The soil loss computed on a monthly scale with the RUSLE approach and accumulated with the routing scheme described in the previous section was employed to evaluate the suspended sediment load at each of the eight sediment gauge stations in the Lo river. The modelling scheme with the parameters as described above was applied to the Lo river basin by using rainfall data from 20 rain gauges located in the basin. The resulting simulated monthly values are compared in Fig. 9 with measurements and in Fig. 10 the mean annual sediment load before the reservoirs impoundment is compared with data. The mean annual simulated soil losses in basins prior to reservoirs operation are in good agreement with observations, as reported in Table 9, with values ranging from 0.17 mm/year at Chiem Hoa to 0.34 mm/year at Thac Ba compared to the observed 0.19–0.35 mm/year range. The coefficient of determination results $R^2 = 0.89$, as Fig. 10 shows. Concerning the effect of reservoir impoundment on suspended sediment load, measured data indicate how the Thac Ba reservoir (2.49×10^9 m^3 storage) and the new Tuyen Quang reservoir (2.245×10^9 m^3 storage) have already changed sediment load since 1971 and 2005 when they were, respectively, in operation. Sediment impoundment in the reservoirs affects suspended sediment load in the river network downstream. The reservoir sedimentation efficiency was estimated 71% and 95% for the Tuyen Quang and Thac Ba reservoirs, respectively, by comparing the sediment yield after and before the dams construction. Assuming a 71% value for the sediment catch efficiency it was possible to reproduce quite well sediment load downstream these reservoirs also after their completion. A fairly good agreement between simulated and observed values for the stations downstream reservoirs is reported in the last two columns of Table 9.

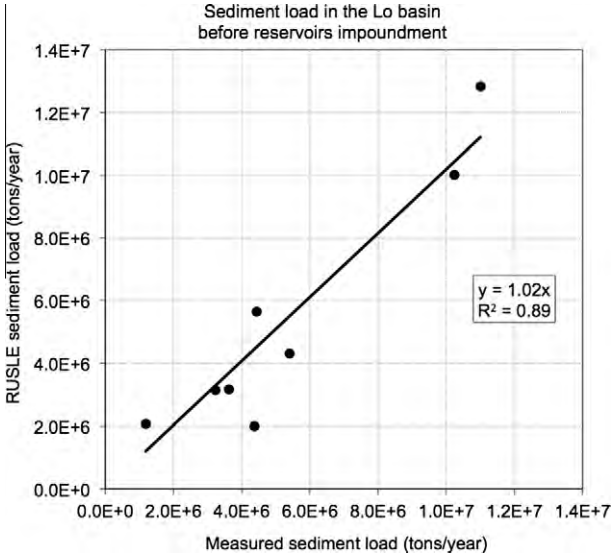

Fig. 10. The relationship between measured and RUSLE-modelled annual sediment load in the Lo basin.

In Fig. 9 and Table 10 statistics of the simulation over the entire 1959–2007 simulation period are reported, including the effect of reservoirs. The graphs show a satisfactory reproduction of the sediment load regime, both in the dry and wet season for all stations. Indicating that no systematic bias occurs, the mean inter-station relative error is 1.4%, being small, 4.7%, at the Vu Quang station, close to the basin outlet, but higher in the smaller basins, as Bao Lac where a 76% overestimation resulted from simulation. The linear correlation coefficient between simulated and observed data is in the 0.66–0.83 range, being 0.72 on average. The mean Nash–Sutcliffe efficiency results to be 0.45, ranging from 0.33 to 0.62. These data provide an indication of the overall predictive uncertainty of the model, which, considering the complexity of the process of sediment detachment and transport and the wide space and time scale investigated, can be considered satisfactory, in the author's expectations. Looking more in detail on the scatter-plot of the monthly simulations at Vu Quang over the entire 1959–2007 simulation period, in Fig. 11, some further considerations can be drawn. About one dozen of simulated values, out of 588 data, heavily underestimate high sediment load data. This occurs also at the Ham Yen station, not shown here, which is not influenced by upstream reservoirs. This underestimation in sediment load can be explained by considering that sediment delivered by landslides and debris flow and by erosion from stream channels are not taken into account in our modelling scheme. These processes occur mainly during high flow events and this can explain the observed biased data. We can argue, however, that sources of sediment other than surface erosion which should be separately evaluated and be better modelled with alternative approaches than RUSLE, as in Gavrilovic (1988, 1998), deliver the coarser fraction to the total sediment load, which does not contribute to the measured suspended sediment load and which deposits in the reservoirs. In addition, the neglected contribution to sediment delivery from landslides, debris flow and riverbed erosion is balanced, at least in part, by the effect of the assumption that no deposition is modelled along the river reach, with the exception of the reservoirs as described later. This can explain how, on one hand, no major systematic bias results from our modelling scheme and, on the other, the sediment load during some high flow events is underestimated.

Table 9
Annual total sediment load (tons/year) in the Lo river basin, measured and simulated with the model. Asterisk * indicate stations downstream reservoirs, for which measured sediment is computed also from the data in the observation period after they came into operation, in brackets in the fourth column.

Station	River	Area (km^2)	Observation period (with reservoirs)	Measured without reservoirs (tons/year)	RUSLE without reservoirs (tons/year)	Measured with reservoirs (tons/year)	RUSLE with reservoirs (tons/year)

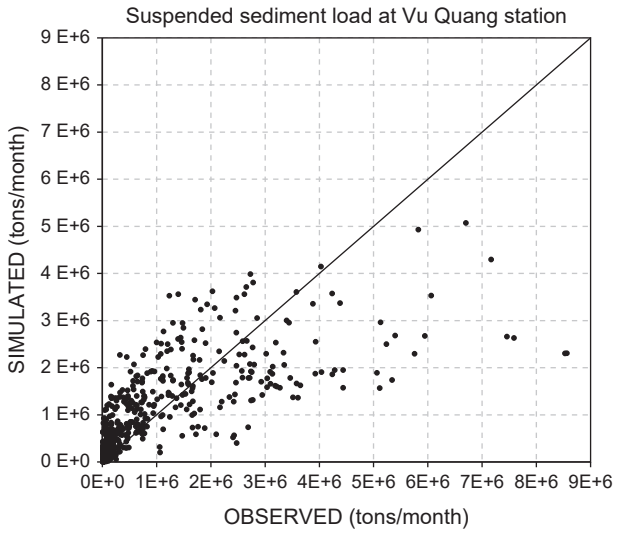

Fig. 11. Scatter plot of the monthly sediment load simulated and measured at the Vu Quang station (37,000 km^2) over the 1959–2007 simulation period.

Because of the complexity of the sediment erosion and deposition and sediment transport processes in large basins, the lack of data on input and parameters for detailed physics based models, the adoption of simplified conceptual schemes, as in our approach and also, for instance, in Le et al. (2007), Ali and De Boer (2009), Tyagi et al. (2008), Moore (1984) seems to be a plausible solution for sediment yield models in environments as that here investigated. We recognise, however, that our modelling approach could be improved by considering also, in a "hydraulic approach", streamflow data to assess localised erosion processes as those occurring in the river streams (see for instance Di Silvio and Nones, 2010). For the implementation of this type of models, however, more data are needed on the channel geometry and particle size distribution than those available, at the moment, to the authors for the rivers here investigated.

5. Land use change effect on suspended sediment load

Soil erosion assessment at the scale of large basins like that of the Lo river is necessary for sustainable land use and management. An assessment of the soil loss under land use changed conditions is valuable for understanding how the different land use classes can affect soil erosion and to predict the impact of anthropogenic influences and climate changes. The effect of land use changes on the hydrological response and the sediment load in the different regions is investigated by several authors (e.g. Le et al., 2007; Pham, 2007; Rosso and Rulli, 2002; Rulli and Rosso, 2005). Concerning the Lo basin, major land use classes correspond to agriculture, forest, urban areas and water respectively. Vegetation cover is changing in the last decades, due to deforestation for agriculture development and forest fires. In particular, Pham (2007) analyzed a small basin upstream the Ba Bê lake, draining an area of 420 km^2 upstream the Tuyen Quang dam and Bac Me, in the Lo basin. He observed a forested area decrease up to 35% in the last decades, with a 20% of forested area converted into rice fields and agricultural crop areas and 15% into bushes, shrubs and meadows. This land use change produced a severe impact on sediment production in that basin.

The effect of projected land use change to soil loss and sediment load over the whole Lo river basin was investigated by projecting a scenario of land use changes. It was obtained by a random

Table 11
Effect of land use changes on annual sedimentation load (tons/year) in the Lo river basin estimated over the 1990–2007 period.

Station	River	Area (km^2)	Measured (with reservoirs) (tons/year)	RUSLE (with reservoirs) (tons/year)	RUSLE (with reservoirs and land use changes) (tons/year)
Bao Yen	Chay	5000	4,315,193	1,851,864	2,114,557
Ha Giang	Lo	8300	3,018,363	2,630,838	2,859,101
Ham Yen	Lo	11,900	4,254,671	4,755,346	6,355,186
Chiem Hoa	Gam	16,500	1,868,613	639,120	833,979
Ghenh Ga	Lo	29,600	3,915,373	4,087,866	5,724,311
Vu Quang	Lo	37,000	4,188,439	4,225,354	5,968,811

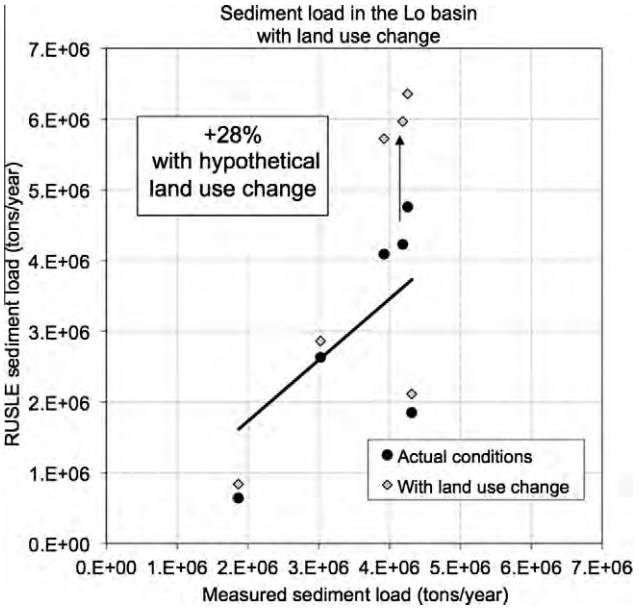

Fig. 12. The effect of hypothetical land use changes on suspended sediment load.

generation of land use change of forested areas using the same statistics of the Pham (2007) case study. The 1990–2007 period, when land use changes occurred was simulated under reference and land use change conditions. The results, summarised in Table 11 and Fig. 12, indicate that the land use change by forest area decreasing of 35% results in a soil loss erosion increase by 28%, compared to reference conditions.

6. Conclusions

Soil erosion is a serious problem in the Lo river basin as suspended sediment load data from stations downstream the Thac Ba and Tuyen Quang dams after their construction ad effect of land use change show. This study demonstrates that a conceptual modelling framework based on monthly precipitation data, distributed GIS information, RUSLE-based estimates of surface erosion and a conceptual sediment transfer scheme is a reasonable solution to model sediment load in the basin, also taking into account in a proper way land use management practices.

The analysis of daily rainfall shows that in the Lo river basin, about 83.3% of rainfall falls with intensity greater than 10 mm/day and enough energy for soil detachment according to the Loureiro and Coutinho (2001) equation, highlighting the major role of rainfall in soil erosion. The RUSLE model coupled with a river network routing scheme which assumes an exponential distribution of sediment travel time with a geomorphology derived time scale was employed to evaluate the soil loss. An extensive data set of monthly suspended sediment load measured at eight stations in the 1959–2007 period was used for model verification, with corresponding specific erosion rate ranging from 0.19 mm/year to 0.58 mm/year. Simulation results in a good agreement, with an $R^2 = 0.89$ statistic and no major bias, with average annual soil loss estimated at eight stations in the Lo river basin under natural basin conditions prior to the dams construction and operation.

The impoundment of two large reservoirs at Thac Ba and Tuyen Quang, in the Chay and Gam river basins has resulted in a considerable reduction of the measured total suspended load with a sediment load reduction of about 95% and 71%, respectively. Assuming the value of 0.71 for the sediment trap efficiency it was possible to simulate suspended sediment load on a monthly scale over the entire 1959–2007. By calibrating the supporting practice factor *P*, the mean inter-station simulation error results 1.4%, being small, 4.7%, at the Vu Quang station, close to the basin outlet, but higher in the smaller basins, as Bao Lac where a 76% overestimation resulted from simulation. The linear correlation coefficient between simulated and observed data is in the 0.66–0.83 range, being 0.72 on average. The mean Nash–Sutcliffe efficiency results to be 0.45, ranging from 0.33 to 0.62, by calibrating the mean sediment transport velocity. These data provide an indication of the overall predictive uncertainty of the model, which, considering the complexity of the process of sediment detachment and transport, including reservoirs sedimentation and the wide space and time scale investigated, can be considered satisfactory, in the author's expectations. A small percentage of simulated values underestimate high sediment load data. This model's limitation can be explained considering that sediment delivered by landslides and debris flow and by erosion from stream channels, processes occurring mainly during high flow events, are not taken into account in our modelling scheme. This balances, in part, the fact that no sedimentation is assumed along the river reach, with the exception of the reservoirs, and can explain how no major systematic bias results from our modelling scheme.

On the basis of observed land use changes in the basin, assuming that 20% of forest area is converted into rice and agricultural crops and 15% into bushes, shrubs and meadows, a 28% increase of sediment load is projected according to the model. This increase can compensate the sediment load decrease, in comparison with the past, observed downstream the dams, because of the reservoirs impoundment. A continuous monitoring of sediment yield, runoff, land use change and river channels is needed to manage soil conservation and the geomorphological equilibrium of the river network in the Lo river basin. Maintenance, at the basin scale, of traditional hillslope agricultural practices as in terraced crops and reforestation remain important but also the reduction of trap efficiency of reservoirs by management of spillways and outlet gates is fundamental to keep the equilibrium of sediments in the Lo river basin.

Acknowledgments

This research was supported by the Italian Ministry of Foreign affairs-Directorate for Development cooperation and Directorate

for Cultural Cooperation and the Vietnam's Ministry of Science and Technology. The data were provided with the help of Ngo Le An and Vu Minh Cat from the Water Resources University of Hanoi and they are thanked for their suggestions and advice. Giampaolo Di Silvio, Carlo Baroni, Stefano Barontini, Baldassare Bacchi are thanked, as well, for their comments and suggestions, together with the reviewers.

ABSTRACT

Coupling erosion formulae with sediment connectivity methods is one promising approach to better represent structural and functional variability of sediment processes. To advance this goal, the probability of connectivity approach is coupled with the revised universal soil loss equation (RUSLE) in a basin with forest and reclaimed mine landuses. Model evaluation showed unforeseen codependency between connectivity formulae and RUSLE. For example, the RUSLE *P* factor was codependent with the probability of downstream transport within the connectivity formula. Researchers should use feedback calibration schemes to resolve lack of model independence. Connectivity modelling advanced prediction of sediment processes because it simulated the unforeseen impact of legacy terracing on sediment connectivity and soil loss. Structural control dominates connectivity in this study, and soil loss and connectivity are self-similar. The structural control is contrary to recent suggestions that functional, dynamic processes control sediment connectivity in all landscapes. Self-similarity also remains an open topic because a number of studies show poor correlation between soil loss and connectivity. On average 12% of forested land and 47% of reclaimed mine land was connected for events studied. Predicted soil loss rates in the reclaimed mine were approximately 30 times greater than the forest land despite the fact that the reclamation is classified as phase 3. Spatially explicit results highlight pathways that should be targeted for remediation, and this study supports the idea of the Forestry Reclamation Approach for remediation of excess soil loss.

1. Introduction

Structural and functional watershed properties are now well known to control sediment yield and connectivity (Bracken et al., 2015; Wohl et al., 2017; Zingaro et al., 2019). Over the past six decades, watershed models have been widely implemented to simulate soil loss and understand controlling sediment processes at the watershed scale (USEPA, 2004), and now play an important role in measuring impacts of sediment on ecology, water supply, and water quality (Morris and Fan, 1998). We find, however, that watershed models currently are hindered for several reasons. Namely, seldom do watershed models represent structural and functional watershed variability at the fundamental spatial and temporal units at which sediment processes occur (Bracken et al., 2015; Nunes et al., 2017; Wohl et al., 2019; Batista et al., 2019). This results from spatial and temporal lumping of sediment processes across landscapes and hydrologic events, disassociating models from physical process and introducing empiricism. In years past, such lumping resulted from limited computing power and availability of spatially explicit data (Walling et al., 1983; Fryirs, 2013).

Coupling sediment models with connectivity theory (see Fryirs, 2013; Bracken et al., 2015; Wohl et al., 2019) and now widely available geospatial data (e.g., KYAPED, 2014) serves as one promising approach to better represent structural and functional variability of watershed properties. The ubiquity of high resolution geospatial data serves as one means to overcome data limitations that currently hinder sediment models, even in environments that have previously been considered "data sparse" (e.g., Fox, 2009).

Our motivation was to better understand structural and functional processes that control sediment yield and sediment connectivity by coupling watershed soil loss modeling with spatially explicit sediment

connectivity simulations. We applied the coupled model to a steep, forested watershed with reclaimed mine land in the Appalachian Region of Eastern Kentucky, USA. In this regard, this paper serves the motivations of: (1) advancing methods for coupling connectivity modelling with erosion rate modelling; (2) understanding spatially explicit soil loss in forested and reclaimed mine land uses; and (3) understanding and discussing controlling structural and functional watershed properties that limit sediment yield and sediment connectivity on forested and reclaimed mine hillslopes. Our intent was to improve process-based knowledge of active sediment pathways and assist with management of soil loss in steep, forested watersheds.

We couple the widely popular Revised Universal Soil Loss Equation (e.g., RUSLE, Renard et al., 1997) with connectivity theory (Bracken et al., 2015; Wohl et al., 2017) to better represent spatially explicit pathways that actively contribute sediment to the stream network. We chose to couple connectivity theory with RUSLE among other erosion models for a number of reasons. First, RUSLE has been widely applied across the United States and Europe (Batista et al., 2019), partially due to its success of implementation and relatively few input requirements (Fox and Martin, 2015). Second, the RUSLE formulation serves as the conceptual foundation for many popular non-point source sediment models, including (Ann)AGNPS (Bingner and Theurer, 2001) and the Soil and Water Assessment Tool (SWAT; Arnold et al., 1998). Third, the availability of high-resolution geospatial data, such as 1 m digital elevation models (DEMs), serves as a basis to improve the spatial resolution of hillslope erosion simulations. Fourth, RUSLE parameters have been incorporated in recent connectivity measures, such as the Index of Connectivity (see Borselli et al., 2008), suggesting that further coupling of the frameworks is possible.

While RUSLE has been widely applied, one underlying assumption of the model is that all soil generated on a hillslope or within a HRU reaches the stream network (Lenhart et al., 2005) and that deposition along hillslope pathways is negligible (de Vente et al., 2013; Zhao et al., 2020). Such assumptions limit the applicability of the model to predict sediment yield only on surfaces with known active erosion pathways (Renard et al., 1997).

To overcome limitations of current watershed models and simulate actively eroding pathways, we suggest coupling RUSLE simulations with connectivity theory. We define connectivity similarly to Heckmann et al., (2018) as an emergent system property that reflects the strength and continuity of sediment linkages between and within system compartments at a given point in time. Connectivity is an emerging field that aims to understand spatially and temporally explicit pathways that facilitate sediment transport (Fryirs, 2013; Bracken et al., 2015; Wohl et al., 2019). Theory and frameworks to understand sediment connectivity have been well developed within the geomorphology and engineering communities (e.g., Hooke, 2003; Borselli et al., 2008; Cavalli et al., 2013; Fryirs 2013; Heckmann et al., 2013; Bracken et al., 2015; Gran and Czuba, 2017; Mahoney et al., 2018, 2020a,b; Ali et al., 2018). Several promising advancements in coupling connectivity equations with soil loss formulae in recent years include studies from Vigiak et al., (2012), Jamshidi et al., (2014), Hamel et al., (2015), Mahoney et al., (2018, 2020a, b), Zhao et al., (2020), and Michalek et al. (2021) among others; the majority of whom have implemented the structurally-based Index of Connectivity from Borselli et al. (2008) to assess connectivity. We find that seldom in the literature have both structural and functional connectivity considerations been coupled with soil loss prediction, yet that structural and functional connectivity processes control sediment transport at both relatively short (event) timescales as well as relatively long (decadal) timescales (Bracken et al., 2015; Wohl et al., 2019; Mahoney et al., 2018; Mahoney et al., 2019; Ali et al., 2018).

In this study, we couple RUSLE with connectivity while seeking to advance methods to quantify the tenets of structural and functional connectivity that consider the magnitude of connections. It is now recognized that connectivity simulations should consider connectivity's magnitude, extent, timing, and continuity (Bracken et al., 2015; Grant et al., 2017; Ali et al., 2018; Wohl et al., 2019; Mahoney et al., 2020a,b). The model recently updated by Mahoney et al. (2020a,b) shows promise to serve this goal. We consider event variability of structural and functional watershed properties using the Probability of Connectivity $P(C)$ model from Mahoney et al., (2018, 2020a,b) and suggest that representing the magnitude of connectivity by coupling $P(C)$ with RUSLE serves as one approach to quantify connectivity's magnitude that is comparable across catchments.

Another motivation of this work is to better understand structural and functional processes that control sediment connectivity and transport in steep, forested catchments and on reclaimed mines, such as those found throughout the Appalachian Coal Belt region, USA (Taylor et al., 2009). Steep, forested catchments in the Appalachian region are well-known for soils with very high infiltration rates and limited runoff production (Hewlett and Hibbert, 1965; Khan and Ormsbee, 1989; Taylor et al., 2009; Fox and Martin, 2015), which is generally attributed to soil texture and macropore formations. Soil macropores efficiently transport subsurface interflow to stream networks (Gupta et al., 2016) and are formed from freeze-thaw processes, dissolution of limestone, and activity and decomposition of flora and fauna (Sloan et al., 1983; Guebert and Gardner, 2001; Warner et al., 2010) and we find the impact of macropores on sediment connectivity is understudied.

The Appalachian Coal Belt's namesake originates from the presence of coal seams located frequently throughout the mountainous region. Surface coal mining is one method commonly used to extract coal in the region and involves removing vegetation, timber, and topsoil from surfaces (Bonta, 2000) to access underlying coal seams which are subsequently excavated (Shrestha and Lal, 2006). During reclamation, land surfaces are regraded with mine spoils, crushed rock, and coal fragments (Wickham et al., 2007) and heavily compacted and reseeded to prevent mass wasting and landslides (Taylor et al., 2009; Warner et al., 2010). Generally, regraded hillslopes remain relatively steep post-reclamation, but are slightly flatter than the surrounding forest hillslopes (Fox and Martin, 2015). Notable difference in hydrology have been observed in reclaimed mine hillslopes compared to forested hillslopes in the region. Namely, compacted surfaces have much lower infiltration rates compared to forested hillslopes resulting in greater runoff production (Warner et al., 2010). We find that structural and functional controls on sediment connectivity in steep, forested hillslopes and reclaimed mine lands in the Appalachian Coal Belt region are understudied. The use of coupled models, such as the probability of connectivity and RUSLE, serves as one approach to better understand controls of sediment processes in these remote regions.

The objectives of this paper were to: (1) couple and evaluate the probability of connectivity model and RUSLE to advance spatially explicit watershed sediment modeling and (2) advance understanding of structural and functional variables that control connectivity and sediment yield in steep, forested watersheds and reclaimed mine land. We apply the model to a steep, forested watershed in Eastern Kentucky, USA with reclaimed mine land to fulfill these objectives.

2. Study site and materials

The study site is the Whitaker Branch watershed (2.63 km^2) located in Letcher County, Kentucky (see Fig. 1). Land use in the watershed is primarily second growth deciduous forest (2.47 km^2) and pastureland (0.16 km^2) which coincides with reclaimed surface mining. The deciduous forest consists primarily of maple beech, yellow poplar, oak, hickory, buckeye, and basswood. Soils in the watershed are primarily silt-loams with high infiltration capacity (Fox, 2009). In the late 19th century timber within the watershed was harvested and subsequently farmed, where contours were implemented for resource conservation purposes. The watershed was subsequently reforested and remained relatively undisturbed for approximately one hundred years, although some farming and residential areas existed in the lower part of the basin. Whitaker Branch watershed is located in the Appalachian Coal Belt and

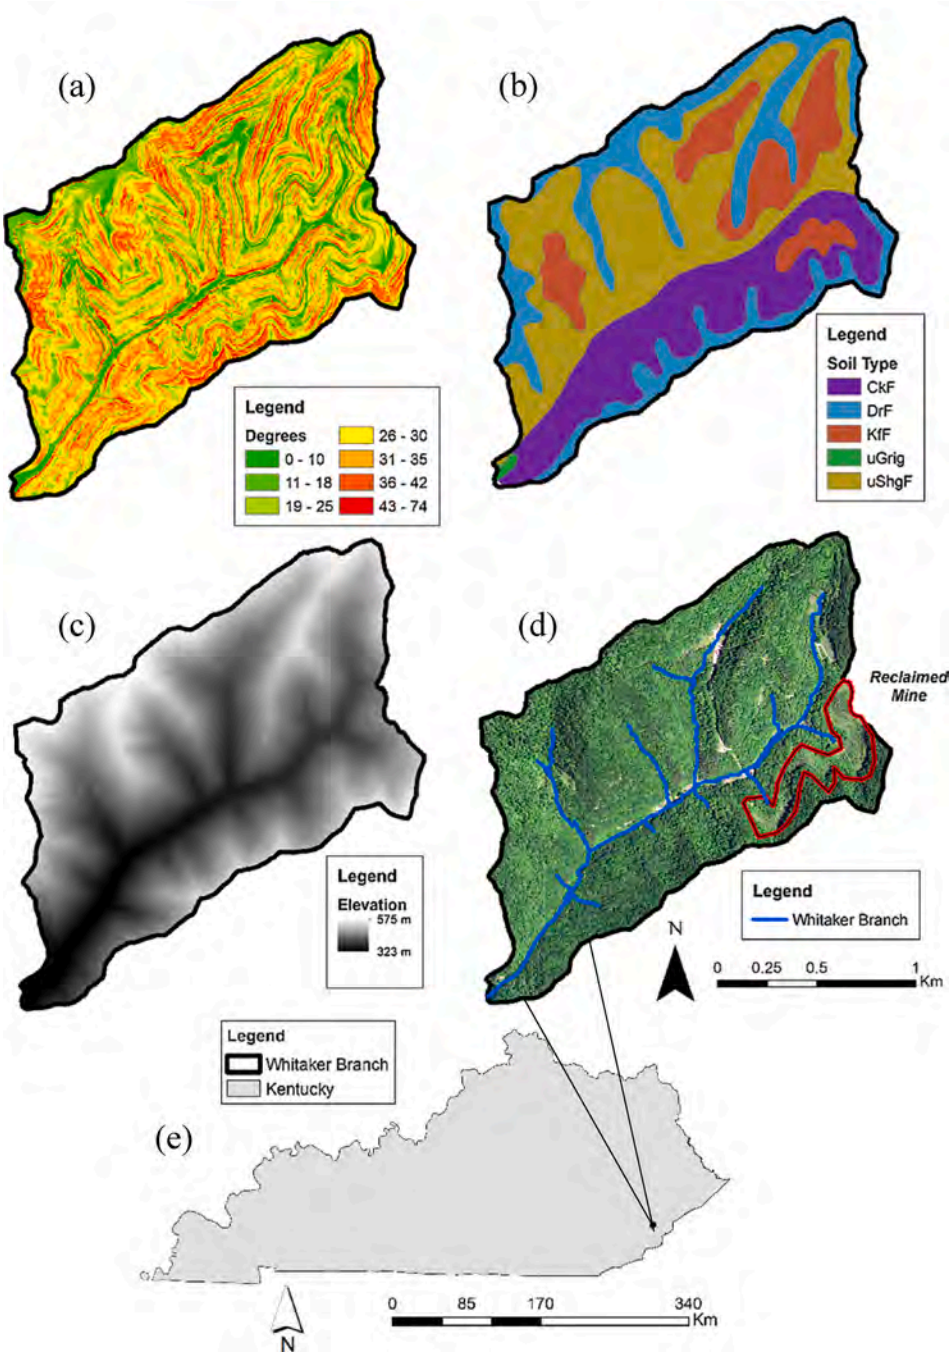

Fig. 1. Whitaker Branch watershed (2.63 km^2) maps in Letcher County, Kentucky including: (a) slope; (b) soil type; (c) elevation; (d) aerial imagery; and (e) location of Whitaker Branch in Kentucky, USA. Whitaker branch consists primarily of forested land (2.47 km^2) and reclaimed mine land (0.16 km^2). Reclaimed mine land is outlined in red in panel (d). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

was subjected to surface mining between 1982 and 1988 and between 1998 and 2004 (Fox, 2009; Fox and Martin, 2015; see Fig. 1). Reclamation of the surface mining site began in 2004 and was completed according to regulations specified from the Surface Mine Reclamation Act (SMCRA). Notably, surfaces were regraded with mine spoils, crushed rock, and residual coal and were heavily compacted to prevent mass wasting (Fox, 2009). Limited regrowth from native trees has been observed as consequence from compaction procedures and due to reseeding with grasses (Fox, 2009; Fox and Martin, 2015).

Watershed morphology is considered to be very steep, with long, narrow ridgetops, and narrow valleys, with some variability due to the reclaimed mine. Average slope in the forested land is 0.51 m m^{-1} and 0.44 m m^{-1} on the reclaimed mine surfaces. Features that promote sediment connectivity include concentrated flow pathways, roads, and surfaces throughout the reclaimed mine (Bonta, 2000; Fox and Martin, 2015). Disconnecting morphology includes soil macropores that limit overland runoff production, and historic terracing, which dissects hillslopes (Fox and Martin, 2015).

Climate in Letcher County, Kentucky is temperate-humid with on average 102 cm of rainfall per year and average temperature of 1.7 °C during winter and 22.8 °C in summer. During the study period (2007), 12 storm events with rainfall that contributed to soil loss were identified. High infiltration rates on the order of 120 mm h^{-1} are common in steep, forested catchments throughout the Appalachian Coal Belt

(Harden and Scruggs, 2003), due to soil texture and the formation of macropores from flora and fauna, freeze–thaw cycling, and dissolution of limestone in the area (Sloan et al., 1983; Taylor et al., 2009; Guebert and Gardner et al., 2001; Warner et al., 2010; Fox and Martin, 2015). Observations throughout watersheds in the Appalachian Coal Belt region indicate that little overland flow is typically generated during storm events due to interception from the forest canopy and high infiltration rates due to the soil texture and macropore pathways (Taylor et al., 2009; Hewlett and Hibbert, 1965; Khan and Ormsbee, 1989; Sloan et al., 1983).

Rainfall-runoff response in the reclaimed surface mine varies from that of steep forested land uses. Reclamation of surface mines impacts infiltration rates of rainfall due to earthwork and compaction, and results in notable runoff production (Shukla et al., 2004; Guebert and Gardner et al., 2001; Warner et al., 2010). Researchers have observed decreases in infiltration from 120 mm h^{-1} to 10–20 mm h^{-1} from pre-mining conditions to post-reclamation (Warner et al., 2010; Taylor et al., 2009). Interception of rainfall is also impacted because of limited tree growth post-reclamation (Angel et al., 2005; Acton et al., 2011). A conceptual model highlighting differences in hydrology on steep, forested hillslopes and reclaimed mine hillslopes is shown in Fig. 2.

We used several materials to conduct probability of connectivity and RUSLE modeling including geospatial data, sediment field measurements, sediment fingerprinting results, previous sediment and hydrologic modeling, and field reconnaissance (see Table 1). Highly-resolved geospatial data used include 1.5 × 1.5 m DEMs, land use and land cover data, and soil data. All geospatial data are freely available across the Commonwealth of Kentucky. Precipitation data collected at the nearby USGS gage in Whitesburg, KY were used as an input to both the hydrologic model and the RUSLE model. Delineation of the reclaimed mine was completed using remote sensing, field reconnaissance, and spatial mapping of statewide mined out areas. We carried out hydrologic modeling using the Soil and Water Assessment Tool (SWAT) *via* ArcSWAT 2012.10.21 to predict event runoff generation and daily soil moisture content. Since the basin is ungauged, we verified hydrologic modeling by comparing annual water budget results generated from the modeling with results from similar catchments in the Appalachian Coal Belt, which improves our confidence in annual sediment yield modelling. We applied the probability of connectivity, $P(C)$, model developed by Mahoney et al. (2018, 2020a,b) to the Whitaker Branch watershed to determine the spatial extent of sediment connectivity during events. Connectivity modeling was carried out using ArcGIS 10.4.1 on a desktop PC (Intel® Core™ i7-6700 CPU at 3.40 GHz; 64-bit operating system, x64-based processor). RUSLE modeling and subsequent uncertainty analyses were performed in ArcGIS 10.4.1 and in Microsoft Excel on a desktop PC (Windows 10, Dell OptiPlex 9010, Intel i7-3770 3.40 GHz, 4 Cores). We utilized total suspended solids (TSS) samples and sediment fingerprinting results presented in Fox and Martin (2015) to determine soil loss rates on forest and reclaimed mine land uses in the watershed, which we used to evaluate the model. Sediment fingerprinting was conducted using stable carbon and nitrogen isotope tracers to identify contribution of sediment sources (Fox and Martin, 2015).

3. Methods

3.1. Sediment flux formulation via connectivity and erosion formulae

Simulation of sediment flux requires multiplication of connectivity formulae and an erosion generation function simulated using RUSLE. Connectivity is formulated using probability theory to reflect the stochastic nature of sediment transport and heterogeneity of hydrologic variables at the watershed scale (Wright and Webster, 1991; Papanicolaou et al., 2003; Borselli et al., 2008; Wohl et al., 2017; Mahoney et al., 2018). Formulation of sediment flux via connectivity theory is originally presented in Mahoney et al. (2020a,b) to reflect tenets of connectivity theory including connectivity's magnitude, extent, and timing (Bracken et al., 2015; Grant et al., 2017; Wohl, 2017; Ali et al., 2018; Wohl et al., 2019) as

$$\dot{m} = E[P(C) \cap P(\tau) \cap P(\gamma)] \quad (1)$$

where $\dot{m}$ is sediment flux generated from a spatial unit at an instant, E is a respective erosion rate, $P(C)$ is the probability of sediment connectivity representing the spatial extent of connectivity during an event, $P(\tau)$ is the probability of sediment timing representing the variability of connectivity and active erosion periods during an event, and $P(\gamma)$ is the

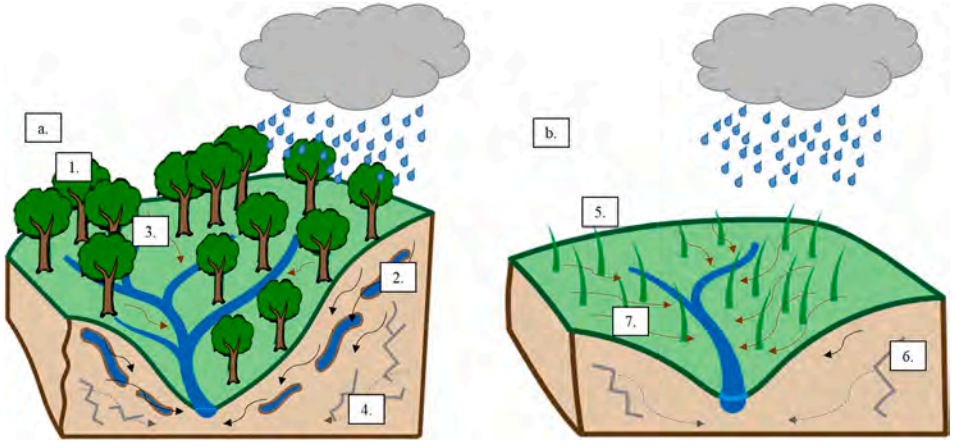

Fig. 2. Conceptual models of sediment connectivity on (a) steep, forested hillslopes and (b) on reclaimed mine land that has been converted to grassland. The following processes are highlighted for steep, forested hillslopes: (1) dense tree canopy increases rainfall interception; (2) frequent presence of subsurface macropores increases infiltration rates and creates preferential flow pathways; (3) sparse concentrated flowpaths transport water and sediment rapidly to stream networks; and (4) attenuated slowflow pathways contribute to baseflow following events. The following processes are highlighted for reclaimed mine lands: (5) conversion to grassland decreases interception rates; (6) compaction of earth during reclamation reduces macropore flow and decreases infiltration rates; and (7) prevalent overland flow pathways efficiently transport water and sediment.

probability of sediment (dis)continuity representing the continuity of sediment connectivity along the pathway. The bracketed probabilities represent aspects of connectivity while the erosion rate is used to represent the magnitude of flux (Mahoney et al., 2020a; Mahoney 2020).

