 to 148). Otherwise, see table 5-C.

[14] Select the appropriate line for the crop, tillage, and productivity level and multiply the listed soil loss ratios by sod residual factors from table 5-D.

[15] Spring residue may include carryover from prior corn crop.

[16] See table 5-C.

[17] Use values from lines 33 to 62 with appropriate dates and lengths of cropstage periods for beans in the locality.

[18] Values in lines 109 to 122 are best available estimates, but planting dates and lengths of cropstages may differ.

[19] When meadow is seeded with the grain, its effect will be reflected through higher percentages of cover in cropstages 3 and 4.

[20] Ratio depends on percent cover. See table 5-C.

[21] See item 12, table 5-B.

TABLE 5-A.—*Approximate soil loss ratios for cotton*

Expected final canopy percent cover:	65	80	95
Estimated initial percent cover from defoliation + stalks down:	30	45	60

COTTON AFTER SOD CROP:

For the first or second crop after a grass or grass-and-legume meadow has been turnplowed, multiply values given in the last five lines above by sod residual factors from table 5-D.

COTTON AFTER SOYBEANS:

Select values from above and multiply by 1.25.

See footnotes at right.

of erosive rainfall at a particular location is an element in deriving the applicable value of cover and management, **C**.

Central and Eastern States

A location's erosion index is computed by summing **EI** values of individual rainstorms over periods from 20 to 25 years. Thus, the expected monthly distribution of the erosion index can be computed from the same data. For each rainfall record abstracted for development of the isoerodent map, the monthly **EI** values were computed and expressed as percentages of the location's average annual erosion index. When the monthly percentages are plotted cumulatively against time, they define **EI** distribution curves such as illustrated in figure 8 for three locations. The three contrasting curves are presented to demonstrate how drastically the normal **EI** distribution can differ among climatic regions.

On the basis of observed seasonal distributions of **EI**, the 37 States east of the Rocky Mountains were divided into the 33 geographic areas delineated in figure 9. The changes in distribution are usually gradual transitions from one area to the next, but the average distribution within any one of the areas may, for practical purposes, be considered applicable for the entire area. The **EI** distributions in the 33 areas, expressed as cumulative percentages of annual totals, are given in table 6. The area numbers in the table correspond to those in figure 9. The data in the table were

[1] *Alternate procedure for estimating the soil loss ratios:*

The ratios given above for cotton are based on estimates for reductions in percent cover through normal winter loss and by the successive tillage operations. Research is underway in Mississippi to obtain more accurate residue data in relation to tillage practices. This research should provide more accurate soil loss ratios for cotton within a few years.

Where the reductions in percent cover by winter loss and tillage operations are small, the following procedure may be used to compute soil loss ratios for the preplant and seedbed periods: Enter figure 6 with the percentage of the field surface covered by residue mulch, move vertically to the upper curve, and read the mulch factor on the scale at the left. Multiply this factor by a factor selected from the following tabulation to credit for effects of land-use residual, surface roughness and porosity.

Productivitty level	No tillage	Rough surface	Smoothed surface
High	0.66	0.50	0.56
Medium	.71	.54	.61
Poor	.75	.58	.65

Values for the bedded period on slopes of less than 1 percent should be estimated at twice the value computed above for rough surfaces.

[2] Rd, crop residue; vol veg, volunteer vegetation.

TABLE 5-B.—*Soil loss ratios for conditions not evaluated in table 5*

COTTON:
See table 5-A.

CROPSTAGE 4 FOR ROWCROPS:
Stalks broken and partially standing: Use col. 4L.
Stalks standing after hand picking: Col. 4L times 1.15.
Stalks shredded without soil tillage: See table 5-C.
Fall chisel: Select values from lines 33-62, seedbed column.

CROPSTAGE 4 FOR SMALL GRAIN:
See table 5-C.

DOUBLE CROPPING:
Derive annual C value by selecting from table 5 the soil loss percentages for the successive cropstage periods of each crop.

ESTABLISHED MEADOW, FULL-YEAR PERCENTAGES:

Grass and legume mix, 3 to 5 t hay	0.4
Do. 2 to 3 t hay	.6
Do. 1 t hay	1.0
Sericea, after second year	1.0
Red clover	1.5
Alfalfa, lespedeza, and second-year sericea	2.0
Sweetclover	2.5

MEADOW SEEDING WITHOUT NURSE CROP:
Determine appropriate lengths of cropstage periods SB, 1, and 2 and apply values given for small grain seeding.

PEANUTS:
Comparison with soybeans is suggested.

PINEAPPLES:
Direct data not available. Tentative values derived analytically are available from the SCS in Hawaii or the Western Technical Service Center at Portland, Oreg. (Reference 5).

SORGHUM:
Select values given for corn, on the basis of expected crop residues and canopy cover.

SUGARBEETS:
Direct data not available. Probably most nearly comparable to potatoes, without the ridging credit.

SUGARCANE:
Tentative values available from sources given for pineapples.

SUMMER FALLOW IN LOW-RAINFALL AREAS, USE GRAIN OR ROW CROP RESIDUES:
The approximate soil loss percentage after each successive tillage operation may be obtained from the following tabulation by estimating the percent surface cover after that tillage and selecting the column for the appropriate amount of initial residue. The given values credit benefits of the residue mulch, residues mixed with soil by tillage, and the crop system residual.

Percent cover by mulch	Initial residue (lbs/A)			
	>4,000	3,000	2,000	1,500
90	4	—	—	—
80	8	[1]8	—	—
70	12	13	[1]14	—
60	16	17	[1]18	[1]19
50	20	22	24	[1]25
40	25	27	30	32
30	29	33	37	39
20	35	39	44	48
10	47	55	63	68

[1] For grain residue only.

WINTER COVER SEEDING IN ROW CROP STUBBLE OR RESIDUES:
Define cropstage periods based on the cover seeding date and apply values from lines 129 to 145.

TABLE 5-C.—*Soil loss ratios (percent) for cropstage 4 when stalks are chopped and distributed without soil tillage*

Mulch cover[1]	Corn or Sorghum		Soybeans		Grain Stubble[4]
	Tilled seedbed[2]	No-till	Tilled seedbed[2]	No-till in corn rd[3]	
20	48	34	60	42	48
30	37	26	46	32	37
40	30	21	38	26	30
50	22	15	28	19	22
60	17	12	21	16	17
70	12	8	15	10	12
80	7	5	9	6	7
90	4	3	—	—	4
95	3	2	—	—	3

[1] Part of a field surface directly covered by pieces of residue mulch.
[2] This column applies for all systems other than no-till.
[3] Cover after bean harvest may include an appreciable number of stalks carried over from the prior corn crop.
[4] For grain with meadow seeding, include meadow growth in percent cover and limit grain period 4 to 2 mo. Thereafter, classify as established meadow.

abstracted from the published **EI** distribution curves.

The percentage of the annual erosion index that is to be expected within each cropstage period may be obtained by reading from the appropriate line of table 6, the values for the last and first date of the period, and subtracting. Interpolate

TABLE 5-D.—*Factors to credit residual effects of turned sod*[1]

Crop	Hay yield	Factor for cropstage period:				
		F	SB and 1	2	3	4
	Tons					
First year after mead:						
Row crop or grain ...	3-5	0.25	0.40	0.45	0.50	0.60
	2-3	.30	.45	.50	.55	.65
	1-2	.35	.50	.55	.60	.70
Second year after mead:						
Row crop	3.5	.70	.80	.85	.90	.95
	2-3	.75	.85	.90	.95	1.0
	1-2	.80	.90	.95	1.0	1.0
Spring grain	3-5	—	.75	.80	.85	.95
	2-3	—	.80	.85	.90	1.0
	1-2	—	.85	.90	.95	1.0
Winter grain	3-5	—	.60	.70	.85	.95
	2-3	—	.65	.75	.90	1.0
	1-2	—	.70	.85	.95	1.0

[1] These factors are to be multiplied by the appropriate soil loss percentages selected from table 5. They are directly applicable for sod-forming meadows of at least 1 full year duration, plowed not more than 1 month before final seedbed preparation.

When sod is fall plowed for spring planting, the listed values for all cropstage periods are increased by adding 0.02 for each additional month by which the plowing precedes spring seedbed preparation. For example, September plowing would precede May disking by 8 months and 0.02(8—1), or 0.14, would be added to each value in the table. For nonsod-forming meadows, like sweetclover or lespedeza, multiply the factors by 1.2. When the computed value is greater than 1.0, use as 1.0.

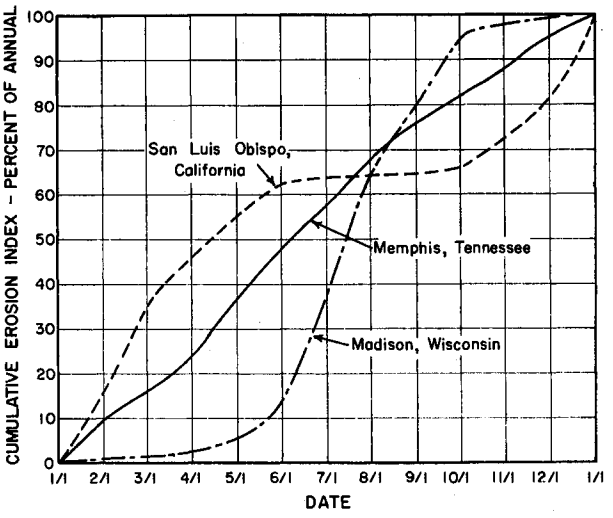

FIGURE 8.—Typical **EI**-distribution curves for three rainfall patterns.

between values in the selected line when the desired dates are not listed.

Western States, Hawaii, and Puerto Rico

Normal rainfall patterns in these mountainous States often change abruptly within a short distance. Figure 9 was not extended to include these States because long-term intensity data were not available for enough locations to delineate boundaries of homogeneous areas. However, **EI** distributions indicated by station records that were abstracted are given in table 7 for reference.

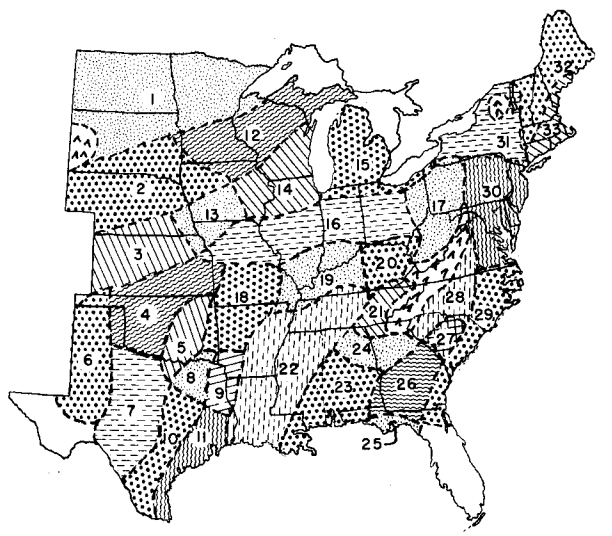

FIGURE 9.—Key map for selection of applicable **EI**-distribution data from table 6.

Winter Periods

Site **EI** values reflect only rain falling at erosive intensities. Where the winter precipitation comes as snow or light rain, **EI** distribution curves may show insignificant percentages for several winter months. Yet, snowmelt and low intensity rains on frozen soil may cause appreciable runoff that is erosive even though the associated maximum 30-minute rainfall intensity is extremely low or zero. The section on **Isoerodent Maps** pointed out that where this type of runoff is significant its erosive force must be reflected in an $\mathbf{R}_s$ value that is added to the **EI** value to obtain **R**. This additional erosive force must also be reflected in the *monthly distribution* of **R**. Otherwise, poor management during the winter period will not be reflected in the USLE estimate of annual soil loss because a zero crop-stage **R** value would predict zero soil loss regardless of the relevant soil loss ratio.

Soil erosion by thaw runoff is most pronounced in the Northwest, where $\mathbf{R}_s$ values often exceed the average annual **EI**. However, it may also be significant in other Northern States. Probable amounts of thaw runoff were not available for inclusion in the calculations of the **EI** distributions given in tables 6 and 7, but the significance and probable time of occurrence of such runoff can be estimated by local people. The procedure for adjusting table 6 cumulative percentages to include this erosive potential will be illustrated.

Based on the previously described estimating procedure, $\mathbf{R}_s$ values in area No. 1, figure 9, appear to equal about 8 percent of the annual **EI**. Assuming that the thaw runoff in that area normally occurs between March 15 and April 15, the percentage in table 6 for April 1 is increased by 4, the April 15 and all subsequent readings are increased by 8, and all the adjusted readings are then divided by 1.08. This procedure corrects the data given in line 1, table 6, for dates April 1 to September 1 to the following cumulative percentages listed in chronological sequence: 5, 9, 10, 13, 18, 29, 41, 53, 66, 79, 91. The other values are unchanged. Such adjustments in monthly distribution of **R** where thaw runoff is significant will be particularly helpful when the USLE is used to estimate seasonal distribution of sediment from agricultural watersheds.

TABLE 6.—*Percentage of the average annual* **EI** *which normally occurs between January 1 and the indicated dates.*[1] *Computed for the geographic areas shown in figure 9*

[1] For dates not listed in the table, interpolate between adjacent values.

Procedure for Deriving Local C Values

Factor **C** in the USLE measures the combined effect of all the interrelated cover and management variables and is defined as the ratio of soil loss from land cropped under specified conditions to the corresponding loss from clean-tilled continuous fallow. It is usually expressed as an annual value for a particular cropping and management system. Soil loss ratios, as used in table 5, express a similar ratio for a short time interval within which cover and management effects are relatively uniform. The cropstage soil loss ratios must be combined in proportion to the applicable percentages of **EI** to derive annual **C** values.

To compute the value of **C** for any particular crop and management system on a given field, one needs first to determine the most likely seeding and harvest dates, rate of canopy development, and final canopy cover. Also, the system to be evaluated must be carefully defined with regard to crop and residue management details. Within the broad limits of tables 5 and 6, these tables then supply the research data needed to complete

[1] Numbers in parentheses are the observed average annual **EI**.

the computation of **C**. The procedure will be explained by an example that, for illustration purposes, was selected to include many changes in field conditions.

Problem. Evaluate **C** for a 4-year rotation of wheat-meadow-corn-corn on moderately sloping land in Central Illinois or Indiana, assuming the following management details and dates: Wheat is seeded October 15 in a 40-percent cover of disked corn residue, and a grass and legume meadow mix is seeded with the wheat. The wheat would normally develop a 10-percent cover by November 1, 50 percent by December 1, 75 percent by April 15, and nearly 100 percent in the maturing stage. It is harvested July 15, leaving an 80-percent surface cover of straw and small grass. The sod developed under 1 full year of meadow, yielding more than 3 t of hay, is turned under in April. The field is disked May 5 and is harrowed and planted to corn May 10. The first-year corn, harvested October 15, is followed by fall chiseling about November 15 and spring disking for second-year corn. Residue cover is 50 percent after fall chiseling and 30 percent after corn planting on May 10. Fertility, row spacing, and plant population for both corn years are such that 10, 50, and 75 percent canopy covers will be developed in 20, 40, and 60 days, respectively, from planting, and final canopy cover is more than 95 percent.

Procedure. Set up a working table similar to the one illustrated in table 8, obtaining the needed information as follows:

Column 1. List in chronological sequence all the land-cover changes that begin new cropstage periods, as previously defined.

Column 2. List the date on which each cropstage period begins.

Column 3. Select the applicable area number

Hv C & pl W	10/15	92						
Rotation totals				4.0			0.3392	
Average annual C value for rotation							.085	

[1] Numbers in parentheses are line numbers in table 5.

[2] Abbreviations: c, canopy cover; C, corn; hv, harvest; pl, plant; TP, moldboard plow; W, wheat.

from figure 9, and from the line in table 6 having the corresponding area number (in this case, 16), read the cumulative percentage of **EI** for each date in column 2. Values for the corn planting dates were omitted in table 8 because the seedbed periods had begun with the spring diskings. The **EI** percentage for May 5 was obtained by interpolating between readings from May 1 and 15.

Column 4. Identify the cropstage periods.

Column 5. Subtract the number in column 3 from the number in the next lower line. If the cropstage period includes a year end, subtract from 100 and add the number in the next lower line. The differences are percentages and may be pointed off as hundredths.

Column 6. Obtain from table 5. Enter the table with crop and management, pounds of spring residue or production level, and percent mulch cover after planting, in that sequence. The data in the selected line are percentages and are used as hundredths in the computation of **C**. For cropstage 3, use the column whose heading corresponds with expected final canopy. For conditions not listed in the primary table, consult supplements 5-A to D. Lines used for the examples are given in parentheses in column 6.

Column 7. From table 5-D.

Column 8. The product of values in columns 5, 6 and 7. The sum of these products is the value of **C** for the entire rotation. Because **C** is usually desired as an average annual value, this sum is divided by the number of years in the rotation.

Column 9. The subtotals in this column are **C** values for the individual crop-years. They also show the relative contributions of the four crops to the rotation **C** value.

Changes in geographic area or in planting dates would affect the **C** value by changing columns 3 and 5. Changes in amount or disposition of residues, tillage practices, or canopy development would change column 6. Thus **C** can vary substantially for a given crop system.

Values of **C** for one-crop systems are derived by the same procedure but would require only a few lines. Also, column 7 is omitted for meadowless systems.

C-Value Tables for Cropland

It will rarely, if ever, be necessary for a field technician or farmer to compute values of **C**. Persons experienced in the procedures outlined above have prepared **C** value tables for specific geographic areas. Such a table will list all the one-crop and multicrop systems likely to be found within the designated area and will list the **C** values for each system for each of the combinations of management practices that may be associated with it. They are usually listed in ascending or descending order of magnitude of the **C** values. The user can then quickly determine all the potential combinations of cropping and management that have **C** values smaller than any given threshold value. Persons in need of **C** values for a particular locality can usually obtain a copy of the applicable table from the nearest SCS state office.

C Values for Construction Areas

Site preparations that remove all vegetation and also the root zone of the soil not only leave the surface completely without protection but also remove the residual effects of prior vegetation. This condition is comparable to the previously defined continuous fallow condition, and **C** = 1. Roots and residual effects of prior vegetation, and partial covers of mulch or vegetation, substantially reduce soil erosion. These reductions are reflected in the soil loss prediction by **C** values of less than 1.0.

Applied mulches immediately restore protective cover on denuded areas and drastically reduce **C** (*1, 2, 20, 27, 43*). Soil loss ratios for various percentages of mulch cover on field slopes are given by the upper curve of figure 6. Where residual effects are insignificant, these ratios equal **C**. The percentage of surface cover provided by a given rate of uniformly spread straw mulch may be estimated from figure 10 (appendix).

Straw or hay mulches applied on steep construction slopes and not tied to the soil by anchoring and tacking equipment may be less effective than equivalent mulch rates on cropland. In Indiana tests on a 20 percent slope of scalped subsoil, a 2.3-t rate of unanchored straw mulch allowed soil loss of 12 t/A when 5 in of simulated rain was applied at 2.5 in/h on a 35-ft plot (*61*). There was evidence of erosion from flow beneath the straw. Mulches of crushed stone at 135 or more t/A, or wood chips at 7 or more t/A, were more effective. (Broadcast seedings of grass after the tests gave good stands on the plots mulched with 135 or 240 t crushed stone, 70 t road gravel, 12 t wood chips, or 2.3 t straw. Stands were poor on the no-mulch and the 15-t rate of crushed stone mulch.)

Table 9 presents approximate **C** values for straw, crushed stone, and woodchip mulches on construction slopes where no canopy cover exists, and also shows the maximum slope lengths on which these values may be assumed applicable.

Soil loss ratios for many conditions on construc-

[1] From Meyer and Ports (*24*). Developed by an interagency workshop group on the basis of field experience and limited research data.

[2] Maximum slope length for which the specified mulch rate is considered effective. When this limit is exceeded, either a higher application rate or mechanical shortening of the effective slope length is required.

[3] When the straw or hay mulch is not anchored to the soil, **C** values on moderate or steep slopes of soils having **K** values greater than 0.30 should be taken at double the values given in this table.

tion and developmental areas can be obtained from table 5 if good judgment is exercised in comparing the surface conditions with those of agricultural conditions specified in lines of the table. Time intervals analogous to cropstage periods will be defined to begin and end with successive construction or management activities that appreciably change the surface conditions. The procedure is then similar to that described for cropland.

Establishing vegetation on the denuded areas as quickly as possible is highly important. A good sod has a **C** value of 0.01 or less (table 5-B), but such a low **C** value can be obtained quickly only by laying sod on the area, at a substantial cost. When grass or small grain is started from seed, the probable soil loss for the period while cover is developing can be computed by the procedure outlined for estimating cropstage-period soil losses. If the seeding is on topsoil, without a mulch, the soil loss ratios given in line 141 of table 5 are appropriate for cropstage **C** values. If the seeding is on a desurfaced area, where residual effects of prior vegetation are no longer significant, the ratios for periods SB, 1 and 2 are 1.0, 0.75 and 0.50, respectively, and line 141 applies for cropstage 3. When the seedbed is protected by a mulch, the pertinent mulch factor from the upper curve of figure 6 or table 9 is applicable until good canopy cover is attained. The combined effects of vegetative mulch and low-growing canopy are given in figure 7. When grass is established in small grain, it can usually be evaluated as established meadow about 2 mo after the grain is cut.

C Values for Pasture, Range, and Idle Land

Factor **C** for a specific combination of cover conditions on these types of land may be obtained from table 10 (*57*). The cover characteristics that must be appraised before consulting this table are defined in the table and its footnotes. Cropstage periods and **EI** monthly distribution data are generally not necessary where perennial vegetation has become established and there is no mechanical disturbance of the soil.

Available soil loss data from undisturbed land were not sufficient to derive table 10 by direct comparison of measured soil loss rates, as was done for development of table 5. However, analyses of the assembled erosion data showed that the research information on values of **C** can be extended to completely different situations by combining subfactors that evaluate three separate and distinct, but interrelated, zones of influence: (a) vegetative cover in direct contact with the soil surface, (b) canopy cover, and (c) residual and tillage effects.

Subfactors for various percentages of surface cover by mulch are given by the upper curve of

TABLE 10.—*Factor* **C** *for permanent pasture, range, and idle land*[1]

Vegetative canopy			Cover that contacts the soil surface					
			Percent ground cover

		W	.42	.23	.14	.089	.042	.011
	50	G	.39	.18	.09	.040	.013	.003
		W	.39	.21	.14	.087	.042	.011
	75	G	.36	.17	.09	.039	.012	.003
		W	.36	.20	.13	.084	.041	.011

[1] The listed **C** values assume that the vegetation and mulch are randomly distributed over the entire area.

[2] Canopy height is measured as the average fall height of water drops falling from the canopy to the ground. Canopy effect is inversely proportional to drop fall height and is negligible if fall height exceeds 33 ft.

[3] Portion of total-area surface that would be hidden from view by canopy in a vertical projection (a bird's-eye view).

[4] G: cover at surface is grass, grasslike plants, decaying compacted duff, or litter at least 2 in deep.

W: cover at surface is mostly broadleaf herbaceous plants (as weeds with little lateral-root network near the surface) or undecayed residues or both.

TABLE 11.—*Factor* **C** *for undisturbed forest land*[1]

Percent of area covered by canopy of trees and undergrowth	Percent of area covered by duff at least 2 in deep	Factor C[2]
100-75	100-90	.0001-.001
70-45	85-75	.002-.004
40-20	70-40	.003-.009

[1] Where effective litter cover is less than 40 percent or canopy cover is less than 20 percent, use table 6. Also use table 6 where woodlands are being grazed, harvested, or burned.

[2] The ranges in listed **C** values are caused by the ranges in the specified forest litter and canopy covers and by variations in effective canopy heights.

figure 6. Subfactors for various heights and densities of canopy cover are given in figure 5. The subfactor for residual effects of permanent pasture, range, idle land, or grazed or harvested woodland has been estimated to vary from 0.45 to 0.10 (*57*). Major influences on this subfactor are plant roots, organic matter buildup in the topsoil, reduced soil compaction, and surface stabilization after long periods without soil disturbance. The **C** values given in table 10 were derived by combining subfactors for specified combinations of type, height, and density of canopy cover; type and density of cover at the soil surface; and probable residual effects of longtime existence of the specified cover on the land. They are compatible with the rather scarce existing soil loss data from undisturbed land areas.

C Values for Woodland

Three categories of woodland are considered separately: (1) undisturbed forest land; (2) woodland that is grazed, burned, or selectively harvested; and (3) forest lands which have had site preparation treatments for re-establishment after harvest.

In undisturbed forests, infiltration rates and organic matter content of the soil are high, and much or all of the surface is usually covered by a layer of compacted decaying forest duff or litter several inches thick. Such layers of duff shield the soil from the erosive forces of runoff and of drop impact and are extremely effective against soil erosion. Where cover by trees and litter is incomplete, the spots with little or no litter cover are partially protected by undergrowth canopy. Factor **C** for undisturbed forest land may be obtained from table 11. These estimated **C** values are supported by the quite limited existing data and also by the subfactor-evaluation procedure discussed in the preceding subsection.

Woodland that is grazed or burned, or has been recently harvested, does not merit the extremely low **C** values of table 11. For these conditions, **C** is obtained from table 10. However, the buildup of organic matter in the topsoil under permanent woodland conditions is an added factor that should be accounted for by a reduction in the **C** value read from table 10. An earlier publication (*57*) recommended a factor of 0.7 for this purpose.

Site preparation treatments for re-establishing trees on harvested forest land usually alter the erosion factors substantially. Canopy effect is initially greatly reduced or lost entirely, and its restoration is gradual. Some of the forest litter is incorporated in the soil, and it may be entirely removed from portions of the area. A surface roughness factor is introduced. Windrowed debris, if across slope, may function as terraces by reducing effective slope length and inducing deposition above and in the windrows. The amount of residual effect retained depends on the amount and depth of surface scalping. Some of the changes are analogous to cropland situations. Some of the relationships available from tables 5 and 10 can be used to evaluate **C** for these conditions, but neither table is directly applicable.

Table 12 presents **C** values computed for Southern Pine Forests that have had site preparation treatments after harvesting. This table was jointly developed (in 1977) by representatives of SEA, SCS, and Forest Service, using factor relationships from tables 5, 10, and 11 as basic guides. Its application on forest lands in other climatic regions may require some modifications of factor values. Research designed to refine and improve tables 10, 11, and 12 is underway.

Tree plantings on converted cropland should, in the initial years, be evaluated similarly to cropland because the forest residual effect which underlies tables 10 to 12 will not be applicable. The subfactor for residual effects may be estimated by selecting from lines 1 to 16 of table 5 the line that most nearly describes the condition of the converted cropland and assuming a residual subfactor equal to the seedbed-period value given in that line. If the cropland has most recently been in

TABLE 12.—*Factor* **C** *for mechanically prepared woodland sites*

	80	.03	.03	.03	.03	.03	.03	.04	.04

[1] Percentage of surface covered by residue in contact with the soil.

[2] *Excellent* soil condition—Highly stable soil aggregates in topsoil with fine tree roots and litter mixed in.

Good—Moderately stable soil aggregates in topsoil or highly stable aggregates in subsoil (topsoil removed during raking), only traces of litter mixed in.

Fair—Highly unstable soil aggregates in topsoil or moderately stable aggregates in subsoil, no litter mixed in.

Poor—No topsoil, highly erodible soil aggregates in subsoil, no litter mixed in.

[3] NC—No live vegetation.

WC—75 percent cover of grass and weeds having an average drop fall height of 20 in. For intermediate percentages of cover, interpolate between columns.

[4] Modify the listed C values as follows to account for effects of surface roughness and aging:

First year after treatment: multiply listed C values by 0.40 for rough surface (depressions >6 in); by 0.65 for moderately rough; and by 0.90 for smooth (depressions <2 in).

For 1 to 4 years after treatment: multiply listed factors by 0.7.

For 4+ to 8 years: use table 6.

More than 8 years: use table 7.

[5] For first 3 years: use C values as listed.

For 3+ to 8 years after treatment: use table 6.

More than 8 years after treatment: use table 7.

meadow, the selected seedbed soil loss ratio is multiplied by a factor from table 5-D. If mulch is applied, a subfactor read from the upper curve of figure 6 is multiplied by the residual subfactor to obtain **C**. When canopy develops, a canopy subfactor from figure 5 is also included.

SUPPORT PRACTICE FACTOR (P)

In general, whenever sloping soil is to be cultivated and exposed to erosive rains, the protection offered by sod or close-growing crops in the system needs to be supported by practices that will slow the runoff water and thus reduce the amount of soil it can carry. The most important of these supporting cropland practices are contour tillage, stripcropping on the contour, and terrace systems. Stabilized waterways for the disposal of excess rainfall are a necessary part of each of these practices.

By definition, factor **P** in the USLE is the ratio of soil loss with a specific support practice to the corresponding loss with up-and-down-slope culture. Improved tillage practices, sod-based rotations, fertility treatments, and greater quantities of crop residues left on the field contribute materially to erosion control and frequently provide the major control in a farmer's field. However, these are considered conservation cropping and management practices, and the benefits derived from them are included in **C**.

Contouring

The practice of tillage and planting on the contour, in general, has been effective in reducing erosion. In limited field studies, the practice provided almost complete protection against erosion from storms of moderate to low intensity, but it provided little or no protection against the occasional severe storms that caused extensive breakovers of the contoured rows. Contouring appears to be the most effective on slopes in the 3- to 8-percent range. As land slope decreases, it approaches equality with contour row slope, and the soil loss ratio approaches 1.0. As slope increases, contour row capacity decreases and the soil loss ratio again approaches 1.0.

Effectiveness of contouring is also influenced by the slope length. When rainfall exceeds infiltration and surface detention in large storms, breakovers of contour rows often result in concentrations of runoff that tend to become progressively greater with increases in slope length. Therefore, on slopes exceeding some critical length the amount of soil moved from a contoured field may approach or exceed that from a field on which each row carries its own runoff water down the slope. At what slope length this could be expected to occur would depend to some extent on gradient, soil properties, management, and storm characteristics.

P Values for Contouring

A joint SEA and SCS workshop group, meeting at Purdue University in 1956, adopted a series of contour **P** values that varied with percent slope. The **P** values were based on available data and field observations supplemented by group judgment. Subsequent experience indicated only a few minor changes. Current recommendations are given in table 13. They are average values for the factor on the specified slopes. Specific-site values may vary with soil texture, type of vegetation, residue management, and rainfall pattern, but data have not become available to make the deviations from averages numerically predictable.

Full contouring benefits are obtained only on fields relatively free from gullies and depressions other than grassed waterways. Effectiveness of this practice is reduced if a field contains numerous small gullies and rills that are not obliterated by normal tillage operations. In such instances, land smoothing should be considered before contouring. Otherwise, a judgment value greater than shown in table 13 should be used when computing the benefits for contouring.

TABLE 13.—**P** *values and slope-length limits for contouring*

Land slope percent	P value	Maximum length[1]
		Feet
1 to 2	0.60	400
3 to 5	.50	300
6 to 8	.50	200
9 to 12	.60	120
13 to 16	.70	80
17 to 20	.80	60
21 to 25	.90	50

[1] Limit may be increased by 25 percent if residue cover after crop seedlings will regularly exceed 50 percent.

Slope-Length Limits

After the 1956 workshop, the SCS prepared reference tables for use with the Corn Belt slope-practice procedure. They included guides for slope-length limits for effective contouring, based largely on judgment. These limits, as modified with later data and observations (*16, 42*), are also given in table 13. Data to establish the precise limits for specific conditions are still not available. However, the **P** values given in table 13 assume slopes short enough for full effectiveness of the practice. Their use for estimating soil loss on unterraced slopes that are longer than the table limits specified is speculative.

Contour Listing

Contour listing, with corn planted in the furrows, has been more effective than surface planting on the contour (*29*). However, the additional effectiveness of the lister ridges applies only from the date of listing until the ridges have been largely obliterated by two corn cultivations. Therefore, it can be more easily credited through **C** than through **P**. This is done by a 50-percent reduction in the soil loss ratios (table 5) that apply to the time interval during which the ridges are intact. The standard **P** value for contouring is applicable in addition to the **C** value reduction.

Potato rows on the contour present a comparable condition from lay-by time until harvest. However, this ridging effect has been already credited in table 5, line 160, and should not be duplicated.

Controlled-Row Grade Ridge Planting

A method of precise contouring has been developed that provides effective conservation on farm fields where the land slope is nearly uniform, either naturally or by land smoothing, and runoff from outside the field can be diverted. The practice uses ridge planting with undiminished channel capacity to carry water maintained throughout the year. It is being studied in Texas (*36*), Arkansas, Mississippi (*8*), and Iowa (*30*). In Texas, the channel cross section, with 40-in row spacing, was nearly 0.5 ft^2, and row grades varied from nearly zero at the upper end to 1 percent at the lower end

of a 1,000-ft length. Measured soil loss compared favorably with that from an adjacent terraced watershed. Soil loss measurements in Mississippi and Iowa showed similar effectiveness during the test periods.

Because each furrow functions as an individual terrace, **P** values similar to those for terracing seem appropriate. Slope-length limits for contouring would then not apply, but the length limits would be applicable if the channel capacity were only sufficient for a 2-year design storm.

Contoured-Residue Strips

Contoured strips of heavy crop-residue mulch, resembling contour stripcropping without the sod, may be expected to provide more soil loss reduction than contouring alone. **P** values equal to about 80 percent of those for contouring are recommended if fairly heavy mulch strips remain throughout the year. If the strips are maintained only from harvest until the next seedbed preparation, the credit should be applied to the soil loss ratio for cropstage 4 rather than the **P** value.

Contour Stripcropping

Stripcropping, a practice in which contoured strips of sod are alternated with equal-width strips of row crops or small grain, is more effective than contouring alone. Alternate strips of grain and meadow year after year are possible with a 4-year rotation of corn-wheat with meadow seeding-meadow-meadow. This system has the added advantage of a low rotation **C** value. A stripcropped rotation of corn-corn-wheat-meadow is less effective. Alternate strips of winter grain and row crop were effective on flat slopes in Texas (*14*), but alternate strips of spring-seed grain and corn on moderate to steep slopes have not provided better erosion control than contouring alone.

Observations from stripcrop studies showed that much of the soil eroded from a cultivated strip was filtered out of the runoff as it was slowed and spread within the first several feet of the adjacent sod strip. Thus the stripcrop factor, derived from soil loss measurements at the foot of the slope, accounts for off-the-field soil movement but not for all movement within the field.

P Values, Strip Widths, and Length Limits

Recommended **P** values for contour stripcropping are given in table 14. The system to which each column of factors applies is identified in the table footnotes. The strip widths given in column 5 are essentially those recommended by the 1956 slope-practice workshop and are to be considered approximate maximums. Reasonable adjustments to accommodate the row spacing and row multiple of the planting and harvesting equipment are permissible. Slope-length limit is generally not a critical factor with contour stripcropping except on extremely long or steep slopes. The lengths given in column 6 are judgment values based on field experience and are suggested as guides.

Buffer Stripcropping

This practice consists of narrow protective strips alternated with wide cultivated strips. The location of the protective strips is determined by the width and arrangement of adjoining strips to be cropped in the rotation and by the location of steep, severely eroded areas on slopes. Buffer strips usually occupy the correction areas on sloping land and are seeded to perennial grasses and legumes. This type of stripcropping is not as effective as contour stripcropping (*4*).

TABLE 14.—**P** *values, maximum strip widths, and slope-length limits for contour stripcropping*

Land slope percent	P values[1]			Strip width[2]	Maximum length
	A	B	C		
				Feet	*Feet*
1 to 2	0.30	0.45	0.60	130	800
3 to 5	.25	.38	.50	100	600
6 to 8	.25	.38	.50	100	400
9 to 12	.30	.45	.60	80	240
13 to 16	.35	.52	.70	80	160
17 to 20	.40	.60	.80	60	120
21 to 25	.45	.68	.90	50	100

[1] **P** values:

A For 4-year rotation of row crop, small grain with meadow seeding, and 2 years of meadow. A second row crop can replace the small grain if meadow is established in it.

B For 4-year rotation of 2 years row crop, winter grain with meadow seeding, and 1-year meadow.

C For alternate strips of row crop and small grain.

[2] Adjust strip-width limit, generally downward, to accommodate widths of farm equipment.

Terracing

The most common type of terrace on gently sloping land is the broadbase, with the channel and ridge cropped the same as the interterrace area. The steep backslope terrace is most common on steeper land. Difficulty in farming point rows associated with contoured terraces led to developing parallel terracing techniques (*16*). Underground outlets, landforming, and variable channel grades help establish parallel terraces. The underground outlets are in the low areas along the terrace line. The ridge is constructed across these areas. Another type of terrace, using a level and broad channel with either open or closed ends, was developed to conserve moisture in dryland farming areas.

Terraces with underground outlets, frequently called impoundment terraces, are highly effective for erosion control. Four-year losses from four such terrace systems in Iowa (*17*) averaged less than 0.4 t/A/year, which was less than 5 percent of the calculated soil movement to the channel. Comparable losses were measured from installations in Nebraska.

Terracing combined with contour farming and other conservation practices is more effective than those practices without the terraces because it positively divides the slope into segments equal to the horizontal terrace interval. The horizontal terrace interval for broadbase terraces is the distance from the center of the ridge to the center of the channel for the terrace below. For steep backslope terraces with the backslope in sod, it is the distance from the point where cultivation begins at the base of the ridge to the base of the frontslope of the terrace below (*44*). With terracing, the slope length is this terrace interval; with stripcropping or contouring alone, it is the entire field slope length.

P Values

Values of **P** for contour farming terraced fields are given in table 15. These values apply to contour farmed broadbase, steep backslope, and level terraces. However, recognize that the erosion control benefits of terraces are much greater than indicated by the **P** values. As pointed out earlier, soil loss per unit area on slopes of 5 percent or steeper is approximately proportional to the square root of slope length. Therefore, dividing a field slope into **n** approximately equal horizontal terrace intervals divides the average soil loss per unit area by the square root of **n**. This important erosion control benefit of terracing is not included in **P** because it is brought into the USLE computation through a reduced **LS** factor obtained by using the horizontal terrace interval as the slope length when entering figure 4 or table 3.

Erosion control between terraces depends on the crop system and other management practices evaluated by **C**. The total soil movement within a contour-farmed terrace interval may be assumed equal to that from the same length of an identical slope that is contoured only. Therefore, if a control level is desired that will maintain soil movement between the terraces within the soil loss tolerance limit, the **P** value for a contour-farmed terraced field should equal the contour factor (col. 2, table 15), and use of these values for farm planning purposes is generally recommended.

With contour stripcropping, the soil deposited in the grass strips is not considered lost because it remains on the field slope. With terraces, most of the deposition occurs in the terrace channels, but research measurements have shown that this deposition may equal 80 percent of the soil moved from the contour-farmed slopes between the terraces (*67*). Use of the contour factor as the **P** value for terracing assumes that all of the eroded soil deposited in the terrace channels is lost from the productive areas of the field. With broadbase terraces, the channels and ridges are cropped the same as

TABLE 15.—**P** *values for contour-farmed terraced fields*[1]

Land slope (percent)	Farm planning		Computing sediment yield[3]	
	Contour factor[2]	Stripcrop factor	Graded channels sod outlets	Steep backslope underground outlets
1 to 2	0.60	0.30	0.12	0.05
3 to 8	.50	.25	.10	.05
9 to 12	.60	.30	.12	.05
13 to 16	.70	.35	.14	.05
17 to 20	.80	.40	.16	.06
21 to 25	.90	.45	.18	.06

[1] Slope length is the horizontal terrace interval. The listed values are for contour farming. No additional contouring factor is used in the computation.

[2] Use these values for control of interterrace erosion within specified soil loss tolerances.

[3] These values include entrapment efficiency and are used for control of offsite sediment within limits and for estimating the field's contribution to watershed sediment yield.

the interterrace slopes, and some of the material deposited in the channels is moved to the ridges in terrace maintenance. The 1956 slope-practice group felt that some of the deposition should be credited as soil saved and recommended use of a terracing practice factor equal to the stripcrop factor (*64*). However, the more conservative values given in column 2 are now commonly used in conservation planning.

When the USLE is used to compute a terraced field's contribution to offsite sediment or watershed gross erosion, the substantial channel deposition must be credited as remaining on the field area. For this purpose, the **P** values given in the last two columns of table 15 are recommended unless an overland flow deposition equation based on transport relationships is used with the USLE.

With widespread use of large multirow equipment, farming with field boundaries across nonparallel terraces is not uncommon in some regions. When terraces are not maintained and overtopping is frequent, $P = 1$ and the slope length is the field slope length. However, if the terraces are periodically maintained so that overtopping occurs only during the most severe storms, **LS** is based on the horizontal terrace interval. If farming across terraces is at an angle that approximates contour farming, **P** values less than 1.0 but greater than the contour factors would be appropriate.

Soil Loss Terrace Spacing

Traditionally, terrace spacing has been based on slope gradient; however, some recent spacing guides have included modifying factors for severity of rainfall and for favorable soil and tillage combinations. A major objective of cropland conservation planning is to hold the productive topsoil in place. Extending this objective to terrace system design suggests limiting slope lengths between terraces sufficiently so that specified erosion tolerances will not be exceeded. Using the USLE in developing spacing guides will make this possible.

The USLE may be written as $LS = T/RKCP$, where **T** is the tolerance limit. If $T/RKP = Z$, then $LS = Z/C$, and $C = Z/LS$. The values **T**, **R**, **K** and **P** are constant for a given location and can be obtained from handbook tables and charts as illustrated in the section **Predicting Cropland Soil Losses.** Factor **C** can be selected as the **C** value of the most erosion-vulnerable crop system that a farmer is likely to use on the terraced field. **LS** can be computed by solving the equation as written above and, with the percent slope known, the maximum allowable length can be read from the slope-effect chart, figure 4.

To illustrate the procedure, assume a 6-percent slope at a location where $R = 175$, $K = 0.32$, $T = 5$, $P = 0.5$, and the most erodible crop expected to occur on the field has a **C** value of 0.24. (An assumption that the field will always be in a sod based rotation or that the operator will always make the best possible use of the crop residues would be too speculative to serve as a guide for terrace spacing.) With these assumptions, $Z = 5/175(0.32)(0.5) = 0.179$ and $LS = 0.179/0.24$, or 0.744. Enter the slope-effect chart, figure 4, on the **LS** scale with a value of 0.744, move horizontally to intersect the 6 percent-slope line and read the corresponding slope length, 120 ft, on the horizontal scale. Add to this value the width of the terrace frontslope and compute the vertical interval: $\left(\frac{120 + 12}{100}\right)6 = 7.9$ ft. However, the horizontal interval should not exceed the slope-length limit for effectiveness of contouring. From table 13 the length limit for contouring on a 6-percent slope is 200 ft, so the computed terrace interval is satisfactory. A small modification in spacing may be made to adjust to an even multiple of machinery width.

The maximum **C** value that will allow a horizontal terrace spacing equal to the length limit for effective contouring on the given slope can also be determined by using figure 4 and table 13. For the conditions in the illustration above, $C = 0.179/LS$. The maximum acceptable length for contouring is 200 ft. From figure 4, the **LS** value for a 200-ft length of 6-percent slope is 0.95. Therefore, the maximum allowable $C = 0.179/0.95$, which is 0.188. With terraces spaced at 200-ft intervals, any cropping and management system with a **C** value of less than 0.188 should provide the level of conservation prescribed by the assumed soil loss tolerance limit of 5 t/A/year.

One additional consideration is important. For a terrace to function satisfactorily, the channel

capacity must be sufficient to carry the runoff safely to a stabilized outlet without excessive channel scour or overtopping of the ridge. SCS engineering practice standards specify a capacity sufficient to control the runoff from a 10-year-frequency, 24-hour storm without overtopping. Some SCS practice standards may require a shorter terrace interval than would be indicated by the foregoing procedure.

The discussion of the topographic factor pointed out that the erosion rate increases as slope length increases. Table 4 lists the relative soil losses for successive equal-length increments of a uniform slope divided into 2, 3, 4, or 5 segments. The third column of table 4 shows that if a uniform 6-percent slope were controlled at a tolerance of 5 t average soil loss, the average loss per unit area from the lower third of the slope would exceed the tolerance by about 38 percent. Soil loss from the upper third would be 43 percent less than the tolerance limit. To have an average rate of 5 t from the lower third, the **T** values used in the spacing calculation would need to be 1/1.38 times the 5-t tolerance, or 3.6 t. This is an approach that can be used to calculate terrace spacings for a higher level of conservation.

Effect of Terraces on Amount and Composition of Offsite Sediment

By reducing runoff velocity and inducing deposition of sediment in the channels, terraces have a profound effect on the amount and composition of offsite sediments from cultivated fields. The type of terrace, the channel grade, and the type of outlet influence the magnitude of the effect.

The greatest reduction in sediment is attained with the impoundment type terrace systems that use underground outlets. With the outlets in the lower areas of the field and terrace ridges built across these areas, temporary ponds are created around the risers of the outlet tile. The outlets are designed to drain the impounded runoff in 1 to 2 days. Thus, the ponds provide a maximum stilling effect, and only the smallest and lightest soil particles are carried off the field in the runoff water. The increased time for infiltration also reduces runoff.

Sediments collected from four impoundment terrace systems over 4 years in Iowa (*17*) showed the following percentages of fine materials:

Soil type	< 0.002 mm	< 0.008 mm
	Percent	*Percent*
Fayette silt loam	78	91
Sharpsburg silty clay loam	68	96
Floyd loam	31	82
Clarion loam	35	78

Sediment concentrations in the runoff ranged from about 1,300 p/m on the Fayette soil to 6,300 p/m on the Clarion. Average annual sediment from the outlets was less than 800 lb/A for all four systems.

Farm chemical losses in runoff vary with type and formulation, amount, placement, and time of rainfall in relation to time of application, as well as with the usual runoff and erosion factors. Principal chemicals are the fertilizers, insecticides, fungicides, and herbicides. Losses are by solution and by suspension of chemical granules or adsorption on soil particles suspended in the runoff water.

Terracing exerts its greatest influence in reducing offsite pollution from those chemicals that are adsorbed on soil particles. Examples of these are the phosphates, organic nitrogen, and persistent organochlorine insecticides. Reductions in offsite *sediment* by terrace systems with contouring are estimated to range from 82 to 95 percent. However, the reductions in chemical transport are generally not proportional to reductions in soil loss because of an enrichment process that applies to the suspensions. The nutrient content of sediments is often 50 percent greater than that of the soil. Offsite delivery of sediment is also affected by watershed characteristics, particularly size of the drainage area. This reduction is measured by a "delivery ratio" that ranges from 0.33 for an area of one-half square mile to 0.08 for a 200-mi^2 area (*45*).

Terracing has the least effect on offsite pollution from those chemicals transported primarily in solution. Annual runoff reductions by terracing and contour farming, at 21 locations throughout the United States, have been estimated to vary only from 9 to 37 percent (*42*). Examples of farm chemicals transported primarily in solution are the nitrates and some herbicides such as 2,4-D ((2,4-dichlorophenoxy) acetic acid). The predominate transport modes for an extensive list of pesticides are listed in volumes 1 and 2 of "Control of Water Pollution From Cropland" (*42*).

APPLYING THE SOIL LOSS EQUATION

The major purpose of the soil loss prediction procedure is to supply specific and reliable guides for selecting adequate erosion control practices for farm fields and construction areas. The procedure is also useful for computing the upland erosion phase of sediment yield as a step in predicting rates of reservoir sedimentation or stream loading, but the USLE factors are more difficult to evaluate for large mixed watersheds. Specific applications of the soil loss equation are discussed and illustrated below.

Predicting Cropland Soil Losses

The USLE is designed to predict longtime-average soil losses for specified conditions. This may be the average for a rotation or for a particular crop year or cropstage period in the rotation. Where the term "average loss" is used below, it denotes the average for a sufficient number of similar events or time intervals to cancel out the plus and minus effects of short-time fluctuations in uncontrolled variables.

Rotation Averages

To compute the average annual soil loss from a particular field area, the first step is to refer to the charts and tables discussed in the preceding sections and select the values of **R, K, LS, C,** and **P** that apply to the specific conditions on that field. For example, assume a field on Russell silt loam soil in Fountain County, Ind. The dominant slope is about 8 percent with a length of 200 ft. Fertility and crop management on this field are such that crop yields are rarely less than 85 bu corn, 40 bu wheat, or 4 t alfalfa-brome hay. The probability of meadow failure is slight.

Factor **R** is taken from the isoerodent map (fig. 1). Fountain County, in west-central Indiana, lies between isoerodents of 175 and 200. By linear interpolation, $R = 185$. **K** is taken from a table of **K** values that were derived either by direct research measurement or by use of the soil erodibility nomograph (fig. 3). For the Russell silt loam soil, $K = 0.37$. The slope-effect chart, figure 4, shows that an 8 percent slope 200 ft long has an **LS** of 1.41. If the field were continuously in clean-tilled fallow, the average annual soil loss from the dominant slope would equal the product **RKLS;** that is, $185(0.37)(1.41) = 96.5$ t/A.

Next, we need to know the effect of the cropping and management system and support practices existing on the field. This effect is represented by factors **C** and **P**. The **C** value for the field may either be derived by the procedure previously presented, using data from tables 5 and 6, or it may be obtained from a centrally prepared **C** value table available from the SCS. For convenience, assume the same crop system and management as were assumed for the problem illustrating the derivation of locality **C** values. From table 8, **C** then equals 0.085. If rows and tillage are in the direction of the land slope, factor $P = 1.0$. The computed average soil loss is then $96.5(0.085)(1.0) = 8.2$ t/A/year.

From table 13, contour farming on 8 percent slopes not exceeding 200 ft in length has a **P** value of 0.5. Therefore, if farming were on the contour, the computed average soil loss for the field would be $96.5(0.085)(0.5) = 4.1$ t. If the length of 8-percent slope was appreciably greater than 200 ft, the effectiveness of contouring could not be assumed, and the **P** value of 0.5 would not be applied unless the slope length was broken by terraces or diversions. Any change in either the crop sequence or the management practices would likely increase or decrease soil loss. This would be reflected in the USLE solution through a change in the **C** value.

When **C** is used at its average annual value for a rotation that includes a sod crop, as was done in the example given in table 8, the heavier losses experienced during row crop years are diluted by trivial losses in the meadow year(s). For holding longtime-average soil losses below some prescribed tolerance limit, this dilution poses no problem. But from the viewpoint of offsite water quality, it may not be desirable. The USLE may also be used to compute the average soil loss for each crop in the rotation or for a particular cropstage period.

Crop-Year Averages

The subtotals in column 9 of table 8 show that

with the assumed management system, **C** for the first-year corn would be 0.130 and for the second-year, 0.138. For the second-year corn, without contouring, the expected average soil loss would equal 185(0.37)(1.41)(0.138), or 13.3 t. If, in the same crop system, the corn residues were plowed down in fall, the **C** value for second-year corn would be 0.29, and the soil loss would average 28 t. On the other hand, no-till planting the second-year corn in a 70-percent cover of shredded cornstalks would reduce the **C** value for this crop to 0.08 and the soil loss to about 8 t. This would also reduce the rotation average for straight row farming to 7 t. Killing the meadow instead of turning it under, and no-till planting, would reduce the **C** value for the first-year corn to 0.01 and the soil loss to less than 1 t. Thus, crop-year **C** values can be helpful for sediment control planning.

Cropstage Averages

Additional information can be obtained by computing the average annual soil loss for each cropstage period. First, the computed cropstage soil losses will show in which portions of the crop year (or rotation cycle) improved management practices would be most beneficial. Second, they provide information on the probable seasonal distribution of sediment yields from the field. When a tabulation like table 8 has been prepared, the values in column 8 will be directly proportional to the cropstage soil losses. They can be converted to tons per acre for a specific field by multiplying them by the product of factors **R**, **K**, **LS**, and **P**.

To estimate the average soil loss for a particular cropstage when such a table has not been prepared, the cropstage soil loss ratio from table 5 is used as **C**. The annual **EI** fraction that is applicable to the selected period is obtained from table 6 and is multiplied by the location's annual erosion index value (fig. 1) to obtain the relevant **R** value. **K**, **LS**, and **P** will usually be assumed to have the same values as for computation of average annual soil losses.

Suppose, for example, that one wishes to predict the average soil loss for the seedbed and establishment periods of corn that is conventionally planted about May 15 on spring plowed soybean land in southwestern Iowa (area No. 13, fig. 9). Suppose also that the corn is on a field for which the combined value of factors **K**, **LS**, and **P** is 0.67 and the fertility and crop management are such that corn planted by May 15 usually develops a 10 percent canopy cover by June 5, 50 percent by June 25, and a final canopy cover of more than 95 percent. Interpolating between values in line 13 of table 6 shows cumulative **EI** percentages of 12, 23, and 43 for these three dates. Therefore, on the average, 11 percent of the annual **EI** would occur in the seedbed period, and 20 percent would occur in the establishment period. From line 109 of table 5, the soil loss ratios for these two cropstage periods under the assumed management are 0.72 and 0.60. From figure 1, the average annual **EI** is 175. The soil loss would be expected to average $0.11(175)(0.72)(0.67) = 9.3$ t/A in the seedbed period and $0.20(175)(0.60)(0.67) = 14$ t in the establishment period. The cropping assumed for this example represents an extremely erodible condition. For second-year corn with good residue management, the applicable soil loss ratios and the predicted soil losses would be much lower.

Individual Storm Soil Losses

The USLE factors derived from tables and charts presented herein compute longtime-average soil losses for specified cover and management on a given field. The USLE is not recommended for prediction of specific soil loss events.

If it is applied to a specific rainstorm, using the storm **EI** for **R** and the relevant cropstage soil loss ratio for **C**, it will estimate the *average* soil loss for a large number of storms of this size occurring on that field and in that cropstage period. However, the soil loss from any one of these events may differ widely from this average because of interactions with variables whose values fluctuate randomly over time (*56*).

When rain falls on relatively dry, freshly tilled soil, most of the water may infiltrate before runoff begins, resulting in a low-average soil loss per unit of **EI** for that storm. When rain falls on presaturated soil, runoff begins quickly, and most of the rain becomes runoff. Such rains usually produce above-average soil loss per **EI** unit. Some rains are accompanied by high winds that increase the impact energy of raindrops; others occur in a fairly calm atmosphere. Some storms begin with a high intensity and seal the surface quickly so that trailing lower intensities encounter a low infiltration rate. In other storms the moderate intensities

precede the high ones. In some seasons the soil is cultivated when wet and remains cloddy; in other seasons it is cultivated when soil moisture is ideal for fine pulverization. A claypan or fragipan subsoil may substantially influence permeability in early spring or in a wet growing season and yet have no significant effect on infiltration rates during intense thunderstorms on dry soil.

The soil loss ratios of table 5 are averages for cropstage periods that cover several weeks to several months. Early in a cropstage period, the ratio will usually be higher than the average because the development of cover is gradual. Later in the period it will be lower than average. In a poor growing season the ratio will be above average because cover and water use by transpiration are below normal. In a favorable growing season, the ratio will be below average. Cover effect in a specific year may be substantially influenced by abnormal rainfall. A crop canopy or conservation tillage practice may delay the start of runoff long enough to be 100 percent effective for moderate storms on a given field and yet allow substantial erosion by prolonged runoff periods.

The irregular fluctuations in these and other variables can greatly influence specific-storm soil losses. However, they do not invalidate the USLE for predicting long-term-average soil losses for specific land areas and management conditions. Their positive and negative effects tend to balance over a longtime period, and their average effects are reflected in the factor-evaluation tables and charts.

Two recent research reports are recommended references for those who find it necessary to estimate specific-storm soil losses (*34, 10*). The authors present modifications of **R** and **LS** that are designed to account for some random effects discussed.

Specific-Year Soil Losses

In any given year, both the annual **EI** and its monthly distribution may differ substantially from the location averages. Therefore, **R** values from figure 1 and **EI** distribution data from table 6 will not correctly reflect specific-year values of these variables. The most accurate procedure is to compute the **EI** value for each storm from a recording-rain gage record for the location and year by the method given in the appendix. The storm values are summed for each cropstage period, and the subtotals are combined with soil loss ratios from table 5 to estimate the soil loss for each cropstage period. The sum of the cropstage soil losses then reflects the effects of possible abnormal **EI** distribution, as well as the corrected **R** value for the specific year. However, the irregular fluctuations in variables discussed in the preceding subsection are often related to abnormalities in rainfall. The plus and minus effects on soil loss may not average out within 1 year but may appreciably bias specific-year soil losses. These biases will not be evaluated by the USLE. Therefore, specific-year estimates of soil loss will be less accurate than USLE estimates of long-term, crop-year averages.

Soil Loss Probabilities

Soil loss probabilities are a function of the combination of the probabilities for annual **EI**, seasonal distribution of the erosive rains, abnormal antecedent soil moisture conditions, favorable or unfavorable conditions for soil tillage and crop development, and other factors. The section on the **Rainfall Erosion Index** pointed out that a location's annual and maximum storm **EI** values tend to follow log-normal frequency distributions and that specific probability values are listed in tables 17 and 18 for 181 key locations. When these probabilities of **EI** are used for **R** in the USLE, the equation will estimate the soil loss that would occur if all the other factors were at their normal levels. However, the seasonal distribution of erosive rains, and the surface conditions in the field, may also be abnormal in years of rainfall extremes. Deriving probable relationships of these variables to extremes in annual **EI** would require longer records than were available.

Stochastic modeling techniques (*66*) are available that could be used to generate synthetic data having the same statistical properties as historical data. Such data could be used to estimate the probable range in specific-year soil losses in a particular rainfall area.

Determining Alternative Land Use and Treatment Combinations

The soil loss prediction procedure supplies the practicing conservationist with concise reference tables from which he can ascertain, for each particular situation encountered, which specific land

use and management combinations will provide the desired level of erosion control. A number of possible alternatives are usually indicated. From these, the farmer will be able to make a choice in line with his desires and financial resources.

Management decisions generally influence erosion losses by affecting the factor **C** or **P** in the erosion equation. **L** is modified only by constructing terraces, diversions, or contour furrows with sufficient capacity throughout the year to carry the runoff water from the furrow area above. **R, K,** and **S** are essentially fixed as far as a particular field is concerned.

When erosion is to be limited within a predetermined tolerance, **T,** the term **A** in the equation is replaced by **T,** and the equation is rewritten in the form **CP** = **T/RKLS.** Substituting the site values of the fixed factors in this equation and solving for **CP** give the maximum value that the product **CP** may assume under the specified field conditions. With no supporting practices, **P** = 1, and the most intensive cropping plan that can be safely used on the field is one for which **C** just equals this value. When a supporting practice like contouring or stripcropping is added, the computed value of **T/RKLS** is divided by the practice factor, **P,** to obtain the maximum permissible cover and management factor value. Terracing increases the value of **T/RKLS** by decreasing the value **L.**

A special USLE calculator, originally designed in Tennessee (*41*) and recently updated, enables rapid and systematic calculation of either average annual soil loss or **T/RKLS** for any specific situation.

Many practicing conservationists prefer to use handbook tables. **C**-value tables for specific geographic areas (fig. 9) are centrally prepared by persons who are experienced in the procedures outlined in a preceding section and who obtain the needed data from tables 5 and 6. Values of **T/RKLS** are also centrally computed and arranged in two-way classification as illustrated in table 16 for **R** = 180, **K** = 0.32, and **T** = 5. Similar tables are prepared for other combinations of **R, K,** and **T.**

A conservationist working in the field usually carries a pocket-sized handbook which includes the **R** value(s), **T** and **K** soil values, applicable tables of **T/RKLS** values, and a table of **C** values for the area. These items will provide all the information needed to use this procedure as a guide

TABLE 16.—*Maximum permissible* **C** *values* (**T/RKLS**) *for* **R** = *180,* **K** = *0.32 and* **T** = *5*

[1] The values for contour farming are **T/RKLSP**, where **P** is dependent on percent slope (see table 13).

[2] Omission of values indicates that the slope-lengths exceed the limits for effectiveness of contouring. Use corresponding values from upper half of table.

for selecting conservation practices in each field. Solving the equation or performing field computations rarely will be necessary.

Example. The first step is to ascertain the soil type, percent slope, and slope length for the field being planned. From his handbook data, the conservationist can then obtain the values of **R, K,** and **T.** To complete the illustration, assume that **R** = 180, **K** = 0.32, **T** = 5, and the field slope is 400 ft long with a nearly uniform gradient of 6 percent. For this combination, the **T/RKLS** table shows a value of 0.064 for straight-row farming with the land slope (table 16). This is the maximum **C** value that will hold the average annual soil loss from that field within the 5-t tolerance limit, if no supporting practices are used. Consulting the **C** value table will show that a **C** as low as 0.064 can be attained only with well-managed, sod-based crop systems, or with no-till planting in residue covers of at least 70 percent.

A logical improvement is to add contouring. Table 13 shows a slope-length limit of 200 ft (250 ft if residue cover after seeding exceeds 50 percent) for contouring on 6-percent slope. Therefore,

the **P** value of 0.5 for contouring will not be applicable on the 400-ft slope without terracing. Construction of three, equally spaced terraces across the slope would divide it into four 100-ft slope lengths. Shortening the slope lengths to 100 ft will assure contour effectiveness and will also reduce the site value of **L**. For a 100-ft length of 6-percent slope farmed on the contour, table 16 shows a **T/RKLSP** value of 0.26. Any combination of cropping and management practices having a **C** value less than 0.26 will now be acceptable. Consulting the table of **C** values will show that with the terraces and contouring, the conservationist can recommend a range of possibilities for land use and management. If a system with a **C** value appreciably less than 0.26 is selected, a higher level of conservation will be attained than required by the 5-t tolerance limit.

Had the slope length in the example been only 200 ft, the contour **P** value of 0.5 (table 13) would have been applicable without the terraces. Table 16 shows that this combination would have permitted use of any system having a **C** value less than 0.18.

Thus, by this procedure a conservationist can list all the alternative crop system and management combinations that would control erosion on a field at an acceptable level. Study of this list will show how an erosion control program can be improved and still increase crop yields or decrease labor and fuel costs. In making a selection from this list, practices needed for control of nutrient and pesticide losses in the runoff (*42*) should also be considered.

Construction Sites

Procedures and data have been presented for predicting erosion losses from specific cropland areas and logically determining alternative ways in which the losses from each field may be held below given tolerance limits. These procedures and data can also be adapted to conditions on highway, residential, and commercial developing areas. The USLE will show under which development plan the area will produce the least sediment, and it will also show about how much sediment the developer will need to trap in sediment basins (*46*) during construction to prevent excessive soil movement to streams or reservoirs.

Evaiuating the erosion factors for construction site conditions is discussed below. However, those primarily concerned with this particular phase of sediment control should also read the preceding discussions of the USLE factors and the procedures for predicting cropland soil losses.

Factor R. For a construction project extending over several years, the average annual **R** value for the site is obtained directly from figure 1. Probabilities of **EI** values greater than average are given in table 17. Using **EI** probabilities for **R** was discussed in the subsection **Soil Loss Probabilities.**

For construction periods of less than 1 year, the procedure outlined for predicting cropland soil losses for specific cropstage periods is appropriate. The portion of the annual **R** value that is applicable to the construction period is obtained from table 6 as illustrated on p. 41 for cropstage averages.

Factor K. Because the soil surface is often unprotected during construction, this factor assumes even greater importance than for cropland. The soil erodibility nomograph (fig. 3) can be especially helpful for sediment prediction and erosion control planning on construction sites because it can predict the changes in erodibility when various subsoil horizons are exposed in the reshaping process. Some subsoils are substantially more erodible than the original topsoil, and others are less erodible. The planner can usually obtain a detailed description of the successive horizons of his soil from published soil survey data. By using the data for each soil horizon separately to follow the steps of the nomograph solution, the **K** value can be determined after various depths of desurfacing. Soil losses from the successive soil horizons, if exposed on similar slopes, would be directly proportional to the horizon **K** values. Information on the subsoil **K** values not only shows the depths of cut that would result in the most or the least soil erosion but also indicates whether return of stockpiled topsoil on the exposed subsoil would be profitable on the particular site.

When a chemical soil additive is used that stabilizes the soil and makes it less erodible, the **K** value is the nomograph solution times a factor for the effectiveness of the chemical additive.

Factor LS. Within limits, the **LS** value for a given length and steepness of uniform slope can be obtained directly from figure 4 or table 3. When the

slope is concave or convex, the figure 4 value needs to be adjusted by the procedure outlined for irregular slopes in the section on **The Topographic Factor.**

Development planning may include measures designed to reduce sediment yield by lowering **LS.** The effect of shortening slope lengths by diversions or stabilized drainageways is credited by entering figure 4 with the reduced slope length. A slope graded to flatten toward the bottom (concave) will lose less soil than an equivalent uniform slope whereas one that steepens toward the bottom (convex) will lose more. Reduction or increase in soil loss can be predicted by the procedure illustrated in the subsection **Irregular Slopes.**

Data are not available to evaluate **LS** on very steep slopes, like 2:1 and 3:1 roadbank slopes, in relation to soil and rainstorm characteristics. The best presently available estimates of **LS** for these slopes can be obtained by the **LS** equation presented earlier. However, values projected by this equation for steep slopes are speculative because the equation was derived from data obtained on slopes of less than 20 percent.

Factor C. Procedures for selecting **C** values for construction sites were given in the **Cover and Management Factor** section.

Factor P. This factor as used for soil conservation planning on cropland would rarely have a counterpart during construction on development areas, and **P** will usually equal 1.0. Erosion-reducing effects of shortening slopes or reducing slope gradients are accounted for through the **LS** factor.

If the lower part of a grass or woodland slope on a development area can be left undisturbed while the upper part is being developed, the procedure outlined for computing the value of **LSC** on irregular slopes is applicable, and sediment deposition on the undisturbed strip must be accounted for separately. For prolonged construction periods, buffer strips of grass, small grain, or high rates of anchored mulch may also be feasible to induce deposition within the area. Such deposition is important for water quality or offsite sediment control, but it should be evaluated from soil-transport factors rather than by a **P** factor.

Alternative plans. When appropriate numerical values of the six erosion factors are combined, their product is the soil loss estimate for the particular area in tons per acre and for the time interval for which **R** was evaluated. With the information supplied by the tables and charts in this handbook, the six factor values can be derived for each feasible alternative plan. Successive solutions of the equation will then provide comparative soil loss estimates to help guide decisions by the developer.

Estimating Upslope Contributions to Watershed Sediment Yield

The importance of predicting watershed sediment yields and identifying the major sediment sources was increased by the Federal Water Pollution Control Act Amendments of 1972, Public Law 92-500. Sources, causes, and potentials of sediment, nutrient, and pesticide losses from cropland, and measures that may be necessary to control these pollutants, are dealt with in depth in a two-volume manual developed by SEA and the Environmental Protection Agency (EPA) (*42*). Volume II, "An Overview," also includes an extensive list of other relevant publications. Only sediment yield prediction will be considered here.

Estimates show that about one-fourth of the amount of sediment moved by flowing water in the United States annually reaches major streams (*42*). The USLE can be used to compute average sheet and rill erosion in the various parts of a watershed, but deposition and channel-type erosion must be estimated by other means. A fully tested equation for sediment transport to use on agricultural land is not now available. One presented by Neibling and Foster (*32*) is perhaps the best now available for use with the USLE. It estimates transport capacity for sand and large silt-sized particles and does not consider the transport of clay particles.

Of the several methods now used for estimating sediment yield, the Gross Erosion-Sediment Delivery Method uses the USLE. A brief description of this method follows. More details are available from the SCS National Engineering Handbook (*45*). The equation is

$$Y = E(DR)/W_s \qquad (6)$$

where **Y** is sediment yield per unit area,

E is the gross erosion,

DR is the sediment delivery ratio, and

W_s is the area of the watershed above the point for which the sediment yield is being computed.

Gross Erosion

Gross erosion is the summation of erosion from all sources within the watershed. It includes sheet and rill erosion from tilled cropland, meadows, pastures, woodlands, construction sites, abandoned acreages, and surface-mined areas; gully erosion from all sources; and erosion from streambeds and streambanks. The relative importance of each of these sources of gross erosion will vary between watersheds.

The USLE can be used to estimate the sediment generated by sheet and rill erosion that is usually, but not always, the major portion of a watershed's gross erosion. Sediment from gully, streambank and streambed erosion, and from uncontrolled roadsides must be added to the USLE estimates. Methods for estimating sediment yields from these sources are discussed in Section 3 of the SCS National Engineering Handbook (*45*).

For small areas like farm fields or construction sites, the six USLE factors can usually be evaluated directly from the information presented in this handbook. For a large heterogeneous watershed, the factors are more difficult to define. Several methods of computing the average slope length and gradient for a large drainage area are available. Using **LS** values based on such averages, together with estimated watershed-average soil and cover factors, simplifies the computing procedure, but the saving in time is at the expense of substantial loss in accuracy. Erosion hazards are highly site specific. The parameters that determine the USLE factor values vary within a large watershed, and the variations are often not interrelated. Combining overall averages in the equation does not reflect the particular way in which the factors are actually combined in different parts of the watershed. Neither does it show which portions of the drainage area are contributing most of the sediment.

A more accurate procedure is to divide the heterogeneous drainage area into subareas for which representative soil type, slope length, gradient, cover, and erosion-control practice factors can be defined. The USLE is then used to compute the sheet and rill erosion on each subarea. For this purpose, eroded soil that is entrapped within the field area by terrace systems is not soil loss. An estimate of the entrapped sediment can be excluded from the USLE soil loss estimates by using values from the last two columns of table 15 as the **P** values. An alternate procedure is to estimate the channel deposition by sediment-transport relationships and subtract this amount from the soil loss computed by using the standard terracing factor (col. 2, table 15) in the USLE. By this procedure, the subarea soil loss computations identify the portions of the drainage area that contribute most of the sediment and also show how much of the sediment derives from tracts that receive heavy applications of agricultural chemicals.

Procedures for computing soil losses from cropped, idle, pasture, range, or wooded areas and from construction or development areas were outlined in the preceding sections. Factor values derived by the prescribed procedures are assumed applicable also for surface-mined areas. However, the effect of mining processes on soil erodibility, **K**, has not been determined. Length and percent slope and deposition within the area also are hard to determine for rugged strip mine spoils. Sometimes nearly all the sediment may be trapped within the bounds of the area. The USLE can be quite useful for predicting the effectiveness of each feasible reclamation plan for such areas.

Sediment Delivery Ratio

Eroded soil materials often move only short distances before a decrease in runoff velocity causes their deposition. They may remain in the fields where they originated or may be deposited on more level slopes that are remote from the stream system. The ratio of sediment delivered at a given location in the stream system to the gross erosion from the drainage area above that location is the sediment delivery ratio for that drainage area. A general equation for computing watershed delivery ratios is not yet available, but the ratios for some specific drainage areas have been computed directly from local data. Helpful guides for estimating this factor for other drainage areas were published by SCS in Section 3 of their National Engineering Handbook (*45*), and most of these guides were also included in a publication by SEA and EPA (*42*). Therefore, the relationships involved will be only briefly summarized here.

Available watershed data indicate that the delivery ratio varies approximately as the 0.2 power of drainage-area size, with representative values of about 0.33 for 0.5 mi^2; 0.18 for 10 mi^2; and 0.10 for 100 mi^2. There were indications that the exponent in this relationship may be as small as 0.1 for very large areas. But the ratio may vary substantially for any given size of drainage area. Other important factors include soil texture, relief, type of erosion, sediment transport system, and areas of deposition within the watershed. Fine soil texture, high channel density, and high stream gradients generally indicate delivery ratios that are above average for the drainage-area size.

A substantial reduction in sediment delivered to a stream may sometimes result in a compensatory increase in channel erosion. Channel erosion produces sediment that is immediately available to the transport system and that may remain in motion as bedload and suspended sediment. The composition of sediment derived from channel erosion will usually differ substantially from that derived from cropland erosion. This is particularly important from the viewpoint of transported chemical pollutants.

With reference to a field-sized area, the delivery ratio can closely approach 1.0 if the runoff drains directly into a lake or stream system with no intervening obstructions or flattening of the land slope. On the other hand, a substantial width of forest litter or dense vegetation below the eroding area may cause deposition of essentially all the sediment except colloidal material. Anything that reduces runoff velocity (such as reduction in gradient, physical obstructions, vegetation, and ponded water) reduces its capacity to transport sediment. When the sediment load exceeds the transport capacity of the runoff, deposition occurs.

From analysis of runoff and soil loss data from small single-cropped watersheds, Williams (*48*) concluded that the need for a sediment delivery ratio could be eliminated by using the watershed runoff times peak rate as the storm **R** value in the USLE.

Accuracy of USLE Predictions

Soil losses computed with the USLE are best available estimates, not absolutes. They will generally be most accurate for medium-textured soils, slope lengths of less than 400 ft, gradients of 3 to 18 percent, and consistent cropping and management systems that have been represented in the erosion plot studies. The farther these limits are exceeded, the greater will be the probability of significant extrapolation error.

An indication of the accuracy of the equation, tables, and charts presented herein was obtained by using them to compute longtime average soil losses for plots in past erosion studies and comparing these with the actually measured losses on each plot. About 53 percent of the differences were less than 1 t/A, 84 percent were less than 2 t, and 5 percent were as much as 4.6 t (*53*). The mean annual soil loss for this 2,300 plot-year sample was 11.3 t. Of those differences that exceeded 1 t/A, 67 percent were from comparisons with plot records whose duration was less than half of a normal 22-year rainfall cycle (*33*). Such short records are subject to bias by cyclical effects and random fluctuations in uncontrolled variables whose effects are averaged in the USLE factor values (*56*). Testing the complete equation against the assembled plot data was statistically valid because the equation for each factor, as a function of several parameters, was independently derived from only selected portions of the data.

The accuracy of a predicted soil loss will depend on how accurately the physical and management conditions on the particular piece of land are described by the parameter values used to enter the factor-evaluation tables and charts. An error in the selection of a factor value will produce an equivalent percentage error in the soil loss estimate. Large-scale averaging of parameter values on mixed drainage areas will usually also reduce accuracy. For reasons previously pointed out and discussed in depth in another publication (*56*), specific-storm or specific-year soil losses and short-term averages may differ substantially from the longtime average predicted by the USLE for the specified physical and management conditions.

APPENDIX

Estimating Percentages of Canopy and Mulch Covers

"Percent canopy cover" is the percentage of the field area that could not be hit by vertically falling raindrops because of canopy interception. It is the portion of the soil surface that would be covered by shadows if the sun were directly overhead. Because the blades from adjacent rows intertwine does not necessarily indicate 100 percent canopy cover.

"Percent mulch cover" is the percentage of the field area that is covered by pieces of mulch lying on the surface. Researchers in Indiana attempted to relate percent cover to mulch rate by photographing numerous small, equal-sized areas in harvested corn fields. The residues on the photographed areas were carefully picked up, dried, and weighed to measure mulch rates, and the photographs were projected on grids to determine percent cover. The indicated average relation of percent cover to dry weight of well-distributed corn stover mulch is shown by the solid-line curve in figure 10. However, observed differences between samples were appreciable. The average relation of percent cover to dry weight of straw mulch uniformly distributed over research plots is shown by the broken-line curve.

A simple method of estimating percent mulch cover on a field is with a cord, preferably not shorter than 50 ft, that has 100 equally spaced knots or other readily visible markings. The cord is stretched diagonally across several rows, and the knots that contact a piece of mulch are counted. This procedure is repeated at randomly selected spots on the field, and the data are averaged to obtain a representative value for the field.

Probability Values of EI in the United States

The annual and maximum-storm values of **EI** at any given location differ substantially from year to year. The observed ranges and 50 percent, 20 percent and 5 percent probabilities of annual **EI** values from 22-year precipitation records at 181 locations in 44 States are listed in table 17. Other probabilities can be derived by plotting the 50 percent and 5 percent values on log-probability paper and joining the two points by a straight line. Annual maxima storm probabilities for the same locations are given in table 18.

Computing the Erosion Index from Recording-Rain Gage Records

Soil loss prediction by the method presented in this handbook does not require computation of **EI** values by application personnel, but the procedure is included here for the benefit of those who may wish to do so.

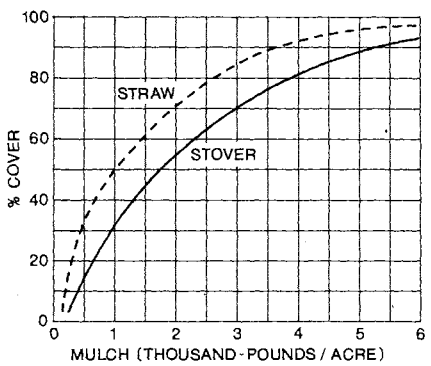

FIGURE 10.—Relation of percent cover to dry weight of uniformly distributed residue mulch.

The kinetic energy of a given amount of rain depends on the sizes and terminal velocities of the raindrops, and these are related to rainfall intensity. The computed energy per inch of rain at each intensity is shown in table 19. The energy of a given storm depends on all the intensities at which the rain occurred and the amount that occurred at each intensity. A recording-rain gage record of the storm will provide this information. Clock time and rain depth are read from the chart at each point where the slope of the pen line changes and are tabulated as shown in the first two columns of the sample computation below. Clock times (col. 1) are subtracted to obtain the time intervals given in column 3, and the depths (col. 2) are subtracted to obtain the incremental amounts tabulated in column 4. The intensity for each increment (col. 5) is the incremental amount times 60, divided by column 3.

Chart readings		For each increment			Energy	
Time	Depth (inch)	Duration (minute)	Amount (inch)	Intensity (in/hr)	Per inch	Total
4:00	0					
:20	0.05	20	0.05	0.15	643	32
:27	.12	7	.07	.60	843	59
:36	.35	9	.23	1.53	977	225
:50	1.05	14	.70	3.00	1074	752
:57	1.20	7	.15	1.29	953	143
5:05	1.25	8	.05	.38	777	39
:15	1.25	20	0	0	0	0
:30	1.30	15	.05	.20	685	34
Totals		90	1.30			1,284
Kinetic energy of the storm = $1{,}284(10^{-2}) = 12.84$						

The energy per inch of rain in each interval (col. 6) is obtained by entering table 19 with the intensity given in column 5. The incremented energy amounts (col. 7) are products of columns 4 and 6. The total energy for this 90-minute rain is 1,284 foot-tons per acre. This is multiplied by a constant factor of 10^{-2} to convert the storm energy to the dimensions in which **EI** values are expressed.

The maximum amount of rain falling within 30 consecutive minutes was 1.08 in, from 4:27 to 4:57. I_{30} is twice 1.08, or 2.16 in/h. The storm **EI** value is $12.84(2.16) = 27.7$. When the duration of a storm is less than 30 minutes, I_{30} is twice the amount of the rain.

The **EI** for a specified time is the sum of the computed values for all significant rain periods within that time. The average annual erosion index for a specific locality, as given in figures 1 and 2, is the sum of all the significant storm **EI** values over 20 to 25 years, divided by the number of years. For erosion index calculations, 6 h or more with less than 0.5 in of precipitation was defined as a break between storms. Rains of less than 0.5 in, separated from other showers by 6 h or more, were omitted as insignificant unless the maximum 15-min intensity exceeded 0.95 in/h.

Recent studies showed that the median dropsize of rain does not continue to increase for intensities greater than about 2.5 to 3 in/h (*7*, *15*). Therefore, energy per unit of rainfall also does not continue to increase, as was assumed in the derivation of the energy-intensity table published in 1958 (62). The value given in table 19 for rain at 3 in/h (7.6 cm/h in table 20) should be used for all greater intensities. Also, analysis of the limited soil loss data available for occasional storms with 30-min intensities greater than 2.5 in/h showed that placing a limit of 2.5 in (6.35 cm)/h on the I_{30} component of **EI** improved prediction accuracy for these storms. Both of these limits were applied in the development of figure 1. They slightly lowered previously computed erosion index values in the Southeast, but average-annual **EI** values for the U.S. mainland other than the Southeast were not significantly affected by the limits because they are rarely exceeded.

Conversion to Metric System

Metric equivalents were not included in the procedures and tables presented in this handbook because direct conversion of each English unit would produce numbers that would be awkward and undesirable. Converting the USLE as a whole is more appropriate. Metric units can then be selected so that each of the interdependent factors will have a metric counterpart whose values will be expressed in numbers that are easy to visualize and to combine in computations.

A convenient unit for measuring cropland soil losses is metric tons per hectare per year. **EI** values of convenient magnitude can be obtained by expressing rainfall energy in metric ton-meters per hectare, expressing intensities in centimeters per hour, and retaining the constant factor of 10^{-2} that has been used consistently for **EI** calculations in English units. Factor **K** will then be in metric tons per hectare per metric **EI** unit. If 22 meters is taken as the basic slope length and 9 percent is retained as the basic slope gradient, the **LS** factor will not be significantly affected. Using these units is recommended and is assumed in the following paragraphs.

The USLE factors will normally be derived directly in these units by procedures outlined below. However, the following conversion factors will facilitate comparisons of the metric factor values with the English values published in this handbook. Factors expressed in the recommended metric units are identified by the subscript, **m**.

Text continues on page 56.

5 ..	273	273	274	275	275	276	277	278	278	279
6 ..	280	280	281	281	282	283	283	284	284	285
7 ..	286	286	287	287	288	288	[2]289			

[1] Computed by the equation $E = 210 + 89 \log_{10} I$, where **E** = kinetic energy in metric-ton meters per hectare per centimeter of roin, and **I** = rainfoll intensity in centimeters per hour.

[2] The 289 value also applies for all intensities greater than 7.6 cm/h.

Values for column 6 are obtained by entering table 20 with the intensities listed in column 5, and their sum, 879, is the kinetic energy (E_m) of the 3.30 cm of rain expressed in metric ton-meters per hectare. The constant factor of 10^{-2} used for the English system should be applied here also so that storm $(EI)_m$ values will usually not exceed 100. The maximum amount of rain in any 30-minute period was 2.74 cm, from 4:27 to 4:57. Therefore $I_{30m} = 2(2.74 = 5.48$ cm/h. $(EI)_m = 8.79(5.48) = 48.17$

The procedure for combining storm **EI** values for local erosion index values was fully described in the preceding section. For predicting average annual soil losses from rainfall and its associated runoff, **R** equals the erosion index. Where runoff from thaw, snowmelt, or irrigation is significant, an R_s factor must be added to the **EI** value as previously discussed.

Where adequate rainfall intensity data are not available, the erosion index cannot be estimated solely from annual precipitation data. It is a function of the sizes and intensities of the individual rainstorms, and these are not closely related to annual precipitation. Therefore a given annual rainfall will indicate only a broad range of possible values of the local erosion index. However, the United States data indicate that the range of likely values can be somewhat narrowed by knowledge of the general climatic conditions in the particular geographic area.

In the U.S. Northern and Northeastern States, the winter precipitation generally comes as snow and low-intensity rains, but erosive intensities occur during the spring and summer. There, the local erosion index values, $(\mathbf{EI})_m$, have ranged from 2**P**-52 to 2.6**P**, where **P** is the average annual precipitation expressed in centimeters. In several Northwestern States, where rain intensities rarely exceed 2.5 cm/h, the annual $(\mathbf{EI})_m$ is generally less than **P**, but $\mathbf{R}_s$ values are high. Near the Gulf of Mexico and along the southern half of the Atlantic Coast, the rainfall characteristics are substantially influenced by coastal storms, 24-h rainfall exceeds 10 cm at least once in 2 years, on the average, and erosive rains occur in nearly every month of the year. There, erosion index values range between 4.2**P** and 6.7**P**. Values computed from the few long-term, recording-raingage records available for the islands of Hawaii and Puerto Rico were also within this range. In the large region between the northern and southern extremes mentioned above, the annual $(\mathbf{EI})_m$ values range from 2.5**P** to 4.5**P**. Brief, high-intensity thunderstorms are common in this region during the summer months, but general rains of longer duration also occur.

Where data are adequate to determine 2-year probabilities of 6-hour rainfall, these probabilities may provide more specific estimates of the local erosion index values. In the U.S. data, local erosion index values were approximately equal to the quantity $27.38\ \mathbf{P}^{2.17}$, where **P** = the 2-year, 6-hour precipitation in inches. Converted to the recommended metric units, $(\mathbf{EI})_m$ equals approximately $6.28\mathbf{P}^{2.17}$, where **P** is expressed in centimeters. However, this estimating procedure should not be substituted for the standard erosion index calculation procedure where adequate intensity data are available.

Factor K. This factor is the average soil loss in metric tons per hectare per unit of $(\mathbf{EI})_m$, measured on unit plots of the given soil. A unit plot is a 22-m length of uniform 9 percent slope that has been in clean fallow for more than 2 years and is tilled to prevent vegetative growth and surface crusting during the period of soil loss measurement. If a gradient other than 9 percent must be used, the data are adjusted by an **LS** factor available from figure 11. If the soil-erodibility nomograph (fig. 3) is used to evaluate $\mathbf{K}_m$, the **K** value read from the nomograph is multiplied by a conversion factor of 1.292.

The most accurate direct measurement of **K** for a given soil is obtained by measuring soil losses from unit plots under natural rain for at least 5 years, beginning 2 years after the clean-fallow condition was established. This permits averaging the interactions of soil erodibility with antecedent soil moisture, storm size, and other randomly distributed variables. The fallow plots receive the same annual tillage as conventionally tilled row crops.

Using rainfall simulators to evaluate **K** is quicker and less costly, but it requires caution. A one-time simulator test, even though replicated on several plots, measures soil loss from only one storm size and rain intensity, on one set of antecedent conditions, and these may or may not represent natural rainfall patterns. When simulated rainfall is used to evaluate **K**, measuring the soil losses for four or five successive 30-minute periods is helpful so that the segmented data can be rearranged to represent small, intermediate, and large storms beginning at various antecedent soil moisture levels. These can be weighted according to their probability of occurrence in natural rainfall (*58*).

Factor LS. Selecting 22 m as the basic slope length and retaining 9 percent as the basic slope gradient leaves the **LS** values essentially unchanged from those used in the English system of units. For uniform slopes, **LS** may be obtained by entering figure 11 with the field slope length expressed in meters. For concave or convex slopes, the value read from figure 11 should be modified by the procedure given in the subsection **Irregular Slopes.**

Factors C and P. Soil loss ratios (table 5) and **P** values (tables 13, 14, 15) are not affected by the units selected for the other factors. However, in countries where crops and farming techniques are different from those reflected in table 5, measurements of soil loss reductions attainable with feasible changes in crop system, tillage methods, and residue management may merit priority over establishing **EI** and **K** values.

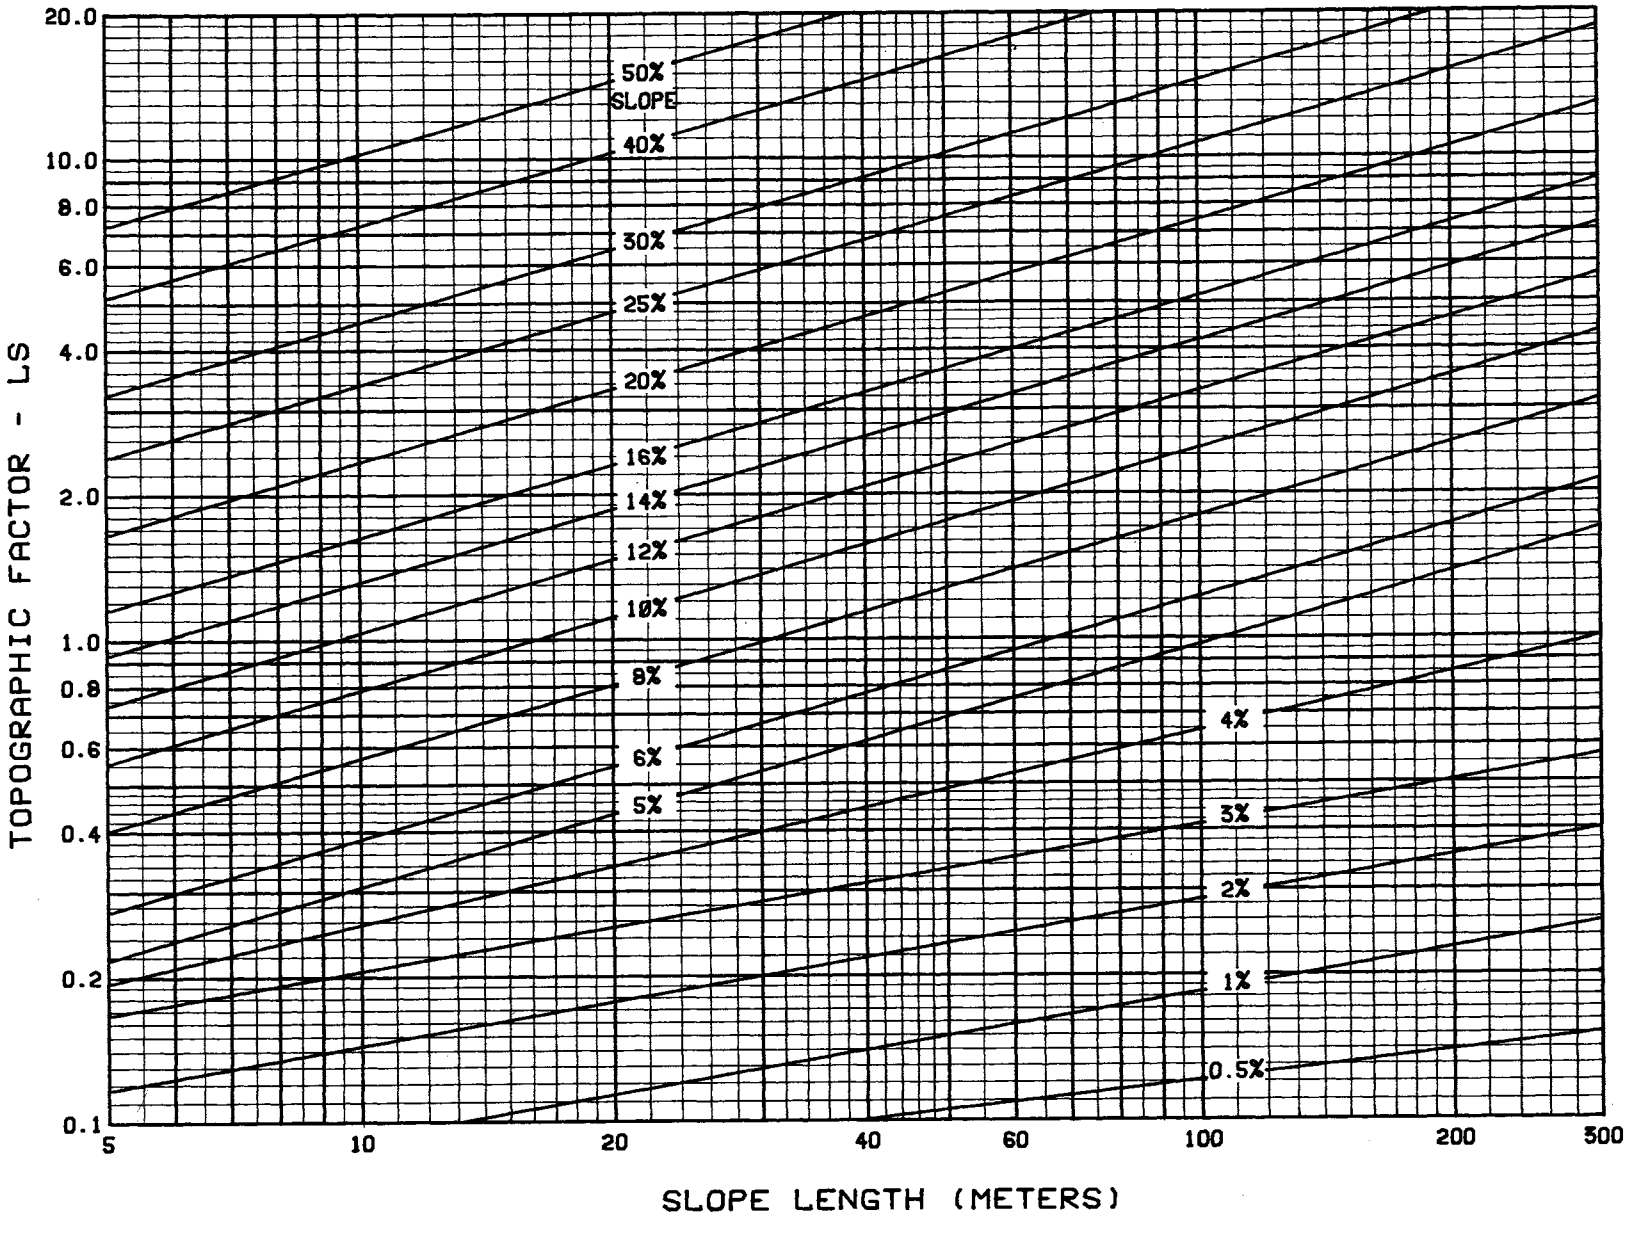

FIGURE 11.—Slope-effect chart for metric system.

PREDICTING RAINFALL EROSION LOSSES— A GUIDE TO CONSERVATION PLANNING

Supplement to Agriculture Handbook No. 537

METRICATION OF THE USLE IN THE INTERNATIONAL SYSTEM OF UNITS (SI)

The metric conversion originally presented in this handbook and in prior publications (*53, 60*) is not completely in the International System of Units (SI), which is expected to gain widespread usage. This supplement presents an alternative conversion in which all the Universal Soil Loss Equation (USLE) factors are expressed in standard SI units or approved multiples thereof, and the order of magnitude of each new unit is similar to the old.

Both conversion systems are authentic, and conservationists who have adopted the originally recommended metric units would not improve their USLE accuracy by changing to the new units. For future conversions, however, the revised procedure, which is fully outlined below, is recommended because its use will facilitate standardization of units.

The USLE terms **A, LS, C,** and **P** need no change from the recommendations in the preceding section. Strictly, the **SI** units for mass and area are kilograms and square meters. Because of common use, however, metric ton (a special name for megagram) and hectare (a special name for square hectometer) will be used. Soil loss (**A**) wil be expressed in metric tons per hectare, and factor **K** in metric tons per hectare per metric **EI** unit. Factors **LS, C,** and **P** are dimensionless. **L** is expressed relative to slope lengths measured in meters, but selecting 22 m as the basic slope length and retaining 9 percent as the basic slope gradient leaves the **LS** values essentially unchanged. **C** and **P** are not affected by the units selected for the other factors.

Factor **R** will be in different units than previously recommended. In the **SI** system, energy is measured in joules and rainfall in millimeters. The use of "centi" as a multiple is minimized. Metric **EI** values can be obtained in standard **SI** units by expressing rainfall energy in megajoules (**MJ**) per hectare and maximum 30-minute intensity (I_{30}) in mm/h, but use of cm/h to express I_{30} is more expedient for the following reasons: With I_{30} expressed in mm/h, the metric **EI** values would be 17 times the magnitude of **EI** in U.S. customary units. Annual erosion index values would be in four- or five-digit numbers, which are harder to visualize and compare mentally than the present smaller numbers. Of greater importance, the large metric **EI** values would result in extremely small metric **K** values, ranging downward from a maximum of about 0.09. Absolute differences between **K** values would be so small that many casual users of the USLE would tend to neglect important soil differences as insignificant.

Reducing the magnitude of I_{30} by a factor of 10 alleviates these disadvantages and does not preclude the use of mm as the unit for rainfall amounts and incremental intensities in energy computations. The energy equation or table will also be expressed in MJ/ha per mm of rain. Only I_{30} will be converted to cm as a matter of expedience. This is directly comparable to the U.S. customary procedure of computing energy in ft-tons/acre and dividing by 100 to obtain more convenient magnitudes. The metric **EI** will then equal storm energy in MJ/ha times I_{30} in cm/h.

Assuming use of the metric units specified above, a comparison of U.S. customary and **SI** dimensions for the terms in the USLE is as follows:

Term	*US customary dimensions*	*SI dimensions*	*Symbol*
A	ton/acre	metric ton/hectare	t/ha
R	$\frac{\text{100 foot-ton inch}}{\text{acre hour}}$	$\frac{\text{megajoule centimeter}}{\text{hectare hour}}$	$\frac{\text{MJ cm}}{\text{ha h}}$
K	$\frac{\text{.01 ton ocre hour}}{\text{ocre foot-ton inch}}$	$\frac{\text{metric ton hectare hour}}{\text{hectare megajoule centimeter}}$	$\frac{\text{t ha h}}{\text{ha MJ cm}}$
L,S,C,P	dimensionless	dimensionless	

The USLE terms will usually be derived directly in the **SI** units by procedures outlined below. However, the following conversion factors will facilitate comparisons of the metric factor values with the U.S. customary values published in this handbook. Terms expressed in metric units are identified by the subscript $_m$.

To convert from:	*multiply by:*	*to obtain:*
A in tons/acre	2.242	A_m in t/ha
E in 100 ft-tons/acre	0.670	E_m in MJ/ha
I_{30} in in/h	2.540	I_{30m} in cm/h
EI in $\frac{\text{100 ft-ton in}}{\text{ocre h}}$	1.702	$(EI)_m$ in $\frac{\text{MJ cm}}{\text{ha h}}$
K in $\frac{\text{.01 ton acre h}}{\text{acre ft-ton in}}$	1.313	K_m in $\frac{\text{t ha h}}{\text{MJ ha cm}}$

UNITED STATES DEPARTMENT OF AGRICULTURE

AGRICULTURE HANDBOOK NUMBER 537

PREPARED BY SCIENCE AND EDUCATION ADMINISTRATION

Factor R. The procedure for computing $(EI)_m$ for a given rain period is similar to that described in the preceding section for computing **EI**, but the input data will be in different units. If the raingage chart used for the example on page 51 had been calibrated in millimeters, the computation would have been as follows:

Chart readings		*Storm increments*			*Energy*	
Time	Depth (mm)	Duration (min)	Amount (mm)	Intensity (mm/h)	Per mm of rain (MJ/ha mm)	Increment total (MJ/ha)
(1)	(2)	(3)	(4)	(5)	(6)	(7)
4:00	0					
:20	1	20	1	3	0.161	0.161
:27	3	7	2	17	.226	.452
:36	9	9	6	40	.259	1.554
:50	27	14	18	77	.283	5.094
:57	30	7	3	26	.242	.726
5:05	32	8	2	15	.222	.444
:15	32	10	0	0	0	0
:30	33	15	1	4	.172	.172
Totals		90	33			8.603

Kinetic energy of the storm: 8.60 MJ/ha

Values for column 6 are obtained by entering the revised table 20 with the intensities listed in column 5. The sum of the products of corresponding values from columns 4 and 6 (8.60) is the kinetic energy, E_m, of the 33 mm of rain expressed in megajoules per hectare. The maximum amount of rain in any 30-minute period was 27 mm, from 4:27 to 4:57. Therefore the maximum 30-minute intensity was 2×27, or 54, mm/h, and $I_{30m} = 54/10 = 5.4$ cm/h. $(EI)_m = 8.60 \times 5.4 = 46.4$ (MJ cm)/(ha h).

For the **EI** computations, the rain occurring between two successive periods of 6 hours or more with less than 1.3 mm (0.05 in) of precipitation is considered one storm. Rain showers of less than 12 mm are omitted as insignificant unless they include a 15-minute intensity of at least 25 mm/h. The erosion index at a given location, as mapped in figures 1 and 2, is the average annual total of storm **EI** values over 20 to 25 years. For predicting average annual soil losses from rainfall and its associated runoff, **R** equals the erosion index. Where runoff from thaw, snowmelt, or irrigation is significant, **R** equals the **EI** plus an R_s value as discussed on page 7.

The erosion index cannot be reliably estimated from annual-rainfall data alone. It is a function of the sizes and intensities of the individual rainstorms, and these have no common relationship to annual rainfall totals. However, later analyses of the U.S. annual erosion index values that had been derived by the above procedure indicated that they were roughly equal to the quantity $27.38\ P^{2.17}$, where **P** = the 2-year, 6-hour rainfall expressed in inches. By direct conversion, the average annual $(EI)_m$ would be roughly estimated by $0.0416\ P^{2.17}$, where **P** is expressed in mm. This estimating formula is appreciably less accurate than the standard erosion index calculation procedure and should not be substituted for it where intensity data are available.

Factor K. The soil-erodibility factor **K** is the average soil loss in metric tons per hectare per unit of metric **EI**, measured on unit plots of the given soil. A unit plot (see p. 8) is a 22-m length of uniform 9 percent slope that has been in clean fallow for more than 2 years and is tilled to prevent vegetative growth and surface crusting during the period of soil loss measurement. If a gradient other than 9 percent must be used, the data are adjusted by the appropriate **LS** factor. If the soil-erodibility nomograph (fig. 3) is used to evaluate K_m, the **K** value read from the nomograph must be multiplied by a conversion factor of 1.313.

The basic slope length used for **K** and **L** in this handbook is 72.6 ft, which equals 22.134 m. For experimental evaluation of factor **K** in metric units, rounding this to 22.0 m is more convenient and introduces no error when 22.0 m is also used as the basic length for **L**, as in figure 11. The slight reduction in basic length increases factor **L** by 0.3 of 1 percent and decreases factor **K** by the same percentage, so the product of **K** and **L** is unchanged. For conversion of the U.S. customary **K** values in this handbook to metric **K** values based on a 22.0 m length, the relatively insignificant potential error is avoided by including an **L**-value of 0.997 in the conversion factor. The **K**-conversion factor of 1.313 given above has been so adjusted.

Factor LS. The preceding paragraph applies here, also. For uniform slopes, **LS** may be obtained by entering figure 11 with the field slope length expressed in meters or it may be computed by the equation

$$LS = (\lambda/22)^m\ (65.41\ \sin^2\theta + 4.56\ \sin\theta + 0.065)$$

where λ = slope length in m; θ = angle of slope; and m = 0.5 if the percent slope is 5 or more, 0.4 on slopes of 3.5 to 4.5 percent, 0.3 on slopes of 1 to 3 percent, and 0.2 on uniform gradients of less than 1 percent. For concave, convex, or mixed-gradient slopes, the value so computed or read from figure 11 should be modified by the procedure outlined on page 16.

Factor C and P. Soil loss ratios (table 5) and **P** values (tables 13, 14, 15) are not affected by the units selected for the other factors and therefore need no conversion.

TABLE 20. (revised).—*Kinetic energy of rainfall at specified intensities, expressed in megajoules per hectare per millimeter of rain*[1]

Intensity (mm/h)	0	1	2	3	4	5	6	7	8	9
0 ..	0	0.119	0.145	0.161	0.172	0.180	0.187	0.193	0.198	0.202
10 ..	.206	.210	.213	.216	.219	.222	.224	.226	.229	.231
20 ..	.233	.234	.236	.238	.240	.241	.242	.244	.245	.247
30 ..	.248	.249	.250	.252	.253	.254	.255	.256	.257	.258
40 ..	.259	.260	.261	.262	.262	.263	.264	.265	.266	.267
50 ..	.267	.268	.269	.270	.270	.271	.272	.272	.273	.274
60 ..	.274	.275	.276	.276	.277	.277	.278	.278	.279	.280
70 ..	.280	.281	.281	.282	.282	.283	.283[2]			

[1] Computed by the equation $e = 0.119 - 0.0873 \log_{10} i$, where e = kinetic energy in megajoules/(hectare millimeter) and i = rainfall intensity in mm/h.

[2] The value of 0.283 also applies for all intensities greater than 76 mm/h.

ABSTRACT

Renard, K.G., G.R. Foster, G.A. Weesies, D.K. McCool, and D.C. Yoder, coordinators. 1997. Predicting Soil Erosion by Water: A Guide to Conservation Planning With the Revised Universal Soil Loss Equation (RUSLE). U.S. Department of Agriculture, Agriculture Handbook No. 703, 404 pp.

The Revised Universal Soil Loss Equation (RUSLE) is an erosion model predicting longtime average annual soil loss (A) resulting from raindrop splash and runoff from specific field slopes in specified cropping and management systems and from rangeland. Widespread use has substantiated the RUSLE's usefulness and validity. RUSLE retains the six factors of Agriculture Handbook No. 537 to calculate A from a hillslope. Technology for evaluating these factor values has been changed and new data added. The technology has been computerized to assist calculation. Thus soil-loss evaluations can be made for conditions not included in the previous handbook using fundamental information available in three data bases: CITY, which includes monthly precipitation and temperature, front-free period, annual rainfall erosivity (R) and twice monthly distributions of storm erosivity (E); CROP, including below-ground biomass, canopy cover, and canopy height at 15-day intervals as well as information on crop characteristics; and OPERATION, reflecting soil and cover disturbances that are associated with typical farming operations.

KEYWORDS: soil erosion, cropland, rangeland, rill erosion, interrill erosion, rainfall-runoff erosivity, soil erodibility, slope length, slope steepness, prior land use, surface cover, crop canopy, surface roughness, soil moisture, contouring, stripcropping, terracing, personal computer, residue decomposition

While supplies last, single copies of this publication may be obtained at no cost from USDA-ARS, Southwest Watershed Research Center, 2000 East Allen Road, Tucson, AZ 85719.

Copies of this publication may be purchased from the National Technical Information Service, 5285 Port Royal Road, Springfield, VA 22161.

Issued January 1997

This publication supersedes Agriculture Handbook No. 537, titled "Predicting Rainfall Erosion Losses: A Guide to Conservation Planning."

CONTENTS

SYMBOLS

A	average annual soil loss (ton· acre^{-1}· yr^{-1})
A	coefficient used to describe the shape of the residue decomposition response to temperature (°C) (ch. 5)
A_{wr}	winter soil loss from rills alone (ton· acre^{-1}· yr^{-1})
a	- coefficient used in unit rainfall energy relation (ch. 2) - location-dependent constant (ch. 3) - coefficient dependent on residue characteristics and climate variables (ch. 5) - coefficient dependent on contour ridge height (ch. 6)
a_1, a_2	coefficients used in determination of the discharge rate when deposition ends within a strip
B	amount of deposition considered to benefit the long-term maintenance of the soil resource (ton· acre^{-1}· yr^{-1})
B_a	above-ground biomass (lb· acre^{-1})
B_b	below-ground root biomass (lb· acre^{-1})
B_s	weight of residue on the surface (lb· acre^{-1})
B_{si}	weight of a particular type of residue (lb· acre^{-1})
B_{ur}	mass density of live and dead roots in the upper layer of soil (lb· acre^{-1}· in^{-1})
B_{us}	mass density of incorporated surface residue in the upper layer of soil (lb· acre^{-1}· h^{-1})

b	- coefficient used in unit rainfall energy relation (ch. 2) - location dependent constant (ch. 3) - coefficient describing effectiveness of surface cover (dimensionless) (ch. 5) - coefficient dependent on contour ridge height (ch. 6)
C	cover-management factor (dimensionless)
CC	canopy-cover subfactor (dimensionless)
C_B	coefficient representing the relative effectiveness of the total subsurface biomass in controlling erosion (dimensionless)
C_f	surface-soil-consolidation factor (dimensionless)
c	- location-dependent constant (ch. 3) - coefficient dependent on contour ridge height (ch. 6)
c_d	consolidation factor dependent on a decay parameter and time since the soil was disturbed (dimensionless)
c_{uf}	coefficient representing the impact of soil consolidation on the effectiveness of incorporated surface residue (dimensionless)
c_{ur}	coefficient describing the effectiveness of live and dead root mass in controlling erosion (acre· in· lb^{-1})
c_{us}	coefficient describing the effectiveness of incorporated surface residue in controlling erosion (acre· in· lb^{-1})
D	- period length (d) (ch. 5) - if > 0, erosion rate at a point (mass· $area^{-1}$· $time^{-1}$) (ch. 6) - if < 0, deposition rate (mass· $area^{-1}$· $time^{-1}$) (ch. 6)
D_b	minimum value of detachment as it decreases over time after consolidation relative to the detachment immediately after disturbance (dimensionless)

D_e	- equivalent roughness decay coefficient (dimensionless) (ch. 5) - sediment produced on the slope by detachment (ton· acre^{-1}· yr^{-1}) (ch. 6)
D_g	mean geometric particle diameter (mm)
D_n	net erosion (ton· acre^{-1}· yr^{-1})
D_r	roughness decay coefficient (dimensionless)
D_y	sediment transported from slope (ton· acre^{-1}· yr^{-1})
d	coefficient dependent on contour ridge height (ch. 6)
d_t	decay parameter (d^{-1})
E	storm energy (ft· tonf· acre^{-1})
EI	storm erosivity (ft· tonf· in· acre^{-1}· h^{-1}, or hundreds of ft· tonf· in· acre^{-1}· h^{-1}). Also a percentage of annual R
$(EI)_{10}$	storm erosivity of single storm with 10-yr return frequency (hundreds of ft· tonf· in· acre^{-1}· h^{-1})
EI_{30}	storm erosivity, interchangeable with EI (hundreds of ft· tonf· in· acre^{-1}· h^{-1})
EI_t	total storm erosivity since the most recent complete tillage operation; adjusted proportionately for operations disturbing less than 100% of the surface (hundreds of ft· tonf· in· acre^{-1}· h^{-1})
e	rainfall kinetic energy per unit of rainfall (ft· tonf· acre^{-1}· in^{-1})
e_m	rainfall kinetic energy (metric) (MJ· ha^{-1}· mm^{-1})
e_{max}	a maximum unit energy as intensity approaches infinity (ft· tonf· acre^{-1}· in^{-1})
F	coefficient dependent on temperature characteristics and shape of the residue decomposition response to temperature

F_c	fraction of land surface covered by canopy (dimensionless)
F_d	fraction of the soil surface disturbed by a field operation
F_u	fraction of the soil surface undisturbed by a field operation
f	function of ( )
f_i	primary particle size fraction (%)
f_r	runoff reduction factor (dimensionless)
f_{ri}	initial runoff reduction factor (dimensionless)
G	soil loss for a slope length (ton· ft^{-1}· yr^{-1})
g	sediment load (ton· ft^{-1}· yr^{-1})
g_{db}	sediment load at location where deposition begins within strip (ton· ft^{-1}· yr^{-1})
g_{de}	sediment load at location where deposition ends within strip (ton· ft^{-1}· yr^{-1})
g_p	sediment load at the end of the slope that would occur if the strips caused no deposition (ton· ft^{-1}· yr^{-1})
g_λ	sediment load at the end of the slope (ton· ft^{-1}· yr^{-1})
H	distance raindrops fall after striking the crop canopy (ft)
I	precipitation intensity (in· h^{-1})
I_{30}	maximum 30-min intensity (in· h^{-1})
i	- rainfall intensity (in· h^{-1}) - subscript indicating a particular segment or strip
i_m	rainfall intensity (metric) (mm· h^{-1})
K	soil erodibility factor (ton· acre· h· [hundreds of acre-ft· tonf· in]$^{-1}$)

K_{av}	EI weighted average annual soil-erodibility value (ton· acre· h· [hundreds of acre-ft· tonf· in] $^{-1}$)
K_b	saturated hydraulic conductivity of the soil with rock fragments (in· h^{-1})
K_f	saturated hydraulic conductivity of the fine soil (< 2 mm) fraction (in· h^{-1})
K_i	soil erodibility factor at any time, t_i (in calendar days) (ton· acre· h· [hundreds of acre-ft· tonf· in] $^{-1}$)
K_{max}	maximum value of soil erodibility for a given soil (ton· acre· h· [hundreds of acre-ft· tonf· in] $^{-1}$)
K_{min}	minimum value of soil erodibility for a given soil (ton· acre· h· [hundreds of acre-ft· tonf· in] $^{-1}$)
K_{nom}	soil erodibility as determined from the nomograph (ton· acre· h· [hundreds of acre-ft· tonf· in] $^{-1}$)
K_r	ratio of average seasonal (monthly) K-factor value over the average annual K value (dimensionless)
K_{wr}	rill soil erodibility for winter period (ton· acre· h· [hundreds of acre-ft· tonf· in] $^{-1}$)
k_t	sediment transport coefficient (ton· ft^{-1}· yr^{-1})
L	slope length factor (dimensionless)
$(LS)_{wr}$	rill slope length and steepness relationship for winter period (dimensionless)
M	- product of primary particle size fractions (dimensionless) (ch. 3) - amount of deposition on a strip (ton· $acre^{-1}$· yr^{-1}) (ch. 6)
M_a	average residue mass during a time period (lb· $acre^{-1}$)

M_b	residue mass at beginning of a time period ($lb \cdot acre^{-1}$)
M_e	residue mass at end of a time period ($lb \cdot acre^{-1}$)
m	slope length exponent (dimensionless) (ch. 4 and 6)
m_i	arithmetic mean of particle size limits of particular particle size (mm)
N	- number of residue types (ch. 5) - runoff index (dimensionless) (ch. 6)
n	- number of slope segments (ch. 4) - number of time periods used in summation (ch. 5) - number of strips (ch. 6)
n_i	ratio of root mass in the upper 4 in of soil to the total below-ground root biomass (dimensionless)
n_t	Manning's n
OM	organic matter (%)
P	support practice factor (dimensionless)
P	annual precipitation (in)
PLU	prior land use subfactor (dimensionless)
P_b	base value of the P factor for contouring (dimensionless)
P_{eff}	effective P-factor value for irregular slopes (dimensionless)
P_g	off-grade contouring P factor (dimensionless)
P_m	minimum P-factor value (dimensionless)
P_{mb}	minimum P-factor value for a given ridge height with base conditions (dimensionless)
P_o	on-grade contouring P factor (dimensionless)
P_s	P-factor value for stripcropping (dimensionless)

P_t	total rainfall since most recent field operation (in)
P_{wr}	winter conservation practice factor (dimensionless)
P_y	sediment delivery ratio of a slope under stripcropping or terracing (dimensionless)
P_1	calculated values of climate variable for first half-month period within a month
P_2	calculated values of climate variable for second half-month period within a month
p	- code for soil permeability (ch. 3) - coefficient dependent on residue characteristics (ch. 5)
Q	runoff amount from the 10-yr storm EI (in)
Q_k	computed runoff amount for the soil and cover-management condition indicated by subscript k (in)
q	runoff discharge rate ($ft^3 \cdot sec^{-1} \cdot ft^{-1}$)
q_{de}	runoff discharge rate for condition where sediment load equals transport capacity and deposition within strip ends ($ft^3 \cdot sec^{-1} \cdot ft^{-1}$)
R	average annual erosivity factor (hundreds of $ft \cdot tonf \cdot in \cdot acre^{-1} \cdot yr^{-1}$)
R	rainfall in the 15-d period (in)
R_a	roughness after biomass adjustment (in)
R_c	rainfall erosivity adjustment factor (hundreds of $ft \cdot tonf \cdot in \cdot acre^{-1} \cdot yr^{-1}$) (ch. 2)
R_{eq}	equivalent average annual erosivity factor (hundreds of $ft \cdot tonf \cdot in \cdot acre^{-1} \cdot yr^{-1}$)
$(R_{eq})_{wr}$	equivalent R factor of rills for winter period (hundreds of $ft \cdot tonf \cdot in \cdot acre^{-1} \cdot yr^{-1}$)

$(R_{eq})_{wt}$	total equivalent R factor for winter period (hundreds of ft· tonf· in· $acre^{-1}$· yr^{-1})
R_i	calculated initial roughness immediately following the previous field operation (in)
r_{max}	maximum surface random roughness; caused by protruding roots, rocks, and other effects of the long-term climate vegetative community when the soil is fully reconsolidated (in)
r_{min}	minimum surface random roughness; caused by rainfall-induced decay of tillage clods (in)
r_{nat}	for the current time period, the calculated surface random roughness caused by the factors creating r_{max} (in)
R_o	minimum average 15-day rainfall required for optimum decomposition (in)
R_n	net roughness following a field operation (in)
R_{np}	net roughness following the previous field operation (in)
R_u	roughness of surface before disturbance and roughness of the undisturbed portion of surface (in)
R_v	volume of rock fragments > 2 mm (%)
R_t	random roughness after most recent field operation (in)
R_w	weight of rock fragments > 2 mm (%)
r	excess rainfall depth (in)
r_f	roughness factor
r_i	roughness index
S	slope steepness factor (dimensionless)
SC	surface-cover subfactor (dimensionless)
SLR	soil-loss ratio (dimensionless)

$(SLR)_{wr}$	winter soil-loss ratio for rilling (dimensionless)
SM	soil-moisture subfactor (dimensionless)
S_p	land area covered by surface cover (%)
SR	surface-roughness subfactor (dimensionless)
s	- code for soil structure (ch. 3) - slope steepness (%) (ch. 4 and 6) - slope steepness (sine of slope angle) (ch. 6)
s_c	slope steepness for which a value of P_b is desired (sine of slope angle)
s_e	slope steepness above which contouring is ineffective (sine of slope angle)
s_{eb}	slope steepness for a given ridge height on base conditions at which contouring loses its effectiveness (sine of slope angle)
s_f	slope steepness along the furrows (sine of slope angle)
s_l	steepness of the land (sine of slope angle)
s_m	slope steepness at which contouring is most effective (sine of slope angle)
T	- soil-loss tolerance (ton· $acre^{-1}$) - transport capacity of runoff (ton· ft^{-1}· yr^{-1})
T_a	average temperature in 15-day decomposition period (°F)
T_{av}	average daily air temperature (°F)
T_o	optimum temperature in 15-day decomposition period (°F)
t	mean monthly temperature (°F)
t_c	time for 95% of disturbance effect to disappear by consolidation (yr)

t_{con}	amount of time required for the soil to fully reconsolidate following disturbance (yr)
t_d	time since soil was disturbed (yr)
t_i	any time (calendar days)
t_{max}	time of year when the soil erodibility factor is at a maximum (calendar days)
t_{min}	time of year when the soil erodibility factor is at a minimum (calendar days)
u_i	ratio of root mass to above-ground biomass (dimensionless)
V_f	fall velocity of sediment ($ft \cdot sec^{-1}$)
V_r	rainfall amount (in)
W	ratio of the rainfall in a 15-d period to the minimum average 15-d rainfall required for optimum residue decomposition
x	- length of each slope segment (ft) (ch. 4) - relative distance from top of the slope to the lower edge of a strip (absolute distance/slope length) (dimensionless) (ch. 6)
x_c	distance along slope length where contouring is assumed to be fully effective (ft)
x_{de}	location where deposition within strip ends (ft)
x_*	normalized distance along slope length (dimensionless)
x_1	unstable aggregate size fraction less than 0.250 mm (%)
x_2	product of modified silt fraction (0.002 to 0.1 mm) and modified sand fraction (0.1 to 2 mm)
x_3	base saturation (dimensionless)
x_4	silt fraction (0.002 to 0.050 mm) (%)
x_5	sand fraction (0.1 to 2 mm) (%)

x_6	aggregation index (dimensionless)
x_7	montmorillonite in soil (%)
x_8	bulk density of the 50- to 125-mm depth ($g \cdot cm^{-3}$)
x_9	dispersion ratio (dimensionless)
x_{10}	parameter M (product of primary particle size fractions) (dimensionless)
x_{11}	citrate-dithionite-bicarbonate extractable percentage of Al_2O_3 plus Fe_2O_3 (%)
α	ratio of the area covered by a piece of residue to the mass of that residue ($acre \cdot lb^{-1}$)
β	ratio of rill to interrill erosion (dimensionless)
Δt	length of frost-free period or growing period (calendar days)
δ	constant with value of either 0 or 1
ζ	transport capacity factor ($ton \cdot ft^{-1} \cdot yr^{-1}$)
θ	slope angle (degrees)
λ	slope length (ft)
λ_c	critical slope length (ft)
ξ	erosion factor ($ton \cdot acre^{-1} \cdot yr^{-1}$)
σ	excess rainfall rate ($length \cdot time^{-1}$)
ϕ	ratio of sediment fall velocity to excess runoff rate (dimensionless)

PREFACE

The Revised Universal Soil Loss Equation (RUSLE) is an update of Agriculture Handbook No. 537, containing a computer program to facilitate the calculations. RUSLE also includes the analysis of research data that were unavailable when Agriculture Handbook No. 537 was completed. Although the original Universal Soil Loss Equation (USLE) has been retained in RUSLE, the technology for factor evaluation has been altered and new data have been introduced with which to evaluate the terms for specified conditions.

The rainfall-runoff erosivity factor (R) database has been expanded in the western United States, and a correction has been developed for the portion of rain falling on ponded water. The soil erodibility factor (K) has been made time varying to reflect freeze-thaw conditions and consolidation caused by moisture extraction of a growing crop, an alternative regression equation was developed for volcanic tropical soils, and a correction was developed for rock fragments in the soil profile. The topographic factors, slope length and steepness (LS), have been revised and algorithms developed to reflect the ratio of rill to interrill erosion. The cover-management factor (C) has been altered from the seasonal soil-loss ratios to a continuous function that is the product of four subfactors representing prior land use (PLU), surface cover (SC), crop canopy (CC), surface roughness (SR), and (for cropland in the Northwestern Wheat and Range Region) soil moisture (SM). These subfactors include consideration of the root mass in the upper 4 in of the soil profile, as well as changes in crop cover and root mass with time, tillage, and residue decomposition. Climatic data that include monthly precipitation and temperature, the frost-free period, rainfall-runoff erosivity, and twice monthly distributions for the EI (product of kinetic energy and maximum 30-min precipitation intensity) are used for consideration of the seasonal variations in K, C, and the support practice factor (P). P has been expanded to consider conditions for rangelands, contouring, stripcropping, and terracing.

The calculations in RUSLE are more involved than those in USLE and are facilitated with a computer program.

CHAPTER 1. CONTENTS

PURPOSE OF HANDBOOK

Scientific planning for soil conservation and water management requires knowledge of the relations among those factors that cause loss of soil and water and those that help to reduce such losses. Controlled studies on field plots and small watersheds have supplied much valuable information on these complex interrelations of factors. But the maximum benefits from such research can be realized only when the findings are applied as sound practices on the farms, ranches, and other erosion-prone areas throughout the United States. Specific guidelines are needed for the selection of the control practices best suited to the particular needs of each site.

Such guidelines are provided by the procedure for soil-loss prediction presented in this handbook. The procedure methodically combines research information from many sources to develop design data for each conservation plan. Widespread field experience for more than four decades has proved that this technology is valuable as a conservation-planning guide.

The procedure is founded on the empirical Universal Soil Loss Equation (USLE) (described in handbooks by Wischmeier and Smith 1965, 1978) that is believed to be applicable wherever numerical values of its factors are available. Research has supplied information from which at least approximate values of the equation's factors can be obtained for specific farm or ranch fields or other small land areas throughout most of the United States. Tables and charts or the personal-computer program presented in this handbook makes information readily available for field use.

The Revised Universal Soil Loss Equation (RUSLE) includes analyses of data not available when the previous handbooks were prepared. The analyses are documented so that users can review, evaluate, and repeat them in the process of making local analyses. Debate on this revision of USLE is important. Any such debate should be focused on the data, theory, and concepts described in the chapters. Many reviewers have helped with the debate. Their reviews were essential, and they should help to establish the credibility of this revision.

Judgments were necessary during the revision because some data were limited and inconclusive, and a few were conflicting. The decisions were made by the use of the collective knowledge of a number of erosion scientists. Furthermore, the technology was revised to permit the addressing of problems

not included or inadequately addressed in earlier versions of USLE. The current revision is intended to provide the most accurate estimates of soil loss without regard to how the new values compare with the old values.

This revision updates the content of the earlier handbooks (Wischmeier and Smith 1965, 1978) and incorporates new material that has been available informally or in scattered research reports and professional journals. Some of the original charts and tables have been revised to conform with additional research findings, and new charts and tables have been developed to extend the usefulness of RUSLE. In some instances, expanding a table, chart, or computer program sufficiently to meet the needs for widespread field application required the projection of empirical factor relationships appreciably beyond the physical limits of the data from which the relationships were derived. Estimates obtained in this manner are the best information available for the conditions they represent. These instances are identified in the chapter discussions of the specific erosion factors, tables, charts, and computer program.

The background material for each RUSLE factor value is presented in the text that helps the user select correct values of individual factor parameters. This revision, with its background chapters, user's guide, and associated computer program, will provide erosion technology for use in addressing problems being proposed in the last decade of the 20th century or until new technology becomes available, such as that from USDA's Water Erosion Prediction Project (WEPP) (Foster and Lane 1987, Lane and Nearing 1989).

HISTORY OF EROSION-PREDICTION EQUATIONS

Efforts to mathematically predict soil erosion by water started only about a half century ago. The development of erosion-prediction technology began with analyses such as those by Cook (1936) to identify the major variables that affect soil erosion by water. Cook listed three major factors: susceptibility of soil to erosion, potential erosivity of rainfall and runoff, and soil protection afforded by plant cover. A few years later, Zingg (1940) published the first equation for calculating field soil loss. That equation described mathematically the effects of slope steepness and slope length on erosion. Smith (1941) added factors for a cropping system and support practices to the equation. He also added the concept of a specific annual soil-loss limit, and he used the resulting equation to develop a graphic method for selecting conservation practices for certain soil conditions in the midwestern United States.

Progress continued on methods to predict erosion during World War II, but publication of the research was delayed until after the war. Browning and associates (1947) added soil erodibility and management factors to the Smith (1941) equation and prepared more extensive tables of relative factor values for different soils, crop rotations, and slope lengths. This approach emphasized the evaluation of slope-length limits for different cropping systems on specific soils and slope steepness with and without contouring, terracing, or stripcropping. Smith and Whitt (1947) presented a method for estimating soil losses from fields of claypan soils. Soil-loss ratios at different slopes were given for contour farming, stripcropping, and terracing. Recommended limits for slope length were presented for contour farming. Relative erosion rates for a wide range of crop rotations were also given. Then Smith and Whitt (1948) presented a "rational" erosion-estimating equation, $A = C \cdot S \cdot L \cdot K \cdot P$, which broadened the application to principal soils of Missouri. The C factor was the average annual soil loss from claypan soils for a specific rotation, slope length, slope steepness, and row direction. The other factors for slope steepness (S), slope length (L), soil erodibility (K), and support practice (P) were dimensionless multipliers used to adjust the value of C to other conditions. P-factor values were discussed in detail. Smith and Whitt acknowledged the need for a rainfall factor to make this equation applicable over several states.

The Milwaukee, Wisconsin, regional office of USDA's Soil Conservation Service (SCS) recognized the value of a soil-loss equation for farm planning and teamed with researchers in that region to develop a system for regional application. The result was the slope-practice method of estimating soil loss for use in the Corn Belt. To adapt the Corn Belt equation for use in other regions, a workshop for erosion specialists from throughout the United States was held in Ohio in 1946. Workshop participants reviewed soil-loss data from all over the United States, reappraised the factors previously used, and added a rainfall factor. The resulting so-called Musgrave equation included factors for rainfall, flow characteristics of surface runoff as affected by slope steepness and slope length, soil characteristics, and vegetal cover effects (Musgrave 1947).

Graphs to solve the Musgrave equation were prepared by Lloyd and Eley (1952). They tabulated values for many major conditions in the northeastern states. Van Doren and Bartelli (1956) proposed an erosion equation for Illinois soils and cropping conditions that estimated annual soil loss as a function of nine factors. One of the factors was soil loss as measured on research plots; soil loss was adjusted to site conditions by several factors used by previous researchers and also factors for prior erosion and management levels.

The state and regional erosion-prediction equations were so useful that soil conservation leaders recommended that an effort be initiated to develop a national equation. As a result, the Agricultural Research Service (ARS) established the National Runoff and Soil Loss Data Center at Purdue University (West Lafayette, Indiana) in 1954. The Data Center was given the responsibility of locating, assembling, and consolidating all available data from runoff and erosion studies throughout the United States for further analyses (Wischmeier 1955). During subsequent years, Federal-state cooperative research projects at 49 U.S. locations contributed more than 10,000 plot-years of basic runoff and soil-loss data to this Center for summarizing and overall statistical analyses.

To hasten the development of a national equation, joint conferences of key researchers and users were held at Purdue University in February and July of 1956. The participants concentrated their efforts on reconciling the differences among existing soil-loss equations and on extending the technology to regions where no measurements of erosion by rainstorms had been made. The equation that resulted had seven factors; they were for crop rotation, management, slope steepness, slope length, conservation practice, soil erodibility, and previous erosion. The group established the maximum permissible loss for any soil as 5 ton$\cdot$ acre$^{-1}\cdot$ yr^{-1} but set lower limits for many soils. Workshop participants concluded that insufficient data were

available to justify adding a rainfall factor; subsequent analyses at the Data Center led to a rainfall factor for the states east of the Rocky Mountains. Subsequent study also showed that the equation's crop rotation and management factors could be combined into one factor (Wischmeier et al. 1958).

Using the data assembled at the Data Center along with conclusions from deliberations at the 1956 conferences and subsequent analyses, Wischmeier, Smith, and others developed USLE as described in earlier handbooks (Wischmeier and Smith 1965, 1978). USLE quantifies soil erosion as the product of six factors representing rainfall and runoff erosiveness, soil erodibility, slope length, slope steepness, cover-management practices, and support conservation practices.

USLE was designed to provide a convenient working tool for conservationists. A relatively simple technique was needed for predicting the most likely average annual soil loss in specific situations. A goal for the equation was that each factor (1) could be represented by a single number; (2) could be predicted from meteorological, soil, or erosion research data for each location; and (3) must be free from any geographically oriented base. The term "Universal" in USLE distinguishes this prediction model from the regionally based models that preceded it. However, the use of USLE should be limited to situations in which its factors can be accurately evaluated and to conditions for which it can be reliably applied (Wischmeier 1976).

USLE overcame many of the deficiencies of its predecessors. The form of USLE is similar to that of previous equations, but the concepts, relationships, and procedures underlying the definitions and evaluations of the erosion factors are distinctly different. Major changes include (1) more complete separation of factor effects so that results of a change in the level of one or several factors can be more accurately predicted; (2) an erosion index that provides a more accurate, localized estimate of the erosive potential of rainfall and associated runoff; (3) a quantitative soil-erodibility factor that is evaluated directly from research data without reference to any common benchmark; (4) an equation and nomograph that are capable of computing the erodibility factor for numerous soils from soil survey data; (5) a method of including the effects of interactions between cropping and management parameters; and (6) a method of incorporating the effects of local rainfall patterns throughout the year and specific cropping conditions in the cover and management factor (Wischmeier 1972).

Regression analysis of the assembled data determined the mathematical relationship between each USLE factor and soil loss. Effects of slope length and steepness, crop sequence, and soil- and crop-management practices were

most accurately described as percentage increases or decreases in soil loss. A multiplicative model was selected for the equation. It uses four dimensionless factors to modify soil loss as described by dimensioned rainfall and soil factors.

USLE was introduced at a series of regional workshops on soil-loss prediction in 1959-62 and by a U.S. Department of Agriculture special report (USDA 1961). Several years of trial use by SCS and others plus extensive interaction between the developers and users resulted in improved factor values and the evaluation of additional conditions. Finally, USLE was presented in Agriculture Handbook No. 282 (Wischmeier and Smith 1965).

Widespread acceptance of USLE took time but came progressively as more regions and groups began to use this equation. During the same period, important improvements in USLE expanded its usefulness by providing techniques for estimating site values of its factors for additional land uses, climatic conditions, and management practices. These include a soil-erodibility nomograph for farmland and construction areas, topographic factors for irregular slopes, cover factors for range and woodland, effects of tillage practices on cover and management, prediction of erosion in construction areas, estimated erosion index values for the western states and Hawaii, soil erodibility factors for benchmark Hawaiian soils, and improved design and evaluation of erosion-control-support practices. These improvements were incorporated in an updated version of USLE, published as Agriculture Handbook No. 537 (Wischmeier and Smith 1978).

The erosion-research history that led to the development of USLE (Smith and Wischmeier 1962, Meyer 1984, Meyer and Moldenhauer 1985) shows that USLE was the logical culmination of several decades of innovative effort by scientists having unusual expertise and dedication. Since its introduction, USLE has had a tremendous impact and has become the major soil conservation planning tool in the United States and abroad.

Since the publication of Agriculture Handbook No. 537, additional research and experience have resulted in improvements in USLE. These include new and (in some instances) revised isoerodent maps; a time-varying approach to reflect freeze-thaw conditions and consolidation caused by extraction of moisture by a growing crop for the soil erodibility factor (K); a subfactor approach for evaluating the cover-management factor (C) for cropland, rangeland, and disturbed areas; a new equation to reflect slope length and steepness (LS) (the new terms also reflect the ratio of rill to interrill erosion); and new conservation-practice values (P) for both cropland and rangeland practices. Finally, the computations are now implemented using a personal

computer. These changes are detailed in this revision in the chapters for each RUSLE factor.

The revision of USLE described in this handbook incorporates the latest information available for using this erosion-prediction approach. Research on the principles and processes of erosion and sedimentation by water is continuing in order to improve the methods of predicting and controlling erosion. Knowledge from such research has been used in developing physically based models such as the erosion and sedimentation components of CREAMS (Knisel 1980, Foster et al. 1981a). Development of a new generation of technology for predicting water erosion is under way by a USDA team in WEPP working with other agencies and academic institutions (Foster and Lane 1987). The goal of this WEPP effort is a process-oriented model or family of models that are conceptually superior to the lumped-model RUSLE and are more versatile as to the conditions that can be evaluated. The WEPP technology is expected to replace RUSLE sometime in the future.

SOIL-LOSS TOLERANCE

A major purpose of the soil-loss equation is to guide the making of methodical decisions in conservation planning. The equation enables the planner to predict the average rate of soil erosion for each of various alternative combinations of cropping systems, management techniques, and erosion-control practices on any particular site. The term "soil-loss tolerance" (T) denotes the maximum rate of soil erosion that can occur and still permit crop productivity to be sustained economically. The term considers the loss of productivity due to erosion but also considers rate of soil formation from parent material, role of topsoil formation, loss of nutrients and the cost to replace them, erosion rate at which gully erosion might be expected to begin, and erosion-control practices that farmers might reasonably be able to implement. When predicted soil losses are compared with the value for soil-loss tolerance at that site, RUSLE provides specific guidelines for bringing about erosion control within the specified limits. Any combination of cropping, ranching, and management for which the predicted erosion rate is less than the rate for soil-loss tolerance may be expected to provide satisfactory control of erosion. Of the satisfactory alternatives offered by this procedure, the alternative(s) best suited to a particular farm or other enterprise may then be selected.

Values of soil-loss tolerance ranging from 1 to 5 ton$\cdot$ acre$^{-1}\cdot$ yr^{-1} for the soils of the United States were derived by soil scientists/conservationists, agronomists, engineers, geologists, and Federal and state researchers at six regional workshops between 1959 and 1962. Factors considered in defining these limits include soil depth, physical properties and other characteristics affecting root development, gully prevention, on-field sediment problems, seeding losses, reduction of soil organic matter, and loss of plant nutrients. Since the early discussions, several reports have been produced in which soil-loss tolerance is discussed (Schmidt et al. 1982, Johnson 1987). The passage of Public Law 95-192 and the 1977 Soil and Water Resources Conservation Act (RCA) prompted considerable interest in the effect of soil erosion on crop productivity. New experimental research and computer simulation models have furthered the interest in soil-loss tolerances. Two symposia proceedings of note that resulted from this activity are "Erosion and Soil Productivity" (ASAE 1985) and "Soil Erosion and Crop Productivity" (Follett and Stewart 1985). Needless to say, many issues about soil-loss tolerance remain unresolved.

A deep, medium-textured, moderately permeable soil that has subsoil characteristics favorable for plant growth has a greater tolerable soil-loss rate than do soils with shallow root zones or high percentages of shale at the surface. Widespread experience has shown that the concept of soil-loss tolerance may be feasible and generally adequate for indefinitely sustaining productivity levels.

Soil-loss limits are sometimes established to prevent or reduce damage to offsite water quality. The criteria for defining the tolerance limits of field soil-loss tolerance limits for this purpose are ***not*** the same as those for tolerances designed to preserve cropland productivity. Soil depth is not relevant for offsite sediment control, and uniform limits on erosion rates still allow a range in the amount of sediment per unit area that is delivered to a stream. Soil material eroded from a field slope may be deposited along field boundaries, in terrace channels, in depressional areas, or on flat or vegetated areas traversed by overland flow before it reaches a watercourse. Erosion damages the cropland on which it occurs, but sediment deposited near its place of origin does not directly affect water quality.

If the soil-loss tolerance established for sustained cropland productivity fails to attain the desired water-quality standard, other limits that consider other factors should be established rather than altering the value for soil-loss tolerance. Other factors may include distance of the field from a major waterway, sediment-transport characteristics of the intervening area, sediment composition, needs of the particular body of water being protected, and the probable magnitude of fluctuations in sediment loads (Stewart et al. 1975). Placing limits on sediment yield might provide more uniform water-quality control than would lowering the limits on soil movement from field slopes. The sediment-yield criteria would also require fewer restrictions on the selection of crop system for fields in which only small percentages of eroded soil become off-farm sediment.

As currently used in conservation-planning activities, T values are often an issue of policy. We recommend that T values remain as originally defined and intended: namely, the erosion rate that can occur and yet permit crop productivity to be sustained economically. If issues of water quality, economics, and policy are to be addressed for erosion control, we recommend that they be designated T_{WQ} (soil loss for water-quality concerns), T_{EP} (soil loss for economic planning), and T_{POL} (soil loss for policy concerns).

SOIL-LOSS EQUATION

The erosion rate for a given site results from the combination of many physical and management variables. Actual measurements of soil loss would not be feasible for each level of these factors that occurs under field conditions. Soil-loss equations were developed to enable conservation planners, environmental scientists, and others concerned with soil erosion to extrapolate limited erosion data to the many localities and conditions that have not been directly represented in the research.

Erosion and sedimentation by water involve the processes of detachment, transport, and deposition of soil particles (Foster 1982). The major forces are from the impact of raindrops and from water flowing over the land surface. Erosion may be unnoticed on exposed soil surfaces even though raindrops are eroding large quantities of sediment, but erosion can be dramatic where concentrated flow creates extensive rill and gully systems. Factors affecting erosion can be expressed in an equation of the form (Renard and Foster 1983)

$$E = f\,(C, S, T, SS, M) \qquad [1\text{-}1]$$

where

E = erosion,
f = function of ( ),
C = climate,
S = soil properties,
T = topography,
SS = soil surface conditions, and
M = human activities.

Sediment yield should not be confused with erosion; the terms are not interchangeable. Sediment yield is the amount of eroded soil that is delivered to a point in the watershed that is remote from the origin of the detached soil particles. In a watershed, sediment yield includes the erosion from slopes, channels, and mass wasting, minus the sediment that is deposited after it is eroded but before it reaches the point of interest (fig. 1-1). USLE and RUSLE do not estimate sediment yield.

USLE is essentially an expression of the functional relationship shown in equation [1-1] (Wischmeier and Smith 1965, 1978). Both USLE and RUSLE compute the average annual erosion expected on field slopes as

$$A = R \cdot K \cdot L \cdot S \cdot C \cdot P \qquad [1\text{-}2]$$

where

A = computed spatial average soil loss and temporal average soil loss per unit of area, expressed in the units selected for K and for the period selected for R. In practice, these are usually selected so that A is expressed in ton· $acre^{-1}$· yr^{-1}, but other units can be selected (that is, t· ha^{-1}· yr^{-1}).

R = rainfall-runoff erosivity factor—the rainfall erosion index plus a factor for any significant runoff from snowmelt.

K = soil erodibility factor—the soil-loss rate per erosion index unit for a specified soil as measured on a standard plot, which is defined as a 72.6-ft (22.1-m) length of uniform 9% slope in continuous clean-tilled fallow.

L = slope length factor—the ratio of soil loss from the field slope length to soil loss from a 72.6-ft length under identical conditions.

S = slope steepness factor—the ratio of soil loss from the field slope gradient to soil loss from a 9% slope under otherwise identical conditions.

C = cover-management factor—the ratio of soil loss from an area with specified cover and management to soil loss from an identical area in tilled continuous fallow.

P = support practice factor—the ratio of soil loss with a support practice like contouring, stripcropping, or terracing to soil loss with straight-row farming up and down the slope.

RUSLE is an erosion model designed to predict the longtime average annual soil loss (A) carried by runoff from specific field slopes in specified cropping and management systems as well as from rangeland. Widespread use has substantiated the usefulness and validity of RUSLE for this purpose. It is also applicable to nonagricultural conditions such as construction sites.

RUSLE users need to be aware that A (in addition to being a longtime average annual soil loss) is the average loss over a field slope and that the losses at various points on the slope may differ greatly from one another. On a long uniform slope, the loss from the top part of the slope is much lower than the slope average, and the loss near the bottom of the slope is considerably higher. For instance, a 360-ft uniform slope that averages 20

ton· acre^{-1} will have an average of less than 7 ton· acre^{-1} loss on the first 40 ft but over 29 ton· acre^{-1} loss on the last 40 ft. If the slope steepness changes within that length, the variation can be even greater. This suggests that even if a field soil loss is held to "T," soil loss on some portion of the slope may reach or exceed 2T, even when the ephemeral gully and other types of erosion that are not estimated by RUSLE are ignored. These higher-than-average rates generally occur at the same locations year after year, so excessive erosion on any part of the field may be damaging the soil resource.

With appropriate selection of its factor values, RUSLE will compute the average soil loss for a multicrop system, for a particular crop year in a rotation, or for a particular crop stage period within a crop year. Erosion variables change considerably from storm to storm about their means. But the effects of the random fluctuations such as those associated with annual or storm variability in R and the seasonal variability of the C tend to average out over extended periods. Because of the unpredictable short-time fluctuations in the levels of influential variables, however, present soil-loss equations are substantially less accurate for the prediction of specific events than for the prediction of longtime averages.

USLE has also been used for estimating soil loss from disturbed forested conditions. RUSLE does not address this particular application. Users of such technology are referred to Dissmeyer and Foster (1980, 1981).

Some recent research addresses the application of USLE technology to mine spoils and reconstructed topsoil (Barfield et al. 1988). The effects of compaction on erosion are significant in such instances and are treated as an integral part of the subfactor for calculating C (see ch. 5). Furthermore, slope steepness effects on soil loss from disturbed lands (McIsaac et al. 1987a) are treated specifically in chapter 4 with the application of an LS table (see table 4-3). Other RUSLE terms remain unchanged by massive land disturbance such as that associated with construction. It is important to realize that the amount of research on effects of land disturbance on RUSLE technology is not as extensive as that associated with most other applications.

The soil-loss equation was initially developed in U.S. customary units. The factor definitions are interdependent, and the direct conversion of acres, tons, inches, and feet to metric units produces integers that are best suited for expressing equations in that system. Only U.S. customary units are used in the equation and factor-evaluation materials, but the metric equivalents are given in appendix A.

Numerical values for each of the six factors were derived from analyses of research data and from National Weather Service precipitation records. For most conditions in the United States, the approximate values of the factors for any particular site may be obtained from charts and tables in this handbook or by use of the computer program developed to assist with the RUSLE evaluation. Users in localities or countries where the rainfall characteristics, soil types, topographic features, or farm practices are substantially beyond the range of present U.S. data will find these charts, tables, and computer program incomplete and perhaps inaccurate for their conditions. However, RUSLE provides guidelines that can reduce the amount of local research needed to develop appropriate technology for their conditions.

The RUSLE User Guide (ch. 7) illustrates how to select factor values either with the computer program or by use of data from the tables and charts. Users who have no experience with the soil-loss equation may wish to read chapter 7 next. After users have referred to the computer program and have located the values used therein, they may readily move to the intervening chapters (ch. 2-6), which define the technical details associated with the factors. The soil-loss-prediction procedure is more valuable as a guide for the selection of practices if the user has general knowledge of the principles on which the equation is based. Therefore, the significance of each factor is discussed before the introduction of the computer program and before the reference table or chart from which local values may be obtained. Limitations of the data available for evaluation of some of the factors are also discussed.

Chapters 2-6 are written as background for the development of the technology to permit evaluation of the individual RUSLE factors. Although liberal use is made of material from previous versions of USLE (Agriculture Handbooks No. 282 in 1965 and No. 537 in 1978), direct quotes from that material are not always noted. The computer program, intended to assist the user of this technology, is a new development that was not a part of earlier versions.

The authors acknowledge the efforts of Laura J. Yohnka for processing the many drafts prior to completion and E. Sue Anderson for finishing work on the final copy.

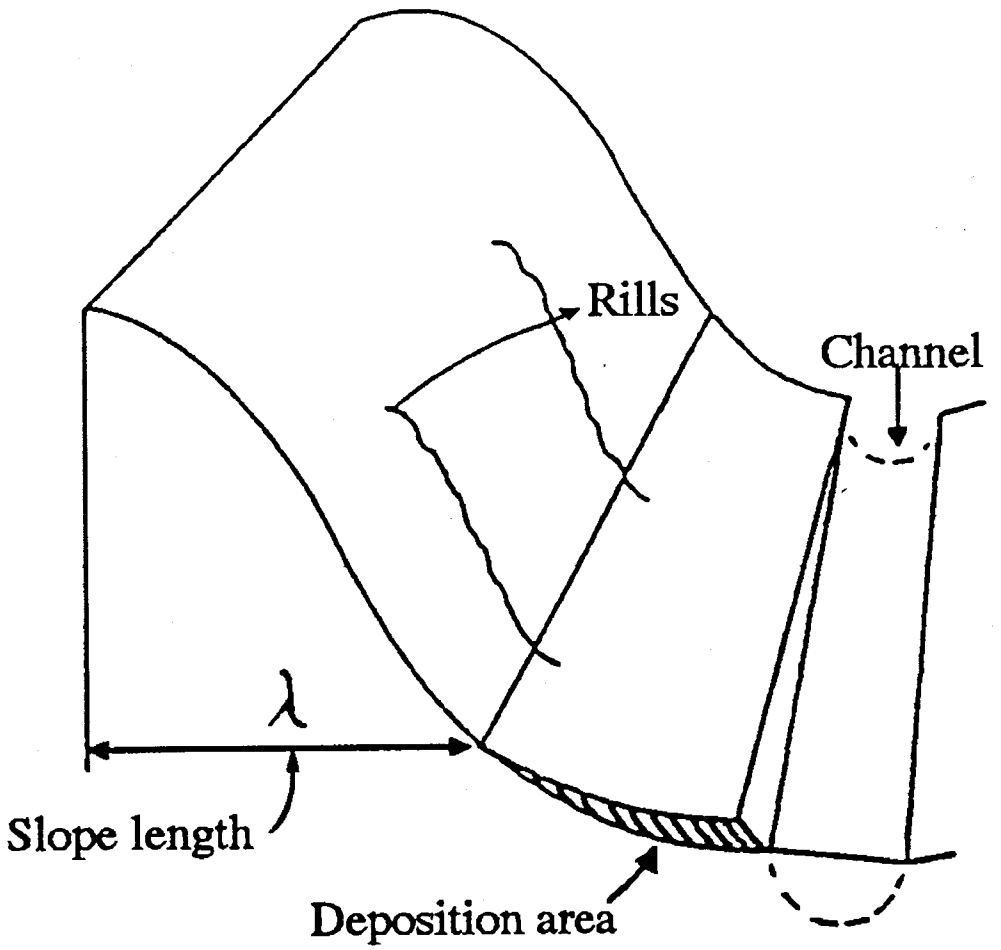

Figure 1-1. Schematic slope profile for RUSLE applications for interrill and rill erosion. λ is the RUSLE slope length (to the point where deposition occurs). Sediment yield is the sediment transported out of the channel section summed for time periods such as a storm event, month, crop stage, or year.

CHAPTER 2. RAINFALL-RUNOFF EROSIVITY FACTOR (R)

CHAPTER 2. CONTENTS

The rainfall and runoff factor (R) of the Universal Soil Loss Equation (USLE) was derived (Wischmeier 1959, Wischmeier and Smith 1958) from research data from many sources. The data indicate that when factors other than rainfall are held constant, soil losses from cultivated fields are directly proportional to a rainstorm parameter: the total storm energy (E) times the maximum 30-min intensity (I_{30}).

Rills and sediment deposits observed after an unusually intense storm have sometimes led to the conclusion that significant erosion is associated with only a few severe storms--that significant erosion is solely a function of peak intensities. However, more than 30 yr of measurements in many states have shown that this is not the case (Wischmeier 1962). The data show that a rainfall factor used to estimate average annual soil loss must include the cumulative effects of the many moderate-sized storms as well as the effects of the occasional severe ones.

The numerical value used for R in USLE and in RUSLE must quantify the effect of raindrop impact and must also reflect the amount and rate of runoff likely to be associated with the rain. The erosion index (R) derived by Wischmeier appears to meet these requirements better than any of the many other rainfall parameters and groups of parameters tested against the plot data. The local value of this index may be obtained directly from maps. However, the index does not include the erosive forces of runoff from snowmelt, rain on frozen soil, or irrigation. A procedure for evaluating R for locations where this type of runoff is significant is given in this chapter under "R Equivalent (R_{eq}) for Cropland in the Northwestern Wheat and Range Region."

In RUSLE, the computational scheme is identical to that used in USLE, with a few exceptions (as noted later).

EI PARAMETER

The value of EI for a given rainstorm equals the product of total storm energy (E) times the maximum 30-min intensity (I_{30}), where E is in hundreds · ft· tonf · $acre^{-1}$, and I_{30} is in in · h^{-1}. EI is an abbreviation for energy times intensity, and the term should *not* be considered simply an energy parameter. Data show that rainfall energy itself is not a good indicator of erosive potential. The storm energy indicates the volume of rainfall and runoff, but a long, slow rain may have the same E value as a shorter rain at much higher intensity. Raindrop erosion increases with intensity. The I_{30} component reflects the prolonged peak rates of detachment and runoff. The product term EI is a statistical interaction term that reflects how total energy and peak intensity are combined in each particular storm. Technically, the term indicates how particle detachment is combined with transport capacity. Appendix B illustrates how the calculations are made from recording-raingage data.

The relation of soil loss to the EI parameter is assumed to be linear, and the parameter's individual storm values are directly additive. The sum of the storm EI values for a given period is a numerical measure of the erosive potential of the rainfall within that period. The average annual total of the storm EI values in a particular locality is the rainfall erosion index (R) for that locality. Because of apparent cyclical patterns in rainfall data, early published values for rainfall erosion indices (for example, in Agriculture Handbook No. 537) were based on 22-yr station rainfall records. Longer records are advisable, especially when the coefficient of variation of annual precipitation is large.

Rain showers of less than 0.5 in were omitted from the erosion index computations, unless at least 0.25 in of rain fell in 15 min. Furthermore, a storm period with less than 0.05 in over 6 h was used to divide a longer storm period into two storms. Exploratory analyses showed that erosion from these light rains is usually too small for practical significance and that, collectively, they have little effect on the distribution of the annual EI or erosion. The cost of abstracting and analyzing 4,000 location-years of rainfall-intensity data used to develop the initial R-factor map was greatly reduced by adopting the threshold value of 0.5 in.

The energy of a rainstorm is a function of the amount of rain and of all the storm's component intensities. The median raindrop size generally increases

with greater rain intensity (Wischmeier and Smith 1958), and the terminal velocities of free-falling waterdrops increase with larger drop size (Gunn and Kinzer 1949). Since the energy of a given mass in motion is proportional to velocity squared, rainfall energy is directly related to rain intensity. The relationship, based on the data of Laws and Parsons (1943), is expressed by the equation

$$e = 916 + 331 \log_{10} i, \qquad i \leq 3 \text{ in} \cdot h^{-1} \qquad [2\text{-}1]$$

$$e = 1074 \qquad i > 3 \text{ in} \cdot h^{-1} \qquad [2\text{-}2]$$

where e is kinetic energy in ft· tonf · $acre^{-1}$ · in^{-1}, and i is intensity in in· h^{-1} (Wischmeier and Smith 1958). A limit of 3 in · h^{-1} is imposed on i because median drop size does not continue to increase when intensities exceed 3 in · h^{-1} (Carter et al. 1974).

The corresponding SI metric-unit version of the equations are (Foster et al. 1981b, app. A)

$$e_m = 0.119 + 0.0873 \log_{10}(i_m) \qquad i_m \leq 76 \text{ mm} \cdot h^{-1} \qquad [2\text{-}3]$$

$$e_m = 0.283 \qquad i_m > 76 \text{ mm} \cdot h^{-1} \qquad [2\text{-}4]$$

where e_m has units of megajoule per hectare per millimeter of rainfall (MJ · ha^{-1} · mm^{-1}).

Other investigators have also presented algorithms for computing the kinetic energy for drop distributions in other geographic areas of the continental United States [for example, McGregor and Mutchler (1977) in Mississippi, Carter et al. (1974) in the South Central United States, Tracy et al. (1984) in southeastern Arizona, and Rosewell (1983, 1986) in Australia].

Brown and Foster (1987) used a unit energy relationship of the form

$$e = e_{max} [1 - a \exp (-b \cdot i)] \quad [2\text{-}5]$$

where

e_{max} = a maximum unit energy as intensity approaches infinity, and

a and b = coefficients.

Kinnell (1981, 1987) showed that this distribution described unit energy-intensity relationships in Zimbabwe and Florida. Additional work by Rosewell (1983, 1986) showed that the relationship also fit data in Australia, the McGregor and Mutchler (1977) data, and the Laws and Parsons (1943) data. Unfortunately, these applications showed some variability in the a and b coefficients. Brown and Foster stated in their analysis that they recommended

$$e_m = 0.29 [1 - 0.72 \exp (-0.05 i_m)] \quad [2\text{-}6]$$

for calculating unit energy, where e_m has units of MJ $\cdot$ ha^{-1} $\cdot$ mm^{-1} of rain and i_m has units of mm $\cdot$ h^{-1}. Brown and Foster also stated that this equation is a superior analytical form by having a finite positive value at zero intensity as data show and approaching an asymptote at high intensities as a continuous function. The U.S. customary units equivalent of equation [2-6] is

$$e = 1099[1 - 0.72 \exp (-1.27 i)] \quad [2\text{-}7]$$

where i has units of in $\cdot$ h^{-1} and e has units of ft $\cdot$ tonf $\cdot$ acre^{-1} $\cdot$ in^{-1}.

Then

$$R = \frac{\sum_{i-1}^{j} (EI_{30})_i}{N} \quad [2\text{-}8]$$

where $(EI_{30})_i = EI_{30}$ for storm i, j = number of storms in an N year period.

These equations were used for developing the isoerodent maps of figures 2-1 to 2-4.

The isoerodent maps of figures 2-1 and 2-9 were developed from equations [2-1] and [2-2]. We recommend that all future calculations be made using equation [2-6] or equation [2-7], especially in other countries where RUSLE technology is being developed.

Sample calculations of EI_{30} are given in appendix B.

ISOERODENT MAPS

Local values of the rainfall erosion index may be taken directly from isoerodent maps or from the CITY database in the computer program as explained in chapter 7. The plotted lines on the maps are called isoerodents because they connect points of equal rainfall erosivity. Erosion index values for locations between the lines can be obtained by linear interpolation.

The original isoerodent map (Wischmeier and Smith 1965) was developed from 22-yr station rainfall records by computing the EI value for each storm that met the previously defined threshold criteria. Isoerodents were then located between these point values with the help of published rainfall intensity-frequency data (U.S. Weather Bureau 1958) and topographic maps. The 11 western states were omitted from the initial map because sufficient long-term recording-raingage records were not available for establishing lines of equal erosion index values.

The isoerodent map was extended with an estimation procedure to the Pacific Coast in 1976 and was printed in Agriculture Handbook No. 537. Results of investigations at the USDA-ARS National Soil Erosion Research Laboratory at Purdue University showed that the known erosion index values in the Western Plains States and the North Central States are approximated with reasonable accuracy by the equation $R = 27.38P^{2.17}$ where P is the 2-yr frequency, 6-h rainfall amount (Wischmeier 1974). Although the isoerodents developed were compatible with the few point values that had been established in the western United States, the isoerodents were not sufficiently accurate to reflect the known spatial variability of the mountain and valley topography of the region.

In an agreement between Oregon State University, U.S. Department of Agriculture's Soil Conservation Service (SCS) and Agricultural Research Service (ARS), and the National Weather Service, 713 stations were used to determine relationships between values of EI calculated on a 15-min measurement interval basis and on values of EI calculated for the same storm on a 60-min measurement interval basis. In contrast to the calculations in the eastern United States, all storms were included to calculate EI. Of these stations, 225 had record periods of 12 yr or longer and precipitation measurement resolutions of 0.01 in. Values of coefficient of determination (r^2) in excess of 0.8 were obtained by use of the model $(EI)_{15} = b[\ (EI)_{60}\ ]$.

Values of the regression parameter b ranged from 1.08 to 3.16, varying widely from one climatic zone to the next.

To supplement this work, 1,082 stations were used to calculate $(EI)_{60}$. Of these stations, 790 had 20-yr record lengths or longer. These data values were adjusted to a 15-min measurement interval using the correction cited above. Computed values of $(EI)_{60}$ for each 60-min station were multiplied by the average regression parameter b (computed for all 15-min stations in the climatic zone containing the 60-min station) to obtain equivalent 15-min values, $(EI)_{15}$. These values were then adjusted to an equivalent breakpoint basis by use of $R = 1.0667\ (R)_{15}$ (Weiss 1964). The resulting isoerodent map (R) was prepared by hand contouring the adjusted R values for stations with record periods of at least 20 yr. The resulting isoerodent maps for the West is a significant improvement over that available in Agriculture Handbook No. 537 (Wischmeier and Smith 1978). Seasonal EI distributions were developed for 84 climate zones in the western States. The maximum storm 10-yr-frequency EI values were calculated as part of the project. In this analysis, for areas where winter precipitation is predominantly snowfall, the snowfall months were excluded from the EI development. Thus, in the CITY database, the winter months show zero percent EI.

In Hawaii, isoerodent maps of figure 2-5 were computed by the use of class-A weather stations to compute R and by relating these values to National Weather Service intensity-frequency data for Hawaii. EI distribution data were also calculated for select Hawaiian stations to use in the calculation of seasonally weighted K values (ch. 3) and C values (ch. 5).

If the soil and topography were exactly the same everywhere, average annual soil losses from plots maintained in continuous fallow would be in direct proportion to these erosion index values.

R Values for Flat Slopes

Although the R factor is assumed to be independent of slope in the structure of RUSLE, splash erosion is less on low slopes. On flat surfaces, raindrops tend to be more buffered by water ponded on the soil surface than on steep slopes. Higher rainfall intensities that are correlated with higher R factors also tend to increase the depth of ponded surface water, which in turn protects the soil from rainfall impact (Mutchler 1970). To account for this soil protection by a ponded water layer on low slopes under high rainfall rates, the R factor should be adjusted using a relationship having the form (modified from Mutchler and Murphree 1985)

$$R_c = f(I, S) = f(R, S) \quad [2\text{-}9]$$

where

R_c = rainfall erosivity adjustment factor,
f = function of ( ),
I = precipitation intensity,
S = slope steepness, and
R = RUSLE rainfall erosivity term.

To compute R_c assume that the 10-yr-frequency storm EI value provides an indication of storm intensity and therefore the amount of water ponded on the land surface. In this procedure, the 10-yr EI value of a CITY database is used with a runoff index (a constant CN = 78 was used) and Manning's equation to compute a flow depth ratio, y. This flow depth ratio is then used in the equation $R_c = \exp(-0.49 \cdot [y-1])$. Figure 2-6 is the result of such calculations for a variety of land slopes. For further discussion, refer to chapter 6.

EI DISTRIBUTION USED IN CALCULATION OF K FACTOR AND C FACTOR

To calculate the seasonal or average annual soil erodibility factor (K) and the seasonal or average annual cover-management factor (C), the distribution of EI is needed. In RUSLE, the EI distribution (as a percentage of the annual value) is used for twenty-four 15-d periods, corresponding with the 1st and 16th days of the month.

Figure 2-7 shows the 120 homogeneous climatic zones in the contiguous United States used in RUSLE. The EI distribution values for each of these zones have been determined and are available in the computer code. Table 2-1 shows the EI distributions for the 120 zones and 19 Hawaiian zones, as well as the equivalent EI distribution for the frozen soil area of the Northwestern Wheat and Range Region.

Most of the climatic zones in figure 2-7 also have a single station containing information on precipitation and temperature (by month), the frost-free period, and the annual R. For example, about 140 climate stations (including 19 in Hawaii) are in the computer files. A user of the computer files may want to enter additional climate data for a zone. In other instances, a user may have to enter a climate station into the program before making soil-loss estimates in that region. The climate zones of figure 2-7 represent uniform EI distributions rather than uniform precipitation data or temperature data or both. Thus, in the western United States, orographic trends may pose problems within many of the zones and the user may need to input the additional data to reflect the orographic differences.

Although 19 stations are included in the Hawaiian climatic data files, the tremendous variability in precipitation, R, and temperature are only partially included. Therefore, caution must be used when making soil-loss estimates with RUSLE in Hawaii.

EI DATA FOR 10-YR-FREQUENCY STORMS

In the P-factor calculation for contour farming (ch. 6), the 10-yr-frequency storm EI value is required. These 10-yr EI data are used to credit the effect of contour practices on the support practice value. The values were obtained from the data originally calculated for Agriculture Handbook No. 537 (Wischmeier and Smith 1978) involving 181 stations in the eastern United States and from about 1,000 stations used to develop the isoerodent values in the western United States. The maps of these isoerodent values are given in figures 2-9 to 2-12 for the eastern and western United States.

Site-specific data can be obtained by interpolation from these figures. In the RUSLE computer program (see ch. 7 for the subroutine CITY), these values are given for most stations or they can be obtained by interpolation using the figures.

R EQUIVALENT (R_{eq}) FOR CROPLAND IN THE NORTHWESTERN WHEAT AND RANGE REGION

In the dryfarmed cropland areas of the Northwestern Wheat and Range Region (Austin 1981) shown in figure 2-8, the effect of melting snow, rain on snow, and/or rain on thawing soil poses unique problems. Generally, measured soil-loss values in the regions devoted to winter wheat, spring wheat, spring barley, peas, and lentils are much greater than the value that might be expected from R values calculated with the conventional kinetic energy times maximum 30-min intensity (EI). Observations indicate that much of the soil loss occurs by rilling phenomena when the surface part of the soil profile thaws and snowmelt or rain occurs on the still partially frozen soil. To more accurately predict soil losses for this condition, an R_{eq} value has been calculated using the following procedures:

$$(R_{eq})_{wr} = \frac{A_{wr}}{K_{wr}\,(LS)_{wr}\,(SLR)_{wr}\,P_{wr}} \qquad [2\text{-}10]$$

where

$(R_{eq})_{wr}$ = equivalent R factor for winter rilling,
A_{wr} = soil loss over winter in rills alone (measured),
K_{wr} = rill soil erodibility for winter period (estimated),
$(LS)_{wr}$ = LS relationship,
$(SLR)_{wr}$ = soil loss ratio for rilling in winter period (estimated for field condition), and
P_{wr} = supporting practices factor.

The soil loss from rills (A_{wr}) was measured after the winter erosion season from strips on selected fields along a 45- to 50-mi transect across eastern Washington and northern Idaho for a period of 10 yr. This area was subsequently divided into four zones for presentation and interpretation. Similar soil-loss measurements were made in five counties in north-central Oregon for 5 yr (although data were not collected for each county every year). Soil-loss measurements in southeastern Idaho were made for 4 yr. Thus, the rill soil-loss measurements represent a potential of 10 data points.

The winter erodibility value might be obtained by use of the variable K procedure (ch. 3) and by use of the average value of K for the winter period.

However, in RUSLE, K_{av} (EI-weighted average annual K value) is used throughout the entire year; there is no provision for use of an average K value for a particular portion of the year. Therefore, for consistency, K_{av} was used to calculate $(R_{eq})_{wr}$.

The Northwestern Wheat and Range Region LS relationships in RUSLE (ch. 4) were developed from only the Palouse transect data (eastern Washington and northern Idaho). The following LS relationships were used for $(R_{eq})_{wr}$ calculation:

$$(LS)_{wr} = \left[\frac{\lambda}{72.6}\right]^{0.5} (10.8 \sin \theta + 0.03) \qquad s < 9\% \qquad [2\text{-}11]$$

$$(LS)_{wr} = \left[\frac{\lambda}{72.6}\right]^{0.5} \left[\frac{\sin \theta}{0.0896}\right]^{0.6} \qquad s \geq 9\% \qquad [2\text{-}12]$$

Values of $(LS)_{wr}$ were calculated for each segment of the measured slope based on the contributing area above the segment and the segment steepness.

The soil-loss ratio $(SLR)_{wr}$ was calculated from the following factors:

(1) The rotation was assigned a soil-moisture factor using (see ch. 5) ww/p = 0.88, ww/sf = 1.0, wr = 0.5, and ww/sb = 0.72.

(2) Surface residue effect was calculated from a residue effectiveness curve [exp (-0.05 · % cover)].

(3) Growing cover effect was obtained from [1 - fraction of land surface covered by canopy]. Growing cover was generally less than 10% and often less than 5%.

(4) Surface roughness effect was assigned values from 0.7 to 1.2 based on field observations. Most values used were about 1.1.

(5) Incorporated residue effect was obtained from [exp (-0.00045 · lb $acre^{-1}$ residue incorporated at a shallow depth)]. Shallow incorporated residue was assumed to be half of the residue incorporated less decomposition.

The soil-loss ratio $(SLR)_{wr}$ was then computed as the product of these five factors.

The winter support practices factor (P_{wr}) was assumed to be unity. Thus, $(R_{eq})_{wr}$ was calculated for each year for each zone or county by averaging all segment values.

The individual zone $(R_{eq})_{wr}$ was averaged over the years of record to obtain a zonal average value. The data points were reduced from 10 to 7 based on the number of segments and strips in a zone or county in a given year and on the number of years of data in a zone or county. The three points deleted were all from north-central Oregon. These average values were subsequently correlated against published annual precipitation for corresponding zones to obtain

$$(R_{eq})_{wr} = -110.3 + 10.78\ P \qquad r^2 = 0.98 \qquad [2\text{-}13]$$

where P = annual precipitation (in).

Adjustment for Interrill and Non-Winter Soil Loss

Measurements of the rill to interrill ratio soil loss in the Northwestern Wheat and Range Region vary greatly. For example, rill-erosion measurements near the Columbia Plateau Conservation Research Center near Pendleton, Oregon, indicate about a 95% rill soil loss. A rule of thumb based on the old Pullman Conservation Field Station (PCFS) plots near Pullman, Washington, was that 75% of the soil loss came from rill erosion. Recent measurements over a 4-yr period from continuous fallow plots at the PCFS indicate that 85-90% of the soil loss came from rill erosion. In other instances (and varying with treatments), the attempts to separate interrill losses from total soil loss have been essentially unsuccessful. Thus, a somewhat arbitrary ratio of 90% rill loss and 10% interrill soil loss was assumed to adjust the $(R_{eq})_{wr}$ to estimate the total winter equivalent R, $(R_{eq})_{wt}$.

Then

$$(R_{eq})_{wt} = (R_{eq})_{wr} \cdot \frac{100}{90} \qquad [2\text{-}14]$$

The nonwinter component of soil loss was estimated in two ways, each of which gives a ratio of roughly 5% of the annual R_{eq} occurring during the nonwinter periods. Thus, we estimate total annual soil loss as

$$R_{eq} = (R_{eq})_{wr} \cdot \frac{100}{90} \cdot \frac{100}{95} \qquad [2\text{-}15]$$

and finally

$$R_{eq} = -129.0 + 12.61P \qquad [2\text{-}16]$$

For lower precipitation areas of the Northwest Wheat and Range Region with a frozen soil erosion problem, the following relationship will provide a smooth transition from the R_{eq} to the non-R_{eq} zone:

$$R_{eq} = 1.602 \exp(0.2418\ P) \qquad 7.5 < P < 15.0 \qquad [2\text{-}17]$$

Equation 2-17 should be used for $P \leq 15.0$.

The P and R_{eq} maps for the cultivated areas farmed with winter wheat, spring wheat, spring barley, peas, or lentils in the Northwestern Wheat and Range Region are shown in figures 2-13 to 2-16. The small-grain areas include higher elevation forest and grazing land as well as the cultivated valleys and lower slopes. In general, winter wheat is not grown where P is greater than about 35 in. Thus, no R_{eq} values greater than 320 (P = 35.6 in) are plotted in figures 2-15 and 2-16.

It was necessary to distribute the R_{eq} throughout the year. The nonwinter component (5% of the total) was distributed uniformly from April 1 through September 30. The winter component (95% of the total) was distributed from October 1 through March 31. Based on historical soil-loss data from PCFS, the period of major erosivity was assigned to late January and early February. Erosivity then tapered gradually to October 1 and more steeply to March 31 (see Pullman, WA, CITY database for the R_{eq} distribution data).

RAINFALL EROSIVITY IN A COLD MOUNTAINOUS CLIMATE

Data analysis from the precipitation network in southwestern Idaho indicate major problems in assessing the erosivity index. The problems are not uniquely different from those in the Northwestern Wheat and Range Region (area of winter wheat, spring barley, peas, and lentils). RUSLE (and also its predecessor USLE) was designed to account for the effects of raindrop impact and subsequent overland flow on soil erosion (Cooley et al. 1988). In much of the western United States, precipitation occurring as snow should also be accounted for if representative EI estimates are to be produced.

Cooley et al. (1988) found that snowfall accounted for only a minor portion (4%) of EI based on annual precipitation values at low-elevation valley sites. However, at high elevation sites, snowfall accounted for most (up to 71%) of the annual precipitation. Therefore, it is important to use only the rainfall portion of annual precipitation when determining EI in areas where snowfall is significant, rather than using total annual precipitation.

Elevation was observed to have a relatively minor influence on summer (rain) EI values. Summer storms are mainly produced by air-mass thunderstorms and tend to be more random in location and smaller in areal extent than are frontal storms.

The consideration of all storms in estimating EI, rather than only storms that result in more than 0.5 in rainfall [per Wischmeier and Smith (1978) procedure], increased EI by 28-59% on the Reynolds Creek watershed. However, runoff and erosion data for evaluating the significance of these increases were not available.

Cooley et al. (1988) also tested several methods of computing average annual R involving 2-yr-frequency, 6-h-duration precipitation for comparison with long-term breakpoint-data R values (table 2-2). In mountain and range topography like that of southwestern Idaho, caution must be exercised in selecting storm values because snow events can affect the value. Cooley et al. (1988) observed that the storm value decreased by 5-34% when snowfall was eliminated from the annual data set. R decreased by 4-42% when snowfall was removed; that is, summer values were used instead of annual values.

SOUTHWESTERN AIR-MASS THUNDERSTORM

Precipitation gages operated by ARS in Arizona and New Mexico were used to compute EI data for areas dominated by air-mass thunderstorms. Of particular interest is the fact that EI during the summer period amounted to 85-93% of the annual total, which was 50-81 hundreds · ft· tonf · (acre · in · yr)$^{-1}$ (Renard and Simanton 1975).

In still other efforts, Simanton and Renard (1982) calculated the EI for a storm on the 57.7-sq-mi Walnut Gulch Experimental watershed in southeastern Arizona. Figure 2-17 shows the isohyetal values of precipitation determined for the 100 recording raingages for the event of July 22, 1964, and the corresponding isoerodent map. It should be noted that the isoerodent lines have little correlation with the isohyetal lines. An intense air-mass thunderstorm near the upper end of the area caused nearly 100 units of EI whereas only a short distance away (about 5 mi), the EI was less than 50% of the storm maximum.