The theoretical background of Eq. (1) is detailed in Mahoney et al., (2018) and Mahoney et al., (2020a) and we briefly summarize each concept below. $P(C)$ considers structural (e.g., slope, critical shear stress) and functional (e.g., runoff depth, soil moisture) watershed characteristics to predict active and inactive periods and locations of erosion entering a stream network (Borselli et al., 2008; Mahoney et al., 2018; Heckmann et al., 2018). $P(C)$ considers co-occurring sediment process to predict locations within a watershed that are likely connected during an event, as discussed in Sections 3.2 and 3.3 of this paper. $P(\tau)$ predicts temporal connectivity, i.e., temporal variability (Hoffmann, 2015) of sediment flux during an event due to sediment travel time from connected cells (Ali et al., 2018; Mahoney et al., 2020a). Mathematically, $P(\tau)$ represents the percent of landscape units within a watershed that likely contribute sediment to the stream network between two instances, determined via the integration of the frequency distribution of sediment travel time from connected landscape units between two instances of an event (Mahoney et al., 2020a,b; Mahoney, 2020). $P(\gamma)$ predicts (dis)continuity of sediment along a longitudinal pathway (e.g., Fryirs, 2013; Mahoney et al., 2020a), realized as the fraction of sediment lost along a pathway due to a morphologic barrier or a process such as deposition (Grant et al., 2017; Mahoney et al., 2020a). Intersecting probabilities are used to represent the connectivity components of Eq. (1) because detachment and transport must occur sequentially and coincidentally with some degree of sediment continuity for connectivity to be established (Bracken et al., 2015; Grant et al., 2017; Wohl et al., 2019; Mahoney et al., 2020a,b). Additionally, since the intersection probabilities of Eq. (1) simulate conditions necessary for sediment transport to be established, Mahoney et al., (2020a) introduce an erosion rate, E, to estimate the scalar magnitude of sediment flux at the fundamental unit scale.

During this analysis, we focus on estimating connectivity over the entire duration of storm events rather than inter-event variability, thus $P(\tau)$ becomes unity (see Mahoney et al., 2020a,b). Additionally, we find that very little instream deposition of fine fluvial sediment occurs due to the steep stream gradient (Fox, 2009; Fox and Martin, 2015), thus $P(\gamma)$ becomes unity. We note that $P(\gamma)$ has traditionally been formulated to represent instream (longitudinal) deposition rather than cumulative hillslope and stream network (lateral and longitudinal) deposition (e.g., Mahoney et al., 2020a,b; Mahoney, 2020) given recent sentiment to discretize connectivity into lateral, longitudinal, and vertical dimensions (e.g., Fryirs et al., 2007; Fryirs, 2013). In this formulation, hillslope deposition and disconnectivity are treated implicitly within $P(C)$ formula (see Sections 3.2 and 3.3 for justification), similarly to formulations presented in Mahoney et al. (2018) and Mahoney et al. (2020a,b). We emphasize that future work might focus on explicit treatment of deposition for both hillslopes and the stream network at the fundamental unit scale, which has been an area of research for our group. For example, Mahoney (2020) shows how $P(\gamma)$ in the connectivity formula (see Mahoney, 2020, pp. 241, Equation (7)) can also be parameterized to explicitly account for deposition.

Eq. (1) is discretized across the watershed to represent spatially distributed connectivity and flux in fundamental spatial units (e.g., geospatial cells) where erosion and transport processes occur during an event as:

$$\dot{m}_{ij} = E_{ij}[P(C)]_{ij} \tag{2}$$

where i is the event and j is the spatial unit. We utilize 1.5 × 1.5 m DEM cells to represent fundamental spatial units in this study because such resolution has been found to adequately capture morphologic features that influence sediment transport (Lopez-Vicente and Alvarez, 2018; Cantreul et al., 2018; Mahoney et al., 2018). Eq. (3) can be integrated in space and time over the watershed surface and over an event to determine sediment yield for the event as:

$$Y = E[P(C)] \tag{3}$$

where Y is sediment yield.

3.2. Formulation of the probability of sediment connectivity, $P(C)$

The probability of sediment connectivity $P(C)$ is defined as the probability that a landscape unit can detach and transport sediment laterally to the fluvial network (Borselli et al., 2008; Mahoney et al., 2018). $P(C)$ reflects the co-occurrence, or intersection, of several structural and functional (Wohl et al., 2019) sub-processes requisite of transport including sediment supply, sediment detachment, and sediment transport, as formulated by Mahoney et al., (2018) and Mahoney et al., (2020a). $P(C)$ is formulated as

$$P(C) = P(S) \cap P(G) \cap P(T) \cap \{1 - P(B)\} \tag{4}$$

where $P(S)$ is the probability of sediment supply, $P(G)$ is the probability of sediment generation, $P(T)$ is the probability of sediment transport, and $P(B)$ is the probability of a buffer that impedes lateral sediment transport (e.g., Fryirs, 2013). $P(B)$ is an implicit representation of hillslope deposition facilitated by morphologic features that impede lateral sediment transport and ultimately force deposition of upland sediment. Eq. (4) considers intersecting probabilities because each sub-process must occur coincidentally or sequentially for sediment originating in a spatial unit to reach the stream network (Leopold et al., 1964).

When considering that sediment generation and transport can occur via both hydrologic and non-hydrologic (e.g., mass wasting) processes, Eq. (4) is expanded as

$$P(C) = P(S) \cap P(D_H \cup D_{NH}) \cap P(T_H \cup T_{NH}) \cap \{1 - P(B)\} \tag{5}$$

where D_H and D_{NH} represent hydrologic and non-hydrologic detachment, respectively, and T_H and T_{NH} represent hydrologic, and non-hydrologic transport, respectively. Eq. (5) is expanded mathematically as

$$\begin{aligned} P(C) = P(S) \cdot \{P(D_H) + P(D_{NH}) - P(D_H)P(D_{NH})\} \cdot \{P(T_H) + P(T_{NH}) \\ - P(T_H)P(T_{NH})\} \cdot \{1 - P(B)\} \end{aligned} \tag{6}$$

We discretize Eq. (6) for all spatial units across the watershed surface during an event and integrate results to determine the percentage of the watershed that actively contributes sediment to the stream network.

3.3. Application of $P(C)$ for forest and reclaimed mine land

We make several simplifying assumptions regarding application of Eq. (6) to the Whitaker Branch watershed based on conceptual understanding of sediment processes observed during field reconnaissance. Herein we do not explicitly consider non-hydrologic detachment or transport processes based on field visits and previous studies in the watershed (Fox, 2009; Fox and Martin, 2015), which found that deep rooted trees generally stabilized surfaces in the watershed uplands limiting non-hydrologic transport. Additionally, we do not explicitly parameterize buffers $P(B)$ for the watershed because we did not observe the presence of morphologic features known to prohibit lateral sediment transport and connectivity during field reconnaissance and geospatial analysis (Fox, 2009; Fryirs, 2013; Fox and Martin, 2015). Similarly to Borselli et al., (2008), $P(T_H)$ is represented by upstream and downstream components, which conceptually reflects the likelihood for upstream sediment to transport to a cell and sediment generated within a cell to be transported downstream, respectively (Mahoney et al., 2018) as:

$$P(T_H) = P(T_{H-up}) \cap P(T_{H-dwn}) \tag{7}$$

where $P(T_{H-up})$ is the probability of upstream hydrologic transport and $P(T_{H-dwn})$ is the probability of downstream transport.

Thus, Eq. (6) is rewritten as:

$$P(C) = P(S) \cdot P(D_H) \cdot P(T_{H-up}) \cdot P(T_{H-dwn}) \quad (8)$$

Mahoney et al. (2018) explain in detail the parameterization of each subprocess, and we have parameterized Eq. (8) similarly for the Whitaker Branch watershed given our perception of sediment transport processes during field reconnaissance. We briefly discuss the parametrization of Eq. (8) as follows. Fig. 3 shows the probability of connectivity simulation structure adapted from Mahoney et al., (2018) and inputs used to parameterize sub-processes. We implement a Boolean approach similarly to Mahoney et al. (2018) to parameterize each geospatial cell across the Whitaker Branch watershed for each sub-process, where a value of 1 represents that a geospatial cell is connected with respect to the sub-process, and a value of 0 represents that a geospatial cell is disconnected with respect to the sub-process. $P(C)$ results were later integrated across the watershed surface to represent the percentage of the watershed area likely contributing sediment to the stream network.

The probability of sediment supply, $P(S)$ is parameterized as:

$$P(S)_{ij} = \begin{cases} 1, if\ \ sediment\ \ is\ \ present\ \ within\ \ the\ \ cell \\ 0, if\ \ sediment\ \ is\ \ absent\ \ within\ \ the\ \ cell \end{cases} \quad (9)$$

where as before, i is the temporal unit (i.e., a hydrologic event) and j is the spatial unit (i.e., a geospatial cell). We parameterized Eq. (9) by identifying geospatial cells with likely no erodible sediment via field reconnaissance and remote sensing of aerial imagery provided by NAIP during leaf-off time periods, for example, due to an impervious surface or rock outcrop being located within a cell.

The probability of hydrologic detachment is expressed using an excess shear stress approach as:

$$P(D_H)_{ij} = \begin{cases} 1, if\ \ \tau_{f\ \ ij} > \tau_{cr\ \ j} \\ 0, if\ \ \tau_{f\ \ ij} \le \tau_{cr\ \ j} \end{cases} \quad (10)$$

where τ_f is the fluid shear stress in cell j during event i and τ_{cr} is the critical shear stress of the soil. The fluid shear stress is parameterized in cells using the fluid momentum equation as:

$$\tau_{fij} = \gamma H_{ij} S_j \quad (11)$$

where γ is the specific weight of water, H is the depth of runoff in cell j during event i, and S is the slope of cell j. Runoff depth is estimated for

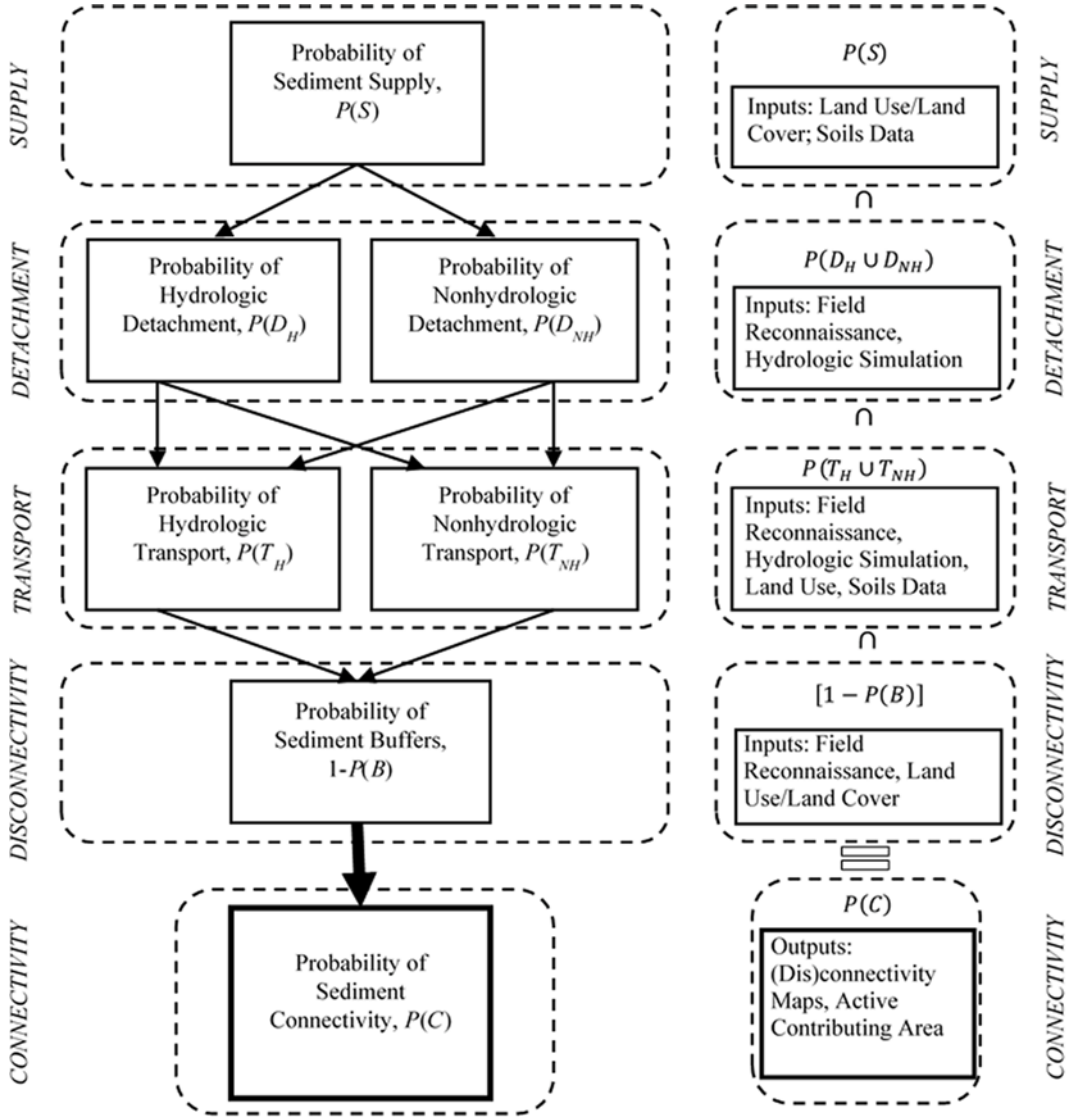

Fig. 3. Probability of connectivity parameterization, adapted from Mahoney et al., (2018).

geospatial cells for the 12 events analyzed during the study period using ArcSWAT 2012.10.21 (see Table 2). Slope is determined in ArcMap 10.4.1 via the Spatial Analyst toolbox. The critical shear stress parameter, τ_{cr}, is treated as a calibration parameter in this study, as will be explained in Section 3.5.

The probability of upstream hydrologic transport is parameterized as:

$$P(T_{H-up})_{ij} = \begin{cases} 1, if \ \ S_j > S_{cr\ ij} \\ 0, if \ \ S_j \le S_{cr\ ij} \end{cases} \quad (12)$$

where as before, S is the slope of cell j and S_{cr} represents a critical slope required to initiate sediment transport in cell j during event i, based on approaches similar to Torri and Poesen (2014). S_{cr} is parameterized similarly to Torri and Poesen (2014), and Mahoney et al., (2018) as:

$$S_{crij} = 0.73\eta_j e^{1.3RFC_j}\left(0.00124S_{0.05ij} - 0.37\right)UA_j^{-b} \quad (13)$$

where $S_{0.05}$ is a function of the daily curve number (taken as a proxy for daily soil moisture content) in cell j during event i, UA is the upstream contributing area of cell j, RFC is the rock fragment content of the soil in cell j as determined from USDA soil surveys, η is a connectivity rill/gully threshold coefficient representing processes that might stifle or promote connectivity (Torri and Poesen, 2014), and b is the runoff turbulence exponent representing the hydraulic regime of runoff facilitating transport (Torri and Poesen, 2014). Daily curve number is estimated for geospatial cells for the 12 events analyzed during the study period using ArcSWAT 2012.10.21 (see Table 2). Mahoney et al. (2018) envisaged that Eq. (12) represented requisites of upstream connectivity since the critical slope threshold is an inverse function of upstream contributing area. The connectivity η parameter and b exponent are treated as calibration parameters in this study, as discussed in Section 3.5. Connectivity parameter ranges are recorded in Table 3. Studies used to derive the parameter ranges are also recorded in Table 3.

The probability of downstream hydrologic transport is parameterized as:

Table 2
Event hydrologic parameters including precipitation, average simulated runoff and curve number across Whitaker Branch watershed, and *EI*, as calculated using Appendix B of Renard et al., (1997).

Event	Date Begin	Date End	Total Precip. (mm)	Avg. SWAT Runoff (mm)	Avg. SWAT Daily CN	EI (MJ·mm·[ha·h]$^{-1}$)

Table 3
Connectivity and RUSLE parameter ranges. b, c, τ_{cr}, C_{Mine}, and C_{Forest} are calibrated parameters. *EI*, *LS*, *K*, and *P* are inputs.

Parameter	Description	Range	Units	Source
b	Connectivity runoff turbulence exponent	0.1–0.5	Unitless	Torri and Poesen (2014)
η	Connectivity rill/gully threshold coefficient	0.1–1.0	Unitless	Torri and Poesen (2014)
τ_{cr}	Critical shear stress	0.5–20.0	Pascal	McCool et al., (1993); Hanson and Simon (2001)
EI	RUSLE storm erosivity parameter	Varies	MJ·mm·[ha·h]$^{-1}$	Renard et al., (1997)
C_{Mine}	RUSLE cropping and management factor for reclaimed mines	0.004–0.008	Unitless	Wischmeier and Smith (1978); Dissmeyer and Foster (1980)
C_{Forest}	RUSLE cropping and management factor for forest land	0.0004–0.0008	Unitless	Wischmeier and Smith (1978); Dissmeyer and Foster (1980)
LS	RUSLE slope length and steepness parameter	Varies	m·m^{-1}	Renard et al., (1997)
K	RUSLE soil erosivity parameter	0.0–0.37	tonne·ha·hr·[ha·MJ·mm]$^{-1}$	Renard et al., (1997)
P	RUSLE practice parameter	0.0–1.0	Unitless	Renard et al., (1997)

$$P(T_{H-dwn})_j = \begin{cases} 1, if \ \ S_j > \dfrac{\sum S_{up}}{N} \\ 0, if \ \ S_j \le \dfrac{\sum S_{up}}{N} \end{cases} \quad (14)$$

where S is the slope in the geospatial cell, $\frac{\sum S_{up}}{N}$ is the average slope of cells upstream of cell j calculated in ArcMap 10.4.1. Physically, Eq. (14) represents locations where the energy in a geospatial cell (represented by the slope) is sufficient for suspended sediments to transport through the geospatial cell to downstream cells (Mahoney, 2017; Mahoney et al., 2018). Hillslope deposition is also represented by the probability of hydrologic detachment $P(D_H)$ and the probability of downstream hydrologic transport $P(T_{H-dwn})$. These formula account for deposition because if the downstream slope of cell j is flatter than the average slope of upstream cells, then downstream transport of sediment is not possible, despite instances when detachment occurs (thus, detached sediment is assumed to deposit along the hillslope in these instances). Conceptually, the $P(T_{H-dwn})$ equation compares fluid energy to transport sediment in downstream cell j represented by the slope to incoming fluid energy represented by the average slope. We note, however, that disconnected cells downstream of upstream connected cells do not necessarily represent deposition from sediment in the connected cell. Rather, these cells are assumed to not contribute additional sediment to the sediment cascade during the hydrologic event (Mahoney, 2017; Mahoney et al., 2018; Mahoney et al., 2019).

Several variables in Eq. (9) through Eq. (14) represent structural and

functional attributes of the Whitaker Branch watershed. Structural connectivity, which represents morphometric properties (e.g., slope, soil texture) of watersheds with little variability from event to event over the course of the study period are represented with the probability of sediment supply $P(S)$ and probability of downstream hydrologic transport $P(T_{H-Dwn})$ (Mahoney et al., 2018; Wohl et al., 2019). We represent functional connectivity, defined as dynamic connectivity processes such as runoff generation and soil moisture flux, using the probability of detachment $P(D_H)$ and the probability of upstream hydrologic transport $P(T_{H-Up})$ (see Mahoney et al., 2018; Wohl et al., 2019). Hydrologic variables used to predict $P(D_H)$ and $P(T_H)$for the 12 events analyzed during the study period were estimated using ArcSWAT 2012.10.21 (see Table 2).

We conducted analyses of the estimated Rouse number for suspended sediments in this system which suggested that once sediment is detached and entrained at the hillslope scale, sediment likely remains suspended, justifying the implicit treatment of deposition in the $P(C)$ formulation for this system. We briefly detail this analysis below. The Rouse number is traditionally used in sediment transport to specify the dominant mode of sediment motion and provides a measure of the shear action of fluid on entrained particles comparatively to particle settling (Chang, 1998). The forest soils of the study watershed (see mapping in Fox, 2009 and Fig. 1) are silt-dominated and are generally classified as silt loam or silty clay loam (McIntosh, 2004). Based on our recent research, the crushed overburden making up the surface soils of reclaimed mining sites in this region also has a median particle size classified as silt (Fox et al., 2020).

Using this information, we analyzed the Rouse number for diameter, d, of 53 μm sediment. The Rouse number is defined as

$$z_* = \frac{\omega}{\kappa u_*} \tag{15}$$

where ω denotes the settling velocity, κ is defined as the von-Karman constant equal to 0.41, and u_* is the shear velocity of the flow. The settling velocity ω is calculated here via the Dietrich (1982) approach for nonspherical particles for $d = 53$ μm particles and is estimated to be 0.3 cm s^{-1}. The shear velocity of the flow is defined as:

$$u_* = (gRS)^{\frac{1}{2}} \tag{16}$$

where R is the hydraulic radius and is approximated as the flow depth H, S is the energy gradient approximated with the hillslope, and g is gravity. The average slope in the forested land is 0.51 m m^{-1} and 0. 44 m m^{-1} on the reclaimed mine surfaces and we assume a 1 cm flow depth in rills during erosion as a low bound on concentrated flow during fluvial erosion. These sediment and hydraulic conditions provide a Rouse number equal to approximately 1/30. Based on these conditions, we examine the possibility of sediment remaining suspended using the Rouse criteria. According to Vanoni (1941) (see Fig. 7.9 from Chang 1998, pp 149) the z_* value of 1/30 corresponds to highly suspended and nearly fully uniform sediment concentration profile. Therefore, it is estimated that sediment will remain suspended and not deposit once detached and entrained in this system.

3.4. RUSLE application to forested land and reclaimed mine

We apply the RUSLE model to represent erosion rates in geospatial cells to simulate sediment flux in Eq. (2). We assume that surface erosion occurs primarily *via* rill and sheet erosion in both the steep, forested hillslopes and the reclaimed mine sites, justifying our use of RUSLE to simulate erosion rates (Renard et al., 1997; Fox and Martin, 2015). The RUSLE model simulates soil loss on hillslopes at an event-basis (Renard et al., 1997) as

$$A = EI \cdot K \cdot LS \cdot C \cdot P \tag{17}$$

where A represents hillslope soil-loss (tonne ha^{-1}), EI is the storm erosivity factor (MJ • mm[ha • hr]$^{-1}$), K is the soil erodibility coefficient (tonne • ha • hr[ha • MJ • mm]$^{-1}$), LS is the slope length and steepness factor (m m^{-1}), C is the cover-management factor (unitless), and P is the supporting practice factor (unitless). We discretize Eq. (17) for geospatial cells to estimate annual soil loss throughout the Whitaker Branch watershed from both steep, forested hillslopes as well as slopes on the reclaimed mine. We modify Eq. (17) to account for connectivity by multiplying cells by $P(C)$ results, which represents the complete parameterization of Eq. (1). Additionally, we make the following assumptions: (1) the EI factor is uniform spatially across the watershed during an event; (2) the K, LS, C, and P factors remain constant temporally throughout the study period; (3) C factors vary between forest and reclaimed mine land uses; and (4) disconnected cells (i.e., $P(C) = 0$) do not yield sediment ($A = 0$). Eq. (17) is thus rewritten as

$$A_{ij} = EI_i \cdot K_j \cdot LS_j \cdot C_j \cdot P_j \cdot P(C)_{ij} \tag{18}$$

Average annual soil loss (tonne ha^{-1}) for steep, forested and reclaimed mine land uses is thus determined as

$$A_{forest} = \sum_{i=1}^{m} \frac{\sum_{j=1}^{n} A_{ij}}{n}, j \in [\text{steep, forest land}] \tag{19}$$

$$A_{mine} = \sum_{i=1}^{m} \frac{\sum_{j=1}^{k} A_{ij}}{k}, j \in [\text{reclaimed mine}] \tag{20}$$

where A_{forest} is the average annual soil loss (tonne ha^{-1}) across the entire steep, forested land use, i is an index representing the storm event, m is the total number of storm events during the study year, j is an index representing the geospatial cell, n is the total number of geospatial cells belonging to the forested land use, A_{mine} is the average annual soil loss (tonne ha^{-1}) across the entire reclaimed mine land use, and k is the total number of geospatial cells belonging to the reclaimed mine land use.

Since Eqs. (19) and (20) are divided by n and k, the total number of geospatial cells that belong to the land use, A_{forest} and A_{mine} represent soil loss rates from the entirety of each land use. Since sediment connectivity occurs on only a fraction of cells belonging to the varying land uses, we modify Eqs. (19) and (20) to represent normalized soil loss for only connected areas as

$$AC_{forest} = \sum_{i=1}^{m} \frac{\sum_{j=1}^{n} A_{ij}}{\alpha_i}, j \in [\text{steep, forest land}] \tag{21}$$

$$AC_{mine} = \sum_{i=1}^{m} \frac{\sum_{j=1}^{k} A_{ij}}{\beta_i}, j \in [\text{reclaimed mine}] \tag{22}$$

where AC_{forest} represents annual soil loss (tonne ha^{-1}) for connected forested land use, α_i is the total number of steep, forested geospatial cells connected during an event, AC_{mine} is the annual soil loss (tonne ha^{-1}) for the reclaimed mine land use, and β_i is the total number of reclaimed mine geospatial cells connected during an event. Also, $\alpha_i \leq n$ and $\beta_i \leq k$.

We parameterize RUSLE as follows: To parameterize the storm erosivity (EI) parameter, we focus only on rainfall events that produce more than 1.3 cm of rainfall and storms that produce at least 0.6 cm of rain in 15-min in accordance with Renard et al. (1997; p. 23). We utilize hourly rainfall data measured at the USGS gage in Whitesburg, Kentucky for 2007 to determine storms appropriate for analysis. 12 events during the study year were identified to produce sediment based on these requisites during 2007 (Renard et al., 1997). We determine EI (MJ • mm[ha • hr]$^{-1}$) values in accordance with Renard et al., (1997) as

$$EI = \sum_{r=1}^{p} 1099 \cdot \left[1 - 0.72 \cdot \exp\left(-1.27 \cdot \frac{\Delta V_r}{\Delta t_r}\right)\right] \cdot I_{30} \cdot 0.1702 \tag{23}$$

where r is a temporal index representing increments of a storm event, p is the total increments in the storm event, ΔV is the depth of rainfall during the increment r (in), Δt is the duration of the increment (h), and I_{30} is the 30-min rainfall intensity. We record EI values in Table 2.

We parameterize the soil erosivity (K) factor using USDA soils maps for the Whitaker Branch watershed and reported K values for each soil type (see Fig. 1 and Table 3). We parameterize the slope length and steepness (LS) factor by: (1) delineating slope lengths from the watershed boundary to the nearest downstream concentrated flow pathway, (2) defining slope along the slope length using the *Slope* tool in ArcGis 10.4.1, and (3) interpolating LS values reported in Table 4-1 from Renard et al., (1997). We parameterize the support practice (P) factor as being equal to 1.0. We justify this given that slopes are relatively steep in both forested hillslopes and reclaimed mine hillslopes (Renard et al., 1997). Additionally, we argue that this avoids overparameterization of the model given that disconnectivity due to terracing is already accounted for in $P(C)$ results (see Section 4.1). We treat the cover-management (C) factor as a calibration parameter in order to more accurately understand impacts of the reclaimed mine on soil loss, as discussed in Section 3.5. We justify using temporally-constant values for K, LS, C, and P given previous study in the watershed (Fox, 2009; Fox and Martin, 2015). RUSLE factor ranges are reported in Table 3.

3.5. Model calibration and evaluation

Data used to calibrate the coupled probability of connectivity and RUSLE models include geospatial analysis and field reconnaissance of sediment transport pathways, sediment fingerprinting analyses, and sediment concentration samples. Field reconnaissance of sediment transport pathways was conducted by Fox (2009) and geospatial analyses were conducted using DEMs (KYAPED, 2014) and orthophotographs. Samples to conduct sediment fingerprinting were collected from forest and reclaimed mine sources as described in Campbell et al. (2009), and instream samples were collected five times during 2007 as described in Fox (2009). TSS samples were collected using a Teledyne ISCO automated pump sampler as reported in Fox (2009) and Fox and Martin (2015). Observed soil loss estimates from forest and reclaimed mine land uses in 2007 were derived from TSS samples and fingerprinting results.

We completed evaluation of the model in two stages (see Fig. 4). In stage one, we calibrated results from the probability of connectivity model by qualitatively comparing spatially distributed connectivity

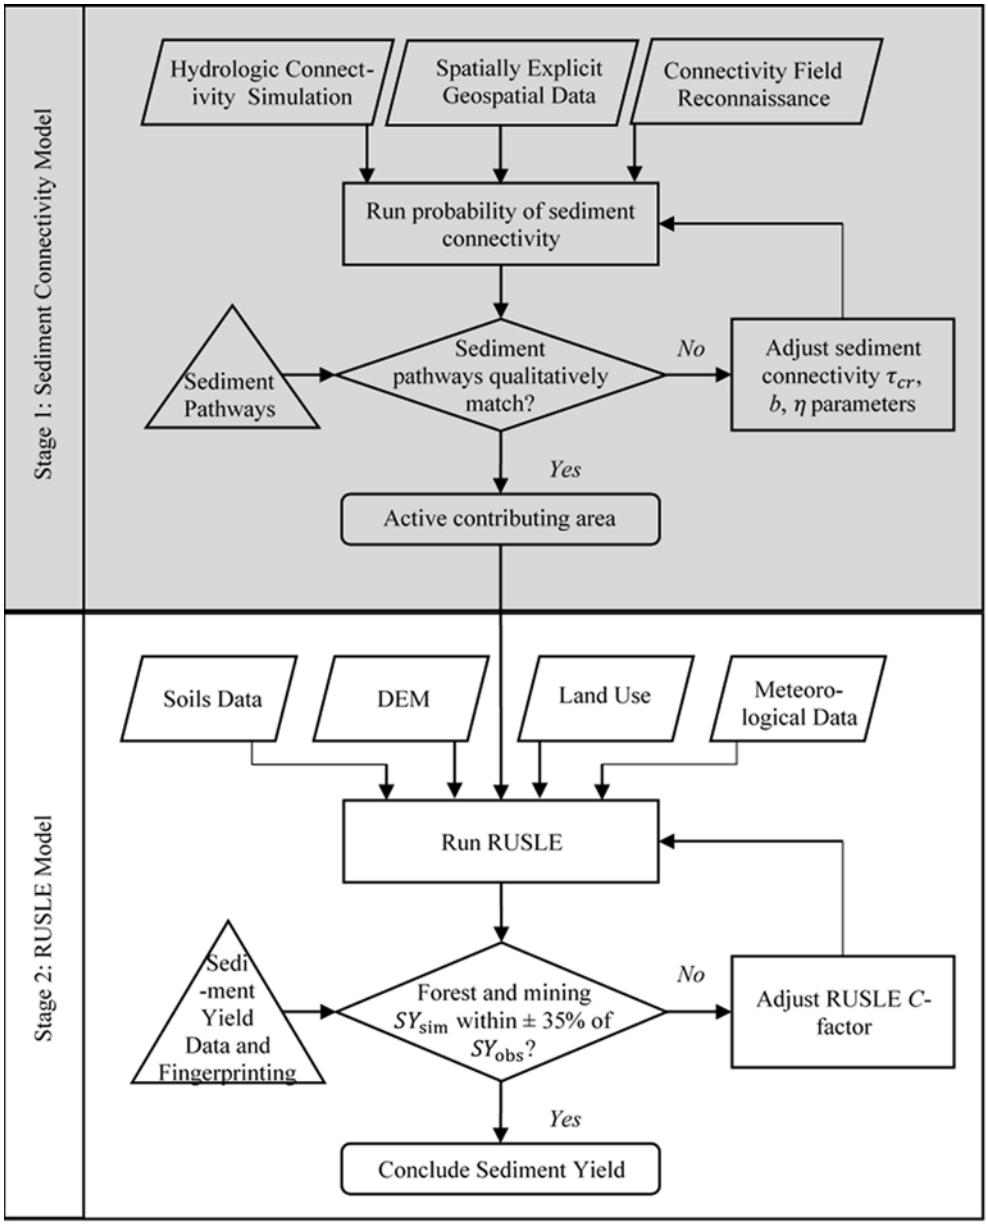

Fig. 4. Sediment flux evaluation flowchart that considers sediment connectivity and erosion simulated *via* RUSLE.

results with sediment pathways identified *via* field reconnaissance and remote sensing. If simulated sediment transport pathways were considered unacceptable, we adjusted connectivity parameters until the realization qualitatively matched known transport pathways. Connectivity parameters calibrated in this stage included: (1) b, the connectivity runoff turbulence exponent, (2) η the rill/gully threshold coefficient, and (3) τ_{cr} the critical shear stress of erodible surfaces. We used literature values to define ranges of parameter values (Torri and Poesen, 2014; McCool et al., 1993; Hanson and Simon, 2001). Since calibration is completed qualitatively, we defined wide parameter ranges to account for potential uncertainty (see Table 3). We justify the use of large parameter ranges given the difficulty of calibrating and validating spatially explicit sediment transport processes.

In stage two, we calibrated results from the combined connectivity and RULSE modeling by comparing simulated sediment yield to observed sediment yield for the forested land use and reclaimed mine (Fox, 2009; Fox and Martin, 2015). If simulated sediment yield was not within ±35% of observed sediment yield, we adjusted C factor for the forested and/or reclaimed mine land use until sediment yield results were acceptable. 35% uncertainty bounds surrounding modeling results considers error due to sediment fingerprinting (approx. 15%, Fox and Martin, 2015) and error due to sediment concentration measurements. Based on previous work, we estimate 20% error from sediment concentration measurements after empirical observations of the variability of ISCO sediment concentration samples. Upon calibrating the model initially, we recalibrated the model starting at stage one to account for landscape units with little or no soil loss that should be considered disconnected, thus we treat calibration of the coupled models as an iterative process.