Figure 2-18 illustrates the annual isohyetal map and the annual isoerodent (R) map, including the data of figure 2-17 plus the other storms occurring during the year. The highly variable rainfall illustrated in figures 2-17 and 2-18 is very typical of air-mass-thunderstorm country as shown on the isoerodent map. The 1.9 ratio of maximum to minimum annual precipitation and the 4.0 ratio of maximum to minimum R are normal occurrences.

The significance of these illustrations is that a single raingage and the EI calculations from it may be inadequate indicators of the soil loss at any specific point unless the precipitation record is collected at that site.

LIMITATIONS IN WINTER R FACTORS

Agriculture Handbook No. 537 suggests that the rainfall erosivity value (R) might be adjusted by multiplying the precipitation falling in the form of snow by 1.5 and then adding the product to EI, the kinetic energy times maximum 30-min intensity. This calculation has been used in the past at some locations, but we currently do not support this approach in RUSLE. The redistribution of snow by drifting, sublimation, and reduced sediment concentrations in snowmelt confuses the problem tremendously. But data are not presently available to support this approximation. Therefore, the developers of RUSLE recognized the weakness of ignoring the problem (except in the cropland areas of the Northwestern Wheat and Range Region where the R_{eq} data are being used).

ACKNOWLEDGMENT

The authors appreciate the assistance of Joe M. Sheridan, ARS, in Tifton, GA, who assisted in preparing portions of the data in this chapter.

[1] Periods are 15-d beginning January 1.
[2] Zones 121-139 are for stations in Hawaii.
[3] Zone 140 is the R_{eq} distribution for Pullman, WA.

Table 2-2.
Average annual and summer EI and 2-yr-frequency 6-h-duration precipitation computed from actual data in southwestern Idaho. Data for EI are compared with data in methods of Wischmeier (1974), Simanton and Renard (1982), Cooley (1980), and Cooley et al. (1988).

	R (hundreds ft · tonf · acre^{-1} · yr^{-1})											
	Precipitation 2-yr 6-h storm[2] (inches)		Observed EI		Wischmeier (1974)[3] $27.38P^{2.17}$		Simanton and Renard (1982) $27.38P^{1.62}$		Cooley (1980)[4] $13.00P^{2.15}$		Cooley et al. (1988) $22.17P^{2.56}$	
Site[1]	Summer	Annual	Summer	Annual	Summer	Annual	Summer	Annual	Summer	Annual	Summer	Annual
057	0.71	0.75	10.5	10.9	12.6	14.3	15.6	17.0	6.2	6.9	9.2	10.6
127	.75	.83	9.5	11.3	14.3	17.7	17	20	6.9	8.6	10.6	13.8
116	.79	.91	10	14.6	16	21.7	18.5	23.2	7.8	10.5	12.1	17.4
155	.83	1.06	16	31	17.7	30.9	20	30.1	8.6	14.8	13.8	36.9
176	.83	1.22	14.2	45.3	17.7	41.8	20	37.7	8.6	19.9	13.8	36.9
163	.91	1.38	17.3	59.3	21.7	54.6	23.2	45.8	10.5	25.9	17.4	50.6

[1] Site elevation: 057 is 3,885; 127 is 5,410; 116 is 4,770; 155 is 5,410; 176 is 6,802, and 163 is 7,100 ft above m.s.l.
[2] Determined from actual gage data. NOAA Atlas 2 (Miller et al. 1973) would not permit defining the orographic results shown.
[3] Wischmeier (1974) and Ateshian (1974) agree within about 2%.
[4] Includes precipitation during winter periods in the form of snow, a questionable computation according to Cooley et al. (1988).

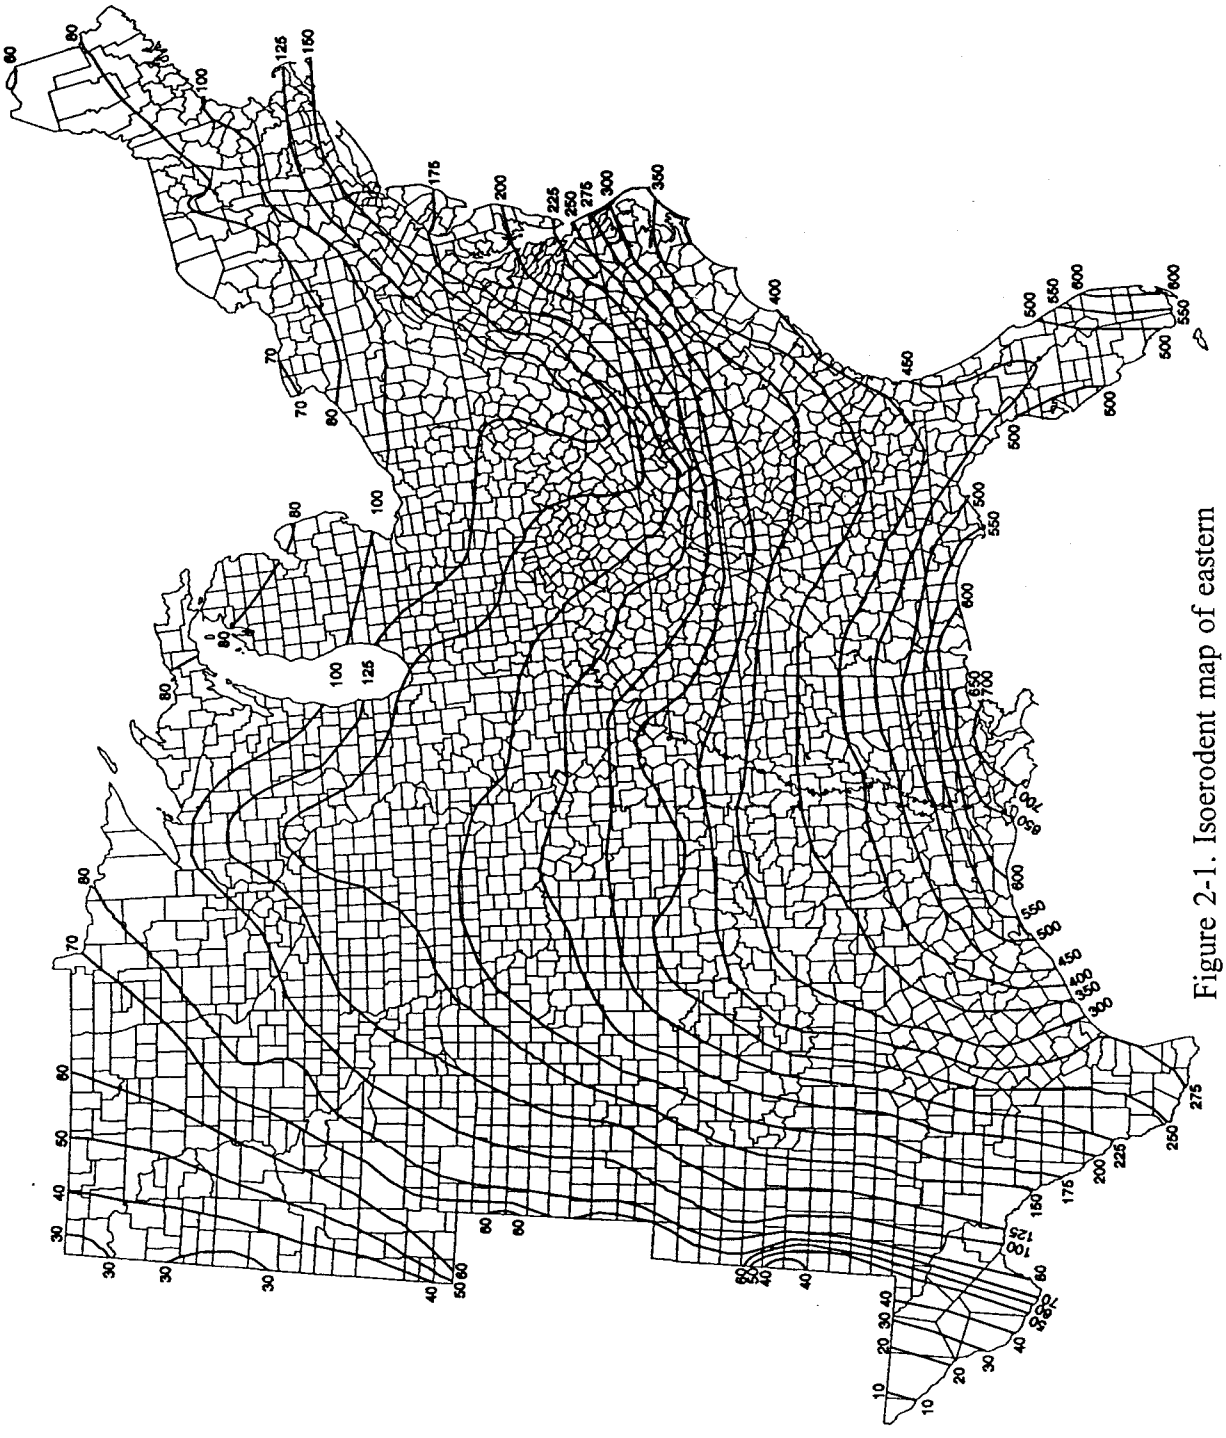

Figure 2-1. Isoerodent map of eastern United States. Units are hundreds ft·tonf·in(ac·h·yr)$^{-1}$.

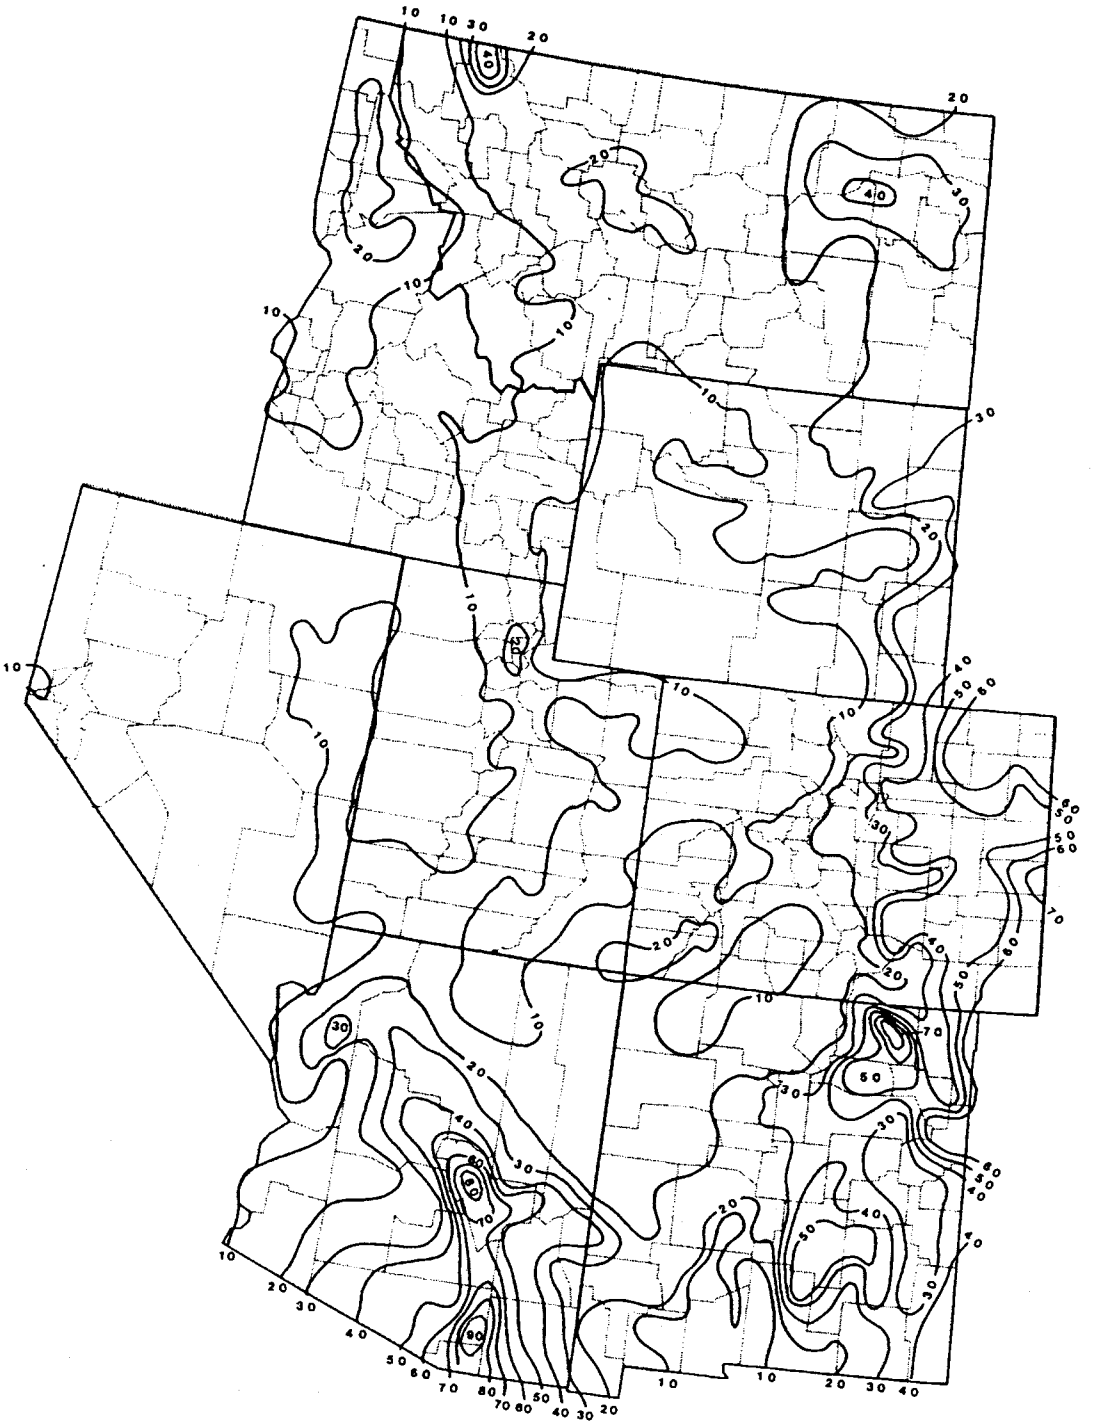

Figure 2-2. Isoerodent map of western United States. Units are hundreds ft·tonf·in(ac·h·yr)$^{-1}$.

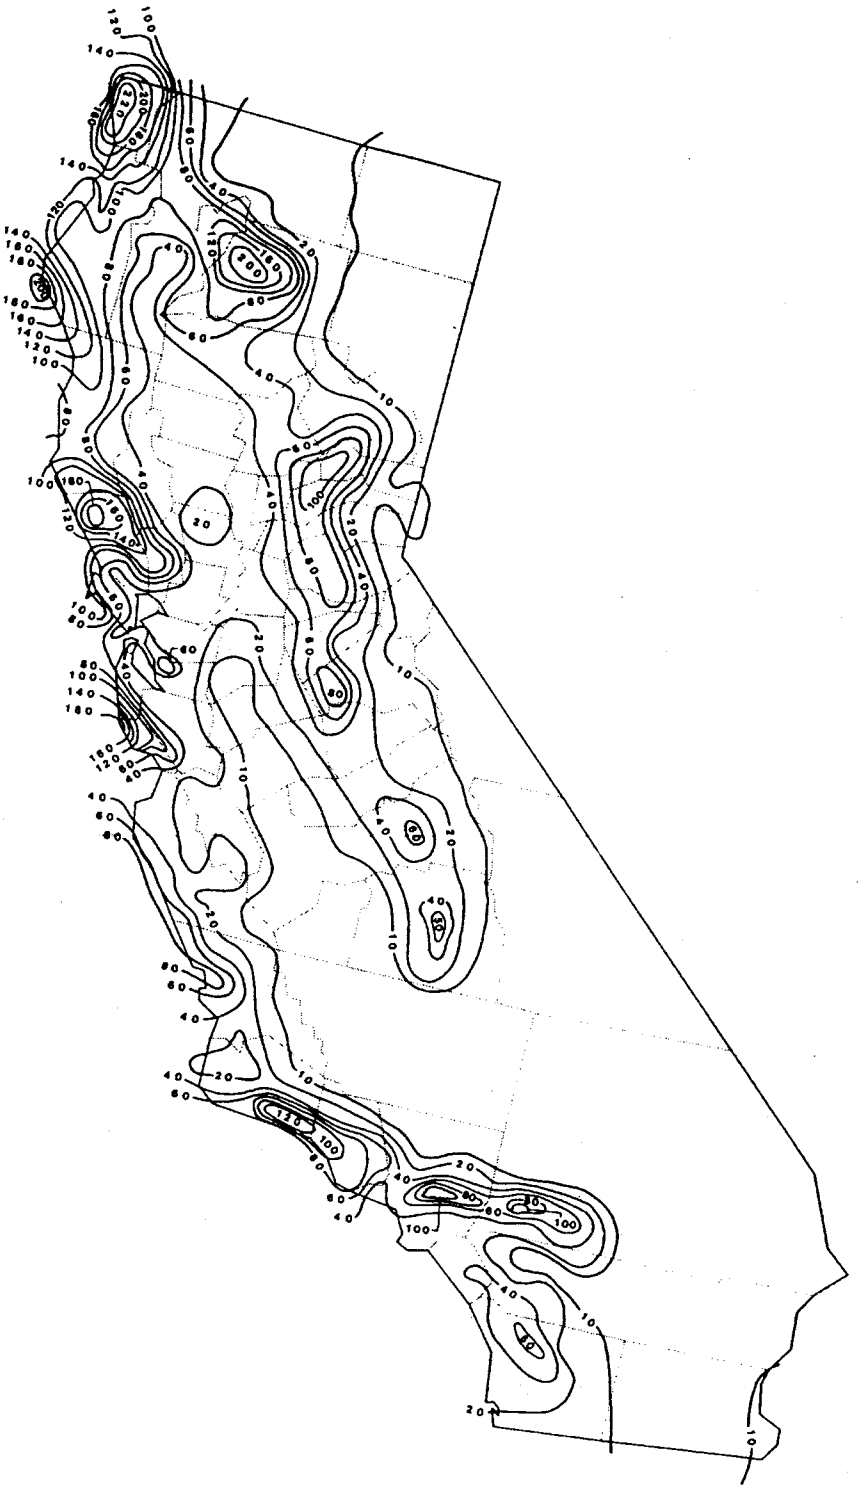

Figure 2-3. Isoerodent map of California. Units are hundreds ft·tonf·in(ac·h·yr)$^{-1}$.

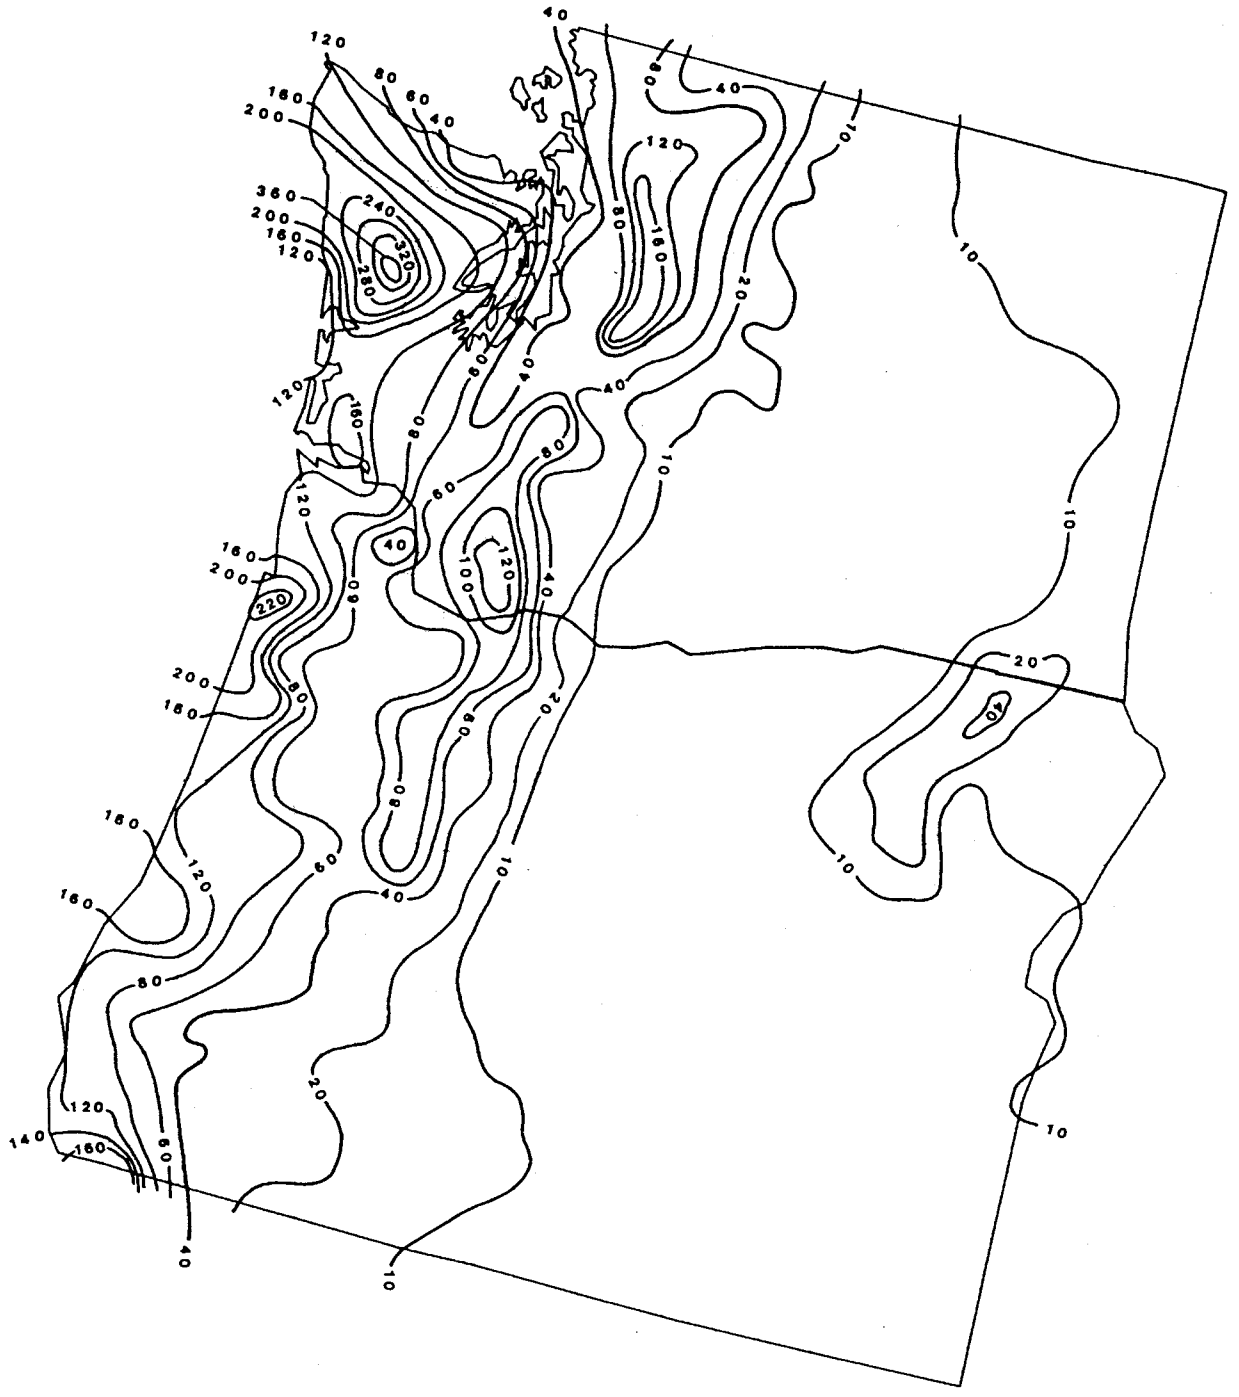

Figure 2-4. Isoerodent map of Oregon and Washington. Units are hundreds ft·tonf·in(ac·h·yr)$^{-1}$.

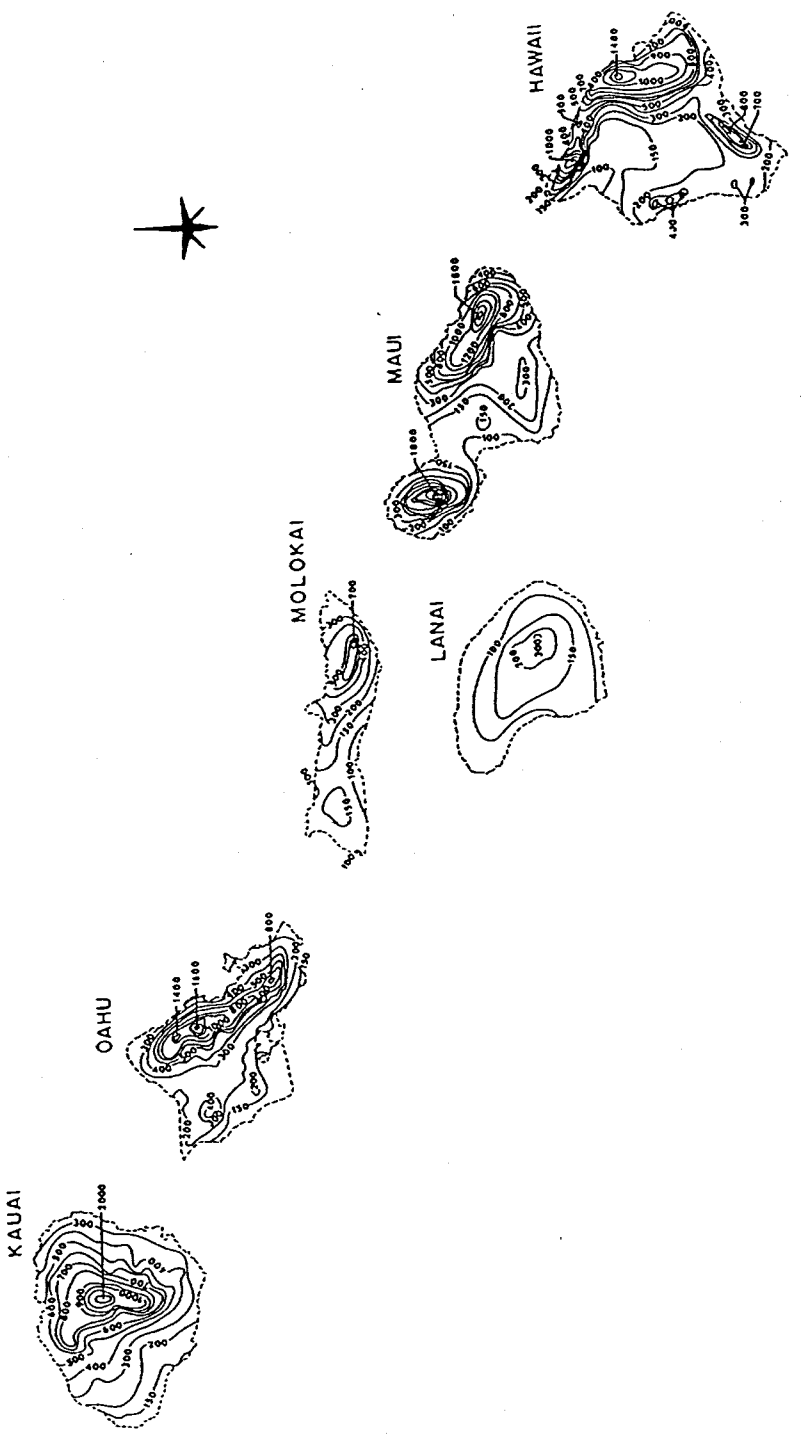

Figure 2-5. Isoerodent map of Hawaii. Units are hundreds $ft \cdot tonf \cdot in(ac \cdot h \cdot yr)^{-1}$.

CHAPTER 3. CONTENTS

Soil erodibility is a complex property and is thought of as the ease with which soil is detached by splash during rainfall or by surface flow or both. From a fundamental standpoint, however, soil erodibility should be viewed as the change in the soil per unit of applied external force or energy. Just as in USLE, RUSLE uses a restrictive and applied definition of soil erodibility. Soil erodibility is related to the integrated effect of rainfall, runoff, and infiltration on soil loss and is commonly called the soil-erodibility factor (K). The soil-erodibility factor (K) in RUSLE accounts for the influence of soil properties on soil loss during storm events on upland areas. In this chapter, the current state of knowledge of K-factor measurements and prediction technology is summarized. Background information is given to facilitate the estimation of K values for soils for which no direct K-value measurements are available. Specific areas of concern in evaluations of soil-erodibility factor are discussed, including seasonal variation of soil-erodibility factors (especially of soils subjected to freezing and thawing) and the evaluation of the soil-erodibility factor for soils with rock fragments.

DEFINITION AND EXPERIMENTAL GUIDELINES

The soil-erodibility factor (K) is the rate of soil loss per rainfall erosion index unit [ton· acre· h(hundreds of acre· ft-tonf· in) $^{-1}$] as measured on a unit plot. The unit plot is 72.6 ft (22.1 m) long, has a 9% slope, and is continuously in a clean-tilled fallow condition with tillage performed upslope and downslope (Wischmeier and Smith 1978). Recommended minimum plot width is 6 ft (1.83 m). Guidelines for preparation and maintenance of natural runoff plots in the United States were issued in 1961 by D.D. Smith (Römkens 1985). They are as follows: "Plow to normal depth and smooth immediately by disking and cultivating two or more times, except for areas where wind erosion during the winter poses a serious hazard. In the latter case, disking or cultivating should be delayed until spring. Plowing shall be each year at the time continuous row crop plots are plowed. Cultivation shall be at new crop planting, routine cultivating times, and when necessary to eliminate serious crust formations. Chemical weed control may be used, if cultivation does not control weed-growth. Plowing and cultivation should be upslope and downslope and should not be on an excessively wet soil."[1]

[1]Administrative communication from D.D. Smith to runoff plot managers (January 1, 1961), "Instructions for establishment and maintenance of cultivated fallow plots."

PRACTICAL INTERPRETATION

In practical terms, the soil-erodibility factor is the average long-term soil and soil-profile response to the erosive powers of rainstorms; that is, the soil-erodibility factor is a lumped parameter that represents an integrated average annual value of the total soil and soil profile reaction to a large number of erosion and hydrologic processes. These processes consist of soil detachment and transport by raindrop impact and surface flow, localized deposition due to topography and tillage-induced roughness, and rainwater infiltration into the soil profile.

INTERACTIONS WITH OTHER SOIL-LOSS FACTORS

The soil-erodibility factor (K) represents the effect of soil properties and soil profile characteristics on soil loss. Some interdependency exists between the K factor and other RUSLE factors. For instance, the traditional topographic relationships for slope length and steepness factors (LS) (Wischmeier and Smith 1978) were derived from soil-loss measurements on mostly medium-textured, poorly aggregated surface soils. It is to be expected that errors and shortcomings in the relationships for topographic effects will carry over into K values if these relationships are used to determine K values.

Similar problems exist for the rainfall-erosivity factor (R). Storm energy may vary substantially among storms due to variations in drop size and due to updraft or downdraft of wind. Some of these variations occur in areas where certain storm types prevail for part of the year (heavy thunderstorms versus gentle rains). Calculations of rainfall energy from rainfall breakpoint data for natural runoff plots using a relationship of specific intensity versus energy (Wischmeier and Smith 1978) may lead to "errors" in the computed K. Seasonal K values may offer some compensation for errors in R values computed from rainfall breakpoint data.

Interactions with the cover-management factor (C) are primarily due to the effect of organic matter or organic carbon on soil loss. The organic-carbon content of soils depends on the annual additions of surface and subsurface crop residue and manure and on their decomposition rate. No sharp delineation can be made where the effects of crop residue cease to be part of a C factor and instead become part of the K factor. Moreover, the processes of organic conversions are related to environmental factors (temperature, wetness, and so on) and thus vary among physiographic regions. A discussion of these processes is beyond the scope of this chapter. Short-term effects such as from the protective cover of mulch or from the mechanical constraints such as disturbance of surface and subsurface residues are related to the C factor, whereas long-term effects such as soil changes or soil structural alterations by organic compounds should be considered part of the K factor.

DETERMINATION OF K FACTOR

Soil-erodibility factors are best obtained from direct measurements on natural runoff plots. Rainfall simulation studies are less accurate, and predictive relationships are the least accurate (Römkens 1985). In each of these methods of determination, requirements for soil and plot conditions as well as methods of evaluation have to be met. These requirements are designed to eliminate the influence of variations in antecedent soil-water and soil-surface conditions and of variations in the rainstorm regimes on the soil-erodibility factor. Only inherent soil properties are considered determinants of the erodibility factor.

Natural Runoff Plots

The major requirement in a study using a natural runoff plot is a database that is large enough and that was obtained over a sufficiently long period. Very few studies exist for which long-term observations are available. For the eastern United States, this period is assumed to be 20-22 yr (Wischmeier 1976). Time and economic factors have limited the establishment of long-term runoff plots and therefore have promoted the development of plot research with simulated rainfall. However, simulated-rainfall procedures often fall short of the requirement of a sufficiently long fallow condition. Table 3-1 lists the soils in the United States on which natural runoff plots for K-factor determinations were established. Note that the observation period on all of these soils fell considerably short of the stated period of 20-22 yr. However, K values of many soils were obtained from long-term runoff data on cropped plots that had been adjusted for the C factor.

The second requirement for soil-erodibility-factor determinations on natural runoff plots is a fallow, tilled surface immediately before and during the observation period. This requirement stipulates the removal or natural degradation of all surface and subsurface plant residue that remained after cropping. The adequacy of this observation period should be determined relative to the climatic conditions in the United States but is usually taken to be 2 yr.

The third requirement for reliable K-value determinations is uniformity of soil and topography within the plot and also adherence to plot-size standards. Topographic uniformity is essential to avoid soil deposition or accelerated soil erosion in localized areas. The selection of plots having a standard length and steepness is important to avoid errors in soil-loss adjustments with topographic factors. Many soils do not occur with slopes of 9%, but standards, once formulated, must be adhered to in order to avoid ambiguities. Actually, the 9%-slope steepness is not rationally based, but was selected as being an average gradient of runoff plots on which early erosion studies in the United States were conducted. Similarly, the 72.6-ft (22.1-m) plot length was the result of the selection of a 1/100-acre (1/250-ha) plot area, given a two-row or 6-ft (1.83-m) plot width.

Rainfall-Simulation Plots

K-factor determinations in simulated-rainfall studies require plot standards that are the same as those for natural runoff plots with respect to size, slope, and preparation. However, the usually very short timespan allowed between cropping and rainfall-simulation runs is insufficient for the adequate degradation of surface or subsurface organic residue. Therefore, in the simulation, surface residue is often removed mechanically or manually before tillage, and corrections for subsurface-crop-residue effects are made through the C factor. Errors may be introduced in K-factor determinations for soils with incomplete removal or degradation of surface and subsurface residues or for soils with incorrect C-factor adjustments.

A second difficulty with the use of rainfall simulation in K-factor evaluations is the selection of weighting factors for soil losses on different antecedent soil-water conditions. Römkens (1985) and Barnett et al. (1965) observed that K values for different antecedent moisture levels need to be weighted in proportion to the occurrence of runoff and erosion in different climates to determine the average annual K value.

RELATIONSHIPS OF K FACTOR AND SOIL PROPERTIES

The physical, chemical, and mineralogical soil properties and their interactions that affect K values are many and varied. Moreover, several erosion mechanisms are operating at the same time, each one relating differently to a specific soil property. It is therefore unlikely that a relatively few soil characteristics will accurately describe K values for each soil. Yet several attempts have been made to relate measured K values to soil properties. Table 3-2 lists the principal studies in the United States and a summary of the results.

Of these studies, the most widely used and frequently cited relationship is the soil-erodibility nomograph (Wischmeier et al. 1971). The nomograph, shown in figure 3-1, comprises five soil and soil-profile parameters: percent modified silt (0.002-0.1 mm), percent modified sand (0.1-2 mm), percent organic matter (OM), and classes for structure (s) and permeability (p). The structure and permeability classes and groups of classes were taken from the Soil Survey Manual (USDA 1951). A useful algebraic approximation (Wischmeier and Smith 1978) of the nomograph for those cases where the silt fraction does not exceed 70% is

$$K = \left[2.1 \cdot 10^{-4}(12-OM)\, M^{1.14} + 3.25(s-2) + 2.5(p-3)\right] / 100 \qquad [3\text{-}1]$$

where M is the product of the primary particle size fractions: (% modified silt or the 0.002-0.1 mm size fraction) · (% silt + % sand). K is expressed as ton· acre^{-1} per erosion index unit with U.S. customary units of ton· acre· h (hundreds of acre· ft-tonf · in)$^{-1}$. Division of the right side of this and subsequent K-factor equations with the factor 7.59 will yield K values expressed in SI units of t· ha· h· ha^{-1}· MJ^{-1}· mm^{-1}.

The nomograph relationship is derived from rainfall-simulation data from 55 midwestern, mostly (81%) medium-textured, surface soils. More than 60% of these soils had an aggregation index smaller than 0.3 (Mannering 1967). The nomograph is well suited for the less aggregated, medium-textured surface soils of the Midwest. Attempts by other investigators to apply the nomograph to other classes of soils have met with limited success. Figure 3-2 shows the relationship between the observed and nomograph-predicted soil-erodibility

factors for the nomograph database and selected U.S. data sets of other soil classes. In most of these studies, aggregate sizes or aggregation indices were the most significant parameters. For details of the relationship between the soil-erodibility factor and soil properties, the reader is referred to the original publications (see table 3-2) or to a review paper by Römkens (1985).

Regression equations for specific classes of soils in the United States are those listed in table 3-2. Unfortunately, substantial intercorrelations exist among many of these variables, thereby affecting the true significance of each property in predicting K values. The relationship for volcanic soils in Hawaii (El-Swaify and Dangler 1976) is given by the expression

$$K = -0.03970 + 0.00311x_1 + 0.00043x_2 + 0.00185x_3 + 0.00258x_4 - 0.00823x_5 \quad [3\text{-}2]$$

where x_1 is the unstable aggregate size fraction in percent less than 0.250 mm, x_2 is the product of % modified silt (0.002-0.1 mm) and % modified sand (0.1-2 mm), x_3 is the % base saturation, x_4 is the silt fraction (0.002-0.050 mm) in percent, and x_5 is the modified sand fraction (0.1-2 mm) in percent. The applicability of equation [3-2] has not been demonstrated for all tropical soils of volcanic origin. Equation [3-2] should be considered for only those soils that are similar to soils found in Hawaii.

For soils in the upper Midwest, the following relationship was developed (Young and Mutchler 1977):

$$K = -0.204 + 0.385x_6 - 0.013x_7 + 0.247x_8 + 0.003x_2 - 0.005x_9 \quad [3\text{-}3]$$

where x_6 is an aggregation index, x_7 is the percentage montmorillonite in the soil, x_8 is the bulk density of the 50-125 mm depth in $g \cdot cm^{-3}$, and x_9 is the dispersion ratio. The presence of the montmorillonite term suggests that this clay mineral significantly impacted the aggregation and granulation characteristics of these soils--the latter by facilitating detachment during drying and transport in subsequent storm events.

For clay subsoils in the Midwest, the following relationship may be useful (Römkens et al. 1977):

$$K = 0.004 + 0.00023x_{10} - 0.108x_{11} \quad [3\text{-}4]$$

where x_{10} is the parameter M (Wischmeier et al. 1971) and x_{11} is the citrate-dithionite-bicarbonate (= CDB) extractable percentage of Al_2O_3 plus Fe_2O_3. This relationship again suggests the importance of the particle size between 0.002 and 0.1 mm in soil-erodibility-factor evaluations for subsoils. The importance of the CDB-extractable amount of the hydrous oxides of iron and aluminum as a predictor for the soil-erodibility factor should be tempered, in view of the small amounts (<3.76%) of these substances present in the soils tested. For highly weathered or cemented soils, equation [3-4] has not been tested and presumably needs modification.

Recently, all available published global data (225 soils) of measured K values, obtained from both natural- and simulated-rainfall studies, were pooled and grouped into textural classes. Only soils with less than 10% of rock fragments by weight (>2 mm) were considered. The mean values of the soil-erodibility factor for soils within these size classes were then related to the mean geometric particle diameter of that class. The resulting relationship, shown in figure 3-3A, can be expressed as

$$K = 7.594\left\{0.0034+0.0405\exp\left[-\frac{1}{2}\left\{\frac{\log(Dg)+1.659}{0.7101}\right\}^2\right]\right\} \quad [3\text{-}5]$$

where

$$Dg(mm) = \exp\left(0.01\sum f_i \ln m_i\right) \text{ with } r^2 = 0.983 \quad [3\text{-}6]$$

and

Dg = geometric mean particle diameter.

Here, f_i is the primary particle size fraction in percent, and m_i is the arithmetic mean of the particle size limits of that size (Shirazi and Boersma 1984). A similar relationship, shown in figure 3-3B with $r^2 = 0.945$, was derived for 138 U.S. soils only. This relationship is

$$K = 7.594\left\{0.0017+0.0494\exp\left[-\frac{1}{2}\left\{\frac{\log(Dg)+1.675}{0.6986}\right\}^2\right]\right\} \quad [3\text{-}7]$$

Figure 3-3 also indicates the variability in K values for each particle size class.

Relationships [3-5] and [3-7] are very useful for predicting K values of soils for which (1) data are limited (for instance, no information about the very-fine-sand fraction or organic-matter content) and (2) the textural composition is given in a different classification system. Also, equations [3-5] and [3-7] are useful for predicting K values of classes of soils other than those on which the nomograph was based, such as soils of textural extremes and well-aggregated soils. Of course, prediction equations [3-5] and [3-7] give an estimate of the K factor based on limited data and therefore yield less accurate values than those obtained from direct measurements or indirectly from regression data for soil types similar to those indicated in table 3-2.

CONSIDERATIONS IN SELECTION OF K VALUES

Several methods can be used to obtain estimates of the average annual value of the soil-erodibility factor. For medium-textured soils—certainly for the poorly aggregated ones of the temperate zones—the nomograph appears to be the best predictive relationship. For tropical soils of volcanic origin, relationship [3-2] may be helpful. For soils or subsoils that contain clay minerals with 2:1 expanding lattices, relationships [3-3] or [3-4] can be used. If K values are to be obtained for soils that do not readily fit any of these categories or for soils with incomplete information (that is, particle-size distribution and organic matter content), the broadly based relationships [3-5] and [3-7] can be selected.

SPECIFIC PROBLEM AREAS

Rill and Interrill Erodibility

Physically based models are being developed to explain the dynamic relationships of the erosion process (detachment, transport, deposition), and the models provide a great opportunity to improve the estimation of erosion. These models are incompatible with the empirically based RUSLE, which predicts long-term average values (effects of subprocesses are lumped). Thus, improved soil-erodibility estimates using soil properties and relating them to erosion processes are not included in this revision (Römkens et al. 1986).

Soils With Rock Fragments

In NRCS's map unit use file (MUUF), 15.6% of land area in the continental United States consists of soils with rock fragments on or in the soil surface (Miller and Guthrie 1984). These rock fragments, when present on the soil surface, significantly reduce soil detachment by rainfall. When present in a coarse-textured-soil profile (having sand and loamy sand textures), the fragments can appreciably reduce infiltration.

To account for these effects, one view has been to include the effect of rock fragments on soil loss solely in the C factor (Box and Meyer 1984, Römkens 1985), and another practice has been to include the effects solely in the K factor. Surface cover by rock fragments varies from site to site on otherwise identical soils. The fragments act as a surface mulch by protecting the soil surface from raindrop impact in a manner similar to that of surface mulches of straw and chopped stalks. Rock fragments are usually not moved by water from interrill areas but remain behind on the soil surface and act as an "armor" (Jennings and Jarrett 1985).

Subsurface rock fragments affect infiltration and thus runoff in a manner similar to that of subsurface residue by reducing the soil void space and soil hydraulic conductivity in coarse-textured soils. Moreover, because soil-mechanical-analysis procedures are based on particle-size fractions smaller than 2 mm, rock fragments larger than 2 mm are usually excluded when estimating K-factor values. However, rock fragments are part of a continuum of particle sizes in the mineral phase of the soil and therefore can be considered as part of the soil-erodibility factor.

This Agriculture Handbook separates the influence of rock fragments on soil loss into two components: (1) a surface cover component that represents the surface-protecting effect of rock fragments and that is accounted for in the C factor in a manner similar to that of crop residue and vegetative mulch, and (2) a subsurface component for sand and loamy-sand textures that represents the soil-loss increase due to the reduction in water infiltration. This latter effect is accounted for in the K factor through adjustments of the permeability class. It is shown below, however, that the subsurface effect of rock fragments can be relatively minor compared to the surface effect. Soil-profile descriptions with permeability classes that include the effect of rock fragments on permeability should not receive such an adjustment.

The hydraulic-conductivity-reducing effect of rock fragments can be determined from the relationship of the saturated hydraulic conductivity and permeability class given in the National Soils Handbook No. 430 (USDA 1983). Some clarification[2] is needed concerning the terminology and tables in that handbook. Rawls et al. (1982) proposed a relationship between the permeability class and the saturated hydraulic conductivity for different soil textures (table 3-3). Many factors other than texture determine the permeability class: for instance, structure, mineralogy, fragipans, sodium, and salinity. However, this relationship provides an estimate for relating changes in the effective hydraulic conductivity due to the presence of rock fragments to changes in the permeability class.

The rate of reduction in the saturated hydraulic conductivity with the presence of increasing amounts of coarse fragments in the soil profile was theoretically derived by Peck and Watson (unpublished data) and later verified for sand columns with inclusions of glass spheres and gravel by Dunn and Mehuys (1984). The relationship is

$$K_b / K_f = 2(1-R_v) / (2+R_v) \qquad [3\text{-}8]$$

[2]Permeability class as defined in the Soil Survey Manual of 1951 and in the USDA-SCS National Soils Handbook No. 430 is actually a hydraulic conductivity class. The relationship between permeability K_p (an intrinsic soil matrix property with dimensions L^2) and the saturated hydraulic conductivity K_h (a property that includes fluid properties of dimensions $L \cdot T^{-1}$) is $K_h = K_p \cdot \rho g \cdot \mu^{-1}$, where μ is fluid viscosity, ρ is fluid density, and g is gravitational acceleration.

where K_b is saturated hydraulic conductivity of the soil with rock fragments, K_f is saturated hydraulic conductivity of the fine soil fraction (<2 mm), and R_v is percent by volume of rock fragments >2 mm.

Brakensiek et al. (1986) simplified equation [3-8] to show that K_b of soil containing rock fragments can be reasonably related to K_f by using only the weight percent of rock fragments >2 mm. This relationship is

$$K_b/K_f = (1 - R_w) \qquad [3\text{-}9]$$

where R_w is percent by weight of rock fragments >2 mm. Using equation [3-9], a given percentage weight of rock fragments in a soil profile will result in an equal percentage reduction in the saturated hydraulic conductivity of the soil. Hence, the corresponding change in the permeability class can be estimated from table 3-3.

For example, a 40% volume of rock fragments in a severely eroding medium-textured soil (K = 0.50) will cause at best a change of one step in the permeability class or a maximum increase of 0.025 units in the soil-erodibility factor. This represents a 5% increase in soil loss. On the other hand, a 40% surface cover with rock fragments causes a reduction in soil loss of about 65% (Box 1981). For a less erodible soil (K = 0.10), a 40% volume of rock fragments represents a maximum increase of 25% in soil loss as reflected through the K value.

Seasonal K Values

K values are difficult to estimate mainly because of antecedent soil-water and soil-surface conditions and because of seasonal variations in soil properties. Because the value of these conditions and properties tends to be consistent for a season, it is thought that seasonal K values can reduce errors in soil-loss estimates. Based on this reasoning, Mutchler and Carter (1983) in the United States and Zanchi (1983) in Italy computed monthly K values. They independently proposed a periodic function of the type

$$K_r = 1 + a \cos(bt - c) \qquad [3\text{-}10]$$

where K_r is the ratio of the average seasonal (monthly) K value over the average annual K value; t is the mean monthly temperature; and a, b, and c are location-dependent constants. Similar reasoning by El-Swaify and

Dangler (1976) and Hosoyamada (1986) led to the introduction of wet/dry K values in Hawaii and cold/warm K values in Japan, respectively.

Variations in K through the seasons seem to be primarily related to three factors: soil freezing, soil texture, and soil water. Of these, the soil-freezing effect is probably the most difficult to evaluate. The effects of all three are now included in the average annual value.

The ability to more accurately predict the soil-erodibility factor for soils that are subjected to freeze-thaw cycles has been hampered by the limited understanding of the processes and temporary changes occurring in soil properties and in the soil profile during the cycles. Although no relationships have been developed, studies have shown that soil freezing and thawing can change properties that affect soil erodibility. These properties include soil structure, hydraulic conductivity, bulk density, aggregate stability, and soil strength (Benoit 1973, Benoit et al. 1986, Sillanpaa and Webber 1961, Formanek et al. 1984, Van Klaveren 1987, Kok and McCool 1990). It has been shown that the soil-water content at the time of initial freezing, the rate of soil freezing, and the number of freeze-thaw cycles can significantly affect soil aggregation and aggregate stability in spring at the time of thawing (Mostaghimi et al. 1988). Freeze-thaw cycling generally leads to low bulk density of the surface soil (Pall et al. 1982). Conditions of low density and high soil water provide a soil surface that is very susceptible to soil detachment and transport. Differences in soil density may persist even after frost layers have thawed. This, combined with intense spring rains, often results in large soil losses. Thus, freezing and thawing tend to increase the soil-erodibility factor.

High soil-water content can lead to the formation of concrete frost that is generally impermeable. Soil erodibility is then at a minimum, due to the soil's frozen conditions. When soil with a concrete frost layer thaws from the surface, drainage is almost nonexistent. Although the soil is not apt to be exposed to many freeze-thaw cycles in these areas, the spring melt period of 3 days to a month or more may still affect soil erodibility. During this period, a thawed surface layer of soil underlaid by a frost lens may exist, thereby impeding infiltration and water movement. Soil-erosion resistance is at a minimum immediately after the soil has thawed and tends to increase with time after thawing (Formanek et al. 1984). The greater the number of freeze-thaw cycles, the longer the erosion resistance of a soil is at a minimum. Because soil during the thawing period is extremely susceptible to erosion caused by snowmelt and rainfall, the soil loss is more likely to occur in that period. In regions where winter soil temperatures hover around the freezing point (such as in much of the Northwest Wheat and Range Region), the soil

surface is apt to undergo many freeze-thaw cycles throughout the winter, which tends to keep erosion rates high during this period. Reductions in surface-shear strength of 50% have been measured in a Palouse silt loam immediately after one freeze-thaw cycle, resulting in increased soil detachability in rills (Formanek et al. 1984).

In the portions of the United States where frozen soil is not a problem, the value for soil erodibility gradually decreases over the course of the growing season until it reaches a minimum sometime near the end of the growing season. Then the erodibility value gradually increases until it again reaches the maximum value. This pattern generally follows the rainfall pattern for many areas. Although the actual length of the growing season varies in warmer areas, a value of 6 mo (183 d) appears to be a reasonable approximation of the time between maximum and minimum values of soil erodibility for many soils in the United States. In areas where the growing season or wet-dry periods are significantly different from 6 mo, the values must be adjusted accordingly.

An approach to modifying K values for a given soil based on seasonal variation in erodibility is to assume an exponential decay function for the rate of decrease in erodibility as the growing season progresses. The rate of change in soil erodibility would vary with different types of soil or soil textures (Kirby and Mehuys 1987). The relationship of soil erodibility to soil texture is adequately determined from the soil-erodibility nomograph (Wischmeier et al. 1971) and has already been determined for most of the significant soil series of the United States. By letting the ratio of K_{max} (the maximum value of soil erodibility for a given soil) to K_{nom} (soil erodibility as determined from the nomograph) be constant for a given soil texture, the magnitude of K_{max} also becomes a function of soil texture.

The time span between K_{max} and K_{min} (minimum value of soil erodibility) varies with location and soil. The limited available data suggest that in the North, maximum values of soil erodibility generally occur at or near the beginning of the frost-free growing season and gradually decline to a minimum value at the end of the frost-free growing season. Data also indicate that t_{max} (time of year at which the soil-erodibility factor is at a maximum) occurs progressively earlier from north to south, whereas t_{min} (time of minimum erodibility) occurs progressively later. This is especially true where frost conditions exist during the winter months. In frost-free areas or areas with only minor frost activity, the time from maximum to minimum soil erodibilities corresponds more closely with periods of high and low rainfall, but seldom exceeds 6 mo.

The magnitude of the range of soil erodibility appears to vary, at least partially, with the soil water at the time of a rainfall event. The probability of the soil being wet at any time is a function of the timing and amount of annual precipitation which, for much of the United States, is reflected in the distribution of annual R values (Wischmeier and Smith 1978). Where average R values are low and monthly R values are less uniformly distributed (as in the northern United States), the range between K_{max} and K_{min} is usually wide (>7). Where R values are high and monthly values are more uniformly distributed (as in the southern United States), the range is usually narrower (<3). Where R values exceed 400, the range approaches unity. Data from long-term natural runoff plots at Morris, Minnesota, and Holly Springs, Mississippi, indicate that in northern Mississippi, K_{max} occurs in about mid-December and K_{max}/K_{min} is approximately 3.7, whereas in central Minnesota, K_{max} occurs in about mid-April and K_{max}/K_{min} is approximately 7.6.

Using data from one eastern Canadian province and from seven states in the midwestern and eastern United States, the following relationships were derived:

Case 1: $t_{max}<t_{min}$

If $t_{max} < t_i < t_{min}$, then

$$K_i = K_{max} \left(K_{min} / K_{max}\right)^{\left(t_i - t_{max}\right)/\Delta t} \qquad [3\text{-}11]$$

where K_i = soil-erodibility factor at any time (t_i in calendar days), K_{max} and K_{min} = soil-erodibility factors at times t_{max} and t_{min}, respectively; Δt = length of frost-free period or growing period (≤183 d); and T_{av} = average daily air temperature.

If $t_i < t_{max}$ or $t_i > t_{min}$, then for $T_{av} > 27°F$,

$$K_i = K_{min} \exp\left[0.009\left(t_i - t_{min} + 365\delta\right)\right] \qquad [3\text{-}12]$$

with $\delta = 1$ if $(t_i - t_{min}) \leq 0$ and $\delta = 0$ if $(t_i - t_{min}) > 0$ and for $T_{av} \leq 27°F$, $K_i = K_{min}$.

Case 2: $t_{max} > t_{min}$

If $t_{max} > t_i > t_{min}$, then for $T_{av} > 27°F$,

$$K_i = K_{min} \exp\left[0.009\ (t_i - t_{min})\right] \quad [3\text{-}13]$$

and for $T_{av} \leq 27°F$, $K_i = K_{min}$.

If $t_i > t_{max}$ or $t_i < t_{min}$, then

$$K_i = K_{max}\ (K_{min}/K_{max})^{\left(t_i - t_{max} + 365\delta\right)/\Delta t} \quad [3\text{-}14]$$

with $\delta = 1$ if $(t_i - t_{max}) \leq 0$ and $\delta = 0$ if $(t_i - t_{max}) > 0$.

However, if equation [3-11], [3-12], [3-13], or [3-14] yields

$K_i > K_{max}$, then put $K_i = K_{max}$, or if $K_i < K_{min}$, then put $K_i = K_{min}$.

The constant 0.009 of equations [3-12] and [3-13] was obtained upon fitting this relationship to the database. Based on data from four southern, four midwestern, and four northern soils, the ratios of K_{max}/K_{min} and K_{max}/K_{nom} and the value of t_{max} for areas where R does not exceed 400 are as follows:

$$K_{max}/K_{min} = 8.6 - 0.019R, \quad [3\text{-}15]$$

$$K_{max}/K_{nom} = 3.0 - 0.005R, \text{ and} \quad [3\text{-}16]$$

$$t_{max} = 154 - 0.44R. \quad [3\text{-}17]$$

If $t_{max} < 0$, then $t_{max} = t_{max} + 365$.

These values, plotted against the distribution of annual-erosivity values, are shown in figure 3-4. Using this method, the average annual value of

erodibility (K_{av}) will normally differ slightly from K_{nom} and can be estimated from the relationship

$$K_{av} = \sum (EI_i)K_i /100 \quad [3\text{-}18]$$

The annual EI distribution for any location in the United States can be found using figure 2-7 and table 2-1. The data from which the above relationships were derived were from the central and eastern United States and Canada. These are areas where isoerodent lines are approximated with reasonable accuracy and generally parallel each other as shown in figure 2-1 of chapter 2. There were no erodibility data available from the western states to include in the analysis. In the western United States there is a great deal more spatial variability of rainfall due to orographic effects caused by the mountain and valley topography, combined with the Pacific maritime influence. Erosivity values calculated from rainfall amount and intensity in most of the cropland areas of the western United States are lower than the ones in the central and eastern United States and Canada, where the variable K relationships were developed. Also in the western states, topography and orographic influences result in large fluctuations in local average air temperatures and length of growing season which are difficult to quantify. More research is needed on the effect of R values and fluctuations in temperature and growing season length on seasonal variation of K values in the western states. Thus it is recommended that K values for the region west of the line shown in figure 3-5 be estimated much as they have been in the past, from either the soil-erodibility nomograph or soil properties and the relationship shown in equation [3-1].

Data from volcanic soils in Hawaii suggest a somewhat different soil erodibility relationship than the one discussed above. There is little seasonal variation of K for these soils since they are not normally subject to freeze-thaw cycles. Thus, for volcanic soils in tropical areas, it is recommended that K values be estimated based on soil properties and the relationship shown in equation [3-2].

Following is an example of calculations for K_i and K_{av} for a Barnes loam (Udic Haploboroll) near Morris in west-central Minnesota with an annual EI of 90 and K_{nom} of 0.28. The frost-free period, or timespan between K_{max} and K_{min}, in west-central Minnesota is slightly less than 5 mo, or about 140 d (U.S. Department of Commerce 1968).

From figure 3-4 we arrive at

$t_{max} = 154\text{-}0.44(90)=114$ days (4/24) $\quad t_{min} = 114+140=254$ days (9/11)

$K_{max}/K_{nom} = 3.00\text{-}0.005(90)=2.55 \quad K_{max} = 2.55(0.28)=0.714$

$K_{max}/K_{min} = 8.60\text{-}0.019(90)=6.89 \quad K_{min} = 0.714/6.89=0.104$

Then, for the period from November 16 through March 15, when $T_{av} \leq 27°F$ (see fig. 3-5), $K_i = 0.104$; from March 16 through April 15 and September 1 through November 15 ($t_i < t_{max}$ and $t_i > t_{min}$), $K_i = 0.104\exp[0.009(t_i\text{-}254+365\delta)]$; and from April 15 through August 31 ($t_{max} < t_i < t_{min}$), $K_i = 0.714\ (0.146)^{(t_i-114)/140}$

From figure 3-5

$$K_{av} = \sum (EI_i)K_i /100 = 28.507 /100 = 0.285$$

Calculation of K_{av} by use of this method provides an annual average value for soil erodibility closely resembling the nomograph value (0.28) but reflecting a more realistic representation of seasonal fluctuations in the value of K. This value is similar to an average annual value of 0.24 for Barnes soil measured from long-term natural runoff plots at Morris (Mutchler et al. 1976).

Figure 3-6 shows a plot of K versus time of year for a Barnes loam from the example shown above and for a Loring silty-clay-loam soil (Glossic Fragiudalf) near Holly Springs, Mississippi (using EI distribution values from Memphis, Tennessee). Calculated values for figure 3-6 are shown in figures 3-7 and 3-8. Figure 3-6 indicates a slight increase in soil erodibility for a Barnes loam in early November. This behavior is due to the fact that once K reaches its minimum value at about the end of the growing season (sometime in early September), erodibility begins to increase again until complete soil freezing occurs (usually in November). Once the soil is frozen, erodibility goes back to a minimum value and remains at that value until spring thawing occurs. The Loring silty-clay-loam soil from Mississippi does not reflect this behavior because complete soil freezing does not occur in that area of the country.

ACKNOWLEDGMENT

The helpful suggestions from and discussions with G.R. Foster, USDA-ARS National Sedimentation Laboratory, W. Lafayette, IN, are acknowledged and appreciated.

G.A. Weesies

CHAPTER 4. CONTENTS

The effect of topography on erosion in RUSLE is accounted for by the LS factor. Erosion increases as slope length increases, and is considered by the slope length factor (L). Slope length is defined as the horizontal distance from the origin of overland flow to the point where either (1) the slope gradient decreases enough that deposition begins or (2) runoff becomes concentrated in a defined channel (Wischmeier and Smith 1978). Surface runoff will usually concentrate in less than 400 ft, which is a practical slope-length limit in many situations, although longer slope lengths of up to 1,000 ft are occasionally found. Unless the surface has been carefully graded into ridges and furrows that maintain flow for long distances, few slope lengths as long as 1,000 ft should be used in RUSLE. Slope length is best determined by pacing or measuring in the field. For steep slopes, these lengths should be converted to horizontal distance for use in RUSLE. Slope lengths estimated from contour maps are usually too long because most maps do not have the detail to indicate all concentrated flow areas that end RUSLE slope lengths. Figure 4-1 illustrates some typical slope lengths. Hints and guidelines for choosing slope lengths are given in a following section.

The slope steepness factor (S) reflects the influence of slope gradient on erosion. Slope is estimated in the field by use of an inclinometer, Abney level, or similar device. Slope may be estimated from contour maps having 2-ft contour intervals if considerable care is used.

Both slope length and steepness substantially affect sheet and rill erosion estimated by RUSLE. The effects of these factors have been evaluated separately in research using uniform-gradient plots. However, in erosion prediction, the factors L and S are usually evaluated together, and values can be selected from tables 4-1, 4-2, 4-3, or 4-4 for uniform slopes. The following sections give the relationships used to develop these tables. Also, a section explains how to apply RUSLE to nonuniform slopes.

SLOPE LENGTH FACTOR (L)

Plot data used to derive the slope length factor (L) have shown that average erosion for the slope length λ (in ft) varies as

$$L = (\lambda/72.6)^m \quad [4\text{-}1]$$

where 72.6 = the RUSLE unit plot length in ft and m = a variable slope-length exponent (Wischmeier and Smith 1978). The slope length λ is the horizontal projection, not distance parallel to the soil surface.

The slope-length exponent m is related to the ratio β of rill erosion (caused by flow) to interrill erosion (principally caused by raindrop impact) by the following equation (Foster et al. 1977):

$$m = \beta/(1 + \beta) \quad [4\text{-}2]$$

Values for the ratio β of rill to interrill erosion for conditions when the soil is moderately susceptible to both rill and interrill erosion were computed from (McCool et al. 1989)

$$\beta = (\sin \theta/0.0896) / [3.0(\sin \theta)^{0.8} + 0.56] \quad [4\text{-}3]$$

where θ = slope angle. Given a value for β, a value for the slope-length exponent m is calculated from equation [4-2].

The middle column in table 4-5, calculated from equations [4-3] and [4-2], gives values for m that are typical of agricultural fields in seedbed condition. When runoff, soil, cover, and management conditions indicate that the soil is highly susceptible to rill erosion, the exponent m should be increased as shown in the right column of table 4-5. This condition is most likely to occur on steep, freshly prepared construction slopes. These values for m were determined by doubling the β values from equation [4-3] before applying equation [4-2].

Conversely, when the conditions favor less rill erosion than interrill erosion, m should be decreased as shown in the left column of table 4-5. Values for m and LS for rangelands are usually taken from tables for the low ratio of rill to interrill erosion; those values were computed by halving the β values from equation [4-3] before applying equation [4-2]. Values in table 4-5 are based on an analysis by McCool et al. (1989).

When deposition occurs in furrows between ridges and in depressions, soil loss is independent of slope length; therefore the slope-length exponent is zero. Chapter 6 on the RUSLE P factor describes how to apply RUSLE to these conditions.

The slope-length exponent for the erosion of thawing, cultivated soils by surface flow (common in the Northwestern Wheat and Range Region described in ch. 2) differs from the values given in table 4-5. For the erosion of thawing soil by surface flow alone (McCool et al. 1989, 1993), a constant value of 0.5 should be used for the slope length exponent m, and LS values from table 4-4 should be used. When runoff on thawing soils is accompanied by rainfall sufficient to cause significant interrill erosion, values from table 4-5 for the low ratio of rill to interrill erosion should be used for the slope-length exponent m, and LS values from table 4-1 should be used.

SLOPE STEEPNESS FACTOR (S)

Soil loss increases more rapidly with slope steepness than it does with slope length. The slope steepness factor (S) is evaluated from (McCool et al. 1987)

$$S = 10.8 \sin \theta + 0.03 \qquad s < 9\% \qquad [4\text{-}4]$$

$$S = 16.8 \sin \theta - 0.50 \qquad s \geq 9\% \qquad [4\text{-}5]$$

Equation [4-5] is based on the assumption that runoff is not a function of slope steepness, which is strongly supported by experimental data for steepness greater than about 9%. The extent of the effect of slope on runoff is highly variable on cultivated soils. Runoff is assumed to be unaffected by slope steepness on rangelands not recently treated with mechanical practices such as ripping. The effect of slope on runoff and erosion as a result of mechanical disturbance is considered in the support practices factor (P) (ch. 6).

McIsaac et al. (1987a) examined soil-loss data from several experiments on disturbed lands at slopes of up to 84%. They recommended an equation of a form similar to that of equations [4-4] and [4-5]. Their coefficient of sin θ was a range that encompassed equations [4-4] and [4-5]. Thus these equations should also be valid for disturbed-land applications.

Equations [4-4] and [4-5] are not applicable to slopes shorter than 15 ft. For those slopes, the following equation should be used to evaluate S (McCool et al. 1987):

$$S = 3.0 (\sin \theta)^{0.8} + 0.56 \qquad [4\text{-}6]$$

This equation applies to conditions where water drains freely from the end of the slope.

For the slope steepness factor given by equation [4-6], it is assumed that rill erosion is insignificant on slopes shorter than 15 ft and that interrill erosion is independent of slope length. Therefore, equation [4-6] should not be applied to slopes where rill erosion is expected to occur. Rill erosion is assumed to begin with a slope length of 15 ft, although it will occur on shorter slopes that are especially susceptible. Conversely, rill erosion will not begin until longer slope lengths are reached on soils that are consolidated and resistant to detachment by flow.

When recently tilled soil is thawing, in a weakened state, and subjected primarily to surface flow, the following equations for S of McCool et al. (1987, 1993) should be used:

$$S = 10.8 \sin \theta + 0.03 \qquad s < 9\% \qquad [4\text{-}7]$$

$$S = (\sin \theta / 0.0896)^{0.6} \qquad s \geq 9\% \qquad [4\text{-}8]$$

Equations [4-7] and [4-8] were used to construct table 4-4.

TOPOGRAPHIC FACTOR (LS)

The combined LS factor in RUSLE represents the ratio of soil loss on a given slope length and steepness to soil loss from a slope that has a length of 72.6 ft and a steepness of 9%, where all other conditions are the same. LS values are not absolute values but are referenced to a value of 1.0 at a 72.6-ft slope length and 9% steepness.

Procedures are developed in this section for predicting soil loss on uniform slopes, where steepness is the same over their entire length; on irregular or nonuniform slopes that may be concave, convex, or complex; and on a particular segment of a slope.

LS Factor Values for Uniform Slopes

Tables 4-1, 4-2, 4-3, and 4-4 give LS values for uniform slopes. These tables should be used for RUSLE-type slopes with a fairly uniform surface. Table 4-1 is used for rangeland and pasture where the ratio of rill to interrill erosion is low. Table 4-2 is used for cropland where the ratio of rill to interrill erosion is moderate. Table 4-3 is used for construction sites where the ratio of rill to interrill erosion is high and the soil has a strong tendency to rill. Table 4-4 is used for thawing soil where most of the erosion is caused by surface flow.

In tables 4-1, 4-2, and 4-3 for slopes longer than 15 ft, S is calculated from equations [4-4] and [4-5]. For slope lengths of 3-15 ft and steepness greater than or equal to 9%, LS values were calculated for the 3-ft slope length using the short-slope equation [4-6] for S and equations [4-3], [4-2], and [4-1] with λ = 15 ft for L. Then for a given slope length of 3-15 ft and a given steepness, a linear relationship (based on the logarithm of length) was used to interpolate between the logarithm of LS at 3 ft and the logarithm of LS at 15 ft to provide intermediate LS values. For slopes of less than 9%, equation [4-4] was used for S, and equations [4-3], [4-2], and [4-1] with λ = 15 ft were used for L. The short-slope equation [4-6] was not used because for very low slopes, the criterion of free draining would not be met. The inapplicability of equation [4-6] is illustrated by the fact that for very low slopes, the use of equation [4-6] indicates a larger LS value at 3 ft than does the use of equation [4-4] at 20 ft.

The range of LS values for slope lengths of 15-1,000 ft is much greater in table 4-3 than in table 4-1, indicating that the range in L is smaller when interrill erosion is dominant than when rill erosion is dominant. Use of the

72.6-ft slope length and 9% steepness as unit conditions in RUSLE leads to the unexpected result that LS values on short slopes for highly erodible conditions (table 4-3) are smaller than those for less erodible conditions (table 4-1). The difference in overall soil loss is accounted for in the K and C factors. Conditions where soil loss varies little with slope length generally have relatively low C-factor values: less than 0.15. Conditions where soil loss varies greatly with slope length typically have high C-factor values. No LS values for slopes shorter than 15 ft are given in table 4-4. At this time, there are no data to use to develop relationships for short slopes under thawing soil conditions.

Irregular and Segmented Slopes

The shape of a slope affects the average soil loss and the soil loss along the slope. For example, the average soil loss from a convex slope can easily be 30% greater than that for a uniform slope with the same steepness as the average steepness of the convex slope. The difference in soil loss is much greater for maximum erosion on the slopes. The average erosion on a concave slope that does not flatten enough to cause deposition is less than that on a uniform slope that is equivalent to the average concave-slope steepness. Maximum erosion along a concave slope, which occurs about one-third of the way along the slope, may nearly equal the maximum erosion on a uniform slope. Therefore, when the slope shape is significantly curved, use of the procedure for an irregularly shaped slope (outlined below) should be considered (Foster and Wischmeier 1974).

If a nonuniform slope of unit width is broken into a number of segments, each with similar characteristics, an equation for sediment yield from the ith segment is (Foster and Wischmeier 1974)

$$E_i = RK_iC_iP_iS_i \left(\lambda_i^{m+1} - \lambda_{i-1}^{m+1}\right) / (72.6)^m \qquad [4\text{-}9]$$

where

E_i = sediment yield from ith segment from top of slope,
R = rainfall and runoff factor,
K_i = soil erodibility for ith segment,
C_i = cover-management factor for ith segment,
P_i = support practice factor for ith segment,
S_i = slope steepness factor for ith segment, and
λ_i = length (ft) from top of slope to lower end of ith segment.

The soil loss per unit area, A_i, for the ith segment is then the sediment yield from that segment divided by the segment length, as follows:

$$A_i = RK_iC_iP_iS_i\left(\lambda_i^{m+1} - \lambda_{i-1}^{m+1}\right) / \left(\lambda_i - \lambda_{i-1}\right) (72.6)^m \qquad [4\text{-}10]$$

The term $S_i \left(\lambda_i^{m+1} - \lambda_{i-1}^{m+1}\right) / \left(\lambda_i - \lambda_{i-1}\right) (72.6)^m$ in equation [4-10] is the effective LS for the segment.

These relationships are applicable to any slope that meets the criteria for the application of RUSLE. The slope segments can be of unequal length. Computations with unequal slope lengths are most easily handled with a digital computer, for example, by use of the RUSLE computer program. However, to illustrate application of the method, slopes of equal segment length will be used. The term for effective segment LS becomes

$$\begin{aligned} LS_i &= S_i\left\{(ix)^{m+1} - [(i-1)x]^{m+1}\right\} / \left[ix - (i-1)x\right] (72.6)^m \\ &= S_i x^m \left[i^{m+1} - (i-1)^{m+1}\right] / (72.6)^m \end{aligned} \qquad [4\text{-}11]$$

where

LS_i = effective LS for ith segment, and
x = length in ft of each segment.

An additional relationship that proves useful is the soil loss per unit area, A_i, from any segment of a uniform slope, as follows:

$$A_i = RK_iC_iP_iS_i\left\{(ix)^{m+1} - [(i-1)x]^{m+1}\right\} / (72.6)^m \; x \qquad [4\text{-}12]$$

The total soil loss per unit area from a uniform slope of n segments of length x is

$$A = RKCPS(nx)^m / (72.6)^m \qquad [4\text{-}13]$$

If equal RKCP values along the slope are assumed, the ratio of soil loss from any segment to soil loss from the total slope is

$$A_i/A = \left\{ \left[(ix)^{m+1} - ((i-1)x)^{m+1}\right] / (72.6)^m \, x \right\} \cdot \left\{(72.6)^m/(nx)^m\right\}$$
$$= \left[i^{m+1} - (i-1)^{m+1}\right] / (n)^m \qquad [4\text{-}14]$$

Values of A_i/A for a range of values of m appear in table 4-6.

The simplest irregular-slope case is for soil and cover to be constant along the slope. To apply the irregular-slope procedure, the convex, concave, or complex slope is divided into equal-length segments and the segments are listed in the order in which they occur on the slope, beginning at the upper end (as shown in table 4-7). The number of segments depends on how many are required to treat each segment as uniform for practical purposes. In many situations, three segments are sufficient, and more than five are seldom needed.

The segments and their slopes are listed in order from the top of the slope, columns 1 and 2 of table 4-7. Then the LS values for the entire slope length at the segment slopes are selected from tables 4-1, 4-2, 4-3, or 4-4 and are listed in column 3. In this example, a moderate ratio of rill to interrill erosion is assumed; thus table 4-2 is used. The ratio of soil loss from the segment to total soil loss is selected from table 4-6, based on the m value from table 4-5, and listed in column 4. Interpolation may be required. (If the evaluation is from a thawing soil, an m value of 0.5 is used.) Column 5 is the product of columns 3 and 4 divided by the number of segments. The total of the values in column 5 is the LS value for the entire slope. The segment LS is given in column 6 as the product of columns 3 and 4. This value will predict average soil loss in a given segment.

In this example, the LS value that gives the average soil loss for the convex slope is 3.76 versus a value of 2.84 for a 400-ft-long uniform slope with a gradient of 10%, the average steepness of the convex slope. Average soil loss on the convex slope is about 32% greater than that on the uniform slope.

The maximum erosion in this example occurs at the end of both the uniform and convex slopes. From table 4-7, the maximum segment LS is 7.58 for the convex slope and (2.84 x 1.38 =) 3.92 for the uniform slope (enter table 4-6 with an exponent value of 0.52 for segment 3). That is, soil loss over the lower third of the convex slope is almost double that for the lower third of the uniform slope.

For a concave slope of the same length with the segments in reverse order, the values in column 3 would be listed in reverse order. The data for a concave slope are given in table 4-8. The weighted average LS for the concave slope is about 15% smaller than that for an equivalent uniform slope. The maximum soil loss for a segment, as indicated by the segment LS values in column 6, is greatest from the middle segment of the slope. Maximum erosion on this segment is about 76% of maximum erosion on the lower length of the uniform slope. Average soil loss on the concave slope is about 85% of that on the uniform slope.

CHANGES IN SOIL TYPE OR COVER ALONG THE SLOPE

The procedure for irregular slopes can include the evaluation of changes in soil type along a slope. The values in column 5 of table 4-7 or 4-8 are multiplied by the respective values of the soil erodibility factor (K) before summing. The procedure is illustrated in table 4-9. In the example, by use of the data from table 4-7, the erosion on the last segment is seen to be 14 times that on the first segment, whereas it was only 10 times that when K was uniform along the convex slope. This example illustrates how erosion can be great if an erodible soil occurs on the lower end of a convex slope. Average soil loss for the convex slope, based on the sum of values in column 6, is 45% greater than that estimated for the average K (0.32) on an equivalent uniform slope.

Within limits, the procedure can be further extended to account for changes in the C and P factors along the slope by adding a column of segment C and P values. The procedure applies to the segments experiencing net erosion but not to the segments experiencing net deposition. The amount of deposition cannot be estimated by RUSLE.

The soil loss from any segment of a slope can be estimated by the irregular-slope procedure previously presented (column 6 in tables 4-7 and 4-8 is the segment LS). This value can be used with the pertinent RKCP value for the slope to estimate average soil loss from the particular segment. Similarly, column 7 in table 4-9 is the segment KLS and can be used with the RCP value for the slope to estimate average soil loss from the particular segment.

ALTERNATIVE METHOD FOR ESTIMATING LS FOR A SEGMENT

One application of the irregular-slope procedure is to estimate soil loss on a slope segment and compare that against a soil-loss-tolerance value. The irregular-slope procedure was illustrated previously to show how average erosion for segments along a slope can be computed.

A modification of the procedure can also be used. The slope is divided into equal-length segments like the three segments for the convex slope in table 4-7. Assume that a soil-loss estimate is needed for segment 3. Find the LS value from table 4-2 for a uniform slope having the steepness of the segment and total slope length to the lower end of the segment (400 ft). In this example, this LS value is 5.34. Multiply this value by the soil loss factor, 1.42, in table 4-6 using the value for the third segment in a three-segment slope. The product is 7.58, which is the LS value to use for computing erosion for the segment.

Computation of LS for the second segment requires obtaining the LS value for the uniform slope based on the segment steepness and the length to the lower end of the particular segment (267 ft). The LS value is 2.29 in this example. The third segment has no effect on what happens on the upslope segments; when the user is working on the second segment with this approach, the problem becomes a two-segment slope. Therefore, the factor value, 1.30, chosen from table 4-6 is for the end segment of a two-segment slope. The LS for the second segment is (2.29 x 1.30 =) 2.98, which is the same value obtained earlier in table 4-7.

RELATION OF SOIL-LOSS-TOLERANCE VALUES TO SEGMENT EROSION

Soil-loss-tolerance values given in soil surveys are based on average soil loss along a uniform slope (Schertz 1983). Even on a uniform slope, soil loss on the lowest segment of the slope may be as much as 70% greater than the average value for the slope. Slope-average soil-loss-tolerance values must first be adjusted before soil-loss values for segments along an irregular slope are compared to them. This adjustment takes into account the position on the slope and is made by multiplying the slope-average soil-loss-tolerance value by soil-loss-factor values from table 4-6. The procedure is illustrated for a uniform slope on cropland where RKCP = 1.0 is assumed and the soil-loss- tolerance value, T, is 2.0 ton· acre^{-1}· yr^{-1}. The adjusted soil-loss-tolerance values for three segments along a 10% uniform slope of 400-ft length are 2.0 x 0.57 = 1.14 ton · acre^{-1}· yr^{-1} for segment 1, 2.0 x 1.05 = 2.10 ton · acre^{-1}· yr^{-1} for segment 2, and 2.0 x 1.38 = 2.76 ton· acre^{-1}· yr^{-1} for segment 3. The soil-loss-adjustment factor for each segment is determined by entering table 4-5 with the appropriate slope and rill to interrill ratio, obtaining an m value (0.52 for a 10% slope and moderate rill/interrill ratio), and then selecting the appropriate factor for each segment from table 4-5. In this example, interpolation is required. The average soil loss for this slope is the product of (LS)(RKCP) or (2.84)(1.0) = 2.84 ton · acre^{-1}· yr^{-1}. Soil-loss values along the slope are found by multiplying this value by the same factor values from table 4-6 that are used to adjust T values for position on the slope. These products give the values of 1.62, 2.98, and 3.92 ton· acre^{-1}· yr^{-1} for segments 1, 2, and 3, respectively. The soil-loss values are now uniform with respect to the adjusted soil-loss-tolerance values along the slope.

For the convex slope in table 4-7, the initial adjusted T values are 1.28, 2.10, and 2.84 ton· acre^{-1}· yr^{-1} for segments 1, 2, and 3, respectively. The mean of these initial segment values is 2.07 ton· acre^{-1}· yr^{-1}, greater than the tolerance for a uniform slope of steepness equal to the average of the segment steepness. Therefore, the user should multiply each segment adjusted T value by the ratio of 2.00/2.07 = 0.96 to produce an average slope tolerance of 2.0 ton· acre^{-1}· yr^{-1}. The final segment adjusted tolerance values are then 1.23, 2.03, and 2.74 ton· acre^{-1}· yr^{-1} for segments 1, 2, and 3, respectively, whereas the soil-loss values for the segments are 0.72, 2.98, and 7.58 ton· acre^{-1}· yr^{-1}. The user should note that soil loss on the upper segment is much less than the adjusted T value;

therefore, erosion on the first segment is considered to be within allowable limits. However, the soil loss on the last segment is much greater than the adjusted T value, so soil loss is judged to be excessive on the last segment of the convex slope.

For the concave slope in table 4-8, the initial adjusted T values are 1.06, 2.10, and 2.60 ton· acre^{-1}· yr^{-1} for segments 1, 2, and 3, respectively. The mean of these initial segment values is 1.92 ton· acre^{-1}· yr^{-1}, less than the tolerance for a uniform slope of steepness equal to the average of the segment steepness. Therefore, the user should multiply each initial segment adjusted T value by the ratio of 2.00/1.92 = 1.04 to produce an average slope tolerance of 2.00 ton· acre^{-1}· yr^{-1}. The final segment adjusted tolerance values are then 1.10, 2.19, and 2.71 ton· acre^{-1}· yr^{-1} for segments 1, 2, and 3, respectively, whereas the soil losses along the slope are 2.83, 2.98, and 1.47 ton· acre^{-1}· yr^{-1}. The soil-loss values for the upper two segments exceed the adjusted T value, and management practices are chosen to reduce these values to the adjusted T value.

GUIDES FOR CHOOSING SLOPE LENGTHS

In training sessions, more questions are asked about slope length than about any other RUSLE factor. Slope length is the factor that involves the most judgment, and length determinations made by users vary greatly. Figure 4-1 illustrates the major slope-length situations that are found in the field. However, additional guides are useful, especially for rangelands and forest lands.

Actually, an infinite number of slope lengths exist in the field. To apply RUSLE, erosion can be calculated for several of them and the results averaged according to the area represented by each slope length. Sometimes a particular position on the landscape is chosen as the location for a slope length. To establish the ends of the slope length, the user walks upslope from that position, moving perpendicular to the contour, until the origin of overland flow is reached. Often this point is not at the top of the hill but at a divide down the nose of a ridge (illustrated in fig. 4-2).

The lower end of the slope length is located by walking downslope perpendicular to the contour until a broad area of deposition or a natural or constructed waterway is reached. These waterways are not necessarily eroded or incised channels, and this lack of channels can make it difficult to determine the end of slope. One aid is to visualize the locations on the landscape where eroded channels or gullies would naturally form. Figure 4-2 illustrates one area where such waterways are located.

If a slope flattens enough near its end, deposition may occur. When erosion and deposition rates are low and erosion has not recently occurred, deposition begins at the point where slope has decreased to about 5%. Deposition does not necessarily occur everywhere a slope flattens.

Sometimes slope decreases as shown in figure 4-3. On those slopes, deposition can end and erosion can occur on the lower end of the slope. To approximate where deposition ends, the user should do the following: First calculate the ratio of the slope steepness at the end to the slope steepness where deposition begins. Subtract that ratio from 1.0, multiply that difference by the distance from where deposition begins to the end of the slope, and add that product to the distance where deposition begins. To illustrate, assume a 400-ft-long slope with a 2% slope at the end. Assume that deposition begins at 250 ft, where the slope is 5%.

The ratio of the slope steepness is 0.40, and the distance from where deposition begins to the end of the slope is 150 ft. The location where deposition ends is 250+(1.0-0.40)(150) = 340 ft. This procedure, an approximation to results of CREAMS simulations, is for gently curving slopes. When the change of slope is very abrupt, deposition may occur over only a 20- to 40-ft distance.

In the case just described, the water is assumed to flow uniformly as broad sheet flow over the depositional area and onto the downslope eroding area, or from a relatively flat area at the top of the slope onto a steep area. The distance to the origin of flow must be considered in computing soil loss. To compute average erosion for the slope, only the segments experiencing erosion are used in the computations. In this case, RUSLE does not compute sediment yield for the slope. Of course, a diversion ditch across the slope would end the slope length and a new one would begin immediately below the ditch. Also, broad sheet flow does not occur in natural riparian vegetation.

All the situations discussed previously have been simplified. A few specific examples may help the user visualize field slope length. Figure 4-4 is a photo of rill erosion on a steep small-grain field in the Pacific Northwest. Although the small watershed is concave, a relatively straight, closely spaced rill pattern has resulted on most of the slope. The pattern is from the top to the bottom of the slope or to the flow concentration at the bottom of the swale. For these particular conditions alone, slope length can be obtained fairly accurately from U.S. Geological Survey (USGS) 7½-min contour maps with a 20-ft contour interval.

Figure 4-5A shows a row cropped watershed after a series of storms during the early stages of crop growth. The concentrated flow channels are spaced rather closely together, leading to fairly short slope lengths for RUSLE computation. Even with the 1-ft contour interval map in figure 4-5B, realistic slope lengths are difficult to estimate without the aerial photograph for guidance.

The effect of different crop managements on the upper and lower portions of a slope is illustrated in figure 4-6. The boundary between the two managements occurs at about the middle of the slope. Presence of the snow drift on the upper part of the slope causes measured slope length to be a poor predictor of soil loss; the distance to the top of the ridge does not provide a realistic estimate of the length that actually provides the snowmelt. Other than the area where a drill wheel track diverts the runoff and creates a flow concentration, the rill pattern is fairly straight and closely spaced. The bottom of the slope where the runoff collects into a larger channel, or deposits sediment at the toe of the slope, is not shown.

Determination of slope lengths on rangeland and forested watersheds is generally more difficult than determination of slope lengths on cropland because of the permanent vegetation and the frequently irregular topography of the former. Three selected small watersheds from the Lydle Gulch and Blacks Creek drainages east of Boise, Idaho, are shown on a portion of the 7½-min USGS quad sheet for Indian Creek Reservoir in figure 4-7. Figure 4-8 is an example of a steep rangeland watershed with little shrubby permanent vegetation. Because of the steepness of the watershed, there are few depositional areas. However, the hillslopes are rough and the ridgetops rounded, slightly complicating the determination of slope length. Even for this simple case, the determination of slope lengths by inspecting a 7½-min quad sheet with a 20-ft contour interval would lead to slope lengths longer than those determined in the field or from a low-level aerial photograph. The slopes of the transects are irregular, but to conserve space in this publication, LS in figure 4-8 was calculated from the total horizontal slope length and total fall.

Figure 4-9 is a photograph of a more complex rangeland watershed. The slope is flatter than that on the area in figure 4-8, and numerous large mounds make the topography very uneven. The drainage channels are rather broad, vegetated, and poorly defined, and the watershed boundaries are difficult to delineate. The shrubby permanent vegetation is more prevalent than that on figure 4-8, obscuring the flow paths on aerial or oblique photographs. Slope lengths are best determined by field inspection. The use of maps with even a 2-ft contour interval will lead to slope lengths much longer than those determined in the field.

The complex and irregular rangeland watershed that appears on figure 4-10 exemplifies conditions frequently found in the field. The watershed is of low slope, has undulating topography with numerous hummocks or mounds, and has shrubby permanent vegetation that masks the drainages. The determination of slope lengths even by field inspection is difficult, particularly when the grass cover is at its maximum and not yet reduced by grazing.

Figure 4-10 shows a complicated flow system where shrubs, grass clumps, and litter are isolated in hummocks scattered over rangeland, and in effect where water flows down a local slope to a locally concentrated flow area. This flow system may be treated as follows: If flow patterns around and among the hummocks are basically parallel, do not treat the flow concentrations as the end of a short slope length. Choose slope lengths by visualizing the surface as being smooth without the hummocks. If, however, major deposition occurs upstream of the hummocks and/or the flow pattern meanders without a direction, treat the slope lengths as short. Note that on figure 4-10, some of the transects pass through clumps of shrubby vegetation.

ACKNOWLEDGMENT

The assistance of Clifton W. Johnson (retired), hydraulic engineer, USDA-ARS, Northwest Watershed Research Center, Boise, ID, in obtaining photographs and field documentation is gratefully acknowledged.

CHAPTER 5. CONTENTS

The C factor is used within both the Universal Soil Loss Equation (USLE) and the Revised USLE (RUSLE) to reflect the effect of cropping and management practices on erosion rates, and is the factor used most often to compare the relative impacts of management options on conservation plans. The C factor indicates how the conservation plan will affect the average annual soil loss and how that soil-loss potential will be distributed in time during construction activities, crop rotations, or other management schemes.

As with most other factors within RUSLE, the C factor is based on the concept of deviation from a standard, in this case an area under clean-tilled continuous-fallow conditions. The soil loss ratio (SLR) is then an estimate of the ratio of soil loss under actual conditions to losses experienced under the reference conditions. Work by Wischmeier (1975) and Mutchler et al. (1982) indicated that the general impact of cropping and management on soil losses can be divided into a series of subfactors. Within RUSLE, this technique is used as modified by Laflen et al. (1985) and Weltz et al. (1987). In this approach the important parameters are the impacts of previous cropping and management, the protection offered the soil surface by the vegetative canopy, the reduction in erosion due to surface cover and surface roughness, and in some cases the impact of low soil moisture on reduction of runoff from low-intensity rainfall. As used in RUSLE, each of these parameters is assigned a subfactor value, and these values are multiplied together to yield a SLR.

An individual SLR value is thus calculated for each time period over which the important parameters can be assumed to remain constant. Each of these SLR values is then weighted by the fraction of rainfall and runoff erosivity (EI) associated with the corresponding time period, and these weighted values are combined into an overall C factor value.

USE OF TIME-VARYING OR AVERAGE ANNUAL VALUES

For areas such as pasture or rangeland that have reached a relative equilibrium, the parameters used in computing SLR values may change very slowly with time, so calculated SLR values will also change little. In these cases, it may prove adequate to calculate a C factor based on a single average SLR representing the entire year. RUSLE provides this option to simplify calculations, but this capability must be used with caution, as the result will no longer reflect changes in the climate's erosive potential through the year.

In almost all cropland scenarios and in many cases where rangeland or pasture are being managed, the crop and soil parameters change with time due to either specific management practices or natural cyclic effects such as winter knockdown and spring growth. This demands that the SLR values be calculated frequently enough over the course of a year or a crop rotation to provide an adequate measure of how they change. This is especially important because the erosion potential is also changing with time, as indicated by the EI distributions discussed in chapter 2. The calculated average annual soil loss should be high if a cropping or management scheme happens to leave the soil susceptible to erosion at a time of high rainfall erosivity. USLE incorporated this effect into calculations of SLR values based on crop-growth stages (Wischmeier and Smith 1978). These values were usually assigned based on tillage type, elapsed time since a tillage operation, canopy development, and date of harvest.

Following the lead of the USLE approach, RUSLE calculations are based on a 15-day time step. This means that SLR values are calculated every 15 days throughout the year, and that the important parameters are assumed to remain constant during those 15 days. In order to maintain a total of 24 periods in a year, the first 15 days of each month are placed in one period, and the remainder in another. Period lengths thus range from 13 days for the second period in February to 16 days for the second period in any month having 31 days.

If a management operation occurs within the period, the parameters can no longer be assumed constant; the half-month period is then broken into two segments and two SLR values are calculated. These segments can in turn be broken into smaller time increments by other management operations. A recalculation of the SLR can therefore be forced by either of two occurrences. The first is the end of a half-month period, because conditions are presumed to

have changed sufficiently to require new calculations. The other occurrence is any field operation or sudden climatic change that affects the soil/vegetation/ residue system, thereby changing the value of the SLR. These are handled by dividing the entire time period of interest into time *segments*. Each segment is bracketed by two *events*, which are defined as either a field operation or the beginning of a new half-month period. A segment can therefore range in length from 0 days (if two events occur on the same day) to a 16-day maximum if a month has 31 days and there are no field operations within a period. A zero-length segment is kept track of for accounting purposes, but requires no SLR calculation because there is no associated EI.

Calculations of the SLR for the average annual and time-varying approaches are the same and require the same input parameters; the difference lies in how often the calculation is performed. In the time-varying approach, the SLR value is calculated at a date in the middle of each time segment, and this value is then weighted by the percentage of EI associated with that segment. In the average annual approach, everything is assumed constant, so the calculation is made once.

COMPUTATION OF HALF-MONTH CLIMATE VARIABLES

Calculation of the time-varying SLR requires values for the rainfall, average air temperature, and fraction of total EI associated with each of the half-month periods throughout the year. This forces additional calculations in order to get smooth half-month values when the available data are supplied on a monthly basis.

Known: M, (M-1), and (M+1), which are monthly values for the month of interest (M), the previous month (M-1), and the subsequent month (M+1).

Wanted: P_1 and P_2, which are calculated values of the variable for the first and second half-month periods in the month, respectively.

For the temperature variables,

$$P_1 = 2 \cdot M \left(\frac{.75(M-1)+.25(M+1)}{(M-1)+(M+1)} \right) ;$$

$$P_2 = 2 \cdot M \left(\frac{.25(M-1)+.75(M+1)}{(M-1)+(M+1)} \right) \qquad [5\text{-}1]$$

This works out so that the average of the two period temperatures is equal to the monthly average. For rainfall,

$$P_1 = M \left(\frac{.75(M-1)+.25(M+1)}{(M-1)+(M+1)} \right) ;$$

$$P_2 = M \left(\frac{.25(M-1)+.75(M+1)}{(M-1)+(M+1)} \right) \qquad [5\text{-}2]$$

This leaves the sum of the two period rainfalls equal to the monthly rainfall.

COMPUTATION OF SOIL-LOSS RATIOS

Based on new descriptions of cropping and management practices and their influence on soil loss (Laflen et al. 1985), soil-loss ratios are computed as

$$SLR = PLU \cdot CC \cdot SC \cdot SR \cdot SM \qquad [5\text{-}3]$$

where SLR is the soil-loss ratio for the given conditions, PLU is the prior-land-use subfactor, CC is the canopy-cover subfactor, SC is the surface-cover subfactor, SR is the surface-roughness subfactor, and SM is the soil-moisture subfactor.

Each subfactor contains cropping and management variables that affect soil erosion. Individual subfactors in equation [5-3] are expressed as functions of one or more variables, including residue cover, canopy cover, canopy height, surface roughness, below-ground biomass (root mass plus incorporated residue), prior cropping, soil moisture, and time.

RUSLE uses a CROP database to store the values required to calculate the impact on soil loss of any vegetation within the management plan. These user-defined sets of values specify the growth characteristics of the vegetation, the amount of residue the vegetation will produce, and the characteristics of that residue. The program uses that information to calculate the change with time of the variables listed above and their impact on the subfactors. RUSLE contains another database to store user-supplied information defining the impacts of management operations on the soil, vegetation, and residues, and uses that information to modify the variables accordingly. The relationships of these databases to the subfactor calculations are explained in more detail in the following sections. Published values used in defining some basic crop and operation database sets are shown in tables 5-1 through 5-7. These values are not suitable for all conditions and will need to be adjusted accordingly. This adjustment can be readily accomplished within the RUSLE program by use of procedures described in chapter 7, using estimates as described in appendix D.

The RUSLE program contains a third database that represents the climate for the area of interest. This is important to the C-factor calculations in two ways: first,

the EI distribution within the database set is used to weight each SLR value in calculating the overall C-factor value. Second, the set also contains temperature and rainfall data, which are needed to calculate the rate of residue decomposition. Note that the climatic data are not used to modify the crop growth characteristics, because these are already defined in the crop database.

In addition to the databases, the RUSLE program contains a module that is important to several of the subfactor calculations. This is a subroutine that calculates the rate of residue decomposition as a function of residue characteristics and climate variables. Based on work by Stott et al. (1990) and Stott and Barrett (1991), this is derived as a first-order rate equation, and is calculated as

$$M_e = M_b \exp(-a D) \quad [5\text{-}4]$$

where M_e is residue mass at end of a time period, M_b is mass at beginning of the period, D is period length in days, and

$$a = p \cdot [\text{minimum of } (W, F)] \quad [5\text{-}5]$$

where p is a coefficient depending on residue characteristics (taken from the CROP database), and W and F are precipitation and temperature factors defined subsequently. The database sets provided with the RUSLE program contain empirically derived values of p for specific crops; new values of p must be found either by experimentation or by modifying existing values to reflect known differences in decomposition rates. See appendix D for more information on this modification. The decomposition relationships continue with

$$W = \frac{R}{R_o} \quad [5\text{-}6]$$

and

$$F = \frac{2\left(T_a + A\right)^2 \cdot \left(T_o + A\right)^2 - \left(T_a + A\right)^4}{\left(T_o + A\right)^4} \qquad [5\text{-}7]$$

where R is rainfall in the half-month period, R_o is minimum average half-month rainfall required for optimum decomposition, T_a is average temperature in the half-month period, T_o is optimum temperature for decomposition, and A is a coefficient used to describe the shape of the decomposition response to temperature. Calibration of these constants against decomposition data yields the values $R_o = 2.6$ in, $T_o = 90$ °F, and $A = 46$ °F. These values provide decomposition rates that seem to accurately reflect data from various regions of the United States, including the Pacific Northwest, Texas, Indiana, and Mississippi. The corresponding values of the crop decomposition constant p are shown in table 5-1. There are not sufficient data to distinguish between the decomposition rates of residue under surface and subsurface conditions, so the values shown in table 5-1 can be used for both. These values can be changed when further tests yield more complete information on p values for surface and subsurface conditions. The program treats the two values separately to allow for these changes.

Because SLR values are for half-month periods, they are calculated for the average residue level during the period, which is defined as

$$M_a = \left[\frac{M_b}{a\ D}\right]\left[\ 1\ -\ \exp(-a\ D)\right] \qquad [5\text{-}8]$$

where M_a is average residue mass during the time period, and the other terms are as defined above. Note that D may be up to 16 days but can be smaller if the half-month period is divided by one or more management operations. Note also that the units of mass need not be specified as long as they are consistent. The RUSLE program calculates residue mass in units of (lb · acre^{-1}).

The RUSLE program separately calculates the amount of residue both on the surface and within the soil, and decomposes each according to climatic conditions and residue characteristics. It also accounts for additions of residue to the surface by harvests, senescence, or other management operations, and for incorporation of residue by tillage operations.

The calculations within RUSLE include three additional assumptions concerning residue incorporation and decomposition. First, it is assumed that residue incorporation cannot occur within a soil depth of less than 2 in, regardless of the depth of tillage defined for the field operation. Next, it is assumed that the residue is evenly incorporated throughout the depth of tillage. Finally, it is assumed that all subsurface residue will decompose at the same rate, without regard for the depth to which it is buried. While these assumptions are of limited validity, they provide an appropriate simplified basis on which to make the calculations.

The effectiveness of both surface and incorporated residues in controlling erosion rates has been found to depend on the mechanism by which the soil tends to erode. In general, soils that erode primarily through the formation of rills are substantially more protected by both surface and buried residues than are soils that erode primarily through sheet erosion in the interrill areas. Examples of soils that rill easily include those with naturally weak structure and those whose structure has been destroyed by disturbance and are in an unconsolidated state. Consolidated soils, or those with good structure, usually have a low ratio of rill to interrill erosion.

For permanent pasture or rangeland, the amounts of canopy cover, surface and subsurface residues, and root mass are relatively constant when compared to the widely varying amounts seen with most agronomic crops. This is especially true for permanent pasture or grassland, where the changes in residue and root mass are likely to be a small fraction of the total masses. If the assumption of constant values for these variables is thought to be adequate, RUSLE allows for calculation of the SLR values based on their average annual values. In this case, there are assumed to be no residue additions or decomposition. The program does allow for some disruption by tillage or other practices on a one-time basis and calculates an exponential decay of this effect.

Prior-Land-Use Subfactor (PLU)

The prior-land-use subfactor (PLU) expresses (1) the influence on soil erosion of subsurface residual effects from previous crops and (2) the effect of previous tillage practices on soil consolidation. The relationship is of the form

$$PLU = C_f \cdot C_b \cdot \exp[(-c_{ur} \cdot B_{ur}) + (c_{us} \cdot B_{us} / C_f^{c_{uf}})] \qquad [5\text{-}9]$$

where PLU is the prior-land-use subfactor (which ranges from 0 to 1), C_f is a surface-soil-consolidation factor, C_b represents the relative effectiveness of subsurface residue in consolidation, B_{ur} is mass density of live and dead roots found in the upper inch of soil (lb · acre^{-1} · in^{-1}), B_{us} is mass density of incorporated surface residue in the upper inch of soil (lb · acre^{-1} · in^{-1}), c_{uf} represents the impact of soil consolidation on the effectiveness of incorporated residue, and c_{ur} and c_{us} are calibration coefficients indicating the impacts of the subsurface residues.

The variable C_f expresses the effect of tillage-induced surface density changes on soil erosion. Tillage operations tend to break soil aggregate bonds, increasing the potential for erosion. This is reflected in the lower erosion rates associated with the undisturbed soils of rangeland or no-till systems. Based on the work of Dissmeyer and Foster (1981), the value of C_f for freshly tilled conditions is 1.0. If the soil is left undisturbed, this value decays exponentially to 0.45 over 7 yr, or over some other length of time specified by the user. The impact of a field operation on this factor is determined by the portion of the surface disturbed. For example, if a planting operation disturbs only 30% of the surface that had already consolidated to the point where $C_f = 0.6$, then 70% of the field would have a value of $C_f = 0.6$, and the disturbed 30% would have a value of $C_f = 1.0$; the overall value would be $[(70\%)(0.6) + (30\%)(1.0)]/(100\%) = 0.72 = C_f$.

The B_u variables are used to calculate the impact on erosion rates of live and dead roots and incorporated residue. The effectiveness of such materials can take two forms. First, roots and residue can control erosion directly by physically binding soil particles together and by acting as mechanical barriers to soil and water movement. Second, roots and residue exude binding agents and serve as a food source for microorganisms that produce other organic binding agents. These serve to increase soil aggregation and thereby reduce its susceptibility to erosion.

It is the subsurface biomass (incorporated residue and roots) near the surface that is most effective in resisting erosion, so the values of B_u are in terms of biomass density (lb · acre^{-1} · in^{-1}) in the top inch of soil. The depth of soil that has these biomass densities will be defined by the pattern of field operations. If the most recent operation affects 100% of the surface and has a disturbance depth of 6 in, the B_u values will be the subsurface biomass densities to a depth of 6 in. It is assumed in RUSLE that residue cannot be mixed into a soil depth of less than 2 in, which makes this the least depth to which the B_u values can apply.

The surface residue is assumed to be evenly incorporated into the soil to the depth of tillage, and the root mass at that depth is also assumed to be mixed in.

Inputs provide information on root mass to a depth of only 4 in, but the assumption of no roots below this will lead to incorrect dilution of the residue if mixing occurs to a depth greater than 4 in. RUSLE therefore includes the assumption that the soil depth of 4-8 in contains a root mass equal to 80% of that in the layer at 0-4 in. Note here that soil layers are defined not by soil characteristics or morphology, but by where the roots grow and how deeply the soil is disturbed.

This concept of the B_u values and soil layers can best be clarified with an example, beginning with 6,000 lb · acre^{-1} of surface residue and 1,000 lb · acre^{-1} of root mass in the top 4 in. This gives B_{ur} = 1,000/4 = 250 lb · acre^{-1} · in^{-1} throughout the top 4 in, a biomass density of (1,000 · 0.8)/(8-4) = 200 lb · acre^{-1} · in^{-1} for the layer at 4-8 in, and B_{us} = 0 because no surface residue has been buried. Assume then a field operation that disturbs 100% of the surface, leaves 70% of the surface residue on the surface, and has a tillage depth (and therefore an incorporation depth) of 6 in. Following the operation, there are two soil layers; the top layer is from the surface down to 6 in, below which is a layer from 6 to 8 in. The top layer has a total root mass of (250 · (4-0)) + (200 · (6-4)) = 1,400 lb · acre^{-1}, or B_{ur} = 1,400/6=233 lb · acre^{-1} · in^{-1}, while the bottom layer still has a root mass density of 200 lb · acre^{-1} · in^{-1}. The top layer also contains (6,000 · 0.3) = 1,800 lb · acre^{-1} of incorporated surface residue, leaving (6,000 · 0.7) = 4,200 lb · acre^{-1} on the surface, and yielding B_{us} = 1,800/6 = 300 lb · acre^{-1} · in^{-1}. If this is followed immediately with another tillage that disturbs 100% of the surface, leaves 75% of the residue on the surface, and has a tillage depth of 2 in, we end up with three soil layers: one from 0-2 in, one from 2-6 in, and one from 6-8 in. The top layer has a total root mass of 233 · 2 = 466 lb · acre^{-1} and a total incorporated residue of (300 · 2) + (4,200 · 0.25) = 1,650 lb · acre^{-1}, resulting in B_{ur} = 466/2 = 233 lb · acre^{-1} · in^{-1} and B_{us} = 1,650/2 = 825 lb · acre^{-1} · in^{-1}. The layers at 2-6 and 6-8 in will still have root mass biomass densities of 233 and 200 lb · acre^{-1} · in^{-1}, and incorporated biomass densities of 300 and 0 lb · acre^{-1} · in^{-1}, respectively.

The RUSLE program keeps track of the biomass in each soil layer, continuously adjusting the root mass and subsurface residue to account for additions and decomposition.

Additional complications arise when a field operation does not disturb 100% of the surface, because the residue incorporation and mixing will vary over the field. The program needs to account for the fact that some portions of the field will be protected by additional subsurface biomass, while other portions will not. As it handles the field operation for B_{ur}, the program calculates three values: one overall without considering spatial variability, one for just those areas with

the added incorporation and mixing, and one for the areas without the additional incorporation and mixing. Equation [5-9] is used to calculate the PLU values associated with each of these last two densities, which are then weighted by the associated surface fraction and added. This average PLU value is put back into equation [5-9] to calculate an equivalent weighted B_{ur}. This is divided by the first overall B_{ur}, which yields an adjustment ratio. Until it is changed by the next tillage operation, this ratio is used to adjust the calculated overall B_{ur} (which changes with residue decay and root growth); B_{ur} is multiplied by the ratio before it is put into equation [5-9]. This simplifies calculations during the time between operations by requiring only calculation of the overall B_{ur}, and by accounting for spatial variability with the adjustment ratio. If this procedure is followed, an operation that disturbs 100% of the surface simply yields an adjustment ratio of 1.0. A similar adjustment is used for B_{us}.

As an example of this adjustment, assume that an operation disturbs 20% of the surface, that in the disturbed area $B_{ur} = 500$ lb · acre^{-1} · in^{-1}, in the undisturbed area $B_{ur} = 200$ lb · acre^{-1} · in^{-1}, and that the overall $B_{ur} = 260$ lb · acre^{-1} · in^{-1}. If the first two values are put back into equation [5-9] with an assumed c_{ur} = 0.0014 acre · in · lb^{-1}, the weighted average PLU is PLU = (0.2 · 0.497) + (0.8 · 0.756) = 0.70. This corresponds to an equivalent density of 251 lb · acre^{-1} · in^{-1}, which yields an adjustment ratio of 251 / 260 = 0.97. This indicates that in this case the uneven residue incorporation is only slightly less effective at controlling erosion than if it were incorporated evenly.

The coefficients C_b, c_{ur}, c_{us}, and c_{uf} describe the relative effectiveness of subsurface biomass in reducing erosion. These were calibrated using information from Van Liew and Saxton (1983), values from table 5 and 5-D in Agriculture Handbook 537 (Wischmeier and Smith, 1978), and an extensive data set collected from a broad series of no-till experiments. This analysis yields C_b = 0.951, c_{ur} = 0.00199 acre · in · lb^{-1}, c_{us} = 0.000416 acre · in · lb^{-1}, and c_{uf} = 0.5. For soils that erode primarily as a result of rainfall and snowmelt on frozen or thawing soils (such as many in the Northwest Wheat and Range Region), subsurface residue has been found to be even more effective, yielding c_{ur} = 0.00398 acre · in · lb^{-1}, c_{us} = 0.000832 acre · in · lb^{-1}, and c_{uf} = 0.5.

The amount of incorporated residue is calculated from the additions of residue to the surface and its subsequent burial by tillage operations. The total subsurface biomass is made up of this incorporated surface residue (B_{us} in equation [5-9]), and the total live and dead root mass (B_{ur} in equation [5-9]). The program keeps track of the live roots as described later, and adds this amount to the root residue when the vegetation is killed. The root residue is decayed through use of the decomposition subroutine.

The impact of surface residue on soil organic matter is described by adding a portion of the decayed surface residue mass to the root-mass residue. Based on analysis of no-till erosion data, this fraction is defined as 0.5.

The amount of live roots in the top 4 in is usually taken directly from the CROP database set. The user is responsible for supplying these values, but estimates of root mass at various times in the growing season for selected agronomic crops are given in table 5-2, and suggested values for pasture and meadow crops are shown in table 5-3. In addition, the program assumes that the soil layer at 4-8 in will contain a root mass concentration equal to 80% of that in the top 4 in. This assumption is required to reflect the mixing of soil layers by tillage operations and the resulting redistribution of root mass.

For many rangeland conditions, values of live root mass are not available. Weltz et al. (1987) developed data for estimating root biomass on rangelands. The effective below-ground root biomass (B_b) is given as

$$B_b = B_a \cdot n_i \qquad [5\text{-}10]$$

where B_a is total average annual site production potential ($lb \cdot acre^{-1}$), and n_i is the ratio of effective root mass to annual site production potential. Suggested values of n_i for many plant communities in western U.S. rangelands and eastern pastures are found in table 5-4. Estimates of B_a can be made using standard production potential techniques, or by use of such guides as Natural Resources Conservation Service (NRCS) range-site descriptions.

On croplands, the amount of above- and below-ground biomass present at a given time depends on initial mass of the residue, root mass, fraction of crop residue incorporated by field operations, and decomposition rate of residue and roots. If the initial residue mass at harvest is not known, it can be estimated by multiplying the grain yield by the residue-to-yield ratio (table 5-1). The percentages of residue cover left on the soil surface after various field operations are shown in table 5-5. These values may vary considerably, depending on crop type, implement speed, and soil and residue conditions. If more than one type of residue cover exists on the surface, this percentage of each of the residues will be left after the field operation.

Canopy-Cover Subfactor (CC)

The canopy-cover subfactor expresses the effectiveness of vegetative canopy in reducing the energy of rainfall striking the soil surface. Although most rainfall intercepted by crop canopy eventually reaches the soil surface, it usually does so

with much less energy than does rainfall that strikes the ground without having been intercepted. The intercepted raindrops fracture into smaller drops with less energy, or drip from leaf edges, or travel down crop stems to the ground. The canopy-cover effect is given as

$$CC = 1 - F_c \cdot \exp(-0.1 \cdot H) \qquad [5\text{-}11]$$

where CC is the canopy-cover subfactor ranging from 0 to 1, F_c is fraction of land surface covered by canopy, and H (ft) is distance that raindrops fall after striking the canopy.

This relationship was given graphically by Wischmeier and Smith (1978) and is shown in figure 5-1 for several heights. It is based on the assumptions that the rainfall fraction intercepted by the canopy is equal to the fraction of the land surface beneath the canopy, and that any rainfall intercepted will leave the canopy at a height H (ft) with a mean drop diameter of 0.1 in. Although Quinn and Laflen (1983) found that stem flow was quite significant and that drop sizes differed from those assumed by Wischmeier and Smith, they did find that the relationship given in equation [5-11] was satisfactory for corn. Others have noted the different effects of various kinds of crops (Armstrong and Mitchell 1987, 1988; Finney 1984; Haynes 1940). Values for F_c and H for each crop are defined by the user. Some suggested values for several crops are listed in table 5-2.

Surface-Cover Subfactor (SC)

Surface cover affects erosion by reducing the transport capacity of runoff water (Foster 1982), by causing deposition in ponded areas (Laflen 1983), and by decreasing the surface area susceptible to raindrop impact. It is perhaps the single most important factor in determining SLR values. Surface cover includes crop residue, rocks, cryptogams, and other nonerodible material that is in direct contact with the soil surface (Simanton et al. 1984, Box 1981, Meyer et al. 1972). The effect of surface cover on soil erosion is given by

$$SC = \exp\left[-b \cdot S_p \cdot \left(\frac{0.24}{R_u} \right)^{0.08} \right] \qquad [5\text{-}12]$$

where SC is the surface-cover subfactor, b is an empirical coefficient, S_p is percentage of land area covered by surface cover, and R_u is surface roughness (in) as defined by equation [5-16].

The b value indicates the effectiveness of surface cover in reducing soil erosion. Laflen et al. (1980) and Laflen and Colvin (1981) found that b values ranged from 0.030 to 0.070 for row crops, and Dickey et al. (1983) found b values of 0.024-0.032 in a rainfall-simulation study on small grains. Within the Northwestern Wheat and Range Region, b values greater than 0.050 have been found for small grains. Simanton et al. (1984) recommended a b value of 0.039 for rangeland conditions with the impact of subsurface biomass removed. The relationship given in equation [5-12] is shown in figures 5-2 and 5-3 for several values of R_c and b.

Even though experimental data reflect a wide variance in b values, additional analyses using modeling techniques have indicated that the selection of an appropriate b value can be made more accurately if the dominant erosion process is known. When rill erosion is the primary mechanism of soil loss (such as for irrigation or snowmelt or for highly disturbed soils), b values should be about 0.050. Fields dominated by interrill erosion have a b value of around 0.025. For typical cropland erosion conditions, a b value of 0.035 is suggested. For rangeland and permanent pasture communities, the b value depends on the general type of vegetation.

The percentage of land area covered by residue can be estimated from residue weight by use of the relationship developed by Gregory (1982), as follows:

$$S_p = \left[1 - \exp \left(-\alpha \cdot B_s \right) \right] \cdot 100 \qquad [5\text{-}13]$$

where S_p is percent residue cover, α is the ratio of the area covered by a piece of residue to the mass of that residue (acre $\cdot$ lb^{-1}), and B_s is the dry weight of crop residue on the surface (lb $\cdot$ acre^{-1}). Typical values for α are given in table 5-1. Percent residue covers for various residue weights from the use of equation [5-13] are illustrated in figure 5-4. If more than one type of residue is present, the resulting total surface cover is calculated by modifying equation [5-13] as

$$S_p = \left\{ 1 - \exp \left[- \sum_{i=1}^{N} \left(\alpha_i B_{si} \right) \right] \right\} \cdot 100 \qquad [5\text{-}14]$$

where N is number of residue types and α_i is ratio of the area covered to the mass of that residue for each type encountered.

Within RUSLE, rather than entering a value for α, the program asks for residue weights associated with specific values of residue cover and calculates the corresponding α value. The program asks for residue weights at 30%, 60%, and 90% surface cover. Only one of these needs to be entered to calculate an α value. If more than one weight is entered, the program will calculate an α value for each and then average them.

Surface-Roughness Subfactor (SR)

Surface roughness has been shown to directly affect soil erosion (Cogo et al. 1984), and to indirectly affect it through the impact on residue effectiveness, implied in equation [5-12]. In either case, this is a function of the surface's random roughness, which is defined as the standard deviation of the surface elevations when changes due to land slope or nonrandom tillage marks (such as dead furrows, traffic marks, and disk marks) are removed from consideration (Allmaras et al. 1966). A rough surface has many depressions and barriers. During a rainfall event, these trap water and sediment, causing rough surfaces to erode at lower rates than do smooth surfaces under similar conditions. Increasing the surface roughness decreases the transport capacity and runoff detachment by reducing the flow velocity.

Roughness and cloddiness of soils also affect the degree and rate of soil sealing by raindrop impact. Soils that are left rough and cloddy typically have higher infiltration rates. Soils that are finely pulverized are usually smooth, seal rapidly, and have low infiltration rates (Sumner and Stewart 1992).

Values of random roughness vary, depending on the type and degree of surface disturbance. Typical values are given in table 5-5 for cropland and table 5-6 for rangeland conditions. These core values may be modified as described in appendix D. Roughness conditions for a given field operation may vary, depending on previous tillage, implement speed, and field conditions.

The impact of surface roughness on erosion is defined by a baseline condition, which sets SR equal to 1 for unit plot conditions of clean cultivation smoothed by extended exposure to rainfall of moderate intensity. These conditions yield a random roughness of about 0.24 in. This makes it possible to get SR values of greater than 1 for practices in which the soil is very finely pulverized and smoothed to a smaller random roughness, as might be the case for some rototilling operations or for repeated cultivations of silt loam soils under dry fallow conditions. For conditions in which repeated disturbance leaves a rougher surface (for example, for continuous cattle-grazing), this final roughness value of 0.24 can be replaced. Chapter 7 describes how this is done.

Except in these cases of fine pulverization, it is assumed that the roughness left after field operations is smoothed by the effects of raindrop impact, approaching a random roughness of 0.24 in as the cumulative rainfall increases. This smoothing is modeled by expanding on the relationship described by Onstad et al. (1984)

$$D_r = \exp\,[1/2\ (-0.14 \cdot P_t) + 1/2\ (-0.012 \cdot EI_t)] \qquad [5\text{-}15]$$

where D_r is the dimensionless roughness decay coefficient, P_t is the total inches of rainfall since the most recent operation that disturbed the entire surface, and EI_t is the total EI amount since that same operation. The value of D_r ranges exponentially from a value of 1.0 for a surface that has experienced no rainfall to a value approaching 0.0 for a surface that has experienced extensive rainfall and has lost most of its roughness.

If the initial roughness is defined as R_i (in inches), the surface roughness just before the current tillage operation (R_u) can be defined as

$$R_u = 0.24 + [D_r\ (R_i - 0.24)] \qquad [5\text{-}16]$$

where R_u is in inches. Since many field operations affect only a portion of the surface, R_u is also the roughness of the portion of the field that is undisturbed by the current field operation.

For that portion of the surface that is affected by the field operation, the resulting roughness has been found to be a function of subsurface biomass present in the top 4 in of soil. This relationship is described by

$$R_a = 0.24 + (R_t - 0.24)\{0.8\ [1 - \exp(-0.0012\ B_u)] + 0.2\} \qquad [5\text{-}17]$$

where R_a is the roughness after biomass adjustment (in), R_t is the original tillage roughness based on the assumption of ample subsurface biomass such as that found with high-yielding midwestern corn (in), and B_u is total subsurface biomass density in the top inch of soil (lb $\cdot$ acre^{-1} $\cdot$ in^{-1}). $B_u = B_{ur} + B_{us}$ as defined for equation [5-9]. Researchers in the Northwestern Wheat and Range Region indicate that the strong relationship of tillage roughness to subsurface biomass does not hold for their conditions (D.K. McCool, personal communication 1994). In that area of the country, equation [5-17] is not used, leaving simply $R_a = R_t$.

This adjusted tillage roughness is then combined with that of the undisturbed portion of the surface as

$$R_n = R_a F_d + R_u F_u \quad [5\text{-}18]$$

where R_n is the net roughness following the field operation (in). F_d and F_u are the fractions of the surface disturbed and undisturbed, respectively, so their sum equals one.

Similarly, the decay coefficient must be adjusted to reflect the fact that only a portion of the field was disturbed. This is done using the relationship

$$D_e = D_r F_u + 1.0 F_d \quad [5\text{-}19]$$

where D_e is the equivalent roughness decay coefficient. Under the assumption that the ratio EI_t/P_t before the operation equals that after, the P_t and EI_t values corresponding to the equivalent roughness decay coefficient are

$$P_t = -2 \cdot \ln(D_e) \Big/ \left[0.14 + 0.012 \left(\frac{EI_{t,b}}{P_{t,b}}\right)\right]; \quad [5\text{-}20]$$

$$EI_t = EI_{t,b} \cdot P_t/P_{t,b}$$

where the subscript b indicates the value before the operation.

These values for the decay coefficient and corresponding precipitation and EI describe a point on a new roughness decay curve, asymptotic to zero at infinite amounts of precipitation, and with a new initial roughness at $P_t = 0$. This new initial roughness R_i (in) is calculated from

$$R_i = 0.24 + \frac{(R_n - 0.24)}{D_e} \quad [5\text{-}21]$$

thereby completely describing the decay curve.

As the computer program steps through each time segment in the rotation, the total rainfall and EI since tillage (P_t and EI_t) are incremented by the amounts in that segment. The value of the roughness decay coefficient for that segment is then calculated by use of equation [5-15], and the current surface roughness is calculated by equation [5-16].

The surface random roughness is affected not only by the soil clods resulting from tillage, but also by the vegetation. If a site is clean-tilled and then left without human intervention, two things will happen: (1) the tillage roughness will decrease as defined previously, and (2) as the years go by, the vegetation will trend toward its climax community, with attendant roughness caused by protruding roots, soil mounded around old basal areas, rocks, and so on.

RUSLE assumes that the formation of this vegetative roughness follows a typical sigmoidal growth curve increasing from the minimum soil roughness (r_{min}, with a default of 0.24 in) to the total roughness when the soil is fully consolidated (r_{max}) over the time required for consolidation (t_{con}). At any time after disturbance (t_d), the relationship will be

$$r_{nat} = r_{min} + \left[\frac{(r_{max} - r_{min})}{1 + \exp \dfrac{\left(0.5 - \dfrac{t_d}{t_{con}}\right)}{0.1}} \right] \qquad [5\text{-}22]$$

where r_{nat} is the roughness caused by the community (in). For each time period the program calculates r_{nat}, and compares its value to R_u as calculated for that same period. If r_{nat} is larger, then R_u is set equal to r_{nat}. In general, this will only occur if the site has not been disturbed for quite some time.

The surface roughness subfactor is then

$$SR = \exp[-0.66(R_u - 0.24)] \qquad [5\text{-}23]$$

Soil-Moisture Subfactor (SM)

Antecedent soil moisture has a substantial influence on infiltration and runoff and hence on soil erosion. In general, antecedent moisture effects are an inherent component of continuous-tilled fallow plots, and these effects are reflected in variation in soil erodibility throughout the year. In most of the continental United States, soil moisture is usually high during susceptible crop stages in spring and early summer, when much of the erosion occurs. Hence the

antecedent soil moisture on cropped plots parallels that on the continuous-tilled fallow plots from which soil-erodibility factors are derived, so no adjustment is made for changes in soil moisture.

In the nonirrigated portions of the Northwestern Wheat and Range Region (Austin 1981) (including eastern Oregon, eastern Washington, and Idaho), soil moisture during critical crop periods depends on crop rotation and management. Winter wheat may be seeded after a previous crop of winter wheat, or after a more shallow-rooted crop, or after summer fallow. When a full year of fallow is used in the rotation, part of the moisture stored over the previous winter is retained in the soil profile. This is particularly true when an effective mulch system is used: either a loose soil and residue mulch in conjunction with a rodweeder, or an untilled residue mulch with direct stubble seeding. These systems are in contrast to continuous cropping, in which soil moisture is at or below the wilting point in the fall before the fall and winter precipitation. Addition of a soil-moisture subfactor (SM) is suggested for this region of the Northwestern Wheat and Range Region (McCool, personal communication 1994). SM reflects these dry fall conditions and the increase in soil moisture over the winter. The soil moisture decrease over the summer depends on the crop rooting depth and soil depth, and the soil moisture replenishment depends on the precipitation amount and soil depth.

When the soil profile is at or near field capacity, SM is 1.0 (such as on April 1 of fig. 5-5), indicating response equivalent to that of a continuous-fallow plot. When the profile is near wilting point to a 6-ft depth, the SM value is 0 (as on September 1 in fig. 5-5), indicating that no runoff and erosion are expected. This assumes that infiltration is not limited by surface conditions. SM increases over the winter from October 1 to March 31. Suggested replenishment-rate relationships are given in figure 5-6. Growing-season (April 1 to July 31) depletion rates for typical crops appear in table 5-7. These relationships and values are typical and may need adjustment for shallow-soil conditions or other considerations.

COMPUTATION OF C FACTOR

Once the SLR's have been calculated for each time interval, they are multiplied by their corresponding percentage of annual EI (Wischmeier and Smith 1978) as seen in table 2-1. These values are then summed and divided by the total percentage of annual EI value for the entire time period being investigated, as

$$C = \left(SLR_1\ EI_1 + SLR_2\ EI_2 + \ldots\ SLR_n\ EI_n\right) / EI_t \qquad [5\text{-}24]$$

where C is average annual or crop value, SLR_i is the value for time period i, EI_i is percentage of the annual or crop EI occurring during that time period, n is number of periods used in the summation, and EI_t is sum of the EI percentages for the entire time period.

For those systems where conditions are not rapidly changing (such as for rangeland, or continuous pasture or meadow), the PLU, CC, SC, and SR subfactor values are assumed to be annual averages, and are simply multiplied together to yield the overall C-factor value. If the assumption of nearly steady-state conditions does not hold, the weighted procedure used for cropland is more appropriate.

COMPUTATION OF C FACTORS FOR SINGLE DISTURBANCES AND FOR ROTATIONS

RUSLE technology can be used to estimate erosion under two very different sets of circumstances. The first circumstance is the one-time disturbance of an area, such as for a construction site, a rangeland under an improvement plan, or a disturbed forest site. In this case, the soil/vegetation/residue system is drastically disturbed but is then allowed to reconsolidate and return to more stable conditions.

The other general circumstance under which RUSLE can be used is a normal cropping rotation, in which the soil/vegetation/residue system is disturbed repeatedly in a cycle of one or more years. For example, a conventionally tilled corn-soybean rotation would have the same field operation (for example, planting of corn) at roughly the same time of year (perhaps May 15) every second year.

For the situation of a single disturbance, proper use of the RUSLE program requires definition of all the important soil/vegetation/residue parameters immediately after the disturbance. This process is described in more detail in chapter 7. For a crop rotation, matters are somewhat more complicated, because the disturbance is usually not so severe and the previous crops and field operations can still have a significant impact. The RUSLE program handles this by running three times through the calculations for the entire rotation, and by returning the calculated SLR values on only the third time through. This procedure allows the system to stabilize and minimizes the impact of the assumed initial conditions on the resulting SLR values.

COMPUTATION OF C FACTORS FOR HILLSLOPES UNDER STRIPCROPPING OR BUFFER STRIPS

For management schemes such as those modeling stripcropping and buffer strips, the vegetation and cropping schemes cause the SLR values to vary not only with time but also with position on the hillslope. For example, in a stripcropping scheme with alternating strips of conventionally tilled corn and good sod-forming grass, at any time half of the field would be under each crop.

The impact of such a scheme on the movement of runoff and the deposition of sediment is taken into account in the P factor (see ch. 6), but this does not account for the protection given the soil by the important parameters within the C factor: things such as random roughness, root mass, surface residue cover, and canopy cover. These must still be represented through the C factor.

This is done by calculating an individual C factor for each strip, and then weighting these by their area on the hillslope. For example, in any true stripcropping rotation scheme, each strip is rotated through the same pattern, so we need make only one C-factor calculation. On the other hand, for buffer strips, we can calculate a C factor for the buffer strips themselves and then calculate a C factor for the cropped areas between the buffer strips. We then calculate an overall C factor by multiplying each of the C factors by the percentage of the hillslope under that practice.

ACKNOWLEDGMENT

The authors acknowledge the kind assistance of Jim Cropper, NRCS, Chester, PA, for his extensive work in developing the CROP database information for forage crops.

Table 5-1.
Parameter values of typical crops[1]

Crop	Residue/yield ratio[2]	Surface p[3]	α[4] (acre · lb^{-1})	Residue at 30% cover[5] (lb · acre^{-1})	Yield	Row spacing[6] (in)	Plant population[6] (plants acre^{-1})

Clover, red	2,100	100	0.1	4
Clover, sweet	1,200	90	2.0	2
Clover, white	1,900	100	0.1	2
Lespedeza, sericea	1,900	100	0.5	3
Trefoil, birdsfoot	2,400	100	0.3	4

[1]These values are for mature, full pure stands on well-drained nonirrigated soils with moderate-to-high available water-holding capacity. These values hold for species shown only within their range of adaptation. Except for biennials, most forages do not attain a fully-developed root system until end of second growing season. Root mass values listed can be reduced by as much as half on excessively drained or shallow soils and in areas where rainfall during growing season is less than 18 in. The values listed are from Bennett and Doss (1960), Denison and Perry (1990), Doss et al. (1960), Holt and Fisher (1960), Kramer and Weaver (1936), Lamba et al. (1949), MacDonald (1946), and Pavlychenko (1942).

CHAPTER 6. CONTENTS

By definition, the support practice factor (P) in RUSLE is the ratio of soil loss with a specific support practice to the corresponding loss with upslope and downslope tillage. These practices principally affect erosion by modifying the flow pattern, grade, or direction of surface runoff and by reducing the amount and rate of runoff (Renard and Foster 1983). For cultivated land, the support practices considered include contouring (tillage and planting on or near the contour), stripcropping, terracing, and subsurface drainage. On dryland or rangeland areas, soil-disturbing practices oriented on or near the contour that result in storage of moisture and reduction of runoff are also used as support practices.

P does not consider improved tillage practices such as no-till and other conservation tillage systems, sod-based crop rotations, fertility treatments, and crop-residue management. Such erosion-control practices are considered in the C factor.

Values for P factors contained in this chapter were obtained from experimental data, supplemented by analytical experiments involving scientific observations of known cause-and-effect relationships in physically based models such as CREAMS (Knisel 1980). Recommended factor values are generally rounded to the nearest five-hundredth.

An overall P-factor value is computed as a product of P subfactors for individual support practices, which are typically used in combination. For example, contouring almost always accompanies stripcropping and terraces.

SUPPORT PRACTICE FACTOR (P) FOR CONTOURING

The effect of contour tillage on soil erosion by water is described by the contour P factor in the Revised Universal Soil Loss Equation (RUSLE). If erosion by flow occurs, a network of small eroded channels or rills develops in the areas of deepest flow. On relatively smooth soil surfaces, the flow pattern is determined by random natural microtopography. When tillage is oriented along the contour, the ridges or oriented roughness will partially or completely redirect the runoff, thereby modifying the flow pattern. When tillage leaves high ridges, runoff stays within the furrows between the ridges, and the flow pattern is completely determined by the tillage marks. High ridges from tillage on the contour cause runoff to flow around the slope, significantly reducing the grade along the flow path and reducing the flow's detachment and transport capacity compared to runoff directly downslope.

When grade is sufficiently flat along the tillage marks, much of the sediment eroded from the ridges separating the furrows is deposited in the furrows (Meyer and Harmon 1985). However, tillage is seldom exactly on the contour. Runoff collects in the low areas on the landscape and if accumulated water overtops the ridges, then rill and concentrated flow erosion usually occur, especially in recently tilled fields (Hill et al. 1944). Runoff from contoured fields is often less than that from fields tilled upslope-downslope (Van Doren et al. 1950). Contour tillage reduces erosion by reducing both the runoff and the grade along the flow path.

Values currently used in USLE (Wischmeier and Smith 1978) for the contour P factor are almost identical to those developed by Smith and Whitt (1947, 1948). At a 0% slope, Smith and Whitt reasoned that the value for the contouring subfactor should be 1.0 because no flow direction is defined. For steep slopes, they reasoned that the contouring subfactor value should be 1.0 for slopes steeper than 25% because a typical ridge 6 in high would store no water. At intermediate slopes, they chose a value of 0.6 for a 2% slope from the plot study of Van Doren et al. (1950) and a value of 0.5 for a 7% slope from the study of Smith et al. (1945).

This handbook recommends values for the RUSLE contour P factor based on erosion theory and analyses of experimental data. Data were from three sources: plots, small watersheds, and solutions of equations derived from erosion theory.

Data Analyses

Plot Data

Data from plot studies on the effect of contouring were found for the 18 locations identified in table 6-1. Plot dimensions varied from study to study with widths as narrow as 6 ft to as wide as 150 ft and lengths of 70 to 400 ft. Six studies were conducted with simulated rainfall, and 12 studies were on natural-runoff plots. The duration of the natural-runoff-plot studies ranged from a few days to 10 yr. Cropping and ridge height varied among the studies.

Contouring affected both runoff and erosion, but erosion was affected more than runoff. The ratio of (1) runoff and soil loss from a treatment tilled on the contour to (2) the runoff and soil loss from the same treatment tilled uphill-downhill was calculated for the period of record at a location. The results for runoff are shown in figure 6-1. The results for soil loss, the RUSLE contour P factor, are shown in figure 6-2.

Watershed Data

Soil-loss data collected from watersheds of 0.15-5 acres at four locations (table 6-2) were analyzed and plotted in figure 6-2. Straightforward comparisons of soil loss from uphill-downhill tillage with soil loss from contour tillage were impossible for many of the watershed studies. For example, the crop rotation at Clarinda, Iowa (Browning et al. 1948), differed among the watersheds. Data from a plot were compared against data from a watershed at LaCrosse, Wisconsin (Hays et al. 1949), to estimate a value for the contouring subfactor. At Bethany, Missouri (Smith et al. 1945), extensive gully erosion in the noncontoured watershed produced sediment that was measured at the watershed outlet but is not estimated with RUSLE. Also, the contoured watershed at Bethany had an extensive network of grassed waterways on 20% of the watershed, resulting in an unusually low sediment yield for this watershed. Therefore, the ratio of sediment yield to erosion from these two watersheds at Bethany gave a value for the contouring subfactor that was probably too low, in general. At Temple, Texas (Hill et al. 1944), areas of the watersheds were not equal. For example, the area of the watershed in the up-and-down tillage was 0.15 acre whereas the area of the contoured watershed was 1.5 acres. Such watershed differences result in appreciable differences in runoff, erosion, and sediment yield, so the data must be appropriately considered.

Analysis With CREAMS

The erosion component of the CREAMS model (Foster et al. 1981a) was used to compute erosion and sediment yield on several hypothetical watersheds under two levels of soil susceptibility to rill and concentrated flow erosion. The configuration of these watersheds was two planes that formed a V with a concentrated flow channel in the middle. Runoff on the planes was analyzed as flow in a series of furrows between ridges spaced 2.5 ft apart. An overland flow channel-channel hydrologic sequence was used in CREAMS to represent the watersheds. The overland-flow element represented the row side slopes, the first channel represented flow in furrows, and the second represented concentrated flow in the V between the planes. The maximum length of the concentrated flow channel in the V was 500 ft. Widths of the planes from their upper edge to the concentrated flow channel were 40 ft and 120 ft for two steep watersheds and 40 ft and 200 ft for two flat watersheds. The steepness of the planes on the steep watersheds was 12%, and the grade along the channel in the V was 6%. The steepness of the planes for the flat watersheds was 6%, and the grade along the channel was 4%. A critical shear stress value of 0.10 lb $\cdot$ ft^{-2} represented a field immediately after secondary tillage—a condition of high susceptibility to erosion by flow (Foster et al. 1980a). A critical shear stress value of 0.20 lb $\cdot$ ft^{-2} represented a field about a month or two after the last secondary tillage—a condition of moderate susceptibility to erosion by flow (Foster et al. 1980a).

Storm characteristics assumed in the analysis were 2.5 in for rainfall amount, 1.6 in for runoff amount, 2.0 in $\cdot$ h^{-1} for peak runoff rate, and 50 ft$\cdot$ tonf$\cdot$ in(acre-h)$^{-1}$ EI units for rainfall erosivity, which represent typical simulated rainstorms used in plot studies (Meyer 1960). These runoff values were not varied by watershed condition even though contouring affects runoff as shown in figure 6-1. Therefore, the computer analysis with CREAMS underestimated the effect of contouring.

Furrow grades in the analysis were 0.5%, 1%, 2%, and 4% for the flat watershed and 6% for the steep watersheds. As the grade of the furrows was increased, the upslope drainage area at the head of the concentrated flow channel was increased and the channel length of the concentrated flow in the V was shortened. The results from furrows on a 0.5% grade were assumed to represent excellent contouring and were plotted in figure 6-2.

Results

Figure 6-2 presents the basic data available in the literature. However, the application of RUSLE to contouring problems requires consideration of the storm erosivity and grade along the tillage marks when RUSLE is used in its standard way of taking slope length and steepness directly downslope.

Effect of Ridge Height

Five curves, drawn by inspection through the data shown in figure 6-2, represent the effectiveness of contouring where ridge heights are very low, low, moderate, high, and very high and where the ridges follow the contour so closely that runoff spills over the ridges uniformly along their length. Data showing the greatest effectiveness of contouring were generally from plots having high ridges (Borst et al. 1945, Moldenhauer and Wischmeier 1960). Conversely, data showing the least effectiveness of contouring were from plots having low ridge heights (Van Doren et al. 1950). The end points of the curves at the steep slopes were based on the steepness where typical ridge heights and row spacings would store no runoff.

These curves were described by the following equations:

$$P_b = a(s_m - s_c)^b + P_{mb} \qquad s_c < s_m \qquad [6\text{-}1]$$

$$P_b = c(s_c - s_m)^d + P_{mb} \qquad s_c \geq s_m \qquad [6\text{-}2]$$

$$P_b = 1.0 \qquad s_c \geq s_e \qquad [6\text{-}3]$$

where P_b = base values of the P factor for contouring, s_m = slope (expressed as sine of the slope angle) at which contouring has its greatest effectiveness, s_c = slope (expressed as sine of the slope angle) for which a value of P_b is desired, s_e = slope steepness (expressed as sine of the slope angle) above which contouring is ineffective, and P_{mb} = the minimum P value for a given ridge height with base conditions. The coefficients a, b, c, and d also vary with ridge height.

The curves described by equations [6-1] and [6-2] pass through P_m at the slope s_m, which varies with ridge height shown in table 6-3, and have a zero slope at s_m. In addition, values for the coefficients a and b must be chosen so that

equation [6-1] passes through 1 at $s_c = 0$ and equation [6-2] passes through 1 at $s_c = s_e$. To meet these boundary conditions, a is given by the equation

$$a = \frac{1 - P_m}{s_m^b} \qquad [6\text{-}5]$$

and c is given by the equation

$$c = \frac{1 - P_m}{(s_e - s_m)^d} \qquad [6\text{-}5]$$

Values for b, d, s_m, and s_e, chosen by inspection to give good fits to the data shown in figure 6-2, are listed along with values for a and c given in table 6-3.

The data in figure 6-2 are assumed to be for the base condition of a 10-yr-frequency storm EI of 100 ft · tonf · in(acre · hr)$^{-1}$ and for a row crop with clean tillage on a soil classified as being in the hydrologic soil group C.

Effect of Storm Severity

Data from field studies indicate that contouring is less effective for large storms than for small storms (Moldenhauer and Wischmeier 1960, Jasa et al. 1986). The reduced effectiveness depends on both amount of runoff and peak rate of runoff. These runoff variables are directly related to rainfall amount and intensity, which are the principal variables that determine EI (storm energy times maximum 30-min intensity), the erosivity factor in RUSLE. Therefore, values for the contouring subfactor should be near 1 (little effectiveness) when EI is high and infiltration into the soil is low, and should be small (greater effectiveness) when EI is low and infiltration is high (Moldenhauer and Wischmeier 1960). Loss of contouring effectiveness is likely to occur from a few major storms (Hill et al. 1944, Jamison et al. 1968). Therefore, erosivity of a single storm, such as the storm having a 10-yr return frequency, should be a better indicator of loss of contouring effectiveness than is average annual erosivity.

In figure 6-2, the highest 10-yr storm EI for the locations represented in figure 6-2 was 165 ft · tonf · in(acre · hr)$^{-1}$ at Temple, Texas (Wischmeier and Smith

1978), where contouring had little effectiveness. Conversely, the lowest 10-yr storm EI was 50 ft · tonf · in(acre · hr)$^{-1}$ at Arnot, New York (Lamb et al. 1944), where contouring was most effective. The contouring P-factor values were also low at Clarinda, Iowa (Moldenhauer and Wischmeier 1960), where the 10-yr storm EI was 76 ft · tonf · in(acre · hr)$^{-1}$. Erosivity was high—140 ft · tonf · in(acre · hr)$^{-1}$ at Batesville, Arkansas (Hood and Bartholomew 1956), where ridge breakovers occurred and the contouring P-factor value was high.

A linear regression analysis using the complete data set showed an increase in the contouring P factor with an increase in the 10-yr single-storm EI [$(EI)_{10}$]. The analysis also showed that effectiveness of contouring increased with increasing ridge height (Moldenhauer and Wischmeier 1960).

The effectiveness of contouring in RUSLE is assumed to vary with runoff, which is a function of both rainfall and infiltration. Runoff, computed using the Natural Resource Conservation Service (NRCS) runoff curve number method and the rainfall amount estimated from the 10-yr single-storm EI, is used as a guide in RUSLE to adjust P-factor values for changes in effectiveness of contouring that result from runoff differences among locations, soils, and cover-management conditions.

Values for the 10-yr storm EI are obtained from the Citycode files in the computer program of RUSLE. These EI values are converted to storm rainfall amounts using the equation (Foster et al. 1980b)

$$V_r = 0.255\ [(EI)_{10}\ ]^{0.662} \qquad [6\text{-}6]$$

where V_r = rainfall amount in inches. Values for rainfall amount, V_r, are used in the NRCS runoff curve method to compute a runoff amount. Cover-management conditions for cropland are grouped in the seven categories described in table 6-4. The runoff index values, equivalent to curve numbers, used to compute runoff for each of these conditions are given in table 6-5. (For Northwestern Wheat and Range conditions and runoff index values, see tables 6-25 and 6-26.)

Runoff was assumed to affect P-factor values for contouring in two ways: the minimum value of the P factor was assumed to vary directly with computed runoff, and the slope steepness above which contouring loses its effectiveness was also assumed to vary directly with runoff. The basis for these assumptions is that the effectiveness of contouring is assumed to be directly proportional to

the shear stress applied to the soil by the runoff. This shear stress is directly proportional to runoff rate and slope steepness to the 1.167 power (Foster et al. 1982). Runoff rate was assumed to be directly proportional to runoff amount. Thus the slope steepness (s_e) at which contouring loses its effectiveness was computed as

$$s_e = s_{eb}\left(\frac{3.72}{Q_k}\right)^{0.857} \qquad [6\text{-}7]$$

where s_{eb} = slope steepness for a given ridge height on base conditions at which contouring loses its effectiveness, Q = computed runoff amount (in) for the given soil and cover-management condition indicated by subscript k, and 3.72 = runoff amount (in) computed for cover-management condition 6, hydrologic soil group C, and a 10-yr storm EI of 100 ft · tonf · in(acre · hr)$^{-1}$. This storm EI is typical of much of the central part of the eastern United States, and the hydrologic soil group C is assumed to be typical of many of the soils in the contouring experiments that produce the data shown in figure 6-2. Similarly, the minimum P-factor value (P_m) is computed from

$$P_m = P_{mb}\left(\frac{Q_k}{3.72}\right) \qquad [6\text{-}8]$$

where P_{mb} = minimum P-factor value for a ridge height on base conditions.

Equations [6-1], [6-2], and [6-3] give P-factor values for base conditions. These curves shift as field conditions vary from the assumed base conditions. The following approach was used to take into account these differences:

The first step is to compute a scaled slope steepness. For a slope steepness of less than s_m, the actual slope steepness is used directly in equation [6-1] to compute a P_b value. For slopes steeper than s_m, the slope used in equation [6-2] is computed from

$$s_c = \frac{(s - s_m)(s_{eb} - s_m)}{(s_e - s_m)} + s_m \qquad [6\text{-}9]$$

The computed P_b value is then scaled as

$$P = 1 - \frac{(1 - P_b)(1 - P_m)}{1 - P_{mb}} \qquad [6\text{-}10]$$

If the steepness exceeds s_e computed from equation [6-7], then P = 1.0. If the value computed by equation [6-10] is less than an absolute minimum value (P_z) given in table 6-3, the absolute minimum P_b value for that ridge height is assigned to P.

Effect of Off-Grade Contouring

Contouring alone is often inadequate for effective erosion control (Hill et al. 1944, Smith et al. 1945, Jamison et al. 1968). Runoff frequently flows along the furrows to low areas on the landscape, where breakovers occur. Grassed waterways are needed in conjunction with contouring to safely dispose of the runoff that collects in natural waterways at the breakovers (Smith et al. 1945).

Erosion in the concentrated flow areas occurs even if contouring is not used, although eroded concentrated flow channels extend farther upslope with contouring. Our analysis with CREAMS showed that if row grade is slight, 0.5% or less, deposition in the furrows more than offsets the erosion in the concentrated flow areas.

As grade along the furrows increases from tillage being off contour, the effectiveness of contouring decreases. Results from CREAMS and experimental data (McGregor et al. 1969, Meyer and Harmon 1985) showed a rapid loss of effectiveness of contouring as grade along the furrows increased. The furrows in these situations were for clean-tilled row crops.

Soil loss estimated with RUSLE using the slope length measured downslope and the contouring factor in figure 6-2 includes the erosion in concentrated flow (ephemeral gully) areas for about 500 ft of a concentrated flow channel. The reason for the inclusion of ephemeral gully erosion by concentrated flow in the P factor is that the watershed data used in the derivation of figure 6-2 were collected on small watersheds that contained eroding ephemeral gully areas.

The equation used in RUSLE to compute P-factor values for off-grade contouring is

$$P_g = P_o + (1 - P_o)\left(\frac{s_f}{s_l}\right)^{1/2} \qquad [6\text{-}11]$$

where P_g = P factor for off-grade contouring, P_o = P factor for on-grade contouring (as computed by equation [6-10]), s_f = grade (expressed as sine of the slope angle) along the furrows, and s_l = steepness (expressed as sine of the slope angle) of the land. This equation is similar to the relationship assumed by Dissmeyer and Foster (1980) for application of USLE to disturbed forest lands. The data collected by McGregor et al. (1969) seem to be the only field data available that can be used to directly evaluate equation [6-11]. Grade along furrows in that study varied between 0.2% and 0.4%. The P-factor value in the McGregor et al. (1969) study was 0.39 for 150-ft wide plots on a 5% slope with off-contour tillage whereas the P-factor value was 0.10 when the furrows were perfectly on the contour. Given a value of $P_o = 0.10$, the value of P_g computed by equation [6-11] for a 0.3% furrow grade is 0.32, slightly less than the 0.39 measured value.

ESTIMATING SOIL LOSS WITH CONTOURING WHEN SLOPE LENGTH EXCEEDS CRITICAL SLOPE LENGTH

Critical Slope Limits

At long slope lengths, contouring loses its effectiveness. Wischmeier and Smith (1978) gave a table of values for critical slope lengths for USLE that represented slope lengths beyond which contouring was assumed to lose much of its effectiveness. These critical slope-length limits were given only as a function of slope steepness, but Wischmeier and Smith suggested that critical slope length increased if residue cover exceeded 50%.

Foster et al. (1982) investigated the hydraulic conditions under which surface residue failed and allowed serious erosion to occur. Their analysis considered the shear stress exerted by the runoff on the soil and the residue. When the shear stress exerted on the residue exceeded a critical value, the residue was assumed to move. Similarly, when the shear stress exerted on soil exceeded a critical shear stress, flow was assumed to erode the soil.

The equation derived by Foster et al. (1982) for movement of mulch used discharge as the principal hydraulic input variable. Critical slope-length limits in RUSLE are computed with a simplification of the Foster et al. (1982) equation for mulch stability. The equation is

$$\lambda_c = \frac{20182 n_t^{1.5}}{s^{1.1667} Q} \qquad [6\text{-}12]$$

where λ_c = critical slope length, n_t = Manning's n, s = slope (expressed as sine of the slope angle), and Q = runoff amount from the 10-yr storm EI. The value 20,182 was obtained by calibrating equation [6-12] to compute a critical slope length of 200 ft for a 7% slope, moderately high ridges, clean-tilled row crops, a soil classified in the hydrologic soil group C, and a 10-yr storm EI of 100 ft · tonf · in(acre · hr)$^{-1}$. This critical slope-length value agrees with Wischmeier and Smith (1978). Values for Manning's n_t are given in table 6-6 and were chosen from those suggested for the CREAMS model (Foster et al. 1980a) and from field research on the movement of mulch (Foster et al. 1982).

Existing recommended values for critical slope length (Wischmeier and Smith 1978) were based on judgment and field observations. The condition chosen for calibration seems to best represent the typical condition that would have been observed in the field. Values for a range of slopes were computed with equation [6-12] and are shown in table 6-7 along with values from Wischmeier and Smith (1978). The values computed by equation [6-12] are very close to those from Wischmeier and Smith (1978) except for slopes less than 4%. A value of 1,000 ft is set in RUSLE as a maximum critical slope length. Values for critical slope length for a range of conditions are given in tables 6-8, 6-9, and 6-10.

Derivation of RUSLE Equation for Effective P

The procedure for applying RUSLE to irregular slopes (Foster and Wischmeier 1974) was used to develop the equations to calculate effective P-factor values. The beginning point in the derivation is RUSLE applied to a point, as follows:

$$D = (m + 1)\, RKSCP \left(x_* \frac{\lambda}{72.6} \right)^m \qquad [6\text{-}13]$$

where D = erosion rate at a point, m = slope-length exponent, R = rainfall-runoff erosivity factor, K = soil erodibility factor, S = slope steepness factor, C = cover-management factor, and P = support-practice factor for contouring.

The normalized distance x_* is x/λ, where x is distance along the slope length λ and 72.6 is length (ft) of the RUSLE unit plot. All factor values apply to conditions at the point x. The derivation is for a uniform slope. If a more complex situation is being analyzed, the full irregular slope procedure should be used.

Equation [6-13] can be rearranged to give

$$D = (m + 1)\, RKSCP \left(\frac{\lambda}{72.6} \right)^m (x_*)^m \qquad [6\text{-}14]$$

where the term $(\lambda/72.6)^m$ is the slope length factor of RUSLE.

Soil loss, G, for the slope length is obtained by integrating equation [6-14] for the two parts of the slope: the upper part where contouring is assumed to be

fully effective and the lower part where no effectiveness of contouring is assumed. The equations for this soil loss are

$$G = \int_0^{x_c} D dx + \int_{x_c}^{1} D dx \qquad [6\text{-}15]$$

Substitution of equation [6-14] into equation [6-15] gives:

$$G = (m+1)\,\lambda \left(\frac{\lambda}{72.6}\right)^m \left(P \int_0^{x_c} x_*^m \, dx_* + \int_{x_c}^{1} x_*^m \, dx_* \right) \qquad [6\text{-}16]$$

Soil loss expressed in units of mass per unit area is obtained by dividing sediment yield G from the slope by slope length λ. Completion of the integration and division by λ gives the equation for soil loss A of

$$A = RKLSC\,[P_{eff}] \qquad [6\text{-}17]$$

where

$$P_{eff} = \left[1 - x_c^{\,m+1}(1 - P)\right] \qquad [6\text{-}18]$$

is the effective P factor to compute average soil loss for the slope length λ. Values for P_{eff} were computed using equation [6-18]. Slope-length exponent values for a range of slopes and rill-to-interrill erosion classes are in table 4-5.

Discussion

Use of the effective P-factor values from table 6-10 gives an estimate of the average soil loss for the slope length λ. Soil loss on the lower part of the slope where contouring has been assumed to fail can be considerably greater than the

average soil loss for the entire slope. When using this method in conservation planning, the conservationist must consider whether it is permissible to allow soil losses on the lower part of the slope in excess of the soil loss tolerance. Chapter 4 describes how to use RUSLE to compute soil loss on segments and how to adjust segment values to compare with soil-loss tolerances to provide for consistency in RUSLE applications.

SUPPORT PRACTICE FACTOR (P) FOR CROSS-SLOPE STRIPCROPPING, BUFFER STRIPS, AND FILTER STRIPS

Stripcropping is a support practice where strips of clean-tilled or nearly clean-tilled crops are alternated with strips of closely growing vegetation such as grasses and legumes. Another form of stripcropping used on cropland in the Northwestern Wheat and Range Region is very rough, tilled strips instead of strips of closely growing vegetation. The crops are generally rotated sequentially so that at some time in the rotation cycle, every crop will have been grown on every strip. To be compatible with the crop rotation, the width of all strips in the system is usually the same. Stripcropping performs best when the upper edge of each strip is perfectly on the contour.

Stripcropping for the control of water erosion is variously described as contour stripcropping, cross-slope stripcropping, and field stripcropping. Each of these practices has the common characteristic of crops in rotation forming strips of nearly equal width. The difference between the practices is the degree of deviation from the contour. All of them, including contour stripcropping, involve some degree of off-grade contouring. The effectiveness of all of them can be determined with the same equations in the RUSLE computer model. All are versions of the same technology with no sharp distinction despite the wide variation in effectiveness, depending on grade of the row. Therefore, the term "cross-slope stripcropping" is used to refer to the various conditions described above.

Buffer strips, located at intervals up the slope, are resident strips of perennial vegetation laid out across the slope. Like the strips in cross-slope stripcropping, they may or may not be on the contour. These strips, predominantly composed of grass species, are not in the crop rotation, are usually much narrower than the adjacent strips of clean-tilled crops, and may be left in place for several years or permanently. The effectiveness of buffer strips in trapping sediment and reducing erosion can also be evaluated by the RUSLE model.

Vegetated filter strips are bands of vegetation at the base of a slope. Riparian filter strips are located along stream channels or bodies of water. These conservation practices are designed to reduce the amount of sediment reaching offsite water bodies. Neither practice traps eroded sediment on the hillslope and therefore has minimal benefit as a P factor.

Densely vegetated strips or very rough strips that induce deposition of eroded sediment are assigned a P-factor value. Deposition must occur on the hillslope in areas where crops are routinely grown to deserve a low P factor indicative of greatest value to soil conservation. Therefore, P-factor values for maintenance of soil productivity are lowest for cross-slope stripcropping, moderate for buffer strips, and highest for filter strips. A P value of 1.0 is often assigned to filter strips because they provide little protection to the majority of the field where crops are grown.

A major advantage of stripcropping is the rotation of crops among the strips. By rotating crops among strips, each clean-tilled crop receives benefit from the sediment deposited in a previous year by the closely growing crop or the rough strip. Stripcropping significantly reduces the rate of sediment moving down the slope. Because filter strips are located at the base of slopes, the strips do not greatly affect this rate. In general, the benefit of deposition depends on the amount of deposition and its location. Sediment deposited far down the slope provides less benefit than does sediment deposited on the upper parts of the slope. With buffer strips, the sediment is trapped and remains on small areas of the slope, such as terraces; thus the entire slope does not benefit as much as it does in stripcropping.

A strip is effective in reducing soil loss when it significantly reduces the transport capacity of the runoff as it leaves one strip and enters the next strip. For deposition to occur, the transport capacity must be reduced to less than the sediment load being transported by the runoff. If no deposition occurs, the P value is 1.0. The following examples illustrate the basis for assigning P-factor values.

Examples

The first example is the situation of strips of a clean-tilled row crop separated by strips of grass hay. It is assumed that the uppermost strip is in corn and that erosion occurs at a high rate on this strip. Sediment load will be large in the runoff at the lower edge of the corn strip. The hay strip has a much greater hydraulic resistance to flow than does the clean-tilled area, and this resistance greatly reduces the transport capacity of the runoff as it enters the hay strip. If transport capacity is reduced at the upper edge of the hay strip to a level much less than the sediment load of the runoff entering the hay strip, much deposition occurs and gives a P-factor value of less than 1. As the runoff moves through a sufficiently wide hay strip, deposition reduces the sediment load to less than the transport capacity of the flow in the hay strip. The flow can be erosive as it exits the lower edge of the hay strip.

The relationship of erodibility of a clean-tilled strip to the transport capacity in the densely vegetated strip is illustrated by the extreme example of strips of concrete separated by dense grass strips. It is assumed that the uppermost strip is concrete. Flow over the concrete has great transport capacity, but its sediment load is very low (and approaches zero) because the concrete is not erodible. Even though the grass strip at the lower edge of the concrete greatly reduces the transport capacity of the flow, no deposition occurs because the transport capacity was not reduced to a level less than the sediment load in the flow. Therefore, the value of the P factor for this case is 1.0.

Another example more realistic than the above concrete-grass example illustrates the same principle. This example involves strips of no-till corn interspersed among strips of grass. It is assumed that the uppermost strip is no-till corn with a very heavy cover of residue. Very little erosion occurs on the strip of no-till corn. When the runoff reaches the grass strip, little reduction in the transport capacity of the runoff occurs because that of the grass is only slightly greater than the hydraulic resistance of the no-till corn. Therefore, since the sediment load in the runoff leaving the strip of no-till corn is very low because of little erosion on the no-till corn, no deposition will occur because the grass strip did not reduce the transport capacity of the runoff to a level less than the sediment load in the flow from the no-till strip. In this case, the P-factor value is 1.0.

In summary, the effectiveness of stripcropping, buffer strips, and filter strips as support practices depends on the sediment load generated from the erodible strips relative to the transport capacity of the strips that have greater hydraulic resistance.

Development of P-Factor Values for Strips

The first step in developing RUSLE P-factor values for strips was to review the literature. Unfortunately, most of the experimental research on stripcropping was conducted from 1930 to 1960 and did not include modern conservation tillage systems (Hill et al. 1944, Borst et al. 1945, Smith et al. 1945, Hays et al. 1949, Hood and Bartholomew 1956, Hays and Attoe 1957). Also, crop yields during that period were much less than modern yields, and canopy cover and residue amounts were less than those with modern practices.

Therefore, published experimental data alone are inadequate for developing the necessary P-factor values for the wide range of current practices. The approach taken was to develop a simple erosion-deposition model based on fundamental erosion concepts (Renard and Foster 1983, Flanagan et al. 1989) that could be used in RUSLE to estimate P-factor values for strips. Steps in addition to developing the model included developing parameter values based on theory and

experimental data from fundamental erosion studies and adjusting parameter values to obtain an adequate fit of the model to the limited field data. The model is included in RUSLE to compute values for the P factor for stripcropping, buffer strips, and filter strips for a wide variety of situations.

A value for the P factor for strips is computed from

$$P_s = \frac{(g_p - B)}{g_p} \qquad [6\text{-}19]$$

where P_s = value for P factor for strips, g_p = sediment load at end of slope that would occur if the strips caused no deposition, and B = credit for deposition.

Table 6-11 shows values for sediment yield from experimental data for stripcropping found in the literature, along with values computed by the model.

The model computes erosion, sediment transport, and deposition on a strip-by-strip basis, routing the sediment from the top to the bottom of the slope. One of the four following conditions exists on each strip:

(1) Net erosion occurs everywhere along the strip.

(2) Net deposition occurs everywhere along the strip.

(3) Net deposition occurs on an upper area of the strip and net erosion occurs on a lower area of the strip.

(4) Runoff ends within a strip, and no runoff or sediment leaves the strip.

The objective in each case is to compute the amount of deposition (M_i) on each strip and the sediment load (g_i) leaving each strip.

Case 1. Net Erosion Occurs Everywhere Along the Slope

For this case to apply, one condition is that the rate of increase in transport capacity along the strip must be greater than the detachment rate along the strip. For this condition, net erosion is computed by

$$D_{ni} = \xi_i \left(x_i^{\,n} - x_{i-1}^{\,n} \right) \qquad [6\text{-}20]$$

where ξ = an erosion factor, x = relative distance from the top of the slope to the lower edge of a strip (absolute distance/slope length), n = an exponent set to 1, and I = subscript indicating a particular strip. Values of ξ are given in table 6-12. Sediment load at the lower edge of the strip is given by

$$g_i = g_{i-1} + D_{ni} \qquad [6\text{-}21]$$

where g = sediment load.

The exponent n is set to 1 for all conditions. The reasoning for this value is that contouring is an integral part of stripcropping. When contouring is completely effective, it eliminates rill erosion. Much of the effectiveness of contouring is because of deposition in the furrows left by tillage. Erosion on strips where cover is dense is minimal and is mostly interrill erosion rather than rill erosion. In both situations, the appropriate value of the exponent is 1 (Renard and Foster 1983). The value of the exponent should be about 1.5 where rill erosion is significant. A single value of 1 is used in RUSLE because the principal intent of equation [6-21] is to provide an index of net erosion.

Local deposition, such as in depressions left by tillage, can occur within a strip because the detachment rate exceeds the rate of increase in transport capacity along the strip. For this condition, the deposition equation developed by Renard and Foster (1983) is used to compute net erosion as

$$D_{ni} = \left[\frac{\left(\frac{\phi dT_i}{dx} + \xi_i \right)}{(1 + \phi)} \right] \left(x_i - x_{i-1} \right) \qquad [6\text{-}22]$$

where $\phi = V_f/\sigma$, V_f = fall velocity of the sediment, and σ = excess runoff rate (rainfall intensity - infiltration rate). A value of 15 was selected by calibration for ϕ. Although the value for ϕ varies with sediment size and density, the single value of 15 is used in RUSLE. Equation [6-23] is based on the following equation for deposition (Renard and Foster 1983):

$$D = \left(\frac{V_f}{q}\right)(T - g) \qquad [6\text{-}23]$$

where D = deposition rate, q = discharge rate, and T = transport capacity of the runoff.

Case 2. Deposition Occurs Everywhere Along Strip

Deposition occurs at the upper edge of a strip if the transport capacity at the upper edge of a strip is less than the sediment load reaching the upper edge. Deposition will occur over the entire strip if the strip is narrow or if runoff rate decreases with distance within the strip. This latter condition occurs where the infiltration rate in a particular strip is much greater than the infiltration rates on upslope areas.

The basic equation used for strips where deposition occurs is equation [6-23]. Discharge rate q is given by the equation

$$q = q_{i-1} + \sigma_i \left(x - x_{i-1}\right) \qquad [6\text{-}24]$$

In RUSLE, the excess runoff rate is computed as the ratio of runoff amount, expressed as a depth, for the given strip condition to the runoff amount from a clean-tilled row-crop strip, which is condition 6 in table 6-4. Runoff amounts are computed by use of the NRCS runoff curve number method and runoff index values given in table 6-5.

When the infiltration rate on a strip is greater than the rainfall intensity, discharge rate decreases within the strip; if the strip is wide, runoff ends within the strip. Because the NRCS runoff curve number method would ordinarily compute no runoff for this condition, the method was modified to compute the rainfall amount that would just produce runoff. This equation is

$$r = V_r - 0.2\left[\left(\frac{1000}{N}\right) - 10\right] \qquad [6\text{-}25]$$

where r = excess runoff depth (in), V_r = rainfall amount, and N = runoff index. The equation for transport capacity (T) is

$$T = \zeta q \qquad [6\text{-}26]$$

where ζ = a sediment transport capacity factor. Values of ζ are relative and were chosen based on the Manning's n_t recommended for the CREAMS model (Foster et al. 1980a), the relation of runoff velocity to Manning's n_t, and the assumed relationship that transport capacity varies with the cube of runoff velocity (Foster and Meyer 1975). Values for ζ are given in table 6-12.

The equation derived from equations [6-24], [6-25], and [6-27] to compute sediment load where deposition occurs along the entire strip is

$$g_i = \left(\frac{\phi dT_i}{dx} + \xi_i \right) q_i \left[\sigma_i (1 + \phi) \right]^{-1} + \left(\frac{q_{i-1}}{q_i} \right)^{\phi} \left\{ g_{i-1} - \left(\frac{\phi dT_i}{dx} + \xi_i \right) q_{i-1} \left[\sigma_i (1 + \phi) \right]^{-1} \right\} \qquad [6\text{-}27]$$

The change of transport capacity with distance dT_i/dx is given by

$$\frac{dT_i}{dx} = \zeta_i \sigma_i \qquad [6\text{-}28]$$

The amount (M) of deposition on the strip is computed from

$$M_i = g_i - g_{i-1} + D_{ni} \qquad [6\text{-}29]$$

Case 3. Both Deposition and Erosion Within a Strip

If the sediment load at the upper edge of a strip is greater than the transport capacity at that location, deposition occurs over an upper area of the strip.

Deposition ends within a strip if the rate of increase in the transport capacity, dT/dx, exceeds the detachment rate ξ, and if the strip is wide. The location where deposition ends is the location where the sediment load equals the transport capacity. The discharge rate (q_{de}) for this condition is given by

$$q_{de} = \left(\frac{a_2 \phi \sigma_i}{a_1 \sigma_i + \xi_i} \right)^{\frac{1}{1+\phi}} \left[q_i \right]^{\frac{\phi}{1+\phi}} \qquad [6\text{-}30]$$

where coefficients a_1 and a_2 are given by

$$a_1 = \frac{\left(\frac{\phi dT_i}{dx} + \xi_i \right)}{\left[\sigma_i \, (1 + \phi) \right]} \qquad [6\text{-}31]$$

$$a_2 = g_{i-1} - a_1 q_{i-1} \qquad [6\text{-}32]$$

The location x_{de} where deposition ends is computed from

$$x_{de} = \frac{\left(q_{de} - q_{i-1} + \sigma_i \, x_{i-1} \right)}{\sigma_i} \qquad [6\text{-}33]$$

The sediment load at the location where deposition ends is given by

$$g_{de} = \zeta_i \, q_{de} \qquad [6\text{-}34]$$

If $dT_i / dx > \xi_i$, sediment load at the lower edge of the strip is given by

$$g_i = g_{de} + \xi_i \left(x_i^{\,n} - x_{de}^{\,n} \right) \qquad [6\text{-}35]$$

If $dT/dx < \xi_i$, sediment load at the lower edge of the strip is given by

$$g_i = g_{de} + \left[\frac{\left(\frac{\phi dT_i}{dx} + \xi_i\right)}{(1 + \phi)}\right](x_i - x_{de}) \quad [6\text{-}36]$$

The amount of deposition (M) is given by

$$M_i = g_i - g_{de} + \left[\frac{\left(\frac{\phi dT_i}{dx} + \xi_i\right)}{(1 + \phi)}\right](x_{de} - x_{i-1}) \quad [6\text{-}37]$$

Another possibility is for net erosion to occur on the upper area of a strip and local deposition to begin within the strip. This condition occurs when the sediment load is less than the transport capacity at the upper edge of a strip and the rate of increase in the transport capacity is less than the detachment rate, $dT_i/dx < \xi_i$. The location where local deposition begins is where sediment load (g_i) equals transport capacity (T). The sediment load at the lower edge of the strip is given by

$$g_i = g_{db} + \left[\frac{\left(\frac{\phi dT_i}{dx} + \xi_i\right)}{(1 + \phi)}\right](x_i - x_{db}) \quad [6\text{-}38]$$

where g_{db} = sediment load where local deposition begins and x_{db} = location where deposition begins. The amount of deposition (M) is zero for this condition if $g_i > g_{db}$. If $g_d < g_{db}$, then $M = g_{db} - g_i$.

Case 4. Runoff Ends Within a Strip

Sometimes the difference in infiltration can be so great between strips that all runoff from upslope is infiltrated within a strip having high infiltration rates. No runoff or sediment leaves these strips.

The location where runoff ends is calculated by use of equations [6-24] and [6-25]. The amount of deposition is the amount of sediment in the runoff entering the strip plus the amount of sediment detached within the strip between the upper edge of the strip and the location where runoff ends.

Application

Computation of P-Factor Value

The P-factor value for stripcropping is computed from

$$P_s = \frac{g_p - B}{g_p} \qquad [6\text{-}39]$$

where P_s = a P-factor value for conservation planning; g_p = potential sediment load if no deposition, other than local deposition, would have been caused by the strips; and B = amount of deposition considered to benefit the long-term maintenance of the soil resource. This benefit is computed by

$$B = \sum_{i=1}^{n} M_i \left(1 - x_{i-1}^{1.5}\right) \qquad [6\text{-}40]$$

where n = number of strips. The potential sediment load (g_p) is computed from

$$g_p = \sum_{i=1}^{n} D_{ni} \qquad [6\text{-}41]$$

where D_{ni} is computed for each strip according to equation [6-20] or [6-22].

The model also computes a sediment delivery ratio (P_y) for the slope by use of the equation

$$P_y = \frac{g_\lambda}{g_p} \qquad [6\text{-}42]$$

where g_λ = sediment load at the end of the slope.

Values for P computed for several stripcrop systems are shown in table 6-13.

The above equations and parameter values given in table 6-12 are used in RUSLE to compute a P-factor value and a sediment-delivery-factor value for any combination of strips, including buffer and filter strips. The parameter values in table 6-12 were developed to produce average annual P-factor values. The data used to determine the parameter values were heavily weighted by erosion in late spring and early summer, conditions when most erosion occurs with row crops in the eastern United States. Thus, the parameter values in table 6-12 most represent these conditions, but other conditions can be represented by choosing parameter values from table 6-12 based on surface conditions at a given time. The model can be applied several times during the year to compute an average P-factor value for the year, or the model can be applied over several years to compute a rotational P-factor value.

The equations used to compute deposition by strips do not take into account deposition in the ponded runoff on the upper side of the grass strip. The effect of the ponded runoff can be partially taken into account by adding the width of the ponded area to the width of the grass strip.

The effectiveness of strips as a soil conservation practice primarily results from the deposition induced at the upper edge of heavily vegetated or rough strips. In traditional applications of stripcropping, uniform-width strips are moved up the slope according to a crop rotation such as corn-wheat-1st yr hay-2d yr hay. In buffer strip applications, permanent vegetated strips that are much narrower than the cropped strips are installed. In rotational stripcropping, clean-tilled crops are grown on the strips where deposition occurred in prior years. In contrast, the benefit of narrow, permanent strips is that sediment is trapped and kept on the slope, but the immediate benefit is localized. The benefit to the entire slope is very little if a permanent strip is narrow and located at the end of the slope. If a single, narrow strip is placed high on the slope, none of the slope segment above the strip benefits from the deposition. This portion of the slope continues to erode at the same rate as if the strip were not present. The strip does, however, decrease the rate at which sediment moves off the slope over the long term; thus

the slope segment below the strip benefits from the deposition induced at the upper edge of the strip.

The P-factor values and the resulting soil-loss values computed by RUSLE are intended to be used in conservation planning for maintenance of the soil resource base. Full credit is not taken for the total amount of deposition for conservation planning. The benefit assigned by equation [6-40] to the deposition depends on the location of deposition. The degree of benefit increases as the location of deposition moves up the slope; conversely, little benefit is assigned when the strip is near the end of the slope. This approach is conceptually consistent with the way that P-factor values are assigned to terraces (Foster and Highfill 1983).

RUSLE also computes a sediment delivery factor. Multiplication of this factor by the product RKLSC gives an estimate of sediment yield leaving the slope. Sediment-yield values are typically less than the soil loss computed with RUSLE because RUSLE does not give full credit to deposition as a benefit for maintenance of the soil resource over the entire slope.

The effectiveness of stripcropping is assumed to be independent of strip width up to the point that rilling begins. Results were varied in experimental studies on the effect of strip width. Once strips become so wide or slope lengths become so long that rilling occurs, stripcropping begins to lose its effectiveness. Because of the complexity of the problem, no approach is suggested to estimate a P-factor value representing the lost effectiveness of stripcropping due to excessively long slope lengths. Critical slope lengths for conservation planning for stripcropping are assumed to be 1.5 times the critical slope length for contouring. Critical slope lengths for stripcropping are related to the maximum slope lengths for contouring because contouring is an integral part of stripcropping. Computation of soil loss when slope lengths exceed critical slope lengths is the same as computation of soil loss for contouring.