We quantified model uncertainty by permuting realizations of parameter ranges and running the probability of connectivity and RUSLE model. We created over 200 permutations of the connectivity and RUSLE model to simulate sediment yield. We justify using a low number of model realizations due to restrictions related to model computing requirements and file size. We iteratively chose parameter ranges to reduce limitations related to the number of realizations (see Table 3). Realizations with simulated sediment yield within ±35% of the observed sediment yield were included in the solution space. We qualitatively validated RUSLE modeling by comparing spatially-explicit R, LS, K, and calibrated C parameters with separate RUSLE modeling that considered lumped R, LS, K, and calibrated C parameters. All lumped parameters were on the same order of magnitude as the zonal average of the spatially explicit analysis.

4. Results and discussion

4.1. Evaluation of coupled connectivity and RUSLE modelling: a need for iterative validation

We found that coupling the probability of connectivity model with RUSLE simulated both observed sediment yield and sediment fingerprinting results well. Optimal parameter values determined during model calibration are recorded in Table 4 and simulated and observed sediment yield results are recorded in Table 5. Uncertainty results suggest that relatively wide ranges of connectivity parameters adequately simulate sediment transport whereas the range for acceptable C factor values is much smaller (see Table 3). Approximately 55% of model realizations were included in the solution space, which we attribute to the tight parameter ranges associated with the C factor. We generally find that optimal parameters make physical sense, however some parameter values warrant further discussion, which is the focus below.

Optimal cropping and management (C) factor values are on the low end of proposed range, but still within the range suggested in research literature (see Table 3), for both the forest and reclaimed mine land surfaces. Low C factors have physical significance in the forested and reclaimed mine land use and likely reflect the presence of morphologic features that buffer sediment transport. In the forested land, subsurface macropore pathways increase rainfall infiltration rates and reduce the depth of runoff produced during storm events (Sloan et al., 1983), which is then manifested as the low C factors. Additionally, microtopography resulting from dense forest root mats and shielding from leaf detritus further reduce sediment transport and hence forest C factor values. Calibrated C factor values were an order of magnitude greater for the reclaimed mine site as compared to the forest, which is to be expected considering the increase in event runoff generation due to the high bulk density and low infiltration capacity of the soils on the reclaimed mine relative to the neighboring forests (Acton et al., 2011). The fact that the C factor was on the low end of suggested ranges for grassland reclaimed coal mine lands is reasonable because the land surface was classified as 'phase 3' of reclamation where final reclamation has been achieved (Fox, 2009). Erosion results in this region have shown erosion rates to reduce drastically once the land surface has entered phase 3 reclamation (Curtis, 1978; Bonta, 2000).

We parameterized the optimal RUSLE practice (P) factor as being equal to one, which indicates that no anthropogenic practices, such as associated with terracing, exist in the watershed to reduce soil loss (Renard et al., 1997). As will be shown in our connectivity results, we found that legacy-associated terracing occurred across the forest landscape of this system. Anthropogenic terracing existed from farming the mountains in the 19th century and early 20th century. This farming and terracing were common in this Appalachian forest region despite the steep slopes, and corn was grown for animal feeding, human consumption and illegally producing alcohol regionally known as 'moonshine' (Kalisz, 1986; Stewart and Bruce, 2003). The legacy terracing typically would warrant parameterization of a P factor less than one. However, our probability of connectivity model results causes these terraced areas to become disconnected. Therefore, the land surface area of the disconnected regions is not included in the calculation of mass flux because mass flux is the product of generation via RUSLE soil loss estimates and the probability of connectivity (see Eq. (1)). A P factor of less than one would over-account for terracing and erroneously reduce the estimated sediment mass flux estimate. For this reason, iterative calibration between RUSLE and connectivity modelling was important to account for unforeseen dependency between variables in Eq. (1). We set the P factor as equal to unity to avoid the dependency in this instance.

Our results suggest coupled connectivity-erosion rate modelling incorporate iterative, dual-calibration strategies where calibration of one model should feed-back or loop into calibration of the second model. Our results present evidence of the utility of such approach in two instances. First, as previously mentioned, we found that calibration of the P factor in RUSLE was unnecessary upon multiplication of the RUSLE results with $P(C)$. Specifically, we find that the probability of downstream hydrologic transport $P(T_{H-Dwn})$ causes terraced areas to be predicted as being disconnected. This is because $P(T_{H-Dwn})$ predicts that there is insufficient fluid energy to transport new sediment downstream due to the flat surfaces of the terraced landscapes (Mahoney et al., 2018). In this regard, care should be taken by the researcher to avoid unforeseen dependency between the coupled formula because, for example, parameterization of the $P(C)$ model may sometimes impact

Table 4
Optimal parameter values for connectivity and RUSLE models.

Parameter	Description	Value	Units
b	Connectivity runoff turbulence exponent	0.38	Unitless
η	Connectivity rill/gully threshold coefficient	0.5	Unitless
τ_{cr}	Critical shear stress (Average)	3.75	Pascal
C_{Mine}	RUSLE cropping and management factor for reclaimed mines	0.006	Unitless
C_{Forest}	RUSLE cropping and management factor for forest land	0.0006	Unitless

RUSLE parameterization. Second, we noticed that upon completing RUSLE modeling that some landscape units in the forest were predicted to produce little to no sediment despite being predicted to be connected according to *P*(*C*). The lack of generation as predicted with RUSLE indicates the magnitude of connectivity is in fact weak on some landscape units such that sediment contribution from these areas is negligible and can be classified as disconnected following the criteria/definition of Heckmann et al., (2018); Wohl et al. (2019) and Ali et al. (2018). We present results from determining event *P*(*C*) with and without considering feedbacks between the models, referred to as initial calibration and final calibration in Table 6. Notably, considering the feedback between the models and iterative calibration caused a reduction in overall connectivity for all events. The result ranges from 0.1% to 13.8% reduction in connectivity, which is relatively high considering final connectivity ranges from 2.9% to 22.4%. This result and need for feedbacks between sediment generation and connectivity estimates is corroborated by recent sentiment in the literature and highlights the importance of considering not only the Boolean connectivity processes (e.g., Fryirs, 2013), but also the magnitude or continuity of connectivity (Grant et al., 2017; Wohl et al., 2019).

The model evaluation results of this study point out the researcher should use caution when coupling connectivity and erosion formula because parameters of the two model types are not necessarily independent. In the present study, the process of terracing impacts both erosion formula in the empirical RUSLE model and net connectivity estimates for predicting the erodible surface area of the basin. We may have under-predicted watershed erosion without this consideration, however, iterative calibration allowed us to account for dependence of the models on one another. As permeations of coupled connectivity and erosion models develop in future years, researchers should at the same time develop new evaluation procedures with qualitative and quantitative checks-and-balances to correct for unforeseen problems from model co-dependency.

Table 6
Probability of connectivity results using initial calibration and final calibration after considering the iterative feedback loop using RUSLE for the entire Whitaker Branch Watershed.

Event	P(C) – Initial calibration	P(C) – Final calibration
1	18.8%	13.7%
2	14.9%	12.3%
3	7.3%	5.5%
4	15.2%	12.5%
5	36.2%	22.4%
6	21.9%	14.0%
7	12.7%	10.2%
8	3.0%	2.9%
9	3.3%	3.2%
10	24.4%	13.9%
11	3.4%	3.3%
12	9.3%	7.5%

The efficacy of coupling connectivity theory and sediment modelling is corroborated by recent findings from Zhao et al. (2020), who, independently from this study, coupled RUSLE with the Index of Connectivity (*IC*) to predict sediment yield. Similar to Vigiak et al., (2012), Zhao et al. (2020) transformed the *IC* using a Boltzmann-type sigmoid function to represent potential sediment delivery ratios from landscape units. The formulation was evaluated to perform well and qualitatively validates the approach presented here.

We emphasize several important differences, however, between the study of Zhao et al., (2020) and the work presented herein. Namely, the *IC* used to represent connectivity is treated quasi-statically (*IC* is calculated once for a simulation in 1990 and once for a simulation in 2010), and thus only captures aspects of structural connectivity (e.g., Heckmann et al., 2018). The ability of the *IC* framework to rapidly assess connectivity elements is noteworthy given that recently developed geospatial toolboxes allow the *IC* to be calculated for a catchment on the order of several hours of simulation time (Crema and Cavalli, 2018). However, *IC* is recognized to only capture elements of structural connectivity due to the morphologic configuration of the watershed (Heckmann et al., 2018; Mahoney et al., 2020a,b). Consideration of functional connectivity is particularly meaningful when simulating sediment transport at relatively shorter timescales (e.g., event-daily) and for small, yet still important hydrologic events, as will be shown later in the results and as highlighted in Mahoney et al. (2018, 2020a,b). Incorporation of functional connectivity elements is one limitation of the current *IC* approach as emphasized by a number of researchers (e.g. Bracken et al., 2013; Heckmann et al., 2018; Mahoney et al., 2020a,b), however, recent developments from Gay et al. (2016), Kalantari et al. (2017) and several others present promise for coupling the *IC* with functional elements. Additionally, coupling elements of the Probability of Connectivity framework presented here and the *IC* may serve to better incorporate functional processes within the *IC*.

4.2. Event *P*(*C*) results: connectivity and disconnectivity in Appalachian forests and minelands

Results highlight behavior of event-based connectivity in the Whitaker Branch watershed. *P*(*C*) results vary between 2.9% connected (event 8) and 22.4% connected (event 5) at the watershed scale (see Table 6). This implies that 2.9% of the catchment and 22.4% of the catchment actively contribute sediment to the stream network during respective events (Ambroise, 2004; Mahoney et al., 2018). *P*(*C*) varied greatly between land uses throughout the 12 events. Namely, *P*(*C*) ranged from 34.4% to 57.1% in the reclaimed mine (μ = 46.8%, σ =

8.1%) and 1.0–34.9% in the forested land ($\mu = 12.1\%$, $\sigma = 9.8\%$) (see Table 5). We attribute the high percentages of connectivity in the reclaimed mine to increased runoff production and hence energy available to transport sediment caused by compaction of soils during reclamation processes.

Predicting the most connected pathways across the landscape was a notable result of this study, and our spatially explicit $P(C)$ results highlight morphologic pathways most sensitive to hydrologic activity in the Whitaker Branch watershed (Figs. 5 and 6). Specifically, our results indicate that landscape units within the reclaimed mine are connected during hydrologic events of low magnitude and remain connected during events of increased hydrologic magnitude (see Fig. 5a–d). Events shown in Fig. 5, Fig. 6, and Fig. 7 are approximately representative of minimum (event 8), 25% quartile (event 12), 75% quartile (event 1), and maximum (event 5) $P(C)$ results. Within the forest, we find that only areas with large upstream contributing area within close proximity to the stream network are connected during events with low hydrologic magnitude (see Fig. 5a and Table 2); and forest hillslopes only become connected during high magnitude events (Fig. 5d). Low connectivity on forested hillslopes in low and moderate events is attributed to the high infiltration rates in forest soils due to soil texture and macropores (Khan and Ormsbee, 1989). In contrast, connectivity occurs on both flat and steep reclaimed mine surfaces with variable upstream contributing areas during events with low hydrologic activity (see Fig. 5a). The connectivity of reclaimed mines is attributed to runoff generation during low and moderate events because of the high bulk density measured for the compacted reclaimed mine sites (Acton et al., 2011). We classify the landscape units within the reclaimed mine as highly sensitive, active pathways for this watershed since they are connected in much greater proportions and more frequently than forested hillslopes. Morphologic features promoting connectivity can be seen visually for both land cover types using orthophotos, gradient models and our connectivity results (Fig. 6). As shown, morphology causing connectivity in both the forest and reclaimed mine land include: (1) concentrated flow paths on steep surfaces in the forestland (Fig. 6a); (2) steep hillslopes between historic terracing (Fig. 6b); and (3) surfaces throughout the reclaimed mine (Fig. 6c).

Disconnectivity of the landscape was another important result of this study, and spatially explicit results also highlight morphologic buffers that disconnect sediments and impede sediment transport throughout the watershed (see Fig. 6a–c; Fryirs, 2013). We examine disconnectivity in Fig. 6 during the event with highest hydrologic activity (event 5),

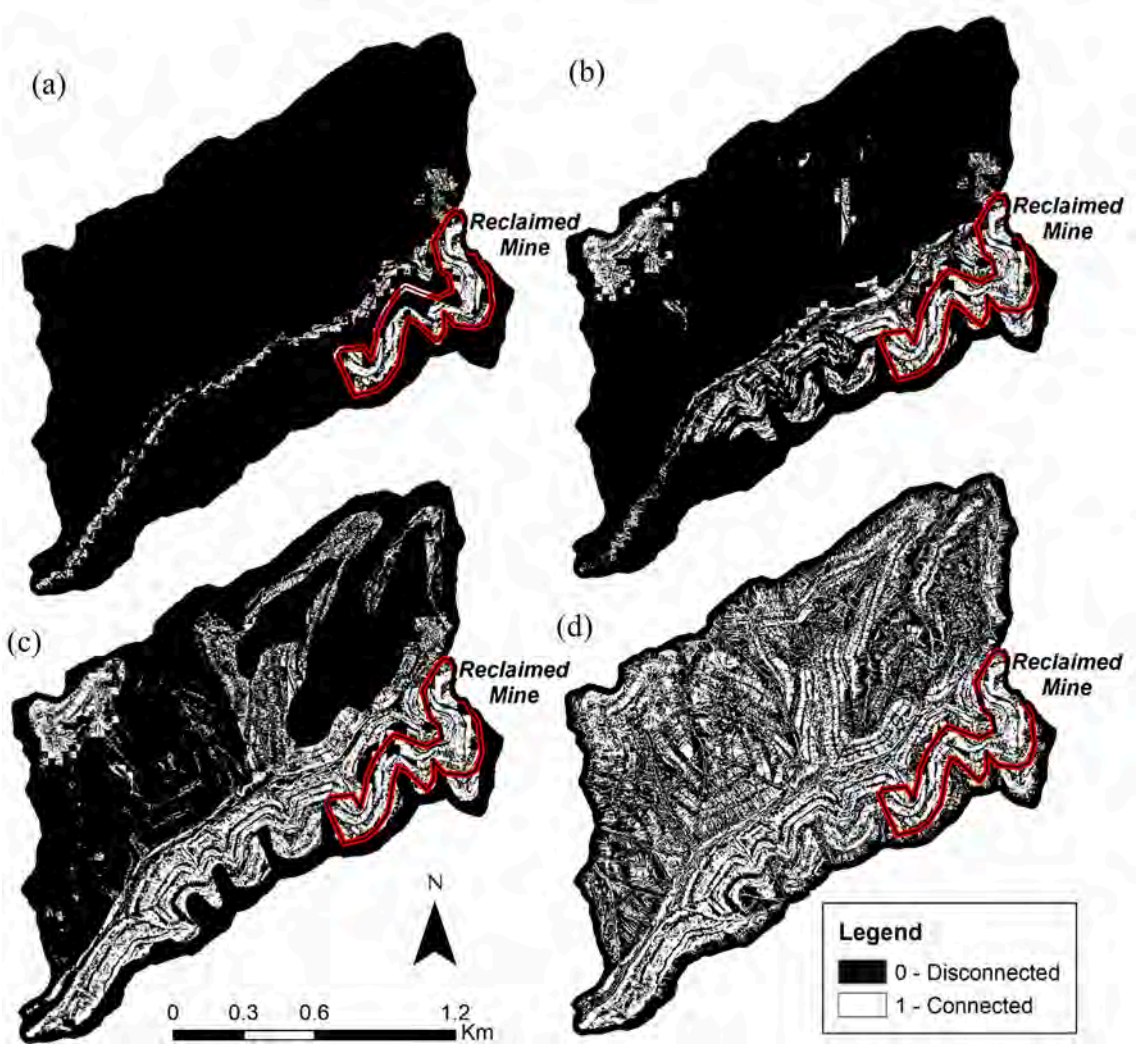

Fig. 5. Spatial probability of connectivity results for four events of increasing hydrologic magnitude in the Whitaker Branch watershed including: (a) 3.0% connectivity during event 8 (July 24, 2007); (b) 9.3% connectivity during event 12 (October 24, 2007); (c) 18.8% connectivity during event 1 (March 1, 2007); and (d) 36.2% connectivity during event 5 (April 14, 2007). These events approximately represent the minimum (event 8), 25% quartile (event 12), 75% quartile (event 1), and maximum (event 5) P(C) results. Note: cells within the watershed are predicted to be either connected (white cells) or disconnected (black cells). Any appearance of a gradient is artificial due to contrasting image/raster cell resolution.

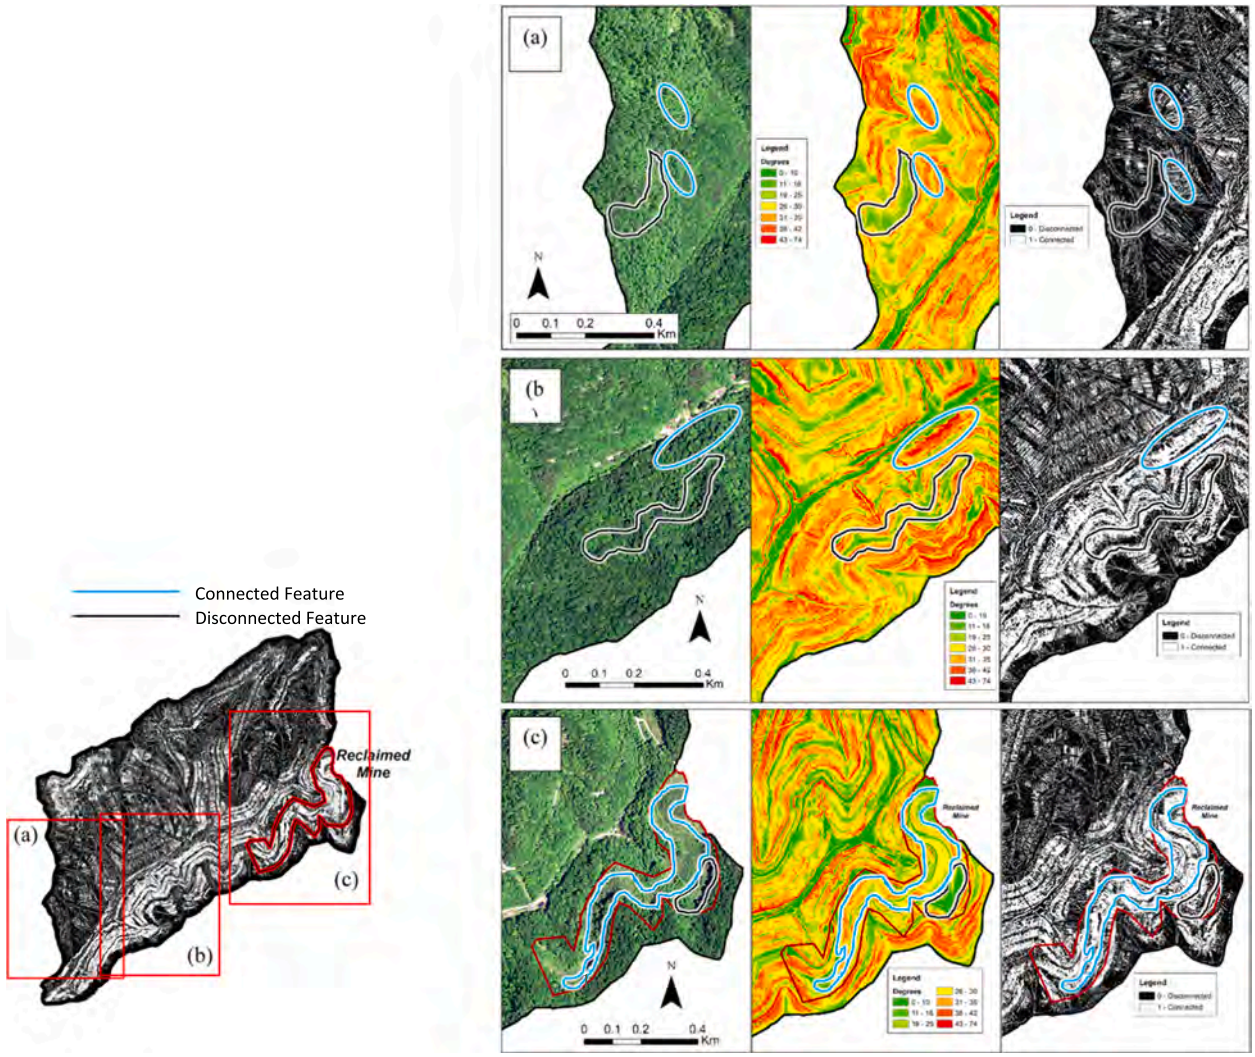

Fig. 6. Probability of connectivity results reveals connected and disconnected morphologic features. Imagery, slope, and probability of connectivity results are shown for three locations within the Whitaker Branch watershed. (a) Connectivity from concentrated forest pathways on steep slopes (circled in blue) and disconnectivity due to soil texture and fast drainage on flat swaths (circled in black). (b) Connectivity caused by steep slopes (circled in blue) and disconnectivity from historic terracing found throughout the watershed (circled in black). (c) Connectivity within the reclaimed mine (circled in blue) and disconnectivity on flat ridgelines created during reclamation (circled in black). The reclaimed mine is circled in red. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

which highlights impedances due to structural watershed properties as opposed to impedances from functional hydrologic variability (e.g., runoff depth or soil moisture content), thus highlighting the upper limit of connectivity in the watershed. Fig. 6a indicates that even on the steepest surfaces, sediment connectivity seldom occurs in forested hillslopes. The prevalence of disconnectivity on these hillslopes is attributed to relatively high sand content of the soil texture and infiltration capacity of the soil. These soil drainage characteristics limit runoff generation and fluid energy to detach and transport sediment despite the steep hillslope gradient (i.e., average gradient = 0.51 m m^{-1}). Other morphologic features influencing disconnectivity on forested hillslopes include microtopography created from exposed tree roots and tree fall which promotes localized pockets of very flat slopes (e.g., 0–10°), decreasing fluid transport capacity. Also, Fig. 6b highlights disconnectivity due to historic terracing found throughout the watershed. Locally flat swaths (see Fig. 6b – slope) occur in contours throughout forested hillslopes and decrease overland fluid energy available to detach and transport sediment. We find that terraces particularly impacted the probability of downstream sediment transport ($P(T_{H-Down})$) and cause localized regions where deposition is likely. Disconnected landscape across the reclaimed mine was found to occur near ridgelines and locally flat areas created during reclamation (see Fig. 6c). Disconnectivity near ridgelines occurs because with very little upstream contributing area is available to accumulate water and produce shearing able to erode sediment. Disconnectivity of flat contours occurs because spoil is placed in lifts during surface mine reclamation (e.g., Skousen and Zipper, 2014). Each lift is constructed with near constant gradient with a slope length on the order of 50 m in this study, and the lifts are compacted in place. In between lifts, a near zero gradient berm of spoil is compacted across the contour and is between 5 and 10 m wide. These berms cause disconnectivity across the mining landscape.

4.3. Functional and structural controls on $P(C)$

Event variability of $P(C)$ sub-processes highlights structural and functional behavior that controls connectivity throughout the Whitaker Branch watershed. Sub-process connectivity probabilities for the Whitaker Branch watershed are shown in Fig. 7a.

We find that generally functional connectivity associated with the probability of hydrologic detachment $P(D_H)$ controls overall probability

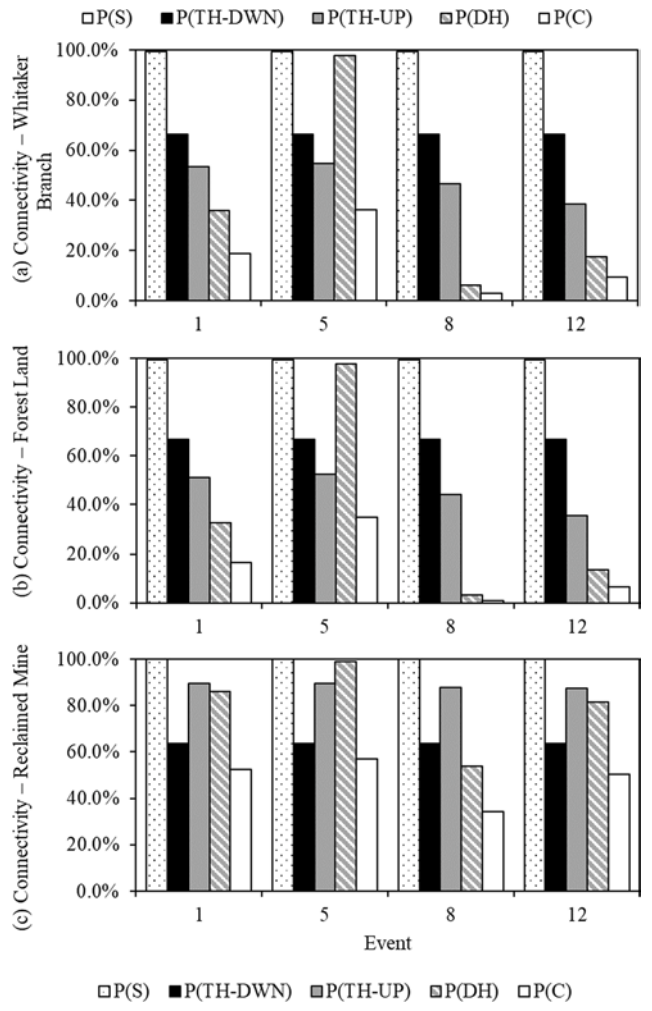

Fig. 7. Variability of sediment connectivity probabilities, including the probability of sediment supply, P(S), probability of downstream hydrologic transport, P(TH-DWN), probability of upstream hydrologic transport, P(TH-UP), probability of hydrologic detachment, P(DH) and probability of connectivity, P(C). Probabilities are shown for selected events in (a) Whitaker Branch, (b) forested land uses, and (c) reclaimed mine land. These events approximately represent the minimum (event 8), 25% quartile (event 12), 75% quartile (event 1), and maximum (event 5) $P(C)$ results.

of connectivity results in the forest and the Whitaker Branch watershed as a whole (see Fig. 7a and b). $P(D_H)$ limits $P(C)$ during all events at and below the 75% quartile (event 1, 8, 12), which indicates that detachment processes control sediment transport and connectivity across most surfaces in the Whitaker Branch watershed. Physically, this result is related to the very high infiltration rates in most soils in the Whitaker Branch watershed, which limits runoff production and hence sediment detachment. Only during the event with most extreme hydrologic activity (event 5) did $P(D_H)$ not limit overall connectivity. We notice similar trends in forest sub-process probabilities (see Fig. 7b), which is to be expected considering forest land covers 94% of the watershed.

Our results indicate notably different processes control the behavior of sediment connectivity in the reclaimed mine, and the structural control and to a lesser degree the functional control associated with the probability of hydrologic transport and detachment, respectively, play a role in the minelands (Fig. 7c). In nearly all events, the structurally dependent probability of downstream hydrologic transport $P(T_{H-Dwn})$ is the limiting connectivity sub-process, indicating that structural watershed variables (e.g., slope, stream density) limit connectivity in the reclaimed mine as opposed to functional variability (e.g., soil moisture content, runoff generation). One reason that this occurs is because soil texture disturbance reduces infiltration rates such that storms frequently produce relatively large runoff volumes compared to the surrounding forest. This results in elevated energy to detach and transport sediment manifested within the model by increased probability of functional sub-processes ($P(D_H)$ and $P(T_{H-Up})$), thus reducing functional control over $P(C)$ results.

Our findings add to an existing discussion of structural and functional control of connectivity in other watersheds, and specifically our results relax the notion that functional (dynamic) processes control sediment connectivity in all landscapes (Bracken et al., 2015; Mahoney et al., 2018). Rather, based on our review and experiences, structural connectivity shows the dominant control on connectivity for steep basins and/or during high magnitude hydrologic events when runoff production is high. Functional connectivity becomes more-and-more controlling on net connectivity for lower gradient basins, well-drained landscapes and/or low and moderate hydrologic events. For example, application of both the probability of connectivity and index of connectivity methods showed the importance of the dominant structural control for high magnitude events in the comparison by Mahoney et al. (2020a). Results of this basin show the importance of structural control for the steep Whitaker Branch catchment and structural control showing differences between land cover types (see Fig. 8). Functional control associated with $P(T_{H-Up})$ seldom limits $P(C)$ in the Whitaker Branch watershed likely because: (i) soil moisture is relatively high in the catchment promoting low critical slope thresholds to initiate erosion; and (ii) the steep slopes throughout the watershed easily overcome

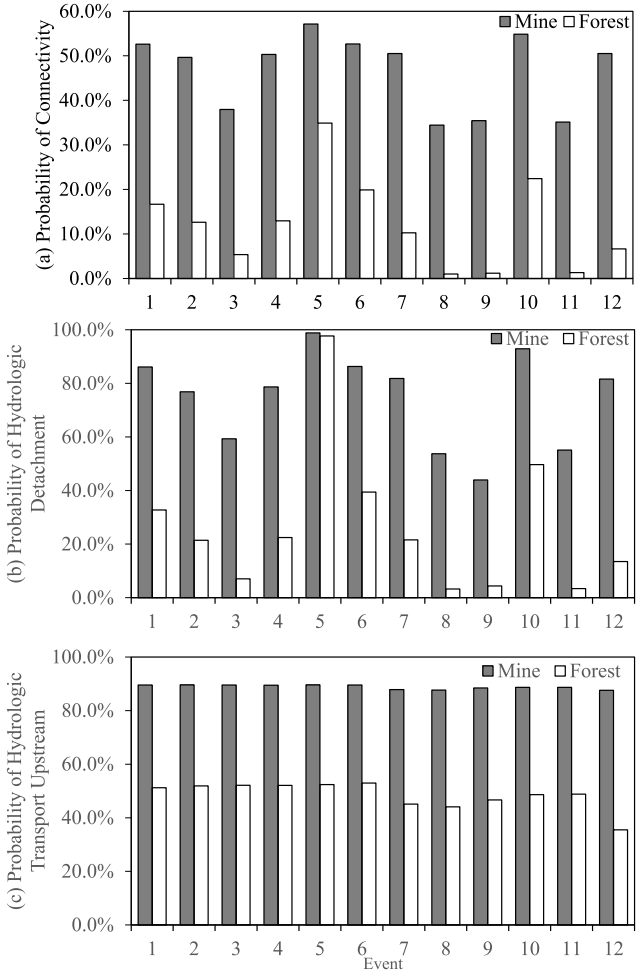

Fig. 8. Results of (a) probability of connectivity, (b) probability of hydrologic detachment and (c) probability of hydrologic upstream transport for each of the 12 hydrologic events for forest and reclaimed mining surface cover.

critical slope thresholds necessary to initiate rill or gully development. On the other hand, recent study has shown the importance of functional controls for lower gradient basins and lower magnitude events. Mahoney et al., (2018) found in the Upper South Elkhorn watershed (65.1 km^2), a gently rolling catchment (average slope 0.07 m m^{-1}) in central Kentucky, that sediment connectivity is generally controlled by the functional probability of upstream transport, $P(T_{H-Up})$, which is a function of soil moisture content, slope, and upstream contributing area. Soils within the Upper South Elkhorn are primarily silt loams and produce large runoff volumes during events, thus promoting detachment of sediment. The relatively flat slopes of the Upper South Elkhorn lack energy required to overcome critical slopes requisite of rill and gully development, explaining the control of $P(T_{H-Up})$on connectivity in the Upper South Elkhorn.

4.4. Coupled $P(C)$ and RUSLE model reveals connectivity and sediment loss rates

Our coupled $P(C)$ and RUSLE model indicates that sediment yield from the reclaimed mine is nearly two times the amount of sediment yield from the forest during the simulation period (see Table 5). This result is significant because the reclaimed mine makes up only 6.0% of the Whitaker Branch watershed. We find that soil loss rates (A) throughout the reclaimed mine are approximately 30 times greater than the forest land. We emphasize that this rate is normalized across the entire surface of the Whitaker Branch watershed (see Eqs. (19) and (20)) as opposed to surfaces where erosion actually occurs (see Eqs. (21) and (22)). When only considering soil loss on connected surfaces (AC), soil loss rates increase by nearly an order of magnitude in the forest land use and by a factor of two in the reclaimed mine (see Table 5). Increased simulated soil loss rates result from connected surfaces occurring, on average, on 12.1% of the forest land use and 46.8% of the reclaimed mine. We emphasize this result because AC soil loss rates are likely more

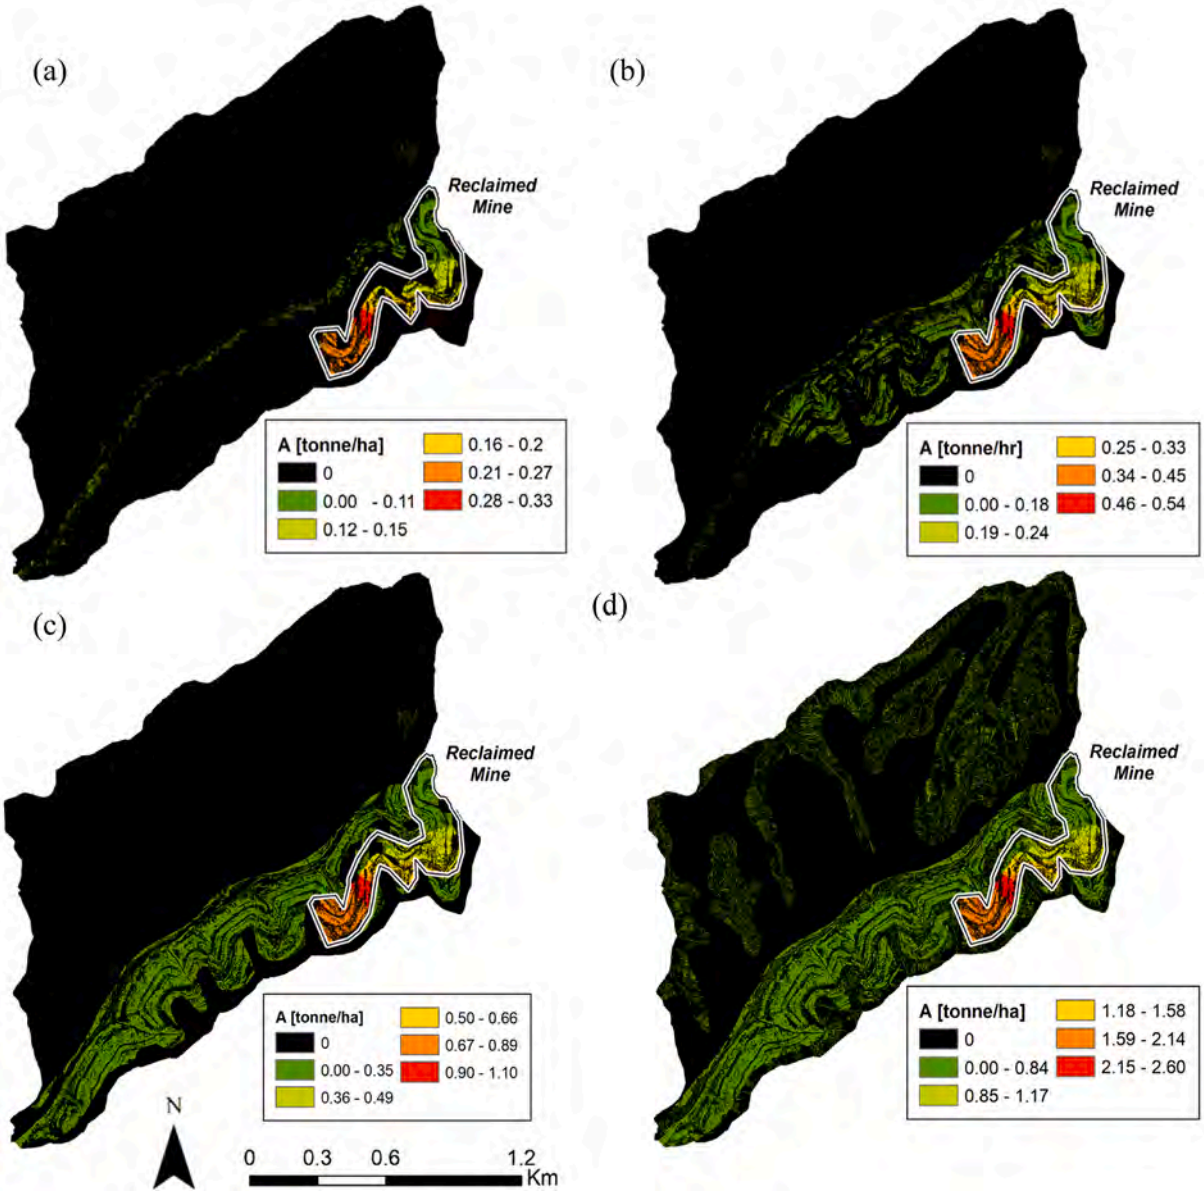

Fig. 9. Spatially-distributed erosion and connectivity results. Distributed connectivity and RUSLE results for four events of increasing probability of connectivity in the Whitaker Branch watershed including: (a) event 8 (July 24, 2007) with 3.0% connectivity; (b) event 12 (October 24, 2007) with 9.3% connectivity; (c) event 1 (March 1, 2007) with 18.8% connectivity; and (d) event 5 (April 14, 2007) with 36.2% connectivity.

realistic of soil loss occurring in the Whitaker Branch watershed. From a management standpoint, this result highlights pathways that should be targeted for remediation within the watershed. Mahoney et al., (2018) found that approximately 90% of sediment is transported in during events with greater than 3% connectivity, which gives us confidence that this analysis captures the majority of important sediment transport events during 2007.