For maximum effectiveness, stripcropping is installed with the upper edge of the strips on the contour. However, strips are sometimes installed off contour, resulting in a grade along the upper edge of the strips. The effectiveness of these strips is difficult to evaluate. Deposition occurring at the upper edge of the densely vegetated strips builds up a ridge of soil that can cause runoff to flow along the upper edge of the strip and not pass through the strips. On tilled strips, runoff can flow along the tillage marks and never reach the strip if tillage is on a grade. The net result is that the system behaves no differently than off-grade contouring with a weighted C factor based on the area occupied by the various strips. This approach produces a P-factor value that represents the minimum

effectiveness of strips. The maximum effectiveness can be estimated by use of the stripcrop model by choosing a designation for the cropped strips having an erodibility greater than that for the contour tilled condition, to represent the reduced effectiveness of off-grade contouring. The overall P factor is a combination of two P factors: one for off-grade contouring, and one for stripcropping with an adjusted surface designation because of increased sediment (resulting from off-grade contouring) reaching the densely vegetated strips.

The stripcrop model in RUSLE estimates the amount of deposition induced by a strip by representing the main factors that affect sediment transport and deposition. However, even though the parameter $\phi = V_f/\sigma$ represents the effect of sediment characteristics, a single value is used for all conditions. Therefore, actual deposition will be greater and sediment delivery will be less than that computed with RUSLE for soils high in either clay or sand content compared to typical silt loam soils. The converse is true for soils whose silt content is higher than that in silt loam soils. Furthermore, upslope localized deposition in depressions left by tillage or deposition by upslope strips reduces the particle size and thus the amount of sediment deposited by downslope strips. In estimating sediment passing through strips that induce deposition, the CREAMS model (Foster et al. 1980a) or the SEDIMOT II model (Wilson et al. 1986) considers more factors over a wider range of conditions than does RUSLE.

SUPPORT PRACTICE FACTOR (P) FOR TERRACING

Terraces reduce sheet and rill erosion on the terrace interval by breaking the slope into shorter slope lengths. Also, deposition along the terraces may trap much of the sediment eroded from the interterrace interval, particularly if the terraces are level and include closed outlets, have underground outlets, or have a very low grade. Deposited sediment remains on the field and is redistributed over a significant portion of the field, thus reducing soil deterioration caused by erosion. In this way, terraces help to maintain the soil resource much as contour stripcropping does. Furthermore, properly designed terraces and outlet channels collect surface runoff and convey it off the field at nonerosive velocities. Without the terraces and outlet channels, runoff in natural waterways on unterraced fields can cause significant erosion.

Deposition Behind Terraces

The amount and location of sediment deposited on terraced fields are important in assigning P-factor values to calculate soil loss for conservation planning. If no soil is trapped, none is saved by deposition. Even if deposition traps all sediment eroded from the interterrace interval, the area benefiting directly is that near the terraces. Some of the interterrace interval is still degraded as if no deposition occurs. The P factor for computing soil loss for conservation planning to maintain the soil resource is computed as a function of spacing between terraces. The maximum benefit assigned to deposition is that half of the deposition directly benefits maintenance of the soil resource at spacings of less than 110 ft. At spacings of greater than 110 ft, the benefit is assumed to decrease to the point that no benefit is assigned for spacings of 300 ft and greater.

Erosion of the upslope and deposition on the downslope portion, within the terrace interval, cause a flatter slope that can be permanently maintained above storage-type terraces. On deep soils, a permanent bench can be formed, resulting in less erosive topography and easier farming (Jacobson 1981).

Measured elevations on gradient terraces (Borst et al. 1945, Copley et al. 1944, Daniel et al. 1943, Pope et al. 1946, Smith et al. 1945) showed that after 8 yr, deposited soil accumulated on terrace ridges, channel bottoms, and front and back slopes. The sediment accumulation on ridges and backslopes was produced by displacement during tillage and terrace maintenance. With closed

outlet and underground outlet terraces, sediment accumulates where runoff enters standing water.

Effect of Grade

An analysis of terrace data from the 1930's and 1940's showed that deposition varies greatly with terrace grade (Foster and Ferreira 1981). Sediment yield from single-terrace watersheds with a range of grades was measured for about 8 yr at several locations. Results of this analysis show that the sediment yield from uniform-grade terraces increases according to the following exponential relationship:

$$P_y = 0.1e^{2.4s} \qquad s<0.9\% \qquad [6\text{-}43]$$

$$P_y = 1.0 \qquad s\geq 0.9\% \qquad [6\text{-}44]$$

where P_y = sediment delivery factor and s = terrace-slope grade (%). The P factor for conservation planning is computed as

$$P = 1 - B(1-P_y) \qquad [6\text{-}45]$$

where B = the benefit assigned to deposition, and the quantity $1-P_y$ = that amount of deposition, comparable to M in the stripcropping computations. Values for B are given in table 6-14.

Terrace P Factor for Conservation Planning

The P factor for terraces for use in conservation planning considers both the benefit of deposition and the amount of sediment deposited. This net soil loss is the soil loss on the interterrace interval minus the amount of deposited soil that is credited for helping to maintain the soil resource. Table 6-15 gives terrace P-factor values for use in conservation planning (Foster and Highfill 1983). Table 6-16 gives values for use in estimating sediment yield from terraces.

To compute soil loss with RUSLE for conservation planning, values for the terrace P factor are multiplied by other factor values for contouring and stripcropping on the interterrace interval.

SUPPORT PRACTICE FACTOR (P) FOR SUBSURFACE DRAINED AREAS

Limited field data indicate that subsurface drainage is effective in reducing overland flow and erosion (Formanek et al. 1987, Bengtson and Sabbage 1988). Both the Formanek and the Bengtson and Sabbage studies reported P values with an average of about 0.6, although individual annual values and storm values varied appreciably.

Because of limited information and differences in procedures among studies, further research is needed to develop a range of P-factor values for subsurface drained areas that are applicable across many conditions of climate, soil, crop, and slope. The technique needing development may well include a procedure similar to that reported by Skaggs et al. (1982). This technique may involve estimating runoff volume, peak runoff rate, and storm EI by use of a physically based model like CREAMS (Knisel 1980) to estimate P-factor values for simulations with and without subsurface drainage situations over a wide range of field conditions.

SUPPORT PRACTICE FACTOR (P) FOR RANGELANDS

The support practice factor (P) in RUSLE reflects the effect on rangeland erosion of mechanical practices such as ripping, root plowing, contour furrowing, and chaining. Some common mechanical practices applied on rangelands are listed in tables 6-17, 6-18, and 6-19. These practices affect erosion in several ways, including the removal of surface cover, which is perhaps the most important single factor affecting erosion. However, that effect is considered by the cover-management factor C in RUSLE. Mechanical practices described by the P factor can affect runoff amount, runoff rate, flow direction of runoff, and hydraulic forces exerted by runoff on the soil.

Almost every mechanical practice that disturbs rangeland soils increases infiltration, which in turn reduces runoff and erosion. An exception is the compaction and smoothing used for water harvesting. The degree to which infiltration is increased depends on the soil. The increase in infiltration and the reduction in runoff can be very large on the coarse-textured soils of the southwestern United States, whereas the increase in infiltration and the reduction in runoff can be slight on fine-textured soils like those in South Dakota. In fact, the crusting of fine-textured soils after mechanical practices that expose the soil can cause decreased infiltration. The ratings for runoff reduction given in tables 6-16, 6-17, and 6-18 are general. More precise ratings are possible from knowledge of the hydrologic properties of local soils.

A practice like contour furrowing that produces ridges and furrows will redirect surface runoff from flowing directly downhill to a flow path around the hill on a reduced grade. The reduced grade can greatly decrease the erosivity of the runoff. A practice like ripping at right angles to the slope, which leaves a very rough surface, also slows the runoff and reduces its erosivity. Depressions formed by the roughness provide areas where sediment is deposited, thus reducing soil loss.

The effectiveness of mechanical practices decreases over time as the soil surface seals and the depressions and furrows are filled with sediment. The rate at which a practice loses its effectiveness depends on the climate, soil, slope, and cover. The estimated times of effectiveness for practices listed in table 6-19 are general and should be adjusted for local conditions. Values for P should be

increased over time from the minimum value immediately after treatment, because the practices are estimated to lose their effectiveness.

Runoff Reduction and Surface Roughness

The effect of increased infiltration and surface roughness are considered together when selecting a value for P because the influence of runoff and surface roughness are interrelated with slope steepness. The effect of surface roughness on the reduction of soil loss will decrease as the slope steepness increases.

Values for the P factor for rangelands for the effect of roughness, infiltration, and slope are computed in RUSLE with the equation

$$P = \frac{D_y}{D_e} \qquad [6\text{-}46]$$

where D_y = sediment transported from the slope, and D_e = sediment produced on the slope by detachment.

The P factor considers that the roughness is assumed to cause some of the sediment produced by detachment to be deposited in the depressions left by the roughness. The amount of sediment leaving the slope (D_y) is computed by the deposition equation used to compute values for P with stripcropping (Renard and Foster 1983), as follows:

$$D_y = \left(\phi \; dT/dx + D_e\right) / \left(1 + \phi\right) \qquad [6\text{-}47]$$

where ϕ = a parameter that indicates how readily sediment is deposited, and dT/dx = change in transport capacity with distance.

A value of 15 was assigned to ϕ, the same as in the stripcropping computations. The equation for dT/dx is based on the transport capacity equation used in WEPP (Foster et al. 1989), as follows:

$$dT/dx = k_t \; s \; \sigma \; r_f \qquad [6\text{-}48]$$

where k_t = a transport coefficient, s = sine of the slope angle, σ = excess rainfall rate (rainfall rate minus infiltration rate), and r_f = a roughness factor.

The parameter k_t was assigned a value of 33.28, which was chosen so that the model would fit experimental data for deposition as a function of slope (Meyer and Harmon 1985). Excess runoff rate is computed from

$$\sigma = 1 - f_r \qquad [6\text{-}49]$$

where f_r is a runoff reduction factor that varies between an initial value at the time of disturbance and zero after decaying over time as the soil consolidates after the disturbance according to

$$f_r = f_{ri}\, c_d \qquad [6\text{-}50]$$

where f_{ri} = the initial runoff reduction, and c_d = the consolidation factor that is given by

$$c_d = \exp\left(-d_t\, t_d\right) \qquad [6\text{-}51]$$

where d_t = a decay parameter, and t_d = time (yr) since the soil was disturbed.

Consolidation is assumed to begin immediately. The decay parameter is computed from

$$d_t = -\ln(0.05) \,/\, t_c \qquad [6\text{-}52]$$

where t_c = time (yr) for 95% of effect of disturbance to have disappeared by consolidation.

Runoff reduction at the time of disturbance is computed by use of the 10-yr frequency single-storm erosivity, and the NRCS runoff index method. Values for runoff index as a function of cover roughness are described in table 6-20; cover roughness conditions are shown in table 6-21. The runoff index values are

a function of the rainfall intensity pattern in a storm. Runoff index values are greater for thunderstorm-type rains than for long-duration, gentle, frontal-activity rains. The ratio of 10-yr storm erosivity, $(EI)_{10}$, to average annual precipitation (P) is used as an index to determine curve number values. For $(EI)_{10}/P > 3$, values for thunderstorm-dominated areas are used; for $(EI)_{10}/P < 1$, values for areas dominated by frontal activity are used. Linear interpolation is used for values of $(EI)_{10}/P$ between 1 and 3.

The roughness factor (r_f) is computed from

$$r_f = 0.23\ r_i^{-1.18} \qquad [6\text{-}53]$$

where r_i is a roughness index (in). The coefficient 0.23 and exponent -1.18 were selected to give values for the roughness factor (r_f), which are similar to the values used for ζ in the stripcropping computations.

The value used for r_i is the value that represents the current surface condition. That value is determined by interpolating between the roughness immediately after disturbance and the roughness after consolidation. Equations [6-50] and [6-51] are used in this interpolation. Roughness values for the RUSLE range condition classes are given in tables 6-21 through 6-24.

Detachment (D_e) is assumed to be the same for all conditions except for the effect of disturbance. Detachment is computed with the equation

$$D_e = D_b + \left(1 + D_b\right) c_d \qquad [6\text{-}54]$$

where D_b is the minimum value of detachment after it decreases over time after consolidation relative to the detachment immediately after disturbance. A value of 0.45 is assumed for D_b, the same as used in the C-factor computations.

Redirection of Runoff

When applied on rangelands, practices like contour furrowing are effective because they redirect surface runoff from a downslope path to a less erosive path around the hill. Any rangeland practice that leaves ridges sufficiently high to redirect runoff in this manner has an effect that is considered in the P factor.

Slope Length and Steepness Taken Downhill

Ideally, the grade along the furrows between the ridges should be flat or near flat so that runoff may spill uniformly over the length of the ridges. Ridges perfectly on the contour ensure maximum runoff storage and infiltration and also minimize runoff and erosion. P values for this condition are computed using equations [6-1] through [6-10] by use of the parameter values given in tables 6-21 through 6-24. Slope length is then taken directly down the hill perpendicular to the contour.

The effectiveness of contouring depends on the storm erosivity and the reduction in runoff caused by mechanical practices. Because a few major storms determine the overall effectiveness of contouring, the erosivity (EI_{10}) of the storm with a 10-yr return interval is recommended as the basis for adjusting contour factor values to account for the influence of storm erosivity.

The effectiveness of contouring depends on the ridge height, as indicated by the contour factor values in figure 6-2. A low-height ridge (2-3 in) is like that left by a typical rangeland drill or light disk. Moderately high ridges are those that are left by an agricultural chisel plow with twisted shanks. Very high ridges (>6 in) are like those left by typical contour furrowing on rangelands.

To get the ridges exactly on the contour is practically impossible. When the ridges are off-contour, runoff flows along the furrows to low places in the landscape. As water accumulates, breakovers in these depressed areas often occur and cause concentrated flow erosion. The effectiveness of contouring is rapidly lost as grade along the furrows increases.

The same relationships used in the cropland section and the parameter values given in tables 6-21 through 6-24 are used to compute the effect of storm erosivity, increased infiltration, ridge height, and grade along the ridges for contouring on rangeland.

Terraces, Diversions, and Windrows

Terrace and diversion channels on a slight grade across a slope will intercept surface runoff and direct it around the slope on a slight grade. As a part of chaining, brush and other debris are sometimes pushed into windrows that are on the approximate contour. If these windrows intercept surface runoff and direct it around the hill, they too should be treated as terraces.

Terraces and similar practices usually reduce the slope length. Therefore, when RUSLE is applied to terraced land, the slope length is taken from the origin of surface runoff on the upslope terrace ridge or other watershed divide to the edge of the flow in the terrace channel. Slope steepness used in the S factor is the slope of the interterrace area. This procedure for selecting slope length is used when the terraces are on a uniform grade. Sometimes the terraces may be on a nonuniform grade and may be so far apart that concentrated flow areas develop on the interterrace interval. When this situation exists, terraces may have little effect on slope length, and the slope is taken in the same way as if the terraces were not present.

Terrace, diversion, or windrow channels on a sufficiently flat grade cause considerable deposition, with the amount deposited being a function of erosion between terraces and channel grade. Sediment yield from the terrace outlets may be obtained by multiplying the RUSLE soil-loss estimate for the interterrace area by the sediment delivery ratio values in table 6-16.

Conservationists debate the value of deposition in terraces for maintaining soil productivity. It is usually given some credit on cropland because tillage is assumed to partially redistribute the deposited sediment. Because tillage is infrequent, if ever, on rangelands, no credit should be given for a benefit of deposition. However, if this credit is taken for conservation planning purposes, the suggested values in table 6-15 may be used.

Undisturbed Strips

Undisturbed strips of land adjacent to channels are sometimes left to minimize the sediment yield into a channel and the accelerated channel erosion. If the undisturbed strips have heavy ground cover, the deposition of sediment can occur when water flows through the strips from the disturbed areas. The effectiveness of these practices on rangeland are judged to be highly variable, and a procedure for applying RUSLE to these strips is not provided.

P-FACTOR VALUES FOR STRIPCROPPING ON CROPLAND IN THE NORTHWESTERN WHEAT AND RANGE REGION

Runoff and erosion processes occur very differently on cropland in the Northwestern Wheat and Range Region than on cropland in other parts of the United States. Much of the erosion occurs during the winter from rain or snowmelt on thawing soils. These soils remain wet and highly erodible over several weeks from repeated freezing and thawing. A transient frost layer near the surface allows little infiltration, producing high amounts and rates of runoff for given amounts and intensities of rainfall.

The definition of cover-management conditions and the values for the runoff indices used in RUSLE for cropland in the Northwestern Wheat and Range Region for these winter conditions differ from values used for other locations. These definitions and the adjusted values for winter are shown in table 6-25 and 6-26, respectively.

Strips with residue and stubble that are rough tilled with implements similar to chisel plows and moldboard plows that turn the soil uphill can have high infiltration rates—often so large that runoff from upslope completely infiltrates within the strip if the strip exceeds about 50 ft. No runoff or sediment leaves the rough-tilled strip. The soil must be left in a rough-tilled condition with residue from the previous crop for these high infiltration rates to occur. Infiltration on these rough strips seems to be greater than that for permanent grass strips.

The cover and roughness of this rough-tilled condition is represented by condition VR in table 6-25. The rough-tilled strip is assumed to behave the same during the winter as at other times during the year. Values for the runoff index for the remaining strips where frost affects infiltration are selected from table 6-26. Values for runoff indices for periods not influenced by frost are selected from table 6-5.

The choice of slope length must be considered where all upslope runoff infiltrates on a strip. Two approaches may be used. The preferred approach is to use the entire slope length as if infiltration did not differ among the strips. The effect of all sediment reaching a strip being deposited within the strip is considered by RUSLE in the computation of P.

The alternative approach is to assume that the effect of the stripcropping system is like that of terraces. A slope length equal to the width of the strip is selected and a P-factor value is computed for terraces assuming a closed-outlet terrace.

Table 6-4.
Description of cropland cover-management conditions used in RUSLE for estimating P-factor values

Categories of conditions	Description of condition
C1. Established meadow (very dense cover)	Grass is dense and runoff is very slow, about the slowest under any vegetative condition. Becomes condition 2 when mowed and baled.
C2. 1st yr meadow, hay (moderately dense cover)	Hay is a mixture of grass and legume just before cutting. Meadow is a good stand of grass that is nearing the end of 1st yr. Becomes condition 4 when mowed and baled.
C3. Heavy (dense) cover or very rough or both	Ground cover for this condition is about 75-95%. Roughness is like that left by a high-clearance moldboard plow on a heavy-textured soil. Roughness depressions appear 7 in or more deep. Vegetative hydraulic roughness like that from a good legume crop (such as lespedeza) that has not been mowed.
C4. Moderate cover or rough or both	Ground cover for this condition is about 40-65%. Roughness is like that left by a moldboard plow in a medium-textured soil. Depressions appear 4-6 in deep. Vegetative hydraulic roughness is similar to that produced by winter small grain at full maturity.
C5. Light cover or moderate roughness or both	Ground surface cover is 10-30%. Surface roughness is like that left by first pass of tandem disk over a medium-textured soil that has been moldboard plowed. This roughness could also be similar to that left after a chisel plow through a medium-textured soil at optimum moisture conditions for tillage. Roughness depressions appear 2-3 in deep. In terms of hydraulic roughness produced by vegetation, this condition is similar to that produced by spring small grain at about 3/4 maturity.
C6. No cover or minimal roughness or both	This condition closely resembles the condition typically found in row cropped fields after the field has been planted and exposed to a moderately intense rainfall. Ground cover is less than about 5%. Roughness is like that of a good seedbed for corn or soybeans. Surface is rougher than that of a finely pulverized seedbed for seeding vegetables.
C7. Clean-tilled, smooth, fallow	Surface is essentially bare, 5% or less of cover. Soil has not had a crop grown on it in the last 6 mo or more, so much of the residual effects of previous cropping has disappeared. Surface is smooth, similar to the surface that develops on a very finely pulverized seedbed exposed to several intense rainfalls. This condition is most likely found in fallow and vegetable fields.

M1-RC-M1-RC (year 3)		
M2-SSG-M2-SSG (year 4)		
RC-RCrt-RCrt-M1	0.65	0.84
Cnt-SBrt-SBnt	1.00	1.00
Crt-SBrt-Crt-WSGrt	0.89	0.96
0.5 filter[8]	0.06	0.51
0.1 filter[9]	0.24	0.91
Buffer strips[10]	0.15	0.67
Buffer strips[11]		0.71
Buffer strips[12]		0.75

[1]Values for filter strip systems are primarily for illustration as filter strips are usually not used to protect upslope areas from productivity loss.
[2]RC = row crop, WSG = winter small grain, SSG = spring small grain, M1 = 1st yr meadow, M2 = 2d yr meadow, C = corn, SB = soybeans, rt = reduced tillage, nt = no till.
[3]Wischmeier and Smith (1978) P = 0.50.
[4]Wischmeier and Smith (1978) P = 0.75.
[5]Wischmeier and Smith (1978) P = 1.00.
[6]Wischmeier and Smith (1978) P = 1.00, but they note that winter small grain can be effective in some cases.
[7]Location of strips by year in rotation; that is, Y1 is year of rotation.
[8]Permanent meadow filter strip that covers 0.5 of slope below row crop.
[9]Permanent meadow filter strip that covers 0.1 of slope below row crop.
[10]Permanent meadow buffer strips located at 0.4-0.5 and 0.9-1.0, separated by row crop strips.
[11]Permanent meadow buffer strips located at 0.35-0.40 and 0.65-0.70, separated by row crop strips.
[12]Permanent meadow buffer strip at 0.4-0.5, separating two row crop strips.

Table 6-14. Benefit assigned to deposition behind terraces

Terrace spacing (ft)	Benefit (B)
≤110	0.5
125	.6
160	.7
200	.8
260	.9
≥300	1.0

Table 6-15.
Terrace P-factor values for conservation planning[1]

Horizontal terrace interval (ft)	Terrace P-factor values			
	Closed outlets[2]	Open outlets, with percent grade of[3]		
		0.1-0.3	0.4-0.7	>0.8
Less than 110	0.5	0.6	0.7	1.0
110-140	.6	.7	.8	1
140-180	.7	.8	.9	1
180-225	.8	.8	.9	1
225-300	.9	.9	1	1
More than 300	1	1	1	1

[1]Multiply these values by other P-subfactor values for contouring, stripcropping, or other support practices on interterrace interval to obtain composite P-factor value.

[2]Values for closed-outlet terraces also apply to terraces with underground outlets and to level terraces with open outlets.

[3]Channel grade is measured on the 300 ft of terrace closest to outlet or 1/3 of total length, whichever distance is less.

Table 6-16.
Sediment delivery subfactor (P_y) for terraces[1]

Terrace grade	Sediment delivery subfactor
%	
Closed outlet	[2]0.05
0 (level)	.10

Table 6-19.
Common mechanical practices applied to rangelands

Practice	Degree of disturbance	Surface configuration	Estimated duration of effectiveness (yr)	Runoff reduction
Rangeland drill	Minimal tillage except in furrow	Low ridges (<2 in) and slight roughness	1–2	None to slight
Contour furrow/pitting	Major tillage 8-12 in deep	High ridges, about 6 in	5–10	Slight to major
Chaining	Severe surface but shallow	Slight to moderate random roughness	3–5	Slight to moderate
Land imprinting	Moderate-sized shallow depressions	Short channels (40 in) and small to moderate	2–3	Slight to moderate
Disk plows, offset disks	Major tillage, about 4-8 in deep	Moderate ridges 2-4 in	3–4	Slight to moderate
Ripping, grubbing, root plowing	Minimal but often deep, 8+ in	Slight to very rough, especially when done at right angles	4–7	Moderate to major

Table 6-20.
Definition of cover-roughness conditions for rangeland

Condition identification	Description
R1	Very rough; plant plus rock cover greater than 50%
R2	Very rough; plant plus rock cover less than 50%
R3	Rough; plant plus rock cover greater than 50%
R4	Rough; plant plus rock cover less than 50%
R5	Moderately rough; plant plus rock cover less than 50%
R6	Moderately rough; established vegetation; plant plus rock cover less than 40%
R7	Slightly rough; plant plus rock cover less than 25%
R8	Slightly rough; established vegetation; plant plus rock cover less than 35%
R9	Smooth; established vegetation; plant plus rock cover less than 25%

[1]Defined in table 6-20

Table 6-25.
Description of cropland cover-management conditions used in RUSLE for estimating P-factor values in the Northwestern Wheat and Range Region.

Categories of conditions	Description of condition
C1. Established sod-forming grass (very dense cover)	The grass is dense and runoff is very slow; about the slowest under any vegetative condition. When moved and baled, this changes to condition 2.
C2. Standing stubble, 1st year grass, or meadow to be cut for hay (moderately dense cover)	The stubble is from a good stand with few rills or flow concentrations. The hay is a mixture of grass and legumes just before cutting. When mowed and baled, this becomes condition 4.
C3. Heavy (dense) cover or very rough or both	Ground cover is about 75 to 95%. Roughness depressions appear to be 5 or more inches deep (Random Roughness >2 ½ inches). Vegetative hydraulic roughness is like that of a good legume crop that has not been mowed.
C4. Moderate cover or roughness or both	Ground cover is about 40 to 65%. Roughness depressions appear to be about 3 to 5 inches deep (Random Roughness 1 ½ to 2 ½ inches), and vegetative hydraulic roughness is like that of a good stand of winter small grain at full maturity.
C5. Light cover or moderate roughness or both	Ground cover is from 10 to 30%. Roughness depressions appear to be 1 to 3 inches deep (Random Roughness ½ to 1 ½ inches), and the vegetative hydraulic roughness is like that of a typical stand of spring small grain at 3/4 maturity.
C6. Minimal cover or minimal roughness or both	Ground cover is 5 to 10% and the roughness is that of a moderately tilled seedbed. The surface is rougher than that of a finely pulverized seedbed for seeding vegetables. Roughness depressions appear to be ½ to 1 inch deep (Random Roughness 1/4 to ½ inch).
C7. Clean, tilled, smooth, fallow	The surface is essentially bare, with less than 5% cover. A crop has not been grown for some time so that the residual effects of previous cropping have disappeared. The surface is smooth, similar to that of a finely pulverized seedbed exposed to one or more intense rainfalls. Roughness depressions appear to be less than ½ inch deep (Random Roughness < 1/4 inch). This condition is most likely found in a fallowed field, but could exist in a vegetable field as well.
VR. Very rough primary tillage	Very rough primary tillage across slope that leaves the soil fractured below normal frost depth. The fractures are expected to last through the winter erosion season, preventing surface sealing and formation of impermeable frost, thus allowing a high rate of infiltration. Roughness depressions are greater than 7 inches deep (Random Roughness > 3 inches).

CHAPTER 7. CONTENTS

WELCOME TO THE RUSLE COMPUTER PROGRAM

Purpose of the User Guide

This User Guide is designed to teach the first-time user how to run the RUSLE computer program, and to answer the questions most frequently asked by more experienced users. Because the program itself provides online help screens that describe the expected user responses, this Guide focuses instead on the reasoning and mechanics behind the responses. The background theory and equations used in soil-loss calculations are described in chapters 1 through 6 of this handbook.

Introduction to the User Guide

The first portion of this User Guide is meant for first-time users. It explains in general terms how RUSLE works and introduces the terminology that will be used in the following sections. This introductory section is not long, and we strongly recommend that novice users read it to familiarize themselves with the program.

The remainder of the User Guide gives specific information on the different parts of the program, including answers to frequently asked questions. This reference section of the User Guide assumes familiarity with the terminology of the program, and may be confusing if you have not read the introductory section.

Within the User Guide, a command or entry that you type in is shown in brackets, [ ], and the name given that command or entry is placed in braces, { }.

INFORMATION FOR FIRST-TIME USERS

Getting RUSLE To Work on Your Machine

Background

The RUSLE computer code was written in the C programming language. Since C is portable, the program can be run on a variety of machines. RUSLE has been tested on IBM-compatible machines with 640 kilobytes of RAM memory using the MS-DOS operating system (version 2.0 or later). It has also been used on large systems under the UNIX operating system, and on the ATT 6386 under both DOS and UNIX. The executable program will run only on the type of machine on which it was compiled; if this is something other than DOS, the machine type will be specifically noted on the diskette labels.

The RUSLE executable program is large and does not have the capability of using expanded memory. It therefore may cause problems if used at the same time as other programs that reside in lower memory, possibly including some shell programs or peripheral drivers. This problem most often shows up as an "out of memory" error message. This can be minimized by not using these memory-resident packages when running RUSLE. Consult your DOS or program manuals or your site consultant for more details.

Loading RUSLE From Supplied Diskette(s) Onto Computer

The RUSLE program can be run directly from the supplied diskette in the floppy drive. As with most other programs, however, RUSLE can be run much faster and more efficiently by loading it onto the hard disk drive.

For DOS systems, RUSLE can be loaded by copying all the files from the diskette(s) onto the hard disk. These files include the RUSLE executable program, the Database files, the files used to create the Help screens, and some miscellaneous system files. These files should be copied into a directory created specifically to run RUSLE, as this will speed execution and make the program easier to use. Consult your DOS system manual for instructions on creating a directory and on copying files from the diskette drive to that directory.

Copying all the files onto the hard disk should also be done when using the RUSLE computer program from within a DOS window environment. The files should still be copied from the supplied diskette(s) into a directory, although this

will be done through use of a file manager. If desired, the windowing package can then be used to link the execution of the RUSLE code to an icon through use of a command line containing one of the commands specified below.

For UNIX systems, the technique for loading the program from the diskette(s) onto the hard disk depends greatly on the system. Consult your system manuals or specialist for instructions.

Running RUSLE

Once the RUSLE files have been loaded into a directory on the hard drive, begin operation by moving into that directory and typing one of the commands listed below. The command [rusle] puts you into the main program and brings up a menu that lists the options for the program. If you want to run only one of the factors or options, simply enter its command. For example, to have access to the CROP Database, the command is [rusle crop]; to run the C-factor subprogram, the command is [rusle c]. The options for the command string are as follows:

[rusle]	to get the RUSLE Main Menu, giving access to all the options
[util]	the three Database Utility programs
[city]	the CITY Database Utility program
[crop]	the CROP Database Utility program
[op]	the OPERATIONS Database Utility program
[r]	R-factor routine only
[k]	K-factor routine only
[ls]	LS-factor routine only
[c]	C-factor routine only
[p]	P-factor routine only

If you choose any option other than [rusle], you will not be able to reach all the other options.

How RUSLE Works

Background

The computer code within RUSLE is responsible only for calculations based on information that you give it; you are responsible for the quality of that information, and most of your time using the program will be spent describing your situation in terms that the program understands.

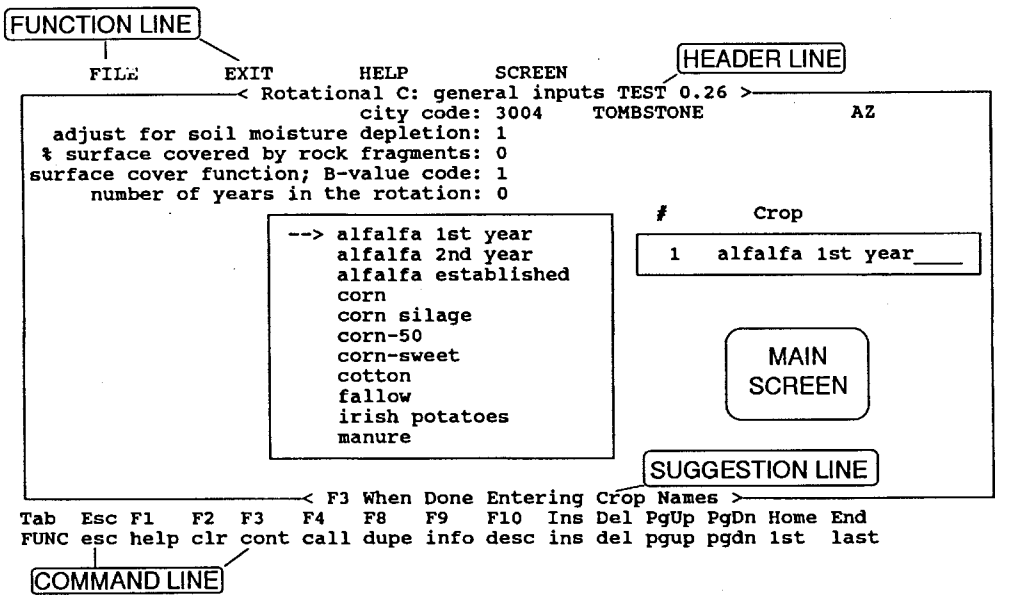
RUSLE is based on a routine that waits for your response. There are two basic types of responses. The first is to answer the question that the program is

asking–a fill-in-the-blank answer. We call this response an "input." The second type of response is a "command," which tells the program what to do next. For example, commands are used to direct the program to carry out the calculations or to move to the next screen. Inputs and commands are often used together. For instance, if the program prompts you for the name of a CROP, you might type in [cotton] as the input, and then give a command by pressing the [ENTER] key.

In most cases, you can respond with either an input or a command, but there are a few cases when only a command is appropriate. For instance, in looking at results, all the program needs to know is when and how you want to move on; the input type of response is not available.

Description of RUSLE Screen

All your interaction with RUSLE will be through screens that have the same general pattern as shown



The screen can be divided into five parts, as follows:

(1) Main Screen

The main portion of the screen is the area in the center, which contains the list of questions and comments. It is here that inputs are entered and results displayed.

(2) Command Line

The bottom two lines of the screen make up the Command Line. Whenever the program is awaiting your response, commands will tell it what to do next. The available commands are listed here on the screen. The upper of these two lines shows which key to press to execute each command; on the lower line below each key is listed a three- or four-letter command description. The section "Giving Program Commands" later in this chapter lists all possible commands and what they do.

(3) Function Line

The top line on the screen is called the Function Line; it defines RUSLE Functions. These are subroutines that perform the housekeeping chores for the program. The FILE Function provides all the options for manipulating Input Files and the Current Input List (see "Input Lists And Files"). The EXIT Function provides options for leaving the program. The HELP Function provides several options for general help on running RUSLE. The SCREEN Function gives the user control over how the screen looks. "The Functions: Program Housekeeping" explains the use of the Function Line.

(4) Header Line

The second line down from the top of the screen is the Header Line, which tells the user the version of RUSLE that is running and the name of the current screen.

(5) Suggestion Line

The third line up from the bottom of the screen is the Suggestion Line, which lists the most likely command or course of action. This displays the suggested response or course of action as you go through the logical sequence of the program.

Input Field

An Input Field is a place where the cursor sits as the program waits for you to answer a question. As mentioned above, your response can be either an answer to the question (input), or a command telling the program what to do next. An input can take any of three forms:

(1) *Filling in a blank.* For example, when the program asks for a CROP name, the appropriate response may be to type [cotton].

(2) *Selecting an option.* The program shows a numbered list of options and asks you to select one. If you have not already chosen one of the options, the entire list will be shown. There are two ways to select an option: Type in the number shown next to the desired option and then press [ENTER] to select it, or use the [ARROW] keys to move through the list and then press [ENTER] to choose the marked option. If one of the options was chosen earlier, the list may not be shown, but the {list} command will display the options again. See "Giving Program Commands" for more information on this command. In some cases the list is always shown, but the marking arrow may not appear within it. In this instance, use of the {list} command will move the arrow into the list.

(3) *Selecting an item from a list.* This works in the same way as the option selection described above, but is based on a list of named items rather than on a numbered list of options. The box in the center of the example screen shown previously contains such a list.

Giving a Command

The second way to respond to an input field is to give the program a command, which tells it what to do next. There are several commands to which the program will always respond, so they are not displayed on the screen. These are the [ARROW] keys and [ENTER]. A list of all possible commands and what they do can be found in the section titled "Program Commands and Controls." Not all of the commands can be used at every place in the program, so the list of commands that are available for use from the current Input Field is shown on the Command Line at the bottom of the screen. A command is given by pressing the key listed on the Command Line.

Calling a Function

One command that is usually available is {FUNC}, which moves the cursor onto the Function Line (the top line of the screen). This allows you to perform the general housekeeping chores shown on that line. These include the FILE routines (see "How RUSLE Gets, Uses, and Saves Information" for an overview or "Input Lists and Files" for complete information), the EXIT routines that allow the user to leave the program, the HELP routines for assistance in using the program (see "Help"), and the SCREEN routine for changing screen colors.

When {FUNC} has been used to move the cursor to the Function Line, use the [RIGHT ARROW] or [LEFT ARROW] keys to move it through the functions. As the cursor moves to a function, the list of associated routines is displayed. [ARROW] up or down through the list until the routine you want is marked, or type in the number of the desired function. Press [ENTER] to select that routine and begin its execution. With the cursor on the Function Line, use the {esc}ape command to return to the Main Screen.

"The Functions: Program Housekeeping" gives more information on calling and using the Function routines.

Getting Help

RUSLE provides two general types of help. The first is additional information on the current input field, describing what sort of input is expected and why. This is always available through the {help} command. The second is made up of general descriptions of RUSLE and its operation, available through the HELP routines of the Function Line.

How RUSLE Gets, Uses, and Saves Information

Background

RUSLE requires a lot of information telling it which calculations to make and what values to use for the variables in each equation. It can get that information from one of three sources: values you enter directly, data that you have stored in Databases, or information that you entered earlier and then stored.

Current Input List

RUSLE maintains a record of all responses to the program questions in a list called the Current Input List. This is updated every time you respond to a question by either entering an input or selecting an option or item. The list does

not include the commands given to the program. When the program begins, this list is cleared (everything is set to 0).

The section titled "Input Lists and Files" provides more information on the Current Input List and its manipulation.

Input Files

Entering information by hand is tedious and inefficient. In order to make it easier to enter information and also to provide a record of the values used, you can save the Current Input List into an Input File. Each Input File thus contains a copy of the Current Input List at the time it was saved, along with a unique name and identifying comments. "Input Lists and Files" explains how to save the Current Input List into an Input File, and how to load one of these files back in as the new Current Input List.

Databases

The RUSLE Databases provide another way of entering data more efficiently by associating a large amount of information with a single Identifier. For example, all the weather information for a specific city can be associated with a city code, which from then on serves as the Identifier for all that information. You need to enter the weather information for that city only once; from then on, you can retrieve any part of that information by just giving the Citycode Identifier.

RUSLE contains three Databases. The CITY Database includes all necessary climatic data identified with a specific city or region. The CROP Database provides information on the growth and residue characteristics of specific crops or other vegetation. The OPERATIONS Database defines how field operations affect the soil, crop, and residue and, through those, the erosion rates. General information on using the Databases can be found in the section titled "Databases," and information unique to an individual Database can be found in the sections "CITY Database," "CROP Database," and "OPERATIONS Database."

You should change the information in the Databases to meet your specific situation and needs. Remember that the Databases exist to make it easier to enter the required information but that the users are still responsible for the validity of the information used in their computations. Appendix D provides valuable advice on how to modify the existing core database information to match your specific situation.

PROGRAM COMMANDS AND CONTROL

From any input field within RUSLE, you have the option of either answering the question or giving the program a command. In general, these commands control the flow of the program by telling it when to move on to the next step or screen, telling it that you want to get back out of the current section, telling it to leave the program altogether, and so on.

Giving Program Commands

There are several commands to which the program will always respond, so these are not shown on the screen. One such command is {ENTER}, given using the [ENTER] key ([RETURN] or [NEW LINE] on some machines). This command tells the program to accept the current value as the answer to the question being asked and to move on to the next question. The other commands not displayed are the [ARROW] commands, which are used to move the cursor. When a [RIGHT ARROW] or [LEFT ARROW] doesn't make sense (as in a vertical list of questions), using either [ARROW] will have the same effect as using [ENTER].

The [ARROW] commands have one additional peculiarity. As described in "Input Field," some questions ask you to choose from a list of options. When no choice has been made, moving the cursor onto that question will automatically display the list and put the cursor in the list. Using [ARROW]'s at this point will move the cursor within the list rather than between questions on the main screen. Once you have answered the question, the list will not be displayed unless you ask for it with the {list} command, so the [ARROW]'s will move the cursor on the Main Screen without interruption.

In addition to [ENTER] and [ARROW], there are usually several other commands to which the program will respond. These vary from screen to screen and question to question, but the available commands will always be listed on the Command Line. The Command Line actually comprises the bottom two lines of the screen. The upper line shows which key to use, and the lower line gives a three- or four-letter description of the command. "Description of RUSLE Screen" shows an example of how this appears on the screen.

List of Commands

A complete list of all possible commands and a brief description of what each does is given below. The command description or name is given within braces, { }, and the associated DOS key for each command is shown within brackets, [ ]. The keys may differ on some machines, but the command description is always as shown here.

{FUNC} [TAB]	places the cursor onto the Function Line to let you do the required housekeeping chores (see "Calling a Function" or "The Functions: Program Housekeeping"). When the cursor is on the Function Line, use {esc}ape to bring it back to the Main Screen.
{esc} [ESC]	allows you to {esc}ape from the current screen or question without giving an answer. This is most commonly used in three places: (1) if you have gotten into a screen or series of screens and want to get back out; (2) after an error or warning message has been displayed, and you want to continue; (3) to continue the program after a result has been displayed.
{help} [F1]	shows one or more screens of additional information to help answer the current question (see "Help"). This usually includes a brief description of how the variable is used in the calculations and also suggestions for possible answers.
{clear} [F2]	{clear}s (sets to 0) all variables associated with the current screen. This is most useful when you want to get a fresh start on a screen containing several mistakes.
{cont} [F3]	{cont}inues program movement to the next logical screen in the sequence. For example, when you have answered all the questions on one screen, this command moves you to the next screen or initiates the calculations. For screens that require only one input or command, the {cont}inue command acts just like an [ENTER], telling the program to accept the current value and to move on.
{call} [F4]	{call}s a subroutine on which the answer might depend. Use of this command will automatically put you into the

required subroutine; when you exit from that, you will return to the current question.

The {call} command is used in three different instances.

(1) When an answer is calculated from the results of several different factors. An example is in estimation of soil loss from the factor values. Each factor is {call}ed individually by use of this command.

(2) When the question asks for the Identifier of a Database Set, as when entering a city code, a crop name, or an operation name. Use of the {call} from one of these locations allows you to examine or modify the information within the associated Database. "Databases" gives more detail.

(3) When the calculation requires information entered in another portion of the program. An example of this is the value of average field slope, which is used in several places but is calculated within the LS factor. If this value has already been calculated, it will be shown; if not, the {call} command must be used to move to that calculation.

{list} [F6] displays a list from which you can select an option or item, as explained in "Input Field." If you have previously selected one of the choices, the list may not be shown but this command will appear as an option. Use of this command displays the list and allows you to move through it using the [ARROW] keys.

There are places in the program where the list is also shown but the marker arrow is not visible. In these cases, a {list} command will move the marker arrow into the list, where the marker can be controlled with the [ARROW] keys.

{save} [F7] {save}s the data shown on the screen into a Database Set named by the Identifier at the top of the screen. Changes

made within the CITY, CROP, or OPERATIONS Database routines will not be saved into those Databases unless this command is used before exiting those routines. If changes have been made, you will be asked whether or not you want to save them before you are allowed to exit.

{dupe} [F8] — used only in the crop listing on the initial C factor input screen, this duplicates an entire operation listing screen into another location within the list. For example, if I {dupe} "corn" from the first place on the list into the fifth, the program will duplicate all operations associated with that first corn onto the fifth screen. It will not change the dates, so this must be done by moving to that screen and modifying them individually.

{info} [F9] — gives information on the Current Input List. When you {save} a Current Input List into an Input File, you are also saving a series of comments describing that List. Use of this command allows you to look at (and change) the descriptive information for the Current Input List.

{desc} [F10] — gives information on the current CROP or OPERATIONS Database Set. These sets also contain a series of descriptive comments, which can be viewed and/or changed from almost anywhere this command is available.

{ins} [INS] — used to insert a line of information just above the line on which the cursor is resting.

{del} [DEL] — used to delete the line of information on which the cursor is resting.

{1st} [HOME] — used to jump to the first in a series of screens or to the beginning of a list.

{last} [END] — used to jump to the last in a series of screens or to the end of a list.

{pgup} [PGUP] — used to move forward one screen in a series of screens or up one screen in a long list of information.

{pgdn} [PGDN]	used to move back one screen in a series of screens or down one screen in a long list of information.

Giving a Command

A command is given by pressing the key listed above the desired command. This directs the program to immediately execute that command.

THE FUNCTIONS: PROGRAM HOUSEKEEPING

Several components of the RUSLE program are not part of the actual program workings but are needed to make the program easier to use. These are called Functions and are used to manipulate Input Files, to exit the program, to manipulate the screen coloring, or to get additional help. They are displayed on the Function Line, which is the top line on the screen. See "How RUSLE Works" for explanation of a sample screen.

Calling a Function

Functions are called by use of the {FUNC} command to move the cursor to the Function Line. Then use the [RIGHT ARROW] or [LEFT ARROW] key to move the cursor to the desired Function. The list of routines associated with that Function will be shown automatically. Either use the [UP ARROW] or [DOWN ARROW] key to select a routine or type in the option number. Press [ENTER] to execute the routine.

Once the cursor has been moved to the Function Line, you can return it to the Main Screen by using {esc}.

The FILE Function

The most commonly used Function in RUSLE is the FILE Function. From here, the Current Input List (see "How RUSLE Gets, Uses, and Saves Information" or "Input Lists and Files") can be cleared (all values set to zero), it can be SAVEd into an Input File, or it can be replaced by values LOADed from an Input File. As described in "Input Lists and Files," the purposes of this function are to allow you to save information so that you don't have to reenter it later, and to keep a record of the inputs used to reach a specific answer.

The EXIT Function

The EXIT Function provides a quick and easy way to get out of RUSLE from anywhere in the program. This Function is not the only way out (a series of {esc} commands will give the same result), but it is the fastest.

The HELP Function

The HELP Function provides general help in operating RUSLE, including such options as introductory information for the novice user and definitions of the various commands. This Function does not give information about the current question, because that role is filled by the {help} command. "Help" gives more detail on the HELP Function and the {help} command.

The SCREEN Function

The SCREEN Function gives the user some control over the appearance of the screen, including a color option for computers with color screens and a black-and-white option for monochrome screens.

HELP

Two types of help are available within the RUSLE program. The first is help for a specific question, available by using the {help} command. This is meant to provide you with information on how the variable fits into the general scheme of RUSLE calculations and with an idea of the expected type and size of answer. The second type of help available is more general information on the workings of RUSLE, available through the HELP Function.

Help for a Specific Question

It is often difficult to know what sort of response is expected when faced with a specific question. The {help} command provides that information. Help information is available for almost every response within the program, such as a blank to fill in, a list to select from, or even a warning message. If you don't know how to respond, try the {help} command.

Information on giving commands is found in "Program Commands and Control."

General Help

If you need more general information on running RUSLE, you can almost always call in the HELP Function. This provides information on the following:

guide to RUSLE
- how RUSLE works
- principal contributors

how to use help

Command keys
- ENTER
- ARROW keys
- Command keys

guide for first-time user

Information on using the Functions is found in "The Functions: Program Housekeeping."

INPUT LISTS AND FILES

As explained briefly in "How RUSLE Gets, Uses, and Saves Information," RUSLE maintains a set of the current values of all important variables used by the program, and this is called the Current Input List. This List is updated every time one of these variables is changed.

The calculated values of the R, K, LS, C, and P factors and of the average annual soil loss are also saved in the Current Input List. This can cause a situation in which some of the inputs have been changed but new results have not been calculated. The results in the Current Input List may thus be meaningless, because they no longer correspond to the inputs in that List. RUSLE keeps track of such potential errors and gives warnings in the Soil Loss Prediction Table when they occur.

To facilitate the use of RUSLE, the FILE Function has been included to store the Current Input List for later use. When the Current Input List is stored (SAVEd), it becomes an Input File. This File contains all the values from the Current Input List at the time of SAVEing, plus any descriptive comments that you added through use of the {info} command. This File can later be LOADed back into the program, replacing all values in the Current Input List with the values in the File. This capability allows you to use that Current Input List later as a template, changing only the necessary input values before calculating another answer. It also gives you a record of the inputs associated with a particular result.

SAVEing the Input List to an Input File

The Current Input List is SAVEd to an Input File through the FILE Function of the Function Line. Refer to "Calling a Function" or "The FILE Function" for detailed information on the Function Line and on how to call a Function. Briefly, you move the cursor to the Function Line with the {FUNC} command. Because the FILE Function is the first one listed on the Function Line, its options will be shown automatically. Select the SAVE option either by marking it with the arrow (using the [UP ARROW] and [DOWN ARROW] keys) or by typing in the number of the SAVE option. [ENTER] to begin the SAVE routine.

This routine will bring up a list of the existing Input Files. To SAVE the Current Input List to an existing Input File, type in its name or move the marker

with the [UP ARROW] and [DOWN ARROW] keys, and then press [ENTER]. *If you SAVE to an existing file, the information previously in it will be lost.*

You can SAVE the Current Input List to a new Input File by typing in a new name, using a maximum of eight characters. All alphanumeric characters (including the underscore, "_") may be used in the name. The program will not allow you to use blank spaces or a period within the name.

It is important that you choose an Input File name that will give you enough information so that you can pick it out of a list, because you may create many of these Files. This is difficult to do within the eight-character limit, but most users have found it helpful to include single-letter descriptions of each crop (for instance, *c* for corn, *b* for soybeans, *a* for alfalfa) followed by a single letter describing the tillage system. As an example of this sort of scheme, we describe a rotation of 4 yr of alfalfa followed by 1 yr of conventionally tilled corn and then 2 yr of no-till corn. One possible name is "4accc2cn," where the *4a* indicates 4 yr of alfalfa, the first *c* indicates that the alfalfa is planted after conventional tillage, the *cc* stands for conventional corn, followed by *2cn*, which describes the 2 yr of corn under no-till. The name you choose depends on which information that you are saving is most important to you. If you are most concerned with location, then the file name should include that. If you are comparing rotations, the location is probably not as important.

Finally, you will be allowed to enter up to five lines of file description, or to modify the comments entered previously through the {info} command. This may include such information as location, rotation, tillage practices–anything that might help you later to identify the file. Once you have entered all the information you want, use the {cont} command to force the actual SAVE to occur.

LOADing an Input File Into the Input List

A new Current Input List can be LOADed from an existing Input File. This allows you to take a File with values close to the ones you want and to change just the variables that differ. This is especially useful when you are making multiple runs under fairly similar conditions.

An Input File is LOADed into the Current Input List by use of the same procedure as for SAVEing, but by choosing the LOAD rather than the SAVE option of the FILE Function. Refer to "Calling a Function" or "The FILE Function" for detailed information on the Function Line and how to call a Function, or to the section immediately preceding this one for a brief description of the procedure.

LOADing an Input File into the Current Input List will replace all values in the List. These values will be lost unless they were SAVEd earlier.

Deleting Unnecessary Input Files

When Input Files are no longer needed, they can be removed using the Delete routine of the FILE Function. Either type in the file name or [ARROW] to the file you want; then [ENTER] to remove it. You can also use the {del}ete command from inside this routine or the LOAD and SAVE routines to erase files.

Using an Input File Created Earlier or Elsewhere

Input Files can be stored and shared with other users. When it is SAVEd, an Input File is stored in the directory in which the program is being run, and the Input File's name is the one you gave it when SAVEing plus a ".rus" suffix. If, for example, you gave the Input File the name "c-b-conv" when SAVEing, it would show up in the directory as the file "c-b-conv.rus."

The File can then be shared by copying it onto a diskette from which other users can copy it into their RUSLE directory. If your Input File has the same name as one already in their directory, they should change the name before copying it. After it is copied into the RUSLE directory, the new Input File will be treated like any of their other Input Files. Refer to your system manuals if you need help in copying or renaming files.

Files created on an older version of RUSLE can usually be used with newer versions of the program. Changes between versions may alter the number, names, and types of variables used by the program, but the program routines can adapt. If the program is looking for a variable that is not found within the old Input File, the variable will be set to zero or left blank. Extra values within the old Input File are ignored. If you are using an Input File created under an earlier program version, go through the program carefully the first time to make sure that all variables are set correctly.

DATABASES

Much of the information needed by the RUSLE calculations comes from a group of three Databases. The CITY Database contains information on climate, the CROP Database holds the parameters defining the characteristics of vegetative growth and residue, and the OPERATIONS Database defines the effects of field operations on the soil, crop, and residues.

Databases provide a way of associating a large amount of data with a single name or number, called the "Identifier." For instance, the CITY Database takes all the information necessary to describe for RUSLE the weather of a specific city or area, and associates that information with a single code number. One Identifier (city code, crop name, or operation name) is assigned to each Database Set, which includes all associated information.

In most cases, the data in each Database are independent of other available information. For example, the CITY Database's weather information is not likely to be affected by which crop is grown or which field operations are used. This independence holds to a lesser degree for the OPERATIONS Database and CROP Database. For example, a crop's growth characteristics will change with weather but likely will not vary as much from location to location as does weather. A corn Database Set may well apply to a fairly large part of the midwestern United States, although the weather within that area may vary considerably.

One key to using the Databases is to decide how many different Sets are required. For example, for how large an area of the Midwest are a set of corn-growth characteristics appropriate, and when will you have to add another CROP Database Set to show differences? How many CITY Database Sets are required to describe an area, given its particular weather patterns? How significant do crop varietal differences have to be to justify another CROP Set? You must answer these questions, and your responses will likely be based on the available data and the difference these changes seem to make in the final results.

Validity of Default Database Information

The values given in the default CROP and OPERATIONS Databases supplied with the program are supported by published literature cited in chapter 5. These values generally apply to the specific combination of location, crop variety,

expected yield, row spacing, planting density, tillage practices, equipment speed, soil conditions, and so forth, used in the studies. The values should therefore be thought of as typical base values designed to give general guidance.

You, the user, are ultimately responsible for ensuring that the information within the Databases fits your local conditions. In general, you should modify the values in the Databases so that the results match your conditions. For instance, if you have seen in field observations and measurements that your soybean residue decays more quickly (or more slowly) than that predicted by RUSLE, you should change the residue decay parameter in the CROP Database until the model matches the information you have. The default Databases provide a strong basis in actual measured values, but these default values should be modified to reflect measured values under your specific conditions. Appendix D describes how to carry out these modifications.

The CITY Database is somewhat different, because the default Database values are based on the same information you are likely to find. You may, however, need to create additional Sets to describe your local conditions.

Calling the Database Utility Routines

The Database Utility routines are used to manipulate the information stored in the Databases. One way to reach these routines is by selecting the Database Utility from the RUSLE Main Menu. More commonly, you can get into the Utility routines for a specific Database from anywhere the Database is used. You can {call} the CITY Database routines from wherever you are asked for a city, the CROP Database routines from wherever you enter a crop name, and the OPERATIONS Database routines from wherever you give a field operation name. Practically speaking, you can {call} the CITY routines from the R, K, C, and P factors, whereas the CROP and OPERATIONS routines can be {call}ed from the input screens of the C factor. "Program Commands and Control" gives details on using commands such as {call}.

When you return from the Utility routines, the program should put you back at the same Input Field from which you {call}ed the routines.

Using the Database Utility Routines

The CITY, CROP, and OPERATIONS Databases are created and maintained by four major subroutines known as Utility routines. There are routines to edit the Database Sets or to create new ones, to print Database Sets, to delete unnecessary Sets from a Database, and to bring in (merge) new Database Sets.

Editing Existing Sets or Creating New Ones

The Edit routine is the most commonly used of the Database routines, and serves to review or revise an existing Database Set or to create a new one. After you choose this option, the program will respond with a list of available Sets, listed by Identifier. Select the desired Database Set by either typing in the Identifier or by [ARROW]ing to the one you want. Then press [ENTER]. The program will respond with a screen of information associated with that Identifier. Use {esc} to return from this option.

To edit an existing Database Set, move the cursor around on the screen to make the changes and then save the changed Set into the Database with the {save} command. See "Program Commands and Control" for how to give commands. Note that the new values will not be kept unless the modified Database Set is specifically {save}d into the Database.

The most efficient way to create a new Database Set is to begin with an existing Set that is similar to the one you want. Type in the new Identifier and then change only the values that need to be changed. To keep the new Database Set, {save} it before you {esc}ape from this Utility routine.

This routine can also be used to rename Database Sets. Call up the Set to be changed, then create a new Database Set by changing the Identifier and {save}ing. This gives you two Sets that are identical except for the Identifiers. You can then bring up the list and {del}ete the original Database Set as described below.

To delete an unnecessary Database Set, type in the name of the Set or use the [UP ARROW] and [DOWN ARROW] keys to move the marker to the Set Identifier; then give the {del}ete command. You will be asked to confirm this request.

Printing Database Sets

The second Utility routine is used to print information in the Database. This gives two options: The first option prints a list of available Sets within the Database, and the second option provides a complete printout of all information associated with a chosen Identifier. If, for some reason, the program cannot find an attached printer or cannot send the information to the printer, a warning will be displayed on the screen.

Background on Database Files

The RUSLE program uses three different computer files for each Database. The Original File contains only those Database Sets supplied with the program. The program will read from this file but cannot write to it, so it remains unchanged. The Working File is the one that you actually use. When you {save} a Set, it is copied here, and the list of Identifiers you usually see is made up from the Sets in this file. Finally, the Delete File contains all sets you didn't need and removed from the Working File. This serves as a file of last resort, allowing you an opportunity to bring back files that you wrongly deleted.

Every time the program is run, it checks to see if a Working File exists. If not, it creates one that is a clone of the Original File. If a Working File does exist, the program leaves it alone; this allows you to put new program versions in the same directory without destroying your Working File.

Deleting Unnecessary Database Sets

The speed and efficiency of the RUSLE program is improved by deleting extraneous information. Since Database Sets are designed to fit local conditions, it is likely that you will want to remove Sets that cannot possibly apply to your conditions. When one of the lists of Database Sets is shown, or when you are within the Create/Edit option of the Database Utility routines, you can do one of the following: Use the [ARROW] keys to mark the correct Set in the list, or type in the name of the Database Set, or move into that Set as if you are going to Edit. Giving the {del}ete command will then bring up a confirmation message, to prevent accidental removals. If you confirm your intentions, the Database Set will be removed from the list. As mentioned in the section below, it is still possible to recover that information.

You may also {del}ete Sets more quickly by using the Delete Database Utility routine. This option is faster because the program does not prompt you to confirm your decision to remove Sets.

Because of the large number of CITY Database Sets and because they are divided by state, the CITY Database Utility contains a special routine that allows you to remove large numbers of Sets from the CITY Database by indicating the names (abbreviations) of the states whose cities you wish to keep. It is then possible to {del}ete specific cities within those states by the procedure described above.

Sets {del}eted from the Working File are simply moved into the Delete File, but Sets removed from the Delete File are permanently deleted.

Restoring Information Deleted From a Database

You can use the "bring new Sets" routine of the Database Utilities to recover Database Sets that were mistakenly {del}eted. Simply specify that you want to bring the Sets in from the list of deleted Database Sets.

Information will be lost if you {save} to an existing Database Set. For example, if you make changes to the "corn" CROP Database Set and then {save} it, the information previously there will be lost, and will be replaced by the new information that will now be stored in the Working File. If there is any chance that you may want to keep this old information, either give the new Set a slightly different name or first {save} the old Set under a different name.

Using Database Sets Created Earlier or Elsewhere

The "bring new Sets" routine of the Database Utilities can also be used to copy Sets created on another computer or by another user. The procedure to do this is as follows:

(1) Before entering RUSLE (from the operating system):

(a) You need to know that the names of the Working, Original, and Delete Files end with the ".dat," ".org," and ".del" suffixes, respectively. The prefixes are "croplist," "oplist," and "citylist" for the CROP, OPERATIONS, and CITY Database Sets, respectively. If you want to copy a CROP Database Set, for example, you are looking for the "croplist.dat" file.

(b) Copy that file into another with a different name and with no suffix.

(c) You need to make this available to your machine. In most cases, this means having a copy of the file on a diskette, but it can also mean having access to it over a network.

(d) Copy that new file into your RUSLE directory. Do NOT copy "croplist.dat" into your RUSLE directory under that name, because doing so will erase your "croplist.dat" file.

(e) Refer to your system manuals for assistance if you have questions about copying files.

(2) After entering RUSLE:

(a) Enter the Utility routines for the Database you want to merge.

(b) Begin the "bring new Sets" routine.

(c) Enter the name of the file from which to merge; this is the name you gave it in step 1.b above. The routine will bring in the Sets within that new file. If a Set in the new file has the same Identifier as one already contained in your Database, you will be asked which to keep.

USING THE RUSLE SOIL LOSS PREDICTION TABLE

Although the individual factors and routines of RUSLE can be run separately, the heart of the erosion prediction package is the RUSLE Soil Loss Prediction Table. This table shows the R, K, LS, C, and P values calculated from the Current Input List as well as the annual soil-loss estimate (A) in tons · acre^{-1}.

Each line of the table corresponds to a single set of inputs. For instance, the top line may contain the results of a conventional tillage rotation on a specific field, the next line may be for the same rotation but using reduced tillage, and the third and fourth lines may examine what happens with different rotations on the same field. As this example shows, one main purpose of the table is to show the effects of alternative management systems, although the table may also be used to make other comparisons.

Relationship of Input Lists and Files to Lines of the RUSLE Table

NOTE: See "How RUSLE Gets, Uses, and Saves Information" and "Input Lists and Files" for a description of the Current Input List and of Input Files.

Each line of the RUSLE table corresponds to a set of inputs. When you enter the table, RUSLE creates a temporary Input File for each table line. This permits you to move freely between lines. The values from the Current Input List will be automatically SAVEd into the temporary Input File for the line you are leaving, and the values from the temporary Input File for the new line are automatically LOADed into the Current Input List.

You can also SAVE the Current Input List into an Input File. This replaces the temporary Input File assigned to that table line with the permanent Input File given whatever name you have assigned.

If you have made changes to the temporary Input Files but have not SAVEd these, the program will warn you of this before allowing you to exit.

You can move the cursor between factors on a single line without changing any values. To compute a factor, move the cursor to that column and use the {call} command. When the computations are complete, the new factor value will be shown on the table.

Entering Values Directly Into the RUSLE Table

You can also enter values into the RUSLE Soil Loss Prediction Table directly. For example, if you know that the R Factor associated with your location is 120, you can type that number in the R Factor column in the table. The program will use any combination of typed and computed results to calculate an estimated annual erosion rate.

Warning Footnotes on the RUSLE Table

Because of the complicated relationships between the RUSLE Soil Loss Prediction Table, the Current Input List, and the Input Files, RUSLE keeps track of potential problems and gives warning messages. These show up as flags placed near the values in the RUSLE table and as warnings in footnotes to the table.

In general, these warnings indicate that the factor values in the table may no longer correspond to the numbers in the Current Input List, which can happen in three instances: (1) if you go into one of the factor routines and make some changes but do not carry through with the calculations, (2) if you enter a factor value directly from the keyboard, and (3) if information used several places in the program is changed in one location without being changed everywhere. For example, the city of interest can be specified within the C factor, but the information is used in the C, R, K, and P factors. If the citycode is changed only in the C factor, the results shown in the other factors may no longer correspond to the Current Input List (with its new citycode). To resolve this, move to each of the other factors and use the {call} command to perform the calculations. A similar difficulty arises when the field slope is changed, because the R, LS, and P factors all use this value.

SPECIFIC GUIDELINES AND ANSWERS TO COMMON QUESTIONS

CITY Database

The CITY Database contains all the climate information used in RUSLE. This information is divided into Database Sets, each of which represents a specific location. You, as the user, must determine the size of area to which that information applies. Areas where climatic patterns change quickly with distance will require more Sets (for instance, in the mountainous regions of the western United States).

Each Set has a unique name called the Citycode Identifier. This is an integer number unique to that Set and may range from 1 to 99,999. Citycode Identifiers may be assigned in any arbitrary order, although a specific ordering scheme is used within the default Database. Each CITY Database Set also has a Block Identifier of two upper-case letters. This is used to group the cities into blocks. In the default Database, the state abbreviation is used.

"How RUSLE Gets, Uses, and Saves Information" gives some background, and "Databases" gives specific details on changing and manipulating this information.

Answers to Common Questions About the CITY Database

How do I name/number a new city?

(1) Select a Citycode Identifier. Although any numbering or naming scheme may be used, the one for the default CITY Database is recommended because changes in the numbering scheme may make it more difficult to share your Database Sets with others, or to incorporate their Sets into your program (see "Using Database Sets Created Earlier or Elsewhere"). The default Database uses a five-digit Citycode Identifier for each Set.

(a) An alphabetical list of states is numbered from 1 (Alabama) to 50 (Wyoming), and the District of Columbia is assigned number 51. The first two digits of the five-digit number indicate the number of the state within that list. Under this scheme, cities in Arizona (the third state in the list) have Citycodes of the form 3XXX (same as 03XXX), and cities in number 14 (Indiana) look like 14XXX.

(b) The three rightmost digits refer to the cities within that state. The default scheme places cities within a state in the order in which they were created, with the first city given the description 001, the next 002, and so on.

(2) Type in the name of the city or area. The name associated with a CITY Database Set is by no means limited to the name of an actual city. In fact, the Set is likely to be applied to a larger area, so the name can be that of a county or anything that identifies the Set. In the default Database, this is the city by which the original weather information was identified.

Note: The default scheme uses the two-letter state abbreviation as the Block Identifier.

When is the Equivalent R value used? Much of the erosion in portions of the Pacific Northwestern Wheat and Range Region is the result of rainfall and runoff on frozen or thawing soils, and erosion rates in that area far exceed those predicted using the standard R values. Also, the distribution of this erosion over the year does not match that expected from the standard EI distribution. These considerations make it necessary to use Equivalent R values to describe the erosivity, rather than the standard values of R.

Within RUSLE, the EI distribution you select for a city determines whether the equivalent R can be used. Figure 2-7 of chapter 2 shows all the distribution areas. The program currently recognizes EI distribution areas 6-10, 14-18, 20-22, 29-41, 45, 58-60, and 63 as those for which the Equivalent R value can be used. If you select one of these areas, you are given the choice of using either the standard EI distribution for that area, a "frozen soil 95-5" default distribution that researchers have found works well for the area, or your own distribution. If you choose one of the options containing a "frozen soil" distribution, an equivalent R value will need to be chosen from figures 2-13 through 2-16 of chapter 2.

How do I select and enter an EI distribution? The EI distribution defines how the precipitation energy-intensity varies over the course of the year. Every area within the continental United States has been assigned a standard distribution, numbered as shown in figure 2-7.

In general, two options are available in the selection of an EI distribution: (1) use of one of the standard distributions, with the number selected from figure 2-7; or (2) creation of a new distribution to meet specific local conditions. If the

latter is done, the distribution will not be given a number, as it no longer corresponds to the numbering in the figure. Instead, it will be given the label "NEW." You then need to enter the EI values for the new distribution.

The exception to the rule is for the cities of the Northwestern Wheat and Range Region, where it is possible to include the effect of rainfall and runoff on frozen or thawing soils. In this case, four options are presented: (1), (2) the options mentioned above; (3) use of the standard 95-5 frozen soil distribution, which will be given the label "REQ"; and (4) manually entering a new frozen soil distribution, given the label "NEW REQ." The use of either of these last two options requires selection of an Equivalent R value.

For what is the city elevation used? The CITY Database Set includes an entry for the city elevation. The elevation is for information only and is not currently used within the RUSLE program.

CROP Database

The CROP Database contains all the information on growth and residue for the vegetation of interest. The information is divided up into Database Sets, each representing a specific crop or plant community. You must decide how many Sets are required to adequately reflect the differences caused by region, variety, or crop stress. This decision can be made only by noting the sensitivity of the outputs to differing inputs.

The information in each Set is associated with a Crop Identifier, which may be any name up to 20 characters long. This may be anything that makes the crop unique and describes it in a way that is meaningful to you. You cannot use some special characters reserved by the program or the operating system, but the program will warn you of these or will not allow you to enter them.

"How RUSLE Gets, Uses, and Saves Information" gives some background, and "Databases" gives specific details on changing and manipulating this information.

Answers to Common Questions About the CROP Database

How do I choose a vegetation/land use category? The crop category is critical in deciding how RUSLE gets and treats the crop information. The possible categories and what they mean to the program are:

(1) *time-varying vegetation:* This category is used for all vegetation where seasonal or cultivation effects cause significant changes in root mass,

canopy cover, or canopy height. This should be used for all cases except where the changes are so small or gradual that they can be ignored.

(2) *time-invariant vegetation:* If there are few seasonal changes in cover, residue, or root mass at the site, choosing this category greatly simplifies calculations. In this case, you need to enter only the average annual values. The use of this information is described in more detail in "C factor."

RUSLE uses these categories in displaying lists of crops. For example, in the calculation of an average annual C-factor value, RUSLE will show the list containing only the crops designated as "permanent"; when asking for a time-varying vegetation, RUSLE will show a list containing only those.

How does the database information control residue levels? Vegetative residue is a basic component of erosion control, and the information in the CROP Database Set determines the amount of residue and how it behaves. Each Set contains residue-decay rate parameters, which are used along with weather data to estimate the decay rates of the surface and subsurface residue.

RUSLE keeps track of the amount of residue by weight, although its effectiveness in controlling erosion is computed as a function of the percentage of cover. To convert between the two, each CROP Database Set contains as many as three values defining the relationship between cover and weight. You must supply at least one of these values, but giving two or three values will yield better results. Each supplied value is used to define a relationship between cover and weight; if you give more than one value, the relationships are averaged.

RUSLE contains routines that make it easier for you to decide how much residue has been added to the surface by a harvest operation. Within the CROP Database you enter the harvest yield and a few other constants, from which RUSLE will calculate a residue weight.

Surface residue is added to the field only by field operations (see "OPERATIONS Database") or by senescence, which is described in the next section. Surface residue is removed only through decay or by a field operation. Subsurface residue, on the other hand, can be added in one of two ways: (1) by the burial of surface residue during a tillage operation, or (2) by the death of the root biomass of vegetation.

The RUSLE program looks for two possible scenarios in adding root biomass to the subsurface residue. The first of these occurs when the vegetation is

completely killed, as might occur with tillage or application of a knock-down herbicide. The second scenario occurs whenever the CROP Database Set indicates a drop in live root biomass, which the program takes as an indication of the conversion of that much root biomass from live roots to subsurface residue.

What is the crop senescence option? In RUSLE, senescence is defined as leaf loss after the plant has reached maturity. The senescence option in the C-factor calculations calls on the CROP Database Set to provide information that may not be readily apparent. If this option is chosen, the crop is assumed to add residue to the surface when the leaves fall. RUSLE handles this by treating a decrease in canopy cover as a similar increase in surface cover. For example, if the canopy cover decreases from 90% to 75%, the total weight of surface residue is presumed to increase by an amount equal to the weight that would give 15% surface cover as defined by the cover-weight relationship.

Do I have to enter all those values for root mass, canopy cover, and canopy fall height? You do not have to enter values for root mass, canopy cover, and canopy height for the entire year. The program searches for the last value of root mass greater than zero and then assigns all remaining root mass, canopy cover, and fall height to the values they have at that point.

How do I handle crops with growth cycles lasting longer than a year? There are two ways of handling a crop whose growth cycle lasts longer than 1 yr: (1) Leave it as a single crop. When the crop goes beyond 1 yr, the program will continue to use the last values of root mass, canopy cover, and canopy height for the rest of the time. (2) Call in a regrowth file, either under an operation within the original crop or as a completely separate crop.

OPERATIONS Database

Field operations are important to the RUSLE program in how they affect the soil, vegetation, and residue. Operations disturb the soil, begin vegetative growth, kill the vegetation, add residue to the surface, or incorporate residue. They may also affect the way the vegetation grows.

This information is divided into Database Sets, with each Set representing a specific operation. You must decide how many Database Sets are required to adequately reflect the differences in the type, speed, and method of use of implements. This decision can be made only by noting the sensitivity of the outputs to differing inputs.

The information in each Set is associated with an Operation Identifier, which may be any name up to 20 characters long. You cannot use some special

characters reserved by the program or the operating system, but the program will warn you of these or will not allow you to enter them. The Operation Identifier may be anything that makes the name of the operation unique and that describes it in a way that is meaningful to you.

The OPERATIONS Database is currently used only in the C-factor calculations.

Answers to Common Questions About the OPERATIONS Database

What are the "effects"? The information in an OPERATIONS Database Set consists of a list of effects of the operation on the soil/vegetation/residue system and any additional information required to define them. The program goes through the effects in the order in which they are given (first #1, then #2, and so on) and calculates the impact of the effect on the soil, vegetation, and residue.

RUSLE allows up to five effects for any field operation, and these are chosen from a list of nine possible effects. If a field operation has more than five effects, these may be split between two operations scheduled to occur on the same day.

The program does not allow you to have more than one residue addition or removal in an operation. For instance, you may not add both residue from the current crop and some other residue within a single operation. This limitation exists because you can enter only a single number to tell the program how much residue you are adding. This also means that you cannot add and remove residue within the same operation.

The nine possible effects are listed below, along with a brief description of their place in the program and the calculations.

(1) *no effect:* The program requires five effects. Actual operation effects are listed first, and any remaining spaces are filled with this null value.

(2) *soil surface disturbed:* A field operation disturbs the soil surface in ways that affect erosion rates: (a) disturbing the soil is the only way to incorporate some of the surface residue; (b) the surface of the soil is loosened, which changes the degree of soil consolidation seen in the prior-land-use subfactor of the soil-loss-ratio (see ch. 5); (c) the surface roughness is altered, changing its impact on erosion rates. Including this effect in the list for an operation automatically brings forward questions that are used to define these changes.

(3) *current crop residue added to surface:* This effect specifies residue from the current crop, which means that the residue and decomposition parameters are taken from the current CROP Database Set. If a regrowth crop has been called in, the parameters are taken from there. If there is no current crop, the program adds residue from the most recent current crop.

The program will ask you to define in one of two ways how much residue is added to the surface. If the operation is a harvest operation (see below), the program will automatically pull in from the CROP Database Set the amount of residue added at harvest. If the operation is not defined as a harvest, you must enter the amount of residue added when you fill in the list of operations within the C-factor inputs.

(4) *other residue added to field:* This effect is used to model the impact of material coming from other sources, such as straw mulch used on a vegetable crop or manure spread on a field. This effect brings up questions asking you to define the cover and decomposition parameters for that residue, as well as what percentage of the applied material is left on the surface.

Because the only way to apply a material to the subsurface region (as with a manure injection) is to disturb the surface, this effect must be followed by a (2) within the same operation. When this is done, the percentage of residue buried by the (2) will be for the residue on the surface before the operation. The (2) effect will not bury any of the residue added to the surface by this operation.

(5) *residue removed/added to field:* This is the only effect that considers the removal of residue from the field. You need to specify whether it is from only the current or most recent crop (for instance, baling of corn stover) or from all previous crops (such as burning of residue). Within the list of operations in the C-factor inputs, you will need to specify how much residue is removed.

(6) *current crop harvested:* Information in the CROP Database Set for each crop indicates how much residue is added to the surface when the crop is harvested. Use of this effect automatically brings in that value as residue added to the surface. Refer to the earlier description of effect (3) for more information.

(7) *crop growth begins:* This effect tells RUSLE to begin the growth cycle found in the CROP Database Set for the vegetation listed at the top of the C-factor input screen, and to set "day 0" in that vegetation's cycle as the date of this operation.

(8) *current crop is killed:* This effect does two things: (a) the canopy cover and fall height are automatically set to 0 because the crop is no longer growing, and (b) the root mass is converted into a subsurface residue and begins to decay. The crop can be killed without adding residue to the surface, but from that point on there is no canopy effect.

(9) *call in a new crop growth set:* This effect begins growth of a regrowth crop whose name you are asked to specify when you define the cropping sequence and field operations. This effect should be used when growth patterns change because of an operation or weather, or simply to bring in a new crop as the current crop. The growth, decomposition, and weight-cover values are all replaced by those of the new growth Set, as are the root mass and canopy values.

In what order should I enter the effects? The effects of an operation must be entered in the order in which they occur. For example, operations that add residue either before or after disturbing the soil will give different results. Adding the residue before the soil disturbance will incorporate some of the residue, whereas adding it afterward will not.

How are residues buried or uncovered? The "% left" variable is defined as the percentage of original residue left on the surface following the operation. This can be defined as a "% wt", which is the percentage of the original surface-residue weight. If defined instead as a "% cov", it is the percentage of surface cover left after the operation. For example, if the residue covered 50% of the surface before the operation and the operation leaves 90% cover, the cover after the operation is $50\% \cdot 90\% = 45\%$.

If there is more than one residue type on the surface, it is assumed that the specified "% cov" refers to each residue type individually and not to the overall cover. For example, if before the operation there was on the surface a weight of wheat residue equivalent to 60% cover plus a weight of soybean residue equivalent to 40% cover, then after an operation leaving 30% cover there would remain on the surface weights of residue equivalent to 18% and 12% cover for the wheat and soybeans, respectively. Depending on the specified residue characteristics, this might well yield an overall percent cover not equal to 30% of the original cover.

You can also use this term to uncover buried residue by specifying that more than 100% of the residue be left on the surface. For example, if before the operation the surface has 50% cover and the operation leaves 120%, the surface cover after the operation is 50% · 120% = 60%. The program is set to limit the total amount of residue cover to 99.99%, and will not bring up more residue than actually exists. The option of uncovering residue can be used with either the percent weight or percent cover options.

R Factor

The RUSLE R factor defines the total annual erosive potential that is due to climatic effects. This factor reflects the impact of geographical location on erosion, including such factors as localized impacts of lakes or mountain ranges and the dominance of frontal or cyclonic activity.

Options

Initial R-factor value. The first option in selecting an R value is to take it directly from the isoerodent maps of figures 2-1 through 2-5 of chapter 2. The R values in the default CITY Database Sets are taken from these. This information is currently available for all locations in the contiguous United States and Hawaii.

Adjusted R value. For fields with very low slopes and in areas with high rainfall, the R value will be modified to reflect the absorption of raindrop impact energy by ponded water. Note that this changes the R factor to a value that applies to only a specific field rather than to a general geographical region, and does not change the R value in the CITY Database Set.

You are asked to indicate whether or not you want this correction. If your field has a very rough surface or has moderate-to-high ridges, more of the surface will be exposed to raindrop impact, thereby increasing detachment. Under these circumstances, do not use the adjustment.

Equivalent R value. As explained in "Answers to Common Questions About the CITY Database" and chapter 2, erosion in parts of the Northwestern Wheat and Range Region far exceeds the amount predicted by the simple R value because much of the erosion occurs on frozen or thawing soils subjected to gentle rains but erosive runoff. If the CITY Database Set you specify was defined as being for such an area, the Equivalent R value can be entered. You are not required to enter this value, because you are not forced to have this effect for cities in this area. "Answers to Common Questions About the CITY Database" explains how to use this effect.

K Factor

The K factor of RUSLE defines the soil erodibility under a set of standard conditions.

Options

Seasonal K value. The seasonal K value attempts to include the effects of freeze-thaw cycles and other factors affecting the temporal variation of soil erodibility. This option requires an original estimate of K, which may be either entered directly or calculated through use of the soil-erodibility nomograph.

Volcanic K value. Data collected in Hawaii for volcanic soils have shown a somewhat different relationship between soil properties and erodibility. If this option is used, K is calculated for the entered data. No seasonal variation of K is needed for these soils, because they are in general not subject to freeze-thaw cycles. These data have not been tested for soils outside Hawaii.

Answers to Common Questions About the K factor

What are the dates of maximum and minimum K for the seasonal K option? The time-varying K calculations yield a K value for each half-month period through the year, with the calculations made at the middle of each period. The date shown for the maximum or minimum K may not correspond to the period with the highest or lowest value if that date is very early or very late in the period.

Why can't I use the time-varying K for the western United States? As described in chapter 3, the algorithms used to calculate the time-varying K work well for the eastern United States, but not for the area west of approximately longitude 105°W. The RUSLE program determines your location by use of the EI distribution zone number, and will not allow the calculations for any areas west of that line.

How is the K nomograph used? The calculation of seasonal K variability uses an original estimate of K. If a Soil Interpretation Record exists, you may enter the K value from it as your estimate. The other option is to develop an initial estimate of K using the K-nomograph method. You get access to the K-nomograph method by {call}ing the subroutine from the Input Field for the original estimate.

What is the soil hydrologic group? Because the soil hydrologic group is a soil property, it is entered within the inputs for the K factor even though it is not

used in the K-factor calculations. It is used solely within the P factor to indicate the effect of runoff on support practices.

How is the # years to consolidate used? The C factor also requires the length of time it takes for the soil to fully reconsolidate in the calculation of the PLU subfactor. Since this is primarily a soil property, it is entered here in the K factor.

How is the % surface covered by rocks used? RUSLE treats rocks on the surface as surface cover rather than through their impact on the K factor. This value is therefore not used in the K-factor calculation, but rather is called in from here for the C-factor routines. However, since surface rock cover is generally a soil characteristic, this input is included here with the other soil inputs.

LS Factor

The RUSLE LS factor accounts for the effects of slope length and slope steepness on soil loss.

Answers to Common Questions About the LS factor

Which LS table should I use? The selection of an LS table depends on the condition of the soil and its susceptibility to rill erosion, presented as a ratio of rill to interrill erosion rates. This susceptibility can be a function of either the innate soil properties (such as texture, aggregation, and structure) or the degree to which the soil is modified by mechanical disturbance. In general, a disturbed soil shows a higher rill-interrill erosion ratio than does an undisturbed soil.

Table 4-1 is used for soils with low rill-interrill erosion ratios, usually including those not disturbed for some time. Table 4-2 applies to soils with a moderate percentage of erosion coming from the formation of rills, including soils that are disturbed relatively frequently. Most agricultural soils fall into this category.

Table 4-3 is used for soils that undergo high degrees of rill erosion, including highly disturbed soils such as those on construction sites. This category also contains agricultural soils that by their nature are susceptible to large amounts of rilling.

Finally, table 4-4 contains LS values for soils subject to thawing, runoff from snowmelt, and rain on frozen soil or snow. This changes the importance of the LS factor in relation to overall erosion rates. In general, these values will be used only for slopes in the Northwestern Wheat and Range Region.

What is the equivalent slope? Several routines within RUSLE require an estimate of the average steepness of the downhill slope, called the "equivalent slope." This estimation is easy for a uniform slope because uniform slope = average slope = equivalent slope. For a complex slope, RUSLE defines the equivalent slope steepness as the uniform slope steepness that gives the same LS value as that calculated for the complex slope. For example, if the complex slope has an overall length of 200 ft and an overall LS = 2.34, the equivalent slope steepness is that for which a uniform slope of 200 ft has an LS = 2.34.

The equivalent slope is calculated automatically in the LS routines. When needed by other parts of the program, these calculations may be {call}ed from there.

How do I get LS printouts? The Print option of the LS factor gives a printout of the tables showing LS values corresponding to a broad range of uniform slope lengths and steepnesses. The output tables are 132 characters wide and do not fit on most printers (which use 8½" x 11" paper), unless the printers can be specially configured to do this. Check your printer manuals.

C Factor

The RUSLE C factor describes the effects of cover and management on average annual soil loss.

Options

Time-varying vs. continuous. The C-factor calculations are used to determine the soil-loss ratio (SLR) subfactors for half-month time periods over which conditions are assumed to remain constant. The exception to this is cases of continuous pasture, meadow, or rangeland, for which conditions are likely to change very little over the course of an entire year. For these cases it would be of little value to make the calculations every half month, because the numbers would change only slightly.

The time-varying option must be used whenever the cropping or plant community changes significantly over a year, or when field operations disturb the soil or plant residues.

Single disturbance vs. rotation. Within the time-varying C option there are also two very different options. The first assumes that there is a single disturbance of the system, with subsequent long-term restabilization. You therefore need to define for the program the condition of the soil, vegetation, and residue immediately after the disturbance, and how the site changes over the years as the soil reconsolidates and vegetation regrows. This alternative fits best for

construction sites, mine spoils, or many of the mechanical rangeland improvement techniques.

The single-disturbance option is selected by placing a zero (0) in the field for the number of years in the rotation. This brings up additional questions concerning the final surface roughness expected for the site, since this number will be a function of the expected long-term vegetation. For the rotation option, it is assumed that there is repeated soil disturbance, which keeps this natural long-term roughness from ever having a significant influence.

The other alternative is to assume a rotation, where the operations are repeated in a cycle through many years. For example, the list of operations for a corn-soybean rotation would be only 2 yr long, but this list would be expected to repeat itself every 2 yr. If the rotation option best fits the system you are describing, the RUSLE program runs through the calculations three times. The program uses the results from the first two times as the initial conditions for the third run. The rotation option is chosen by specifying the number of calendar years in the rotation.

Concepts of the Time-Varying C Factor, With Examples

At first glance it may appear complex, but the time-varying option for calculating a C factor is simple if several basic concepts are understood. Since these concepts are crucial to an understanding of the power and flexibility of the C-factor calculations, they are illustrated through the use of examples. *Values and Database Sets included in the examples are meant solely as illustrations.*

Important parameters in the time-varying C option. The time-varying C option is based on a listing of the field operations, which in turn call in information from the CITY, CROP, and OPERATIONS Databases. The combination of information from these sources defines the changes in crop root mass and canopy cover, in soil roughness and consolidation, and especially in surface and subsurface residue.

Defining the current crop in the time-varying C option. The RUSLE program keeps track of only one set of CROP Database parameters at a time: root mass, canopy cover and height, and residue amount and decay variables. These values are taken from a single CROP Database Set, and the Set in use at a specific time is referred to as the current crop. When a CROP Database Set becomes the current crop, the program automatically pulls in all the information associated with that crop name, replacing the root mass, canopy, and residue values that had been linked to the previous current crop.

There are two ways to identify the current crop, and both of these require the use of a field operation. The first option is to have a planting operation, which instructs the program to install as the current crop the Set named at the top of the operations list screen. The second option is to have a field operation that asks for a regrowth crop. The program will prompt you for the name of that new Set, which it then pulls in as the current crop.

Note that the crop listed at the top of the screen never becomes the current crop unless an operation tells the program to begin its growth. In spite of this, when the results are shown, they will be displayed under this crop name. This means that the crops you list on the initial C-factor screen and that are shown atop each operations list screen serve two purposes: (1) they are used in accounting, defining over what time period the SLR values are summed; and (2) if called on by a planting operation, they can become the current crop.

It is essential that you keep track of which is the current crop, as this defines all the crop and residue parameters. For instance, unless you specifically direct the program otherwise, any residue added to the surface will have the decay and cover characteristics associated with the CROP Database Set for the current crop.

Defining a Set as the current crop causes one additional hidden impact. The date of the operation defining a new current crop (either a planting operation or one requesting a new Set) automatically becomes day zero in the growth cycle in that Set.

Use of regrowth crops within the time-varying C option. Some events drastically alter the growth patterns of the vegetation without killing it completely, such as mowing hay or cutting rangeland brush. In RUSLE, these changes in growth patterns are handled through CROP Database Sets called in as regrowth crops. The regrowth Set is meant to reflect the crop growth and residue patterns as the crop rebounds from the effects of some operation or event that drastically changes those patterns. The date when an operation calls in a regrowth crop becomes day zero in the crop growth cycle, and that Set becomes the current crop.

When you use regrowth crops, you must make sure that proper transition is made between crops. For example, if there is a sudden drop between the last root mass value for the first Set and the first root mass for the second, the program will assume that you meant for this drop to occur, and will add that difference to the subsurface residue. Changes in residue cover and decay

parameters as you move from one crop to the next indicate that subsequent residue additions will have those new characteristics.

How the time-varying option handles root mass. The root mass for the current crop begins growing at either the time of planting or when the crop is called in as a regrowth file. When an operation is defined as killing the current crop, the root mass becomes part of the subsurface residue and begins to decompose at a rate controlled by the decay parameter from the CROP Database Set in which the root mass was defined.

The program will also recognize a drop in root mass either within a CROP Database Set or between crops, as in the transition to a regrowth crop. Any drop in root mass is taken as a similar increase to the subsurface residue pool. If the drop in root mass occurs between Sets, the decay parameter for this residue will be that from the first Set.

Definition of canopy cover in the time-varying option. For the most part, the handling of canopy cover is very straightforward; the program simply takes the values from the current crop Set and uses them to make the calculations. The single possible complication occurs when you choose the senescence option for a crop. This indicates that a drop in canopy cover should cause an increase in residue on the soil surface. The program calculates this effect by looking at the percentage drop in residue cover, and then adding to the surface cover a mass of residue equal to that which would give the same percentage of cover to a bare surface. This amount is defined by the residue cover parameters from the CROP Database Set.

The program does not keep track of drops in canopy cover when you switch to a regrowth crop, because this type of change is usually caused by an operation, which often involves removing canopy material from the field.

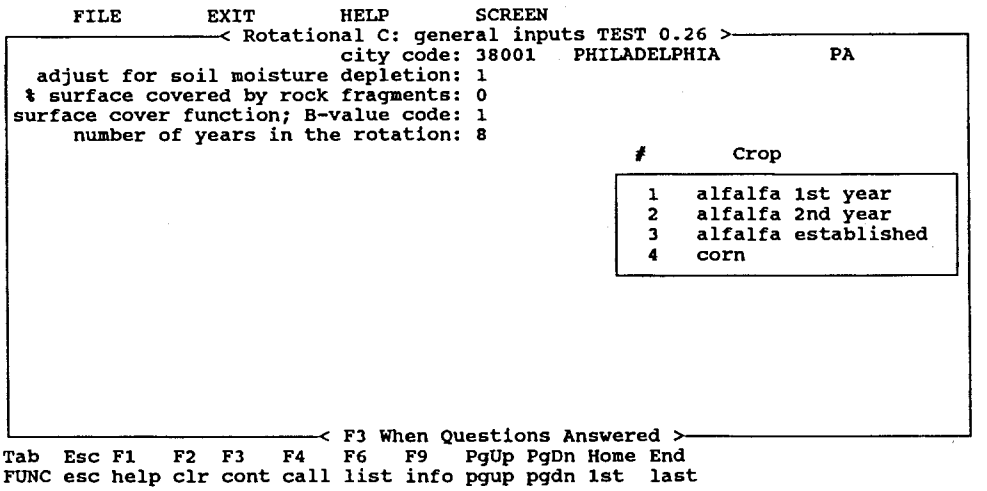
How RUSLE handles surface residues. RUSLE keeps track individually of every residue you add to the field, and calculates its cover and decay relationships based on the specific parameters assigned to that residue when it was still associated with a current crop or when it was added as a "foreign" residue. Most residue additions are for the current crop, so you must be aware of which crop that is and whether its residue parameters are the ones you want.

Residue additions to the soil surface are specified on the screen where you list the operations. In general, you are responsible for telling the program how much residue is being added to the surface, but there is one exception. If you specify that the operation harvests the current crop, this tells the program to look

in the CROP Database Set associated with that crop to find the residue added at harvest. The program then automatically enters that value into the correct place in the list of operations.

Example 1: Five years of Eastern alfalfa cut for hay followed by 3 yr of corn. Many of these concepts become more clear when dealing with specific examples. The first example is for an alfalfa-corn rotation in eastern Pennsylvania, with 5 yr of alfalfa followed by 3 yr of corn.

The first screen describes the location and gives general information about the rotation. The number of years in the rotation is set at 8 since, as we will see later, the first operation in the rotation will not be repeated for 8 yr. The crops indicated in the list were selected from the CROP Database File, and for each crop in the list the program will display a screen on which you will be asked to enter the field operations associated with that crop. The crops in this list need not correspond to calendar years; there can be either more or fewer crops in the list than years in the rotation. This list also does not need to include all CROP Database Sets used in the rotation.



Below is the first screen of information describing the field operations associated with the rotation. All operations that we want included in the calculation for "alfalfa 1st year" are listed here.

```

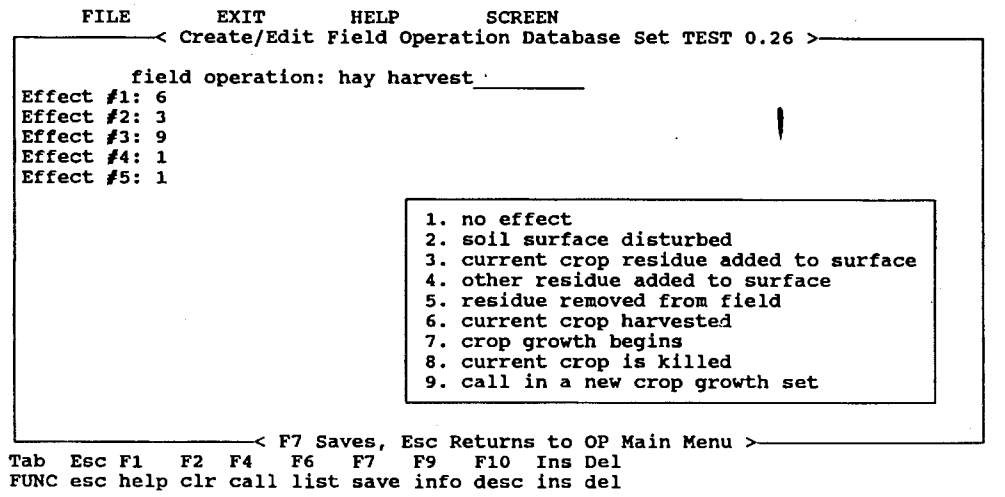
The first three operations in this list are tillage operations, which disturb the soil surface and incorporate some of the surface residue. Since the corn crop came just before these operations in the rotation, the operations will be burying corn residue. The tillage operations will also affect the soil surface random roughness.

The drill operation on April 10 includes an effect entitled "crop growth begins." This takes the CROP Database Set listed at the top of the screen (alfalfa 1st year), installs it as the current crop, and begins its growth cycle.

The hay harvests scheduled in this first year do two things: (1) they completely change the alfalfa growth characteristics, requiring a regrowth Database Set to show how the crop responds after being cut, and (2) they add some alfalfa residue to the field through wastage in the harvest process. There are two ways of handling this residue addition. The first way is as shown above, which uses the OPERATIONS Database Set below.



This Set specifies that the operation harvests the current crop, which causes the program to automatically go into the CROP Database Set for the current crop (in this case, "alfalfa 1st year") and to extract the information required to calculate residue added at harvest. The OPERATIONS Set also specifies that the operation adds residue from the current crop to the field: this is redundant because this is assumed by the program when it sees the harvest effect, but this may be included for the sake of completeness. Finally, the Set states that the operation will significantly affect the crop growth characteristics, requiring a new CROP Database Set to model that regrowth.

The operations list is repeated below for convenience. In it we see the regrowth CROP Database Sets listed in the far right column. Note that from 6/30/1 to 8/15/1, the current crop is "alf. 1st yr regrowth," which once again becomes the current crop with the hay harvest of 8/15/1. This means that on 8/15, the program brings this Set in to replace itself, and once again sets the days of growth to zero and restarts the growth cycle all over again.

```
     FILE        EXIT        HELP        SCREEN
                 < Rotational C: field operations TEST 0.26 >

```

The values in the third column, Res. Add., indicate the amount of residue added to the surface by each operation. Since the "hay harvest" Set listed the operation as a harvest, these values are calculated automatically from information in the CROP Database Set for the current crop. The 600 is calculated from the Set for "alfalfa 1st year" since it is the current crop to that point, and the 450 comes from the "alf. 1st yr regrowth" Set.

The second way of handling the residue additions is to specify the hay harvest simply as adding residue to the surface but not harvesting the crop. The program would then ask you to enter a value in the Res. Add. column rather than automatically calculating a value.

The senescence code for this crop is set at 2, which indicates that the program should consider a drop in canopy cover as an increase in surface cover. The CROP Database Set "alf-1st yr.sen clrso" includes such an effect to model the impact of winter on alfalfa growth, as shown below.

The drop in canopy cover from 70% to 60% from day 45 to day 60 demonstrates the use of the senescence option. The program will use the residue weight/cover relationship from this Set to determine the weight of residue equivalent to 70 - 60 = 10% cover. This weight will then be added to the surface, with the addition distributed evenly over the 15 d in the period.

This completes the information required for the first crop listed on the first general information screen. The second crop listed is "alfalfa 2nd year," which requires the operations listing shown below.

```
     FILE       EXIT       HELP       SCREEN

```

The "begin alfalfa growth" in this listing calls in "alfalfa 2nd year" as the current crop and begins its growth. The hay harvest operations are the same as in the first screen, adding residue to the surface and calling in regrowth crops. As before, the hay harvest operation calculates the amount of residue added based on information in the CROP Database Set of the current crop.

Up to this point we have had a single year's worth of operations on each screen, but this is not a requirement. The screen below shows 3 yr of crops and operations intended to model the alfalfa crop once it has reached fairly stable growth.

```
     FILE        EXIT        HELP        SCREEN

A single screen can contain any number of years' worth of operations, as long as the total number of operations on the screen does not exceed 16. Similarly, a screen may contain operations representing a fraction of a year. The only difference comes in the final accounting. The program calculates an overall rotation C factor and a C factor for the time associated with each screen. For this rotation, the program would calculate separate C factors for each of the first 2 yr, but would lump these 3 yr together into a single C factor.

Note also that the program is not limited to working with calendar years; but it will allow you to divide the time up in any convenient fashion simply by which screen contains which operations.

The screens shown above take care of the 5 yr of alfalfa in the rotation, but we must still handle the 3 yr of corn. In the initial crop listing there was only one corn, so all operations associated with these 3 yr will also have to be lumped together on a single screen, as shown below.

The first operation in this listing is used to kill the alfalfa and also to prepare the soil for the corn-planting operation. The information for this operation is listed below.

```
     FILE        EXIT        HELP        SCREEN

This case is one where the order of the operation's effects is critical. This operation first adds residue to the soil surface. Since the operation is not specified as a harvest, the amount added will not be calculated from information in the CROP Database Set, but will instead have to be entered manually in the Res. Add. column of the operations listing.

After the residue is added, the soil surface is disturbed, thereby incorporating some of that newly added residue. If these effects had been entered in the opposite order, none of this new residue would have been buried by the

operation, because the soil disturbance would have occurred before the residue was added.

Finally, the current crop is killed, immediately removing the effects of crop canopy and turning the root mass into subsurface residue.

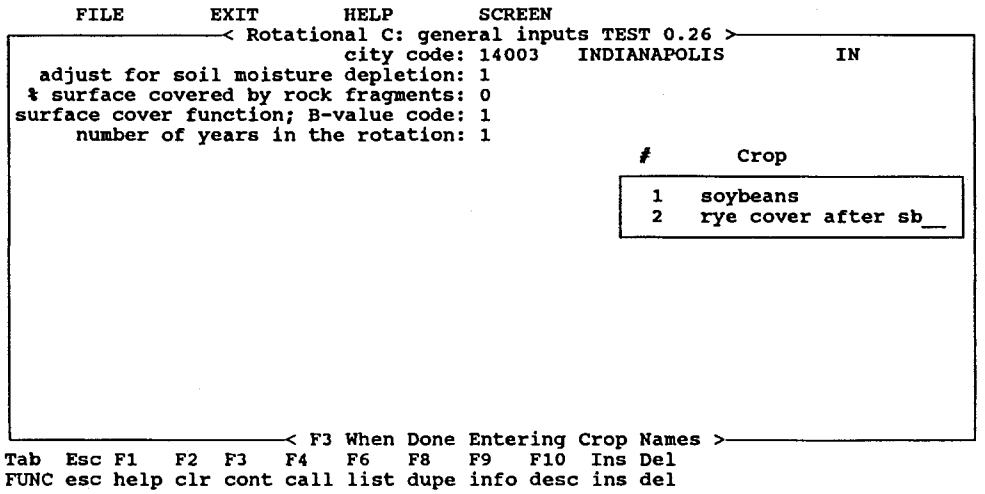
The remainder of the operations in the "corn" listing are relatively straightforward, and are shown below. The "harvest" operation behaves like the "hay harvest" we saw earlier, in that it calculates the amount of residue added to the surface from the CROP Database Set. It does not call in a regrowth Set because harvesting corn also kills it.

The information needed by the rotation is now complete, because the next operation in the series would be the primary tillage before planting alfalfa, which is a repeat of the first operation in the sequence. Note that this would occur on 3/30 of year 9, which is 8 yr after its first occurrence. This is what determined the rotation length of 8 yr. If the rotation length had been entered as 9 yr, the program would assume a fallow period from 10/10/8 to 3/30/10.

Example 2: Continuously cropped conventional soybeans in Indiana with an aerially seeded rye winter cover crop. This example demonstrates how to handle two crops grown simultaneously. The example is based on a continuous conventionally tilled soybean crop, into which rye is aerially seeded when the soybeans are mature. The rye grows as an understory to the soybeans until they are harvested, at which time the rye begins vigorous growth until the onset of winter. The rye is tilled under in the spring before the planting of the next crop of soybeans. Because every operation is repeated every year, the rotation is 1 yr long.

The critical concept is that RUSLE can handle only one current crop, so the CROP Database Set associated with that crop must reflect everything that is growing in the field.

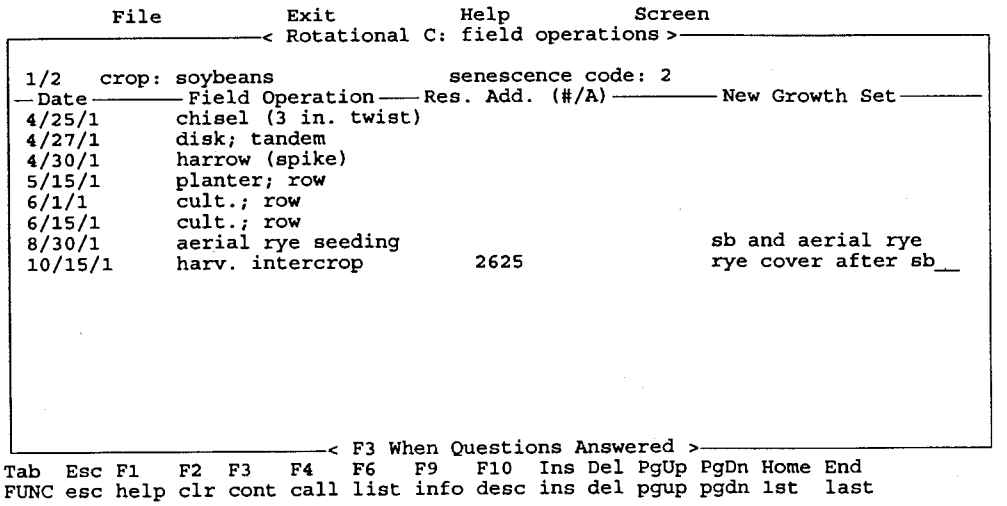
The general information screen for this rotation is shown below.



We could vary the list of crops, depending on how we want the accounting to be done. For instance, if we want only a total rotation value, we could list just soybeans. Another option is as shown above, where we separate the time that the soybeans are growing from the rest of the time.

The operations listing associated with the soybean accounting time is shown below. This includes the planting of the standard soybean file and its growth up to the time of the aerial seeding of the rye. From this point on, the current crop must reflect the root mass and canopy characteristics of not only the soybeans but the combined soybean/rye mixture. These characteristics will be shown in the CROP Database Set "sb and aerial rye" as an increase in root mass and canopy cover and a decrease in canopy height to show the effect of the low-growing rye. The residue characteristics of this Set will still be those of the soybeans, as this is the type of residue that will be added.

At the time of harvest we must not kill the crop, because the rye will continue to grow. Instead, we add the soybean residue to the surface and then call in a regrowth crop to simulate the vigorous rye growth after soybean harvest. The root mass value in this Set will be much lower than that in the combined soybean/rye Set, which the program will recognize as an addition of the soybean roots to the subsurface soybean residue pool. This new Set will have the residue characteristics of the rye, because any residue added to the surface now will be rye residue.



The rye crop is called in as the current crop with the last operation of the soybean listing, but recall that we wanted to account for the time from the soybean harvest to the next planting of soybeans under the rye cover crop. We do this with the first operation shown on the screen above. This "no operation" has no effects on the soil, crop, or residue, but is used to tell the program to begin the accounting under this crop name on this date. (See next figure.)

There are two ways of modeling the impact of a natural phenomenon like winter or drought conditions. First, if the impact is very sudden (as perhaps the first frost that kills tomatoes), you will want to model the impact as an operation. On the other hand, if the effect is more gradual (as it would be for the rye example), it is probably better to develop a CROP Database Set that shows the reduction in canopy cover and live root mass that can be caused by winter damage. Note in the listing below that nowhere within this screen is there an operation that begins the growth of the "rye cover after sb" crop. A current crop is still growing based on information in the previous screen, so there is no need to plant this crop.

```
     FILE        EXIT        HELP        SCREEN
                 < Rotational C: field operations TEST 0.26 >

Example 3: Grazing of rangeland or pasture. The grazing of rangeland or pasture can be handled as the impact of winter on crops was handled. If the grazing is high intensity and can be thought of as occurring at a specific time, it can be treated as an operation, as with the hay harvests shown above. The vegetation would be harvested by the cattle, leaving a rough surface and trampling some residue onto the soil. The grazed area would then begin to regrow, so the high-intensity grazing operation would call in a regrowth crop Set.

On the other hand, if the grazing is long term and low intensity, it is probably best to treat it as a change in the crop growth patterns and to develop a CROP Database Set to reflect these conditions.

Answers to Common Questions About the C Factor

For a single disturbance, how do I define the initial conditions? Remember the factors that you must define: (1) amount of residue on the surface; (2) amount of buried residue; (3) surface roughness; and (4) any vegetative regrowth. This is done by beginning the growth of vegetation whose CROP Database Set reflects that found at the site before its disturbance. This should be grown for several years to reflect the soil consolidation found before the disturbance. The operations used in the disturbance are then listed, making sure that the effects of each operation reflect all of its impacts on the factors listed above.

How do I specify that the operations sequence is a rotation? You command the program to assume a rotation by specifying on the initial C-factor screen the number of years in the rotation. You calculate this by determining how many years it takes before the first operation will occur again. For example, if the first operation in the rotation takes place on May 1 of the first year and will not occur again until May 1 of the fourth year, then there will be 4 - 1 = 3 yr in the rotation. If you want a single disturbance rather than a rotation, simply place a zero in the input field for number of years in the rotation.

For the time-invariant C option, should I use the CROP Database or enter values directly? The C calculations for RUSLE require values from the CROP Database for canopy cover, fall height, and root mass. For continuous crops, these values are assumed to remain relatively constant through the year, so the only entries needed are average annual values. To specify these values, you can either enter them directly within the C factor or use the CROP Database Utility routines (see "Databases" and "CROP Database") to create a Set with these values. Do this with the "permanent" option for the crop/land use category, and then {save} the set under some unique Identifier name.

If you decide to use the CROP Database, the list of all {save}d "continuous" crops will be shown. Select an Identifier to automatically bring in the values from that Set for root mass, canopy cover, and fall height.

Within this time-invariant C option, the values of surface cover and roughness must be typed in directly.

What inputs are required for the time-invariant C option? The variables of surface cover, canopy cover, and fall height are relatively easy to deduce from experience. It is much harder to estimate the mass of roots in the top 4 in of soil. If you choose to not put the required data into a CROP Database Set (see section above), RUSLE will go through a series of questions to help you define the root-mass variable. You will be asked to define the type of plant community and the annual site production potential. The program will use these to calculate a root-mass value directly and, in that case, the program will calculate a corresponding site potential.

What general information is required for the time-varying C option? The first screen within the time-varying C-factor option defines all the general information for the rotation. Soil-moisture depletion should be taken into account only for those areas in which the rainfall is of low amounts and intensities and the soil surface characteristics do not limit infiltration. Thus far, this is supported only by data from the Northwestern Wheat and Range Region,

although there may be other areas to which this option can be applied. The "rock cover" variable should reflect the presence of all rocks and similar "permanent" surface cover, and is changed by {call}ing the K factor. Choose the b-value option that best describes your conditions. For well-consolidated soils dominated by interrill erosion, a low b value should be used; for highly disturbed or thawing soils dominated by rilling, a high b value is more appropriate. All other cases should use the moderate b value.

The crop list on the first screen of this option makes it easy to change an existing Input File. Crops can be {dupe}licated to new spots in the rotation, old crops can be {del}eted from the list, and new crops can be {Ins}erted. When you move a crop within the list, its operations will tag along, but the dates of the operations may need to be changed to show their new place within the rotation.

What information is needed on the operations screens of the time-varying C option? The rotation information screen contains general information about the crop and a list of all associated field operations. Also included is a question on whether a decrease in canopy cover should be seen as a contribution to surface cover. If you specified in the general information that you wanted to account for soil moisture depletion, the depletion rate value associated with the crops on this screen is entered here.

You must enter the dates (using xx/xx/xx to represent month/day/year) and names of all field operations, as well as any additional information required by the effects listed in the OPERATIONS Database Sets for those operations. You have great flexibility in entering the year. You can enter it as a calendar year (1995), as an abbreviated calendar year (95), or as the number of the year in the crop sequence. The program calculates the relative time elapsed, so all of these will be treated the same.

There are some limitations on the operations that you can enter, as follows:

(1) You can have only one current crop. Since there will be interactions between interplanted crops, RUSLE does not allow you to use two separate CROP Database Sets and to have them both growing at once. You must instead combine the Sets into one that reflects the total values of the combined crops. The residue parameters should be for the crop whose residue is added to the surface by a harvest operation; you can call in a regrowth CROP Database Set containing the parameters of the second crop before harvesting it.

(2) If an operation has a "harvest" effect, the program will automatically enter the weight of residue added. For other effects, you will be asked to specify the amount of residue added.

(3) The operation can also ask for the name of a regrowth crop. In this case, a list of the crops is shown, and you must either pick from this list or go into the CROP Database Utility routines to create a new crop.

(4) There are few restrictions on the order in which the operations may be listed, but one restriction is that the current crop must exist in order to be able to do anything with it. The program will issue a warning if you try to do anything with the current crop without having specified something to tell the program just what that crop is.

How are all the different roughness values set and used? The time-varying C-factor calculations use three different random roughness values. The first is the roughness immediately after a soil disturbance operation; this value is defined within the OPERATIONS Database Set for that operation, and is a function of soil condition and of the implement that is used.

The second roughness value is that to which the tillage roughness decays as it is acted upon by raindrop impact and surface flow. The default setting for this roughness is 0.24 in, which is the roughness found on experimental fallow plots exposed to natural rainfall. If desired, this value can be set to reflect continuous re-roughening of the surface, as can happen with cattle grazing. In this case, the initial and final roughness values can be set equal to indicate a constant roughness, or can be adjusted as desired to indicate increasing or decreasing roughness. The final decay roughness value is set in the OPERATIONS Database Set.

The third random roughness value used in this part of RUSLE reflects the impact of the vegetation on soil surface roughness; this will be a function of protruding roots, basal mounding, and so on. This variable represents the site roughness several years in the future (as defined by the number of years to soil consolidation), under the assumption that the site will not be disturbed during that time. The value, therefore, also reflects the assumption of some vegetative community that will come to dominate the undisturbed site over this time period. The program uses this value only for runs with a single disturbance, and uses a sigmoidal growth curve to increase the natural roughness to this value from the minimum value defined in the previous paragraph. The long-term site roughness is set in the general information screen of the time-varying C-factor option if the length of the rotation is set to zero.

What outputs are available for the time-varying C option? The options for showing the results of the rotational C-factor calculations vary primarily in the degree of detail shown. The "Rotation C" option divides the results into the SLR · %EI associated with each crop, whereas the "Operation C" option breaks this down further into the SLR · %EI associated with each operation. The "Half-Month Subfactor" option shows the finest division, displaying each of the SLR subfactors for each calculation period.

There is one difference between the "Operation C" results and the "Half-Month" results that might cause confusion. In Operation C, the values shown for percent surface cover are calculated immediately after the operation, whereas the Half-Month surface cover values are calculated in the middle of the time period.

P Factor

The RUSLE P factor reflects the impact of support practices on the average annual erosion rate.

Options

As with the other factors, the P factor differentiates between cropland and rangeland or permanent pasture. Both options allow for terracing or contouring, but the cropland option contains a stripcropping routine whereas the rangeland/permanent-pasture option contains an "other mechanical disturbance" routine. For the purposes of this factor, the rangeland/permanent-pasture option is based on the support operation being performed infrequently, whereas in the cropland option, the support operation is part of the annual management practice.

One variable seen in the contouring, mechanical-disturbance, and stripcropping routines is a site description. RUSLE asks you to choose from a list of descriptions the one that best fits your conditions. This information is used in several ways, as follows:

(1) The site description is used to assign a runoff index and roughness value to the situation. The runoff index is a measure of the percentage of available precipitation that will be seen as runoff, and is a function of soil type, soil structure, soil surface condition, and surface vegetative cover. The runoff index value is similar to the curve number used in the NRCS Direct Runoff method of calculating runoff volume, and is used here for roughly the same purpose. Runoff index values associated with specific soil hydrologic groups and site descriptions can be changed by

using the {call} command from the Input Field where the site description is requested.

(2) The site description is also used to estimate the effect of surface roughness and vegetative cover on erosion and transport from the slope. A qualitative view of the roughness is given in the site descriptions, but the actual roughness values associated with the descriptions are assigned internally.

Answers to Common Questions About the P Factor

What is the variable ridge height option on the contouring subfactor (cropland or pasture/rangeland option)? This option allows you to define how the contour ridge heights change with time during the rotation. The program calculates a P value for each ridge height and then multiplies that by the percentage of annual EI associated with each period to derive an average annual contouring subfactor.

What is the critical slope length in the contouring subfactor (cropland or pasture/rangeland option)? The effectiveness of contouring breaks down when the slope is so long that runoff causes break-over and subsequent gullying. This point is defined by the critical slope length, which is a function of the slope steepness, ridge height, residue cover, and runoff potential. When the slope is longer than this calculated maximum, the contour credit applies only to the portion above the critical length. The portion below has a P contour subfactor of 1. RUSLE will give you a warning that this is occurring, and will adjust the overall P factor accordingly.

Why are there dual site descriptions in the contour subfactor (pasture/rangeland option only)? After a disturbance, a pasture/rangeland soil will take some years to reconsolidate to a point similar to that before the disturbance. In order to look at this consolidation effect, it is necessary to detail just how the site responds to consolidation and what effect this has on runoff. This information is given by describing the site both immediately after disturbance and after enough time has passed for relatively complete consolidation. The program then assumes an exponential decay function, and allows you to look at any year within that range.

What is the stripcropping subfactor (cropland option only)? The stripcropping P subfactor defines the effectiveness of contoured or cross-slope strips in causing deposition where it might benefit future productivity, and in slowing

and spreading the runoff. These strips can be any combination of crops and/or tillage practices that would affect the surface roughness, infiltration rates, or hydraulic roughness seen by the runoff.

Why does the stripcropping subfactor require {call}ing the contouring routine (cropland option only)? Because stripcropping is closely linked to contouring, the RUSLE program uses the contouring routines to provide information on row grade and critical slope length. If it is needed, the call to the contouring subroutine occurs automatically. When the contouring routine is called from the stripcropping routine, the site description used should be for the "smoothest" strip within the stripcropping rotation.

What is the stripcropping subfactor strip width (cropland option only)? The stripcropping subfactor program requires a complete description of the slope, including the condition and width of each strip. There are two ways of specifying strip width. The first is to indicate the position of the bottom of the strip as a percentage of the total slope length. For example, if a 120-ft slope is divided into four 30-ft strips, their relative positions would be at (30/120), (60/120), (90/120), and (120/120), or 25%, 50%, 75%, and 100%, respectively. The other option is to specify the actual strip widths in feet, which in the above example would be 30, 30, 30, and 30. The disadvantage of this second style is that the total slope length has already been specified in the LS factor. If the total length calculated by adding these strip widths varies from that entered in LS by more than 10%, the RUSLE program issues a warning and requires a response before proceeding.

What is the Other Mechanical Disturbance subfactor (pasture/rangeland option only)? Mechanical disturbance of the soil takes two possible forms: (1) disturbance on the contour, which results in roughness on the contour and redirection of runoff along the rows; and (2) a more random mechanical disturbance, which results in a rough surface that can slow runoff and in depressional areas that can store runoff and increase infiltration. The option chosen depends on whether the roughness that is left after the disturbance is primarily oriented or random. If the roughness has a definite orientation (ridges), choose the contouring option, even though the ridges may not be directly on the contour. If the roughness is more random, choose the Other Mechanical Disturbance option.

SYSTEM CONSIDERATIONS: USING RUSLE WITH YOUR EQUIPMENT

All computer requirements and instructions for loading and running RUSLE are described in detail in "Getting RUSLE To Work on Your Machine."

Using a Printer

RUSLE is meant primarily to be a tool to make it easy to compare cropping and management alternatives, and to speed up these repeated calculations. Although RUSLE will print out some results and inputs, it is not designed to generate documents.

For machines that use DOS, RUSLE looks for an attached printer, as it does also for the 3B2 and 6386 machines running either DOS or UNIX. When run under BSD UNIX, the print routines will look in a file named "printer.use" for the name of the network printer. Check your manuals or consult with a site specialist if problems arise.

Most of the printouts are meant to fit on 8½" x 11" paper. The exception is the printout of LS tables, which may be up to 132 characters wide. If your printer cannot be configured to handle this many characters within 8½ in, you must use wider paper. Note that copies of the tables are available in chapter 4 of this handbook.

Making Copies of RUSLE To Share With Others

RUSLE contains a routine that allows you to copy the program onto a diskette(s) to share with others. This routine is available from the RUSLE Information option of the RUSLE Main Menu, and works only on DOS. This option is not available in UNIX.

Refer to "Using an Input File Created Earlier or Elsewhere" and to "Using Database Sets Created Earlier or Elsewhere" for information on how to send information you have entered to another user.

Reporting Problems and Trouble

RUSLE is a relatively new and complex computer program. A user may find problems that did not arise in preliminary testing. It will greatly help the developers and programmers of RUSLE if you report problems that you find, giving as much information as possible about when and how the problems occurred. This information includes the following:

- screen you were on and question being answered
- command you gave just before the problem showed up
- what (if anything) showed up on the screen
- how the problem manifested itself (program locked up, gave unreasonable answer, and so on.)

SUMMARIES

Command Keys

A complete list of all possible commands and a brief description of what each does are given below. The command description or name is given in braces, { }, and the associated DOS key for each command is given in brackets, [ ]. The keys may differ on some machines, but the command description is always as shown here.

{FUNC} [TAB] places the cursor onto the Function Line to let you do the required housekeeping chores (see "Calling a Function" or "The Functions: Program Housekeeping"). When the cursor is on the Function Line, use {esc}ape to bring it back to the Main Screen.

{esc} [ESC] allows you to {esc}ape from the current screen or question without giving an answer. This is most commonly used in three places: (1) if you have gotten into a screen or series of screens and want to get back out; (2) after an error or warning message has been displayed, and you want to continue; and (3) to continue the program after a result has been displayed.

{help} [F1] shows one or more screens of additional information to help answer the current question (see "Help"). This usually includes a brief description of how the variable is used in the calculations and also suggestions for possible answers.

{clear} [F2] {clear}s (sets to 0) all variables associated with the current screen. This is most useful when you want to get a fresh start on a screen containing several mistakes.

{cont} [F3] {cont}inues program movement to the next logical screen in the sequence. For example, when you have answered all the questions on one screen, this command moves you to the next screen or initiates the calculations. For screens that require only one input or command, the {cont}inue command acts just like an [ENTER], telling the program to accept the current value and to move on.

{call} [F4] {call}s a subroutine on which the answer might depend. Use of this command will automatically put you into the required subroutine; when you exit from that, you will return to the current question.

The {call} command is used in three different instances, as follows:

(1) When an answer is calculated from the results of several different factors. An example is in estimation of soil loss from the factor values. Each factor is {call}ed individually by use of this command.

(2) When the question asks for the Identifier of a Database Set, as when entering a city code, a crop name, or an operation name. Use of the {call} from one of these locations allows you to examine or modify the information within the associated Database. "Databases" gives more detail.

(3) When the calculation requires information entered in another portion of the program. An example of this is the value of average field slope, which is used in several places but is calculated within the LS factor. If this value has already been calculated, it will be shown; if not, the {call} command must be used to move to that calculation.

{list} [F6] displays a list from which you can select an option or item, as explained in "Input Field." If you have previously selected one of the choices, the list may not be shown but this command will appear as an option. Use of this command displays the list and allows you to move through it using the [ARROW] keys.

There are places in the program where the list is also shown but the marker arrow is not visible. In these cases a {list} command will move the marker arrow into the list, where the marker can be controlled with the [ARROW] keys.

{save} [F7] {save}s the data shown on the screen into a Database Set named by the Identifier at the top of the screen. Changes made within the CITY, CROP, or OPERATIONS

Database routines will not be saved into those Databases unless this command is used before exiting those routines. If changes have been made, you will be asked whether or not you want to save them before you are allowed to exit.

{dupe} [F8] is used only in the crop listing on the initial C-factor input screen; this duplicates an entire operation listing screen into another location within the list. For example, if I {dupe} "corn" from the first place on the list into the fifth, the program will duplicate all operations associated with that first corn onto the fifth screen. It will not change the dates, so this must be done by moving to that screen and modifying them individually.

{info} [F9] gives information on the Current Input List. When you {save} a Current Input List into an Input File, you are also saving a list of comments describing that List. Use of this command allows you to look at (and change) the descriptive information for the Current Input List.

{desc} [F10] gives information on the current CROP or OPERATIONS Database Set. These Sets also contain a series of descriptive comments, which can be viewed or changed from anywhere this command is available.

{ins} [INS] is used to insert a line of information just above the line on which the cursor is resting.

{del} [DEL] is used to delete the line of information on which the cursor is resting.

{1st} [HOME] is used to jump to the first in a series of screens or to the beginning of a list.

{last} [END] is used to jump to the last in a series of screens or to the end of a list.

{pgup} [PG UP] is used to move to the previous screen in a series of screens or up one screen in a long list of information.

{pgdn} [PG DN] is used to move to the next screen in a series of screens or down one screen in a long list of information.

Terminology

command :	is an instruction given to RUSLE to control the flow of the program. A *command* is usually given by pressing a key. At any point in the program, the available *commands* are shown on the *Command Line.*
Command Line:	is made up of the bottom two lines of the screen, and contains a list of all the available *commands* at any point in the program. The bottom line shows the three- or four-letter description of the *command,* and the upper line shows the keystroke used to execute it.
Current Input List:	is a list of the current values for all answers to the questions. This is updated every time a new value is entered or a new selection is made from a list, such as the entering or selection of a new city.
Database Set:	is all of the CROP, CITY, or OPERATIONS information associated with a specific *Identifier.* For instance, for the CITY Database, this is all the climatic data for a specific city or region.
file(s):	is an operating system file. See your manual or site specialist for a more complete description.
Function:	is a set of routines used by RUSLE to perform housekeeping tasks. For RUSLE, these consist of the FILE Function to move information back and forth between the *Current Input List* and the *Input Files*, the EXIT Function to leave the program quickly, the HELP Function to obtain general information about the program, and the SCREEN Function to change screen coloring.
Function Line:	is a list of the available *Functions,* shown on the top line of the screen. These can be reached with the {FUNC} *command* to move the cursor to the *Function Line*, using the [ARROW] keys to get the correct *Function* and option, and pressing [ENTER].
Header Line:	is the top line of the *Main Screen*, and the second line down from the top of the actual screen. This shows the program version and the screen name.

Identifier: is a name or number with which to associate the information in a particular *Database Set.* When a list of the names or numbers is shown, selection of the one you want brings in all associated information.

input: is a response typed into an *Input Field* or chosen from a list in response to a program question.

Input Field: is the place where the cursor rests while waiting for your response to a question. You can respond with either an *input* or a *command.*

Input File: is a copy of the *Current Input List* that has been SAVEd. This copy is stored as a file with the name it was given in SAVEing, along with a ".rus" suffix.

Main Screen: is the central part of the screen. It contains all the questions and areas for response.

Suggestion Line: is seen within the line forming the bottom of the *Main Screen.* This line displays the suggested *command* or course of action.

APPENDIX A. CONVERSION TO SI METRIC SYSTEM

SI metric equivalents are not included in the procedures and tables presented in this handbook because direct conversion of each English unit is awkward in many instances and undesirable for a procedure used in the United States. Converting the RUSLE as a whole may be more appropriate. SI metric units can then be selected so that each of the interdependent factors will have a metric counterpart whose values will be expressed in numbers that are easy to visualize and to combine in computations.

A convenient unit for measuring cropland soil losses is metric tons per hectare (table A-1). **EI** values can be obtained by expressing rainfall energy in megajoule· millimeter per hectare· h· yr and expressing intensities in millimeters per hour. Factor **K** will then be in metric tons· hectare· hour per hectare· megajoule· millimeter or metric tons per hectare per unit **EI**. If 22.1 meters is taken as the basic slope length and 9 percent is retained as the basic slope gradient, the **LS** factor will not be affected. Using these units is recommended and is assumed in the following paragraphs.

The RUSLE factors will normally be derived directly in the English units by procedures outlined in Foster et al. (1981). However, the conversion factors in table A-2 will facilitate comparisons of the metric factor values with the English values published in this handbook. Details of the conversions are shown in Foster et al. (1981).

Table A-1.
Dimensions of universal soil loss equation (USLE) factors

Factor	Symbol	Dimensions		Typical U.S. customary units
Rainfall intensity	i or I	[1] $\frac{length}{time}$	$\frac{L}{T}$	$\frac{inch}{hour}$
Rainfall energy per unit of rainfall	e	$\frac{length \cdot force}{area \cdot length}$	$\frac{LF}{L^2L}$	[2] $\frac{foot \cdot tonf}{acre \cdot inch}$
Storm erosivity	EI	$\frac{length \cdot force \cdot length}{area \cdot time}$	$\frac{LFL}{L^2T}$	[3] $\frac{hundreds\ of\ foot \cdot tonf \cdot inch}{acre \cdot hour}$
Soil loss	A	$\frac{mass}{area \cdot time}$	$\frac{M}{L^2T}$	$\frac{ton}{acre \cdot year}$
Annual erosivity	R	$\frac{length \cdot force \cdot length}{area \cdot time \cdot time}$	$\frac{LFL}{L^2TT}$	$\frac{hundreds\ of\ foot \cdot tonf \cdot inch}{acre \cdot hour \cdot year}$
Soil erodibility	K	$\frac{mass \cdot area \cdot time}{area \cdot length \cdot force \cdot length}$	$\frac{ML^2T}{L^2LFL}$	$\frac{ton \cdot acre \cdot hour}{hundreds\ of\ acre \cdot foot \cdot tonf \cdot inch}$
Slope length	L	$\left(\frac{length}{length}\right)^m$	$\left(\frac{L}{L}\right)^m$	
Slope steepness	S	Dimensionless		
Cover-management	C	Dimensionless		
Supporting practices	P	Dimensionless		

[1]F=forces, L=length, M=mass, T=time, m=exponent that varies from 0.2 to 0.5
[2]Tonf indicates ton force. Ton without a subscript indicates ton.
[3]This notation, "hundreds of," means that the numerical value of the factor is 0.01 times its true value. That is, if R=125, its true value is 12,500 ft· tonf· in (acre· h· yr)$^{-1}$. The converse is true for "hundreds of" in the denominator of a fraction.

Source: Foster et al., 1981.

Table A-2.
Conversion factors for universal soil loss equation (USLE) factors.

To convert from	U.S. customary units	Multiply by	To obtain:	SI Units
Rainfall intensity, i or I	$\frac{inch}{hour}$	25.4	$\frac{millimeter}{hour}$	[1] $\frac{mm}{h}$
Rainfall energy per unit of rainfall, e	$\frac{foot \cdot tonf}{acre \cdot inch}$	$2.638 \cdot 10^{-4}$	$\frac{megajoule}{hectare \cdot millimeter}$	[2] $\frac{MJ}{ha \cdot mm}$
Storm energy, E	$\frac{foot \cdot tonf}{acre}$	0.006701	$\frac{megajoule}{hectare}$	[3] $\frac{MJ}{ha}$
Storm erosivity, EI	$\frac{foot \cdot tonf \cdot inch}{acre \cdot hour}$	0.1702	$\frac{megajoule \cdot millimeter}{hectare \cdot hour}$	$\frac{MJ \cdot mm}{ha \cdot h}$
Storm erosivity, EI	[4] $\frac{hundreds\ of\ foot \cdot tonf \cdot inch}{acre \cdot hour}$	17.02	$\frac{megajoule \cdot millimeter}{hectare \cdot hour}$	$\frac{MJ \cdot mm}{ha \cdot h}$
Annual erosivity, R[5]	$\frac{hundreds\ of\ foot \cdot tonf \cdot inch}{acre \cdot hour \cdot year}$	17.02	$\frac{megajoule \cdot millimeter}{hectare \cdot hour \cdot year}$	$\frac{MJ \cdot mm}{ha \cdot h \cdot y}$
Soil erodibility, K[6]	$\frac{ton \cdot acre \cdot hour}{hundreds\ of\ acre \cdot foot \cdot tonf \cdot inch}$	0.1317	$\frac{metric\ ton \cdot hectare \cdot hour}{hectare \cdot megajoule \cdot millimeter}$	$\frac{t \cdot ha \cdot h}{ha \cdot MJ \cdot mm}$
Soil loss, A	$\frac{ton}{acre}$	2.242	$\frac{metric\ ton}{hectare}$	$\frac{t}{ha}$
Soil loss, A	$\frac{ton}{acre}$	0.2242	$\frac{kilogram}{meter^2}$	$\frac{kg}{m^2}$

[1]Hour and year are written in U.S. customary units as h and yr and in SI units as h and y. The difference is helpful for distinguishing between U.S. customary and SI units.
[2]The prefix mega (M) has a multiplication factor of $1 \cdot 10^6$.
[3]To convert ft · tonf to megajoule, multiply by $2.712 \cdot 10^{-3}$. To convert acre to hectare, multiply by 0.4071.
[4]This notation, "hundreds of," means numerical values should be multiplied by 100 to obtain true numerical values in given units. For example, R=125 (hundreds of ft · ton · in (acre · h)$^{-1}$=12,500 ft · tonf h. The converse is true for "hundreds of" in the denominator of a fraction.
[5]Erosivity, EI or R, can be converted from a value in U.S. customary units to a value in units of Newton/hour (N/h) by multiplying by 1.702.
[6]Soil erodibility, K, can be converted from a value in U.S. customary units to a value in units of metric ton · ha (Newton · h)$^{-1}$ [t · h(ha · N)$^{-1}$] by multiplying by 1.317.
Source: Foster et al. 1981

APPENDIX B. CALCULATION OF EI FROM RECORDING-RAINGAGE RECORDS

The energy of a rainstorm can be computed from recording-raingage data. The storm is divided into successive increments of essentially uniform intensity, and a rainfall energy-intensity equation (for example, equations [B-3] and [B-5]) is used to compute the energy for each increment. Because the energy equation and energy-intensity table have been frequently published with energy expressed in ft · tonf · acre^{-1}, this unit was retained in table B-1. However, for computation of EI values, storm energy is expressed in hundreds of foot-tons per acre. Therefore, energies computed by the published formula or by table B-1 must be divided by 100 before multiplying by I_{30} to compute EI.

Soil-loss prediction with USLE does not require the computation of EI values by application personnel, but the procedure is included here for the benefit of those who may wish to compute them.

Mathematically, R is

$$R = \frac{1}{n} \sum_{j=1}^{n} \left[\sum_{k=1}^{m} (E) \left(I_{30}\right)_k \right] \qquad [B\text{-}1]$$

where

E = total storm kinetic energy,
I_{30} = maximum 30-min rainfall intensity,
j = index of number of years used to produce average,
k = index of number of storms in each year,
n = number of years used to obtain average R,
m = number of storms in each year, and
R = average annual rainfall erosivity.

$$EI = (E)\left(I_{30}\right) = \left(\sum_{k=1}^{m} e_r \, \Delta V_r \right) I_{30} \qquad [B\text{-}2]$$

where

e_r = rainfall energy per unit depth of rainfall per unit area ft · tonf · acre^{-1} · in^{-1}, and

ΔV_r = depth of rainfall for the rth increment of the storm hyetograph which is divided into m parts, each with essentially constant rainfall intensity (in).

Unit energy, e, is a function of rainfall intensity and is computed as

$$e_k = 1099 \left[1 - 0.72 \exp \left(-1.27 i_r \right) \right] \quad [B\text{-}3]$$

and

$$i_r = \frac{\Delta V_r}{\Delta t_r} \quad [B\text{-}4]$$

where

Δt_r = duration of the increment over which rainfall intensity is considered to be constant (h), and

i_r = rainfall intensity (in · h^{-1}).

The unit energy equation [B-3] was suggested by Brown and Foster (1987) as a replacement to the relationship used in Agriculture Handbook 537 because the equation not only includes more data for its development but also has a better functional form at low intensities. Equation [B-3] was used for the preparation of the isoerodent maps in the western United States whereas the isoerodent maps in the eastern United States were calculated using the following equation:

$$e_k = 916 + 331 \log_{10}(i_r) \quad [B\text{-}5]$$

We do not recommend using equation [B-5] for future calculations of unit energy.

The EI for a specified time period (such as the annual value) is the sum of the computed value for all rain periods within that time. Thus

$$R = \sum EI_{30}(10^{-2}) \qquad [B\text{-}6]$$

where

R = average annual rainfall erosivity in

$$\frac{\text{hundreds of ft} \cdot \text{tonf} \cdot \text{in}}{\text{acre} \cdot \text{h} \cdot \text{yr}}$$

and the division by 100 is made for convenience of expressing the units.

In the western United States, all storms were included in the calculation of R, except storms where the precipitation occurred as snow. Erosion index calculations in the eastern United States were computed for storms exceeding 0.5 in of precipitation. Rains of less than 0.5 in, separated from other showers by 6 h or more, were omitted as insignificant unless the maximum 15-min intensity exceeded 0.95 in $\cdot$ h^{-1}.

Sample Calculation of EI From Recording-Raingage Records

The kinetic energy of a given amount of rain depends on the sizes and terminal velocities of the raindrops, and these are related to rainfall intensity. The computed energy per inch of rain at each intensity is obtained by solving equations [B-3] and [B-4], or by using table B-1 and reading energy values for the intensity obtained from the recording raingage. The energy of a given storm depends on all the intensities at which the rain occurred and the amount that occurred at each intensity. A recording-raingage record of the storm will provide this information. Clock time and rain depth are read from the chart at each point where the slope of the pen line (from a cumulative record) changes, and are tabulated as shown in the first two columns of the sample computation in table B-2. Clock times (col. 1) are subtracted to obtain the time intervals given in column 3, and the depths (col. 2) are subtracted to obtain the incremental amounts tabulated in column 4. The intensity for each increment (col. 5) is the incremental amount times 60, divided by column 3.

The energy per inch of rain in each interval (col. 6) is obtained by entering table B-2 with the intensity given in column 5 or by solving equations [B-3] and [B-4]. The incremented energy amounts (col. 7) are products of columns 4 and 6. The total energy for this 90-min rain is 1,254 ft $\cdot$ tonf $\cdot$ $acre^{-1}$. This is

multiplied by a constant factor of 10^{-2} to convert the storm energy to the dimensions in which EI values are expressed.

The maximum amount of rain falling within 30 consecutive minutes was 1.08 in, from 4:27 to 4:57. I_{30} is twice 1.08, or 2.16 in $\cdot$ h^{-1}. The storm EI value is 12.54(2.16) = 27.1. When the duration of a storm is less than 30 min, I_{30} is twice the amount of rain.

Comparison of the new unit energy relationship (eq. [B-3]) with the one from Agriculture Handbook 537 (eq. [B-5]) shows less than a 1% difference in the energy of some sample storms (see tables B-3 and B-4).

APPENDIX C. ESTIMATING RANDOM ROUGHNESS IN THE FIELD

Random roughness is the nonoriented surface roughness that is sometimes referred to as cloddiness (Allmaras et al. 1966, Römkens and Wang 1986). Such roughness is usually created by the action of tillage implements. Random roughness is an important component in computing the soil-loss ratio (ch. 5). It can be contrasted with oriented roughness such as the ridges and furrows created by the passage of a tillage implement through the field. Oriented roughness in ridges and furrows is a component of the P factor (ch. 6).

Random roughness is defined as the standard deviation of elevation from a plane across a tilled area, after oriented roughness is accounted for by appropriate statistical procedures. Random roughness can be determined by mechanical profile meters or by more sophisticated devices such as laser profilers. At this time, no rapid, inexpensive technique is available to measure random roughness in the field. Frequently roughness is estimated as either a mean or a range in clod size. It has also been estimated in terms of the number of hits on clods of greater than a given size using a beaded line. Neither technique provides a value of random roughness as needed by RUSLE or other models.

Based on the need for rapid field assessment of random roughness and the lack of a suitable field technique, photographs of areas of selected random roughness conditions were taken to be used as visual guides to estimate random roughness in the field.

Procedure

It was thought essential to document a wide range of surface conditions, from very fine to very rough. Plot areas on the Palouse Conservation Field Station near Pullman, WA, were inspected for suitable conditions. By conducting additional tillage on selected plots, a wide range of roughness conditions was established on nine plot areas. A 6-ft-wide mechanical profile meter with pins on 1/2-in spacing was used to obtain roughness measurements. A 35-mm single-lens-reflex camera with a wide-angle lens was used to record the pin-top heights against a grid background (McCool et al. 1981). The profile meter was set up parallel to the tillage direction, and 10 lines were taken across a 1-m-deep plot. No attempt was made to establish a common datum elevation for all lines. This research differed from that of Allmaras et al.

(1966), in which all points on a rectangular grid were measured from a common datum. Hence, only random roughness parallel to tillage lines is considered in this study.

Black-and-white enlargements, 8x12 in, were obtained from the profile meter photos, and the pin-top elevations were digitized. A regression line was fitted to each set of readings for use as a reference datum, and the standard deviation was calculated for each cross section. The average standard deviation or random roughness was calculated for each plot by averaging these 10 values.

An undisturbed area measuring 1x1 m beside the profile meter transect was photographed at an oblique angle to provide an image similar to that seen by an observer standing a few feet from the plot. These photographs were taken at right angles to the tillage direction.

Results

The nine plot areas yielded random roughness values, R_t, ranging from 0.25 to 2.15 in. Photos of these plots are presented in figures C-1 through C-9. These figures can be used in the field to estimate random roughness. The soil-loss ratio is moderately sensitive to random roughness. Estimating random roughness as 0.50 when it is actually 0.25 results in a 15% error in the soil-loss ratio.

During the data analysis, it was found that the R_t value was linearly related to the difference in elevation between the highest and lowest pin-top reading (i.e., range) for a given cross section. The data from each of the cross sections is plotted in figure C-10. The R_t values were linearly fitted to the range in pin-top elevations as shown by the line in figure C-10, with a coefficient of determination of 0.93.

Thus random roughness can also be estimated by determining the distance from the highest to the lowest point along a furrow or ridge. Averaging a number of these readings in a field provides an average value to use with figure C-10 to obtain a value of R_t.

APPENDIX D. PARAMETER VALUES FOR MAJOR AGRICULTURAL CROPS AND TILLAGE OPERATIONS

The following information and data are to be used to prepare data files for crops and tillage operations used in application of RUSLE to cropland. Data presented for the crops and tillage operations represent "core" values that are to be used as starting points. Procedures are given that can be used to adjust the core values to represent conditions that differ from those described by the core data. Guidelines are also given on how to develop parameter values for crops and tillage operations not listed in the tables by extracting data from the literature or by comparing characteristics of the given crop or operation to crops and operations listed in the "core" data.

Data presented in the following tables were developed by the USDA Agricultural Research Service (ARS) and the Natural Resources Conservation Service (NRCS) for use by NRCS in its national implementation of RUSLE. The values and procedures are based on a review of data in the literature and on the judgment of numerous technical specialists in NRCS and the ARS RUSLE development team.

Use of these values and procedures can greatly help to ensure consistency in the application of RUSLE. If you get inconsistent results with RUSLE, first make checks using "core" values. Then carefully evaluate adjustments to the "core" values to ensure that reasonable adjustments have been made and that RUSLE is responding as expected to each adjustment.

Procedure for Adjusting Values for a "Core" Crop

If RUSLE is being applied to a crop included in the "core" data but the yield differs from the yield of the core crop, adjustments to the parameter values given for the core crop in table 5-1 or 5-2 are needed.

Residue:Yield Ratio

RUSLE has been designed to use a constant residue:yield ratio over the range of yields given in table D-1. If the yield of the given crop falls outside of the range given for the core crop, the residue:yield ratio can be varied with yield. In general, assumption of a constant residue:yield ratio for yields above the upper limit is acceptable. However, this ratio increases significantly as yield

decreases below the lower limit. If the residue:yield ratio is varied as a function of yield outside of the given range, the ratios should be chosen to match the constant ratio value at the upper and lower limits.

The residue:yield ratios given in table D-1 are based on commonly accepted, typical values for this ratio. However, this ratio can vary with crop variety, region, and other factors. A value for this ratio can be selected that differs from the "core" value given in table D-1, but the assumption of a constant value must be observed within the yield range given in table D-1.

Root Mass

Root biomass is adjusted using multiplication factors in table D-2 where root biomass is assumed to be linearly adjusted as a function of aboveground biomass. If yield is within the range where the residue:yield ratio is assumed to be constant, root biomass can be adjusted linearly with yield. One way to make the adjustment is to first determine the multiplication factor based on a ratio of the aboveground biomass. Each root biomass value for the core crop can be multiplied by this factor to determine values for the given crop.[3] The procedure is illustrated in table D-3.

Canopy

Canopy cover (percentage) is adjusted according to the square root (0.5 power) of the ratio of aboveground biomass for the given crop to that for the core crop. The multiplication factors are given in table D-2. If the resulting canopy value exceeds 100%, a value of 100% should be assigned to the canopy value. If the yield is within the range where a constant residue:yield is assumed, yield values can be used to form the ratio of biomass values to determine a multiplication factor. All canopy values of the core crop are multiplied by the adjustment factor to obtain the new set of canopy values. The procedure is illustrated in table D-3.

Effective Fall Height

Effective fall height is adjusted according to the 0.2 power of the ratio of aboveground biomass for the given crop to that for the core crop. The multiplication factors are given in table D-2. If the yield is within the range

[3]The following guide should be used in rounding numbers. Root biomass values are rounded to nearest 10 lb/acre per 4 in depth, canopy percentage to nearest 5 percent, and fall height to the nearest 0.1 ft.

where a constant residue:yield is assumed, yield values can be used to form the ratio of biomass values to determine a multiplication factor. All effective fall height values of the core crop are multiplied by the adjustment factor to obtain the new set of canopy values. The procedure is illustrated in table D-3.

Length of Growing Season and Dormancy

Adjustments may be needed for length of growing season for crops like corn and soybeans and length of the dormancy season for crops like winter wheat. The adjustment made for length of growing season is to add or subtract days from the period of full canopy before senescence begins. Length of the dormancy period is adjusted by adding or subtracting days to the dormancy period. In the southern part of the United States, reduced growth can continue throughout the dormancy period. The core data should be adjusted to account for this effect.

Crops Not Listed Among Core Crops

Situations will arise where RUSLE will be applied to crops not listed in the core data set. Several options are available for obtaining values for these crops. Key variables are amount of aboveground biomass, amount of root biomass at harvest, amount of canopy, and fall height at harvest.

Obtain Data From the Literature

The first option involves selecting published values in the literature. Try to find as much published data as possible. Variations among the sources can be large. The ratio of aboveground biomass to root biomass is not constant during the growing season. Select the root biomass value at maturity as the starting point. Choose values during the growing season that form an S-shaped curve similar to the data shown for the core crops. The same applies for canopy and effective fall height. Choose a residue:yield ratio value that can be assumed to be constant over the mid 50% yield range of the crop.

Obtain Data From NRCS

The second option is to contact the State Agronomist in an office of the Natural Resources Conservation Service (NRCS) of the USDA. Very likely NRCS has already developed a data set for a crop that can be used directly or that can be modified.

Compare Crop Characteristics to Characteristics of a Core Crop

The third alternative is to compare characteristics of the given crop to those of a similar core crop and adjust parameter values accordingly. For example, peanuts might be compared to soybeans.

Relation of Ground Cover Percent to Mass

In many cases, ground cover is the single most important factor affecting erosion. Therefore, the single most important crop variable is amount of residue at harvest and at planting time. Table D-4 lists values for the "core" crops for relating percent ground cover to mass.

Percent ground cover is not an accurate indicator of amount of biomass when percent cover exceeds 90%, as at harvest. The exponential shape of the curve that describes the relation of residue cover to residue mass is not sensitive to mass at high percent cover values. Mass can change greatly with little detectable change in cover above 90%, especially for covers greater than 95%. However, percent cover for values less than 75% is a reliable indicator of cover mass on the surface.

Even though percent cover is the single most important variable affecting erosion, loss of residue is on a mass basis. While cover is readily measured, mass of cover is not easily measured. Soil particles must be carefully washed from the residue, and leaves and stems must be carefully recovered. Also, the residue rapidly loses mass shortly after harvest, which is not reflected in a corresponding loss of cover.

If RUSLE is using the proper mass of residue at harvest but is giving a poor estimate of cover before spring tillage, two possibilities should be checked. One is that the decomposition parameter value used to compute loss of residue is in error; the other possibility is that the relationship of residue cover to residue mass is in error.

If the residue cover after planting is not correct but was correct before the first tillage operation at planting time, the most likely cause is that the value of residue left by the tillage operation is incorrect. If the residue after planting is correct but is not correct at the end of the growing season, the decomposition parameter value is incorrect.

Be Cautious

Because erosion is sensitive to cover, care should be taken to ensure that cover values are reasonable. However, when adjustments are needed, analyze

the reason for the problem and make adjustments carefully and methodically. Sometimes the problem is not as it appears.

Decomposition Parameter Values

Loss of residue over time is computed in RUSLE as a function of temperature and rainfall. Parameter values for decomposition are given in table D-5.

Data used in RUSLE to evaluate the adequacy of the decomposition parameter values should be field measurements of the loss of residue cover. Obviously, other factors such as soilborne organisms can affect residue loss. These effects are empirically captured in the decomposition parameter values. Thus, a decomposition parameter value should be based on field measurements and not laboratory decomposition tests.

The decomposition computations in RUSLE do not consider standing stubble separate from biomass on the soil. As a consequence, RUSLE may overestimate the loss of standing stubble. However, a decomposition parameter value can be applied to the biomass in the soil that is different from the parameter value for biomass on the soil.

RUSLE does not treat the plant components of leaves, stems, and roots separately. All components are assumed to be lost at the same rate. Furthermore, RUSLE does not vary the decomposition parameter value based on the state of decomposition to consider, for example, that decomposition may initially proceed more rapidly than in later stages.

Decomposition is related more closely to soil moisture than to the rainfall values used in RUSLE to compute loss of residue. Also, temperature varies within a day, and both temperature and rainfall vary from day to day. Monthly values in RUSLE are disaggregated into smoothed daily values for the RUSLE computations. The result is that decomposition parameter values for a given crop may need adjustment by climatic region. For example, a much larger decomposition parameter value is needed for wheat in the Northwestern Wheat and Range Region than in other parts of the United States.

Given these considerations and the limitations of the simple equations used in RUSLE to compute loss of biomass, decomposition parameter values are chosen to provide the best overall results.

Adjusting Parameter Values for Operations in the Core List

Table 5-5 contains parameter values for the core list of field implements used in many cropland operations. When an operation in the core list does not match the operation as applied in your situation, the following adjustments can be made.

Depth of Incorporation

For a given type of implement, a single value is used for depth of incorporation. For example, a value of 6 in is used for all chisel plows regardless of actual depth of tillage. Values for depth of incorporation are chosen based on information given in table D-6.

Roughness

A roughness value assigned to a tillage operation can be adjusted up or down one roughness step as shown in table D-7. For example, a moldboard plow has a roughness value of 1.9 in for its core value. It could be assigned a value of 2.3 for a clay soil that is very rough or a value of 1.5 for a sandy soil that is relatively smooth after plowing. The roughness index as used in RUSLE represents both the effects of depressional storage and the degree of pulverization.

Amount of Residue Left

Since surface cover has such a great effect on erosion, the value for the amount of residue left by an operation should be selected carefully. In general, values should be rounded to the nearest 10% or perhaps to the nearest 5%. Consideration should be given to whether the residue is fragile or nonfragile. Nonfragile residues are assumed in table 5-5. A very important consideration, especially if information is obtained from the literature, is whether or not residue mass or percent cover was used to indicate how much residue was left by the tillage operation.

Obtaining Parameter Values for Operations Not in the Core List

If a particular operation is not in the core list, values for the operation can often be obtained from the NRCS, which has developed values for an array of operations. This approach is preferred because the NRCS values have been tested and evaluated for consistency with other operations. The next best alternative is to choose values based on data in literature. The third and last desirable option is to compare characteristics of the particular operation against those of operations in the core list. If values are obtained from the literature or by comparison with operations in the core list, the following must be observed. The depth of incorporation is based on type of tillage operation as described in table D-6. The value of roughness that is assigned to a tillage operation is based on the tillage occurring in a medium-textured soil at a high level of management, meaning that large amounts of residue from a high yielding crop like corn has been routinely incorporated into the soil.

Table D-1. Residue:yield ratio and yield range over which to use a constant residue:yield ratio

Crop	Residue:yield ratio	Range[1]
Corn	1.0	50 to 150 bu(acre)$^{-1}$
Soybeans	1.5	15 to 45 bu(acre)$^{-1}$
Cotton	[2]4.5	300 to 1000 lbs(acre)$^{-1}$lint
Sorghum	1.0	40 to 90 bu(acre)$^{-1}$
Winter wheat	1.7	25 to 60 bu(acre)$^{-1}$
Spring wheat	1.3	25 to 60 bu(acre)$^{-1}$
Spring oats	2.0	30 to 80 bu(acre)$^{-1}$

[1]If yield is less than the minimum value in the range, the residue:yield ratio may need to be increased. If yield is greater than the maximum value in the range, the residue:yield ratio may need to be decreased.
[2]Value given is for shredding stalks in the fall. Use 3.0 for stalks shredded in the spring.

Table D-2. Multiplication factors to adjust RUSLE plant data from core data

Ratio of biomass at maturity of given crop to biomass of core crop	Multiplication factor for root biomass[1]	Multiplication factor for canopy percent[2]	Multiplication factor for fall height[3]
0.1	0.1	0.32	0.63
.2	.2	.45	.72
.3	.3	.55	.79
.4	.4	.63	.83
.5	.5	.71	.87

[4]1.0	1.0	1.00	1.00
1.1	1.1	1.05	1.02
1.2	1.2	1.10	1.04
1.3	1.3	1.14	1.05
1.4	1.4	1.18	1.07
1.5	1.5	1.22	1.08
1.6	1.6	1.26	1.10
1.7	1.7	1.30	1.11
1.8	1.8	1.34	1.12
1.9	1.9	1.38	1.14
2.0	2.0	1.41	1.15

[1]Adjustment factor for roots = (M_g / M_c), where M_g is aboveground biomass for given crop and M_c is aboveground biomass for core crop.
[2]Adjustment factor for canopy percenter = $(M_g / M_c)^{0.5}$
[3] Adjustment factor for fall height = $(M_g / M_c)^{0.2}$
[4]Represents core crop

Table D-3. Data adjustment examples for root biomass, percentage of canopy cover, and fall height[1].

	Root biomass percent adjustments		Canopy percent adjustments		Fall height adjustment in feet	
Days	Core crop	Given crop	Core crop	Given Crop	Core Crop	Given Crop
30	180	110	10	10	0.5	0.4
45	350	210	50	40	1.0	0.9
60	530	320	80	60	1.7	1.5
75	840	500	100	80	2.5	2.2
90	1060	640	100	80	3.0	2.7
150	1060	640	70	55	3.0	2.7

[1]The following example is used:

- Core crop is corn at 125 bu(acre)$^{-1}$
- Given crop is corn at 75 bu(acre)$^{-1}$. Ratio of biomass at maturity for given crop to that core crop = 0.6.

Table D-4. Percent cover to mass relationship for core crops.

	Mass (lbs(acre)$^{-1}$) at various percentages of residue cover		
Crop	30	60	90
Corn	950	2400	6050
Soybeans	600	1600	—
Cotton	1600	4150	—
Sorghum	1050	2700	6750
Winter wheat	600	1550	3850
Spring oats	600	1550	3850

Table D-5. Decomposition coefficient values

Crop	Coefficient
Alfalfa	0.020
Brome grass	.017
Corn	.016
Cotton	.015
Peanuts	.015
Small grain	[1].008
Small grain cover crop killed while in vegetative stage	.017
Sorghum	.016
Soybeans	.025
Sunflowers	.016
Tobacco	.015

[1] Use 0.017 for the Northwestern Wheat and Range Region.

Table D-6. Depth of incorporation according to type of tillage operation

Operation	Depth of incorporation (in)
Primary tillage operations that invert soil, such as moldboard plow	8
Primary tillage operations that do not invert soil, such as chisel plows and heavy plowing disks	6
Operations involving widely spaced shanks that inject significant amounts of biomass into the soil, such as manure injectors	6
Secondary tillage operations involving disks, such as tandem disk	4
Bedding and ridging operations, such as listers, hippers, and similar tools (cultivators used in ridge-till cropping are not included in this category)	4
Secondary tillage operations involving shank type tools that mix the soil significantly, such as field cultivators	3
Shank type operations using widely spaced shanks where minimal mixing occurs, such as subsoilers and anhydrous fertilizer knife-type applicators	2
Secondary tillage operations and other operations that disturb only a shallow upper layer or that leave crop residue in a shallow upper layer, such as harrows, planters, row cultivators, and tools where minimal mixing occurs	2

Table D-7. Adjustments to random roughness index in inches to represent smoother and rougher surfaces than represented by "core" value

Smoother surface	Core roughness value	Rougher surface
0	0.1	0.2
0.1	.2	.4
.2	.4	.8
.4	.8	1.2
.8	1.2	1.6
1.2	1.6	2.0
1.6	2.0	2.4
2.0	2.4	2.8

Procedure: Identify a "core" roughness value. If the site specific condition is significantly smoother than the core surface, use the roughness value from the "smoother surface" column, and conversely for a rougher surface.

P.O. Box 1157
Oxford, Mississippi

C.K. Mutchler, (retired) research agricultural engineer
USDA-ARS, National Sedimentation Laboratory
P.O. Box 1157
Oxford, Mississippi

J.W.A. Poesen, research scientist
Belgium National Fund for Scientific Research
Laboratory of Experimental Geomorphology
University of Leuven
Leuven, Belgium

J.P. Porter, agricultural engineer
USDA-NRCS, Flint Area Office
G-4312 S. Dort Hwy., Suite B
Burton, Michigan
(formerly at USDA-ARS, National Soil Erosion Research Laboratory)

K.G. Renard, (retired) research hydraulic engineer
USDA-ARS, Southwest Watershed Research Center
2000 East Allen Road
Tucson, Arizona

M.J.M. Römkens, soil physicist/agricultural engineer
USDA-ARS National Sedimentation Laboratory
P.O. Box 1157
Oxford, Mississippi

J.M. Sheridan, research hydraulic engineer
USDA-ARS, Southeast Watershed Research Laboratory
P.O. Box 946
Tifton, Georgia

J.R. Simanton, hydrologist
USDA-ARS, Southwest Watershed Research Center
2000 East Allen Road
Tucson, Arizona

G.A. Weesies, agronomist
USDA-NRCS, National Soil Erosion Research Laboratory
Purdue University
West Lafayette, Indiana

D.A. Whittemore, software engineer
USDA-ARS, National Soil Erosion Research Laboratory
Purdue University
West Lafayette, Indiana

D.C. Yoder, agricultural engineer and assistant professor
Department of Agricultural Engineering
University of Tennessee
Knoxville, Tennessee
(formerly with USDA-ARS, National Soil Erosion Research Laboratory)

R.A. Young, (retired) agricultural engineer
USDA-ARS, North Central Soil Conservation Research Laboratory
North Iowa Avenue
Morris, Minnesota

MEMBER ASAE | ASSOC. MEMBER ASAE | MEMBER ASAE | MEMBER ASAE | FELLOW ASAE

ABSTRACT

A reanalysis of historical and recent data from both natural and simulated rainfall soil erosion plots has resulted in new slope steepness relationships for the Universal Soil Loss Equation. For long slopes on which both interrill and rill erosion occur, the relationships consist of two linear segments with a breakpoint at 9% slope. These relationships predict less erosion than current relationships on slopes steeper than 9% and slopes flatter than about 1%. A separate equation is proposed for the slope effect on short slopes where only interrill erosion is present. For conditions where surface flow over thaw-weakened soil dominates the erosion process, two relationships with a breakpoint at 9% slope are presented.

INTRODUCTION

The slope steepness factor S in the Universal Soil Loss Equation (USLE) (Wischmeier and Smith, 1978) expresses the effect of slope gradient on sheet and rill erosion. The equation published for S in Agriculture Handbook (AH) 537 (Wischmeier and Smith, 1978), the main guideline manual for the USLE is:

$$S = 65.4 \sin^2 \theta + 4.56 \sin \theta + 0.0654 \quad \ldots\ldots\ldots [1]$$

where: θ = angle of the slope. The factor S evaluated for a given steepness is the ratio of soil loss on the particular slope to that from a nine percent slope, when all other conditions are the same. Nine percent slope is the steepness of the USLE unit plot (Wischmeier and Smith, 1978), and equations for S are normalized to give a value of 1.0 at this steepness. This report covers our review and analysis of data on the effect of slope on sheet and rill erosion and presents revised relationships for the USLE slope factor S.

Article was submitted for publication in September, 1986; reviewed and approved for publication by the Soil and Water Div. of ASAE in June, 1987.

BACKGROUND

Zingg (1940) was one of the early researchers to relate erosion to slope steepness. He analyzed simulated rainfall data from Kansas (Duley and Hays, 1932) and Alabama (Diseker and Yoder, 1936), which indicated that soil loss varied with slope steepness to the 1.49 power, and from simulated rainfall plots at Bethany, MO, which indicated that soil loss varied with slope steepness to the 1.37 power. The plots at Bethany were 2.4 and 4.8 m long and 1.1 m wide on slope steepnesses of 4, 8, and 12%. For application, Zingg recommended:

$$S = (s/9)^{1.4} \quad \ldots\ldots\ldots [2]$$

where: s = slope steepness in percent. The 9 in the denominator of equation [2] normalizes Zingg's original equation to 9% steepness for consistency with the USLE unit plot concept.

The next slope factor equation in the series of soil loss equations that preceded the USLE was Smith and Whitt's (1947) equation which, when normalized to 9% steepness, can be written as:

$$S = 0.025 + 0.052\, s^{4/3} \quad \ldots\ldots\ldots [3]$$

Smith and Whitt derived their slope equation from Neal's (1938b) data from laboratory plots 3.7 m long by 1.1 m wide under simulated rainfall. Earlier, Neal (1938a,b) concluded from his data that soil loss from saturated soil varied with steepness to the 0.7 power.

The slope factor in the empirical equation developed by the Musgrave (1947) committee was:

$$S = (s/9)^{1.35} \quad \ldots\ldots\ldots [4]$$

Musgrave (1947) did not specifically identify the data used to derive equation [4], but evidently they came from studies reported by Borst et al., (1945); Browning et al.,(1948); Dickson et al., (1940); Diseker and Yoder, (1936); Duley and Hays, (1932); Lamb et al., (1944); Hays et al.,(1949); Hill et al., (1944); Knoblauch and Brill, (1940); Krusekopf, (1943); Lillard, (1941); Lillard et al., (1941); Neal, (1938a); Pope et al., (1946) and Smith et al., (1945).

Smith and Wischmeier (1957) reported a slope steepness function in their review of factors affecting sheet and rill erosion. When normalized to a 9% slope, their equation was:

$$S = 0.00650\, s^2 + 0.0453\, s + 0.0650 \quad \ldots\ldots\ldots [5]$$

which is identical to equation [1] except that percent slope, s, was used instead of sine of the slope angle. Equation [5] was derived primarily from data collected at

La Crosse, WI from natural rainfall plots on slopes of 3, 8, 13, and 18% (Hays et al., 1949). The plots were 11.1 and 22.1 m long by 4.3 m wide. Smith and Wischmeier (1957) used data from Zingg's rainfall simulator study at Bethany, MO and from studies on natural rainfall plots on two slope steepnesses at Dixon Springs, IL (Gard and Van Doren, 1949) and Zanesville, OH (Borst et al., 1945) to validate the slope effect relationship derived from the La Crosse data*. They also derived another slope effect equation from analysis of data from Blacksburg, VA where plots were 17.7 m long and 4.6 m wide on slope steepnesses of 5, 10, 15, 20, and 25% (Lillard et al., 1941)*. Smith and Wischmeier's equation for the Blacksburg data, when normalized to a 9% slope, was:

$$S = 0.044 + 0.10\,s - 0.00073\,s^2 \quad \ldots\ldots\ldots\ldots [6]$$

The effect of slope steepness on erosion is nearly linear in this equation. However, Smith and Wischmeier gave this relationship minor treatment in their 1957 article and in later major USLE publications (Wischmeier and Smith, 1965, 1978).

Agriculture Handbook 282 (Wischmeier and Smith, 1965), the first major, widely distributed, guideline manual for the USLE, used equation [5] for the S factor, while its revision, AH537 (Wischmeier and Smith, 1978), used equation [1]. The only change from 1965 to 1978 in the S factor was to change slope percent (actually tangent of the slope angle) to sine of the slope angle, which is consistent with the relationship for the shear force of surface flow on its boundary (Chow, 1959):

$$\tau = \gamma\, R \sin\theta \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots [7]$$

where: τ = shear stress of the flow on the boundary, γ = weight density of the runoff, and R = hydraulic radius. On slopes less than about 20%, values for sine and tangent of the slope angle are nearly equal, and therefore the change from tangent to sine had little impact on lower slopes. Above 20%, tangent of the slope angle increases rapidly and approaches infinity for a vertical slope whereas sine of the angle approaches one. The change from tangent to sine reduced S from about 19 to 15 for a 50% slope. For slopes of such steepness, no field data are available to test these values. However, flume tests at the Utah Water Research Laboratory (Israelsen et al., 1980) produced similar results at slopes of up to 84%.

Another major USLE slope factor equation is the one recommended for application of the USLE to steep slopes in the Pacific Northwest Wheat and Range Region (McCool et al., 1987):

$$S = (\sin\theta/0.0896)^{0.6} \quad \ldots\ldots\ldots\ldots\ldots [8]$$

This equation was derived from measured cross sections of rills on slopes ranging from 1.5 to 56%. Since most of the erosion was caused by surface flow over thawing soils that have a high silt content, little accuracy was lost by omitting estimates of interrill erosion.

*Smith and Wischmeier used data from these locations that were collected after the cited reports were published. Those data are on file at the USDA-National Soil Erosion Research Laboratory (NSERL).

ANALYSIS

General

Data on the effect of slope on erosion were assembled from reports on about 20 studies summarized in Table 1. Most of the data we used are available in the reports identified in the References and Data Sources Section except for data from a Mississippi study and the complete data sets from La Crosse, WI and Blacksburg, VA, which are on file at the USDA-National Soil Erosion Research Laboratory (NSERL). The data were analyzed to derive a revised slope factor equation for the USLE.

Even though the USLE estimates long term, average annual soil loss, it accounts for the seasonal variation in climate and cover. A specific procedure is used to derive a weighted value for the USLE's cover-management factor C to account for the average seasonal variation in climate's erosivity and cover, tillage, and other similar cropping-management effects (Wischmeier and Smith, 1978). However, no such weighting is used for the other USLE factors even though S and other factors vary with climate, season, crop, soil condition, and tillage direction and type (Lombardi, 1979). We were unable to develop equations for S to account for these variations, partly because the equation structure of the USLE is inconvenient for varying the S factor according to current theory based on erosion processes (Foster et al., 1977). Consequently, we chose relationships that, in our judgment, best described the entire data set and erosion theory in general. For purposes of clarity for the remainder of this report, the terms low slopes and steep slopes will designate slope steepnesses of relatively low, less than about 9%, and relatively high, greater than about 9%, gradients, respectively.

Steep Slopes

The largest and most complete single data set was from the natural rainfall plots at La Crosse, WI and covered 25 years from 1939 through 1963. Only the first 5 years of the data were reported by Hays et al. (1949); the remaining data are on file at the NSERL. Plot management for the first 5 years was continuous small grain, tilled up and down hill. During the remaining 20 years, the plots were cropped across slope on the contour, with a 3-year rotation of corn-small grain-hay. Year to year variation in soil loss was much less from the continuous small grain than it was from the rotation cropping.

Analysis of the complete La Crosse data set gave a slope effect equation that was almost identical to equation [1]. However, when the up and down hill data were analyzed separately from the contour data, the two resulting slope effect relationships differed significantly, as Fig. 1 shows. The up and down hill tillage matched the USLE unit plot definition whereas contour tillage did not (Wischmeier and Smith, 1978). The additional slope effect from contouring is considered in the USLE's supporting practices factor P, and therefore, the effect of contouring should be excluded from the slope steepness factor.

At La Crosse, runoff was slightly affected by slope for up and down hill tillage, but, runoff increased significantly with slope for the contour tillage. The increase of runoff with slope was apparently caused by the reduction in surface storage of the contour tillage as slope increased. Therefore, the increase in runoff with

slope partially caused the greater slope effect on erosion with contouring.

Break in Slope Effect Equation

A trend that emerged from the data collected at the other locations (Nichols and Sexton, 1932; Diseker and Yoder, 1936) was that erosion increased at a slower rate for the low slopes than for the steep slopes, as Fig. 2 illustrates. One possible reason for these two regions in the slope effect relationship is that little or no rill erosion occurs on the low slopes, and interrill erosion, the other major component of total soil loss is not greatly affected by slope (Foster, 1982). When the slope exceeds a critical steepness, rill erosion begins, which causes total soil loss to increase rapidly with slope (Meyer and Harmon, 1985). The idea of rill erosion beginning at a particular slope is consistent with rill erosion theory where the shear stress of runoff must exceed a critical shear stress value for the particular soil condition before the flow begins to detach sediment (Meyer et al., 1976; Foster and Lane, 1983).

Another factor is that runoff varied more with steepness on the low slopes than on the steep slopes. Above a slope of about 8%, runoff did not vary significantly with steepness, as the data in Table 2 show.

As Meyer and Harmon (1985) showed for a ridge-furrow surface configuration, transport capacity of runoff controls soil loss when slope steepness is slight.

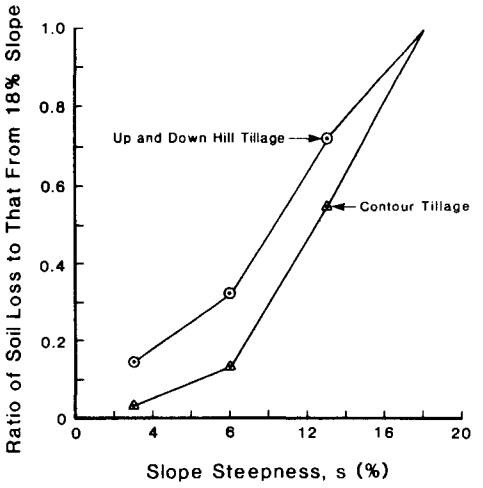

Fig. 1—Effect of tillage direction on the relation of soil loss to slope steepness at La Crosse, WI.

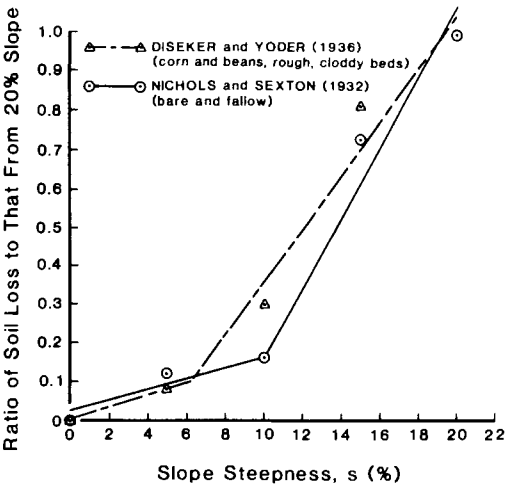

Fig. 2—Erosion increases more rapidly on steep slopes than on low slopes.

*Study number refers to Table 1.

†Slope ranges were broken down into thirds or quarters depending on the specific data set.

‡$(V_{i+1} - V_{i-1})/[\bar{V}(s_{i+1} - s_i)]$ where V_{i+1} = runoff volume for the slope steepness s_{i+1}, in percent, V_{i-1} = runoff volume for the slope steepness s_i in percent, and $\bar{V}$ = average runoff volume for all steepnesses.

§Slope and runoff data not considered valid over this range.

‖Unpublished data on file at the National Soil Erosion Research Laboratory.

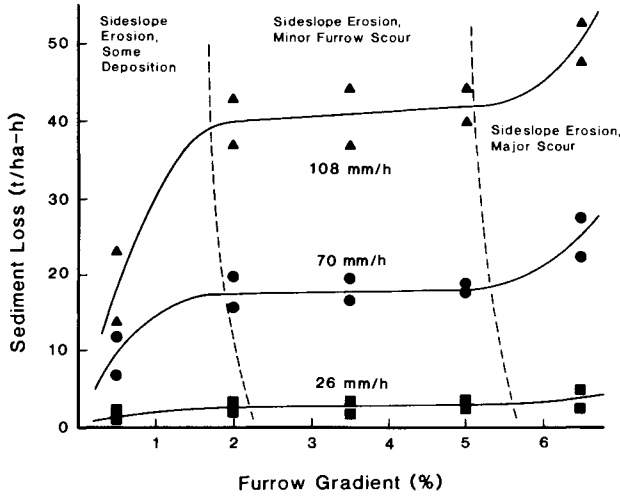

Fig. 3—Effect of row furrow gradient and rain intensity on sediment losses from the ends of bedded rows (from Meyer and Harmon, 1985).

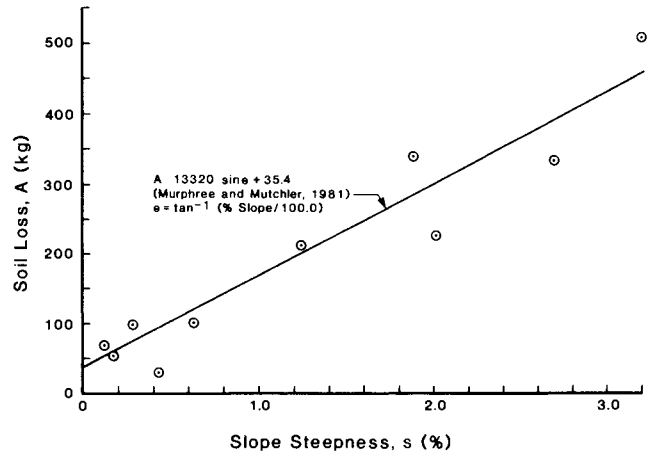

Fig. 4—Effect of slope steepness on soil loss for low gradient slopes (from Murphree and Mutchler, 1981).

Therefore, soil loss increases with steepness on low slopes as steepness increases transport capacity of runoff. When slope steepness had increased to about 2%, Meyer and Harmon (1985) observed that the flow in the furrows could transport all of the sediment eroded from the ridges by interrill erosion. However, the flow did not cause rill erosion in the furrows until a steepness of about 5% was reached, as Fig. 3 shows.