Spatially explicit $P(C)$ and RUSLE modeling extends our view of sediment transport in the Whitaker Branch watershed and highlights connected pathways that produce the most sediment in the watershed (see. Fig. 9). In the four events presented in Fig. 9, soil loss rates within the reclaimed mine are greater than rates in the forest. This result highlights that the pathways most sensitive to connectivity are also pathways that contribute the greatest soil loss rates. Spatially explicit results of the coupled $P(C)$ and RUSLE model also highlight areas that are predicted to be connected but ultimately produce little sediment (see for example Fig. 5d and Fig. 9d). In particular, we find that forested regions of the watershed north of Whitaker Branch are predicted to be connected (Fig. 5d), yet produce zero or near zero soil loss, implying disconnectivity (Fig. 9d). We attribute this result to particularly rocky soils located throughout the forested hillslopes that increases effective critical shear stress of the soil and reduces potential for soil loss. This result highlights the importance of considering connectivity's magnitude in addition to the extent of connectivity during connectivity simulations (Fryirs, 2013; Bracken et al., 2015; Wohl et al., 2017).

Recent reclamation literature suggests that in addition to detrimentally impacting rainfall and runoff infiltration processes, excessive compaction of reclaimed soils reduces rates of native tree growth and promotes growth of short-rooted grasses (Acton et al., 2011). Our spatially explicit results highlight that connectivity occurs frequently and soil loss rates are greatest within the reclaimed mine. Angel et al. (2005) has suggested that one strategy to improve soil stabilization and regrowth of native trees on reclaimed mines is to compact soils and leave approximately 1 m of relatively loose spoil on top of compacted surface, now known as the Forestry Reclamation Approach (FRA; Williamson and Barton, 2020). This method limits mass wasting and recreates soil conditions akin to forested land uses. Related to the results herein, we suggest that this method likely decreases sediment connectivity and soil loss in the reclaimed mine because reestablishment of native trees and recreation of surface microtopography increases interception and infiltration of precipitation and runoff.

We plotted event soil loss against probability of connectivity results (see Fig. 10) and noticed a positive linear trend for both the forest ($R^2 = 0.95$) and reclaimed mine ($R^2 = 0.55$), implying a strong relationship exists between connectivity and soil loss. Relationships between soil loss and connectivity in the forest and reclaimed mine show trends of self-similarity, which implies that in steep watersheds, probability of connectivity might be a predictor of normalized soil loss based on land use.

Our results that *P(C)* is a good predictor of sediment yield agrees with findings from Vigiak et al., (2012) who found that calibrated hillslope sediment delivery ratio (HSDR), a function of the Index of Connectivity (Borselli et al., 2008), was well correlated with specific sediment yield. Vigiak et al., (2012) linked HSDR and IC and found HSDR predicted specific sediment yield well.

However, it is noteworthy that this result contrasts findings from Mahoney et al., (2018) and Mahoney et al., (2020a,b) where probability of connectivity was poorly related to soil loss and sediment yield ($R^2 = 0.26$ and $R^2 = 0.007$, respectively). This is because connectivity simulations presented in Mahoney et al., (2018, 2020a,b) were conducted in the much flatter Upper South Elkhorn watershed. We find that subprocesses controlling connectivity vary in the Whitaker Branch and Upper South Elkhorn watershed. Specifically, in the Whitaker Branch watershed, the probability of hydrologic detachment, $P(D_H)$, a function of runoff depth and slope, controls $P(C)$ results. Variability of soil loss (A), as determined by RUSLE, is also largely a function of event rainfall and runoff, which may explain the good relationship. This contrasts the Upper South Elkhorn where $P(C)$ is largely controlled by $P(T_{H-Up})$, which implies that such self-similarity is only realized in certain systems with very steep slopes where rill and gully development does not control sediment transport.

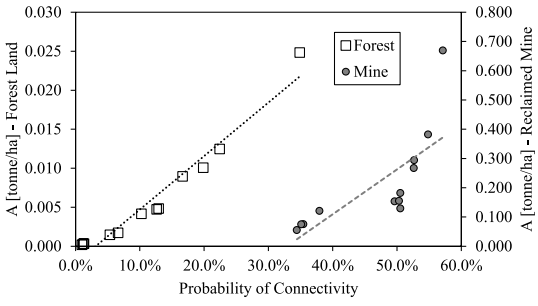

Fig. 10. Soil loss for land uses versus probability of connectivity results.

5. Conclusion

The conclusions of this study are as follows:

(1) The coupled probability of connectivity and RUSLE model simulates sediment transport on forested and reclaimed mine hillslopes well. However, unforeseen dependencies between connectivity formulae and RUSLE need to be accounted for. For example, the *P* factor in RUSLE was codependent with $P(C)$, and the *P* factor needed to be held at unity to account for dependence when coupling the models. We suggest future coupled models of connectivity and RUSLE should consider incorporating feedback calibration schemes, as was carried out in this study, to resolve potential overlap and discrepancies between connectivity modelling and RUSLE modelling.

(2) The coupled *P(C)* and RUSLE model tended to predict sediment transport well in this system. That being said, the *P(C)* model treats deposition in a rather implicit manner (i.e., parameterization of buffers through field assessment; a flatter downstream gradient classifying a given cell as disconnected), rather than an explicitly including a deposition formula in each cell of the upland model. Per our analyses of the Rouse number, this treatment is justified for the conditions of this study. However, explicit treatment of deposition could be improved upon in our sediment connectivity formula, and this has been an area of research for our group.

(3) Our understanding of sediment transport on steep hillslopes with forest and mining land uses was advanced because an unforeseen impact of legacy terracing controlled both sediment connectivity and soil loss. Legacy terracing following historic deforestation in forested land and subsequent surface mining activities in the reclaimed minelands created disconnectivity throughout the basin. Disconnectivity was also predicted to occur because of soil macropores and the high sand content of soils that increase infiltration rates in forested land, and because of constructed berms between compacted spoil lifts on reclaimed mine surfaces. Results show, on average, 12% of the drainage area of Appalachian forests was connected during hydrologic events and 47% of the drainage area of reclaimed minelands was connected. Connectivity was prevalent in concentrated flow paths in both land types.

(4) Structural control tended to dominate connectivity in this study, and soil loss and connectivity are self-similar. The structural control results are contrary to the notion that functional (dynamic) processes control sediment connectivity in all landscapes. Summarizing in the context of other published studies suggests structural control dominates connectivity for steep basins with

high runoff, and functional connectivity becomes more-and-more controlling for lower gradient basins, well-drained landscapes, or low to moderate hydrologic events. Self-similarity between soil loss and connectivity implies that in steep watersheds, probability of connectivity might be a predictor of normalized soil loss based on land use. This topic remains somewhat open because one recent study agrees with our findings but others suggest the probability of connectivity can be poorly correlated with soil loss and sediment yield in some basins.

(5) The soil loss rates of the reclaimed mine are approximately 30 times greater than the forest land despite the fact that the reclamation is classified as phase 3. Soil loss rates that consider spatially explicit connectivity are, on average, an order of magnitude higher in the forested land use and double in the reclaimed mine compared to analyses that assume lumped contributions from land uses. From a management perspective, spatially explicit results highlight pathways that should be targeted for remediation. Reforestation has been promoted in the region, and this study supports the idea that reforestation will likely decrease sediment connectivity and soil loss in the reclaimed mine because reestablishment of native trees and recreation of surface microtopography increases interception and infiltration of precipitation and runoff.

Suspended Sediment Delivery to Puget Sound in the Lower Nisqually River, Western Washington, July 2010–November 2011

By Christopher A. Curran, Eric E. Grossman, Christopher S. Magirl, and James R. Foreman

Abstract

On average, the Nisqually River delivers about 100,000 metric tons per year (t/yr) of suspended sediment to Puget Sound, western Washington, a small proportion of the estimated 1,200,000 metric tons (t) of sediment reported to flow in the upper Nisqually River that drains the glaciated, recurrently active Mount Rainier stratovolcano. Most of the upper Nisqually River sediment load is trapped in Alder Lake, a reservoir completed in 1945. For water year 2011 (October 1, 2010–September 30, 2011), daily sediment and continuous turbidity data were used to determine that 106,000 t of suspended sediment were delivered to Puget Sound, and 36 percent of this load occurred in 2 days during a typical winter storm. Of the total suspended-sediment load delivered to Puget Sound in the water year 2011, 47 percent was sand (particle size >0.063 millimeters), and the remainder (53 percent) was silt and clay. A sediment-transport curve developed from suspended-sediment samples collected from July 2010 to November 2011 agreed closely with a curve derived in 1973 using similar data-collection methods, indicating that similar sediment-transport conditions exist. The median annual suspended-sediment load of 73,000 t (water years 1980–2014) is substantially less than the average load, and the correlation (Pearson's $r = 0.80$, $p = 8.1E\text{-}9$, $n=35$) between annual maximum 2-day sediment loads and normalized peak discharges for the period indicates the importance of wet years and associated peak discharges of the lower Nisqually River for sediment delivery to Puget Sound. The magnitude of peak discharges in the lower Nisqually River generally is suppressed by flow regulation, and relative to other free-flowing, glacier-influenced rivers entering Puget Sound, the Nisqually River delivers proportionally less sediment because of upstream sediment trapping from dams.

Introduction

Fluvial sediment delivery is fundamental to the formation of river deltas that support critical estuarine habitat for fish and ecosystem development and in Puget Sound can both benefit and threaten estuarine ecosystems (Czuba and others, 2011). Understanding the rate of sediment delivery in rivers entering Puget Sound is important in the assessment of the resiliency of nearshore ecosystems threatened by sea level rise and for predicting the efficacy of present and future nearshore restoration efforts (Cereghino and others, 2012).

The Nisqually River flows into southern Puget Sound providing important riverine and estuarine ecological function. Because of Tribal and Federal land holdings, much of the lower Nisqually River near Puget Sound contains a still-functioning riparian floodplain (Collins and others, 2012), and a major restoration project was completed in 2009 on the Nisqually River Delta to further improve the ecological health of the lower river corridor (U.S. Fish and Wildlife Service, 2010). Compared to other rivers entering Puget Sound (Czuba and others, 2011), the lower Nisqually River carries a relatively light sediment load because of substantial sediment accumulation in Alder Lake, a reservoir upstream of the 101-m-high Alder Dam, completed in 1945. Before 1945, the natural sediment load in the lower Nisqually River likely was suppressed by the predecessor to Alder Dam, the 11-m-high La Grande Dam completed in 1912 (Czuba and others, 2012a). In contrast, the sediment load in the Nisqually River upstream of Alder Lake is relatively large because of sediment generated from Mount Rainier (Czuba and others, 2012a).

Numerous geologic and sediment-transport studies have described the formative fluvial geomorphology of the Nisqually River or estimated the sediment load in the river and its tributaries. Nelson (1974) published a study of sediment measurements in the Nisqually and Deschutes River Basins, sampling suspended sediment from 1971 to 1972 at 16 sites. Downstream of Alder Lake, Nelson (1974) reported sediment loads of 95,000 t/yr for the Nisqually River at Nisqually and 91,000 t/yr for the Nisqually River above Powell Creek, near McKenna. Nelson (1974) also reported that mountainous catchments away from Mount Rainier produce a sediment yield at least one order of magnitude less than rivers directly draining Mount Rainier, and that catchments draining the Puget Lowland typically yield sediment at rates of about two orders of magnitude less than rivers draining Mount Rainier.

Based on bathymetric measurements of sediment accumulation in Alder Lake, Czuba and others (2012b) reported sediment yield similar to that of Nelson (1974) for the Nisqually River upstream of Alder Lake. Czuba and others (2012b) determined that from 1945 to 2011, the upper Nisqually River carried, on average, 1,200,000 ±180,000 t/yr of sediment and reported that 83–98 percent of this sediment load into Alder Lake originated from Mount Rainier. Czuba and others (2012b) also estimated that the trap efficiency of Alder Lake was 90 ±5 percent and that the long-term mean sediment load transported past Alder Dam was 120,000 ±18,000 t/yr. Using historical bathymetric surveys of Alder Lake, Czuba and others (2012b) reported that the average sediment load in the upper Nisqually River was just 860,000 ±300,000 t/yr from 1956 to 1985, indicating that sediment loads from Mount Rainier from 1956 to 1985 were less than the long-term average. This observation is notable because sediment sampled in 1971 and 1972 (Nelson, 1974) may have reflected sediment-transport conditions less in magnitude than the long-term mean.

Purpose and Scope

This report documents the timing and quantity of suspended-sediment load delivered by the Nisqually River to Puget Sound for July 25, 2010–November 30, 2011, which includes water year 2011 (October 1, 2010–September 30, 2011), for use in conjunction with nearshore circulation models to assess the sedimentation potential and efficacy of restoration efforts in the Nisqually River Delta. Sediment data collected in this study were used to develop sediment rating curves for estimating suspended-sediment load as a function of discharge and suspended-sediment concentration as a function of turbidity. Comparisons with a previous, similar study (Nelson, 1974) were made to assess differences in sediment-transport conditions and to estimate the mean annual suspended-sediment load delivered by the river to Puget Sound. Hydrology for the lower Nisqually River is examined from the long-term record of U.S. Geological Survey (USGS) streamgages in the basin and is used to provide a hydrologic context for the results of 2011 sediment loads. Turbidity is used as a surrogate measurement for suspended-sediment concentration (SSC) and, with sediment sample data, is used for assessing seasonal characteristics of sediment transport. This report includes the results of sediment-sample concentrations and particle size, and continuous turbidity data collected from July 2010 to November 2011.

Description of the Nisqually River Basin and Study Site

The Nisqually River is in the southeastern region of Puget Sound, a marine water body in western Washington formed as a result of Pleistocene glaciation (fig. 1; Booth, 1994; Porter and Swanson, 1998). The Nisqually River drains the Cascade Range, a part of the Puget Lowland, and the southwestern flank of Mount Rainier, a 4,392-m glaciated, recurrently active volcano (Crandell, 1971; Nelson, 1974; Sisson and Vallance, 2008; Czuba and others, 2012b). The Nisqually River formed after the retreat of the Puget Lobe of the Cordilleran Ice Sheet from the Puget Lowland about 16,000–17,000 years ago (Porter and Swanson, 1998). In establishing its late-Pleistocene course toward Puget Sound, the river incised into glacial till deposits (Collins and Montgomery, 2011) with a slope adequate to convey the large sediment loads originating from Mount Rainier. Active volcanism at Mount Rainier during the Holocene (Crandell, 1971; Scott and others, 1995; Sisson and Vallance, 2008) spawned multiple lahars, some large enough to travel to Puget Sound (Scott and others, 1995). Large-scale volcanism and associated increased sedimentation has not occurred on Mount Rainier in the past 150 years, but rainfall-induced debris flows from Mount Rainier and large floods have promoted ample sediment transport filling a portion of Alder Lake (Czuba and others, 2012b). The lower 5 km of the Nisqually River and its estuary occupy a former marine embayment of Puget Sound, acting as a Holocene sediment deposition zone; the river delta is the product of sediment deposition from the Nisqually River during the Holocene (Collins and Montgomery, 2011).

Discharge in the lower Nisqually River is regulated by the 100-m-high Alder Dam and smaller La Grande Dam, each owned and operated by Tacoma Power for flood control and hydroelectric power generation. The three primary tributaries draining Mount Rainier in the Nisqually River Basin are the mainstem Nisqually River, Kautz Creek, and Tahoma Creek. Major tributaries Mineral Creek and the Little Nisqually River enter upstream of Alder Dam and drain the Cascade Range away from Mount Rainier. Downstream of Alder Dam, the Mashel River is the only sizeable Nisqually River tributary draining mountainous terrain. Tributaries Ohop, Tanwax, and Muck Creeks all enter downstream of the Mashel River, but these tributaries drain predominantly the low-gradient Puget Lowland and sediment loads in these tributaries are relatively small (Nelson, 1974).

Figure 1. U.S. Geological Survey streamgages and sediment-monitoring site in the Nisqually River Basin, western Washington.

The climate of the Nisqually River Basin is predominantly wet and temperate (National Oceanic and Atmospheric Administration, 2010). The prevailing wind direction is from the south or southwest during the rainy season (October–June) and from the northwest during the relatively dry summer from July to September. During the winter, cold air from the Canadian interior occasionally flows southward, covering the region. The average January maximum temperature in the Puget Lowland is about 6 °C (43 °F) and the minimum temperature is about -1 °C (30 °F). During July, the average maximum temperature is about 24 °C (75 °F) and the average minimum temperature is about 10 °C (50 °F). Annual precipitation in the Puget Lowlands is about 1,000 mm (40 in.), and the winter season snowfall is about 380 mm (15 in.). Precipitation increases with altitude; annual rainfall in the Cascade Range in high-altitude catchments typically is 1,550–2,500 mm (60–100 in.), and total annual snowfall is between 10 and 15 m (400–600 in.) at altitudes of 1,200–1,600 m (4,000–5,500 ft) (National Oceanic and Atmospheric Administration, 2010).

Basin Hydrology

Mean annual discharge for the Nisqually River near National (USGS streamgage 12082500) is 22.0 m^3/s (777 ft^3/s) for the period of 1943–2014 (72 years), with dominant hydrologic inputs from rainfall in winter and snowmelt in spring and summer (table 1). Downstream of Alder Lake, the mean annual discharge for the Nisqually River at McKenna (USGS streamgage 12089500) is 36.9 m^3/s (1,301 ft^3/s). Late summer and autumn discharge is sustained by groundwater and glacial melt from Mount Rainier. The largest peak-flow events in the basin are caused by heavy autumn or winter precipitation associated with atmospheric rivers, strong synoptic systems from the Pacific Ocean that tap into tropical moisture sources (Neiman and others, 2011).

In the upper basin, the largest recorded peak discharge occurred in November 2006 during a large atmospheric river that caused widespread damage to Mount Rainier National Park (Czuba and others, 2012b). The peak discharge in the upper basin (Nisqually River near National, USGS streamgage 12082500) during the November 2006 event was 617 m^3/s (21,800 ft^3/s). Widespread flooding also affected the region in February 1996 when discharge peaked at 600 m^3/s (21,200 ft^3/s) on the Nisqually River near National. Smaller peak-flow events in the upper basin usually occur in late spring and early summer with the seasonal snowmelt. The lower basin is regulated by Alder Dam (constructed in 1945), which strongly affects the peak-flow hydrology. Although the February 1996 storm resulted in the peak discharge of record for the Nisqually River at McKenna (USGS streamgage 12089500) of 1,420 m^3/s (50,000 ft^3/s), the 2006 peak discharge was more tightly controlled by regulation at Alder Dam and resulted in a discharge of 436 m^3/s (15,400 ft^3/s). Hydrologic data at USGS streamgages typically are reported by water year, which is defined as the 12-month period October 1, for any given year through September 30, of the following year.

Sediment-Monitoring Site

The USGS sediment-monitoring site installed as part of this study, the Nisqually River near Yelm (site 12089970), is in the lower Nisqually River, 19.2 km upstream of the river mouth, 1.6 km downstream of the Centralia Power Canal outlet, and 15.8 km downstream of USGS streamgage Nisqually River at McKenna (12089500) (fig. 1). The lower Nisqually River is defined herein as the reach downstream of the outlet of the Centralia Power Canal about 20.8 km upstream of the mouth of the river at Puget Sound. The mixed-diurnal tidal influence in the lower river extends to about 5 km upstream of the mouth. The largest tributary in the lower river, Muck Creek, is 1.5 km downstream of the sediment-monitoring site, and remains a potential sediment source not included in this study. The drainage area of the basin at the sediment monitoring site is 1,520 km^2, and 50 percent of this area is upstream of the Alder and La Grande Dams.

Table 1. Summary of discharge at U.S. Geological Survey streamgages and a sediment-monitoring site in the Nisqually River Basin, western Washington.

[Mean annual discharge and discharge data for water years 1973 and 2011 are available at http://waterdata.usgs.gov/wa/nwis/sw. Water year is defined as the 12-month period October 1, for any given year through September 30, of the following year. **Abbreviations:** km^2, square kilometer; m^3/s, cubic meter per second]

[1]Discharge affected by regulation or diversion.

[2]Calculated from available discharge data.

[3]Estimated from the sum of discharge at streamgages 12089208 and 12089500 with consideration for time of travel.

Methods of Data Collection and Analysis

Discharge

A 15-minute time series of discharge, required for calculating suspended-sediment loads, was estimated for the sediment-monitoring site Nisqually River near Yelm (site 12089970) from the summation of instantaneous (15-minute) discharge records at Nisqually River at McKenna (streamgage 12089500; http://waterdata.usgs.gov/nwis/uv?site_no=12089500), 15.8 km upstream of the monitoring site, and Centralia Power Canal near McKenna (streamgage 12089208; http://waterdata.usgs.gov/wa/nwis/uv/?site_no=12089208), 23 km upstream of and where water is diverted from the main Nisqually River into the canal (fig. 1). To account for travel time in discharge between the upstream streamgages and the study site, a mean water velocity of 1.4 m/s was estimated between the streamgages and the study site, and 15-minute discharge records were lagged by 3.25 and 4.5 hours for the records at streamgages 12089500 and 12089208, respectively. To evaluate the accuracy of the estimated record, discharge was measured on site with a tethered boat equipped with an acoustic Doppler current profiler (usually in conjunction with suspended-sediment sample collection) over a range of flow conditions, following methods outlined by Mueller and others (2013). Discharge measurements made on site were compared with the estimated 15-minute discharge record to ensure consistency (table 2) and differences were less than 5 percent.

Suspended Sediment

Suspended-sediment samples were collected at various times over a range of flows at Nisqually River near Yelm (12089970) during water year 2011. The Equal Discharge Increment (EDI) and Equal-Width Increment (EWI) methods (Edwards and Glysson, 1999) were used to collect discrete, cross-section representative samples using depth-integrated, isokinetic samplers (fig. 2*A*) approved by the Federal Interagency Sedimentation Program and used routinely by USGS personnel (Davis, 2005). Additionally, an Isco automated-pump sampler was used to collect daily point samples of suspended sediment. The sampler intake was placed at the edge of the active channel (fig. 2*B*), and the sampler was programmed to collect 200-mL subsamples at 6-hour intervals, which were composited into a single daily 800 mL sample. A cross-section coefficient was used to account for potential bias in sample concentration due to the location of the sampler intake, and computed as the ratio of mean concentration in the cross section (from EDI or EWI samples) to the concentration of pumped samples (Edwards and Glysson, 1999). All samples were analyzed to determine the concentration of suspended sediment and the percentage of sand-size sediment (particles larger than 0.063 mm in size) at the USGS sediment laboratory at the Cascade Volcano Observatory in Vancouver, Washington.

Table 2. Instantaneous discharge measured at U.S. Geological Survey (USGS) sediment-monitoring site (Nisqually River near Yelm, 12089970) in 2010, compared with estimated discharge determined from summation of flows at upstream USGS streamgages (Nisqually River at McKenna, 12089500, and Centralia Power Canal near McKenna, 12089208), Nisqually River Basin, western Washington.

[**Estimated discharge:** Computed as the sum of discharges recorded at Nisqually River near McKenna (12089500) and Centralia Power Canal (12089208), adjusted for travel time. **Abbreviations:** m^3/s, cubic meter per second; m/s, meter per second]

Date	Local time	Discharge (m^3/s)		Percent difference	Measured mean water velocity (m/s)
		Measured	Estimated

Continuous Turbidity

River turbidity was continuously monitored during most of water year 2011 in which sediment sampling was conducted, with the exception of intermittent periods when instrument failure or excessive fouling occurred, and during a 6-week period in January–February when the instrument was lost during a high-flow event. Turbidity was measured using a YSI-6136 turbidity sensor with an optimal range of 0 to 1,000 Nephelometric Turbidity Units (YSI, Inc., 2007). This sensor was housed in a 2-inch steel pipe suspended over the thalweg of the river in a boom-type mount from the downstream bridge rail (fig. 2*C*). This mounting arrangement allowed turbidity measurements in an actively flowing part of the river channel and decreased the likelihood of debris build-up around the sensor face or on the mounting hardware, which could foul sensor readings. Turbidity data were recorded at 15-minute intervals and the sensor was serviced approximately once per month for downloading data and performing cleaning and calibration checks.

Sediment Load Computation

A daily record of suspended-sediment load at the monitoring site (12089970) was determined for water year 2011 based on the suspended-sediment concentration (SSC) of field samples and the discharge record following methods described by Porterfield (1972) and Koltun and others (2006). For periods when Isco samples were not available, turbidity was used as a surrogate for SSC. A regression was developed between SSC from cross-section samples and concurrently measured turbidity following methods outlined by Rasmussen and others (2009). A 15-minute time series of SSC was computed by applying the regression equation with 15-minute turbidity data and, for consistency with the daily time-step of the Isco sampler, daily mean suspended-sediment concentrations were determined. For periods when neither turbidity data nor pump sampler data were available, SSC was computed from discharge at the sediment-monitoring site (12089970) using a regression equation developed for this purpose.

Suspended Sediment Delivery

Discharge in Water Year 2011

Mean discharge at Nisqually River near National (streamgage 12082500) was 30 percent greater than average (28.6 m^3/s [1,010 ft^3/s]) in water year 2011, and at Nisqually River at La Grande (12086500), mean discharge was 31 percent greater than average (53.5 m^3/s [1,890 ft^3/s]). Farther downstream at Nisqually River at McKenna (streamgage 12089500), which includes discharge from Mashel and Ohop Creeks, mean discharge was 42 percent greater than average (52.3 m^3/s [1,850 ft^3/s]) in water year 2011 and, for water diverted around the McKenna streamgage through the Centralia Power Canal, it was near average (15.2 m^3/s [537 ft^3/s]). Seasonally, discharge in the Nisqually River upstream and downstream of reservoirs was greater than average for most months in water year 2011, except for February, when discharge was average. Discharge was substantially greater in January (+58–83 percent) and during the typical spring freshet period of April–June (+18–96 percent; fig. 3).

Examination of the hydrographs of daily mean discharge for all Nisqually River streamgages and the sediment-monitoring site in water year 2011, as shown in figure 4, indicates typical seasonal patterns of precipitation-induced discharge peaks and flow regulation (storage and release) from reservoir operations. Regulation of peak discharge was minimal during December and January storms, but for the rest of the year, peak discharges were moderated and did not occur downstream because of water storage behind dams. Discharge recorded at the McKenna streamgage (12089500) was greater than at the La Grande streamgage (12086500), particularly peak discharges, and represents contributions from Ohop and Mashel Creeks. The hydrograph for Nisqually River near Yelm (12089970) is estimated as the sum of daily mean discharges recorded at the McKenna and Centralia Canal streamgages.

In water year 2011, the instantaneous (15-minute) peak discharge at all streamgages in the Nisqually River Basin occurred on January 16, and at the McKenna streamgage (12089500), the instantaneous peak discharge was 346 m^3/s (12,200 ft^3/s) and the corresponding maximum daily mean discharge was 306 m^3/s (10,800 ft^3/s). Although affected by flow regulation, the peak discharge at the McKenna streamgage (12089500) in water year 2011 has occurred on average about once every 2.3 years, as determined from USGS software PEAKFQ (Veilleux and others, 2014) and based on 58 years of record (1948–68, 1978–2014). On average, daily mean discharge at the McKenna streamgage has equaled or exceeded 190 m^3/s (6,700 ft^3/s) three times per water year. In water year 2011, this discharge was exceeded for only 2 days (January17, 2011, for daily discharges of 306 m^3/s [10,800 ft^3/s] and 267 m^3/s [9,430 ft^3/s], respectively), suggesting that in terms of the frequency, the number of substantial discharge events was less than average in water year 2011 (fig. 5).

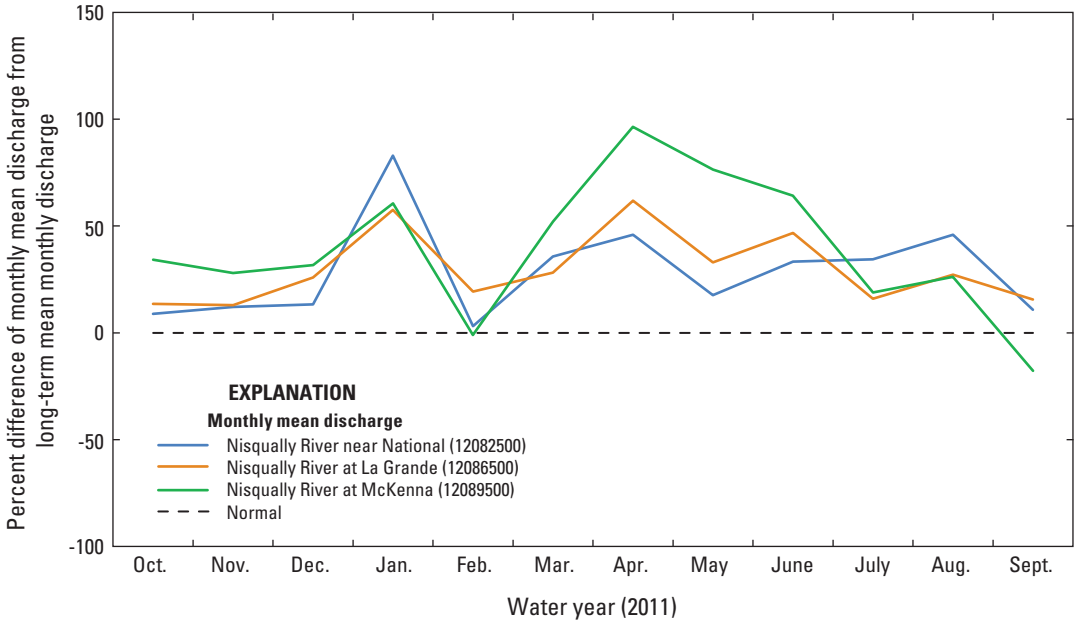

Figure 3. Monthly mean discharges at U.S. Geological Survey streamgages in water year 2011 relative to long-term mean monthly discharges for each streamgage, Nisqually River Basin, western Washington.

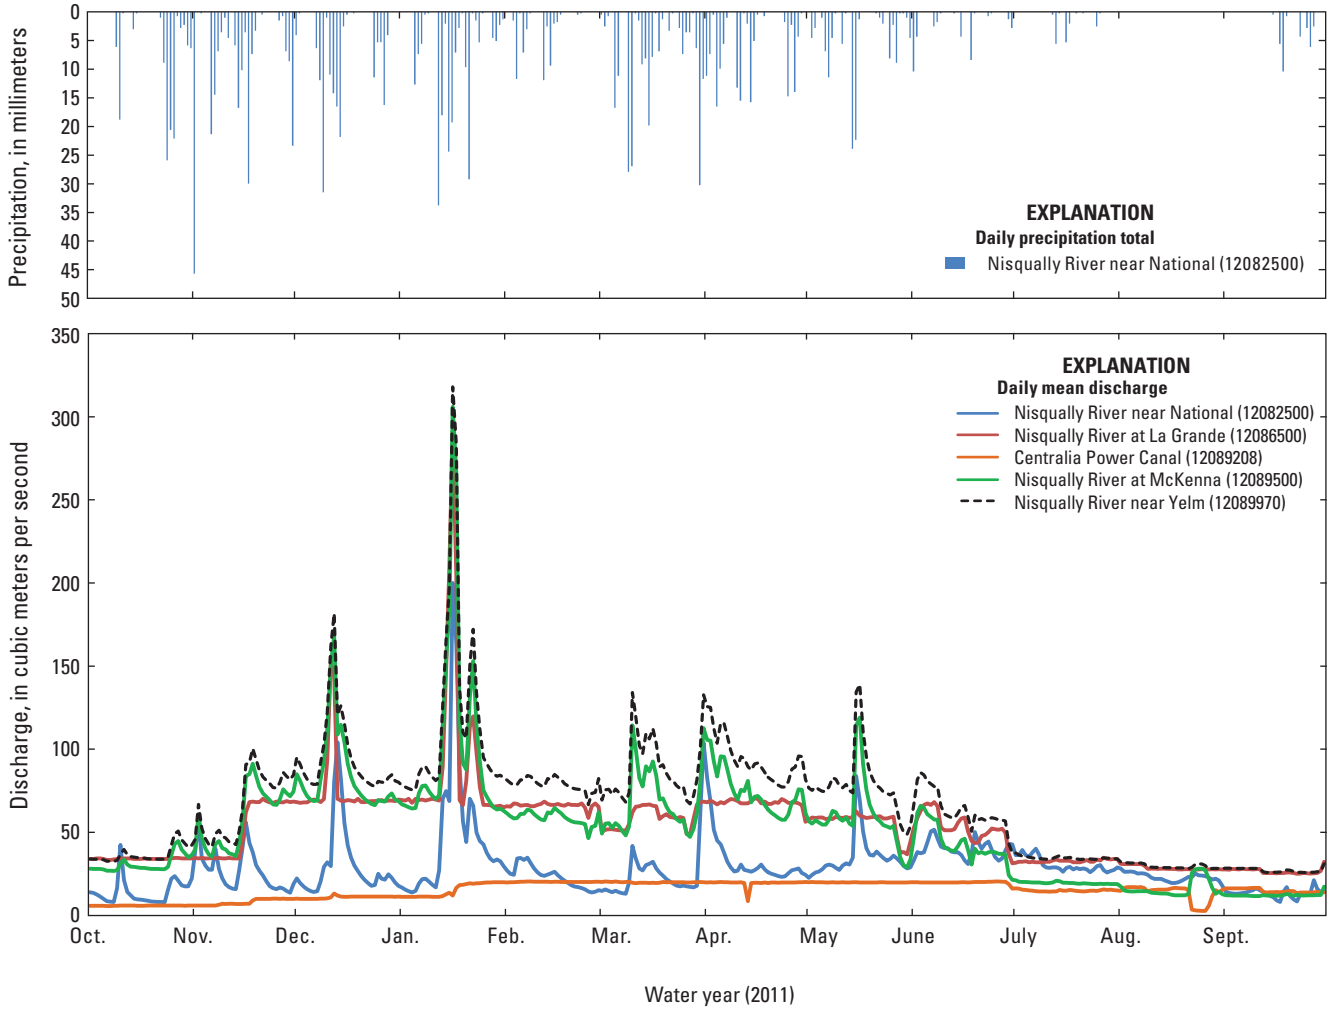

Figure 4. Daily precipitation at U.S. Geological Survey streamgage Nisqually River near National (12082500) and daily mean discharge of the Nisqually River at U.S. Geological Survey streamgages 12082500, 12086500, 12089208, and 12089500, and daily mean discharge estimated at sediment-monitoring site 12089970, Nisqually River Basin, western Washington, water year 2011.

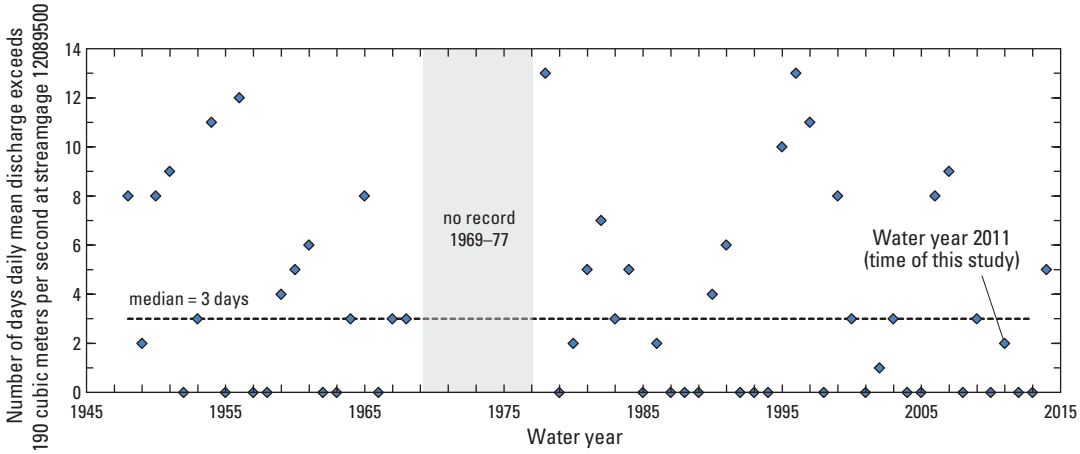

Figure 5. Number of times daily mean discharge exceeded 190 cubic meters per second in a water year (October 1–September 30) based on 57 years of discharge record (1943–68, 1978–2013) at U.S. Geological Survey streamgage Nisqually River at McKenna (12089500), Nisqually River Basin, western Washington.

Turbidity

Although continuous 15-minute turbidity data were recorded for more than 76 percent of the study period (36,175 of 47,448 times), extended time gaps (as much as 38 days) occurred because of sensor fouling, malfunction or power loss, and equipment loss. A tabulation of daily median turbidity data determined from 15-minute data, as well as periods of missing data, is shown in appendix A. A notable time gap in the turbidity record occurred during January 14–February 21, 2011, when the turbidity sensor was lost during a winter storm; this gap included the occurrence of the annual peak discharge on January 16, 2011. The recorded 15-minute turbidity data are tabulated in appendix B, the average turbidity was 14 Formazin Nephelometric Units (FNUs), and values ranged from 0.6 to 320 FNUs.

Suspended Sediment Load in Water Year 2011

From August 24, 2010, to September 30, 2011, suspended-sediment concentrations were obtained from 16 cross-section representative samples collected using EDI or EWI sampling methods and from 167 point samples using an Isco sampler. The EDI and EWI samples were paired with concurrently recorded turbidity (when available), and a regression model was developed for estimating suspended-sediment concentration from turbidity (fig. 6). Daily suspended-sediment concentrations were computed at USGS sediment-monitoring site Nisqually River near Yelm (12089970) during July 25, 2010–November 30, 2011 (fig. 7*C*) based on a combination of daily Isco samples (fig. 7*B*) and the continuous turbidity record when daily Isco samples were not available. Isco sample SSCs were 1.4 to 4.4 times higher than concurrent EDI/EWI samples and this bias, caused by the location of the sampler intake in the cross-section, decreased with increasing SSC and discharge. In lieu of a single cross-section correction factor, a linear regression (appendix C) relating the SSC of Isco samples to concurrent EWI samples was used to correct for bias in Isco sample SSC. For days when neither Isco sample data nor turbidity data were available, SSC was estimated from discharge (appendix D); during the water year 2011, this occurred on 29 days: October 1–8, 2010, February 8–9, March 6-7, June 26, 29, July 2, August 2–3 September 5, 2011.

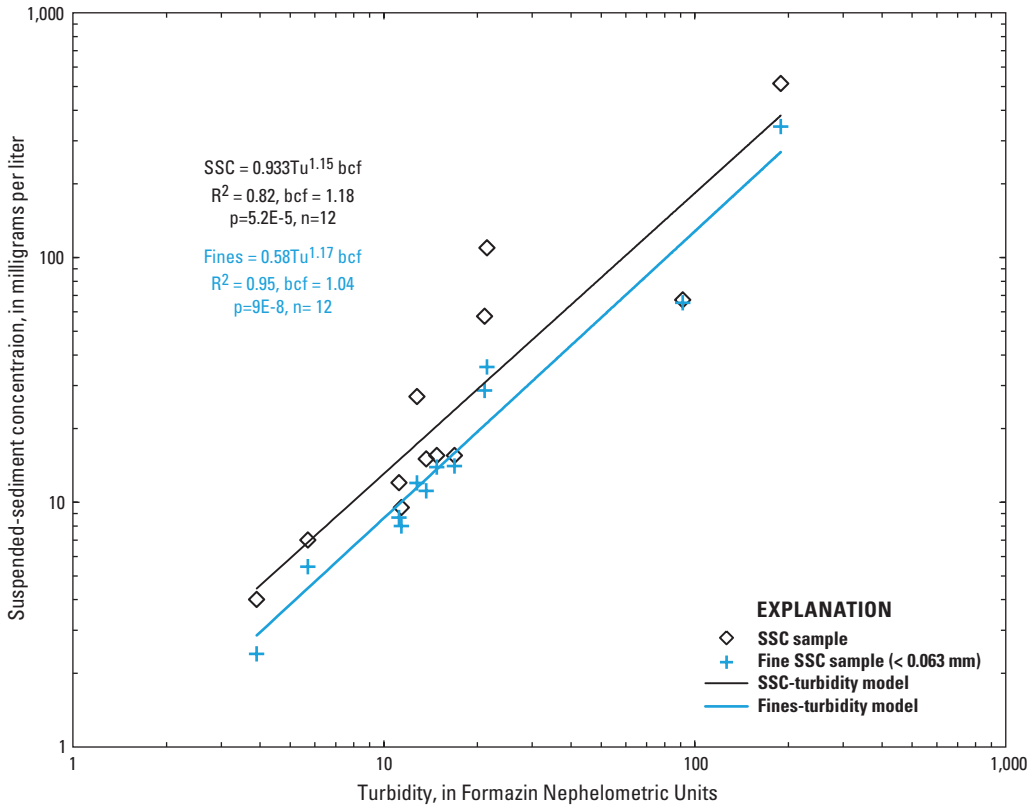

Figure 6. Regression models for estimating suspended-sediment concentration (SSC) and fine suspended-sediment concentration (fines, size less than 0.063 millimeters) from turbidity (YSI-6136 turbidity sensor) at the Nisqually River near Yelm (site 12089970), western Washington.

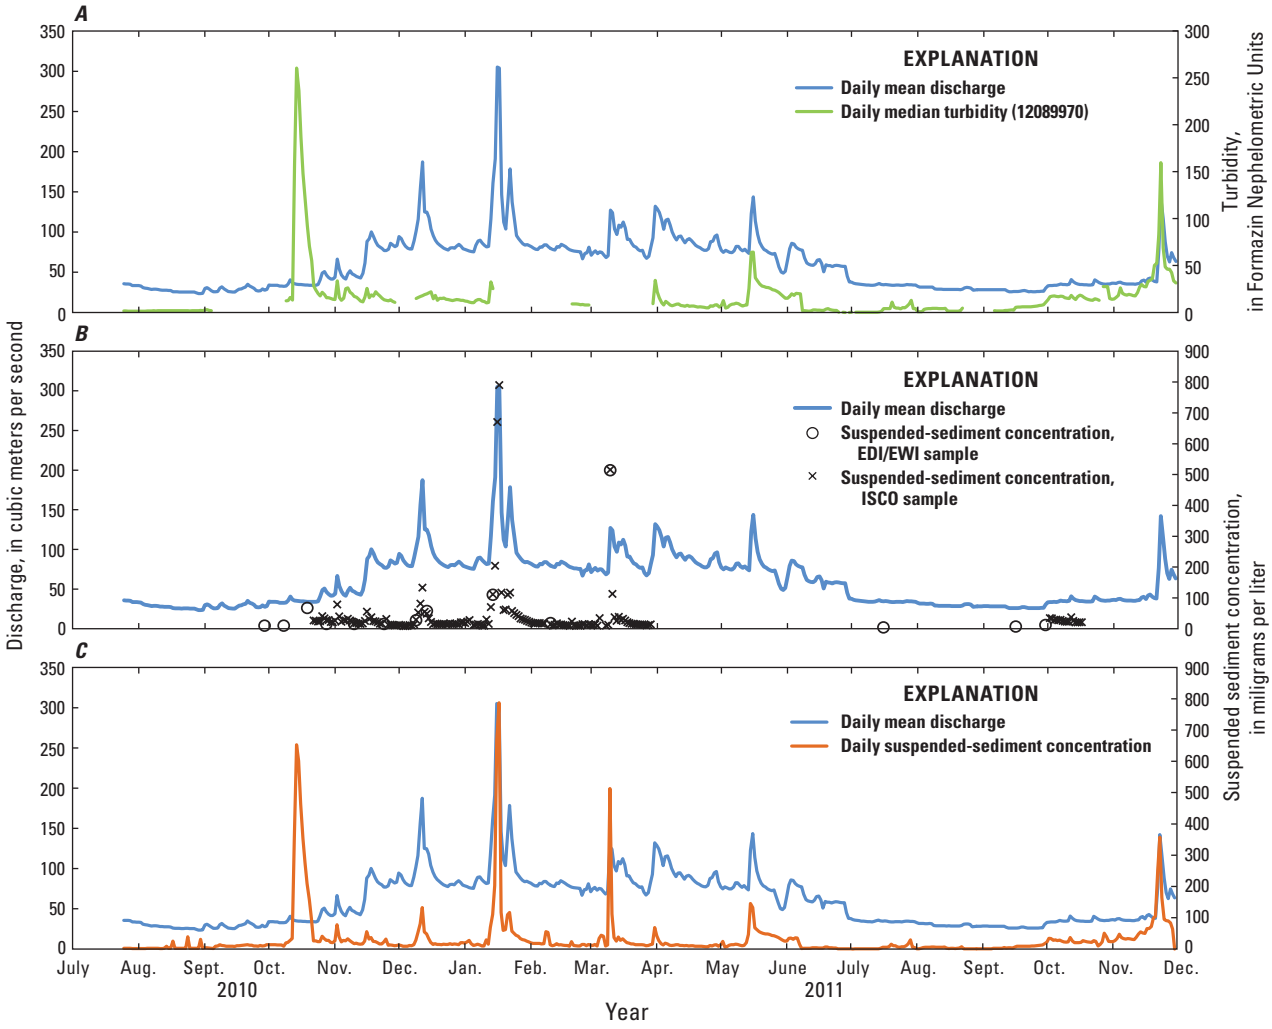

Figure 7. Daily suspended-sediment concentrations as determined from field samples and continuous turbidity, and discharge at Nisqually River near Yelm (site 12089970), western Washington, August 1, 2010–November 30, 2011.

The daily SSC for the monitoring period ranged from 1 to 787 mg/L; the average daily SSC was 33 mg/L and the median daily SSC was 13 mg/L. The maximum daily SSC was derived from Isco samples collected during a winter storm on January 17, 2011, for which the daily suspended-sediment load was 20,700 t. From October 13 to 19, 2010, a turbidity event occurred during seasonally low flows and is attributed to the release of turbid water from Alder Reservoir to maintain instream flows; the maximum daily SSC for this period was 651 mg/L on October 14, 2010. The suspended-sediment concentrations for discrete samples collected using the EDI or EWI methods are shown in table 3.

Daily suspended-sediment loads computed at sediment-monitoring site (Nisqually River near Yelm,12089970) for water year 2011 are shown in figure 8. The computed annual load of 104,000 t does not include the contribution from Muck Creek. Suspended-sediment load for Muck Creek is estimated at 2,000 t in water year 2011 based on the previous calculation by Nelson (1974) of 1,500 t/yr and a discharge weighting factor of 1.3 (to reflect the observed 30 percent greater than normal discharge) for the water year 2011. Thus, total suspended-sediment delivery from Nisqually River to Puget Sound for water year 2011 is 106,000 t. Of this suspended-sediment load, 36 percent (38,300 t) was generated in 2 days (January 16–17) during a typical winter storm. Of the total suspended-sediment load calculated for the water year 2011, 47 percent was sand (particle size >0.063 mm) and the remainder (53 percent) was silt and clay.

Table 3. Suspended-sediment sample data from cross-section representative samples collected at USGS sediment-monitoring site (Nisqually River near Yelm, 12089970), western Washington, 2010–11.

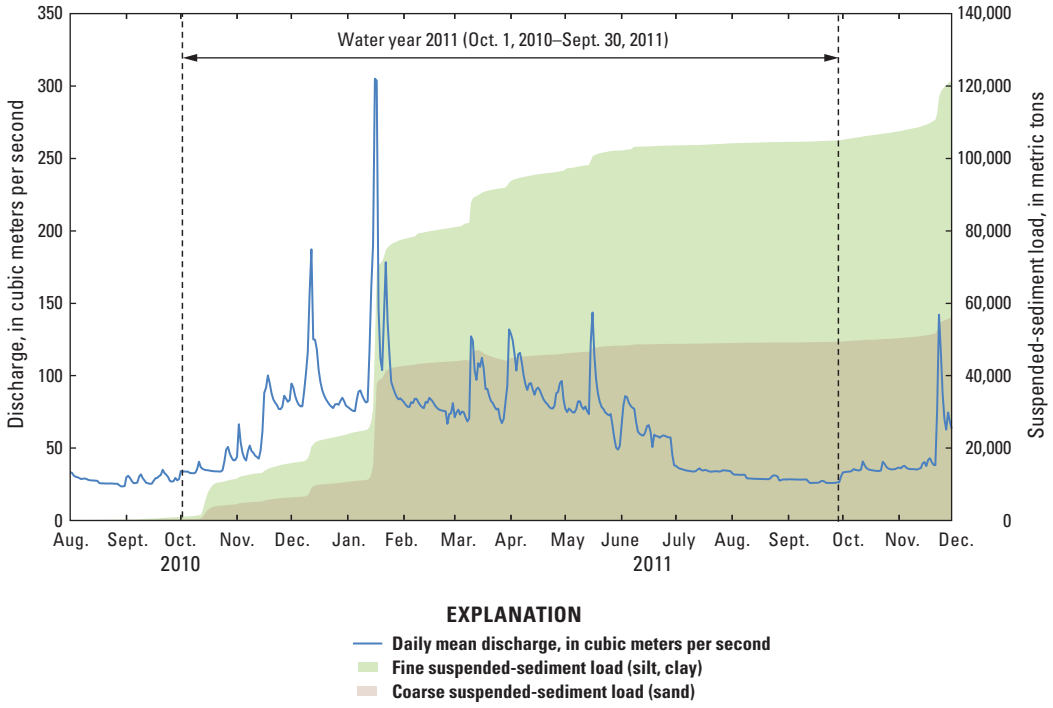

Figure 8. Discharge and cumulative suspended-sediment load calculated for sediment-monitoring site (Nisqually River near Yelm, 12089970), western Washington, water year 2011.

Comparison with Previous Estimates of Suspended-Sediment Load

The concentrations of EDI and EWI samples collected in this study (table 3) were used with concurrently measured or estimated discharge to develop by regression a sediment-rating curve for estimating suspended-sediment load as a function of discharge. A similar curve was developed using suspended-sediment concentrations and discharges reported graphically by Nelson (1974) and shown in table 4. Because regression models defining each curve were similar, the data were combined to develop a single sediment-rating curve (fig. 9) for the purpose of estimating suspended-sediment load at the sediment-monitoring site (Nisqually River near Yelm, 12089970). The model that defines the sediment-rating curve is:

$$L_s = 0.00199Q^{2.68}bcf \quad (1)$$

where

L_s is the suspended-sediment load in metric tons per day (t/d), and

Q is the discharge in cubic meters per second, and *bcf* is the bias correction factor equal to 1.17.

The coefficient of determination for the model (R^2) is 0.85, the p-value is 6.7E-13, and the number of observations is 30. Bias correction for the model output, required as a result of log-transforming regression variables and model uncertainty (Helsel and Hirsch, 1992; Rasmussen and others, 2009) was calculated using a parametric method (Ferguson, 1986) described in Helsel and Hirsch (1992).

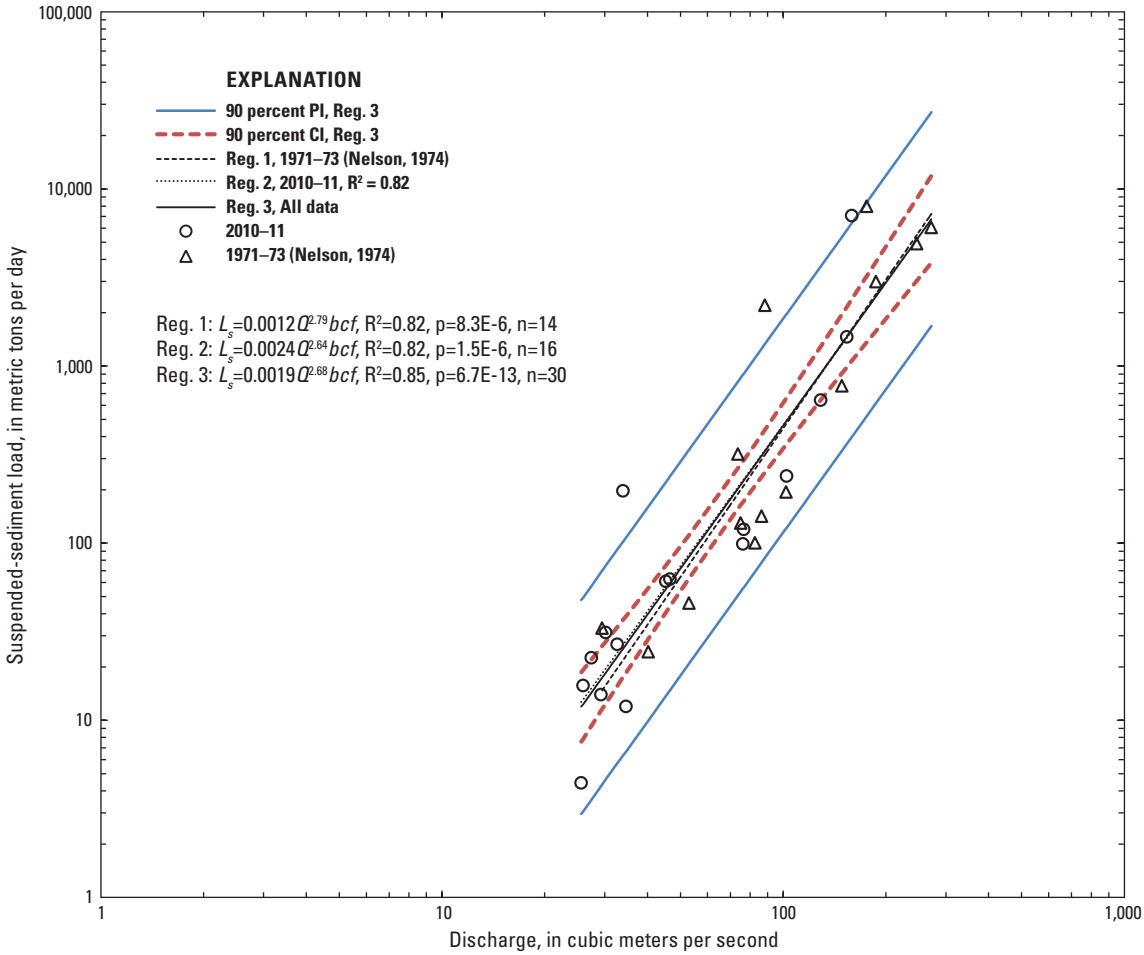

Figure 9. Regression model for estimating suspended-sediment load (L_s) from river discharge (Q) at sediment-monitoring site (Nisqually River near Yelm, 12089970), western Washington. Model was based on combined sediment data from this study and Nelson (1974) (Reg., regression model; PI, prediction interval for individual estimates; CI, confidence interval for the regression mean; *bcf*, bias-correction factor equal to 1.17; R^2, coefficient of determination; p, p-value; n, number of observations).

Table 4. Suspended-sediment concentrations and discharges reported by Nelson (1974) for samples collected at the Nisqually River near Nisqually, Washington, 1971–73, and computed suspended-sediment load used in developing a sediment-rating curve.

[**Abbreviations:** mg/L, milligram per liter; m^3/s, cubic meter per second; t, metric ton]

Sample No.	Suspended-sediment concentration (mg/L)	Water discharge (m^3/s)	Suspended-sediment load per day (t)
1	534	176	8,120
2	288	88.4	2,200
3	257	272	6,040
4	230	246	4,900
5	185	187	2,990
6	60	149	771
7	50	73.7	318
8	22	102	194
9	20	75.1	130
10	19	86.4	142
11	14	82.7	100
12	13	29.5	33
13	10	53.0	46
14	7	40.2	24

Using the combined sediment-rating curve (n=30) for the sediment-monitoring site (Nisqually River at Yelm, 12089970) and an estimated annual suspended-sediment contribution of 1,500 t from Muck Creek, average annual suspended-sediment load delivered by the lower Nisqually River to Puget Sound is estimated at 99,000 t/yr, with an uncertainty range of -37 to +54 percent (62,000–152,000 t/yr) at 90 percent confidence. This estimate is based on the combined record of daily discharges from water years 1980–2014 at McKenna (12089500) and the Centralia Power Canal (12089208) when discharges at both streamgages were reported (fig. 10; http://waterdata.usgs.gov/wa/nwis/sw). For comparison, the sediment-rating curve applied in water year 2011 resulted in an annual sediment load of 119,000 t, or 14 percent more than the load derived from the combined turbidity and Isco sample data in water year 2011.

The maximum annual suspended-sediment load for water years1980–2014 was estimated at 580,000 t for water year 1996, and the maximum 2-day total for this year was 250,000 t. The median annual load of 73,000 t is substantially less than the average (99,000 t), and the correlation (Pearson's $r = 0.80$, $p = 8.1E\text{-}9$, $n = 35$) between annual maximum 2-day sediment loads and normalized peak discharges for the period (water years 1980–2014; fig. 10) indicates the importance of wet years and associated peak discharges of the lower Nisqually River for sediment delivery to Puget Sound.

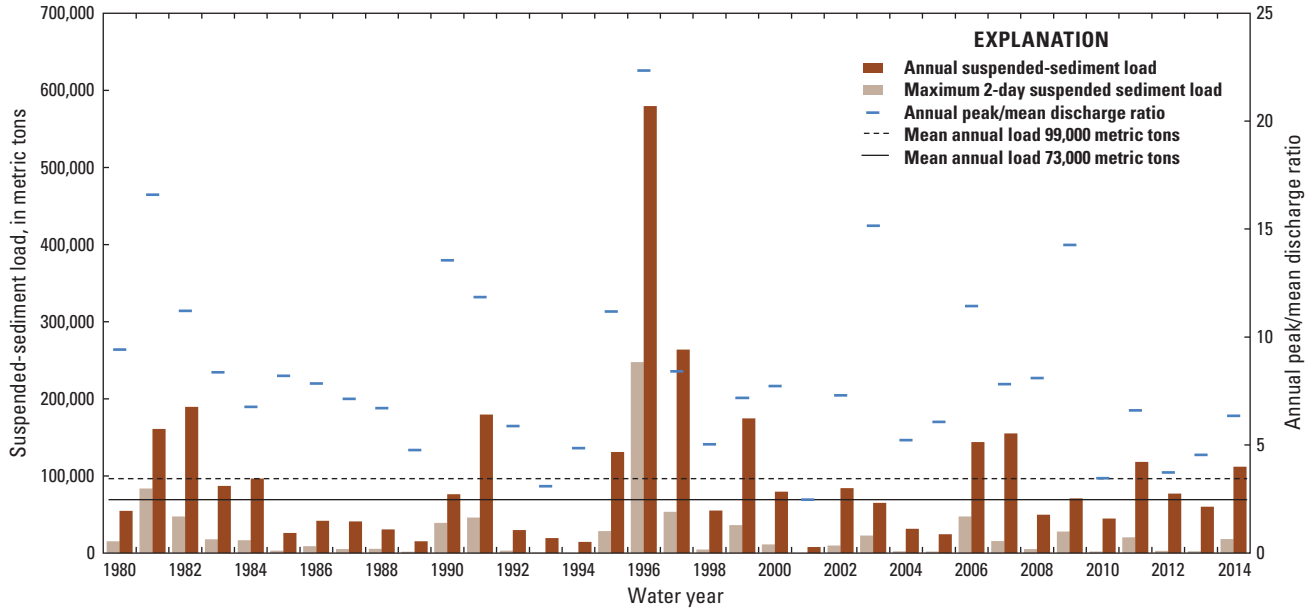

Figure 10. Annual and maximum 2-day totals of suspended-sediment load at sediment-monitoring site Nisqually River near Yelm (12089970), and the ratio of annual peak discharge to annual mean discharge at streamgage Nisqually River at McKenna (12089500), western Washington, water years 1980–2014.

Summary

This report documents the timing and quantity of suspended-sediment load delivered by the Nisqually River to Puget Sound in water year 2011 (October 1, 2010–September 30, 2011), for use in conjunction with nearshore circulation models to assess the sedimentation potential and efficacy of restoration efforts in the Nisqually River Delta. For water year 2011, daily sediment and continuous turbidity data were used to determine that 106,000 metric tons (t) of suspended sediment was delivered to Puget Sound (104,000 t at Nisqually River near Yelm, Washington, and an estimated 2,000 t from Muck Creek), and 36 percent of this load occurred in 2 days of a typical winter storm. Mean discharge in the Nisqually River upstream and downstream of reservoirs was about 30 percent greater than average, and monthly mean discharge was greater than average for all months except February, which was average. The magnitude of peak discharges in the lower Nisqually River generally is dampened by flow regulation and reservoirs, which trap sediment. Of the total suspended-sediment load delivered to Puget Sound in water year 2011, 47 percent was sand (particle size >0.063 millimeters), and the remainder (53 percent) was silt and clay. A sediment-transport curve developed from suspended-sediment samples collected during 2010–11 agreed closely with a curve derived in 1973 using similar data-collection methods, indicating that similar sediment-transport conditions exist. Using the transport curve, the mean annual suspended-sediment load delivered by the lower Nisqually River near Yelm to Puget Sound is estimated at 99,000 t/yr (-37 to +54 percent at 90 percent confidence) for water years 1980–2014. The sediment-transport curve applied to daily discharge in water year 2011 resulted in an annual suspended-sediment load that was 14 percent greater than the load determined using a combined turbidity and Isco sampler approach. The median annual suspended-sediment load of 73,000 t is substantially less than the average load (99,000 t), and the correlation (Pearson's $r = 0.80$, $p = 8.1E\text{-}9$, $n = 35$) between annual maximum 2-day sediment loads and normalized peak discharges for the period indicates the importance of wet years and associated peak discharges of the lower Nisqually River for sediment delivery to Puget Sound.

Major Groundwater Flow Directions in the Sinking Creek and Meadow Creek Drainage Basins of Giles and Craig Counties, Virginia, USA

Joseph W. Saunders, R. Keith Ortiz, and William F. Koerschner, III
3207 Melody Lane, Lansing, Michigan 48912

Abstract

Groundwater tracing with fluorescein dye has determined the resurgence points for underground drainage from ten sinking streams in a compound anticlinal carbonate valley in the Virginia mountains (eastern US). Springs of five of six underground drainage basins are involved in distributary flow patterns, with co-resurgences located from 100 to 2000 m apart and all but one co-resurgence pair operating only in higher flow stages. The fluorescein tracing indicated that the surface and subsurface drainage divides roughly coincided where the eastern continental divide crossed the valley, despite the headward growth of the Atlantic Ocean drainage at the expense of the Mexican Gulf drainage.

Zusammenfassung

Die mit Fluoresceinfarbstoff Grundwasserausspürung hat in einem zusammengesetzten kalksteinenen Anticlintal den Gebirgen Virginias (östliche US) den Brunnen der von zehn sinkenden Bächen unterirdischen Entwässerung versetzt. Aus die Brunnen sechs unterirdischen Einzugsgebieten schliessen sich fünf in Austeilungsfliessanlagen. Die Ko-austeilungsbrunnen stellen sich 100 bis zu 2000 m entfernt. Bis auf eins Ko-austeilungsbrunnenpaare verbinden such nur bei den höheren Fliess-ständen. Die Farbstoffausspürung deutet an, dass die oberflächlichen und unterirdischen Wasserscheide ungefähr zusammentreffen, wo die östliche Kontinental-wasserscheide das Tal durchschneidet. Wegen der von Atlantikentwässerung talaufwärts Erweiterung bewegen die Wasserscheide westlich auf Kosten vom Golf von Mexiko schon fort.

Introduction

In the central Appalachian mountains of the eastern United States, two of the major structural settings in which karst has developed are the long mountains and the anticlinal valleys. Both settings are characterized by topographic orientations along the trends of regional folding and faulting. Anticlinal valleys where narrow are typically floored with limestone or dolomite, whereas underlying clastic units commonly have been exposed in the wider anticlinal valleys, leaving the carbonates in strips on either side of the valley. Most of the anticlinal valleys maintain a relatively uniform width, and several terminate in distinct valley heads where the carbonates or underlying clastics on the floor plunge beneath the sandstones with typically form the rims of the valleys. Where faults are found on the valley floor, they are usually associated with crosssectional asymmetry of the valley.

The two anticlinal valleys studied here contain two major surface streams. Meadow Creek leaves the eastern valley head through a gap after rising at two large springs nearby. Westward flowing Sinking Creek heads at a spring complex 10 km from the end of the eastern valley, which has been made somewhat asymmetric by the Saltville Fault that enters the western end of the valley near Newport and runs the entire length of the valley. North of Newport, Sinking Creek crosses the fault complex and flows northward into a second valley. Clover Hollow at the eastern end of this second valley has a simple anticlinal structure. Westward to the New River the valley is wider with more complex structure.

Stratigraphically, both valleys are rimmed with Silurian sandstones. Cambro-Ordovician dolomites form the central floor of Clover Hollow and the eastern valley, with Ordovician limestones on the floor and lower slopes on either side of the dolomitic core. The dolomite is more resistant to weathering and tends to form a central ridge down the middle of Clover Hollow and the eastern valley, bordered on both sides by parallel talwegs on limestone. Westward from Clover Hollow both the valley and the limestone exposures on either side of the dolomitic core widen.

Surface drainage in the two valleys consists of small mountainside streams and the two master streams Sinking Creek and Meadow Creek. Most if not all mountainside streams heading near the rims of the valleys sink upon encountering the limestone. Flow from some of these sinking streams resurfaces at springs along Sinking Creek or Meadow Creek, with flow from the remainder resurging at either of the two rises of Meadow Creek or along the New River. Both Sinking Creek and Meadow Creek sink completely for much of the year.

Methodology

Sodium fluorescein in quantities of ½ to 8 kg was applied to sinking streams in the period 1974-1978. Fresh activated charcoal granules contained in 5 cm square staple-bound envelopes of nylon screening was used to absorb the fluorescein. Elution was accomplished with 10% KOH in 95% ethanol, with an ultraviolet lamp used to aid in visualization if necessary. With few exceptions, the charcoal traps were collected only once from each location for each test. Duplicate traps were usually placed in diferent spots at each spring to minimize risk of theft or chance contamination.

Results of Water Tracing and Descriptions of Major Groundwater Basins

Thirteen fluorescein dye tests were made from eleven locations in the two valleys to a total of ten springs from the New River in the west to the Meadow Creek Gap in the east. The sink-to-spring straight lines shown on the map (Figure 1) indicate that multiple outlets for groundwater are not unusual in the structural settings encountered there. Four of the six major groundwater systems studied discharge from more than one outlet.

Meadow Creek Drainage

Meadow Creek waters reach the Roanoke River and the Atlantic Ocean after leaving the anticlinal valley at Meadow Creek Gap. The eastern anticlinal valley is actually a hanging valley, surrounded on both sides by Atlantic-bound streams at 400-450 m elevation, which is at least 150 m below the lowest elevation in the anticlinal valley. Meadow Creek rises at two large springs near the gap through the sandstone rim. Local base level in the eastern end of the anticlinal valley, as well as the elevation of the springs, is determined by the elevation at which Meadow Creek spills over the lowest point of the rim. Meadow Creek has no doubt, grown immensely from a small mountainside stream on the outer rim wall of the anticlinal valley to a major karst-headed stream by the continuing process of headward drainage caputre to the west. Fractures in the valley head associated with the anticlinal plunge provided the weaknesses needed by the early mountainside predecessor of Meadow Creek to breach the sandstone rim and initiate piracy of the headwaters of the Gulf of Mexico bound Sinking Creek. Because of the steeper drainage gradient through the Meadow Creek Gap than westward along Sinking Creek to the New River, the Eastern Continental Divide (between the Atlantic Ocean and the Gulf of Mexico) has been moving westward.

Fluorescein dye tracing has established that there are two branches of Meadow Creek, with drainage being roughly divided by the central dolomitic core in the anticlinal valley. The northern branch is predominantly a surface stream fed by several small springs. After a surface route of four kilometers, it sinks in all flow stages into a large closed depression known as the Sinks of Meadow Creek. The north branch of Meadow Creek resurges at Dudding Spring 2 km from the Sinks. A portion of subterranean Meadow Creek can be seen at Cove Cave 500 m west of Dudding Spring. Cove Cave ends downstream in collapse, whereas upstream sumps. Most of the 60 m length of Cove Cave appears to be developed along or near the Saltville Fault. At high flow stages water discharges from the cave entrance. Thus the north branch of Meadow Creek has both a perennial and an intermittent rise.