According to erosion theory and the data of Meyer and Harmon (1985), the S factor relationship can be divided into three steepness regions: (a) where soil loss is limited by transport capacity of the runoff and deposition of rainfall detached sediment occurs, (b) where flow is sufficient to transport most sediment from interrill erosion, but is not sufficient to cause rill erosion, and (c) where flow is sufficient to transport all sediment from interrill erosion and also cause rill erosion. No deposition occurs with cases (b) and (c). However, the location of these regions varies with many factors and we judged that derivation and use of such a three region S relationship was beyond the practicality of the USLE equation strucure.

In the data analyzed, breaks in the soil loss-steepness relationship between low slopes and steep slopes were not always abrupt. The value of the steepness separating low slopes from steep slopes in the steepness relationship varied with runoff rate, soil erodibility, critical shear stress, cover, and other factors. Over the 14 data sets that exhibited a break in slope, on the average, the break occurred at about 8%.

As stated previously, the La Crosse data set was the most complete set analyzed, particularly for steep slopes. The La Crosse data exhibited a break in slope at 8% (Fig. 1). Therefore, we concluded that the La Crosse data for up and down hill tillage on the 8, 13, and 18% slopes (Fig. 1) were in the region where rill erosion was occurring and that the La Crosse data from the 3% slope was either in the region where transport capacity limited soil loss or where rill erosion was insignificant. Then, we fitted a straight line through the data points for the steeper three slopes and normalized the resulting equation to 9% slope:

$$S = 16.8 \sin \theta - 0.50 \quad \ldots\ldots\ldots\ldots\ldots\ldots [9]$$

Low Slopes

The largest and most complete data set for the low slopes was collected by Murphree and Mutchler (1981) on rainfall simulator plots that were 22.9 m long by 3.7 m wide with a range in steepness from 0.1 to 3%. The plot surface was smooth without ridges. Murphree and Mutchler (1981) published an equation that expressed the linear relationship of soil loss with slope steepness for low slopes ($r^2 = 0.97$). The metric equivalent of this linear relationship is shown in Fig. 4. Based on the size and completeness of the data set, we considered this relationship to be representative of low slopes.

Three alternatives were considered to develop a relationship for the steepness effect of low slopes: (a) The relationship of Murphree and Mutchler could be normalized to intersect the La Crosse steep slope relationship, equation [9], at 8% slope; (b) The Murphree and Mutchler relationship could be normalized and forced to give the same value as the La Crosse data at 3% slope; or (c) The Murphree and Mutchler data could be normalized to give a value of 1.0 at 9% slope. If the first approach were chosen, the S value at 8% slope would be 0.83 and at 3% slope would be 0.33. If the second alternative were selected, the S value at 3% slope would be 0.35, at 8% slope would be 0.88, and at 9% slope would be 0.98. The third alternative would give an S value of 0.35 at 3% slope and 0.89 at 8% slope, quite similar to the results of the second alternative. Using alternative three, the percent difference between the observed and fitted value at 8% slope is about the same as that at 3% slope if the alternative one is used; the breakpoint at 9% slope is compatible with the unit plot concept and the lumped equation structure of the USLE. Thus alternative three was selected. The resulting equation for low slopes from the relationship of Murphree and Mutchler is:

$$S = 10.8 \sin \theta + 0.03 \quad \ldots\ldots\ldots\ldots\ldots\ldots [10]$$

Comparison with other Data

The remaining data were analyzed to determine the fit of equations [9] and [10]. Fig. 5 illustrates how well linear relationships fit selected data sets. By inspection, the slope factor relationships were judged to be linear provided separate equations were fitted to the low and steep slopes. The breakpoint steepness between the

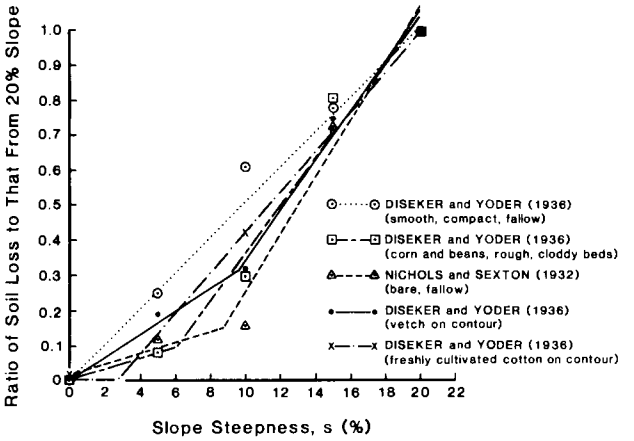

Fig. 5—Linear relationships of soil loss to slope steepness.

regions varied greatly between data sets (5 to 10%) and some data sets did not require a breakpoint.

The data in Fig. 5 represented up and down hill tillage or contoured tillage where ridges were low and runoff was not greatly affected by slope above 8%. Soil conditions ranged from freshly tilled, where critical shear stress is low, to consolidated, where critical shear stress can be large (Foster and Lane, 1983). However, no data were from thawing soils where critical shear stress is extremely low (Formanek et al., 1984).

Table 3 gives values of S estimated for an 18% steepness for the data considered in the study. Even though the values vary considerably with treatment and location, equations [9] and [10] satisfactorily represent the data as a whole. For example, the mean value for S for the 18% steepness was 3.53 (standard deviation = ± 3.08). However, some S values like those from the data of Hart (1984) and Nichols and Sexton (1932) were unrealistically high because of very low soil loss at the 9% unit plot steepness. When S values greater than 5.01 were omitted, the average S value was 2.35 (standard deviation = ± 0.79). Since most erosion is caused by the moderate to high intensity storms (Wischmeier, 1962) that would cause significant erosion on a 9% slope, deletion of the high values was justified. Therefore, the value of 2.48 for S for an 18% slope from equation [9] is reasonable in comparison with the data as a whole.

The average S value for the 3% slope was 0.32 (standard deviation = ±0.16) when the negative values in Table 3 were counted as zeroes. When the negative values were not included, the average S was 0.36 (standard deviation = 0.13). The value of 0.35 from the proposed S factor, equation [10], is therefore reasonable.

At the 0.5% slope, the average of all S values, including a zero for each negative value in Table 3, was 0.13 (standard deviation = ± 0.12), and when the negative values were excluded, the average S value was 0.17 (standard deviation = ± 0.11). These values are somewhat greater than the value of 0.08 from equation [10]. If the contention of Murphree and Mutchler (1981) that the USLE S factor overestimates for very low slopes is correct, then equation [10] is acceptable. Variability in the soil loss-steepness relationships for low slopes seemed to be caused by soil, recency of tillage, roughness, contouring, and cover affecting both runoff amount and rate.

The variation in S values for the experimental data for the low slopes was sometimes related to whether the breakpoint between the low and steep regions occurred below or above 9% steepness. When the data contained no slope steepness greater than 9% or no breakpoint occurred within the range of the slopes in a study, S values at the low slopes were typically large. Problems caused by the position of the breakpoint with respect to

9% steepness in the soil loss-steepness relationships can not be easily resolved with the lumped equation structure of the USLE.

Thawing Soils

The largest data set was that collected in the Palouse Region of the Pacific Northwest by McCool (McCool et al., 1987). The data were collected by measuring rills in cooperators' fields along an 80-km transect at the end of the winter erosion season. The project covered an 11-year period with one year excluded because of drought. Several hundred data points were obtained on slopes ranging from 1.5 to 56% steepness. The mean slope was 28.4%, and 95% of the data points were collected from slopes between approximately 9 and 48% steepness. For slopes of 9% or greater steepness we recommend use of equation [8].

For slopes of less than 9% steepness we recommend equation [10]. The difference between equations [8] and [10] is less than 10% for slopes between 7 and 9%. For lesser slopes the low shear strength of thawing soil and the relatively low runoff rates of the Palouse Region create a condition where transport capacity apparently limits soil loss. Thus the large S values obtained by extrapolating equation [8] to slopes of 5% or less appear unrealistic.

Short Slopes

The USLE does not apply to slope lengths shorter than about 4 m (Foster et al., 1981). Little rill erosion occurs on such short slope lengths and most of the soil loss is by interrill erosion. The equation derived by Foster (1982) from analysis of data from Lattanzi et al. (1974) is recommended for estimating interrill erosion:

$$S = 3.0 (\sin \theta)^{0.8} + 0.56 \quad \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

Lattanzi et al. (1974) used 0.61 m long slopes under simulated rainfall. Data in Table 4 from the studies of Singer and Blackard (1982), Evett and Dutt (1985), and Rubio-Montoya and Brown (1984) show that equation [11] is reasonable.

DISCUSSION

Table 5 gives values from our revised S factor (equations [9] and [10]), AH537's S factor (equation [1]), thawing soil S factor (equations [8] and [10]), Zingg's S factor (equation [2]), and one S factor for short slopes (equation [11]). As expected, our S values for slopes steeper than 9% are less than those from AH537. For example, at a 50% slope, the AH537 S value is over twice that from equation [9]. The lower values are consistent with the linear treads in erosion as a function of slope that are evident in most of the data.

Hart (1984) concluded that AH537 S values are too large on slopes as steep as 30%. Although the increase in erosion with steepness on the contour tilled plots at La Crosse was greater than that for the up and down hill tilled plots, erosion still increased linearly with slope above a steepness of 8%, as Fig. 1 shows. However, this increased slope effect is caused by contouring and is

*Our recommendation for the slope factor for long slopes.
†Slope factor in Agriculture Handbook 537 (Wischmeier and Smith, 1978).
‡Our recommendation for erosion of thawing soils.
§Zingg's (1940) slope factor.
‖Our recommendation for short slopes.

taken into account in the USLE P factor. When only data from up and down hill tillage from La Crosse are considered, the erosion-slope relationship is linear with little indication of the trend that the quadratic equation in AH537 gives for very steep slopes. Our recommendation for reduced S values for steep slopes is consistent with the general consensus among field users of the USLE that AH537 S values for steep slopes are too high.

Values for S from equation [10] differ from AH 537 values for slopes less than 9%. The value from equation [10] is 36% greater than the AH537 value at a 3% slope and 18% greater at a 6% slope. Slope factor values from AH537 for slopes less than 3% are questionable because they are an extrapolation of a quadratic equation fitted to a section of data showing an apparent curved trend that seems uncharacteristic of the soil loss-steepness relationship at both low and steep slopes. The soil loss-steepness effect in the data of Murphree and Mutchler (1981) is linear for slopes ranging from 0.1% to 3% steepness. The S value for the La Crosse data from the 3% slope with up and down hill tillage is 0.35, while the AH537 value is 0.26 and the value from equation [10] is 0.35. These differences result from our analysis being limited to data from the up and down hill tillage at La Crosse while Smith and Wischmeier (1957) apparently combined the up and down hill and contoured data sets. We believe that the S factor should be derived from data where tillage was up and down hill, which justifies our larger S values for slopes lower than 9%.

As Table 5 shows, the McCool et al. (1987) S factor equation gives lower S values at steep slopes than does equation [9]. The exact reason for this difference is not known, but it may be related to the low resistance of thawing soil to rill detachment and the relatively low runoff rates of the major thawing soil areas. Extrapolation of equation [8] to slopes of less than 5% would give S values considerably larger than either those from AH537 or equation [10]. For slopes of less than 9%, equation [10] appears more realistic than equation [8].

Equation [11], the S equation for short slopes, applies where runoff occurs as broad sheet flow at the end of the slope. As Table 5 shows, soil loss increases much more slowly with slope on interrill areas than it does on long slopes. Researchers studying interrill erosion have noted the great difference between their results and the USLE slope factor (Harmon and Meyer, 1978; Lattanzi et al., 1974; Meyer et al., 1975; Singer and Blackard, 1982).

The USLE slope length factor does not apply to short slopes because most of the soil loss on them is from interrill erosion, which does not vary greatly with slope length (Foster et al., 1981; Foster, 1982). A short slope is therefore defined as one where erosion is caused principally by raindrop impact. In theory, erosion per unit area on such slopes should be independent of slope length (Meyer et al., 1975; Foster, 1982). Erosion did not vary between the 3 and 6 m long plots used in a natural runoff study by Evett and Dutt (1985).

For the most part, equation [11] applied well to all of the short slope data indicating that slope length is not a major factor on short slopes. When slope exceeded 8%, erosion increased rapidly from rill erosion on Neal's (1938a,b) 3.7 m long plots. This added contribution from rill erosion steepened the slope factor relationships as slope increased above 8%. When slope exceeded about 10%, erosion of the sandy soil on a 1.2 m long slope in Singer and Blackard's (1982) study rapidly increased. This increase in soil loss may have been caused by greater transport capacity that carried large sand particles that could not be transported on lower slopes. Also, Monke et al. (1977) observed increased soil loss when they added flow to a 0.61 m slope length, which also suggests that increased transport capacity resulted in greater soil loss. The significant increase of erosion on the steep slopes of Gabriels et al. (1975) may have been caused by rill erosion. Up to a 16% slope, these results do not differ greatly from equaton [11]. Therefore, equation [11] principally describes conditions where detachment by raindrop impact limits soil loss rather than transport capacity of the thin interrill flow and raindrop impact.

The reason for the low S factor values from Neal's (1938a,b) lower slopes is not apparent. One possible explanation is that his rainfall simulator did not enhance sediment transport capacity as much as did rainfall in the other studies (Moss et al., 1979). Therefore, soil loss in Neal's study could have been controlled by transport capacity at the low slopes, while detachment by raindrop impact controlled soil loss in other studies like Lattanzi et al. (1974), Singer and Blackard (1982), Evett and Dutt (1985), and Rubio-Montoya and Brown (1984). The effect of transport capacity controlling soil loss would have been more important on Neal's 3.7 m long slopes versus the approximate 1 m slopes in other studies. Soil loss also varied more in Zingg's (1940) study than it did in the studies of Lattanzi et al. (1974), Singer and Blackard (1982), Evett and Dutt (1985), and Rubio-Montoya and Brown (1984). The difference may have been caused by a rougher surface and rill erosion on Zingg's plots. On short rough field slopes and soils with higher susceptibility to rill erosion, equation [11] could be adjusted to be consistent with Zingg's data.

A value of 4 m is suggested as a general value for the shortest slope length for use in the USLE (Foster et al., 1981). This slope length value is based on the length where soil loss values from a fundamentally based erosion equation having separate components for rill and

interrill erosion begins to depart from USLE values as slope length is decreased (Foster et al., 1981). Neal (1938a,b) in his study of erosion on 3.7 m long beds in the laboratory under simulated rainfall observed rill erosion when steepness was greater than 8%. Likely his soil was easily eroded by flow, or rainfall detachment was low.

Data were insufficient to eliminate discontinuities between equation [11] and equations [9] and [10]. Much of the difficulty is related to the equation structure of the USLE, which lumps rill and interrill erosion. A model structure having separate rill and interrill components would eliminate the discontinuities.

SUMMARY

Field data from about 20 studies on the effect of slope on sheet and rill erosion were analyzed to revise the relationship for the slope steepness factor in the Universal Soil Loss Equation (USLE). Slopes studied ranged from 0.1 to 32% steepness. Data sets used to develop the revised relationships included a slope range of 0.1 to 18%. The two relationships derived from the analysis apply respectively to ranges of slope steepness less than 9% and equal to or greater than 9%. Application to slopes greater than 18% represents an extrapolation beyond the observed data.

These relationships more reasonably predict soil loss values from research studies on both low and steep slopes as compared to those values computed with the present USLE slope steepness relationship. Therefore, the following equations are recommended for use in the USLE:

$$S = 10.8 \sin \theta + 0.03 \qquad s < 9\% \quad \ldots\ldots\ldots\ldots [10]$$

$$S = 16.8 \sin \theta - 0.50 \qquad s \geq 9\% \quad \ldots\ldots\ldots\ldots [9]$$

where: S = USLE slope steepness factor and θ = angle of slope having a steepness of s expressed in percent. These equations apply best to relatively smooth surfaces where tillage is up and down hill, and runoff does not vary with slope for steepnesses above 8%. The effect of contour tillage on the soil loss-slope steepness relationship is considered in the USLE supporting practices factor P.

For conditions when erosion is principally by surface flow over thawing soil the following equations are recommended:

$$S = 10.8 \sin \theta + 0.03 \qquad s < 9\% \quad \ldots\ldots\ldots\ldots [10]$$

$$S = (\sin \theta / 0.0896)^{0.6} \qquad s \geq 9\% \quad \ldots\ldots\ldots\ldots [8]$$

where: 0.0896 = the sine of the angle of a 9% slope.

None of the above equations apply to short slopes where all of the erosion is caused by raindrop impact and runoff freely discharges from the end of the slope. For these short slopes, the recommended slope factor equation is:

$$S = 3.0(\sin \theta)^{0.8} + 0.56 \quad \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

This equation does not apply to slopes longer than 4 m.

The above equations represent a summary of the data. Among data sets, the soil loss-slope steepness relationships varied greatly with soil, slope length, steepness, tillage, cover, runoff, and other factors. Also, discontinuities exist between the slope effect equation for short slope lengths and that for long slopes. However, the USLE equation form, which lumps rill and interrill erosion components, greatly complicates considering the variety of factors that affect the S factor relationships. A more fundamentally based model structure of separate components for rainfall and runoff detachment on interrill and rill areas, and the transport and deposition of sediment by flow would greatly facilitate consideration of these other factors. However, at present the USLE represents the best available practical technology for estimating sheet and rill erosion.

Slope Steepness Effects on Soil Loss from Disturbed Lands

G. F. McIsaac, J. K. Mitchell, M. C. Hirschi
ASSOC. MEMBER ASAE | MEMBER ASAE | ASSOC. MEMBER ASAE

ABSTRACT

THERE was close agreement between observed slope steepness effect on soil loss from disturbed lands and that predicted by the USLE slope steepness factors in two categories: (a) for slopes less than 4 m in length, and (b) for slopes greater than 4 m in length but less than 9% steepness. For slopes greater than 4 m in length and between 9 and 33% steepness, the USLE tended to over estimate the observed slope steepness effect. A slope steepness factor equation for this slope range was developed which provides a range of slope steepness factors for a given slope corresponding to the range of slope steepness effects that have been observed experimentally.

INTRODUCTION

There is considerable potential for soil erosion by rainfall and runoff on reclaimed mine lands, construction sites and other "disturbed lands." In these settings, plants, roots and topsoil are commonly removed leaving the exposed soil or subsoil in a highly erodible condition. Quantifying erosion from these areas is necessary to manage on-site and off-site impacts of soil erosion.

The most extensively researched and commonly used method of estimating erosion from rainfall and runoff is the Universal Soil Loss Equation (USLE) (Wischmeier and Smith, 1978). The USLE uses empirically derived relationships and, therefore, is expected to give the most reliable estimates of erosion for conditions which closely resemble those from which the model relationships were developed: medium textured agricultural soils with slopes from 3 to 18% and less than 122 m in length.

Gilley et al. (1977), Stein et al. (1983) and Hahn et al. (1985) observed that the USLE tended to over estimate the effect of slope steepness on soil loss from various reclaimed mine lands. Disturbed lands, such as reclaimed mine soils, may have significantly different characteristics than cropland, such as the lack of soil structure (Thomas and Jansen, 1985), an abundance of gravel and stones (Ashby et al., 1984 and Bonta and Sutton, 1983), surface sealing (Gilley et al., 1977) and a lack of roots or organic matter. These factors may lead to significantly different erosion rates than predicted by the USLE. The presence of stone fragments in soil has been shown to reduce the rate of erosion (McCormack et al., 1984) and runoff (Edwards et al., 1984) from cropland and rangeland.

The objective of this study was to determine whether the USLE slope steepness factors are in agreement with observed slope steepness effects on soil loss from distrubed lands and, if necessary, to develop a slope steepness factor equation that is more appropriate for disturbed land yet which is compatible with the present USLE equation structure.

THE USLE SLOPE STEEPNESS FACTORS

The slope steepness factor of the USLE is defined as the ratio of soil loss from a field slope to that from a uniform, nine percent slope under otherwise identical conditions (Wischmeier and Smith, 1978). Wischmeier and Smith (1978) recommended the following relation between slope steepness and slope steepness factor, which was derived from a Fayette soil under crop production in Wisconsin:

$$S = 65.4\sin^2\theta + 4.56\sin\theta + 0.0654 \quad \ldots\ldots\ldots\ldots [1]$$

where S is the slope steepness factor and θ is the angle of inclination of the land from the horizontal. At this writing, McCool et al. (1987) are proposing a revision of the USLE slope steepness factor. Based on a reanalysis of the Fayette soil data, McCool et al. (1987) recommend the following equation for slopes greater than 9%:

$$S = 16.8\sin\theta - 0.5 \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

For slopes less than 9%, McCool et al. (1987) recommend:

$$S = 10.8\sin\theta + 0.03 \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

which is based upon erosion from the Fayette soil under natural rainfall, and a Dubbs silt loam soil under simulated rainfall.

Equations [1] through [3] were developed from plots 22 m in length. McCool et al. (1987) contend that equations [1] through [3] do not apply to slopes less than 4 m in length. They argue that rill erosion is negligible in areas less than 4 m in length and to estimate the slope steepness effect on soil loss from slopes in this range, McCool et al. (1987) recommend the following slope factor equation:

$$S = 3.0\sin^{0.8}\theta + 0.56 \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

Article was submitted for publication in June, 1986; reviewed and approved for publication by the Soil and Water Div. of ASAE in April, 1987. Presented as ASAE Paper No. 86-2037.

This study was part of Project No. 10-309 of the Agricultural Experiment Station, College of Agriculture, University of Illinois at Urbana-Champaign.

Reclaimed mine land data were collected as part of Project 10-344 of the Illinois Agricultural Experiment Station.

In this study, we compared slope steepness effects predicted by equations [1] through [4] to observed slope steepness effects on soil loss from distrubed lands.

PROCEDURE

We conducted a review of published and unpublised studies in which soil loss was measured from disturbed soils over a range of slopes. Using these reported erosion measurements, ratios of soil loss at a various slope steepness to the soil loss measured or estimated for 9% sloe under otherwise identical conditions were calculated. This ratio is consistent with the definition of the USLE slope factor (Wischmeier and Smith, 1978). For convenience and clarity, this ratio is referred to as the soil loss ratio in this study.

In studies where soil loss was measured at 9% slope (Israelsen et al., 1980; Bonta and Sutton, 1983; Lang et al., 1984; Andrews, 1981 and Watts, 1982), the measured soil losses at various slopes were divided by the mean soil loss measured at 9% slope.

If soil loss was not measured at 9% slope, we estimated a mean soil loss at 9% slope for the given experimental conditions using regression analysis. Various linear and non-linear regression models were tested with soil loss (or soil loss per unit of EI if the data were available) as the dependent variable and a measure of slope steepness as the independent variable. The measures of slope steepness tested were percent slope and sine of the angle of inclination (sin θ). From the regress model with the greatest coefficient of determination, we estimated soil loss at 9% slope, and then divided observed losses by this value to obtain the soil loss ratio for various slopes.

In order to reduce the variability in soil loss due to rainfall, soil loss was divided by the rainfall erosivity factor (EI) as described by Wischmeier and Smith (1978) or as reported by the individual investigators. In these cases, the calculated soil loss ratio was actually a ratio of soil loss per EI at the given slope to the soil loss per EI at 9% slope.

We conducted regression analyses to identify relationships between soil loss ratio and slope steepness under various conditions. Separate regression analyses were conducted for each soil type and rain source (natural or simulated). In these regressions, soil loss ratio was the dependent variable and percent slope and sin θ were tested as independent variables. For slopes less than 4 m in length, we also conducted regressions with sin θ to the 0.8 power as the independent variable.

Finally, regression analyses were conducted with various combinations of experimental conditions in order to identify equations which best describe the slope steepness effect on soil loss from the entire sample of disturbed soils analyzed in this study.

TABLE 1. SOIL LOSS PER EI FOR A SANDY CLAY LOAM SPOIL MATERIAL UNDER SIMULATED AND NATURAL RAINFALL (GILLEY ET AL., 1977 AND 1981).

Rain type	Tillage	Slope, %	Soil Loss x 10^3 per EI, Mg h/MJ mm	Annual soil loss, Mg/ha
simulated	roto-tilled	4.6	5.3	–
simulated	roto-tilled	17.0	8.7	–

		17.6	337.0	82.87

DATA SOURCES

Gilley et al. (1977 and 1981) reported soil loss from sodic, surface sealing mine spoil under simulated and natural rainfall. Plots 4 m wide and 22.1 m long were established on a sandy clay loam spoil. Rainfall simulations following the method of Meyer (1960) were conducted on one roto-tilled and one untilled plot at 4.6 and 17% slope. Plots for the natural rainfall study were maintained at 0.7, 4.8 and 17.6% slope. In the first year (1975) the natural rainfall plots were roto-tilled four times. In the second year (1976) the plots were not tilled. annual soil loss and EI values (considering only those storms which produced more than 0.25 mm of runoff) appear in Table 1.

Israelsen et al. (1980) measured soil loss from slopes of 9, 25, 50 and 84% in a tilting soil bin 5.9 m long and 1.2 m wide. We considered these soils disturbed since they were reconstructed in the soil bin for the experiment. Three soil materials were tested: a washed sand, a Nibley silty clay loam, and a Cecil gravelly clay loam. The soils were tilled up and down the slope to approximate a crop

management factor (C) of 1.0. For an additional treatment, the Nibley soil was compacted and not tilled. Simulated rainfall was applied at intensities of 64, 100 and 144 mm/h. Soil loss from the sand was not affected by slope steepness. Soil loss reported by Israelsen et al. (1980) for the three other soil treatments appear in Table 2.

The rainfall erosivity in the study of Israelsen et al. (1980) appears to have been affected by the slope steepness since the fall distance of the rain drops varied from 5.3 to 1.1 m depending upon slope steepness and location in the soil bin. Israelsen et al. (1980) addressed this variation and reported an RLS factor (rainfall erosivity times the slope steepness and slope length factors) for each slope steepness and rainfall intensity.

*d = dry run, rain applied for 1h on relatively dry soil.
w = wet run, rain applied for ½h, 1h after the conclusion of the dry run.
v = very wet run, rain applied for ½h, approximately ½h after the wet run.

We calculated EI values for eahc storm and slope steepness by dividing the reported RLS by the LS factor (Wischmeier and Smith, 1978) for the experimental conditions. These values also appear in Table 2.

Bonta and Sutton (1983) measured runoff and soil loss from natural rainfall on surface mined land for two years with slopes ranging from 9 to 33%. Plots were 22 m long, 4.6 m wide and prepared with a bulldozer and a road grader. Treatments consisted of 0 and 20 cm of reclaimed topsoil on mine spoil which were maintained in a fallow condition. The mean soil loss from several sampling intervals in Bonta's study appear in Table 3.

Hahn et al. (1985) measured soil loss from simulated rainall (following the method of Meyer and McCune, 1958) on two mine reclamation sites (Ayreshire and Solar Sources) with slopes ranging from 5 to 16% and a constant slope length of 11 m. Both sites were reclaimed with topsoil that had been stockpiled during the mining operation. The reclamation area was smoothed with a bulldozer and the experimental plots were disked up-and-down hill before rainfall simulation.

Hahn et al. (1985) did not report measured soil loss but reported soil loss normalized by the method described by Meyer (1960) in which soil loss is divided by the square of the ratio of the mesured rainfall intensity to the target rainfall intensity. However, due to uncertainty

about their rain gauge measurements, Hahn calculated the rainfall intensity from the runoff in the final 20 min of the simulated rainfall. Neither the measured nor the calculated rainfall intensities were reported by Hahn et al. (1985).

Moldenhauer and Hahn (personal communication, 1985) provided the rain gauge and soil loss measurements and the calcuated rainfall intensities used in the study of Hahn et al., 1985. In our judgment, the calculated rainfall intensities used by Hahn et al. (1985) were too variable for simulated rainfall. We calculated soil loss per EI ratios using the actual rain gauge measurements. Soil loss and rainfall erosivity data for a reclaimed A horizon silt loam soil at the Solar Sources location appear in Table 4. Data provided by Moldenhauer and Hahn from a reclaimed B horizon silt loam soil at the Solar Sources site appear in Table 5 and were also used in our regression analyses.

Soil loss and rainfall erosivity data from reclaimed A horizon silt loam soils at the Ayreshire location appear in Table 6. Some of these data were taken from Mitchell et al. (1983). Data from reclaimed B horizon silt loam soil at the Ayreshire site appear in Table 7. These data were provided by Mitchell and Moldenhauer (1981).

Andrews (1981) measured soil loss from 1-m square plots of two reclaimed mine soils (Mecco and Sunspot) under simulated rain at 63 mm/h at 4.5 and 9% slope. Andrews conducted these tests over a 2-h period and these data appear in Table 8. Soil was packed in the bin to approximate average bulk density observed at the

reclamation sites.

Watts (1982) measured soil loss from 1-m square plots of reclaimed mine soil under simulated rainfall at 64 mm/h. One mine soil (Captain) was tested at 4.5 and 9% slope, and the other (Ayreshire) was tested at 6 and 12% slope. Measured soil losses after 2 h of rainfall for three replicates of each slope appear in Table 9.

Lang et al. (1984) measured soil loss from 1-m square plots of surface mined topsoil at 9 and 3% slope under simulated rainfall. Two surface mined topsoils (Falkirk and Indian Head mines) which had been stockpiled were air dried, rolled, passed through a 1.27 cm sieve, and packed to a bulk density of 1.18 g/cc, except for the top 2 cm of soil which was not packed. The two soils were tested at 2 levels of antecedent moisture content, two slopes and three levels of surface cover. These data appear in Table 10.

RESULTS

Regression analyses indicated that in nearly all cases the effect of slope steepness on soil loss, soil loss per EI

and soil loss ratio was best described as a linear function of either percent slope or sine of the angle of inclination (sin θ). Regressions with percent slope as the independent variable tended to have a slightly greater coefficient of determination than the corresponding regression using sin θ as the independent variable, but the differences were not significant.

The linear regression results with soil loss ratio as the dependent variable and sin θ as the independent variable for individual soil types and experimental conditions appear in Table 11. The regression coefficients ranged

‡ Dry run, wet run, and very wet runs are simulated rain storms which have been previously described.
§ Soil loss ratios calculated from cumulative soil loss from three simulated rain storms (dry, wet and very wet runs).
‖ Central data set includes all soil loss ratios calculated for slopes greater than 4 meters in length and less than 33% steepness excluding the data of Gilley et al. (1977), the fine sandy loam reclaimed topsoil of Bonta and Sutton (1983) and the tilled Nibley soil of Israelsen et al. (1980).

from 147 to 1.4. The mean value of the regression coefficients was 23.8 with a standard deviatio of 36.8.

The three largest regression coefficients (147, 40.9 and 24.4) were all from data of Israelsen et al. (1980) and describe the slope steepness effect for slopes from 9 to 84%. The maximum slope in the other studies was 33%. Regresssion analysis considering only the 9 and 25% sloeps of the Israelsen et al. (1980) gives coefficients of 7.6, 16.9 and 1.4 for the compacted Nibley, tilled Cecil, and the tilled Nibley soils, respectively, which are similar to regression coefficients observed for the other studies. The greater regression coefficients for steeper sloeps may reflect the initiation of mechanisms of soil movement which do not occur at lesser slopes. Sidle et al. (1985) report that slopes greater than 47% are subject to avalanches and earth slumps.

For slopes of 33% or less, the smallest regression coefficients were observed from the tilled Nibley soil (Israelsen et al., 1980), the reclaimed fine sandy loam soil (Bonta and Sutton, 1983) and the sandy clay loam spoil under simulated rainfall (Gilley et al., 1981).

The regression coefficients for the sandy clay loam of Gilley et al. under simulated rainfall (1977) were significantly less than the regression coefficients for the same soil under natural rainfall (Gilley et al. 1981). The cause of this difference is unknown. For the simulated rainfall experimetns, a total of 128 mm of rain was applied in 2 days. In the natural rainfall study, erosion measurements were based on 233 mm of rainfall over the 2-yr period. It would appear that a greater portion of the natural rain fell on initially dry soil, a condition which appears to lead to a greater effect of slope steepness on soil loss, as observed by Hahn et al. (1985).

Results of regressions with selected combinations of soil loss ratios for slopes longer than 4 m appear in Table 12.

Considering soil loss ratios from individual simulated rain storms at the Ayreshire and Solar Sources locations, the regression coefficient decreases from 15.8 for the initial rain storm (dry run) to 6.7 for the third rain storm (very wet run). For most plots, the dry run was the first rainfall after disking, the soil was relatively dry and rain was applied for approximately 1 h. The wet and very wet runs were ½ h storms which followed the dry runs. The trend for the regression coefficient to decrease from the dry to the very wet run indicates that the slope steepness effect for an individual storm is influenced by antecedent moisture content, duration of rainfall and/or cumulative rainfall effects on the soil surface. Therefore, an annual slope steepness factor may be influenced by annual distribution of rainfall and tillage.

For slopes of 33% or less, we observed that most of the regression coefficients were between 6.9 and 18.8 (Table 11). We refer to the soil loss ratios from the studies with regression coefficients within this range as the central data set, which includes all of the calculated soil loss ratios except for those of the tilled Nibley soil (Israelsen et al., 1980), the reclaimed fine sandy loam soil (Bonta and Sutton, 1983). Regression coefficients for these conditions were considerably less than 6.9. When these data are omitted from the regression analyses, the following linear regression equation is the best fit of the data with a coefficient of determination of 0.80:

$$SLR = 12.1 \sin \theta - 0.10 \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

When only slopes greater than 8% in the central data set are considered in the regression analysis, the regression coefficient decreases to 10.7 and the regression coefficient of determination decreases to 0.66. This result suggests a lesser regression coefficient as slope steepness increases which is in contradiction to the slope steepness effect observed for the Fayette soil (equations [1], [2] and [3]).

The soil loss ratios calculated for all soil textures with slope lengths greater than 4 m and slopes of 33% or less were best described as a quadradic function of sin θ:

$$SLR = -24.8 \sin^2 \theta + 15.7 \sin \theta - 0.19 \qquad r^2 = 0.61$$

$$\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [6]$$

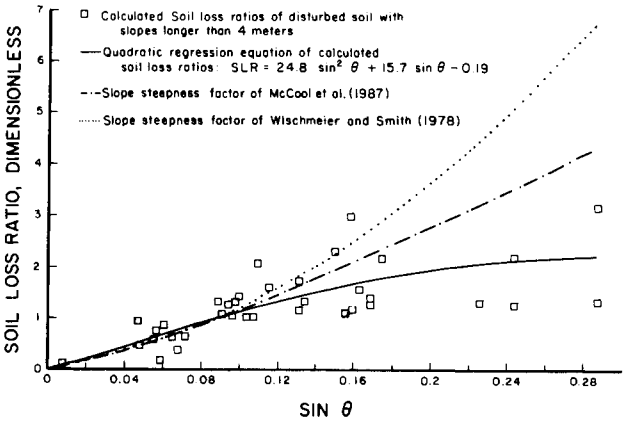

Fig. 1—Calculated soil loss ratios for disturbed lands with slopes greater than 4 m in length, quadratic regression equation [6] from this study, and USLE slope steepness factors of Wischmeier and Smith (1978) and McCool et al. (1987).

where SLR is the soil loss ratio as previously defined. Equations [1], [2], [3], [6] and the calculated soil loss ratios appear in Fig. 1. For slopes less than 9% there is close agreement between all slope factor equations. For slopes greater than 9%, there is considerable divergence.

McCool et al. (1987) reported some conditions in which the slope steepness effect could be expressed as a single linear equation for slopes up to 20%. Lillard et al. (1941) observed a linear effect of slope steepness on soil loss from contoured cropland at slopes up to 25%. Normalization to 9% slope of the soil loss vs. slope steepness relation of Lillard et al (1941) results in a coefficient of sin θ of 11.0.

McCool et al. (1987) argue that the effect of slope steepness increases for steeper slopes due to initiation of soil detachment by runoff. According to Meyer (1985), soil loss at low slopes is mostly interrill erosion limited by the transport capacity of the runoff. As slope steepness increases, soil erosion becomes limited by the rainfall detachment rate. As slopes exceed 5 to 10%, the runoff develops enough energy to detach particles and cause substantial rill erosion.

We offer two hypotheses which, if correct, may explain why lesser soil loss ratios were observed for disturbed lands than predicted by equations [1] and [2]. First, at steep slopes, soil detachment by runoff may have been limited by stone fragments, or a compacted layer caused by the action of bulldozers and road graders used in the mine reclamation process. Thus, reclaimed mine land may be less susceptable to rill erosion than cropland. Secondly, erosion at steep slopes might have been further limited by the quantity of rainfall and runoff, which, due to the relatively short periods of observation, may not have included very high intensity rainfall and therefore, may not reflect the long term slope steepness effects of these soils.

Soil loss ratios for slopes less than 4 m were equally well described by linear functions of percent slope, sin θ, or sin θ to the 0.8 power. The results of the later regression are presented in Table 13. The regression coefficients ranged from 1.8 to 5.7. The mean regression coefficient is 3.9, and soil loss ratios from all of these studies were best described by the following equation:

$$SLR = 4.0 \sin^{0.8} \theta + 0.4 \quad \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

RECOMMENDATIONS

To estimate the effect of slope steepness on soil erosion from disturbed lands for slopes less than 4 m in length, we recommend equation [4]. For slopes greater than 4 m in length and less than 9% steepness we recommend equation [3]. Between 9 and 30% steepness for slopes greater than 4 m in length, we recommend the following equation:

$$S = (12 \pm 7)\sin\theta + B \quad \ldots\ldots\ldots\ldots\ldots\ldots [8]$$

where S is the slope steepness factor, θ is the angle of inclination of the land from the horizontal, and B is an intercept chosen such that S = 1.0 at 9% slope.

A regression coefficient of 12 represents a median value of the conditions tested in this study. However, for various experimental conditions, regression coefficients ranged from 1.4 to 18.8. Thus, the range of regression coefficients provided in equation [8] expresses much of the variation in slope steepness effects which has been observed experimentally.

Equation [8] is based upon soil loss from research plots at slopes up to 33%. For slopes greater than 33%, soil may be transported by mechanisms other than sheet and rill erosion (Sidle et al., 1985). Consequently, even the maximum slope factor extrapolated from equation [8] may underestimate soil loss.

Additional research is needed to evaluate the effect of slope steepness on soil loss from disturbed lands. Our results indicate that slope steepness effects are influenced by antecedent moisture content and/or cumulative effects of rainfall on the soil surface. The variation in slope steepness effects may also be influenced by soil texture and the presence of stone fragments. The avilable data are insufficient to quantify exact slope steepness effects for given conditions of soil texture, compaction or rainfall distribution pattern. Reserach is needed which addresses the interactions of slope steepness, tillage, rainfall intensity, antecedent moisture content and soil texture on soil erosion by rainfall on distrubed land.

SUMMARY AND CONCLUSIONS

The effect of slope steepness on soil loss from disturbed lands was evaluated. From soil erosion measurements, we calculated ratios of soil loss from disturbed land at various slopes to soil loss measured or estimated for 9% slope under otherwise identical conditions.

Results indicate close agreement between observed soil loss ratio and that predicted by the USLE slope steepness factors for two slope categories: (a) slopes less than 4 m in length, and (b) slopes greater than 4 m in length and less than 9% steepness. For slopes between 9 and 33% and slope lengths greater than 4 m, the USLE tended to overestimate the observed soil loss ratios. The relationship between slope steepness and soil loss ratio varied considerably across experimental conditions, however most of the soil loss ratios fell within a central range.

For slopes greater than 4 m in length and between 9 and 30% steepness we developed a slope steepness factor equation for estimating soil erosion from disturbed land. This equation provides a range of possible slope steepness factors, corresponding to those observed under experimental conditions.

Further research is recommended on the influence of soil texture, antecedent moisture content, and cumulative rainfall effects on slope steepness effects.

Slope Length Effects on Soil Loss for Steep Slopes

B. Y. Liu, M. A. Nearing,* P. J. Shi, and Z. W. Jia

ABSTRACT

Empirical soil erosion models continue to play an important role in soil conservation planning and environmental evaluations around the world. The effect of hillslope length on soil loss, often termed the *slope length factor*, is one of the main and most variable components of any empirical model. In the most widely used model, the Universal Soil Loss Equation (USLE), normalized soil loss, *L*, is expressed as a power function of slope length, λ, as $L = (\lambda/22.1)^m$, in which the slope exponent, *m*, is 0.2, 0.3, 0.4, and 0.5 for different, increasing slope gradients. In the Revised Universal Soil Loss Equation (RUSLE), the exponent, *m*, is defined as a continuous function of slope gradient and the expected ratio of rill to interrill erosion. When the slope gradient is 60% and the ratio of rill to interrill erosion is classified as moderate, the exponent *m* has the value of 0.71 in RUSLE, as compared with 0.5 for the USLE. The purpose of this study was to evaluate the relationship between soil loss and slope length for slopes up to 60% in steepness. Soil loss data from natural runoff plots at three locations on the Loess Plateau in China and data from a previous study were used. The results indicated that the exponent, *m*, for the relationship between soil loss and the slope length for the combined data from the three stations in the Loess Plateau was 0.44 ($r^2 = 0.95$). For the data as a whole, the exponent did not increase as slope steepness increased from 20 to 60%. We also found that the value of *m* was greater for intense storms than for less intense storms. These experimental data indicate that the USLE exponent, $m = 0.5$, is more appropriate for steep slopes than is the RUSLE exponent, and that the slope length exponent varies as a function of rainfall intensity.

BECAUSE PHYSICALLY BASED MODELS are either not well tested or require many input parameters, empirical soil loss models still play an important role in soil conservation planning. This is especially true for those areas where extensive soil and biological data that are required by process-based models are not readily available. The USLE (Wischmeier and Smith, 1978) is the most widely used empirical erosion model worldwide. The USLE was revised recently as the RUSLE (Renard et al., 1997). The slope length factor is one of the main factors for soil loss predictions in both the USLE and RUSLE. It is also one of the most variable factors, as we discuss below.

The slope length factor has often been expressed as (Zingg, 1940):

$$L' = a\lambda^m \quad [1]$$

where L' is soil loss (mass per unit area per unit time), λ (m) is slope length, and *a* and *m* are empirical coefficients. Normalizing to a unit plot of length 22.13 m, both the USLE and RUSLE use the equation

$$L = (\lambda/22.13)^m \quad [2]$$

where *L* is soil loss normalized to the 22.13-m-long slope. The differences of slope length factors from the literature can be compared directly by comparing the *m* values. Zingg (1940) proposed 0.6 as the slope length exponent. Musgrave (1947) suggested 0.3. A study conducted at Purdue University in 1956 recommended 0.5 ± 0.1 (Wischmeier et al., 1958). In the USLE (Wischmeier and Smith, 1978), the *m* values recommended were 0.2, 0.3, 0.4, and 0.5 for slope gradients <1, 1 to 3, 3.5 to 4.5, and 5% or greater, respectively. Thus, when the slope gradient is >5%, the slope length factor for the USLE does not change with slope steepness. However, in RUSLE, *m* increases continuously with the slope steepness according to (Renard et al., 1997)

$$m = \beta/(1 + \beta) \quad [3]$$

and

$$\beta = (\sin\theta/0.0896)/3.0\ \sin\theta^{0.8} + 0.56) \quad [4]$$

where β is the ratio of rill erosion to interrill erosion, and θ is the angle of the slope. When slope steepness is equal to 9%, the slope length exponent for both USLE and RUSLE is 0.5. When the slope is <9%, the USLE has a greater slope length factor than RUSLE. When the slope is steeper than 9%, USLE has a lesser slope length factor than RUSLE. The greatest differences are for the steepest slopes (Fig. 1). According to Eq. [3] and [4], the slope length exponent, *m*, is 0.71 for a 60% a 60-m-long slope with a moderate rill/interrill erosion ratio. Under these conditions, RUSLE will have a slope length factor, *L*, which is 23% greater than that for the USLE.

Many classifications of slope steepness for soil and land surveys take 30% as a starting point for "steep" slopes (McDonald et al., 1984; Liu and Tang, 1987). The data used to develop the USLE and RUSLE involved slopes only up to 18% (McCool et al., 1989). However, McCool et al. (1993) studied the effect of both slope length and slope steepness on cropped slopes up to 56% gradient in the northwestern wheat (*Triticum aestivum* L.) region of the United States by performing field surveys of rill networks. Several hundred data points were used in their study. Mean slope steepness was 28.4%, with 95% of the data points collected on slopes ranging from 9 to 48%. The authors concluded by recommending a slope length exponent, *m*, of 0.5.

The purpose of our study was to analyze experimental data for slopes up to nearly 60% in steepness to evaluate the relationship between soil loss and slope length for

steep slopes. The results were compared with USLE and RUSLE slope length factors. The data we chose are from three field stations with slope gradients steeper than 30%, which we consider here to be classified as steep.

MATERIALS AND METHODS

Natural rainfall soil loss data from three locations on the Loess Plateau of China were used: the Ansai (36°56′N, 109°16′E), Zizhou (37°31′N, 109°47′E), and Suide (37°29′N, 110°08′E) experimental stations. Soil texture in the Loess Plateau region changes from south to north (Liu, 1966). The plateau is divided into three zones: clayey loess in the southern part, typical loess in the middle, and sandy loess in the north. Stations used in this study were located in the typical loess and sandy loess zones. Two of the soils were fine-silty, mixed mesic Typic Udorthents, and the soil at Zizhou was a fine-loamy, mixed mesic Typic Udorthents (Table 1). The region is semiarid with annual rainfall ranging from 485 to 541mm. More than 60% of the precipitation occurs from June through September. Most of the soil losses were caused by these heavy storms. Soil loss caused by storms with >45mm h^{-1} maximum 30-min intensity (I_{30}) was 80.4% of the total soil loss for the 20-m-long plot in the Ansai station. All of the soils at these three stations were susceptible to rill erosion. After each storm, extensive rilling would be seen in the fields. Rills in this area tend to be rectangular in cross section and generally develop within, but not to the bottom of, the tillage layer. Plots at Zizhou were 15 m wide, and for the other two sites the plot widths were 5 m. The slope lengths, measured horizontally, ranged from 10 to 60 m. The slope steepness was 57.7% for Ansai station and ≈40% for other two stations (Table 2). The plots were selected from a larger database using the criteria of 30% slope or steeper with all other conditions identical. Soil loss was measured by sampling the sediment concentration of the runoff, which was collected in either metal tanks and divisors or concrete pools.

Table 2. Average annual runoff and soil loss from the three experiment sites.

Plot number	Slope length	Slope gradient	Annual runoff	Annual soil loss	Annual soil loss normalized to 22.1 m
	m	%	mm	Mg ha^{-1}	Mg ha^{-1}
			Ansai

29	40	42.8	17.9	28.00	1.26
34	60	40.4	14.0	36.59	1.64
			Zizhou		
4	20	40.4	23.9	91.84	0.90
2	40	40.4	27.5	153.14	1.51
3	60	40.4	24.1	143.11	1.41

The data collected from the Ansai site (Jiang et al., 1991) were from 5 yr of fallow conditions from 1985 to 1989. The slope lengths were 10, 20, 30, and 40 m. Data from the Suide site were for 4 yr from 1957 to 1960 and for the Zizhou site were 5 yr from 1963 to 1967. The latter two sites were conventionally tilled farmland. Generally, the crop cover was very sparse due to insufficient soil moisture and the steep slope. The plots were cropped in a 3-yr rotation of millet [*Setaria italica* (L.) Beuv.], soybean [*Glycine max* (L.) Merr.], and potato (*Solanum tuberosum* L.). The slope lengths at Suide were 10, 40, and 60 m, and at Zizhou they were 20, 40, and 60 m.

Since the data used in this study were collected at three field stations, the soil loss was different from site to site. In order to compile and compare the data together, the soil loss was normalized to 22.13 m for all the sites. Because no soil loss was measured at a slope exactly 22.13 m long, regression equations were fitted for each of the data sets according to Eq. [1]. Regression analysis was conducted on each data set individually to calculate the soil loss on the 22.13-m-long slope, then that value was used to normalize the measured values for each site.

RESULTS AND DISCUSSION

We used the average annual soil loss data to analyze the slope length relationships. Average annual soil loss and normalized values are presented in Table 2. The steepest slope of 57.7% was at the Ansai station, for which, according to the RUSLE equations, the slope

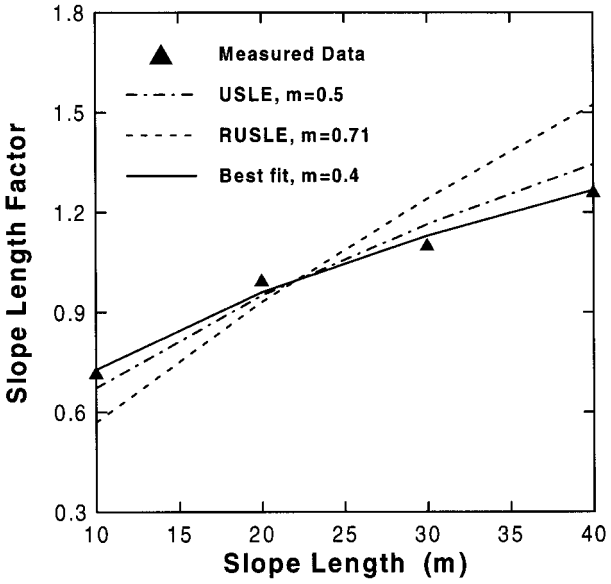

Fig. 2. Slope length factors for measured data on a 57.7% slope at the Ansai station compared with the Universal Soil Loss Equation (USLE; m = 0.5) and Revised Universal Soil Loss Equation (RUSLE) slope length factor (m = 0.71) curves.

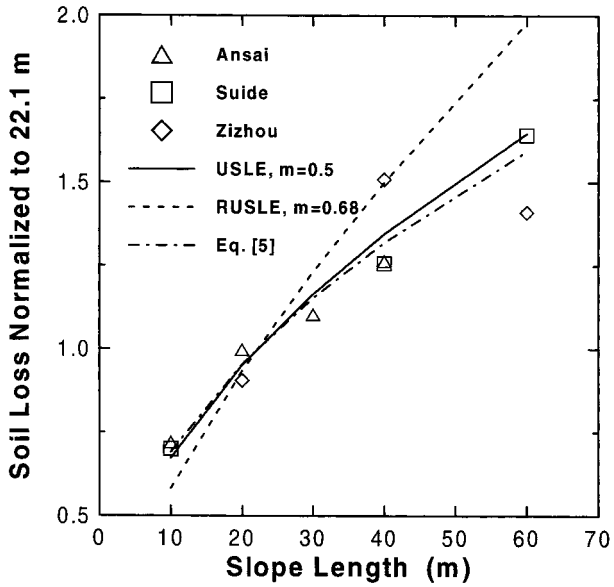

Fig. 3. Soil loss normalized to 22.13-m length from the natural rainfall plot data used in this study and the best-fit curve (m = 0.44) for all measured data combined.

length exponent, m, would be 0.71. As seen in Fig. 2, we found that the RUSLE L factor was greater than that from the measured data. The RUSLE overpredicted soil loss by 20% compared with the best-fit equation (m = 0.4) for the 40-m slope (Table 3) and underpredicted data for the 10-m slope by 21.8%. In contrast, the USLE overpredicted the measured soil loss by only 6% for the 40-m plot and underpredicted by 7.6% for the 10-m plot compared with the best-fit equation for the data. The other two data sets were collected on ≈40% slopes. The best-fit slope length exponents for the measured data at Suide and Zizhou were 0.46 and 0.44, respectively (Table 3). In summary, the data from these three stations did not indicate that the slope length exponent increased with a slope steepness increase from ≈40 to 60%.

Compiling all of the normalized soil loss data from the three stations together, Eq. [5] was derived for the combined data set (r^2 = 0.95):

$$L = (\lambda/22.13)^{0.44} \quad [5]$$

From Fig. 3 we can see that the USLE relationship and Eq. [5] for slope length fit the measured data reasonably well (r^2 = 0.91). Interestingly, the average length exponent for the steep Loess Plateau slopes was 0.44, while the average of the 10 exponents from studies in the USA was 0.46 (McCool et al., 1989). The results from our data also compare very well with the results of McCool et al. (1993) for slopes with an average steepness of 28.4% and a maximum steepness of 56%.

In China, and in other parts of the world, slopes up to 60% are not unusual for cropped farmland. Thus, it is important to know and use the best relationship between slope length and soil loss for steep slopes. The RUSLE uses Eq. [3] and [4] to calculate the ratio of rill/interrill erosion (β) and the length exponent (m). Equation [3] was based on the Foster and Meyer's analyses (Foster and Meyer, 1975; Foster et al., 1977). The basic assumption was that if soil loss is primarily from rills, the exponent will approach one, but it will approach zero where erosion is dominantly from interrill processes (Meyer et al., 1975). For slopes where both rill and interrill erosion occurred, the exponent, m, can be

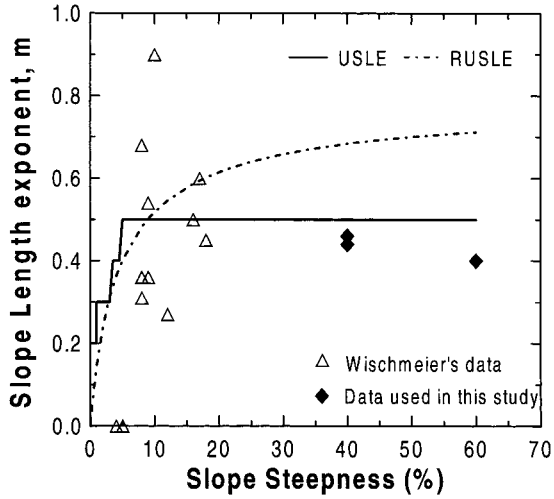

Fig. 4. Slope length exponents from the data of Wischmeier et al. (1958) and from the Loess Plateau of China compared with relationships from the Universal Soil Loss Equation (USLE) and Revised Universal Soil Loss Equation (RUSLE) as a function of slope steepness.

Table 4. Average soil loss at the Ansai station cataloged according to maximum 30-min rainfall intensity. The numbers of storms measured were 23, 9, 3, and 4 for intensities of <15, 15–30, 30–45, >45 mm h^{-1}, respectively.

Slope length	Maximum 30-min rainfall intensity (mm h^{-1})							
	<15		15–30		30–45		>45	
	Runoff	Soil	Runoff	Soil	Runoff	Soil	Runoff	Soil
m	mm	Mg ha^{-1}	mm	Mg ha^{-1}	mm	Mg ha^{-1}	mm	Mg ha^{-1}
10	1.18	0.35	2.12	4.04	14.72	15.49	35.58	93.16
20	0.85	0.37	2.08	5.83	13.30	21.60	34.14	129.17
30	0.66	0.31	1.42	4.69	10.38	20.63	33.46	149.87
40	0.56	0.28	1.50	7.40	12.30	27.30	33.35	164.76

calculated by Eq. [3]. The ratio β (Eq. [4]) was developed by McCool et al. (1989) by dividing Foster's interrill equation into his rill equation (Foster et al., 1977) and then simplifying with several assumptions to obtain Eq. [4]. According to Eq. [3] and [4], the slope length exponent is continually increasing with slope gradient. The USLE relationship, on the other hand, is constant when slopes are greater than 5%.

The fitted exponent of slope length from this study at 57.7% slope was 0.40, and at 40% slope values were 0.46 and 0.44. Several measured data distributed at a joint ARS-SCS workshop held in 1956 at Purdue University by W.H. Wischmeier (McCool et al., 1989) show that when slope steepness was 16% at Lacrosse, WI; 17% at Marcellas, NY; and 18% at Arnot, NY, the slope length exponent was 0.5, 0.6, and 0.45, respectively. These results, together with our data, indicate that when slope steepness is increased from 20 to 40 and 60%, the slope length exponent does not increase (Fig. 4).

The USLE plot data (McCool et al., 1989) showed that the slope length exponent may vary from 0 to 0.9. Wischmeier et al. (1958) point out that at the majority of locations, runoff did not differ significantly with plot length for the 15 studies. However, three of them showed decreasing runoff with increased slope length. For these three studies, the length-exponent was zero. For the studies in Guthrie, OK, and in Bethany, MO, runoff showed a significant increase with increased slope length. For these two studies, the length exponent was high: 0.68 and 0.9. From these data, we might surmise that the two high values, which were collected at 8 and 10% slopes, were caused by the runoff increasing with slope rather than by increasing slope steepness per se.

The data separated by a maximum 30-min storm intensity from the Ansai station (Table 4) showed that the slope length exponent was a function of the maximum 30-min rainfall intensity (I_{30}) (Table 5). Tables 4 and 5 also provide further evidence that runoff rates may be the controlling factor for the slope length factor. The group of storms with I_{30} >45 mm h^{-1} showed the greatest effect of slope length on erosion and also showed an essentially unchanging runoff depth as a function of slope length (Table 4). Low intensity storms of <15 mm h^{-1} actually showed a negative value of slope length exponent *m* and exhibited a large decrease in runoff depth as a function of slope length increase.

Table 5. Results of regression analyses on slope loss as a function of slope length at different rainfall intensities according to Eq. [1] for the Ansai station.

Rainfall intensity	*a*	*m*	R^2
mm h^{-1}			
<15	0.54	−0.16	0.61
15–30	1.88	0.34	0.59
30–45	6.86	0.36	0.86
>45	36.43	0.41	0.99

CONCLUSIONS

Soil loss data from natural runoff plots at three sites on the Loess Plateau of China were reported in this study. The experimental data for slope lengths from 10 to 60 m on steep slopes showed that the relationship between slope length and soil loss was well approximated by the USLE equation, and not as well by the RUSLE equations. The exponent, *m*, for the relationship between soil loss and the slope length for the combined data from the three stations in the Loess Plateau was 0.44 ($r^2 = 0.95$). The three data sets from the slopes of 57.7, 40.4, and 40.4%, together with the USLE plot data distributed at Purdue University by Wischmeier et al. (1958), indicate that the slope length exponent does not increase with slope gradient increase from ≈20 to 60%. Rainfall intensity and runoff influenced the slope length exponent greatly. The slope length exponent showed greater sensitivity to differences in rainfall and runoff than to slope length per se.

Characteristics and Modeling of Runoff Hydrographs for Different Tillage Treatments

B. Yu,* S. Sombatpanit, C. W. Rose, C. A. A. Ciesiolka, and K. J. Coughlan

ABSTRACT

Surface runoff rate is a critical variable in determining the rate of soil erosion and sediment transport. Rainfall and runoff data at 1-min intervals from an experiment site at Khon Kaen, Thailand, were used to test a three-parameter runoff model originally developed for bare plots in relation to soil erosion studies. The site has a sandy soil with a slope of 3.6%. Plot length and width were 30 and 5 m, respectively. Four tillage treatments with three replicates each were considered: up- and down-slope cultivation, two contour cultivation treatments with tillage depth of 25 and 50 cm, respectively, and no tillage. Runoff data for 200 individual runoff hydrographs showed that runoff amount and peak runoff rate for the no tillage treatment were significantly less than those for other treatments at the site. On average, runoff amount and peak runoff rate for the no tillage treatment were 37 and 44%, respectively, of those for the up- and down-slope cultivation. Results for contour cultivation practices are between the two extremes, although the water retention was not greater with greater tillage depth as we originally thought would be the case at the site. For these 200 runoff events for the four treatments, the model for runoff hydrographs worked well, with an average coefficient of efficiency of 0.90 and an average standard error of 0.88 mm h^{-1}. The model performance is particularly good for large storm events with high volumetric runoff coefficient. The three model parameters vary considerably from event to event and from treatment to treatment. The initial infiltration amount was found to be inversely related to prior 10-d rainfall at the site; the spatially averaged maximum rate of infiltration can be related to the maximum retention or the Soil Conservation Service (SCS) Curve Number, and the hydrologic lag time is least variable among different storm events and tillage treatments, but tends to decrease with peak runoff rate.

Surface runoff rate plays a critical role in determining the rate of soil loss from agricultural lands. This is especially the case during large events with high stream power (Proffitt and Rose, 1991). In the Universal Soil Loss Equation (Wischmeier and Smith, 1978), the effect of rainfall and runoff is encapsulated in a rainfall and runoff factor, known as the *R*-factor, to represent the long-term climatic influence on soil erosion. As such, the *R*-factor should not be used to determine the soil loss on an event basis. In process-based water erosion models, runoff rate is explicitly required in order to determine the rate of soil loss. For example, in the Water Erosion Prediction Project (WEPP; Laflen et al., 1991; Flanagan and Nearing, 1995), which represents a new generation of process-based erosion models, the peak runoff rate is used to determine the rate of both interrill and rill erosion (Foster et al., 1995). In GUEST (Rose, 1993; Misra and Rose, 1996), a theoretical expression is derived for sediment concentration at the transport limit based on the stream power, which is in turn a function of the runoff rate. It is important therefore to predict runoff rates for given rainfall intensity, soil, and topographical characteristics.

As part of projects funded by the Australian Centre for International Agricultural Research (ACIAR), rainfall intensity and runoff rate were measured at 1-min intervals at a number of sites in Australia and Southeast Asia. One of the research objectives was to develop hydrologic models to predict runoff rates from rainfall rates for a range of soil types, slopes, slope lengths, and management practices in the tropical and subtropical regions of Australia and Southeast Asia. A three-parameter infiltration and runoff routing model was developed and validated using data from bare plots from six sites in Southeast Asia and Australia (Yu et al., 1997b). Apart from satisfactory performance of the model in terms of modeled hydrographs for these sites, two subsequent studies gave further support of the model as a tool for predicting runoff rate. Yu (1998) showed that one of the infiltration parameters is implicitly related to the widely used SCS Curve Number method for runoff estimation (Soil Conservation Ser-

Modification of the RUSLE slope length and steepness factor (LS-factor) based on rainfall experiments at steep alpine grasslands

A B S T R A C T

The slope length and slope steepness factor (LS-factor) is one of five factors of the Universal Soil Loss Equation (USLE) and its revised version (RUSLE) describing the influence of topography on soil erosion risk. The LS-factor was originally developed for slopes less than 50% inclination and has not been tested for steeper slopes. To overcome this limitation, we adapted both factors slope length L and slope steepness S for conditions experimentally observed at Swiss alpine grasslands. For the new L-factor (L_{alpine}), a maximal flow path threshold, corresponding to 100 m, was implemented to take into account short runoff flow paths and rapid infiltration that has been observed in our experiments. For the S-factor, a fitted quadratic polynomial function (S_{alpine}) has been established, compiling the most extensive empirical studies. As a model evaluation, uncertainty intervals are presented for this modified S-factor. We observed that uncertainty increases with slope gradient. In summary, the proposed modification of the LS-factor to alpine environments enables an improved prediction of soil erosion risk including steep slopes.

- Empirical experiments (rainfall simulation, sediment measurements) were conducted on Swiss alpine grasslands to assess the maximal flow length and slope steepness factor (S-factor).
- Flow accumulation is limited to a maximal flow threshold (100 m) at which overland runoff is realistic in alpine grassland.
- Slope steepness factor is modified by a fitted S-factor equation from existing empirical S-factor functions.

Method details

Existing approaches for S- and L-factor parametrization

The LS-factor is a product of the slope length (L-) and the slope steepness (S-factor). The most widely used slope length factor represents the ratio of observed soil loss related to the soil loss of a standardized plot (22.13 m). Originally Wischmeier and Smith [1] defined the L-factor as Eq. (1):

$$L = \left(\frac{\lambda}{22.13}\right)^{m} \tag{1}$$

where λ represents the length of the slope in meters and m the different slope steepness. Later, Eq. (2) was adapted for the RUSLE-approach to better describe soil loss with increasing slope steepness. Desmet and Govers [2] transformed the original L-factor (Eq. (1)) into a GIS-approach (Eq. (2)) considering the flow accumulation and adding a ratio of rill to interrill erosion (Eq. (3)):

$$L_{i,j} = \frac{\left(A_{i,j-in} + D^2\right)^{m+1} - A_{i,j-in}^{m+1}}{D^{m+2} * X_{i,j}^{m} * 22.13^{m}} \tag{2}$$

where $A_{i,j-in}$ is the flow accumulation in m^2 at the inlet of a grid cell (i,j). D is the grid cell size in m and $X_{i,j}$ equals to $\sin a_{i,j} + \cos a_{i,j}$ where $a_{i,j}$ is the aspect of the grid cell (i,j). The coefficient m (Eq. (3)) represents the ratio of rill and interrill erosion and is calculated by the β-value (Eq. (4)):

$$m = \frac{\beta}{\beta + 1} \tag{3}$$

with a range between 0 (ratio of rill to interrill erosion close to 0) and 1.

$$\beta = \frac{\frac{\sin\theta}{0.0896}}{\left[0.56 + 3 * (\sin\theta)^{0.8}\right]} \tag{4}$$

where θ is the slope angle in degrees.

For the S-factor, most often the empiric function proposed by McCool et al. [3] is used to determine the slope steepness factor in the Revised Universal Soil Loss Equation (RUSLE). McCool et al. [3] differentiate the relation between soil loss and slope steepness in radians (s) with two functions. One for slopes with an inclination less than 9% and the other greater or equal 9%. The functions are as follows:

$$S = 10.8s + 0.03 \qquad for \quad slope \quad steepness \quad in \quad percent < 9\% \tag{5}$$

$$S = 16.8s - 0.50 \qquad for \quad slope \quad steepness \quad in \quad percent \geq 9\% \tag{6}$$

The S-factor after McCool et al. [3] is particular recommended for areas with low summer rainfall amounts [4]. Many other empirical S-factors were developed since the 1940s (Table 1) but all S-factors have in common that empirical evidence and thus validity is limited to slope gradients less than 50%.

Proposed adaption of the L-factor

Often, GIS modeled potential flow path length on slopes, expressed as flow accumulation in a GIS-environment, is driven by gravity and theoretically unlimited [13]. In particular cases, these potential flow path lengths can reach many kilometers and enormous runoff volumes. The flow accumulation can be constrained by streets or houses as ending points of the potential flow paths as discussed by Winchell et al. [14].

In 2016, we conducted 19 different rainfall simulation experiments on south facing slopes in an alpine environment (Val Piora, Switzerland) with different conditions regarding soil moisture (dry, moist), steepness (36°–82°), and vegetation (low, medium, full vegetation cover) to observe the flow path lengths. The rainfall simulations were realized with an Eijkelkamp mini rainfall simulator (type M1.09.06. E, Eijkelkamp, NL; Fig. 1) for erosion tests with a rainfall intensity of 640 mm/h and an energy of 4 J mm^{-1} m^{-2}. This rainfall energy is comparable with the average rainfall energy of Val Piora (station Piotta; 5.6 J mm^{-1} m^{-2}; [15]). Regardless of the conditions, our observations revealed short surface flow path lengths at the scale of meters with a rapid infiltration into shallow alpine soils (see Appendix A.

Table 1
Review of selected S-factors (S).

Source	function	Description
Zingg [5]	$S = \left(\frac{s}{9}\right)^{1.4}$	s = slope steepness in percent
Musgrave [6]	$S = \left(\frac{s}{9}\right)^{1.35}$	s = slope steepness in percent
Smith and Whitt [7]	$S = 0.025 + 0.052s^{\frac{4}{3}}$	s = slope steepness in percent
Smith [8]	$S = 0.00650s^2 + 0.0453s + 0.065$	s = slope steepness in percent
Smith [8]	$S = 0.044 + 0.10s - 0.00073s^2$	s = slope steepness in percent
Wischmeier and Smith [1]	$S = 65.4\sin\theta^2 + 4.56\sin\theta + 0.0654$	θ = slope steepness in radians
McCool et al. [9]	$S = \left(\frac{\sin\theta}{0.00896}\right)^{0.6}$	θ = slope steepness in radians
Foster [10]	$S = 3(\sin\theta)^{0.8} + 0.56$	θ = slope steepness in radians
McCool et al. [3]	$S = 16.8\sin\theta - 0.5$	θ = slope steepness in radians
McCool et al. [3]	$S = 10.8\sin\theta + 0.03$	θ = slope steepness in radians
Nearing [11]	$S = -1.5 + \frac{17}{1+e^{2.3-6.1\sin\theta}}$	θ = slope steepness in radians
Liu et al. [12]	$S = 21.91\sin\theta - 0.96$	θ = slope steepness in radians
S_{alpine} present study	$S = 0.0005s^2 + 0.1795s - 0.4418$	s = slope steepness in percent

Fig. 1. Different set ups and preconditions of the rainfall simulation experiment on steep slopes in Val Piora, Ticino, Switzerland.

supplementary material). Our measurements and observations show, that potential flow paths without considering infiltration is not realistic for alpine environments and thus, requesting a maximal flow threshold for the estimation of the slope length factor L. McCool et al. [16] and Winchell et al. [14] limited the slope length to a maximal threshold of 333 m (1000 feet) as longer slope length appear only occasionally. According to McCool et al. [16], the usual threshold in many cases is 121 m (400 feet). As a compromise of their suggestion and our observed short flow path lengths in the Swiss Alps, we decided to limit the maximal flow length to 100 m.

The threshold is implemented as a condition either directly in SAGA GIS or in RSAGA after creating the flow accumulation grid:

$$A_{alpine\,i,j-in} = ifelse(A_{i,j-in} > thresh,\ thresh,\ A_{i,j-in}) \tag{7}$$

where $A_{alpine\,i,j-in}$ is the constraint flow accumulation in m^2 at the inlet of a grid cell (i,j) considering a threshold value *thresh*. That constraint flow accumulation value is inserted into the L-factor equation for the alpine environment (Eq. (8)):

$$L_{alpine\,i,j} = \frac{\left(A_{alpine\,i,j-in} + D^2\right)^{m+1} - A_{alpine\,i,j-in}^{m+1}}{D^{m+2} * X_{i,j}^{m} * 22.13^{m}} \tag{8}$$

Likewise to Eq. (2), D is the grid cell size in m and $X_{i,j}$ equals to $\sin a_{i,j} + \cos a_{i,j}$ where $a_{i,j}$ is the aspect of the grid cell (i,j). The coefficient m is the ratio of rill (β-value) to interrill erosion according to the above mentioned Eqs. (3) and (4).

For our calculation of L-factor using a 2 m resolution Digital Elevation Model, the maximal flow length of 100 m, corresponds to a threshold of 50 cells multiplied by the cell size of 2 m (Fig. 2).

Additionally, maximal flow path length was constrained by a field block cadaster. The cadaster defines hydrological units of continuous agricultural land, that are separated by landscape elements acting as flow boundaries (e.g., forests, streets, urban areas, water bodies, or ditches) following the approach of Winchell et al. [14].

Proposed adaption of the S-factor

In 2014, we conducted a total of 16 rainfall simulations on alpine slopes to assess the soil loss rates related to different slope inclinations (Table 2; [17]). The experiments were conducted at a north and south facing slope both with grassland cover in the mountains of the Urseren Valley, Switzerland. At each slope two transects were selected with slope gradient ranging from 20 to 90%. We used a field hybrid rainfall simulator modified after Schindler Wildhaber et al. [18] with an intensity of 60 mm $h^{-}1$, which is comparable to a high rainfall event in this area.

The experimental sites showed small variation in vegetation cover, soil erodibility, and slope length (due to the effect of slope angle), therefore all experimental plots were normalized to average values of

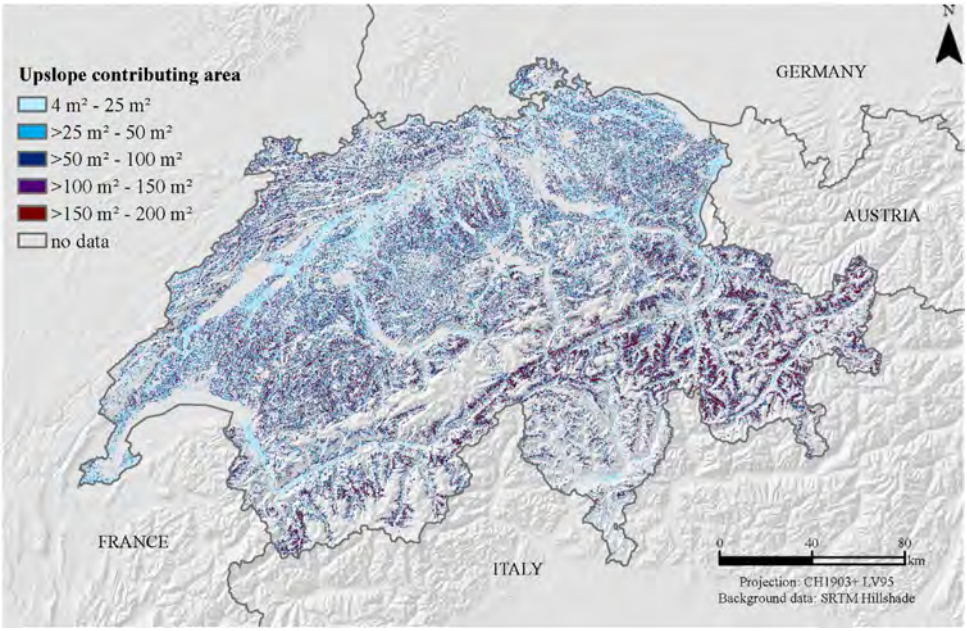

Fig. 2. Constraint flow accumulation grid with a maximal flow path length of 100 m.

[a] By C-factor with 35% vegetation cover, L-factor of 1.2, and K-factor of 0.031.

the respective factors. S-factors were fitted to observed soil loss versus sine of the slope angle using an exponential, power, and polynomial equation to the original dataset with all observation and a dataset excluding one outlier (N° 13), and three outliers (N° 12, 13, 16). The nine regression lines yield R^2 estimates between 0.18 and 0.70, but differ largely with increasing slope steepness. This range of S-factors with increasing steepness is comparable to previous developed empirical S-factor equations (Table 1,Fig. 1). Therefore, we decided that a fitted function (S_{alpine} in Table 1, Fig. 3) complying the most important S-factors from the literature would be most suitable to describe the soil loss behavior

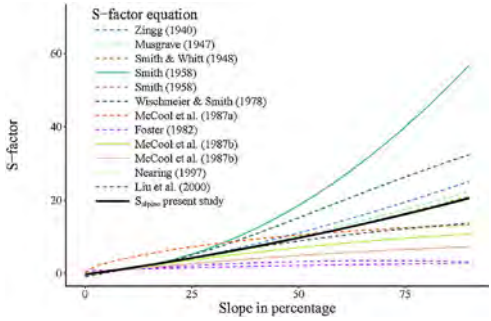

Fig. 3. Review and behavior of different empirical S-factor functions and the fitted function for steep alpine environments (S_{alpine}).

at steep slopes. The aggregated S function and is a quadratic polynomic function with progressive growth (Eq. (9)):

$$S_{alpine} = 0.0005s^2 + 0.7956s - 0.4418 \quad (9)$$

where s is the slope steepness in percent.

S_{alpine} is very close to the empirical normalized function proposed by Musgrave [6] for a slope steepness of 9%.

The Swiss LS-factor map including the Alps

The resulting modeled mean LS_{alpine}-factor of Switzerland is 14.8. The LS-factor increases with elevation gradient from a mean of 7.0 in the zone <1500 m a.s.l. to 30.4 in the zone >1500 m a.s.l. A cluster of highest mean LS-factors can be found across the Alps (Fig. 4). The lowest mean LS-factors are

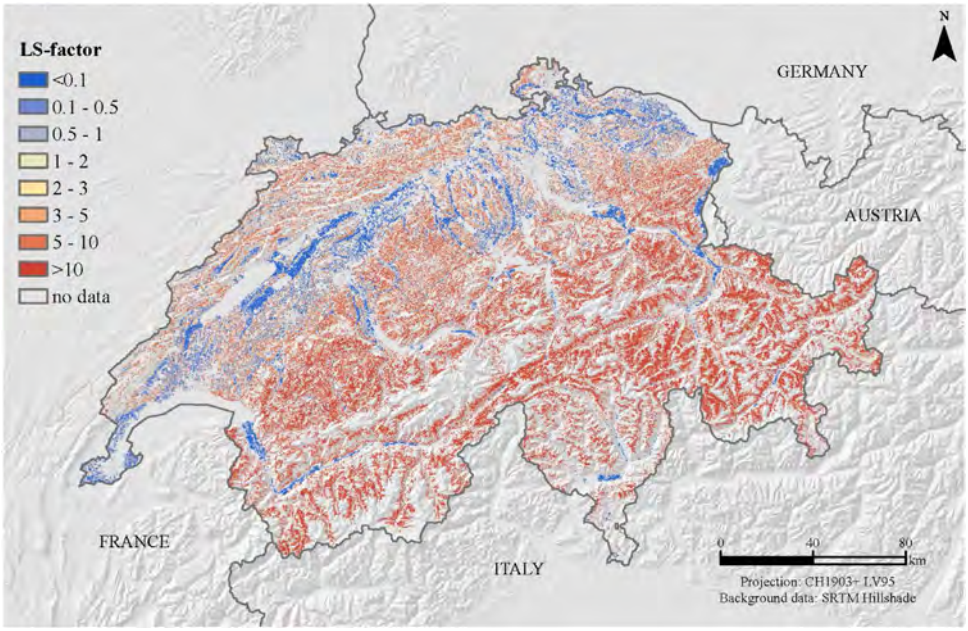

Fig. 4. LS_{alpine}-factor map (spatial resolution 2 m) for Switzerland derived by the digital elevation model SwissAlti3D.

in the Swiss lowlands. South-western facing slopes have higher LS-factors (17.6) compared to plain surfaces (0.04) and north facing slopes (12.5).

Quality assessment and method uncertainties

The original LS-factor has its origin in empirical field experiments and is developed for a maximum slope steepness of 50%. Validation of existing equations for slopes that are steeper than 50% is a challenge. However, while previous studies at inclinations >25% with approximately 20 plot measurements ([19], 24 plots; [20], 19 plots; [12], 9 plots; [21], 22 plots; [18], 6 plots) were successful in delineating and S-factor equation, in our case the variability of the data impeded a unique solution of the S-factor equation. To account for this high variability and still existing uncertainty, the way forward is to include the variability in the LS-factor calculation.

We investigated the deviation in percentage of our proposed S_{alpine} to a conservative function and a rather progressive function. The conservative function (S_{cons}) is based on the translated and scaled sine functions of Eqs. (5) and (6) by McCool et al. [3] with a proportional and slightly digressive growth. The progressive function (S_{prog}) is a quadratic polynomic function according to Smith and Whitt [7] with a progressive growth, but a higher coefficient than the here presented fitted function S_{alpine} (Eq. (10)) for S_{alpine}.

$$S_{prog} = 0.00650s^2 + 0.0453s + 0.065 \tag{10}$$

where s is the slope steepness in percent.

Low uncertainty has a deviation close to 0%. Higher percentages equals to a higher deviation of $S_{cons/prog}$ to S_{alpine}.

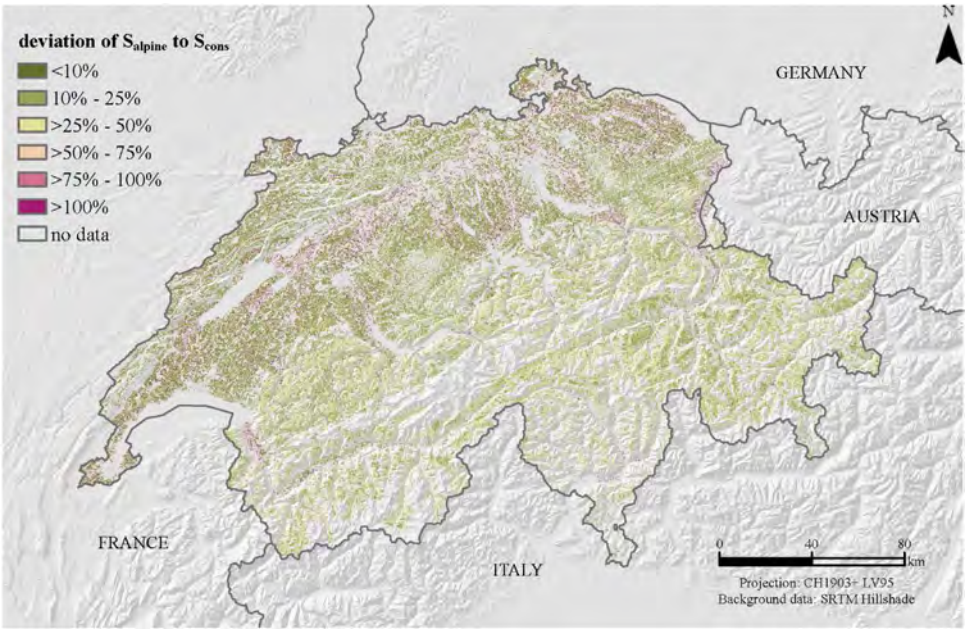

Fig. 5. Deviation in percentage of S_{alpine} to S_{cons} as an indicator of quality for the proposed S_{alpine}-factor. S_{alpine} is a lumped S-factor of a total of 12 empiric S-factor equations of the literature (Eq. (9)). It can be seen as an approximation to the high slope gradients in alpine environments. S_{cons} complies with the proposed S-factor of McCool et al. [3] (Eqs. (5) and (6)). The deviation is presented in percentage.

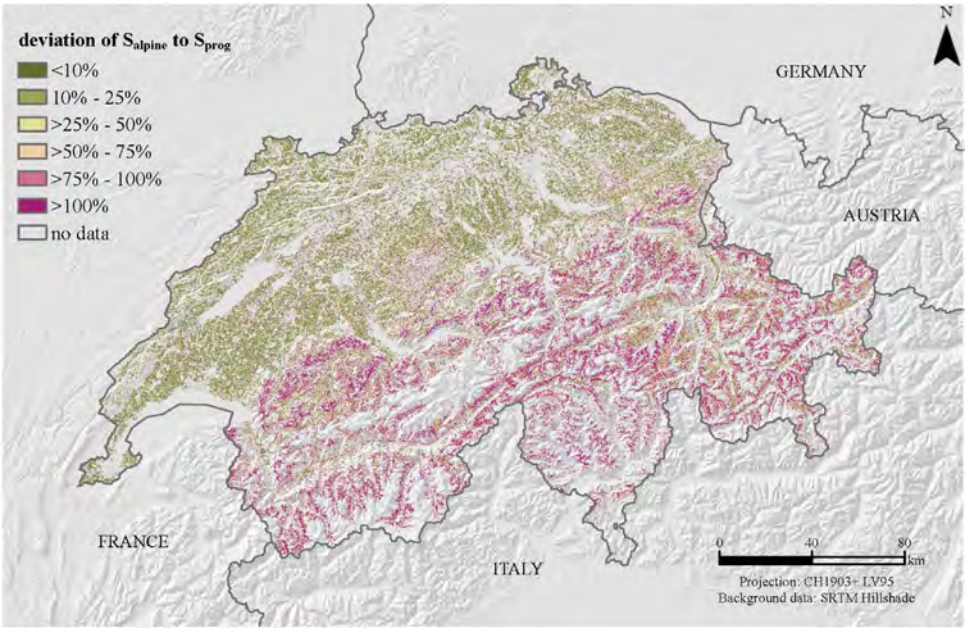

Fig. 6. Deviation in percentage of S_{alpine} to S_{prog} as an indicator of quality for the proposed S_{alpine}-factor. S_{alpine} is a lumped S-factor of a total of 12 empiric S-factor equations of the literature (Eq. (9)). It can be seen as an approximation to the high slope gradients in alpine environments. S_{prog} complies with the proposed S-factor of Smith and Whitt [7] (Eq. (10)). The deviation is presented in percentage.

The deviation of S_{alpine} to S_{cons} shows higher deviations in areas with less slope gradiants (parts of Swiss midland) (Fig. 5). The steep slope areas in the Alps have deviations of 25%–50%. Both functions, S_{alpine} and S_{cons} predict the steep alpine environment in a comparable way. The deviation of the progressive S-factor (Sprog) and S_{alpine} diverge much more in the Alps whereas the equations are rather fitting in flatter regions (Fig. 6). A sharp edge of low divergence to high divergence is marked by the northern Alpine foothill with increasing slope gradients.

This relationship of deviation and slope gradient is not surprising as the uncertainty of many equations rises with slope steepness (cf. Fig. 3). García-Ruiz et al. [22] identified an increasing trend of uncertainty for 624 measured erosion rates and slope gradients across the world for slope steepness >11°.

The LS-Factor map of the Swiss agricultural land use unit is visually compatible with the LS-factor maps of the European Union provided by Panagos et al. [23] (Fig. 7). In contrast to the modeling of the total country area by Panagos et al. [23] we constrained the LS-factor to agricultural soils incl. grasslands using a field cadaster. The main differences are found on steeper slopes >50%, which have been excluded in the European approach. Furthermore, the European map relies on the conservative Eqs. (5) and (6) by McCool et al. [3]. Additionally, different spatial resolutions of Digital Elevation Models (2 m versus 25 m) are influencing the slope and aspect mapping and thus the LS-factor [24–26].

It should be considered that the number of rainfall experiments for the L-factor (n = 19) and the S-factor (S = 16) is short and limited only to grasslands which are the predominant land use at Swiss alpine slopes [27]. Rainfall simulations in alpine environments are difficult to conduct due to the harsh terrain and climate conditions. Often, the temporal period for measurements is limited by the late melt out of snow cover and the short vegetation period [28]. To better model the S-factor for steep

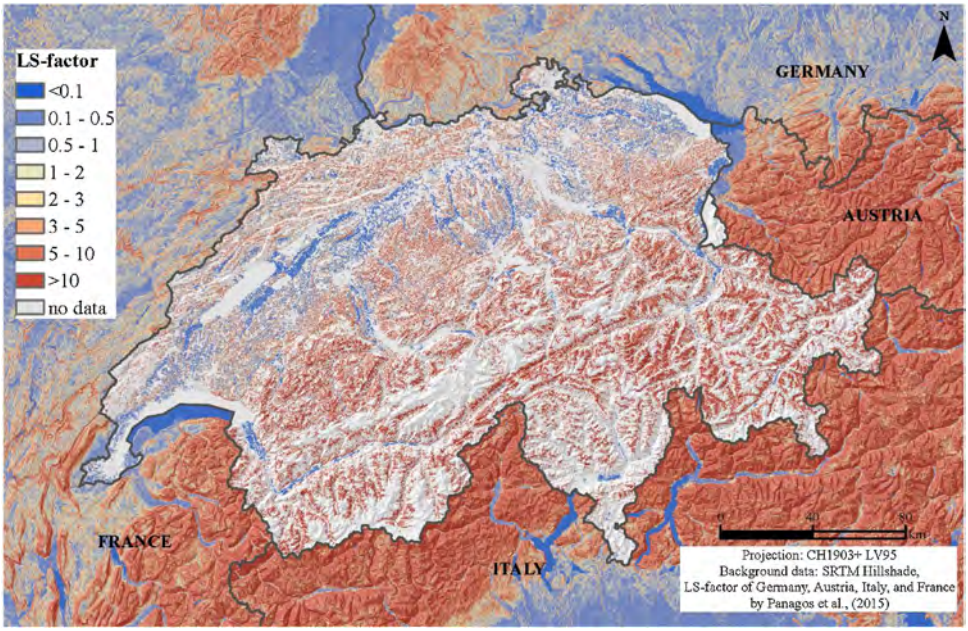

Fig. 7. LS-factor for the Swiss agricultural area (incl. Liechtenstein) embedded in the European Union's LS-factor map (for total country area) by Panagos et al. [23].

alpine slopes further measurements (e.g., rainfall simulation experiments) are needed to constrain S-factor assessment for steep slopes.

Additional information

Introduction

The slope length factor L and slope steepness factor S, often lumped together as the topographic factor LS. The LS-factor is one of the factors (R rainfall erosivity, C cover and management factor, K soil erodibility, P support practices) of the Universal Soil Loss Equation (USLE) and its revised version (RUSLE) [1,29]. LS is a factor that describes the influence of the topography to the soil erosion risk by considering the length of a slope and the influence of surface runoff which can be active on eroding soil material before it infiltrates or continuous as interflow. Furthermore, it includes the steepness of a slope as runoff on steeper slopes has a higher gravity and therefore is more relevant for erosion.

With the availability of Digital Elevation Models the calculation of LS-factors in GIS environments was made possible even for large-scale erosion modeling approaches. Winchell et al. [14] revealed a reasonable agreement of GIS-based LS-factor and field measured LS-factors of the US Natural Resource Inventory database for the Mississippi Catchment.

Originally, the LS-factor was assessed on a 9% steep slope with a length of 22.13 m (72.6 feet) [1]. Owing to its empirical character, LS-factors are usually limited to a maximum slope angle of 50% (26.6°) [3,12]. As Switzerland is a country with a high elevation gradient from 192 m a.s.l. to 4633 m a.s.l. (mean elevation 1288 m a.s.l.) and a mean slope gradient of up to 36% (20°), a not negligible fraction of slopes (4.7%) exceeds the limitation of 50%. Yet, no uniform equation to assess the LS-factor for steep slopes like in the alpine environment of Switzerland was presented to the scientific community. Only a few studies are dealing with LS-factors on steep slopes (e.g. [12]). For example, slopes >50% were disregarded in the most recent European Union's LS-factor map by Panagos et al. [23].

To overcome that limitation in LS-factor modeling on steep slopes, we (i) limited the potential flow path length to a maximal flow and (ii) choose the most representative equation for Swiss steep slopes.

Data statement

Raw data were generated at Swisstopo and provided only for scientific purposes. Derived data supporting the findings of this study are available from the corresponding author SS on request.

Acknowledgments

This work was supported by the Swiss Federal Office for the Environment (FOEN) (grant numbers N° N222-0350 and N° P182-1535). The authors would like to thank Christine Alewell for the methodological support and Pascal Bircher for the advice in data handling with SAGA GIS/RSAGA and the upgrade of the existing field block cadaster of Switzerland. Our thank goes to M. Schulthess, C. Keller, N. Bongni, S. Rothenbühler, and A. Aeschbach for the support in the field and the footage. The authors thank Swisstopo for making their data available for this research. The authors would like to thank two anonymous referees for their valuable comments and suggestions to improve the quality of the paper.

Revised Universal Soil Loss Equation
Version 2

(RUSLE2)

(for the model with release date of May 20, 2008)

USDA-Agricultural Research Service

Washington, D.C.

August 2013

Table of Contents

Acknowledgements

RUSLE2 was developed cooperatively by the USDA-Agricultural Research Service (ARS), the USDA-Natural Resources Conservation Service (NRCS), and the Biosystems Engineering and Environmental Science Department of the University of Tennessee. Each project participant maintains a RUSLE2 Internet site directed toward their specific interests. Consult these sites for a list of the employees of these organizations who contributed to the development of RUSLE2. Contributors from several other organizations also participated in the development of RUSLE2.

The USDA-ARS was responsible for providing the erosion science on which RUSLE2 is based including the mathematical equations used in RUSLE2, core data values used to calibrate RUSLE2, scientific documentation, and a user's reference guide for RUSLE2.

The USDA-NRCS was the principal client for RUSLE2. The NRCS provided information to ensure that RUSLE2 could be easily used in their local field (district) offices. The NRCS also developed an extensive RUSLE2 operational (working) database, primarily for cropland. The NRCS has developed RUSLE2 templates and user guides specifically for their purposes.

The University of Tennessee participated in the development of the mathematical equations used in RUSLE2, developed the computer science used in RUSLE2, and developed the RUSLE2 computer program. They also developed user guides and other RUSLE2 information for their clients.

The interests and needs of a wide variety of other users were considered during RUSLE2's development. RUSLE2 was developed to be land-use independent to give RUSLE2 the widest applicability range possible and to accommodate the needs of these users.

This RUSLE2 Science Documentation was reviewed by USDA-Natural Resources Conservation Service technical specialists from several disciplines; Kenneth G. Renard (retired), USDA-Agricultural Research Service, Tucson, Arizona; and Seth Dabney, USDA-Agricultural Research Service, Oxford, Mississippi.

Preface

The Revised Universal Soil Loss Equation, Version 2 (RUSLE2) is used to guide conservation and erosion control planning at the local field office level. RUSLE2 estimates average annual rill and interrill erosion based on site-specific conditions. In a typical application, the planner identifies several potential erosion control alternatives for the site and estimates erosion for each alternative. The planner then chooses the alternative that provides adequate erosion control and best meets other requirements.

RUSLE2 is computer-based technology that involves a computer program, mathematical equations, and a large database. The RUSLE2 user describes a specific site by making selections from the database. RUSLE2 uses this information in its mathematical equations to compute erosion estimates for alternative erosion control practices for the site.

RUSLE2 can be used to estimate rill and interrill erosion where mineral soil is exposed to the erosive forces of impacting raindrops and water drops falling from vegetation and surface runoff produced by Hortonian overland flow. RUSLE2 is land use independent and can be applied wherever these conditions exist. RUSLE2 can be used on cropland, pastureland, rangeland, constructions site, reclaimed mine land, landfills, mine tailings, mechanically disturbed and burned forestlands, military training sites, and similar lands.

This document describes the RUSLE2 science, which is primarily embodied in the mathematical equations used in RUSLE2. The RUSLE2 User's Reference Guide, a companion document, describes how RUSLE2 works, how to interpret values computed by RUSLE2, how to select and enter values into the RUSLE2 database, and how to judge the adequacy of RUSLE2. Additional information is available on the RUSLE2 Internet site maintained by the USDA-Agricultural Research Service: http://www.ars.usda.gov/Research/docs.htm?docid=6010. Additional information is also available on RUSLE2 Internet sites maintained by the USDA-Natural Resources Conservation Service and the University of Tennessee.

Each chapter in this document stands alone with its own list of symbols given at the end of the chapter. Symbols are defined on their occurrence. Refer to the list of symbols at the end of each chapter because symbol usage differs between chapters.

RUSLE2 uses mathematical equations from several disciplines. In most cases, the symbols that are common in a given discipline are used in this document, which results in the same symbol being used for multiple variables, even within the same chapter. Using the typical symbol for a given variable was considered to be more useful than having a unique symbol for each variable.

Also, topics overlap between chapters. The topics within and between chapters are organized according to the mathematical structure of RUSLE2 rather than along a user oriented structure, which is followed in the RUSLE2 User Reference Guide. Consequently, the mathematical representation of key variables such as residue may be discussed in several places in this document. Cross references to other sections where this variable is discussed are included for the major variables.

Disclaimer

The purpose of RUSLE2 is to guide and assist erosion-control planning. Erosion-control planners should consider information generated by RUSLE2 to be only one set of information used to make an erosion-control decision. RUSLE2 has been verified and validated, and every reasonable effort has been made to ensure that RUSLE2 works as described in RUSLE2 documentation available from the USDA-Agricultural Research Service. However, RUSLE2 users should be aware that errors may exist in RUSLE2 and exercise due caution in using RUSLE2.

Similarly, this RUSLE2 Science Documentation has been reviewed by erosion scientists and RUSLE2 users. These reviewers' comments have been faithfully considered in the revision of this document.

Every reasonable effort has been made to ensure that this document is accurate. The USDA-Agricultural Research Service alone is responsible for this document's accuracy and how faithfully the RUSLE2 computer program represents the information in this document.

Glossary of Terms

Term	Description
10 yr EI	Storm EI with a 10-year return period
10 yr-24 hr EI	Storm EI for the 10 yr-24 hr precipitation amount
10 yr-24 hr precipitation	24 hour precipitation amount having a 10 year return period
Antecedent soil moisture subfactor	See cover-management subfactors
Average annual, monthly, period, and daily erosion	RUSLE2 computes average daily erosion for each day of the year, which represents the average erosion that would be observed if erosion was measured on that day for a sufficiently long period. Average period, monthly, and annual erosion are sums of the average daily values
Average erosion	Average erosion is the sediment load at a given location on the overland flow path divided by the distance from the origin of overland flow path to the location
b value	Coefficient in equation for effect of ground cover on erosion, values vary daily with rill-interrill erosion ratio and residue type
Buffer strips	Dense vegetation strips uniformly spaced along overland flow path; can cause much deposition
Burial ratio	Portion of existing surface (flat) cover mass that is buried by a soil disturbing operation (dry mass basis-not area covered basis)
Calibration	Procedure of fitting an equation to data to determine numerical values for equation's coefficients
Canopy cover	Cover above soil surface; does not contact runoff; usually vegetation
Canopy shape	Standard shapes used to assist selection of fall height values
Canopy subfactor	See cover-management subfactors
Climate description	Input values for variables used to represent climate, stored under a location name in the climate component of RUSLE2 database

Concentrated flow area	Area on landscape where channel flow occurs; ends overland flow path
Conservation planning soil loss	A conservation planning erosion value that gives partial credit to deposition as soil saved, credit is function of location on overland flow path where deposition occurs
Contouring	Support erosion control practice involving ridges-furrows that reduces erosion by redirecting runoff around hillslope
Contouring failure	Contouring effectiveness is lost where runoff shear stress exceeds a critical value
Contouring description	Row grade used to describe contouring; stored in contouring component of RUSLE2 database; ridge height in *operation* description used in cover-*management* description also key input
Core database	RUSLE2 database that includes values for base conditions used to validate RUSLE2; input values for a new condition must be consistent with values in core database for similar conditions
Cover-*management* description	Values for variables that describe cover-management, includes dates, *operation* descriptions, *vegetation* descriptions, vegetation production levels (yields), external *residue* descriptions and amount applied, cover-*management* descriptions named and saved in the management component of RUSLE2 database
Cover-management subfactors	Cover-management subfactor values used to compute detachment (sediment production) by multiplying subfactor values; subfactor values vary through time as cover-management conditions vary temporally
Canopy	Represents how canopy affects erosion; function of canopy cover and fall height, canopy varies through time
Ground cover	Represents how ground cover affects erosion; function of portion of soil surface covered
Surface roughness	Represents how soil surface roughness affects erosion; function of roughness index
Soil biomass	Represents how live and dead roots in upper 10 inches and buried residue in upper 3 inches and less affect erosion
Soil consolidation	Represents how a mechanical disturbance affects erosion;, erosion decreases over time after last disturbance as the soil consolidates (soil consolidation as used in RUSLE2 represents soil particles rebonding during soil wetting and drying; rebonding process is not

	to occur by mechanical compaction)
Ridging	Represents how ridges increase detachment (sediment production)
Ponding	Represents how a water layer on soil surface reduces erosion
Antecedent soil moisture	Represents how previous vegetation affects erosion by reducing soil moisture; used only in Req zone
Critical slope length	Location where contouring fails on a uniform overland flow path
Cultural practice	Erosion control practice such as no-till cropping where cover-management variables are used to reduce erosion
Curve number	An index used in NRCS curve number method to compute runoff; RUSLE2 computes curve number values as a function of hydrologic soil group and cover-management conditions
Database	RUSLE2 database stores both input and output information in named descriptions
Dead biomass	Represents live above ground and root biomass converted to dead biomass by *kill vegetation* process in an *operation* description; dead biomass decomposes
Dead root biomass	A *kill vegetation* process in an *operation* description converts live root biomass to dead root biomass; dead roots decompose at the same rate as surface and buried residue
Decomposition	Loss of dead biomass as a function of material properties, precipitation, and temperature; decomposition rate for all plant parts and buried and surface biomass is equal; decomposition rate for standing residue is significantly decreased because of no soil contact
Deposition	Process that transfers sediment from sediment load transported by runoff to soil surface; net deposition causes sediment load to decrease with distance along overland flow path; depends on sediment characteristics and degree that sediment load exceeds sediment transport capacity; enriches sediment load in fines; computed as a function of sediment particle class fall velocity, runoff rate, and difference between sediment load and transport capacity
Deposition portion	Portion of overland flow path where net deposition occurs
Detachment	Separates soil particles from soil mass by raindrops, waterdrops falling from vegetation, and surface runoff; net detachment causes

	sediment load to increase along overland flow path; detachment is non-selective with respect to sediment characteristics; computed as function of erosivity, soil erodibility, distance along overland flow path, steepness of overland flow path, cover-management condition, and contouring
Disaggregation	Mathematical procedure used to convert monthly precipitation and temperature values to daily values assuming that daily values vary linearly; daily precipitation values sum to equal monthly values, average daily monthly temperature values equals average monthly temperature value
Diversion/terrace/ sediment basin	A set of support practices that intercept overland flow to end overland flow path length.
Diversions	Intercepts overland flow and directs it around hillslope in channelized flow, grade is sufficiently steep that deposition does not occur but not so steep that erosion occurs
EI_{30}	Storm (rainfall) erosivity; product of storm energy and maximum 30 minute intensity; storm energy closely related to rain storm amount and partly to rainfall intensity
Enrichment	Deposition is selective, removing the coarse and dense particles and leaving the sediment load with increased portion of fine and less dense particles
Enrichment ratio	Ratio of specific surface area of sediment after deposition to specific surface area of soil subject to erosion
Eroding portion	Portion of overland flow path where net detachment (erosion) occurs
Erosivity	Index of average annual rainfall erosivity at a location; closely related to rainfall amount and intensity; monthly erosivity is average sum of individual storm values in month, annual erosivity is average sum of values in year; storm rainfall amount must be ½ inch or more to be included in sum
Erosivity density	Ratio of monthly erosivity to monthly precipitation amount
External residue	Material, usually biomass, added to soil surface or placed in the soil; affects erosion as surface residue and buried residue produced by vegetation
Fabric (silt) fence	Fabric about 18 inches wide placed against upright posts on the contour; porous barrier that ponds runoff and causes deposition;

	widely used on construction sites
Fall height (effective)	Effective fall height is the effective height from which waterdrops fall from canopy; depends on canopy shape, canopy density gradient from bottom to top of canopy, and top and bottom canopy heights
Filter strip	A single strip of dense vegetation at the end of an overland flow path; can induce high amounts of deposition
Final roughness	Soil surface roughness after roughness has decayed to unit-plot conditions; primarily represents roughness provided by soil resistant clods
Flattening ratio	Describe how much standing residue that an operation flattens; ratio of standing residue before operation to standing residue after operation; values depend on operation and residue dry mass basis.
Flow interceptors	Topographic features (ridge or channel) on an overflow path that collects overland flow and directs the runoff around hillslope; ends overland flow path; diversions, terraces, and sediment basins are flow interceptors
Gradient terraces	Terraces on a uniform grade (steepness)
Ground cover	Represents the portion of the soil surface covered by material in direct contact with soil; includes plant litter, crop residue, rocks, algae, mulch, and other material that reduces both raindrop impact and surface flow erosivity
Ground cover subfactor	See cover-management subfactors
Growth chart	The collection of values that describe the temporal vegetation variables of live root biomass in upper 4 inches, canopy cover, effective fall height, and live ground cover; values are in a *vegetation* description in the vegetation component of the RUSLE2 database
Hortonian overland flow	Overland flow generated by rainfall intensity being greater than infiltration rate; although flow may be concentrated in micro-channels (rills), runoff is uniformly distributed around hillslope
Hydraulic (roughness) resistance	Degree that ground cover, surface roughness, and vegetation retardance slow runoff; daily values vary as cover-management conditions change
Hydraulic element	RUSLE2 hydraulic elements are a channel and a small

	impoundment
Hydraulic element flow path description	Describes the flow path through a sequence of hydraulic elements; named and saved in hydraulic element flow path component of RUSLE2 database
Hydraulic element system description	Describes a set of hydraulic element paths that are uniformly spaced along the overland flow path described without the hydraulic element system being present, named and saved in the hydraulic element system component of the RUSLE2 database
Hydrologic soil group	Index of runoff potential for a soil profile at a given geographic location, at a particular position on the landscape, and the presence or absence of subsurface drainage
Impoundment	A flow interceptor; impounds runoff; results in sediment deposition; represents impoundments typical of impoundment terraces on cropland and sediment basins on construction sites
Impoundment parallel terrace	Parallel terraces; impoundments occur where terraces cross concentrated flow areas; impoundments drains through risers into underground pipe
Incorporated biomass	Biomass incorporated (buried) in the soil by a *soil disturbing* operation; also biomass added to the soil by decomposition of surface biomass; amount added by decomposition of surface material is function of soil consolidation subfactor
Inherent organic matter	Soil organic matter content in unit-plot condition
Inherent soil erodibility	Soil erodibility determined by inherent soil properties, measured under unit-plot conditions (see soil erodibility)
Initial conditions	Cover-management conditions at the beginning of a no-rotation cover-*management* description
Initial input roughness	Roughness index value assigned to *soil disturbing* operation for the base condition of a silt loam soil having a high biomass on and in the soil; actual initial roughness value used in computations is a function of soil texture, soil biomass, existing roughness at time of soil disturbance, and tillage intensity
Injected biomass	Biomass placed in the soil using an *add other residue/cover* process in a *soil disturbing operation* description; biomass placed in lower half of disturbance depth (see operation processes)
Interrill erosion	Erosion caused by water drop impact; not function of distance along overland flow path unless soil, steepness, and cover-

	management conditions vary, interrill areas are the spaces between rills; very thin flow occurs on interrill areas
Irrigation	Water artificially added to the soil to enhance seed germination and vegetation production
Land use independent	RUSLE2 applies to all situations where Hortonian overland flow occurs and where raindrop impact and surface runoff cause rill and interrill erosion of exposed mineral soil; the same RUSLE2 equations are used to compute erosion regardless of land use
Live above ground biomass	Live above ground biomass provided by vegetation (dry matter basis); converted to standing residue (dead biomass) by a *kill vegetation* process in an *operation* description.
Live ground (surface) cover	Parts of live above ground biomass that touches the soil surface to reduce erosion.
Live root biomass	RUSLE2 distributes input values for live root biomass in upper four inches over a constant rooting depth of 10 inches for all vegetation types and plant growth stages; a *kill vegetation* process in an *operation* description converts live root biomass to dead root biomass. Primarily refers to fine roots that are annually produced, RUSLE2 uses live and dead root biomass in the upper 10 inches to compute a value for the soil biomass subfactor
Local deposition	Deposition that occurs very near, within a few inches, the point of detachment in surface roughness depressions and in furrows between ridges; given full credit for soil saved
Long term roughness	Roughness that naturally develops over time; specified as input in cover-*management* description; depends on vegetation characteristics (e.g., bunch versus sod forming grasses, root pattern near soil surface) and local erosion and deposition, especially by wind erosion; RUSLE2 computes roughness over time; fully developed by *time to soil consolidation*
Long term vegetation	Permanent vegetation like that on pasture, range, reclaimed mined land, and landfills; vegetation description can include temporal values starting on seeding date through maturity, any arbitrary date, or only for the annual cycle of vegetation at maturity
Management alignment offset	Used to sequence cover-management descriptions along an overland flow path to create alternating strips
Mass-cover relationship	Equation used to compute portion of soil surface covered by a

	particular residue mass (dry basis)
Mass-yield relationship	Equation used to compute standing biomass (dry basis) as a function of vegetation production (yield) level
Maximum 30 minute intensity	Average rainfall intensity over the continuous 30 minutes that contains the greatest amount in a rain storm
Non-erodible cover	Cover such as plastic, standing water, snow, and other material that completely eliminates erosion; material can be porous and disappear over time
Non-uniform overland flow path	Soil, steepness, and/or cover-management vary along an overland flow path; path is divided into segments where input selections are made for each segment
NRCS curve number method	Mathematical procedure used in RUSLE2 to compute runoff; a daily runoff value is computed using the 10 yr-24 hr precipitation amount and temporally curve number values that vary as cover-management varies
NWWR	Northwest Wheat and Range Region, a region in the Northwestern US covering eastern Washington and Oregon, northern Idaho (see Req zone)
Operation	An operation changes soil, vegetation, or residue; typically used to represent common farm and construction activities such as plowing, blading, vehicular or animal traffic, and mowing; also used to represent burning and natural processes such as killing frost and germination of volunteer vegetation.
Operation disturbance depth	Surface residue buried by a *soil disturbing* operation is a function of operation disturbance depth
Operation description	Information used to describe an operation, named and stored in the operations component of the RUSLE2 database
Operation processes	An operation is described by a sequence of processes; used to describe how an operation changes cover-managements conditions that affect erosion
No effect	Has no effect on computations; commonly used to reference dates in a cover-management description and to cause RUSLE2 to display information for a particular set of dates
Begin growth	Tells RUSLE2 when to begin using data from a particular *vegetation* description

Kill vegetation	Converts live above ground biomass to standing residue and to convert live root biomass to dead root biomass
Flatten standing residue	Converts a portion of the standing residue to surface residue
Disturb (soil) surface	Mechanically disturbs soil; required to bury surface residue; resurfaces buried residue; required to create roughness and ridges; required to place material (external residue) directly into the soil
Add other cover	Adds material (external residue) to the soil surface and/or places it in the soil
Remove live above ground biomass	Removes a portion of the live above ground biomass; leaves a portion of the affected biomass as surface (flat) residue and standing residue
Remove residue/cover	Removes a portion of standing and surface (flat) residue
Add nonerodible cover	Adds nonerodible cover such as plastic, water depth, snow, or other material that allows no erosion for portion of soil surface covered, cover disappears over time; cover can be porous; cover has no residual effect; not used to represent erosion control blankets and similar material
Remove nonerodible cover	Removes portion of nonerodible cover
Operation speed	Surface residue buried by a soil disturbing operation is a function of operation speed
Overland flow path	Path taken by overland flow on a smooth soil surface from its point of origin to the concentrated flow area that ends the overland flow path; runoff is perpendicular to hillslope contours
Overland flow path (profile) description	Includes values for steepness, names for *soil* and cover-*management* descriptions for segments along an overland flow path; a uniform overland flow path (profile) is where steepness, soil, or cover-management does not vary with distance along overland flow path; a convex profile is where steepness increases with distance; a concave profile is where steepness decreases with distance; a complex profile is a combination of convex, concave, and/or uniform sub-profiles or where soil and/or cover-management vary along the overland flow path

Overland flow path length	Distance along the overland flow path from the origin of overland flow to the concentrated flow area (channel) that intercepts runoff to terminate overland flow;, does not end where deposition begins (see USLE slope length and steepness)
Overland flow path segments	Overland flow path is divided into segments to represent spatial variability along an overland flow path; conditions are considered uniform within each segment
Overland flow path steepness	Steepness along the overland flow path, not hillslope steepness (see USLE slope steepness)
Permeability index	Index for the runoff potential of the soil under the unit-plot condition; used in RUSLE2's soil erodibility nomographs, similar to inverse of hydrologic soil group
Plan description	Collection of RUSLE2 *profile* descriptions used to computed weighted averages for a complex area based on the portion of the area that each profile represents; named and saved in plan component of RUSLE2 database
Ponding subfactor	See cover-management subfactors
Porous barriers	Runoff flows through a porous barrier; does not affect overland flow path; typically slows runoff to cause deposition; examples are stiff grass hedges, fabric (silt) fences, gravel dams, and straw bales
Precipitation amount	Includes all forms of precipitation; RUSLE2 disaggregates input monthly values into daily values to compute decomposition and temporal soil erodibility
Production (yield) level	A measure of annual vegetation live above ground biomass production; user defines yield measure and preferred units on any moisture content basis; input value used to adjust values in a vegetation description at a base yield; maximum canopy cover in base vegetation description must be less than 100 percent
Profile description	Information used to describe profile (overland flow path); includes names for location, topography, soil, cover-management, and support practices used to make a particular RUSLE2 computation, named and stored in profile component of RUSLE2 database
Profile shape	See overland flow path description
Rainfall (storm) energy	Computed as sum of products of unit rainfall energy and rainfall amount in storm intervals where rainfall intensity is assumed uniform; storm energy is closely related to rain storm amount

Rainfall intensity	Rainfall rate express as depth (volume of rainfall/per unit area) per unit time
Remote deposition	Deposition that occurs a significant distance (tens of feet) from the point where the sediment was detached; examples include deposition by dense vegetation strips, terraces, impoundments, and toe of concave overland flow paths; only partial credit given to remote deposition as soil saved; credit depends on location of deposition along overland flow path; very little credit given for deposition near end of overland flow path
Req	Equivalent erosivity for the winter months in the Req zone; used to partially represent Req effect
Req effect	Refers to Req equivalent erosivity; erosion per unit rainfall erosivity in the winter period in the Req zone is much greater than in summer period; winter effect is much greater than in other regions because of a greatly increased soil erodibility; effect partially results from an elevated soil water content, increased runoff, and soil thawing
Req zone	Region where erosion is elevated in the winter months because of the Req effect; region primarily in eastern WA and OR, portions of ID, CA, UT, CO, and limited area in other western US states
Residue	Has multiple meanings in RUSLE2; generally refers to dead biomass, such as crop residue, created when vegetation is killed; plant litter from senescence; and applied mulch material (external residue) such as straw, wood fiber, rock, and erosion control blankets used on construction sites; material is generally assumed to be biomass that decomposes; also used to represent applied material like rock that does not decompose
Residue description	Values used to describe residue, named and stored in the residue component of the RUSLE2 database
Residue type	Refers to fragility and geometric residue characteristics; affects residue amount buried and resurfaced by an operation; affects degree that residue conforms to surface roughness; affects erosion control on steep slopes like those on construction sites
Resurfacing ratio	Portion (dry mass basin) of the buried residue in the soil disturbance depth that a soil disturbing operation brings to the soil surface; function of residue and operation properties
Retardance	Degree that vegetation (live above ground biomass) and standing residue slows runoff; varies with canopy cover; function of

	production (yield) level; part of *vegetation* description
Ridge height	Height of ridges created by a *soil disturbing* operation; major variable along with row grade that determines contouring effectiveness; decays as a function of precipitation amount and interrill erosion
Ridge subfactor	See cover-management subfactors
Rill erosion	Caused by overland flow runoff; increases with distance along the overland flow path
Rill to interrill erosion ratio	Function of slope steepness, rill to interrill soil erodibility, and how cover-management conditions affect rill erosion different from interrill erosion
Rock cover	Rock cover entered in the *soil* description; represents naturally occurring rock on soil surface; operations do not affect this rock cover; rock cover created by an operation that *adds other cover* (rock residue) is treated as external residue; soil disturbing operations bury and resurface rock added as external residue
Root biomass	See dead and live root biomass
Root sloughing	Annual decrease in root biomass, RUSLE2 adds the decrease in live root biomass to dead residue biomass pool
Rotation	Refers to whether a list of operation descriptions in a cover-*management* description are repeated in a cycle; length of cycle is rotation duration; list of operation descriptions are repeated in RUSLE2 until computed average annual erosion value stabilizes; eliminates need to specify initial conditions; *operation* descriptions in a no-rotation cover-*management* descriptions are sequentially processed in a single pass, first *operation* descriptions in cover-*management* description establish initial conditions
Rotation duration	Time (length of cycle) before the list of *operation* descriptions in a rotation type cover-*management* description repeats; time period over which RUSLE2 makes its computation in a no-rotation cover-*management* description
Rotational strip cropping	A rotation type cover-management description that involves periods of dense vegetation that are sequenced along the overland flow path to create strips of alternating dense vegetation that cause deposition
Row grade	Grade along furrows separated by ridges; usually expressed as

	relative row grade, which is the ratio of grade along the furrows to steepness of the overland flow path
Runoff	RUSLE2 computes runoff using NRCS curve number method and the 10 yr-24 hour precipitation amount; used to compute contouring effect, contouring failure (critical slope length), and deposition by porous barriers, flow interceptors, and concave overland flow path profiles
Sediment basin	Small impoundment typical of those used on cropland and construction sites; discharge is usually through a perforated riser that completely drains basin in about 24 hours
Sediment characteristics	Deposition is computed as a function of sediment characteristics, which are particle class diameter and density and the distribution of sediment among particle classes
Sediment particle classes	RUSLE2 uses sediment particle classes of primary clay, silt, and sand and small and large aggregate classes, diameter of aggregate classes and the distribution of sediment among particle classes at point of detachment is function of soil texture; RUSLE2 computes how deposition changes the distribution of sediment particle classes
Sediment load	Mass of sediment transported by runoff per unit hillslope width
Sediment transport capacity	Runoff's capacity for transporting sediment; depends on runoff rate, overland flow path steepness, and hydraulic roughness; deposition occurs when sediment load is greater than runoff's transport capacity
Sediment yield	Sediment load at the end of the flow path represented in a RUSLE2 computation; flow path ends at overland flow path unless hydraulic elements (channel or impoundment) are present; sediment yield for site only if RUSLE2 flow path ends at site boundary
Segments	The overland flow path divided into segments based on topography, soil, and cover-management to represent spatial variation
Senescence	Decrease in vegetation canopy cover; senescence adds biomass to surface (flat) residue unless RUSLE2 is instructed that a decrease in canopy cover, such as leaves drooping, does not add to surface residue
Shear stress	Total runoff shear stress is divided into two parts of that acting on the soil (grain resistance) and that acting on surface residue, surface

	roughness, live vegetation, and standing residue (form resistance); shear stress acting on the soil is used to compute sediment transport capacity; total shear stress is used to compute contouring failure; also function of runoff rate and steepness of overland flow path
Short term roughness	Roughness created by a soil disturbing operation, decays over time as a function of precipitation amount and interrill erosion
Slope length exponent	Exponent in equation used to compute rill-interrill erosion as a function of distance along overland flow path, function of rill to interrill erosion ratio.
Soil biomass subfactor	See cover-management subfactors
Soil consolidation effect	Represents how wetting/drying and other processes cause soil erodibility to decrease over time following a mechanical soil disturbance; increase in soil bulk density (mechanical compaction) not the major cause of reduced soil erodibility; affects runoff, accumulation of biomass in upper 2 inch soil layer, and soil biomass effectiveness
Soil consolidation subfactor	See cover-management subfactors
Soil description	Describes inherent soil properties that affect erosion, runoff, and sediment characteristics at point of detachment on unit plot conditions, named and saved in the soil component of the RUSLE2 database
Soil disturbance width	Portion of the soil surface disturbed; weighted effects of disturbance computed as a function of erosion on disturbed and undisturbed area to determine an effective time since last disturbance, effective surface roughness, and effective ground cover
Soil disturbing operation	*Operation* description that contains *disturb soil* process
Soil erodibility	RUSLE2 considers two soil erodibility effects, one based on inherent soil properties and one based on cover-management; inherent soil erodibility effect represented by K factor value empirically determined from erosion on unit plot; part related to cover-management is represented in cover-management subfactors
Soil erodibility nomograph	Mathematical procedure used to compute a K factor value, i.e., inherent soil erodibility
Soil loss	Proper definition is the sediment yield from a uniform overland

	flow path divided by the overland flow path length; loosely used as the net removal of sediment from an overland flow path segment
Soil loss from eroding portion	Net removal of sediment from the eroding portion of the overland flow path
Soil loss tolerance (T)	Erosion control criteria, objective is that "soil loss" be less than soil loss tolerance T value, special considerations must be given to non-uniform overland flow paths to avoid significantly flawed conservation and erosion control plans
Soil mechanical disturbance	Mechanical soil disturbance resets soil consolidation effects; *disturb soil* process must be included in an *operation* description to create surface roughness and ridges and to place biomass into the soil
Soil saved	Portion of deposited sediment that is credited as soil saved; computed erosion is reduced by soil saved to determine a conservation planning soil loss value; credit depends on location of deposition along overland flow path
Soil structure	Refers to the arrangement of soil particles in soil mass; used to compute soil erodibility (K) factor values
Soil texture	Refers to the distribution of primary particles of sand, silt, and clay in soil mass subject to erosion
Standing residue	Created when live vegetation is *killed*, decomposes at a reduced rate; falls over at a rate proportional to decomposition of surface residue
Strip/barrier *description*	Support practice, describes porous barriers, named and stored in the strip/barrier component of RUSLE2 database
Subfactor method	See cover-management subfactors
Subsurface drainage description	Support practice that lowers water table to reduce soil water content, runoff, and reduces erosion; RUSLE2 uses difference between hydrologic soil groups for drained and undrained conditions to compute erosion as affected by subsurface drainage, named and save in subsurface drainage component of RUSLE2 database
Support practices	Erosion control practice used in addition to cultural erosion control practice, hence a support practice; includes contouring, filter and buffer strips, rotational strip cropping, silt (fabric) fences, stiff grass hedges, diversions/terraces, gravel dams, and sediment basins

Surface (flat) residue	Material in direct contact with the soil surface; main source is plant litter, crop residue, and applied mulch (external residue).
Surface roughness	Random soil surface roughness; combination of soil peaks and depressions that pond runoff; created by a *soil disturbing* operation, decays as a function of precipitation amount and interrill erosion
Surface roughness index	A measure of soil surface roughness; standard deviation of surface elevations measured on a 1 inch grid about mean elevation; effect of ridges and land steepness removed from measurements
Surface roughness subfactor	See cover-management subfactors
Temperature	Input as average monthly temperature; disaggregated into daily values, used to compute biomass decomposition and temporal soil erodibility
Template	Determines the computer screen configuration of RUSLE2 and inputs and outputs; determines the complexity of field situations that can be described with RUSLE2
Terraces	Flow interceptors (channels) on a sufficiently flat grade to cause significant deposition
Three layer profile schematic	Some RUSLE2 templates include an overland flow path schematic having individual layers to represent cover-management, soil, and topography; used to graphically divide the overland flow path into segments to represent complex conditions
Tillage intensity	Degree that existing soil surface roughness affects roughness left by a soil disturbing operation
Tillage type	Identifies where a soil disturbing operation initially places buried residue in soil, also refers to how operation redistributes buried residue and dead roots
Time to soil consolidation	Time required for 95 percent of the soil consolidation effect to be regained following a soil disturbing operation
Topography	Refers to steepness along the overland flow path and the length of the overland flow path
Uniform slope	Refers to an overland flow path where soil, steepness, and cover-management along the overland flow path do not vary along flow path

Unit rainfall energy	Energy content of rainfall per unit of rainfall; function of rainfall intensity
Unit plot	Base condition used to determine soil erodibility; reference for effects of overland flow path steepness and length; cover-management, and support practices; continuous tilled fallow (no vegetation; tilled up and downhill, maintained in seedbed conditions; topographic, cover-management, support practice factor values equal 1 for unit-plot condition
USLE slope length and steepness	USLE slope length is distance to a concentrated flow (e.g., terrace or natural waterway) or to the location where deposition occurs; USLE soil loss is sediment yield from this length divided by length (mass/area); USLE steepness is steepness of the slope length, uniform steepness often assumed
Validation	Process of ensuring that RUSLE2 serves its intended purpose as a guide to conservation and erosion control planning.
Vegetation description	Information used by RUSLE2 to represent the effect of vegetation on erosion; includes temporal values in growth chart, flow retardance, and biomass-yield information; named and stored in the vegetation component of the RUSLE2 database
Verification	Process of ensuring RUSLE2 correctly solves the mathematical procedures in RUSLE2
Worksheet description	A form in RUSLE2 program; used to compare conservation and erosion control practices for a given site; used to compare erosion computer for profile descriptions; named and saved in the worksheet component of the RUSLE2 database

Rusle 2 Science Documentation

1. ABOUT RUSLE2

1.1. Introduction

The Revised Universal Soil Loss Equation, Version 2 (RUSLE2) is a computer program that estimates rill and interrill erosion by solving a set of mathematical equations (Toy et al., 2002). RUSLE2 makes estimates based on site specific conditions, which allows erosion control practices to be tailored to each specific site. The RUSLE2 user describes the site by making selections from the RUSLE2 database. RUSLE2 uses this information to compute its erosion estimates. The purpose of RUSLE2 is to serve as a guide to conservation and erosion control planning. RUSLE2 is land use independent and applies to all conditions where rill and interrill erosion occurs when mineral soil is exposed to the erosive forces of impacting raindrops and water drops falling from vegetation and runoff produced by Hortonian overland flow. RUSLE2 computes erosion and deposition along a single overland flow path. RUSLE2 also computes deposition in channels and small impoundments that end overland flow paths.

RUSLE2 has three major components. One component is the science component that includes the mathematical equations that RUSLE2 uses to compute erosion and deposition. Inputs to the equations are user selected to represent the four major factors that affect erosion at a specific site. Those factors are climate (determined by location), inherent soil properties including soil erodibility, topography, and land use.

The second major RUSLE2 component is the RUSLE2 database. The RUSLE2 user makes selections from the database to describe site-specific conditions. The database contains information that describes climate (weather) at various locations, soils, cover-management systems, vegetations, residues, operations, porous strips and barriers, flow interceptors including diversions and terrace channels and small impoundments, subsurface drainage systems, irrigation systems, overland flow paths, worksheets, and plan views (collections of overland flow paths). A single overland flow path is the basic RUSLE2 computational unit. Erosion can be compared in a worksheet for multiple erosion control alternatives for a single overland flow path or multiple overland flow paths. A plan view is used to compute erosion on overland flow areas in spatially complex landscapes.

The third major RUSLE2 component is the computer program. The program includes a powerful computational engine that organizes and solves the mathematical equations, database maintenance tools, and an interface (computer screen) that accepts user inputs and displays computed values.

The USDA-Agricultural Research Service had overall lead responsibility for developing RUSLE2 and lead responsibility for developing the science (i.e., mathematical equations used in RUSLE2). The University of Tennessee had lead responsibility for developing

the RUSLE2 computer program including its interface and computational engine. The USDA-Natural Resources Conservation Service had lead responsibility for developing user requirements as the principal RUSLE2 client and the RUSLE2 database for cropland. Other organizations developed database information, user guides, and instructional material for RUSLE2. For example, the University of Denver developed database information and other materials for application of RUSLE2 to construction sites, reclaimed mined land, landfills, and other highly disturbed lands.

This document describes the RUSLE2 science, which is primarily embodied in the mathematical equations used in RUSLE2 to compute erosion and deposition estimates.

1.2. Major requirements

The RUSLE2 erosion prediction technology was designed to meet several requirements, many of which affected RUSLE2's science and the equations. These requirements included:

1) Purpose of RUSLE2 is to serve as a guide to conservation and soil erosion control planning at the local field office level.

2) Be easy to use.

3) Be robust so that computed erosion values are not overly sensitive to small changes in variables where input values involve considerable uncertainty. Helps ensure good estimates when extrapolated beyond range of data used to derive RUSLE2.

4) Input values are physically meaningful to typical RUSLE2 users and directly measurable where possible.

5) Not require resources beyond those available at the field office level, especially for the USDA-Natural Resources Conservation Service that is the primary RUSLE2 user.

6) Produce useful information for conservation and erosion control planning that is consistent with the resources (i.e., expertise, time, effort, and other costs) required to implement and use RUSLE2.

7) Lead to desired conservation and erosion control planning decisions as expected based on available erosion research data, accepted erosion science, field experience, and professional judgment.

8) Apply to Hortonian overland flow where rill and interrill erosion is caused by mineral soil being exposed to the erosive forces of surface runoff and impacting waterdrops from rainfall and rainwater falling from vegetation.

9) Be land-use independent by using relationships based on the fundamental variables that affect erosion.

10) Produce accurate erosion estimates comparable to measured research values and estimated by the Universal Soil Loss Equation (USLE).

11) Be an evolution of the USLE and RUSLE1.

12) Be thoroughly and carefully reviewed and evaluated to ensure that RUSLE2 performs acceptably.

13) Recommendations on how to best apply RUSLE2 would be a part of the RUSLE2 development and documentation.

1.3. Major guiding principles used to develop RUSLE2 science

The following principles guided the development of the RUSLE2 science according to the requirements listed in **Section 1.2**.

1) The USLE is accepted in term of its conceptual basis, equation structure, empirical derivation, and computed values by both the scientific and user communities.

2) The USLE is valid (i.e., serves its intended purpose) for conservation and soil erosion control planning.

3) RUSLE2 development will start from the USLE structure and extend that structure and empirical derivation.

4) RUSLE2 will represent main effects that can be considered in the conservation and erosion control planning. These main effects are those established by empirical data and fundamental erosion science.

5) Erosion data available for empirically deriving RUSLE2 equations are very limited. The data set is small in relation to the many variables and their many complex interactions that affect erosion. The dataset is not a statistically robust data set because of non-uniform coverage of important variables. The data contain much unexplained variability that can not be resolved.

6) Equations will be chosen to best represent established main effects rather than using regression procedures to fit equations to data to provide the best overall statistical fit. Equations will be chosen based on main effects conclusively established by empirical data, fundamental erosion science, practical experience, professional judgment, and overall good judgment (common sense).

7) First establish mathematical relationships empirically using experimental data and then use process-based equations based on fundamental erosion science to extend the RUSLE2 beyond the available research data.

8) Start from a mean, typical, or accepted value consistent with the USLE unit-plot concept and use normalized variables to compute values that deviate about the

value for a base condition to capture main effects. Equations and limits will be selected to produce a robust erosion prediction technology.

9) Minimize use of geographic zones and variable classes to avoid step changes (discontinuities) between zones and classes.

10) Achieve land-use independence by having a single set of equations that vary as a continuous function of the major variables that affect erosion across all land uses.

11) Make judgments in the context of reasonableness and appropriateness for conservation and erosion planning and implementation. Do the results make good overall sense? If one had perfect knowledge, what would be the planning decision? RUSLE2 is a tool for conservation and erosion control planning, not a scientific product designed to produce new scientific knowledge and understanding.

2. BASIC MATHEMATICAL STRUCTURE

RUSLE2 computes values for the three fundamental erosion processes of detachment (sediment production), transport, and deposition.[1] The empirical equation form of the USLE is used to compute detachment while process-based equations are used to compute sediment transport and deposition. These equations, which are written for a point in time and a location on an overland flow path, are integrated in both time and distance to produce average annual and spatial estimates for segments along the overland flow path and for the entire overland flow path.

2.1. Detachment (Sediment Production) Equation

The USLE in its original form is:

$$A = RKLSCP \qquad [2.1]$$

where: A = average annual erosion rate (mass/area·year) for the slope length λ, R = erosivity factor (erosivity unit/area·year), K = soil erodibility factor (mass/ erosivity unit), L = slope length factor (dimensionless), S = slope steepness factor (dimensionless), C = cover-management factor (dimensionless), and P = support practice factor (dimensionless).[2] The USLE, equation 2.1, has two parts, the part that computes unit-plot erosion and the part that adjusts unit plot-erosion to represent actual field conditions. The part that computes unit-plot erosion is:

---

[1] Refer to the RUSLE2 User's Reference Guide for detailed explanations of RUSLE2 terms. Also, see **Glossary of Terms** section in this document.

[2] See List of symbols at end of this chapter.

$$A_u = RK \quad [2.2]$$

where: A_u = average annual erosion (mass/area·year) for the unit plot (mass/area·year).[3] The terms LSCP are normalized with respect to the unit plot and, therefore, have a value of 1 for unit plot conditions.[4] In effect, the USLE computes erosion for unit plot conditions with the product RK and then uses the terms LSCP to adjust the unit plot erosion to account for differences between unit plot conditions and actual field conditions.

Equation 2.2 is a temporal integration of the basic USLE equation that computes unit-plot erosion for individual storms as:

$$a_{us} = (EI_{30})K \quad [2.3]$$

where: a_{us} = the unit-plot erosion (mass/area) from the storm that has the rainfall erosivity EI_{30} (force·length/area)(length/time), E = rain storm energy (force·length/area), and I_{30} = average intensity (length/time) over the continuous 30 minutes with the most rainfall in the storm. The linear relationship between unit plot erosion and storm erosivity EI_{30} means that the erosivity factor R can be computed for a locations as:

$$R = \sum_{j=1}^{M_r} \sum_{m=1}^{M_{s(j)}} (EI_{30})_m \Big/ M_r \quad [2.4]$$

where: EI_{30} = storm erosivity for storm events greater than 0.5 inches (12 mm), $M_{s(j)}$ = the number of storms in the *jth* year, M_r = number of years in the record being used to compute erosivity.[5]

The linear relationship between erosion on the unit plot and erosivity mathematically means that average daily erosion can be computed as:[6]

$$a_u = rK \quad [2.5]$$

---

[3] The unit plot is 72.6 ft (22.1 m) long on a 9 percent slope, maintained in continuous fallow, tilled up and down hill to a seedbed condition periodically to control weeds and break crusts that form on the soil surface.

[4] The terms A_u, R, and K have dimensions and units. The terms LSCP are ratios of erosion from a given field condition to erosion for the unit-plot condition, and these terms are, therefore, dimensionless and have no units.

[5] See RUSLE2 User's Reference Guide for a detailed description of the computation of RUSLE2 erosivity values.

[6] Daily erosion computed by RUSLE2 is a long-term average erosion for that day.

where: a_u = daily erosion from the unit plot on the *ith* day and r = the average daily erosivity on the *ith* day. Average daily erosivity values are determined by the disaggregation of average monthly erosivity input values into daily values (see **Section 3.1**).

Although the terms LSCP vary with time as field conditions change, the cover-management factor C is the only one of these USLE terms that is mathematically integrated with time. An average annual representative value is selected for the other terms. The mathematical equation used in the USLE to compute erosion for a crop stage period is:

$$a_k = KLS \, \mathrm{Pr}_k \, c_k \qquad [2.6]$$

where: a, r, and c = the erosion, erosivity, and cover-management (soil loss ratio) factors, respectively, for the *kth* crop stage.[7] The erosivity for the *kth* crop stage is given by:

$$r_k = f_k R \qquad [2.7]$$

where: f_k = the portion of the average annual erosivity that occurs during the *kth* crop stage.[8] Therefore, the average annual cover management C factor in the USLE is computed as:

$$C = \left(\sum_{k=1}^{M_k} f_k c_k \right) \Big/ N_c \qquad [2.8]$$

where: M_k = the number of crop stages over the period of N_c years involved in the computation, such as years in a crop rotation or years after disturbance of a construction site, used to compute erosion.

The mathematics of the USLE equation structure, therefore, allows RUSLE2 to compute an average daily erosion as:

$$a = rklScp_p \, p_c \, p_d \qquad [2.9]$$

---

[7] A crop stage period is a time interval over which a constant soil loss ratio can be assumed. The soil loss ratio is the ratio of erosion with a given cover-management condition to the unit plot erosion for the same period, with all other conditions being the same between the two cover-management conditions.

[8] Erosivity varies during the year. The empirical curve that describes this temporal distribution is referred to as the EI distribution.

where: r = daily erosivity (erosivity unit/area·day), k = daily soil erodibility factor (mass/erosivity unit), l = daily slope length factor dimensionless, c= daily cover-management (soil loss ratio) factor (dimensionless), p_p = daily ponding subfactor (dimensionless), p_c = daily contouring subfactor (dimensionless), and p_d = daily subsurface drainage subfactor (dimensionless).[9] The average daily erosion computed by equation 2.9 is the average erosion (mass/area) for the slope length λ. All terms in equation 2.9 use average daily values except for the slope steepness factor that is assumed to be constant in RUSLE2 for all conditions except for variations in slope steepness.[10]

2.1.1. Equation for rill and interrill detachment combined

Equation 2.9 is converted to an equation that computes rill and interrill erosion combined at a point so that RUSLE2 can be applied to non-uniform overland flow paths where soil, steepness, and cover-management vary along the overland flow path. This equation is (Foster and Wischmeier, 1974):

$$D = (m+1) r k (x/\lambda_u)^m S c p_p p_c p_d \qquad [2.10]$$

where: D = average daily net detachment by both rill and interrill erosion (mass/area) at a point at the distance x from the origin of the overland flow path, λ_u = the unit plot length (72.6 ft, 22.1 m), and m = daily slope length exponent. The value for each term, except erosivity r, is the value for the term at the location x on the overland flow path.

2.1.2. Equation for interrill erosion

Interrill erosion is assumed to occur even when RUSLE2 computes deposition (see **Sections 2.3.1, 2.3.6, and 2.3.8**). The RUSLE2 equation for interrill erosion is:

$$D_i = 0.5 r k S_i c p_r p_c p_d \qquad [2.11]$$

where: D_i = daily interrill erosion (mass/area·day), and S_i = the slope steepness factor for interrill erosion. Equation 2.11 for interrill erosion is similar to equation 2.10 for rill and interrill erosion combined except that equation 2.11 has no distance (x) term, has a slope steepness factor specifically for interrill erosion, and has a 0.5 factor. The reason for not having a distance term is that detachment on interrill areas is caused by impacting

---

[9] RUSLE2 describes the effect of other support practices besides contouring on erosion. Those effects are described using process-based equations that compute deposition rather than a P factor value as in the USLE.

[10] Lower case symbols are used in equation 2.9 to distinguish between the daily factor values used in RUSLE2 and the average annual factor values used in the USLE. An upper case symbol is used for the slope steepness factor because a constant value is used in RUSLE2 that is equivalent to the USLE slope steepness factor value.

raindrops and waterdrops falling from vegetation. Detachment on interrill areas is assumed to be uniform along the overland flow path provided soil, steepness, or cover-management does not change along the overland flow path (Foster and Meyer, 1975; Foster et al., 1977a; Toy et al., 2002).

The slope steepness factor for interrill erosion differs from the slope steepness for rill erosion because the detachment forces produced by impacting waterdrops differ from the detachment forces produced by flow in rill areas. The interrill erosion slope steepness factor in equation 2.11 was empirically derived from experimental data (Lattanzi et al., 1974; Foster, 1982; McGregor et al., 1990). The slope steepness factor in the equation 2.10 represents the effect of slope steepness on rill and interrill erosion combined. The 0.5 factor in equation 2.11 results from the assumption that interrill erosion and rill erosion are equal for unit plot conditions (Foster and Meyer, 1975; Foster et al., 1977b; McCool et al., 1989).

2.1.3. Ratio of rill to interrill erosion

The slope length exponent m in equation 2.10 is a function of the ratio of rill to interrill erosion. RUSLE2 computes the slope length exponent m as (Foster et al., 1977b; McCool et al., 1989):

$$m = \beta/(1+\beta) \qquad [2.12]$$

where: β = ratio of rill to interrill erosion. The typical slope length exponent in the USLE is 0.5, which is the value computed by equation 2.12 when rill and interrill erosion are equal. The slope length exponent m computed by equation 2.12 varies about 0.5 as the ratio of rill erosion to interrill erosion varies about 1. The base condition for rill erosion equaling interrill erosion is for unit plot conditions.

The ratio of rill to interrill erosion is computed from:[11]

---

[11] Equations 2.11 and 2.13 illustrate an important design principle in RUSLE2. The terms that represent interrill erosion in equation 2.13 differ from those in equation 2.11 used to compute absolute interrill erosion, which seems inconsistent. The design philosophy in RUSLE2 is that RUSLE2 starts from accepted empirical values, which is 0.5 for the slope length exponent for unit plot conditions. Empirical values are used to the extent that they can be determined from experimental data, especially to represent main effects. The best possible empirical value is determined from the experimental data, and then the accepted empirical value is adjusted using process-based equations. The adjustment is up or down about the accepted empirical value, which is almost always a ratio in RUSLE2 because the LSCP variables are non-dimensional ratios. This approach of adjusting up or down about an accepted empirical ratio value rather than computing absolute values gives RUSLE2 increased robustness and avoids RUSLE2 giving seriously erroneous values when it is extrapolated. The ratio of rill to interrill ratio can be computed more accurately than can an absolute value for interrill erosion. The advantage of equation 2.11 is that it computes values that are close to erosion values computed by the USLE, which is a more conservative and robust approach than computing an absolute value of interrill erosion using variables from equation 2.13.

$$\beta = \left(\frac{K_r}{K_i}\right)\left(\frac{c_{pr}}{c_{pi}}\right)\left(\frac{\exp(-b_r f_g)}{\exp(-0.025 f_g)}\right)\left(\frac{s/0.0896}{3s^{0.8}+0.56}\right) \quad [2.13]$$

The ratio K_r/K_i = the inherent rill to interrill soil erodibility ratio (see **Section 4.3**), which is computed as a function of soil texture to reflect that some soils are inherently more susceptible to rill erosion than to interrill erosion than are other soils. The term c_{pr}/c_{pi} = the rill to interrill erosion ratio for prior land use soil erodibility (see **Section 6.2.2**), which reflects how soil consolidation and soil biomass affect rill erosion differently from how it affects interrill erosion. The ratio $\exp(-b_r f_g)/\exp(-0.025 f_g)$ reflects how ground cover affects rill erosion more than it affects interrill erosion, where b_r and 0.025 = coefficients (percent^{-1}) that express the relative effectiveness of ground cover for reducing rill erosion and interrill erosion, respectively (see **Section 6.2**), and f_g = ground cover expressed as a percent (see **Section 6.2.2**).

The term $(s/0.0896)/(3s^{0.8}+0.56)$ [where s = steepness of overland flow path (sine of slope angle)] reflects how steepness affects rill erosion differently than it does interrill erosion (Foster, 1982). This term assumes that rill erosion varies linearly with steepness.

The assumption in equation 2.12 that rill erosion varies with a slope length exponent of 1 (McCool et al., 1989) is consistent with the maximum slope length exponent of 1 observed in the experimental plot data used to derive the USLE [AH537 (Wischmeier and Smith, 1978)]. The maximum exponent of 1 is also consistent with the variation of erosion with discharge on steep slopes (Meyer et al., 1972) but is less than a value of 0.75 reported in other field research (Govers, 1991; McCool et al., 1989) where rill erosion is the dominant erosion process.

The slope length exponent base value is 0.5. Equation 2.12 increases or decreases this value as rill erosion increases or decreases relative to interrill erosion. The terms in equation 2.13 represent the main variables that affect rill erosion relative to interrill erosion.

Given that rill erosion varies with a slope length exponent of 1, the rill erosion term in equation 2.13 should have included a slope length term. The reason that a slope length term is not in equation 2.13 is because of mathematical limitations in devolving the USLE equation structure into rill and interrill erosion terms. If a slope length term had been included in equation 2.13, RUSLE2 could not have met the requirement that erosion computed for the entire overland flow path length be independent of how many overland flow path segments are used in the computations when other conditions are uniform along the overland flow path (see **Section 5.Appendix 1**).

2.2. Spatial and Temporal Integration

RUSLE2 requires both a spatial and temporal integration. The spatial integration is made by solving the governing equations along the overland flow path each day. Temporal integration is made by summing daily values to obtain totals for the computation

duration.[12] The average annual erosion is the sum of the daily values divided by the number of years (duration) in the computation.

If RUSLE2 were applied to only spatially uniform overland flow paths, equation 2.9 could be analytically solved for each day and the values summed to compute total erosion for a **rotation duration**. However, the solution is complex when soil, steepness, and cover-management vary along the overland flow path (i.e., spatially non-uniform overland flow paths), especially when deposition occurs.[13] RUSLE2 performs a spatial integration each day to compute daily spatially-distributed erosion, deposition, and sediment load values along the overland flow path. The spatial integration process in RUSLE2 is referred to as **sediment routing**, a common term used in hydraulic analyses.

2.3. Sediment Routing (Spatial Integration)

2.3.1. Continuity equation

The RUSLE2 governing equation that is spatially integrated is the steady state continuity (conservation of mass equation) given by (Foster, 1982):

$$dg / dx = D_i + D_{rorp} \qquad [2.14]$$

where: g = sediment load (mass/unit overland flow width·time), x = distance along the overland flow path from its origin, and D_{rorp} = either rill erosion rate (D_r) (mass/area· time) or deposition (D_p) (mass/area· time) by runoff in rill areas.

Equation 2.14 is solved numerically because it can not be analytically solved except for the special case of a uniform overland flow path where neither soil, steepness, nor cover-management vary along the overland flow path. RUSLE2 applies in the general case where any or all of these variables change along the overland flow path. The numerical solution requires that the overland flow path be divided into segments as illustrated in Figure 2.1 where the soil, steepness, and cover-management conditions are uniform over each segment. The numerical form of equation 2.14 for this computation is:

$$g_i = D_i\left(x_{(i)} - x_{(i-1)}\right) + \int_{x_{(i-1)}}^{x_{(I)}} D_{rorp}\,dx + g_{(i-1)} \qquad [2.15]$$

---

[12] Computation duration is the rotation duration (cycle length) for a **rotation** type cover-management description. The computation duration is the length of time specified for the duration of a no-rotation type cover-management description.

[13] RUSLE2 is much more powerful than the USLE because the USLE can not be applied to spatially non-uniform conditions that cause deposition (Foster and Wischmeier, 1974).

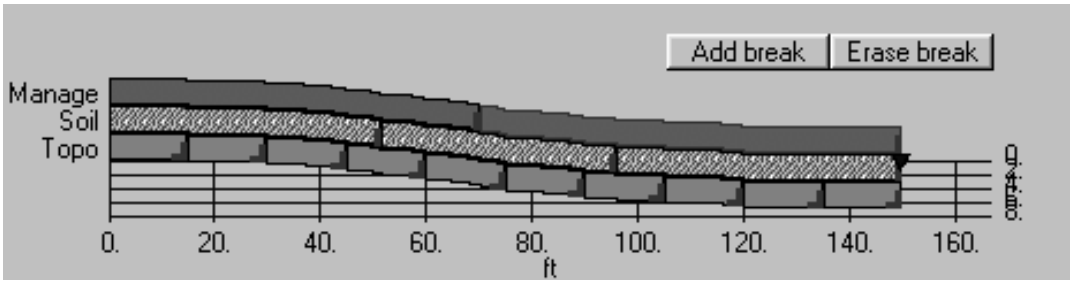

Figure 2.1. Schematic of the three layers that represent an overland flow path (a RUSLE2 hillslope(overland flow path) profile).

The lower and upper ends of the segment are delineated by $x_{(i)}$ and $x_{(i-1)}$, respectively, and the segment length is the difference $x_{(i)} - x_{(i-1)}$. Equation 2.12 is applied sequentially along the overland flow path starting at x = 0, which is the origin of the overland flow path. The incoming sediment load $g_{(i-1)}$ to the first segment at x = 0 is zero because no runoff enters at the origin of the overland flow path. The sediment load, g_{i-1}, entering the *ith* segment is known from the computation for the upslope *(i-1)th* segment. The sediment load g_i is the sediment load leaving the *ith* segment.

Rill and interrill erosion combined are computed with equation 2.10 rather computing interrill erosion and rill erosion separately as implied in equation 2.15. Equation 2.10 is solved analytically over the segment by assuming that soil, steepness, and cover-management are uniform over the segment. If deposition occurs, interrill erosion D_i is computed with equation 2.11 and the integral for deposition D_p is solved numerically (see **Section 2.3.6**).

The RUSLE2 assumption of uniformity within a segment causes step changes in input variables and certain computed variables where segments adjoin. Each soil, steepness, and cover-management variable is constant over a segment, but these variables make step changes at the common point between two segments. For example, the steepness values for two segments are not averaged to obtain a single steepness value at the intersection of two segments. Consequently, computed detachment and deposition values are discontinuous (i.e., step change) across segment intersections where soil, steepness, or cover-management changes between segments. However, runoff rate and sediment load are continuous at adjoining segment points. These step changes require sufficiently short segments to represent variables that vary continuously along the overland flow path. An example is a concave overland flow path (profile) where steepness continuously decreases from its upper end to lower end. A preliminary sensitivity analysis can be conducted to determine appropriate segment lengths for developing an erosion control plan for a specific site.

RUSLE2 could have been constructed to accommodate both step and continuous changes with distance. However, the benefits of representing both continuous and step changes were judged insufficient to merit the increased complexity in the equations, inputs, and programming for most RUSLE2 applications in erosion control planning. Step changes seem to occur more frequently than continuous changes in variables along an overland

flow path in most field situations. RUSLE2 represents these step changes, such as those associated with buffer strips and intersection of land slopes on construction sites.

2.3.2. Transport capacity-detachment limiting concept

RUSLE2 uses the transport capacity-detachment limiting concept to compute rill detachment or deposition (Foster et al., 1981a). The assumption is that rill erosion occurs where runoff transport capacity exceeds sediment load. Rill erosion is assumed not to be affected by the degree that sediment load fills runoff's sediment transport capacity, except where rill erosion would overfill transport capacity if rill erosion were to occur at its capacity rate. In this situation, rill erosion occurs at the rate that just fills transport capacity.[14]

A very important RUSLE2 assumption is that detachment and deposition by flow in rill areas at a location on an overland flow path can not occur simultaneously. Another important assumption is that both rill and interrill erosion are non-selective (Foster et al., 1985b). When rill and interrill detachment occur, the detached sediment contains all of the sediment classes having a distribution and size based solely on soil texture (see **Section 4.7**). That is, neither rill nor interrill detachment processes can "reach into the soil" and selectively remove sediment from particular sediment classes and not remove sediment from other particle classes. The basis of this assumption is that most soils are cohesive. Detachment is a process that separates soil particles from the soil mass by breaking cohesive bonds within the soil. This separation process produces sediment in all sediment classes because not all bonds in the soil are uniformly broken, much like striking a piece of concrete with a hammer produces a mixture of particles.[15]

Another important RUSLE2 assumption is that interrill erosion and deposition in rill areas occur simultaneously. When flow causes rill erosion, small incised channels are eroded. When deposition by runoff in rill areas occurs, the deposition is spread across the slope so that deposition covers the entire local area unless ridges are present (Toy et al., 2002). Therefore, a case can be made that no interrill erosion occurs on depositional areas, especially where deposition rates are high and flow is deep to protect the underlying soil surface from raindrop impact. However, even in these cases, deposition and water depths are quite spatially non-uniform, resulting in local areas that are not

---

[14] The concept of the interaction between rill erosion, sediment load, and transport capacity is valid, especially in ideal conditions and has advantages for RUSLE2 (Foster and Meyer, 1975; Foster, 1982). However, rill erosion in most field conditions is highly variable along rills where very intense local erosion occurs (e.g., at headcuts) and intervening areas of very low rill erosion. Because the hydraulic equations used in RUSLE2 do not represent this high degree of spatial non-uniformity, RUSLE2 can not adequately capture this important interaction.

[15] Soils can contain gravel that runoff does not transport. Conceptually, those particles are not assumed in RUSLE2 to be a part of the cohesive soil mass. The reason that gravel particles are not transported is that the runoff does not have sufficient transport capacity to move these particles. The effect of gravel and rock fragments on erosion is taken into account in RUSLE2 (see **Section 4.6**).

protected by deposited sediment or deep water. Also, many soil disturbing operations, such as tillage, leave surface roughness and ridges where soil protrudes above the flow and is directly exposed to interrill erosion. The RUSLE2 assumption is that interrill erosion and deposition by rill flow occurs simultaneously has the important benefit of allowing RUSLE2 to compute local deposition in soil surface roughness, furrows between ridges, and similar local roughness features.[16]

2.3.3. Basic deposition equation

RUSLE2 computes deposition when sediment load exceeds transport capacity using (Foster et al., 1981a; Foster, 1982):

$$D_p = (\alpha_d V_f / q)(T_c - g) \qquad [2.16]$$

where: D_p = deposition rate (mass/area·time), α_d = a deposition coefficient determined by calibration, V_f = fall velocity of the sediment in still water (length/time), q = overland flow (runoff) rate (volume/overland flow width·time) where flow depth is assumed to be uniform across the slope, T_c = transport capacity (mass/overland flow width·time). Equation 2.16 is solved for each sediment class (see **Section 4.7**). The distribution of the total transport capacity among the sediment classes is assumed to equal the distribution of the total sediment load among the classes. Equation 2.16 gives RUSLE2 its capability for computing deposition's selectivity where coarse, dense sediment is deposited more readily than fine, less dense sediment. The orders of magnitude variation in sediment fall velocity among the sediment classes is the major factor in computing selective deposition.

2.3.4. Sediment transport capacity equation

The RUSLE2 equation for sediment transport capacity of runoff in the rill areas is (Foster and Meyer, 1972; Foster and Meyer, 1975; Nearing et al., 1989, Finkner et al., 1989):

$$T_c = K_T \zeta q s \qquad [2.17]$$

where: the coefficient K_T coefficient for sediment transportability (mass/volume) and the ζ = coefficient for effect of hydraulic resistance on sediment transport capacity (dimensionless).

---

[16] Equation 2.11, which computes interrill erosion, actually computes sediment load delivered to rill flow rather than detachment on interrill areas. An improved approach is to use separate equations to compute detachment, deposition, and sediment transport on interrill areas, but that approach was judged to be too complex for RUSLE2. The RUSLE2 limitation regarding interrill erosion is that RUSLE2 does not compute sufficient enrichment of fines in the sediment although interrill erosion is appropriately computed. However, this limitation can be overcome by using the procedure described by Foster (1982) that can be used to compute distribution of sediment by sediment class delivered from interrill areas as a function of soil surface roughness.

A RUSLE2 assumption is that all sediment regardless of its composition is equally transportable, and therefore, a single value for sediment transportability is used in RUSLE2 (see **Section 4.7**). This assumption is questionable because the transportability of coarse sediment is much less than for fine sediment. Sediment transport capacity equations are available that could be used to vary sediment transportability as a function of sediment characteristics, but these equations were judged not to be sufficiently robust for RUSLE2 (Foster and Meyer, 1972; Alonso et al., 1981). For example, slight changes in fine sediment properties significantly affect overland flow's sediment transport capacity computed with sediment transport equations. Slight spatial variations in overland flow hydraulics that can not be described in RUSLE2 also dramatically affect overland flow's sediment transport capacity. Using a complex sediment transport equation is not warranted when RUSLE2 does not capture important details in describing flow hydraulics. Furthermore, the effect of sediment transportability is partially captured by RUSLE2's soil erodibility factor (see **Section 4.1**).[17]

A value for the transportability coefficient K_T was obtained by fitting RUSLE2 to experimental data where deposition occurred on a concave profile overland flow path (Foster et al., 1980c). Sediment transport capacity equals sediment load at the location where deposition begins. Values for K_T were adjusted until computed sediment transport capacity matched the measured sediment load at the location where deposition began in the field study. The K_T value was validated by computing deposition along on the same overland flow path used to determine the K_T value the point where deposition started. The K_T value was also validated by computing deposition for other laboratory and field experimental data (Foster et al., 1980; Neibling and Foster, 1982; Lu et al., 1988). Deposition was computed with RUSLE2 for a wide range of field conditions and those values were inspected for reasonableness and consistency with field observations (see the **RUSLE2 User's Reference Guide**).

The RUSLE2 calibrated value for K_T is 250,000 (lbs_m/ft^3). This value is based on the following set of units. T_c: $lbs_m/(sec \cdot ft\ width)$, ζ: dimensionless, q: $ft^3/(sec \cdot ft\ width)$, s: dimensionless.

The coefficient ζ represents the effect of hydraulic resistance on runoff's sediment transport capacity. This coefficient, which is the ratio of transport capacity with a hydraulic rough surface to transport capacity for a hydraulic smooth surface, varies from essentially 0 for a very hydraulic rough surface to 1 for a hydraulically smooth surface. Hydraulic resistance (roughness) is provided by soil surface roughness, ground cover (material in direct contact with the soil surface), and vegetation retardance. Flow over a soil surface applies a total shear stress. Part of the shear stress is applied to form

---

[17] RUSLE2 is a hybrid empirical/process-based model. Many of the variables and equations used in RUSLE2 are not nice and crisp where elemental properties and processes are described. For example, the RUSLE2 soil erodibility factor represents both detachability and transportability. RUSLE2 has been validated to ensure that it acceptably computes erosion over the vast majority of situations where RUSLE2 is applied. See the RUSLE2 User's Reference Guide for a discussion of RUSLE2's validation.

roughness (soil surface roughness, ground cover, and vegetation retardance) and the other part is applied to grain roughness (the individual soil particles and aggregates at the soil-flow interface). The shear stress exerted on grain roughness is assumed to be responsible for sediment transport (Foster et al., 1981a; Foster, 1982). The grain roughness shear stress decreases as form roughness increases, and consequently values for ζ decrease as form roughness increase (see **Section 3.4.1**). RUSLE2 computes a change in ζ, and thus sediment transport capacity, as cover-management conditions change.

2.3.5. Runoff

RUSLE2 uses flow rate values for runoff to compute sediment transport capacity (see **Section 2.3.4**), contouring effectiveness (see **Section 7.1**), and contouring failure (see **Section 3.4.3**). Discharge rate at a location along an overland flow path is computed with:

$$q = q_{(i-1)} + \sigma\left(x - x_{(i-1)}\right) \qquad [2.18]$$

where: q = discharge rate at the location x between the segment ends x_{i-1} and x_i, q_{i-1} = discharge rate at x_{i-1}, and σ = excess rainfall rate (rainfall rate minus infiltration rate) on the *ith* segment. Excess rainfall rate is computed using the NRCS runoff curve number method that computes runoff depth (see **Section 3.3.1.1**). The RUSLE2 assumption is that excess rainfall rate equals runoff depth divided by one hour. The difference between the two is accounted for in calibration coefficients including the K_T value for sediment transport capacity in equation 2.17. The RUSLE2 principle is to capture runoff's main effects sufficiently well for erosion control planning. RUSLE2 computes excess rainfall rate as a function of hydrologic soil group, surface roughness, ground cover, soil biomass, and soil consolidation to represent cover-management's effect on runoff.

In most cases, runoff rate q increases within each segment, where the rate of increase depends on infiltration within the segment. RUSLE2 computes a decreasing runoff rate within a segment if infiltration rate in the segment is sufficiently high (see **Sections 2.3.8.3.3 and 3.3.1.1**).

2.3.6. Numerical solution of deposition equation

The deposition equation (equation 2.16) combined with the continuity equation (equation 2.14) must be integrated to compute deposition over a segment of an overland flow path. RUSLE2 solves these equations numerically because an analytical solution was not found. Equations 2.15 and 2.16 along with an equation for transport capacity were written in discrete form for each sediment class as:

$$\frac{D_{pk(1)} + D_{pk(2)}}{2} = \frac{\alpha_d V_{fk}}{[(q_{(1)} + q_{(2)})/2]}\left(\frac{T_{ck(1)} + T_{ck(2)}}{2} - \frac{g_{k(1)} + g_{k(2)}}{2}\right) \qquad [2.19]$$

$$g_{k(2)} = g_{k(1)} + D_{ik}\Delta x + \left(\frac{D_{pk(1)} + D_{pk(2)}}{2}\right)\Delta x \qquad [2.20]$$

and

$$T_{ck} = (g_k / g)T_c \qquad [2.21]$$

where: D_{ik} = interrill erosion for the *kth* sediment class, D_{pk} = deposition rate of the *kth* sediment class, α_d = a deposition coefficient, V_{fk} = fall velocity for the *kth* sediment class, T_{ck} = transport capacity for the *kth* sediment class, T_c = the total sediment transport capacity for all sediment classes, g_k = sediment load for the *kth* sediment class, g = total sediment load, and Δx = the length of the distance step used in the numerical integration. The subscript (1) refers to the upstream end of the distance step and the subscript (2) refers to the downstream end of the distance step.

These equations are combined and solved for the deposition rate D_2, which is the only unknown, at the lower end of the distance step. The solution is by trial and error because a value for sediment transport capacity for a sediment class is not known until a value for the total sediment load is computed. The total sediment load can not be computed until sediment load is computed for each sediment class. The trial-and-error solution starts with the sediment load distribution computed in the previous distance step. This distribution is updated with each trial-and-error iteration until the total sediment load becomes stable.

An alternative approach and perhaps simpler approach is to numerically solve equations 2.15 as:

$$g_{k(2)} = D_{ik}\Delta x + \left(\frac{D_{pk(1)} + D_{pk(2)}}{2}\right)\Delta x + g_{k(1)} \qquad [2.22]$$

Substitution for D_2 using equation 2.14 in equation 2.22 gives:

$$g_{k(2)} = D_{ik}\Delta x + \left(\frac{D_{pk(1)} + (\alpha_d V_{fk} / q_2)(T_{ck(2)} - g_{k(2)})}{2}\right)\Delta x + g_{k(1)} \qquad [2.23]$$

Equation 2.23 is solved for the sediment load $g_{k(2)}$, the only unknown in equation 2.23, at the end of the distance step. A trial-and-error solution is also required for this procedure as well because transport capacity for a single sediment class computed with equation 2.21 depends on the total sediment load.

Regardless of the numerical procedure, the boundary condition must the determined for each segment (see **Section 2.3.8.2)**. This boundary condition is the deposition rate of each sediment class determined at the upper end of the *ith* segment to start the step by step solution of the equations. The deposition rate at the lower end of the *(i-1)th* segment can not be used as the boundary condition for the upper end of the *ith* segment because deposition values are not continuous at common points of segments. Deposition rates change stepwise at these points even though discharge rate and sediment load are continuous at these points. Steepness makes a step change at common segment points.

The deposition rate at the upstream end of the *ith* segment is computed from:

$$D_{puk(i)} = \left(\alpha_d V_{fk} / q_{(i-1)}\right)\left(T_{cuk(i)} - g_{k(i-1)}\right) \quad [2.24]$$

where: equation 2.24 is solved for each sediment class using sediment transport capacity computed for each class using equation 2.21. The sediment load $g_{k(i-1)}$ is the sediment load at the end of the upslope *(i-1)th* segment, which is the same as the sediment load at the upper end of the *ith* segment because sediment load is continuous along the overland flow path.

A value of 3 was determined by calibration for the deposition coefficient. Values for α_d were adjusted until the computed sediment distribution matched observed distributions for situations where deposition occurred (Foster et al., 1980c). This calibration coefficient is partly needed to adjust for runoff depth rather than excess rainfall rate being used to compute runoff rate.

The numerical procedure used to compute deposition must be carefully chosen so that computed values are not affected by arbitrary division of a segment. Segments by definition are uniform in soil, steepness, and cover-management. Dividing a portion of the overland flow path where conditions do not change into segments as illustrated in Figure 2.2 should not affect the detachment and erosion computations. Also, the computations for a segment must not be affected by downslope conditions, including overland flow path length beyond the segment.

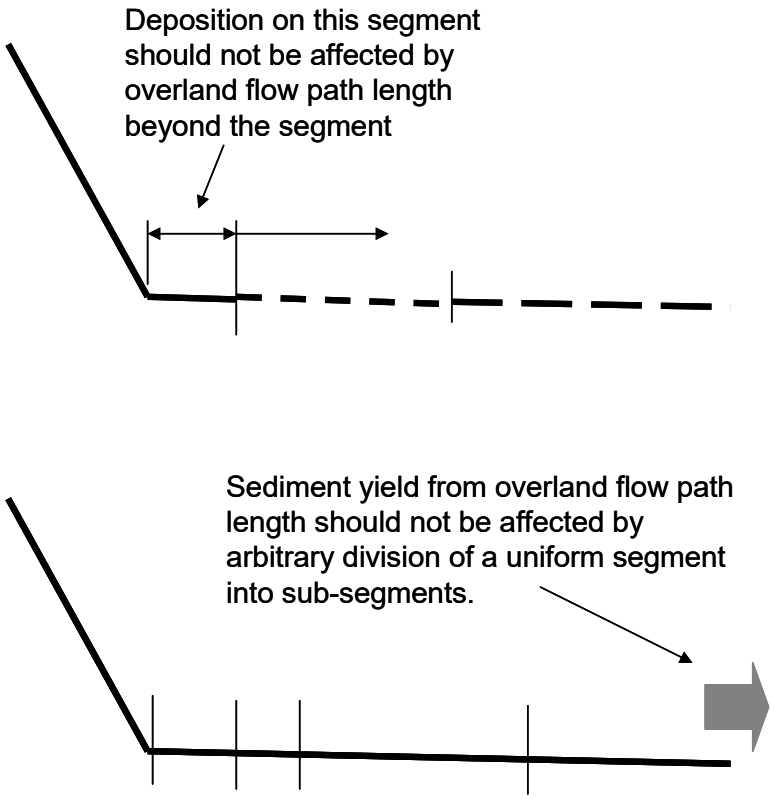

Figure 2.2. Situations where overland flow path lengths and segment divisions should have no effect on computed deposition.

The RUSLE2 procedure avoids these problems by dividing the entire overland flow path into a particular number of segments. The number of sub-segments used in RUSLE2 for an overland flow path length is 200. The sub-segments are only used in the segments having deposition. Thus, the density of sub-segments within a particular segment is the same for all segments. The number of sub-segments within a segment x_{i-1} to x_i is:

$$n_i = \left[\left(x_i - x_{i-1}\right)/\lambda_o\right] n_o \qquad [2.25]$$

where: n_i = an integer number of sub-segments within the *ith* segment, λ_o = the overland flow path length, and n_o = 200, the number of sub-segments for the entire overland flow path length. The length of the sub-segment Δx used in the numerical solution of the deposition equations is:

$$\Delta x = \left(x_{(i)} - x_{(i-1)}\right)/n_i \qquad [2.26]$$

These equations ensure that the end sub-segments within a particular segment begin and end on the segment ends.

A sensitivity analysis was conducted to determine how the sediment delivery ratio (sediment yield/sediment production) for an overland flow path like the ones in Figure

2.2 varied as a function of n_o, the number of sub-segment for the entire overland flow path length. The variation in sediment delivery ratio was about 5 percent as the number of sub-segments for the overland flow path length varied from 100 to 10,000. The value of 200 was chosen, which gives acceptable accuracy while minimizing computer run time.

2.3.7. Concept of a representative storm

Runoff is a key RUSLE2 variable used to compute erosion reduction by support practices including contouring, porous barriers, and flow interceptors and deposition on concave overland flow paths. The intent for using RUSLE2 as a guide to erosion control planning is that RUSLE2 compute the relative erosion control effectiveness of support practices by location. For example, support practices like contouring are less effective in the southern US than in the northern US because of differences in storm severity (Foster et al., 1997). RUSLE2 is calibrated to compute the effectiveness of support practices at the base Columbia, Missouri location. RUSLE2 compute the deviation in support practice effectiveness by the degree that climatic conditions at a specific location vary from those at the base Columbia, Missouri location. This approach gives RUSLE2 increased robustness.

RUSLE2 uses the 10 year (return period-frequency), 24 hour (storm duration) P_{10y24h} precipitation amount to capture the climatic variation by location to compute erosion control by support practices.[18] This precipitation variable is used as an index of storm severity. A more erosive storm than an average annual storm is used as a storm severity index because support practice effectiveness, especially for contouring, depends on storm severity (Foster et al., 1997). For example, contouring can greatly reduce erosion for small storms but fail completely for large storms.

The effect of support practices and concave overland flow path profile shape on erosion and deposition depends much more on runoff than the combination of raindrop impact and runoff. RUSLE2 uses a representative storm in process-based equations to compute runoff that in turn is used to compute deposition. The daily erosion and deposition values computed with this representative storm are scaled to match the daily detachment values computed with equation 2.10 (**see Section 2.3.9**). The same representative storm is used in the process-based equations for each day, but the computed daily runoff values vary as cover-management conditions change daily. The representative storm is used as an index for storm severity at a location. The intent is not to compute actual runoff on each day but to compute runoff values that show the how relative effectiveness of support practices and concave overland flow path profiles changes daily for the index storm. The index storm captures main-effect differences between locations. RUSLE2 computes comparable P-factor type effects for each day rather than using a single temporally constant P factor value like the USLE and RUSLE1.

---

[18] The 10 year-24 hour precipitation procedure used in RUSLE2 is a replacement for the 10 year EI procedure used in RUSLE1.

RUSLE2 also computes an erosivity value for the P_{10y24h} index storm in addition to runoff. The storm erosivity r_{10y24h} for the 10 year-24 precipitation amount P_{10y24h} is computed from:

$$r_{10y24h} = 2\gamma_m P_{10y24h} \quad [2.27]$$

where: γ_m = the maximum monthly erosivity density at the location. Monthly erosivity density is the ratio of average monthly erosivity to average monthly precipitation amount (see **Section 3.2.1.4.1**).

2.3.8. Solving the sediment routing equations segment by segment

The sediment routing equations are solved using the value for the 10 year-24 hour precipitation amount P_{10y24h} used as an index storm. Although the same storm is used each day, computed sediment load changes daily as cover-management conditions temporally change. Daily sediment load values computed using the representative index storm are scaled to compute daily sediment load values appropriate for the daily erosivity values (see **Section 2.3.9**).

2.3.8.1. Inconsistency between slope effect in detachment and sediment transport capacity equations

Inconsistencies occur between the empirical detachment equation (equation 2.10) and the process-based sediment transport capacity equation (equation 2.17) because of differences in the steepness terms in the equations. The steepness effect in equation 2.10 for detachment is a two piece linear equation (see **Section 5.6**), whereas the steepness effect in equation 2.17 for sediment transport capacity is a single linear term. Equations 2.10 and 2.17 are calibrated to be close at the unit-plot nine percent steepness. However, the steepness effect in equation 2.10 can exceed the steepness effect in equation 2.17 at both flat and steep slopes depending on values for the other terms in the equations. Although equation 2.10 is generally assumed to represent detachment limiting conditions in RUSLE2, this empirical equation reflects a mixture of both detachment and transport capacity limiting at low steepness. The assumption used to deal with this and other similar inconsistencies that occur between the empirical USLE formulation and the process-based equations is that RUSLE2 gives the empirical USLE erosion estimate for uniform overland flow paths.[19]

The inconsistencies between these two steepness effects could not be reconciled for non-uniform overland flow paths at low steepness, but RUSLE2 was very carefully evaluated to ensure that the inconsistencies have little effect in conservation planning.

---

[19] These inconsistencies could be eliminated by developing RUSLE2 so that it uses all process-based equations rather than combining the empirical USLE equation with process-based equations. However, the RUSLE2 hybrid approach combines the best of the empirical USLE approach with the best of the process-based approach (see **Section 1.2 and 1.3**).

2.3.8.2. Boundary values

Boundary values must be determined for each segment to solve the sediment routing equations. The equations are solved sequentially starting with the first segment at the origin of the overland flow path and then moving downslope segment by segment. The computed values for runoff and sediment load at the end of the last segment become boundary values for the next segment. The major boundary values for the first segment at x = 0 is that no inflow of either runoff or sediment occurs (i.e., $q_0 = 0$ and $g_0 = 0$).

2.3.8.3. Special boundary conditions cases

Five special cases were used to organize the sediment routing computations and to set boundary values.

2.3.8.3.1. Case 1: First segment

The first segment is a special case because of the no-inflow boundary condition and because the sediment load leaving this segment must equal the sediment load computed by the USLE (i.e., equation 2.10), (assuming the RUSLE2 factor values are used in the USLE). The first segment directly matches the USLE uniform slope assumptions.

Many RUSLE2 conservation and erosion control planning applications involve a uniform overland flow path. In these situations, RUSLE2 uses a single uniform overland flow path segment and only the equations for the Case 1: First Segment special case in its sediment routing computations.

An important logic check for the first segment is to determine if local deposition is computed within the segment. RUSLE2 computes no deposition if the rate of increase in sediment transport capacity with distance dT_c/dx is greater than the interrill erosion rate D_i within the first segment. The rate of increase in transport capacity in the first segment is computed as:

$$dT_c / dx = K_T \zeta \sigma s \qquad [2.28]$$

Excess rainfall rate σ is computed using the 10 year-24 hour representative storm P_{10y24h} and the interrill erosion rate D_i is computed with equation 2.11 using the representative (index) storm erosivity r_{10y24h} (see **Section 3.2.4**).

2.3.8.3.1.1. $dT_c/dx > D_i$ - No local deposition

RUSLE2 computes no local deposition in the first segment when the rate of increase in sediment transport capacity with distance dT_c/dx is greater than the interrill erosion rate D_i. No local deposition occurs because runoff's sediment transport capacity is sufficient to transport the sediment load produced by interrill erosion. The interrill erosion rate $D_{i10y24h}$ in the first segment is computed using the erosivity r_{10y24y} value computed with equation 2.27 for the P_{10y24h} representative storm. In that case, the sediment load leaving

the segment is given by equation 2.15 after rill and interrill erosion are combined into a single term as:[20]

$$g = r_{10y24h} k S c p_p p_c p_d x_{(1)}^{m_i+1} / \lambda_u^{m_i} \quad [2.29]$$

where: g = the total sediment load for all sediment classes and $x_{(1)}$ = distance to downstream of the first segment.[21] The sediment load g_k of each sediment class at the end of the first segment is given by:

$$g_k = \psi_k g \quad [2.30]$$

where: ψ_k = sediment mass in the *kth* sediment class (fraction). This special case is detachment limiting. Therefore, the distribution of sediment classes in the sediment load at the end of segment 1 for Case 1 where $dT_c/dx > D_i$ equals the distribution of the sediment classes at the point of detachment (see **Section 4.7.5**). The enrichment ratio is one (1) for this case because no deposition is computed (see **Section 4.7.6**).

2.3.8.3.1.2. $dT_c/dx < D_i$ - Local deposition occurs

When the interrill erosion rate D_i within the first segment exceeds the rate of increase in transport capacity with distance dT_c/dx, local deposition is computed. Even though local deposition is computed, equation 2.29 is used to compute sediment load at the end of the first segment to ensure that RUSLE2 gives the USLE result for the first segment. However, local deposition enriches the sediment in fines. RUSLE2 computes quasi-deposition and -sediment load values to estimate the distribution of the sediment classes for the sediment leaving the first segment. The sole purpose of this computation is to obtain the sediment distribution; this computation does not affect the value computed for sediment load at the end of the first segment, which is computed with equation 2.29.

Equations 2.14, 2.16, 2.17, and 2.18 were solved in closed form to compute the quasi-deposition and -sediment load values in segment 1 (Renard and Foster, 1983). The equation used to compute deposition is:

---

[20] The units for sediment load depend on the units used for erosivity r, soil erodibility k, distance x, and length λ_u. For example, in the US customary units system for the USLE, the typical units for sediment load g would be ($tons_m$/acre·day)·ft. These set of units are multiplied by (2000 lbs_m/ton)/(43560 ft^2/acre) to obtain a consistent set of units of lbs for mass and ft for length. In RUSLE2, erosion values are computed for each day using a daily erosivity value (see **Sections 2.1 and 3.1**), which is the reason for the day unit in sediment load. The sediment amount values have mass units. In the US customary USLE units, lbs-mass and lbs-force are equal. In the SI system, kg is the recommended unit for sediment mass, although the output would likely be displayed in metric tonnes. See AH703 (Renard et al., 1997) for additional discussion of USLE/RUSLE units.

[21] Equation 2.29 is the USLE equation form when the slope length λ is substituted for x_i and the equation is divided by slope length λ to compute average erosion for the slope length.

$$D_{qk} = \left[\left(a_d V_{fk} / \sigma\right)/\left(1 + a_d V_{fk} / \sigma\right)\right]\left[\left(dT_c / dx - D_i\right)\psi_k\right] \quad [2.31]$$

$$g_{qk} = \psi_k T_c - qD_{qk} / \left(a_d V_{fk}\right) \quad [2.32]$$

$$q = \sigma x_{(1)} \quad [2.33]$$

$$T_c = K_T \zeta q s \quad [2.34]$$

where: D_{qk} and g_{qk} are the quasi-deposition and -sediment load variables used specifically to compute the distribution of the sediment load among the sediment classes for the first segment when local deposition occurs and $x_{(1)}$ = the distance to the end of the first segment. The subscript k refers to sediment class. Equations 2.31-2.34 are solved for each sediment class. The fraction of the sediment load in each sediment class for the sediment load at the end of the first segment is computed as:

$$\omega_k = g_{qk} / \sum_{k=1}^{5} g_{pk} \quad [2.35]$$

where: ω_k = the portion of the total sediment load leaving the first segment that is composed of sediment in the *kth* sediment class and 5 is the number of sediment classes used in RUSLE2. The sediment load in each sediment class at the end of the first segment is computed as:

$$g_k = \omega_k g \quad [2.36]$$

The enrichment ratio for the sediment at the end of the first segment is greater than 1 based on the portion of the interrill erosion that RUSLE2 computes as deposited in the first segment. Enrichment ratio is based on specific surface area of the sediment (see **Section 4.7.6**).

2.3.8.3.2. Case 2: Detachment over entire segment

Two boundary conditions must be met for detachment to be computed over an entire segment. The incoming sediment load at the upper end of the segment must be less than transport capacity at the upper end of the segment. The mathematical condition for this check is that $g_{i-1} < T_{cu(i)}$ where $T_{cu(i)}$ = transport capacity at the upstream end of the *ith* segment. This transport capacity is computed using the runoff discharge rate q_{i-1}, the slope steepness s_i, and sediment transport capacity coefficient ζ_i for the ith segment. Therefore, transport capacity at the upstream end of the *ith* segment $T_{cu(i)}$ does not equal the transport capacity $T_{cl(i-1)}$ at the downstream end of the *(i-1)th* segment if steepness and/or cover-management changes between the segments.

The second condition is that the potential sediment load at the end of the segment computed as the sum of the incoming sediment load plus the sediment produced by interrill erosion within the segment is less than the transport capacity at the lower end of the segment. This potential sediment load is computed as:

$$g_{p(i)} = g_{(i-1)} + D_{i(i)}\left(x_{(i)} - x_{(i-1)}\right) \quad [2.37]$$

where: g_p = potential sediment load. The boundary condition is that this potential sediment load be less than transport capacity at the downstream end of the segment, i.e., $g_{p(i)} < T_{cl(i)}$.

2.3.8.3.2.1. Sediment load when rill erosion occurs at capacity rate

A subsequent check must also be made to determine if rill erosion can occur at its capacity over the segment. A second potential sediment load is computed as:

$$g_{p(i)} = g_{(i-1)} + r_{10y24h} k_{(i)} S_{(i)} c_{(i)} p_{p(i)} p_{c(i)} p_{d(i)} \left(x_{(i)}^{m_i+1} - x_{(i-1)}^{m_i+1}\right) / \lambda_u^{m_i} \quad [2.38]$$

where rill erosion is assumed to occur at its capacity rate. If this potential sediment load is less than sediment transport capacity at the lower end of the segment, rill erosion is assumed to occur at its capacity rate and the sediment load leaving the segment is given by equation 2.38.

The distribution of the sediment load among the sediment classes is computed by:

$$g_{k(i)} = g_{k(i-1)} + \psi_k \left(g_{(i)} - g_{(i-1)}\right) \quad [2.39]$$

which results from detachment being non-selective.[22] That is, the distribution of the sediment added within the sediment load, $g_{(i)} - g_{(i-1)}$, is assumed to be the same as sediment at the point of detachment.

2.3.8.3.2.2. Sediment load when rill erosion at less than capacity rate

If potential load computed by equation 2.39 exceeds the transport capacity at the downstream end of the segment, rill erosion is limited to the rate that will just fill transport capacity, which means that sediment load at the end of the segment is given by:

$$g_{(i)} = T_{Cl(i)} \quad [2.40]$$

Even though rill erosion is not computed at its capacity rate, some rill erosion is computed, and, therefore, no local deposition is computed. The distribution of the sediment load at the end of the segment is given by equation 2.39.

---

[22] Sediment characteristics at the point of detachment change as soil texture changes by segment. RUSLE2 starts at the first segment with the five sediment classes for that segment based on soil texture. RUSLE2 adds sediment classes to represent soil texture changes in the segments along the overland flow path.

2.3.8.3.3. Case 3: Detachment on upper portion of segment, deposition on lower portion of segment

An example where detachment occurs on the upper portion of a segment and deposition occurs on the lower portion of the segment is illustrated in Figure 2.3. Infiltration rate on the *ith* (second) segment is greater than the rainfall rate, which causes the runoff rate to decrease within the segment. Sediment load increases within the segment while sediment transport capacity decreases within the *ith* segment. Deposition begins at the point where sediment load equals transport capacity.

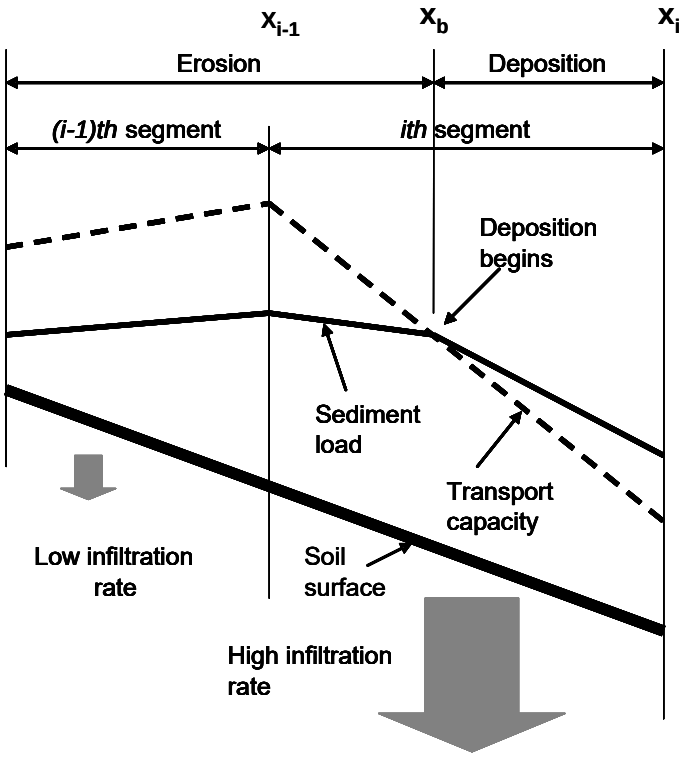

Figure 2.3. Illustration where detachment ends and deposition begins within the ith segment

Two conditions must be met for this case. The first condition is that the incoming sediment load is less than sediment transport capacity at the upstream end of the segment, i.e., $g_{(i-1)} < T_{cu(i)}$. The second condition is that the potential sediment load at the lower end of the segment computed with equation 2.37 is greater than the transport capacity at the downstream end of the segment.

When this condition is met, deposition begins at the location where the sediment load equals transport capacity. The sediment load where deposition begins is given by:

$$g_b = g_{(i-1)} + D_{i(i)}\left(x_b - x_{(i-1)}\right) \qquad [2.41]$$

where: g_b = sediment load at the location x_b = where deposition begins. The sediment transport capacity T_{cb} where deposition begins is given:

$$T_{cb} = K_T \zeta_{(i)} s_{(i)} \left\lfloor q_{(i-1)} + \sigma_i \left(x_b - x_{(i-1)} \right) \right\rfloor \quad [2.42]$$

where: σ = the excess rainfall rate (rainfall rate minus infiltration rate).[23] Equations 2.41 and 2.42 are combined and solved to determine a value for the location x_b where deposition begins.

The sediment load by sediment class at the location where deposition begins is given by:

$$g_{bk} = g_{k(i-1)} + \psi_k \left(g_b - g_{(i-1)} \right) \quad [2.43]$$

Deposition is computed on the portion of the segment from x_b to x_i using equations 2.19-2.21. The main boundary values are that deposition rate is zero and sediment load equals sediment transport capacity at $x = x_b$. These equations compute values for total sediment load and sediment load for each sediment class at the lower end of the segment.

2.3.8.3.4. Case 4: Deposition over entire segment

Figure 2.4 illustrates deposition occurring over an entire segment. In this case, the width of the vegetation strip is so narrow that sediment transport capacity does not increase within the strip to where it exceeds sediment load. The first boundary condition for this case is that the incoming sediment load is greater than sediment transport capacity at the upper end of the segment. The second condition is that the interrill erosion rate D_i within the segment is greater than the increase in sediment transport capacity with distance dT_c/dx within the segment. This boundary condition is the same as the incoming sediment load plus sediment production by interrill erosion within the segment being greater than sediment transport capacity at the lower end of the segment.

Equation 2.24 is used to compute the deposition rate at the upper end of the segment, which is a boundary value along with the incoming discharge rate $q_{(i-1)}$ and sediment load $g_{(i-1)}$ from the immediate upslope segment. These boundary values are used in equations 2.19-2.21 to compute deposition within the segment and values for total sediment load and sediment load by sediment class at the lower end of the segment.

---

[23] Excess rainfall rate is negative for situations where RUSLE2 computes a decreasing runoff rate within a segment (see **Section 3.3.1.1**).

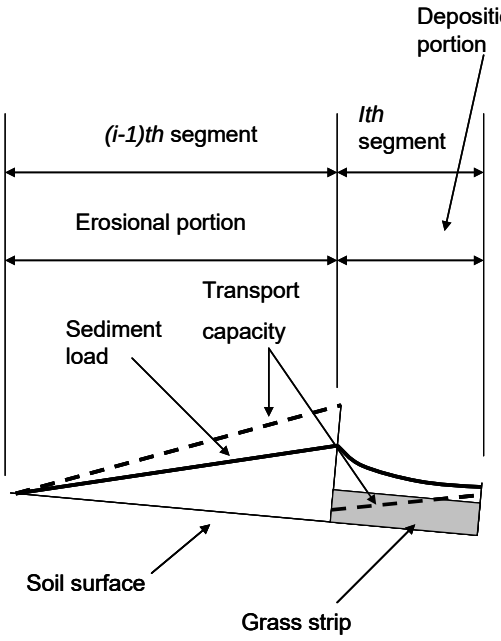

Figure 2.4. Narrow grass where deposition occurs over entire segment

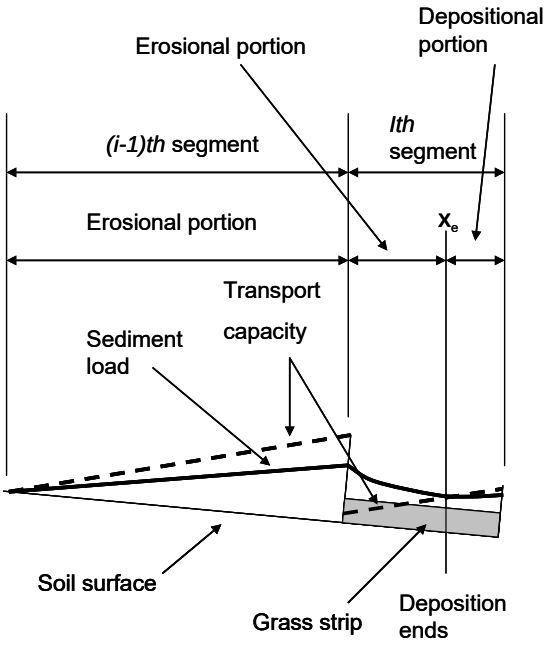

Figure 2.5. Grass strip sufficiently wide that deposition ends within segment and erosion occurs on lower portion of segment

2.3.8.3.5. Case 5: Deposition over upper part of segment, detachment over lower part of segment

Figure 2.5 illustrates deposition ending within a segment. Another example of deposition ending within a segment is illustrated in Figure 2.2 provided the segment is sufficiently long. As discussed in **Section 5.3**, RUSLE2 assumes that segments are discontinuous, even when used to represent a smooth, continuous concave overland flow path profile. The result is that RUSLE2 computes deposition on the upper portion of the segment and detachment on the lower portion of the segment if the segment is sufficiently long. This result is opposite from that for a smooth, continuously decreasing slope steepness where detachment occurs on the upper portion of the segment and deposition occurs on the lower portion of the segment where deposition begins. The error from not properly computing the location of the deposition is minimized by choosing short segment lengths to represent smooth, continuous overland flow path profiles.

The first boundary condition is that incoming sediment load is greater than the transport capacity at the upper end of the segment. The second boundary condition is that the incoming sediment load plus the sediment produced by interrill erosion within the segment is less than the transport capacity at the lower end of the segment. This boundary condition is the same as the boundary condition that the rate of increase in transport capacity with distance dT_c/dx is greater than the interrill erosion rate D_i within the segment. These boundary conditions are required but are not sufficient to determine

that deposition ends within the segment if the segment length is short. The location x_e where deposition ends within the segments is determined by solving equations 2.19-2.21 and 2.24. Deposition ends at the location where computed deposition rate becomes zero. These equations compute the total sediment load g_e and the sediment load of each sediment class $g_{e(k)}$ at the location that deposition ends.

Detachment occurs on the lower portion of the segment. The potential sediment load at the end of the segment is computed from:

$$g_{p(i)} = g_e + r_{10y24h} k_{(i)} S_{(i)} c_{(i)} p_{p(i)} p_{c(i)} p_{d(i)} \left(x_i^{m_i+1} - x_e^{m_i+1} \right) / \lambda_u^{m_i} \qquad [2.44]$$

This potential sediment load is checked against sediment transport capacity at the lower end of the segment. If the sediment transport capacity at the lower end of the segment exceeds this sediment load, then the sediment load leaving the segment is the potential sediment load computed by equation 2.44, i.e, $g_{(i)} = g_{p(i)}$. However, if the potential sediment load computed with equation 2.44 exceeds the transport capacity at the end of the segment, then rill erosion is limited to the rate that will just fill sediment transport capacity. In that case, the sediment load at the end of the segment equals sediment transport capacity at the lower end of the segment, i.e., $g_{(i)} = T_{cl(i)}$.

The sediment load for each sediment class at the end of the segment is given by:

$$g_{k(i)} = g_{ek} + \psi_k \left(g_{(i)} - g_e \right) \qquad [2.45]$$

2.3.9. Scaling values computed with representative storm to create daily values

The daily sediment load values computed using the sediment routing equations and the representative storm P_{10y24h} must be scaled to compute daily sediment load values appropriate for the daily erosivity values. This scaling factor is computed as the ratio of sediment load computed at the end of each segment with the sediment routing equations and the sediment load at the lower end of each segment that would be produced if detachment occurs at detachment capacity for the representative storm. That sediment load g_{detcap} is computed as:

$$g_{\det cap(i)} = r_{10y24h} k_{(i)} S_{(i)} c_{(i)} p_{p(i)} p_{c(i)} p_{d(i)} \left(x_{(i)}^{m_i+1} - x_{(i-1)}^{m_i+1} \right) / \lambda_u^{m_i} \qquad [2.46]$$

The scaling factor δ_i for each *ith* segment is computed as:

$$\delta_{(i)} = g_{(i)} / g_{\det cap(i)} \qquad [2.47]$$

A sediment load based on detachment capacity comparable to $g_{detcap(i)}$ is computed using daily values for erosivity and the other factors as:

$$g_{daily\,\det cap(i)} = r k_{(i)} S_{(i)} c_{(i)} p_{p(i)} p_{c(i)} p_{d(i)} \left(x_{(i)}^{m_i+1} - x_{(i-1)}^{m_i+1} \right) / \lambda_u^{m_i} \qquad [2.48]$$

where: $g_{dailydetcap(i)}$ = daily sediment load at end of *ith* segment that would be produced if full detachment occurred in each segment, r = the daily erosivity value determined from the disaggregation of the monthly erosivity values (see **Section 3.1**), and all of the other values in equation 2.48 are the same daily values used in the sediment routing equations.

The daily sediment load value is computed as the product of this daily detachment sediment load and the sediment load scaling factor as:

$$g_{daily(i)} = \delta_{(i)} g_{daily\,\det cap(i)} \qquad [2.49]$$

where: $g_{daily(i)}$ = average daily sediment load at the end of the *ith* segment. The average daily net erosion rate $D_{daily(i)}$for the *ith* segment is computed as:

$$D_{daily(i)} = \left(g_{daily(i)} - g_{daily(i-1)}\right) \Big/ \left(x_{(i)} - x_{(i-1)}\right) \qquad [2.50]$$

2.3.10. Computing average annual erosion values for conservation and erosion control planning[24]

RUSLE2 computes average annual values for four variables used in conservation and erosion control planning. These variables are: (1) average annual erosion rate for the entire overland flow path (sediment yield from the overland flow path), (2) average annual detachment rate for the entire overland flow path, (3) average annual erosion rate for the eroding portion of the overland flow path, and (4) an average annual conservation planning soil loss for the overland flow path that gives partial credit to deposition as soil saved.

2.3.10.1. Average annual erosion rate for entire overland flow path (sediment yield)

The average annual erosion rate for the entire overland flow path is the ratio of the average annual sediment amount leaving the overland flow path divided by the overland flow path length. The sediment load at the end of the last segment on the overland flow path is also known as sediment yield or sediment delivery from the overland flow path.

The average annual sediment load at the end of the overland flow path is given by:

$$G_{\lambda} = \left(\sum_{j=1}^{J_d} g_{daily\lambda(j)} \right) \Big/ M_d \qquad [2.51]$$

where: G_{λ} = the average annual sediment load (i.e., sediment yield, sediment delivery) at the end of the overland flow path, $gdaily\lambda_{(j)}$ = the daily sediment load at the end of the overland flow path on the *jth* day, M_d = the number of years in the computation period

---

[24] See the RUSLE2 User's Reference Guide for detailed information on these variables and how they are used in conservation and erosion control planning.

(duration entered in cover-management description, see **Section 2.2**), and J_d = the total number of days in the computation period (i.e., $J_d = 365 \cdot M_d$). The subscript n refers to each day in the computation period and the subscript I is the index value of the last segment used to describe the overland flow path.

The average annual erosion rate (sediment yield, sediment delivery) for the overland flow path is given by:

$$A_{sedyld} = G_\lambda / \lambda_o \qquad [2.52]$$

where: A_{sedyld} = the average annual erosion rate for the overland flow path length, λ_o.

2.3.10.2. Average annual detachment rate (sediment production) for entire overland flow path

The average annual detachment rate for the entire overland flow path represents a measure of total sediment production on the overland flow path. This variable is a measure of local erosion and sediment that has been moved away from its local point of origin. RUSLE2 computes detachment on each segment in its sediment routing computations and a sediment load value based on detachment. That sediment load is given by:

$$g_{\det(i)} = g_{\det(i-1)} + D_{i(i)}\left(x_{(i)} - x_{(i-1)}\right) + \Delta g_{r(i)} \qquad [2.53]$$

where: g_{det} = the sediment load produced by detachment at the lower end of the *ith* segment and ΔG_r = the sediment amount produced by rill erosion within the segment. Interrill erosion D_i is assumed to occur over an entire segment regardless of whether deposition occurs. If deposition does not occur, rill detachment occurs. Rill detachment in each segment is computed as described for each of the special cases in **Section 2.3.8.3**.

The average annual sediment load produced by detachment at the end of the overland flow path is given by:

$$G_{\det\lambda} = \left(\sum_{j=1}^{J} g_{\det\lambda(j)}\right) \Big/ M_d \qquad [2.54]$$

where: $G_{det\lambda}$ = the average annual sediment load at the end of the overland flow path. The average annual detachment rate for the entire overland flow path is given by:

$$A_{\det} = G_{\det\lambda} / \lambda_o \qquad [2.55]$$

where: A_{det} = the average annual detachment rate for the entire overland flow path.

2.3.10.3. Average annual erosion rate for eroding portions of the overland flow path

The average annual sediment load is computed for each segment as:

$$G_{(i)} = \left(\sum_{j=1}^{J_d} g_{daily(i,j)} \right) \Big/ M_d \qquad [2.56]$$

The average annual erosion rate for each segment is given by:

$$D_{aseg(i)} = \left(G_{(i)} - G_{(i-1)}\right)/(x_{(i)} - x_{(i-1)})/\left(x_{(i)} - x_{(i-1)}\right) \qquad [2.57]$$

where: $D_{aseg(i)}$ = the average annual erosion rate for the *ith* segment. Positive values for $D_{aseg(i)}$ values indicate net erosion and negative values indicate deposition. The eroding portions of the overland flow path are the segments where $D_{aseg(i)}$ is positive. The value for average annual erosion rate for the eroding portions of the overland flow path is computed as:

$$A_{erod} = \left[\left(G_{(l1)} - G_{(u1)}\right) + \left(G_{(l2)} - G_{(u2)}\right) + \left(G_{(l3)} - G_{(u3)}\right) + \ldots\right] / \qquad [2.58]$$

$$\left[\left(x_{(l1)} - x_{(u1)}\right) + \left(x_{(l2)} - x_{(u2)}\right) + \left(x_{(l3)} - x_{(u3)}\right) + \ldots\right]$$

where: A_{erod} = average annual erosion rate for the eroding portions of the overland flow path, the subscript l refers to the downstream end of an eroding portion of the overland flow path, the subscript u refers to the upstream end of an eroding portion of the overland flow path, and the subscript 1, 2, 3, and ... refers to individual eroding portions of an overland flow path.

2.3.10.4. Conservation planning soil loss

The conservation planning soil loss variable gives partial credit for remote deposition as soil saved. The credit that is given to remote deposition along an overland flow path as soil saved is computed as (Foster et al., 1997):[25]

$$b_{d(i)} = 1 - \left(x_{du(i)} / \lambda_o\right)^{1.5} \qquad [2.59]$$

where: $b_{d(i)}$ = the fraction of the deposition in the *ith* segment that is credited as soil saved (i.e., deposition benefit) and $x_{du(i)}$ = the location of the upper edge of deposition in the

---

[25] Remote deposition is the deposition of sediment some distance from the location on the overland flow path that the sediment is detached. Examples of remote deposition are deposition upslope of dense vegetation strips, on the toe of concave overland flow path profiles, and in terrace channels. Local deposition is deposition very near the point of detachment such as deposition in the depressions created by random roughness and in the furrows between ridges on a low grade. Local deposition is given full credit as soil saved, which is implicit in the empirical equation structure for computing detachment. Local deposition associated with random roughness is explicitly computed only for the first segment in an overland flow path description. Deposition computed for segments other than the first segment for overland flow paths involving multiple segments is considered to be remote deposition and is given partial credit as soil saved according to equation 2.59.

segment in which the deposition occurs. A significantly reduced benefit is computed when the deposition occurs close to the overland flow path end, which is the location x = λ. The credited deposition in a segment is computed as:[26]

$$\Delta g_{pb(i)} = \Delta g p_{a(i)} b_{d(i)} \quad [2.60]$$

where: $\Delta g_{pb(i)}$ = daily deposited sediment credited as soil saved (mass/width) and $\Delta g_{pa(i)}$ = the daily computed total deposition for the segment before any credit is taken (mass/width). The daily conservation planning sediment load along the overland flow path is computed as:

$$g_{cp(i)} = g_{cp(i-1)} + \Delta g_{pb(i)} + \Delta g_{i(i)} + \Delta g_{r(i)} \quad [2.61]$$

where: g_{cp} = daily conservation planning sediment load along the overland flow path, $\Delta g_{i(i)}$ = total interrill detachment within the segment (mass/width) and $\Delta g_{r(i)}$ = total rill detachment within the segment (mass/width). Interrill erosion D_i is assumed to occur over an entire segment regardless of whether deposition occurs. If deposition does not occur, rill detachment occurs. Rill detachment in each segment is computed as described for each of the special cases in **Section 2.3.8.3**.

The average annual conservation planning sediment load at the end of the overland flow path or at the end of terrace channels for the computation period is given by:

$$G_{cp\lambda} = \left(\sum_{j=1}^{J_d} g_{cp\lambda(j)} \right) \Big/ M_d \quad [2.62]$$

where: $G_{cp\lambda}$ = the average annual sediment load for conservation planning.

The conservation planning soil loss is given by:

$$A_{cp} = G_{cp\lambda} / \lambda_o \quad [2.63]$$

where: A_{cp} = the average annual conservation planning soil loss.

Deposition occurs in terrace channels that are on a sufficiently low grade. The credit for soil saved computed for this deposition is computed with (Foster and Highfill, 1983; Foster et al., 1997):

$$a_{cpt} = a_{ty} \exp\left[-0.011\left(\lambda_t - 100\right)\right] \quad \lambda_t > 100 \quad [2.64]$$

---

[26] These computations are made using the scaled values that match the daily erosivity values.

$$a_{cpt} = 0.45 a_{ty} \quad \lambda_t \le 100 \qquad [2.65]$$

where: a_{cpt} = the daily conservation planning sediment yield [average erosion for area (mass/area)] when deposition occurs in terrace channels, a_{yt} = daily sediment yield [average erosion for area (mass/area)] from terrace channels, and λ_t = terrace spacing (feet). The average annual conservation planning soil loss for conservation planning is:

$$A_{cp} = \left(\sum_{j=1}^{J_d} a_{cp(j)} \right) \Big/ M_d \qquad [2.66]$$

2.3.10.5. Comments on conservation and erosion control planning variables

The values for all four of these conservation and erosion control planning variables are equal for a uniform overland flow path. If a dense vegetation strip is located at the end of the overland flow path, the value for average erosion rate for the entire overland flow path (sediment yield) will be much lower than the other values because of deposition caused by the grass strip and its backwater. The highest value of the four will be the average erosion rate for the eroding portion of the overland flow path. In this example, this part of the overland flow path is from its origin to the location where deposition begins at the upper edge of the backwater created by the vegetation strip. The value for the average detachment rate for the entire overland flow path will be less than the average erosion rate for the eroding portion of the overland flow path because of the greatly reduced detachment in the backwater and in the vegetation strip itself. The conservation planning soil loss will be less than the detachment value but greater than the sediment yield value because of the partial credit taken for deposition as soil saved. In this example, the conservation planning soil loss value will be closer to the detachment value than to the sediment yield value. Not much credit (benefit) is given to the deposition because it occurs near the end of the overland flow path (see the RUSLE2 User's Reference Guide).

2.4. List of symbols

a = daily erosion (mass/area·day)

a_{cpt} = daily conservation planning soil loss for terraces (mass/area·day)

a_{yt} = daily average sediment yield expressed for terrace interval expressed as average erosion for area (mass/area·day)

a_k = erosion in *kth* crop stage (mass/area)

a_u = unit plot daily erosion (mass/area·day)

a_{us} = unit plot erosion for a single storm (mass/area)

A = average annual erosion (mass/area·year)

A_{cp} = average annual conservation planning soil loss (mass/area·year)

A_{det} = average annual detachment rate for the entire overland flow path (mass/time·year)

A_{erod} = average annual erosion for the eroding portions of the overland flow path (mass/area·year)

A_{sedyld} = average annual erosion rate for the overland flow path length (mass/area·year)

A_u = unit plot average annual erosion (mass/area·year)

b_d = deposition in a segment credited as soil saved (i.e., deposition benefit) (fraction)

b_r = **b** value, coefficient for ground surface) cover effectiveness for rill erosion ($percent^{-1}$)

c = daily cover-management factor (soil loss ratio) (dimensionless)

c_k = cover-management factor (soil loss ratio) for *kth* crop stage (dimensionless)

c_{pr}/c_{pi} = rill to interrill prior land use soil erodibility ratio

C = average annual cover-management factor (dimensionless)

D = daily detachment by rill and interrill erosion combined (mass/area·day)

D_{aseg} = average annual erosion for a segment (mass/area·day)

D_i = daily detachment by interrill erosion (mass/area·day)

D_i = interrill erosion rate (mass/area·time)

D_{daily} = average daily net erosion for a segment (mass/area·day]

D_p = deposition rate in rill areas (mass/area· time)

D_{pk} = deposition rate for the *kth* sediment class (mass/area·time)

D_{puk} = deposition rate at the upstream end of a segment for the *kth* sediment class (mass/area·day)

D_{qk} = quasi-deposition rate in first segment for *kth* sediment (mass/area· time)

D_r = rill erosion rate(mass/unit area· time)

D_{rorp} = either rill erosion (D_r) or deposition (D_p) in rill areas (mass/area·time)

$\exp(-b_r f_g)/\exp(-0.025 f_g)$ = rill erosion surface cover effect to interrill erosion surface cover effect ratio

E = rain storm energy (force·length/area)

EI_{30} = rain storm erosivity (force·length/area)·(length/time)

f_g = ground (surface) cover (percent)

f_k = portion of average annual erosivity that occurs during *kth* crop stage (fraction)

g = sediment load (mass/unit overland flow width· time)

g_b = sediment load at the location where deposition begins within segment (mass/width· time)

g_{bk} = sediment load for the *kth* sediment class at the location where deposition begins within segment (mass/width· time)

g_{cp} = daily conservation planning sediment load (mass/width·day)

$g_{cp\lambda}$ = daily conservation planning sediment load at end of overland flow path (mass/width·day)

g_{daily} = daily sediment load (mass/width· day)

$g_{daily\lambda}$ = daily sediment load at end of overland flow path (mass/width· day)

$g_{dailydetcap}$ = daily sediment load that would be produced if detachment occurred at detachment capacity (mass/width· day)

g_{det} = daily sediment load produced by detachment (mass/width· day)

g_{detcap} = daily sediment load that would result from detachment at capacity rate (mass/width· day)

g_{ek} = sediment load where deposition ends for *kth* sediment class (mass/width· time)

g_k = sediment load for *kth* sediment class (mass/width· time)

g_0 = 0, sediment load at x = 0 (mass/width· time)

g_p = potential sediment load at end of segment (mass/width· time)

g_{qk} = quasi-sediment load for *kth* sediment class rate for first segment (mass/width·time)

$G_{cp\lambda}$ = average annual conservation planning sediment load at end of overland flow path (mass/width·year)

$G_{det\lambda}$= average annual sediment load produced by detachment at end of overland flow path (mass/width·year)

G_λ = average annual sediment load (i.e., sediment yield, sediment delivery) at end of overland flow path (mass/width·year)

I_{30} = average intensity over the continuous 30 minutes with most rainfall in storm (distance/time)

J_d = number of days in computation period (J_d =365M_d)

k = daily soil erodibility factor (mass/erosivity unit)

K = average annual soil erodibility factor (mass/erosivity unit)

K_r/K_i = inherent rill to interrill soil erodibility ratio

K_T = sediment transportability coefficient (mass/volume)

l = daily slope length factor (dimensionless)

L = average annual slope length factor (dimensionless)

m = daily slope length exponent (dimensionless)

M_c = number of year in computation for cover-management computation

M_d = number of years in the computation period

M_k = number of crop stages in computation period

M_r = number of years in the record being used to compute erosivity

$M_{s(j)}$ = the number of storms in the *jth* year

n_i = number of sub-segments within the *ith* segment (integer)

n_o = 200, number of sub-segments for the entire overland flow path length, used to solve numerical deposition equation

p_c = daily contouring subfactor dimensionless)

p_d = daily subsurface drainage subfactor (dimensionless)

p_p = daily ponding subfactor (dimensionless)

P = average annual support practice factor (dimensionless)

P_{10y24h} = 10 year(return period)-24 hour (storm duration) precipitation amount (length)

q = overland flow (runoff) rate (volume/width·time)

q_0 = 0, discharge rate at x = 0 (mass/width·time)

r = daily erosivity (erosivity unit/area·day)

r_k = erosivity during *kth* crop stage (erosivity unit/area)

r_{10y24h} = storm erosivity associated with 10 year-24 hour precipitation amount P_{10y24h} (erosivity unit)

R = average annual erosivity factor (erosivity unit/area·year)

$(s/0.0896)/(3s^{0.8}+0.56)$ = steepness effect for rill erosion to interrill erosion ratio

s = overland flow path steepness (sine of slope angle)

S = average annual slope steepness factor (dimensionless)

S_i = slope steepness factor for interrill erosion

T_c = sediment transport capacity in rill areas (mass/overland flow width·time)

T_{ck} = transport capacity for *kth* sediment class (mass/width·time)

T_{clk} = sediment transport capacity at the downstream (lower) end of segment (mass/width·time)

T_{cuk} = sediment transport capacity at the upstream (upper) end segment (mass/width·time)

T_{cb} = sediment load where deposition begins (mass/width·time)

V_f = sediment fall velocity (length/time)

V_{fk} = sediment fall velocity for *kth* sediment class (length/time)

x = distance from origin of overland flow path (length)

x_b = location where deposition begins (length)

x_e = location where deposition ends (length)

x_{ud} = location of upper edge of deposition in a segment in which deposition occurs (length)

α_d = deposition coefficient (dimensionless)

β = daily ratio of rill to interrill erosion for unit plot length

δ = scaling factor used to compute daily sediment load

Δg_i = daily sediment load produced by interrill erosion in a segment (mass/width·day)

Δg_{pa} = daily sediment load deposited in a segment before any credit is taken for deposition benefit (mass/width·day)

Δg_{pb} = daily sediment load deposited in a segment credited as soil saved (mass/width·day)

Δg_r = daily sediment load produced by rill erosion in a segment (mass/width·day)

Δx = length of the distance step used in the numerical integration to compute deposition (length)

γ_m = the maximum monthly erosivity density at the location (erosivity unit/length)

ζ = coefficient for effect of hydraulic resistance on sediment transport capacity

K = the number of crop stages

λ = slope length (length)

λ_o = overland flow path length (length)

λ_u = unit plot length (length)

σ = excess rainfall length rate (rainfall rate - infiltration rate) (length/time)

ψ_k = sediment mass in *kth* sediment class (fraction)

indices

i = segment along overland flow path

j = year

k = crop stage

k = sediment class

m = storm

1 and 2 = subscript 1 for upstream (upper) end of distance step and subscript 2 for downstream (lower) end of distance step in numerical integration of deposition equation

3. CLIMATE (WEATHER), RUNOFF, AND HYDRAULICS

The major weather variables used by RUSLE2 are monthly erosivity, precipitation, and temperature and the 10 year (return period)-24 hour (storm duration) precipitation amount. Erosivity values are an index of erosive rainfall at a location for causing rill and interrill erosion. Erosivity is a major variable in the equations used to compute detachment (e.g., see Section **2.1**). Precipitation and temperature influence the loss of biomass on and in the soil and how that loss varies among locations (e.g., see **Section 10.4.1**). Precipitation and temperature also affect the temporal distribution of soil erodibility and how that distribution varies by location (see **Section 4.5**). The 10 year-24 hour precipitation amount is a representative (index) storm that is used to compute the effect of ponding on erosivity, deposition on concave overland flow path profiles, deposition by dense vegetation strips, deposition in terrace channels, and the effectiveness of contouring (e.g., see **Section 7.1**). These computations are made using runoff and flow hydraulics based equations.

3.1. Disaggregation of monthly values into daily values

RUSLE2 uses daily values for erosivity, precipitation, and temperature to compute daily erosion (see **Section 2.1**). The RUSLE2 disaggregation procedure converts (disaggregates) the input monthly erosivity, precipitation, and temperature into daily values.

3.1.1. Basic disaggregation procedure

The same basic disaggregation procedure is used for monthly temperature, precipitation, and erosivity. The procedure assumes that daily values vary linearly within each month according to a two-piece linear equation. A requirement is that the average of the daily values in a month equals the input monthly value.

The daily value at the beginning of a month is assumed to equal the mean of the monthly values for the current and immediately preceding month and the daily value at the end of the month equals the mean of the monthly values for the current and next month as illustrated in Figure 3.1. That is:

$$Y_b = (M_{(j)} + M_{(j-1)})/2 \qquad [3.1]$$

and

$$Y_e = (M_{(j+1)} + M_{(j)})/2 \qquad [3.2]$$

where: M = the average monthly value of the variable being disaggregated, Y_b = the daily value at the beginning of the *jth* month, Y_e = the daily value at the end of the month, and the index j refers to the month.

Figure 3.1 illustrates an example of increasing monthly values. The same equations apply to both increasing and decreasing values. A second set of equations apply for local maximums and local minimums illustrated in Figure 3.2.

3.1.1.1. Increasing or decreasing monthly values

The third major value is the time t_c where the two linear lines in Figure 3.1 equal the average monthly value M_j. The value for t_c is determined so that the total area under the two linear lines equals the average monthly value M_j. The area under the two lines is given by:

$$M_{(j)} = t_c(Y_b + M_{(j)})/2 + (1 - t_c)(M_{(j)} + Y_e)/2 \quad [3.3]$$

A value for t_c is determined by rearranging equation 3.3 as:

$$t_c = [M_{(j)} - (Y_e + M_{(j)})/2]/[(Y_b + M_{(j)})/2 - (Y_e + M_{(j)})/2] \quad [3.4]$$

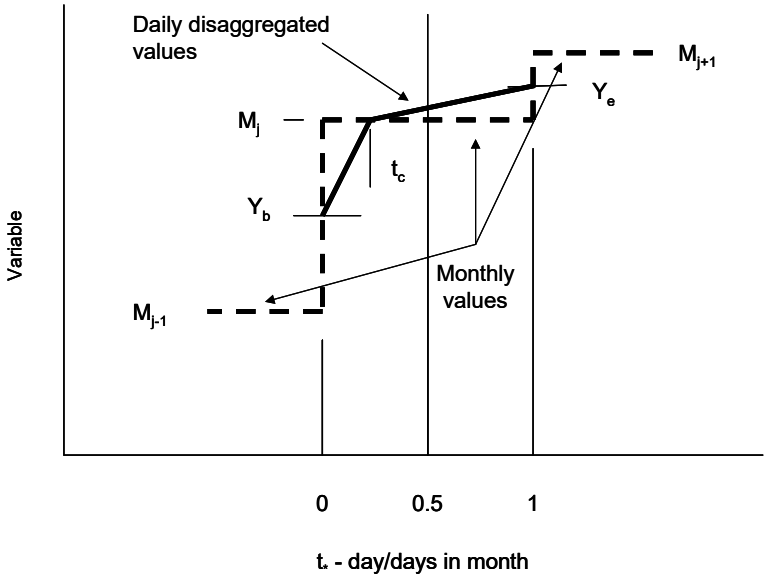

Figure 3.1. Illustration of two linear equations used to disaggregate monthly values into daily values for increasing or decreasing monthly values.

The equation used to compute daily values for times less than t_c is given by:

$$y_d = (d / D_{(j)})[(M_{(j)} - Y_b)/t_c] + Y_b \quad [3.5]$$

where: y_d = the daily value on day d of the month and D_j = the number of days in the month. The equation to compute daily values for times greater than t_c is given by:

$$y_d = (1 - d / D_{(j)})[(M_{(j)} - Y_e)/(1 - t_c)] + Y_e \quad [3.6]$$

3.1.1.2. Local maxima and minima

Figure 3.2 illustrates a local maximum. The equations apply both to local maximums and minimums.

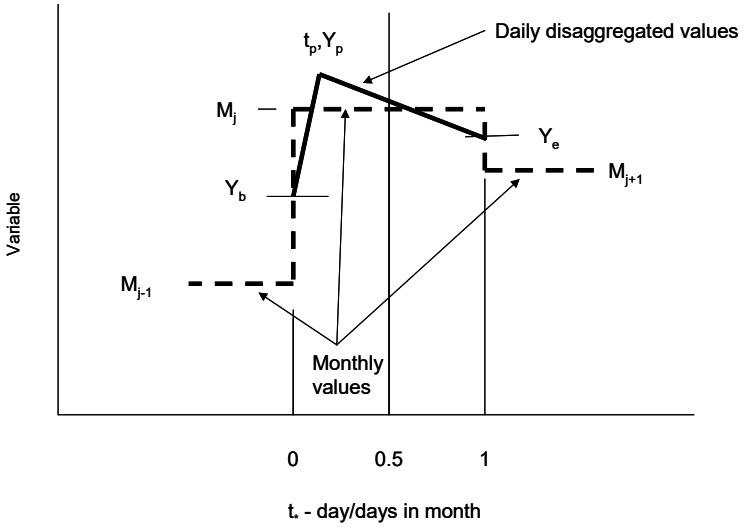

Figure 3.2. Illustration of two linear equations used to disaggregate monthly values for a local maxima or minima.

The daily value at the beginning and end of the month are computed using equations 3.1 and 3.2. The total area under the two lines must equal the average monthly value as:

$$M_{(j)} = (Y_b + Y_p)t_p / 2 + (Y_p + Y_e)(1 - t_p) / 2 \quad [3.7]$$

where: Y_p = the maximum value during the month that occurs at time t_p. Equation 3.7 is rearranged so that a value for the maximum value Y_p can be computed from:

$$Y_p = 2M_{(j)} + t_p(Y_e - Y_b) - Y_e \quad [3.8]$$

The equation for the time of the peak t_p is given by:

$$t_p = 1 - (M_{(j)} - Y_b)/(2M_{(j)} - Y_b - Y_e) \quad [3.9]$$

The equation for daily values for times less than the time of the peak is given by:

$$y_d = (d / D_{(j)})(Y_p - Y_b)/t_p + Y_b \quad [3.10]$$

and the equation for times after the time to peak is given by:

$$y_d = [(Y_p - Y_e)/(1 - t_p)](1 - d / D_{(j)}) + Y_e \quad [3.11]$$

3.1.2. Disaggregation procedure for temperature and erodibility

The disaggregation procedure is applied directly as described in **Section 3.1.1** for temperature. Figure 3.3 illustrates disaggregation of monthly temperature values into daily values for Columbia, Missouri. Notice that the date of the minimum daily temperature occurs in the third week of January as expected.

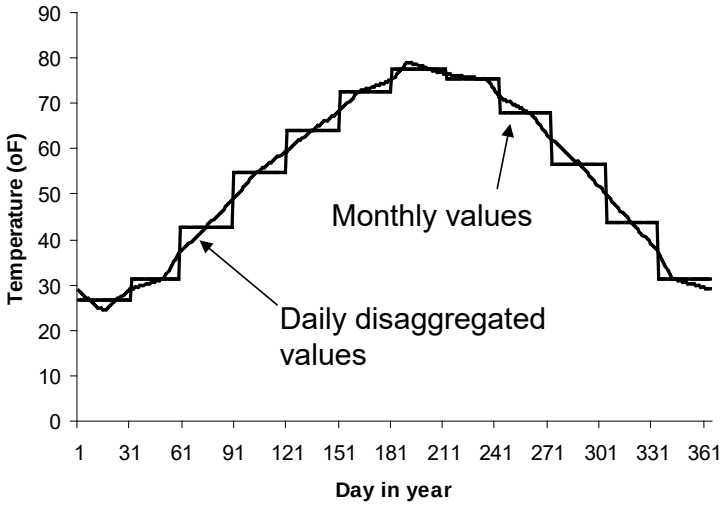

Figure 3.3. Daily temperature values obtained by disaggregating monthly temperature values at Columbia, Missouri.

3.1.3. Disaggregation procedure for precipitation and erosivity

When the disaggregation procedure is applied to monthly precipitation and erosivity, the average monthly value is divided by number of days in the month to obtain a mean daily value for the month. The disaggregation procedure is applied to the mean daily value in each month. Daily precipitation and erosivity values must be checked for negative values in very low rainfall areas like Yuma, Arizona. Daily precipitation and erosivity values are set to zero when negative values are computed. Setting these values to zero results in the sum of the disaggregated daily values being slightly greater than the monthly values in the months when the negative values occur. This adjustment has an insignificant effect on computed erosion values. Figure 3.4 shows daily disaggregated precipitation values for Columbia, Missouri.

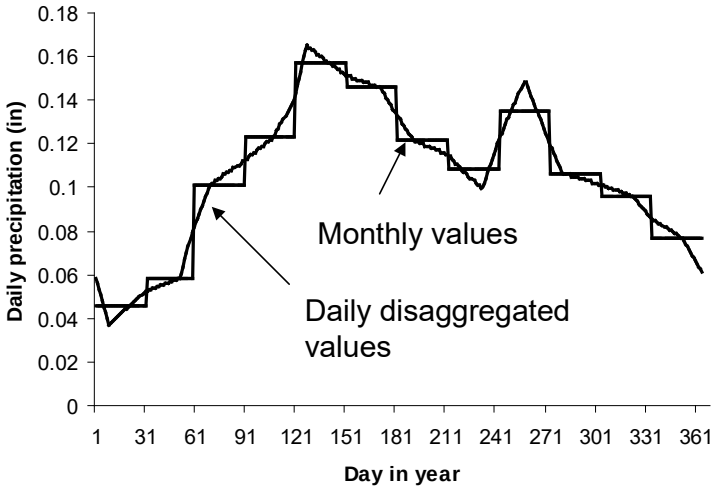

Figure 3.4. Daily precipitation values obtained from disaggregating monthly precipitation values at Columbia, Missouri.

3.2. Climate (weather) variables

The four basic RUSLE2 weather variables are monthly erosivity, precipitation, and temperature and the 10 year-24 hour precipitation amount. Selection of values for these variables is described in the RUSLE2 User's Reference Guide. This section describes underlying concepts, principles, and equations for processing weather data to develop input values consistent with RUSLE2 procedures and RUSLE2's purpose as a guide to conservation and erosion control planning.

3.2.1. Erosivity

RUSLE2 disaggregates average monthly erosivity values to obtain daily erosivity values used to compute daily erosion (see **Section 3.1**). Monthly erosivity values can be input directly into RUSLE2 in three ways, the recommended procedure for the Continental US is to input average monthly values for erosivity density.[27] Erosivity density, which is the ratio of monthly erosivity to monthly precipitation, is multiplied by monthly precipitation to obtain monthly erosivity values. The first step in developing average monthly erosivity density values is to compute erosivity values for individual storms using measured weather data.

[27] RUSLE2 can uses monthly erosivity values (1) computed by multiplying monthly erosivity density and precipitation values (see **Section 3.2.1.4.1**), (2) input directly, or (3) determined from input values for annual erosivity and the biweekly temporal distribution of erosivity.

3.2.1.1. Storm erosivity

Erosivity, the product of a storm's energy and its maximum 30 minute intensity, for an individual storm is computed as (Wischmeier and Smith,1978):

$$r_s = EI_{30} \quad [3.12]$$

where: r_s = storm erosivity, E = storm energy, and I_{30} = maximum 30-minute intensity. Maximum 30 minute intensity is the average intensity over the continuous 30 minutes in the storm with the most rainfall. Storm energy is computed using (Renard et al., 1997):

$$E = \sum_{k-1}^{m} e_k \Delta V_k \quad [3.13]$$

where: e = unit energy (energy content per unit area per unit rainfall depth) in the *kth* period, and ΔV = the amount (depth) of rainfall in the *kth* period, k = index for periods during the rainstorm where rainfall intensity is considered uniform, and m = the number of periods in the rainstorm. Unit energy is computed from (Brown and Foster, 1987; McGergor et al., 1995; Renard et al., 1997):

$$e_k = 0.29[1 - 0.72\exp(-0.082 i_k)] \quad [3.14]$$

where: e_k = the unit energy [MJ/(mm·ha)] for the *kth* period and i_k = rainfall intensity (mm/h) for the *kth* period.[28]

Data for storms less than 0.5 inch (12 mm), non-rainfall precipitation events, and extreme storm erosivity events with a return period greater than 50 years are excluded in the RUSLE2computation of storm erosivity.

3.2.1.2. Determining average annual erosivity values from measured precipitation data

Data from 15-minute precipitation gages that provide rainfall intensity values are required to compute storm erosivity values using equations 3.12-3.14. Modern data from 1960 through 1989 (1960-1999 in several cases) were analyzed to determine rainstorm erosivity and precipitation values at approximately 3700 15-minute precipitation gage locations across the Continental US (Hollinger et al., 2002). Erosivity values computed for the qualifying storms (i.e., rain events where amount was 0.5 inch or greater) were summed over the record length and divided by the years of record to determine an average annual erosivity value for each 15-minute precipitation station.

---

[28] See Foster et al. (1981) and AH703 (Renard et al., 1997) for a discussion of RUSLE2 units and how to convert between customary US units and SI units.

The plan was to develop an average annual erosivity contour map based on values computed from measured data at as many 15-minute precipitation gage locations as possible. Initial maps had many "bull's eyes" and irregular spatial trends rather than smooth trends required for RUSLE2 application as a guide for conservation planning. Data analysis showed that short and differing record lengths among locations greatly contributed to undesired spatial variability. The analysis also showed that the record length should be at least 18 years for directly computing average annual erosivity from measured 15-minute precipitation gage data. Even then the spatial variability among precipitation gage locations was sometimes too great.

3.2.1.3. Need for consistency in conservation and erosion control planning

Consistency in computed erosion estimates (hence, consistency in erosivity values) between locations within geographic regions and between regions is just as important as the absolute erosion estimates computed with RUSLE2. Land users impacted by erosion prediction perceive inconsistency and variability in erosion estimates for no apparent reason to be unfair, especially when the results negatively affect them. The probability distribution (return periods) of storms in a measured precipitation record used to compute erosivity values should be the consistent among locations. To illustrate, the average annual erosivity values at Wink, Texas and Pecos, Texas, towns in West Texas, computed from measured 15-minute precipitation data differed by a factor of two for no obvious reason. Inspection of the data showed that a 600-year return period storm caused the much larger average annual erosivity at one location.

The benefits or costs incurred by land users impacted by RUSLE2 should not be determined by the "luck of the draw" based on where they happen to be located. Furthermore, extreme events, such as a 100-, 200-, and 600-year storms, in the last 30 years are a very poor indicator of events likely to occur in the next 30 years. An average annual record that excludes extreme events is the best predictor of the immediate future for conservation planning where the objective is to protect the on-site soil resource from excessive degradation by erosion. However, other erosion prediction applications such as protecting highly sensitive water bodies and designing sediment storage in reservoirs may well require a different consideration of extreme events and a different set of input erosivity values than those developed for RUSLE2. Most erosion control practices are not designed or expected to withstand extreme events because in most cases failure does not cause catastrophic damages and the practices can be reinstalled without great costs.

Therefore, all storms with a return greater than 50 years were deleted from the measured data used in the RUSLE2 analysis to develop erosivity values.

3.2.1.4. Erosivity density approach to developing erosivity values

3.2.1.4.1. Erosivity density analysis

The RUSLE2 erosivity density approach for determining monthly erosivity values was developed in consideration of RUSLE2's consistency requirements for conservation planning and to maximize the information that could be extracted from the measured 15-minute precipitation data. RUSLE2 multiplies input values for average monthly erosivity

density by input values for average monthly precipitation to compute monthly erosivity values as:

$$R_{m(j)} = \alpha_{(j)} P_{md(j)} \quad [3.15]$$

where: R_m = average monthly erosivity, α = average monthly erosivity density, and P_{md} = average monthly precipitation determined from daily precipitation gage data, all for the *jth* month. Erosivity density refers to the erosivity content per unit precipitation. Erosivity density for a month is computed from measured 15-minute precipitation data as:

$$\alpha = \frac{\sum_{i=1}^{n} E_{(i)} I_{30(i)}}{\sum P_{15}} \quad [3.16]$$

where: all values were determined from 15-minute precipitation gage data including precipitation amount P_{15} from all storms and storm energy E is computed using equations 3.13 and 3.14, i = the index for storm in a month and n = total number of storms greater than 12 mm but smaller than a 50-yr event in a given month. Unit energy e_k for each *kth* period is computed from the average intensity for each 15-minute period in the storm (i.e., $i_k = \Delta V_k/15$ minutes and V_k = the rainfall amount in the *kth* 15-minute period). The I_{30} values used in equation 3.16 using 15-minute precipitation data were multiplied by a 1.04 factor to account for the fact that maximum intensity values from the 15-minute precipitation data are slightly lower than those computed with breakpoint rainfall (Hollinger et al., 2002). Breakpoint rainfall data are data divided into non-uniform periods where constant rainfall intensity can be assumed for each period. Breakpoint data are preferred rather than 15-minute precipitation data for computing storm erosivity.[29]

Approximations can be made in Equation 3.16 to aid the interpretation of erosivity density. Unit energy e does not vary greatly with intensity such that storm energy can be approximated with $\hat{e}P_{15}$ where $\hat{e}$ = effective unit energy for a month (Foster et al., 1982d). By assuming a representative $\bar{I}_{30}$ for the month, erosivity density is approximated by:

[29] The storm data including computed storm erosivity values were provided by the Illinois State Water Survey. The analysis of erosivity data was a joint effort between the Illinois State Water Survey, the USDA-ARS and NRCS, and the University of Tennessee.

$$\alpha \approx \frac{\bar{I}_{30}\hat{e}\sum_{i=1}^{n} P_{15(i)}}{\sum_{i=1}^{n} P_{15(i)}} \qquad [3.17]$$

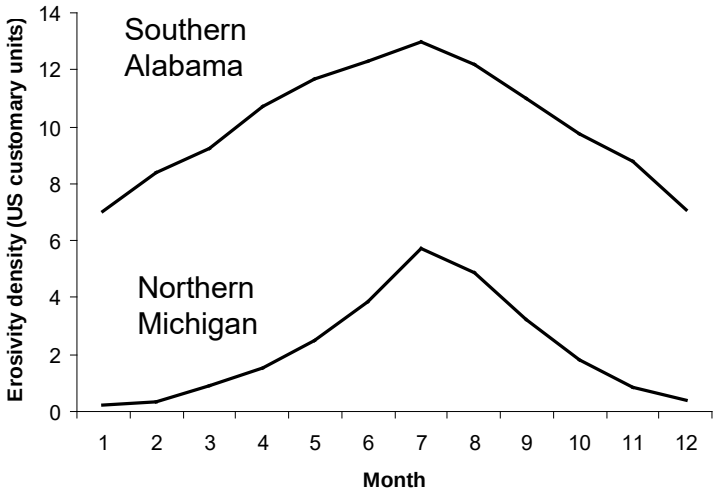

Figure 3.5. Erosivity density values for two locations.

where: $\bar{I}_{30}$ = the representative maximum 30-minute intensity for the month. Equation 3.17 in turn reduces to:

$$\alpha \approx \hat{e}\bar{I}_{30} \qquad [3.18]$$

Equation 3.18 shows that erosivity density varies directly with 30-minute rainfall intensity.

Erosivity density varies by location as illustrated in Figure 3.5 that shows that erosivity is higher in Southern Alabama than in Northern Michigan. In both locations, erosivity density is higher in the summer months than in the winter months, which according to equation 3.18, is caused by rainfall intensity varying with season. Rainfall intensity is greater in the summer than in the winter, resulting in erosivity being greater in the summer than in the winter for a given amount of rainfall. Also, most of the precipitation in Northern Michigan in the winter is snow and, therefore, is not included in the rainfall erosivity index.[30]

[30] The storm precipitation and erosivity values used in this analysis were provided by the Illinois State Water Survey and the USA-Natural Resources Conservation Service Water and Climate Center. These

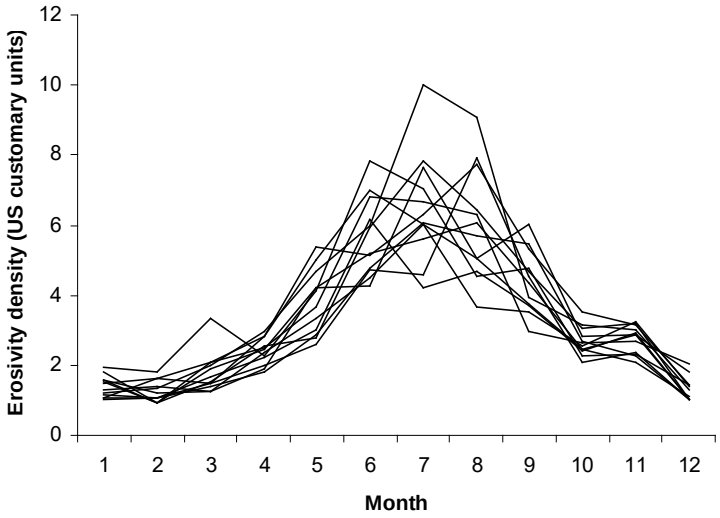

Figure 3.6. Spatial and temporal variability in erosivity density for locations in Southwestern Indiana.

Spatial and temporal variation in the erosivity density values computed from the 15-minute precipitation data was a major problem. Erosivity density values computed directly from the 15-minute precipitation data, as illustrated in Figure 3.6 for 15-minute gage locations in the southwest quadrant of Indiana, do not provide the smooth temporal and spatial trends required for RUSLE2 as a conservation and erosion control planning tool. Spatially averaging the erosivity density values by quadrant in Indiana smoothed the erosivity density values, both temporally and spatially, across Indiana as illustrated in Figure 3.7.

Geographic information systems (GIS) techniques, including kriging, were used to spatially average the erosivity density values computed from 15-minute precipitation data measured at the various gage locations. The procedure is similar to a spatial, moving average fitting technique and produced results similar to that illustrated in Figure 3.7.[31] Before kriging was applied, the monthly erosivity density values computed from the measured data in a relatively small region, such as a quadrant of Indiana, were inspected and analyzed for outliers. Monthly erosivity density values that departed from the mean in this local region by more than two times the standard deviation were considered outliers. Rather than excluding the entire dataset for a location (i.e., deleting the location from the entire data set), the outlier data point was adjusted to be consistent with other

---

values are computed from measured weather data collected by the National Weather Service. See (Hollinger et al., 2002) for additional information.

[31] The GIS and kriging analysis was conducted by the Department of Biosystems Engineering and Environmental Science, University of Tennessee, Knoxville.

monthly erosivity density values at the location. Adjusting individual monthly data points kept the number of locations in the dataset as large as possible. In most cases, the same outliers at a location identified by the statistical test could also be identified by inspection. Outliers were monthly erosivity density value outside the smooth trend obtained by averaging the data points in the local region as was done in Figure 3.7. This process of identifying and adjusting outliers typically involved two or three iterations.

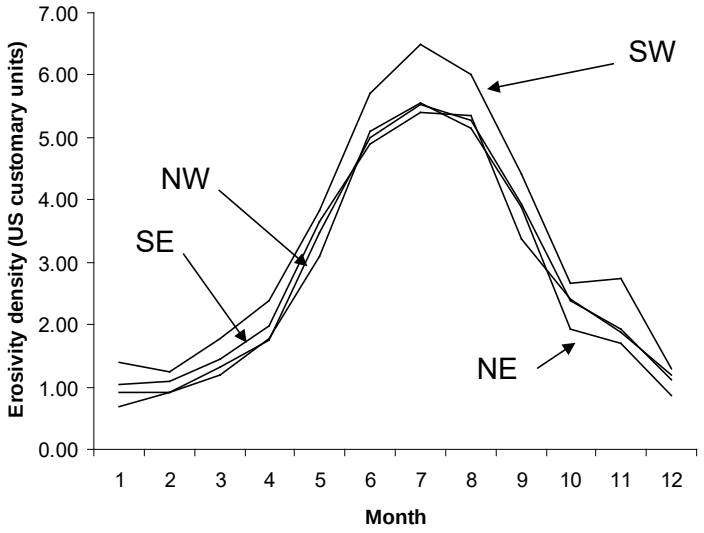

Figure 3.7. Erosivity density values spatially averaged for the four quadrants in Indiana.

A compromise was made in the number of nearest neighbors used in the kriging analysis. Using the 10 nearest neighbors worked well in the eastern US, but it did not work well along the eastern side of the Cascade Mountains in Washington and Oregon where erosivity density values decrease very rapidly with distance in this area. This rapid decrease necessitated using five rather than 10 nearest neighbors. This problem was also related to a very low density of 15-minute precipitation stations in the region. Using the five nearest neighbors also worked better than 10 nearest neighbors along coastlines and borders between Canada and Mexico where no precipitation data were available.

This procedure produced erosivity density values that varied smoothly over the Continental US, including mountainous regions. The hypothesis that erosivity density was not affected by mountainous terrain was tested in two ways. The first test involved fitting a linear equation to erosivity density values as a function of elevation at the 15-minute precipitation gage locations in a local region. The region had to relatively small, such as a quadrant of Utah, to avoid cross and spurious correlations. For example, the linear equation could not be fitted to erosivity density values for the entire state of Montana. When erosivity density values for all of Montana were included in the analysis, erosivity density values appeared to be a function of elevation, but that correlation was spurious. Elevation decreases from west to east across Montana while erosivity density increases across Montana. The increase in erosivity density across

Montana was not caused by elevation but by a west to east broad geographic increase in erosivity density.

Measured precipitation data from the 15-minute precipitation gages were available to compute erosivity density values for elevations up to about 10,000 ft. Statistical analysis for eleven local regions in mountainous areas throughout the western US and two local regions in the eastern US were conducted to determine if the hypothesis that erosivity density varied with elevation could be rejected. The analysis involved fitting a linear equation to the erosivity density values as a function of elevation. The data for three regions are shown in Figure 3.8-3.10. The result of the analysis was that the hypothesis that erosivity density values are independent of elevation could not be rejected. This test was not especially robust because of data variability. Elevation clearly affects erosivity density in the winter months because an increasing fraction of the precipitation occurs as snow at higher elevations. However, the assumption of no effect of elevation on erosivity density values in the summer months is considered acceptable.

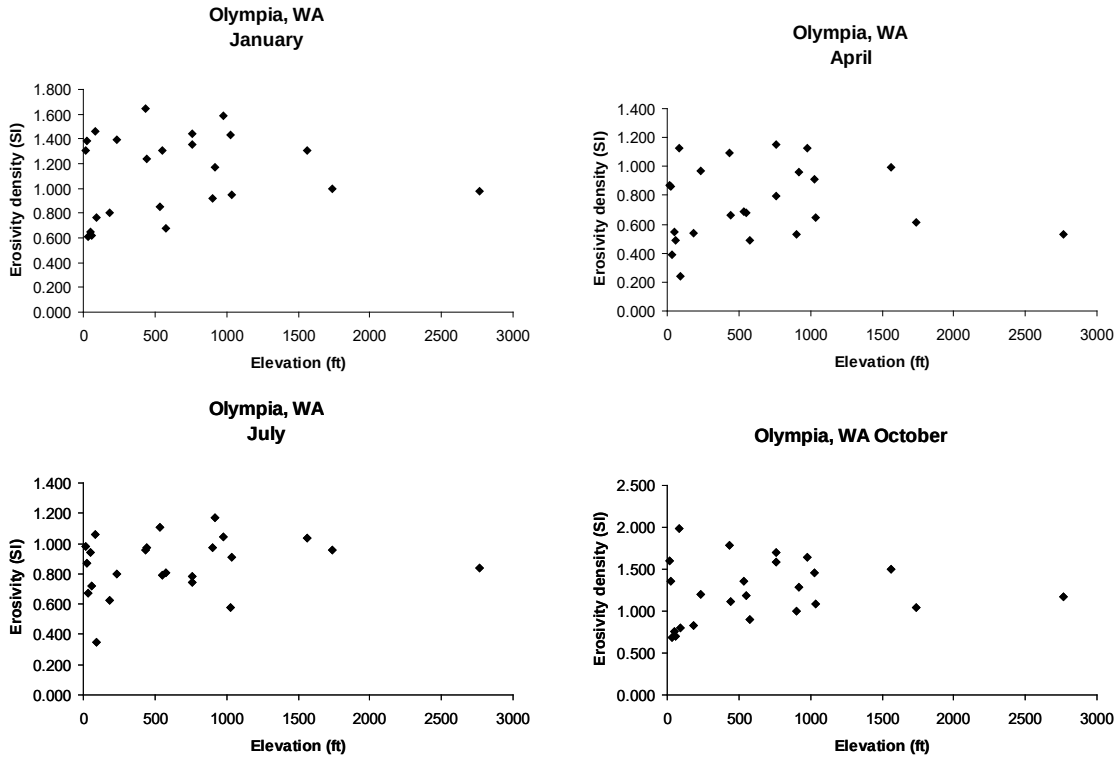

Figure 3.8. Variation of erosivity density with elevation in the Olympia, Washington region.

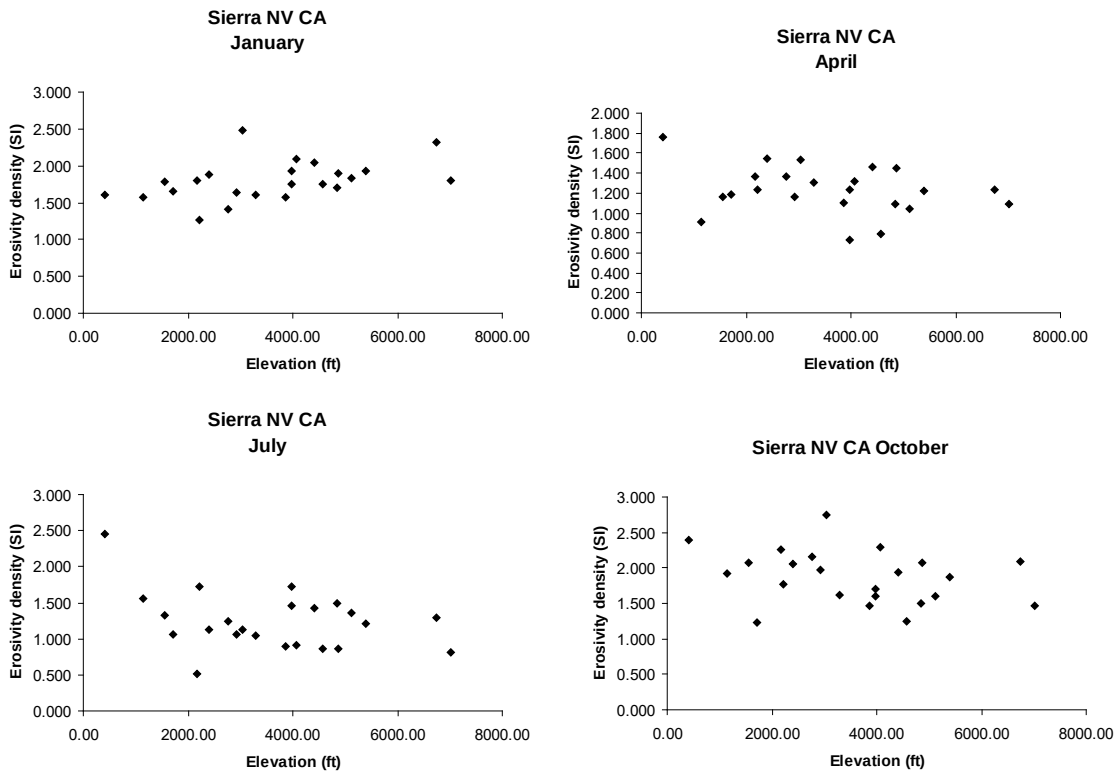

Figure 3.9. Variation of erosivity density with elevation in Sierra NV-CA region.

Another test of the hypothesis that erosivity density values are independent of elevation was to inspect a map, shown in Figure 3.11, of average 30 minute intensity for all storms in the data set (Hollinger et al., 2002). Even though these data were extensively smoothed as a part of the contouring process, the map shows no effect of mountainous terrain in the Western US on maximum 30-minute intensity. Equation 3.18 shows that erosivity density is approximately proportional to maximum 30-minute rainfall intensity. Therefore, if 30-minute intensity is independent of elevation in mountainous regions, as indicated in Figure 3.11, then erosivity density is independent of elevation. This result means that the effect of mountainous terrain on erosivity can be fully captured in how terrain affects monthly precipitation. While these tests are not especially robust, the erosivity density approach is a major improvement over previously available erosivity values in AH703 (Renard et al., 1997) for the Western US.

3.2.1.4.2. Advantages of erosivity density approach

The erosivity density approach has major advantages. It produces consistent, smoothly varying erosivity density values across the US as desired for conservation and erosion control planning. The erosivity density approach uses data from daily precipitation gage stations, which are far more numerous than the 15-minute precipitation stations, to fill in erosivity values between the 15-minute precipitation gage locations where erosivity was computed from measured precipitation data. The erosivity maps for the Eastern US in AH282 (Wischmeier and Smith, 1965) and AH537 (Wischmeier and Smith, 1978) were based on approximately 2000 data points (see AH282). However, storm erosivity was computed from detailed intensity precipitation data comparable to the 15-mintue

precipitation data at only 181 locations. An equation involving 2 year-6 hour precipitation amount and other variables was fitted to average annual erosivity values computed from the measured detailed precipitation data at the 181 locations (AH282, AH537). This equation was then used to estimate average annual erosivity values at the approximately 2000 locations used to draw the AH282 and AH537 erosivity maps for the Eastern US. The erosivity density approach using monthly precipitation measured by daily precipitation gages to compute erosivity at any particular location serves this function in RUSLE2.

The USLE and RUSLE1 use EI distribution zones in the US to describe the spatial variations in the temporal distribution of erosivity during the year. The temporal distribution of erosivity is assumed to be constant within a zone. Differences in temporal erosivity distributions between zones resulted in major differences in erosion estimates across certain zone boundaries. For example, Little Rock, Arkansas is very close to a EI zone boundary. The USLE and RUSLE1 compute a 25 percent change in erosion across the EI zone boundary at this location for a conventionally tilled corn cropping system. The impact of this step change is that a client should not be expected to change management practices unless estimated erosion changes by at least 25 percent. RUSLE2's estimated erosion values vary smoothly across the US because RUSLE2 does not use such zones. See RUSLE2 User's Reference Guide for a discussion on how aggregating input weather data by counties affects estimated erosion across county boundaries.

Precipitation data measured by daily precipitation gages are much more stable and reliable and have much less missing data than precipitation data measured with the 15-mintue precipitation gages. That is, the quality of the 15-minute precipitation data is less than the quality of the daily precipitation data. The erosivity density approach computes a ratio in contrast to the standard approach that computes an absolute sum. The data requirements for computing a ratio of monthly erosivity to monthly precipitation amount are less demanding than for computing an absolute erosivity sum. An absolute sum is greatly affected by missing data, unless the missing data are so small that the missing values have little effect on the sum. In contrast, missing data have no effect on the ratio if the missing data are not biased. Although the missing 15-minute precipitation data were surely biased, problems caused by missing data and errors in reconstructing missing data are much less in the ratio erosivity density approach than in the absolute standard approach.

The erosivity density approach also reconciles differences in precipitation amounts measured by the daily and 15-minute precipitation gages. The Illinois State Water Survey provided precipitation data for 14 locations in West Texas and Eastern New Mexico where daily and 15-minutes precipitation gages were located sufficiently close so that annual precipitation measured by the two gages types could be compared. Overall, the annual precipitation measured by the 15-minute gages was 85 percent of that measured by the daily gages. The annual precipitation measured by the 15-minute gages was less than that measured by the daily gages for all 14 locations. The ratio of the precipitation amounts for the two gage types ranged from 0.76 to 0.94. This disparity between gage types affects erosivity density values much less than it does absolute

erosivity values. The erosivity density approach computes monthly erosivity values, determined from 15-minute precipitation gage data that are consistent with the monthly precipitation values, determined from daily precipitation gage data, used in RUSLE2.

A shorter record length and a record with more missing data can be used to compute erosivity density values than can be used to directly compute erosivity values with the standard method. Record length, including both number of years and number of storms, is especially critical in the Western US where spatial density of 15-minute precipitation gages is low, spatial and temporal variability is great, and records are often short with missing data. Twenty years was the minimum data record length considered to be acceptable for computing erosivity values for the Eastern US. That record length was actually too short using the standard procedure, but it was a compromise to include as many stations as possible. A data record length of 15 years was judged to be satisfactory for computing erosivity density values in the Eastern US. This conclusion was based on analysis of precipitation data collected by the USDA-Agricultural Research Service in Northern Mississippi in a research environment where data quality was very carefully maintained (McGregor et al. 1995). As Table 3.1 shows, a record length of 10 years was acceptable for these data using the erosivity density approach. Most important, the analysis showed that a shorter length of record could be used in the erosivity density approach than in the standard approach.

Table 3.1. Percent error in estimating monthly R from measured preciptiation data. Ratio refers to erosivity density approach. Abs refers to standard approach that computes absolute values.

The length of record in years and number of storms in the record are more important in the Western US than in the Eastern US. Figure 3.12 shows the effect of record length for a precipitation gage located in Beaver County, Utah. The example in Figure 3.12 is not very robust, but it represents typical conditions for the 15-minute precipitation data in the Western US where the data record was short, the data was highly variable and contained relatively few storms, and number of the 15-minute gage locations was sparse. The erosivity density approach much more effectively uses the limited data in the Western US than does the standard procedure.

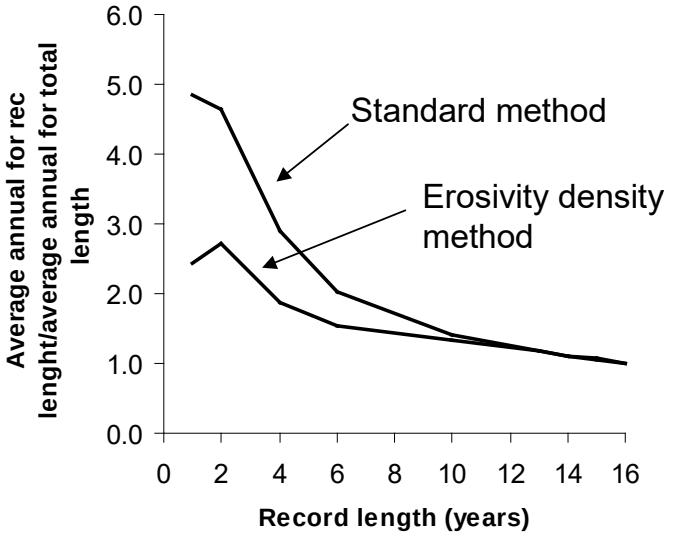

Figure 3.12. Effect of record length on variation of average annual values for erosivity and erosivity density for Beaver County, Utah.

Data for a gage location were not automatically discarded because of a short record length in the Western US in order to include as many stations as possible. The overall curve of monthly erosivity density by month computed by averaging erosivity density values in a local region was examined (e.g., see Figures 3.6 and 3.7), and the data for the location were left in the analysis if the trend at the location matched the local regional trend. When the trends in a dataset at a location did not match the overall trend, the record length at the location was almost always short.

3.2.1.4.3. Comments on erosivity density approach

Precipitation amount is a very poor indicator of erosivity (Wischmeier, 1958; Foster et al., 1982). Measures of both rainfall intensity and amount are required in erosivity measures and indices. Monthly erosivity values computed using the erosivity density method have the immediate appearance of being solely a function of monthly precipitation amount. The erosivity density value for each month depends strongly on intensity as shown by equation 3.18. The erosivity density method also seems to conflict with the empirical result that storm erosivity is a nonlinear function of storm amount (Richardson et al., 1983). The empirical erosivity density values account for this nonlinearity. Nonlinear mathematical relationships can be linearized by dividing the solution space into sufficiently small intervals so that linear equations can be assumed within each interval. The erosivity density approach is a linearized procedure that captures the effect of both intensity and nonlinearity between storm erosivity and storm amount.

Care must be taken in developing and applying the erosivity approach in other situations, especially when it is used where only very limited precipitation data are available. The erosivity density method can be quite useful in these situations, but sufficient data must be available and analysis must be conducted to determine the variation of erosivity density values over the region where the method is being applied. Assuming constant erosivity density values over too large of a region can produce very erroneous results.

3.2.1.4.4. Alternative procedures for estimating erosivity involving precipitation amount

Lack of adequate precipitation data to derive RUSLE2 erosivity values is a major limitation in applying RUSLE2 in many countries. Erosivity values are estimated from storm, monthly, and annual precipitation amounts. Rainfall intensity is a critical element in erosivity indices and any estimation procedure must account for how intensity varies over space and time in relation to precipitation amount. The effect of intensity on erosivity varies by location and by month as Figure 3.5 and equation 3.18 indicate.

A procedure to estimate storm or daily erosivity from storm or daily precipitation, respectively, uses the equation (Richardson et al., 1983):

$$r_s = a_p P_s^b \qquad [3.19]$$

where: r_s = storm or daily erosivity, P_s = storm or daily precipitation amount, and a and b are coefficients that vary by location and month. Values for a_p and b are determined by empirically fitting equation 3.19 to observed data. The procedure requires sufficient data and analysis to determine values for a_p and b over space and by month or season. The Illinois State Water Survey (ISWS) attempted to apply this procedure to US data but concluded they had insufficient data to properly compute a and b values (Hollinger et al., 2002). Another problem was that they used a logarithmic transformation and linear regression in fitting equation 3.19 to the data rather than a nonlinear fitting procedure. The logarithmic transformation-linear regression procedure returns the mean of the logarithms of the observed values rather than the mean of the absolute observed values. Erosivity values that would be used in RUSLE2 produced by the ISWS procedure had a systematic error by being too low by about 10 percent. Use of equation 3.19 can work if the proper precautions are followed and sufficient data are available to determine values for a_p and b in equation 3.19 over space and time by month or season.

Another procedure is to compute storm erosivity using a design storm that has a particular intensity distribution (Cooley, 1980; Brown and Foster, 1987). The requirement for this procedure is that design storm intensity distributions vary over space and time. A few design storms are available that vary intensity distributions over space in the US, but no design storms seem to be available that vary intensity distributions by month or season.

A modified Fournier index is widely used to estimate erosivity where precipitation data are very limited. A value for the modified Fournier index is computed from (Renard and Freimund, 1994):

$$F = \frac{\sum_{j=1}^{12} P_{m(j)}^2}{\sum_{j=1}^{12} P_{m(j)}} \qquad [3.20]$$

where: F = the modified Fournier index, P_m = average monthly precipitation, and j = index for each month. The usual procedure is to fit a linear equation involving average annual erosivity as a function of the modified Fournier index (Fournier, 1960). Values of the modified Fournier index were computed at the US locations listed in Table 3.2. Average annual erosivity values at these locations are plotted as a function of the modified Fournier index in Figure 3.13.

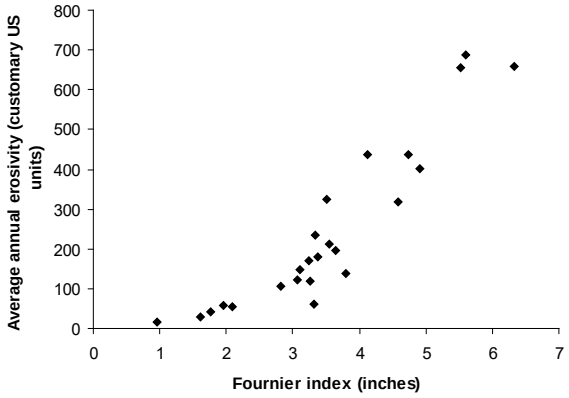

Figure 3.13. Relation of average erosivity to modified Fournier index for several US locations.

These results show that the relation between average annual erosivity and the modified Fournier index is nonlinear rather than linear. Renard and Freimund (1994) also found that the relationship of average annual erosivity to the modified Fournier index was nonlinear where erosivity varied with the index raised to the 1.85 power for US data that are comparable to data represented in Figure 3.13. That equation is given by:

$$R = a_F F^{1.85} \qquad [3.21]$$

where: R = average annual erosivity. When this equation form is fitted to the data represented by Table 3.2, the exponent is 2.24. The difference in these exponent values is caused by differences in datasets and fitting procedures.

Another concern with the modified Fournier index is whether the square of monthly precipitation in equation 3.20 is the appropriate value for the exponent. A modified Fournier index with a generalized value for the exponent would be computed as:

$$F_r = \frac{\sum_{j=1}^{12} P_{m(j)}^{z}}{\sum_{j=1}^{12} P_{m(j)}} \qquad [3.22]$$

$$R = a_r F_r \qquad [3.23]$$

where: F_r = the modified Fournier index where a value for the exponent z is determined by fitting equations 3.22 and 3.23 to observed data. In this formulation, the relationship between average annual erosivity and the generalized modified Fournier index is linear as shown in equation 3.23. The value for the exponent b most likely varies with the dataset. A value of 3.02 was obtained when equations 3.22 and 3.23 were fitted to the data represented in Table 3.2. Figure 3.14 shows a comparison between the values computed by equations 3.20 and 3.21 and equations 3.22 and 3.23. The values computed by equation 3.21 are slightly better than the values computed with equations 3.22 and 3.23. Using equations 3.20 and 3.21 or equations 3.22 and 3.23 is an improvement over fitting a linear equation to the standard modified Fournier index with the square exponent.

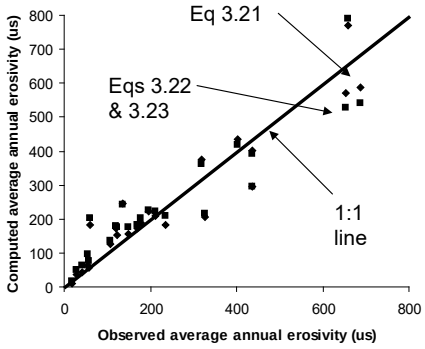

Figure 3.14 Comparison of alternate ways of using a modified Fournier index to estimate average annual erosivity.

The best approach for fitting either equations 3.20 or 3.21 or equations 3.22 and 3.23 is to divide the data into subsets by geographic region where the relationship between precipitation amount and intensity is constant over the region. A separate equation is fitted to the sub-dataset for each region. If the regions are too large, the variation in the relationship of intensity to precipitation amount over geographic space will be too large. Otherwise, the error in estimated erosivity will be very large. For example, the range in average annual erosivity in Figure 3.13 is from about 50 to 325 (US units) for a modified Fournier index value of about 3.5 inches. Obviously this great difference in erosivity for a particular value of the modified Fournier index results in very large errors in estimated erosion.

The implicit assumption in the modified Fournier procedure is that the monthly precipitation distribution coincides with the monthly intensity distribution. That is, the monthly precipitation distribution must coincide with the monthly erosivity density distribution. These distributions coincide well at Minneapolis, Minnesota but not at Oxford, Mississippi. The effect of the coincidence of the distributions on the monthly erosivity distribution is illustrated in Figure 3.15. The monthly erosivity distribution computed from the Fournier index, assuming a square power as in equation 3.20, compares reasonably well with the observed distribution at Minneapolis but compares very poorly at Oxford. Therefore, if the Fournier index is used to estimate monthly erosivity for the USLE, RUSLE1, or RUSLE2, the monthly erosivity density distribution must correspond closely to the monthly precipitation distribution.

Another procedure to estimate erosivity from monthly or annual precipitation amounts is to empirically fit equations involving these variables to observed data (Renard and Freimund, 1994). These procedures work satisfactorily only if the spatial and temporal

variations in the relationship between precipitation amount and intensity are taken into account. For example, average annual erosivity ranged from 88 (US units) to 470 (US units) for an average annual precipitation of 39 inches in the data analyzed by Renard and Freimund (1994). This variation in average annual erosivity for a particular average annual precipitation is much too great to be useful in erosion prediction used for

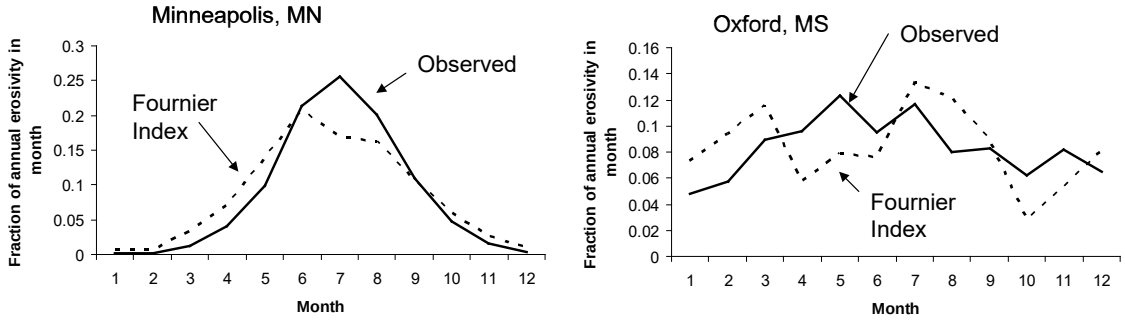

Figure 3.15. Comparison of monthly erosivity distributions computed with the modified Fournier index with observed monthly erosivity distributions.

conservation and erosion control planning. The data should be divided into subsets according to the relation of intensity to precipitation amount.

Any method used to estimate erosivity from precipitation amount MUST take into account how the relationship between precipitation and intensity varies over space and time.

3.2.2. Precipitation

RUSLE2 uses average monthly precipitation values as input values for precipitation. RUSLE2 uses the disaggregation procedure described in **Section 3.1** to disaggregate average monthly precipitation values into daily values. A consistent and sufficient record length should be used to determine average monthly precipitation values from measured data. A 22-year record length was used to develop erosivity values for the USLE (Wischmeier and Smith, 1958, 1965, 1978) because climate was thought to vary in a 22-year cycle. The modern accepted record length seems to be 30 years for hydrologic modeling. The National Weather Service has assembled 30-year data records for the locations where daily precipitation was measured. These data have been reviewed to correct erroneous and missing data. In addition, the USDA-NRCS, National Weather Service, and other agencies used the PRISM (Daly et al., 1997) computer program that extrapolates the measured data at each weather station to compute monthly precipitation values across the US on a 4 km grid. This mathematical procedure adjusts measured values for the effect of elevation, proximity to a coastline, and other variables that spatially affect precipitation. RUSLE2 users should contact their USDA-NRCS state office for precipitation data to use in RUSLE2.

The data available from the NRCS, referred to as the PRISM data, were analyzed to ensure that the probability distribution of the data is uniform for all locations. For example, extreme summer precipitation events can be highly localized. The PRISM data

should be reviewed to ensure that the return periods for the precipitation input data are uniform among locations where RUSLE2 is being applied so that a land user is not unfairly affected by the happenstance of extreme precipitation occurring at their location and not at other locations (See RUSLE2 User's Reference Guide). In general, events having a return period greater than 50 years should be excluded when using RUSLE2 for conservation and erosion control planning.

3.2.3. Temperature

RUSLE2 uses average monthly values for input temperature values. RUSLE2 uses the disaggregation procedure described in **Section 3.1** to compute average daily temperature values from average monthly input values. The time period used to obtain monthly precipitation values should be the same as that used to obtain average monthly temperature values so that precipitation and temperature input values will be consistent. The most recent 30 years is an acceptable period over which to obtain average monthly temperature values. However, the data should be reviewed to ensure that the data record does not contain unusually extreme events that would have extraordinary effect on RUSLE2's computations. Extreme events in the observed temperature data do not seem be as severe as in the precipitation record.

The best source of temperature values for use in RUSLE2 is from the USDA-NRCS. Their data have been produced with the PRISM program that takes into account how elevation and other variables affect temperature. Like precipitation, the USDA-NRCS PRISM temperature values are available on a 4 km grid across the US.

3.2.4. 10 year-24 hour precipitation

RUSLE2 uses the precipitation amount for a 24-hour event that has a 10-year return period as a representative storm to compute the effect of ponding on rainfall erosivity, runoff's sediment transport capacity, and the location along an overland flow path length that contouring fails (e.g., see **Section 3.4.3**). The fundamental structure of RUSLE2 computes daily erosion for unit plot conditions (see **Section 2.1**), which in turn is multiplied by non-dimensional ratios to account for effects of topography, cover-management, and support practices. A single storm is used to compute values for these non-dimensional ratios that involve ponding and runoff. The RUSLE2 intent is to capture main effects related to runoff as they vary with location, soil, and cover-management. RUSLE2 starts with accepted USLE values and uses runoff computations to adjust the ratio values up or down as runoff departs from a base condition. An advantage of this approach is ratio values vary less temporally than erosivity, which allows a single precipitation event to be used to compute runoff. Most of the temporal variation is captured by the temporal varying erosivity. Other temporal differences are captured by computing daily runoff for the representative storm as cover-management variables change temporally. The 10 year-24 hour precipitation was chosen to make the runoff computations because most of the rill-interrill erosion at a site is caused by moderate to large rainfall events (Wischmeier and Smith, 1958, 1978).

The 10-year EI storm was used for the same purpose in RUSLE1 [Foster et al., 1997; AH703 (Renard et al., 1997)]. The procedure in RUSLE1 computed a precipitation amount for the 10 year-EI storm using an empirical equation. This equations was derived by fitting storm erosivity values as a function of storm precipitation amount (Richardson et al., 1983). The RUSLE1 procedure worked satisfactory for the eastern US but not for the Western US, especially in the Northwest Wheat and Range Region (NWRR) that includes the eastern portions of Washington and Oregon and northern portion of Idaho. Winter precipitation causes most of the erosion in the NWRR. This precipitation occurs at a very low intensity, which has low unit energy whereas most of the erosion in the Eastern US is caused by summer precipitation at high unit energy. Directly using the 10 year-24 hour precipitation values more accurately computes runoff for RUSLE2 purposes than computing runoff from a precipitation value computed from an erosivity-precipitation equation empirically derived from eastern US data as was done in RUSLE1.

An erosivity value is needed for the 10 year-24 hour precipitation amount. This erosivity value should reflect the 10 year-24 hour precipitation amount and unit energy at the location. The equation used in RUSLE2 to compute the erosivity for the 10 year-24 hour precipitation amount is:

$$EI_{10y24h} = 2\alpha_m P_{10y24h} \qquad [3.24]$$

where: EI_{10y24h} = the storm erosivity associated with the 10 year-24 hour precipitation amount, α_m = the maximum monthly erosivity density at the location, and P_{10y24h} = the 10 year-24 hour precipitation amount. The 2 coefficient in equation 3.24 was obtained by calibrating equation 3.24 to observed values for the 10-year EI from modern precipitation data in the Eastern US (Hollinger et al., 2002).

Equation 3.24 is consistent with the procedure used to compute monthly erosivity using monthly precipitation amount and monthly erosivity density (see **Section 3.2.1.4.1**). The implicit assumption is that the 10 year-24 hour precipitation event occurs in the month having the maximum erosivity density. A procedure that uses the erosivity density from the month with the maximum precipitation was evaluated. That procedure gave inconsistent results because of spatial variability in the month with the maximum precipitation. The month having the maximum precipitation varies greatly within a relatively small region, which in turn results in relatively large variations in the monthly erosivity density values used in equation 3.24.

The main role of using the 10 year-24 hour precipitation event in RUSLE2 and the 10 year EI in RUSLE1 was to compute the variation in the effectiveness of support practices, especially contouring and strip cropping, across the US. The 10-year EI map published in AH703 (Renard et al., 1997) shows numerous narrow ridges and valleys for the 10-year EI contours. Those narrow ridges and valleys were judged to represent unexplained variability in the measured data used to compute 10-year EI values rather than trends in precipitation important in support practice effectiveness. The smooth trends in the widely accepted maps of the 10 year-24 hour precipitation for the Eastern

US were judged to much more accurately represent precipitation trends important in support practice effectiveness.

3.2.5. Req

In the Northwest Wheat and Range Region (NWRR), erosion per unit erosivity is much greater during the winter months than during the summer months and much greater than for the Eastern US. A unique set of conditions in the NWRR related to highly saturated thawing soil produces a highly erodible soil condition (McCool et al. 1995). The approach used in RUSLE2 computes erosion using standard soil erodibility values (see **Section 4.1**) and adjusted erosivity, i.e., Req for the effective (equivalent) average annual erosivity. Also, a special monthly erosivity distribution is used to distribute the annual Req erosivity over each month.

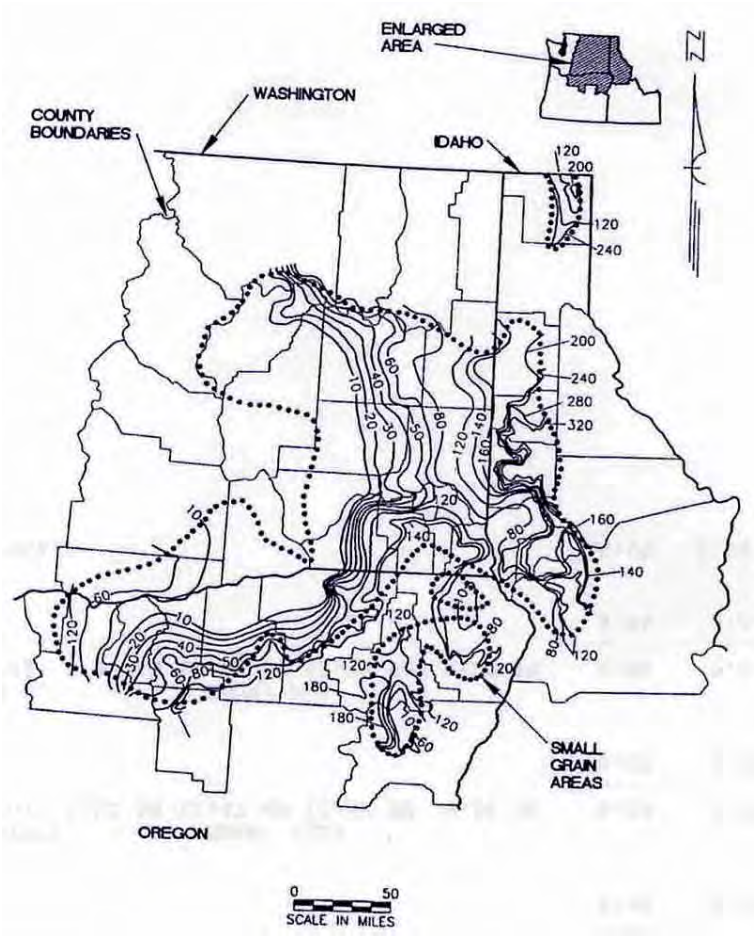

Figure 3.16. Area in Oregon, Washington, and Oregon where RUSLE2 Req procedure works best. Ignore contour lines.

The principal source of data for determining Req has been from research erosion plots operated by the USDA-ARS at Pullman, WA and Pendleton, OR. The procedure is to measure erosion on plots having the unit plot cover-management condition (see **Section 2.1** and **Footnote 3**) and to adjust measured erosion values for the effect of length and steepness to account for differences between the actual plots and unit plots. The adjusted average annual erosion value is divided by the standard soil erodibility value to produce an Req value. The distribution of measured erosion on unit-plot conditions by month is used to obtain an Req erosivity distribution.

The RUSLE2 Req procedure works well for the region shown in Figure 3.16, which is mainly northeastern Oregon, eastern Washington and northern Idaho. The Req effect

occurs in other parts of the Western US, but the Req relationships for these regions have not been well determined. RUSLE2 compute Req as a function of average annual precipitation based on conditions across eastern Washington. Whether that relationship applies in other regions where the precipitation and temperature differs from that in eastern Washington is a concern. Certainly the monthly distribution for Req differs in other regions where the monthly distribution of precipitation differs from that in eastern Washington. The Req distribution for eastern Washington should not be used at other locations without making adjustments for differences in monthly precipitation and temperature distributions.

Another consideration is that winter temperatures are so low at some locations that soil freezing significantly decreases erosion, which is represented by a decreased soil erodibility value during that period. Also, snow covers the soil at high elevations to prevent winter erosion. Another factor is erosion by snowmelt in late winter and early spring, but RUSLE2 is not designed to estimate erosion by snowmelt. Erosion research at Morris, Minnesota showed that only about seven percent of the erosion occurred by snowmelt (Knisel, 1980). Thawing and recently thawed soil can be highly erodible in late winter and early spring in all locations, including the eastern US. Even though soil erodibility can be greatly increased for a short time, less than three weeks, not much erosion occur if little erosivity occurs during this period, which is the case in Minnesota. A similar effect occurs in the Mid-South region. This effect is partially captured in the temporal soil erodibility equation for the mid-south US and similar regions (see **Section 4.5**).

The Req effect is described in detail in the **RUSLE2 User's Reference Guide**. Additional information can be obtained by contacting D.K. McCool, USDA-ARS, Pullman, WA, and by reviewing his scientific publications.

3.3. Runoff

RUSLE2 uses the 10 year-24 hour index (representative) storm to compute runoff depth, which is subsequently used as an index to compute deposition, erosion control effectiveness of support practices, and effect of water depth (ponding) on erosion (see **Sections 2.3.3, 7 and 3.4.5**). This procedure captures runoff's main effects but not every detail. For example, RUSLE2 uses this approach to estimate how contouring effectiveness differs between the Northern and Southern US.

Both runoff amount and rate are important for computing erosion. RUSLE2's equations for runoff hydraulics (see **Section 3.4**) are based on runoff rate. RUSLE2 computes a daily sediment load to erosivity ratio, which RUSLE2 multiplies by daily erosivity to estimate daily erosion, deposition, and sediment load (see **Section 2.3.9**). The RUSLE2 assumption is that excess rainfall rate (depth/time) equals runoff depth divided by one hour. Rainfall depth is the major determinant of excess rainfall rate. The 10 year-24 hour precipitation amount is used each day to compute daily runoff depth as cover-management conditions temporally vary. The resulting runoff values are indices of how runoff varies by location as a function of soil and cover-management.

3.3.1. Computation of runoff

RUSLE2 uses the NRCS curve number method to compute runoff depth as a function of precipitation amount and curve number (Haan et al., 1994). Curve number values vary with cover-management, hydrologic soil group, and antecedent soil moisture. A moderate antecedent soil moisture condition is used in RUSLE2.

3.3.1.1. NRCS curve number method

The NRCS curve number equation computes runoff depth as:

$$Q = \frac{(P - 0.2S)^2}{P + 0.8S} \qquad [3.25]$$

where: Q = runoff depth, P = precipitation depth, and S = a variable computed with:

$$S = 1000 / N - 10 \qquad [3.26]$$

where: N = curve number and inches are the units for P, Q, and S.

A requirement for equation 3.25 is that precipitation depth P is greater than 0.2S. Equation 3.25 was modified so that RUSLE2 computes decreasing runoff rate with distance along the overland flow path where a segment has a much higher infiltration rate than do upslope segments. The modified equation computes the additional precipitation amount that would be needed to just produce runoff for the precipitation depth P as:

$$P_a = P - 0.2\left[\left(\frac{1000}{N}\right) - 10\right] \qquad [3.27]$$

where: P_a = the additional precipitation (inches) needed to produce runoff.

Excess rainfall rate σ (inches/hour) in equation 2.18 is set equal to Q (inches) in equation 3.25 or to P_a (inches) in equation 3.27 if P < 0.2S (see **Section 2.3.5**). The negative excess rainfall rate causes RUSLE2 to compute a decreasing discharge rate along the overland flow path.

3.3.1.2. Curve number as function of cover-management variables

RUSLE2 uses equations that are functions of cover-management variables to compute curve number N values. Curve number values vary daily as cover-management variables including ground cover, soil surface roughness, soil biomass, and soil consolidation, change daily (see **Section 6**).

Equations were derived for RUSLE2 that compute curve number values as a function of cover-management variables and hydrologic soil group. First, curve number values was assigned to each hydrologic soil group for a wide range of cover-management conditions based on standard NRCS procedures for non-Req conditions and measured runoff from USDA-ARS research plots at Pullman, Washington for Req conditions. These curve

number values are comparable to those used in RUSLE1. The equations used to compute RUSLE2 curve numbers were empirically derived using equation forms chosen to represent the trend of curve number values as a function of key cover-management variables. Coefficient values for these equations were obtained by fitting the equations to the assigned curve number values.

3.3.1.2.1. Standard conditions – no Req, no non-erodibile cover, no irrigation, no adjustment made for subsurface drainage

Curve number N represents the effect of cover-management on runoff and the inherent potential of the soil for producing runoff. Hydrologic soil group is the variable used in RUSLE2 to represent the inherent runoff potential of the soil. Cover-management affects runoff in several ways. For example, improved soil management, which is represented in RUSLE2 by increased soil biomass, decreases runoff. Mechanical soil disturbance like tillage reduces runoff on soils having no biomass in comparison to the soils not disturbed for several years. Soil biomass and soil consolidation interact to affect runoff. Soil consolidation increases runoff when soil biomass is very low, typical of construction sites not recently mechanically disturbed. Conversely, soil consolidation decreases runoff when soil biomass is very high, typical of undisturbed, high production pasture. Increased soil surface roughness and ground cover decrease runoff depending on soil biomass levels. Curve numbers and how they are affected by cover-management are also a function of soil properties as represented by hydrologic soil group. For example, cover-management decreases runoff more on soils having a high infiltration potential, hydrologic soil group A, than on soils having a low infiltration potential, hydrologic soil group D.

RUSLE2 curve number equations were calibrated to curve number values commonly used by NRCS (Haan et al., 1994). Indices in these empirical equations reflect how cover-management is known to affect infiltration and runoff.

The main RUSLE2 equation used to compute curve number values is:

$$N = [N_{u100} - s_u(1 - s_c)]\, f_B \exp(b_D B_s) \qquad [3.28]$$

where: N = curve number used in equations 3.25, 3.26, and 3.27 to compute runoff, N_{u100} = a curve number value that represents the effect of ground cover and soil roughness on curve number on a soil recently mechanically disturbed (i.e., $s_c = 1$), s_u = the change in curve number per unit change in the soil consolidation subfactor (see **Section 6.6**), f_B = a fraction, which along with the term $\exp(b_D B_s)$, describes the main effect of soil biomass and its interaction with soil consolidation on curve number, b_D = a coefficient that is a function of the soil consolidation subfactor s_c, and B_s = soil biomass. Soil biomass B_s is the sum of buried residue averaged over the residue accounting depth (see **Section 6.2**) and the live and dead root biomass averaged over the upper 10 inch soil depth (see **Section 6.2.1**). Units for B_s are biomass on a dry basis/(land area·unit soil depth). The accounting depth for buried residue decreases from 3 inches to 1 inch as the soil consolidation subfactor s_c decreases from 1 to 0.45 (see Section **6.6**).

The curve number N_{u100} is determined by starting with a base curve number for a recently mechanically tilled soil. This curve number is decreased for increases in both ground cover and adjusted soil surface roughness r_a greater than 0.24 inch, which is the base roughness value assumed for unit plot conditions (see **Section 2.1** and **Footnote 3**). Curve number values increase when adjusted roughness is less than 0.24 inch, which represents a condition where runoff is greater than from the unit plot condition. The adjusted soil surface roughness is used in equation 6.26 to compute a soil surface roughness subfactor value (see **Section 6.3**).

The equations used to compute N_{u100}, which do not consider any effect of soil biomass or soil consolidation on curve number, are given by:

Table 3.3. Curve number and coefficient values used in standard RUSLE2 curve number equations (not Req)

Hydrologic soil group	N_{s100}	N_{uB}	N_{lB}	N_{u45}	N_{lb45}	b_B (in ac/lbs$_m$)	a_{cu}	a_{cl}	a_{ru}	a_{rl}	a_{45}
A	87.0	87.0	53.0	94.0	70.0	0.00219	-12.0	-6.5	-12.0	6.5	-0.12
B	92.0	92.0	68.0	98.0	82.0	0.00174	-12.0	-6.5	-12.0	6.5	-0.12
C	93.0	93.0	75.0	98.6	84.6	0.00200	-7.0	-5.0	-7.0	5.0	-0.07
D	94.0	94.0	79.0	98.7	88.4	0.00153	-5.0	-3.0	-5.0	4.0	-0.05

$$N_{u100} = N_{s100} + a_{cu}(f_g/100) + a_{ru}\{1-\exp[-1.7(r_a-0.24)]\} \quad [3.29]$$

$$N_{u100} = N_{s100} + a_{cl}(f_g/100) + a_{rl}[(0.24-r_a)/0.24] \ \ r_a \le 0.24 \text{ in} \quad [3.30]$$

where: N_{u100} = a curve number for a recently mechanically disturbed soil (i.e., s_c = 1) with no soil biomass, N_{s100} = a starting curve number value for unit plot conditions that are recently mechanically disturbed, adjusted soil surface roughness r_a = 0.24 in, and no soil biomass, a_{cu} = a coefficient for the effect of ground cover when surface roughness is greater than 0.24 inches, a_{cl} = a coefficient for the effect of ground cover when surface roughness is less than 0.24 inches, f_g = ground cover (percent), a_{ru} = a coefficient for the effect of soil surface roughness when roughness is greater than 0.24 inches, a_{rl} = a coefficient for the effect of adjusted soil surface roughness when the adjusted soil surface roughness is less than 0.24 inches, and r_a = adjusted soil surface roughness index (inches) (see **Section 6.3**). Values for starting curve number N_{s100} and the coefficients a_{cl}, a_{clu}, a_{rl}, and a_{ru}, which vary with hydrologic soil group, are given in Table 3.3.

The main effect of soil consolidation is represented in the terms involving s_u, which is the rate of change in the curve number per unit change in the soil consolidation subfactor s_c. The equation for s_u is given by:

$$s_u = (N_{u100} - N_{u45})/0.55 \quad [3.31]$$

where: N_{u45} = the curve number for a fully consolidated soil with no ground (surface) cover or soil biomass and soil surface roughness = 0.24 inches, 0.55 = the range in the

soil consolidation subfactor s_c from 1 for a recently mechanically disturbed soil to 0.45 for a fully consolidated soil. Values for the curve number N_{u45}, given in Table 3.3, are for a fully consolidated soil with no ground cover and soil biomass.

The fraction f_B represents the main effect of soil biomass on curve number. A value for f_B is computed with:

$$f_B = [(N_{uB} - N_{lB})\exp(-b_B B_s) + N_{lB}] / N_{uB} \quad [3.32]$$

where: N_{uB} = the curve number value when no biomass is present in the soil and the soil has been recently mechanically disturbed, N_{lB} = the curve number for a very high soil biomass (i.e., when $\exp(-b_B B_s)$ is near zero) and the soil has been recently mechanically disturbed, and b_B = a decay coefficient that represents how the curve number decreases exponentially as a function of soil biomass. Curve number values for N_{uB} and N_{lB} are given in Table 3.3. The effect of soil biomass on curve number is assumed to be greater in soils having a low runoff potential, i.e., hydrologic soil group A, than soils having high runoff potential, i.e., hydrologic soil group D. Values for the decay coefficient b_B, are also given in Table 3.3.

The term $\exp(b_D B_s)$ in equation 3.28 represents how the interaction between soil biomass and soil consolidation affect curve number values. A value for the coefficient b_D is computed from:

$$b_D = \ln(N_l / N_u) / 1750 \quad [3.33]$$

where: N_l and N_u = lower and upper curve numbers, respectively, that represent the difference in curve numbers for a soil with no soil biomass and one with a high soil biomass of 1750 lbs_m/(acre·in) value. The value for N_u is computed from:

$$N_u = N_{u100} - s_u(1 - s_c) \quad [3.34]$$

A value for the lower curve number that is comparable to the upper curve number N_u is computed as:

$$N_l = N_{u100} - s_l(1 - s_c) \quad [3.35]$$

where: s_l is computed from:

$$s_l = (N_{l100} - N_{l45}) / 0.55 \quad [3.36]$$

The curve number N_{l45} is adjusted for ground cover is computed as:

$$N_{l45} = N_{lb45}(1 + a_{45} f_g / 100) \quad [3.37]$$

where: a_{45} = a coefficient having values given in Table 3.3. Soil surface roughness is assumed not to affect curve number for a fully consolidated soil with high soil biomass.

Values for the index curve number N_{lb45} used to calculate curve numbers for fully consolidated soil at high soil biomass with no ground cover are also given in Table 3.3.

Table 3.4. RUSLE2 (R2) curve numbers computed for Columbia, Missouri compared with curve numbers used in RUSLE1 (R1) for A, B, C, and D hydrologic soil groups

Cover-management condition		A		B		C		D	
R1 class	Description	R1	R2	R1	R2	R1	R2	R1	R2
C1	Established meadow, very dense cover with high soil biomass	30	45	58	64	71	71	78	78
C2	Mixed grass-legume hay, moderate cover, and moderate to high soil biomass	46	61	66	75	78	80	83	85
C3	Heavy cover (75-95%) or very rough with moderate biomass	54	46	69	62	79	70	84	77
C4	Moderate cover (40-65%) or rough with moderate soil biomass	55	54	72	66	81	75	85	81
C5	Light cover (10-30%), moderate roughness, and low to moderate soil biomass	56	61	75	70	83	76	87	82
C6	Essentilly no cover (5%), minimal roughness and low to moderate soil biomass	64	67	78	78	85	82	89	84
C7	Very little soil biomass and smooth	77	84	86	90	91	91	94	93
	Cut soil, no soil biomass without mulch		94		98		99		99
	Cut soil, no soil biomass with 4000 lbs/ac straw mulch		94 - 63		98 - 77		98 - 82		99 - 87
	Fill soil, graded smooth with no mulch		87 - 88		92 - 93		93 - 94		94 - 95
	Fill soil, graded smooth with 4000 lbs/ac straw mulch		81 - 85		86 - 90		89 - 92		91 - 94

Notes:
The curve numbers from RUSLE2 were taken at planting time because theRUSLE1 curve numbers are most applicable for that period.
The range in RUSLE2 curve numbers for the construction site conditions are for the 12 month period

A-hydrologic soil group (lowest runott potential) to D-hydrologic soil group (highest runoff potential)

RUSLE2 computed curve number values as shown in Table 3.4 along with the curve number values used in RUSLE1. RUSLE2 adequately captures the trends in curve numbers for land use that varies from construction sites to dense grass. RUSLE2

computes higher curve number values for the A-hydrologic soil group soils (low runoff potential) than those used in RUSLE1. However, the higher curve numbers are considered more appropriate for RUSLE2 applications. RUSLE2 also computes curve number values that are consistent with those reported for a wide range of land uses (Haan et al. 1994).

3.3.1.2.2. Req conditions, no irrigation, no adjustment made for subsurface drainage

The procedure described in Section 3.3.1.2.1 is also used to compute runoff for Req conditions, but different runoff curve number and coefficient values are used. A major effect in the Req zone is that infiltration is very low during the winter unless residue cover, soil biomass, and soil surface roughness is very high. The soil becomes highly saturated resulting in a very high portion of the precipitation becoming runoff during the winter period. High residue cover, soil biomass, and surface roughness seem to keep open macro-pores for significantly increased infiltration. The values given in Table 3.5 are used during by RUSLE2 for the winter Req period to compute runoff while the values given in Table 3.3 can be used for the summer months.

Table 3.5. Curve number and coefficient values used in RUSLE2 curve number equations for Req conditions

Hydrologic soil group	N_{s100}	N_{uB}	N_{lB}	N_{u45}	N_{lb45}	b_B (in ac/lbs$_m$)	a_{cu}	a_{cl}	a_{ru}	a_{rl}	a_{45}
A	92.0	92.0	22.0	94.0	70.0	0.00024	-12.0	-6.5	-25	2.0	-0.12
B	97.0	97.0	58.0	98.0	82.0	0.00020	-12.0	-6.5	-25	2.0	-0.12
C	98.0	98.0	73.0	98.6	84.6	0.00025	-7.0	-5.0	-15	2.0	-0.07
D	98.0	98.0	78.0	98.7	88.4	0.00020	-5.0	-3.0	-10	2.0	-0.05

3.3.1.2.3. Effect of non-erodible cover on runoff

RUSLE2 assumes no detachment for the portion of the soil surface covered by non-erodible cover. However, RUSLE2 assumes that non-erodible cover can be permeable. A RUSLE2 input value used to describe non-erodible cover is the fraction of the non-erodible cover that is fully permeable so that infiltration is controlled by the underlying soil. All of the precipitation is assumed to become runoff for the remaining portion of the non-erodible cover. The overall effective curve number for this condition is computed by RUSLE2 as:

$$N = N_b(1 - f_\mu) + f_\mu[N_b f_\rho + 100(1 - f_\rho)] \quad [3.38]$$

where: N = overall, effective curve number used in equation 3.25 or 3.27 to compute runoff, f_μ = fraction of the soil surface covered by non-erodible cover, f_ρ = fraction of the non-erodible cover that is permeable, N_b = the curve number for the portion of the soil not covered by the non-erodible cover, and 100 = the curve number for the non-permeable portion of the non-erodible cover. A 100 curve number means that all of the precipitation becomes runoff.

3.3.1.2.4. Effect of subsurface drainage on runoff

The RUSLE2 procedure for adjusting for subsurface drainage is to select a hydrologic soil group that describes runoff potential for the undrained condition and one that describes runoff potential for the drained condition (see **Sections 7.4** and the RUSLE2 User's Reference Guide). RUSLE2 uses the hydrologic soil group assigned to the drained and undrained soil conditions to compute runoff using the values in either Table 3.3 or 3.4.

A RUSLE2 input for subsurface drainage is the portion of the area represented by the overland flow path that is subsurface drained. RUSLE2 uses this input to compute an effective curve number value for the entire overland flow path. The effective curve number is computed with:

$$N = N_d f_d + N_{ud}(1 - f_d) \quad [3.39]$$

where: N = effective curve number used in equation 3.25 or 3.27 to compute runoff, N_d = curve number for the drained condition, N_{ud} = the curve number for the undrained condition, and f_d = the fraction of the area represented by an overland flow path that is drained.

3.3.1.2.5. Effect of irrigation on runoff

RUSLE2 computes the effect of irrigation on erosion when rainfall occurs. RUSLE2 does not compute erosion caused by the applied water. RUSLE2 computes increased erosion on irrigated areas because increased soil moisture increases soil erodibility and residue decomposition and decreases soil surface roughness. However, RUSLE2 does not compute increased runoff caused by irrigation.

3.4. Hydraulics

RUSLE2 uses shear stress as the hydraulic variable to compute sediment transport capacity and locations where contouring fails. Runoff's total shear stress is applied to surface soil particles, ground cover, soil surface roughness elements, and stems of live and standing dead vegetation. Total shear stress is computed with (Chow, 1959):

$$\tau_t = \gamma y s \quad [3.40]$$

where: τ_t = total shear stress (force/unit area), γ = weight density of water (force/volume), y = flow depth (length), and s = overland flow path steepness (sine of slope angle). Flow depth is computed with the Manning equation as (Chow, 1959):

$$y = \left(\frac{q n_t}{1.49 s^{1/2}} \right)^{3/5} \quad [3.41]$$

where: q = discharge rate, n_t = total Manning's n (index for hydraulic roughness-resistance), and the 1.49 is used when US customary units [q - ft3/(sec·ft width), y – ft] are used.

3.4.1. Concept of grain and form roughness

The total shear stress can be divided into two parts (Graf, 1971), the part referred to as grain roughness shear stress that acts on surface soil particles and the part referred to as form roughness shear stress that acts on ground cover, stems of live and dead standing vegetation, and soil surface roughness elements. Grain roughness shear stress is assumed to be responsible for sediment transport while form roughness shear stress is assumed to be responsible for contouring failure (Foster, 1982; Foster et al., 1982b).

3.4.2. Grain roughness shear stress for computing sediment transport capacity

RUSLE2 uses Equation 2.17 to compute sediment transport capacity. That equation is based on the assumption that sediment transport capacity can be computed as:

$$T_c = K_T \tau_g^{3/2} \qquad [3.42]$$

where: T_c = sediment transport capacity (mass/width·time), and τ_g = grain roughness shear stress(force/aea). By using the concept that flow depth can be divided into parts associated with grain and form roughness, equations 3.41 and 3.42 can be combined with a Manning's n for grain roughness to give equation 2.17 where the coefficient ζ is given by (Foster et al., 1982b):

$$\zeta = 0.0008 n_t^{-1.5} \qquad [3.43]$$

where: the coefficient ζ has absorbed γ and the Manning's n_g value for grain roughness, which is assumed to be 0.01.[32] Total Manning's n_t is computed by RUSLE2 as a function of soil surface roughness, ground cover, live vegetation biomass, and standing residue biomass (see **Section 3.4.6**).

3.4.3. Form roughness shear stress for computing contouring failure

3.4.3.1. Main equations

RUSLE2 computes form roughness shear stress as a function of discharge rate as:

$$\tau_f = a_f q^{0.85714} s / n_t^{1.2857} \qquad [3.44]$$

---

[32] This equation is based on US customary units of ft^3/sec per ft width for discharge rate (q), ft for flow depth (y), and lbs_f/ft^2 for shear stress (τ).

where: τ_f = grain roughness shear stress and a_f =a coefficient that includes γ in equation 3.40, 1.49 in equation 3.41, and other empirical coefficients. RUSLE2 assumes contouring failure where form roughness shear stress computed with equation 3.44 exceeds a critical shear stress. A value for critical shear stress for contouring failure was determined by calibrating equation 3.44 to critical slope length values given in AH537 (Wischmeier and Smith, 1978). The resulting critical shear stress for contour failure is 3619 value when US customary units are used in the equations. The value for a_f in equation 3.44 is absorbed in the critical shear stress value along with conversion factors that would be used to convert excess rainfall rate to ft/sec rather than using inches/hour. Form roughness shear stress for contouring failure is computed with:

$$\tau_f = q_i^{0.85714} s / n_t^{1.2857} \qquad [3.45]$$

where: the discharge rate q_i is computed using excess rainfall rate (σ_i) in inches/hour rather than ft/sec as $q_i = x\sigma_i$ and x = distance (feet) along overland flow path.[33]

The critical slope length values beyond which contouring failure is assumed were based on judgment of soil conservation technical specialists and were not determined by research. These values were developed at a 1956 workshop (Wischmeier and Smith, 1978) and therefore represented observations from research studies and field observations from the early 1930's to the mid 1950's The base condition used in calibrating the critical shear stress for contouring failure represents those conditions rather than modern conditions. The assumed base condition is conventionally tilled, low yield (50 bu/ac), continuous corn at Columbia, Missouri. The operations assumed for this cropping system include a moldboard plow in the spring for primary tillage, two secondary tillage operations to prepare the seedbed, row planter to seed the crop, row cultivator to control weeds, and harvest. Table 3.6 shows a comparison between the values computed with RUSLE2 and those given in AH537 (Wischmeier and Smith, 1978). The values compare well except at very flat steepness where RUSLE2 computed values are much longer than those given in AH537. The values computed by RUSLE2 are considered acceptable.

Table 3.6. Critical slope lengths

	Critical slope length (ft)	
Slope steepness (%)	AH537	RUSLE2
1.5	400	>1000
4.0	300	384
7.0	200	200
10.5	120	125
14.5	80	86
18.5	60	66
23.0	50	51

RUSLE2 sets the contouring subfactor value to 1 for those portions of the overland flow path where form roughness shear stress exceeds the critical shear stress for contouring failure (see **Section 7.1**). No adjustments are made in the cover-management subfactors used to compute detachment in equation 2.10. RUSLE2 also computes the location

[33] Mixed units are given in these equations for consistency with the equations used in the RUSLE2 computer program to facilitate a comparison of computer code with this documentation.

where runoff shear stress acting on form roughness equals the critical shear stress for contour failure. That equation is:

$$q_c = 13900 n_t^{1.5} / s^{1.1667} \quad [3.46]$$

where: q_c = the discharge rate (where excess rainfall rate in equation 2.18 is in units of in/hr) at which contouring fails. The location of this discharge rate can be determined from equation 2.18.

RUSLE2 computes where contouring fails along overland flow paths as a function of location (i.e., as reflected by the $P_{10y\text{-}24h}$ precipitation amount), runoff, soil infiltration potential, overland flow path steepness, and cover-management conditions. For example, RUSLE2 computed critical slope length values are a function of crop yield. Increased crop yield increases critical slope length. The increased biomass improves soil properties that increase infiltration and reduce runoff, increases soil surface roughness, and increases ground cover provided by crop residue. The critical slope length increases from 103 to 151 ft for an increase in corn yield from 50 to 115 bu/ac in a grain corn-silage corn-alfalfa hay-alfalfa hay-alfalfa hay crop rotation for an overland flow path on a silt loam soil at 20 percent steepness at LaCrosse, Wisconsin. Tillage systems that leave increased surface soil roughness and surface crop residue cover also increase RUSLE2 computed critical slope length as illustrated in Table 3.7.

Table 3.7. RUSLE2 computed critical slope lengths for three tillage systems for continuous 50 bu/ac corn.

	RUSLE2 computed critical slope length (ft)		
Slope steepness (%)	Conv till	Mulch till	No-till
1.5	>1000	>1000	>1000
4.0	384	594	837
7.0	200	310	436
10.5	125	194	273
14.5	86	134	188
18.5	66	101	143
23.0	51	79	112

RUSLE2 does not compute contouring failure as a function of how soil properties affect the soil's critical shear stress for contouring failure. This capability is desirable, but sufficient empirical data are not available to develop the required critical shear stress values as a function of soil properties. Contouring failure in RUSLE2 is assumed not to be a function of ridge height or grade along the ridges-furrows. Clearly contouring failure is a function of ridge height because ridge height affects storage of runoff water and the likelihood of ridge breakover especially in low areas. However, accurately describing flow hydraulics and water storage on a specific field site is very difficult because of imperceptible variations of row grade and ridge heights along the ridges-furrows. Although RUSLE2 has these shortcomings, it was developed to guide conservation planning, and in that context, RUSLE2 is a major improvement over the USLE and RUSLE1.

3.4.3.2. Form roughness shear stress below segment having a high hydraulic roughness

RUSLE2 assumes a gradual rather than a step decrease in total hydraulic roughness where total hydraulic roughness decreases from one overland flow path segment to the

next segment. Consequently, the form roughness shear stress increases gradually rather than abruptly between segments. An example is runoff exiting from dense vegetation onto a relatively smooth, bare soil surface. The dense vegetation spreads the runoff so that the flow has a laterally uniform depth as it exits the vegetation. Form roughness shear stress is assumed to be less when flow depth is laterally uniform than when concentrated in rills. A distance is required below the dense vegetation for the runoff to become concentrated in rills with increased form roughness shear stress.

This concept is implemented in RUSLE2 by assuming that the effective total hydraulic roughness decreases exponentially below a segment having a high total hydraulic roughness. The equation for the total Manning's n_t in the transitional region is:

$$n_{et} = n_{tl} + (n_{tu} - n_{tl}) \exp[-0.065(x - x_u)] \qquad [3.47]$$

where: n_{et} = Manning's n_t in the transitional zone, n_{tl} = the total Manning's n_t in the lower segment, Manning's n_{tu} = the Manning n_t in the upper segment, x = distance along the overland flow path (ft), and x_u = the distance to the upper end of the lower segment (ft). Figure 3.17 shows the RUSLE2 computed decrease in Manning's n_t below a hay strip in a typical strip cropping system used in LaCrosse, Wisconsin and evaluated in research studies (Hays and Attoe, 1957; Hays et al., 1949). Also, erosion from other strip cropping systems was also studied at other locations (Borst et al., 1945; Hill et al.,. 1944; Hood and Bartholomew, 1956; Smith et al. 1945). RUSLE2 gives similar results for these systems discussed in AH703 (Renard et al., 1997; Foster et al., 1997).

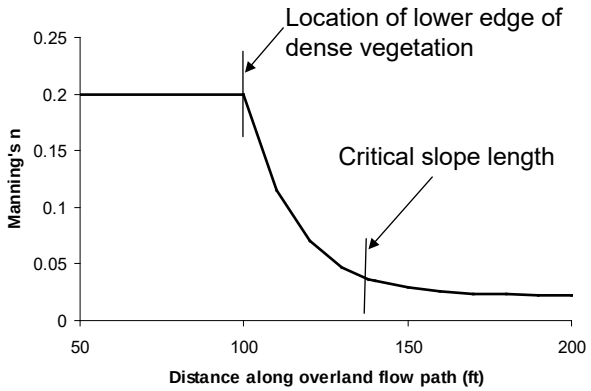

Figure 3.17. Decrease in Manning's n_t along overland flow path below a segment having a high Manning's n_t.

The reduction in form roughness shear stress by runoff spreading reduces the portion of an overland flow path where form roughness shear stress can exceed critical shear stress for contouring failure. The result is that contour strip cropping increases computed critical slope length (i.e., the location where contouring fails). The assumption that contour strip cropping increases critical slope length has long been accepted and used in conservation planning [e.g., see AH282 (Wischmeier and Smith, 1965) and AH537 (Wischmeier and Smith, 1978)]. In AH537, the critical slope length (referred as slope length limits in AH537) is doubled for contour strip cropping without regard to cover-management condition such as type, quality, and density of vegetation on each overland flow path segment. However, the AH537 contouring factor values for contour strip cropping do vary with cover-management condition.

Data from research in Wisconsin (Hays and Attoe,1957; Hays et al., 1949) were the best available in the 1950's to guide development of critical slope length concepts and values by erosion scientist and soil conservation specialists for use in the USLE (AH282, AH537). The RUSLE1 developers judged that critical slope length with strip cropping was 1.5 times the critical slope length without strip cropping [AH703 (Renard et al., 1997)]. A major RUSLE2 improvement is that RUSLE2 computes how location (i.e., $P_{10y\text{-}24h}$ precipitation), runoff, overland flow path steepness, cover-management conditions, number of strips, and relative placement of strips along an overland flow path affect critical slope length. The RUSLE2 procedure is far more comprehensive that previous USLE and RUSLE1 procedures.

The 0.065 ft^{-1} value in equation 3.47 was selected to give critical slope length values considered appropriate for the LaCrosse, Wisconsin experimental contour strip cropping (Hays et al., 1949). For example, RUSLE2 computes a critical slope length of 103 ft on a 20 percent steep overland flow path for the crop rotation used in the contour stripping studies without the crops being arranged in strips. That is, cover-management along the overland flow path is uniform at any particular time although cover-management temporally changes during the crop rotation. The crop rotation is a year of grain corn and a year of silage corn conventionally tilled with a moldboard plow, and three years of alfalfa hay fall seeded immediately after the silage corn is harvested. The assumed corn yield is 50 bu/acre, a typical yield in the 1930's and 1940's. The RUSLE2 computed critical slope length is 191 ft when the crops are arranged in a four strip contour strip cropping system.

The RUSLE2 computed critical slope length is a function of number of strips along the overland flow path. For example, the RUSLE2 computed critical slope length is 153 ft for the LaCrosse, Wisconsin crop rotation placed in two rather than four strips. Strip width is 50 ft for the four-strip system on a 200 ft overland flow path length while it is 100 ft for the two-strip system. As Figure 3.17 shows, about 38 ft is required for total effective hydraulic roughness computed with equation 3.47 to decrease to where form roughness shear stress exceeds the critical shear stress for contouring failure. Strip width should be no wider than 38 ft, according to Figure 3.17 for these conditions, to prevent form roughness shear stress from exceeding the critical shear stress for contour failure. The 100 ft strip width in the two-strip contouring strip cropping system greatly exceeds 38 ft. In contrast, the 50 ft wide strip in the four-strip contour strip cropping system is sufficiently narrow that the form roughness shear stress only exceeds critical shear stress for contouring failure over the last 9 ft of the overland flow path length.

3.4.3.3. Determining location where contouring failure occurs

RUSLE2 uses rules to determine where the form roughness shear stress exceeds critical shear stress for contouring failure within an overland flow path segment.

3.4.3.3.1. Discharge rate increases within segment

If discharge rate increases within a segment and form roughness shear stress at both the upper and lower ends of the segment is less than the critical shear stress for contouring failure, contouring failure does not occur within the segment. If form roughness shear

stress exceeds the critical shear stress for contouring failure at both the upper and lower ends of the segment, contouring failure occurs over the entire segment. However, if form roughness shear stress at the upper end of the segment is less than the critical shear stress for contouring failure, and form roughness shear stress at the lower end of the segment exceeds critical shear stress for contouring failure, contouring failure occurs over the lower portion of the segment beginning at the location where form roughness shear stress equals the critical shear stress for contouring failure. This location is computed with equations 2.18 and 3.46.

3.4.3.3.2. Discharge rate decreases within segment

If discharge rate decreases within a segment and form roughness shear stress at both the upper and lower ends of the segment is less than the critical shear stress for contouring failure, contouring failure does not occur within the segment.

If form roughness shear stress at the upper end of the segment is less than the critical shear stress for contouring failure but exceeds critical shear stress for contouring failure at the lower end of the segment, contouring failure occurs over the lower portion of the segment beginning at the location where form roughness shear stress equals the critical shear stress for contouring failure. This location is computed with equations 2.18 and 3.46.

If form roughness shear exceeds the critical shear stress for contouring failure at both the upper and lower ends of the segment, the possibility exists for contouring failure on upper and lower portions of the segment without contouring failure in the middle portion of the segment. RUSLE2 determines where the form roughness shear stress is a maximum within the segment and if that shear stress is greater than the critical shear stress for contouring failure, then contouring failure occurs over the entire segment. If the minimum form roughness shear stress within the segment is less than the critical shear stress for contouring failure, then form roughness shear stress equals the critical shear stress at two locations within the segment. These locations are determined with equations 2.18 and 3.46.

If form roughness shear stress is less than the critical shear stress for contouring failure at both the upper and lower ends of the segment, the possibility exists that form roughness shear stress increases to a value greater than the critical shear stress for contouring failure within the segment and then decreases to below this critical shear stress above the lower end of the segment. Contouring failure occurs on a middle portion within the segment. This check can be made by computing the maximum form roughness shear stress within the segment, and if it exceeds the critical shear stress for contouring failure, this condition exists. The portion where contouring fails lies in the middle of the segment between the two locations where form roughness shear stress equals the critical shear stress for contouring failure, which are determined from equations 2.18 and 3.46.

3.4.3.4. Runoff rate used to compute contouring failure

To compute contouring failure, RUSLE2 computes a daily runoff rate that varies with both cover-management and the probability of an intense storm occurring when

contouring is susceptible to failure. The daily precipitation amount used to compute contouring failure is assumed to vary linearly with the temporal daily erosivity distribution (see **Sections 3.1 and 3.2.1**) with the maximum daily precipitation occurring on same day that the maximum daily erosivity occurs. This daily precipitation amount is computed as:

$$P_{cf} = (f_{Rd} / f_{Rmx}) P_{10y24h} \quad [3.48]$$

where: P_{cf} = the daily precipitation amount used to compute contouring failure, f_{Rdj} = the fraction of the annual erosivity that occurs on the *jth* day, and f_{Rmx} = the fraction of the annual erosivity that occurs on the day when maximum daily erosivity occurs.[34] **The time varying precipitation computed with equation 3.48 is only used to compute contouring failure. It is not used anywhere else in RUSLE2.**

3.4.4. Backwater

Backwater occurs at locations on an overland path where total hydraulic roughness makes a step increase, such as at the upper edge of a dense vegetation strip. This backwater is especially important because most of the deposition caused by dense vegetation strips occurs in the backwater (Dabney et al., 1995; Flanagan et al., 1989; Foster et al., 1980a; Hayes et al., 1984; McGregor et al., 1999). Ignoring backwater length would cause RUSLE2 to greatly underestimate deposition when computing deposition caused by narrow, dense vegetation strips.

The Manning equation is used in RUSLE2 to compute flow depth at the upper edge of segments where Manning's n_t makes a step increases. An effective backwater length is computed from this flow depth assuming that the backwater is level. The combined equation for computing backwater length is:

$$\Delta x_b = 3.44[n_t q_u / (1.49 s_{lh}^{0.5})]^{0.6} / s_{uh} \quad [3.49]$$

where: Δx_b = the backwater length (ft), q_u = discharge rate (ft^2/s) at the upper edge of the segment having the high total Manning's n_t, s_{lh} = the steepness of the segment having the high Manning's n (**sine** of the slope angle), and s_{uh} = steepness of the immediately upslope segment (the **tangent** of the slope angle). The 3.44 value in equation 3.49 was determined by calibration. The coefficient was adjusted until RUSLE2 computed the observed sediment yield from plots having a dense 1.5 ft wide dense stiff grass hedge below conventionally tilled cotton on a 5 percent steepness at Holly Springs, Mississippi (McGregor et al., 1999). The RUSLE2 computed backwater length was compared to

---

[34] In an early version of RUSLE2, contouring failure was computed with the single precipitation P10y,24h precipitation amount. Runoff rate varies temporally only as cover-management variables varied temporally. Although RUSLE2 was calibrated to give the correct critical slope length, the timing of contouring failure was out of phase with precipitation during the year. Use of Equation 3.48 gave the correct timing for contouring failure.

measured backwater values and locations of deposited sediment above the stiff grass hedge. Although the upper edge of deposition moves upslope as deposited sediment accumulates (Dabney et al., 1995), this dynamic effect is not considered in RUSLE2. The RUSLE2 computed backwater length is an index that captures the effects of location through the 10 year-24 hour precipitation amount, runoff, hydraulic roughness, and overland flow path steepness. The maximum computed backwater length is limited to 15 ft to prevent RUSLE2 from computing excessively long backwater lengths on relatively flat overland flow paths. Also, RUSLE2 assumes a 3 ft minimum for special cases like fabric filter fence on construction sites (see **Section 7.2**). RUSLE2 adds the computed backwater length to the lower edge of the segment having the high total Manning's n_t and decreases the length of the immediate downslope segment by the same amount except for the segment at the end of the overland-flow path.

3.4.5. Ponding

Water deeper than about 3 mm reduces raindrop impact erosivity (Mutchler, 1970; Mutchler and Murphree, 1985; Mutchler and Young. 1975). The judgment of soil conservation specialists is that water depth reduces erosion on flat overland flow paths in high erosivity locations, such as the lower Mississippi Delta [AH703 (Renard et al., 1997)]. Erosivity (R) values along the Gulf Coast Region were reduced to consider this effect in the USLE (e.g., compare erosivity values between AH282 (Wischmeier and Smith, 1965) and AH537 (Wischmeier and Smith, 1978). RUSLE1 uses a ponding subfactor that reduces effective erosivity based on flow depth if ridges are not present. Water depth (ponding) was assumed to have no effect on erosivity in RUSLE1 when high ridges are present. However, in RUSLE2, the ponding effect is assumed to reduce erosivity regardless of the presence or absence of ridges.

The 10 year-24 hour precipitation amount is used to compute a runoff amount using equation 3.25. A normalized flow depth is computed using the Manning equation as:

$$y_n = (v_r / 3.03)^{0.6} (0.01/s)^{0.3} \qquad [3.50]$$

where: y_n = the normalized flow depth, v_r = the runoff amount (inches), computed with P10y24h precipitation amount, 3.03 = a reference runoff depth (inches) selected to represent runoff and 0.01 = a reference overland flow path steepness to represent slopes typical of cotton production in the Mississippi Delta where the water depth effect is most highly important. This ponding effect has been studied by Mutchler et al. (1982), Mutchler and McGregor (1983), Mutchler and Murphree (1985), and McCool et al. (1987). This normalized flow depth is then used to compute a ponding subfactor value using:

$$p_r = \exp[-0.49(y_n - 1)] \text{ if } p_r < 0.4, p_r = 0.4 \text{ if } p_r > 1, p_r = 1 \qquad [3.51]$$

where: p_r = the ponding subfactor for the effect of water depth on raindrop impact erosivity. The minimum value for the ponding subfactor is 0.4. The 0.49 value in equation 3.51 was chosen by calibration to represent the judgment of erosion scientists and soil conservationists regarding the ponding effect [AH537 (Wischmeier and Smith,

1978), AH703 (Renard et al., 1997)]. Example values for the average annual ponding factor are given in Table 3.8 where daily ponding values have been weighted by the temporal erosivity distribution (see **Sections 3.1** and **3.2.1**).

Table 3.8. Example values for the ponding subfactor

Location, 0.5% steepness	Value	Steepness (%), at Jackson, MS	Value
New Orleans, LA	0.58	0.001	0.45
Baton Rouge, LA	0.63	0.005	0.73
Jackson, MS	0.73	0.01	0.85
Memphis, TN	0.82	0.02	0.96
Columbia, MO	0.86	0.04	1.00

3.4.6. Manning's n_t as a function of cover-management and row grade

RUSLE2 computes total Manning's n_t values as a function of soil surface roughness, ground cover, live vegetation, and standing residue using:

$$n_t = 0.11[1-\exp(-0.6r_n)] + [0.075(f_g/100)/\exp(0.35r_n)] + n_v + n_s \text{ if } n_t < 0.01,\ n_t = 0.01 \quad [3.52]$$

$$r_n = r_a \text{ if } r_n > 5, r_n = 5 \text{ inches} \quad [3.53]$$

where: n_t = total Manning's n_t, $r_n = r_a$ = adjusted roughness index value (inches) used to compute roughness subfactor values (see **Section 6.3**), f_g = net ground (surface) cover (percent) (see **Section 6.2**), n_v = Manning's n contributed by live vegetation (see **Section 9.2.6**), and n_s = the Manning's n contributed by standing residue (see **Section 10.4.3**). Equation 3.52 was derived from multiple data sets where overland flow velocity was measured for a wide variety of conditions. Manning's n values derived from these measurements have been compiled and used in numerous models including CREAMS, RUSLE1, and scientific articles (Foster et al., 1980b; Foster, 1982; Foster et al., 1982a; Foster et al., 1997; Gilley and Finkner, 1991; Gilley and Kottwitz, 1994; Gilley and Kottwitz, 1995).

Equation 3.52 represents form and form roughness combined rather than representing them as two separate terms. The condition on n_t in equation 3.52 is to prevent total Manning's n_t from being less than the grain roughness Manning's n_g of 0.01.

The ground (surface) cover and soil surface roughness combination term in equation 3.52 reduces the effect of ground cover on hydraulic roughness as soil surface roughness increases. Ground cover in depressions is inundated by ponded water and deposited sediment so that ground cover has reduced effect on runoff hydraulics as soil surface roughness increases.

The condition that adjusted roughness not be greater than 5 inches is primarily because no research data were available at high roughness values to derive equation 3.52. Actually the high soil surface roughness condition has little effect on computed Manning's n_t values. For example, the first term in equation 3.52 is 0.105 for $r_a = 5$ inches and 0.11 for $r_a = 10$ or more inches.

Net ground cover is (1 – the fraction of soil surface not covered by ground cover). Net ground cover takes into account surface residue overlapping rock cover and live ground cover overlapping both surface residue and rock cover.

The maximum Manning's n value for vegetation in rows perpendicular to the overland flow path (i.e., on the contour) is computed with:

$$n_{vmxc} = 0.017154 R_v + 3.82 \times 10^{-5} R_v^5 \quad [3.54]$$

where: n_{mvxc} = the Manning's n for live vegetation in rows on the contour at maximum canopy cover and R_v = vegetation retardance at maximum canopy cover for vegetation in rows on the contour, which is a measure of how much vegetation and porous barriers like fabric fences slow runoff. Input retardance values are chosen to represent the combined hydraulic roughness of the vegetation in rows and bare soil between the rows for vegetation at its maximum growth in the RUSLE2 vegetation description.[35] Using these input retardance values listed in Table 3.9, RUSLE2 computes a retardance value based on vegetation production (yield) level (see **Section 9.3.1**). The Manning's n_{mvc} represents the effect of stems and any vegetation component, besides live ground cover, that slows runoff. Live ground cover values in the RUSLE2 vegetation description are used to represent the effect of leaves and similar plants components touching the soil surface and slowing runoff.

Table 3.9. Retardance classes used in RUSLE2

Class	Retardance index
no retardance (wide plant spacing in strip-row)	0
low retardance (corn)	1
moderate low (soybeans, cotton)	2
moderate (dense wheat)	3
moderate high (legume hay before mowing)	4
high (legume-grass hay before mowing)	5
very high (dense sod)	6
extreme (stiff grass hedge, silt fence)	7

Table 3.10. Factor values used to multiply Manning's vegetation n on contour to obtain Manning's n value for orientation parallel to overland flow path

Row width	Factor
Vegetation on ridges	0.063
Wide row	0.125
Moderate row spacing	0.250
Narrow row spacing	0.500
Very narrow row spacing	0.750
No rows (broadcast)	1.000

The hydraulic roughness for vegetation rows oriented parallel to the overland flow path (up and down hill) differs from the hydraulic roughness for the vegetation's rows on the contour. RUSLE2 computes a value for the Manning's n_{mvud} for vegetation in rows parallel to the overland flow path by multiplying the contour vegetation Manning's n_{vmxc}

[35] Assignment of retardance values considers the geometrical arrangement of the vegetation rows. For example, retardance for small grain represents the net retardance for multiple grain rows whereas the retardance for a narrow stiff grass hedge considers only a single row of the vegetation. In the case of the stiff grass hedge, the overland flow path is divided into segments to represent the bare soil separately from the vegetation in a situation where backwater created by the dense vegetation has an important effect on deposition.

by a factor based on the user entered row width. Values for this factor are given in Table 3.10. The **No rows (broadcast)** input means that the vegetation is randomly spaced in both directions so that no row orientation exists. Manning's n is the same in all directions. The **Vegetation on ridges** represents vegetation rows so widely spaced or the vegetation being on ridges so that the vegetation stems have no effect on hydraulic roughness.

Depending on row grade (steepness along the vegetation rows), vegetation Manning's n varies between the Manning's n for vegetation rows on the contour and the Manning's n for the vegetation rows oriented up and down hill. The RUSLE2 equation used to compute vegetation Manning's n for intermediate row orientations is:

$$n_{vrg} = n_{vud} + (n_{vc} - n_{vud})[1 - (s_r / s_{ud})^{1/2}] \quad [3.55]$$

where: n_{vrg} = vegetation Manning's n for the row grade s_r, n_{vc} = vegetation Manning's n for rows on the contour (perpendicular to the overland flow path), n_{vud} = vegetation Manning's n for rows parallel to overland flow path (i.e., up and down slope), s_r = row grade (tangent of slope angle), and s_{ud} = overland flow path steepness (tangent of slope angle).

RUSLE2 assumes that vegetation Manning's n varies temporally as the vegetation's effective fall height varies (see **Section 6.1**). The equation used to compute vegetation Manning's n values through time is:

$$n_v = n_{vmx}(h_f / h_{fmx})^{0.3} \quad [3.56]$$

where: n_{vm} = the vegetation Manning's n at maximum growth in the vegetation description, h_f = the daily effective fall height for a particular vegetation description and h_{fmx} = the maximum daily effective fall height for the vegetation description (see **Section 9**).

When live vegetation is killed in RUSLE2, it becomes standing residue that continues to provide hydraulic roughness. The hydraulic roughness caused by standing residue is assumed to vary through time as:

$$n_s = n_{sk}(B_{td} / B_{tk}) \quad [3.57]$$

where: n_s = Manning's n for standing residue on day d, n_{sk} = Manning's n for the standing residue on the day that the live vegetation is killed, B_{td} = standing residue biomass (dry matter basis) on day d, and B_{tk} = the live vegetation biomass (dry matter basis) on the day that the vegetation is killed (see **Section 9.2.5**).

3.5. List of symbols

a_{cl} = a coefficient used to compute curve number values as a function of ground (surface) cover when surface roughness is less than 0.24 inches

a_{cu} = a coefficient used to compute curve number values as a function of ground (surface) cover when surface roughness is greater than 0.24 inches

a_f = coefficient used to compute form roughness shear stress

a_F = coefficient used to compute average annual erosivity from Fournier index

a_p = coefficient in equation that computes storm or daily erosivity from storm or daily precipitation

a_r = coefficient used to average annual erosivity from RUSLE2 modified Fournier index

a_{rl} = a coefficient used to compute curve number values as a function of soil surface roughness when soil surface roughness is less than 0.24 inches

a_{ru} = a coefficient used to compute curve number values as a function of soil surface roughness when soil surface roughness is greater than 0.24 inches

a_{45} = coefficient used to compute curve number values for fully consolidated soils as a function of ground (surface) cover

b= exponent in equation that computes storm or daily erosivity from storm or daily precipitation

b_B = a decay coefficient used how the curve number values decreases exponentially as a function of soil biomass

b_D = a decay coefficient used to compute how curve number values are affected by the interaction of the soil consolidation factor and soil biomass

B_s = soil biomass per unit depth (dry mass/area·soil depth)

B_{tk} = live above ground biomass on day that vegetation is killed (mass/area)

B_{td} = live above ground biomass on day d (mass/area)

D = number of days in the month

e = unit storm energy (energy content per unit area per unit rainfall depth) [force-distance/(area·length)]

$\hat{e}$ = effective unit storm energy directly (force-length)/(area·length)

E = storm energy (force-distance/area)

EI_{10y24h} = the storm erosivity associated with the 10 year-24 hour precipitation amount (erosivity units)

EI_{30} = storm erosivity (erosivity units)

f_B = a fraction that represents the main effect of soil biomass on curve number values

f_d = fraction of area represented by an overland flow path that is subsurface drained

f_g = net ground (surface) cover (percent)

f_{Rd} = fraction of the annual erosivity that occurs on *jth* day

f_{Rmx} = fraction of the annual erosivity that occurs on day when maximum daily erosivity occurs

f_μ = portion of the soil surface covered by non-erodible cover (fraction)

f_ρ = portion of the non-erodible cover that is permeable (fraction)

F = the modified Fournier index

F_r = the RUSLE2 modified Fournier index

h_f = daily effective fall height for a particular vegetation description (length)

h_{fmx} = maximum daily effective fall height for the vegetation description (length)

i = rainfall intensity for a period during rainstorm (length/time)

I_{30} = maximum 30-minute intensity for a rain strom (length/time)

$\bar{I}_{30}$ = representative maximum 30 minute intensity for rain storms occurring in amonth (length/time)

m = number of periods in a storm used to compute storm energy

M = monthly value of climate variable being disaggregated

n = number of rainstorms in a month

n_{et} = Manning's n_t in the transitional zone below a high hydraulic resistance segment

n_g = grain roughness Manning's n

n_k = Manning's n for standing residue on day that live vegetation is killed

n_s = Manning's n contributed by standing residue

n_{sk} = Manning's n contributed by standing residue on the day that live vegetation is killed

n_t = total Manning's n

n_{tl} = total Manning's n_t in segment downslope of high hydraulic resistance segment

n_{tu} = Manning n_t in upslope high hydraulic resistance segment

n_v = Manning's n contributed by live vegetation

n_{vc} = vegetation Manning's n for rows (strips) on the contour (perpendicular to the overland flow path)

n_{vmx} = vegetation Manning's n at maximum growth in the vegetation description

n_{vmxc} = Manning's n for live vegetation in rows (strips) on the contour at maximum canopy cover

n_{vrg} = vegetation Manning's n for row grade s_r

n_{vud} = vegetation for Manning's n for rows up and down slope (parallel to overland flow path)

N = curve number in NRCS curve number method used to compute runoff

N_b = curve number for the portion of the soil not covered by the non-erodible cover

N_d = curve number for the drained condition

N_l = lower curve numbers that represents difference in curve numbers for a soil with no soil biomass and one with a high soil biomass of 1750 lbs_m/(acre·in) value

N_{lb45} = index curve number for fully consolidated soil at high soil biomass with no ground cover

N_{lB} = the curve number for a very high soil biomass and the soil has been recently mechanically disturbed

N_{l45} = N_{lB} curve number adjusted for ground cover

N_{s100} = a starting curve number value for unit plot conditions

N_u = upper curve numbers that represents difference in curve numbers for a soil with no soil biomass and one with a high soil biomass of 1750 lbs_m/(acre·in) value

N_{uB} = curve number value when no biomass is present in the soil and the soil has been recently mechanically disturbed

N_{ud} = curve number for the undrained condition

N_{u45} = the curve number for a fully consolidated soil with no ground (surface) cover or soil biomass and soil surface roughness = 0.24 inches

N_{u100} = curve number value that represents the effect of ground cover and soil roughness on curve number on a soil recently mechanically disturbed with no soil biomass

p_r = daily ponding subfactor

P = precipitation depth (length)

P_a = additional precipitation required so that zero runoff would be computed when infiltration is greater than precipitation (length)

P_{cf} = daily precipitation amount used to compute contouring failure (length)

P_{md} = average monthly precipitation from daily precipitation gage data (length)

P_m = average monthly precipitation (length)

P_s = storm or daily precipitation amount (length)

P_{10y24h} = the 10 year-24 hour precipitation amount (length)

P_{15} = storm precipitation amount determined from 15-minute precipitation gage data (length)

q = discharge rate (volume/width·time)

q_c = discharge rate (where excess rainfall rate is in units of in/hr) at which contouring fails (volume/width·time)

q_i = discharge rate $q_i = x\sigma_i$ computed using excess rainfall rate in inches/hour rather than ft/sec

q_u = discharge rate at upper edge of segment having high hydraulic resistance (volume/width·time)

Q = runoff depth computed with NRCS curve number method (length)

r_a = adjusted soil surface roughness index (length)

r_n = adjusted soil surface roughness index used to compute Manning n for soil surface roughness (length)

r_s = storm erosivity (erosivity units)

R = average annual erosivity (erosivity units)

R_m = average monthly erosivity (erosivity units)

R_v= vegetation retardance at maximum canopy cover for vegetation in rows (strips) on contour, which is a measure of how much vegetation and porous barriers like fabric fences slow runoff

s = overland flow path steepness (sine of slope angle)

s_c = soil consolidation subfactor

s_l = change in lower curve numbers per unit change in soil consolidation subfactor

s_{lh} = steepness of segment having high hydraulic resistance (**sine** of slope angle)

s_r = row grade (**tangent** of slope anagle)

s_u = change in upper curve number per unit change in the soil consolidation

s_{ud} = steepness of overland flow path (**tangent** of soil angle)

s_{uh} = steepness of segment immediately upslope of high hydraulic resistance segment (**tangent** of slope angle)

S = a variable in NRCS curve number equation used to compute runoff

t_c = time during month that disaggregated value equals monthly value

t_p = time during month of peak or minimum of climate variable being disaggregated

T_c = sediment transport capacity (mass/width·time)

x = distance along overland flow path (length)

x_u = the distance to the upper end of segment immediately downslope of high hydraulic resistance segment (length)

y = flow depth (length)

y_d = daily value of climate variable being disaggregated

v_r = runoff amount used to compute ponding subfactor (length)

y_n = normalized flow depth used to compute ponding subfactor

Y_b = daily value of climate variable being disaggregated at beginning of month

Y_e = daily value at end of month

Y_p = maximum value of climate variable being disaggregated when peak or minimum occurs within month

z = exponent in RUSLE2 modified Fournier index

α = average monthly erosivity density (erosivity units/length)

α_m = maximum monthly erosivity density

Δx_b = backwater length upslope of a segment having a high hydualic resistance (length)

ΔV = rainfall depth during a period in a rainstorm (length)

γ = weight density of water (force/volume)

σ_i = excess rainfall rate in inches/hour (length/time)

τ_f = form roughness shear stress (force/area)

τ_g = grain roughness shear stress (force/area)

τ_t = total shear stress (force/area)

ζ = coefficient that has absorbed γ and the Manning's n_g for grain roughness

Indices

i – storm

j - month

k – period during a rainstorm

4. SOIL

4.1. Erodibility

The major RUSLE2 soil variable is the soil erodibility factor. A value for the soil erodibility factor for soils that have their soil horizons in place and have not been disturbed other than for cultivation can be selected from the USDA-NRCS soil survey database. However, soil erodibility values are not available for all soils, especially highly disturbed soils where the original soil layers have been mixed. RUSLE2 includes two sets of equations referred to as the standard soil erodibility nomograph and the RUSLE2 modified soil erodibility nomograph. These nomographs can be used to estimate soil erodibility factor values for most situations (See RUSLE2 User's Reference Guide), especially where the original soil profile has been disturbed.

The RUSLE2 soil erodibility factor is a measure of soil erodibility under unit plot conditions. These conditions empirically measure soil erodibility where cover-management effects are removed so that the measured erosion represents how inherent soil properties and local climate affect soil erodibility as defined in RUSLE2. The RUSLE2 soil erodibility factor is not an inherent soil property like soil texture. It is defined in terms of the RUSLE2 erosivity variable and, therefore, should not be used in other erosion prediction technologies that use a different erosivity factor than the RUSLE2 erosivity factor. Conversely, soil erodibility factor values from other erosion models that use an erosivity factor that differs from the RUSLE2 erosivity factor can not be used in RUSLE2.

The RUSLE2 soil erodibility factor, which is the same as the USLE and RUSLE1 soil erodibility factor (Wischmeier and Smith, 1965 and 1978; Römkens et al,, 1997), is a measure of erosion per unit erosivity EI for unit plot conditions. The RUSLE2 soil erodibility factor is a function of local climate in addition to soil properties because erosion per unit erosivity is greater where runoff is increased per unit erosivity. For example, if the same soil properties were to occur in two locations, the RUSLE2 soil erodibility factor would be increased in locations where frequent, high, intense rainfall occurs that produces increased runoff per unit precipitation. Unfortunately, the soil erodibility nomograph commonly used to estimate soil erodibility factor values, including those in RUSLE2, is not a function of climate variables. However, the RUSLE2 temproal soil erodibility equation described below takes location into account.

4.1.1. Standard soil erodibility nomograph

The standard soil erodibility nomograph (Wischmeier et al., 1971) was derived from erosion data produced by applying simulated rainfall to about 55 agricultural soils, primarily in Indiana (Wischmeier. and Mannering, 1969). Although these soils

represented a range of inherent soil properties, the standard nomograph best fits medium textured soils.

The equation for the standard soil erodibility nomograph is:[36]

$$K = (k_t k_o + k_s + k_p)/100 \qquad [4.1]$$

where: K = soil erodibility factor, k_t = texture subfactor, k_o = organic matter subfactor, k_s = soil structure subfactor, and k_p =soil profile permeability subfactor.

4.1.1.1. Texture subfactor

The soil texture subfactor equation is (Wischmeier et al., 1971):

$$k_{tb} = 2.1[(P_{sl} + P_{vfs})(100 - P_{cl})]^{1.14}/10000 \qquad [4.2]$$

$$k_t = k_{tb} \qquad \text{if} \quad P_{sl} + P_{vfs} \le 68\% \qquad [4.3]$$

where: P_{sl} = percent silt, P_{vfs} = percent very fine sand based on the total soil primary particles and not just the portion of the sand content, and P_{cl} = percent clay. Although equation 4.2 was derived using regression analysis, Wischmeier et al. (1971) used judgment to graphically draw the k_t relationship for $P_{sl} + P_{vfs}$ percentage above 68 percent. The RUSLE2 equations fitted to the Wischmeier et al. (1971) graphical curves are:

$$k_{t68} = 2.1[68(100 - P_{cl})]^{1.14}/10000 \qquad [4.4]$$

$$k_t = k_{tb} - [0.67(k_{tb} - k_{t68})^{0.82}] \qquad \text{if} \quad P_{sl} + P_{vfs} > 68\% \qquad [4.5]$$

where: k_{t68} = base soil texture subfactor in soil erodibility nomograph when $P_{sl} + P_{vfs} > 68\%$.

4.1.1.2. Organic matter subfactor

The equation for the soil erodibility nomograph organic matter subfactor is:

$$k_o = (12 - O_m) \qquad [4.6]$$

where: O_m = percent inherent soil organic matter. Inherent organic matter is the organic matter content of the soil in unit plot conditions. The experimental plots used to develop the soil erodibility nomograph were not in unit plot condition (Wischmeier and

---

[36] Units for K and associated variables are US customary units

Mannering, 1969). Above ground biomass was removed but the plots were not maintained in a tilled fallow condition for more than a few months. Soil organic matter had not reached inherent soil organic matter levels for unit plot conditions, which resulted in measured soil organic matter being higher than it would have been in unit plot conditions. However, measured erosion values were adjusted to remove land use residual effects from previous cover-management conditions (see **Section 6**), but organic matter content values were not adjusted to unit plot conditions.

The organic matter relationship in the soil erodibility nomograph ***can not be used*** to evaluate how biomass additions and organic farming practices affect rill and interrill erosion. Those effects are considered in RUSLE2's cover-management relationships (see **Section 6**). Furthermore, the experimental conditions used to derive the soil erodibility nomograph were very dissimilar to organic matter conditions associated with organic farming or application of manure, biological waste, or other biological soil amendments.

4.1.1.3. Soil structure subfactor

The soil erodibility nomograph soil structure subfactor refers to how the arrangements of soil primary particles in aggregates and the arrangement of aggregates in the soil affect erosion under unit plot conditions. Four structural classes are used in the nomograph. These classes are 1-very fine granular, 2-fine granular, 3-medium or coarse granular, and 4-blocky, platy, or massive. These classes are defined in the USDA-NRCS soil survey manual. The classes used to derive the soil erodibility nomograph were those in use in the mid-1960's when the experiments were conducted. The definitions for those classes should be used to assign RUSLE2 values for soil structure.

The equation for the soil erodibility nomograph soil structure subfactor is:

$$k_s = 3.25(S_s - 2) \qquad \text{if } (k_t k_o + k_s) \geq 7 \qquad [4.7]$$

$$k_t k_o + k_s = 7 \qquad \text{if } (k_t k_o + k_s) < 7 \qquad [4.8]$$

where: S_s = the soil structure class. The graphical soil structure relationship in the soil erodibility nomograph has a slight "knee" close the origin of the subfactor (Wischmeier et al., 1971), which is represented with equation 4.8.

4.1.1.4. Soil profile permeability subfactor

The soil permeability subfactor is a measure of the potential of the soil profile in unit-plot conditions for generating runoff. Six permeability classes that range from 1-rapid (very low runoff potential) to 6-very slow (very high runoff potential) are used to rate the soil profile for infiltrating precipitation and reducing runoff. The USDA-NRCS soil survey definitions for soil profile permeability used in the mid-1960's should be used to assign a soil permeability class in applying the soil erodibility nomograph. ***The assigned permeability class must not be based on a permeability measurement of the surface soil layer.*** The permeability rating should take into account the presence of restricting layers such as rock, claypan, or fragipan. Also, the rating should consider landscape position.

For example, the permeability rating for a sandy soil underlain by a restricting layer might be moderate for the soil at the top of a hillslope but be very slow if the soil is at the bottom of the hillslope. The input permeability rating should consider the presence of rock fragments. ***The permeability rating should not reflect current or past cover-management on runoff; it is a rating for the soil in unit plot condition*** (see **Sections 4.6 and 7.4** and RUSLE2 User's Reference Guide). The RUSLE2 temporal soil erodibility equation described in **Section 4.5** takes into account how the permeability rating varies as climate varies among locations.

The equation for the permeability subfactor is given by:

$$k_p = 2.5(P_r - 3) \qquad [4.9]$$

where: P_r = the soil profile permeability class.

4.1.2. RUSLE2 modified soil erodibility nomograph

Soil erodibility factor values computed with the standard soil erodibility nomograph do not show the expected range or trend for very high sand soils and very high clay soils typical of highly disturbed lands, such as reclaimed mined land and construction sites. This problem seemed most associated with the soil structure subfactor. Soil erodibility is expected to decrease as soil structure changes from very fine granular to blocky, platy, or massive because of the role of clay as a bonding agent and its effect on soil structure.

The unexpected trend in the soil structure subfactor most likely resulted from the empirical derivation of the standard soil erodibility nomograph from a relatively small database where the soils were predominantly medium texture (Wischmeier and Mannering, 1969; Wischmeier et al., 1971). Consequently, the data points were not uniformly distributed among the major variables that affect soil erodibility. Furthermore, all of the nomograph variables are correlated with each other, which can result in empirical equations derived from a small database not reflecting proper trends for how major variables affect soil erodibility. For example, soil structure is related to soil texture. The soil structure subfactor in the standard soil erodibility nomograph may well represent an interactive effect rather than a main effect in the particular dataset used to derive the standard soil erodibility nomograph.

After reviewing measured erosion data from high clay soils typical of construction sites (Römkens et al., 1975; Römkens et al., 1977; Roth et al., 1974), the judgment was made to modify the soil structure subfactor in the standard nomograph. The modification results in the RUSLE2 modified nomograph computing soil erodibility values that decrease as soil structure goes from fine granular to blocky, platy, and massive and decrease as soil structure goes from fine granular to coarse granular. Soil erodibility factor values computed with the RUSLE2 modified soil erodibility nomograph are smaller than those computed with the standard nomograph for high clay and high sand soils.

4.1.2.1. Soil structure subfactor

The soil structure subfactor equation used in the RUSLE2 modified soil erodibility nomograph is:

$$k_s = 3.25(2 - S_s) \quad [4.10]$$

The difference between this equation and the comparable equation, equation 4.7, in the standard soil erodibility nomograph is the algebraic sign on the variables in the second term in equations 4.7 and 4.10. A nice feature of both the standard and the RUSLE2 modified nomographs is that they use equations referenced to a midpoint. The equations compute values about the midpoint well established by the experimental data. The midpoint for the soil structure subfactor is the fine granular structure. Both soil erodibility nomographs give the same soil erodibility factor values for the fine granular soil structure, but the two nomographs give different trends for departures from this midpoint soil structure.

4.1.2.2. Other subfactors in RUSLE2 modified soil erodibility nomograph

All other subfactors in the RUSLE2 modified soil erodibility nomograph are the same as those used in the standard nomograph.

4.1.3. Special soil erodibility cases

Special cases, described in the RUSLE2 User's Reference Guide, exist where neither RUSLE2 soil erodibility nomograph applies. Equations are available in AH703 (Renard et al., 1997) and elsewhere (El-Swaify and Dangler, 1976; Mutchler et al., 1976; Young and Mutchler. 1977; Roth et al., 1974) to estimate soil erodibility for some of these special conditions. However, these equations were not included in RUSLE2 even though some of them were included in RUSLE1 [AH703 (Renard et al., 1997)]. The equations were judged to give poor results or to use variables that were not properly defined or could not be easily measured for input in typical RUSLE2 applications. Soil erodibility values can be user determined outside of RUSLE2 and entered in RUSLE2.

4.2. Very fine sand

Soil texture is the single most important variable in estimating soil erodibility. In many cases, the standard soil texture such as clay loam, silt loam, or sandy loam based on the USDA classification may be known or can be estimated. However, as Wischmeier et al. (1971) found, this standard classification does not work as well as including the very fine sand fraction with the silt fraction. Unfortunately, the sand, silt, and clay content may be known for a soil, but information on the very fine sand fraction may not be available. A mechanical analysis of the soil is required to determine the very fine sand fraction. The following RUSLE2 equation was developed to estimate the very fine sand fraction from sand, silt, and clay content:

$$P_{vfs} = (0.74 - 0.62P_{sd}/100)P_{sd} \quad [4.11]$$

where: P_{vfs} and P_{sd} are in percent. Regression analysis was used to fit equation 4.11 to the USDA-NRCS soil survey data for Lancaster County, Nebraska.

4.3. Rill to interrill soil erodibility

RUSLE2 computes a ratio of rill to interrill erosion used to compute a slope length exponent in equation 2.10 (e.g., see **Section 2.1.3**) and a **b** value in the subfactor equation for the ground cover effect on erosion (see **Section 6.2**). The RUSLE2 equation used to compute a value for the rill to interrill soil erodibility ratio is:

$$K_r / K_i = (P_{sd}/100)[(1-\exp(-0.05P_{sd})] + 2.7(P_{sl}/100)^{2.5}[1-\exp(-0.05P_{sl})] \quad [4.12]$$

$$+ 0.35(P_{cl}/100)[1-\exp(-0.05P_{cl})]$$

where: K_r/K_i = the rill to interrill soil erodibility ratio and all soil texture values are in percent. Rill to interrill soil erodibility ratio values computed with equation 4.12 are shown in Table 4.1 at the central point of the textural classes.

Table 4.1. Rill to interrill soil erodibility ratio as a function of soil texture

Soil textural class	Rill to interrill soil erodibility ratio
Clay	0.36
Clay loam	0.50
Loam	0.65
Loamy sand	0.82
Sand	0.89
Sandy clay	0.61
Sandy clay loam	0.65
Sandy loam	0.7
Silt	1.91
Silt loam	1.04
Silty clay	0.53
Silty clay loam	0.73

Equation 4.12, like many RUSLE2 equations, is based on computing variations about a mid or central point that is well established by experimental data. As shown in Table 4.1, equation 4.12 gives a value of 1 for the reference silt loam soil. Equation 4.12 computes values that vary about one as soil texture deviates from silt loam. Although soil erodibility data from the Water Erosion Prediction Project (WEPP) were reviewed as the basis for deriving equation 4.12 (Elliot et al., 1989; Laflen et al., 1991a), the equation was derived based on judgment.

For example, increased clay content is assumed to reduce rill erosion much more rapidly than it reduces interrill erosion. Conversely, soils very high in silt are assumed to have increased rill erosion relative to interrill erosion. Increased rill erosion relative to interrill erosion is expected because of reduced clay content that reduces soil cohesiveness, which increases rill erosion more than interrill erosion. In addition, soils high in silt produce increased runoff, which increases rill erosion more than interrill erosion.

Soils high in sand are more susceptible to rill erosion than interrill because of low clay content and reduced cohesiveness. However, offsetting the increase in rill erosion susceptibility is decreased runoff, which would reduce rill erosion more than interrill erosion because rill erosion is directly related to runoff. Overall, the rill to interrill soil erodibility ratio is assumed to be reduced for soils high in sand but not as much as for soils high in clay.

Equation 4.12 quantifies concepts and advice that users were expected to consider in RUSLE1 for selecting LS and ground cover effect relationships [(AH703 (Renard et al., 1997)]. Equation 4.12 is considered to be a significant improvement over RUSLE1 procedures.

4.4. Geographic soil erodibility variability

Even when soil properties are identical, RUSLE2 soil erodibility factor values should vary with location because of climatic differences among locations. For example, erosion is greater per unit rainfall erosivity in locations such as the southern US, where frequent, high, and intense rainfall occurs, than in the northern Great Plains. Average annual soil erodibility factor values also vary with the temporal distribution of erosive precipitation because of the interaction between the temporal variation of erosive precipitation and the temporal variation of soil erodibility values [(AH703 (Renard et al., 1997)]. The temporal variation of erosive precipitation varies among locations

The RUSLE2 standard and modified soil erodibility nomographs do not take these factors into consideration. The data used to derive the standard soil erodibility nomographs were produced by uniform intensity simulated rainfall applied in a sequence of three events. The first simulated storm was 60 minutes of rainfall at 2.5 in/hr on dry soil conditions. The second storm was 30 minutes of rainfall at 2.5 in/hr approximately 24 hour later. The third storm was also 30 minutes long at 2.5 in/hr that occurred approximately 15 minutes after the second storm. When Wischmeier et al. (1971) developed the standard soil erodibility nomograph, they weighted measured erosion values produced by each simulated storm to compute an average annual soil erodibility factor value. This sequence of storms reflects a greater likelihood of a storm on dry conditions than on wet conditions.

This weighting procedure was assumed to apply at all locations, which is probably satisfactory for conservation planning on cropland in the eastern US. However, major questions arise about applying the soil erodibility nomograph to the western US where the precipitation patterns and rainfall amounts and intensities differ significantly from that used to derive the soil erodibility nomograph.

Although questions can be raised about the applicability of the soil erodibility nomograph for these and other reasons, the RUSLE2 assumption is that the nomographs provide soil erodibility values suitable for conservation and erosion control planning. Some of the nomograph issues are not significant with respect to conservation planning when uncertainty in the RUSLE2 soil erosion estimates are considered (See Section 17, RUSLE2 User's Reference Guide) because other factors have a much greater effect on rill-interrill erosion than does the soil erodibility factor.

The temporal soil erodibility equation described in **Section 4.5** takes into account soil erodibility factor values vary with location as temperature and precipitation var with location. Also, the effect of rainfall amount, intensity, and temporal climate patterns are considered in RUSLE2 equations for estimating rill-interrill erosion from rainfall on irrigated lands (see **Section 7.5**).

4.5. Temporal soil erodibility factor values

Along with factors for slope length, cover-management, and supporting practices, the RUSLE2 soil erodibility factor varies temporally (Mutchler and Carter, 1983). Erosion is significantly increased if peak soil erodibility occurs, for example, when cover-management conditions are most susceptible to erosion. An equation is needed to compute daily soil erodibility so that daily erosion can be computed to improve the mathematical accuracy of the RUSLE2 (see **Section 2.1**).

Soil erodibility is high for thawing soil and for the immediate period after the soil has thawed because the soil's susceptibility to detachment is increased (Van Klaveren and McCool, 1998.). Also, soil erodibility is high when soil moisture is high, which increases runoff per unit rainfall and hence erosion per unit erosivity. Erosion on the unit plot per unit erosivity is soil erodibility in RUSLE2. Runoff per unit rainfall is increased on the unit plot, and hence rill erosion is increased, when rainfall is frequent and soil evaporation is low. Soil erodibility may also be related to biological activity in the soil, which is a function of soil moisture and temperature (Vigil and Sparks, 2004).[37]

Although the reasons for soil erodibility varying temporally are partially known, adequate equations for temporal soil erodibility are lacking. The pattern for temporally varying soil erodibility seems well defined for plots at Morris, Minnesota and Holly Springs, Mississippi but not at other locations (Mutchler and Carter, 1983). A complication in making soil erodibility measurements is the coincidence of plot maintenance with highly erosive rains. The unit plots used to experimentally determine soil erodibility factor values are periodically tilled to break the soil crust and to control weeds. Erosion per unit erosivity, hence RUSLE2's soil erodibility factor, can be very high if a highly erosive rain occurs immediately after plot tillage.

The RUSLE1 temporal soil erodibility equations were reexamined and found to work poorly at most of the 11 locations where temporal soil erodibility data are available. Also, the equations performed very poorly in Minnesota and northern Iowa where computed temporal soil erodibility factor values varied too much with slight differences in weather between adjacent counties. Furthermore, the empirically derived RUSLE1 temporal soil erodibility equations are not applicable in the Western US. Consequently, a new temporal soil erodibility equation was derived for RUSLE2 using data collected at the locations listed in Table 4.2. The record length for these data is about 10 years.