The south branch of Meadow Creek rises from an im-

Introduction

In the central Appalachian mountains of the eastern United States, two of the major structural settings in which karst has developed are the long mountains and the anticlinal valleys. Both settings are characterized by topographic orientations along the trends of regional folding and faulting. Anticlinal valleys where narrow are typically floored with limestone or dolomite, whereas underlying clastic units commonly have been exposed in the wider anticlinal valleys, leaving the carbonates in strips on either side of the valley. Most of the anticlinal valleys maintain a relatively uniform width, and several terminate in distinct valley heads where the carbonates or underlying clastics on the floor plunge beneath the sandstones with typically form the rims of the valleys. Where faults are found on the valley floor, they are usually associated with crosssectional asymmetry of the valley.

The two anticlinal valleys studied here contain two major surface streams. Meadow Creek leaves the eastern valley head through a gap after rising at two large springs nearby. Westward flowing Sinking Creek heads at a spring complex 10 km from the end of the eastern valley, which has been made somewhat asymmetric by the Saltville Fault that enters the western end of the valley near Newport and runs the entire length of the valley. North of Newport, Sinking Creek crosses the fault complex and flows northward into a second valley. Clover Hollow at the eastern end of this second valley has a simple anticlinal structure. Westward to the New River the valley is wider with more complex structure.

Stratigraphically, both valleys are rimmed with Silurian sandstones. Cambro-Ordovician dolomites form the central floor of Clover Hollow and the eastern valley, with Ordovician limestones on the floor and lower slopes on either side of the dolomitic core. The dolomite is more resistant to weathering and tends to form a central ridge down the middle of Clover Hollow and the eastern valley, bordered on both sides by parallel talwegs on limestone. Westward from Clover Hollow both the valley and the limestone exposures on either side of the dolomitic core widen.

Surface drainage in the two valleys consists of small mountainside streams and the two master streams Sinking Creek and Meadow Creek. Most if not all mountainside streams heading near the rims of the valleys sink upon encountering the limestone. Flow from some of these sinking streams resurfaces at springs along Sinking Creek or Meadow Creek, with flow from the remainder resurging at either of the two rises of Meadow Creek or along the New River. Both Sinking Creek and Meadow Creek sink completely for much of the year.

Methodology

Sodium fluorescein in quantities of ½ to 8 kg was applied to sinking streams in the period 1974-1978. Fresh activated charcoal granules contained in 5 cm square staple-bound envelopes of nylon screening was used to absorb the fluorescein. Elution was accomplished with 10% KOH in 95% ethanol, with an ultraviolet lamp used to aid in visualization if necessary. With few exceptions, the charcoal traps were collected only once from each location for each test. Duplicate traps were usually placed in different spots at each spring to minimize risk of theft or chance contamination.

Results of Water Tracing and Descriptions of Major Groundwater Basins

Thirteen fluorescein dye tests were made from eleven locations in the two valleys to a total of ten springs from the New River in the west to the Meadow Creek Gap in the east. The sink-to-spring straight lines shown on the map (Figure 1) indicate that multiple outlets for groundwater are not unusual in the structurd settings encountered there. Four of the six major groundwater systems studied discharge from more than one outlet.

Meadow Creek Drainage

Meadow Creek waters reach the Roanoke River and the Atlantic Ocean after leaving the anticlinal valley at Meadow Creek Gap. The eastern anticlinal valley is actually a hanging valley, surrounded on both sides by Atlantic-bound streams at 400-450 m elevation, which is at least 150 m below the lowest elevation in the anticlinal valley. Meadow Creek rises at two large springs near the gap through the sandstone rim. Local base level in the eastern end of the anticlinal valley, as well as the elevation of the springs, is determined by the elevation at which Meadow Creek spills over the lowest point of the rim. Meadow Creek has no doubt, grown immensely from a small mountainside stream on the outer rim wall of the anticlinal valley to a major karst-headed stream by the continuing process of headward drainage caputre to the west. Fractures in the valley head associated with the anticlinal plunge provided the weaknesses needed by the early mountainside predecessor of Meadow Creek to breach the sandstone rim and initiate piracy of the headwaters of the Gulf of Mexico bound Sinking Creek. Because of the steeper drainage gradient through the Meadow Creek Gap than westward along Sinking Creek to the New River, the Eastern Continental Divide (between the Atlantic Ocean and the Gulf of Mexico) has been moving westward.

Fluorescein dye tracing has established that there are two branches of Meadow Creek, with drainage being roughly divided by the central dolomitic core in the anticlinal valley. The northern branch is predominantly a surface stream fed by several small springs. After a surface route of four kilometers, it sinks in all flow stages into a large closed depression known as the Sinks of Meadow Creek. The north branch of Meadow Creek resurges at Dudding Spring 2 km from the Sinks. A portion of subterranean Meadow Creek can be seen at Cove Cave 500 m west of Dudding Spring. Cove Cave ends downstream in collapse, whereas upstream sumps. Most of the 60 m length of Cove Cave appears to be developed along or near the Saltville Fault. At high flow stages water discharges from the cave entrance. Thus the north branch of Meadow Creek has both a perennial and an intermittent rise.

The south branch of Meadow Creek rises from an impounded spring at the fish hatchery. In contrast to the north side of the anticlinal valley, drainage to the fish hatchery spring on the south side is entirely underground, excepting the sinking streams along 9 km of mountainside. Like the resurgences on the north side of the valley, the Fish Hatchery spring is developed in the limestone. It is the only major limestone spring in the study area that does not have a major associate distributary outlet, although there are two small flood outlets located within 30 m. It is likely that the difference in mass wasting which has kept drainage on the south side of the Meadow Creek valley well underground, whereas the surface of the north side of the valley is lower with predominantly surface drainage is due to the much higher dip and the Saltville Fault on the north side.

Head of Sinking Creek

Sinking Creek upstream from Newport is fed by numerous small to moderate sized springs in dolomite and limestone. The creek there is draining land with a low doline density. 1500 m west of the topographic divide with Meadow Creek, Sinking Creek rises at Early Spring on the south side of the valley. In higher flow stages an intermittent spring 100 m away becomes the surface head of Sinking Creek. A fluorescein trace in high flow from a mountainside sinking stream just west of the surface drainage divide tested positive in Early Spring and the intermittent spring, as well as at Slovensky Spring 300 m to the northwest. Considering that a sinking stream just east of the topographic divide had been traced to the fish hatchery spring, it would appear that the Eastern Continental Divide, known locally as "the Alleghenу", coincides approximately with the groundwater divide.

Travertine Spring on Sinking Creek at Saltville Fault Complex near Newport

There is a conspicous travertine deposit 2 m high, 10 m wide and 6 m long associated with a small spring along Sinking Creek where the Saltville Fault complex crosses the creek.

Subterranean Meander Cutoffs at Link's Bend

Dye dropped in Sinking Creek upstream of Link's Bend was detected in charcoal traps in Link Spring on the west (downstream) side of the bend the following day, and was thought to be visible in the spring at dusk forty minutes after the drop. No intake point is visible along the creek bank at the bend, so the waters that reappear at Link Spring after cutting under the neck of the meander must sink into the floor of the creek. There is a 30 m crawlway cave just above creek level on the upstream side of Link'a Bend almost directly upstrike from Link Spring. This small cave probably originated as a meander cutoff, and may still function as such during very high creek levels. To the south and out on the bend is Link's Cave, with about 300 m of passage and major trend along the strike. Link's Cave most likely is an abandoned subterranean meander cutoff route.

Clover Hollow Drainage

Most mountainside drainage in Clover Hollow sinks soon after encountering the limestone; only during very heavy runoff does surface drainage flow directly into Sinking Creek. Dye placed in Clover Hollow Cave and two sinking streams on the north side of Clover Hollow in separate traces was recovered in both Smokehole Spring and Tawney Spring on Sinking Creek, indicating a flow split. A careful examination of the main stream in Smokehole Cave behind the spring revealed a location where the cave stream split, with a major porportion entering a humanly impassable crevice while the remainder continued on out to Smokehole Spring. Subsequent in-cave dye drops from both just upstream and just downstream of the stream fork in Smokehole Cave, with traps at Smokehole Spring and the upstream reaches in Tawney's Cave behind Tawney Spring, indicated that all flow entering the crevice at the stream fork in Smokehole Cave resurged only at Tawney's Cave and Tawney Spring, whereas flow not entering the crevice resurged at Smokehole Spring. Together, these traces indicated that a single flow split existed.

Surveys of Tawney's Cave and Smokehole Cave indicate that the two caves are closely situated and represent major conduits for past and present drainage from Clover Hollow. It is clear that during the evolution of Smokehole Cave flow shifted direction from a westerly strike parallel trend to a southerly trend across the strike to the present Smokehole entrances, leaving large passage abondoned on the west side of the cave.

A dye trace from a sinking stream 1500 m north of the Smokehole-Tawney spring complex indicates that drainage from the far side of the dolomitic core is being transmitted across the strike and through the core rather than along the strike to a more distant spring. The next logical step in a study of the Clover Hollow karst hydrology would be the indentification of cave stream branches corresponding to the traced sinking streams in Clover Hollow, and subsequent analysis of waters from these tributaries of likely contrasting transmission routes.

The Rise of Sinking Creek

For about half the year the entire surface course of Sinking Creek down to the junction with the New River contains flowing water. At the lower flow stages the total flow of the creek is swallowed by several sink oints, the first visible one at a distance of 5 km from the New River. No passable openings are visible along the creek in the vinicity of the sinkpoints.

Despite being one of the largest springs in Virginia, the rise of Sinking Creek on the New River has a noticeably unimpressive appearance. Water discharges from a 30 m stretch of rubble forming part of a railroad embankment at the foot of a cliff.

Besides the trace of Sinking Creek to the rise on the New River, only one other sink point was traced to that rise. The stream sinking into Williams Cave 1500 m northwest of Tawney's Cave was traced in low flow stage to the rise of Sinking Creek only. Two traces in high flow stage, however, were detected both at the Sinking Creek to the New River is one of high doline density with very little flowing water, precluding an easy trace to define the low flow divide between Bell Spring and the rise of Sinking Creek.

Bell Spring Drainage

Doe Run was traced to Bell Spring from an upstream sink point, one of several along the stream course. A considerable portion of the doline field east and south of Doe Run probably drains to Bell Spring as well, aa do areas within a mile of Sinking Creek during high flow stages, as the traces from Williams Cave demonstrated.

Guidelines and Procedures for Computing Time-Series Suspended-Sediment Concentrations and Loads from In-Stream Turbidity-Sensor and Streamflow Data

By Patrick Rasmussen, John R. Gray, G. Douglas Glysson, and Andrew C. Ziegler

Abstract

In-stream continuous turbidity and streamflow data, calibrated with measured suspended-sediment concentration data, can be used to compute a time series of suspended-sediment concentration and load at a stream site. Development of a simple linear (ordinary least squares) regression model for computing suspended-sediment concentrations from instantaneous turbidity data is the first step in the computation process. If the model standard percentage error (*MSPE*) of the simple linear regression model meets a minimum criterion, this model should be used to compute a time series of suspended-sediment concentrations. Otherwise, a multiple linear regression model using paired instantaneous turbidity and streamflow data is developed and compared to the simple regression model. If the inclusion of the streamflow variable proves to be statistically significant and the uncertainty associated with the multiple regression model results in an improvement over that for the simple linear model, the turbidity-streamflow multiple linear regression model should be used to compute a suspended-sediment concentration time series. The computed concentration time series is subsequently used with its paired streamflow time series to compute suspended-sediment loads by standard U.S. Geological Survey techniques.

Once an acceptable regression model is developed, it can be used to compute suspended-sediment concentration beyond the period of record used in model development with proper ongoing collection and analysis of calibration samples. Regression models to compute suspended-sediment concentrations are generally site specific and should never be considered static, but they represent a set period in a continually dynamic system in which additional data will help verify any change in sediment load, type, and source.

Introduction

Collection, computation, storage, and publication of suspended-sediment concentrations (*SSC*s), suspend-sediment loads (*SSL*s), and related environmental data can be important parts of investigations to evaluate the effects of fluvial sediment on a water resource (Glysson, 1989a). Suspended sediment can adversely affect water supply, recreation, aquatic life, flood control, transportation, fisheries, reclamation, and navigation (Angino and O'Brien, 1968). The U.S. Environmental Protection Agency (2008) lists sediment and other solid-phase constituents to be the most prevalent source of impairment of the Nation's surface water.

Traditionally, *SSC* data have been derived from analytical results from physical samples collected by methods described by Edwards and Glysson (1999), Nolan and others (2005), and Gray and others (2008). *SSL* data have been computed from *SSC* and streamflow data by methods described by Porterfield (1972) and Koltun and others (1994, 2006). The traditional U.S. Geological Survey (USGS) computation technique presented by Porterfield (1972) is predicated on the availability of more frequent than daily (continuous) streamflow time-series data and a concurrent trace of *SSC* interpolated from physical samples, and where necessary, *SSC* estimates. Interpolated and estimated parts of a *SSC* trace for a stream site can include periods during which a substantial cumulative fraction of the annual *SSL* occurs. Hence, considerable hydrologic judgment often is required to compute sediment records by Porterfield's (1972) method.

Turbidity is an expression of the optical properties of a sample that causes light rays to be scattered and absorbed rather than transmitted in straight lines through the sample (Anderson, 2005; ASTM International, 2007). Turbid water results from the presence of suspended and dissolved matter such as clay, silt, finely divided organic matter, plankton, other microscopic organisms, organic acids, and dyes (ASTM International, 2007).

The magnitude of turbidity in streams, lakes, and estuaries is often proportional to *SSC*. When proportional, the turbidity-*SSC* relation can be quantified through linear regression analysis (Walling, 1977; Gilvear and Petts, 1985; Buchanan and Schoellhamer, 1995; Lewis, 1996; Christensen and others, 2000; Uhrich and Bragg, 2003; Lietz and Debiak, 2005; Rasmussen and others, 2005; Lee and others 2009). The turbidity-*SSC* regression model, in turn, can be used to compute *SSC* values from turbidity data within the turbidity

meter's measurement range. Continuously monitored turbidity data enable computation of a *SSC* time series that can be used with its paired streamflow time series to compute continuous *SSL* without the routine need for interpolation or estimation.

When the turbidity-*SSC* model is deemed adequate, regression-computed *SSC* can provide a more reliable and reproducible *SSC* time series with smaller uncertainty values than either a sediment-transport curve using streamflow as the sole independent variable for computations of *SSC* (Rasmussen and other, 2005; Lee and others, 2008) or arguably with *SSC* data produced by Porterfield's (1972) computational method (for which there is no quantitative method for deriving uncertainty). When the turbidity-*SSC* model is deemed inadequate, the addition of streamflow as a second model variable may result in an acceptable time series of *SSC*. The turbidity- or turbidity-and-streamflow-based computational scheme to produce *SSC* data has a number of advantages over that of Porterfield's (1972) method, as follows:

1. No subjective interpolation or estimation is required;
2. The computational procedure is precisely reproducible;
3. The scheme takes full advantage of the available database and computational resources; hence, it can substantially reduce the time and effort needed to compute *SSL* records; and
4. Estimates of uncertainty can be computed for the *SSC* time series.

The turbidity- or turbidity-and-streamflow-based computational scheme also has advantages over the traditional sediment-transport curve method (Glysson, 1987). The reliability of *SSL* computed from a transport curve depends on a number of factors, including the range of streamflow and *SSC* over which the data were collected to define the curve, the number and reliability of the concentration-discharge relations used to define the curve, and whether the data are representative of water and sediment loads for the computational period (Gray and Simões, 2008). Walling (1977) found that annual *SSL* computed using a sediment-transport curve could result in errors of as much as 280 percent, whereas errors in monthly *SSL* could range between +900 percent and -90 percent. Glysson and others (2001) compared *SSL* computed by the Porterfield (1972) method and a transport curve for 34 years of streamflow and suspended-sediment records at the USGS streamgage on the Rio Grande at Otowi Bridge, New Mexico. Daily *SSL* computed by these two techniques differed by as much as 4,000 percent, whereas the maximum difference in annual *SSL* computations was 526 percent. *SSL* for the 34-year period of record differed by 38 percent. Lee and others (2008) compared the uncertainty of annual *SSL* computed using a sediment-transport curve and a turbidity-*SSC* model at three sites near John Redmond reservoir, Kansas. The uncertainties associated with the annual *SSL* derived from sediment-transport curves ranged from 16–20 percent, whereas those derived from the turbidity-*SSC* model ranged from 1.1–3.2 percent.

Glysson and others (2001) observed that estimates of *SSL*s that are based on sediment-transport curves are subject to significant errors, in part because of the large range in *SSC* that can occur at any given water discharge. They concluded that, although a well-defined, carefully constructed and judiciously applied sediment-transport curve can be a useful tool for estimating *SSL*, *SSL* estimates derived from sediment-transport curves should not be considered a substitute for daily-sediment records computed by Porterfield's (1972) method. Lewis (1996) indicated that regression models using turbidity instead of streamflow improved the root-mean-squared errors of sediment rating curve estimates by 7 to 15 percent.

Hence, the use of a linear regression model to compute *SSC* from turbidity time-series data, and in some cases, turbidity and streamflow time-series data measured at a fixed location in a stream provide statistical estimates of uncertainty of *SSC* (Christensen and others, 2000). The use of a linear regression model, depending on the characteristics of the sediment in suspension, is likely a more accurate method for estimating a *SSC* time series than either the Porterfield (1972) method or traditional transport-curve method (Walling, 1977; Horowitz and others, 2003; Putnam and Pope, 2003).

SSC computed from regression models can be used for a variety of purposes, including use to describe variability in suspended-sediment conditions, to evaluate *SSC* relative to water-quality criteria and water-resource management goals, and to compare the *SSC* and *SSL* characteristics among watersheds. Computed *SSC* and streamflow data in riverine applications can be used to compute *SSL* to reservoirs, which in turn can be used to infer loss of reservoir capacity. Computed *SSC* and *SSL* also can be used in the study of channel morphology and basic process analysis of sediment sources. Also, by relating the continuous, time-series turbidity data to the sampled *SSC*, it may be possible to identify the sources and timing of sediment transport more accurately than on the basis of periodic sample collection. Subsequently, computed daily, monthly, seasonal, and annual *SSL* can be used to assess differences in fluvial-sediment characteristics between basins as a function of hydrologic conditions, contributing drainage area, land use, sediment sources, and (or) human activity. Turbidity time-series data also can be used to compute a variety of constituent concentrations—for example, total nitrogen and total phosphorus (Rasmussen and others, 2005) and indicator bacteria (Rasmussen and Ziegler, 2003) that correlate well with *SSC*, which in turn can be used to compute loads of those constituents.

Historically, most State agencies have collected samples for analyses of total suspended solids (*TSS*) in lieu of *SSC* samples (Pruitt, 2003). This is largely a consequence of the fact that the U.S. Environmental Protection Agency presently only recognizes the *TSS* analytical method (American Public Health Association, American Water Works Association, and Water Pollution Control Federation, 2005). *TSS* data tend to be biased low, particularly when sand constitutes more than about 20 percent of the mass of the water-sediment mixture (Gray and others, 2000; and Glysson and others, 2000, 2001). For

systems that convey primarily silt- and clay-sized sediment in suspension, Christensen and others (2000) and Rasmussen and others (2008) have used turbidity-*TSS* models to compute *TSS* values with acceptable uncertainties. However, *TSS* data are acceptable alternatives to *SSC* data only after being conclusively documented in a published report that the *TSS* data can adequately represent *SSC* data over the range of expected flows at a site (U.S. Geological Survey, 2000).

Purpose and Scope

This report provides guidelines and procedures for computing time series of *SSC* and *SSL* from time series of turbidity and streamflow data using a generally site-specific, simple or multiple regression model relating *SSC* from periodically collected in-stream water samples to in-stream turbidity measurements. Included is the requisite knowledge to:

1. Develop and evaluate an empirical statistical relation between turbidity and *SSC* measurements;
2. Compute time series of *SSC* and *SSL* from turbidity and streamflow time-series data; and
3. Maintain a long-term *SSC* record.

Examples of applications of the analytical and computational methods described herein are provided using data from USGS streamgages in California, Florida, Kansas, and Oregon. Although this guidance is for application in a riverine environment, selected aspects of the guidelines may be adapted for use in lacustrine or estuarine applications.

References to principles of sediment transport, sampling techniques, and related field procedures, along with quality-control procedures, are presented because an understanding of these principles and procedures is fundamental to the computation of time-series suspended-sediment records. Concepts, statistical procedures, and techniques are presented for computing *SSC* and *SSL* time series. Material in this report includes procedures and techniques to maintain a multiyear *SSC* time series and to prepare suspended-sediment data for public dissemination. Selected duplication of material contained in other publications and guidelines is necessary and intentional to provide guidance for computing *SSC* and *SSL* from turbidity and streamflow data. Specific USGS guidance on methods for computing and storing computed suspended-sediment data in the USGS National Water Information System (NWIS) database is presented.

Related Guidelines

Porterfield (1972) describes two basic types of sediment records—daily and periodic—calculated from sampled *SSC* and using gage height and (or) streamflow data to synthesize the *SSC* trace for unsampled periods. Daily records are prepared for sites where sufficient determinations of *SSC* and streamflow are obtained to enable computation of daily *SSL* (Porterfield, 1972). The end product is a tabulation of daily time-weighted mean *SSC*, *SSL*, and, in many cases, periodic determinations of particle-size distributions of suspended sediment and bed material. These are combined with other hydrologic data and released, usually by water year (October 1 through following September 30), by the USGS in stream-site data sheets for specific States or in the Open-File or Scientific Investigation Report series. Periodic records are prepared for sites where frequency of determination of *SSC* and (or) streamflow are insufficient to justify computation of daily *SSL* or where only miscellaneous samples are collected infrequently. In addition to publication of the records, the data and supporting documentation on computations are maintained on file in the USGS Water Science Centers and are available for examination or for use in interpretative reports and research.

Wagner and others (2006) provide basic guidelines and procedures used by USGS personnel for operating water-quality monitors, including site selection, field procedures, calibration of continuous water-quality monitors, record computation and review, and data reporting. In addition, Wagner and others (2006) present methods for servicing fixed-location water-quality monitors (including turbidity sensors) in freshwater environments and estuaries. Alternative methods for servicing monitors also are included. These basic guidelines are minimal requirements that may be modified to meet local environmental conditions or specific study objectives. Knowledge of monitoring-equipment operation and first-hand knowledge of the salient aspects of the watershed form the core of the data-evaluation process. Record-computation procedures presented in Wagner and others (2006) provide a uniform set of minimum requirements for computing water-quality records. Examples of the application of scientific judgment in the evaluation of data records are presented and are, by necessity, site specific. Other specific examples also are included to demonstrate the range of environmental conditions that affect the evaluation process.

Equipment and procedures for collection and measurement of fluvial sediment are described by Edwards and Glysson (1999), which contains two major sections regarding suspended-sediment equipment and techniques that are germane to developing turbidity/suspended-sediment relations. The “Sediment-Sampling Equipment” section includes information on the characteristics and limitations of various models of Federal Interagency Sedimentation Project (2008) isokinetic, depth- and point-integrating samplers (Davis, 2005), non-isokinetic single-stage samplers, automatic pumping samplers, and selected support equipment. The “Sediment-Sampling Techniques” section in Edwards and Glysson (1999) includes information on sediment-discharge measurements, including collection of representative samples, characteristics of sampling sites, equipment selection relative to the sampling conditions and needs, depth- and point-integration sampling techniques, surface and dip sampling, determination of sampler transit rates, sampling programs, and cold-weather sampling. The sediment-sampling equipment and techniques sections in Edwards and Glysson (1999), the subject matter of

which is also the focus of Nolan and others (2005) and Gray and others (2008), provide the fundamental information for collecting representative water-sediment samples. The derived *SSC* data, in turn, are used in correlations to turbidity. A more detailed description of suspended-sediment data-collection techniques is beyond the scope of this report.

Although streamflow computations can be accomplished by several techniques depending on site and equipment characteristics, they usually entail collection of stage records along with periodic streamflow measurements. Stage records are obtained from a water-stage recorder. Streamflow measurements usually are made with a current meter (Rantz and others, 1982; Kennedy, 1984) or acoustic Doppler current profiler (Lipscomb, 1995; U.S. Geological Survey, 2002). The methods are consistent with the American Society for Testing and Materials (ASTM) standards and generally follow the standards of the International Organization for Standardization (ISO). A more detailed description of streamflow time-series computation is beyond the scope of this report.

Helsel and Hirsch (2002) provide a stand-alone text of applied statistical methods for hydrology. Their chapters "Simple Linear Regression" and "Multiple Linear Regression" are cited throughout this guide and are essential for understanding and performing the statistical procedures presented.

Types of Turbidity Sensors

There are many methods for quantifying water clarity, including Secchi and black disks, laser diffraction (Gray and others, 2003; Gray and Gartner, 2009; Gray and Gartner, in press), digital-optic techniques (Gray and others, 2003; Gooding, in press) and optical light scattering and absorption techniques (table 1; Gray and others, 2003; Rasmussen and others, in press). The techniques in this report are predicated on use of either of two types of turbidity sensors that are based on nephelometric or optical-backscatter (OBS) principles and are commonly used to measure turbidity for the purposes of computing *SSC* (Gray and Gartner, 2006). These sensors are designed for extended in-situ deployment, are relatively inexpensive, and are either self recording or produce signals compatible with a data logger.

Table 1. Selected specifications for selected turbidity instruments (Anderson, 2005).

Light source	Multiple or single light sources	Detection angle	Single or multiple detectors	Designated units
White or broadband (400–680 nanometers)	Single	90-degree detection angle	Single	NTU (nephelometric turbidity unit)
White or broadband (400–680 nanometers)	Single	90-degree detection angle	Multiple detectors, ratio compensation	NTRU (nephelometric turbidity ratio unit)
White or broadband (400–680 nanometers)	Single	30- (plus or minus 15) degree detection angle (backscatter)	Single	BU (backscatter unit)
White or broadband (400–680 nanometers)	Single	180-degree detection angle (attenuation)	Single	AU (attenuation unit)
White or broadband (400–680 nanometers)	Multiple	Detectors at 90 degrees and possibly other angles to each beam	Multiple	NTMU (nephelometric turbidity multibeam unit)
Near infrared (780–900 nanometers) or monochrome	Single	90-degree detection angle	Single	FNU (formazin nephelometric unit)
Near infrared (780–900 nanometers) or monochrome.	Single	90-degree detection angle	Multiple detectors, ratio compensation	FNRU (formazin nephelometric ratio unit)
Near infrared (780–900 nanometers) or monochrome	Single	30- (plus or minus 15) degree detection angle (backscatter)	Single	FBU (formazin backscatter unit)
Near infrared or monochrome	Single	180-degree detection angle (attenuation)	Single	FAU (formazin attenuation unit)
Near infrared (780–900 nanometers) or monochrome (including Great Lakes Instruments, Inc., 1992—Method 2)	Multiple	Detectors at 90 degrees and possibly other angles to each beam	Multiple	FNMU (formazin nephelometric multibeam unit)

Unlike absolute measurements of selected physical properties of water, such as specific conductance, pH, temperature, or dissolved oxygen, turbidity is a relative index of scattering and absorption of light in water. Turbidity is not a direct measure of suspended particles in water but instead is a measure of the scattering and absorbing effect such particles have on light (Sadar, 1998). Anderson (2005) provides a review of available turbidity sensor technologies with a decision tree to select a suitable instrument for a specific site or application and guidelines for calibration, operation, quality-assurance procedures, and reporting of data. Several characteristics of the water and suspended-sediment mixture, such as particle size, shape, and color, can affect the optical measurement (Sadar, 1998; Davies-Colley and Smith, 2001; Ziegler, 2002a,b; Anderson, 2005; Downing, 2005, 2006). The effects of these characteristics are discussed in the section on "Factors Affecting Relation Between Turbidity and Suspended-Sediment Concentration."

Nephelometry

Nephelometry is the measurement of light scattering using a light detector 90 degrees from the incident light (U.S. Environmental Protection Agency, 1999). Nephelometric measurements reflect the collective optical properties of solution that cause light to be scattered or attenuated rather than transmitted in straight lines through the solution; the larger the amount of scatter or attenuation of light, the larger the value measured by the nephelometric turbidity meter. Nephelometric measurements typically are expressed in turbidity units defined by the light source, detection angle, and whether the sensor has single or multiple detectors (table 1). Approved methods (in 2008) for the measurement of turbidity include those that conform to at least three protocols. These are stated in: (1) U.S. Environmental Protection Agency (USEPA) Method 180.1 (U.S. Environmental Protection Agency, 1979), (2) ISO Method 7027 (International Organization for Standardization, 1999), and (3) standard methods recommended by the American Water Works Association and the Water Environment Federation (Clesceri and others, 1998).

Wagner and others (2006) describe methods for measuring turbidity with submersible-type (fig. 1) and nonsubmersible nephelometric sensors. The nephelometric measurements shown in the examples in this report were made with either an YSI 6026 or YSI 6136 turbidity probe (YSI Incorporated, 2003). These YSI sensors conform to the ISO Method 7027 and ASTM D-7315 measurement standards. Each has a light

Figure 1. Three self-cleaning nephelometric turbidity sensors—*A,* YSI Incorporated (Yellow Springs, Ohio) model 6136 turbidity sensor, *B,* Hydrolab (Loveland, Colorado) self-cleaning turbidity sensor, and *C,* Forest Technology Systems (Blaine, Washington) model DTS-12 turbidity sensor.

source of 860 ± 30 nanometers (nm) with a single detector oriented at 90 degrees from the incident light path. Nephelometric readings from the YSI 6026, YSI 6136, and other turbidity sensors can be different and not directly equivalent (Sadar, 1998; Davies-Colley and Smith, 2001; Landers, 2003; YSI Incorporated, 2003; Ziegler, 2003a; Rasmussen and others, 2005). Different turbidity values, therefore, can be measured for an individual sample by different turbidity sensors conforming to the same standard method. See the "Changes to Turbidity Sensor Model or Type" section of this report for a discussion of data processing from different turbidity sensors.

Optical Backscatter

OBS sensors measure the same properties as nephelometric sensors, but the angle between the light source and the detector is less than 90 degrees. An OBS sensor is typically a cylinder utilizing an optical window from which light is both emitted and received (fig. 2; Downing and others, 1981; Downing, 1983). A pulse of either white or near-infrared light is transmitted through the optical window and is scattered or reflected by particles in front of the window in a 165-degree conical zone within some distance. Some of this scattered or reflected light is returned to the optical window where a receiver converts the backscattered light to a proportional voltage output. The relation of OBS sensor voltage output to *SSC* varies depending on the size, shape, and optical properties of the suspended sediment (Levesque and Schoellhamer, 1995). Downing (2006) provides a thorough discussion of the history and use of OBS measurements to compute *SSC*. Typically, OBS sensors are used at locations where the nephelometric sensor maximum reporting level, ranging from 1,000 to 2,000 formazin nephelometric units (FNUs) or *SSC* values larger than 1,000 milligrams per liter (mg/L), are exceeded frequently.

Relation of Turbidity to Suspended-Sediment Concentration

A constituent concentration may be computed as a function of another measurement by means of linear regression models (Helsel and Hirsch, 2002). *SSC*, for example, can be computed from turbidity and (or) streamflow measurements by means of linear regression. The regression methods used in this guide are described in Helsel and Hirsch (2002) and are similar to those applied by Gilvear and Petts (1985), Lewis (1996), Christensen and others (2000), Uhrich and Bragg (2003), Lietz and Debiak (2005), and Rasmussen and others (2005).

To illustrate the techniques and methods discussed in these guidelines, turbidity, streamflow, and *SSC* data from USGS streamgage 07144100, Little Arkansas River near Sedgwick, Kansas, are used. A riverine example is presented because it is the most likely and common application of this method. Some of the methods discussed are not applicable to lacustrine or estuarine applications. Data sets and regression model examples of other riverine and estuarine data sets are provided in Appendix 1.

Steps in the procedure for computing time-series records of *SSC* and *SSL* are given in the checklist shown in figure 3. There are three major steps to completing the computation:

1. Compilation of a model-calibration data set of concurrent turbidity, streamflow, and *SSC* values;

2. Development of a linear regression model to compute instantaneous values of *SSC*; and

3. Computation and storage of instantaneous values of *SSC* and daily values of *SSL*.

Compilation, development, and computation methods are described in detail in the following sections.

Model-Calibration Data Set

Compilation of the model-calibration data set is the first step in the development of a linear regression model. The model-calibration data set consists of concurrent instantaneous in-stream measurements of turbidity and streamflow, and sampled *SSC* values that correspond to the paired turbidity-streamflow measurements. Appendix 2 discusses retrieval of these data types from the USGS National Water Information

[NWIS, U.S. Geological Survey National Water Information System; ADAPS, U.S. Geological Survey Automated Data Processing System; QWDATA, U.S. Geological Survey water-quality database; SSC, suspended-sediment concentration; SSL, suspended-sediment load, R^2, coefficient of determination; RMSE, root-mean-squared error; MSPE, model standard percentage error; PRESS, prediction error sum of squares; VIF, variance inflation factor; R^2a, adjusted coefficient of determination ; MVUE, minimum-variance unbiased estimator; ANCOVA, analysis of covariance]

Figure 3. Checklist for development, verification, and approval of a regression model to compute suspended-sediment concentration and load time-series data.

System (NWIS) database. The sampled *SSC* must be representative of the mean cross-sectional *SSC* value at the time of collection. The rationale for examination and quality assurance of the data are presented in the following paragraphs. The computation of turbidity and streamflow time-series data are assumed to have been completed by means of established USGS guidelines and procedures (Wagner and others, 2006; U.S. Geological Survey, variously dated). The guidance that follows is intended only to supplement procedures presented in Wagner and others (2006).

Evaluation of Fixed-Location and Cross-Section Turbidity

Comparisons of fixed-location and cross-section in-stream turbidity measurements should be part of the turbidity record analysis (Wagner and others, 2006). Fixed-location, in-stream (hereinafter referred to as "fixed-location") turbidity measurements collected concomitant with cross-section turbidity measurements should be retrieved from the "approved" time-series data set (U.S. Geological Survey, 2006, p. 20, 188–195). The turbidity cross-section measurements should be made with a properly cleaned and calibrated field turbidity sensor of the same make and model as the fixed-location turbidity sensor. Cross-section turbidity measurements are collected at several points across the stream routinely near the surface and periodically at different depths (Anderson, 2005). Those points at suspended-sediment sampling verticals are used for either the equal-width increment or equal-discharge increment methods (Edwards and Glysson, 1999; Nolan and others, 2005; Gray and others, 2008). These measurements are averaged and used in evaluations of the representativeness of data produced from fixed-location turbidity time-series measurements (fig. 4).

Large turbidity values warrant special evaluation. Although the values may be valid, spurious data can occur, including those recorded when turbidity exceeds the sensor's maximum recording level. Sensor-measurement truncation produces constant-value artifacts when in-stream turbidity levels exceed the maximum recording level of the sensor (1,000–2,000 mg/L for most nephelometric sensors and 4,000–50,000 mg/L for most OBS). The maximum recording level is unique for each turbidity sensor and should be routinely quantified and documented for each sensor (Anderson, 2005). Because the maximum recording level of the sensor is reported for all turbidity values equal to or larger than the maximum recording level, truncation is manifested as a horizontal line or plateau in the temporal turbidity trace of plotted data (fig. 5). Routine calibration of the turbidity sensor can change the maximum recording level; therefore, turbidity measurements within about 10 percent of the maximum recording level should be evaluated to determine if those values are artifacts of truncation. Generally, these values should not be used as part of the model-calibration data set.