---

[37] The RUSLE2 soil erodibility factor is solely related to unit plot conditions. Soil erodibility is also influenced by cover-management conditions but those effects, such as related to soil moisture and runoff, are considered in cover-management variables (see **Section 6**).

Table 4.2. Locations where unit plot conditions were used to determine monthly soil erodibility factor values

Location
Tifton, GA
Watkinsville, GA
Holly Springs, MS
Bethany, MO
Independence, IA
Beaconsfield, IA
Castana, IA
Clarinda, IA
Morris, MN
LaCrosse, WI
Presque Isle, ME

Temporal soil erodibility values grouped by geographic area are shown in Figure 4.1. A similar pattern in the temporal erodibility values by location was expected for each geographic area, especially for the four Iowa locations. The patterns are similar for the two northern Midwestern US and Northern Maine locations where almost no rill-interrill erosion occurs during the winter. The patterns are mostly similar for the two Georgia locations but differ significantly from the pattern at Holly Springs, Mississippi. The difference in patterns, especially among the Iowa locations, indicates that other variables besides weather, such as timing of plot maintenance with erosive rains, affect temporal soil erodibility.

With the exception of the southern locations, the data do not capture the increased soil erodibility in late winter and early spring during and immediately after soil thawing. The very few data available for these conditions are not usable because of very large variability. In many cases, measurements were not made during late winter and early spring because measuring equipment was difficult to operate during cold weather. Also, increased soil erodibility during the thawing and recently thawed period seems to be related to a unique set of conditions that do not occur every year.

Regardless of these limitations, a temporal soil erodibility equation seemed advisable for

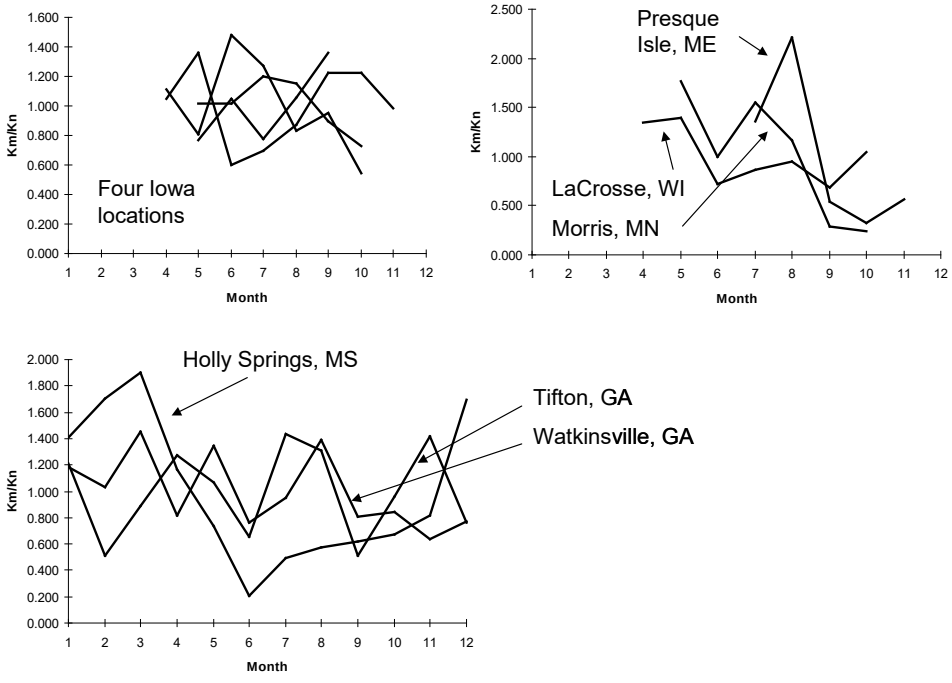

Figure 4.1. Monthly variation in soil erodibility at several locations.

RUSLE2. An equation for RUSLE2was empirically derived from these data.

4.5.1. Basic assumptions

The RUSLE2 assumption is that the soil erodibility value entered in RUSLE2, whether user entered or computed with either of the RUSLE2 soil erodibility nomographs, represents average soil erodibility for a summer period. The RUSLE2 summer period is defined for temporal soil erodibility purposes as the period when average daily temperature exceeds 40 ^{o}F. Analysis of soil erodibility data at Pullman, WA indicates that a better definition is the time between when average daily temperature reaches 45 ^{o}F early in the year to when it decreases to 35 ^{o}F late in the year.

The major assumption used to derive the RUSLE2 temporal soil erodibility equation is that monthly precipitation and temperature can be used as indices to estimate the temporal variability in soil erodibility during the RUSLE2 summer period.

4.5.2. Temporal soil erodibility for the summer period referenced to summer conditions at location

Average values for the ratio of monthly soil erodibility to average soil erodibility for the RUSLE2 summer period were computed for the data collected at the locations listed in Table 4.2. Average soil erodibility for the RUSLE2 summer period was computed as the total erosion for the period of record divided by total erosivity, excluding storms less than 0.5 inches (see **Section 3.2.1**). The period of record at all locations closely corresponded to the RUSLE2 summer definition because the plots were not operated during the winter as can be seen in Figure 4.1. However, the plots were operated throughout the year in the southern US locations and the total data for the year were used to compute an average erodibility value for the southern locations.

The resulting equation from fitting the data is:

$$K_j / K_n = 0.591 + 0.732(P_j / P_s) - 0.324(T_j / T_s) \qquad [4.13]$$

where: K_j = average daily soil erodibility factor value for the *jth* day, K_n = soil erodibility value from the RUSLE2 soil erodibility nomographs or user entered into RUSLE2, T_j = average daily temperature for the *jth* day (^{o}F), T_s = the average temperature for the RUSLE2 summer period defined above, P_j = the average daily precipitation, and P_s = the average precipitation for the RUSLE2 summer period. This equation follows the expected trends of increased soil erodibility when precipitation is high and decreased soil erodibility when temperature is high. Equation 4.13 does not describe increased soil erodibility during or immediately after soil thawing.

The fit of equation 4.13 to the observed data at three locations is shown in Figure 4.2, which also represents the fit at the other locations. Equation 4.13 is a major improvement over the RUSLE1 equations as can be seen by inspection and by comparing the sum of squares of differences between observed and computed values. However, the fit of

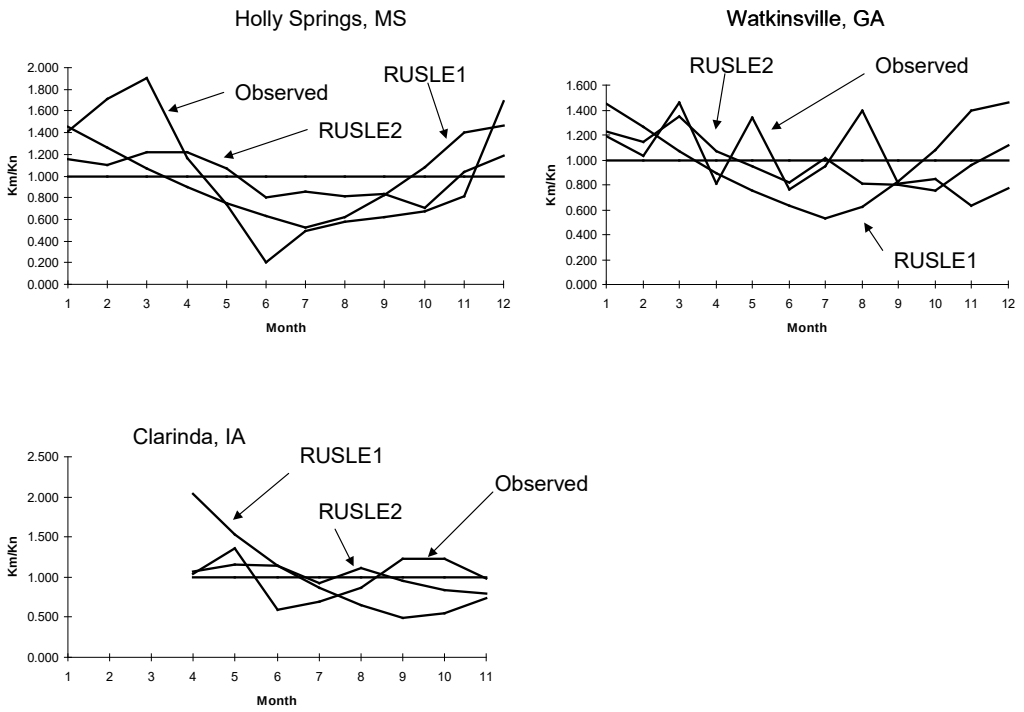

Figure 4.2. Fit of RUSLE2 temporal erodibility equation (equation 4.13), RUSLE1 equation, and constant value to observed data.

equation 4.13 is only slightly better than assuming a time invariant soil erodibility factor value for the summer period.

Computed values from equation 4.13 are shown in Figure 4.3 for Tombstone, Arizona and compared to values computed with the RUSLE1 equations and observed values. Very clearly, equation 4.13 performs much better than the RUSLE1 equations, which illustrates why a time invariant soil erodibility factor value should be assumed when applying RUSLE1 to the western US. The observed values shown in Figure 4.3 were obtained by applying rainfall each month with a rainfall simulator.[38] The observed values are not

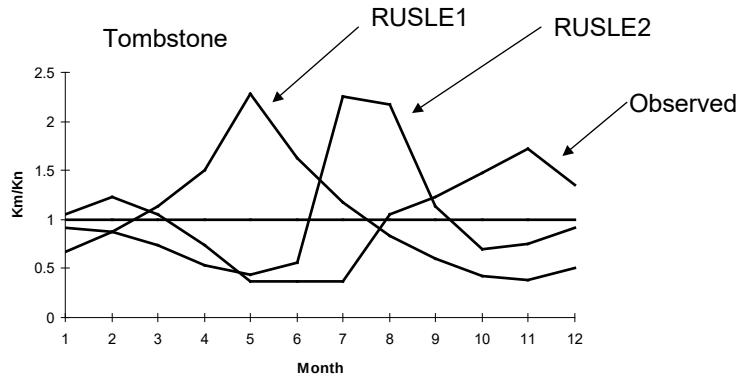

Figure 4.3. Fit of temporal erodibility equations to data from simulated rainfall on rangeland plots at Tombstone, Arizona.

[38] USDA-Agricultural Research Service, Tucson, Arizona.

directly comparable to soil erodibility values produced by natural precipitation because of temporal differences between natural precipitation and the uniform precipitation of the simulated rainfall. Nevertheless, the fit of equation 4.13 to the observed Tombstone, Arizona data is comparable to the fit of equation 4.13 to soil erodibility values produced by natural rainfall in the eastern US.

Therefore, the recommendation is that the RUSLE2 temporal soil erodibility equation be used for all locations in the US except for Req periods (see **Section 3.2.5** and RUSLE2 User's Reference Guide).

4.5.3. Temporal soil erodibility for the summer period referenced to summer conditions at Columbia, Missouri

Equation 4.13 does acceptably well in capturing the relative temporal variations in soil erodibility at a location. Equation 4.13 is an improvement over using a constant soil erodibility factor at a location.

However, equation 4.13 gives exceptionally high soil erodibility values that do not seem reasonable in many western US locations. For example, equation 4.13 computes summer soil erodibility values at Tombstone, Arizona that are twice the average erodibility for summer period (i.e, the period that average daily temperature exceed 100 ^{o}F). The soil erodibility nomograph gives the same average erodibility for both Columbia, Missouri and Tombstone when soil properties are the same at the two locations.. However, the absolute July soil erodibility at Tombstone should not be higher than the absolute July soil erodibility at Columbia.

The root cause of the problem is that the soil erodibility nomograph is not a function of climate at a location. This deficiency does not cause major problems in the Eastern US, but it does cause great problems in the Western US.

To fix this problem, the P_s and T_s variables in equation 4.13 were changed from location values to values at Columbia, MO. The temporal soil erodibility equation referenced to Columbia, Missouri is:

$$K_j / K_n = 0.591 + 0.732(P_j / 0.123) - 0.324(T_j / 62.8) \qquad [4.14]$$

$$If\ (K_j / K_n) > 2.0\ \text{ then }\ (K_j / K_n) = 2.0$$

$$If\ (K_j / K_n) < 0.4\ \text{ then }\ (K_j / K_n) = 0.4$$

where: P_j = daily precipitation (inches), 0.123 (inches) = the daily average reference precipitation at Columbia, Missouri, T_j = the daily temperature (^{o}F), and 62.8 (^{o}F) = the daily average reference temperature at Columbia, Missouri. The j subscript is for the *jth* day. The reference precipitation and temperature value for Columbia, Missouri are for the time period that the average daily temperature is above 40 ^{o}F.

Either the standard or RUSLE2 soil erodibility nomographs can be used to determine a value for the nominal soil erodibility factor K_n, or another soil erodibility value can be used if values computed by the RUSLE2 soil erodibility nomographs are not applicable. The upper limit of 2 and the lower limit of 0.4 for the ratio K_j/K_n provides robustness by preventing extreme precipitation and temperature from excessively affecting daily soil erodibility factor values.

4.5.4. Temporal soil erodibility for the winter period

Equation 4.14 is used to compute temporal RUSLE2 soil erodibility factor values in the winter period as well as the summer period, except when average daily temperature is less than 30 ^{o}F. The RUSLE2 temporal soil erodibility equation for average daily temperature less than 30 ^{o}F is:

$$K_{(j)} / K_n = (K_{s(j)} / K_n) \exp[-0.2(30 - T_{(j)})] \qquad [4.15]$$

where: $K_{s(j)}$ = the soil erodibility factor value computed with equation 4.14 on the *jth* day, T_j = the average daily temperature on the *jth* day (^{o}F), and 30 = the average daily temperature below which soil erodibility is reduced because of soil freezing (^{o}F). The *exp* term in equation 4.15 computes a K_j/Kn value less than 0.05 when average daily temperature is less than 15 ^{o}F. The exponential decay term in equation 4.15 takes into account the fact that temperature in some years on a given day will not be less than freezing even though average daily temperature is below freezing. Also, the temperature used in equation 4.15 is air temperature rather than soil temperature.

Equation 4.15 does not compute increased erosion during and immediately after soil thawing.

4.5.5. Temporal soil erodibility for winter and summer periods combined

Figure 4.4 shows temporal soil erodibility factor values computed for the entire year at selected locations. Note the difference in the mean soil erodibility factor value among the locatins for the same base soil erodibility factor value.

4.5.6. Temporal soil erodibility for the Req regions

Winter erosion processes differ greatly from summer erosion processes in the Northwest Wheat and Range Region (NWRR) and other areas in the Western US (McCool et al., 1995). Soil erodibility is very high during the winter in these regions, resulting in very high erosion. This winter effect is accounted for in RUSLE2 by assuming an equivalent erosivity known as Req. Equation 4.14 can be used to estimate temporal erodibility for the summer period defined as the time between the day when average daily temperature reaches 45 ^{o}F early in the year and decreases to 35 ^{o}F late in the year. Equation 4.15 does not apply where Req effects are assumed to occur (see **Section 3.2.5** and RUSLE2 User's Reference Guide).

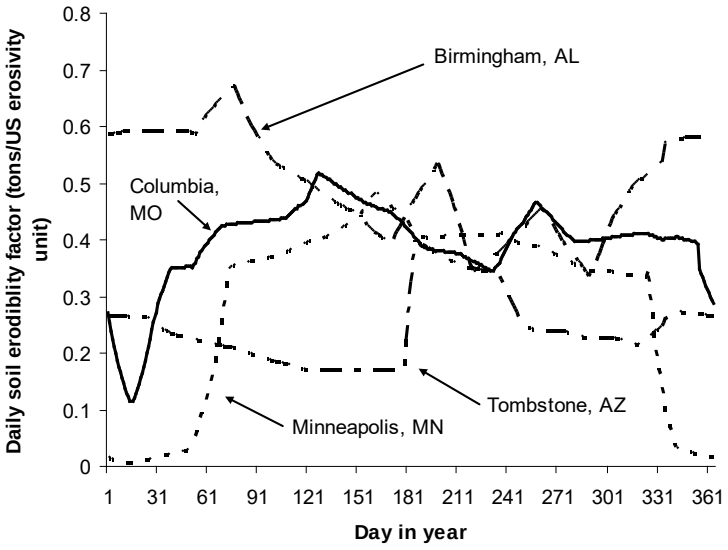

Figure 4.4. RUSLE2 computed temporal soil erodibility factor values for the same base soil erodibility factor value. The temporal soil erodibility factor equations are referenced to Columbia, Missouri.

4.6. Effect of rock on soil erodibility

Rock on and in the soil affects rill-interrill erosion. RUSLE2 treats rock on the soil surface as ground cover (see **Section 6.2**). Rock in the soil is assumed to affect runoff and this effect on erosion is represented by choosing a soil erodibility factor value based on how rock in the soil profile is assumed to affect runoff under unit plot conditions. **User entered soil erodibility values should reflect how rock in the soil profile affects erosion but not account for any effect of rock on the soil surface.**

The permeability class input should reflect how rock in the soil profile affects runoff when a RUSLE2 soil erodibility nomograph is used to compute a soil erodibility factor value. Although RUSLE2 includes the RUSLE1 soil erodibility nomograph equations used to estimate how rock in the soil profile affect soil erodibility (Römkens et al., 1997), these equations should not be used in RUSLE2, especially for construction sites and reclaimed surface mine lands. Toy and Foster (1998) describes how to adjust input values to the RUSLE2 modified soil erodibility nomograph to estimate the effect of large rock fragments in the soil on soil erodibility. 20-40=+1; 40-60=+2; 60-80=+3; >80=+4; max permeability is class=6 (very slow).

A value for soil surface cover provided by rock that is a natural part of the soil can be entered in RUSLE2's soil input. RUSLE2 assumes that this rock cover is not affected by mechanical soil disturbing operations. Rock cover can also be represented in RUSLE2 as an operation that adds surface cover, but RUSLE2 handles this rock cover differently from how it handles rock cover entered in the soil input. Rock cover represented as surface cover added by an operation is affected by soil disturbing operations and

RUSLE2 treats this rock as an organic material. Special inputs are required when rock cover is represented in this way (see **Section 10.1** and RUSLE2 User's Reference Guide).

The USDA-NRCS soil survey database includes soil erodibility factor values that have been adjusted for rock cover on the soil surface. **NRCS soil erodibility factors values adjusted for rock surface cover must not be used in RUSLE2.** The ground cover subfactor relationship used by NRCS to adjust for rock surface cover differs from the comparable RUSLE2 relationship (see **Section 6.2.1**). The surface cover relationship used by the NRCS is the USLE mulch cover subfactor [AH537 (Wischmeier and Smith, 1978)], which has an approximate 0.026 **b** value whereas the approximate RUSLE2 **b** value is 0.035. The error in estimated erosion from this difference for a 20 percent rock cover is 20 percent.

Also, RUSLE2 uses a net ground cover that takes into account surface residue and live ground cover overlapping rock surface cover. This overlap is not taken into account when NRCS soil erodibility factor values adjusted for rock surface cover are used, which can result in serious errors because the ground (mulch) cover relationships are highly non-linear (see RUSLE2 User's Reference Guide). The error in estimated erosion from neglecting the overlap for a 50 percent residue cover and a 20 percent rock cover is 30 percent even when if the proper **b** value had been used in the NRCS adjustment.

4.7. Sediment characteristics

RUSLE2 computes deposition and enrichment ratio as a function of sediment characteristics (see **Sections 2.3.3** and **4.7.6**). Diameter, specific gravity, distribution among sediment particle classes, and composition of sediment particle classes are the RUSLE2 variables used to describe sediment characteristics. RUSLE2 uses only soil texture and inherent soil organic matter content to compute values for sediment characteristics at the point of detachment although soil management affects these sediment characteristics. Sufficient information was not available to develop equations for the effect of soil management on sediment characteristics at the point of detachment.

The RUSLE2 equations used to compute sediment characteristics at the point of detachment are described by (Foster et al., 1985b). The RUSLE2 intent in representing sediment characteristics is to capture main effects rather than precisely representing all variables that affect sediment characteristics at the point of detachment. Also, more detail, such as more than the five sediment particle classes used in RUSLE2 equations is desired for computing deposition. However, the desired information is not readily available for most RUSLE2 applications as a conservation planning tool in local field offices. The RUSLE2 approach is far better than assuming that sediment characteristics at the point of detachment are the same as the characteristics of dispersed samples of the soil subject to detachment. A critically important point is that sediment is eroded as a mixture of aggregates and primarily particles. Assuming that sediment is composed entirely of primary particles produces serious errors when computing deposition. RUSLE2 computes how deposition changes sediment characteristics so that the characteristics of sediment leaving an overland flow path, terrace/diversion channels, and

small impoundments can be quite different from the characteristics of the soil being eroded, especially where RUSLE2 computes a high degree of deposition.

4.7.1. Definition of sediment particle classes

Five sediment particle classes are used to represent the sediment produced by detachment for each soil along an overland flow path. The five classes are primary clay, primary silt, small aggregate, large aggregate, and primary sand. Sediment from cohesive soils is eroded as a mixture of primary particles (small mineral particles that the soil can be divided into) and aggregates (conglomerates of primary particles) (Foster et al., 1985b). Also, the sediment distribution for many cohesive soils is bimodal, having a peak in the silt-size range and a peak in the sand-size range (Meyer et al., 1980). The two aggregate sediment particle classes represent these two peaks in the sediment distribution. The three primary sediment particle classes represent primary particles in the sediment while the two aggregate classes represent aggregates in the sediment.

4.7.2. Density of sediment particle classes

Densities, expressed as specific gravity, of the sediment particle classes are given in Table 4.3. The slightly reduced density for the primary clay class relative to the primary silt and sand classes is because of the platy nature of clay particles. The difference is of no consequence in RUSLE2. The significantly reduced densities of the aggregate classes from the primary particle classes reflect how aggregates are conglomerates of primary particles with internal open spaces in them that are partially or fully filled with water. Sediment particle density is especially important for sediment sizes larger than 0.1 mm because density seems to affect deposition by overland flow as much as size (Lu et al., 1988; Neibling and Foster, 1982). A smaller density is assigned to the large aggregate class than to the small aggregate class because density decreases as aggregate size increases (Foster et al., 1985b).

Table 4.3. Densities of sediment particle classes

Particle class	Density (specific gravity)
Primary clay	2.60
Primary silt	2.65
Small aggregate	1.80
Large aggregate	1.60
Primary sand	2.65

4.7.3. Diameters of sediment particle classes

The diameters of the sediment particle classes are given in Table 4.4. The diameter of each primary particle class is fixed. However, the diameter for each aggregate sediment particle class varies with soil clay content, which reflects the role of clay as a bonding agent.

Table 4.4. Diameter of sediment particle classes.

Particle class	Diameter		
	Symbol	Size (mm)	Condition where equation applies
Primary clay	d_{cl}	0.002	
Primary silt	d_{sl}	0.010	
Small aggregate	d_{sa}	0.030	$P_{cl} < 25$
	d_{sa}	$0.2(P_{cl}/100 - 0.25) + 0.03$	$25 \le P_{cl} \le 60$
	d_{sa}	0.100	$P_{cl} > 60$
Large aggregate	d_{la}	0.300	$P_{cl} \le 15$
	d_{la}	$2P_{cl}/100$	$P_{cl} > 15$
Primary sand	d_{sd}	0.200	

The diameter of each aggregate class is a function of soil clay content for certain ranges of clay content. RUSLE2 adds aggregate sediment particle classes as necessary along the overland flow path where soil clay differs by segment to represent unique particle classes having different diameters. The same primary sediment particle classes are used for all soils along an overland flow path because the diameters used for these classes do not vary with soil.

4.7.4. Distribution of sediment mass among particle classes at point of detachment

As shown in Table 4.5, the distribution of sediment mass among the sediment particle classes at the point of detachment depends mainly on the soil's clay content. Seventy four percent of the clay in the sediment at the point of detachment is in the aggregate sediment particle classes while only 26 percent is in the primary clay sediment particle class.

Table 4.5. Distribution of sediment mass among particle classes at the poi				
Particle class	Fraction			
	Symbol		Condition	Comment
Primary clay	F_{cl}	$0.26P_{cl}/100$		
Primary silt	F_{sl}	$P_{sl}/100 - F_{sa}$		
Small aggregate	F_{sa}	$1.8P_{cl}/100$	$P_{cl} < 25$	
	F_{sa}	$0.45 - 0.6(P_{cl}/100 - 0.25)$	$25 \le P_{cl} \le 50$	If $F_{sl} < 0$, F_{sl} =0.0001 and
	F_{sa}	$0.6P_{cl}/100$	$P_{cl} > 50$	$F_{sa} = P_{sl}/100 - F_{sl}$
Large aggregate	F_{la}	$1 - F_{cl} - F_{sl} - F_{sa} - F_{sd}$		If $F_{la} < 0$, each fraction is multiplied by the same fraction to give F_{la} = 0.0001
Primary sand	F_{sd}	$(P_{sd}/100)(1 - P_{cl}/100)^5$		
Note:				
If the clay content of the large aggregate class is less than $0.5P_{cl}$, the value for F_{sa} must be reduced to meet this condition.				

Soil clay content determines the fraction of the sediment mass that is in the small aggregate sediment particle class at the point of detachment. The fraction of the sediment in the primary silt class at the point of detachment is the soil's silt content less the silt fraction computed to be in the small aggregate class. The fraction of sediment mass in the small aggregate class at the point of detachment can not be larger than the silt content in the soil.

Both clay and sand content in the soil determine the fraction of the sediment mass that is in the primary sand sediment particle class at the point of detachment. The role of soil clay content in determining this fraction increases rapidly as soil clay content increases. The fraction of sediment mass in the large aggregate sediment particle class at the point of detachment is computed as 1 minus the sum of the fractions of the other four sediment particle classes. The fractions for the other four classes are adjusted when the fraction of the large aggregate sediment particle class is computed as being less than zero.

4.7.5. Composition of each sediment particle class

Detachment in RUSLE2 is assumed to be non-selective. Consequently, the sediment's primary particle composition at the point of detachment is the same as the composition of the surface soil subject to detachment.

4.7.5.1. Primary clay sediment particle class

The primary sediment particle is composed of primary clay and the organic matter associated with the clay.[39] The RUSLE2 assumption is that the ratio of organic matter to clay on a mass basis is the same for all sediment particle classes where clay is present. That ratio is given by:

$$r_{om,cl} = P_{om} / P_{cl} \quad [4.16]$$

where: $r_{om,cl}$ = the fraction (mass) of the primary clay sediment particle class that is composed of organic matter and P_{om} = 100 times the ratio of mass of organic matter in the soil to the mass of soil mineral particles.

4.7.5.2. Primary silt sediment particle class

The primary silt sediment particle class is composed solely of silt. This particle class contains no organic matter because the class contains no clay.

4.7.5.3. Small aggregate sediment particle class

The small aggregate sediment particle class is composed of clay, silt, and organic matter. This particle class contains no sand by definition. The size of the small aggregate particle class is too small to contain any sand except very fine sand. However, the RUSLE2 assumption is that this particle class does not contain even very fine sand. The distribution of the clay and silt is assumed to equal the proportion of clay and silt in the soil subject to detachment. That is,

$$f_{cl,sa} = P_{cl} /(P_{cl} + P_{sl}) \quad [4.17]$$

where: $f_{cl.sa}$ = the fraction (mass) of the small aggregate that is composed of clay. The fraction of the small aggregate that is composed of silt is given by:

$$f_{sl,sa} = P_{sl} /(P_{cl} + P_{sl}) \quad [4.18]$$

where: $f_{sl,sa}$ = the fraction (mass) of the small aggregate that is composed of silt. The fraction of the small aggregate that is composed of organic matter is given by:

$$f_{om,sa} = r_{om,cl} f_{cl,sa} \quad [4.19]$$

where: $f_{om,sa}$ = fraction (mass) of the small aggregate sediment class composed of organic matter.

---

[39] The terms clay, silt, and sand sometimes refer to particle sizes. However, as used herein, clay, silt, and sand refer to mineral particles in the clay, silt, and sand sizes. The fractions of the primary particles sum to 1. Organic matter is not considered in determining fraction of the particles classes.

4.7.5.4. Large aggregate sediment particle class

The large aggregate sediment particle class is assumed to be composed of clay, silt, sand, and organic matter. The total of each constituent among the sediment particles classes must equal the constituent's amount in the soil. The mass of a constituent, except organic matter, in the large aggregate is computed as the total minus the sum of that constituent in the other sediment particle classes That is:

$$f_{cl,la} = (P_{cl}/100 - F_{cl} - f_{cl,sa}F_{sa})/F_{la} \quad [4.20]$$

$$f_{sl,la} = (P_{si}/100 - F_{si} - f_{sl,sa}F_{sa})/F_{la} \quad [4.21]$$

$$f_{sd,la} = (P_{sd}/100 - F_{sa})/F_{la} \quad [4.22]$$

Equations 4.20-4.22 directly result from the RUSLE2 assumption that detachment is a non-selective process, which requires that the distribution of the constituents in the sediment at the point of detachment be the same as that in the soil subject to detachment. A check is made of the clay content in the large aggregate sediment particle class. Because clay and the organic matter associated with it are assumed to be bonding agents for the two aggregate classes, clay must be sufficient in the large aggregate class to give those particles stability. To meet this requirement, the RUSLE2 assumption is that the clay content in the large aggregate class must be at least half of the soil's clay content. If the clay content in the large aggregate particle class computed with equation 4.20 is less than half the soil's clay content, the fraction F_{sa} of the small aggregate sediment particle class is reduced to meet this requirement.

The fraction of the organic matter in the large aggregate sediment particle class is given by:

$$f_{om,la} = f_{cl,la}r_{om,cl} \quad [4.23]$$

4.7.5.5. Primary sand sediment particle class

The primary sand class is solely composed of sand. It contains no organic matter because it contains no clay.

4.7.6. Specific surface area

Table 4.6. Specific surface area of soil/sediment constituents.

Constituent	Specific surface area (m^2/g)
Clay	20
Silt	4
Sand	0.05
Organic matter	1000

Each constituent of clay, silt, sand, and organic matter is assigned a specific surface area so that RUSLE2 can compute an enrichment ratio based on specific area of the soil subject to detachment and the computed sediment yield from the overland flow path, terrace/diversion channel, or small impoundment, represented in a RUSLE2 computation. Specific surface area is the total surface area of the soil or sediment per unit mass. The specific surface areas used in RUSLE2 are given in Table 4.6,

which were used in the CREAMS model (Foster et al.1980a, 1980b; Foster et al., 1981a). As Table 4.6 shows, most of the surface area is associated with organic matter and clay with almost no specific surface area associated with sand. Because organic matter is directly associated with the clay, the specific surface of both the soil and the sediment is directly related to clay content in each.

Specific surface area of the soil subject to detachment and the sediment leaving the RUSLE2 flow path is used to compute an enrichment ratio as:

$$E_r = S_{sed} / S_{soil} \qquad [4.24]$$

where: E_r = enrichment ratio, S_{sed} = the specific surface area of the sediment and S_{soil} = the specific surface area of the soil. The enrichment ratio is a measure of the degree that RUSLE2 computes that deposition enriches the sediment in fine particles, especially clay. Deposition is a selective process that first deposits particles that are coarse and dense, which have a low specific surface area, leaving the sediment enriched in fine particles that have a high specific surface area. The enrichment ratio increases as deposition increases. A sediment delivery ratio can be computed as the ratio of sediment yield at the end of the RUSLE2 flow path divided by the total amount of sediment produced by detachment. Enrichment ratio increases as the sediment delivery ratio decreases. A low sediment delivery ratio represents a high degree of deposition. Enrichment ratio is a relative term and not an absolute term. A high enrichment ratio means that the specific area of the sediment is greater than that of the soil that produced the sediment, but the specific surface area of the sediment may still be low if the soil being eroded has a high sand content and a low inherent organic matter content.

Table 4.7. RUSLE2 computed enrichment ratios for a filter strip

Soil textural class	Enrichment ratio
Clay	1.95
Clay loam	2.23
Loam	2.65
Loamy sand	7.56
Sand	11.50
Sandy clay	2.13
Sandy clay loam	3.07
Sandy loam	3.47
Silt	0.94
Silt loam	1.58
Silty clay	1.19
Silty clay loam	1.44

The enrichment ratio computed by RUSLE2 is strongly affected by soil texture as shown in Table 4.7. Interestingly, the highest enrichment ratio is for a sand soil while the lowest enrichment ratio is for a high silt soil. Enrichment ratio values are moderate for high clay soils. These results are directly related to the sediment being a mixture of aggregates and primary particles, the role of clay as a bonding agent in determining size of the large the aggregates, and the distribution of sediment between the small aggregate and large aggregate sediment particle classes. An important point to remember when interpreting and using the RUSLE2 computed enrichment ratio values is that about 74 percent of the clay is in the small and large aggregate particle classes at the point of detachment. RUSLE2 computes that a moderate sized large aggregate class is deposited at a rate comparable to the primary sand sediment particle class. Because much of the clay is assumed to be in the large aggregate class, a significant amount of clay is deposited when the large aggregate class is deposited.

The enrichment ratio values computed by RUSLE2 are very different from those that would be computed if the sediment at the point of detachment was assumed to be composed entirely of primary particles. High sand soils have very low clay contents such that the portion of the sediment in the aggregates classes at the point of detachment is low. The aggregate classes, which contain most of the clay, have small diameters for high sand soils and are, therefore, less readily deposited. Consequently, the enrichment ratio for sediment from high sand soils is generally high as illustrated in Table 4.7. In contrast, the diameters of both the small and large aggregate classes, which contain most of the clay, are very large for the high clay soils. These aggregates classes are more readily deposited than the aggregate classes produced by high sand soils. The result is that a higher fraction of the clay in a high sand soil remains in the sediment after deposition than for a high clay soil.

Essentially no enrichment occurs with the high silt soil because of the very low clay content and a very high portion of the sediment at the point of detachment being in the primary silt class that is not readily deposited. Most of the clay is in the aggregate classes that are more readily deposited than the primary silt class where most the sediment is concentrated at the point of detachment.

Although specific surface area of clay varies significantly with clay mineralogy, RUSLE2 does not consider that effect. Also, RUSLE2 uses the inherent soil organic matter content under unit plot conditions in these computations. Soil organic matter content as influence by cover-management is a more appropriate measured than inherent soil organic matter content.

The enrichment ratio values computed by RUSLE2 represent an index. The enrichment ratio value indicates the concentration of sediment associated chemicals in the sediment relative to their concentration in the soil. Calibration should be used to empirically relate the concentration of chemicals on sediment to the RUSLE2 enrichment ratio values because the values computed by RUSLE2 are lower than expected (Knisel et al., 1980).

4.8. Time to soil consolidation

Soil consolidation refers to the soil becoming resistant to erosion over time after a mechanical soil disturbance and not to a mechanical increase in bulk density of the soil (see **Section 6.6**). RUSLE2 computes time to soil consolidation as function of annual precipitation using:

$$t_c = 20 \quad P_a < 10 \qquad [4.25]$$

$$t_c = 26.5 - 0.65P_a + 0.5 \quad 10 \le P_a \le 30 \qquad [4.26]$$

$$t_c = 7 \quad 30 < P_a \qquad [4.27]$$

where: t_c = the time to soil consolidation (years) and P_a = annual precipitation (inches). The equation that computes values for the soil consolidation subfactor uses the ratio of

time since last mechanical soil disturbance to time to soil consolidation and computes subfactor values that asymptotically approach the 0.45 final value (see **Section 6.6.2**). The time to soil consolidation is defined as the time for 95 percent of the reduction in the soil consolidation subfactor to occur. The time to soil consolidation occurs when the soil consolidation factor equals 0.4775, which is 95 percent of the decrease from 1 for the soil consolidation subfactor immediately after a mechanical soil disturbance to the final 0.45 value.

After a mechanical soil disturbance, the soil becomes resistant to detachment by the soil experiencing wetting and drying cycles in the presence of soil moisture and bonding agents including clay and organic matter (Foster et al., 1985b). Mechanical compaction of the soil is assumed to have little effect on this increase in erosion resistance in RUSLE2. The seven year time to soil consolidation is based on analysis of fallow plot data from Zanesville, Ohio (Borst et al., 1945), which are the only sufficient data available to empirically determine time to soil consolidation. This seven year period is assumed to apply to all areas where annual precipitation is greater than 30 inches. The increase of time to soil consolidation based on average annual precipitation is an approximate way to capture the idea that soil consolidation occurs more slowly in the western US than in the eastern US because of reduced rainfall amount and reduced number of rainfall events. Equations 4.25 and 4.26 are based on judgment.

4.9. List of symbols

b = coefficient used to compute ground cover subfactor values

d_{cl} = diameter of primary clay sediment class (mm)

d_{la}= diameter of large aggregate sediment class (mm)

d_{sa}= diameter of small aggregate sediment class (mm)

d_{sd} = diameter of primary sand sediment class (mm)

d_{sl} = diameter of primary silt sediment class (mm)

E_r = enrichment ratio

$f_{cl.la}$ = mass portion of large aggregate sediment class composed of clay (fraction)

$f_{cl.sa}$ = mass portion of small aggregate sediment class composed of clay (fraction)

$f_{om,la}$ = mass portion of large aggregate sediment class composed of organic matter (fraction)

$f_{om,sa}$ = mass portion of the small aggregate sediment class composed of organic matter (fraction)

$f_{sd,la}$ = mass portion of large aggregate sediment class composed of sand (fraction)

$f_{sl,la}$ = mass portion of large aggregate sediment class composed of silt (fraction)

$f_{sl,sa}$ = mass portion of small aggregate sediment class composed of silt (fraction)

F_{cl} = mass portion of sediment at point of detachment composed of primary clay sediment class (fraction)

F_{la} = mass portion of sediment at point of detachment composed of large aggregate sediment class (fraction)

F_{sa} = mass portion of sediment at point of detachment composed of small aggregate sediment class (fraction)

F_{sd} = mass portion of sediment at point of detachment composed of primary sand sediment class (fraction)

F_{sl} = mass portion of sediment at point of detachment composed of primary silt sediment class (fraction)

k_o = organic matter subfactor in soil erodibility nomograph

k_p =soil profile permeability subfactor in soil erodibility nomograph

k_s = soil structure subfactor in soil erodibility nomograph

k_t = texture subfactor in soil erodibility nomograph

k_{tb} = base soil texture subfactor in soil erodibility nomograph for all soil textures

k_{t68} = base soil texture subfactor in soil erodibility nomograph when $P_{sl} + P_{vfs} > 68\%$.

K = soil erodibility factor[40]

K_j = average daily soil erodibility factor value for the *jth* day

K_n = soil erodibility value from RUSLE2 soil erodibility nomographs or user entered for summer periods

K_r/K_i = rill to interrill soil erodibility ratio

$K_{s(j)}$ = soil erodibility factor computed with equation 4.14

O_m = inherent soil organic matter (percent)

P_a = annual precipitation (inches)

P_{cl} = portion of soil mass composed of clay based on total soil primary particles (percent)

P_j = average daily precipitation (inches)

P_{om} = 100 times ratio of mass of organic matter in soil to mass of soil mineral particles

P_r = soil profile permeability class used in soil erodibility nomograph

P_s = average precipitation for the RUSLE2 summer period (inches)

P_{sd} = portion of soil mass composed of sand based on total soil primary particles (percent)

P_{sl} = portion of soil mass composed of silt based on total soil primary particles (percent)

P_{vfs} = portion of soil mass composed of very fine sand based on total soil primary particles, not the portion of sand content (percent)

---

[40] US customary units used for K and associated variables

$r_{om,cl}$ = mass portion of the primary clay sediment class composed of organic matter (fraction)

S_s = soil structure class used in soil erodibility nomograph

S_{sed} = specific surface area of sediment

S_{soil} = specific surface area of soil subject to erosion

t_c = time to soil consolidation (years)

T_j = average daily temperature for the *jth* day (^oF)

T_s = average temperature for the RUSLE2 summer period (^oF)

5. TOPOGRAPHY

This section describes mathematical consequences of RUSLE2's equation structure rather than providing additional equations except for the steepness factor and adjusting soil loss tolerance values for position along the overland flow path.

Equations that describe how topography affects rill-interrill erosion where the overland flow streamlines are parallel are described in **Section 2**. Those equations provide RUSLE2's fundamental, underlying mathematical structure. Those equations accommodate spatial variability in soil, steepness, cover-management, and support practices along the overland flow path. Those equations compute whether detachment or deposition occurs along the overland flow path. RUSLE2 computes its erosion and sediment load values using a numerical solution of the governing RUSLE2 equations written as a function of distance along the overland flow path. The numerical solution is a spatial integration of the governing equations. Furthermore, RUSLE2 performs a temporal integration of the governing equations, where the slope length exponent m in equation 2.10, along with soil erodibility and cover-management relationships change daily.

5.1. Converging-diverging streamlines on overland flow areas

The RUSLE2 assumption is that overland flow streamlines are parallel. Consequently, RUSLE2 does not estimate how converging or diverging overland flow affects rill-interrill erosion. An analysis based on a simple process-based erosion model showed that rill-interrill erosion with converging overland flow is about 7/6 times that where the streamlines are parallel (Toy and Foster, 2000). The same analysis showed that rill-interrill erosion with diverging overland flow is about 5/6 times that where the streamlines are parallel.

5.2. Topographic equations for overland flow having parallel streamlines on uniform overland flow paths

RUSLE1 requires users to select a slope length exponent value, m in equation 2.10, based on land use classes [AH703, (Renard et al., 1997); Toy and Foster, 1998]. The RUSLE1 slope length exponent is time invariant and thus does not change as cover-management conditions change temporally. Overland flow path steepness is the only variable considered in adjusting the slope length exponent in the USLE [AH537 (Wischmeier and Smith, 1978)].

A RUSLE2 major improvement is that it computes slope length exponent values as a function of overland flow path steepness, soil, and cover-management conditions. Consequently, the RUSLE2 slope length exponent varies as cover-management conditions vary temporally. RUSLE2 automatically computes slope length exponent values from basic input data rather than the user selecting a value as required by RUSLE1.

The slope length exponent should vary with position along the overland flow path according to erosion theory (Foster and Meyer, 1975). However, equation 2.10 is based on the assumption that the slope length exponent is a not a function of position x. The slope length exponent not varying with position greatly simplifies RUSLE2 mathematics and numerical procedures (see **Section 2.3**) and gives RUSLE2 increased robustness for overland flow paths longer than 150 ft (see **Section 5-Appendix I**).

If equation 2.10 is used to compute erosion for a slope length exponent that varies with position, RUSLE2 computes erroneous erosion values for a uniform overland flow path divided into segments, even if conditions are the same for all segments. Computed erosion should be independent of the number and length of segments used to represent a uniform overland flow path.

Some of the sediment produced by interrill erosion is deposited in "rill" areas when overland flow path steepness is low and interrill erosion is sufficiently high. RUSLE2 computes no rill erosion when it computes deposition. RUSLE2 computes this local deposition[41] when interrill erosion rate is greater than the increase in transport capacity with distance along the overland flow path (i.e., $D_i > dT_c/dx$ where D_i = interrill erosion rate, T_c = runoff's sediment transport capacity, and x = distance). Interrill erosion is computed with equation 2.11, dT_c/dx is computed using equation 2.17, and deposition and net erosion is computed using equation 2.16 and its companion equations. RUSLE2-computed net erosion does not vary with distance along the overland flow path as expected (Renard and Foster, 1983; Meyer and Harmon, 1985).

Erosion values computed with equations 2.16 and 2.17 differ from values computed by the empirical USLE, which is equation 2.10. This inconsistency, which should not occur, results from RUSLE2 combining the empirical USLE equation with a process-based sediment transport capacity equation. These equations do not work well together for this condition. A choice must be made as to whether the USLE based erosion value or the process-based erosion value will be the RUSLE2-computed value.

A RUSLE2 development principle is that RUSLE2 compute erosion values agree with USLE computed values (see **Section 1**). The conflict between equation 2.16 and the USLE equation forms, therefore, is resolved by having RUSLE2 produce the same results as the USLE. However, RUSLE2 uses equation 2.16 to compute how local deposition change sediment characteristics.

This procedure works well for local deposition on a uniform overland flow path not subdivided into segments. Subdivision without changing any of the segment variable values should not affect computed erosion and sediment values. Subdivision does not

---

[41] Local deposition is where sediment is deposited almost adjacent to the point of detachment such as in soil surface roughness depressions and in furrows between ridges. Remote deposition is where sediment is deposited a significant distance from the point detachment such as at the upper edge of dense vegetation strips and on the toe of concave-shaped overland flow path profiles.

affect computed erosion values but does affect computed enrichment ratio values when RUSLE2 computes local deposition. The RUSLE2-computed enrichment ratio value is correctly computed when a uniform overland flow path is not subdivided.

RUSLE2 was constructed so that its remote deposition computations are independent of segment subdivision. An example of remote deposition is the deposition that occurs at the upper end of a 0.5 percent segment downslope from a one percent steep segment. RUSLE2 also computes local deposition on the 1 percent steep segment if interrill erosion is sufficiently great.

RUSLE2 makes these computations correctly if the upper one percent segment is not subdivided. However, if that segment is subdivided, it will compute erroneous enrichment ratio values, especially if the subdivision is near the upper end of the segment. The erosion values are affected only very slightly by subdivision of the upslope segment.

The error in the enrichment ratio values caused by subdividing the overland flow path is a RUSLE2 flaw. This flaw can not be eliminated because of differences in equation structure between the USLE and the process-based sediment transport capacity equation used in RUSLE2. The enrichment ratio error could have been prevented by developing RUSLE2 entirely from process-based equations. However, RUSLE2's power of giving the well-accepted, empirically derived USLE values would have been lost. RUSLE2 was derived, developed, and evaluated to ensure that inconsistencies, which can not be totally eliminated, are acceptable for the purpose of conservation and erosion control planning. Fortunately, most RUSLE2 conservation planning applications assume a uniform overland flow path without subdivision.

5.3. Topographic equations for overland flow having parallel streamlines on non-uniform overland flow paths

RUSLE2 uses the equations described in **Section 2** to compute erosion and sediment load on non-uniform overland flow paths. The overland flow path is divided into segments where soil, steepness, or cover-management change along the overland flow path. The governing equations are numerically solved along the overland flow path starting at the upper end of the overland flow path where overland flow originates (see **Section 2.3**).

Each soil, steepness, and cover-management variable that changes between segments is treated as a step rather than a continuous change (see **Section 2.3.1**). Assuming step changes is appropriate for most cover-management changes, whereas continuous change is appropriate for changes in soil and steepness for overland flow paths on most natural landscapes.

Steepness at the intersection of two segments could be treated as the average of the steepness of the two segments, which is appropriate for describing an overland flow path where steepness changes continuously along the overland flow path, such as a concave overland flow path profile. However, a continuous change in steepness is not appropriate for constructed slopes where steepness makes a step change. Examples include the

intersection a landfill's top with a sideslope and the intersection of a hillslope cut with a flat area. RUSLE2 assumes a step change in steepness to accommodate step changes in steepness common to constructed slopes. The effect of step changes in representing gradual soil and steepness changes along an overland flow path is minimized by dividing the overland flow path into several segments (see the RUSLE2 User's Reference Guide).

A concern in applying RUSLE2 to non-uniform overland flow paths is dealing with changes in infiltration caused by soil and cover-management changes along the overland flow path. RUSLE2 considers how changes in infiltration along an overland flow path affect contouring failure, sediment transport capacity, and deposition. RUSLE2 does not consider how changes in infiltration along an overland flow path affect detachment on a downslope segment. While interrill erosion on a particular segment is only affected by infiltration rate on that segment, rill erosion on a segment is affected by both the runoff generated on that segment and by the runoff that arrives from the upslope area of the overland flow path. This effect can be partially represented by adjusting the upslope overland flow path length to reflect runoff coming into a downslope segment.

Nevertheless, a conflict exists in RUSLE2 between the way that overland flow path distance is treated for computing runoff and the way that overland flow path distance is treated for computing detachment. An example situation is runoff from an upslope pasture draining onto a cultivated field where infiltration on the pasture area is much higher than on the cultivated area. If the actual overland flow length is entered, RUSLE2 computes detachment values that are too high on the cultivated area because runoff reaching the cultivated area will be much less than is implicitly assumed in RUSLE2. If an effective overland flow path length is entered to correctly compute detachment on the cultivated area, RUSLE2 computes runoff rates that are too low on the cultivated area and incorrectly computes detachment on the pasture area. See the RUSLE2 User's Reference Guide for recommendations for selecting overland flow path lengths where infiltration varies greatly along an overland flow path.

The resolution to this problem is to have derived RUSLE2 using process-based erosion equations. Given that most RUSLE2 conservation planning applications involve uniform overland flow paths or overland flow paths where infiltration does not vary greatly along the path, RUSLE2 is considered to produce satisfactory results for most conservation planning applications.

5.4. Applying RUSLE2 to complex topography with converging and diverging overland flow

The RUSLE2 User's Reference Guide describes the proper procedure for applying RUSLE2 to complex topography. The effect of converging and diverging overland flow on RUSLE2 computed erosion is discussed in **Section 5.1**.

The USLE and RUSLE1 are used in GIS applications to compute erosion on topographically complex areas where overland flow converges and diverges. In these

applications, overland flow path distance is considered equivalent to upslope drainage area (Desmet and Govers, 1996). This assumption is questionable as discussed in **Sections 5.2** and **5.Appendix I**. The slope length exponent should be a function of upslope drainage area. If the slope length exponent is used as a function of upslope drainage area, the proper numerical procedure must be used. The irregular slope procedure derived by Foster and Wischmeier (1974) assumes that the slope length exponent does not vary with position along the overland flow path. If the slope length exponent is varied with the Foster and Wischmeier irregular slope procedure, erroneous erosion values will be computed (see **Sections 5.3** and **5.Appendix I**).

RUSLE2 is much more complex than the USLE or RUSLE1 regarding the rill to interrill erosion ratio used to compute slope length exponent values. RUSLE2 may be used in GIS applications to represent complex topography where distance along an overland flow path is assumed to be comparable to upslope drainage area. Such applications should be made ***only*** **where infiltration rate varies little spatially and where convergence or divergence of overland flow is minimal.**

A much better approach than using the RUSLE2 equations is to derive separate rill erosion, interrill erosion, and deposition equations using RUSLE2 assumptions, concepts, and equations. In this approach, a discharge rate can be properly computed from upslope drainage area. The discharge rate can be used to compute rill erosion, sediment transport capacity, deposition, and contouring failure. Interrill erosion is computed independent of upslope drainage area.

A common error in using the USLE and RUSLE1 in GIS applications is that excessively long overland flow path lengths are assumed. Inadequate resolution in topographic data, results in excessively long overland flow paths and poor representation of steepness along the overland flow path (Toy and Foster, 2000). The maximum overland flow path length allowed in RUSLE2 is 1,000 ft (see RUSLE2 User's Reference Guide). In fact, overland flow is collected in concentrated flow areas within 200 ft on most farm fields (Foster, 1985).

When using GIS applications to compute erosion, deposition, and sediment yield, separate relationships should be used to compute sediment production and sediment transport capacity needed to compute deposition. Desmet and Govers (1996) illustrate this procedure.

5.5. Slope length exponent

5.5.1. Slope length exponent for standard (non-Req) conditions

The slope length exponent is the exponent m in equations 2.10 and 5.1. The RUSLE2 slope length exponent is a function of the rill to interrill erosion ratio just is it was in RUSLE1 [Foster and Meyer, 1975; McCool et al., 1989; AH703 (Renard et al., 1997)]. However, in contrast to RUSLE1 where the slope length exponent is time invariant, the RUSLE2 slope length exponent varies daily as cover-management conditions change. A

value for the RUSLE2 slope length exponent for standard, non-Req conditions is computed daily using equations 2.12 and 2.13 (see **Section 5.2**).

5.5.2. Slope length exponent for Req conditions

The erosion processes that occur during the winter Req conditions (see **Section 3.2.5** and RUSLE2 User's Reference Guide) differ from those that occur with standard rill-interrill erosion. Most of the erosion during Req conditions is by surface runoff. The empirically derived RUSLE2 soil length exponent for Req conditions is m = 0.5 (McCool et al., 1989, 2002); [AH703, (Renard et al., 1997)]. The slope length exponent for Req conditions is time invariant and does not vary with the rill to interrill erosion ratio.

The slope length exponent (equations 2.12 and 2.13) for standard, non-Req rill-interrill erosion can be used for the non-Req period (summer period) at Req locations. Standard rill-interrill erosion can be assumed for the summer months at Req locations. This summer period defined for RUSLE2 as the time between the day when average daily temperature becomes greater than 45 ^{o}F early in the year to the day average daily temperature falls to 35 ^{o}F late in the year (see **Section 4.5.1**).

5.6. Steepness effect on rill-interrill erosion

5.6.1. Steepness factors for standard (non-Req) conditions

An interrill erosion steepness factor is used in equation 2.11 and 6.13 to compute interrill erosion and to compute the rill to interrill erosion ratio in several equations (e.g., equations 2.13). A steepness relation for rill erosion is needed to compute rill erosion (e.g., equation 6.13) and the rill to interrill ratio in several equations including equations 2.13. Also, a steepness factor equation is needed to compute rill-interrill erosion combined in equation 2.10.

The same equation used for interrill erosion in RUSLE1 is also used in RUSLE2 [Foster, 1982; AH703 (Renard et al., 1997)]:

$$S_i = 3s_i^{0.8} + 0.56 \qquad [5.1]$$

where: S_i = the interrill erosion steepness factor, s_i = steepness of the interrill area (sine of slope angle). Equation 5.1 is referenced to the unit-plot steepness so that the equation gives a value of 1 for nine percent steepness. The interrill steepness is the same as the overland flow path steepness in RUSLE2. However, the overland flow path steepness and the interrill steepness are not always the same as the land steepness. An example is when RUSLE2 is used to compute erosion on ridge side slopes, where the interrill and overland flow path steepness equals the steepness of the ridge side slopes (see RUSLE2 User's Reference Guide).

A simple rill erosion equation is assumed to compute the rill to interrill erosion ratio (Foster and Meyer, 1975). The steepness factor for rill erosion is:

$$S_r = s_r / 0.0896 \qquad [5.2]$$

where: S_r = the rill erosion steepness factor and s_r = steepness of the rill area (sine of slope angle). This steepness factor is normalized to the nine steepness of the unit plot. The steepness of the rill area is the same as the overland flow path steepness, which can differ from the land steepness.

A third steepness factor is used to compute rill-interrill erosion in equation 2.10. The relationship of rill-interrill erosion for a wide range of studies is shown in Figure 5.1 (McCool et al., 1987). These erosion data were normalized to the erosion for 20 percent steepness rather than to the unit plot nine percent steepness.

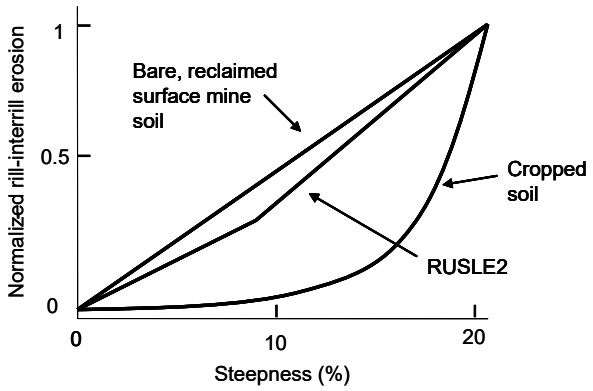

Figure 5.1. Effect of slope steepness on rill-interrill erosion.

The steepness factor for rill-interrill differed greatly among cover-management conditions. At one extreme is where erosion varied linearly for a bare reclaimed, surface mine soil. Steepness had little effect on runoff in this case. At the other extreme is erosion for a cropped soil where the relationship between erosion and steepness is very non-linear. In this case, runoff increased as steepness increased. Most of the erosion for the cropped soil at low steepness is caused by interrill erosion with little or no rill erosion. Once the overland flow path steepness exceeds a critical steepness, rill erosion begins, which results in rill-interrill erosion increasing rapidly. Runoff's shear stress must exceed a critical shear stress for rill erosion to begin, much like contouring failure. The resulting rill erosion equation would have rill erosion being proportional to the difference between shear stress applied to the soil and a critical shear stress related to soil conditions (Meyer et al., 1975b; Foster, 1982; Graf, 1971; Foster et al., 1980a).

The relation of rill-interrill erosion to overland flow path steepness should be a function of the rill to interrill erosion ratio and a critical shear stress at which rill erosion begins. However, in contrast to the temporally varying slope length effect, RUSLE2 uses an invariant slope steepness factor. Although erosion theory indicates reasons why the steepness factor should vary, the experimental plot data were not sufficient to develop a RUSLE2 steepness factor as a function of the rill to interrill erosion ratio, critical shear stress, or other variables. Consequently, RUSLE2 uses the invariant steepness relationship illustrated by the middle curve in Figure 5.1. The equation for that curve is given by [McCool et al., 1987; AH703 (Renard et al., 1997)]:

$$S = 10.8s + 0.03 \quad s_p < 9\% \qquad [5.3]$$

$$S = 16.8s - 0.50 \quad s_p \geq 9\% \qquad [5.4]$$

where: S = steepness factor in equation 2.10, s = overland flow path steepness (sine of slope angle) and s_p = overland flow path steepness (100 times tangent of slope angle). Equations 5.3 and 5.4 give a value of 1 referenced to the unit plot 9 percent steepness rather than the 20 percent steepness in Figure 5.1.

5.6.2. Steepness factor for Req conditions

A special steepness factor relationship is used for Req winter conditions because erosion processes for the Req condition differ significantly from the standard rill-interrill erosion conditions. Most of the erosion is caused by surface runoff during the Req conditions. The empirically derived steepness factor for Req conditions is given by [McCool et al., 1987; McCool et al., 1997; AH703 (Renard et al., 1997)]:

$$S = 10.8s + 0.03 \quad s_p < 9\% \qquad [5.5]$$

$$S = (s / 0.0896)^{0.6} \quad s_p \geq 9\% \qquad [5.6]$$

where: 0.0896 = the sine of the angle for 9 percent unit plot steepness. Equations 5.4 and 5.6 are also referenced to the unit plot steepness.

Equations 5.3 and 5.4 can be used for the summer period at locations where the Req winter effects occur.

5.7. Topographic relationships for short overland flow paths (x ≤ 15 ft)

Equation 2.10 does not apply for short overland flow path distances because these equations compute a zero erosion rate for a zero overland flow path length. Erosion rate should equal the interrill erosion rate at the origin of overland flow (x = 0). Experimental interrill erosion studies show that overland flow path length must be about 15 feet before rill erosion begins to occur (Meyer and Harmon, 1989), a distance that is also consistent with field observations, including rainfall simulator studies of the variables that affect rill-interrill erosion (Meyer et al., 1975ab). Therefore, equation 2.10 is assumed not to apply to short overland flow path distances less than 15 ft.

5.7.1. Overland flow steepness < 9 percent

The overland flow path distance x is set to 15 ft when the actual overland flow path distance is less than 15 ft to represent the concept that interrill erosion is independent of distance. The preferred steepness factor for interrill erosion is equation 5.1, but his equation conflicts with the empirically derived rill-interrill erosion S factor given by equation 5.3 for steepness less than 9 percent. Therefore, the rill-interrill erosion steepness factor, equation 5.3, is used for all overland flow distances less than 15 ft if the overland flow path steepness is less than 9 percent. The variables used for $(x/\lambda_u)^m S$ in equation 2.10 are $(15/72.6)^m S_i$ where S_i is the rill-interrill steepness factor computed from

equation 5.3, 15 = 15 ft, the overland flow path length assumed for all overland flow path lengths less than 15 ft, and 72.6 = 72.6 ft, the unit plot length.

5.7.2. Overland flow path steepness ≥ 9 percent

5.7.2.1. Overland flow path length ≤ 3 ft

The inconsistency between the interrill steepness factor, equation 5.1, and the rill-interrill steepness, equation 5.4, does not occur when overland flow path steepness exceeds 9 percent. If the overland flow path length is less than or equal to 3 ft, the rill-interrill steepness factor in equation 2.10 equals the interrill steepness factor, equation 5.1. The overland flow path distance is set to 15 ft regardless of actual overland flow path distance. The variables used for $(x/\lambda_u)^m S$ in equation 2.10 are $(15/72.6)^m S_i$ where S_i is the interrill steepness factor computed from equation 5.1, 15 = 15 ft, the overland flow path length assumed for all overland flow path lengths less than 15 ft, and 72.6 = 72.6 ft, the unit plot length.

5.7.2.2. Overland flow path 3 ft < x ≤ 15 ft

A logarithmic interpolation is used to transition between the interrill steepness factor, equation 5.1, at a 3 ft overland flow distance to the rill-interrill steepness factor, equation 5.4, at a 15 ft overland flow distance. This interpolation is computed as:

$$\alpha_3 = (3/72.6)^m S_i \qquad [5.7]$$

$$\alpha_{15} = (15/72.6)^m S \qquad [5.8]$$

where: α_3 and α_{15} = the combined distance and steepness factor for 3 ft and 15 ft overland flow path lengths, respectively, at the given steepness, 15 = 15 ft, the assumed overland flow path distance for all actual overland flow path distances less than 15 ft. The interrill steepness factor S_i, equation 5.1, is used to compute and S = the rill-interrill steepness factor, equation 5.3, is used to compute the steepness effect at a 15 ft overland flow distance. A logarithmic interpolation is made between α_3 in equation 5.7 and α_{15} in equation 5.8 as:

$$\ln(\alpha_x) = [\ln(\alpha_{15}) - \ln(\alpha_3)][(\ln(x) - \ln(15)]/[\ln(15) - \ln(3)] + \ln(\alpha_3) \qquad [5.9]$$

$$\alpha_x = \exp[\ln(\alpha_x)] \qquad [5.10]$$

where: α_x = the combined length and steepness factor at the overland flow distances between 3 and 15 ft and an overland flow path steepness greater than 9 percent. This distance and steepness factor value is used in equation 2.10 for the variables $(x/\lambda_u)^m S$.

5.8. Effect of position along overland flow path on soil loss tolerance (T) factor

The powerful conservation planning approach of comparing an estimated erosion rate to an allowable erosion rate developed in the mid 1940's (Mannering, 1981; McCormack and Young, 1981; Toy et al., 2002). Erosion control practices resulting in an estimated erosion rate that is less than the allowable erosion rate are considered to provide adequate erosion control for the site. Soil loss tolerance (T) values assigned to soil mapping units in the USDA-NRCS Soil Survey are widely used for allowable erosion rate on croplands.[42] Other values for the erosion control criteria are used when RUSLE2 is applied to other lands including construction sites and rangelands. For example, very low soil loss tolerance values are used for very fragile soils that are easily damaged by erosion. Soil loss tolerance values larger than those used for cropland are often used for construction sites for the disturbance and reclamation periods. However, cropland soil loss tolerance values are used for the after-reclamation period where maintenance of the soil for long-term vegetation production is the primary erosion control concern.

Erosion is not considered excessive if the estimated erosion rate is less than the T value. The procedure implicitly assumes a uniform overland flow path, which is common practice in most erosion prediction applications and in research used to determine soil loss tolerance (T) values. The average erosion rate for the entire overland flow path, rather than maximum erosion rate, is compared to the soil loss tolerance (T) value.

The erosion rate computed with RUSLE2 varies along even a uniform overland flow path from an interrill erosion rate at the origin of overland flow ($x = 0$) to $(m+1)$ times the average erosion rate for the entire overland flow path length at the end of the path ($x = \lambda$). Therefore, erosion rate over the approximate lower one half of uniform overland flow paths exceeds T when the average erosion rate for the overland flow path equals T. That is, the conservation planning criteria does not require that maximum erosion rate along an overland flow path be less than soil loss tolerance; only that average erosion rate for a uniform overland flow path be less than soil loss tolerance [AH703 (Renard et al., 1997); Toy et al., 2002].

Comparing average erosion rate for the overland flow path to soil loss tolerance is not appropriate for overland flow paths on non-uniform shape profiles, especially convex profiles. To make these comparisons, RUSLE2 computes an adjusted soil loss tolerance value that is compared against the RUSLE2 estimated erosion rate for each segment along a non-uniform overland flow path (see the RUSLE2 User's Reference Guide). The comparison with the adjusted T value puts conservation planning on the same basis for non-uniform overland flow paths as for a uniform overland flow path. The adjusted soil

---

[42] Soil loss tolerance (T) values have a specific definition in the NRCS Soil Survey and NRCS RUSLE2 applications. However, T in general RUSLE2 applications refers to the erosion control criteria used in a specific RUSLE2 application. This value can be quite different from the assigned NRCS T value depending on the application. See the RUSLE2 User's Reference Guide.

loss tolerance values are the T factor values for the soil on *jth* segment times a factor value computed with [(AH703 (Renard et al., 1997)]:

$$F_j = (x_j^{m_i+1} - x_{j-1}^{m_i+1}) / [(x_j - x_{j-1})\lambda^{m_i}] \quad [5.11]$$

where: F_j = the factor that is used to multiply the soil loss tolerance (T) value to obtain a soil loss tolerance value adjusted based on the position of the *jth* segment along the overland flow path, x_j = distance to the lower end of the *jth* segment, m_j = slope length exponent for the *jth* segment, and λ = the entire length of the overland flow path. The ratio of computed erosion rate to the adjusted soil loss tolerance value is the same for all segments along a uniform overland flow path.

5.9. Conservation planning soil loss

RUSLE2 computes a conservation planning soil loss where deposition is given partial credit based on the location where the deposition occurs along the overland flow path. This type of deposition, which is referred to as remote deposition, occurs on concave overland flow path profiles and at the upper edge of dense vegetations strips. The use of conservation planning soil loss in conservation planning is discussed in the RUSLE2 User's Reference Guide, and the equations used to compute a value for conservation planning soil loss are given in **Section 2.3.10.4**.

Partial credit for deposition as soil saved also is taken with terraces. The deposition credit decreases as terrace spacing increases beyond 90 ft. However, the credit for deposition remains constant for terrace spacing closer than 90 ft.

High ridges spaced about 3 ft apart on a uniform, nearly flat grade act like small terraces. RUSLE2 can be applied to the ridge side slopes just like RUSLE2 is applied to the inter-terrace interval. The furrows between the ridges act like terrace channels. The deposition in the furrows should be treated as local deposition rather than remote deposition. The conservation planning soil loss that RUSLE2 computes for this case incorrectly assumes that this deposition is remote deposition. The user should ignore the conservation planning soil loss and use sediment yield as the conservation planning soil loss.

5.10. List of symbol

a = coefficient that is product of terms that do not vary with x in $D = ax^m$

a_e = product of terms that do not vary with x in $D = a_e x_e^m$ when x_e is the overland flow distance adjusted in proportion to upslope drainage area for converging runoff surface

a_p = product of terms that do not vary with x in equation $D = a_p x^m$ when runoff streamlines are parallel

a_T = product of terms that do not vary with x in sediment transport capacity equation $T_c = a_T q$

A = average combined rill-interrill erosion rate for the slope length λ (mass/area·time)

D = combined rill-interrill erosion (detachment) rate at location x along an overland flow path (mass/area·time)

D_i = interrill erosion rate (mass/area·time)

D_r = rill erosion rate (mass/area·time)

D_{rc} = capacity rill erosion rate (mass/area·time)

F = factor used to multiply soil loss tolerance (T) to obtain adjusted soil loss tolerance value based on position of segment along overland flow path

g = sediment load (mass/width·time)

g_λ = sediment load at end of overland flow path

k_c = product of terms that do not vary with x in equation $A = k_c \lambda^m$

k_r = product of terms that do not vary with x in rill erosion equation $D_r = k_r x$

m = slope length exponent

q = discharge rate (volume/width·time)

q_c = discharge rate at which runoff shear stress applied to soil equals the soil's critical shear stress

s = overland flow path steepness (sine of slope angle)

s_i = interrill area steepness (sine of slope angle)

s_p = overland flow path steepness (100 times tangent of slope angle)

s_r = rill area steepness (sine of slope angle)

S = combined rill-interrill erosion steepness factor

S_i = interrill erosion steepness factor

S_r = rill erosion steepness factor

T = soil loss tolerance (mass/area·time)

T_c = runoff's sediment transport capacity (mass/width·time)

$T_{c\lambda}$ = runoff's sediment transport capacity at end of overland flow path (mass/width·time)

W = width of runoff surface at location x (length)

x = distance along overland flow path (length)

x_e = distance along overland flow path that is proportional to upslope drainage area for converging runoff surface (length)

α_x = combined length and steepness factor at overland flow distances between 3 and 15 ft and overland flow path steepness greater than 9 percent

α_3 = combined distance and steepness factor for 3 ft overland flow path length at a particular steepness

α_{15} = combined distance and steepness factor for 15 ft overland flow path length at a particular steepness

Δ = change in a variable

β = ratio of rill erosion sediment load to interrill erosion sediment load

λ = overland flow path length

λ_u = unit plot overland flow path length (72.6 ft, 22.1 m)

ρ = term in equation $\beta = \rho x$

σ = excess rainfall rate (length/time)

Indices

j – segment

5.Appendix 1. Slope length exponent that varies with position

5.Appendix 1.1. Derivation of equations

The RUSLE2 slope length exponent m does not vary with position along the overland flow path. The topographic equations for the slope length exponent m varying with position along the overland flow path are much more complex than the equations used in RUSLE2. The additional complexities and reduced robustness did not warrant their use in RUSLE2 for routine erosion-control planning in local field offices. However, a variable slope length exponent m that varies with position along the overland flow path is very important for applying RUSLE2 to landscapes where surface runoff converges or diverges. Representation of flow convergence/divergence must be considered when RUSLE2 equations are used in GIS models applied to three dimensional landscapes.

In the 1940's when erosion prediction was first developed as an erosion-control planning tool, the following simple empirical equation became widely accepted for describing how erosion varies with overland flow path length for uniform slopes (Zingg, 1940).[43]

$$A = k_c \lambda^m \qquad [V.1]$$

where: A = average erosion rate (mass/area·time) for the slope length λ, k_c = a term that combines the other terms used to compute A that are not a function of λ, and m = the slope length exponent. Equation V.1 is a derived equation. The equation that actually represents the measured field data is:

$$g_\lambda = k_c \lambda^{m+1} \qquad [V.2]$$

where: g_λ = the sediment load (mass/width·time) at the end of the slope length λ, which was the measured sediment discharge from the plots used to measure erosion. The term A in equation V.1 was determined by dividing equation V.2 by the slope length λ. Soil loss A was the variable needed in erosion-control planning.

Equation V.2, not equation V.1, is the starting point for developing RUSLE2 (and the USLE and RUSLE1) equations that represent spatial variability along overland flow paths (Foster and Wischmeier, 1974). The equation for detachment at any point along a uniform overland flow path can be derived by differentiating equation V-2 as:

$$D = dg / dx \qquad [V.3]$$

where: D = detachment rate (mass/area·time) at the location x along an overland flow path. The derivation of a detachment equation is simple where the slope length exponent m is not a function of position x along the overland flow path. By inspection, equation

---

[43] Uniform means that steepness does not vary with x and the surface runoff streamlines are parallel.

V.2 is recognized to compute sediment load g (mass/width·time) at any position x along a uniform slope as well as sediment load at the end of the overland flow path. If m does not vary with position, the detachment equation is:

$$D = (m+1)k_c x^m \qquad [V.4]$$

Equation V.4 is equation 2.10 with terms except x and m combined in k_c. **Thus, equation 2.10 is based on the assumption that m does not vary with x**. Consequently, the rill to interrill erosion ratio term in equation 2.13 does not contain a distance (x or λ) term. Equation V.4 does not correctly compute detachment if m is varied by segment. If that computation is attempted, sediment load values at the end of the overland flow path for a uniform overland flow path become a function of how many segments and their lengths that are used to divide the overland flow path even if conditions do not vary between segments. **Therefore, if the slope length exponent m is to vary with position x, a new detachment equation must be derived to replace equation 2.10**.[44]

The slope length exponent m was observed to vary from about 0 to 1 for measured ersion data (McCool et al., 1989). Other than m increasing with slope steepness up to five percent steepness, possible reasons for m varying did not seem to be understood when the USLE was developed (Wischmeier and Smith, 1975; Foster and Meyer, 1975).

As early as the mid 1940's, detachment on overland flow areas was recognized to be caused by raindrop impact and surface runoff (Ellison, 1947). Detachment by flow varied much more along the overland flow path than detachment by raindrop impact. These terms are written as (Meyer and Wischmeier, 1969; Foster and Meyer, 1975):

$$D = D_r + D_i \qquad [V.5]$$

where: D_r = rill erosion (mass/area·time), D_i = interrill erosion (mass/area·time), and D = the total of rill and interrill erosion (mass/area·time) at the location x. Interrill erosion is assumed not to vary along a uniform overland flow path, while rill erosion is assumed to vary with (Foster and Meyer, 1975):

$$D_r = k_r x \qquad [V.6]$$

where: k_r = a product of terms that do not vary with x. The combined equation for rill-interrill erosion is therefore:

---

[44] RUSLE2 did not have the slope length exponent m as a function of x to avoid extrapolation too far beyond the experimental data. Only two sets of plots used to derive RUSLE2 had overland flow path lengths greater than 150 ft. Not having the slope length exponent vary with position x significantly increases RUSLE2's robustness, which is important for an erosion control planning tool.

$$D = k_r x + D_i \quad [V.7]$$

Equation V.4 was chosen as the basic RUSLE2 detachment equation because a wide array of empirically derived and **accepted** factor values are available for that form (see **Section 1**). Equation V.7 was used to extrapolate equation V.4 to conditions beyond that represented in the USLE plot data.

The RUSLE2 approach was to start with equation V.4 and mold it to equation V.7 as much as possible. However, the difference in equation form between equations V.4 and V.7 causes conflict within RUSLE2. Rules were established to deal with those conflicts (see **Section 2.3.8.3**).

The m value for equation V.7 increases from 0 at x = 0 to 1 as either x or k_r becomes large or D_i becomes small (McCool et al., 1989). Mathematical analysis of equation V.7 shows that the slope length exponent m varies from 0 to 1 and is a function of the rill to interrill erosion ratio as (Foster and Meyer, 1975):

$$m = \beta/(\beta + 1) \quad [V.8]$$

where: β = the ratio of rill sediment load to interrill erosion sediment load, which is equation 2.12. The equation for β from equation V.7 is:

$$\beta = \frac{(k_r x / 2)}{D_i} \quad [V.9]$$

which is equation 2.13 with an x term in the numerator.

Equation V.9 can be simplified to:

$$\beta = \rho x \quad [V.10]$$

where: $\rho = k_r/2D_i$. Substitution of equation V.10 into equation V.8 gives:

$$m = \rho x/(\rho x + 1) \quad [V.11]$$

Substitution of equation V.11 into equation V.2 gives:

$$g = k_c x^{[\rho x/(\rho x+1)]+1} \quad [V.12]$$

The equation form for sediment load when the slope length exponent m varies with position x differs significantly from equation V.2, which is the RUSLE2 form. An equation for D can be derived by differentiating equation V.12 with respect to x. The resulting equation is much more complicated than equation V.4 used in RUSLE2. However, equation V.12 can be solved numerically to determine values for average detachment for a segment to route sediment downslope as described in **Section 2.3**. However, equation V.12 was not used in RUSLE2 because of concerns about its robustness.

Equation V.12 is based on the assumption that equation V.6 describes rill erosion. Equation V.6 could be written as:

$$D_r = k_r q \qquad [V.13]$$

where: q = discharge rate (volume/width·time), q = σx where σ = excess rainfall rate (length/time) that is assumed to be constant along the overland flow path, and k_r = a collection of terms that do not vary with x.

A case can be made for two other rill erosion equation forms. One form is (Meyer et al., 1975):

$$D_r = k_r (q - q_c) \qquad if\,(q \le q_c) D_r = 0 \qquad [V.14]$$

where: q_c = the discharge rate where runoff shear stress applied to soil exceeds the soil's critical shear stress and rill erosion begins and k_r = the collection of terms that do no vary with x.

A case can also be made for (Foster and Meyer, 1975):

$$D_r = D_{rc}(1 - g / T_c) \qquad [V.15]$$

where: D_{rc} = detachment capacity (mass/area·time) computed with equation V.6 or V.14 and T_c = runoff's sediment transport capacity (mass/width·time). Transport capacity is computed with:

$$T_c = a_T q \qquad [V.16]$$

where: the term a_T is the product of terms that do not vary with position x. Equation V.15 reduces rill erosion as transport capacity becomes filled with sediment on long overland flow paths or where sediment production rate by rill or interrill erosion is very high.

As Figure V.1 shows, the ax^m form (equation 2.10) fits well the equation form D_i+k_rx except for short overland flow paths. This deficiency is corrected as described in Section 5.7. However, neither of these two equation forms fits V.14 or V.15, an equation form that involves a critical shear stress term for estimating rill erosion.

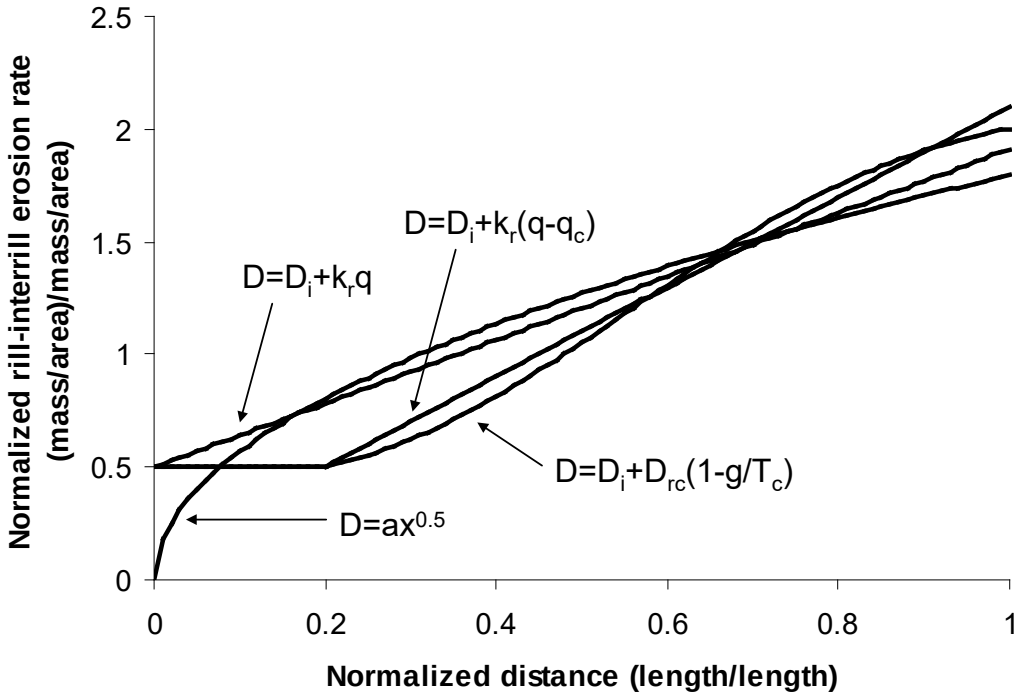

Figure V.1. Variation of detachment along an overland flow path for various rill erosion equation forms.

These advanced rill erosion equation forms greatly complicate RUSLE2 mathematics and further reduce RUSLE2's robustness of. A questionable gain in accuracy while losing robustness is not a wise choice for RUSLE2 as an erosion control planning tool. Choices were made in RUSLE2 that favor robustness for erosion control planning. RUSLE2 may not be as accurate as it could be but it is less likely to give poor results because of uncertainties when extrapolated.

5.Appendix 1.2. Implications for use of RUSLE2 in GIS models

A sediment transport capacity equation should be included with RUSLE2 detachment equations when RUSLE2 is used in a GIS model that computes that computes the spatial variability in erosion and deposition over the landscape. Equation 2.10 is used to compute sediment production (detachment) and equation 2.17 and other equations are used to compute deposition. A sediment transport capacity is required to compute deposition, and a deposition equation like equation 2.16 should be used also. The RUSLE2 sediment production equation (i.e., equation 2.10) does not and can not be used to compute deposition that occurs on the toe of many natural hillslopes.

Also, the RUSLE2 detachment equation 2.10 should be modified to compute how erosion varies with either converging or diverging surface runoff. Applying equation 2.10

without varying the slope length exponent m can result in significant error, even when the overland flow path length is varied in proportion to upslope drainage area.

5.Appendix 1.2.1. Computing detachment and sediment transport capacity

RUSLE2 computes sediment transport capacity per unit width as a function of discharge rate per unit width. An equivalent overland flow path length can be used to represent a converging or diverging landscape to compute discharge rate per unit width and sediment transport capacity per unit width. However, RUSLE2 does not compute the proper sediment production (detachment) values because equation 2.10 does not contain a runoff term. The equivalent overland flow path length that works for computing sediment transport capacity is not the equivalent length required to compute detachment. Furthermore, even though the overland flow path length is adjusted, the slope length exponent m also should be varied with position along the overland flow path to properly represent convergence/divergence in computing detachment with equation 2.10.

5.Appendix 1.2.2. Equations for RUSLE2 in a GIS model

A simple erosion model can be used to evaluate the behavior of RUSLE2 equations in a GIS model. The watershed for a single rill on a hillslope where the streamlines are parallel is a rectangle of width W and length λ. The watershed for a single rill on a converging surface is pie (wedge) shaped. The width at the upper end is 2W and 0 at the lower end. Figure V.2 shows a plot of computed erosion along the overland flow path where streamlines are parallel and where streamlines converge. Erosion was computed with the equation form D_i+k_rq using discharge rate computed by multiplying the excess rainfall rate by the upslope area divided by the watershed width at x. This equation form is assumed to give the desired values, and thus the other equation forms are compared against this one.

The x in the ax^m equation form in Figure V.2 is proportional to upslope drainage area. As Figure V.2 shows, the ax^m approximation does well where streamlines are parallel except for short overland flow paths. In contrast, the ax^m approximation does not work well where the streamlines converge.

When discharge is assumed to be a broad sheet flow across the individual rill watersheds, discharge rate rapidly increases and approach infinity as x approaches λ, the overland flow path length. A corresponding increase in rill erosion is computed. An infinite discharge rate per unit width at $x = \lambda$ computes an infinite rill erosion rate. Such high erosion rates near the end of converging surfaces are not observed in the field. Consequently, the broad sheet flow assumption should not be used without carefully constructed limits on converging surfaces. This problem does not exist on diverging surfaces.

A better approach than assuming broad sheet flow across the entire rill watershed is to assume that surface runoff is concentrated in defined rills. The overland flow path ends where the interrill path length becomes zero, which is where the rill edges meet. Discharge rate (volume; not volume per unit width) does not go to infinity, which means that rill erosion rate does not go to infinity (Toy and Foster, 2000).

The other equation form evaluated in Figure V.2 is equation V.12 where the slope length exponent varies with distance along the overland flow path. This equation was solved numerically to compute detachment along the overland flow path. In these computations, the slope length exponent m was varied with discharge rate rather actual distance to reflect the increase in rill erosion as the surface runoff converges. This approach, while improved, is less than satisfactory.

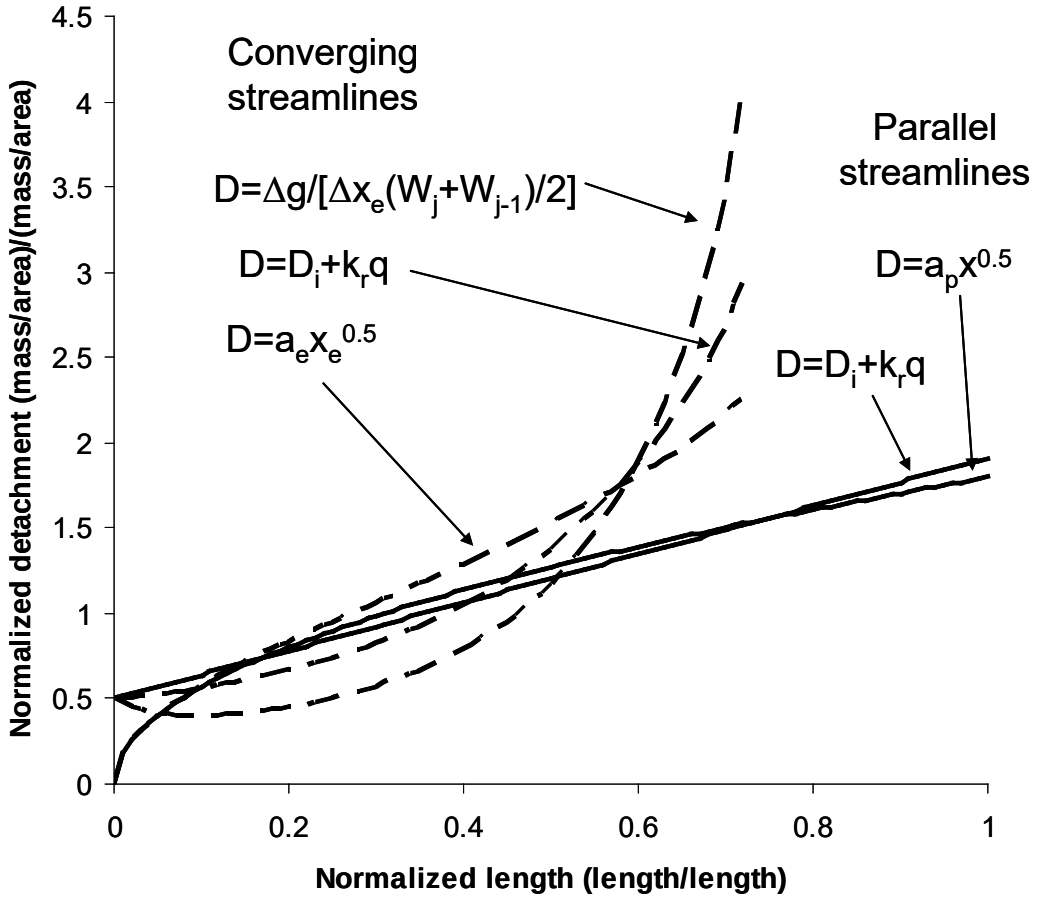

Figure V.2. Erosion along the overland flow paths for parallel and for a converging streamlines.

None of the approximations compare well to the preferred erosion equation that has separate terms for rill and interrill erosion. The best approach in applying RUSLE2 in a GIS model is to devolve the equation 2.10 into separate terms for rill and interrill erosion. Discharge rate can be computed and used directly in both the detachment and sediment transport equations without having to make the overland flow path length proportional to

upslope drainage area. This approach would significantly simplify RUSLE2 and would remove the inconsistencies between equation forms.

6. COVER-MANAGEMENT

Equation 2.10 includes the term c used to compute the main effect of cover-management on detachment. The c factor is the product of subfactors as:[45]

$$c = c_c g_c s_r r_h s_b s_c s_m \quad [6.1]$$

where: c = daily cover-management factor, c_c = daily canopy subfactor, g_c = daily ground (surface) cover subfactor, daily s_r =soil surface roughness subfactor, r_h = daily ridge height subfactor, s_b = daily soil biomass subfactor, s_c = daily soil consolidation subfactor, and s_m = daily antecedent soil moisture subfactor used when RUSLE2 is applied in Req zones (see RUSLE2 User's Reference Guide). A daily cover-management c factor value is computed using daily values for each of the subfactors in equation 6.1.[46]

6.1. Canopy subfactor

Canopy is live and dead vegetative cover above the soil surface that intercepts raindrops but does not contact the surface runoff. The portion of the above ground plant biomass touching the soil surface is treated as live ground cover. The canopy subfactor equation is (Wischmeier, 1975; Yoder et al. 1997):

$$c_c = 1 - f_{ec} \exp(-0.1 h_f) \quad [6.2]$$

where: f_{ec} = daily effective canopy cover (fraction) and h_f = daily effective fall height (ft). Equation 6.2 is based on how canopy cover affects the impact energy of waterdrops falling from canopy that has intercepted rainfall. The impact energy of a waterdrop striking the soil surface is:

$$e_d = m_d V^2 / 2 \quad [6.3]$$

where: e_d = impact energy of the waterdrop, m_d = waterdrop mass, and V_d = the waterdrop impact velocity.

Canopy cover affects waterdrop impact energy in several ways. Canopy cover increases the size of waterdrops falling from the canopy. Waterdrops falling from canopy have

---

[45] The RUSLE2 subfactor procedure is an extension of the RUSLE1 procedure [AH703 (Renard et al., 1997)]. The RUSLE2 procedure has several scientific improvements and added capability, and it uses of a daily time step rather than the RUSLE1 half-month time step. The RUSLE1 and RUSLE2 subfactor procedures are patterned after ones developed and used by Wischmeier (1975); (Wischmeier, 1978); Dissmeyer and Foster (1981); Mutchler et al. (1982); and Laflen et al. (1985).

[46] This section describes the subfactor relationships. Other sections describe how RUSLE2 computes values for variables used by the subfactor equations.

about a 3 mm drop diameter compared to 1.5 mm for median drop diameter of raindrops (Wischmeier, 1975). Therefore, canopy must be sufficiently close to the ground surface for waterdrops falling from canopy to have reduced impact velocity to offset the increased mass of waterdrops falling from canopy in comparison to raindrops. Because of the increased drop size, the impact energy of water drops falling from tall canopies, (e.g., 30 ft high) exceeds the impact energy of raindrops (Chapman, 1948). Equation 6.2 is based on an assumed 3 mm diameter for waterdrops falling from canopy and empirical fall velocities of waterdrops based on effective fall height h_f (Gunn and Kinzer. 1949).

Equation 6.2 should be interpreted as empirically representing the main effects of canopy cover on detachment with a particular equation form rather than describing how a physical variable, impact energy, affects detachment. Equation 6.2 does not directly represent all of the ways that canopy affects detachment. For example, some of the intercepted rainfall becomes stem flow and reaches the soil surface without falling from the canopy. Also, some of the intercepted rainfall evaporates from the vegetation, never to reach the soil surface by drop impact or stemflow. Also, RUSLE2 does not consider how wind driven rainfall in conjunction with vegetation affects erosion.[47]

Input effective fall height values are chosen based on judgment of how canopy of a particular plant type affects erosion (see RUSLE2 User's Reference Guide). The reference fall height, illustrated in Figure 6.1, is one third of the distance from the bottom of the canopy to the top of a canopy for a cylindrical shaped canopy where the vegetative surface area is uniformly distributed along the vertical axis of the canopy.

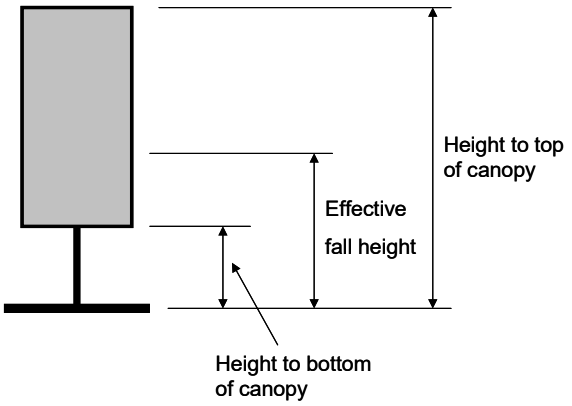

Figure 6.1. Effective fall height for a cylindrical shaped, uniform gradient canopy.

RUSLE2 also includes an equation that can be used to compute effective fall height. The equation is a function of canopy shape, vertical gradient of vegetative surface area, and heights to the bottom and top of the canopy. The effective fall height equation is:

$$h_f = h_b + a_s a_g (h_t - h_b) \qquad [6.4]$$

where: h_b = the height to the bottom of the canopy, h_t = the height to the top of the canopy, and a_s = a coefficient that is a function of canopy shape, and a_g = a coefficient

[47] An improved approach would be to divide equation 6.2 into two parts, one part related to interrill erosion and one part related to rill erosion.

Table 6.1. Values for the coefficient a_s used to estimate effective fall height as a function of canopy

Canopy shape	Value
Inverted trianagle	0.5
Rectangle	0.33
Diamond	0.29
Round	0.29
Triangle	0.25

Table 6.2. Values for coefficient a_g used to estimate fall height as a function of concentration of surface area within canopy.

Location of surface surface area concentration	Value
Top	1.33
Toward top	1.17
Uniform	1.00
Toward bottom	0.88
Bottom	0.75

related to the height within the canopy where vegetative surface area is concentrated. Values for the coefficient a_s and a_g are given in Tables 6.1 and 6.2, respectively.

Some vegetation communities involve multiple plant types that produce over and under stories. RUSLE2 uses only a single set of variables to represent the net effect of canopy on erosion. RUSLE2 does not mathematically combine sets of values for over and under stories nor does RUSLE2 separately compute how each canopy type affects erosion. RUSLE2 uses a single set of values in equation 6.2 to compute the net canopy effect for the vegetation that exists on any given day.

In addition to varying with plant community type, effective fall height varies with production (yield) level and with time as vegetation emerges, grows, matures, and experiences senescence. The RUSLE2 computes effective fall height as a function of production (yield) level and time (see **Sections 9.1** and **9.3.3.3)**.

Canopy cover directly above ground cover is assumed not to affect erosion. The equation used to compute daily effective canopy cover f_{ec} is:

$$f_{ec} = f_c(1 - f_g) \qquad [6.5]$$

where: f_c = daily canopy cover (fraction) and f_g = daily net ground cover, which takes into account the overlap of different types of ground (surface) cover (see **Section 10.2.4**). Net ground cover equals 1 – fraction of the soil surface exposed to direct waterdrop impact from either rainfall or waterdrops falling from canopy.

Furthermore, the RUSLE2 assumption is that canopy cover affects erosion the same way as does ground cover when effective fall height becomes zero. Therefore, the value for the canopy subfactor c_c can not be less than the ground cover subfactor g_c when ground cover equals the effective canopy cover value f_{ec}.

6.2. Ground cover subfactor

Ground cover is provided by material directly in contact with the soil surface. Ground cover affects both waterdrop impact, which in turn affects interrill erosion, and surface runoff, which in turn affects rill erosion. The RUSLE2 equation for the ground cover subfactor is given by (Foster and Meyer, 1975; Laflen et al., 1985; Yoder et al., 1997):

$$g_c = \exp[-bf_g(0.24/R_a)^{0.08}] \qquad [6.6]$$

where: **b** = a coefficient (percent^{-1}) that describes the relative effectiveness of the ground (surface) cover for reducing erosion, f_g = net ground cover (percent), R_a = adjusted roughness used to compute the soil surface roughness subfactor (inches) (see **Section 6.3**), and 0.24 is the assumed adjusted soil surface roughness value (inches) for unit plot conditions. Research has shown that a single variable, portion of the soil surface covered by material directly in contact with the soil surface, describes how all types of ground (surface) cover affects rill-interrill erosion. Analysis based on fundamental erosion mechanics shows that large diameter, long pieces of material, such as intact corn stalks, perpendicular to the overland flow path should affect rill-interrill erosion per unit of soil surface covered more than small diameter, flat pieces (Brenneman and Laflen, 1982). A special concern is how rock fragments on the soil surface affects rill-interrill erosion (see **Section 4.6**). However, when data from various types and rates of surface cover are combined, portion of the soil surface covered seems adequate as a single ground cover variable to use in the ground cover subfactor, equation 6.6 (Box, 1981; Dickey et al., 1983; Dickey et al., 1985; Laflen and Colvin, 1981; Meyer et al., 1972; Simanton et al., 1984; Meyer et al., 1970; Swanson et al., 1965; 1970; Mannering and Meyer, 1963; Meyer and Mannering, 1967).

Net ground cover used in equation 6.6 takes into account the overlap of ground cover materials. For example, applied materials, such as mulch and erosion control blankets, and plant residue are assumed to lie on top of rock cover entered in the RUSLE2 soil input. Live ground cover is assumed to lie on top of applied material and plant residue. Thus, net ground cover (percent) is 100 – bare ground (percent).

The soil surface roughness term in equation 6.6 computes a reduced effect of ground cover on rough soil surfaces. The RUSLE2 assumption is that ground cover in soil depressions is covered by water and deposited sediment, and therefore has no effect on erosion.

The RUSLE2 ground cover subfactor computed with equation 6.6 only partially captures the effect of ground (surface) cover material on rill-interrill erosion. A RUSLE2 ground cover subfactor value is primarily the ratio of rill-interrill erosion at a given point in time with ground (surface) cover to rill-interrill erosion from the same soil in unit plot conditions. The effect most represented by the RUSLE2 ground cover subfactor is how the physical presence of surface cover material affects the erosive forces applied to the soil by impacting raindrops and waterdrops falling from canopy and surface runoff. Other subfactors, such as soil surface roughness and soil biomass, are affected by ground (surface) cover materials (see **Sections 6.3 and 6.5**).

Many of the **b** values reported in the literature were determined by plotting erosion solely a function of ground cover. The RUSLE2 **b** values used in equation 6.6 are not the same as the literature **b** values. The RUSLE2 **b** values are smaller than the literature values because the literature **b** values include other effects not included in equation 6.6. Erosion values were computed with RUSLE1 for a range of corn yields for mulch-till and no-till cropping systems to illustrate this difference. The net **b** value for equation 6.6 without the surface roughness terms fitted to erosion values plotted as a function as cover immediately after planting was 0.058. In comparison, the **b** values used in equation 6.6

as used in RUSLE1 were 0.031 for the mulch till systems and 0.04 for the no-till systems. The conclusion of this preliminary analysis using RUSLE1, which uses a similar but simpler cover-management subfactor method, is that **b** values used in the RUSLE2 subfactor method can not be compared to widely reported literature values. Also, terms in addition to ground cover are needed in the RUSLE2 subfactor procedure to adequate how cover-management affects erosion, even for the same cover-management practice.

6.2.1. b value (ground cover effectiveness index)

6.2.1.1. Literature b values

Research shows that **b** values derived from measured erosion data range from approximately 0.025 to greater than 0.1 (Box, 1981; Colvin and Gilley. 1987; Dickey et al., 1983; Gilley et al., 1986; Laflen et al., 1980; Laflen and Colvin, 1981; Mannering and Meyer, 1963; Meyer and Mannering, 1967; Meyer et al., 1970; Meyer et al., 1972; Simanton et al., 1984). The reason for a variation in **b** is obvious in some cases. For example, Mannering and Meyer (1963) and Meyer and Mannering (1967) conducted two similar studies involving wheat straw applied to recently tilled soil. In one case, infiltration increased significantly as mulch rate increased, which in turn gave a larger **b** value than was the case where mulch rate did not affect infiltration. In some cases, large **b** values resulted when other effects of a tillage system including soil surface roughness and residue incorporation were lumped with the ground cover effect.

6.2.1.2. Rill-interrill effect on b values

Another reason for a range of **b** values is related to the erosion mechanics of rill and interrill erosion. A given amount of ground cover reduces rill erosion more than interrill erosion as illustrated in Figure 6.2 (Foster and Meyer, 1975). The term in equation 2.13 that represents the effect of ground cover on the rill to interrill erosion ratio is:

$$\frac{g_{cr}}{g_{ci}} = \left[\frac{\exp(-b_r f_g)}{\exp(-0.025 f_g)} \right] \qquad [6.7]$$

where: g_{cr} = the surface cover subfactor for rill erosion, g_{ci} = the surface cover subfactor for interrill erosion, b_r = the coefficient for how ground cover affects rill erosion and 0.025 = the value for the coefficient for how ground cover affects interrill erosion.[48] Consequently, RUSLE2 **b** values range between the **b** value (0.025) for interrill erosion and the **b** value (b_r) for rill erosion. The **b** value of 0.025 used in RUSLE2 for interrill

[48] Although not used in RUSLE2 an improved approach would be to assume that the **exp** expression for ground cover effect on interrill erosion should end where it becomes tangent to the linear line in Figure 6.2, where values follow the linear line to zero for a completely covered surface.

erosion was derived from the Lattanzi et al. (1974) and McGregor et al. (1988) data (Foster, 1982).

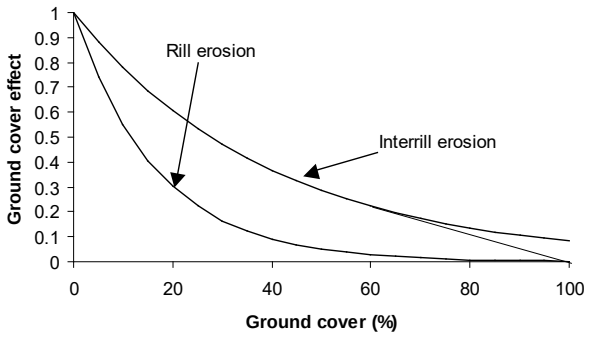

Figure 6.2. Effect of ground cover on rill and interrill erosion

The **b** value for rill erosion is the upper limit for the range of **b** values computed by RUSLE2. A 0.05 b_r value was chosen for soil conditions where ground (surface) cover does not affect infiltration, and the largest values used for b_r by RUSLE2 is 0.06 for situations where increased ground (surface) has a major effect on infiltration. RUSLE2's upper limit on **b** values is less than values reported in the literature, partly because RUSLE2 accounts for other subfactor effects that researchers included in a ground-cover type effect. Also, the reduced upper limit for **b** values was chosen so that RUSLE2 would be conservative in its computations of how much mulch, crop residue, and other ground cover materials reduce erosion for conservation planning purposes.

The coefficient b_r is assumed to increase in RUSLE2 from 0.05 to a maximum of 0.06 as ground cover increases, buried residue in the soil accounting depth increases, and the soil consolidation subfactor decreases. Mechanical soil disturbance is assumed to disrupt macro-pores and large aggregates, which increases runoff and increases erosion for a given ground cover. Conversely, biomass accumulates in a shallow, undisturbed soil surface layer with time after a mechanical soil disturbance increases infiltration, which in turn reduces runoff and rill erosion. The equation for the rill erosion ground cover effectiveness coefficient is given by:

$$b_r = 0.05 + 0.01 c_a \qquad [6.8]$$

where: c_a = coefficient for the combined effect of buried residue and soil consolidation on ground (surface) cover effectiveness in relation to rill erosion. The equation for c_a is:

$$c_a = 3.52 \times 10^{-6} B_{rs}^2 (1 - s_c) \text{ if } c_a > 1 : c_a = 1 \qquad [6.9]$$

where: B_{rs} = buried residue mass (dry basis) density [$lbs_m/(ac \cdot in)$] in the accounting soil depth d_{rs}. The value for the coefficient c_a varies between 0 and 1. A value of zero is computed when the soil has been recently mechanically disturbed, which sets b_r to a value of 0.05 and a value of 1 for the combination of high buried residue and low soil consolidation subfactor. If a value greater than 1 is computed for c_a, the value is set to 1.

The equation for the soil accounting depth for the effect of buried residue on erosion is given by:

$$d_{rs} = 1 + 2(s_c - 0.45)/0.55 \quad [6.10]$$

where: d_{rs} = the soil depth (inches) over which the density of buried residue mass is computed, 1 = the minimum accounting depth (inches) when the soil is fully consolidated (i.e., $s_c = 0.45$), 2 = the range (inches) over which the accounting depth varies as a function of the soil consolidation subfactor s_c (see **Section 6.6**), and 0.55 = the range of the soil consolidation subfactor. The maximum accounting depth is 3 inches when the soil has just been mechanically disturbed (i.e., s_c =1).

Values computed by equation 6.10 are rounded to the nearest 1 inch. RUSLE2 divides the soil depth into 1-inch intervals and accounts for soil biomass within these 1-inch intervals. RUSLE2 does not subdivide soil depth intervals further in making its buried residue density computations.

6.2.1.3. RUSLE2 b value equations

RUSLE2 uses a series of equations to compute a **b** value for equation 6.6 based on the fundamental concept that **b** values are a function of the rill to interrill erosion ratio. The starting point for developing these equations is the simple equation that computes erosion when ground cover is present as:

$$D_c = D_b \exp(-bf_g) \quad [6.11]$$

where: D_c = rill-interrill erosion when ground (surface) cover is present and D_b = rill and interrill erosion when ground cover is not present (bare soil). Therefore, a **b** value is computed by rearranging equation 6.11:

$$b = -\ln(D_c / D_b)/ f_g \quad [6.12]$$

The equation for rill-interrill erosion D_c when ground cover is present is:

$$D_c = D_{ib}(3s^{0.8} + 0.56)\exp(-0.025 f_g) + D_{rb}(s/0.0896)\exp(-b_r f_g) \quad [6.13]$$

where: D_{rb} and D_{ib} = rill and interrill erosion, respectively, when ground cover in not present (bare soil). A value for rill erosion for bare soil is computed from:

$$D_{rb} = [\alpha/(\alpha + 1)] \quad [6.14]$$

where: the term α in equation 6.14 represents a rill to interrill erosion ratio for bare soil. Equation 6.14 is the same as β in equation 2.13 without the ground cover effect. The term $(3s^{0.8} + 0.56)$ adjusts for the effect of overland flow path steepness on interrill erosion and the term s/0.0896 adjusts for the effect of overland flow path steepness on rill

erosion.[49] Rill and interrill erosion D_{rb} and D_{ib} are normalized so that they sum to 1 for a base, reference condition. Consequently, interrill erosion D_{ib} is computed from:

$$D_{ib} = 1 - D_{rb} \quad [6.15]$$

The term D_b in equations 6.11 and 6.12 is computed as:

$$D_b = D_{ib}(3s^{0.8} + 0.56) + D_{rb}(s / 0.0896) \quad [6.16]$$

The next step is to compute a value for the rill to interrill erosion ratio for bare soil as:

$$\alpha = (K_r / K_i)a_2 a_4 \quad [6.17]$$

where: the rill to interrill soil erodibility ratio (K_r/K_i) is computed using equation 4.12 and the coefficients a_2 and a_4 describe how soil consolidation, soil biomass, and conformance of the ground cover to the soil surface affect the rill to interrill erosion ratio for the purpose of computing a **b** value.

The coefficient a_2 is given by:

$$a_2 = a_1 + a_b \text{ if } a_2 > 8 : a_2 = 8 \quad [6.18]$$

where: the coefficient a_1 is given by:

$$a_1 = 1 - \{0.9[(1 - s_c) / 0.55][1 - \exp(-0.0022 B_{rt})]\} \quad [6.19]$$

where: B_{rt} = mass (dry basis) density (lbs_m/acre·inch) of the total of the live and dead roots in the soil accounting depth (10 inches) for roots. The a_1 coefficient represents how the rill to interrill erosion ratio changes as the soil becomes consolidated and as live and dead root biomass in the soil increases. This coefficient reflects how soil consolidation and root biomass affect rill erosion differently than it does interrill erosion.

The coefficient a_b, which represents how soil consolidation and buried residue affects the rill to interrill erosion ratio, is given by:

$$a_b = 1.76x10^{-5} B_{rs}^2 (1 - s_c) \quad [6.20]$$

---

[49] No adjustment is made for overland flow path length because of mathematical limitations in devolving the USLE equation structure into rill and interrill terms while meeting the requirement that erosion computed for the entire overland flow path be independent of how many overland flow path segments are used in the computations when other conditions are uniform along the overland flow path.

The a_b coefficient computes the effect of buried residue on the b value increasing as soil consolidation increases, such as for no-till crop, pasture, range, and similar lands that are not mechanically disturbed and B_{rs} = buried residue mass density in the soil accounting depth for buried residue.

Research shows that straw mulch cover is less effective at reducing rill-interrill erosion on steep overland flow paths characteristic of construction sites where mulch is applied to a smooth cut or graded soil in comparison to mulch applied to steep cropland soils [Meyer and Ports, 1976; AH537 (Wischmeier and Smith, 1978), Meyer et al., 1970; 1971; 1972].

RUSLE2 computes this effect assuming that the lost of ground (surface) effectiveness is determined by how well the mulch material conforms to the soil surface and stays in place. The coefficient a_4 describes how conformance of ground cover to the soil surfaces affects the rill to interrill erosion ratio. Poor conformance of ground cover to the soil surface affects rill erosion more than it does interrill erosion. The equation for a_4 is:

$$a_4 = a_3 + (1 - a_3)[1 - \exp(-0.0055 B_{rt})] \quad [6.21]$$

where: the equation for a_3 is given by:

$$a_3 = \exp[-\psi(\lambda / s^{1/2})^{0.6} s] \quad [6.22]$$

where: λ = the overland flow path length and ψ = a coefficient that describes conformance of ground cover to the soil surface.

Three classes of ground (surface) cover conformance that vary with material properties are used in RUSLE2 (see RUSLE2 User's Reference Guide). The values used for the conformance coefficient ψ are 0.0 for material like gravel that very closely conforms to the soil surface, 0.15 for materials that conform to the soil surface much like typical pieces of soybean stems and wheat straw after having passed through a combine, and 0.3 for corn stalks and woody debris that do not conform well to the soil surface.

Equations 6.21 and 6.22 compute reduced effectiveness of mulch, erosion control blankets, and similar materials applied on construction sites where overland flow paths are steep and long and no roots or plant stems are present. Both live and dead roots provide plant stems that help hold ground cover in place so that runoff does not dislodge and move mulch downslope or undercut erosion control blankets (Foster et al., 1982a). The tendency for mulch failure and rill erosion under erosion control blankets increases when these materials bridge soil surface roughness elements.

6.2.2. Slope length exponent m

Equations 2.12 and 2.13 are the equations used to compute the slope length exponent **m**. Values for the prior land use residual effect term in equation 2.13 are computed with:

$$c_{pr} / c_{pi} = 0.45 + 1.55(s_c s_b)^2 \quad [6.23]$$

Equation 6.23 is based on the assumption that soil consolidation and soil biomass have a greater relative effect on rill erosion than on interrill erosion. The term for effective ground cover in equation 2.13 is computed from:

$$f_{ge} = f_g(0.4 + 0.6\delta) \quad [6.24]$$

where: the cover adjustment term δ is given by:

$$\delta = (b_r - 0.05)/0.01 \quad [6.25]$$

Equations 6.24 and 6.25 reflects how ground cover has a greater effect on rill erosion than on interrill erosion when the soil has not been mechanically disturbed recently and soil biomass is high in the soil surface layer (e.g., no-till type crop, pasture, range, and similar undisturbed lands).

6.2.3. Non-uniform ground cover

The user can divide the overland flow path into segments to partially represent spatial variability of ground cover. However, RUSLE2 assumes that ground cover is spatially uniform within a segment. When a soil disturbing operation occurs that disturbs only a portion of the soil surface, RUSLE2 computes detachment on both the undisturbed and disturbed portions, and it then determines the overall detachment based on the relative areas of the undisturbed and disturbed portions. An effective ground cover that gives the overall detachment is then back calculated using equation 6.6. The effective surface residue mass associated with that ground cover is determined (see **Section 10.2**). The ratio between this effective mass and the actual mass is maintained as surface residue is lost by decomposition.

6.2.4. b and m values for Req conditions

Most of the erosion during the winter Req period in Req areas is caused by rill erosion. Constant values of 0.50 and 0.046 are used for the slope length exponent **m** and the ground cover effectiveness index **b** for these conditions. These values are based on analysis of experimental research data (McCool et al., 2002).

6.2.5. Comments on b and m equations

The equations used to describe how ground cover affects erosion are empirically based on the RUSLE2 developers' judgment of how various factors affect the ratio of rill to interrill erosion. These empirical equations replace user inputs of selecting LS tables and **b** values [AH703 (Renard et al., 1997)] or land use classes (Toy and Foster, 2000). Although the equations were not fitted to experimental research data, the equations qualitatively represent both laboratory and field research findings.

These equations for **b** and **m** values, along with other cover-management equations, give RUSLE2 its **land use independence**. RUSLE2 uses fundamental variables common to all land uses to compute how cover-management affects rill-interrill erosion.

6.3. Soil surface roughness subfactor

6.3.1. How surface roughness created by mechanical soil disturbance affects erosion

The soil surface roughness subfactor represents how random soil surface roughness created by mechanical soil disturbance affects rill-interrill erosion. Soil surface roughness includes depressions where local deposition occurs and soil peaks of large, stable soil aggregates that are resistant to detachment depending on soil biomass content. Infiltration is increased, which reduces runoff and rill erosion. Also, soil surface roughness slows surface runoff, which reduces its erosivity.

The RUSLE2 equation for the soil surface roughness subfactor is:

$$s_r = \exp[-0.66(R_a - 0.24)] \qquad [6.26]$$

where: R_a = daily adjusted roughness value (inches) and 0.24 inches (6 mm) = the adjusted roughness value assigned to unit plot conditions. Equation 6.26 was derived from research measurements of roughness and erosion (Cogo et al., 1984).

The reference condition where the soil roughness subfactor s_r equals 1 is the unit plot condition during and after intense rainfall. The reference unit plot soil surface roughness of 0.24 (6 mm) is produced by a harrow or similar soil finishing tool after disking or similar tools used to prepare seedbeds. Most soil surface conditions are rougher than the unit plot conditions, which give s_r values less than 1. However, some soil surfaces are smoother than the unit plot. Equation 6.26 gives s_r values up to 1.17 for soil surface roughness smoother than 0.24 inches, the roughness value assumed for unit-plot conditions. Mechanical soil disturbing operation such as roto-tilling that finely pulverizes soil, cutting and filling with a blade, and rolling a finely pulverized soil surface produces a surface that is smoother than the unit plot soil surface.

6.3.2. Random roughness as affected by soil biomass

Biomass production (yield) level affects the soil surface roughness subfactor. The effect of biomass production level on the roughness subfactor, as seen in experimental soil loss ratio values [AH537 (Wischmeier and Smith, 1978)] is illustrated in Table 6.3. The roughness subfactor values in Table 6.3 were computed by dividing the soil loss ratio for the fallow crop stage period by the soil loss ratio for the seedbed period.[50] The only essential difference in soil conditions between these two short periods is soil surface roughness.

---

[50] Crop stages are periods where soil loss ratio values are considered constant in the USLE [AH537 (Wischmeier and Smith, 1978)]. The fallow period is for the time between when the soil is first tilled with a primary tillage tool such as a moldboard plow and when the soil is first tilled afterwards with a secondary tillage tool to prepare a seedbed. The seedbed period is the time between the first secondary tillage following primary tillage to when canopy cover of the planted crop reaches 10 percent.

Table 6.3. Effect of corn production level and soil biomass on soil surface roughness subfactor s_r

		Soil loss ratio		
Yield (bu/acre)	Management	Fallow	Seedbed	Roughness subfactor
112	Grain	0.31	0.55	0.56
87	Grain	0.36	0.60	0.60
67	Grain	0.43	0.64	0.67
49	Grain	0.51	0.68	0.75
112	Silage	0.66	0.74	0.89
87	Silage	0.67	0.75	0.89
67	Silage	0.68	0.76	0.89
49	Silage	0.69	0.77	0.90

Experimental roughness subfactor values increased as production (yield) level decreased as shown in Table 6.3. Similarly, experimental roughness subfactor values [AH537 (Wischmeier and Smith, 1978)], as shown in Table 6.4, were significantly reduced when a corn grain crop followed an established meadow (sod), which has a very high soil biomass. Roughness subfactor values increased as hay yield decreased and increased in the second year of corn following sod. Residual soil biomass was less in the second year after the sod than in the first year immediately after the meadow. Also, roughness subfactor values were higher when corn followed small grain than when it followed sod. The small grain provided less soil biomass than did the sod.

Table 6.4 Effect of sod on soil surface roughness subfactor s_r for moldboard plow period

Hay yield (tons/acre)	Year after sod	Roughness subfactor
4	1	0.35
2.5	1	0.38
1.5	1	0.39
4	2	0.49
2.5	2	0.50
1.5	2	0.50

Roughness subfactor values are interpreted as being a function of soil biomass level caused by different yield levels, soil biomass level determined by whether crop residue is removed such as with silage or left with grain harvest, and the difference in biomass level caused by type of preceding crop such as hay, small grain, or row crop grain. Recommendations for the USLE [AH537 (Wischmeier and Smith, 1978)] are that non-sod forming meadows such as sweet clover or lespedeza have less effect on rill-interrill erosion than does sod forming vegetation, which is explained by the difference in soil biomass production between these vegetation types.

RUSLE2 computes initial soil roughness after a mechanical soil disturbance as a function of the soil biomass in the soil disturbance depth using:

$$R_{ib} = 0.24 + (R_{it} - 0.24)\{0.8[1 - \exp(-0.0015 B_{td})] + 0.2\} \qquad [6.27]$$

where: R_{ib} = the initial roughness adjusted for the soil texture and biomass effect, R_{it} (inches) = the initial roughness after the input roughness value is adjusted for soil texture and B_{td} = the total mass (dry basis) [$lbs_m/(acre \cdot inch)$] of buried residue and live and dead roots averaged over the soil disturbance depth after the operation. The 0.24-inch value is the roughness value assumed for unit plot conditions. The 0.2 value reflects the portion of the roughness value that is not affected by soil biomass.

6.3.3. Adjusting roughness input values for soil texture

Input roughness entered in the RUSLE2 database for a soil disturbing operation is adjusted for soil texture before equation 6.27 is used to adjust for the soil biomass effect on roughness. The equation that adjusts input roughness values for soil texture is:

$$R_{it} = R_{in}[0.16(P_{sl}/100)^{0.25} + 1.47(P_{cl}/100)^{0.27}] \quad [6.28]$$

where: R_{in} = the input roughness value entered for a soil disturbing operation in the RUSLE2 database, P_{sl} = percent silt in the soil, and P_{cl} = percent clay in the soil. The roughness values R_{it} adjusted for soil texture are the same as roughness input R_{in} values for the reference silt loam soil texture. Roughness values computed by equation 6.28 are greater than the roughness input values for soils high in clay and less than roughness input values for soils high in sand. Equation 6.28 was developed based on judgment and field observations of how soil surface roughness varies with soil texture when mechanically disturbed.

6.3.4. Assigning input roughness values for operations

Input values entered in the RUSLE2 database for soil surface roughness created by a mechanical soil disturbing operation are assigned according to the soil surface roughness that the operation creates for a base, reference condition. This condition is a smooth, silt loam soil (clay = 15%, silt = 65%) having a very high soil biomass (dry basis) density of greater than 1000 $lbs_m/(acre \cdot inch)$ in the soil disturbance depth, which includes both buried residue and dead roots. These soil biomass levels occur where crop yield exceeds 200 bu/acre corn, 70 bu/acre wheat, and 4 tons/acre hay or pasture land (see RUSLE2 User's Reference Guide).

The roughness index used in RUSLE2 for input values assigned to soil disturbing operations in the RUSLE2 database is the standard deviation soil surface elevations measured on a 1-inch grid. The elevations are relative to a plane that removes elevation differences caused by land steepness and ridges.

6.3.5. Effect of existing roughness at time of soil disturbance (tillage intensity effect)

Roughness left by a soil disturbing operation is a function of the operation itself and existing roughness at the time of the operation. The RUSLE2 assumption is that existing roughness has no effect if the roughness, adjusted for soil texture and biomass, left by a soil disturbing operation is greater than the existing soil roughness at the time of the operation. However, the RUSLE2 assumption is that the roughness left by a soil disturbing operation is a function of existing roughness if the adjusted roughness created by an operation is less than existing roughness. In this case, the resulting roughness is a function of the initial adjusted roughness, existing roughness, and tillage intensity of the soil disturbing operation. Tillage intensity is a measure of the aggressiveness of the soil disturbing operation for obliterating existing roughness. The equation for how existing roughness and tillage intensity affect soil roughness is:

$$R_{aa} = (1 - \xi)(R_{ae} - R_{ib}) + R_{ib} \quad [6.29]$$

where: R_{aa} = the adjusted roughness immediately after a soil disturbing, ξ = tillage intensity for the operation, R_{ae} = existing adjusted roughness immediately before the operation, and R_{ib} = the input roughness for the soil disturbing operation after adjustment for soil biomass and soil texture, which is computed with equation 6.27.

A tillage intensity of 1 means that the soil disturbing operation is so aggressive that existing roughness has no effect on the roughness left by the operation. Examples of these operations include moldboard plows and roto-tillers. Conversely, a tillage intensity of 0 means roughness after the soil disturbing operation is the same as existing roughness before the operation. Harrows that have a tillage intensity of 0.4 are examples of operations where existing roughness has a significant effect on roughness left after a soil disturbing operation.

6.3.6. Roughness decay

Roughness diminishes (decays) after a mechanical soil disturbance because of soil slumping (i.e., settlement and subsidence) caused by the presence of moisture, interrill erosion wearing away roughness peaks, and local deposition in roughness depressions. The RUSLE2 equation used to represent this effect is given by [AH703 (Renard et al., 1997)]:

$$f_r = \exp[-0.07(P_d + I) - 0.006 r_d c_c g_{ci})] \quad [6.30]$$

where: f_r = the fraction of the current roughness greater than 0.24 inch that remains, P_d = the daily precipitation amount (inches), I = daily amount (inches) of water added by irrigation, r_d = the daily erosivity (US customary units), and g_{ci} = the interrill ground cover factor. The term in equation 6.30 associated with precipitation amount represents roughness loss by settlement and subsidence and the term associated with erosivity represents roughness loss by interrill erosion. The RUSLE2 assumption is that half of the roughness loss is by settlement and the other half is by interrill erosion. Roughness loss by local deposition is not explicitly represented. Roughness decay is not computed as a function of soil properties including texture and soil biomass. The adjustment made to initial roughness by equations 6.27 and 6.28 is assumed to adequately represent the effect of soil texture and soil biomass on roughness at any time.

The interrill ground cover factor is given by:

$$g_{ci} = \exp(-0.025 f_g) \quad [6.31]$$

where: f_g = the net ground cover (percent). Daily adjusted roughness used in equation 6.26 is computed as:

$$R_a = 0.24 + f_r (R_{ap} - 0.24) \quad [6.32]$$

where: R_{ap} = adjusted roughness on the previous day. The RUSLE2 assumption is that roughness is not decayed when the input initial roughness in the RUSLE2 database for a soil disturbing operation is less than the unit plot roughness of 0.24 inch.

6.3.7. Base roughness value

The 0.24-inch value in equations 6.27 and 6.32 represents a base roughness value for unit plot conditions. The assumption is that soil clods persist so that the unit-plot surface never becomes perfectly smooth. The unit plot final roughness value is not varied as a function of soil texture because that effect is empirically accounted for in the RUSLE2 soil erodibility factor. However, RUSLE2 allows the user to enter a "final" roughness value for an operation that is greater than 0.24 inch to represent conditions where roughness decays to a final value greater than 0.24 inch. If an input final roughness value greater than 0.24 inch is entered in the RUSLE2 database for a soil disturbing operation, RUSLE2 uses that value instead of the 0.24 value in equations 6.27 and 6.32. RUSLE2 does not allow roughness to decay to a value less than 0.24 inch, even if the input final roughness is less than 0.24 inches. The input initial and final roughness values can be used force RUSLE2 to use a particular roughness in its computations (see RUSLE2 User's Reference Guide).

6.3.8. Long term roughness development

A natural soil roughness develops over time after the last mechanical soil disturbance. The final natural roughness is a function of soil properties, vegetation characteristics, and local erosion and deposition. RUSLE2 assumes that the time required for this long-term roughness to develop equals the time to soil consolidation (see **Section 4.8**). The RUSLE2 equation used to compute long term roughness is given by:

$$R_l = 0.24 + (R_{alf} - 0.24) / \{1 + \exp[(0.5 - t_d / t_c) / 0.1]\} \qquad [6.33]$$

where: R_l = daily long term roughness, R_{alf} = the adjusted final long term roughness value, t_d = number of days since the last mechanical soil disturbance, and t_c = the time to soil consolidation (days). A value for R_{alf} is computed using equations 6.27and 6.28 using the input long-term natural roughness values entered in the RUSLE2 database. The biomass value used in equation 6.27 is based on total soil biomass including buried residue and dead and live roots in the upper 4 inches of the soil. The value input for final long-term roughness for a given cover-management description is relative to the reference condition for short term roughness associated with mechanical soil disturbance (see **Section 6.3.4** and RUSLE2 User's Reference Guide). RUSLE2 adjusts this input value for soil texture and soil biomass just as it does roughness created by mechanical disturbance. The assumption is that vegetation must be present for long term surface roughness to develop and be effective. Equation 6.33 is illustrated in Figure 6.3 where the time to soil consolidation is 7 years.

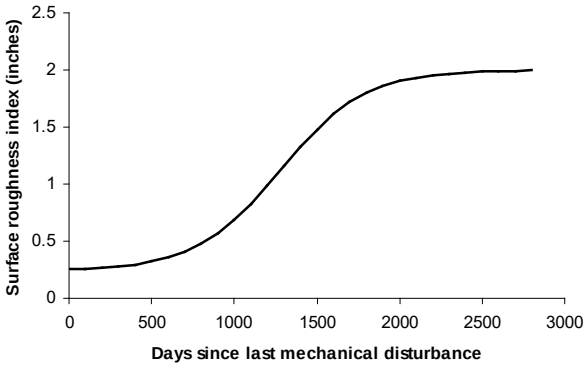

Figure 6.3. Development of long term roughness as a function of time since last mechanical soil disturbance.

RUSLE2 tracks both short term roughness resulting from mechanical soil disturbance and long term roughness development. RUSLE2 uses the maximum of the two roughness values in equation 6.26 to compute a soil surface roughness subfactor value.

6.3.9. Accounting for spatial variability in roughness

RUSLE2 can take soil surface roughness spatial variability partially into account by dividing the overland flow path into segments. However, roughness is assumed to be uniform within a segment. Some mechanical soil disturbing operations disturb the soil in strips. For these operations, RUSLE2 computes soil surface roughness subfactor values for both the undisturbed and disturbed areas and the overall soil surface roughness subfactor value based on the portion of the soil surface that the operation disturbs. RUSLE2 then back-calculates an effective roughness using equation 6.26 that gives the effective roughness subfactor value. This single effective roughness value is assigned to the segment and decayed over time using equation 6.30.

6.3.10. Comments on roughness subfactor

RUSLE2 captures the main effects of roughness on rill-interrill erosion. The intent is not to explicitly model soil roughness to produce roughness values comparable to field measured values except for input values determine from the reference condition (see **Section 6.3.4**). For example, internal RUSLE2 computed roughness values are less than those measured in the field on construction sites where soil clay content is high. The roughness effect on erosion is more than the geometric effect of soil surface roughness slowing runoff, ponding water, and depositing sediment. It also includes an infiltration effect that is less related to soil surface roughness than are the other erosion processes. The adequacy of the soil roughness relationships in RUSLE2 should be judged on the basis of how well RUSLE2 computes rill-interrill erosion as affected by soil disturbing operations that create soil surface roughness.

6.4. Ridge height subfactor

6.4.1. Effect of ridges on rill-interrill erosion

Ridges affect erosion primarily in two ways. When the ridges are oriented parallel to the overland flow path, ridges increase rill-interrill erosion because of increased interrill erosion on the ridge sideslopes. This effect is represented by the ridge height subfactor. When ridges are nearly perpendicular to the overland flow path, ridges alter the runoff

flow path by partially redirecting runoff around the hillslope or by ponding runoff behind the ridges if the ridges are perfectly on the contour. This effect of ridges is considered in the contouring subfactor (see **Section 7.1**).

Increased ridge height increases ridge sideslope (interrill) steepness, which in turn increases interrill erosion steepness (Lattanzi et al., 1974). RUSLE2 uses only ridge height to compute ridge height subfactor values although both ridge height and spacing determine interrill steepness. Accurately identifying ridge spacing or number of ridges per unit overland flow path width is difficult whereas ridge height can be easily visualized and measured.

6.4.2. Reference condition for ridge height subfactor

The reference condition for the ridge height subfactor, as with all cover-management subfactors, is the unit plot condition. Unit plots are prepared to a seedbed condition (see **Section 2.1** and **Footnote 3**) using tools like spike tooth harrow that leave small ridges up and down slope. The RUSLE2 ridge subfactor must be 1 for the unit plot condition. Unit plot conditions are not static because the unit plots are periodically tilled to break soil crusts and to control weeds. A ridge subfactor value of 1 for unit plot conditions represents an average over time because of periodic ridge formation and decay.

The ridge subfactor equations are also derived for the reference condition of the ridges being parallel to the overland flow path (i.e., up and down slope).

6.4.3. Ridge height subfactor for low steepness

The RUSLE2 ridge height subfactor is constant for overland flow path steepness less than six percent as determined from experimental data and the judgment of scientists who experimentally measured the effect of ridges on rill-interrill erosion from almost flat slopes (<1%) to land steepness as great as 5 percent (Young and Mutchler, 1969; Mutchler and Murphree, 1985; McGregor et al., 1999).[51] The RUSLE2 ridge height subfactor equations derived from experimental data are:

$$r_{h6} = 0.9(1 + 0.0582H^{1.84}) \quad H \le 3 \text{ inches} \qquad [6.34]$$

$$r_{h6} = 2.136[1 - \exp(-0.484H)] - 0.336 \quad H > 3 \text{ inches} \qquad [6.35]$$

where: r_{h6} = daily ridge height subfactor when the overland flow path steepness is less than or equal to 6 percent and H = daily ridge height (inches). The significance of the 0.9 in equation 6.34 is that the minimum ridge height subfactor is 0.9 for a flat soil surface and the maximum ridge height subfactor from equation 6.35 is 1.8, which is consistent

[51] C.K. Mutchler and K.C. MCGregor. 1999. Effect of ridge height on erosion on low slopes. Personal communication. Scientists (retired) at the USDA-National Sedimentation Laboratory, Oxford, Mississippi.

with the values given in AH537 (Wischmeier and Smith, 1978) for applying the USLE to cotton production on high ridges [Mutchler et al., 1982; Mutchler and Murphree, 1985, AH537 (Wischmeier and Smith, 1978)]. Also, equation 6.34 gives a subfactor value of 1 for a ridge height of 1.42 inch, which represents unit plot conditions except for the difference between six percent steepness and the unit plot nine percent steepness.

6.4.4. Adjustment for effect of overland flow path steepness

Interrill steepness is affected by land steepness. Interrill steepness is much greater than land steepness on flat slopes than on steep slopes. For example, local interrill steepness with high ridges (about 8 inches high when formed) like those used in cotton production in the Mississippi Delta is about 20 percent (Meyer and Harmon, 1985; Mutchler and Murphree, 1985), which is the interrill steepness when the land is flat (about 0.5%). As land steepness increases, local interrill steepness increases but much more slowly than does land steepness. Local interrill steepness of the ridge sideslope almost equals land steepness on steep slopes. For example, the same ridges that give a 20 percent steep ridge sideslope on a 6 percent land steepness give a 54 percent interrill steepness on a land steepness of 50 percent. The ridge height subfactor, therefore, approaches 1 for steep overland flow paths.

A simple rill-interrill erosion model was used to develop equations for the ridge height subfactor for overland flow path steepness greater than six percent. That simple equation is:

$$D_t = 0.5[(s/0.0896) + (3s_i^{0.8} + 0.56)] \qquad [6.36]$$

where: the 0.5 represents the assumption that rill and interrill erosion are equal for unit plot conditions (Foster and Meyer, 1975; Foster et al., 1977a, 1977b; Foster, 1982), the term s/0.0896 represents the effect of steepness on rill erosion, and the term $(3s_i^{0.8} + 0.56)$ represents the effect of steepness on interrill erosion. Steepness s_i of the interrill area is greater than the steepness s of the rill area because ridge height increases interrill steepness (i.e., the ridge sideslope steepness).

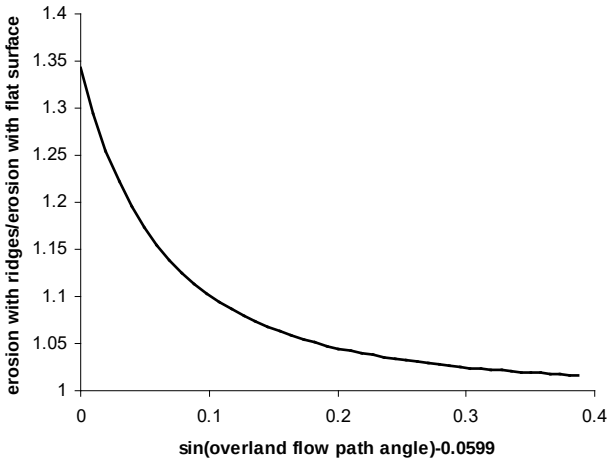

Figure 6.4. Effect of overland flow path steepness on the ratio of erosion with a 20% ridge sideslope to erosion from a flat surface.

Equation 6.36 was solved for overland flow path steepness between and 6 and 50 percent for a range of ridge side slope steepness and for a flat (i.e., non-ridged soil surface). Erosion computed for a given ridge sideslope steepness for a

particular flow path steepness was divided by erosion for a flat soil surface at that same overland flow path steepness. An example of those values is shown in Figure 6.4 for a ridge sideslope of 20 percent. The RUSLE2 equations used to represent this effect are:

$$r_h = r_{h6} \quad s_p < 6\% \qquad [6.37]$$

$$r_h = 1 + (r_{h6} - 1)\exp[-a_h(s - 0.05989)] \quad s_p \geq 6\% \qquad [6.38]$$

where: s_p = overland flow path steepness (100 times tangent of slope angle) and a_h is computed from:

$$a_h = 16.02 - 0.927H \quad H \leq 10 \text{ inches} \qquad [6.39]$$

$$a_h = 6.75 \quad H > 10 \text{ inches} \qquad [6.40]$$

where: ridge height H has units of inches.

6.4.5. Effect of row grade on ridge height subfactor

The ridge height subfactor equations given above apply to the reference condition of the ridges being parallel to the overland flow path (i.e., up and down slope). As relative row grade (i.e., ratio of grade along the ridges to overland flow path steepness) decreases from 1 (up and down slope) to 0 (on contour), the ridge subfactor value should become 1. The effect of ridge height on rill-interrill erosion is represented in the contouring subfactor when the ridges are on the contour (see **Section 7.1**). However, this requirement can not be met because of RUSLE2's mathematical structure. Instead, the ridge subfactor value is 0.9 when ridges are perfectly on the contour, which is the ridge height subfactor value for a flat soil surface.

The equations that compute ridge height subfactor values as a function of ridge orientation (i.e., relative row grade) are:

$$r_h = 0.9 - (0.9 - r_{h,u\&d})g_r^2 \quad r_{h,u\&d} \leq 1 \qquad [6.41]$$

$$r_h = 0.9 + (r_{h,u\&d} - 0.9)g_r^2 \quad r_{h,u\&d} > 1 \qquad [6.42]$$

where: $r_{h,u\&d}$ = the ridge height subfactor value when ridge orientation is parallel to the overland flow path, which are computed equations 6.37 and 6.38 and g_r = relative row grade (grade along the ridges/overland flow path steepness).

6.4.6. Ridge height decay

Ridge height decays because of settlement and interrill erosion. Settlement occurs quickly after the ridges are formed when water is presence. The RUSLE2 assumption is that forty percent of the initial ridge height is lost by settlement while the remaining sixty percent is lost by interrill erosion based on analysis of experimental data (Lyles and.

Tatarko. 1987).[52] Thus, the initial ridge height left by a soil disturbing operation is divided into two parts as:

$$H = H_s + H_e \quad [6.43]$$

where: H_s = daily ridge height component associated with settlement and H_e = daily ridge height component associated with interrill erosion. The initial value for H_s is 0.4 times the ridge height left by the soil disturbing operation, while the initial value for H_e is 0.6 times the ridge height left by the soil disturbing operation. The daily settlement component ridge height is computed as:

$$H_s = H_{sp} \exp = [-0.2343(P_d + I)] \quad [6.44]$$

where: H_{sp} = the daily ridge height associated with settlement from the previous day. The daily interrill erosion ridge height is computed as:

$$H_e = H_{ep} - a_e r_d c_c g_{ci} \quad [6.45]$$

where: H_{ep} = ridge height associated with interrill erosion for the previous day and the coefficient a_e is computed as:

$$a_e = 0.033 - 0.002 H_i \quad H_i \leq 10 \text{ inches} \quad [6.46]$$

$$a_e = 0.013 \quad H_i > 10 \text{ inches} \quad [6.47]$$

where: the units for a_e are inches/(US customary EI unit) and H_i = initial ridge height left by the soil disturbing operation (inches). The reason for the coefficient a_e is a function of ridge height is the RUSLE2 assumption that high ridges have a wide base so that the overall loss of ridges having a wide base occurs more slowly than does the loss of ridges with a narrow base. The minimum allowable ridge height is zero. These equations and their coefficients were derived from research data (Lyles and Tatarko, 1987) and from field observations in cotton fields in the Mississippi Delta.[53]

6.4.7. Effect of existing ridge height, soil, and cover-management on ridge height when new ridges are formed

The RUSLE2 assumption is that existing ridges have no effect on the ridges created by a soil disturbing operation. Also, the RUSLE2 assumption is that initial ridge height.

---

[52] K.C. McGregor. 1999. Field observations of ridge height decay in the Mississippi Delta. Personal communtation. Scientist (retired), USDA-National Sedimentation Laboratory, Oxford, Mississippi.

[53] McGregor, K.C. 1999. Loss of ridge heights in the spring in the Mississippi Delta. Personal communication. Scientist (retired), USDA-National Sedimentation Laboratory, Oxford, Mississippi.

Ridge height at formation is determined entirely by the soil disturbing operation. The effect of existing ridges and soil and cover-management conditions on ridge height can be taken into account in RUSLE2 by creating multiple soil disturbing operation decriptions having a range of ridge height values. The user then selects a particular operation description for RUSLE2 input that gives the desired ridge height for the given situation.

6.4.8. Comments on ridge height subfactor

The intent in RUSLE2 is to capture the main effect of ridge height on rill-interrill erosion as ridge height interacts with land steepness and to capture the main effect of variables that cause ridge height to decay. The intent is not to explicitly model ridge height. The adequacy of the RUSLE2 ridge height subfactor equations should be judged on the basis of how well RUSLE2 computes rill-interrill erosion as a function of soil disturbing operations that create ridges.

RUSLE2 not giving 1 for the ridge subfactor when ridges are perfectly on the contour is a limitation of RUSLE2's empirical mathematical structure not being consistent with process-based equations. RUSLE2 was constructed so that these problems do not significantly affect RUSLE2's utility as a conservation and erosion control planning tool.

6.5. Soil biomass subfactor

6.5.1. Soil biomass effect

The RUSLE2 soil biomass subfactor estimates how soil biomass affects rill-interrill erosion [Mannering et al., 1968; Foster et al., 1985c; McGregor et al., 1990; Brown et al., 1989; Toy et al., 2002; Van Liew and Saxton, 1983, AH537 (Wischmeier and Smith, 1978)]. Soil biomass represented by RUSLE2 includes buried residue, live roots, and dead roots.

Live roots produce exudates that reduce soil erodibility. Also, live root biomass is a measure of plant transpiration, which reduces soil moisture that in turn increases infiltration and decreases runoff. Dead roots add organic matter to the soil that increases infiltration and decrease soil erodibility. Both live and dead roots mechanically hold the soil in place, hold soil in "clumps" when the soil is mechanically disturbed, and reduce waterdrop impact and runoff erosivity if the roots are exposed.

Buried residue is biomass that has been mechanically incorporated into the soil. RUSLE2 also "incorporates" up to 25 percent of the daily decomposition of surface residue into the soil to represent the accumulation of high organic matter at the soil surface for no-till and other conditions where little or no soil disturbance occurs (Kay and VanderBygaart, 2002; Shelton and Bradley, 1987). Incorporated biomass, such as crop residue, manure, or bio-solids in sewage waste, provides organic compounds that increase infiltration and decrease soil erodibility [Browning et al., 1948; Copley et al., 1944; Hays et al., 1949; AH537 (Wischmeier and Smith, 1978)]. Also, pieces of organic material,

such as incorporated crop residue, can be sufficiently large to mechanically reduce rill erosion (Brown et al., 1989).

6.5.2. Soil biomass subfactor equation

The equation for the RUSLE2 soil biomass subfactor is:

$$s_b = 0.951\exp(-0.0026B_{rt} - 0.0006B_{rs} / s_c^{0.5}) \quad s_b \le 0.9035 \qquad [6.48]$$

$$s_b = \exp[-1.9785(0.0026B_{rt} + 0.0006B_{rs} / s_c^{0.5})] \quad s_b > 0.9035 \qquad [6.49]$$

Equation.6.49 is used for very low soil biomass where the soil biomass subfactor s_b is greater than 0.9035. Equation 6.48 does not give the required value of 1 for unit plot conditions that has no soil biomass (i.e., B_{rt} and $B_{rs} = 0$). The common point of s_b = 0.9035 results from the product of 0.951 in equation 6.48 and 0.95, the upper value for which the exp(…) term in equation 6.48 is assumed to apply.

The coefficient values in equation 6.48 were obtained by fitting the equation to soil biomass subfactor values estimated from research-based soil loss ratio values. The values points for no-till and mulch (reduced) till were obtained from the literature.[54] The other values selected from AH537 (Wischmeier and Smith, 1978). These values are given in Table 6.5, and the fit of equation 6.48 to the observed values is shown in Figure 6.5. The data points (soil loss ratio values) shown in Table 6.5 were selected across the range of soil biomass represented by Table 5, AH537. Equation 6.48 fits the observed values well except for the 112 bu/acre corn following 1.5 tons/acre meadow.

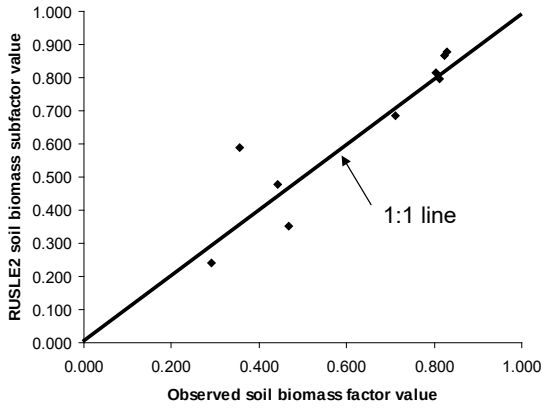

Figure 6.5. Comparison of RUSLE2 soil biomass values to observed values

Observed soil biomass subfactor values were estimated from the soil loss ratio values given in Table 6.5. Soil biomass subfactor values were computed from soil loss ratio values by rearranging equation 6.1 to solve for the soil biomass subfactor and substituting RUSLE2 estimated values for the other subfactors. Soil loss ratio values were substituted for cover-management factor c in equation 6.1.

Using soil loss ratios in Table 5, AH537 for the seedbed crop stage period for conventional, clean tillage,

[54] More than 100 articles were reviewed to evaluate the effect of no-till and mulch till cropping on rill-interrill erosion. Those articles are listed in the **Additional References Section**.

which is most like the unit plot condition, minimizes the error in estimated subfactor values used in equation 6.1 to estimate soil biomass subfactor values. The major subfactor affecting soil loss ratio values for the seedbed crop stage for conventional, clean tillage is soil biomass although some ground (surface residue) cover is present and soil surface roughness is rougher than for unit-plot conditions.

Soil loss ratio values given in Table 5, AH537 are assumed to apply to the reference silt loam soil at Columbia, Missouri. RUSLE2 was used to compute subfactor values for ground cover (surface residue) and surface roughness for all conditions listed in Table 6.5 and soil consolidation for the no-till data condition. The canopy subfactor value was 1 for all conditions and the soil consolidation subfactor was 1 except for no-till. RUSLE2 was used to compute soil biomass values using values in the RUSLE2 **core database** (see RUSLE2 User's Reference Guide).

Table 6.5. Soil biomass subfactor values used to derive RUSLE2 subfactor equation

			Soil biomass factor	
Cover-management (yield)	Data source	Seedbed soil loss ratio	Obs	RUSLE2
conv corn 112 bu/ac	AH537	0.55	0.71	0.69
conv corn 50 bu/ac	AH537	0.68	0.80	0.82
conv corn sillage 112 bu/ac	AH537	0.74	0.81	0.79
conv corn sillage 50 bu/ac	AH537	0.77	0.83	0.88
conv corn 112 bu/ac soybeans 25 bu/ac	AH537	0.72	0.82	0.87
conv corn 112 bu/ac after meadow 4 tons/acre	AH537	0.18	0.29	0.24
conv corn 112 bu/ac after meadow 1.5 tons/acre	AH537	0.29	0.35	0.59
no till corn 112 bu/ac	literature	0.028	0.47	0.35
mulch till corn 112 bu/ac	literature	0.24	0.44	0.48

The soil consolidation term s_c in equation 6.48 gives increased credit for buried residue to represent no-till cropping and other undisturbed soil conditions. For example, a given amount of buried residue at the soil surface decreased rill-interrill erosion more with no-till than with clean tillage. Increased soil macro-pores and aggregation develop in the upper few inches of soil under no-till cropping and other undisturbed soil conditions (Kay and VanderBygaart, 2002). Frequent, routine tillage and other mechanical soil disturbance prevent these conditions from developing. Mechanical soil disturbance disrupts these favorable soil conditions for reducing rill-interrill erosion, and time is required for these soil conditions to become reestablished. The term $1/s_c^{0.5}$ in equation 6.48 and 6.49is used as an index for the development of these favorable soil properties.

Values for the accounting depths d_{rs}, described in **Section 6.2** for buried residue, and d_{rt} for roots were determined during the fitting of equation 6.48 and 6.49. The best fit was obtained with a buried residue accounting depth of three inches for conventional, clean tillage, which is represented by s_c =1. The accounting depth is reduced to 1 inch as the soil consolidation subfactor value decreases from 1 for a soil recently mechanically disturbed to 0.45 for a fully consolidated soil (see equation 6.10). The accounting depth for buried residue reflects the soil depth over which buried residue has its major effect on infiltration, soil erodibility, and runoff erosivity.

The accounting depth determined for roots was 10 inches. This depth contains the bulk of roots for most vegetation, especially major agricultural crops like corn, soybeans, and wheat. The apparent depth over which roots affect erosion is greater than that for buried residue because live roots affect infiltration by extracting soil water. The 10-inch accounting depth for roots is also influenced by the common depth of 10 inches for modern moldboard plows, which invert the soil. Moldboard plow bring roots near the bottom of the plow depth to near the soil surface. Moldboard plows also move surface residue and buried residue near the soil surface to near the bottom of the plow depth, where the buried residue has little effect on rill-interrill erosion. Although the case can be made that live roots and dead roots should be treated differently in RUSLE2 because of moisture extraction, the effect of live roots and dead roots per unit mass are considered to be the same for both live and dead roots.

See **Sections 8.2** and **9.2.1** for additional comments.

6.5.3. Soil biomass subfactor equation for Req conditions

When RUSLE2 is applied to Req conditions (see **Section 3.2.5** and the RUSLE2 User's Reference Guide), soil biomass values are multiplied by 1.65 to give increased erosion reduction per unit biomass. Most of the rill-interrill erosion for Req conditions is rill erosion, and soil biomass has a greater relative effect on rill erosion than on interrill erosion (Van Liew and Saxton,1983; Brown et al., 1989; McGregor et al., 1990). The 1.65 value was determined by fitting RUSLE2 to data collected at Pullman, Washington (McCool et al., 2002).

6.5.4. Applicability of soil biomass subfactor equation for biomass additions

The data used to derive equations 6.48 and 6.49 were for cropped conditions where the biomass source was vegetation grown on-site. RUSLE2 must also represent the effect of incorporation of applied biomass from other sources including animal manure, compost, bio-solids in sewage and similar waste, and forest litter. The applicability of RUSLE2 for these conditions was evaluated by computing and comparing rill-interrill RUSLE2 erosion estimates with measured erosion in research studies. Tables 6.6 and 6.7 show estimated and observed erosion values for surface application of manure and its incorporation into the soil using primary tillage at Clarinda, Iowa and La Crosse, Wisconsin (Browning et al, 1948; Hays et al., 1949). Table 6.8 shows erosion values for various biomass types applied and incorporated in the soil for cotton grown at Statesville, North Carolina (Copley et al., 1944). RUSLE2 is judged to adequately estimate how surface applied and soil incorporated biomass affects rill-interrill erosion.

Table 6.6. Effect of manure additions on erosion at Clarinda, Iowa

			Ratio of erosion with manure to erosion without manure	
Cover	Yield (bu/ac)	Manure application (tons/acre wet basis)	Obs	RUSLE2
Corn	22	0	1.00	1.00
Corn	30	8	0.42	0.39
Corn	36	16	0.21	0.20
Fallow		0	-	-
Fallow		8	0.79	0.42
Fallow		16	0.63	0.24

Table 6.7. Effect of manure additions on erosion at La Crosse, Wisconsin

			Ratio of erosion with manure to erosion without manure	
Cover	Yield (bu/ac)	Manure application (tons/acre wet basis)	Obs	RUSLE2
Corn	30	0	1.00	1.00
Corn, manure spring applied	30	8	0.82	0.42
Corn, manure fall applied	30	8	0.80	0.42
Fallow		0	1.00	1.00
Fallow, manure spring applied		5	0.85	0.75

Several factors complicate this analysis. One factor is data variability. Incorporated animal manure decreased erosion much more at Clarinda, Iowa than at La Crosse, Wisconsin. RUSLE2 seems to seriously over estimate the effect of manure applied to fallow conditions at both Clarinda and La Crosse. A comparison of observed erosion with manure applied to corn with erosion for manure applied to fallow soil at Clarinda indicates a much greater effect of the corn biomass than is supported by data in Table 5, AH537 (Wischmeier and Smith, 1978). Another problem with the experimental data is that manure applied to the corn at La Crosse did not reduce erosion as much as expected based on the results for the fallow soil. Such unexplained variability in erosion data is common.

Another complicating factor is how well the biomass was incorporated into the soil by the 6-inch deep manual spading operation used on the research plots to replicate moldboard plowing. The RUSLE2 inputs were based on the assumption that the spading incorporated the biomass more like a chisel plow than like a moldboard plow. Assuming that the incorporation was like a moldboard plow rather than a chisel plow results in RUSLE2 estimating that the ratio of erosion with incorporated biomass to erosion without incorporated biomass increases from 0.42 to 0.48 for applying 8 tons/acre of manure at Clarinda, Iowa. Consequently, the uncertainty in how the spading operation incorporated the biomass does not seem to account for the large difference between the RUSLE2 values and the measured values for fallow conditions.

Table 6.8. Effect of biomass additions on erosion with cotton at Statesville, North Carolina

Yield (lbs/acre seed cotton)	Biomass type	Biomass application (tons/acre wet basis)	Ratio of erosion with biomass to erosion without manure	
			Obs	RUSLE2
800	-	none	1.00	1.00
1800	Animal manure	8	0.19	0.27
1800	Compost	12	0.39	0.21
1800	Compost	18	0.13	0.16
1800	Compost	60	0.03	0.04
1800	Wood litter	24	0.09	0.13
1800	Pine needles	24	0.10	0.13

Another complicating factor is that the reported application rates were on a wet basis rather than a dry basis required as input to RUSLE2. The dry biomass was assumed to be 25 percent of the wet basis application rates for all biomass types. The erosion ratios for fallow conditions at La Crosse assuming a 6 inch deep moldboard plowing are 0.65, 0.48, and 0.29 for the dry biomass inputs of 2000, 4000, and 8000 lbs/acre, respectively. Errors in estimating the dry biomass can have a significant effect on the RUSLE2 estimate erosion.

RUSLE2 assumes that the effect of all types of buried residue on rill-interrill erosion is described solely by biomass amount on a dry basis. Mechanical characteristic, such as diameter and length of individual pieces, of buried residue are assumed not to affect rill-interrill erosion in RUSLE2. This assumption is supported by the experimental and RUSLE2 results for the Statesville, North Carolina data.

The experimental results given in Tables 6.6 - 6.8 do not indicate the effect of biomass addition on rill-interrill erosion with modern farming practices. The depth of incorporation in these studies, which were conducted primarily in the late 1930's, was six inches while common modern moldboard plows incorporate material to 10 inches deep. Changing incorporation depth affects the RUSLE2 estimated ratio of erosion with incorporated biomass to erosion without biomass incorporation. Increasing incorporation depth from 10 to 6 inches increases the erosion ratio from 0.42 assuming a chisel plow type incorporation in the soil (0.48 assuming a moldboard plow incorporation) to 0.82 assuming incorporation with a modern moldboard plow for the 8 tons/acre manure spring application to corn at La Crosse, Wisconsin. The reason for the major difference is the effect of machine operation depth on the fraction of the biomass that is incorporated (see **Section 8.2.4.2**) and the biomass density in the surface 3-inch soil depth.

6.5.5. Soil biomass subfactor for pasture, range, and similar undisturbed lands

The equations for the soil biomass subfactor, equations 6.48 and 6.49, are considered to apply to all land use conditions (i.e., that is RUSLE2 is land-use independent). Range, pasture, and other undisturbed lands are highly variable in both time and space. Accurately measuring root biomass is extremely difficult, if not impossible for undisturbed lands because of temporal and spatial variability. Reliable measurements of

root biomass and buried residue are not available to either directly validate equations 6.48 and 6.49 or derive alternative equations for these lands.[55] Therefore, erosion data from research plots under simulated rainfall were used to derive effective root biomass values for rangeland plant communities rather than use measured root biomass values. [56]

The common approach for applying the USLE [AH537 (Wischmeier and Smith, 1978)] and RUSLE1 [AH703 (Renard et al., 1997)] to undisturbed lands is to input values that represent average annual conditions to make a single erosion computation using subfactors similar to those in equation 6.1 to for the year rather than to compute daily erosion. This approach can also be used in RUSLE2, although a better approach is to use time varying inputs to represent temporal effects on rill-interrill erosion (see RUSLE2 User's Reference Guide). The lack of both measured soil biomass data and research that establishes how soil biomass and its characteristics affect rill-interrill erosion required derivation of effective root biomass ratio values, which is defined as the ratio of effective root biomass to average annual above ground biomass production on a dry basis. Values for this ratio vary by plant community and were determined directly from experimental soil erosion research data (See RUSLE2 User's Reference Guide; Simanton et al., 1991). This derivation empirically accounts for differences between cropland and undisturbed land conditions and overcomes the impossibility of measuring root biomass on undisturbed lands.

First, a **c** factor value was computed for each site from measured erosion data by rearranging equation 2.1 as:

$$c_p = A_p / [R_p K_n (\lambda_p / \lambda_u)^m S_p] \qquad [6.50]$$

where: c_p = the c factor value for the measured erosion data obtained from applying simulated rainfall to field plots 12 ft wide by 35 ft long, A_p = measured erosion, R_p = the erosivity for the simulated rainfall, K_n = the soil erodibility value determined by applying the standard soil erodibility nomograph (see **Sections 4.1.1** and **4.1.2**) using soil property values measured at each site, λ_p = the plot length, λ_u = unit plot length, and S_p = the slope steepness factor computed from the measured plot steepness. Next an observed soil biomass subfactor value s_c was computed for each experimental site by rearranging

---

[55] An extensive review of measured root biomass for rangeland plant communities was conducted during the development of RUSLE1. The variability in these values, as indicated in Table 5-4, [AH703 (Renard et al., 1997) , is far too great to use these values as either input to RUSLE2 or to develop a soil biomass subfactor, especially a temporally varying one, for these conditions.

[56] Data from the WEPP study (Simanton et al., 1991) were used in the analysis to compute effective root biomass values. Data from the USDA Range Study Team study Spaeth et al., 2003) were considered for use in the development of RUSLE2. However, the data were not used because of inconsistencies in the data, which were not resolved by the researchers who collected the data (see the RUSLE2 User's Reference Guide).

equation 6.1, substituting c_p values for c and values for the subfactors, and solving for the soil biomass subfactor s_b value.

An effective root biomass value was computed by rearranging equation 6.48 and assuming no buried residue effect (i.e., assuming $B_{rs} = 0$). RUSLE2 does not consider a buried residue effect when using a single average annual input for root biomass. This RUSLE2 application method also requires using RUSLE2 inputs that add surface residue that does not decompose (see RUSLE2 User's Reference Guide). The value for the effective root biomass was divided by the average annual dry matter above ground biomass production to compute a value for effective root biomass ratio for the site. These values were averaged where the same plant community occurred at multiple sites. RUSLE2 multiplies the input value for above ground annual production by the effective root biomass ratio to obtain a value for effective root biomass B_{rt} that is used in equation 6.48 or 6.49 to compute a value for the soil biomass subfactor. Derivation of RUSLE2 effective root biomass values was the same as that used to derive comparable values for RUSLE1 [Yoder et al., 1997; AH703 (Renard et al., 1997)], except that RUSLE2 equations and procedures were used for equations 6.1, 6.48, and 6.50.

The RUSLE2 User's Reference Guide discusses how time varying inputs can be used in RUSLE2 to represent changes in time during the establishment of permanent cover on mechnanically disturbed lands such as construction sites, reclaimed mined lands, rangelands, military training grounds, and logged and burned forest lands. This Guide also describes how time varying inputs can be used in RUSLE2 to represent long-term vegetation that has reached maturity on undisturbed land. Using time varying inputs for canopy and root biomass allows RUSLE2 to compute a litter cover produced by senescence, soil biomass produced by dead (soughed) roots, and soil biomass produced by buried residue that are a function of plant community, production level, and location (Reeder et al., 2001).

RUSLE2 was fitted directly to the measured erosion data for rangelands to determine the soil biomass effect for these lands. However, RUSLE2 erosion estimates for undisturbed lands, especially rangelands, are much more uncertain than erosion estimates for cropland. This increased uncertainty exists for all erosion prediction technologies and is not unique to RUSLE2. Reasons for this uncertainty and its magnitude are discussed in detail in the RUSLE2 User's Reference Guide.

6.5.6. Sources of soil biomass in RUSLE2

The sources of soil biomass in RUSLE2 are biomass applied to the soil surface or directly injected into the soil, above ground biomass from vegetation grown on site, and roots from vegetation grown on-site. The amount of applied biomass is a direct input to RUSLE2 (see **Section 10**). The amounts of above ground and root biomass for vegetation grown on-site are directly related to RUSLE2 inputs (see **Section 9**). Once live above ground biomass becomes dead biomass (i.e., residue) by senescence or killed by an operation such as mowing, it disappears by decomposition discussed in **Section 10.3.** Similarly, once live roots become dead roots either by the plants being killed or by root sloughing, this biomass disappears by decomposition. Operations, including soil

disturbing operations, move biomass between the various biomass pools and redistribute biomass within the soil (see **Section 8**). The RUSLE2 User's Reference Guide describes the RUSLE2 biomass pools in detail and how these pools are manipulated in RUSLE2.

6.5.7. Transfer of surface residue to soil biomass by decomposition in RUSLE2

The organic matter content of the approximate 2-inch soil depth for no-till cropped soil is about twice that for conventional, clean-till cropping (Kay and VanderBygaart, 2002; Shelton and Bradley, 1987). A RUSLE2 assumption is that biomass occurs in the soil only by roots grown in the soil or a mechanical soil disturbing operation incorporating biomass. To accommodate the accumulation of high organic matter level in a shallow soil surface layer where little or no mechanical soil disturbance occurs, such as for no till croplands and undisturbed lands, RUSLE2 assumes that a portion of the daily surface residue decomposition is added to the top 2-inch soil layer. Once in this soil layer, this biomass is treated as any other buried residue that is subject to decomposition and has the same effect on rill-interrill erosion as any other buried residue.

This empirical procedure is used as a mechanism for increasing soil biomass in the upper soil layer when the soil is minimally disturbed. The equation used to compute this buried residue addition is:

$$f_b = 0.25[(1/s_c) - 1] \qquad [6.51]$$

where: f_b = the fraction of the daily biomass decomposed from surface residue that is added to the buried residue biomass in the upper 2-inch soil layer. The 0.25 value was determined during the fitting of equation 6.48 to observed data. The 0.25 variable was adjusted so that RUSLE2 computes a soil biomass in the top 2-inch soil layer for the no-till data point that is approximately twice the soil biomass for conventional, clean tillage. The structure of equation 6.51 was chosen so that the rate of change in the effect of soil consolidation is least immediately after a mechanical soil disturbance (i.e., $s_c = 1$). The rate of increase in f_b increases as the soil approaches full soil consolidation (i.e., $s_c = 0.45$).

The soil consolidation s_c subfactor term in equation 6.51 and the time to soil consolidation (see **Section 4.8**) determine the time required after a conversion from conventional, clean tillage to no tillage for soil biomass to come to a new equilibrium. Seven years is used for the time to soil consolidation in the eastern US, which is too short for all of the soil biomass changes to occur (Kay and VanderBygaart, 2002). However, seven years for time to soil consolidation is sufficient for RUSLE2 to represent particulate organic matter, and seven years seems sufficiently long for most major land use changes that affect rill-interrill erosion in the context of conservation planning. The time to soil consolidation is also used to compute change in soil erodibility when no biomass is present. Consequently, thus the RUSLE2 time to soil consolidation variable is a compromise for describing multiple effects.

Equation 6.51 computes no transfer of biomass from the surface residue to the buried residue when the soil has been recently mechanically disturbed, which is indicated by s_c =

1, which gives $f_b = 0$ from equation 6.51. If the soil is totally undisturbed where $c_s = 0.45$, $f_b = 0.31$, which means that for each day, approximately 30 percent of the surface residue that is lost by decomposition on that day is added to the buried residue in the upper 2-inch soil depth. In no-till corn cropping where the only soil disturbing operation is a planter that disturbs 15 percent of the soil surface, the c_s ranges from 0.54 to 0.61 during the year. The approximate annual average is 0.58, which gives a value of 0.18 from equation 6.51. That is, approximately 18 percent of the daily surface residue decomposition is added to the upper 2-inch soil depth for typical no-till corn cropping in comparison to almost 30 percent being added for a completely undisturbed soil condition (e.g., a pasture or rangeland).

6.5.8. Spatial variability in the soil biomass subfactor

Soil biomass and the soil biomass subfactor are assumed to be spatially uniform within a segment along the overland flow path, even when the soil is disturbed in strips. Non-uniformity in soil biomass along the overland flow path can be represented by dividing the overland flow path into segments.

6.5.9. Comments on soil biomass subfactor

The purpose of the soil biomass subfactor is to capture the main effect of live and dead roots and buried residue on rill-interrill erosion. The RUSLE2 soil biomass relationships are not meant to be a model of soil biomass that stands alone from how it used in RUSLE2 to estimate rill-interrill erosion for conservation and erosion control planning. The soil biomass subfactor does not capture all interactions, such as how the effect of soil biomass on erosion is affected by soil texture.

The importance of the soil biomass subfactor is often overlooked in evaluating how cover-management practices affect rill-interrill erosion. For example, large amounts of biomass added to the soil can greatly reduce rill-interrill erosion as indicated in Table 6.8. Similarly, large amounts of live and dead root biomass also greatly reduce erosion.

RUSLE2 only uses biomass amount as the variable to capture how soil biomass affects erosion. For example, RUSLE2 makes no distinction between how small and larges roots affect erosion. However, preference in selecting root biomass input values is given to fine roots instead of coarse roots (see RUSLE2 User's Reference Guide). Not much of the mass of coarse roots is entered for root biomass because coarse roots are assumed to have relatively little effect on erosion. Fine roots are assumed to have much greater effect on erosion per unit biomass than do coarse roots. Fine roots have greater surface area per unit mass than coarse roots and often are very close to the soil surface where they have a greater effect on runoff and erosion than coarse roots. Fine roots are readily sloughed and become a part of the soil organic matter pool.

Research to directly determine the effect of buried residue on rill-interrill erosion has been limited and incomplete (Van Liew and Saxton, 1983; Brown et al., 1989; McGregor et al., 1990; Box, Jr. and Bui, 1993). Research to measure soil buried residue and its characteristics as they affect rill-interrill erosion is difficult and is very incomplete.

However, research, such as that summarized in AH537 (Wischmeier and Smith, 1978), conclusively shows that root biomass reduces erosion. No studies have shown how root characteristics affect rill-interrill erosion.

Getting good results from RUSLE2 requires that instructions in the RUSLE2 User's Reference Guide for selecting input values be carefully followed. RUSLE2's soil biomass subfactor equation and other subfactor equations were calibrated using the data in the RUSLE2 **core database**. When those values and the procedures described in the RUSLE2 User's Reference Guide are followed, RUSLE2 users can expect good results from RUSLE2 for conservation and erosion control planning. If one disagrees with the soil biomass values used by RUSLE2, one can not simply change RUSLE2 input values because of RUSLE2 having been calibrated using values from the RUSLE2 **core database**. If soil biomass values are changed, the soil biomass subfactor equation must be re-derived because the RUSLE2 equation was derived using RUSLE2 computed soil biomass values.

The importance of this point can not be over emphasized.

6.6. Soil consolidation subfactor

6.6.1. Soil consolidation effect

The RUSLE2 assumption is that mechanical soil disturbance by tillage, construction activities, and other soil loosening operations significantly increases soil susceptibility to erosion. Rill-interrill erosion immediately after a mechanical soil disturbance is assumed to be about twice that when the soil has not been disturbed for an extended period. The effect is much greater for rill erosion than for interrill erosion (Foster, 1982; Foster et al., 1982c).

The term soil consolidation does not accurately connote the process by which soil becomes less susceptible to erosion over time. The reduction in soil erodibility over time represented by the soil consolidation subfactor is related to internal cohesive soil bonding increasing over time rather than to a mechanical increase in soil bulk density. Cohesive bonding increases as the soil experiences wetting and drying cycles in the presence of organic matter and chemical bonding agents in the soil (Foster et al., 1985c; Toy et al., 2002). The important role of soil moisture is the reason for the time to soil consolidation being a function of average annual precipitation between 10 and 30 inches (see **Section 4.8**).

The soil consolidation effect is based on a comparison of erosion from a soil in the unit plot condition to erosion of the same soil that has not been mechanically disturbed for some time after being left in unit-plot condition by the last mechanical soil disturbance. Soil disturbance also affects the ground cover, soil surface roughness, and soil biomass subfactors in addition to the soil consolidation subfactor. The soil consolidation subfactor represents solely the effects of soil loosening on erosion relative to time since the last mechanical soil disturbance that left unit plot conditions. The soil consolidation

subfactor variable is also used to compute values for the soil biomass subfactor, rill to interrill erosion ratio, and runoff curve number. Therefore, the effect of soil loosening computed by RUSLE2 can be significantly greater than the effect represented by the soil consolidation subfactor.

6.6.2. Soil consolidation subfactor equation

The equation for the RUSLE2 soil consolidation subfactor is:

$$s_c = 0.45 + \exp\{-3.314[0.1804 + (t_d / t_c)^{1.439}]\} \quad [6.52]$$

where: t_d = days since last mechanical soil disturbance and t_c = the time to soil consolidation The 0.45 value in equation 6.52 represents the minimum soil consolidation subfactor value that occurs for time exceeding the time to soil consolidation.[57] The soil consolidation subfactor value is 1 for $t_d = 0$, which is immediately after a mechanical soil disturbance. A plot of equation 6.52 is shown in Figure 6.6 for two times to soil consolidation.

Equation 6.52 was derived from experimental erosion data collected from natural runoff plots at Zanesville, Ohio (Borst et al., 1945). Erosion was measured for a few years from a plot periodically tilled to maintain unit plot conditions. Tillage was stopped and erosion measurements were continued for several years after tillage stopped. Measured annual erosion values were adjusted based on the annual erosivity to account for weather differences between years. Observed soil consolidation subfactor values were computed by dividing the adjusted annual erosion values after tillage stopped by adjusted average annual erosion before tillage stopped.

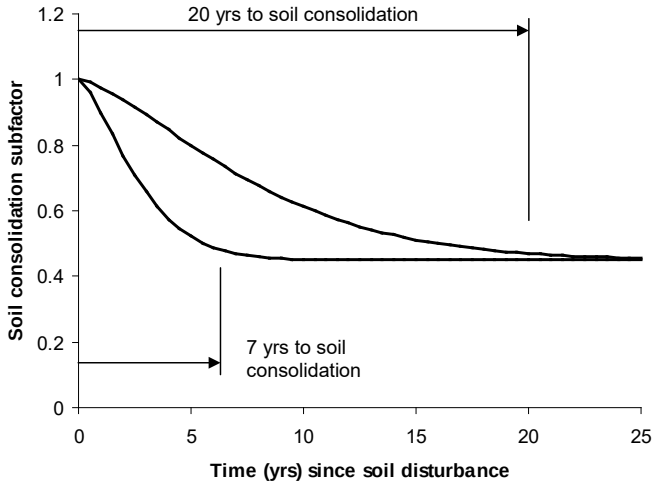

Figure 6.6. Variation of the soil consolidation subfactor as a function of time after last mechanical soil disturbance.

Experimental erosion studies on mine spoil and reconstructed shoed that compaction can increase rill-interrill erosivity by as much as 40 percent (Barfield et al.,

[57] Equation 6.52 approaches 0.45 asymptotically. The time to soil consolidation is defined as the time when 95 percent of the decrease in the soil consolidation subfactor has occurred (see **Section 4.8**).

1988). About half of this effect can be captured in RUSLE2 by inputting a 0 soil surface roughness value for the soil disturbing operation used to describe the compaction. The 0 input value for soil surface roughness represents a smooth soil surface that is assumed to result from the compaction. This value is increased to represent the roughness effect left by a compactor such as a sheep's foot roller that leaves some soil surface roughness.

6.6.3. Spatial variability effect on soil consolidation subfactor

RUSLE2 accommodates spatial variability along the overland flow path when the overland flow path is divided into segments. RUSLE2 also represents the effect of operations that disturb only a portion of the soil surface (e.g., strip tillage) based on the fraction of the soil surface that the operation disturbs. An effective value for the soil consolidation subfactor is computed as the weighted average of $s_c = 1$ for the portion disturbed and the s_c value for the undisturbed portion at the time of the mechanical soil disturbance. An effective time since soil disturbance is calculated by rearranging equation 6.52 and solving for the time t_d that gives the effective s_c value (see **Section 8.3.1**). The time since last soil disturbance is reset to this effective time, and time accounting for soil consolidation begins again from the effective time value.

6.6.4. Comments on soil consolidation subfactor

The RUSLE2 soil consolidation subfactor only captures the soil loosening effect on rill-interrill erosion in the broadest terms. The soil consolidation subfactor is the most poorly defined of all the RUSLE2 cover-management subfactors. Very little empirical and not much fundamental research has been conducted to determine how the soil consolidation effect varies with climate, soil texture, and other factors. The RUSLE2 soil consolidation subfactor is determined from a single set of data collected at a single location on a single soil texture. The effect is greater for rill erosion than for interrill erosion (Foster et al., 1982c). However, the soil consolidation effect on rill erosion can be quite variable. In one study, rill erosion of a silt loam soil decreased by about 75 percent over about a year's time (Dissmeyer and Foster, 1981). In another study, sediment eroded from ridges and deposited in furrows became quite resistant to erosion in just four weeks (Foster et al., 1982c).

The soil consolidation effect surely must be a function of soil texture. For example, the range in the soil consolidation subfactor for soils high in sand is assumed to be less than for silt loam soils. Also, the time to soil consolidation is assumed to be a function of soil texture. However, available research information is not sufficient to include these effects in the RUSLE2 soil consolidation subfactor.

The RUSLE2 assumption is that mechanical soil compaction (i.e., mechanical increases in soil bulk density) does not affect rill-interrill erosion. Soil compaction has two offsetting effects. One is to decrease infiltration, which increases runoff and hence rill-interrill erosion. The other effect is to decrease erosion by decreasing the detachability of soil particles by raindrop and runoff forces. The assumption of no effect of soil compaction on erosion is false for a high clay soil being mechanically compacted at optimum soil moisture. Soil compaction of a high clay soil can greatly reduce rill erosion

(Graf, 1971). Available research information was not sufficient to include a RUSLE2 relationship that computes erosion as a function of soil bulk density. An input value less tha 0.24 inches for soil surface roughness can be used to represent increase in erosion caused by compaction. Also, the soil erodibility factor value can be reduced to represent decreased erosion caused by compaction of high clay soils.

RUSLE2 does represent the effect on rill-interrill erosion of subsoiling, scarifying, and similar mechanical soil disturbances designed to break up soil to increase infiltration, which in turn decreases runoff and erosion. RUSLE2 represents this effect though the soil surface roughness subfactor (see the RUSLE2 User's Reference Guide).

The RUSLE2 soil erodibility factor does not represent the effect of soil compaction. Soil compaction is a cover-management effect. Changing a soil erodibility input value to represent soil compaction is for convenience only in RUSLE2 because no other input method is available to represent the effect of compaction. RUSLE2 soil erodibility are based on the tilled unit plot condition.

6.7. Antecedent soil moisture subfactor

The antecedent soil moisture subfactor is used only when RUSLE2 is applied to Req conditions (see **Section 3.2.5**).

6.7.1. Antecedent soil moisture effect

Rill-interrill erosion under Req conditions is highly sensitive to soil moisture [AH703 (Renard et al., 1997); Van Klaveren and McCool,1998]. High soil moisture significantly increases erosion during the winter Req period. Freezing and thawing cycles in the presence of very high soil moisture and other processes dramatically increase soil erodibility during the winter months at Req locations [see RUSLE2 User's Reference Guide, AH703 (Renard et al., 1997); Van Klaveren and McCool,1998). Highly saturated soil in the tilled surface layer plays a major role in Req processes that do not occur to nearly the same degree or regularity in non-Req locations.

6.7.2. Antecedent soil moisture subfactor equations

The RUSLE2 antecedent soil moisture subfactor equations are a refinement of those in RUSLE1 [Yoder et al., 1997; AH703 (Renard et al., 1997); McCool et al., 2002]. The year is divided into periods of soil moisture replenishment (October 1 – March 31), stable at maximum soil moisture (April 1 – April 30), depletion (May 1 – July 31), and stable at minimum soil moisture (August 1 – September 30).

6.7.2.1. Replenishment (October 1 – March 31)

The average daily soil moisture replenishment rate is computed as:

$$R_m = 0.5/182 \quad P_a \le 10 \text{ inches} \qquad [6.53]$$

$$R_m = [0.5 + 0.062(P_a - 10)]/182 \quad 10 < P_a \leq 18 \text{ inches} \qquad [6.54]$$

$$R_m = 1/182 \quad P_a > 18 \text{ inches} \qquad [6.55]$$

where: R_m = an index (dimensionless) for daily moisture replenishment rate, P_a = average annual precipitation (inches), and 182 = number of days over which replenishment occurs.

$$s_m = s_{mp} + R_m \quad if\,(s_m > 1) : s_m = 1 \qquad [6.56]$$

where s_m = daily antecedent soil moisture subfactor and s_{mp} = the soil moisture subfactor on the previous day.

6.7.2.2. Depletion (May 1 – July 31)

The daily soil moisture depletion rate is computed as:

$$D_m = \phi_m / 91 \qquad [6.57]$$

where: D_m = an index (dimensionless) for daily moisture depletion rate, ϕ_m = the total soil moisture depletion as a function of vegetation, and 91 is the number of days over which depletion is assumed to occur. Example values for ϕ_m are given in Table 6.9.

$$s_m = s_{mp} - D_m \quad if\,(s_m < 0) : s_m = 0 \qquad [6.58]$$

6.7.2.3. Minimum and maximum periods (April 1 – April 30) and (August 1 – September 30)

The soil moisture subfactor is assumed not to change during the minimum period between the depletion and replenishment periods and the maximum period between the replenishment and depletion periods. That is:

$$s_m = s_{mp} \qquad [6.59]$$

6.7.2.4. Initial s_m value

Table 6.9. Soil moisture depletion index for vegetation grown in Req location

Vegetation	Depletion index
Winter wheat and other deep rooted crops	1.00
Spring wheat and barley	0.75
Spring peas and lentils	0.67
Shallow rooted crops	0.50
Summer fallow	0.00
Vegetation that has been killed	0.00

The initial default value for the antecedent soil moisture subfactor s_m is 1. The initial condition is not important when cover-management practice are rotations (i.e., the set of operations is repeated in cycles). RUSLE2 runs until dynamically stable conditions are reached. However, when the cover-management practice is not a rotation, the initial operations in the cover-management description are used to set the desired initial

condition (see RUSLE2 User's Reference Guide). Specific values can not be entered in the RUSLE2 computer program to set initial values of RUSLE2 variables.

6.7.2.5. Applicability of RUSLE2 antecedent soil moisture subfactor equations

The RUSLE2 antecedent soil moisture subfactor equations (equations 6.53 - 6.59) strictly apply only to the portion of the Req zone from central Washington across northern Idaho and in northeastern Oregon illustrated in Figure 3.16 (also, see RUSLE2 User's Reference Guide). Although Req conditions occur in other locations, equations 6.53 – 6.59 do not apply to those locations because of differences in precipitation patterns.

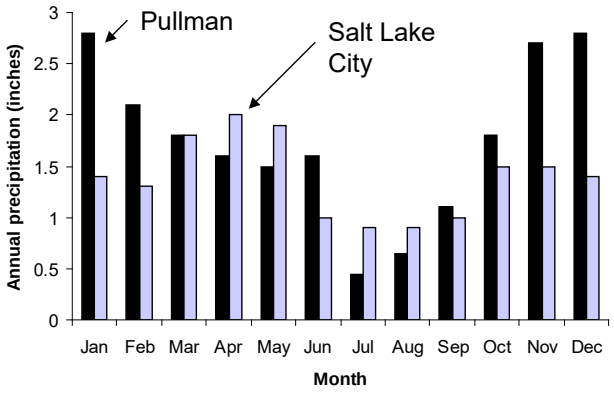

Figure 6.7. Distribution of monthly precipitation at Pullman, Washington (P_a = 20.9 inches) and Salt Lake City, Utah (P_a = 16.9 inches)

These equations were empirically derived from data collected at Pullman, Washington. Differences in monthly precipitation distributions between Pullman Washington and Salt Lake City, Utah are illustrated in Figure 6.7. Equation 6.53 – 6.55 do take into account differences in annual precipitation between locations but not differences in monthly precipitation and vegetation extraction patterns. Replenishment and depletion rates are expected to differ among locations as monthly precipitation distributions vary.

6.7.3. Comments on antecedent soil moisture subfactor

The antecedent soil moisture subfactor is a very important variable at Req locations. For example, changing the moisture depletion variable ϕ_m from 1, its standard value, to 0 for no moisture depletion, increased estimated erosion from 8.9 to 14 tons/acre per year for a typical conventional, clean-till continuous wheat crop at Pullman, Washington. Given that the antecedent soil moisture subfactor has a major effect on rill-interrill erosion emphasizes the need for improved equations for this subfactor as a function of monthly precipitation distribution.

The RUSLE2 antecedent soil moisture subfactor should be used only for Req locations. The antecedent soil moisture subfactor equations were empirically derived from data collected at Pullman, Washington where climatic conditions are very different from those in other US regions. Antecedent soil moisture affects rill-interrill erosion in all locations. Those effects are empirically described by the canopy and soil biomass subfactors and by the precipitation and temperature variables used to compute temporal soil erodibility factor values (see **Section 4.5**). Using the antecedent soil moisture subfactor in non-Req location causes serious errors in RUSLE2 estimated erosion.

6.8. Validation of cover-management factor values

RUSLE2 should represent the effect of cover-management on rill-interrill erosion better than it does for any other major factor. Rill-interrill erosion varies more as cover-management varies over its likely range than it does for the likely range of any other factor. Cover-management type erosion control practices are used more widely than any other type of erosion control practice. RUSLE2 must accurately estimate how cover-management affects erosion to avoid excessive expense of installing more erosion control than necessary. Likewise, RUSLE2 must accurately estimate how cover-management affects erosion to ensure adequate erosion control and prevention of excessive damages. The RUSLE2 User's Reference Guide extensively discusses the validity of RUSLE2 for estimating how cover-management affects rill-interrill erosion.

Tables 6.10 – 6.12 illustrate how well the RUSLE2 cover-management subfactors compute soil loss ratios in relation to summarized experimental data taken from AH537 (Wischmeier and Smith, 1978) and other sources. As these tables show, RUSLE2 estimates very well the variation in soil loss ratios as a function of crop stage periods and as a function of the major cover-management variables that affect rill-interrill erosion.

In addition, an extensive set of literature was reviewed and analyzed in validating RUSLE2 for conservation tillage especially no till (see **Section 12.23**).

Table 6.10. Soil loss ratios for conventional clean tilled continuous 112 bu/ac from AH537 and RUSLE2 computed values.

Crop stage (defined in AH537)	AH537 soil loss ratio	RUSLE2 computed soil loss ratio
Fallow	0.31	0.28
Seedbed	0.55	0.54
1 - 10% < canopy cover < 50%	0.48	0.52
2 - 50% < canopy cover < 75%	0.38	0.3
3 - 75% < canopy cover to maturity	0.23	0.18
4 after harvest (stalks spread)	0.06	0.06

Table 6.11. Soil loss ratio values for conventional clean till flat planted continuous 750 lbs/acre cotton at Holly Springs, Mississippi.

Crop stage (defined in AH537)	AH537 soil loss ratio	RUSLE2 computed soil loss ratio
Fallow	0.39	0.54
Seedbed	0.64	0.74
1- 10% canopy cover < 35%	0.59	0.74
2 - 35% < canopy cover < 60%	0.46	0.49
3 - 60% canopy cover to maturity	0.32	0.23
Defoliation to Dec 31	0.26	0.24
Jan 1 to Feb. tillage	0.32	0.32

Table 6.12. Soil loss ratio values for conventional clean till ridge (hipped) continuous planted 750 lbs/acre cotton at Holly Springs, Mississippi.

Crop stage (defined in AH537)	AH537 soil loss ratio	RUSLE2 computed soil loss ratio
1st hip, no prior tillage	0.84	0.88
Split ridges with a “do-all”	0.54	0.52
Hip after 2 prior tillages	1.08	1.01
Split ridges with a “do all”	0.62	0.58
Hip after 3 or more tillages	1.1	1.12
Split ridges with a “do all”	0.64	0.64
Seedbed	0.64	0.64
1 - 10% canopy cover < 35%	0.59	0.64
2 - 35% < canopy cover < 60%	0.46	0.45
3- 60% canopy cover to maturity	0.32	0.21
Defoliation to Dec 31	0.22	0.23
Jan 1 to Feb. tillage	0.32	0.27

6.9. List of symbols

a_b = coefficient related to buried residue and soil consolidation used to compute a_2

a_e = coefficient used to compute loss of ridge height by interrill erosion (inch/customary US erosivity unit)

a_g = coefficient related to height within the canopy where vegetative surface area is concentrated, used to compute effective fall height

a_h = coefficient used to compute ridge subfactor values

a_s = coefficient that is a function of canopy shape, used to compute effective fall height

a_1 = coefficient related to soil biomass and soil consolidation used to compute a_2

a_2 = coefficient, along with a_4, for how soil consolidation, soil biomass, and conformance of ground cover to the soil surface affect rill to interrill erosion ratio

a_3 = coefficient related overland flow path length and steepness and conformance of ground cover to soil used to compute a_4

a_4 = coefficient, along with a_2, for how soil consolidation, soil biomass, and conformance of ground cover to the soil surface affect rill to interrill erosion ratio

A_p = measured erosion from simulated rainfall applied to plots used to determine c_p factor values (mass/area)

b = coefficient for how ground (surface) cover affects rill-interrill erosion ($percent^{-1}$)

b_r = coefficient for how ground cover affects rill erosion ($percent^{-1}$)

B_{rs} = buried residue mass (dry basis) density in soil accounting depth for buried residue (mass/area·length)

B_{rt} = live and dead root mass (dry basis) density in soil accounting depth for roots (mass/area·length)

B_{td} = total mass (dry basis) density of buried residue and live and dead roots averaged over soil disturbance depth after the operation (lbs_m/acre·inch)

c = daily cover-management factor

c_a = coefficient for combined effect of buried residue and soil consolidation on ground cover effectiveness in relation to rill erosion

c_c = daily canopy subfactor

c_p = c factor value for measured erosion data obtained from applying simulated rainfall to field plots

c_{pr}/c_{pi} = rill to interrill prior land use soil erodibility ratio

d_{rs} = accounting soil depth for buried residue (inches)

D_b = rill-interrill erosion when ground cover is not present (bare soil) (mass/area)

D_c = rill-interrill erosion when ground cover is present (mass/area)

D_{ib} = interrill erosion when ground cover is not present (bare soil) (mass/area)

D_m = index for daily moisture depletion rate

D_{rb} = rill erosion when ground cover in not present (bare soil) (mass/area)

D_t = normalized rill-interrill erosion

e_d = waterdrop impact energy (force-distance)

f_b = fraction of the daily biomass decomposed from surface residue added to buried residue biomass in upper 2-inch soil layer

f_c = daily canopy cover (fraction)

f_{ec} = daily effective canopy cover (fraction)

f_g = ground (surface) cover (fraction or percent when used to compute g_c)

f_{ge} = effective ground cover used to compute values for slope exponent m (percent)

f_{gn} = net ground cover, portion of soil surface covered

f_r = fraction of today's soil surface roughness greater than 0.24 inch that remains after today's loss of roughness

g_c = daily ground (surface) cover subfactor

g_{ci} = interrill erosin ground (surface)cover subfactor

g_{cr} = rill erosion ground (surface)cover subfactor

g_r = relative row grade (grade along the ridges/overland flow path steepness)

h_b = height to canopy bottom (length)

h_f = daily effective fall height (feet)

h_t = height to canopy top (length)

H = daily ridge height (inches)

H_e = ridge height component associated with interrill erosion (inches)

H_{ep} = previous day ridge height component associated with interrill erosion (inches)

H_s = ridge height component associated with settlement (inches)

H_{sp} = previous day ridge height component associated with settlement (inches)

I = daily amount of water added by irrigation (inches)

K_n = soil erodibility value determined from standard soil erodibility nomograph using soil property values measured at each site (mass/erosivity unit)

K_r/K_i = rill to interrill soil erodibility ratio

m = slope length exponent

m_d = waterdrop mass

P_a = average precipitation (inches)

P_{cl} = mass portion of soil composed of clay (percent)

P_d = daily precipitation (inches)

P_{sl} = mass portion of soil composed of silt (percent)

r_d = daily erosivity (erosivity units)

r_h = daily ridge height subfactor

$r_{h,u\&d}$ = ridge height subfactor value when ridge orientation is parallel to overland flow path

r_{h6} = daily ridge height subfactor when overland flow path steepness is less than or equal to 6 percent

R_a = daily adjusted sil surface roughness roughness used to compute soil surface roughness subfactor values (inches)

R_{aa} = adjusted soil surface roughness immediately after soil disturbing operation (inches)

R_{ae} = existing adjusted soil surface roughness before a soil discturbing operation (inches)

R_{alf} = adjusted final long term soil surface roughness value after input value for long term roughness adjusted for soil texture and soil biomass (inches)

R_{ap} = adjusted soil surface roughness on previous day (inches)

R_{ib} = initial soil surface roughness after input roughness adjusted for soil texture and biomass (inches)

R_{in} = input soil surface roughness value for reference condition for soil disturbing operation (inches)

R_{it} = initial soil surface roughness after input roughness value adjusted for soil texture (inches)

R_l = daily adjusted long long term soil surface roughness (inches)

Req = equivalent erosivity related to greatly increased soil erodibility during winter months in Nrthwestern US

R_m = index for daily moisture replenishment rate

R_p = erosivity for simulated rainfall applied to plots used to determine c_p factor values (erosivity units)

s = overland flow path steepness (sine of slope angle)

s_b = daily soil biomass subfactor

s_c = daily soil consolidation subfactor

s_i = interrill area steepness (sine of slope angle)

s_m = daily antecedent soil moisture subfactor used in Req zone

s_p = overland flow path steepness (100 times tanget of slope angle)

s_r = daily soil surface roughness subfactor

S_p = slope steepness factor computed from steepness of plots used with simulated rainfall to determine c_p factor values

t_c = time to soil consolidation (days)

t_d = time since the last mechanical soil disturbance (days)

V = waterdrop impact velocity (length/time)

α = rill to interrill erosion ratio for bare soil

δ = cover adjustment term used to compute slope length exponent

ξ = tillage intensity

λ = overland flow path length (length)

λ_p = length of plots used with simulated rainfall to determine c_p factor values

λ_u = unit plot length (72.6, 22.1 m)

ϕ_m = the total soil moisture depletion as a function of vegetation

ψ = coefficient related to conformance ground (surface) cover to soil surface

7. SUPPORT PRACTICES

7.1. Contouring (ridging)

7.1.1. Description of contouring (ridging)

Contouring is an erosion control practice where ridges are placed on the contour around the hillslope perpendicular to the overland flow path. Runoff flows uniformly over the ridges along their length when the ridges are perfectly on the contour and the ridge top is level. Ponded water in the furrows between the ridges reduces detachment and causes a major portion of the sediment eroded from the ridges to be deposited in the furrows.

These ideal conditions seldom occur in the field. Breakovers occur in low ridge areas and where the soil is susceptible to rill erosion. Erosion reduction with contouring is reduced when breakovers occur. However, erosion reduction occurs even with breakovers if furrow (row) grade is sufficiently flat to cause deposition in the furrows or to cause reduced rill erosion in relation to the rill-interrill erosion that occurs when the ridges are parallel to the overland flow path. Runoff travels long distances in the furrows between high ridges to concentrated flow areas where ephemeral gully erosion occurs. RUSLE2 does not explicitly estimate ephemeral gully erosion (see RUSLE2 User's Reference Guide), although ephemeral gully erosion occurred in the small watersheds used to derive the RUSLE2 contour subfactor relationships. Thus, ephemeral gully erosion is partially included in RUSLE2 erosion estimates for contoured conditions.

The effect of ridging (contouring) on rill-interrill erosion must be considered even when ridging is not used explicitly as an erosion control practice. For example, tillage direction in an agricultural field is often parallel to a field boundary, which results in ridges at an angle to the overland flow path. Rill-interrill erosion varies between the extremes of being minimal when the ridges are perfectly on the contour and maximum when the ridges are parallel to the overland flow path.

The base, reference unit plot condition is that ridges-furrows are parallel to the overland flow path. Thus, the RUSLE2 contouring subfactor represents the effect of ridge-furrow orientation with respect to the overland flow path on rill-interrill erosion.

7.1.2. Contouring (ridging) effect

Figure 7.1 is a graph of experimental data that shows how contouring affects rill-interrill erosion on plots that ranged in width from12 to 150 ft and small watersheds that were about 5 acres in area (Foster et al., 1997; see other references in **Section 7.1** and **Section 12.2.1**).

Each type of measurement area has shortcomings. A shortcoming of watersheds is that measured sediment from watersheds includes sediment produced by ephemeral gully erosion, which is not estimated by RUSLE2. A shortcoming of plots narrower than about

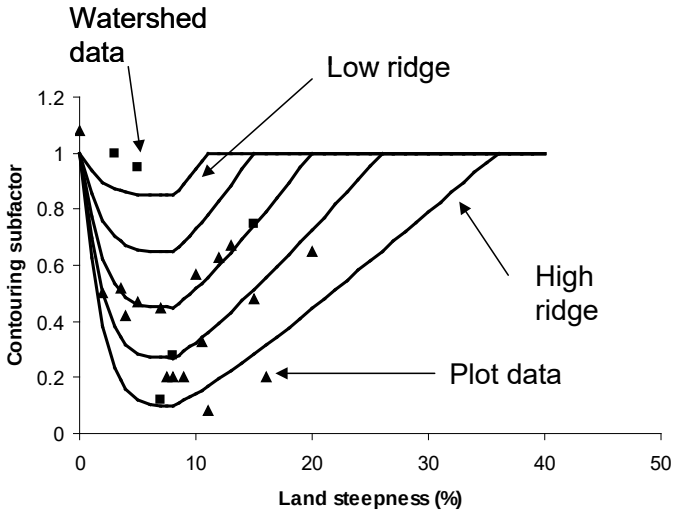

Figure 7.1. Experimental data from plots and small watershed (~ 5 acres) for effect of contouring (ridging) on rill-interrill erosion and fitted lines for effect of ridge height on contouring.

20 ft is that runoff rates are too low at the ridge breakovers. Several plot widths exceeded 20 ft with some as wide as 150 ft, which are sufficiently wide to represent field contouring. Although, neither plot nor watershed data are entirely satisfactory, data from both plots and watersheds were combined to derive RUSLE2 contouring subfactor equations.

The well accepted general contouring subfactor relationship is an upward concave curve that starts at 1 for a zero steepness, decreases to a minimum as land steepness increases to an approximate 8 percent steepness and then increases to 1 at an upper steepness beyond which contouring is assumed not to reduce erosion [AH537 (Wischmeier and Smith, 1978)]. Contouring has no effect at zero land steepness because no flow direction is defined. Contouring has no effect beyond a maximum steepness that is a function of ridge height because the land is so steep that no water can be stored by the ridges.

The range in the data illustrated in Figure 7.1 for the effect of contouring on rill-interrill erosion is assumed to be caused primarily by a ridge height variation. Experimental data show that contouring's erosion reduction increases as ridge height increases (Moldenhauer and Wischmeier, 1960). Increased ridge height increases storage of runoff, decreases interrill detachment, and increases deposition in the furrows, which is the basis for the curves in Figure 7.1 being a function of ridge height. Also, dense plant stems in narrow rows on the contour have the same effect on rill-interrill erosion as ridges on the contour (Daniel et al., 1943; Van Doren et al., 1950). Experimental data show that contouring is less effective for large intense runoff events than for small ones (Moldenhauer and Wischmeier, 1960). In some cases, erosion on watersheds was greater with contouring than with tillage up and down hill as illustrated in Figure 7.1 (Hill et al., 1944). These examples of increased erosion are associated with concentrated flow erosion where ridge-breakovers occurred. Thus, the effective of contouring on rill-interrill erosion depends on storm, soil, and cover-management characteristics that affect runoff.

A long accepted principle by soil conservationists is that contouring fails if the overland flow path length exceeds a critical length that is a function of land steepness [(AH282 (Wischmeier and Smith, 1965); AH537 (Wischmeier and Smith, 1978)]. That critical length is assumed in RUSLE2 to be a function of the shear stress applied to the soil by

runoff, which in turn is a function of storm characteristics, inherent potential of the soil for generating runoff, and how cover-management affects runoff and the shear stress that runoff applies to the soil.

The RUSLE2 contouring subfactor equations are very similar to the comparable RUSLE1 equations [Foster et al, 1997, AH703 (Renard et al., 1997)] except for the RUSLE2 equations being a function of daily ridge height, runoff, and cover-management conditions.

7.1.3. Contouring (ridging) subfactor equations

The RUSLE2 contouring equations were developed to give accepted values for a base, reference condition of conventional, clean tilled 50 bu/ac corn grown on a silt loam hydrologic C soil group soil located at Columbia, Missouri.[58] This management practice was common when the contouring data were collected from the mid 1930's to the mid 1950's for much of the data represented in Figure 7.1.

The RUSLE2 equations vary contouring subfactor values about base, reference values as climate, soil, and cover-management conditions depart from the base, reference condition. The RUSLE2 equations were structured to meet required boundary conditions and were calibrated to experimental data to give similar contouring subfactor values used by the USLE and computed by RUSLE1 for base, reference conditions. In contrast to the RUSLE1 equations that used a representative ridge height and cover-management condition to represent the cover-management practice to compute an average annual contouring subfactor value (Foster et al, 1997), the RUSLE2 equations compute daily contouring subfactor values as climate, cover-management, runoff, and ridge height vary daily.

7.1.3.1. Base equations

The data shown in Figure 7.1 were collected from several locations in the eastern US. However, the data were insufficient for directly deriving explicit equations and coefficient values that consider all of the major variables related to contouring's effect on rill-interrill erosion. The data in Figure 7.1 were assumed to represent the overall effect of contouring for the base, reference condition described in **Section 7.1.3**.

The first step in deriving the RUSLE2 contouring equations was to develop a set of equations that represent the base, reference condition. Those equations, which follow similar RUSLE1 equations, are given by:

---

[58] These farming conditions differ from current farming practices. Also, these farming practices are not typical of rangelands, surface mine reclamation, construction sites, and other conditions where ridging (contouring) is used to control rill-interrill erosion. RUSLE2 includes procedures to account for these differences.

$$p_b = a_c(s_m - s_c)^4 + p_{bm} \quad s_c < s_m \qquad [7.1]$$

$$p_b = c_c(s_c - s_m)^{1.5} + p_{bm} \quad s_m \le s_c < s_{be} \qquad [7.2]$$

$$p_b = 1 \qquad s_{be} \le s_c \qquad [7.3]$$

where: p_b = base contouring subfactor value, s_c = a scaled land steepness (sine of slope angle), s_m = the land steepness (sine of slope angle) at which $p_b = p_{bm}$, the minimum base contouring value and s_{be} = the steepness (sine of slope angle) at which the contouring subfactor reaches 1. Values for the coefficients a_c and c_c are computed from:

$$a_c = (1 - p_{bm}) / s_m^4 \qquad [7.4]$$

$$c_c = (1 - p_{bm}) / (s_{be} - s_m)^{1.5} \qquad [7.5]$$

These equations satisfy the boundary conditions that $p_b = 1$ at $s_c = 0$, $p_b = p_m$ at $s_c = s_m$, $p_b = 1$ at $s_c = s_{be}$, and the slope of equations 7.1 and 7.2 is zero at $s_c = s_m$.

7.1.3.2. Ridge height adjustments

The minimum contouring subfactor value p_{bm}, which occurs at $s = s_m$, is assumed to be a function of ridge height as (Moldenhauer and Wischmeier, 1960):

$$p_{bm} = 0.05 + 0.95\exp(-0.5512H_e) \;\; if\,(H_e > 8) : H_e = 8 \text{ inches} \qquad [7.6]$$

where: H_e = daily effective total ridge height (inches), which is the sum of the daily soil ridge height H (see **Sections 6.4.6 and 8.3.5**) and the daily effective vegetation ridge height H_{vr} (see **Section 9.2.7**). The steepness s_{bm} at which the base contouring subfactor is minimum (i.e., $p_b = p_{bm}$) is also assumed to be a function of effective ridge height as:

$$s_{bm} = 4[1 - \exp(-0.7903H_e)] + 4 \;\; if\,(H_e > 8) : H_e = 8 \text{ inches} \qquad [7.7]$$

The steepness s_{be} at which the contouring subfactor p_b becomes 1 as steepness increases is assumed to be a function of effective ridge height as:

$$s_{be} = \sin\{\tan^{-1}[(9 + 53.09H_e / 8) / 100]\} \; if\,(H_e > 8) : H_e = 8 \text{ inches} \qquad [7.8]$$

where: s_{be} = the steepness (sine of slope angle) that the contouring subfactor becomes 1. Maximum effective ridge height for equations 7.6, 7.7, and 7.8 is limited to 8 inches.[59]

---

[59] The uncertainty of contouring's erosion control effectiveness at any specific site is greater than for all other erosion control practices. Also, data for the effect of ridge height and other factors on the erosion control effectiveness of contouring are very limited for a wide range of conditions. Contouring using high ridges can be highly effective, especially in low rainfall areas, but result in very high erosion for rarely

7.1.3.3. Runoff adjustments

The minimum contouring subfactor values p_{rm} at s_m are assumed to vary directly with the ratio of runoff with the given climate, soil, and cover-management condition to the runoff for the base, reference condition as:

$$p_{rm} = p_{bm}(d_r / 4.16) \quad [7.9]$$

where: p_{rm} = the minimum contouring subfactor value adjusted for runoff, d_r = runoff depth (inches) for the 10 year-24 hour precipitation amount P_{10y24h} at the given location, soil, and cover-management condition on the day that a contouring factor value is computed, and 4.16 (inches) = runoff computed with the 10 year-24 hour storm for the base, reference condition (see **Section 2.3.7**).

The steepness at which the contouring subfactor becomes 1 for a given condition is assumed to be related to the shear stress that the runoff applies to the soil. It is computed from:

$$s_{re} = s_{be} /(d_r / 4.16)^{0.8571} \quad [7.10]$$

where: s_{re} = the runoff adjusted steepness (sine of slope angle) above which the contouring subfactor equals 1.

7.1.3.4. Steepness scaling

A scaled steepness s_c is used to compute a base contouring p_b subfactor value using equation 7.1, 7.2, or 7.3. The equation for the scaled steepness at low steepness is given by:

$$s_c = s \quad s \le s_m \quad [7.11]$$

where: s = the steepness (sine of slope angle) of the overland flow path. The scaled steepness for $s > s_m$ is given by:

$$s_c = s_{bm} + \frac{(s - s_{bm})(s_{be} - s_{bm})}{s_{re} - s_{bm}} \quad s > s_m \quad [7.12]$$

The reason that steepness used to compute a p_b value must be scaled is that the upper steepness where the contouring subfactor becomes equal to 1 varies as conditions vary from the base, reference condition.

---

occurring intense storms. The 8 inch limit in these equations was chosen based on professional judgment and experience (see **Section 7.1.5**). See the RUSLE2 User's Reference Guide for guidance on using RUSLE2 to evaluate the erosion control effectiveness of contouring (ridging).

7.1.3.5. Contouring subfactor scaling

The contouring subfactor value must also be scaled because the contouring factor value at s_m for the given condition differs from the contouring subfactor value for the base, reference conditions. The contouring subfactor value for level furrow (row) is computed from the scaling equation as:

$$p_{c0} = 1 - \frac{(1 - p_b)(1 - p_{rm})}{1 - p_{bm}} \quad if\,(p_{c0} > 1) : p_{c0} = 1 \qquad [7.13]$$

where: p_{c0} = the contouring subfactor for a zero row grade (grade along furrows separating the ridges).

7.1.3.6. Contouring subfactor limits

Contouring subfactor values computed by equation 7.13 must be within certain limits. The upper limit is that contouring subfactor values can not be greater than 1. The other limit is a lower limit assumed to be acceptable for conservation and erosion control planning. RUSLE2 must account for the possibility of an extreme storm occurring even when annual erosivity and the P_{10y24h} precipitation amounts are low. The lower limit for contouring subfactor values is computed from:

$$p_{c0,\min} = 0.05 + 0.95 \exp(-h_e) \qquad [7.14]$$

$$if\,(p_{c0} > p_{c0,\min}) : p_{c0} = p_{c0,\min} \qquad [7.15]$$

where: $p_{c0,min}$ = minimum contouring subfactor value for a given ridge height.

7.1.3.7. Adjusting for row grade

The RUSLE2 assumption, which is the same as the RUSLE1 assumption, is that contouring rapidly loses its effectiveness as row grade increases (Foster et al., 1997).

$$p_c = p_{c0} + (1 - p_{c0})(s_f / s_p)^{1/2} \qquad [7.16]$$

where: p_c = the daily contouring subfactor and s_f = grade along the furrows separating the ridges (row grade) (100·tangent of slope angle). The variable s_f/s_p is designated as the relative row grade and sp =land steepness (100·tangent of slope angle). Measured erosion on 150 ft wide plots on a 5 percent land steepness showed that the contouring subfactor values vary with row grade (McGregor et al., 1969). The observed contouring subfactor values were 0.10 and 0.39 for the ridges perfectly on the contour and ridges on a 0.3 percent row grade, respectively. Given the observed p_{c0} = 0.10 contouring subfactor value for ridges perfectly on the contour (i.e., row grade = 0), the computed contouring subfactor value from equation 7.16 is 0.32, which is slightly less than the 0.39 observed value.

7.1.4. Contouring failure

The RUSLE2 assumption is that contouring fails when the shear stress applied to the soil by runoff exceeds a critical shear stress. The contouring subfactor is set to 1 for those portions of the overland flow path where contouring failure is computed. The equations used in these computations are described in **Section 3.4.3**.

Once contouring failure occurs at a location on an overland flow path, the daily contouring subfactor remains at 1 until the next soil disturbing operation. The RUSLE2 assumption is that contouring failure results from runoff breaking through the ridges, and thus the contouring effect can be regained only after ridges are re-established to fill the breakthrough areas. The RUSLE2 procedure is that only a soil disturbing operation creates ridges that repair the ridge breakthroughs that represent contouring failure (see RUSLE2 User's Reference Guide).

7.1.5. Comments on contouring subfactor

RUSLE2 allows row grade to be input as absolute row grade or as relative row grade. In most applications, relative row grade should be used as the input for consistency with the concepts behind equation 7.16 for the effect of row grade on the contouring subfactor. Using relative row grade implicitly results in the quality of contouring being treated equally regardless of land steepness (see RUSLE2 User's Reference Guide).

RUSLE2 accurately represents the general trends of how major variables affect contouring's reduction on rill-interrill erosion. However, local conditions that can not be easily measured or visualized, especially before a storm event, greatly affect contouring's effectiveness. For example, slight and imperceptible variations in ridge height and furrow grade along the ridges greatly affect the number and locations of breakovers. Therefore, while RUSLE2 accurately represents the overall effect of contouring on rill-interrill erosion, the uncertainty in how contouring affects rill-interrill erosion on a specific site is greater than for any other major RUSLE2 variable (see RUSLE2 User's Reference Guide).

7.2. Porous barriers

7.2.1. Description of porous barriers

A porous barrier is a portion of the overland flow path that has a significantly higher hydraulic resistance than the overland flow path immediately upslope of the barrier. The RUSLE2 assumption is that runoff passes through porous barriers. That is, porous barriers do not end the overland flow path. Porous barriers include strips of dense vegetation used in rotational strip cropping; grass buffers, filter strips, and stiff grass hedges; a strip of dense vegetation left undisturbed along a channel on construction and logging sites; and fabric fences and gravel bag dams used on construction sites (see RUSLE2 User's Reference Guide).

7.2.2. Processes associated with porous barriers

The significantly increased hydraulic resistance of the porous barrier slows and ponds runoff in backwater at the upper edge of the barrier. Runoff's sediment transport capacity is greatly reduced in both the backwater and within the porous barrier. Deposition occurs if the sediment transport capacity is reduced to less than the sediment load coming into the backwater and barrier. Most of the deposition caused by porous barriers actually occurs in the backwater. The upper edge of deposited sediment and backwater advance upslope as deposition occurs in the backwater, which increases transport capacity within the backwater. Eventually the backwater becomes filled with sediment and most of the incoming sediment load is then transported into the barrier itself. However, RUSLE2 does not account for sediment accumulation within the backwater and change in sediment transport capacity as sediment accumulates in the backwater.

Runoff is assumed to pass through porous barriers. Infiltration rate within the barrier can be much higher than that on the overland flow path immediately upslope of the barrier, which reduces runoff downslope of the barriers. The high hydraulic resistance in a porous barrier can eliminate rill erosion and spread runoff within the barrier so that runoff exits the barrier as a thin uniform depth flow along the lower edge of the barrier. Spreading of the runoff reduces its erosivity immediately downslope of a porous barrier.

7.2.3. RUSLE2 equations used to describe porous barriers

The RUSLE2 equations used to compute deposition caused by porous barriers and the sediment load leaving porous barriers are described in **Sections 2.3 and 3.4**. This section describes key features of these equations.

RUSLE2 uses the same cover-management values to compute detachment within the backwater as it uses to compute detachment within the porous barrier. The RUSLE2 assumption is that detachment downslope of a porous barrier is not affected by the barrier except as the barrier affects contouring failure. RUSLE2 does not compute how increased infiltration on an overland flow path segment affects detachment on downslope segments because of reduced runoff. That is, RUSLE2 computes the same detachment, except for contouring failure, immediately downslope of a porous barrier regardless of the presence or absence of the barrier.

The conceptual basis for this assumption is that spreading the overland flow by the porous barrier reduces runoff erosivity. However, the very low sediment concentration in the runoff leaving the barrier increases runoff erosivity. Flow has greater erosivity when it has a very low sediment load in contrast to when the runoff's sediment transport capacity is nearly filled with sediment (Foster and Meyer, 1975; Foster, 1982). The RUSLE2 assumption is that these two effects on runoff erosivity offset each other.

The assumption that downslope detachment is unaffected by high infiltration on an upslope segment is obviously invalid where a porous barrier is sufficiently wide and has a sufficiently high infiltration rate to significantly reduce the runoff that leaves the barrier.

The RUSLE2 User's Reference Guide describes how to choose RUSLE2 inputs to partially represent conditions where high infiltration and reduced runoff affects downslope detachment.

RUSLE2 computes reduced runoff from segments, including those with porous barriers, having high infiltration rates. RUSLE2 computes reduced sediment yield from these segments if transport capacity is less than sediment load within the segment because of reduced runoff. Also, reduced runoff from high infiltration segments affects downslope sediment transport capacity and deposition computations. For example, computed deposition and sediment load on a concave shaped overland flow profile is affected by high infiltration and reduced runoff for an upslope segment.

RUSLE2 computes how reduced runoff caused by high infiltration within a porous barrier and runoff spreading by the barrier affects shear stress applied by runoff to the soil immediately downslope from the barrier. Contouring failure is assumed to occur if this shear stress exceeds a critical shear stress (see **Section 3.4.3**). RUSLE2 computes reduced erosion below a porous barrier where RUSLE2 computes no contouring failure below the barrier but computes contouring failure without the barrier.

Hydraulic resistance is a major variable that affects the amount of deposition caused by a porous barrier. A Manning's n value, RUSLE2's measure of hydraulic resistance, is computed as a function of retardance (see **Section 3.4.6**), which varies temporally as vegetation changes through time. All porous barriers are represented in RUSLE2 as strips of vegetation, even when the barriers are non-vegetative including fabric fences, gravel bags, and similar behaving barriers. Non-vegetative porous barriers slow runoff as do vegetative porous barriers.

Eight retardance classes are used to describe porous barriers based on the degree that a barrier slows runoff (see **Section 3.4.6** and RUSLE2 User's Reference Guide). The eighth retardance class is a special case used to describe barriers such as stiff grass hedges and silt fences that provide maximum retardance. The minimum backwater length that RUSLE2 uses for this retardance class is 3 ft, whereas no minimum backwater length is used for the other retardance classes (see **Section 3.4.4**). The maximum backwater length allowed by RUSLE2 is 15 ft for all retardance classes.

7.2.4. Effect of row grade

Runoff must pass through porous barriers for them to reduce sediment load. A ridge of soil at the upper side of porous barriers left by tillage or deposited sediment or debris collected on a fabric fence causes runoff to flow along the upper edge of the barrier and never enter the barrier if the grade along the upper edge of the barrier is too steep. The barrier acts as a flow interceptor (see **Section 7.3**) that ends the overland flow path.

Inputs used to describe porous barriers can be entered in two ways. One way is to select porous barriers from a list of supporting practices. When this input method is used, RUSLE2 requires that the relative row grade for the barrier be less than 10 percent. RUSLE2 assumes that trapping efficiency is independent of row grade for relative row

grade less than 10 percent. The RUSLE2 assumption with this input method is that runoff does not enter the barrier but runs along the upper edge of the barrier if the relative row grade along the upper edge of the barrier exceeds 10 percent. In that case, the barriers operate as a flow interceptor barrier.

The other way to input information to describe porous barriers in RUSLE2 is to divide the overland flow path into segments and enter information for each segment, including those segments used to represent the porous barriers. When this input method is used, RUSLE2 assumes that runoff enters the porous barrier regardless of the relative row grade along the upper edge of the porous barrier (see RUSLE2 User's Reference Guide).

7.2.5. Spatial variability

When the RUSLE2 input method of selecting a support practice is used to represent porous barriers, RUSLE2 assumes that multiple barriers are spaced uniformly along the overland flow path length. Also, the conditions are assumed to be the same for each barrier. When the input method of dividing the overland flow path into segments is used, each segment can be described individually and barriers can be spaced non-uniformly. Conditions are assumed to be uniform within a segment.

7.2.6. Validation of RUSLE2 computed values

7.2.6.1. Strip cropping

RUSLE2 computed values for the effect of strip cropping and narrow stiff grass hedges on sediment yield from an overland flow path were compared with measured data reported in the literature (Foster et al., 1997, see references this section). Because strip cropping data are highly variable, many more years of data and/or experimental plots and small watersheds are required to accurately evaluate strip cropping than for any other soil conservation practice. Sediment yield from strip cropping is closely related to the storm events that occur when the erodible strips are at the end of the overland flow path. Data must be recorded over a sufficiently long duration for representative storms to occur on the erodible strips in all positions along the overland flow path. Sediment yield is much less when an extreme event occurs when an erodible strip is near the upper end of the overland flow path than at the lower end of the overland flow path. Data from such a storm would indicate that strip cropping is much more effective than it actually is. Very little of the available strip cropping data are for an adequate duration. Also, much of the strip cropping data are inconsistent. In one study, erosion with a small grain in a rotation in a strip cropping system was much less than when in the same crop rotation was not in strip cropping.

Priority was given to ensuring that RUSLE2 fits strip cropping data from Wisconsin (Hays et al., 1949; Hays and Attoe,1957) and to values given in AH282 and AH537 (Wischmeier and Smith, 1965, 1978) for a base, reference condition. Strip cropping has been used extensively and highly successfully since the 1930's in the La Crosse, Wisconsin region. The support practice factor values given in AH282 and AH537 have been well accepted in conservation planning by USDA-NRCS personnel for this region. Also, the Wisconsin data seem to be of higher quality than most of the other available

data. Wischmeier and Smith (1965, 1978) and technical and scientific personnel from the USDA-Agricultural Research Service and Soil Conservation Service reviewed these same data and developed recommendations included in AH282 and 537. These values are established and accepted based on many years of field applications of the USLE.

The values in AH282 and AH537 are that strip cropping reduces sediment yield from the end of an overland flow path by 50 percent "For 4-year rotation of row crop, small grain with meadow (mixture of legume and grass hay), and 2 years of meadow. A second row crop can replace the small grain if meadow is established in it [AH537 (Wischmeier and Smith, 1978)]." The comparable RUSLE2 computed value is 0.43 for the base, reference condition of a 150 ft long, six percent steep overland flow path on a silt loam soil at Columbia, Missouri for crops and yields comparable to those represented in the data on which the AH282 and 537 values are based. The comparable measured values from research in Wisconsin are 0.42 and 0.55 (Hays et al, 1949; Hays and Attoe, 1957).

The AH282/537 values for the ratio of sediment yield with strip cropping to sediment yield without strip cropping is 0.75 "For 4-year rotation of 2 years row crop, winter grain with meadow seeding, and 1-year meadow." The RUSLE2 computed value is 0.54.

The AH282/537 values for the ratio of sediment yield with strip cropping to sediment yield without strip cropping is 1 "For alternate strips of row crop and small grain." RUSLE2 also computes a value of 1 for this condition.

7.2.6.2. Stiff grass hedges

RUSLE2 computed value of 0.25 for fraction of the incoming sediment load from a conventional, clean tilled cotton that is trapped by a stiff grass hedge at Holly Springs, MS is very close to the measured value of 0.25 (McGregor et al., 1999). RUSLE2 computes a value of 0.20 for no-till cotton upslope of the stiff grass hedge while the measured value was 0.43. The study was run for three years. The hedges were much better established and uniform in the third year of the experiment than in the first year. The fraction of the incoming sediment load that was trapped by the hedges in the third year was 0.29 and 0.33 for the conventional and no-till managements, respectively, which are close to the RUSLE2 computed values.

7.2.7. Comments on porous barriers

The RUSLE2 intent for computing how porous barriers affect erosion is for the purpose of conservation and erosion control planning where the main effects of the major variables are captured. The equations are based on well accepted hydraulic principles. The performance of porous barriers is highly dependent on how well the barriers are installed and maintained. For example, fabric fences are widely used on construction sites to control sediment leaving the site. However, very poor sediment control occurs in far too many cases because of substandard installation and/or maintenance. The actual sediment trapping of fabric in a typical field situation is much less than the sediment trapping measured in laboratory studies.

A comparable situation exists with vegetative strips that are poorly established and/or maintained. For example, non-uniform grass stands within a strip or damage caused by tillage, construction activities, or other soil disturbing operations can significantly reduce sediment trapping efficiency.

RUSLE2 does not represent the variations that result from poor installation and maintenance. RUSLE2 represents the performance of porous barriers that are installed and maintained according to specifications and inspections.

The RUSLE2 equations and input values were chosen to represent barriers that perform well in the field but less than would be measured in carefully controlled laboratory hydraulic studies.

7.3. Interceptor barriers

7.3.1. Characteristics of interceptor barriers

Interceptor barriers are topographic features that end the overland flow path. Examples of interceptor barriers represented by RUSLE2 include terraces, diversions, and small impoundments. Terraces are defined as channels on a sufficiently flat grade to cause deposition while diversions are channels are on a sufficiently steep grade that deposition does not occur in them but are not on such a steep grade that erosion occurs in them. Impoundments are water bodies where flow velocities are almost negligible. RUSLE2 represents typical impoundments comparable to those used with impoundment terraces in farm fields [e.g., parallel tile outlet (PTO) terraces] and small sediment basins used on construction sites.

Interceptor barriers reduce erosion by cutting overland flow path length and causing deposition. RUSLE2 also computes how deposition by interceptor barriers affects sediment characteristics. RUSLE2 does not compute ephemeral gully erosion that occurs in concentrated flow areas (channels) (Foster, 1985).

7.3.2. Channels (Terraces/diversions)

7.3.2.1. Deposition and sediment load equations

Deposition occurs in a channel when the incoming sediment load exceeds sediment transport capacity of flow in the channel (Foster, 1982; Foster et al., 1980a). Deposition rate is computed in RUSLE2 using (Renard and Foster, 1983):

$$D_{p(k)} = f_{(k)}\left(\frac{\phi_{(k)}}{1+\phi_{(k)}}\right)\left(\frac{dT_c}{dx} - g_o\right) \quad dT_c / dx < g_o \qquad [7.17]$$

$$D_{p(k)} = 0 \quad dT_c / dx \geq g_o \qquad [7.18]$$

$$\phi_{(k)} = 400000 V_{f(k)} / q_o \qquad [7.19]$$

where: $D_{p(k)}$ = deposition rate for the *kth* particle class [mass/(unit channel length·time)], $f_{(k)}$ = fraction, based on mass, of the total incoming sediment load g_0 (mass/unit channel length·time) from the overland flow area made up of the *kth* particle class, T_c = sediment transport capacity of the flow in the channel (mass/time), x = distance along the channel $V_{f(k)}$ = the fall velocity (ft/sec) of the *kth* sediment particle class, and q_o = the discharge rate at the end of the overland flow path (ft^3/sec per ft channel length). Equation 7.17 is derived from equation 2.16 and the assumptions of uniform channel grade, uniform sediment input from the overland flow area along the channel length, incoming sediment load for each particle class exceeds the sediment transport capacity in the channel for that particle class, and channel sediment transport capacity for each particle is proportional to the distribution (mass basis) of the incoming sediment load.

The change in sediment load with distance along the channel is computed using:

$$dT_c / dx = 450 s_{ch}^{1.16} q_0 \qquad [7.20]$$

where: T_c = transport capacity (lbs_m/sec), s_{ch} = grade (steepness) of the channel (sine of channel slope angle), and x = distance along the channel (ft). Equation 7.20 was derived from the assumptions that transport capacity is directly proportional to the 3/2 power of shear stress applied to the channel boundary by the flow and that Manning's equation is used to compute hydraulic radius for flow in the channel (Foster and Meyer, 1975; Foster, 1982; Foster et al., 1980). The channel's hydraulic roughness is assumed to be that of deposited sediment that covers soil surface roughness, surface residue, and standing vegetation. The effect of standing live or dead vegetation on deposition in channels is not considered in RUSLE2 because most of the deposition is assumed to occur when little vegetation is present, such as at seedbed time when crops are planted. The 450 coefficient value in equation 7.20 was determined by calibrating RUSLE2 to compute values similar to those given by the RUSLE1 sediment delivery ratio equation, which was empirically derived from field data [AH703(Renard, 1997); Foster et al., 1997; Foster and Ferreira, 1981; Foster and Highfill, 1983).

Equation 7.17 and its companion equations compute a uniform deposition rate along the channel. The sediment leaving the channel is computed with:

$$g_{ch(k)} = g_{o(k)} - D_{p(k)} \qquad [7.21]$$

where: $g_{ch(k)}$ = the sediment load (mass/unit channel length·time) leaving the end of the channel for the *kth* particle class. The sediment load leaving the channel expressed as the ratio of sediment load at the end of the channel to unit drainage area for the channel is computed with:

$$A_{ch(k)} = g_{ch(k)} / \lambda_o \qquad [7.22]$$

where: $A_{ch(k)}$ = the sediment load for the *kth* particle class leaving the end of the channel expressed as mass/time per unit drainage area and λ_o = the length of the overland flow path that discharges into the channel. The sediment delivery ratio for the channel for the *kth* particle class is given by:

$$\omega_{(k)} = 1 - D_{p(k)} / g_{o(k)} \quad [7.23]$$

where: $\omega_{ch(k)}$ = sediment delivery ratio for a channel for the *kth* sediment particle class. Total sediment load is computed by summing the sediment load values for the five RUSLE2 particle classes (see **Section 4.7**).

7.3.2.2. Comments on channels

When flow interceptors are represented in RUSLE2 as a support practice, the spacing between flow interceptors is the same for all flow interceptors represented by the support practice. However, non-uniform spacing among flow interceptors can be represented by manually entering appropriate spacing values. Similarly, the grade is assumed the same for all channels when flow interceptors are represented as a support practice. However, separate grade values for each channel can be entered in RUSLE2.

RUSLE2 requires that a representative channel grade be chosen for channels on a non-uniform grade. This limitation can be of consequence for parallel terraces where grade varies along the channel. In most of these situations, channel grade is flattest at the upper channel end with grade increasing along the channel. RUSLE2's estimates for deposition for these conditions are less accurate than for uniform grade channels. A grade flatter than the average channel grade for its length is the appropriate input grade.

RUSLE2 does not represent channels where sediment inflow varies along the channel length. Not many field situations occur where this limitation is of consequence.

The RUSLE2 equations used to compute deposition in channels are based on commonly used equations for channel hydraulics. However, RUSLE2 is a conservation and erosion control planning tool, not a hydraulic design tool. Appropriate hydraulic equations should be used to design the channels represented in RUSLE2. Channels are usually designed to accommodate runoff rate from a particular design storm under particular soil and cover conditions whereas most conservation and erosion control planning is based on average annual erosion rates for the range of cover-management conditions expected over the time period being represented in the RUSLE2 computation. See the RUSLE2 User's Reference Guide for information on the types of channels represented by RUSLE2.

7.3.3. Impoundments

7.3.3.1. Sediment delivery ratio equation

The RUSLE2 assumption is that sediment transport capacity in impoundments is essentially zero. Impoundments are treated as a fixed length settling basin in RUSLE2. The RUSLE2 equation for computing sediment deliver ratio for an impoundment is:

$$\omega_{(k)} = \exp(-c_i V_{f(k)}) \quad [7.24]$$

where: $\omega_{i(k)}$ = the sediment delivery ratio for an impoundment for the *kth* sediment particle class. Sediment delivery ratio is the ratio of sediment mass leaving the sediment basin to incoming sediment mass.

A 10000 $(ft/sec)^{-1}$ value for the coefficient c_i for a base reference silt loam soil was determined by fitting equation 7.24 to experimental data for impoundments used in parallel tile outlet terraces (Laflen et al., 1972). The average trapping efficiency of those impoundments was 94 percent. Literature reporting measured trapping efficiency of sediment basins on construction sites was reviewed during the development of RUSLE1.06 (Toy and Foster, 2000; Bonta and Hamon, 1980, Fennessey and Jarret, 1997; USEPA, 1976 a, 1976b). The trapping efficiency of these basins is comparable to that for impoundment terraces when the sediment basins are well designed, constructed, and maintained and perform at maximum efficiency. Also, no deposition is assumed to occur between the point that the sediment is detached and where the sediment reaches the impoundment. If deposition occurs along the overland flow path upstream of the impoundment, trapping efficiency will be less than computed by RUSLE2 (see **Section 7.3.3.2**).

Many sediment basins on construction sites do not perform at maximum efficiency because of poor design, the basins being partly filled with sediment, and water/sediment chemistry that keeps fine sediments highly dispersed.

The RUSLE2 user can select a base sediment delivery ratio for the reference silt loam soil texture to accommodate trapping efficiency variations by specific site. The c_i coefficient values used in RUSLE2 for a range of sediment delivery ratios are given in Table 7.1.

Table 7.1. Values for the coefficient c_i used to compute sediment delivery ratio for deposition of sediment from reference silt loam soil in impoundments.

Sediment trapping ratio (%)	c_i $(ft/sec)^{-1}$
6.4	10000 (1)
10	5900
15	3500
20	2300
25	1700

Note (1): Coefficient value determined by fitting RUSLE2 equation to experimental data for impoundment terraces

7.3.3.2. Effect of incoming sediment characteristics

RUSLE2 computes trapping efficiency for impoundments solely as a function of incoming sediment characteristics. RUSLE2 does not consider basin geometry or flow withdrawn characteristics in these computations. However, RUSLE2 computes sediment delivery ratios as a function of texture of the soil that produces the sediment, upslope deposition amount, and the feature that produces the upslope deposition as shown in Table 7.2 because these variables affect sediment characteristics. As a point of reference, the RUSLE2 computed sediment characteristics leaving the uniform overland flow path represented in Table 7.2 are the same as the sediment characteristics at the point of detachment because

RUSLE2 computed no local deposition for this particular overland flow path.

Table 7.2. RUSLE2 computed sediment delivery ratio for sediment basin in various flow sequence.

	Flow path			
Soil texture	uniform overland flow path into basin	steep flow segment onto low steepness segment into basin	uniform flow path into grass strip into basin	uniform overland flow path into basin into basin
silt loam	0.064	0.469	0.317	0.678
silt	0.068	0.157	0.101	0.216
silty clay	0.119	0.612	0.581	0.825
clay	0.105	0.741	0.905	0.902
loamy sand	0.014	0.125	0.531	0.890
sand	0.009	0.127	0.333	0.900

The primary particle distribution of the soil producing the sediment does not accurately indicate the RUSLE2 computed sediment delivery ratio for impoundments. Sediment is eroded as a mixture of primary particles and aggregates (see **Section 4.7**). The size and density distributions of the sediment do not parallel the distribution of primary particles in the soil. Clay is assumed in RUSLE2 to be a bonding agent that influences aggregate sizes and densities and the mass distribution between the particle classes, especially the small and large aggregates. Consequently, sediment eroded from high clay soils has a large portion of the sediment in aggregates of increased size. Conversely, soils very high in silt produce poorly aggregated sediment that is almost entirely in small-sized primary silt particles that are not rapidly deposited. Soils high in sand produce poorly aggregated sediment that is almost entirely in sand-sized primarily particles that are readily deposited. Consequently, the sediment delivery ratio computed for sediment eroded from high clay soils is not proportionally higher than that for silt loam soils when no upslope or local deposition occurs. **Expecting RUSLE2 computed sediment delivery ratio values for an impoundment to be directly related to the primary particle distribution of either the soil or sediment is a very serious error.**

As illustrated in Table 7.2, RUSLE2 computed sediment delivery ratio values for impoundments also vary with the type of upslope feature that causes deposition. Even though the sediment delivery ratios for the overland flow path with a low steepness segment, a grass strip, and a sediment basin are comparable, the characteristics of the sediment leaving each of these flow paths and entering a sediment basin are quite different because of differences in upslope erosion and deposition processes. RUSLE2 computes a relatively high interrill erosion rate for the overland flow path that has the low steepness segment in comparison to the one with a dense grass strip at the end of the overland flow path. Interrill erosion is very low in the grass strip, which adds very little sediment to the sediment load in the grass strip in contrast to interrill erosion adding sediment to the sediment load on the low steepness segment. The sediment leaving the grass strip is finer than the sediment leaving the low steepness segment. Consequently, the RUSLE2 computed sediment delivery ratio values for impoundments are generally larger for the grass strip overland flow path than for the low steepness segment overland flow path. Sediment delivery ratios for sediment eroded from high silt soils are not affected as much as for the other soil textures because sediment eroded from the high silt soils is poorly aggregated and has a very narrow size range in a relative small size range.

Sediment delivery ratio values are high for a basin downstream of another sediment basin. That is, much less sediment trapping occurs in the second basin than in the first basin, except for the sediment eroded from the high silt soils. The upstream sediment basin removes almost all of the sediment that is easily deposited.

7.3.3.3. Design

RUSLE2 should not be used to design sediment basins unless regulations explicitly state that RUSLE2 can be used. The RUSLE2 values computed for impoundments are for the purpose of conservation and erosion control planning. The accuracy of RUSLE2's computations for sediment trapping by small impoundments is comparable to that for other erosion and sediment control practices. The specific hydraulic and sediment trapping performance of impoundments depends on many complex, interactive variables. Accepted design procedures should be used to design impoundments (e.g., see Haan et al., 1994).

7.3.3.4. Comments

RUSLE2 results for sediment trapping by impoundments must be interpreted very carefully. The flow path up to the sediment basin must be properly represented. For example, RUSLE2 seriously under-computes sediment delivery by an impoundment if a uniform steepness overland flow path is assumed when in fact the overland flow path has a segment at the lower end of the overland flow path that causes a high degree of deposition. Likewise, when RUSLE2 computed values are compared to research and field measurements, the RUSLE2 inputs must be very carefully selected to accurately represent measurement conditions. The characteristics of the sediment entering the experimental basin must match those assumed in RUSLE2. For example, as Table 7.2 shows, if upstream deposition is not considered, the sediment delivery values computed by RUSLE2 will be much less than is measured.

Another consideration is that RUSLE2 does not represent basin geometry, degree that the basin is filled, and other factors. The assumption in RUSLE2 is that the basin is well designed and maintained. Standards and specifications for design, construction, and maintenance of impoundments should be a principal tool used to ensure expected results.

7.3.4. Hydraulic flow paths

Simple channels and impoundments can be combined into simple hydraulic flow paths. RUSLE2 can represent an overland flow area discharging into a channel from a single side and the channel in turn discharging into an impoundment or a series of impoundments. Non-uniform conditions along the channel can not be represented. RUSLE2 can not represent a channel on a particular grade discharging into a channel on a different grade. That is, RUSLE2 can not represent channels in series nor can RUSLE2 represent an impoundment discharging into a channel. However, RUSLE2 can represent overland areas discharging into a channel from both sides. Also, RUSLE2 can represent an overland flow area discharging directly into an impoundment without involving a channel. (See the RUSLE2 User's Reference Guide)

7.3.5. Benefit of deposition caused by porous barriers and flow interceptors

7.3.5.1. Concepts

Deposited sediment trapped on the hillslope by porous barriers and by flow interceptors including channels/impoundments (e.g., terraces) is assumed to be a soil conservation benefit. Landscape quality is degraded less when sediment is retained by deposition on the hillslope.

Partial credit is taken for deposition on the hillslope as soil saved based on the location of the deposition along the overland flow path (see Section **2.3.10.4)**. The credit taken for deposition caused by flow interceptors is less than the credit taken for porous barriers because most flow interceptors are much more permanent and the deposition more localized than with porous barriers. Porous barriers such as grass strips are assumed to be periodically removed and reestablished in new locations. An increased portion of the hillslope benefits from deposition with these barriers than occurs with flow interceptor such as impoundment-type terraces. Full credit for deposition as soil saved is taken for rotational strip cropping (see Section **2.3.10.4**).

Partial credit is given to deposition as soil saved with flow interceptors (e.g., channels/impoundments in farm fields) because the deposition is localized although the deposited sediment is spread over a significant-sized area on either side of channels/impoundments in farm fields. The absolute size of this area is the same regardless of channel/impoundment spacing. Consequently, the fraction of the total field area over which the sediment is spread becomes less as channel/impoundment spacing increases.

Deposition near the end of the original overland flow path before porous/interceptor barriers were placed is assumed to be less valuable for maintaining landscape quality than sediment deposited near the upper end of the overland flow path. This concept is consistent with that used to compute the benefit of deposition on the overland flow area (see **Section 2.3.10.4**).

Deposition is a selective process that enriches the deposited sediment in coarse particles. Even though coarse sediment is deposited first, clay and silt primary particles are deposited because sediment is assumed to be a mixture of primary particles and aggregates so that fine primary particles are deposited along with sand particles (see **Section 4.7.5**). The assumption that deposition on overland flow areas is predominantly sand is erroneous. Thus, deposition is assumed to be beneficial because deposited sediment includes clay and silt particles even though the deposited sediment is partially enriched in sand.

7.3.5.2. Equations for benefit of deposition caused by flow interceptors

The RUSLE2 equation for the benefit of deposition by a flow interceptor is:

$$b_{s(i)} = 0.45 \exp[-0.011(\delta_{s(i)} - 100)] \quad \delta_{s(i)} \geq 100 \text{ ft} \qquad [7.25]$$

$$b_{s(i)} = 0.45 \quad \delta_{s(i)} < 100\,\text{ft} \qquad [7.26]$$

where: $b_{s(i)}$ = the fraction of the deposition that is credited as soil saved for the *ith* flow interceptor and δ_s = flow interceptor spacing (ft). The credit $b_{p(i)}$ for deposition as affected by the *ith* flow interceptor location along the original overland flow path is computed with:

$$b_{p(i)} = 1 - (\lambda_{s(i)} / \lambda_o)^{1.5} \qquad [7.27]$$

where: $\lambda_{s(i)}$ = distance from the origin of overland flow for the original overland flow path to the *ith* flow interceptor and λ_o = the overland flow path length without flow interceptors. The conservation planning sediment load (see **Section 2.3.10.4**) for each channel is computed from:

$$g_{cp(i)} = g_{o(i)}[1 - (b_{s(i)} + 0.2b_{p(i)})(1 - \omega_{(i)})] \qquad [7.28]$$

where: $g_{cp(i)}$ = the conservation planning sediment load per unit channel length for the *ith* channel, the $g_{o(i)}$ = the sediment load for conservation planning from the overland flow area immediately above the *jth* channel, and ω = sediment delivery ratio. The conservation planning soil loss in term of mass per unit area for the area represented by the overland flow path without channels is:

$$A_{cp} = \left(\sum_{i=1}^{J} g_{cp(i)} \right) \Big/ \lambda_o \qquad [7.29]$$

where: A_{cp} = the conservation planning soil loss (mass/area) for the area represented by λ_o and i = the index for each flow interceptor along the original overland flow path, and J = number of flow interceptors.

7.4. Subsurface drainage

The effect of subfactor drainage on detachment is represented by the subsurface drainage subfactor p_d in equation 2.10.[60] In general, research has shown that subsurface drainage reduces rill-interrill erosion by approximately 40 percent (Bengston and Sabbage, 1988; Formanek et al., 1987; Schwab and Fouss, 1967; Schwab, 1976; Skaggs et al., 1982). The reduction is caused by reduced runoff and an increased vegetation production (yield) level. The input value for production (yield) level in vegetation descriptions should reflect production level under subsurface drained conditions. RUSLE2 does not adjust production (yield) level as a function of environmental inputs.

---

[60] The effect of subsurface drainage on runoff is discussed in **Section 3.3.1.2.4**.

The runoff effect on erosion with subsurface drainage is assumed to be same as the soil erodibility factor being a function of a soil's runoff potential. Therefore, equation 4.9, the permeability subfactor equation used to compute soil erodibility factor values, is used to compute how subsurface drainage affects detachment. The subsurface drainage subfactor is computed as:

$$p_d = K_d / K_u \quad if\,(p_d < 0.2) : p_d = 0.2 \qquad [7.30]$$

where: K_d and K_u = soil erodibility factors (US customary units) for the drained and undrained conditions, respectively (see **Section 4.1**). A minimum value of 0.2 is set for the subsurface drainage subfactor. A base soil erodibility factor value without the permeability subfactor is computed as:

$$K_b = K_u - 0.025(P_{ru} - 3) \qquad [7.31]$$

where: K_b = a base soil erodibility factor value (US customary units) computed without the permeability subfactor and P_{ru} = the soil profile permeability class for the undrained condition. The soil erodibility factor with subsurface drainage is computed with:

$$K_d = K_b + 0.025(P_{rd} - 3) \qquad [7.32]$$

where: P_{rd} = the soil profile permeability class for the drained condition.

Hydrologic soil group (see **Section 3.3.1 and** RUSLE2 User's Reference Guide) used in NRCS soil survey descriptions is used as the RUSLE2 input to describe how subsurface drainage affects soil profile permeability class. The RUSLE2 relationship between hydrologic soil group and the soil profile permeability class is given in Table 7.3.

Table 7.3. Relation between hydroligc soil groups and permeabiltiy classes.

Hydrologic soil group	Permeability class
A	1
B	2.67
C	4.33
D	6

RUSLE2 computed subsurface drainage subfactor values are shown in Table 7.4. As expected, subsurface drainage reduces the subsurface drainage subfactor the greatest when subsurface drainage causes the greatest change in hydrologic soil group from D to A in contrast to a change from D to C. The erosion reduction is also related to the soil erodibility (K factor) value. The subsurface drainage subfactor reduction is greatest when soil erodibility factor values are low. This effect results from the additive equation form used to compute soil erodibility factor values (See **Section 4.1.1**). Location has only a slight effect on the RUSLE2 subsurface drainage subfactor and probably should be greater than is computed by RUSLE2. However, the values computed by RUSLE2 are considered adequate for conservation and erosion control planning. Other erosion estimation procedures can be used when increased accuracy is desired (Skaggs et al., 1982).

Table 7.4. Subsurface drainage subfactor values as affected by soil erodibility factor value (US customary units) for undrained soil condition and for a change in hydrologic soil group by hydrologic soil group.

	subsurface drainage subfactor p_d			
Location	K = 0.20 D to A	K = 0.20 D to C	K = 0.30 D to A	K = 0.55 D to A
Ft Wayne, IN	0.38	0.83	0.58	0.77
Raleigh, NC	0.38	0.78	0.57	0.76
Jackson, MS	0.38	0.75	0.60	0.77

7.5. Irrigation

RUSLE2 computes how irrigation affects rill-interrill erosion caused by precipitation, but RUSLE2 does not compute erosion caused by water drop impact and surface runoff directly produced by the applied irrigation water. The increase soil moisture from irrigation affects rill-interrill erosion by precipitation during the irrigation period because of increased soil erodibility, increased biomass decomposition, decreased soil surface roughness and ridge height, and increased vegetation production (yield). The effect of irrigation on production (yield) level is accounted for by inputting yield values appropriate for production under irrigated conditions. RUSLE2 does not adjust production (yield) level as a function of environmental inputs.

7.5.1. Effect on soil erodibility

The effect of increased soil moisture on soil erodibility during the irrigation period is computed using equation 4.14 that computes temporal (daily) values for the soil erodibility factor. This equation is modified by adding the daily amount of water added by irrigation to the daily precitation amount as:

$$K_{(j)} / K_n = 0.591 + 0.732[(P_{(j)} + I_{(j)}) / 0.123] - 0.324(T_{(j)} / 62.8) \qquad [7.33]$$

$$If\,(K_{(j)} / K_n) > 2.0 \quad \text{then} \quad (K_{(j)} / K_n) = 2.0$$

$$If\,(K_{(j)} / K_n) < 0.4 \quad \text{then} \quad (K_{(j)} / K_n) = 0.4$$

where: $K_{(j)}$= the soil erodibility factor on the *jth* day, K_n = the soil erodibility factor value computed with a RUSLE2 soil erodibility nomograph for the frost free period defined as the period that average daily temperature $T_{(j)}$ is above 40 ^{o}F, 62.8 = the average temperature during the frost free period (^{o}F), $P_{(j)}$ = daily precipitation (inches), $I_{(j)}$ = average daily water added by irrigation (inches), and 0.123 = average daily precipitation during the frost free period (inches).

The average daily water added by irrigation on the *jth* day is computed from:

$$I_{(j)} = V_{w(j)} - P_{(j)} \;\; if\,(I_{(j)} < 0) : I_{(j)} = 0 \qquad [7.34]$$

where: $V_{w(j)}$ = consumption use (inches) by the vegetation on the *jth* day (Schwab et al., 1966). Plant consumption use values are input for the vegetation descriptions that represent irrigated conditions.

7.5.2. Effect on soil surface roughness, ridge height, and decomposition

The daily amount of water added by irrigation is added to the daily precipitation amount to compute the effect of irrigation on soil surface roughness (see **Section 6.3.6** and equation 6.30), ridge height (see **Section 6.4.6** and equation 6.43), and decomposition (see **Section 10.3.1** and equation 10.5).

7.5.3. Effect on vegetation

Individual vegetation descriptions must be created to describe vegetation under irrigated conditions. These descriptions include values for consumptive water use that are a function of the soil properties and location and location where the RSULE2 computation is being made. Figure 7.2 illustrative consumptive use values for a particular corn crop grown at Lincoln, Nebraska.

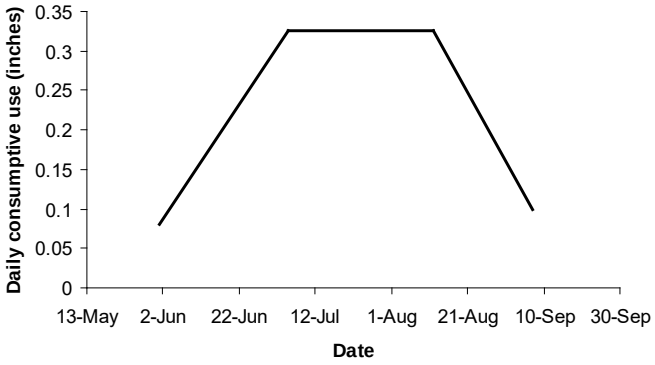

Figure 7.2. Daily consumptive water use for a 120 day corn crop grown at Lincoln, Nebraska.

The input yield for the vegetation description is the yield expected for the consumptive use water values entered because RUSLE2 does not compute how environmental conditions affect yield. RUSLE2 adjusts consumptive use values in its yield adjustment procedures directly in proportion to live above ground biomass (see **Section 9.3**).

7.6. List of symbols

a_c = coefficient used to compute values for base contouring subfactor values

$A_{ch(k)}$ = sediment load for *kth* particle class leaving end of the channel (mass/ unit drainage area·time)

A_{cp} = conservation planning soil loss for the area having channels (mass/area)

$b_{p(i)}$ = deposition credit as affected by the *ith* flow interceptor location along the original overland flow path

$b_{s(i)}$ = fraction of the deposition that is credited as soil saved for the *ith* flow interceptor

c_c = coefficient used to compute values for base contouring subfactor values

c_i = coefficient used to sediment delivery ratio in an impoundment for base reference silt loam soil

d_r = runoff depth for P_{10y24h} storm (inches)

$D_{p(k)}$ = deposition rate for *kth* sediment class (mass/unit channel length·time)

$f_{(k)}$ = mass fraction of the incoming sediment load g_0 from the overland flow area made up of *kth* sediment class

$g_{ch(k)}$ = sediment load leaving end of the channel for *kth* particle class (mass/unit channel length·time)

$g_{cp(i)}$ = conservation planning sediment load for the *jth* channel (mass/unit channel length)

g_o =total incoming sediment load from overland flow area (mass/unit channel length·time)

$g_{o(k)}$ = incoming sediment load from overland flow area (mass/unit channel length·time)

$g_{o(i)}$ = sediment load for conservation planning from overland area immediately above the *jth* channel (mass/unit channel length·time)

H = daily soil ridge height (inches)

H_e = daily effective total ridge height, which is sum of soil ridge height and effective vegetation ridge height (inches)

H_{vr} = daily effective vegetation ridge height (inches)

I_j = average water added by irrigation on *jth* day (length)

J = number of flow interceptors along an overland flow path

K_b = base soil erodibility factor value computed without the permeability subfactor (US customary units)

K_d = soil erodibility factor for drained condition (US customary units)

K_j = soil erodibility factor on the *jth* day (US customary units)

K_n = soil erodibility factor computed with a RUSLE2 soil erodibility nomograph for frost free period (US customary units)

K_u = soil erodibility factor for undrained condition (US customary units)

p_b = base contouring subfactor value

p_{bm} = minimum base contouring subfactor value

p_c = the daily contouring subfactor

p_{c0} = contouring subfactor for a zero row grade

$p_{c0,min}$ = minimum contouring subfactor value for a given ridge height

p_d = subsurface drainage subfactor

p_{rm} = minimum contouring subfactor value adjusted for runoff

P_j = daily precipitation (length)

P_{rd} = the soil profile permeability class for the drained condition

P_{ru} = the soil profile permeability class for the undrained condition

P_{10y24h} = 10 year-24 hour precipitation amount (length)

q_o = discharge rate at end of the overland flow path (volume/ unit channel length·time)

s = overland flow path steepness (sine of slope angle)

s_{be} = land steepness at which the contouring subfactor reaches 1 (sine of slope angle)

s_{bm} = land steepness at which contouring subfactor value is minimum (sine of slope angle)

s_c = scaled land steepness (sine of slope angle)

s_{ch} = grade of the channel (sine of channel angle with horizontal)

s_f = grade along the furrows separating the ridges (row grade) (100 time tangent of slope angle)

s_f/s_p = relative row grade

s_m = land steepness at which $p_b = p_{bm}$ (sine of slope angle)

s_p = land steepness (100 time tangent of slope angle)

s_{re} = runoff adjusted land steepness above which contouring subfactor equals 1 (sine of slope angle)

T_c = total sediment transport capacity for all sediment classes of the flow in the channel (mass/time)

$V_{w(j)}$ = daily consumption watercuse by vegetation (length)

$V_{f(k)}$ = fall velocity of *kth* sediment class (length/time)

x = distance along the channel (length)

$\delta_{s(i)}$ = *ith* flow interceptor spacing (feet)

λ_o = overland flow path length without flow interceptors (length)

$\lambda_{s(i)}$ = distance from origin of overland flow for the original overland flow path to the *ith* flow interceptor (length)

$\phi_{(k)}$ = a deposition coefficient for the *kth* sediment class ($length^{-1}$)

$\omega_{(k)}$ = sediment delivery ratio for *kth* sediment class

$\omega_{(i)}$ = total sediment delivery ratio for the *ith* flow interceptor

Indices

i – flow interceptor

j - day

k – sediment class

8. OPERATIONS

A RUSLE2 operation is an event that changes vegetation, residue, or soil conditions. RUSLE2 uses a set of rules and 10 processes to represent how operations affect rill and interrill erosion (see the RUSLE2 User's Reference Guide). RUSLE2 computes erosion based on user supplied descriptions of the variables that affect rill-interrill erosion. For example, RUSLE2 does not use simulation modeling to compute how environmental conditions affect vegetation. This section discusses the RUSLE2 equations used to describe how operations affect vegetation, residue, and soil variables.

8.1. Effect on vegetation

RUSLE2 uses **begin growth**, **kill vegetation**, and **remove live vegetation processes** to describe how operations affect vegetation variables.

8.1.1. Begin growth

The **begin growth** process tells RUSLE2 to stop using data in the current vegetation description and start using data from another vegetation description. The change occurs on the date of the operation that uses the **begin growth** process (See RUSLE2 User's Reference Guide).

RUSLE2 uses only a single vegetation description on any particular date. RUSLE2 does not combine data from multiple vegetation descriptions to represent a composite of vegetations having different properties. For example, a single vegetation description is used to describe a rangeland plant community that involves multiple plant types such as shrubs that provide an over-story and grasses that provide an under-story under the shrubs with open space between the individual shrub-grass clumps.

8.1.2. Kill vegetation

The **kill vegetation** process transfers the biomass (dry mass basis) of live vegetation to the dead standing residue pool and transfers live root biomass to the dead root biomass pool in the soil. Both the standing residue and dead root biomass pools disappear by daily decomposition.

8.1.3. Remove live vegetation

The purpose of the **remove live vegetation** process is to determine the amount of residue left by a field operation like a hay harvest that removes live biomass and leaves both standing and surface residue. The standing and surface residue biomass left by a remove live vegetation process is computed as:

$$\Delta B_{tr} = f_{tl}(f_{lr} B_{al}) \quad [8.1]$$

$$\Delta B_{sr} = f_{sl}(f_{lr} B_{al}) \quad [8.2]$$

where: ΔB_{tr} = the biomass left as standing residue that is added to the existing standing biomass pool, $f_{lr}B_{al}$ = the live biomass that is affected by the operation, f_{tl} = the fraction of the affected biomass that is left as standing residue, f_{lr} = the fraction of the above ground live biomass that is affected by the operation, B_{al} = existing live vegetation biomass, ΔB_{sr} = the biomass left as surface residue that is added to the existing surface residue biomass pool, and f_{sl} = the fraction of the affected biomass that is left as surface residue. These residue biomass values are added to the existing biomass values in the respective residue pools.

The amount of live aboveground biomass left after a remove live biomass process is computed from:

$$B_{al} = (1 - f_{lr})B_{alp} \qquad [8.3]$$

where: Bal = the mass (dry basis) of the above bround live biomass that is left after the operation and Balp = the mass (dry basis) of the above bround live biomass that exists immediately before the operation.

8.2. Effect on residue/dead roots

RUSLE2 tracks the three residue pools of standing residue, surface residue, and buried residue. Operations that include a **flatten standing residue** process transfer biomass from the standing residue pool to the surface residue pool. Operations that include a **disturb soil** process bury transfer surface residue to the buried residue pool and transfers buried residue to the surface residue pool. RUSLE2 rules are that standing residue can not be buried without first being flattened and live above ground biomass can not be flattened or buried without first being killed (i.e., transferred from the live above ground biomass pool to the standing residue pool).

8.2.1. Flatten standing residue

The **flatten standing residue** process transfers biomass from the standing residue pool to the surface residue pool using:

$$\Delta B_{tr} = f_f B_{tr} \qquad [8.4]$$

where: f_f = the fraction of the existing standing residue that is flattened (i.e., added to the surface biomass pool).[61] The standing residue biomass pool after the operation is computed as:

---

[61] Flattening, burial, and resurfacing ratios are based on mass, not portion of the soil surface covered (see RUSLE2 User's Reference Guide).

$$B_{tr} = B_{trp}(1 - f_f) \quad [8.5]$$

where: B_{tr} = mass (dry basis) of the standing residue immediately after the operation and B_{trp} = the mass (dry basis) that existed immediately before the operation.

8.2.2. Burial of surface residue

Burial of surface residue is the transfer of biomass from the surface residue pool to the buried residue pool. The amount of surface residue that is buried is computed by:

$$\Delta B_{sr} = f_b B_{sr} \quad [8.6]$$

where: ΔB_{sr} = the mass of the surface residue that is transferred to the buried residue pool and f_b = the fraction of the surface residue that is buried.

The surface residue mass is computed by (Wagner and Nelson, 1995):

$$B_{sr} = (B_{trp} f_f + B_{srp})(1 - f_b) + B_{brp} f_u \quad [8.7]$$

where: B_{sr} = the surface residue mass (dry basis) immediately after the operation, B_{srp} = the surface mass immediately before the operation, f_u = the fraction of the buried residue mass that is resurfaced and B_{brp} is the amount of buried biomass in the soil disturbance depth immediately before the operation. Note that the surface residue mass in equation 8.7 is the sum of the existing surface residue mass plus the mass added by flattening of standing residue and the mass of buried residue that is resurfaced.

8.2.3. Resurfacing of buried residue

The mass of buried residue that is resurfaced by the operation is computed from:

$$\Delta B_u = f_u B_{br} \quad [8.8]$$

where: ΔB_u = residue that is resurfaced from soil disturbance depth, f_u = the resurfacing ratio, and B_{br} = the mass of buried residue in the soil disturbance depth. RUSLE2 does not consider the resurfacing of dead roots.

8.2.4. Determining values for the flattening, burial, and resurfacing ratios

8.2.4.1. Base reference values

A single data point can be used to determine a value for the flattening ratio. However, equation 8.7 involves the two unknowns of burial and resurfacing ratios, which requires at least two data points to determine values for these two ratios. The proper data for determining values for these ratios is where the same operation is repeated multiple times, preferably at least four times. Only two data sets were found that meet this requirement (Brown et al., 1992; Wagner and Nelson, 1995) and even then the (Brown et al., 1992) data set did not include standing residue. Most data previously used to

determine burial ratio values are not usable because they are from situations where a particular operation was used a single time.

Base reference values for the flattening ratio were determined by fitting equation 8.5 to observed data reported by (Wagner and Nelson, 1995). Values for the burial and resurfacing ratios were determined by fitting equation 8.7 to observed data reported by (Brown et al., 1992; Wagner and Nelson, 1995). Surface residue biomass values were estimated for the (Brown et al., 1992) data from measured surface residue cover values using equation 10.1 that estimates surface cover as a function of surface biomass (see **Section 10.2**).

The minimization function that was minimized to fit equations 8.5 and 8.7 to measured data to determine flattening, burial, and resurfacing ratio values is:

$$\delta = \left\{ \sum_{n=1}^{N} \left[\ln(y_{e(n)} - \ln(y_{o(n)} \right]^2 \right\} \Big/ N \qquad [8.9]$$

where: δ = the function that is minimized, $y_{e(n)}$ = estimated value for the *nth* data point, $y_{o(n)}$ = observed value for the *nth* data point, and N = number of observations. A minimization function using logarithms rather than absolute values gives a more uniform relative error among the observations in comparison to a minimization function that uses absolute values. A minimization function using absolutes values gives flattening, burial, and resurfacing ratio values that are biased to the large surface biomass values. Equations 8.5 and 8.7 were fitted by the soil disturbing implement types represented in the observed data. The flattening, burial, and resurfacing ratio values obtained by fitting equations 8.5 and 8.7 were used to guide assign values in the RUSLE2 core database (see the RUSLE2 User's Reference Guide).

8.2.4.2. Effect of soil disturbance depth on residue burial

The input value for burial ratio is for a reference depth, which is assumed to the manufacturer recommended or normal operating depth for the implement, machine, tool, or other residue burial process.

The effect of operation depth (i.e., soil disturbance depth) on the residue burial ratio is computed using:

$$\alpha_d = [1 - (1 - y_d / y_m)^{2.7}] / [1 - (1 - y_{rc} / y_m)^{2.7}] \qquad [8.10]$$

where: α_d = an adjustment factor for depth, y_{rc} = reference soil disturbance depth, y_d = the soil disturbance depth of the operation, and y_m = the maximum soil disturbance depth for

the operation. The fit of equation 8.10 to observed data is shown in Figure 8.1 (Hanna et al., 1995; Hill and Stott, 2000; Johnson, 1988).[62]

8.2.4.3. Effect of speed on surface residue burial

The effect of operation speed on residue burial ratio values is computed using:

$$\alpha_s = [0.6 + 0.4(v_s / v_m)^{1/2}] / [0.6 + 0.4(v_r / v_m)^{1/2}] \quad [8.11]$$

where: α_s = an adjustment factor for speed, v_r = reference speed, v_s = operation speed, and v_m = maximum operation speed. The fit of equation 8.11 to observed data is shown in Figure 8.2 (Hanna et al., 1995; Hill and Stott, 2000; Johnson, 1988).

8.2.4.4. Combined effect of soil disturbance depth and speed on surface residue burial

The burial ratio for the effect of both depth and speed is computed from:

$$f_b = \alpha_d \alpha_s f_{br} \quad [8.12]$$

where: f_{br} = the burial ratio for the given residue type for the reference soil disturbance depth y_{rc} and reference operation speed v_r.

8.2.5. Distribution of buried residue and dead roots by soil disturbing operations

Soil disturbing operations resurface buried residue but not dead roots, redistribute existing buried residue in the soil, redistribute dead roots in the soil, and bury surface residue. RUSLE2 makes these computations in three steps. The first step computes inversion of the burial material. The second step computes the redistribution of existing buried residue and dead roots and resurfacing of buried residue from the upper soil layer(s). The third step computes the mass distribution by soil layer of the material buried by the

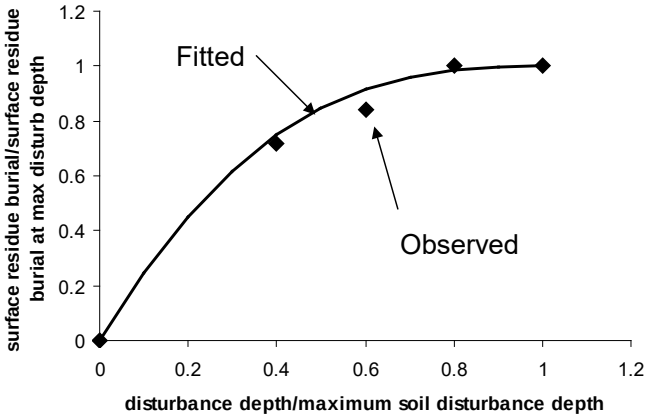

Figure 8.1. Effect of soil disturbance depth on surface residue burial.

[62] R.L. Raper, USDA-Agricultural Research Service, researched the literature and assembled the data used to derive the equations for effect of soil disturbance depth and operation speed on residue burial and equations for distribution of buried material by soil layer.

operation.

8.2.5.1. Types of soil disturbance operations

Types types of soil disturbing operations are used in RUSLE2 to describe how these operations distribute bury residue and dead roots in the soil. These types are: inversion, mixing with some inversion, and mixing. The *inversion* type represents machines like moldboard plows and soil disturbances (e.g., hand tillage with a spading fork) that primarily bury and mix material in the soil by inverting the disturbed soil layer. The *mixing with some inversion* type represents machines like field cultivators, chisel plows, tandem disks, and scarifiers and soil disturbances that bury material in the soil primarily by mixing with some inversion. The *mixing* type represents machines like rotary powered machines (e.g., rototillers); shank machines used to inject manure, fertilizers, and other materials into the soil; and soil disturbances that incorporate material by mixing with essentially no inversion. The mixing type also represents materials pressed into the soil by cattle trampling, sheep's foot compactors, and similar operations. Burial of residue by compression does not involve soil disturbance.

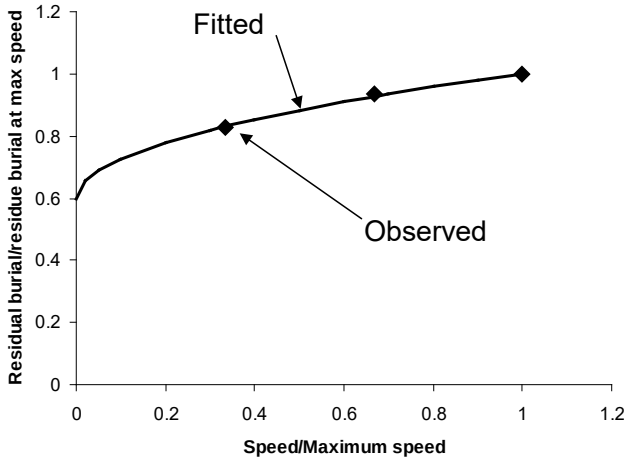

Figure 8.2. Effect of speed on surface residue burial.

8.2.5.2. Equations for redistribution of buried residue and dead roots

A sifting concept is used in RUSLE2 to compute redistribution of buried material by soil disturbing operations. RUSLE2 computes separately the redistribution of buried residue and dead roots. Conceptually, soil disturbance "sifts" each soil layer so that some of the buried material (i.e., buried residue or roots) is retained in each layer and the remainder moves downward to the next soil layer.[63]

RUSLE2 assumes that no material moves upward except by inversion-type soil disturbances. The first step is to compute inversion of the buried material for inversion type soil disturbing operations. This computation assigns the existing buried material

[63] The RUSLE2 equations used to redistribute buried residue and dead roots are based on empirical data reported in the literature cited in **Section 12.2.4.**

mass in the bottom soil layer to the top soil layer, the existing material in the top layer to the bottom layer, the existing material in the next to bottom soil layer is assigned to the soil layer next to top layer, and so forth. For example, the buried material mass in the top soil layer after inversion is set equal to the material mass in the bottom soil layer before inversion and the mass in the bottom layer after inversion is set equal to the mass in the top soil layer before inversion.

The next step for all soil disturbing operations is to "sift" the soil layers to compute the buried material that leaves each soil layer using:

$$\Delta B_{(i)} = (1 - \phi_{k(i)})(B_{p(i)} + \Delta B_{(i-1)} - R_{(i)}) \qquad [8.13]$$

where: $\Delta B_{(i)}$ = the buried material (dry mass/area) that moves from the *ith* soil layer to the *(i+1)th* layer, $\Delta B_{(i-1)}$ = the buried material (dry mass/area) that moves from the *(i-1)th* soil layer to the *)th* layer ϕ_k = the mass fraction of the buried material in the *ith* layer that is retained for the *kth* type soil disturbance operation, $B_{p(i)}$ = existing buried material (mass/area) in the *ith* soil layer, $R_{(i)}$ = the buried residue (dry mass/area) that is resurfaced for the *ith* layer. The soil disturbance depth is divided into 10 layers to make these computations where i = index for the soil layers (i = 1 for surface soil layer). The computations start with the top layer and proceed downward. The inflow to the top layer is set to zero in this step. The amount of material that enters the top layer by burial is added in the third step described below.

The fine roots tightly bound to soil particles dead roots are assumed to have the greatest effect on erosion. Therefore, the RUSLE2 assumption is that dead roots are not resurfaced.[64]

Values for R in equation 8.13 are zero when equation 8.13 is used to compute the redistribution of dead roots. The total mass of buried residue that is resurfaced is computed using equation 8.8. The value for R in the top soil layer (i.e., R_1) in equation 8.13 is set to the value computed by 8.8. If the value computed by equation 8.8 exceeds the buried residue mass in layer 1, the value for the mass removed is set equal to the buried residue in layer 1 before sifting. The remainder of the buried residue mass needed to provide the mass computed by equation 8.8 is removed from layer 2. If the buried residue mass in layer 2 is insufficient, the entire buried residue before sifting is removed from layer 2. The check moves to subsequent layers until the total resurfaced residue mass computed by equation 8.8 is satisfied.

---

[64] The fact that soil disturbing operations surface dead roots is recognized. However, the fraction of dead roots in the soil that is resurfaced is considered to be much smaller than the fraction of buried residue that is resurfaced.

Table 8.1. Retention coefficient Φ values for redistributing buried material among soil layers

	Type soil disturbance operation		
Layer	Inversion w/mixing	Mixing w/inversion	Mixing
1 (top)	0.40	0.32	0.50
2	0.40	0.39	0.56
3	0.40	0.47	0.61
4	0.40	0.54	0.67
5	0.40	0.62	0.72
6	0.40	0.69	0.78
7	0.40	0.77	0.83
8	0.40	0.84	0.89
9	0.50	0.92	0.94
10	1.00	1.00	1.00

Values for the retention coefficient ϕ are given in Table 8.1. The value of 1 for the *10th* layer denotes that no buried material passes through the bottom layer in the soil disturbance depth. Retention values for the mixing-type soil disturbing operations are assumed to increase linearly from the value for the top layer to 1 for the bottom layer. This increase with depth means that buried material is more likely to move downward in the upper part of the disturbed soil layer than in the lower part. The increased retention coefficient values with depth indicate greater retention because of less stirring and mixing in the bottom of the soil disturbed layer. In contrast, stirring, mixing, and retention are assumed to be nearly uniform with depth for inversion-type soil disturbing operations as shown in Table 8.1.

The retention ϕ values in Table 8.1 were determined by fitting equation 8.13 to measured data where the same operation was repeated multiple times. These data conclusively show that buried material redistributed by multiple events of mixing with some inversion and mixing types soil disturbing operations forms a bulge that moves downward in the soil rather than producing a uniform distribution (see RUSLE2 User's Reference Guide). In contrast, the distribution of buried material becomes nearly uniform with multiple events of an inversion-type soil disturbing operation. Retention values were independent of characteristics of the buried material.

The third step is to distribute surface residue by soil layer when it is buried by a soil disturbing operation. That mass is added to the buried residue mass after sifting as computed with equation 8.13 for redistribution and resurfacing of existing buried residue. The equation used to compute the distribution of surface residue when it is buried in the soil by mixing-type soil disturbing operations is:

$$M = (y / y_d)^b \qquad [8.14]$$

where: M = cumulative normalized mass (cumulative mass above depth in soil/total mass buried in soil depth disturbed by operation) of buried residue with depth (i.e., M = 0 at y = 0 and M =1 at y = y_d), y = depth in soil, y_d = soil disturbance depth for a specific soil disturbing operation, and b = 0.5 for *mixing with some inversion* type soil disturbing operations and b = 0.3 for *mixing* type soil disturbing operations.

The comparable equations for inversion-type soil disturbing operations are:

$$M = 0.28\{\exp[1.83(y / y_d) - 1]\} \quad y / y_d \le 0.6 \qquad [8.15]$$

$$M = 1 - 0.441\{[1 - (y / y_d)] / 0.4\}^{1.4} \quad y / y_d > 0.6 \qquad [8.16]$$

Equations 8.14 - 8.16 were derived from observed data where surface material was buried by a single occurrence of an operation when no buried residue existed in the soil. The distributions of buried residue computed by equations 8.14 – 8.16 are shown in Figure 8.3.

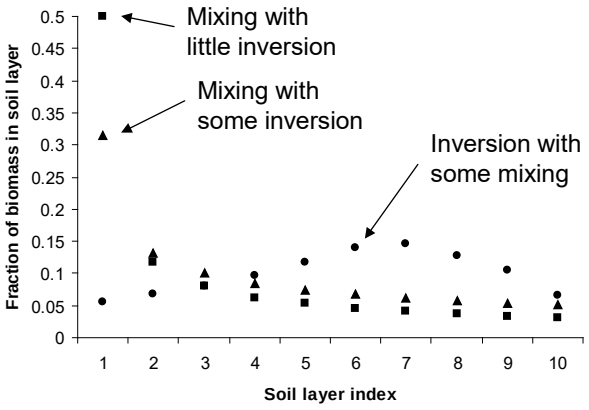

Figure 8.3. Distribution of residue by soil layer when initially buried by a soil disturbing operation.

In summary, RUSLE2 computes buried residue mass in each soil layer after an operation by (1) computing inversion of buried residue biomass if the operation is an inversion-type operation, (2) using equation 8.13 to compute redistribution of existing buried residue mass caused by stirring and mixing (i.e., sifting), and (3) using equations 8.14 – 8.16 to distribute the surface biomass among soil layers that is buried by the operation, which is added to the buried residue mass computed in step 2. The steps for computing redistribution of dead roots is to (1) add the dead roots produced by the kill live vegetation process to the existing dead roots in each soil layer if the operation includes a kill vegetation process, (2) invert the dead roots by soil layer if the operation is an inversion type operation, and (3) compute the sifting of dead roots using equations 8.13.

8.2.6. Add other cover

The **add other cover** process is used to apply material to the soil surface and/or place (inject) material into the soil.

8.2.6.1. Add cover to soil surface

The **add other cover** process has the inputs of the residue, amount (dry mass basis) added as well as the portion added to the soil surface and the portion placed (injected) in the soil. The mass of the material added to the soil surface is added to the surface residue pool.

8.2.6.2. Injection of material (residue) into the soil by a soil disturbing operation

The **add other cover** process along with a **disturb soil** process are used together to inject material into the soil. This material is assumed to be added in the lower half of the disturbed soil depth in a parabolic distribution. The equations for cumulative mass with depth for material injected into the soil are:

$$M = 6\left[\frac{(2y/y_d - 1)^2}{2} - \frac{(2y/y_d - 1)^3}{3}\right] \quad y/y_d \geq 0.5 \qquad [8.17]$$

$$M = 0 \quad y/y_d < 0.5 \ [8.18] \qquad [8.18]$$

where: m = cumulative normalized mass (cumulative mass above depth in soil/total mass), y = depth in soil, and y_d = soil disturbance depth. The mass placed in the soil is added to the buried residue pool.

8.2.7. Remove residue cover

The **remove residue cover** process is used to describe removal of standing and surface residue. Inputs for this process include the portions of the standing and surface residue masses that are removed. The masses of standing and surface residue are reduced by these portions. Another input is whether the residue removal applies to all residues involved in the RUSLE2 computation or only the last residue added to the soil surface in the computation. An example is where corn and wheat grain crops are grown in sequence. The harvest of each crop leaves residue. The straw is baled (removed) but the corn residue is left in the field. The input to remove the last residue is selected in this situation. Another example is burning where all residues is selected.

8.2.8. Add/remove non-erodible cover

8.2.8.1. Description of add/remove non-erodible cover processes

The **add non-erodible** cover process sets detachment to zero for the portion of the soil surface covered with non-erodible cover. That is:

$$c = c_\omega(1 - f_\mu) \qquad [8.19]$$

where: c = the c in equations 2.10 and 6.1 used to compute detachment, c_ω = the c term in equation 2.10 without the non-erodible cover effect, and f_μ = the portion of the soil surface covered by non-erodible cover. Equation 8.19 in effect adds a non-erodible cover subfactor to equation 6.1.

Non-erodible cover also affects runoff. The equations used to adjust cover number values used to compute runoff when non-erodible cover is present are given in **Section 3.3.1.2.3**.

The **remove non-erodible cover** process removes non-erodible cover. The input value is the portion of the existing non-erodible cover that is removed by the operation. A 100 percent input value removes all of the existing non-erodible cover. A 40 percent input value removes 40 percent of the existing non-erodible cover. For example, assume that the existing non-erodible cover is 72 percent on the day of an operation that removes 40

percent of the non-erodible cover. The remaining non-erodible cover is 43 percent [72·(100-40)/100] after the operation.

8.2.8.2. Loss of non-erodible cover over time

RUSLE2 assumes that non-erodible cover disappears over time because of photo-chemical and other processes. The equation for the loss of non-erodible cover is given by:

$$f_\mu = f_0 \exp(-\alpha_\mu \Delta t_\mu) \quad [8.20]$$

where: f_0 = the fraction of the soil surface covered by non-erodible cover immediately after an operation affects non-erodible cover (i.e., added or removed) and Δt_μ = the days since the non-erodible cover was affected. The coefficient α_μ = a coefficient (days^{-1}) that describes the rate of loss of non-erodible cover. Equation 8.20 is not written as a function of environmental conditions. To consider the effect of environmental conditions on this cover loss, users select α_μ values that reflect both material properties and local environmental conditions. Consequently, α_μ values can differ among locations for the same material based on variation of environmental conditions between locations.

8.3. Effect on soil

The **disturb soil** process is used to describe how operations affect the soil. An operation that includes a disturb soil process is referred to as a soil disturbing operation. Soil disturbing operations loosen the soil, buries surface residue, resurfaces buried residue, redistributes buried residue and dead roots, affects soil roughness, and affects ridges. Some operations such as planting disturb only a portion of the soil surface.

8.3.1. Loosen soil

The effect of an operation loosening the soil is described by the soil consolidation subfactor. The equation for the soil consolidation subfactor is given in **Section 6.6.2**.

For those operations that do not disturb the entire soil surface area, RUSLE2 computes a net soil consolidation subfactor as:

$$s_{cn} = f_d + (1 - f_d) s_{cu} \quad [8.21]$$

where: $s_{c,n}$ = the net soil consolidation subfactor for the overall soil surface, f_d = the fraction of the soil surface that is disturbed, $s_{c,u}$ = the soil consolidation subfactor for the portion of the soil surface not disturbed by the operation, and 1 = the consolidation subfactor value for the soil surface portion that is disturbed.

An effective soil consolidation time t_{de} since last soil disturbance is computed by solving equation 6.52 for the time that gives the value for the net soil consolidation subfactor value computed with equation 8.21. The time used in equation 6.52 to compute the soil consolidation subfactor starts from this effective soil consolidation time.

8.3.2. Burying and resurfacing residue

Soil disturbing operations bury surface residue and resurface buried residue. The RUSLE2 assumption is that surface residue can only be buried by disturbing the soil. The equations used to compute residue mass buried and resurfaced by soil disturbing operations are given in **Section 8.2**. Important variables used in these computations are the fraction of the surface residue mass that the operation buries and the faction of the buried residue mass in the soil disturbance depth that is resurfaced. **The burial and resurfacing ratios apply to the entire soil surface and not just to the portion of the soil surface that is disturbed** (see the RUSLE2 User's Reference Guide).

Some soil disturbing operations that disturb only a portion of the soil surface. The RUSLE2 procedure that determines an effective surface residue biomass for the entire surface is described in **Section 6.2.3**.

8.3.3. Redistribution of buried residue and dead roots

Soil disturbing operations redistribute existing buried residue and dead roots on the date of the operations. The equations used in these computations are given in **Section 8.2.5**.

The RUSLE2 assumption is that soil disturbance is required to place material in the soil (e.g., manure and fertilizer injection). The equations used to compute the distribution of material placed in the soil by an **add other cover** process are given in **Section 8.2.6.1**.

8.3.4. Soil surface roughness

A soil disturbing operation affects soil surface roughness. An operation can either smooth the soil surface (i.e., reduce soil surface roughness) or roughen the soil (i.e., increase soil surface roughness). Roughness decays over time because of subsidence (settlement), interrill erosion, and local deposition.

The RUSLE2 assumption is that soil surface roughness can only be created by a soil disturbing operation. Consequently, operations with a disturb soil process must be used to represent soil surface roughness creation.

8.3.4.1. Inputs for soil surface roughness in an operation description

Three inputs are used in a **disturb soil** process to describe soil surface roughness. One input is initial roughness, which is the roughness created by the operation when performed on a smooth surface under the base, reference condition of high biomass and silt loam soil (see **Section 6.3.1** and **6.3.6** and RUSLE2 User's Reference Guide). Equations given in **Sections 6.3.2, 6.3.3,** and **6.3.5** are used to adjust this initial roughness value for soil texture, biomass, and existing soil surface roughness to represent site specific conditions where RUSLE2 is being applied.

RUSLE2 computes soil surface roughness decay over time as a function of precipitation and interrill erosion using equations given in **Section 6.3.6**. RUSLE2 computes roughness decay to the final roughness value input for the particular operation. The final

roughness value is usually set to 0.24 inches and not adjusted for soil texture or soil biomass. This final roughness value represents persistent, highly stable soil clods that remain even after extensive erosivity applied to the reference silt loam soil in unit plot conditions. The roughness subfactor value is 1 for unit plot conditions (see **Section 6.3.1**). Final roughness on unit plots varies by soil texture, but that effect on rill-interrill erosion is captured in the soil erodibility factor (see **Section 4.1**).

In special cases such as construction sites where a high clay soil is scarified, a final roughness value greater than 0.24 inches can be entered to represent an increased roughness effect (see the RUSLE2 User's Reference Guide). A final roughness value less than 0.24 inches is entered for operations, such as for fine seedbeds typical of vegetable production or smooth surfaces left by a blading operation on a construction site, that create roughness smoother than that for unit-plot conditions (see **Section 2.1**). When the final roughness value is less than 0.24 inches, the initial roughness input value should be the same as the final roughness input value. RUSLE2 computes no roughness decay when the final roughness input is less than 0.24 inches.

8.3.4.2. Partial soil disturbance

In contrast to the assumption made for burying and resurfacing residue, the RUSLE2 assumption is that the input roughness values only apply to the portion of the soil surface disturbed. A net soil surface roughness value is computed as:

$$s_{rn} = f_d s_{rd} + (1 - f_d) s_{ru} \qquad [8.22]$$

where: s_{rn} = the net soil surface roughness subfactor immediately after a soil disturbing operation that occurs on day t, s_{rd} = the soil surface roughness subfactor for the disturbed portion of the soil surface immediately after the operation on day t, and s_{ru} = the soil surface roughness subfactor for the undisturbed portion of the soil surface on day of the operation. The starting value in equation 6.26 for the roughness subfactor immediately after the operation that is decayed is the s_{rn} value computed with equation 8.22.

RUSLE2 assumes that an operation that disturbs only a portion of the soil surface disturbs some of the undisturbed soil. Consequently, multiple occurrences of an operation that disturbs only a portion of the soil surface ultimately disturb most of the soil surface. That is, RUSLE2 can not represent an operation that disturbs the same area with each occurrence of the operation.

8.3.4.3. Tillage intensity (effect of existing roughness)

The RUSLE2 assumption is that the roughness left by a soil disturbing operation can depend on existing roughness. The input for this effect is a **tillage intensity** value assigned to the disturb soil process (see RUSLE2 User's Reference Guide). Tillage intensity refers to the degree that a soil disturbing operation obliterates existing roughness (i.e., conversely the degree that existing roughness affects roughness left by the soil disturbing operation). A tillage intensity value of 1 means that the soil disturbing operation is so aggressive that existing roughness has no effect on roughness left by the

operation. For example, the tillage intensity value of 1 is used to describe moldboard plows and rototillers. A tillage intensity of 0 means that the operation does not affect existing roughness. Harrows used as secondary tillage to create a seedbed are assigned 0.4 for tillage intensity to reflect that existing roughness has a significant effect on the roughness left by harrows. For example, the soil surface roughness after a harrow is greater when it follows a moldboard plow than when it follows a tandem disk used for secondary tillage. The tillage intensity effect is computed using:

$$R_a = (R_{ae} - R_{ao})(1 - \xi) + R_{ao} \quad R_{ao} \le R_{ae} \qquad [8.23]$$

$$R_a = R_{ao} \quad R_{ao} > R_{ae} \qquad [8.24]$$

where: R_a = adjusted roughness after a soil disturbing operation, R_{ae} = existing adjusted roughness immediately before the operation, ξ = tillage intensity, and R_{ao} = the adjusted roughness left by the operation when applied to a smooth surface. Roughness values used in equations 8.23 and 8.24 have been adjusted for soil texture and biomass effects using the procedures described in **Section 6.3**.

8.3.5. Ridges

The RUSLE2 assumption is that only soil disturbing operations create ridges. Consequently, operations with a disturb soil process must be used to represent ridge creation.

The ridge input for the **disturb soil** process is initial ridge height. In contrast to soil surface roughness, the input ridge height is not adjusted for soil texture, soil biomass, existing ridges, or portion of the soil surface disturbed. For example, the ridge height left by a planter run on top of existing ridges depends on the existing ridge height. This effect is represented in RUSLE2 by having a set of planter descriptions in the RUSLE2 database for a range of ridge heights. A particular planter entry is selected from this input set based on the operations that precede the planter operation (see the RUSLE2 User's Reference Guide).

8.4. List of symbols

b = exponent in equation for distribution of buried residue left by an operation

$B_{(i)}$ = buried material in *ith* soil layer (mass/area)

B_{al} = live vegetation biomass (mass/area)

B_{br} = buried biomass in soil disturbance depth (mass/area)

B_{sr} = surface residue (mass/area)

B_{tr} = stading residue biomass (mass/area)

c = daily cover-management factor value in equation 2.10 with non-erodible cover effect

c_{ω} = daily cover-management factor in equation 2.10 without non-erodible cover effect

f_b = portion of surface residue that is buried (fraction)

f_{br} = burial ratio for given residue type for reference soil disturbance depth and speed

f_d = portion of the soil surface that is disturbed (fraction)

f_f = portion of existing standing residue biomass that is flattened a flatten standing residue process operation (fraction)

f_{lr} = portion of above ground live biomass that is affected by a **remove live vegetation** process operation (fraction)

f_n = faction of soil surfaced by non-erodible cover

f_{sl} = portion of affected biomass that is left as surface residue by a **remove live vegetation** process operation (fraction)

f_{tl} = portion of affected biomass that is left as standing residue by a **remove live vegetation** process operation (fraction)

f_u = portion of the buried residue biomass in soil disturbance depth that is resurfaced that is resurfaced (fraction)

f_0 = portion of soil surface covered by non-erodible cover immediately after an operation affects non-erodible cover (i.e., added or removed) (fraction)

f_{μ} = portion of soil surface covered by non-erodible cover (fraction)

M = cumulative buried residue normalized with depth (cumulative mass above depth in soil/total mass buried in soil disturbance depth) bured by a **soil disturb** process operation

N = number of data points

$R_{(i)}$ = buried residue niomass that is resurfaced from a soil layer (mass/area)

R_a = roughness after a soil disturbing operation (length)

R_{ae} = existing roughness immediately before the operation (length)

R_{ao} = the roughness left by the operation when applied to a smooth surface (length)

s_{cn} = net soil consolidation subfactor

s_{cu} = soil consolidation subfactor for the portion of soil surface not disturbed by operation

s_{rn} = net soil surface roughness subfactor immediately after a soil disturbing operation that occurs on day t

s_{rd} = soil surface roughness subfactor for disturbed portion of the soil surface immediately after the operation

s_{ru} = soil surface roughness subfactor for undisturbed portion of the soil surface on day t

v_m = maximum operation speed (length/time)

v_r = reference speed (length/time)

v_s = operation speed (length/time)

y = depth in soil (length)

y_d = soil disturbance depth of operation (length)

y_{en} = estimated value for the *nth* data point

y_m = the maximum soil disturbance depth for operation (length)

y_{on} = observed value for the *nth* data point

y_{rc} = reference soil disturbance depth (length)

α_d = adjustment factor for depth

α_s = adjustment factor for speed

α_μ = coefficient that describes rate of loss of non-erodible cover ($days^{-1}$)

δ = function that is minimized

$\Delta B_{(i)}$ = buried material that moves from *ith* soil layer to *(i+1)th* layer (mass/area)

$\Delta B_{(i-1)}$ = buried material that moves from (*i-1)th* soil layer to *i)th* layer (mass/area)

ΔB_{sr} = standing residue added to surface residue biomass pool by a **remove live vegetation** operation process or surface residue biomass transferred to the buried residue pool by a **soil disturb** process operation (mass/area)

ΔB_{tr} = live above ground biomass added to standing biomass pool added by a **remove live vegetation** process operation or biomass lost from standing residue bimass and added to surface bimass by a **flatten standing residue** process in an operation (mass/area)

$\Delta B_{u(i)}$ = residue biomass that is resurfaced from soil disturbance depth by a **soil disturb** process operation (mass/area)

Δt_{μ} = time since non-erodible cover was affected (days)

ξ = tillage intensity

$\phi_{k(i)}$ = portion of buried material in the *ith* layer that is retainedby a *kth* type soil disturbance operation (fraction)

Indices

i – soil layer

j – day

k - type of soil disturbance operation

n – data point

9. VEGETATION

The input variables used to describe vegetation are biomass (dry basis) at maximum canopy cover and the temporal variables of root biomass (dry basis) in the upper 4-inch (100 mm) soil depth, canopy cover, effective fall height, and live ground cover. These variables are used to compute values for the temporal variables of the live root biomass by soil layer, dead root biomass produced by root sloughing, live above ground biomass, biomass produced by senescence that falls to the soil surface, and retardance. All of these variables are used to compute values for the cover-management subfactors (see **Section 6**), curve numbers used to compute runoff (see **Section 3.3.1.2**), and hydraulic resistance (see **Section 3.4.6**). The RUSLE2 User's Reference Guide describes selection of input values for variables used to describe vegetation.

9.1. Input of temporal variables

Input values for the temporal vegetation variables are often manually constructed and entered in RUSLE2 using values in the RUSLE2 core database as a guide (see RUSLE2 User's Reference Guide). This procedure works satisfactorily for simple vegetation descriptions for annual agricultural and horticultural crops and annual descriptions for mature perennial plant communities. However, creating and entering values for vegetation descriptions for long term vegetation from seeding to maturity is cumbersome and time consuming. RUSLE2 includes a long term vegetation tool that can be used to create long term vegetation descriptions (see RUSLE2 User's Reference Guide).

Temporal variables used to describe vegetation are assumed to vary linearly between the times in the data points entered for these variables. The time between data points should be sufficiently small to accurately represent non-linear variations.

9.2. Computed temporal vegetation variables

9.2.1. Live root biomass by soil layer

RUSLE2 uses input values for live root biomass in the upper 4-inch soil depth to compute daily live root biomass values in individual soil layers.

The literature was reviewed to obtain measured data for root biomass and its distribution in the soil at plant maturity for the major agricultural crops of corn, soybeans, cotton, and wheat; several vegetable crops; and several pasture/range plant communities (see **Section 12.2.5**). The RUSLE2 equations for the distribution of live root biomass in the soil were derived from these data, especially the data by Long (1959). These equations are:

$$M_r = y[24.24y\exp(-5.50y) + 0.778] \quad y \le 0.533333 \qquad [9.1]$$

$$M_r = 0.783391 + 0.147688(y - 0.533333) \quad 0.533333 < y \le 2 \qquad [9.2]$$

$$M_r = 0 \quad 2 < y \qquad [9.3]$$

where: M_r = cumulative root biomass (dry basis) above the depth y, y = Y/15, Y = depth (inches) in soil (Y = 0 at soil surface), and 15 = a reference depth (inches) used to normalize the depth variable y. A plot of these equations by 1 inch layer is shown in Figure 9.1.

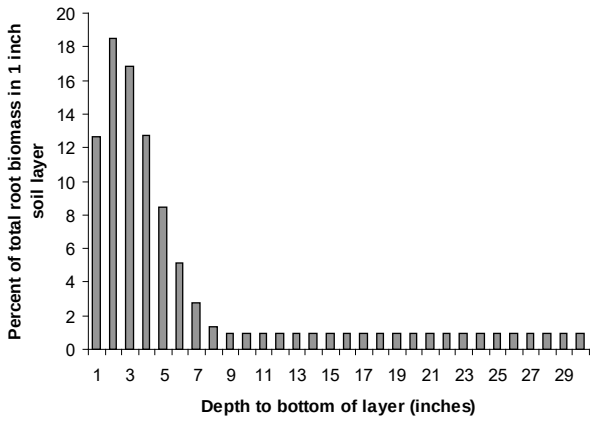

Figure 9.1. Fraction of total root biomass in 1 inch soil layers.

No data were found for measured root biomass in 1-inch soil layers. Accurately measuring roots is very difficult in soil layers as thin as 1-inch, especially near the soil surface. Preference was given to data where root biomass was measured in soil layers sufficiently thick to obtain accurate measurements, which is one of the reasons why the input value for root biomass is based on the upper 4-inch soil layer. This depth also contains the bulk of the roots that significantly affect rill-interrill erosion as discussed below.

The shape of the curve in Figure 9.1 within the upper 4-inch soil layer is based on judgment. A power equation gave the best fit to the observed data, but it was not used because a power equation form gives maximum root biomass density at the soil surface. The judgment is that root mass in the upper 1-inch layer is less than that at a slightly deeper soil depth. Soil moisture at the soil surface is reduced because of evaporation when soil surface (residue) cover is minimal, which in turn results in reduced root biomass near the soil surface. Increased surface residue reduces evaporation, which increases soil moisture at the soil surface. The form of equation 9.1, which represents reduced root biomass near the soil surface, was judged more appropriate overall for RUSLE2 than the power equation form. The shape of the curve in the upper 4-inch soil depth is of minimal consequence because RUSLE2 uses the average root biomass density in the upper 10-inch soil depth to compute runoff curve values, b values for effect of ground (surface) cover, slope length exponent, soil surface roughness, and soil biomass subfactor values (see **Sections 3.3.1.2, 6.2.1, 6.2.2, 6.3, and 6.5**).

A major result from the literature review and data analysis was that rooting depth for the roots judged to have the greatest effect on rill-interrill erosion do not vary greatly among agricultural crops and pasture/range plant communities. However, the rooting depths for most vegetable crops were about one half of that for agricultural crops. A rooting depth of 30 inches was assumed in RUSLE2 for all plant communities, including vegetable crops. Other RUSLE2 assumptions based on data analysis were that 85 percent of live root biomass was above the 15-inch depth, the live root biomass distribution by depth was the same for all plant communities, and rooting depth does not temporally vary.

The adequacy of these RUSLE2 assumptions must be judged in terms of RUSLE2's stated purpose of being an easily used guide for erosion control planning. Do RUSLE2's erosion estimates adequately represent the effect of temporal variability in root biomass for purposes of erosion control planning? Such an evaluation described in the RUSLE2 User's Reference Guide shows that RUSLE2 meets that criterion. Capturing the main effects of root biomass rather than all of the details is adequate for RUSLE2 purposes.

RUSLE2 uses average live root biomass density in the upper 10 inch soil depth to compute values for the soil biomass subfactor (see **Section 6.5.2**). The RUSLE2 live root distribution described by equations 9.1 and 9.2 compute that 61 percent of the total live root biomass is in the upper 4-inch soil depth and 80 percent is in the upper 10-inch soil depth. The constant rooting depth assumption does not result in large errors for estimating the soil biomass subfactor because the input variable is the root biomass in the upper 4-inch soil depth that contains more than half of the total root biomass.[65] Temporal live root biomass values given in the RUSLE2 Core Database (see the RUSLE2 User's Guide) were scaled from measured values at plant maturity. RUSLE2 accurately computes expected erosion estimates for times before the vegetation reaches maturity for major agricultural crops (see RUSLE2 User's Reference Guide), which strongly indicates that these assumptions are adequate for RUSLE2 purposes.

These assumptions are in accordance with the RUSLE2 objective to provide a system where the major vegetation variables affecting rill-interrill erosion can be easily described and measured and values for variables used to describe vegetation can be easily entered in RUSLE2. The objective is to sufficiently represent vegetation for RUSLE2 to estimate the effects of vegetation for conservation and erosion control planning. The adequacy of RUSLE2 for conservation and erosion control planning is the criteria for judging these RUSLE2 relationships. **The RUSLE2 User's Reference Guide guidelines must be followed to ensure accurate RUSLE2 erosion estimates.**

9.2.2. Live root biomass becoming dead root biomass

RUSLE2 uses a single vegetation description on any particular day (see **Section 8.1.1**). An operation that includes a **kill vegetation** process transfers the entire live root biomass in each soil layer to the dead root biomass in the corresponding soil layer. RUSLE2 does not allow killing a portion of the live root biomass. That effect can be accomplished by using an operation that includes a **begin growth** process that instructs RUSLE2 to begin using values for a new vegetation description. RUSLE2 assumes that the difference between the live root biomass on the last day that a vegetation description is used and the live root biomass on day zero in the new vegetation description represents dead root biomass that is added to the existing root biomass. RUSLE2 assumes that a decrease in

---

[65] A possible RUSLE2 improvement would be to temporally vary rooting depth according to plant community. Similarly, the root distribution should also be varied with plant community and plant growth stage. These improvements were judged to excessively complicate RUSLE2.

root biomass from one day to the next represents root sloughing (Reeder et al., 2001). Each daily decrease in live root biomass is added that day to the dead root biomass.

9.2.3. Live above ground biomass

RUSLE2 vegetation descriptions are divided into new growth, senescence, and regrowth periods, illustrated in Figure 9.2, to compute temporal values for live above ground biomass as a function of canopy cover.[66]

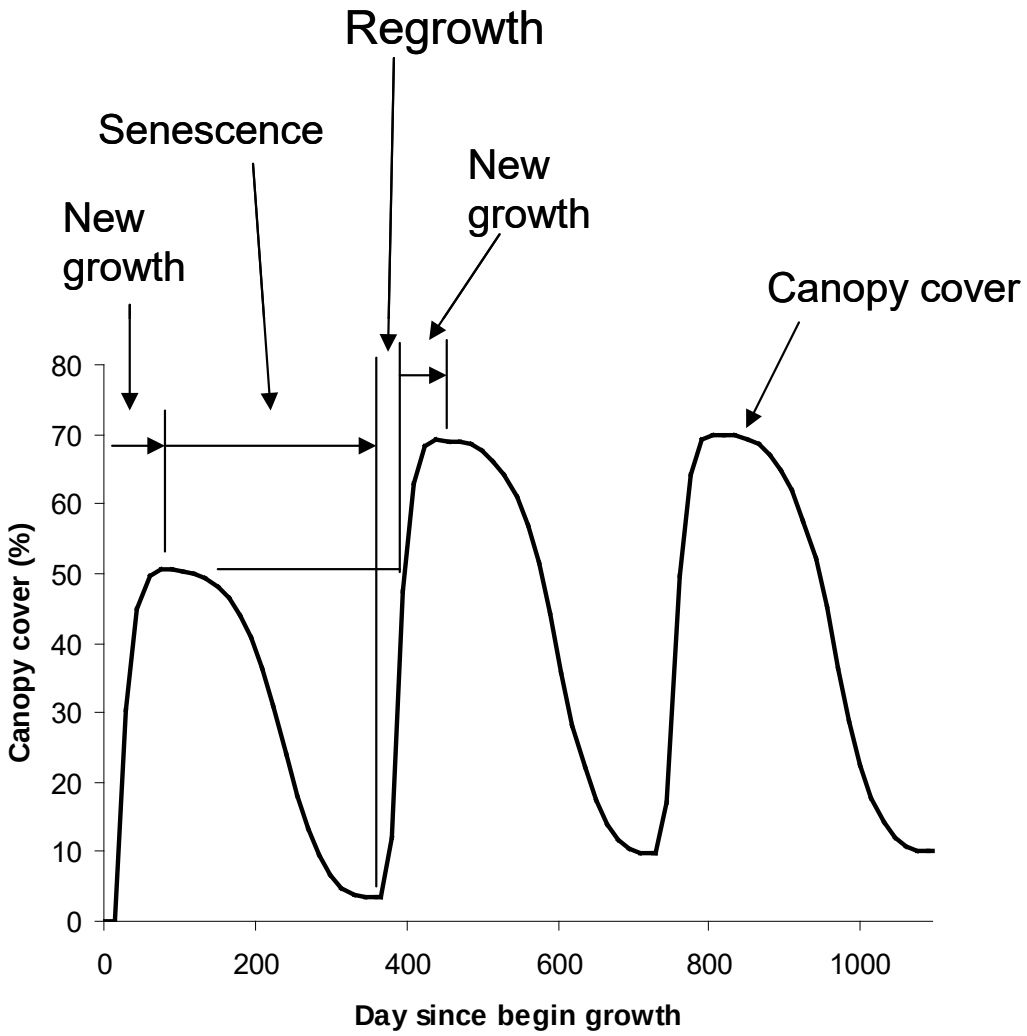

Figure 9.2. Vegetation growth periods used to compute live above ground biomass as a function of canopy cover.

9.2.3.1. New growth period

A **new growth** period is the time during which particular canopy cover values are first reached in a vegetation description. For example, the canopy cover from the seeding date to the first canopy cover maxima is a new growth period as illustrated in Figure 9.2. A second new growth period occurs in the second year over the time that canopy cover increases from the value of the first local canopy cover maxima in the first year to the local canopy cover maxima in the second year, also illustrated in Figure 9.2. A similar third new growth period, not illustrated, occurs in the third year. A composite of plant materials including leaves and stems is assumed to be produced during new growth periods.

The local canopy cover maxima that occurs in the third year for the vegetation description illustrated in Figure 9.2 is also the absolute canopy cover maxima for the vegetation description. The local canopy cover minima that occurs immediately after the absolute local canopy cover maxima is defined in RUSLE2 as the local absolute canopy cover minima for the vegetation description, even though other local canopy cover minima are less than this canopy cover. Values for the absolute canopy maxim and minima and the corresponding live above ground biomass values for these canopy values are user RUSLE2 inputs.

Live above ground biomass is computed from canopy cover during a new growth period using:

$$B_l = B_{lamx}(C / C_{amx})^{1.5} \qquad [9.4]$$

where: B_l = daily live above ground biomass during a new growth period, B_{lamx} = the live above ground biomass at absolute maximum canopy cover for a vegetation description, C = daily canopy cover, and C_{amx} = canopy cover at absolute maximum canopy cover for a vegetation description.

9.2.3.2. Senescence period

A **senescence** period is the time over which canopy cover decreases in a vegetation description from a local canopy cover maxima to a local canopy cover minima as illustrated in Figure 9.2. The equation used to compute live above ground biomass for a senescence period is:

$$B_l = B_{lmn(k)} + (B_{lmx(k)} - B_{lmn(k)})[(C - C_{mn(k)}) / (C_{mx(k)} - C_{mn(k)})]^{1.5} \qquad [9.5]$$

where: $B_{lmn(k)}$ = live above ground biomass at the *kth* local canopy cover minima, $B_{lmx(k)}$ = live above ground biomass at the *kth* local canopy cover maxima, $C_{mn(k)}$ = canopy cover at the *kth* local minima, and $C_{mx(k)}$ = canopy cover at the *kth* local maxima. The index k refers to canopy cover maxima-canopy cover minima combinations where canopy cover minima occur after the corresponding canopy cover maxima.

The live above ground biomass and canopy cover at local canopy cover minima must be on the curve given by:

$$B_{lmn(k)} = B_{lamn}(C_{mn(k)} / C_{mn(1)})^{1.5} \quad [9.6]$$

where: B_{lamn} = the absolute minimum live above ground biomass which occurs at $C_{mn(1)}$ = the first minimum canopy cover defined in **Section 9.2.3.1.** Values for live above ground biomass and canopy cover at local maxima must fall along the curve defined by equation 9.4.

The live above ground biomass-canopy cover curves for the new growth and the senescence periods are illustrated in Figure 9.3 for the first year of the vegetation description represented in Figure 9.2. The live above ground biomass for a given canopy cover during the senescence period is greater than that during the new growth period. Canopy cover loss during the senescence period is primarily by leaves falling to the soil surface. The biomass per unit canopy cover is much less for leaves than for the material, primarily stems, left standing during senescence. Each daily decrease in live above ground biomass is assumed to be biomass that falls and reaches the soil surface. This daily above ground biomass loss is added to the daily surface residue pool.

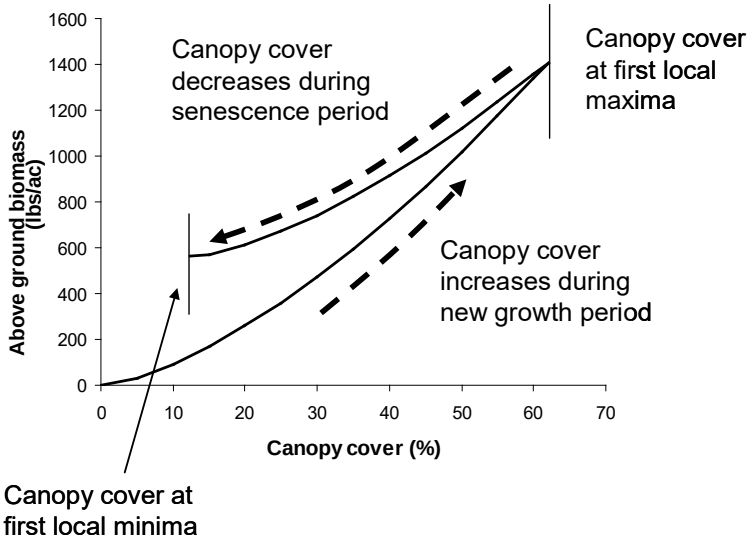

Figure 9.3. Live above ground biomass-canopy cover relationships for new growth and senescence periods during first year.

Equations 9.4 and 9.5 compute a decrease in live above ground biomass for a decrease in canopy cover. However, a decrease in live above ground biomass can occur with some plant communities with canopy cover remaining at 100 percent. An exponential equation form was evaluated to describe these plant communities. However, an exponential type equation was not used in RUSLE2 because such an equation can not be easily calibrated using the desired RUSLE2 inputs. Also, the exponential equation form did not give desired values for low canopy cover values.

Multiple vegetation descriptions are used in a RUSLE2 cover-management description to describe significant changes in live above ground biomass during periods when canopy cover changes very little. The inputs for these vegetation descriptions are selected so that

RUSLE2 computes a significant change in live above ground biomass for very little change in canopy cover such as from 99.9 percent to 99.5 percent. Such small changes in canopy cover have essentially no effect on canopy subfactor values (see **Section 6.1**). Additional vegetation descriptions are used for times during the cover-management description that canopy cover changes rapidly.

9.2.3.3. Regrowth period

The **regrowth** period starts from the canopy cover and live above ground biomass at the last local minima that was reached in the RUSLE2 computations as illustrated in Figure 9.2. Equation 9.5 is used to compute live above ground biomass values for the regrowth period as the live above ground biomass-canopy cover relationship retraces the senescence curve as illustrated in Figure 9.4. Most of the live biomass added during this period is assumed to be leaves and other material that has low biomass for the canopy cover that it provides. The regrowth period ends when canopy cover becomes equal to the canopy cover value of the last local maxima. A new growth period begins at this

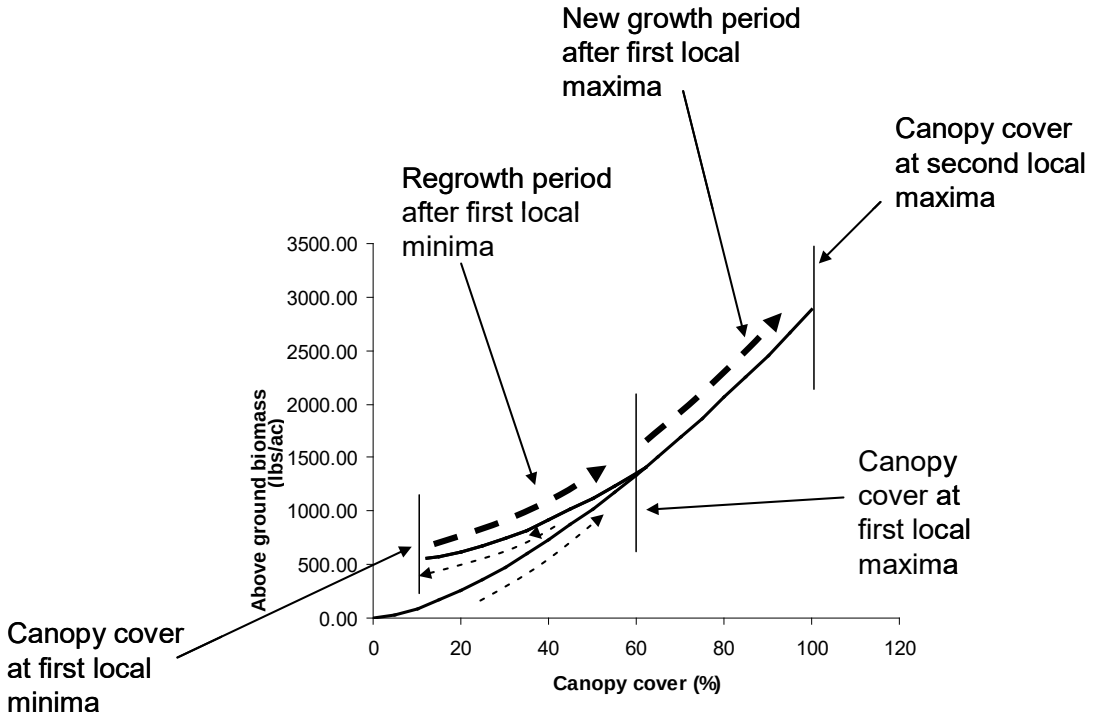

Figure 9.4. Live above ground biomass-canopy cover relationships for regrowth and new growth periods during second year.

point and continues until canopy cover becomes equal to the canopy cover of the next local maxima as illustrated in Figures 9.2 and 9.4. Equation 9.4 is used to compute values for live above ground biomass from canopy cover values during this new growth period. Once the next local maximum is reached, the next senescence period begins where equation 9.5 is used to compute live above ground biomass values.

Computations for this sequence of vegetation periods are repeated until the end of the RUSLE2 computation period.

9.2.3.4. Special cases

9.2.3.4.1. Annual plant communities that experience senescence

Most agricultural crops are annual and are described with either a single new growth period or by a single new growth period and a senescence period. Soybeans and cotton are examples of crops that experience senescence.

9.2.3.4.2. Annual plant communities that experience a decrease in canopy cover without a corresponding decrease in live above ground biomass

RUSLE2 also represents vegetation (e.g., corn and wheat) where canopy cover decreases by leaves drooping instead of falling to the soil surface. In this special case, the live above ground biomass does not decrease as canopy cover decreases. However, RUSLE2 can not represent perennial (long term) vegetation (i.e., multiple sequences of new growth-senescence-regrowth periods in the vegetation description) that has these characteristics.

9.2.4. Litter fall by other processes than senescence

9.2.4.1. Simultaneous birth and death of live above ground biomass

Litter is produced during the increase in growth period before canopy cover begins to decrease by senescence (Dubeux et al., 2005; Thomas and Asakawa, 1993). The litter produced during this period adds substantially to the surface residue produced by litter fall during senescence.

The amount of litter fall during the increase in growth period and into the first part of the senescence period is computed using:

$$L_f = c_f (B_l - B_{lmn(k)}) \;\; if\,(B_l < B_{lmn(k)}) : L_f = 0 \qquad [9.7]$$

where: L_f = day litter fall rate (mass/area·day) during the birth-death period and c_f = coefficient for birth-death litter fall (day^{-1}). A single value of 0.01 day^{-1} probably can be used almost all vegetation types (Dubeux et al. 2005; Thomas and Asakawa, 1993). However, this conclusion needs further research.

Litter fall is computed using equation 9.7 into the senescence period until the rate of litter falls computed by the difference in above ground biomass in a day exceeds the litter fall rate computed by equation 9.7.

9.2.4.2. Litter fall caused by mechanical traffic

Mechanical traffic by humans, animals, and vehicles can transfer biomass from the canopy to the soil surface that adds to surface residue. That biomass transfer is estimated by:

$$L_m = c_m(B_l - B_{lmn(k)}) \;\; if\,(B_l < B_{lmn(k)}) : L_f = 0 \qquad [9.8]$$

where: L_m = litter fall rate (mass/area·day) caused by mechanical traffic and c_m = a litter fall coefficient (day^{-1}) for the litter fall caused by mechanical traffic. The input value for c_m is based on the user's judgment.

9.2.4.3. Adjustment in above ground biomass for litter fall

RUSLE2 does not adjust live above ground biomass for litter fall. The user entered input values for canopy cover are assumed to represent the canopy that exists in the field regardless of what affects canopy cover. RUSLE2 converts those values to biomass, which like the canopy cover values are the live above ground biomass that exists regardless of how it came to be. RUSLE2's litter fall computations describe the disposition of live above ground biomass.

9.2.5. Operations that affect live vegetation

Operations that include **begin growth**, **kill vegetation**, **remove live biomass, and Process: Perennial biomass & current standing res removal** processes affect live above ground biomass. A **begin growth** process instructs RUSLE2 to begin using values from a new vegetation description. RUSLE2 assumes no relationship between live above ground biomass for the two vegetation descriptions although a relationship is assumed for live root biomass (see **Section 9.2.2**). The RUSLE2 assumption is that a decrease in live root biomass between the last day that a vegetation description is used to compute daily erosion and the live root biomass on day zero in the new vegetation description is biomass added to the existing dead root biomass pool. In contrast, no such connections are assumed for live above ground biomass. The RUSLE2 user explicitly use operations, such as **remove live biomass**, to describe the fate of live above ground biomass between vegetation descriptions when a begin growth process is executed. Within the period represented by a vegetation description, the RUSLE2 assumption is that a decrease in canopy cover represents a senescence period and the decrease in live above ground biomass during a senescence period is daily added to the surface residue biomass pool.

Consequently, RUSLE2 assumes that a new growth vegetation period begins on day zero for a new vegetation description when a begin growth process is executed. This assumption applies to transplanted crops and to vegetation that regrows after hay harvest or mowing where canopy and live above ground biomass are greater than zero on day zero in the vegetation description. Similarly, an operation that includes the **remove live biomass** process can leave live above ground biomass after the operation. RUSLE2 assumes that a new growth period begins immediately after the remove live biomass process is executed. The increase in live above ground biomass is assumed to be a composite of above ground plant components, including stems and leaves, during a new growth vegetation period in contrast to the increase in live above ground biomass being primarily leaves during the regrowth period that follows a senescence period.

A **kill vegetation** process transfers the entire live above ground biomass that exists on the day that the process is executed to the standing residue pool. The relation between standing residue biomass and canopy cover is given in **Section 9.2.3**.

9.2.6. Temporal standing live vegetation Manning's n

Standing vegetation contributes to total hydraulic resistance (see **Section 3.4**). The temporal contribution of standing live vegetation, not including live ground cover, to Manning's n is computed using:

$$n_v = n_{vmx}(h_f / h_{fmx})$$

where: n_v = daily Manning's n contributed by live standing vegetation not including live ground cover, n_{vmx} = maximum Manning's n contributed by live standing vegetation, not including live ground cover, during the period represented by the vegetation description, h_f = daily effective fall height, h_{fmx} = maximum effective fall height during the vegetation description, and i = subscript for day. Manning's n contributed by standing live vegetation is most affected by stems. Of the temporal input or computed variables used in a RUSLE2 vegetation description, Manning's n for standing live vegetation was assumed to be best related to effective fall height. The Manning's n contributed by live ground (surface) cover is consider in the relation of Manning's n to net ground (surface) cover (see **Section 3.4.6**)

Table 9.1. Coefficient a_H values used to multiply maximum effective vegetation ridge height on contour to obtain effective vegetation ridge height for effect of row spacing

Row width	Coefficient a_H
Vegetation on ridges	0.25
Wide row (≥ 30 inches)	0.50
Moderate row spacing (15 to 20 inches)	0.75
Narrow row spacing (7 to 10 inches)	1.00
Very narrow row spacing (≤5 inches)	0.50
No rows (broadcast)	0.00

Maximum Manning's n for live standing vegetation for a vegetation description is computed from the user input vegetation retardance at maximum canopy cover. Vegetation retardance is a function of vegetation stem density and orientation of vegetation strips (rows) to the overland flow path (see **Section 3.4.6**). The live vegetation Manning's n when vegetation strips (rows) are on the contour (i.e., perpendicular to the overland flow path) is computed using equation 3.54. A Manning's n value for live standing vegetation for vegetation in rows up and downhill (i.e., parallel to the overland flow path) is computed using values in Table 3.10. The live standing vegetation Manning's n for the actual orientation of vegetation rows to the overland flow path (i.e., row grade) is computed using equation 3.55.

9.2.7. Temporal effective vegetation ridge height

Densely spaced stems of vegetation rows on the contour affect rill-interrill erosion much like soil ridges (see **Section 7.1.3**). An effective live vegetation ridge height is added to the soil ridge height to obtain an effective total ridge height used to compute values for the contouring subfactor in equation 7.6. The effect of live standing vegetation rows on erosion depends on row spacing. If row spacing is zero (i.e., the vegetation is not in rows and the plant stems are randomly spaced over the entire soil surface), orientation of vegetation rows to the overland flow path and row spacing has no meaning or effect on

the contouring subfactor. The erosion reduction (i.e., contouring effect) for effective live standing vegetation ridge height increases as vegetation row spacing increases to a maximum at the narrow row width of approximately 8 inches). Erosion reduction by effective vegetation ridge height decreases as row spacing widens beyond the narrow row spacing. This effect is represented by the coefficient α_h values given in Table 9.1.

The maximum effective live standing vegetation ridge height for contour vegetation strips (rows) for a vegetation description is computed using:

$$H_{vmx} = 0.5 a_H R_v \quad if\,(R_v > 7) : R_v = 7 \qquad [9.10]$$

where: H_{vmx} = maximum effective live standing vegetation ridge height (inches) for the vegetation description when vegetation strips (rows) are on the contour, a_H = the coefficient that adjusts for row spacing (inches), and R_v = the retardance class at maximum canopy cover in the vegetation description (see **Section 9.3.1**).

Daily effective live standing vegetation ridge height H_v is computed using:

$$H_v = H_{vmx} (h_f / h_{fmx})^{0.3} \qquad [9.11]$$

Like Manning's n for live standing vegetation, of the temporal vegetation variables, effective live vegetation ridge height is assumed to be most related to effective fall height.

9.3. Adjust input values for vegetation production (yield) level

Input values in RUSLE2 vegetation descriptions are functions of vegetation production (yield) level, and each RUSLE2 vegetation description applies to a particular production (yield) level. RUSLE2 computes values in a vegetation description for a new production (yield) level by adjusting values in a base vegetation description. The maximum canopy cover in the base vegetation description must be less than 100 percent for RUSLE2 to make the proper mathematical computations. RUSLE2 can use a base vegetation description that has a maximum canopy cover of 100 percent to adjust for production (yield) levels greater than the production (yield) level for the base vegetation description, but RUSLE2 can not use a base vegetation description with a 100 percent maximum canopy cover to adjust to a lower production (yield) level.

Biomass values used in RUSLE2 computations are on a dry basis, but input values for vegetation production (yield) level are on a user defined basis. The user inputs information that RUSLE2 uses to convert production (yield) level value on the user defined basis to the dry basis needed for RUSLE2's computations (see RUSLE2 User's Reference Guide).

Multiple RUSLE2 vegetation descriptions can be used to compute erosion for a particular plant community over the period represented in the RUSLE2 computation (i.e., rotation duration). For example, vegetation descriptions are used to describe a multiple year alfalfa hay production system. The first vegetation description describes the alfalfa crop

from seeding to first hay harvest, the second vegetation description describes regrowth after each hay harvest in the first harvest year, the third vegetation description describes senescence and regrowth after senescence to the first hay harvest in the second harvest year, and so on. Input values such for live above ground biomass at maximum canopy apply to that particular vegetation description and not to the vegetation as a whole over the RUSLE2 computation period, such as the example alfalfa crop.

9.3.1. Live above ground biomass at maximum canopy cover

A major vegetation input is live above ground biomass at maximum canopy cover for a particular vegetation description. When multiple vegetation descriptions are used to represent a particular vegetation, the live above ground biomass entered for each vegetation description is for the maximum canopy cover in that particular vegetation description.

The RUSLE2 assumption is that live above ground biomass at maximum canopy varies linearly as a function of production (yield) level. That is:

$$B_{lamx} = a_y + b_y Y_d \qquad [9.12]$$

where: B_{lamx} = live above ground biomass (dry basis, mass/area) at maximum canopy cover for the vegetation description and Y_d = production (yield) level (dry basis, mass/area). The user provides inputs that RUSLE2 uses to convert production (yield) level in user units to biomass on a dry basis. These equations have the form:

$$Y_d = b_u Y_u \qquad [9.13]$$

where: Y_u = production level (yield) in user defined units and b_u = a conversion factor that RUSLE2 computes from user inputs. The values for the coefficients a_y and b_y in equation 9.12 are computed from user inputs for two live above ground biomass at maximum canopy cover-production (yield level) data points (see RUSLE2 User's Reference Guide).

9.3.2. Retardance at maximum canopy cover

Retardance for live vegetation at maximum canopy cover is computed from:

$$R_v = c_R + d_R Y_u \qquad [9.14]$$

where: R_v = retardance at maximum canopy cover for a vegetation description and Y_u = production (yield) level in user defined units for the vegetation description. The user enters two input data points for retardance-production (yield) level that RUSLE2 uses to determine values for the coefficients c_R and d_R in equation 9.14. RUSLE2 uses eight retardance classes that vary with the degree that vegetation grown in strips (rows) on the contour slows runoff (see Table 3.9). Equation 9.14 computes continuous values that are used in equation 3.54 to compute Manning's n values.

Vegetation descriptions are used to describe both live vegetation and porous barriers (fabric fences, gravel bag dams, and similar mechanical devices used on construction sites to trap and retain sediment on site) (see **Section 7.2** and RUSLE2 User's Reference Guide). The yield input for the vegetation description selected to describe these devices is used to represent the degree that the installed device retards runoff. The eighth retardance class is reserved for conditions that provide extremely high retardance such as stiff grass hedges, fabric (silt) fences and gravel bag dams. RUSLE2 computes backwater length caused by vegetation strips and flow retarding devices as a function of Manning's n, which are computed from the retardance class for the vegetation description (see **Section 3.4.4**). RUSLE2 assigns a minimum backwater length of 3 ft for the extremely high retardance class but uses the backwater length computed for the other retardance classes. RUSLE2 assumes a maximum backwater length of 15 ft for all vegetation/mechanical retarding strips.

9.3.3. Temporal input vegetation variables

Simple equations based on values computed by the EPIC model (Williams et al., 1989) are used in RUSLE2 to compute values for the temporal variables of root biomass, canopy cover, effective fall height, live ground cover, and consumptive water use.

9.3.3.1. Root biomass

Live root biomass values are assumed to vary linearly with live above ground biomass at maximum canopy cover. Live root biomass values for a new vegetation are computed as a function of production level (yield) using:

$$B_{rn(j)} = B_{rb(j)}(B_{lamxn} / B_{lamxb}) \qquad [9.15]$$

where: $B_{rn(j)}$ = root biomass value in the new vegetation description for the *jth* data point, $B_{rb(j)}$ = root biomass value for the *jth* data point in the base vegetation description, and B_{lamxb} = absolute maximum live above ground biomass in the base vegetation description. A value for the live above ground biomass at absolute maximum canopy B_{lamxn} in the new vegetation description is computed using equation 9.12 and the production (yield) level value for the new vegetation description.

9.3.3.2. Canopy cover

The equation used to adjust canopy cover values for production (yield) level is:

$$C_{n(j)} = C_{b(j)}(B_{lamxn} / B_{lamxb})^{0.5} \qquad [9.16]$$

where: $C_{n(j)}$ = canopy cover for *jth* data point the new vegetation description and $C_{b(j)}$ = the corresponding canopy cover value for the *jth* data point in the base vegetation description.

9.3.3.3. Effective fall height

The equation used to adjust effective fall height values for production (yield) level is:

$$h_{fn(j)} = h_{fb(j)}(B_{lamxn} / B_{lamxb})^{0.2} \quad [9.17]$$

where: $h_{fn(j)}$ = effective fall value for the *jth* data point in the new vegetation description and $h_{fb(j)}$ = corresponding effective fall height value for the *jth* data point in the base vegetation description.

9.3.3.4. Live ground cover

The equation used to adjust live ground cover values as a function of production (yield) level is:

$$f_{lgcn(j)} = f_{lgcb(j)}(B_{lamxn} / B_{lamxb})^{0.5} \quad [9.18]$$

where: $f_{lgcn(j)}$ = live ground cover value for the *jth* data point in the new vegetation description (percent) and $f_{lgcb(j)}$ = corresponding live ground cover value for the *jth* data point in the base vegetation description (percent).

9.3.3.5. Consumptive water use

Consumptive water use is used to compute how irrigation affects rill-interrill erosion by precipitation (see **Section 7.5**). Consumption water use is a function of production (yield) level. The equation used to adjust consumptive water use values as a function of production (yield) level is:

$$V_{wn(j)} = V_{wb(j)}(B_{lamxn} / B_{lamxb}) \quad [9.19]$$

where: $V_{wn(j)}$ = consumptive water use value for the *jth* data point in the new vegetation description and $V_{wb(j)}$ = corresponding values for consumptive water use value for the *jth* data point in the base vegetation description.

9.4. List of symbols

a_y = coefficient used to compute live above ground biomass at absolute maximum canopy cover for a vegetation description

a_H = coefficient used to computed effective vegetation ridge height from vegetation retardance (inches)

b_u = coefficient used to convert user defined yield units to dry mass

b_y = coefficient used to compute live above ground biomass at absolute maximum canopy cover for a vegetation description

B_l = daily live above ground biomass (dry basis) during a new growth period (mass/area)

B_{lamn} = live above ground biomass (dry basis) at first minimum canopy cover $C_{mn(1)}$ for a vegetation description (mass/area)

B_{lamx} = absolute maximum live above ground biomass (dry basis) at absolute maximum canopy cover for a vegetation description (mass/area)

$B_{lmn(k)}$ = live above ground biomass (dry basis) at *kth* local canopy cover minina in a vegetation description (mass/area)

$B_{lmx(k)}$ = live above ground biomass (dry basis) at *kth* local canopy cover maxima in a vegetation description (mass/area)

B_{lamxb} = live above ground biomass at absolute maximum canopy cover in base vegetation description (mass/area)

B_{lamxn} = live above ground biomass at absolute maximum canopy cover in new vegetation description (mass/area)

$B_{rb(j)}$ = root biomass value for the *jth* data point in the base vegetation description (mass/area in upper 4-inch depth)

$B_{rn(j)}$ = root biomass value for the *jth* data point in the new vegetation description (mass/area in upper 4-inch depth)

$B_{t,mn}$ = live above ground biomass (dry basis) at a local canopy cover minima (mass/area)

$B_{t,mx}$ = live above ground biomass (dry basis) at a local canopy cover maxima (mass/area)

c_f = coefficient for birth-death litter fall (day^{-1})

c_m = cooefficient fr litter fall caused by mechanical traffic (day^{-1})

c_R = coefficient used to compute retardance from user input yield

C = daily canopy cover (fraction)

C_{amx} = canopy cover at absolute maximum canopy cover for a vegetation description (fraction)

$C_{mn(k)}$ = canopy cover at the *kth* local canopy minima (fraction)

$C_{mx(k)}$ = canopy cover at the *kth* local canopy maxima (fraction)

$C_{b(j)}$ = canopy cover value for *jth* data point in base vegetation description (fraction)

$C_{n(j)}$ = canopy cover for *jth* data point in new vegetation description (fraction)

d_R = coefficient used to compute retardance from user input yield

$f_{lgcb(j)}$ = live ground cover value for *jth* data point in base vegetation description (percent)

$f_{lgcn(j)}$ = live ground cover value for *jth* data point in new vegetation description (pecent)

h_f = daily effective fall height (length)

$h_{fb(j)}$ = effective fall height value for the *jth* data point in the base vegetation description (length)

$h_{fn(j)}$ = effective fall value for *jth* data point in new vegetation description (length)

h_{fmx} = maximum effective fall height for a vegetation description (length)

H_v = daily effective live standing vegetation ridge height (inches)

H_{vmx} = maximum effective live standing vegetation ridge height for a vegetation description

L_f = daily litter fall during birth-death period (mass/area·day)

L_m = daily litter fall caused by mechanical traffic (mass/area·day)

M_r = cumulative root biomass (dry basis) above the depth y (mass/area)

n_v = daily Manning's n contributed by live standing vegetation not including live ground cover

n_{vmx} = maximum Manning's n contributed by live standing vegetation not including live ground cover for a vegetation description

R_v = vegetation retardance class at maximum canopy cover for a vegetation description

$V_{wb(j)}$ = corresponding values for consumptive water use value for *jth* data point in base vegetation description (inches)

$V_{wn(j)}$ = consumptive water use value for *jth* data point in the new vegetation description (inches)

y = normalized depth in soil from soil surface Y/15 inches

Y = depth in soil from soil surface (inches)

Y_d = production (yield) level (dry basis) (mass/area)

Y_u = production level (yield) in user defined units

15 = reference depth in inches for determining root mass distribution in soil

Indices

j – data point

k - refers to canopy cover maxima-canopy cover minima combination where canopy cover minima occur after a canopy cover maxima

10. RESIDUE AND DEAD ROOTS

10.1. Description of residue and dead roots

Residue and dead roots are materials lost by decomposition. RUSLE2 includes standing, surface, and buried residue pools that account for material produced when live above ground biomass is converted to standing residue (**Sections 6.1, 6.2, 6.5, and 9.2.5**). RUSLE2 accounts for the movement of residue mass between these pools by harvest, tillage, ripping, and other operations that affect vegetation, residue, and soil (see **Section 8.2**). The RUSLE2 surface residue pool also includes material such as mulch, manure, and erosion control blankets applied to the soil surface (see **Section 6.2**). The RUSLE2 buried residue pool includes material such as manure and bio-solids in sewage sludge that are injected or incorporated into the soil (see **Sections 6.3 and 6.5**).

Mass in the RUSLE2 dead root residue pool results from live root biomass associated with a vegetation description being transferred to the dead root biomass pool (see **Sections 6.5.6 and 9.2.2**).

The general RUSLE2 assumption is that residue and dead roots are organic materials that decompose. RUSLE2 also describes the effects of non-organic material such as erosion control blankets and rock placed on the soil surface or incorporated into the soil. However, special inputs are used to represent non-organic material (see **Section 10.2.5**).

Crop residue and plant litter are composed of diverse components including stems, leaves, seed pods, and chaff. Similarly, dead roots vary from very fine to coarse roots. A single residue description is used to represent a composite of these components for a particular vegetation description

10.2. Relation of portion of soil surface covered to surface residue mass

10.2.1. Size criteria for counting residue

To be counted as ground cover, soil surface material must remain in place, not be moved downslope by surface runoff during a rainstorm, and not be moved away by wind. The minimum size required to be counted as ground cover for RUSLE2 purposes must meet this criteria. **No single size should be used for all ground cover material in all situations**. For example, small pieces of residue will stay in place at the upper end of an overland flow path that would be moved at the lower end of a long overland flow path. Similarly, residue will be stable on a very flat overland flow path that would be moved on a steep overland flow path. Small residue pieces can be stable among a gradation of residue sizes but be unstable when the residue is uniformly composed of the small pieces. Small residue pieces that are stable at high residue surface covers may be unstable at low residue surface covers.

Equations that compute the hydraulic stability of mulch and crop residue were considered for RUSLE2 but were rejected because the equations were judged not to be sufficiently robust for RUSLE2 purposes (Foster et al., 1982a, 1982b).

Rock fragments on the soil surface require special consideration. The same stability considerations for other surface residue also apply to counting surface rock fragments as surface cover. Another factor is whether the rock fragments are a part of the soil matrix or simply "loose" rock on the soil surface that acts like surface cover. An approximate guideline is that rock fragments must be larger than 5 mm on coarse textured soils in arid and semi-arid regions where runoff is low and larger than 10 mm in other regions to be counted as ground cover.

10.2.2. Equation for computing residue cover from residue mass

RUSLE2 tracks surface residue (material in direct contact with the soil surface) on a dry mass basis (mass/area). However, the portion of the soil surface covered is the major variable used in equation 6.6 to compute how ground cover (surface residue) affects rill-interrill erosion. The RUSLE2 equation that computes portion of the soil surface covered by surface residue is:

$$f_g = 1 - \exp(-\alpha B_s) \qquad [10.1]$$

where: f_g = fraction of the soil surface covered by residue when no other residue type is present and B_s = surface residue mass (dry mass/area). RUSLE2 computes a value for the coefficient α using equation 10.1 rearranged and user entered values for the residue mass that provides 30, 60, or 90 percent soil cover.

A typical example of surface residue mass-cover data is illustrated in Figure 10.1. A common feature of these data is their high variability, which in turn greatly affects the variability in computed erosion estimates. For example, cover ranges from 0.70 to 1.0 percent in Figure 10.1 at a mass of 150 g/m^2. This range in cover gives ground cover subfactor values for g_c in equation 6.6 (**b** = 0.04 percent^{-1} and R_a = 0.24 inches) that range from 0.018 to 0.061. The portion of the soil surface covered ranges from 0.55 to 0.85 percent for a residue mass of 50 g/m^2, which gives values of 0.033 to 0.11 for g_c. In both cases, erosion

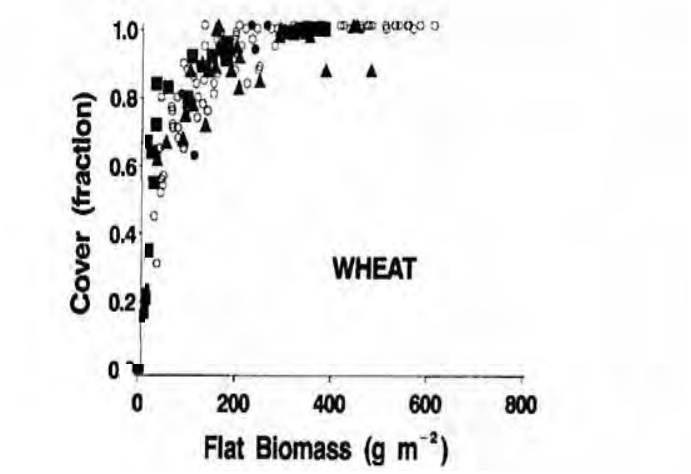

Figure 10.1. Measured data for relationship of residue cover to surface residue mass. (Source: Steiner et al., 2000).

can differ by a factor of 3 for a given surface residue mass. Therefore, even if RUSLE2 could estimate surface residue mass perfectly, RUSLE2's estimated portion of the soil surface covered, and its corresponding estimated erosion, could be significantly in error when compared to an individual measurement of soil surface cover.

Given this variability, the best that RUSLE2 can represent is differences in major residue types. Expecting RUSLE2 to accurately estimate percent residue cover at a particular location on a landscape at a particular point in time is unreasonable.

Data reported in the literature for residue cover as a function of residue mass vary greatly from study to study and even within a particular study as illustrated in Figure 10.1. The values used in the RUSLE2 Core Database were chosen as representative values for conservation and erosion control planning, realizing that numerous studies give values that differ from the RUSLE2 values. For example, surface cover ranged from about 65 percent to 100% for a flat wheat residue mass of about 1500 lbs/acre (168 g/m^2) in the Steiner et al. (2000) study, which is significantly greater than the 58 percent that the RUSLE2 Core Database values compute for the same residue mass. The RUSLE2 Core Database values for wheat straw are based on AH537 (Wischmeier and Smith, 1978) values, which were primarily derived from data reported by Mannering and Meyer (1963), Meyer and Mannering (1967) and Meyer et al. (1970).

The variation among some plant varieties is so great than different mass-cover relationships should be used for major variety types. For example, Stott (1995) noted that α values for corn varied from about 0.00023 to 0.00045 $(lbs/acre)^{-1}$ for corn residue based on her measurements and data reported in the literature. Stott recommended that the 0.00023 acre/lbs value (60 percent cover at 4000 lbs/acre flat corn residue mass) be used for corn grown after the mid 1980's and that the RUSLE2 Core Database value of 0.00038 $(lbs/acre)^{-1}$ (60 percent cover at 2400 lbs/acre corn residue mass) be used for corn grown before the mid 1980's. RUSLE2 satisfactorily estimates flat residue cover at planting for a wide range of soil and conservation tillage methods as Table 10.1 shows, with the recognition that the corn in these studies was grown before the mid 1980's.

Another example is that soybean varieties grown in the Midwest US differ from those grown in the Mid-South US. The RUSLE2 Core Database mass-cover value for soybeans varieties grown in the Midwestern US is that 600 lbs/acre of soybean residue gives 30 percent soil surface cover [AH703 (Renard et al., 1997)] while the mass-cover value for the variety of soybeans grown in the Mid-South US is that 1460 lbs/acre of soybean residue gives 30 percent soil surface cover (Mutchler and Greer, 1984).[67]

The RUSLE2 Core Database values for surface residue mass-cover relationships should be used for routine RUSLE2 applications. When RUSLE2 users wish to use values for residue mass-cover other than those in the RUSLE2 Core Database, users should review and analyze data from multiple sources because of the great variability in these data within a study as illustrated in Figure 10.1 and between studies. RUSLE2 was calibrated to measured erosion values using the values in the RUSLE2 Core Database. That is, RUSLE2 was calibrated to give expected erosion values. **Unexpected serious error in RUSLE2 computed erosion estimates can occur when input residues values are improperly changed from those in the RUSLE2 Core Database (see the RUSLE2 User's Reference Guide). If a change is made in residue input values, RUSLE2 computed erosion values with the new input values should be compared against erosion measured with the residue represented in the new input values.**

10.2.3. Reasons for variability in the surface residue mass-residue cover relationship

A major reason for the variability in the residue mass-residue cover relationship is that crop residue, plant litter, and similar materials are composed of multiple plant components (e.g., leaves, stems, seed pods, and chaff) and pieces that vary in composition, geometry, size, mass, and surface area covered per unit dry mass. RUSLE2 uses a single residue description to represent residue as a composite of multiple components. Consequently, α in equation 10.1 is a function of the relative mass of each residue component in the composite and varies temporally as the relative mass of each residue component varies temporally. For example, the α value for corn and soybean residue immediately after harvest differs significantly from the α value several months later because leaves cover more area than do stems per unit mass and leaves decompose much more rapidly than do the stems. In contrast to corn and soybeans, field measured data at Bushland, Texas showed that α values for barley, oats, spring wheat, and winter wheat did not vary from 24 to 400 days after harvest (Steiner et al., 2000). However, data variability, as in all studies of residue mass-residue cover, may have masked temporal changes in the residue mass-residue cover relationship.

The RUSLE2 assumption is that residue properties such as α in equation 10.1 are time invariant for the period represented by a residue description in a RUSLE2 computation. Consequently, equation 10.1 is a compromise and the values in the RUSLE2 Core Database used to compute α were chosen to compute erosion values appropriate for conservation and erosion control planning (see RUSLE2 User's Reference Guide). The input values that RUSLE2 uses to compute α values should be carefully selected to ensure that equation 10.1 gives the best erosion estimates for the time periods that have the greatest effect on average annual erosion. User entered values for a new residue description being added to a RUSLE2 database should be consistent with values in the RUSLE2 Core Database. Procedures described in the RUSLE2 User's Reference Guide must be followed.

In some cases, temporal changes in residue properties can be represented in RUSLE2 by using multiple residue descriptions during the RUSLE2 computation period. Using multiple residue descriptions requires using an operation that includes a **remove residue/cover process** to remove the existing material and another operation that includes an **add other cover process** that adds the removed material back to the soil surface using a new residue description. The computer mechanics of using RUSLE2 in this way are not convenient for routine conservation and erosion control planning. However, the procedure is mentioned to illustrate RUSLE2's capability for computing the effects of temporal variations of residue properties. Technical specialists for agencies using RUSLE2 in routine conservation planning can use this technique to evaluate the uncertainty in RUSLE2 erosion estimates resulting from the assumption that residue properties do not vary temporally (see RUSLE2 User's Reference Guide).

10.2.4. Overlap of residue

The user assigns a single residue description to each vegetation description and to each operation description in a cover-management description that adds material to the soil surface (see RUSLE2 User's Reference Guide). For example, a corn-soybeans crop rotation involves two residue descriptions, one for corn and one for soybeans. The mass for each residue description is tracked separately. A daily ground cover value is computed with equation 10.1 for each residue description. A net ground cover value is used in equation 6.6 to compute a value for the ground cover subfactor, not the sum of the ground cover values computed with equation 10.1 for each residue description when multiple residue descriptions are involved. RUSLE2 takes into account the overlap of residue applications to compute net ground cover. The RUSLE2 assumption is that the portion of material that overlaps underlying material has no effect on rill-interrill erosion. The computation of net ground cover is illustrated for crop residue or mulch applied to a soil surface with existing rock cover. The net ground cover for these two residue descriptions (e.g., crop residue or mulch and rock) is computed as:

$$f_{gn} = f_{gr} + f_{gm}(1 - f_{gr}) \qquad [10.2]$$

where: f_{gn} = net ground cover (fraction), f_{gr} = ground cover (fraction) computed with equation 10.1 provided by the rock surface residue cover assuming no other material is present, and f_{gm} = ground cover (fraction) computed with equation 10.1 for crop residue or mulch assuming no other material is present. Equations 10.1 and 10.2 are used repeatedly to account for each residue description used in a particular RUSLE2 computation to compute a net ground cover value. The overall net ground cover value is used in equations 6.6, 6.7, and related equations to compute the effect of surface residue cover on rill and interrill erosion. A ground cover subfactor g_c is not computed for each residue description.

10.2.5. Inputs for non-organic residue

In some cases, a material is applied to the soil surface that significantly affects erosion but has less effect on erosion when incorporated into the soil than routine plant residue. The mass values entered in the residue description for cover-mass data points can be scaled to be so small that the mass values used for the material when incorporated in the soil are so small that they have no effect on soil biomass subfactor values (see **Section 6.5**). Input values for mass of these materials applied to the soil must be accordingly scaled. The objective in these RUSLE2 applications is that RUSLE2 uses desired ground cover values to compute ground cover subfactor values using equation 6.6 but uses such small residue mass values that soil biomass factor values computed with equation 6.48 are hardly affected if the material is incorporated into the soil (see RUSLE2 User's Reference Guide**)**.

The importance of using recommended RUSLE2 inputs and following RUSLE2 procedures described in the RUSLE2 User's Reference Guide can not be over-emphasized, especially when making comparisons with the USLE, RUSLE1, and much of the historical data used to develop those models as well as RUSLE2. However, crop characteristics and yield, especially for corn, has changed greatly from the 20 bu/ac corn yield common in the 1930's data used to determine the AH282 and 537 soil loss ratio values, which were used to calibrate RUSLE2, to modern 200 bu/ac high production corn yields. The values in the RUSLE2 Core Database are considered adequate for evaluating modern crops and cropping practices, especially when RUSLE2 erosion computed values are being compared with values computed with the USLE or RUSLE1.

Consideration should be given to changing input values to represent modern crops and cropping practices in certain RUSLE2 applications. In doing so, the procedures described in the RUSLE2 User's Reference Guide should be carefully followed, and input values must be based on multiple data sources, not a single source. RUSLE2 was calibrated to compute expected erosion rates as a function of the principal variables affecting erosion. Therefore, RUSLE2's computation of what appears to be an erroneous cover value does not necessarily mean that RUSLE2's computed erosion values are erroneous.

Improper inputs without consideration of RUSLE2's calibration can result in very serious errors in RUSLE2 computed erosion values.

10.3. Decomposition of residue and dead roots

10.3.1. Description of equations

Both residue and dead roots are assumed to be lost over time as a result of decomposition and other processes related to precipitation and temperature. The basic RUSLE1 decomposition equations are used in RUSLE2 [AH703 (Renard et al., 1997); Yoder et al., 1997; Stott et al., 1990; Stott et al., 1995], which are a simplification of the decomposition equations used in the erosion prediction model WEPP (Laflen et al., 1991b; Flanagan and Nearing, 1995).[68] The main decomposition equation is:

$$B = B_p \exp(-\beta D) \qquad [10.3]$$

where: B = the mass in a particular residue/dead root pool after decomposition B_p= the mass in the pool on the previous day, and D = the number of days in the period over

[68] Also, see references listed in the **Decomposition Subsection** of the **References Section**.

which decomposition is being computed, which is a single day in RUSLE2 (i.e., D = 1 day). A daily value for the coefficient β is computed from:

$$\beta = \phi[\min(W_f, T_f)] \qquad [10.4]$$

where: ϕ = a decomposition coefficient (day^{-1}) that is a function of biomass type, W_f = a moisture function, and T_f = a temperature function. Equation 10.4 is based on the assumption that decomposition on a particular day is limited by either moisture or temperature on that date.

Moisture must be present for decomposition to occur. Daily precipitation is used in RUSLE2 as an indicator of moisture available for decomposition. RUSLE2 does not compute moisture in residue/dead root pieces or in the soil that contacts residue/dead roots. Decomposition rate decreases if moisture decreases below the moisture content for optimum decomposition. RUSLE2 does not take into account reduced decomposition at excessively high moisture contents. Daily values for the moisture function W_f are computed from:

$$W_f = (P + I)/P_b \;\; if[(P + I)/P_b > 1] : W_f = 1 \qquad [10.5]$$

where: P = daily precipitation (inches), I = daily amount (inches) of water added by irrigation, and P_b = base daily precipitation (inches) at which optimum decomposition occurs. A value of 0.173 inch (4.4 mm) was determined by fitting the RUSLE2 decomposition equations to the field data identified in Table 10.2.

Decomposition also varies with temperature. Decomposition decreases as temperature decreases below 32 ^{o}C, the optimum temperature at which decomposition rate is maximum. Similarly, decomposition decreases as temperature increases above 32 ^{o}C. Daily values for the temperature function are computed from:

$$T_f = \frac{2(T + A)^2 (T_o + A)^2 - (T + A)^4}{(T_o + A)^4} \;\; if(T < -10) : T_f = 0 \qquad [10.6]$$

where: T = daily air temperature (^{o}C), T_o = the optimum temperature (^{o}C) for decomposition (32 ^{o}C), and A = 8 ^{o}C. The value for A was set so that when air temperature becomes less than – 10 ^{o}C, the temperature function is set to zero.[69] The reason that the temperature function does not become zero at a higher temperature, such as near 0 ^{o}C, is that temperature varies between a minimum and maximum during the day and average temperature on a given day varies about the long-term average temperature for that day. Air temperature rather than soil temperature is used in the temperature

[69] An adjustment should have been made to equation 10.6 to flatten the top of the curve around the 32 ^{o}C temperature for maximum decomposition to account for within day and year-to-year variation in temperature about the average daily temperature used in RUSLE2. See Schomberg et al. (2002).

function because soil temperature data are not readily available for use in RUSLE2. Like precipitation, air temperature is an indicator variable rather than the actual temperature that the decomposing material experiences. Values for the RUSLE2 decomposition coefficient ϕ differ from values for decomposition coefficient in similar equations used in other erosion prediction models such as WEPP (Stott et al., 1995), WEPS (Steiner et al., 1995), and RWEQ (Schomberg and Steiner, 1997).

The RUSLE2 composition coefficient ϕ can be expressed in terms of residue half life, which is defined as the time required for half of the residue mass to decompose at optimum temperature and moisture (i.e., $W_f = 1$ and $T_f = 1$). The relation of residue half life $D_{1/2}$ to the decomposition coefficient ϕ is given by:

$$D_{1/2} = -\ln(0.5)/\phi \qquad [10.7]$$

where: $D_{1/2}$ = residue half life (days) and ln(0.5) = 0.693.

The same decomposition coefficient ϕ values and moisture (W_f) and temperature (T_f) functions are used in RUSLE2 for buried and surface residue and dead roots (see **Section 10.3.3** for discussion of the reasons for this decision). Also, RUSLE2 decomposition coefficient ϕ values and the W_f and T_f functions are assumed not to vary with depth in the soil, soil texture, soil management, or residue mass. The same W_f and T_f functions are used to estimate decomposition of standing residue, but the RUSLE2 decomposition coefficient ϕ value for standing residue is 0.3 of that for surface and buried residue because moisture available for decomposition of standing residue is assumed to be much less than moisture available for decomposition of surface and buried residue (Douglas et al., 1980; Ghidey and Alberts, 1993; Steiner et al., 1994) (see **Section 10.3.3** for discussion of the reasons for this decision).

10.3.2. Calibration of equations

Values for the daily base precipitation P_b in equation 10.5 and values for the decomposition coefficient ϕ were determined by fitting the decomposition equations to measured data. Resulting P_b and ϕ values are given in Table 10.2.

The decomposition equations were fitted to the field data using daily average precipitation and temperature values disaggregated (see **Section 3.1**) from long term average monthly precipitation and temperature rather than actual precipitation and temperature values. Using long term-averages in these computations had a smoothing effect. Also, RUSLE2 uses average daily precipitation regardless of whether precipitation actually occurs, and thus values determined for P_b and ϕ are a function of RUSLE2's mathematical structure. Furthermore, the RUSLE2 purpose is to

capture the main differences in decomposition between locations rather than to precisely compute decomposition as a function of soil and cover-management. Furthermore, empirical data available to calibrate RUSLE2's decomposition equations were not sufficient to empirically determine coefficient values that are functions of soil and cover-management.

The RUSLE2 decomposition equations should be calibrated with several years of data at a location for a particular residue type and placement so that the data represent the expected range of climatic conditions at that site over a 10 to 30 year period. Unfortunately, most residue decomposition studies involve only a single year. Even when only single years of data were available, the RUSLE2 average daily precipitation and temperature values were used to calibrate the RUSLE2 decomposition equations.

Data sets were assembled from as many locations for each residue type as were available. Field residue mass-area and decomposition data are highly variable. Multiple sets of data

for the same residue type were used as much as possible. The RUSLE2 decomposition equations were fitted to averages of these data by residue type and location.