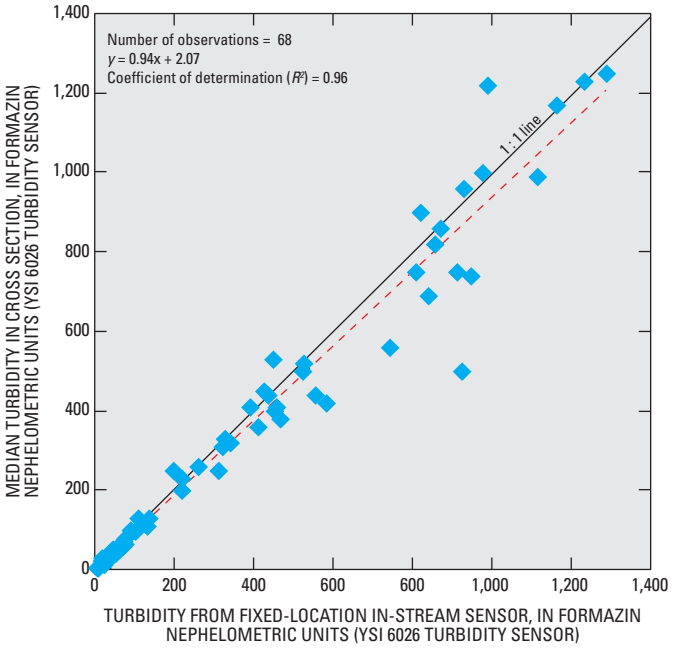

Figure 4. Comparison of fixed-location and median cross-section turbidity measurements for U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas, November 1998–June 2005.

Exceptions should be clearly noted and fully explained as part of the summary in the station analysis (Appendix 1 at the back of this report). The use of turbidity sensors to compute *SSC* at a site subject to frequent turbidity truncation may not be appropriate. OBS sensors should be used for streams where a significant percentage of *SSL* occurs at *SSC* values exceeding about 2,000 mg/L. However, currently (2009) most OBS sensors are not self cleaning and require more frequent routine maintenance.

Determination of Turbidity and Streamflow Associated with Suspended-Sediment Concentrations

Turbidity and streamflow corresponding to each *SSC* sample should be determined from the time-series data sets–preferably, time-weighted averages of turbidity and streamflow values recorded immediately before, immediately after, and during the *SSC* sample collection (fig. 5). The hydrographer should ensure that the turbidity and streamflow time-series data retrieved from the USGS time-series database, ADAPS, have a data-aging status of "approved" (U.S. Geological Survey, 2006, p. 20 and 188–195). Once turbidity and streamflow values have been determined for each *SSC* value, the hydrographer should compile a data set for statistical analyses.

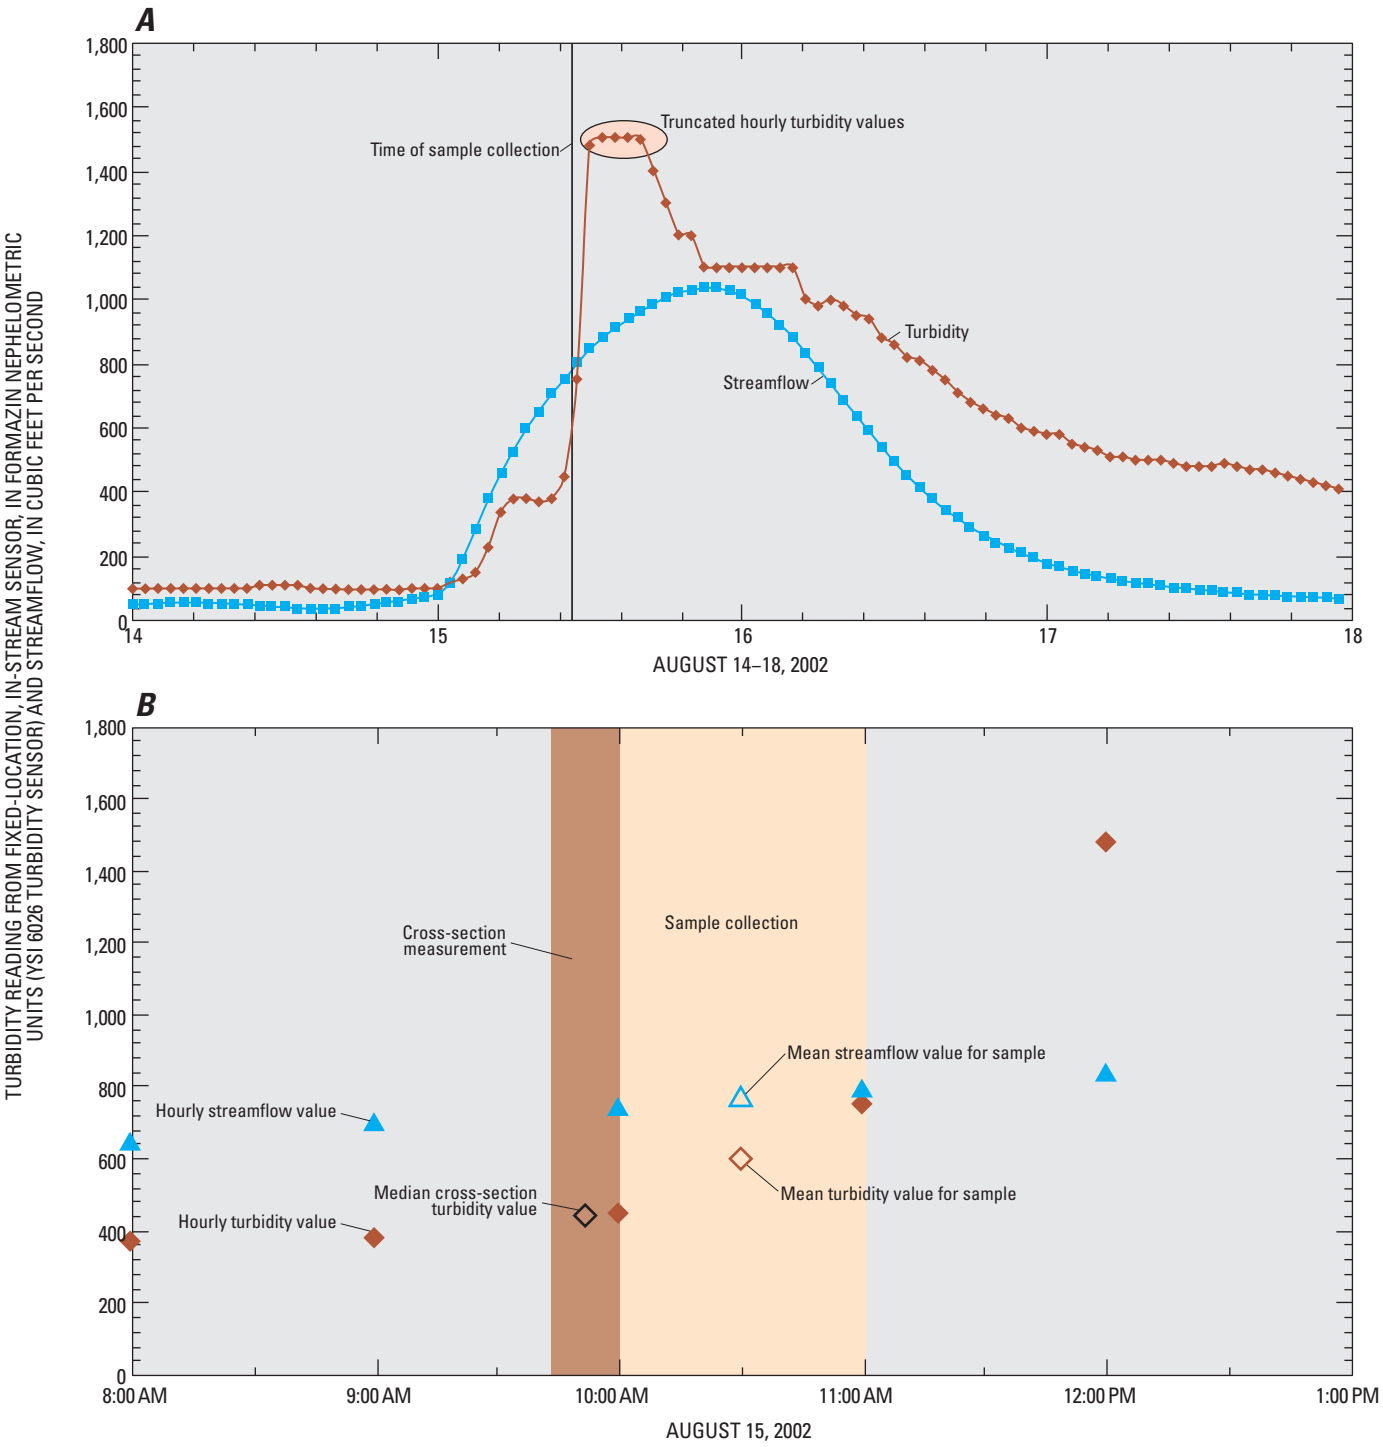

Figure 5. *A,* Time-series turbidity and streamflow data, August 14–18, 2002, and *B,* duration of cross-section turbidity and suspended-sediment sample collection, August 15, 2002, at U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas.

Identification of Outliers

The development of a *SSC* regression model should be preceded by evaluation of a scatterplot of the turbidity and *SSC* calibration data. The hydrographer can sometimes discern outliers on the basis of the scatter of the data. Helsel and Hirsch (2002, p. 11, 31–34, 246–248) provide additional guidance on the identification and treatment of outliers.

Once an outlier is identified, the hydrographer should use all technically supportable analytical tools and methods to attempt to discredit the value in question. This includes:

1. Confirmation that the correct value was entered into the database;
2. Evaluation of laboratory analytical results; and
3. Review of the field notes to ensure that proper collection techniques were used or to otherwise identify factors that might lend credit to or that might refute the outlier.

Remove outliers from the analysis that can be discredited with a high degree of confidence. Conversely, if an outlier cannot be discredited, the hydrographer must determine the type of adjustment and document the attempts to verify the value in the station analysis summary (Appendix 1). Outliers that cannot be discredited may affect the analysis and may help the hydrographer better understand the relations among site turbidity, *SSC*, and streamflow. Numerous outliers may be indicative of problems with the measuring apparatus and (or) monitoring site that may in turn warrant corrective measures.

In the comparison of Little Arkansas River fixed-location turbidity measurements to *SSC* (fig. 6), five data points plotted outside the scatter and pattern of the other 68 data points. Inspection of field and laboratory notes and results of particle-size analyses indicated that these outliers should be either corrected or removed. One of the five outliers was derived from a sample that arrived at the laboratory with a loose bottle lid and an abnormally small sample volume. On the basis of this information, it was surmised that some sample water had leaked while most if not all of the sediment remained at the container's bottom, resulting in a spuriously large *SSC*. The discredited outlier was removed from the data set.

Values for two *SSC* samples that plot as outliers on opposite sides of the data scatter (identified as "Database entry errors for *SSC* values" in figure 6) were evaluated. The field forms for these samples confirmed that turbidity values in the database matched the turbidity measurements made concomitant with *SSC* sample collection. However, a review of the analytical summaries for the *SSC* samples indicated that data-entry errors comprising misplaced decimal points resulted in one value appearing as 10-fold its true value and the other one-tenth of its true value. The two sample results were duly corrected in the database and replaced the erroneous values in the model-calibration data set.

Evaluation of the particle-size analyses performed on the suspended-sediment samples collected at relatively low streamflows indicated an abnormally large percentage of sand

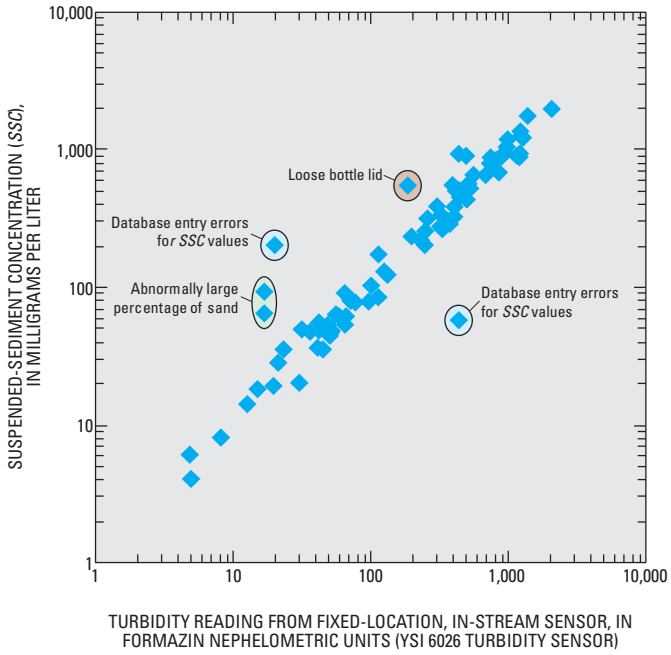

Figure 6. Comparison of turbidity to suspended-sediment concentration in water from U.S. Geological Survey streamgage on Little Arkansas near Sedgwick, Kansas, August 2000–June 2005.

(particle sizes exceeding 63 micrometers [µm]) for two other outliers. Typically, sand in samples collected at this site during similar low streamflow conditions constitutes no more than 2 percent of the sediment mass. Sand in these two samples constituted 10 and 30 percent of the dry sediment mass. Transport of sand at these low streamflows is unsupported by sedimentological theory and samples collected previously at this site. The outliers were deemed to be artifacts attributable to sampling error (inadvertently scooping sand-size bed material into the suspended-sediment sampler) and were removed from the data set.

A revised scatterplot identified no other data points that deviated sufficiently from the rest to justify further scrutiny.

Adequacy of Model-Calibration Data Set

An adequate model-calibration data set consists of an appropriate number of instantaneous, manual *SSC* samples and concurrent turbidity and streamflow measurements collected throughout the observed range of hydrologic conditions for the period of record (Glysson, 1989b; Rasmussen and others, 2002). The number of samples is often cited as the primary criterion for determining if a data set is adequate for computational purposes. Initially, approximately monthly samples collected over a 2- to 3-year period for the range of hydrologic conditions may be needed. Although the sample total is relevant, the distribution of the data over the range of observed turbidity, *SSC*, and streamflow values for the site is

of paramount importance. A regression model developed from 15 samples more or less evenly distributed throughout the seasons and range of turbidity and streamflow at a site might result in a more representative model than one developed using a 50-sample data set where distribution of values defines only a limited time or range of the sedimentological conditions over which the model will be applied. Defining turbidity-*SSC* relations during medium and high streamflow periods normally takes precedence over more equal spacing of data collection throughout the year, particularly if the purpose is to compute *SSL*. For example, where the number of site visits to collect manual samples is limited, sample collection should be skewed toward medium and higher flows. Regardless of the range of data values, the data points representing the extremes will have the greatest effect in determining the slope of the relation. For instance, erroneously large turbidity values during low streamflow and low *SSC* conditions can artificially increase the slope of the regression line.

Another factor to be considered when determining the adequacy of a data set is the amount of variability in the relation between turbidity and *SSC*. The larger the variability in the relation between turbidity and *SSC* at a site, the greater the need is to collect more samples. Often, the hydrographer's challenge is to adequately characterize this variability with the fewest number of samples.

Serial correlation (also called autocorrelation) occurs when data are collected close enough in time that the regression assumption of data independence is violated. For instance, multiple samples may be collected during the rising and falling limb of a single runoff period. The serial correlation between the multiple data points can cause underestimation of the regression uncertainty. Helsel and Hirsch (2002, p. 250–251) present methods for identifying the presence of serial correlation. If serial correlation is detected, the solution is to randomly select a single data point from each group of correlated data. The single point should be used in the model-calibration data set. Alternately, Glysson (1987) describes a procedure by which mean *SSC* values are computed for each of several contiguous, discrete *SSC* intervals for the data set. These mean values are used to develop the regression equation.

Duration curves represent another tool to evaluate the distribution of *SSC* data and adapt subsequent sample-collection strategies. Ideally, turbidity and streamflow associated with the *SSC* samples should span the ranges of the time-series turbidity and streamflow values for the site (Rasmussen and others, 2002). For example, turbidity and streamflow values associated with discrete *SSC* sample data are plotted on duration curves of turbidity and streamflow (fig. 7*A* and *B*). The turbidity duration curve in figure 7*A* was developed from hourly recorded turbidity measurements by the fixed-location sensor for the study period. The turbidity values associated with the *SSC* samples were plotted along the duration curve. Sample collection can be determined by closely monitoring the real-time turbidity and streamflow time-series data and optimizing sample-collection times to coincide with duration-curve segments undefined by sample values. As new *SSC* samples are collected, the hydrographer should add the corresponding turbidity and streamflow values to the duration-curve plots so that overall temporal distribution of samples can be assessed. Routine use of this tool will maximize the potential that the model-calibration data set optimally represents the range of turbidity and streamflow conditions.

Turbidity values for one or more years are sorted (or ranked) from smallest to largest to construct a turbidity duration curve from a turbidity time series. Then, exceedance probabilities are calculated for each turbidity value using Cunnane's plotting position (Cunnane, 1978; Helsel and Hirsch, 2002). The minimum turbidity-value duration percentage is 100 percent (all values within the data set are larger than or equal to this value). The maximum turbidity-value duration percentage is 0 percent (no values within the data set exceed this value). All the turbidity values within the data set are plotted according to calculated probabilities forming the turbidity duration curve. Symbols are plotted on the curve at the probability computed for turbidity values associated with each *SSC* sample. A streamflow duration curve can be constructed in a similar manner by substituting a streamflow time series for the turbidity time series. Streamflow duration curves representing the study period and, if different, the entire period of record provide study period and long-term comparisons.

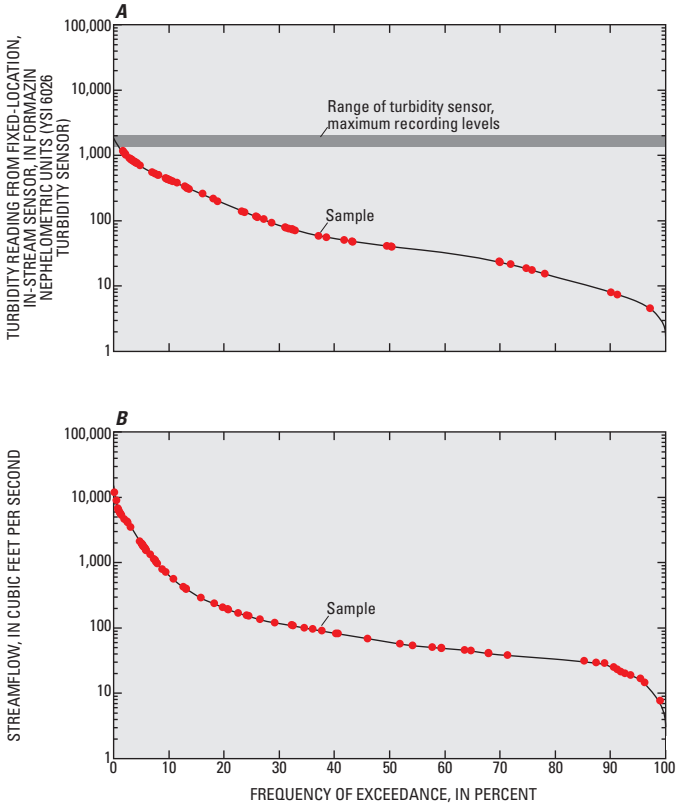

Figure 7. Duration curves for *A,* turbidity and *B,* streamflow and corresponding values associated with suspended-sediment concentration samples collected at U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas, 1999–2005.

Update of Station Analysis

The station analysis for a stream site should be updated to summarize the data analyses performed. This summary should include the rationale behind:

1. Determination of turbidity and streamflow values associated with each *SSC* value;
2. Acceptance or exclusion of turbidity values near the sensor-dependent turbidity maximum recording level;
3. Identification of outliers of turbidity, streamflow, and (or) *SSC* values; and
4. Determination of the adequacy of the model-calibration data set using turbidity and streamflow duration curves.

Other information necessary to complete the station analysis includes a table of summary statistics of the model-calibration data set. General statistics of the model-calibration data set and the time-series data set indicate the representativeness of the model-calibration data set (table 2). The minimum and maximum turbidity values for the model-calibration data set define the ideal limits for which the resulting regression model should be used to compute *SSC* values. An understanding of suspended-sediment transport processes and sound hydrologic judgment—ideally drawn from years of experience—is required when deciding if values outside these limits are appropriate.

The hydrographer should review data plots, duration curves, and data statistics to evaluate the sufficiency of the model-calibration data set for developing a reliable regression model. If any of these categories are insufficient, the hydrographer may opt to suspend the model analysis and focus on additional sample collection so that the model-calibration data set may better represent the range of the time-series data set. As new sample results are added to the model-calibration data set, these same steps can be used to evaluate how the new data enhance or otherwise alter the model.

Table 2. Statistical summary of model-calibration data set for U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas, November 1998–June 2005.

[mg/L, milligrams per liter; FNU, formazin nephelometric units; ft^3/s, cubic feet per second]

Summary statistic	Calibration data set (68 samples)			Time-series data set (61,200 hourly values)	
	Suspended-sediment concentration (mg/L)	Turbidity (FNU)	Streamflow (ft^3/s)	Turbidity (FNU)	Streamflow (ft^3/s)
Minimum	4	4	8	1	3
Maximum	1,250	1,300	12,000	2,000	15,000
Mean	350	370	1,500	140	380
Median	240	240	210	41	60
Standard deviation	350	380	2,500	260	1,200

Regression Model Development

The key elements for computing *SSC* time-series data from periodic instantaneous *SSC*, turbidity, and streamflow data are the type and goodness-of-fit of the regression model used in the computation. A number of quantifiable variables can be used to compute *SSC* in streams, including turbidity; hydrologic characteristics, including streamflow, stream stage, streamflow rise or fall, and rates of rise and fall; precipitation rate and intensity; and seasonality, sediment sources, and land use. The explanatory variables turbidity and streamflow generally are the most important in *SSC* regression analysis. Thus, these guidelines focus on turbidity and, to a lesser extent, streamflow as explanatory variables of *SSC*. A SLR model relating turbidity to *SSC* is often sufficient for reliable computations of *SSC*. Criteria are provided for determining the sufficiency of a SLR model and for determining when a multiple linear regression (MLR) model relating both turbidity and streamflow to *SSC* results in a significant improvement over the SLR model that is based on turbidity alone. Typically, addition of a streamflow variable is more likely to improve the turbidity-*SSC* regression as the percentage of the *SSC* that is sand-size or larger material (coarser than 63 μm) increases. Concepts for development and use of a SLR model to compute *SSC* and, when appropriate, a MLR model as a function of turbidity and streamflow to compute *SSC*, are explained in the following sections. The following regression analysis is site-specific and applies to a single model-calibration data set. A comparison between sites and model-calibration data sets is beyond the scope of this report. Specifically excluded from these guidelines is use of a SLR model for routine computation of *SSC* solely from streamflow due to varying degrees of hysteresis common in the *SSC*-streamflow relation. Currently (2009), ADAPS is limited to only SLR models using turbidity for computing a more frequent than daily *SSC* time series (U.S. Geological Survey, 2003). For example, ADAPS cannot compute more frequent than daily *SSC* using streamflow or more than one explanatory variable.

There are a variety of approaches to building an appropriate model, including SLR and MRL (Helsel and Hirsch, 2002) and Kendell-Theil robust line (Granato, 2006). The following sections provide some general guidance on develop a linear regression model using turbidity and streamflow as explanatory (x) variables and *SSC* as the response (y) variable. Linear regression is not only used to derive a final model to compute *SSC* but also is used in the intermediate steps to determine the final model form. The hydrographer may need to evaluate the performance of more than one intermediate regression model before determining the optimal model for computing *SSC*. Regression results are an effective means for

evaluating whether or not variables should be transformed and which variables are necessary to best estimate the variability in *SSC*. The following sections describe methods by Helsel and Hirsch (2002) for deriving the optimal regression model for computing *SSC*. A detailed summary of SLR development for turbidity-*SSC* and evaluation of MLR for turbidity and streamflow-*SSC* is presented in example 1 of Appendix 1. Complete and detailed presentations of these regression methods are not presented in these guidelines and procedures but can be found in Helsel and Hirsch (2002, p. 221–263 and 295–321). S-Plus (Insightful Corporation, 2001) is the USGS-supported statistics software package for performing SLR and MLR analyses. Microsoft® Excel®can be used, but results from Excel should always be verified with S-Plus derived results. Results from both software packages are provided in example 1 of Appendix 1.

Correlation

Correlation coefficients measure the strength of association between two variables (Helsel and Hirsch, 2002). The most commonly used measure of correlation is Pearson's *r*. This correlation also is called the linear correlation coefficient because *r* measures the linear association between two variables (Helsel and Hirsch, 2002, p. 218). Measures of correlation have the characteristic of being dimensionless and scaled to lie in the range $-1 \leq r \leq 1$. When there is no correlation between two variables, $r = 0$. When the increase or decrease in the variables is synchronous, *r* is positive. When the variables vary in opposite directions, *r* is negative. When one variable is a measure of time or location, correlation becomes a test for temporal or spatial trend, respectively.

Whenever a correlation coefficient is calculated, it should be presented with a scatter plot of the data. No single numerical measure can substitute for insights that can be gained from visual examination of such a plot. Scatter plots and correlations of turbidity, streamflow, and *SSC* values are simple and convenient ways of identifying which of the variables are statistically related and whether transformation of the data might improve the relation between the explanatory and response variables (fig. 8). The hydrographer can get a better idea from a simple analysis of which or both of two variables—turbidity and streamflow—are superior for computing *SSC*. Generally, the closer the correlation coefficient is to 1 (perfect positive correlation), the stronger the association between variables.

For MLR, multicollinearity—a case of MLR in which the explanatory variables are themselves highly correlated—can result in undesirable consequences for model results. Helsel and Hirsch (2002, p. 305) suggest computing a variance inflation factor (VIF) for measuring multicollinearity. The VIF for turbidity and streamflow is readily computed by using the coefficient of determination (R^2) from the regression of turbidity on streamflow (equation 11.6 in Helsel and Hirsch, 2002, p. 305). A VIF larger than 10 (or a Pearson's *r* larger than 0.95 between turbidity and streamflow) indicates multicollinearity between turbidity and streamflow, and suggests that the use of either variable would explain about the same amount of variability and that the two variables should not be used together as explanatory variables in a MLR (Helsel and Hirsch, 2002, p. 305–6). The scatter plot and VIF of data from the Little Arkansas River near Sedgwick, Kansas (fig. 9), suggest that turbidity and streamflow are not strongly multicollinear and could be used as explanatory variables in a MLR model to compute *SSC*.

Simple Linear Regression for Computation of Suspended-Sediment Concentrations

Values of a response variable can be expressed in terms of a single explanatory variable or many explanatory variables using linear regression models (Helsel and Hirsch, 2002). An explanatory variable such as turbidity can be used in a regression model to compute the response variable *SSC*. The most common estimation technique is SLR, as presented in chapter 9 of Helsel and Hirsch (2002). SLR models can be computed using many statistical software packages. SLR analysis of the Little Arkansas River model-calibration data set yields the plots shown in figure 10 using untransformed data and in figure 11 using $\log_{10}$-transformed data.

A list of diagnostics for linear regression can be used to evaluate various steps in the model- building process (Helsel and Hirsch, 2002, p. 226–7). The coefficient of determination adjusted (R^2_a) for the number of explanatory variables (or, equivalently, the degrees of freedom) in the model indicates the fraction of variability in the response variable that is explained by the model. The root-mean-squared error (*RMSE*) is a measure of the variance between regression-computed and observed values. The *RMSE* is approximately equal to one standard deviation (σ) or the 67-percent prediction interval and is expressed in the same units as the response variable. *RMSE* expressed in log units is not directly comparable with *RMSE* expressed in milligrams per liter. *RMSE* can be expressed as a percentage (Hardison, 1969), hereinafter referred to as the model standard percentage error (*MSPE*). *MSPE* can be used to compare any regression model. For *RMSE* expressed in $\log_{10}$ units, the *MSPE* interval is:

$$\text{Upper } MSPE = \left(10^{RMSE} - 1\right) \text{x } 100, \text{ and}$$
$$\text{Lower } MSPE = \left(1 - 10^{-RMSE}\right) \text{x } 100. \quad (1)$$

For *RMSE* expressed in milligrams per liter, the *MSPE* interval is:

$$MSPE = \pm \frac{RMSE}{\bar{y}} \text{x } 100, \quad (2)$$

where

$\bar{y}$ is the mean of the response variable.

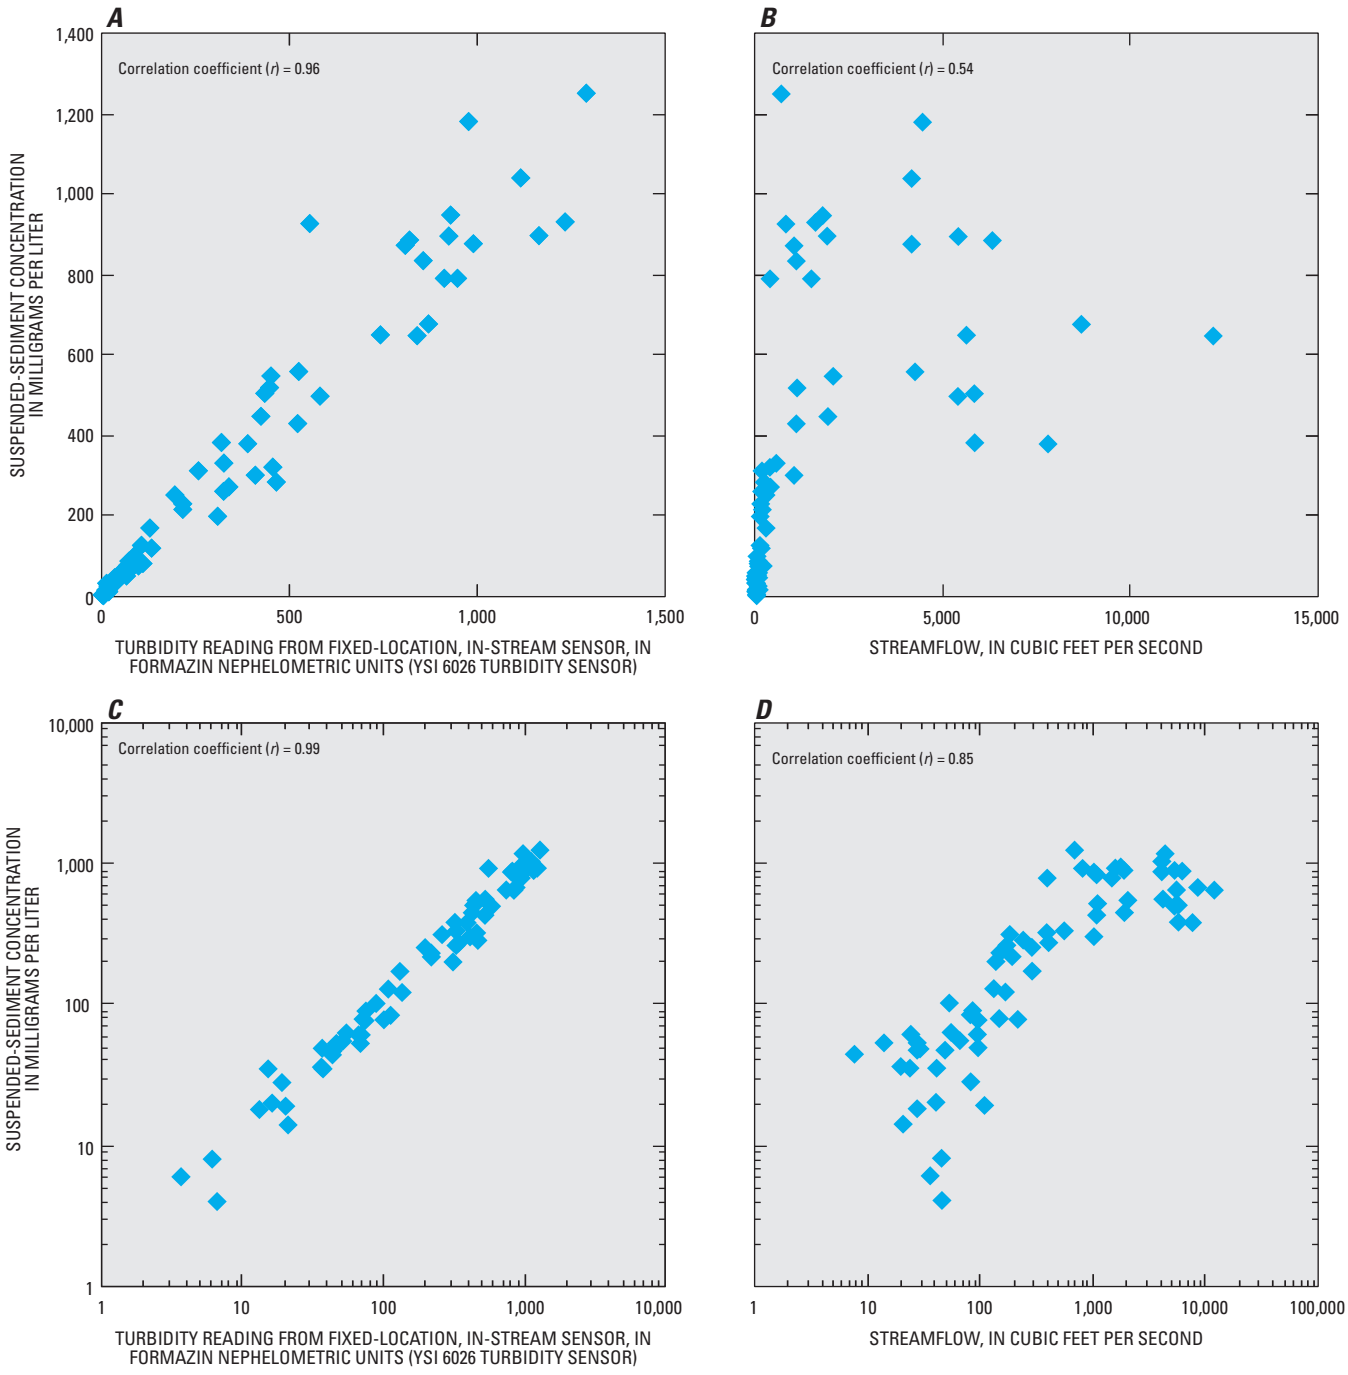

Figure 8. Relations between *A,* turbidity and suspended-sediment concentration, *B,* streamflow and suspended-sediment concentration in linear space, *C,* turbidity and suspended-sediment concentration, and *D,* streamflow and suspended-sediment concentration in $\log_{10}$ space for U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas, 1999–2005.