Calibration of the RUSLE2 decomposition equations involved fitting them to field data to determine values for the base precipitation P_b and the decomposition coefficient ϕ. The first step in the fitting was to allow both P_b and ϕ to vary. The results for some of those fittings are shown in Table 10.2 for the P_b entries other than "4.4 assumed." A consideration was whether both P_b and ϕ varied by residue type and location. Based on an inspection of the fitted P_b and ϕ values, the conclusion was that a constant value of 4.4 mm (0.173 inches) could be used for P_b for the entire US except in the Palouse region (Req region, see **Section 3.2.5**) in the Northwestern US.

The use of a constant P_b = 4.4 mm value also was evaluated qualitatively by making computations for numerous locations across the US for several residue types. The 4.4 mm value worked well everywhere except for the Req region where a 0.5 mm value worked better. As Table 10.2 shows for the Pullman, WA location, use of the 0.5 mm P_b value gave ϕ values of 0.01 day^{-1} for wheat residue that are comparable to 0.008 day^{-1} values determined in other parts of the country. The reason for the low P_b values in the Req region is that the soil is highly saturated during the winter months when almost all of the erosion occurs and moisture does not limit decomposition even though daily precipitation is not high. If the 4.4 mm P_b value is used in the Req region, the ϕ value for wheat is 0.017 day^{-1} rather than the 0.008 day^{-1} for other parts of the US (see **Section 10.3.3.9**).

Table 10.3. Recommended values for the decomposition coefficient Φ in RUSLE2 with A = 8 °C and P_b = 4.4 mm (0.173 inches) based on fitting decomposition equations to measured data.

Crop	Decomposition Coefficient Φ (day^{-1})
Alfalfa	0.015
Blue stem hay	0.012
Corn	0.016
Cotton	0.015
Sorghum	0.016
Soybeans (Midwest US)	0.025
Soybeans (Mid South US)	0.015
Wheat in Eastern US (soft white wheat)	0.008
Wheat in Northwest Wheat and Range Region (NWRR) (hard red wheat)	0.017

Note: If P_b = 0.5 mm, then Φ = 0.01 day^{-1} for NWRR wheat

Once the P_b value was set at 4.4 mm, the calibration was repeated where values of ϕ were determined by fitting the decomposition equations to the field data. Table 10.2 entries for the "4.4 assumed" value for P_b are where the decomposition equations were fitted to the data with the P_b value fixed at 4.4 mm. The fitted values for ϕ were inspected and the ϕ values chosen for the RUSLE Core Database are shown in Table 10.3. Figure 10.2 shows how well RUSLE2 decomposition equations fit field data using the 4.4 mm P_b value and Table 10.2 ϕ values for surface residue. Decomposition of buried residue is discussed in **Section 10.3.3.3**.

The ϕ value for the Eucalypt litter was determined using a different calibration approach from the one used to determine the ϕ values shown in Table 10.2.

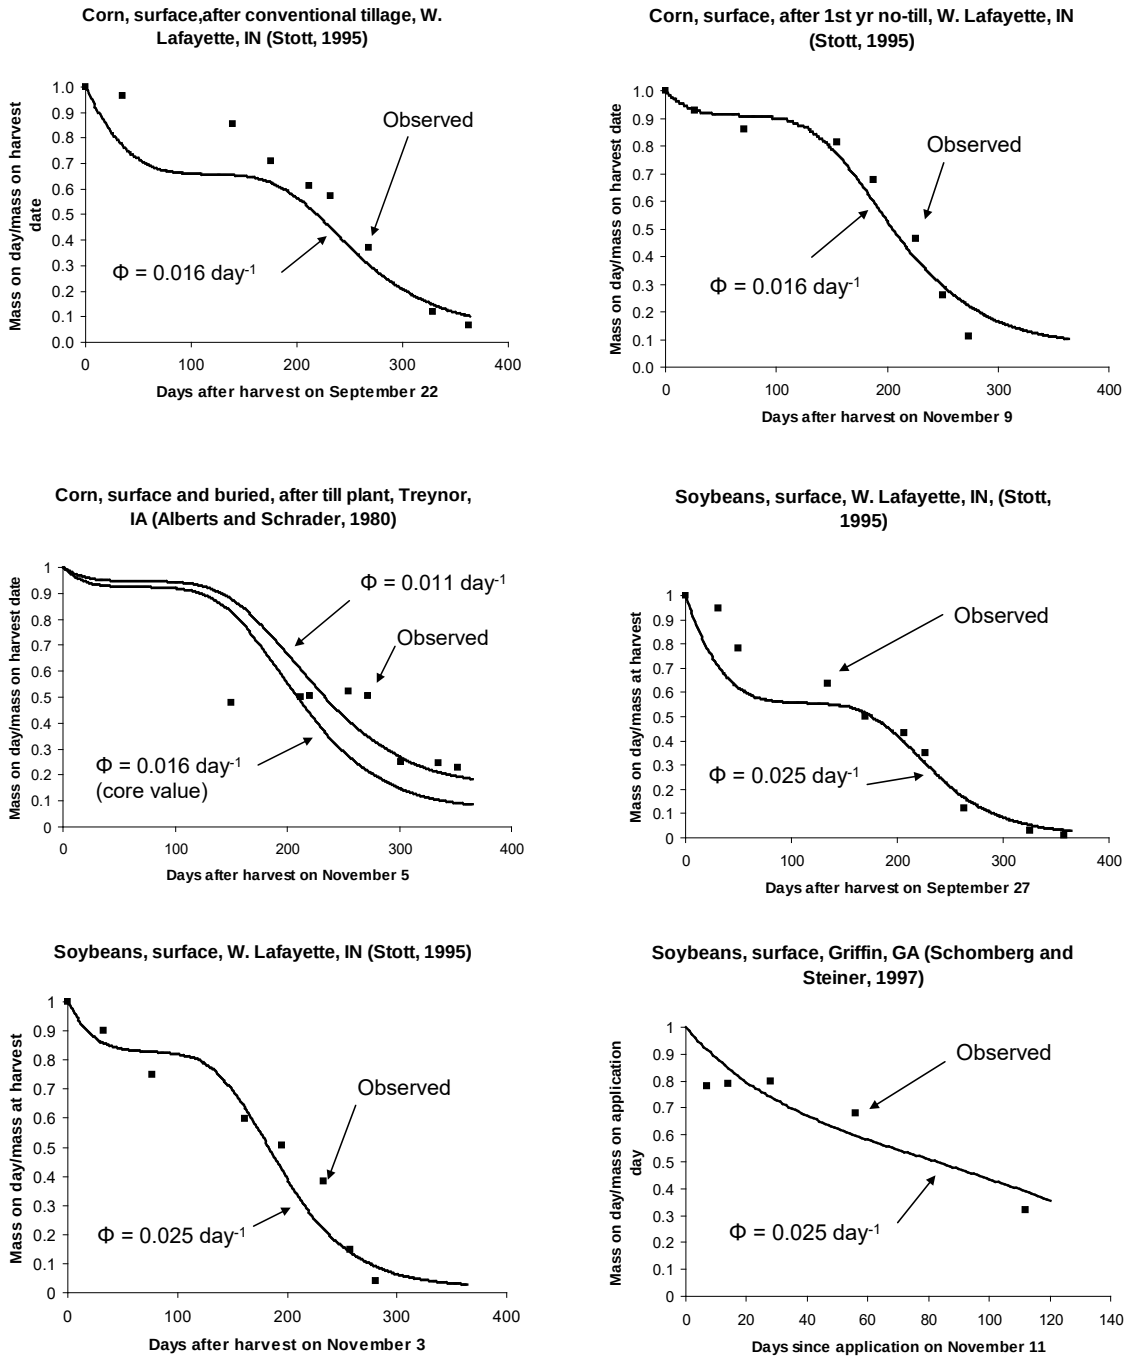

Figure 10.2. Comparison of RUSLE2 decomposition estimates using RUSLE2 Core Database values in comparison with field data.

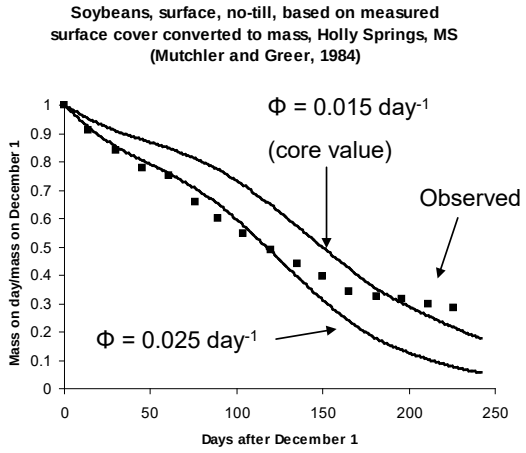

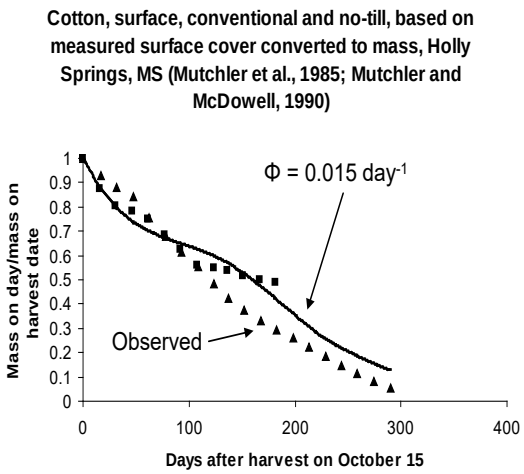

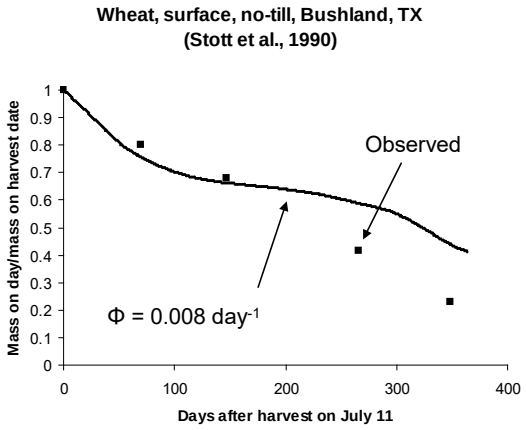

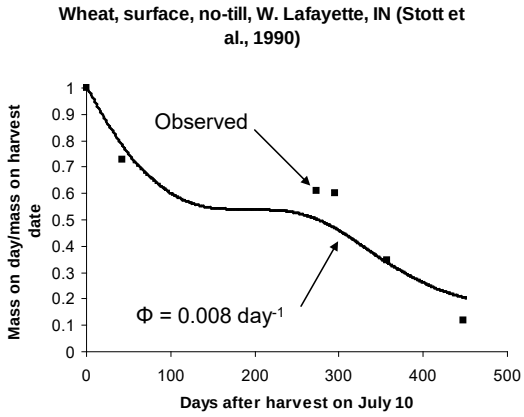

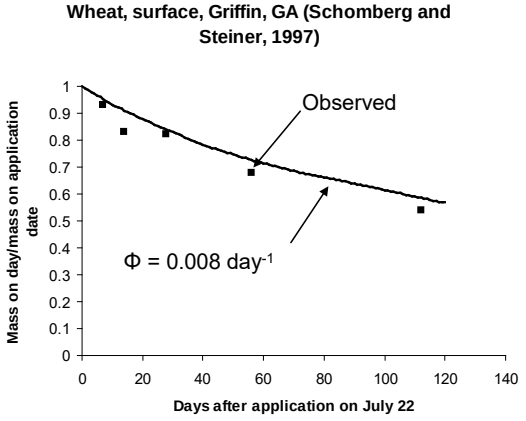

Figure 10.2. Comparison of RUSLE2 decomposition estimates using RUSLE2 Core Database values in comparison with field data. (continued)

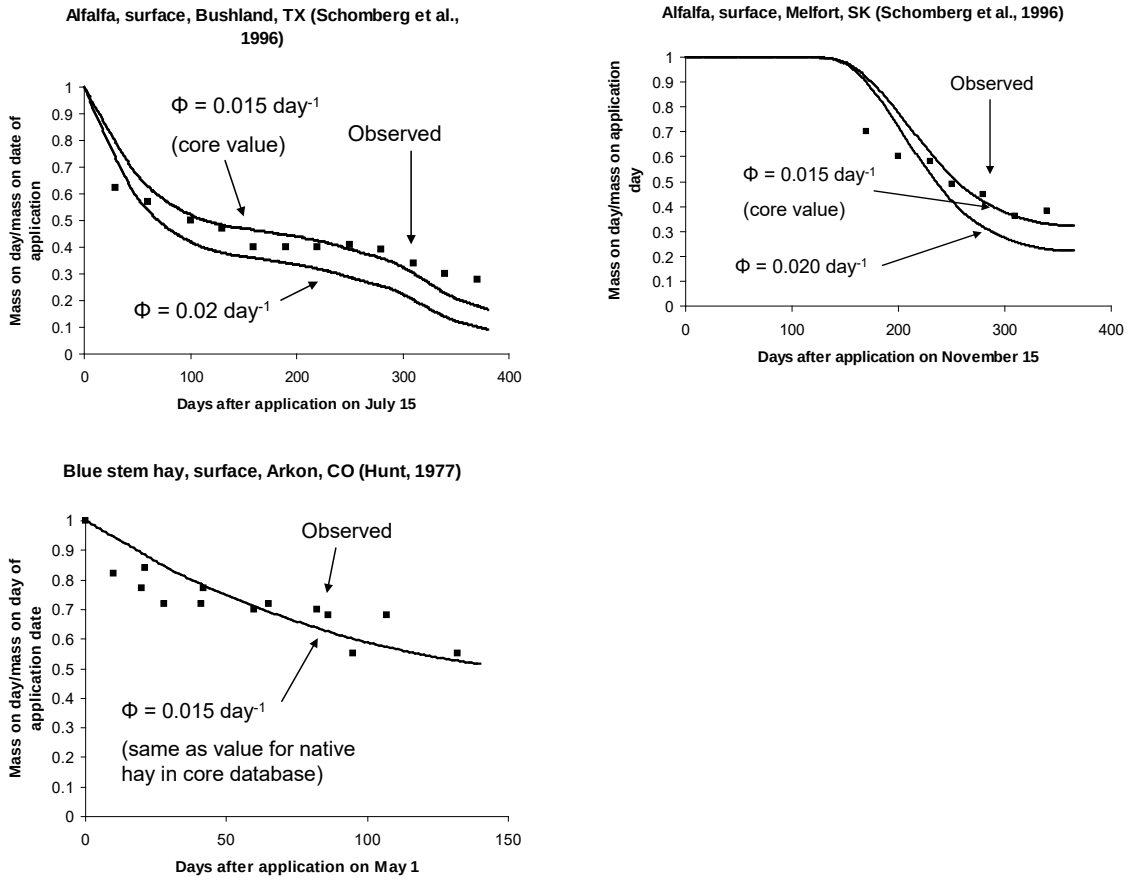

Figure 10.2. Comparison of RUSLE2 decomposition estimates using RUSLE2 Core Database values in comparison with field data. (continued)

Rather than fitting the RUSLE2 decomposition equations to the loss of residue mass over time, a ϕ value was determined for the Eucalypt litter by fitting RUSLE2 decomposition equations to an increasing residue mass over time until the mass reached a stable maximum. The Eucalypt litter data shown in Figure 10.3 are for surface residue (litter) accumulation following a forest fire in the Southwestern Australian Eucalypt forest (Birk and Simpson, 1980). This application illustrates RUSLE2's capability for computing both the accumulation of a surface litter layer where the biomass input is produced by aboveground senescence and the accumulation of a similar below ground biomass pool produced by root growth and death (root senescence, turnover).

An inspection of Figure 10.2 shows that RUSLE2 captures well the effect of location and material type on residue decomposition over time. A constant P_b value over almost all of the US works surprisingly well. Also, assuming the same ϕ value for a residue type works well for locations where climate differs greatly. For example, compare the results for alfalfa at both Griffin, Georgia and Melfort, Saskatchewan.

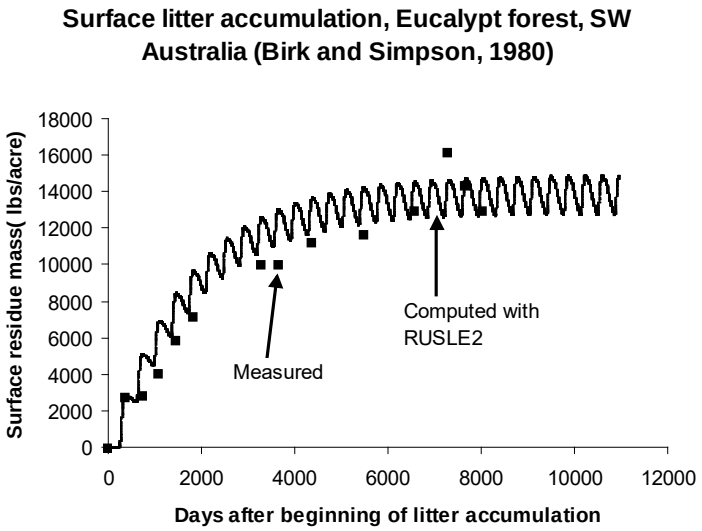

Figure 10.3. Computing the accumulation of a litter layer for an Eucalypt forest in Southwestern Australia.

An expectation is that RUSLE2 database developers can use values in the RUSLE2 Core Database to guide assignment of decomposition coefficient ϕ values for other residue types based on a comparison of residue characteristics. This procedure works but it requires more thought that initially expected. For example, a ϕ value of 0.02 day^{-1} was originally assigned for alfalfa before the ϕ value of 0.015 day^{-1} illustrated in Figure 10.2 was obtained by fitting measured field data. A ϕ value of 0.012 day^{-1} was assigned for native hay before the same ϕ value was determined by fitting measured data for the blue stem hay illustrated in Figure 10.2. The procedure of using values in the RUSLE2 Core Database as a guide in selecting decomposition coefficient values for other residue types will give reasonable RUSLE2 results for erosion control planning provided a careful comparison is made between residue types. The role of stems seems to be a major factor to consider in selecting ϕ values.

10.3.3. Basis for RUSLE2 decomposition decisions

RUSLE2's computation of residue loss is based on decomposition principles even though residue loss occurs by other processes besides decomposition. RUSLE2 is calibrated to field data representative of actual conditions as much as possible. RUSLE2 computations of residue and soil biomass loss are consistent with RUSLE2's purpose to be a **guide** to erosion control planning. Many decisions involved judgment during the formulation and calibration of RUSLE2's residue loss (decomposition) equations. This section describes the basis for those decisions.

10.3.3.1. User expectations

RUSLE2 computes residue decomposition and portion of the soil surface covered essentially using RUSLE1 procedures. Based on the RUSLE1 experience, some users will scrutinize RUSLE2's computed values for ground (surface, flat) residue cover more closely than RUSLE2's computed erosion values. RUSLE2 users are well aware of the importance of ground cover for controlling erosion. RUSLE2 users can not visually estimate erosion rates but they can visually measure ground (surface) cover. If RUSLE2's computed ground cover values do not meet their expectations, they assume

that RUSLE2's erosion computations must also be wrong, which is often a false assumption.

Surface residue cover is a major variable used in judging the adequacy of cropland erosion control measures. USDA-Natural Resources Conservation Service (NRCS) standards and specifications for certain conservation practices require a minimum surface residue cover at planting (e.g., 30 percent). The RUSLE2 decomposition procedures were carefully constructed to ensure that RUSLE2 computes appropriate surface residue cover values for conservation planning, as demonstrated by the values shown in Table 10.1. The RUSLE2 decomposition procedures were designed specifically for RUSLE2's use as a conservation planning tool, not for residue management and certainly not to advance residue decomposition science and modeling. The RUSLE2 intent is to capture main differences in loss of residue/dead roots between material types and locations in the context of estimating average annual erosion rates for comparison against a criteria such as the USDA-NRCS soil loss tolerance (T) values (Toy et al., 2002).

While RUSLE2 users can easily measure residue cover, which they can compare with RUSLE2 computed values, they must exercise great caution in their measurements and evaluations of RUSLE2's adequacy for computing residue cover and corresponding erosion estimates. Residue mass-cover data are highly variable as illustrated in Figure 10.1. The cotton data in Table 10.2 illustrates the variability in decomposition data among multiple data sets collected under near identical conditions for the same residue type. Making a few field measurements is not the proper way to evaluate RUSLE2's computed residue cover values. The RUSLE2 User's Reference Guide provides information on how to adjust RUSLE2 inputs to obtain particular RUSLE2 computed residue cover values.

10.3.3.2. Residue sampling method

RUSLE2's computation of residue loss is based on dry mass, which requires field measurements of residue mass over time are needed to calibrate RUSLE2. The mesh bag and the "grab" sample are the two techniques used most often to determine surface residue mass in decomposition experiments. The mesh bag method involves inserting residue in a mesh bag and placing the bag on the soil surface or in the soil. The grab sample method involves removing amd unconfined residue from a sample area. Each method has significant drawbacks (Dabney, 2005).

The residue loss measured by the mesh bag method is a function of mesh size (Dabney, 2005). The mesh bag method tends to underestimate residue loss. The residue loss determined using the common 1 mm mesh bags has to be multiplied by a factor that ranges from 1 to greater than 2 to represent the loss of unconfined residue.

Conversely, the grab sample method tends to overestimate residue loss and has its own shortcomings including the difficulty of removing soil particles attached to the residue. Another difficulty is retrieving the entire residue from the sample area because fragile residue pieces can be broken and not recovered.

The difference in measured residue loss by sampling methods is very significant as illustrated in Figure 10.4. Using the RUSLE2 Core Database values, RUSLE2 computes that a 150 bu/acre corn crop produces 8200 lb/acre of residue. The corn residue mass remaining after 12 months at Bushland, Texas measured by the bag method would be 4100 lbs/acre (Schomberg et al., 1995, 1997) (see Figure 10.4). The percent soil surface cover provided by this residue mass is 79 percent and the ground cover subfactor value computed with equation 6.6 is 0.042.

The RUSLE2 decomposition equations were fitted to corn residue loss at W. Lafayette, Indiana measured using the grab sample method (Stott, 1995). The RUSLE2 computed value for residue mass remaining after 12 months using climate data for Bushland, Texas is 1480 lbs/acre. The percent soil surface cover provided by this residue mass is 43 percent and the ground cover subfactor value is 0.18, which is four times the value based on mesh bag measurements. Consequently, RUSLE2 computes greatly different erosion estimates depending on which set of data is used to calibrate RUSLE2's residue loss (decomposition) equations.

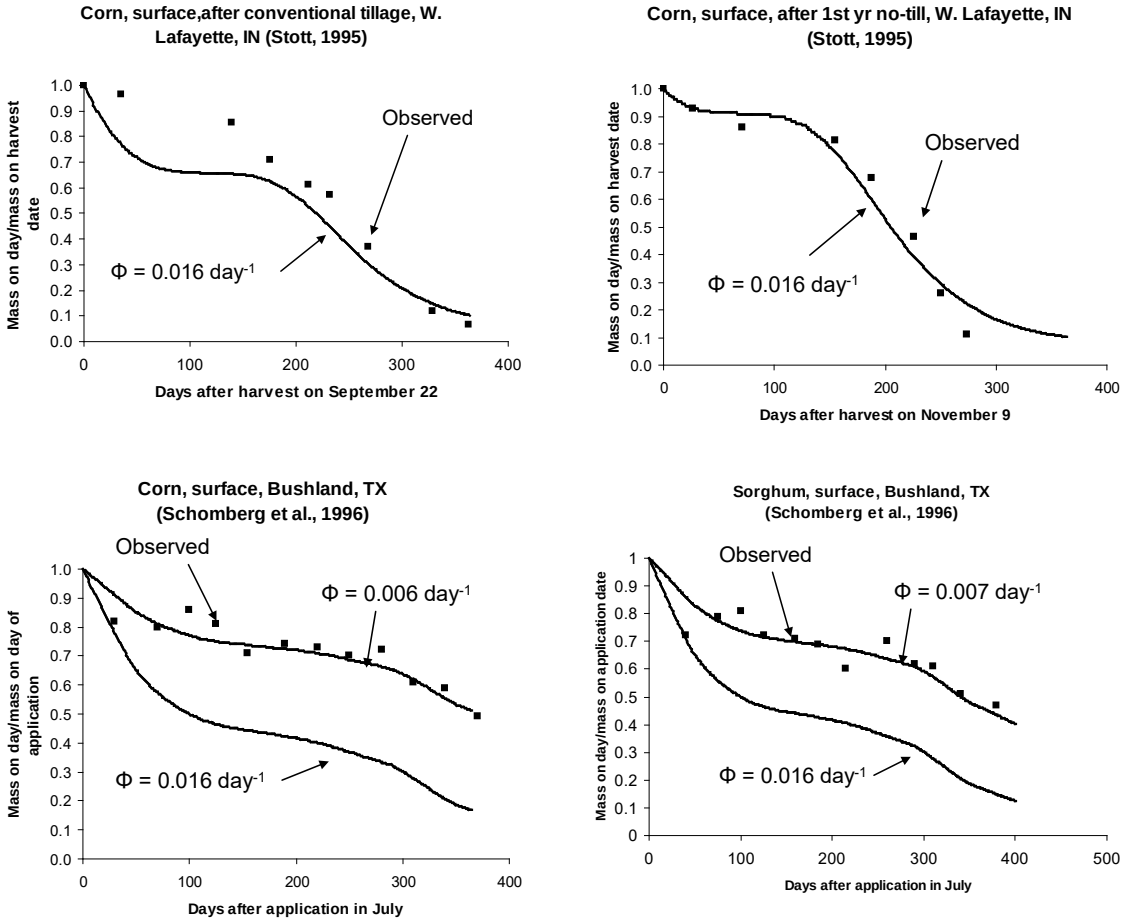

Figure 10.4. Comparison of observed and RUSLE2 computed decomposition of corn residue at W. Lafayette, Indiana and corn and sorghum residue at Bushland, Texas.

The difference in the measured Bushland, Texas data for corn and the RUSLE2 computed values based on a calibration to corn data measured at W. Lafayette, Indiana is not attributable to the RUSLE decomposition equations not performing equally well at the two locations. When wheat straw decomposition was measured by grab sampling from the soil surface (Stott et al., 1990; Stott, 1995; Stenier et al., 1999), measured decomposition at Bushland, Texas was consistent with data collected at W. Lafayette, Indiana and the RUSLE2 decomposition equations performed equally well at both locations (see Figure 10.2).

The difference in measured residue loss between the mesh bag and the grab sampling method is too large too ignore, which required a choice of one sampling method over the other. The grab sampling method was chosen for the development of RUSLE2. The conditions represented by this method, including the loss of residue by wind and other processes besides decomposition, better represent actual field conditions than does the mesh bag method. The differences between the two sampling methods seemed to be greatest for corn and wheat and much less for soybeans and forage crops. Decomposition coefficient ϕ values were determined for corn and wheat from the grab sample method while decomposition coefficient values were determined for forage crops from the mesh bag method.

Surface residue cover data were used to determine decomposition coefficient ϕ values for cotton and soybeans at Holly Springs, Mississippi. These data are field measured values for ground cover, which are the values most important in computing the effect of surface residue on rill-interrill erosion. These field data were considered to be superior to residue loss data measured with the mesh bag method.

The RUSLE2 decomposition coefficient ϕ value determined for corn is assumed to apply to grain sorghum based on the similarity in decomposition of corn and sorghum residue measured at Bushland, Texas by the mesh bag method. While the absolute decomposition values determined by the mesh bag method are not considered acceptable for RUSLE2 use, the mesh bag method is useful for determining relative differences in decomposition among residue types.

Other experimental procedures besides use of the mesh bag can affect decomposition results. The Ghidey and Alberts (1993) dataset includes decomposition values for roots and buried, surface, and above surface residue. Their data differ significantly from data considered best for RUSLE2 as illustrated in Figure 10.5. Oven drying the residue at 65 ^{o}C for 24 hours before placing the residue in the field may have contributed to the differences illustrated in Figure 10.5 in addition to mesh bags being used to measure residue loss.

10.3.3.3. Residue placement

RUSLE2 considers three placements of residue: (1) standing above ground, (2) soil surface, and (3) buried in the soil.

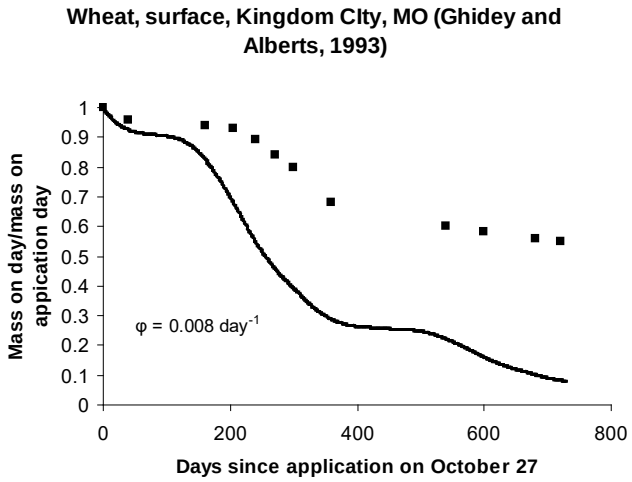

Figure 10.5. Difference in decomposition between that measured by Ghidey and Alberts (1993) and other data considered better for RUSLE2.

The RUSLE2 decomposition coefficient ϕ value used for above ground biomass is 0.3 times the ϕ value used for surface and buried residue. The decomposition coefficient ϕ value for above ground residue should be about 0.75 times the surface/buried residue ϕ value based on data collected by Douglas et al. (1980) and Ghidey and Alberts (1993). However, these data are questionable because the bundled residue samples used in these experimental studies do not represent individual pieces of standing stubble residue. Standing residue would retain much less moisture than the bundled residue samples. The 0.3 value performed satisfactorily in RUSLE2's computation of loss of standing residue (see **Section 10.4.1**)

The RUSLE2 assumption is that buried residue is lost at the same rate that soil surface residue is lost, although the common assumption is that buried residue decomposes more rapidly than does surface residue (Dabney, 2005). An example of measured data illustrating this apparent difference is shown in Figure 10.6. Like other residue aspects, the difference in decomposition rates for surface and buried residue varied greatly in the data reviewed by Dabney (2005) with no clear trend. Overall, the apparent decomposition rate for buried residue, regardless of residue type, was 1.3 times the decomposition rate of surface residue. Additional adjustment is required to obtain decomposition estimates of unconfined residue because the mesh bag sampling method was used in 10 out of 12 studies reviewed by Dabney (2005).

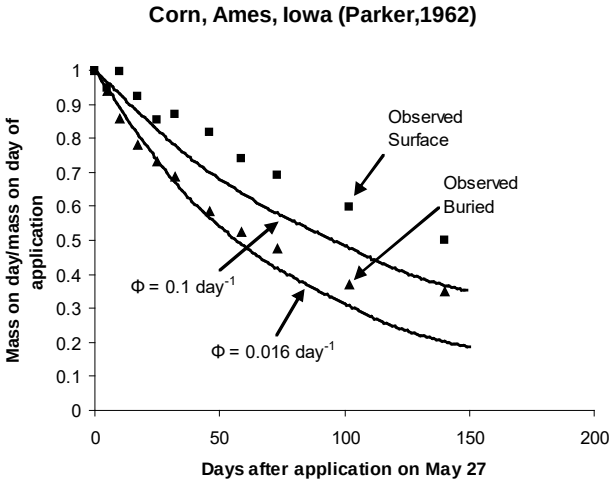

Figure 10.6. Difference in decomposition of residue in bags buried in the soil and placed on the soil surface.

Just as discussed in **Section 10.3.3.2** for surface residue, an adjustment also must be made for the mesh size effect on measured buried residue decomposition.

Instead of multiplying the mesh bag measured residue loss by 2 to obtain an estimate of unconfined surface residue loss, the measured mesh bag buried residue loss should be multiplied by 1.3 to estimate unconfined buried residue loss. Assume that the mesh bag measured surface residue loss is 1000 lbs/acre. The estimated actual loss is 2·1000 = 2000 lbs/acre. The measured mesh bag loss for buried residue is 1.3·1000 = 1300 lbs/acre based on the data reviewed by Dabney (2005), where the 1.3 factor accounts for the apparent higher decomposition rate for buried residue than for surface residue. Next, the 1300 value needs to be multiplied by the 1.3 factor to account for mesh bags underestimating the loss of unconfined buried residue. The buried residue loss of unconfined residue is therefore 1.3·1300 = 1700 lbs/acre. Consequently, these computations show that surface residue is lost at a greater rate (2000 lbs/acre versus 1700 lbs/acre) than is buried residue when the different effect of mesh size on decomposition of surface and buried residue is properly considered. The problem with these computations and with the mesh bag sampling method is the uncertainty involved in adjusting for mesh size and other factors related to how well decomposition in mesh bags represents actual field conditions.

The RUSLE2 intent is not to capture soil differences or placement within soil differences because RUSLE2 does not use soil moisture accounting routines. The buried residue studies cited by Dabney (2005) involved residue mesh bags placed 6 inches deep, which only partly simulates residue burial with a moldboard plow. A moldboard plow distributes residue throughout the disturbed soil layer even though most of the residue is buried in the lower half of the disturbed soil depth (see **Section 8.2.5.2**). Conservation tillage tools like disks, chisel plows, and field cultivators used for primary tillage leave most of the residue in the upper half of the disturbed soil depth (see **Section 8.2.5.2**), which residue buried at six inches does not represent. Furthermore, RUSLE2 uses the residue mass buried in the upper two or three inches to compute the effect of buried residue on erosion (see **Section 6.5**). The soil is drier at this shallow depth than at the six-inch measurement depth, and thus decomposition in this surface layer would be more like decomposition of surface residue than decomposition of residue buried at six inches. Therefore, mesh residue bags buried six inches deep do not represent typical field conditions.

Similarly, the placement of residue filled mesh bags on the soil surface does not represent typical field conditions. As Parker (1962) noted, a distinct boundary between surface residue and the soil surface does not exist in many cropland situations. For example, many residue pieces are both partially buried and exposed in conventional and mulch-till forms of cropping systems where tillage buries a portion of the residue left from the previous year's harvest. Soil splash by raindrop impact and local deposition behind residue pieces bonds the residue to the soil (Brenneman and Laflen, 1982; Toy et al., 2002). Also, the boundary between residue and the soil is not distinct in long-term no-till cropping systems. These effects are not captured by mesh bags placed on the soil surface.

The RUSLE2 objective is to produce reliable erosion estimates for conservation and erosion control planning. Increasing RUSLE2's decomposition rate for buried residue would not improve its erosion estimates but in fact would degrade them. The RUSLE2

computed ratio of erosion during the seedbed period for cropland going from turned sod to conventionally tilled 112 bu/ac yield corn to erosion for the same yield corn continuously cropped is 0.42, whereas the observed value is 0.40 [Table 5-D. AH537 (Wischmeier and Smith, 1978)].[70] However, the RUSLE2 computed ratio value is 0.95 for the second year while the observed value is 0.85. RUSLE2 computes this residual effect from turned sod using buried residue and dead root biomass values in equations 6.48 and 6.49. The first year erosion ratio value is computed well as a function of soil biomass before significant soil biomass loss by decomposition is computed. The fact that an accurate erosion ratio value is computed for the first year indicates that RUSLE2 is computing the proper effect of soil biomass when the estimated soil biomass is accurate. However, the fact that RUSLE2 computes too little soil biomass effect the second year indicates that RUSLE2 is computing too little soil biomass and a corresponding erosion that is too high. Consequently, increasing the decomposition coefficient ϕ value to represent buried residue decomposing more rapidly than surface residue will further degrade RUSLE2's performance for computing the effect of soil biomass.

These RUSLE2 erosion ratio values were computed using a decomposition coefficient ϕ value of 0.0017 day^{-1} for permanent grass vegetation residue. This decomposition coefficient value was originally selected based on comparison with other decomposition coefficient values in the RUSLE2 Core Database. However, recent analysis shown in Figure 10.2 for the blue stem hay shows that 0.012 day^{-1} is an appropriate value for decomposition coefficient ϕ value for blue stem hay. The erosion ratios computed with this ϕ value are now 0.36 compared to the observed 0.4 for the first year and 0.84 compared to the 0.85 observed for the second year, which is a significant improvement.

These results illustrate that the greater requirement is to accurately capture main effects before trying to capture minor effects. No basis exists for RUSLE2 computing decomposition of buried residue at a faster rate than surface residue. The RUSLE2 assumption that surface and buried residue decomposes at the same rate is strongly supported by both data, consideration of actual field conditions, increased accuracy of computed erosion values, and increased RUSLE2 robustness.

10.3.3.4. Roots

Fine roots are the most important roots in RUSLE2. A reasonable assumption is that the decomposition of fine roots is the same as buried residue. This assumption may need

---

[70] In this case, conventional tillage refers to a spring moldboard plow used for primary tillage followed two weeks later with a tandem disk and harrow or a tandem disk and field cultivator for secondary tillage used to create a seedbed.

reconsideration. Having the decomposition coefficient values the same for residue and roots gives RUSLE2 increased robustness, especially until additional information is learned about the distribution of root sizes and other root properties in the soil, the birth and death of roots, and how roots affect rill-interrill erosion. The RUSLE2 intent is to empirically capture the main effect of roots as an index rather than be a full description of how roots affect erosion.

10.3.3.5. Interdependence among calibration inputs for residue

No reliable data were found where both soil biomass and erosion were measured in the same experiment. Consequently, observed values for buried residue, dead root, and live root biomass were not used to calibrate the soil biomass subfactor equations 6.48 and 6.49 (see **Section 6.5**). Instead, RUSLE2 computed values for soil biomass were used to calibrate the soil biomass subfactor equations. In addition, "observed" soil biomass subfactor values were back-calculated from observed soil loss ratio values given in Table 5, AH537 (Wischmeier, and Smith, 1978) using RUSLE2 computed subfactor values for ground cover, soil surface roughness, ridge height, and soil consolidation for the seedbed crop stage of a silt loam soil at Columbia, Missouri, the RUSLE2 reference (base) location. Equation 6.1 was rearranged to compute values for s_b, the soil biomass subfactor. Soil loss ratio values from Table 5, AH537 are substituted for c in equation 6.1. Values for the other subfactors in equation 6.1 were RUSLE2 computed for the conditions listed in Table 6.5.

This soil biomass subfactor calibration approach has several consequences. The soil biomass subfactor absorbs the error and uncertainty in the other subfactors for the calibration conditions. The seedbed crop stage is the best crop stage for calibrating the soil biomass subfactor. Calibrating the soil biomass subfactor for this crop stage minimizes errors in the other subfactors because they deviate less from unit-plot conditions for the seedbed crop stage than for any other crop stage.

The only independent cover-management input in the calibration of the soil biomass subfactor, equations 6.48 and 6.49, is crop yield. All other cover-management inputs involved in the calibration are derived from yield, RUSLE2 Core Database values, and RUSLE2 procedures such as residue loss by decomposition and redistribution of soil biomass by mechanical soil disturbance. Therefore, a change in either RUSLE2 Core Database values or a RUSLE2 procedure used to compute subfactor values involved in the soil biomass subfactor calibration invalidates the calibration. **Consequently, a change in one of these items without recalibration produces erroneous RUSLE2 computed erosion estimates**.

The RUSLE2 assumption is that buried residue and dead roots decompose at the same rate as surface residue. This calibration approach has the advantage that it is partially self correcting if these assumptions are wrong. The empirically determined coefficient values in equations 6.48 and 6.49 compensate for erroneous soil biomass estimates used in the calibration as long as the relative values are accurate.

RUSLE2 has been developed and carefully validated to ensure that it computes the desired erosion values across the full range of conditions where RUSLE2 is expected to be used. Therefore, a change made to one RUSLE2 procedure, such as residue decomposition, requires a second change to ensure that RUSLE2 continues to compute expected erosion values.

Interdependence among RUSLE2 residue variables must be considered when changes are made so that RUSLE2 computes different ground (surface) cover values. To illustrate, What if RUSLE2 computed surface cover values seem questionable (see the **RUSLE2 User's Reference Guide** for additional discussion)? What RUSLE2 variable should be changed to improve surface cover estimates? The first step is to ensure that the data or observations being used as the basis for a change represent main effects rather than a minor effect or unexplained variability that RUSLE2 is not designed to capture.

The next step is to assess RUSLE2's computed erosion estimates to determine if these values should be changed along with the change in surface cover values. RUSLE2 was calibrated to give expected erosion estimates with an assumed set of values. A difference between an observed surface cover value and a RUSLE2 computed surface cover value does not necessarily mean that RUSLE2 is computing erroneous erosion estimates. What evidence, other than surface cover values, shows that RUSLE2 erosion estimates also need changing? An independence assessment should be made to determine if different erosion values should also be computed.

Changing decomposition coefficient ϕ values changes RUSLE2 computed surface cover values, but changing ϕ values also affects RUSLE2 computed soil biomass values and even soil surface roughness values that are a function of soil biomass. Therefore, a change in a ϕ value affects erosion in more ways than just changing surface cover. The question that should be asked before changing a ϕ value is: What evidence indicates that different soil biomass values should be computed along with different surface cover values?

Another way to change RUSLE2 computed surface cover values is to change above ground biomass as a function of yield. In addition to changing surface cover values, this change also affects soil biomass and soil surface roughness values. Once again, RUSLE2 computed erosion values are affected by changes in other variables besides surface cover.

The simplest way to change RUSLE2 computed surface cover values is to change surface residue mass-cover input values in the residue description (i.e., values for α in equation 10.1). Changing this relationship directly changes surface cover without changing other residue variables that affect erosion.

RUSLE2 changes should be carefully thought out to avoid unintended consequences.

10.3.3.6. Dealing with multiple component residue descriptions

A single RUSLE2 residue description is assigned to each vegetation description. A residue description represents a composite of the residue components produced by the particular vegetation.

Residue produced by vegetation includes: (1) pieces having a wide range in geometry that affect decomposition (e.g., fine and coarse roots and stems); (2) multiple components (e.g. leaves, stems, seed pods, and chaff); (3) variation in composition within a component (e.g., corn stalks having decomposition resistant exterior shells and easily decomposed interior material); (4) components, especially stems, that decompose from the inside out without changing outside dimensions (e.g., wheat straw); (5) decomposition properties that vary with growth stage (e.g., tender young leaves that decompose much more rapidly than mature leaves); (6) differences between above ground and below ground plant components (e.g., leaves that decompose more rapidly than roots); and (7) multiple species within a plant community (e.g., multiple plant species on rangelands and multiple weed species on permanent, unimproved pasture lands and landfills). RUSLE2 uses a single mass-cover coefficient α and decomposition coefficient ϕ to represent residue even though residue is composed of multiple components, each having its own α and ϕ values.

Effective RUSLE2 mass-cover coefficient α and decomposition coefficient ϕ values vary temporally as the residue decomposes. Values for these coefficients are functions of the relative composition of residue components that decompose at different rates. Consequently, the assigned RUSLE2 mass-cover and decomposition coefficient values are a compromise. The result is that RUSLE2 computes decomposition rates that are too slow in the beginning and too fast at the end. However, a review of Figure 10.2 shows that a single value decomposition coefficient ϕ works satisfactorily for a year for residue produced by typical agricultural crops, especially considering the unexplained variability in residue data.

Priority was given to fitting RUSLE2 computed decomposition values to observed values within the first year after residue application. Thus, RUSLE2 most accurately estimates decomposition of the easily and rapidly decomposable portions of the residue and not the residue that remains after one year, as illustrated in Figure 10.7. Most RUSLE2 applications involve a substantial annual input of biomass from crop production or senescence by permanent vegetation, which minimizes errors in RUSLE2 decomposition estimates beyond one year after residue application.

An example of a multiple component residue is the residue produced by a cover crop bi-culture of hairy vetch and rye that is killed at corn planning time in central Illinois (Ruffo

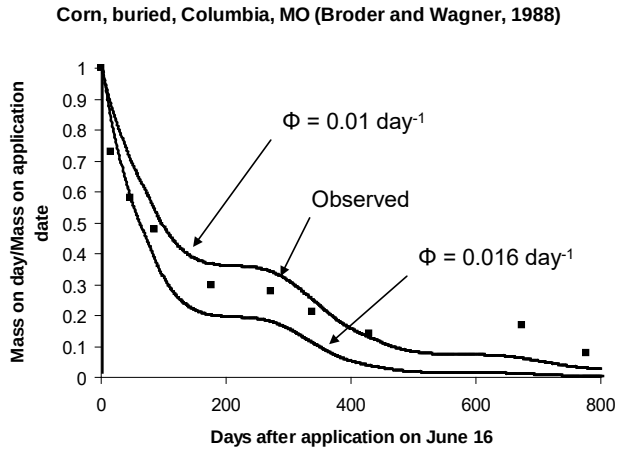

Figure 10.7. RUSLE2's estimate of residue decomposition over a 2-year period.

and Bollero, 2003). The hairy vetch cover crop residue component (ϕ = 0.032 day^{-1}) decomposes much more rapidly than does the rye cover crop component (ϕ = 0.017 day^{-1}).

Figure 10.8 shows RUSLE2 decomposition computations for hairy vetch and rye grown as mono-culture cover crops and a 1:1 bi-culture cover crop based on dry mass on the day that the cover crop is killed. The curve labeled "by-component" is the decomposition that should be computed for the bi-culture. The "by-component" values shown in Figure 10.8 were computed outside of RUSLE2.

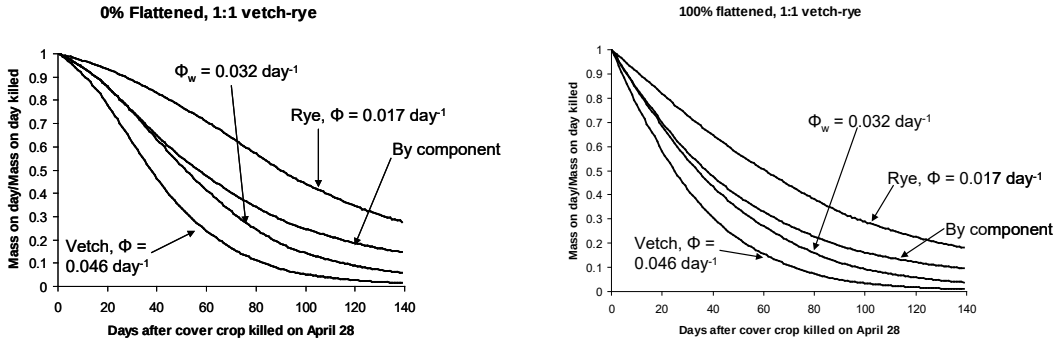

Figure 10.8. RUSLE2 computed decomposition of a 1:1 vetch-rye cover crop killed on April 28 in central Illinois. The Φ_w value is a weighted value based on dry mass on the date that the vegetation was killed.

A single value for the decomposition coefficient ϕ must be entered in the single composite RUSLE2 residue description that must be used to represent the combined residue produced by the hairy vetch and rye. One approach is to enter a weighted ϕ value based on dry mass of the hairy vetch and rye at the time that the cover crop vegetation is killed. As Figure 10.8 shows, initially RUSLE2 accurately computes decomposition but soon computes too much decomposition. The effective decomposition coefficient ϕ value should approach the ϕ value for rye over time as the hairy vetch decomposes much more rapidly than does the rye. An alternative input value for ϕ is an average of the weighted ϕ_w value at the time that the bi-culture cover crop is killed and the ϕ value for rye. RUSLE2 computes too little decomposition initially but computes much improved decomposition values after most of the vetch has decomposed.

Rather than developing a RUSLE2 procedure that adjusts the decomposition coefficient value as decomposition progresses, the best approach would be to modify RUSLE2 to accommodate multiple residue descriptions being assigned to a single vegetation description. In fact, the original RUSLE2 plan was to describe residue by its component parts. Using a residue description for each residue component would significantly improve RUSLE2's computations of residue decomposition and surface residue cover as a function of residue mass. Insufficient data existed for determining decomposition coefficient values for each plant residue component for the vast array of vegetations involved in RUSLE2 applications as a land use independent model.

The large decomposition coefficient ϕ values in Figure 10.8 for the hairy vetch and rye cover crops, 0.046 and 0.017 day^{-1}, respectively, illustrate how the decomposition coefficient ϕ is a function of crop stage. The ϕ value for mature hairy vetch residue is 0.020 day^{-1} while the ϕ value for mature rye is 0.0080 day^{-1}. The RUSLE2 decomposition coefficient values are about twice the values when the vegetation is killed as a cover crop when it is approximately half mature in comparison to the decomposition coefficient values for the vegetation after it reaches full maturity.

10.3.3.7. Effect of loading (application) rate

The decomposition coefficient ϕ seems to be a function of residue mass initially added to the soil surface as illustrated in Figures 10.9 and 10.10 (Steiner et al., 1999; Stott et al., 1990). **If initial surface residue mass affects the decomposition coefficient, the decomposition coefficient ϕ must also be a function of surface residue mass at any time after the residue is added to the soils surface.** The trend in both Figures 10.9 and 10.10 is that the decomposition coefficient ϕ decreases as surface residue mass increases. Therefore, Figure 10.9 and 10.10 imply that decomposition accelerates as surface residue mass decreases. However, this implication is inconsistent with the expectation that decomposition slows as the readily decomposable residue components disappear first, leaving the residue components that resist decomposition.

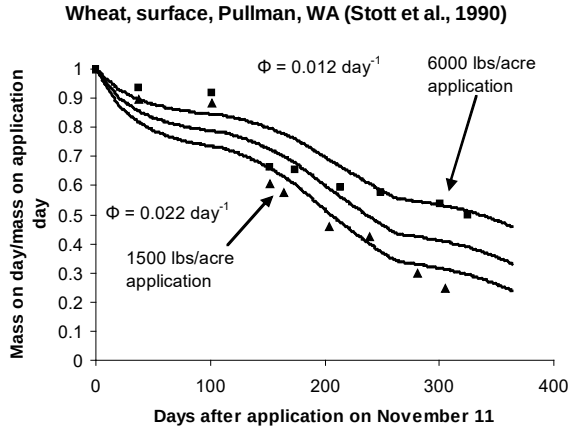

Figure 10.9. Effect of residue application rate on the decomposition coefficient ϕ.

Another concern is the great variability in decomposition coefficient values as illustrated in Figure 10.10. The RUSLE2 decomposition coefficient ϕ is proportional to the k decomposition coefficient in Figure 10.10. The comparable range in

ϕ for the range in k in Figure 10.10 for wheat straw is from 0.004 to 0.012 day^{-1}. RUSLE2 computes that 2100 and 600 lbs/acre of residue remain after 1 year for a 4000 lbs/ace wheat straw application at Columbia, Missouri for the ϕ values of 0.004 and 0.012 day^{-1}, respectively. The respective surface covers are 72 and 30 percent and the respective ground cover subfactor values, assuming **b** = 0.04 percent^{-1} in equation 6.6 (see **Section 6.3**), are 0.0561 and 0.301, which is a 5:1 erosion ratio. The uncertainty in decomposition coefficient ϕ values is much greater than the variation in ϕ as a function of application rate and surface residue mass as shown in Figure 10.10, especially for residue mass less than 6000 lbs/acre (600 g/m^2).

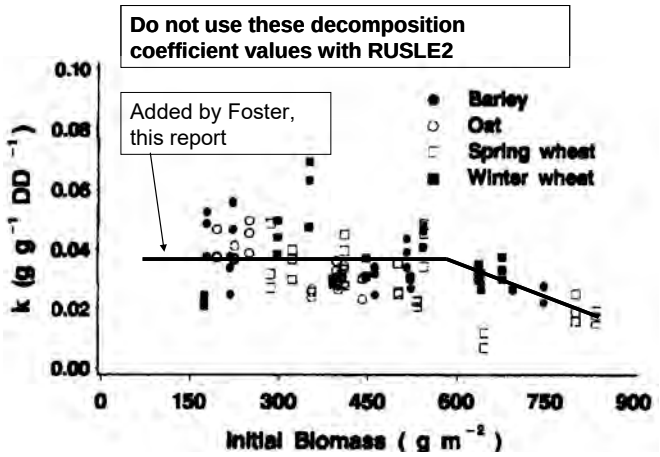

Figure 10.10. Variation of decomposition coefficient k (comparable to ϕ) values from another decomposition model with residue application rate. (Data source: Steiner et al., 1999; Line added by Foster, this report)

Furthermore, are the results illustrated in Figure 10.9 and 10.10 indicative of decomposition of the wide array of vegetation residue including vegetables, corn, wheat, hay, litter on rangelands, Eucalypt forest litter, and erosion control materials used on construction sites? Are the results illustrated in these figures indicative of application conditions that range from wheat straw being blown onto a construction site to wheat straw left in conventionally, reduced, and no-tilled fields?

The conclusion for RUSLE2 purposes is that the decomposition coefficient ϕ is not a function of residue application rate or surface residue mass. The uncertainty illustrated in Figure 10.10 reinforces the conclusion that RUSLE2 represents decomposition differences between major residue and erosion control material types, but not difference in small grain types, for example. An improvement in RUSLE2's decomposition computations can be gained by representing residue components such as legume and grasses and stems, leaves, seed pods, and chaff. Much more research is needed before the RUSLE2's decomposition coefficient ϕ can be made a function of application rate or surface residue mass. Furthermore, a standardized set of decomposition data for a wide range of materials are needed to determine RUSLE2 ϕ values.

10.3.3.8. Effect of irrigation on residue decomposition

RUSLE2's accuracy for estimating increased decomposition caused by irrigation was assessed using data reported by Schomberg et al. (1994) for decomposition of surface and buried alfalfa, wheat, and sorghum residue in mesh bags. Water varying in amounts from 5 to 336 mm was added by sprinkler irrigation during the study year in addition to 305

mm of natural precipitation. The long term average annual precipitation at Bushland, TX is 480 mm. The monthly precipitation and temperature distributions during the study are shown in Figure 10.11. Although monthly temperatures during the study were close to the long term values, the study's monthly precipitation distribution differed significantly from the long average distribution. The water added in each irrigation is given in Figure 10.12.

The objective of this analysis was to determine how well RUSLE2 computes the effect of added irrigation water on residue decomposition, not to determine decomposition coefficient ϕ values. The first step in the analysis was to adjust the decomposition coefficient ϕ value until a good fit was obtained between computed decomposition and

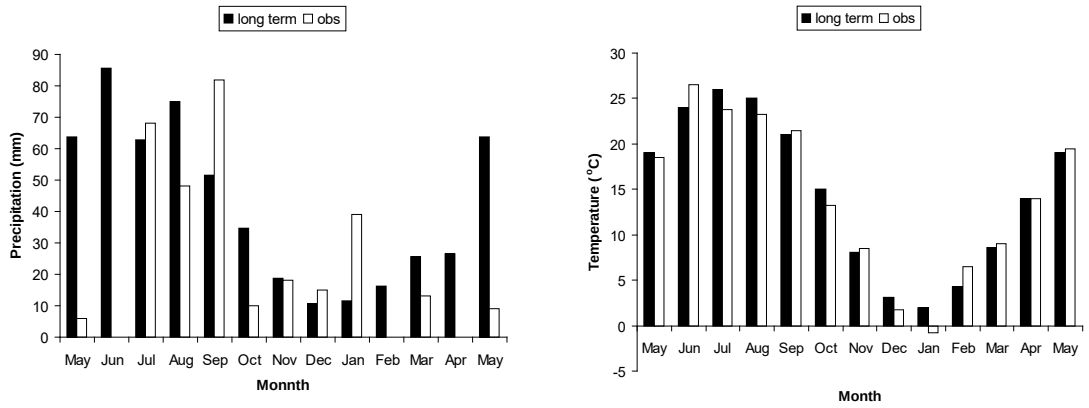

Figure 10.11. Long term average monthly precipitation (480 mm annual) and actual monthly precipitation (305 mm annual) and long term average monthly temperature and actual monthly temperature for Schomberg et al. (1994) study

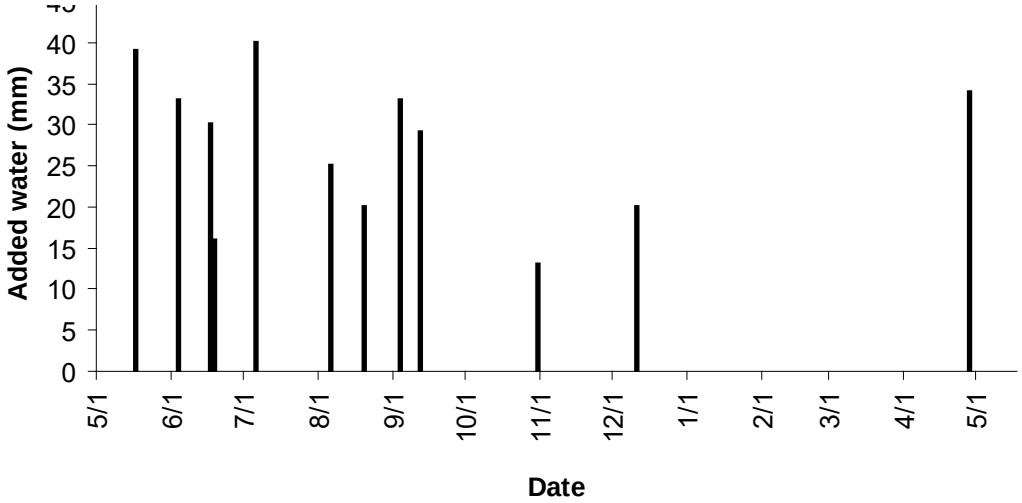

Figure 10.12. Water applied by sprinkler irrigation (total application of 336 mm) in Schomberg et al. (1994) study.

observed decomposition for the no-irrigation (only natural precipitation) condition.

Observed monthly precipitation and temperature values shown in Figure 10.11 were used in the analysis.

The decomposition coefficient ϕ value determined for natural precipitation alone was used to compute decomposition for the 305 mm natural precipitation plus 336 mm of added irrigation water distributed as shown in Figure 10.12. The results of those computations are shown in Figure 10.13.

Variability is a common problem in decomposition data. The data in Schomberg et al. (1994) study also was highly varied. For example, the fraction of surface sorghum residue remaining on December 10 was 53 percent while the fraction remaining on March 10 was 70 percent, which is an obvious error because residue mass does not increase over time. Another problem with these data is that the range in decomposition of surface residue as a function of added irrigation water is not consistent with the range in the observed data for surface sorghum and wheat residue.

As Figure 10.13 shows, the conclusion is that RUSLE2 described well how sprinkler irrigation affects decomposition of both surface and buried residue in the Schomberg et al. (1994) study. Furthermore, RUSLE2 described decomposition well for the natural

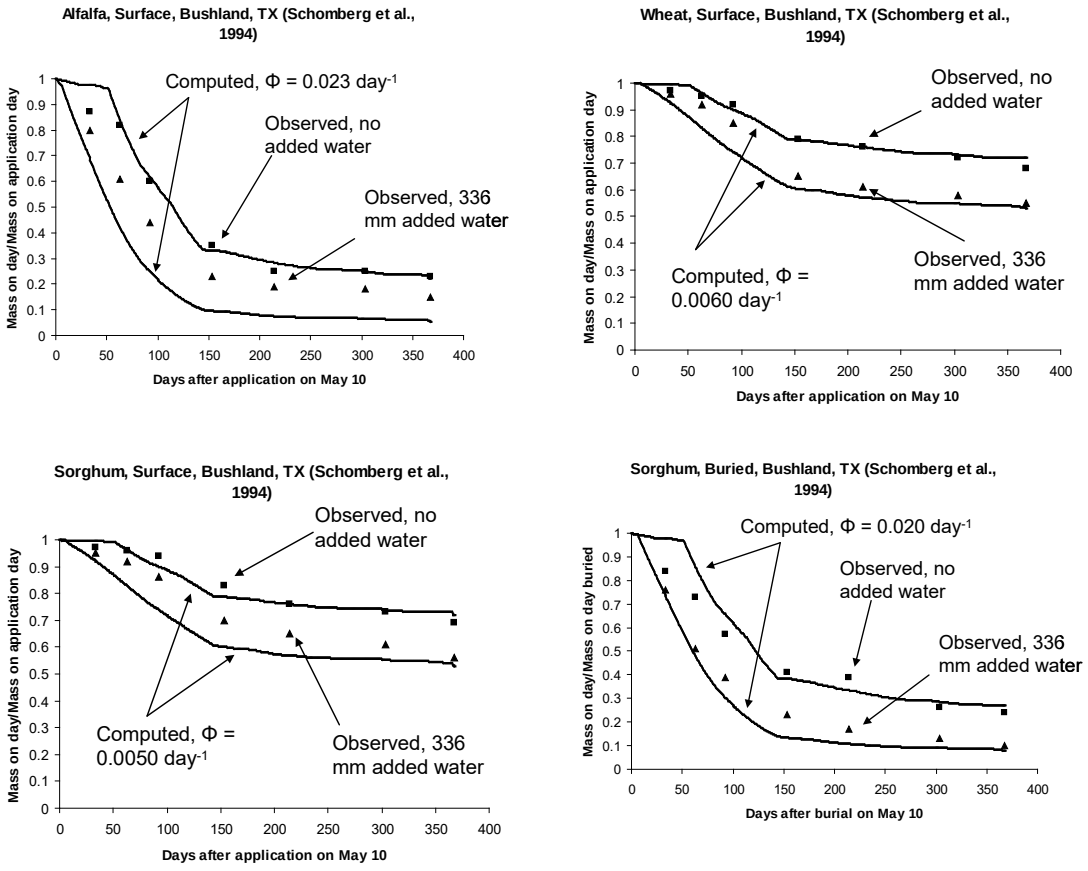

Figure 10.13. Effect of irrigation of buried and surface residue (data source: Schomberg et al., 1994)

precipitation without irrigation even though the actual monthly precipitation distribution did not vary smoothly month to month.

The Schomberg et al. (1994) data show major differences in decomposition rate between surface and buried residue. These differences seem to be a direct result of experimental procedures. That issue is discussed in detail in **Section 10.3.3.2**.

These results also show that decomposition of both surface and buried residue is a dampened process that does not react quickly to changes or irregularities in precipitation or temperature. Surface residue apparently continues to decompose longer after a water-application event that seems to have been assumed in some decomposition models (Schomberg and Steiner, 1997; Steiner et al., 1999). Decomposition of surface residue seems much more related to local soil moisture at the contact between the residue and soil than was previously considered.

An important question is whether residue decomposes the same per unit water added by irrigation as it does by unit water added by natural rainfall. Decomposition may be less per unit water applied by sprinkler irrigation than applied by natural rainfall. Water droplets in the irrigation-applied water have very low impact energy in comparison to natural rainfall. Thus, natural rainfall splashes many more soil particles that increase the contact between the soil and the residue (Foster et al., 1985a) than does sprinkler irrigation applied water. Irrigation-applied water may wash away soil particles previously bonded to the residue by rainfall. Also, deposition of sediment produced interrill-rill erosion (Brenneman and Laflen,1982) increases soil bonding between residue and soil at low residue application rates that does not occur with irrigation-applied water.

The type of irrigation should be considered in selecting irrigation inputs for RUSLE2. This decomposition analysis was based on sprinkler irrigation. The irrigation input values for sprinkler irrigation should be based on the water that actually reaches the soil. This amount can be significantly less than the amount discharged from the irrigation nozzles because of wind and evaporation losses.

Also, decomposition may be less on ridges when furrow irrigation is used than with flood irrigation on a smooth surface. Similarly, decomposition of surface residue may be reduced with drip irrigation. However, be careful in making adjustments to irrigation amounts because RUSLE2 uses the same amount in computing decomposition of both surface and buried residue. Also, RUSLE2 uses irrigation input values to compute temporal soil erodibility (see **Section 4.5**).

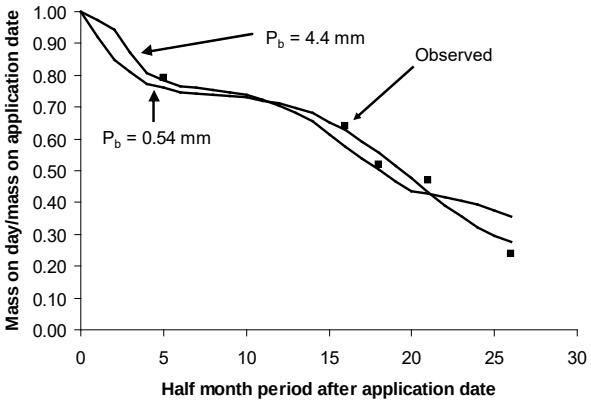

Figure 10.14. Effect of changing the base daily precipitation P_b value in the moisture function used to compute wheat straw residue decomposition at Pullman, Washington.

10.3.3.9. Special considerations for the NWRR and Req zones

The climate in the Northwest Wheat and Range Region

(NWRR), which is within the larger Req zone (see RUSLE2 User's Reference Guide), differs significantly from the climate in non-Req areas. An example is the relationship of monthly precipitation amount relative to number of precipitation events (see **Section 10.3.4.2**). Consequently, should the decomposition equations and coefficient values differ for the NWRR and the entire Req zone from those for other regions? To evaluate this possibility, the base moisture P_b value in the moisture function (W_f, equation 10.5) was determined by fitting the decomposition equations specifically to decomposition data collected at Pullman, Washington. A P_b value of 0.54 mm produced improvement for some data sets as illustrated in Figure 10.10, but not for all data sets. When 0.54 mm is used for P_b in equation10.5, RUSLE2 computes decomposition being controlled throughout the year by the temperature function (T_f, equation 10.6) at Pullman, Washington. When P_b = 4.4 mm, RUSLE2 computes that decomposition is controlled by the moisture function from May through October. Computing that decomposition is controlled by moisture when average monthly precipitation is as low as 0.45 inches (11 mm) in July and 0.64 inches (16 mm) in August seems more appropriate than the temperature function controlling decomposition during these dry months.

Decomposition coefficient ϕ values determined for wheat using P_b = 0.54 mm are essentially the same as decomposition coefficient values determined for wheat in other regions using P_b = 4.4 mm. Consequently, the difference in decomposition coefficient values in Table 10.2 between the NWRR and other regions may not be related to wheat varieties as implied in Table 10.2, but related to having an appropriate description of the moisture function W_f for the NWRR.

The recommendation is that 4.4 mm be used for P_b for the NWRR and Req zone along with the Req specific decomposition coefficient values given in Table 10.3 until additional research is conducted. This additional decomposition research for the Req zone, including the NWRR, can be conducted simultaneously with additional research needed on other RUSLE2 Req relationships throughout the Req zone, especially for locations outside of the central Washington to northern Idaho and Northeastern Oregon region.

10.3.4. Comparison of RUSLE2, RWEQ, WEPP, and WEPS decomposition

The RUSLE2 water erosion and RWEQ (Fryrear et al., 1998) wind erosion prediction technologies use comparable empirical structures involving long-term average monthly climate and management inputs and both were originally intended for conservation planning in USDA-Natural Resources Conservation Service (NRCS) field offices. The NRCS initially placed a high priority on RUSLE2 and RWEQ using the same equations and parameter values for computing residue mass values. Later the NRCS adopted WEPS (Hagan et al., 1996) instead of RWEQ for field office conservation planning. WEPS is a process-based simulation model that uses stochastic climate inputs. The comparable water erosion prediction model is WEPP (Flanagan and Nearing, 1995).

RUSLE2 and WEPS should compute comparable residue mass values because these models are being implemented by NRCS for routine conservation planning, and WEPP may be implemented in the future. Although erosion prediction clients may not know the residue mass values that these models should compute, clients readily recognize differences in values computed by the models and question differences when none should exist. Such differences reduce the creditability of the models and the conservation plans developed using them.

Decomposition estimates of surface applied residue were computed using RUSLE2, RWEQ, WEPP, and WEPS at the locations listed in Table 10.4.

Table 10.4. Locations for RWEQ, WEPP, and WEPS decomposition computations

Location	Annual precipitation (inches)	Model	Comments
Jefferson City, Missouri	37.8	All	Near Columbia, Missouri
Minneapolis, Minnesota	27.0	ALL	
W. Lafayette, Indiana	37.0	RWEQ	
Scottsbluff, Nebraska	15.1	WEPP/WEPS	
Jamestown, North Dakota	18.3	RWEQ	Used in Figure 10.19
Amarillo, Texas	20.1	RWEQ	Near Bushland, Texas
Borger, Texas	20.7	WEPP/WEPS	Near Bushland, Texas
Denton, Texas	33.1	WEPP/WEPS	
Dallas, Texas	36.0	WEPP/WEPS	
Houston, Texas	46.4	WEPP/WEPS	
Galveston, Texas	39.8	WEPP/WEPS	
Holly Springs, Mississippi	54.2	WEPP/WEPS	
Jackson, Mississippi	53.8	RWEQ	
Gulfport, Mississippi	60.0	WEPP/WEPS	
Mobile, Alabama	62.3	All	
Spokane, Washington	16.0	RWEQ	
Tucson, Arizona (Davis)	11.2	RWEQ	Davis-Monthan Air Force Base
Tucson, Arizona (Campbell)	12.4	WEPP/WEPS	University of Arizona Agricultural Experiment Station on Campbell Avenue
Albuquerque, New Mexico	9.3	RWEQ	Used in Figure 10.19

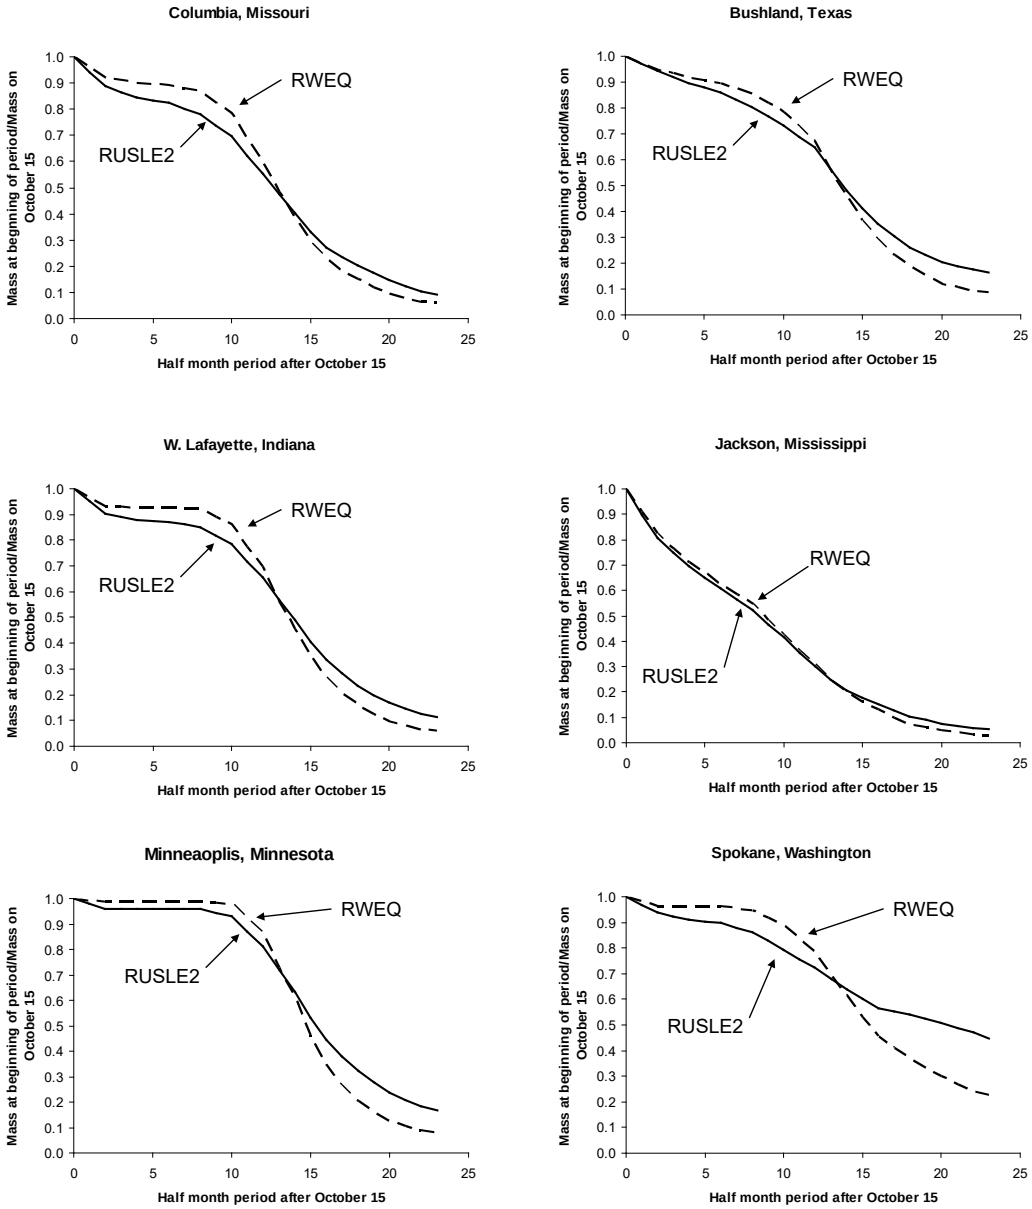

Figure 10.15. Residue decomposition computed with RUSLE2 and RWEQ

For the RWEQ computations, mulch was assumed to be surface applied on October 15 at 4500 lb/acre to a seedbed condition with no existing above ground or below ground biomass for all locations except Tucson, Arizona. The mulch was assumed to be applied on January 1 at Tucson.

The RWEQ decomposition coefficient value was adjusted to give the best fit of computed residue mass to RUSLE2 computed values at Columbia (Jefferson City), Missouri. This RWEQ decomposition coefficient value was used for all other locations, and the same RUSLE2 decomposition value was used for all locations.

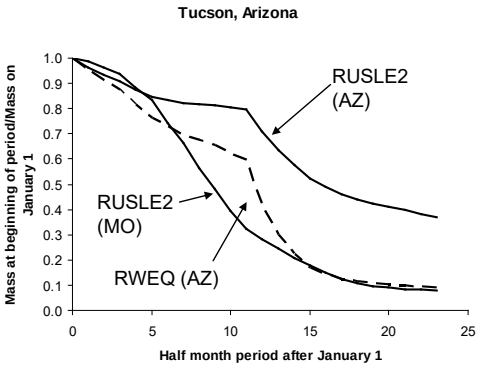

Figure 10.16. Residue decomposition computed with RUSLE2 and RWEQ at Tucson, Arizona

For the WEPP computations,[71] the same 4500 lbs/acre mulch rate was assumed to be applied on May 10, except for Tucson where the mulch was assumed to be applied on January 1. The mulch was applied to a soil that had not been tilled for a year. No above ground or below ground biomass was assumed. WEPP was run for 10 years with the same mulch amount applied each year with no soil disturbance throughout the 10 year simulation period.

WEPP computes daily residue mass for each annual mulch application. Daily computed surface residue mass for each mulch application was averaged for the 10 year simulation period. The WEPP computed residue mass values are equivalent to conducting annual experiments where the fate of mulch applied each year is determined. The WEPP computations represent each annual application placing new mulch on mulch remaining from previous years rather than mulch being applied each year to bare soil.

The RUSLE2 decomposition coefficient ϕ value was adjusted to give the best fit of RUSLE2 computed residue values to WEPP computed values for Columbia (Jefferson City), Missouri for a silt loam soil. This RUSLE2 decomposition coefficient value was used for all locations and the same WEPP decomposition coefficient value was used for the same silt loam soil for all locations.

Decomposition was computed with WEPP at the locations listed in Table 10.4. RUSLE2 computed decomposition values compared well with WEPP computed values for locations where temperature rather than moisture was the factor limiting decomposition. At locations where RUSLE2 computed that moisture limited decomposition, WEPP conputed decomposition amounts that were significantly greater than RUSLE2 computed, which was especially evident a Tucson, Arizona where the WEPP computed decomposition was essentially the same as decomposition computed at Columbia, Missouri even though average annual precipitation at Tucson as only 12 inches in comparison to 38 inches at Columbia, Missouri. Consequently, WEPP seems to be computing too much decomposition in dry locations.[72]

---

[71] The WEPP version used in these computations was dated May 18, 2006, which was downloaded from the USA-ARS WEPP Internet site in April 2008. This version is the most recent version available to the public.

[72] These results have been reported to Dennis Flanagan, lead WEPP developer, USDA-Agricultural Research Service, W. Lafayette, Indiana. WEPP developers are investigating whether WEPP may be

The WEPS compuations were made using the WEPS hydrology component rather than WEPS with the WEPP hydrology component.[73] The same 4000 lbs/acre mulch rate was assumed to be annually applied on October 15 at all locations. The management practice used to make the compuations represented a soil tilled with a moldplow plow and a tandem disk that buried all of the previous year's mulch and did not resurface any buried residue. WEPS was run for 15 years. Daily surface residue mass values were averaged

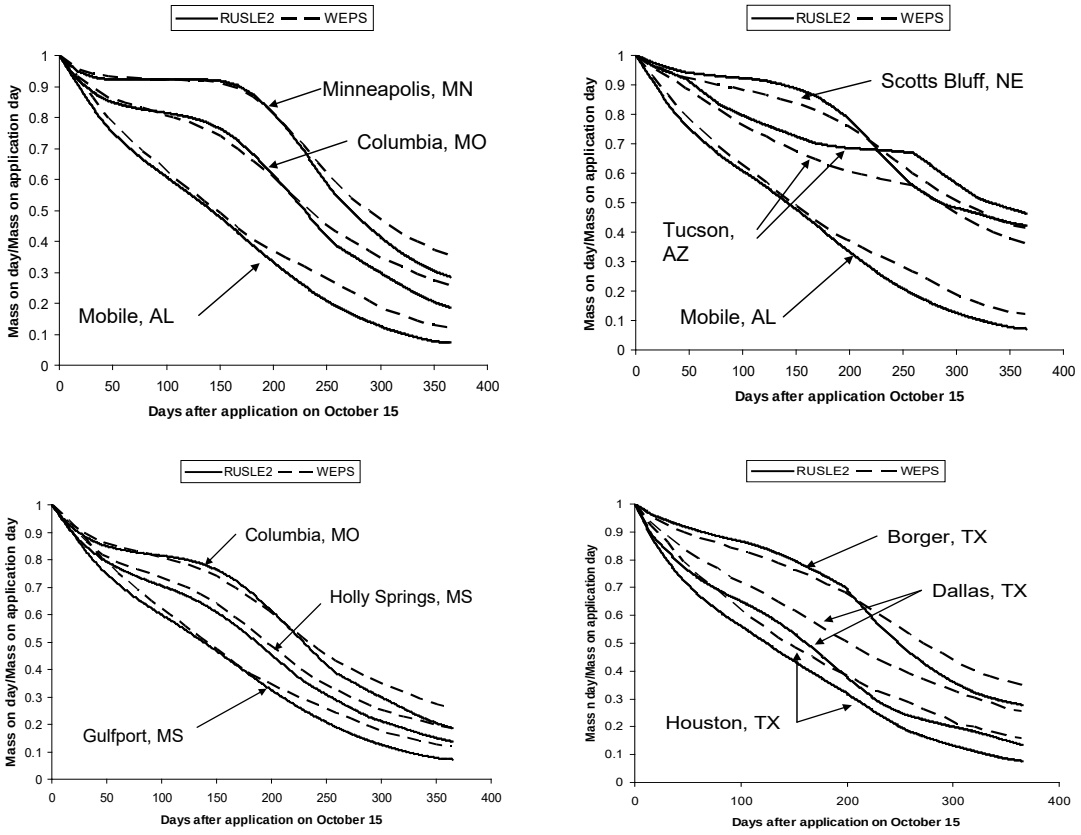

Figure 10.17. Residue decomposition computed with RUSLE2 and WEPS

for the 15 year simulation. The results are plotted in Figure 10.17.

The same WEPS decomposition coefficient value was used for all WEPS computations. The RUSLE2 decomposition coefficient ϕ value was adjusted to give the best fit of

---

computing too much decomposition at Tucson and other dry locations. Possible WEPP changes may made sometime soon (May 10, 2008).

[73] The WEPS version used in these computations was dated April 14, 2006, which was provided by Larry Wagner, lead WEPS developer, USDA-Agricultural Research Service, Manhattan, Kansas.

RUSLE2 computed residue values to WEPS computed values for Columbia (Jefferson City), Missouri for the Morley silty clay loam soil. This RUSLE2 decomposition coefficient value was used for all subsequent RUSLE2 computations.

10.3.4.1. Structure of decomposition computations

All four models (RUSLE2, RWEQ, WEPP, and WEPS) use moisture and temperature functions to compute decomposition. RUSLE2, WEPS, and WEPP use equation 10.4 that takes a minimum of the moisture and temperature functions instead of the product of these functions used in RWEQ. The differences in computed decomposition resulting from the RUSLE2 minimum structure and the RWEQ product structure are illustrated in Figures 10.15 and 10.16. With the exception of the Tucson location, the consistent trend is that the product structure computes reduced decomposition during cool periods and increased decomposition during warm periods.

Using a minimum of the moisture and temperature functions was judged to be better than the product of the functions based on an inspection of Figures 10.2 and 10.15.

The minimum of the moisture and temperature functions, which is equation 10.4, is also used in WEPP and WEPS. The Gregory et al. (1985) decomposition model was originally used in RUSLE1, but it was replaced with a modification of the WEPP decomposition model (Stott, 1991; Stott et al., 1995) because the Gregory et al. model also was judged to compute too little decomposition during cool periods and too much decomposition during warm periods.

10.3.4.2. Moisture function

10.3.4.2.1. Comparison with RWEQ

RUSLE2's moisture function used to compute decomposition is given by equation 10.5. The RWEQ moisture function is given by (Fryrear et al., 1998; Schomberg and Steiner, 1997):

$$W_{fwe} = 1.25 N_p / D_p \qquad [10.8]$$

where: W_{fwe} = the RWEQ moisture function used to compute decomposition, N_p = the number of precipitation events in the period D_p (days). The Schomberg and Steiner (1997) justification for using number of precipitation events is that surface residue does not remain moist long after a precipitation event, which conceptually implies that residue moisture content following a precipitation event is independent of the event's precipitation amount, which seems questionable. The moisture retained by residue depends greatly on residue type and mass and its contact with the soil mass. Similarly, the Schomberg-Steiner assumption seems questionable for mulch-till and no-till cropping systems where the soil-residue interface is not well defined and surface residue pieces are partially covered by soil. The assumption also seems questionable during fall and spring periods when evaporation is reduced. Dew may provide a significant moisture source, even on very hot days (Heilman et al, 1992).

Decomposition was computed with RUSLE2 and RWEQ at the locations identified in Table 10.4, and the computed values are shown in Figures 10.15 and 10.16. Except for the Tucson location, the RUSLE2 and RWEQ moisture functions performed similarly. The reason for the similar performance is that number of precipitation events in a given period in the RWEQ moisture function actually serves as a surrogate for precipitation amount used in the RUSLE2 moisture function. Precipitation amount in a given period is highly correlated with number of precipitation events in the period and the relationship is essentially the same across the eastern US as shown in Figure 10.18. However, a disadvantage of the RWEQ moisture function even in this region is that number of precipitation event is more spatially varied than precipitation amount. Also, data on number of precipitation events are much less available than long term monthly precipitation values, such as those that were easily found and used to compute decomposition in Canada (see Figure 10.2) and SW Australia (see Figure 10.3).

The RUSLE2 and RWEQ decomposition estimates differ greatly for Tucson, Arizona as shown in Figure 10.16. In this figure, decomposition was computed at Columbia, Missouri with RWEQ for mulch applied on January 1, the same as for Tucson. RWEQ computed the same decomposition for both Tucson and Columbia even though annual rainfall at Tucson (Davis) was only 11 inches in comparison to 38 inches at Columbia (see Table 10.4). The reason that RWEQ computes the same decomposition at the two locations is that the number of storms is comparable for the two locations even though annual precipitation differs significantly between the locations. Similarly, the number of storms per month in relation to monthly precipitation amount is high at Spokane Washington during the cool period, which is the reason for the difference between decomposition computed by RUSLE2 and RWEQ Spokane being greater than at the other locations in Figure 10.15.

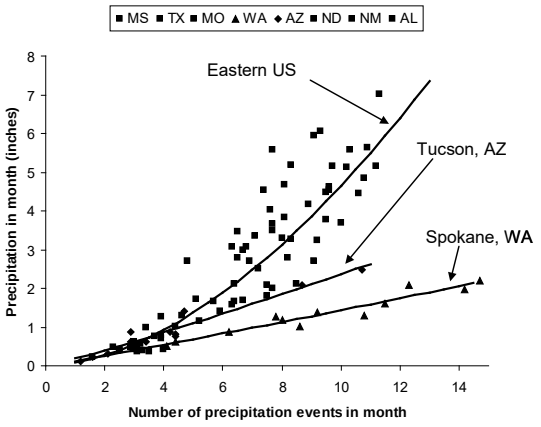

Figure 10.18. Relation of average monthly precipitation to number of precipitation events in a month.

Use of the RWEQ moisture function in RUSLE2 would require varying the decomposition coefficient value with location in the western US. This requirement is similar to the base precipitation value P_b in equation 10.5 needing to be changed so that the same RUSLE2 decomposition coefficient values can be used in the Palouse Region and in the eastern US (see **Sections 3.2.5 and 10.3.2**).

Overall, using precipitation in the RUSLE2 moisture function is judged superior to using number of precipitation events as in RWEQ. Using number of precipitation events would provide no fundamental improvement in RUSLE2's decomposition estimates. Precipitation amount appears to be superior in low precipitation regions in the western

US. Precipitation amounts are much more readily available and spatially stable than number of precipitation events in a given period.

10.3.4.2.2. Comparison with WEPP

The WEPP moisture function is given by (Stott et al., 1995):

$$W_{fwp} = \theta_t / \theta_o \qquad [10.9]$$

where: W_{fwp} = the WEPP moisture function used to compute decomposition of surface residue, θ_t = water content (volume of water/volume of bulk soil)[74] of the tilled soil layer and θ_o = the optimum water content (volume water/volume of bulk soil) for decomposition. The WEPP assumption is that the optimum moisture content for decomposition is 0.6 times the soil's pore space (volume pore space/volume of bulk soil). Consequently, the decomposition computed by WEPP should be a function of soil, tillage, and other factors that affect infiltration (e.g., precipitation, soil properties, and cover-management), soil water retention (e.g., soil properties), and soil water extraction (e.g., drainage and evapo-transpiration) (Alberts et al., 1995).

The present WEPP version does not computes the same decomposition amount at Tucson, Arizona as it does in Columba, Missouri, even average annuaj precipitation at Tucson is 12 inches in comparison to 38 inches at Columbia. These WEPP computations were judged tgo be erroneous, thus further computations were not made with WEPP. Changes are anticipated in WEPP to deal with this apparent problem (May 10, 2008).

10.3.4.2.3. Comparison with WEPS

The WEPP moisture function is given by (Hagan et al., 1996):

$$W_{fws} = \theta_s / \theta_f \qquad [10.10]$$

where: W_{fws} = the WEPP moisture function used to compute decomposition of surface residue, θ_s = water content (volume of water/volume of bulk soil) of the surface soil layer, which is thinner than the WEPP tilled soil layer, and θ_f = field capacity water content of the surface soil layer (volume water/volume of bulk soil), which is considered to be the optimum water content for decomposition. Soil water content in the surface soil layer is affected by precipitation, infiltration, drainage, and extraction. Consequently, WEPS decomposition should be a function of soil and cover-management.

As illustrated in Figure 10.17, RUSLE2 computed decomposition values compared well with WEPS computed values for locations where temperature rather than moisture was the factor limiting decomposition. However, a difference in trend between the RUSLE2 and WEPS compuated values was apparent at these locations where computed

---

[74] Bulk soil includes the volume of both soil particles and pore space.

decomposition rates were less for WEPS than for RUSLE2 during the maximum precipitation period. WEPS computed decomposition was significantly less than RUSLE2 computed decomposition at Tucson, Arizona. RUSLE2 computed less decomposition during the dry periods at Tucson than did WEPS. WEPS computed much less decomposition than did RUSLE2 at Dallas, Texas. The distinguishing feature at Dallas is a double peaked precipitation pattern. Precipitation (≈ 2.1 inches/month) in July and August is about half the precipitation in April and May (≈ 4.6 inches) and September and October (≈ 3.6 inches/month). In contrast to Tucson where RUSLE2 computed less decomposition than did WEPS, RUSLE2 computed more decomposition at Dallas than did WEPS.

Apparently the WEPS soil moisture values are dampened more than are the RUSLE2daily precipitation values used to compute decomposition, even at locations where precipitation is moderately high and greater such as Columbia, Missouri; Holly Springs and Gulfport, Mississippi; and Mobile, Alabama. This same dampening may be responsible for the differences at Tucson and Dallas.

These differences raise questions about the adequacy of the WEPS computed soil moisture values at all locations, but especially at locations where monthly precipitation changes greatly in a short time, and how well the RUSLE2 moisture function performs in dry regions. The decomposition data illustrated in Figure 10.2 are inadequate to definively make a determination about RUSLE2's moisture function used to compute decomposition or to show whether RUSLE2 or WEPS better computes decomposition.

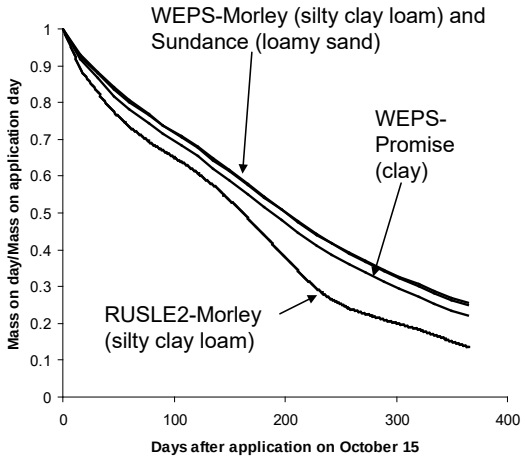

Figure 10.19. Effect of soil texture on WEPS computed decomposition at Dallas, Texas.

Figure 10.19 shows WEPS computed decomposition values for three soil textures at Dallas, Texas. The effect of soil texture on WEPS computed decomposition values are not great. RUSLE2 does not consider soil textue in its decomposition computations.

Figure 10.20 shows the effect of soil disturbance on WEPS computed decomposition. Whether the soil was only moldboard plowed or was moldboard plowed and disked had no effect on WEPS computed decomposition. However, WEPS computed increased decomposition for a soil not disturbed, which is the appropriate direction for computing decomposition for no-till farming practices.

10.3.4.3. Temperature function

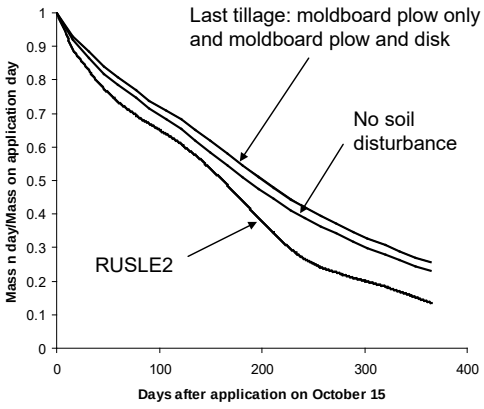

Figure 10.20. Effect of soil disturbance on WEPS computed decomposition

The same basic temperature function, equation 10.6, is used in RUSLE2, WEPP, WEPS, and RWEQ. Both RUSLE2 and WEPP compute a daily temperature function value using average daily temperature computed as the average of the maximum and minimum temperature for the day. RWEQ and WEPS compute a daily temperature function value by computing a temperature function value for both the daily maximum and minimum temperatures and averaging those two temperature function values. RUSLE2 and RWEQ use long term daily and monthly temperature values, respectively, whereas WEPP and WEPS uses stochastically generated daily temperature values.[75]

Each model uses slightly different values for the variables A and optimum temperature T_o in equation 10.6. For example, RWEQ and WEPS use A = 0 ^oC whereas RUSLE2 uses A = - 8 ^oC to compensate for using long-term average daily temperature in RUSLE2. RUSLE2 computes decomposition for a long term average daily temperature as low as -10 ^oC. In WEPP, A = -6.1 ^oC, which compensates for use of daily average temperature in computing a daily temperature function value. The optimum temperature value use in RUSLE2, RWEQ, and WEPS is 32 ^oC while 33 ^oC is used in WEPP.

RUSLE2 and WEPP compute almost identical long term average decomposition for conditions where the temperature function entirely controls rather than the moisture function. Little of the differences between RUSLE2 and WEPS in Figure 10.17 appear to be caused by differences in the temperature functions used to compute decomposition.

The RWEQ/WEPP temperature function approach is superior at high temperatures to the RUSLE2 approach. Flattening the temperature function around the optimum temperature, T_o in equation 10.6 would improve the RUSLE2 temperature function. The best approach would be to replace the RUSLE2 temperature function as described by Schomberg et al. (2002).

The end result is that RUSLE2 computed temperature function values at high temperatures were not a significant factor in fitting the measured decomposition data illustrated in Figure 10.2. In each case, the moisture function was limiting rather than the temperature function when temperatures were high. At low temperatures, the

[75] The RUSLE2 input is long term average monthly that RUSLE2 disaggreagtes into daily temperatures.

temperature function was limiting, where RUSLE2's temperature function is judged adequate.

Schomberg et al. (2002) found no improvement in the fit of RUSLE2 computed decomposition to measured data with their improved temperature function. However, their new temperature function required a decomposition coefficient ϕ value of 0.0048 day^{-1} in comparison to 0.0041 day^{-1} for the temperature function described by equation 10.6. Thus, decomposition coefficient values are moisture and temperature function dependent and model dependent in other ways including how soil moisture is computed for example.

10.3.4.4. Summary comments on RUSLE2 decomposition computations

For RUSLE2, WEPS, WEPP to give comparable long term surface residue cover estimates, decomposition data that best represents field conditions must be identified and used to calibrate all these models.

The RUSLE2 decomposition equations use simple inputs so that RUSLE2 is convenient for use in conservation and erosion control planning. The RUSLE2 purpose is not to accurately model residue decomposition processes in a research context. RUSLE2 users must be aware of RUSLE2 procedures and how to select RUSLE2 inputs to best represent residue for each particular application. Input values described in the RUSE2 User's Reference Guide and in the RUSLE2 Core Database were chosen to ensure that RUSLE2 is adequate for conservation and erosion control planning. RUSLE2 is a complex procedure that involves many mathematical relationships with numerous interactions. Input values must be carefully selected to avoid RUSLE2 computing erroneous erosion values when adjusting RUSLE2 inputs to obtain a desired value for a particular variable such as the portion of the soil surface covered by residue. Avoid changing a single variable such as the decomposition coefficient so that RUSLE2 computes an expected surface residue cover immediately before harvest.

The RUSLE2 decomposition procedures are better than those in RWEQ, a comparable model for wind erosion. Also, RUSLE2 computes decomposition values that are comparable to those computed by WEPS and WEPP, process-based models for wind and water erosion, respectively, when all three models are calibrated to the same data. The soil moisture computations in both WEPS and WEPP should be reveiwed for dry regions and regions when monthly precipitation is double peaked. Decomposition values computed by WEPS do not appear to vary much with soil texture or soil disturbance. Conquently, decomposition computed by RUSELE2 will not differ significantly from the values computed for WEPS when soil and cover-management vary at a location. Advantages of RUSLE2 are that it is robust, uses simple inputs, gives good results, and is easy to use, important attributes for its intended purpose of guiding conservation and erosion control in local field offices.

The RUSLE2 User's Reference Guide describes steps that should be observed in adjusting RUSLE2 input related to values computed for soil surface residue covered.

10.4. Standing residue

10.4.1. Decomposition

Certain operations convert live vegetation to standing residue (see **Section 8**). A portion of the standing residue is assumed to fall each day and become surface residue. Also, standing residue decomposes daily. This decomposition is computed using equations 10.3-10.6 but with a decomposition coefficient ϕ value that is 0.3 of that used to compute surface residue decomposition because reduced moisture is available for decomposition of standing residue.

RUSLE2 computes the decomposition of a unit stem mass assumed to represent decomposition at the base of standing residue stems. This decomposition is computed using equations 10.3 - 10.6 and the same decomposition coefficient ϕ value used to compute surface residue decomposition. That is, decomposition at the stem base is assumed to occur at the same rate as surface residue decomposition.

The portion of the standing residue mass that remains standing over time is assumed to be related to the portion of the remaining unit stem base mass. The RUSLE2 equation for this relationship is:

$$\gamma_t = -2.62\gamma_s^3 + 4.57\gamma_s^2 - 0.95\gamma_s \qquad [10.11]$$

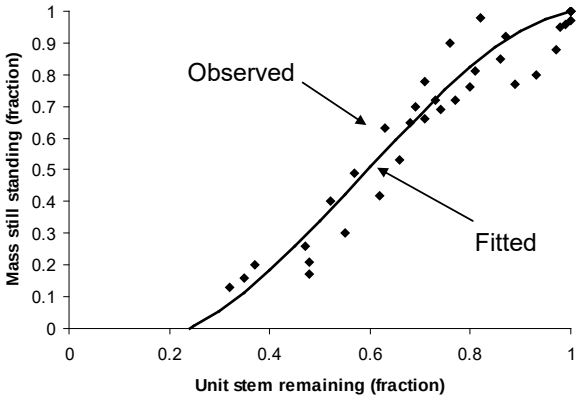

Figure 10.21. Relation of standing residue mass to computed unit stem base mass. (Data source: Steiner et al., 1994)

where: γ_t = portion (fraction) of original standing residue mass that remains and γ_s = portion (fraction) of the original unit stem base mass that remains at any given time. Equation 10.11 was derived by fitting to measured wheat data collected in Texas, Oregon, and North Dakota as illustrated in Figure 10.21 (Steiner et al., 1994). No similar data were found for other vegetation communities. However, equation 10.11 is

considered to be adequate for other plant types besides small grain.

10.4.2. Canopy cover-mass relationship

During the live period for a vegetation description, canopy cover is known directly from user input. These canopy cover values are used to estimate temporal values for live above ground biomass (see **Section 9.2.5**).

Once live above ground biomass is transferred to standing residue, the known variable is standing residue mass. This biomass is computed from standing live above ground biomass converted to standing residue on the conversion date, decomposition of standing residue over time, and the amount of the standing residue that has become surface residue computed with equation 10.11.

RUSLE2 computes canopy cover for standing residue using:

$$f_t = \mu B_t^{2/3} \qquad [10.12]$$

where: f_t = canopy cover provided by the standing residue and B_t = daily standing residue biomass (dry mass/area). The value for the coefficient μ is determined from:

$$\mu = f_{to} / B_{to}^{2/3} \qquad [10.13]$$

where: f_{to} and B_{to} = canopy cover and biomass (dry mass/area), respectively, when the standing residue is created from live above ground biomass.

10.4.3. Manning's n, effective vegetation ridge height, and effective fall height for standing residue

Values for the Manning's n and effective ridge height for standing residue are computed using:

$$n_t = n_{to}(B_t / B_{to}) \qquad [10.14]$$

$$H_t = H_{to}(B_t / B_{to}) \qquad [10.15]$$

where: n_t = the daily standing residue Manning's n, n_{to} = the live vegetation Manning's n on the day that the standing residue was created, H_t = daily effective standing residue ridge height (inches), and H_{to} = effective ridge height (inches) of the live vegetation on the day that the standing residue was created. The effective ridge height for standing residue is computed from:

$$h_f = h_{fo}(f_t / f_{to}) \qquad [10.16]$$

where: h_f = the daily effective fall height, h_{fo} = the effective fall height for the vegetation on the day that the standing residue was created, f_t = daily canopy cover, and f_{to} = the canopy cover of the vegetation on the day that the standing residue was created.

Although RUSLE2 uses a single vegetation description on any given day, RUSLE2 tracks multiple standing residue descriptions. RUSLE2 assumes that the overall Manning's n for standing residue and the overall effective ridge height for each standing residue description are the sums of the respective values for each standing residue description. The net effective fall height of the standing residue is weighted by the canopy cover for each standing residue description. These values are independent of corresponding values for live vegetation.

This approach for representing a composite of vegetation and multiple standing residue descriptions should involve interactions similar to those assumed for overlapping ground cover. However, the RUSLE2 procedure is judged to be satisfactory for conservation and erosion control planning. Only a few residue descriptions are used in most cover-management descriptions and most standing residue is removed by tillage or other operations.

10.5. List of symbols

A = a reference temperature in temperature function used to compute decomposition (-8 ^{o}C)

b = coefficient that desribes the effectiveness for a particular residue type for reducing erosion (percent^{-1})

B = mass (dry) in a particular residue/dead root pool (mass/area)

B_s = surface residue dry biomass (mass/area)

B_t = standing residue dry biomass (mass/area)

B_{to} = standing residue dry biomass on day when standing residue is created (mass/area)

c = daily cover-management factor

D = time in period over which decomposition is being computed (days)

D_p = period over which N_p precipitation events occur (days)

$D_{1/2}$ = residue half life (time)

f_g = ground (surface) residue cover (fraction)

f_{gm} = ground (surface) cover for crop residue or mulch assuming no other material is present (fraction)

f_{gn} = net ground (surface) cover provided by total surface residue mass (fraction)

f_{gr} = ground (surface) cover provided by the rock surface residue cover assuming no other surface residue is present (fraction)

f_t = canopy cover provided by the standing residue (fraction)

f_{to} = canopy cover provided by standing residue on day that standing residue is created (fraction)

g_c = daily ground cover subfactor

h_{fi} = effective fall height of standing residue (feet)

h_{fo} = effective fall height for the vegetation on day that the standing residue was created (feet)

H_t = effective standing residue ridge height (inches)

H_{to} = effective ridge height of live vegetation on day that the standing residue was created (inches)

n_t = standing residue Manning's n

n_{to} = live vegetation Manning's n on day that the standing residue was created

I = daily amount of water added by irrigation (inches)

N_p = Number of precipitation events in the period D_p

P = daily precipitation (inches)

P_b = base daily precipitation in moisture function used to compute decomposition (inches)

s_b = daily soil biomass subfactor

T = daily air temperature (^oC)

T_f = daily temperature function used to compute decomposition

T_o = optimum temperature for decomposition (^oC)

W_f = daily moisture function used to compute decomposition in RUSLE2

W_{fwe} = RWEQ moisture function used to compute decomposition

W_{fwp} = WEPP moisture function used to compute decomposition

W_{fws} = WEPS moisture function used to compute decomposition

α = coefficient in equation used to compute surface residue cover for a given residue mass [(mass/area^{-1})]

β = coefficient used to compute residue decomposition (day^{-1})

γ_s = portion of the unit stem base mass (dry basis) that remains

γ_t = portion of standing residue mass (dry basis) that remains

θ_f = field capacity moisture content (volume water/volume bulk soil)

θ_o = optimum soil moisture content for residue decomposition (volume water/volume bulk soil)

θ_s = soil moisture content for the surface soil layer (volume water/volume bulk soil)

θ_t = soil moisture content of the tilled soil layer (volume water/volume bulk soil)

μ = coefficient in equation used to compute canopy cover from standing biomass $(\text{mass/area})^{-2/3}$

ϕ = decomposition coefficient that is a function of biomass type (day^{-1})

ϕ_w = weighted decomposition coefficient for residue description composed of two or more distinct residue types (day^{-1})

Indices

i - day

11. SUMMARY

11.1. RUSLE2 overview

The Revised Universal Soil Loss Equation, Version 2, (RUSLE2) is a tool specifically developed to guide erosion control planning at the local field office. RUSLE2 computes estimates of soil erosion caused by rainfall and its associated overland flow. RUSLE2 computes soil erosion estimates based on site-specific conditions for climate, soil, topography, and land use. Typically, RUSLE2 is used to compute soil erosion estimates for alternative erosion control measures that might be applied at a specific site. The erosion control practices that result in erosion estimates less than the erosion control criteria are considered acceptable. Consequently, erosion control can be tailored to site-specific conditions and requirements by using RUSLE2.

RUSLE2 is land-use independent. It applies to all land conditions where mineral soil is exposed to the erosive forces of raindrop impact and surface runoff produced by Hortonian overland flow. This overland flow occurs when rainfall intensity exceeds the infiltration rate of rainwater into the soil. RUSLE2 applies to cropland; permanent pastureland; construction sites; military training grounds; landfills and similar waste disposal sites; rangelands; disturbed forestlands; right-away along highways, pipelines, and electric transmission lines; and other similar lands.

The basic spatial RUSLE2 computational unit is the overland flow path selected to represent the site. Surface runoff follows this path from its origin to where overland flow becomes collected in a channel. The overland flow path can be divided into segments so that RUSLE2 can capture the effects of soil, steepness, and land use conditions varying along the overland flow path. RUSLE2 computes net erosion or deposition (mass/area) for each segment, sediment load (mass/unit flow width) at the end of each segment and at the end of the overland flow path, and sediment characteristics at the detachment point and in the sediment load at the end of each segment.

RUSLE2 also computes deposition in terrace channels assuming uniform conditions along these channels and deposition in small impoundments used on overland flow areas. RUSLE2 does not compute erosion in concentrated flow areas, referred to as ephemeral gully erosion, that terminate the overland flow path.

The basic temporal RUSLE2 computational unit is the long-term average for each day during the computation period used to represent a site's land-use condition. RUSLE2 management descriptions used to represent land-use conditions can be rotations where land use conditions are repeated in cycles or non-rotations where land-use conditions exist only for a single duration. The rotation cycle duration is the computation period. Rotation-type management descriptions are typically used to represent cropland and similar land uses. Also, rotation-type management practices are used to represent permanent land-use conditions that do not change from year to year.

Non-rotation type management descriptions are used to represent one-time land use conditions, such as reclamation of construction sites and surface mines. The computation period for these examples is from final grading through the number of years required for the site to become stabilized.

RUSLE2 sums long-term average daily erosion values to compute average annual values for the computation period used in the management description, for each year, and other sub-periods within the overall computation period. The average annual erosion value for the overall computation period typically is used in erosion control planning. The RUSLE2 computed average annual erosion for the site is compared to the site's erosion control criteria, which is an allowable average annual erosion rate based on the on-site and off-site damages that soil erosion would cause.

RUSLE2 computes how temporal variability of climate, soil, and land-use conditions affects erosion. Soil erosion is greatest when periods of maximum erosivity coincide with periods when the soil is most susceptible to erosion. Climatic erosivity typically varies greatly during the year. Also, land-use conditions vary during the year, ranging from bare soil after a major mechanical disturbance to dense cover provided by mature vegetation. Even erosion susceptibility of a site in permanent vegetation can vary significantly during the year as above ground and below ground biomass grow and subside. Even if vegetative cover and soil biomass do not vary temporally, soil erodibility varies during the year. Soil erodibility is greatest during periods of high soil moisture.

11.2. RUSLE2 mathematical structure

RUSLE2 is hybrid soil erosion prediction (estimation) technology because it is a combination of the empirical, index-based Universal Soil Loss Equation (USLE) and process-based equations for the detachment, transport, and deposition of soil particles. RUSLE2 computes a long-term average daily sediment production value using the USLE factors for erosivity, soil erodibility, slope length, slope steepness, cover-management, and support practice. Each USLE factor, except the one for slope steepness, is modified in RUSLE2 to compute a daily value rather than the standard USLE average annual value.

The USLE mathematical structure is (Wischmeier and Smith, 1978):

$$A = RKLSCP$$

where: A = average annual erosion (mass/area·year), R = average annual erosivity factor (erosivity units/area·year), K = average annual soil erodibility factor (mass/erosivity unit), L = average annual slope length factor (dimensionless), S = average annual slope steepness factor (dimensionless), C = average annual cover-management factor (dimensionless), and P = average annual support practice factor (dimensionless) . Each USLE factor, except the erosivity factor, has the mathematical structure of:

$$F = \left(\sum_{i=1}^{I} f_i \phi_i \right) \Big/ N$$

where: F = average annual factor, f_i = factor value for the *ith* time period, ϕ_i = the fraction of the annual erosivity that occurs during the *ith* period, I = the number of sub-periods in the computationl period for the management description used to represent a site's land use conditions, N = number of years in the computation period. Thus, the USLE has the mathematical structure of:

$$A = R\left[\left(\sum_{i=1}^{I_k} k_i \phi_i \right) \Big/ N_k \right]\left[\left(\sum_{i=1}^{I_l} l_i \phi_i \right) \Big/ N_l \right]\left[\left(\sum_{i=1}^{I_s} s_i \phi_i \right) \Big/ N_s \right]\left[\left(\sum_{i=1}^{I_c} c_i \phi_i \right) \Big/ N_c \right]\left[\left(\sum_{i=1}^{I_p} p_i \phi_i \right) \Big/ N_p \right]$$

where: k_i = soil erodibility factor for the *ith* period (mass/erosivity unit), I_k = the number of periods in the N_k years used to determine an average annual soil erodibility factor value, l_i = slope length factor for the *ith* period (dimensionless), I_l = the number of periods in the N_l years used to determine an average annual slope length factor value, s_i = slope steepness factor for the *ith* period (dimensionless), I_s = the number of periods in the N_s years used to determine an average annual slope steepness factor value, c_i = cover-management factor for the *ith* period (dimensionless), I_c = the number of periods in the N_c years used to determine an average annual cover-management factor value, p_i = support practice factor for the *ith* period (dimensionless), and, I_p = the number of periods in the N_p years used to determine an average annual support practice factor value. In practice, the USLE mathematical structure is:

$$A = RKLS\left[\left(\sum_{i=1}^{I_c} c_i \phi_i \right) \Big/ N_c \right] P$$

where: temporally constant values for K, L, S, and P are used throughout the computation period.

The basic RUSLE1 mathematical structure is the same as the USLE structure except that a temporal soil erodibility factor is used as (Renard et al., 1997):

$$A = R\left[\left(\sum_{i=1}^{24} k_i \phi_i \right) \Big/ 24 \right] LS\left[\left(\sum_{i=1}^{24 N_c} c_i \phi_i \right) \Big/ 24\, N \right] P$$

where: each year is divided in 24 half month periods and N = years in the overall computation period. Additional sub-periods are added if an operation that disturbs the soil, vegetation, or residue occurs within a half month period.

The RUSLE2 mathematical structure is:

$$A = \left(\sum_{i=1}^{365N} r_i k_i l_i s_i c_i p_i \right) \Big/ N$$

where: r_i = daily erosivity factor (erosivity unit/year), k_i = daily soil erodibility factor (mass/area·erosivity unit), l_i = daily slope length factor (dimensionless), s_i = daily slope steepness factor (dimensionless), c_i = daily cover-management factor (dimensionless), and p_i = daily support practice factor (dimensionless), all long term averages for the *ith* day, and N = number of years in the overall computational period. In practice, a single time-invariant slope steepness S is used instead of a daily s_i slope steepness factor.

The difference in mathematical structure between the USLE, RUSLE1, and RUSLE2 results in the three methods giving different erosion estimates even when each method gives the same average annual values for each USLE factor. Also, RUSLE2 considers much more interdependence between the factors than either the USLE or RUSLE1 considers.

Fundamentally, the USLE applies to a uniform overland flow path where neither soil, steepness, cover-management, nor support practice vary along the flow path. A mathematical procedure is available to apply the USLE to non-uniform overland flow paths where deposition does not occur. The USLE can not be applied to overland flow paths where steepness along the flow path decreases sufficiently to cause deposition.

The same mathematical structure used in process-based erosion prediction technologies to compute deposition along non-uniform overland flow paths is used in RUSLE1 and RUSLE2. Deposition is computed at locations along the flow path where the sediment load exceeds surface runoff's sediment transport capacity. RUSLE2 computes deposition using the equation:

$$D_p = (\alpha V_f / q)(T_c - g)$$

where: D_p = deposition rate (mass/area·time), α = an empirically determined deposition coefficient (dimensionless), V_f = the sediment's fall velocity (length/time), q = surface runoff rate (volume/unit overland flow width·time), T_c = surface runoff's sediment transport capacity (mass/unit overflow width·time), and g =sediment load (mass/unit overflow width·time) being transported by surface runoff.

Five sediment classes (primary clay, primary silt, small aggregate, large aggregate, and primary sand) are used in RUSLE2 to represent sediment characteristics. RUSLE2 computes the distribution of the sediment among these classes and the diameters of the aggregate classes at the point of detachment as a function of soil texture. The specific gravity of the aggregate classes is about 65 percent of that for the primary particle classes. RUSLE2 computes how deposition changes sediment characteristics along the overland flow path by applying the deposition equation to each sediment class. RUSLE2 also computes an enrichment ratio based on the specific surface of the sediment load and the specific surface area of the surface soil.

Both the deposition and sediment transport capacity equations are functions of runoff rate. A daily runoff rate index is computed using the NRCS runoff curve number method and the 10 year-24 hour precipitation amount. RUSLE2 computes a daily curve number value as a function of daily cover-management variables.

RUSLE2 computes how soil surface conditions affect runoff's sediment transport capacity. The computation is based on a division of runoff shear stress between that acting on roughness elements, including live vegetation, standing residue, surface residue cover and soil surface roughness, and that acting on the soil grain roughness, which is the part responsible for sediment transport. A daily division of shear stress is computed using daily cover-management variables.

RUSLE2's erosivity and soil erodibility definitions and variables are the same as those used by the USLE, which are based on the unit-plot concept. Also, RUSLE2 can use the standard USLE soil erodibility nomograph to compute soil erodibility factor values for undisturbed soil profiles or a modified nomograph for highly disturbed soil conditions. RUSLE2 computes a daily erodibility factor value that is varied about the base soil erodibility factor values using daily precipitation and temperature values. Daily erosivity is computed as the product of average annual erosivity and the fraction of the annual erosivity that occurs on each day.

The RUSLE2 slope length factor, which is the same as the USLE and RUSLE1 slope length factor, is given by:

$$l_x = \left(x/\lambda_u\right)^m$$

where: l_x = slope length factor used to compute erosion at any location x along an overland flow path (dimensionless), λ_u = unit plot length, and m = a slope length factor exponent. Sediment is detached from the soil mass on overland flow area by impacting raindrops (interrill erosion) and surface runoff (rill erosion). Interrill erosion is uniform along a uniform overland flow path, in which case the exponent m = 0. Rill erosion increases along an overland flow path as runoff increases, in which case m = 1. RUSLE2 computes a daily exponent value (between 0 and 1) that depends on the ratio of rill-to-interrill erosion. This ratio is computed as a function of how soil texture, slope steepness, and surface cover affects rill erosion relative to interrill erosion. The rill-to-interrill erosion ratio changes daily as cover-management changes daily.

The RUSLE2 slope steepness factor is the same as the one used in RUSLE1. This factor is time invariant in RUSLE2.

11.3. Land use subfactors

11.3.1. Cover-management subfactors

The use of basic cover-management variables to compute daily cover-management factor and runoff curve number values gives RUSLE2's its land-use independence. Cover-management factor values are computed as the product of several subfactors. These subfactors are canopy, ground (surface) cover, soil surface roughness, soil ridging, soil consolidation, soil biomass, and ponding. An additional soil moisture subfactor is used when RUSLE2 is applied to cropland in certain areas of the northwestern US.

The canopy subfactor describes how above ground canopy (cover that does not touch the soil surface) affects rainfall erosivity. The variables used in this subfactor include fraction of the soil surface covered by canopy and effective fall height of water drops falling from the canopy. RUSLE2 includes equations that estimate effective fall height based on top and bottom canopy heights, canopy shape, and the vertical gradient of canopy mass.

In contrast to canopy cover, ground (surface) cover rests directly on the soil surface. The main component of the equation that computes ground cover subfactor is:

$$c_g = \exp(-bf_g)$$

where: c_g = the subfactor for ground cover. **b** = coefficient for effectiveness of ground cover for reducing erosion (percent^{-1}), and f_g = ground cover (percent). The **b** coefficient, which is a measure of the effectiveness of ground cover for reducing erosion, is a function of the rill-to-interrill erosion ratio. RUSLE2 computed **b** values vary from 0.025 when the erosion is entirely interrill erosion to 0.06 when the erosion is entirely rill erosion. An additional soil surface roughness term is added to this equation in RUSLE2 to account for surface cover having less effect as soil surface roughness increases.

The soil surface roughness subfactor represents how soil surface roughness influences erosion by reducing runoff's erosivity, by causing deposition in local depressions, and by ponding water that protects a portion of the soil surface from direct raindrop impact. Daily soil surface roughness subfactor values are computed as a function of the daily soil surface roughness index. Soil surface roughness decreases daily from the initial soil surface roughness left by a mechanical soil disturbance. RUSLE2 computes the daily decrease in the soil surface roughness index using values for daily precipitation and daily interrill erosion. The soil surface roughness index value left after a mechanical soil disturbance is computed as a function of the soil surface roughness index that exists at the time of the soil disturbance, the soil surface roughness index created by the mechanical soil disturbance applied to a standard soil condition, soil texture, soil biomass, and the degree that the mechanical soil disturbance obliterates existing soil surface roughness.

The soil ridging subfactor represents the effect of ridge side slope on interrill erosion. The soil ridging subfactor is a function of daily ridge height, which is a surrogate for ridge side slope. RUSLE2 decreases daily ridge height from an initial ridge height left by

a mechanical soil disturbance as a function of daily precipitation and daily interrill erosion.

The soil consolidation subfactor represents how a bare soil without soil biomass becomes less erodible over time as the soil experiences wetting and drying cycles. Soil consolidation in RUSLE2 refers to the re-bonding of soil particles after a mechanical soil disturbance. The RUSLE2 assumption is that mechanical soil compaction (increase in soil bulk density) does not decrease erosion. RUSLE2 computes soil consolidation subfactor values as a function of the time since the last mechanical soil disturbance. The RUSLE2 time to soil consolidation is seven years but increases to 20 years where average annual precipitation is less than 30 inches.

The soil biomass subfactor represents how soil biomass reduces erosion. RUSLE2 computes daily soil biomass subfactor values as a function of the daily amounts of live roots, dead roots, and buried biomass in the soil and the soil consolidation subfactor. Plant litter, crop residue, manure, and other types of biomass on the soil surface that is incorporated in the soil by mechanical soil disturbance adds to buried soil biomass. Also, injection of manure, sewage sludge, and other organic materials into the soil adds soil biomass. The runoff and erosion reduction computed by the soil biomass subfactor significantly increases as the soil becomes “consolidated” after a mechanical soil disturbance.

The ponding subfactor accounts for how a water layer on the soil surface decreases raindrop impact erosivity in high rainfall regions where land is nearly flat. The variables used to compute ponding subfactor values are land steepness and daily runoff depth, which in turn is a function of the 10 year-24 hour precipitation amount, soil properties, and cover-management.

The antecedent soil moisture subfactor, which is used only on cropland in the northwestern US, accounts for how previous cropping reduces soil moisture that in turn reduces erosion in subsequent cropping periods.

11.3.2. Support practice subfactors

The contouring subfactor computes how contour ridging affects rill erosion and sediment transport by redirecting surface runoff. Contouring subfactor values are computed as a function of daily runoff rate, overland flow path steepness, and ridge-furrow grade

RUSLE2 computes the location along an overland flow path (critical slope length) beyond which contour ridges fail. This computation is a function of the daily runoff rate, daily cover-management conditions, and land steepness.

RUSLE2 computes how profile shape(uniform, convex, concave, and complex) along the overland flow path affects erosion, deposition, and sediment yield from the overland flow path represented in a RUSLE2 computation. RUSLE2 computes the amount of deposition on concave portions of the overland flow path, how this deposition affects sediment characteristics by enriching the sediment in fine and less dense particles.

Strips of dense vegetation placed along overland flow paths can significantly reduce erosion and sediment yield. RUSLE2 computes the reduction in sediment production, the amount of deposition caused by the dense vegetation strips, and the change in sediment characteristics.

Terraces and diversions placed along an overland flow path reduce erosion by decreasing overland flow path length. RUSLE2 also computes deposition and its effect on sediment characteristics in low grade terraces assuming a uniform terrace grade. RUSLE2 does not compute erosion by flow in these channels.

RUSLE2 computes deposition in small impoundments such as small sediment basins used on construction sites and small impoundments created by parallel tile outlet terrace systems. A simple settling-type equation is used to compute deposition by sediment particle class.

The deposition computed by RUSLE2 depends on the characteristics of the sediment reaching the deposition area. Sediment characteristics at the point of detachment are computed as a function of soil texture, but deposition along the overland flow path enriches the sediment in fines and less dense particles that are deposited less readily. Consequently, less deposition is computed in dense grass strips, terrace channels, and in impoundments if upstream deposition has been computed.

RUSLE2 computes how irrigation affects erosion caused by rainfall and its associated overland flow. RUSLE2 takes into account increased yield and increased soil moisture, which increases biomass decomposition and soil erodibility, caused by the irrigation. RUSLE2 does not compute the erosion directly caused by irrigation itself.

The subsurface drainage subfactor represents how subsurface drainage reduces erosion by reducing surface runoff. This subfactor is based on how much subsurface drainage reduces a soil's runoff potential. The runoff potential (permeability) subfactor in RUSLE2's computation of unit-plot soil erodibility is used to adjust the soil erodibility value to account for the subsurface drainage effect.

11.4. Biomass accounting

Biomass on and in the soil has a great effect on soil erosion. The input value for production (yield) level provides the starting point for RUSLE2's biomass accounting. RUSLE2 tracks the conversion of live standing vegetation to dead standing residue by natural and mechanical processes. RUSLE2 accounts for soil surface biomass accumulation from standing residue becoming surface residue caused by standing residue falling by natural processes and mechanical events, by litter fall, and by events that add surface biomass such as straw mulch applications. RUSLE2 estimates the biomass in litter added to the soil surface by senescence based on the decrease in canopy cover.

The RUSLE2 sources of soil biomass are live and dead roots, soil surface biomass that is buried by mechanical soil disturbance, decomposed soil surface biomass that is added to soil, and biomass injected into the soil. RUSLE2 adds the daily decrease in live root

biomass to dead root biomass. Live roots decrease annually as a part of the growth cycle of perennial vegetation, and live roots become dead roots when vegetation is killed by a mechanical operation or a natural process such as frost.

RUSLE2 computes the daily decomposition loss of standing residue, surface residue, buried residue, and dead roots as a function of daily precipitation and temperature. The same decomposition coefficient value is used for all plant parts and whether the material is on the soil surface or buried in the soil. However, the decomposition coefficient for standing dead vegetation is assumed to be 30 percent of that for surface and buried material.

RUSLE2 uses a specific set of rules to transfer biomass between standing residue, surface residue, and buried residue pools. For example, live above ground biomass must be converted first to standing residue before live vegetation biomass can become surface residue. Next, standing residue must be converted to soil surface residue. Only surface residue can be buried. That is, standing residue can not be directly buried without first being converted to surface residue. A mechanical soil disturbing operation is required to bury or place residue in the soil, and a mechanical soil disturbing operation is required to resurface previously buried residue.

11.5. Cover-management descriptions

Users provide a cover-management description that RUSLE2 uses to compute how cultural practices affect erosion. A RUSLE2 cover-management description is a list of operations by date, vegetation descriptions and production levels (yields), and residue descriptions and amounts for material added to the soil surface or injected into the soil. A cover-management description is a rotation when the list of operations are repeated in a cycle with a particular duration, which is typical for cropland and permanent vegetation, or a non-rotation when each operation occurs only once over a particular duration, which is typical of construction sites.

11.6. Operation descriptions

Operations are events that affect the soil, vegetation, or residue. The user selects from several processes to describe the effects of an operation. **Begin growth** is the process that tells RUSLE2 to begin using data in a particular vegetation description on a particular date. **Add residue** is used to apply mulch. A residue description that describes the mulch characteristics is assigned in the cover-management description. **Kill vegetation** is the process used to convert live vegetation to standing residue and live roots to dead roots. It is used to describe harvest of an annual crop and to describe frost killing annual vegetation.

The **disturb soil** process describes a mechanical soil disturbance. For example, the operation description for a heavy offset disk includes a **disturb soil** process. The **disturb soil** process includes inputs for burial and resurfacing values for each of the five RUSLE2 residue types, the fraction of the standing residue that is converted to surface residue, the fraction of surface residue that is buried, and the fraction of the buried residue that is

resurfaced by the operation. The **disturb soil** process includes a designation for whether the operation buries residue by inverting the soil, by mixing the residue with the soil, by a combination of mixing and inversion, or by pressing the residue into the soil. The **disturb soil** process also includes values for soil disturbance depth, surface roughness left by the operation for a standard condition, and ridge height left by the operation, the degree that the operation obliterates existing soil roughness , and fraction of the soil surface disturbed by the operation.

An operation such as straw baling may include a **remove residue** process to describe reduction in surface residue cover after a small grain harvest, for example.

An operation description can include multiple processes. The sequence of the processes is critically important. For example, having an **add residue** process before a **disturb soil** process gives a very different surface residue cover than if the **add residue** process comes after the **disturb soil** process.

11.7. Vegetation descriptions

Computing the effects of vegetation on erosion is an important RUSLE2 feature. RUSLE2 uses values for vegetation variables including temporal canopy cover, effective fall height, live above ground biomass, and root biomass to compute cover-management subfactor and runoff values. Values for these variables are entered in vegetation descriptions.

RUSLE2 does not model vegetation growth as a function of environmental conditions. Instead RUSLE2 vegetation descriptions apply in particular ecological zones. Each vegetation description is for a particular base production (yield) level. The RUSLE2 user chooses the vegetation description for the site where RUSLE2 is being applied and a appropriate yield for the site is entered in the cover-management description. RUSLE2 adjusts the base vegetation description values according to the input yield value for the site.

11.8. Residue descriptions

A residue description is assigned to each vegetation description to describe the characteristics of residue produced by the vegetation. Also, a residue description is used to describe material added to the soil surface (e.g., straw mulch) and material (e.g., sewage sludge) injected into the soil. The residue description includes a decomposition coefficient value that describes how rapidly the residue decomposes under a standard condition, the fraction of the soil surface covered by a given residue mass, and designation of residue type that denotes the fragility of the residue and how well the residue conforms to the soil surface.

11.9. Climate descriptions

Climate descriptions contain the data on long term average monthly precipitation, temperature, and erosivity values that RUSLE2 uses to compute erosion. Each climate description is for a particular location, county, or rainfall zone.

11.10. Soil descriptions

Soil descriptions contain data on soil properties that RUSLE2 uses to compute erosion and deposition. These properties include soil texture, soil erodibility, runoff potential, rock cover, and time to soil consolidation, all for the reference unit plot condition. RUSLE2 includes soil erodibility nomographs that are used to estimate soil erodibility values from values for basic soil properties.

11.11. RUSLE2 databases

The user runs RUSLE2 by making menu selections from the RUSLE2 database. Each description in the database is stored by an identifier name. In a typical RUSLE2 application, the user selects a climate description by location, soil description by soil mapping unit or some other designator, cultural practice by a cover-management description identifier, and support practices by their identifiers, all appropriate for the site specific conditions. The user enters overland path steepness and length values based on the overland flow path chosen to represent the site.

A wide array of RUSLE2 descriptions, especially for cropland, is available from the USDA-Natural Resources Conservation Service (NRCS). Information can be downloaded and imported into your working RUSLE2 database from the NRCS National RUSLE2 Database and from the database of other RUSLE2 users.

Users can adjust values stored in their working RUSLE2 database to better match site conditions. Also, users can create new database entries. New user chosen values must be consistent with values in the RUSLE2 **Core Database**. RUSLE2 was calibrated using a particular set of **core values**. User input values must be consistent with these **core values** in order to obtain good results with RUSLE2 regardless of how much a user may disagree with the **core values**. If a **core value** were to be changed, other RUSLE2 internal or input values would have to be changed as well, because RUSLE2 has been calibrated to give desired erosion estimates with the **core value**. These core values are contained in the RUSLE2 **Core Database**.

11.12. RUSLE2 validation

The equations for the subfactors were primarily calibrated using data from Agriculture Handbook 537 (Wischmeier and Smith, 1978), which is a summary of more than 10,000 plot-years of data. Additional data from the literature were used to calibrate the equations for conditions not represented by the AH537 data. Erosion values were computed with RUSLE2 for a wide range of conditions, including conditions not represented by existing research data. These values were inspected to ensure that they

were consistent with the available research data and consistent with professional judgment.

Ground (surface) cover is perhaps the single most important RUSLE2 variable, at least for cropland conditions. The surface cover left by a cropping system immediately after planting in a key variable used by soil conservationists in judging the effectiveness of a particular cropping system. The adequacy of RUSLE2 for estimating surface cover was very carefully evaluated. An extensive array of literature was reviewed in this evaluation. Scientists have reported differences in RUSLE2 estimates with those made by other comparable erosion models. When RUSLE2 is fitted to the same data used to fit other methods, RUSLE2's estimates of surface cover are almost the same as those estimated by other methods for long term average conditions. The differences were primarily caused by variability in residue data and by differences in techniques used to measure residue mass as it decomposes.

11.13. List of symbols

A = average annual erosion (mass/area·year)

b = coefficient for effectiveness of ground cover for reducing erosion (percent^{-1})

c_g = the subfactor for ground cover (dimensionless)

c_i = cover-management factor for the *ith* period (dimensionless)

C = average annual cover-management factor (dimensionless)

D_p = deposition rate (mass/area·time)

f_g = ground cover (percent)

f_i = factor value for the *ith* time period

F = average annual factor

g =sediment load (mass/unit overflow width·time)

I = the number of sub-periods in the computation period for the management description used to represent a site's land use conditions

I_c = the number of periods in the N_c years used to determine an average annual cover-management factor value

I_k = the number of periods in the N_k years used to determine an average annual soil erodibility factor value

I_l = the number of periods in the N_l years used to determine an average annual slope length factor value

I_p = the number of periods in the N_p years used to determine an average annual support practice factor value

I_s = the number of periods in the N_s years used to determine an average annual slope steepness factor value,

k_i = soil erodibility factor for the *ith* period (mass/erosivity unit)

K = average annual soil erodibility factor (mass/erosivity unit)

l_i = slope length factor for the *ith* period (dimensionless)

l_x = slope length factor used to compute erosion at any location x along an overland flow path (dimensionless)

L = average annual slope length factor (dimensionless)

m = a slope length factor exponent

N = number of years in the computation period

N_c = number of years used to determine an average annual cover-management factor value

N_k = number of years used to determine an average annual soil erodibility factor value

N_l = number of years used to determine an average annual slope length factor value

N_s = number of years used to determine an average annual slope steepness factor value

p_i = support practice factor for the *ith* period (dimensionless)

P = average annual support practice factor (dimensionless)

q = surface runoff rate (volume/unit overland flow width·time)

r_i = erosivity factor for the *ith* period (erosivity unit/area·year)

R = average annual erosivity factor (erosivity unit/area·year)

s_i = slope steepness factor for the *ith* period (dimensionless)

S = average annual slope steepness factor (dimensionless)

T_c = surface runoff's sediment transport capacity (mass/unit overflow width·time)

V_f = the sediment's fall velocity (length/time)

x = distance along overland flow path (length)

α = an empirically determined deposition coefficient (dimensionless)

ϕ_i = the fraction of the annual erosivity that occurs during the *ith* period

λ_u = unit plot length (72.6 ft, 22.1 m)

Indices

i - time period (days)

SUMMARY

This study addresses the problem of modelling sediment erosion at the catchment scale, in order to predict the possible impact of reservoirs and land use changes on sediment load in South East Asia. The investigated basin is the Lo river basin, (38,165 km^2 in Viet Tri), a left tributary of the Red River, where the Thac Ba and the recently built Tuyen Quang reservoirs have already been changing downstream sediment load since 1971 and 2005 when they were, respectively, in operations. The RUSLE equation is adopted in a distributed GIS framework to assess catchment erosion, and is coupled with a sediment accumulation and routing scheme to model suspended sediment load in the Lo basin at a monthly scale. Monthly precipitation were collected and used as input to the model. Suspended sediment load data, measured at eight gauging stations in Vietnam, from 1959 to 2007, were compared with the model's simulated sediment yield. Resulting average Nash–Sutcliffe efficiency is 0.45, ranging from 0.33 to 0.62 and bias is 5% at Vu Quang, close to the basin outlet, and results 1.4% by averaging biases at the eight stations, thus confirming that the model is adequate. Effects of reservoirs were analysed by modelling erosion and sediment yield passing from natural to impounded conditions and resulted in a suspended sediment load reduction of about 95% and 75% downstream, respectively, the Thac Ba reservoir in the Chay river and the Tuyen Quang reservoir in the Gam river. Land use change scenarios, parameterized on the basis of observed land use changes in the impounded basin and assuming that 20% of forest area is converted into rice and agricultural crops and 15% into bushes, shrubs and meadows, are expected to induce a 28% increase of suspended sediment load which can compensate, at least in part, sedimentation in reservoirs. Also agricultural and hillslope maintenance practices can modify sediment erosion in the basin.

1. Introduction

The dynamic equilibrium of sediment erosion, transport and deposition in a river basin can be modified by natural factors, as climate and vegetation changes, and anthropogenic factors, as reservoirs impoundment, agricultural and land use practices (Walling, 2011). In several countries with a fast developing economy, as Vietnam, the need of energy for national industrialisation and modernisation and of water demand for irrigation purposes in the dry season is leading to the construction of large reservoirs which trap sediments and change the sediment load in the downstream river network. This study addresses the problem of erosion at the catchment scale, and on a monthly time basis, in order to predict the possible impact of reservoirs and land use changes on sediment load in the Red River (Song Hong) basin, and specifically in the Lo river subcatchment, in Vietnam. Data and observations over 49 years show, in fact, that since the operation of reservoirs started, downstream sediment load and localised erosion phenomena have changed, thus rising some concern on the geomorphological equilibrium of the area. Similar dynamics are documented by Yang et al. (2006, 2007) and by Xu and Milliman (2009) about the impact, for instance, of the Three Gorges Dam on the Yangtze River in China after its impoundment.

Soil erosion prediction and assessment is a challenge to researchers and a wide range of models have been developed for erosion and sediment transport evaluation and they differ in terms of complexity, processes considered, and data required for model calibration and model use. In general there is no 'universal' model for all applications. The selection of the most suitable model is a logical process affected by numerous factors including the intended use, the characteristics of the catchment being considered and the data available.

According to Merritt et al. (2003), erosion and sediment transport models are subdivided into three main categories, depending on the physical processes simulated, the model algorithms describing these processes and the data dependence of the model: (a) empirical or statistical, (b) conceptual, and (c) physics based. The distinction between models is not clear and therefore can be somewhat subjective. They are likely to contain a mix of modules from each of these categories.

Depending from the scientific environment where they are developed and apart from their different degree of sophistication, models proposed in the literature for assessing the river sediment load may be broadly classified in two categories: (a) models mainly oriented on the watershed-slopes' processes and (b) models mainly oriented on the river processes. Models of type (a) generally are developed in the agricultural and hydrologic engineering community and concentrate their attention on the rill and interril "surface erosion" especially on agricultural crops. They need, however, to be completed by a simplified, at least, sediment transfer model through the downstream river network (Moore, 1984). Models of (b) type, by contrast, represent the evolvement of theoretical and experimental research on sediment transport in rivers mainly performed by hydraulic engineers and are less focused on the processes on hillslopes which are one of the major sources of sediments to rivers.

In summary, models (a) and (b) are in principle correct, provided that both the sediment production from the watershed slopes and their routing along the river system are altogether accounted for with sufficient accuracy, no matter if most of the information is coming from the watershed or from the river.

In this paper, aiming at assessing the sediment transport at the basin scale, on a monthly time-scale, and in the lack of detailed information on stream geometry and sediment size distribution in rivers, a type (a) of modelling framework, completed with a conceptual sediment transport scheme, was adopted.

Focusing on the type (a) of hillslope models, empirical models accounting for sediment eroded from the catchment, like USLE (Wischmeier and Smith, 1978), MUSLE (Williams, 1975), RUSLE (Renard et al., 1997), are generally the simplest and most widely applied of the three model types, especially for large scale basins like the ones we investigated. They are based primarily on the analysis of observations and seek to characterise the basin response from these data (Wheater et al., 1993). A physical meaning is sometimes attributed to parameter values in empirical models obtained by calibration, without an appropriate conceptualisation of processes. Empirical models are often criticised for employing unrealistic assumptions about the physics of the catchment system, ignoring the heterogeneity of catchment inputs and characteristics, such as rainfall and soil types, as well as ignoring the inherent non-linearities in the catchment system (Wheater et al., 1993).

Conceptual models, like EMSS (Vertessey et al., 2001), HSPS (Johanson et al., 1980) are usually based on the representation of a catchment as a series or by a combination of known hydraulic structures like storages, channels etc. (see also Tyagi et al., 2008). They analyse mechanisms of sediment and runoff generation and propagation by representing each of them in the model structure. Conceptual models tend to include a general description of catchment processes, without including the specific details of process interactions, which would require detailed catchment information (Sorooshian, 1991). Parameter values for conceptual models have typically been obtained through calibration against observed data, such as stream discharge and sediment load measurements (Abbott et al., 1986). Due to the requirement that parameter values should be determined by comparing calibration with observed data, conceptual models tend to suffer from problems associated with the identifiability of their parameter values (Jakeman and Hornberger, 1993).

Physics-based models like WEPP (Laflen et al., 1991), TOPOG (CSIRO, 1991), AUGUSTO (Rulli and Rosso, 2005, 2007), are based on the solution of fundamental physical equations describing the processes involved in erosion and sediment transport. The equations used in such models are the equations of conservation of mass and momentum for flow and the equation of conservation of mass for sediment (Bennett, 1974; Pilotti and Menduni, 1997). The parameters used in physics-based models, as surface roughness, vegetation cover, soil particle size distribution, are measurable and have a physical meaning. However, a parameter calibration is unavoidable, because of the high spatial variability of some parameters involved in the processes, and the uncertainty in their measurements at some points. This poses severe problems in defining criteria for the acceptability of a model setup (Liu et al., 2009).

Each model type of hillslope erosion serves a purpose, and a particular model type may not categorically be considered more appropriate than others in all situations (Merritt et al., 2003).

In this paper a distributed Revised Universal Soil Loss Equation (RUSLE) formulation was coupled with a river network routing scheme to simulate suspended sediment load on a monthly basis at eight stream gauging stations, with the objective to assess the potential impact of reservoirs and land use changes on suspended sediment load in the Lo river basin. The study area is the Lo river basin, (38,165 km^2 in Viet Tri), a left tributary of the Red River (138,960 km^2 in Son Tay), where the Thac Ba reservoir (2.49×10^9 m^3 storage volume) and the new Tuyen Quang reservoir (2.245×10^9 m^3 storage volume) already changed sediment load after 1971 and 2005 when they were started to be regulated mainly for hydropower generation. Sediment load in this area was recently investigated by Le et al. (2007) who simulated runoff and suspended sediment on a daily basis for the year 2003 using a simple lumped modelling approach. In this paper the suspended sediment load was simulated over the 1959–2007 period, thus covering different climatic and land use conditions and including the effect of the construction of the two reservoirs mentioned above. Distributed information about topography, land use, and rainfall interpolated on a 1 km resolution grid was used to compute sediment erosion with a RUSLE formulation adapted to local conditions and a river network routing scheme to simulate suspended load on a monthly basis at several sites. Parameters of the RUSLE collected by Vezina et al. (2006) and by Pham (2007) in subbasins of the Lo basin were taken as a reference. In the second section, the physiographic characteristics of the Lo basin are described, together with the rainfall, runoff and suspended sediment regime. The third section describes the modelling approach adopted. Results are presented and discussed in the following section, where the effect of reservoirs is assessed and, finally, the potential impact of land use changes is investigated.

2. The Lo river basin

The Lo river is a main branch of the Red River (Song Hong), located on the eastern side of the basin (see Fig. 1). The river sources start from Ping Yuan of Yuanshan, in the Yunnan Province (China). The location of the river source is 105°37′E longitude, 23°35′N latitude, at an altitude of 1100 m above sea level. The location of the river mouth is 105°27′E longitude, 21°18′N latitude. The Lo river at the Viet Tri gauge, at an altitude of 16 m a.s.l., has a catchment area of 38,165 km^2 of which 22,600 km^2 are in Vietnam. The length of the Lo river is 470 km and 275 km are in Vietnam. It flows through the Cao Bang, Tuyen Quang and Yen Bai provinces in Vietnam and flows into the Thao river at Viet Tri, in the Phu Tho province, where the main stream takes the name of Red River (Song Hong). The average basin altitude is 880 m and the basin area above the

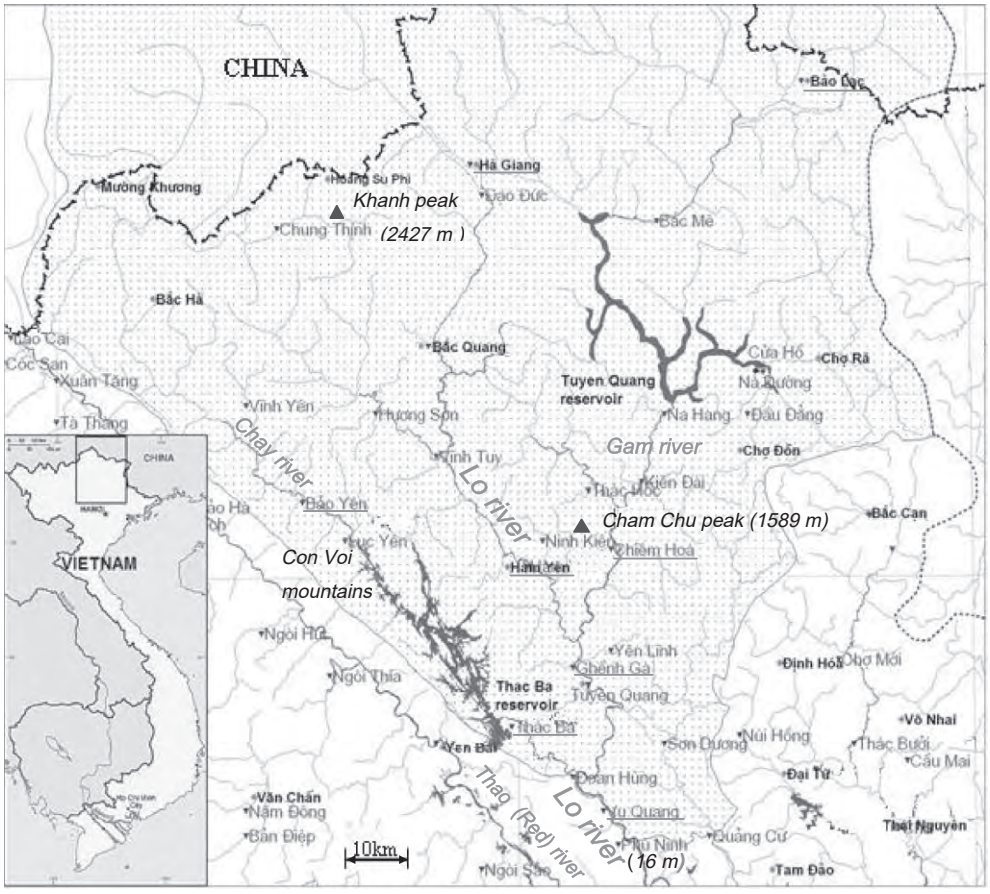

Fig. 1. The Lo river basin gauged at Phu Ninh (dotted area) with the hydrometric and, underlined, the eight suspended sediment load measurement stations considered in this study. The investigated area of the basin in Vietnam is zoomed here.

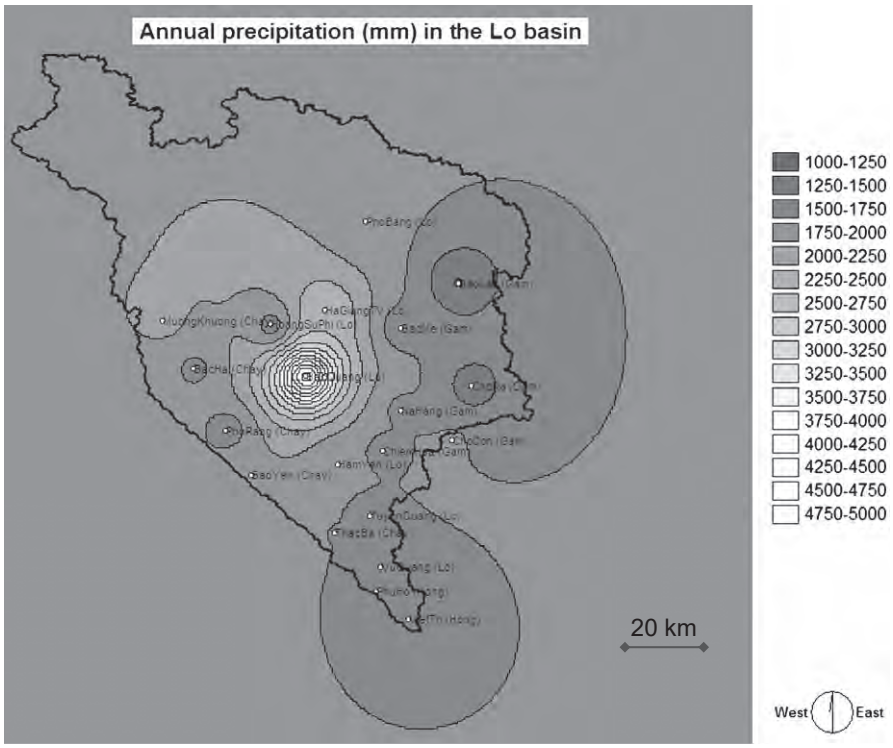

Fig. 2. Annual precipitation in the Lo basin, with the position of the rainguage stations (1959–2007).

altitude of 250 m covers more than 80% of the total basin area. The average slope of the Lo basin surface is 19.7%. The maximum elevation decreases from 2000 m altitude in China to 1000–1500 m altitude in Vietnam. The mountain topography is separated by four main rivers. The Thao and Chay rivers are separated by the Con Voi mountain range and Bac Ha plateau. The Khanh mountain ridge, reaching an altitude of 2427 m above sea level divides the Chay and the Lo rivers.

The drainage density is unevenly distributed in the basin. The western and the north-western parts of the basin are highlands where the rainfall amount is higher than in the south-eastern part (see Fig. 2). The river density ranges from 0.5 to 2.0 km/km^2, measured on 1:50,000 scale maps. Because of the lower rainfall amount, in the eastern and north-eastern part of the basin the drainage density is smaller, about 0.5 km/km^2. There are some major hydrometric stations in the Lo river, with runoff and suspended sediment load data records that go back more than 30 years, such as the Ha Giang station that gauges a 8300 km^2 basin drainage area, Ham Yen (11,900 km^2), Chiem Hoa (16,500 km^2), Ghenh Ga (29,600 km^2) and Vu Quang station with a basin 37,000 km^2 in size (see Fig. 1), for which 49 years of data were available for this study.

2.1. Terrain and geomorphology

Focusing on the Tuyen Quang province, which is representative for the Lo basin, where a new reservoir has been in operation since 2005, the terrain is dissected by a complex system of streams, rivers, heaps of mountains, hills, and deep valleys. Terrain height differentiation among areas in the province is large: the highest area is Cham Chu peak (Ham Yen District) with an altitude of 1589 m, the lowest place is the Southern Son Duong having an elevation of only 23 m above sea level.

From North to South, the basin can be divided into three altitudinal zones.

- *Terrain of high mountains:* it is mainly located in the northern part of the province and the terrain topography is very rough and difficult to access, with mountains up to the Cham Chu peak.
- *Terrain of low mountains:* includes about 40% of the area of the whole province, placed mainly in the southern part of the province including the southern part of Chiem Hoa, Ham Yen, Yen Son, and Son Duong district. The average elevation of this area is less than 500 m a.s.l. Peaks with an elevation over 500 m a.s.l. are the La mountain peak (550 m) and Lich mountain (933 m).
- The lower altitude zone includes fluvial plains and river valleys. Several fluvial fans develop at hills' foot and within main valleys originated from confluent rivers and they are very convenient for agricultural cultivation. Hills surrounding fluvial plains and fans show mild topography with residual hills of karst cones. This type of terrain is not very extended, only accounting for 10% of the area of the whole province, including the rest of Yen Son, the Son Duong District and Tuyen Quang.

The area surrounding Tuyen Quang shows the following geomorphologic features: river valley geomorphology develops along valleys of major rivers such as Lo, Gam, and Pho Day River. Karst geomorphology is a typical geomorphologic feature of limestone mountains, concentrated mainly in the Na Hang district, the mountainous area of Chiem Hoa, the Son Duong district. Mountains higher than 700 m a.s.l. are distributed mainly in the Na Hang district, north of Ham Yen, and Chiem Hoa district. Mountains ranging from 300 to 700 m a.s.l. include a large area, distributed mainly in Ham Yen, Yen Son, the Son Duong districts and part of the Chiem Hoa district. Low hills having an elevation less than 300 m a.s.l. are distributed mainly in the South of Yen Son, and in the Ham Yen district. Terrain's slope of Tuyen Quang is divided into four classes: areas with slope of less than 8% accounting for about 14% of the total province area, area with slope of 8–15% accounting for about 34%, area with slope of 15–25% accounting for about 26% and area with slope of more than 25% accounting for 21%. In the Lo basin, major land use classes correspond to agricultural land, forest, urban areas and water bodies.

2.2. Rainfall and runoff regime

Rainfall in the Lo basin is relevant, with a 1880 mm annual average, but uneven in distribution and highly variable in space and time, as shown in Figs. 2 and 3, depending on local terrain conditions and monsoon circulation in Northern Vietnam. The Ha Giang province is the rainiest, reaching an annual rainfall depth of 4815 mm measured, on average, at the Bac Quang station from 1961 to 2007. Similar to other areas in northern Vietnam, the climatic regime is divided into two seasons: the rainy season and the dry season. The rainy season is from May to October; the dry season is from November to April of the following year. Average annual rainfall on a climatic basis in the Tuyen Quang province fluctuates in the range from 1500 to 1800 mm. There are 150 rainy days per year on average. The rainy season occurs in summer with a total seasonal rainfall ranging, at different stations, in the 1310–2130 mm range, accounting for 85–94% of total annual rainfall; the dry season takes place in winter with a total seasonal rainfall ranging from 134 to 225 mm, only comprising 6–25% of the total annual rainfall. The most rainy months are July, August and September with rainfall of 250–320 mm/month, and up to 950 mm/month measured in September 2000 in Tuyen Quang town. The months with the lowest average rainfall are January and December with rainfall reaching only 16–25 mm/month. The fluctuations of monthly and annual rainfall in the 1959–2007 period in some stations of the Lo basin are reported more in detail in Le et al. (2010).

The runoff regime reflects the rainfall regime with mean annual runoff of 871 mm at the Vu Quang station, the runoff measurement station closer to the Lo basin outlet. More detailed information on interannual variability of runoff for eight stations are reported in Le et al. (2010).

2.3. Suspended sediment data

The runoff and suspended sediment load data used in the present analysis were measured at eight gauging stations in the Lo river

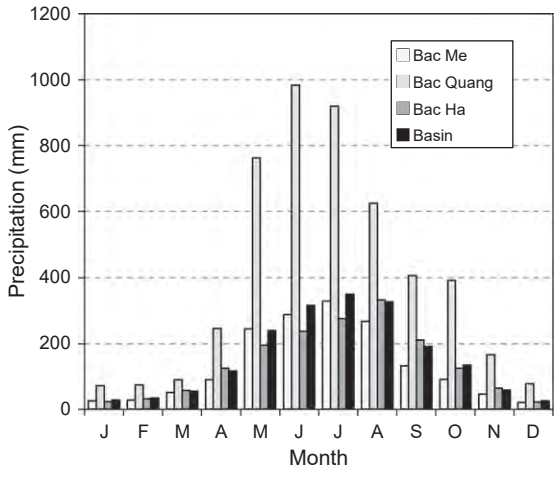

Fig. 3. Monthly precipitation regime in the Lo basin (1959–2007).

basin from 1959 to 2007. During that period two reservoirs, Thac Ba and Tuyen Quang, were put into operation. In Table 1, the mean suspended sediment load in the selected stations is reported, obtained by averaging daily sediment load data at the eight stations. Starting from 1971 the Thac Ba reservoir was in operation resulting, in the following years, in a dramatic drop in suspended sediment load. The average sediment concentration over the 1971–1975 period had fallen to 0.026 kg/m^3 from the 0.529 kg/m^3 average over the 1959–1963 and 1966–1970 period, prior to the dam construction with a resulting suspended sediment trap efficiency of 95%. In Fig. 4, the effect of the Thac Ba reservoir on suspended sediment impounds can be observed.

Starting with December 2004 the Tuyen Quang reservoir, draining an area of 13,454 km^2 computed from the digital river network was in operation. The average sediment concentration measured in the downstream Chiem Hoa (16,500 km^2) station over the 2005–2007 period dropped to 0.184 kg/m^3 from the 1965–2004 years period when it was 0.436 kg/m^3 with a resulting suspended sediment trap efficiency of 71% of the Tuyen Quang reservoir. Fig. 5 illustrates the effect of the Tuyen Quang reservoir on sediment load. These data are consistent with those by Nguyen et al. (2003) who reported that the suspended sediment load at the Son Tay station (138,960 km^2) decreased from 114×10^6 tons/year in the period 1958–1985 to 73×10^6 tons/year in the period 1986–1997, after the Hoa Binh reservoir, draining an area of 51,800 km^2, on the Da river has come into operation. Estimates of specific sediment load in the Da river at Hoa Binh are 1.200 kg/m^3 for the 1958–1985 period and 0.300 kg/m^3 for the 1986–1997 period, corresponding to a trap efficiency of 75%, as reported by Le et al. (2007). Such a significant decrease in suspended sediment load increases the flow capacity to erode the river channels and, indeed, erosion of riverbanks, bridge abutments and piers has been already

Table 1
Annual total suspended sediment load (10^6 tons/year) in the Lo river basin.

Year Area (km^2)	Bao Yen 5000	Thac Ba 6170	Ha Giang 8300	Ham Yen 11,900	Bao Lac 4060	Chiem Hoa 16,500	Ghenh Ga 29,600	Vu Quang 37,000

observed downstream the Thac Ba and Tuyen Quang reservoirs, rising the concern of river management authorities. Riverbank erosion between the Vu Quang and Viet Tri hydrometric stations, in particular, is becoming a relevant problem.

3. RUSLE sediment erosion and transport modelling

3.1. The RUSLE modelling of sediment erosion

In our modelling approach, on the basis of the hydrological, the physiogeographic data available and their resolution and the research objectives, the sediment delivered from river bed erosion and landslides, which has a coarser grain size and mainly contributes to bed load (Patel and Ranga Raju, 1996) was not computed. Moreover, sediment deposition in reservoirs only, and not that along the river network, is considered in our conceptual modelling approach, thus balancing, at least in part, the underestimation of sediment supply.

As a result of these assumptions the RUSLE approach was adopted here for the computation of suspended sediment load at the catchment scale and an extended data set is used to test and verify our hypotheses. The Universal Soil Loss Equation (USLE, Wischmeier and Smith, 1978), and the revised version of it, named RUSLE (Renard and Freimund, 1994; Yoder and Lown, 1995; Renard et al., 1997), were developed to predict the long term average annual erosion, A, from field sized areas. Here the RUSLE approach was applied in a distributed manner, using a 1 km resolution GIS which makes spatial soil erosion assessment feasible with a reasonable cost and accuracy in larger areas. In particular, the RUSLE is a set of mathematical equations that estimate average annual soil loss and sediment yield resulting from interrill and rill erosion. RUSLE is one of the most popular and effective empirical models for the assessment and prediction of soil erosion due to water runoff. It was not originally intended to be valid for large study areas. However, satisfactory results on large-scale watersheds were also reported by many researchers.

The RUSLE basic equation includes six factors: R the rainfall-runoff erosivity factor, K the soil erodibility factor, L the slope length factor, S the slope gradient factor, C the crop and management factor and P the conservation support practice factor. The USLE/RUSLE model is often represented by the equation:

$$A = R \cdot K \cdot LS \cdot C \cdot P, \tag{1}$$

where A is average soil loss per unit of area during a unit period of time, usually one year (tons ha^{-1} year^{-1}).

R is average rainfall and runoff factor, the erosion potential of rainstorms (MJ ha^{-1} mm h^{-1}).

The conceptual framework to estimate the R factor in RUSLE has been significantly improved over that assumed in the original USLE approach. For this study, the threshold-type equation of Loureiro and Coutinho (2001) is adopted:

$$R = \frac{1}{N}\sum_{i=1}^{N}\sum_{m=1}^{12}(7.05 \cdot \text{rain}_{10} - 88.92 \cdot \text{days}_{10})_{m,i}, \quad (2)$$

where N is the number of observation years, rain_{10} is monthly rainfall, when $\geqslant 10$ mm, otherwise it is set to zero, day_{10} is monthly number of days with rainfall $\geqslant 10$ mm.

Eq. (2) gives a higher erosion potential of rainfall with higher monthly rainfall, rain_{10}. It also accounts for the fact that, for a given rainfall amount, the lower are the rainy days, days_{10}, the higher is the rainfall intensity and erosion potential, as expected. Using the above equation the monthly R factor value for rain gauges of the Lo river basin were computed and the resulting average annual R factor, interpolated with Thiessen polygons for the period 1959–2007, is shown in Fig. 6.

K is the average soil erodibility factor (tons MJ^{-1} h mm^{-1}). Some soil types are naturally more prone to soil erosion due to their physical structure. Erodibility is a function of soil texture, organic matter content and permeability.

In this study, the K factor is assumed equal to 0.022 according to literature data for watershed units in Vietnam's northern highlands (see Vezina et al., 2006; Pham, 2007), reported in Table 2 and Table 3. Such a value is also in agreement with literature data about China, (Zhang et al., 2004, 2008), which report a mean value of 0.038 in a 0.004–0.091 range and 0.0144 in a 0.0016–0.0381 range.

LS is the slope length and the slope gradient factor. Slope has a major effect on the rates of soil erosion. The higher the slope, the higher is the velocity of overland flow, thus increasing the shear stresses on the soil particles. As slope length increases, the overland flow and flow velocity also steadily increase, leading to greater erosion forces applied to the soil surface.

In this study, the equation of Moore and Burch (1986), adopted also, among others, by Pilotti and Bacchi (1997) for estimates of erosion at the catchment scale, was used.

$$LS = \left(\frac{A_s}{22.1}\right)^{m'} \cdot \left(\frac{\sin\beta}{0.0896}\right)^{n'}, \quad (3)$$

where A_s is the area of plot per unit width. Considering that crops are divided into small parcels in mountainous slopes of Vietnam, the standard reference value of 22.1 m was assumed. m', n' are coefficients set equal to 0.6 and 1.3, respectively and β is slope angle, computed from the DEM.

Feralit red-brown from gabrostone	0.117648	0.027
Feralit from typical limestone	0.130215	0.026

C is the cropping, vegetation and management factor and determines the relative effectiveness of soil and crop management systems in terms of preventing soil loss ($C = 1$ with bare soil, no vegetation and without management practices; $C < 1$ otherwise, with values close to zero in forested areas where surface erosion is mitigated by vegetation). The C factor plays a critical role in determining the rate of erosion. The leaves of plants protect the soil from raindrop impact and the roots hold the soil together. Plants also tend to increase infiltration of water, thus reducing the volume of overland flow running down the slope. The C factors of the Lo basin for individual crops in addition to mixed farming systems was selected from literature data as adopted for northern Vietnam (Vezina et al., 2006; Pham, 2007), as shown in Tables 4 and 5. These data were adapted to digital land use maps adopted by FAO, resulting in the cropping factor reported in Table 6 and shown in Fig. 7.

P is a supporting practice factor. It reflects the effects of practices that will reduce the amount and rate of the water runoff and thus reduces the amount of erosion, the higher the supporting practice, the lower the value of the P factor. The support practice factor expresses the effect of support practices such as contour cultivation, strip cropping around contours, arable land terrace and bench terrace and it cannot be assessed from coarse resolution land use map, as those available for this research. Table 7 reports the value of the P factor of the Lo basin adopted by Pham (2007), according to the International Soil Science Association, and Table 8 collects the values adopted by Vezina et al. (2006) for Vietnam's northern highlands. In this study, an average P factor is assumed and set to 0.2 because of the dominant soil conservation practices

Table 4

Corn	0.80

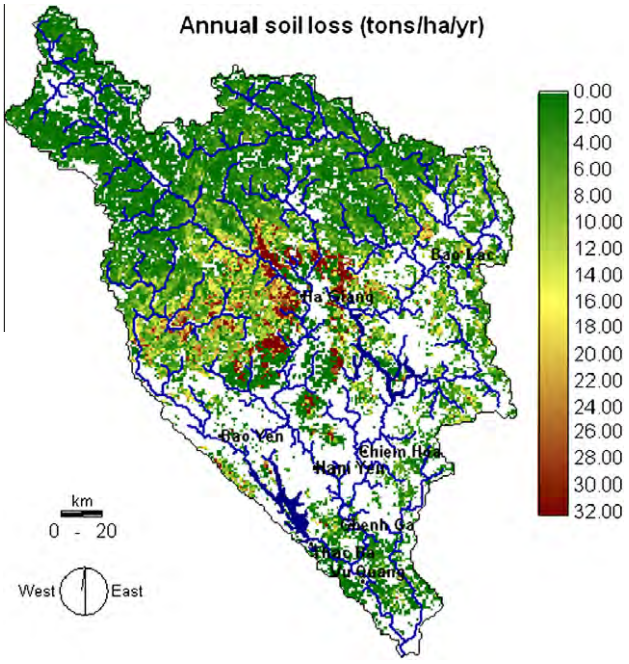

Fig. 8. Average soil loss (tons ha^{-1} $year^{-1}$) in the Lo river basin.

3.2. Sediment transport

The resulting mean annual soil losses evaluated with the RUSLE model are shown in Fig. 8. In particular, soil losses were computed on a monthly basis and then were accumulated across a channel network extracted from a 1-km resolution DEM using the standard D8 flow direction method (O'Callaghan and Mark, 1984). The resulting river network is in a good agreement with the observed 'blue lines', although a more accurate description of the drainage system could be achieved with more sophisticated methods (e.g. Orlandini and Moretti, 2009). The D8 scheme, already adopted by Ranzi et al. (2002), is part of the DIMOSHONG model (DIstributed hydrological MOdel for the Shong HONG) which was already applied for flood forecasting in the Red River basin (Ranzi et al., 2007; Ngo et al., 2010).

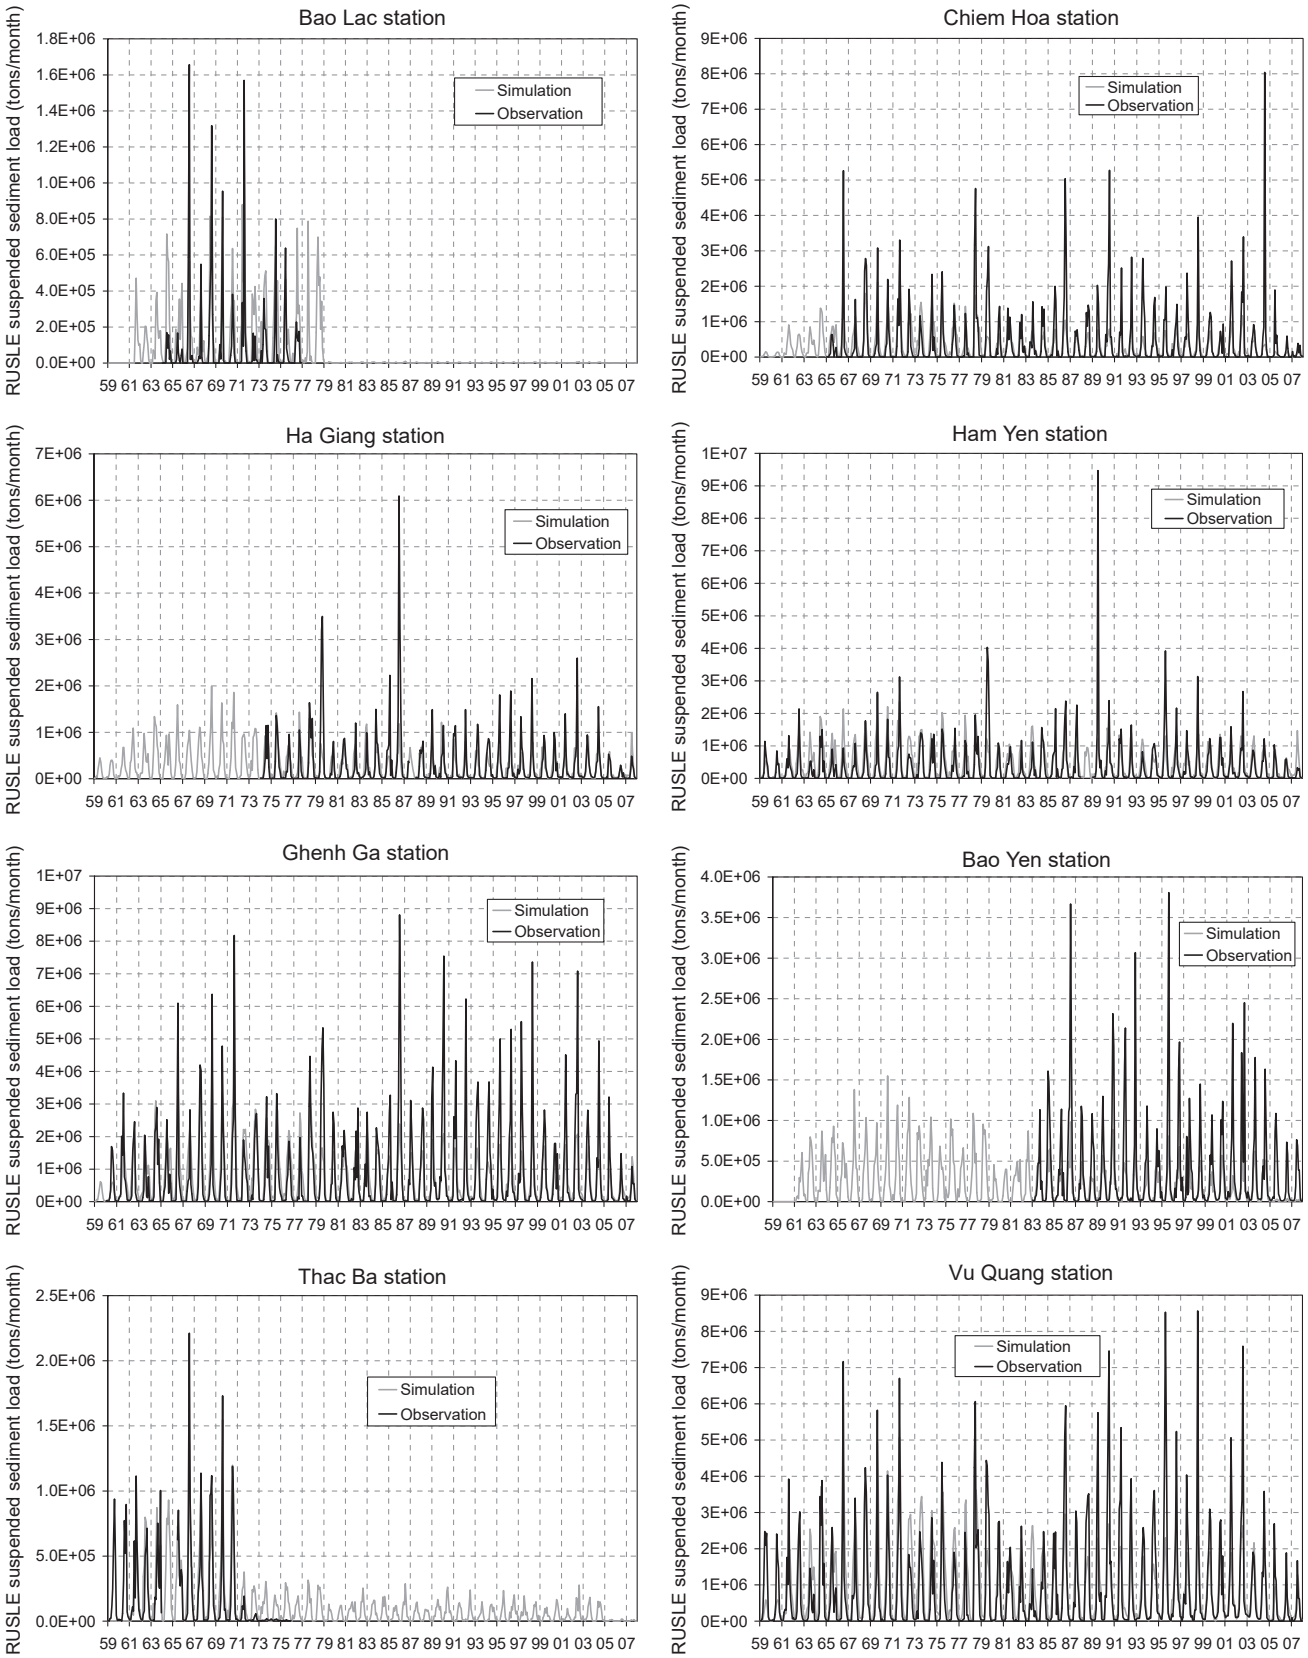

Fig. 9. Monthly sediment yield simulated and observed at eight hydrometric stations in the Lo river basin.

The accumulated monthly sediment production S_k, expressed in tons/day, in each of the basins upstream eight measurement stations ($k = 1,\ldots,K = 8$) is then routed through the channel network with a conceptual, lumped scheme, aiming at reproducing the dominant mode of behaviour of the sediment transport process (Moore, 1984). For the sediment translation function a plausible

assumption is that the travel time of sediments in the basin is a random variable with exponential distribution, with mean travel time θ_k, expressed in days and estimated as the ratio of a length scale, L_k, and of a velocity scale, V. The length scale is assumed as a power law function of each basin area, A_k, according to the Hack's law, $L = 1.4A^{0.6}$, with L being the mainstream length expressed in kilometres and the area A in km^2 (Hack, 1957; Rigon et al., 1996).

Assuming each kth basin as a storage, feeded by sediments detached from its hillslopes at a constant rate S_k during each month and releasing a sediment discharge $q_{s,k}(t)$ at its outlet, in the above assumption the sediment stored in the basin $W(t)$ is proportional to $q_{s,k}(t)$:

$$W_k(t) = \theta_k q_{s,k}(t), \tag{4}$$

and the equation of mass conservation for sediments at the basin scale becomes the differential equation of a linear reservoir:

$$dW_k(t)/dt = \theta_k dq_{s,k}(t)/dt = S_k - q_{s,k}(t), \tag{5}$$

which can be solved given the initial condition $q_{s,k}(t = 0) = q_{s,0,k}$.

In this conceptual and lumped modelling framework, the suspended sediment discharge $q_{s,i,k}$ (tons/day) at each kth basin's gauging station at the end of each ith month with duration of T days, results as:

$$q_{s,i,k} = q_{s,i-1,k}e^{-T/\theta_k} + S_{k,i}(1 - e^{-T/\theta_k}) \quad (\text{tons/day}), \tag{6}$$

and the monthly sediment yield is:

$$V_{s,i,k} = q_{s,i-1,k}\theta_k(1 - e^{-T/\theta_k}) + S_{k,i}T + S_{k,i}\theta_k(e^{-T/\theta_k} - 1) \quad (\text{tons}). \tag{7}$$

The optimal value for the spatio-temporal mean sediment transport velocity, which is the second model's parameter we calibrated, was estimated as $V = 0.5$ m/s by minimising, as objective function, the mean inter-basin Nash–Sutcliffe efficiency coefficient, NS, of the simulated vs. observed monthly sediment yield V_s, which resulted NS = 0.45.

4. Results and discussion