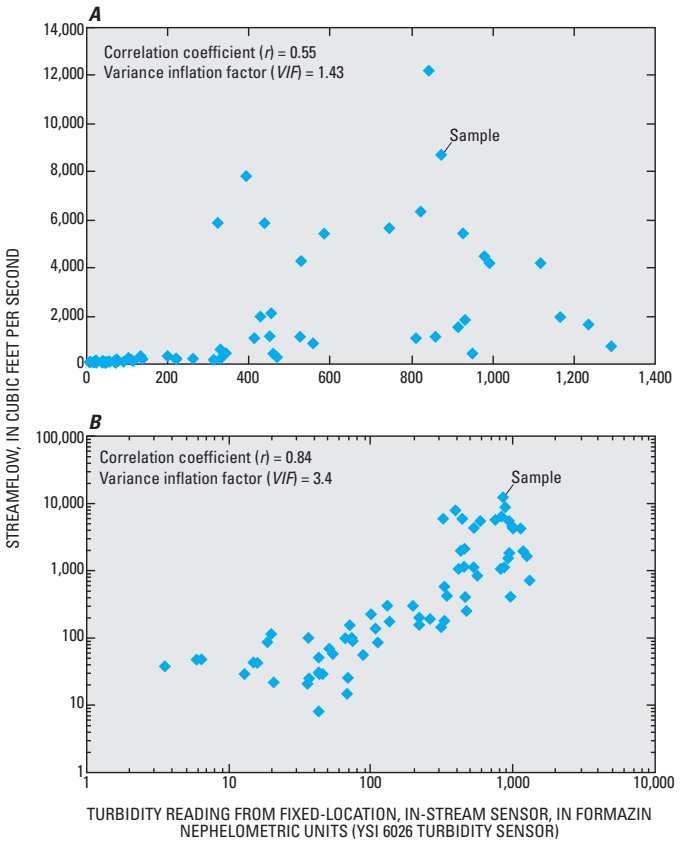

Figure 9. Comparison of turbidity and streamflow at the time of sample collection in *A*, linear space and in *B*, $\log_{10}$ space for U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas, 1999–2005.

The lowest *MSPE* corresponds to the model with the least uncertainty associated with regression-computed values. The PRESS (prediction error sum of squares) statistic is one of the best measures of the quality of a regression model and also can be computed using *RMSE* (Helsel and Hirsch, 2002, p. 247). Table 3 presents when and how a diagnostic statistic can be used for comparison among regression models. Note that none of these diagnostic statistics can be used to compare regression with different response variables units.

Transformation of Data

The purposes for transformation of data prior to an analysis are to make the residuals more symmetric, linear, and homoscedastic (associated with a constant variance). Helsel and Hirsch (2002, p. 252–4) describe the rationale for and the results of data-set transformations. Serious problems can occur when regression models are developed and residuals do not possess the assumed characteristics of symmetry, linearity, and homoscedasticity. Comparisons of transformed and untransformed data and regression results are presented throughout this section so that the hydrographer can better understand how data transformation improves the computation of *SSC*s.

Base-10 logarithmic transformation is one of several mathematical functions that sometimes can be used to transform data sets so that the assumptions for linear regression analysis are met. Helsel and Hirsch (2002, p. 12–14) discuss other transformation options and characteristics. Logarithmic base-10 transformation has been shown to be effective in normalizing residuals of turbidity-*SSC* regressions. Hydrographers should start with base-10 logarithm transformation but are encouraged to experiment with other transformation options to determine if a different transformation of the data-set results in a model that better satisfies the assumed residual characteristics for regression analysis. Other considerations should include the ease of retransforming the results from the model, the bias associated with the retransformation, and rationale for complex transformations. As Helsel and Hirsch (2002) point out, it is better to choose a single transformation for data from several sites than it is to have custom transformations for every data set. The examples presented here use a logarithmic base-10 transformation of both the response and explanatory variables, which is equivalent to the power function regression performed on untransformed variables and used for many streamflow-*SSC* transport curves (Glysson, 1987; Curtis and others, 2006). From Helsel and Hirsch (2002), page 315.

"Should *y* (*SSC*) be transformed? To decide whether to transform the *y* variable, plot residuals against predicted values for the untransformed data. Compare this to a residuals plot for the best-transformed model, looking for three things:

Table 3. Diagnostic statistics of linear regression for evaluation and comparison of regression models (Helsel and Hirsch, 2002).

[R^2, coefficient of determination; R^2_a, adjusted coefficient of determination; *RMSE*, root-mean-squared error; *MSPE*, model standard percentage error; ↑, maximize; ↓, minimize]

Type of models being compared	R^2	R^2_a	*RMSE*	PRESS	*MSPE*
Same response variable (*y*) units	↑	↑	↓	↓	↓
Differing response variable (*y*) units					↓
Same *y* and same number of *x* variables	↑	↑	↓	↓	↓
Same *y* and varying number of *x* variables		↑	↓	↓	↓
Should *y* be transformed?					↓
Should *x* ('s) be transformed?	↑	↑	↓	↓	↓

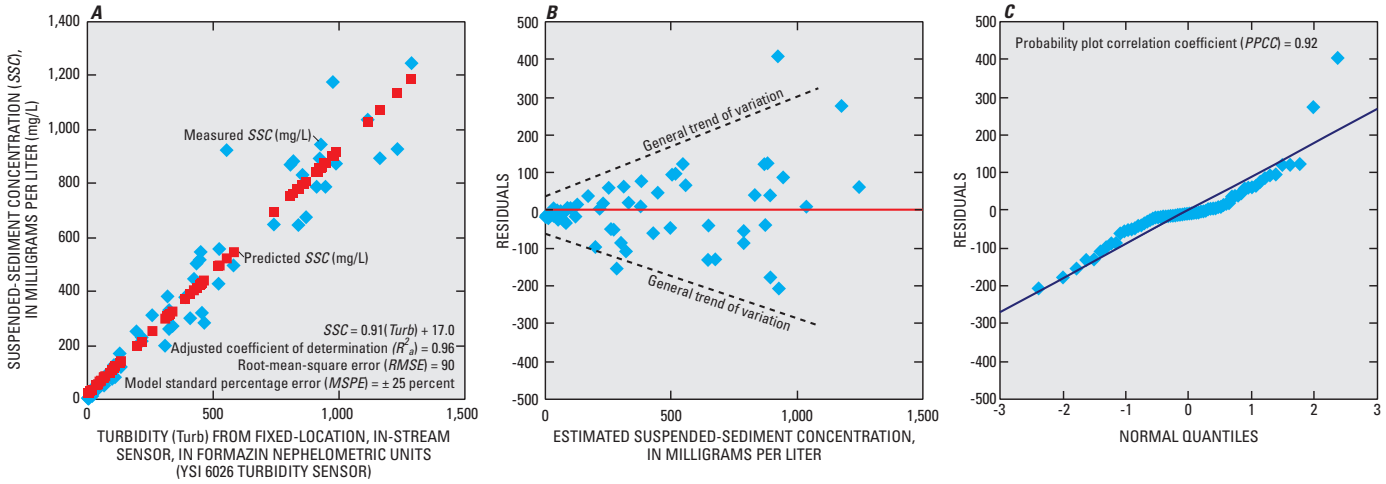

Figure 10. Results of simple linear regression analysis for *A,* turbidity and suspended-sediment concentration data, and a comparison of *B,* computed suspended-sediment concentrations and regression residuals, and *C,* probability plot of residuals for U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas, 1999–2005.

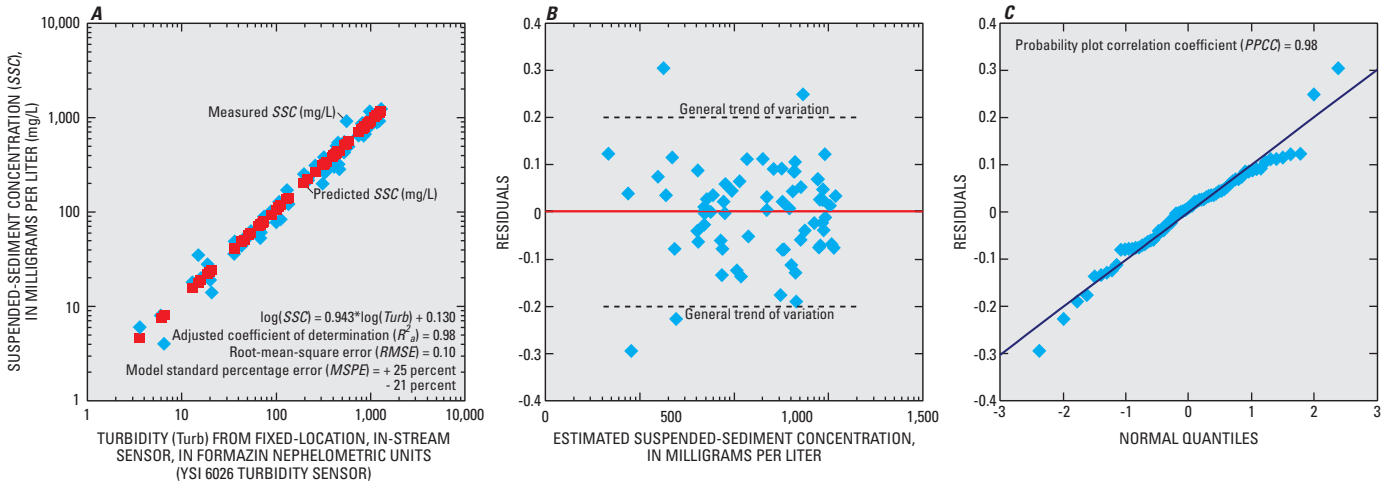

Figure 11. Results of simple linear regression analysis using log-transformed data for *A,* turbidity and suspended-sediment concentration data, and comparison of *B,* estimated $\log_{10}$ suspended-sediment concentration and regression residuals, and *C,* probability plot of residuals for U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas, 1999–2005.

1. Constant variance across the range of the *y* (*SSC*);
2. Normality of residuals; and
3. A linear pattern, not curvature, centered vertically around the zero residual line.

The statistics R^2, R^2_a, *RMSE*, and PRESS are not appropriate for comparison among models having different units of *y*.

Should *x* (or several *x*'s) be transformed? The decision about whether to transform an *x* variable should be made using partial-residual plots. Check for the same three patterns of constant variance, normality, and linearity. Considerable help can be obtained from statistics such as R^2_a (maximize it), or *RMSE* or PRESS (minimize it). Many transformations can be rapidly checked with such statistics, but a residuals plot should always be produced and inspected prior to accepting or rejecting a transformation scheme."

Model Residual Analysis

Regression models are evaluated by examining the model residuals. Ordinary residuals are defined as the difference between the observed values and the model estimates (the term "model estimate" is used here because the values are estimates of actual samples or observed values). The residual error (e_i) for the computed *SSC* values should be random and, in theory, should be normally distributed with a mean of zero and a constant variance (Helsel and Hirsch, 2002). The residuals from a regression of *SSC* on turbidity indicate how

the model-estimated *SSC* varies from the observed *SSC*. A residual value of 0 indicates that the model-estimated *SSC* is equal to the observed value. A positive residual indicates that the observed value was larger than the estimated value, and a negative residual indicates that the observed value was less than the estimated value.

The variance of the residuals can be evaluated by plotting them against the model estimated *SSC* (figs. 10*B* and 11*B*). The residuals plotted in figure 10*B* indicate a heteroscedastic pattern (nonconstant variance; as indicated by the dashed lines) where the variability of the residuals increases as estimated *SSC* values increase, which suggests the need for some sort of variance stabilizing transformation of the response variable. The residuals plot for the $\log_{10}$-transformed regression (fig. 11*B*) indicates a homoscedastic pattern (constant variance) and a more normal distribution. Normality of residuals can be evaluated by plotting residuals on a normal-probability plot (figs. 10*C* and 11*C*) and computing the probability plot correlation coefficient (PPCC; Helsel and Hirsch, 2002, p. 253). Non-normally distributed residuals will not be linear or equally distributed on a normal-probability plot and have a smaller PPCC. The probability plot for the $\log_{10}$-transformed regression provides a more linear, even distribution of residuals and a slightly larger PPCC than the residuals from the regression with untransformed variables (figs. 10*C* and 11*C*). The plots in figures 10*B* and 11*B* confirm that $\log_{10}$ transformation provides more homoscedastic, normally distributed residuals.

Simple Linear Regression Model and Bias Correction Factor

The SLR model for the Little Arkansas River near Sedgwick, Kansas, for data collected from November 1998 to June 2005 is shown below with basic model information, regression coefficients, model diagnostics, and Duan's bias correction factor (Duan, 1983):

$$\log_{10}(SSC) = 0.943\log_{10}(Turb) + 0.130, \quad (3)$$

where

SSC is suspended-sediment concentration, in milligrams per liter, and

Turb is turbidity, in formazin nephelometric units, measured with YSI model 6026.

Model information:

Number of measurements = **68**,
root-mean-squared error (*RMSE*) = **0.10**,
model standard percentage error (*MSPE*) = **+ 25.9 and -20.6 percent**,
90-percent prediction interval = **± 41 percent**,
adjusted coefficient of determination (R^2_a) = **0.98**,
PRESS = **0.663**.
Duan's bias correction factor = **1.03**.

Coefficients:

	Value	Standard error	t-statistic	p-value
Intercept	**0.130**	**0.041**	**3.02**	**0.0035**
$\log_{10}$(turbidity)	**0.943**	**0.018**	**50.9**	**1.13E-54**

Correlation matrix of coefficients:

	Intercept	$\log_{10}(Turb)$
Intercept	1	
$\log_{10}(Turb)$	-0.9588	1

Some of the regression statistics are useful in evaluating this regression model. For example, the *RMSE* (even though it is expressed in log units), the *MSPE*, and the 90-percent prediction interval indicate the range in uncertainty associated with each regression-computed *SSC* value. R^2_a indicates that the regression model explains 97 percent of the variability in sampled *SSC*. The PRESS is only relevant for comparisons to other regression models with the same response variable units. The t-statistics for the *y* intercept and coefficient (slope) of $\log_{10}$(turbidity) are larger than 2, and the p-values are less than 0.05, indicating that both are significant and should be included in the final model form. Helsel and Hirsch (2002, p. 239) discuss the option of omitting the *y* intercept (thus forcing the *y* intercept to equal zero). There are several tests the hydrographer can perform to help aid in the decision, but generally, omitting the *y* intercept is discouraged. Hydrographers are encouraged to develop a regression model by forcing the *y* intercept to equal zero as an iterative step in better understanding the data set and the effect of certain data points, specifically the smaller turbidity-*SSC* values.

Transformation of the response variable (*SSC*) has a consequence that must be considered when computing *SSC*: The regression estimates must be retransformed to the original units, a step that introduces a bias (usually negative) in computed *SSC* values (Miller, 1951; Koch and Smillie, 1986) unless the data are perfectly and positively correlated [as the R^2_a approaches 1.0, the bias correction factor (BCF) also approaches 1.0]. The bias arises because regression estimates are the mean of *y* given *x* in log units, and retransformation of these estimates is not equal to the mean of *y* given *x* in linear space. To correct for this retransformation bias, Duan (1983) introduced a nonparametric BCF called the "smearing" estimator (Helsel and Hirsch, 2002, p. 256). The equation to compute the smearing BCF for base-10 logarithmic transformation is:

$$BCF = \frac{\sum_{i=1}^{n} 10^{e_i}}{n}. \quad (4)$$

where

n is the number of samples, and

e_i is the residual or the difference between each measured and estimated concentration, in log units.

Regression-computed *SSC* values for Little Arkansas River near Sedgwick, Kansas, are corrected for bias by multiplying the retransformed *SSC* value by the BCF.

Model-calibration data plotted concomitant with the bias-corrected model line may not always result in what appears to be the best fit of the data. For BCFs larger than 1.0, model values will plot on the high side (more data points are below the curve than above it; fig. 12); that is, when the results of the simple linear-regression line are multiplied by the BCF and plotted, the curve is shifted upward from the original position. This same effect of BCFs with sediment-transport equations has been shown to fit data on the high side in other sediment-transport studies (Bent, 2000). There also is an exact, minimum-variance unbiased estimator (MVUE; Cohn and others, 1989), but MVUE assumes a normal distribution of the residuals, which frequently is not the case.

A comparison of measured and model-estimated *SSC* indicates the accuracy of the regression model (fig. 13). The closer that points plot to the 1:1 line the more accurate the model predictions are.

Once the turbidity-*SSC* model is determined, the hydrographer needs to consider the potential benefits of adding streamflow as an explanatory variable. SLR analysis is preferred for sites where turbidity is the measure most strongly correlated with *SSC* or where *MSPE* is less than 20 percent. Sites with a homogeneous source of suspended sediment and more than about 80 percent of the suspended material finer than 63 µm are the best candidates for *SSC* computations using the SLR model. When turbidity is less correlated with *SSC* or when the MPSE is larger than 20 percent or sand (particle size coarser than 63 µm) constitutes an increasing percentage of the sediment in suspension as *SSC* increases, streamflow in addition to turbidity may better describe the variability in *SSC*. MLR model building is similar to SLR but should not precede SLR model development. Methods for building MLR models are discussed in a later section of this report titled "Multiple Linear Regression."

Prediction Intervals

Prediction intervals can be used to evaluate the uncertainty of *SSC* regression-computed values (Helsel and Hirsch, 2002). Prediction intervals define a range of values for the regression estimate associated with a known level of certainty. For a given turbidity value (explanatory variable), the 90-percent prediction interval represents a range of values within which there is a 90-percent certainty that the true *SSC* value occurs. The larger the 90-percent prediction interval, the more uncertainty there is associated with computed *SSC*. The prediction interval for a single response y_i is approximately:

$$E(y_i) \pm t \times s, \quad (5)$$

where

$E(y_i)$ is the regression-estimated value, at x_i;

t is the value of the student's t distribution having n-2 degrees of freedom (n is the number of observations) with the exceedance probability of $\alpha/2$ (alpha value obtained from t tables in the appendix of most statistics textbooks) for 90-percent prediction interval $\alpha = 0.10$; and

s is the standard error of regression or the *RMSE*.

Multiple Linear Regression

As previously stated, MLR represents an alternate tool for computing *SSC*s when the SLR *MSPE* is larger than 20 percent. However, MLR should only be considered for use when the p-value (probability value) of the partial F statistic (Helsel and Hirsch, 2002, p. 298) for streamflow is less than 0.025. Comparison plots of the residuals from the turbidity-*SSC* SLR to streamflow can indicate when an MLR model may decrease the amount of variability explained. The residual plots for the Little Arkansas River near Sedgwick, Kansas, indicate that there is little or no change in variability with streamflow (fig. 14*A* and *B*). Neither of these plots supports the addition of streamflow to the *SSC* model.

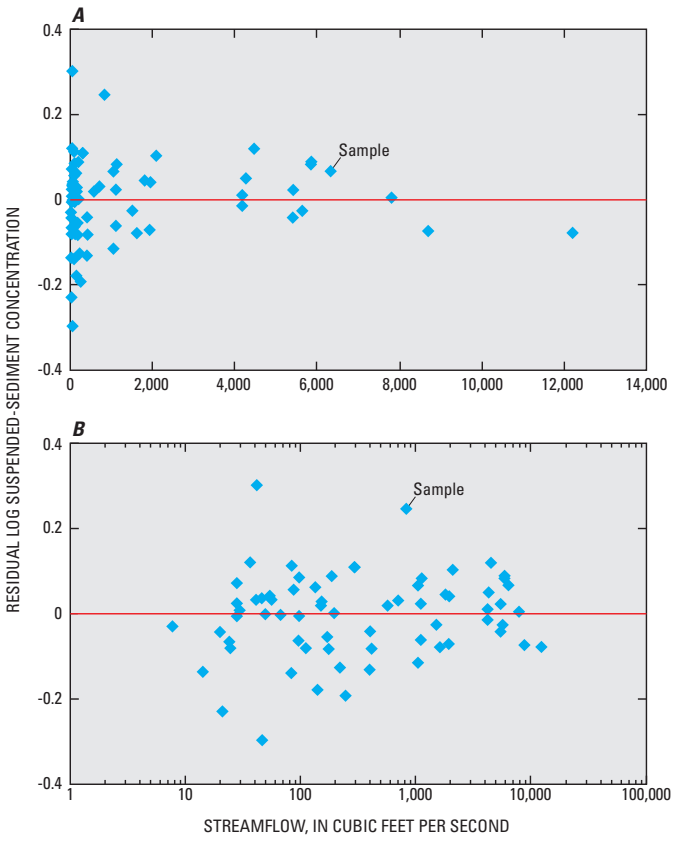

Figure 14. Comparison of streamflow in *A,* linear space and in *B,* $\log_{10}$ space to residuals from a simple linear regression analysis of turbidity and suspended-sediment concentrations for U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas, 1999–2005.

Other methods for evaluating which explanatory variables to include in the regression model are part of MLR model-building method described in Helsel and Hirsch (2002, p. 312–315). The possible explanatory variables in this case include turbidity and streamflow. Turbidity and streamflow are typically $\log_{10}$ transformed for a better regression model, but any combination of transformed or untransformed explanatory variables can be evaluated.

The *MSPE* for the SLR model of the Little Arkansas River near Sedgwick, Kansas, is larger than 20 percent, indicating that a MLR model with streamflow and turbidity should be considered. The streamflow variable is deemed significant in the regression model if the p-value of the partial F statistic is less than a predetermined alpha value (α) of 0.025. As shown in table 4, the p-value is larger than 0.025 for streamflow in the MLR model for the Little Arkansas River near Sedgwick, Kansas, indicating that the SLR model–and not a MLR model–should be used for computing *SSC*. The R^2_a should never be the sole criterion used to assess the appropriateness of a regression model because a large R^2_a can occur even though the linear fit is poor (see Helsel and Hirsch, 2002, p. 18 and 228, and Glysson, 1987, p. 39–43). The regression diagnostics are reported in the default regression model output from Microsoft Excel or the "Regression Subset Selection" option of the USGS library for S-Plus for Windows (Slack and others, 2003).

Comparison plots of measured and model-estimated *SSC* for the SLR and MLR models can indicate the regression model with the most accuracy (fig. 15*A* and *B*). The closer the points plot to the 1:1 line, the more accurate the model predictions are. The variance of the MLR residuals should be evaluated and compared to the SLR residuals (fig. 15*A* and *B*). The measured/estimated *SSC* and residual plots are nearly identical for the SLR and MLR models, suggesting that the models produce similar results.

Regression Model Summary

The regression model selected to compute *SSC* time-series values for the Little Arkansas River near Sedgwick, Kansas, is the turbidity-*SSC* SLR model. Comparisons with the MLR model indicate that the addition of the streamflow variable slightly improved the *SSC* prediction but not sufficiently so as to justify its inclusion. In general, the simplicity of a SLR model is preferred over a MLR model that imparts modest improvement in accuracy to the computational process. Currently (2009), ADAPS (U.S. Geological Survey, 2003) can compute *SSC* using a SLR model. The use of ADAPS for computing *SSC* is desired because of the documentation of the regression model and when it was used. Had the MLR model been chosen, *SSC* values would have to be

Table 4. Expressions for determining use of simple linear regression (SLR) or multiple linear regression (MLR) models for U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas.

[*n,* number of samples; R^2_a, adjusted coefficient of determination; *RMSE*, root-mean-squared error in log units; *MSPE*, model standard percentage error; n/a, not applicable]

Explanatory variables	*n*	R^2_a	*RMSE*	*MSPE*	p-value for streamflow	t-statistic for streamflow
Turbidity	68	0.975	0.101	+25.9, -20.6	n/a	n/a
Turbidity and streamflow	68	0.977	0.098	+25.3, -20.2	0.043314	2.06

computed outside of ADAPS and then loaded to ADAPS (see Appendix 2).

A summary of regression information and expressions should be recorded in the station analysis for "Suspended Sediment" (example 1 of Appendix 1). The summary contains information specific to the development of the regression model. The hydrographer should summarize the reasoning for selection of the model, the final regression model and associated statistics, and the dates for which the model was used to compute *SSC* and *SSL*. A senior hydrographer should review the summary to determine its adequacy.

Computation of Suspended-Sediment Concentration and Load Time-Series Record

SSC time series should be computed at the same time step as the measured in-stream turbidity and streamflow time series by means of an appropriate regression model. Depending on the model form and which explanatory variables are used, the regression model can be implemented as a turbidity-*SSC* rating in NWIS to calculate a *SSC* time series. Details for developing a *SSC* time series within NWIS are presented in Appendix 2.

Log_{10}-transformed SLR models can be expressed as a power function and used to compute instantaneous values of *SSC* in ADAPS. The "equation rating" in ADAPS computes instantaneous values for the output data description (DD) and *SSC* on the basis of instantaneous values of the input DD (turbidity; U.S. Geological Survey, 2003). Retransformation of the $\log_{10}$-transformed SLR model (equation 6) is shown in equation 7.

The $\log_{10}$-transformed SLR model follows:

$$\log_{10}(SSC) = b_1 \log_{10}(Turb) + b_0, \quad (6)$$

where

SSC is suspended-sediment concentration, in milligrams per liter;
b_1 is the slope;
Turb is turbidity; and
b_0 is the y intercept.

The $\log_{10}$-transformed SLR model (equation 6) can be retransformed and corrected for bias with a BCF resulting in equation 7:

$$SSC = 10^{b_0} Turb^{b_1} \times BCF. \quad (7)$$

For the Little Arkansas River near Sedgwick, Kansas, the model, $\log_{10}SSC = 0.943\log_{10}Turb + 0.130$, and *BCF*, 1.03, can be retransformed to $SSC = 10^{0.130}Turb^{0.943} \times 1.03$, or

$$SSC = 1.39Turb^{0.943}. \quad (8)$$

The hydrographer also should consider and perhaps limit computed values extrapolated beyond the range of explanatory variable values (minima and maxima of the explanatory variables). The veracity of extrapolated model values must be evaluated. Typically, the number of extrapolated values can be minimized if: (1) the range of the model-calibration data set is maximized by collecting samples at both extremes, and (2) the make and model of the fixed-location turbidity sensor are identical to the manually deployed field-turbidity sensor with similar maximum recording levels. Computed values that are substantially beyond the range of the calibration data should be withheld from public display until those values can be verified by new *SSC* data. If a replacement or supplemented sensor has a maximum recording level that is more than 10 percent larger than the maximum value of the calibration data set, the computed *SSC* values greater than the calibration data set maximum should be withheld from display until those values can be verified with samples collected in the range between the new sensor maximum recording level and the upper limit of the regression model.

Estimates for Periods of Missing Data

USGS policy (2009) precludes storage of estimated instantaneous values of turbidity in the NWIS database (Office of Water Quality Technical Memorandum 2005.03; U.S. Geological Survey, 2005). However, data collected from sources other than the fixed-location turbidity sensor can be used to supplement discrete periods of missing turbidity time-series record, which includes periods for which measured turbidity values are considered unreliable, such as from turbidity sensor

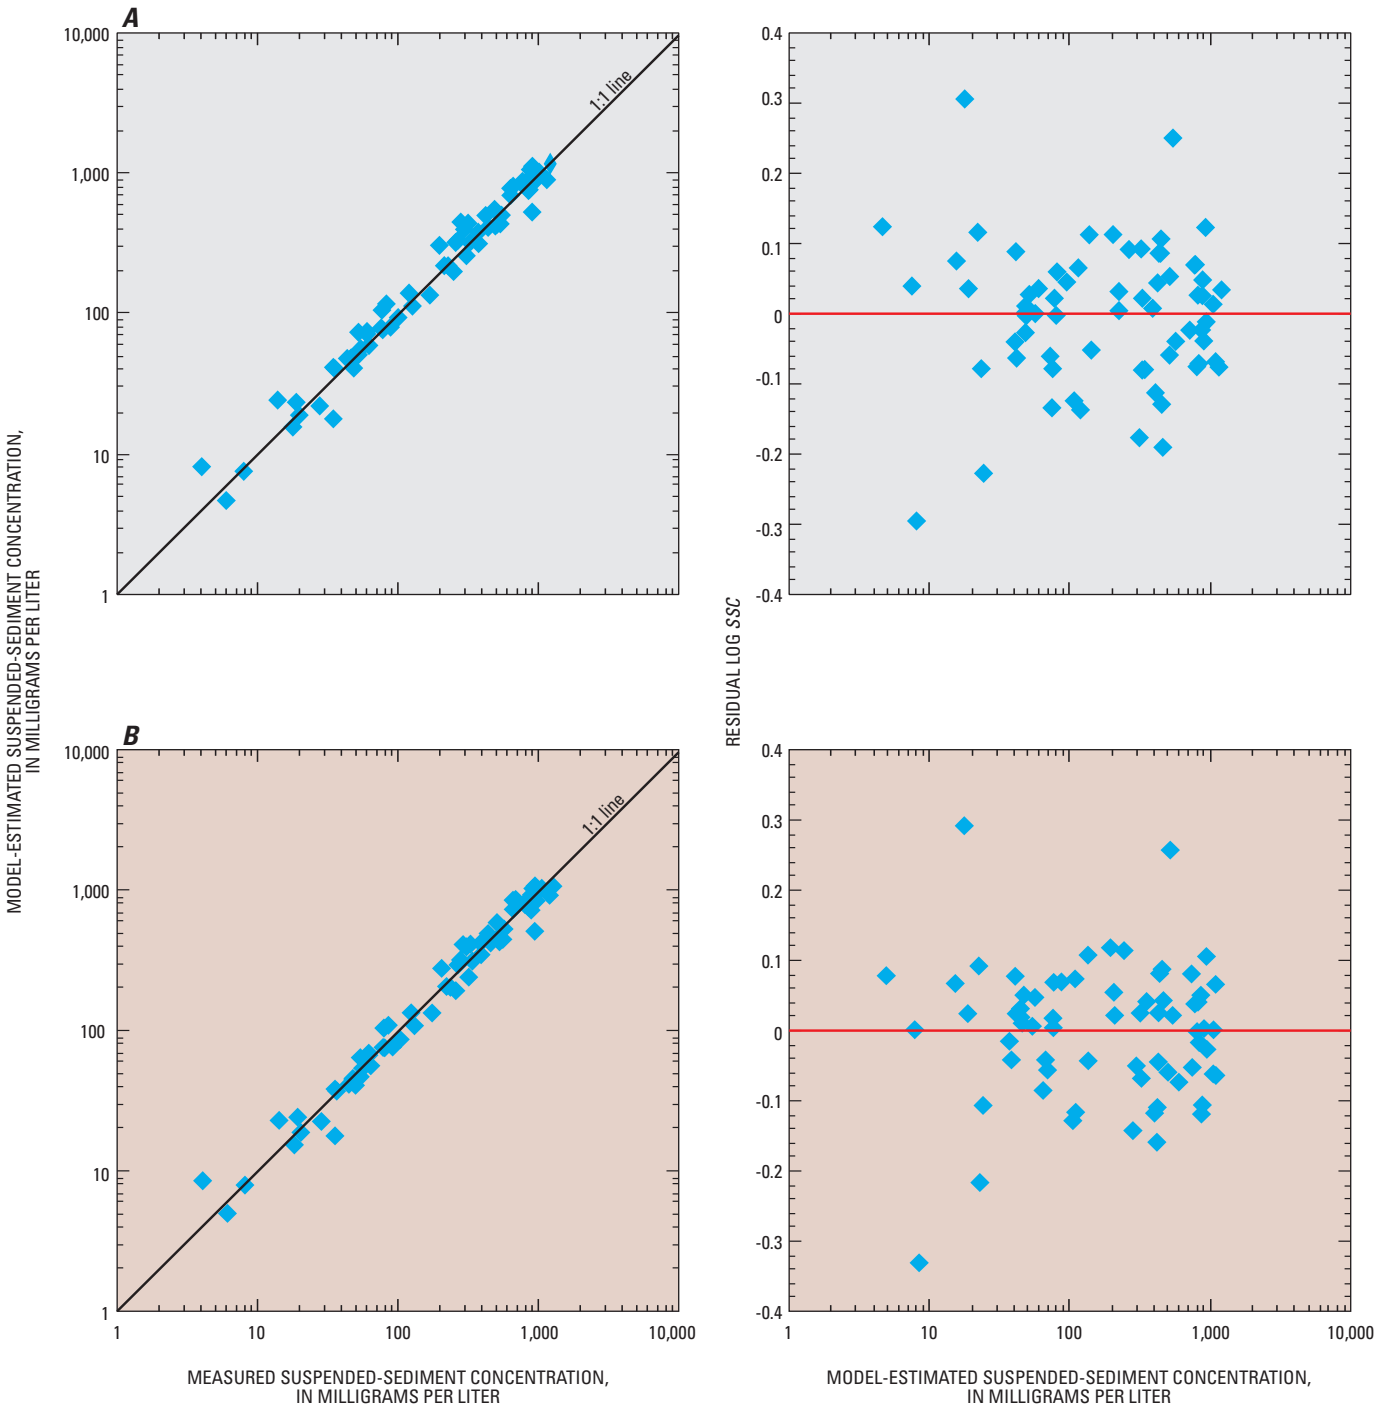

Figure 15. Comparison of measured and estimated suspended-sediment concentrations and residuals in log space from *A,* simple and *B,* multiple linear regression models for U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas.

truncation at large *SSC* values. For example, onsite measurements made using a cleaned and calibrated field sensor while the fixed-location sensor is being cleaned and calibrated can be used to fill in a part of the missing turbidity time-series record during the site visit.

The appropriateness of estimating mean daily turbidity values is governed by a number of factors, the most effectual of which are the duration of the missing record, availability of flow data for the missing-record period, and the availability of data describing historical relations among turbidity, streamflow, and *SSC*. Daily statistics for periods containing missing data should be calculated with an appropriate level of scrutiny and in accordance with Wagner and others (2006). Mean daily turbidity values should not be calculated solely for the purpose of calculating mean daily *SSC* values. Daily *SSC* values should be estimated by methods described by Porterfield (1972) or Koltun and others (2006). The hydrographer should note in the station analysis that the uncertainties associated with *SSC* estimates derived from estimated turbidity data are unknown. Rasmussen and Ziegler (2003), Bragg and others (2007), and Lee and others (2009) demonstrate different techniques for estimating missing or truncated instantaneous values of turbidity and *SSC*.

Estimation of missing or truncated instantaneous *SSC* values (without estimating turbidity values) in some instances can be performed outside of ADAPS to meet study objectives. The method(s) used in those instances to develop estimates should be well documented and peer reviewed.

Computation of Suspended-Sediment Load Time-Series Record

A time series of *SSL* is calculated from *SSC* and streamflow for the same site. Instantaneous *SSL* is calculated using the following equation:

$$SSL_i = SSC_i \times Q_i \times c, \tag{9}$$

where

SSL_i is the computed suspended-sediment load, in tons per second, or pounds per second;
SSC_i is the computed suspended-sediment concentration for the ith value, in milligrams per liter;
Q_i is the streamflow for the ith value, in cubic feet per second; and
c is a constant, 3.121×10^{-8}, for converting the units to tons per second, or 6.242×10^{-5} for pounds per second.

The instantaneous *SSC* and streamflow values also can be used to compute daily, monthly, or annual *SSL*s using the following equation:

$$SSL_n = \sum_{i=1}^{n} \frac{\left(C_1 + C_{i-1}\right) \times \left(Q_i + Q_{i-1}\right) \times \left(t_i - t_{i-1}\right)}{4} \times c, \tag{10}$$

where

SSL_n is the computed suspended-sediment load for the desired time period, in tons;
C_i is the suspended-sediment concentration for the ith time, in milligrams per liter;
C_{i-1} is the suspended-sediment concentration for the ith minus 1 time, in milligrams per liter;
Q_i is the streamflow for the ith value after midnight, in cubic feet per second;
Q_{i-1} is the streamflow for the ith minus 1 value after midnight, in cubic feet per second;
t_i is the time for the ith value after midnight;
t_{i-1} is the time for the (ith-1) value after midnight;
c is a constant, 0.0027, for converting the units to tons per day; and
n is the number of instantaneous values within the desired period (day, month, year).

The hydrographer should identify any periods of missing record and determine how to provide the best estimate of *SSL* for periods when computed *SSC* data, streamflow data, or both are missing. The options to estimate *SSL* include: (1) interpolate the missing values between known values, taking into consideration other available data, (2) estimate *SSL* on the basis of some other data, such as streamflow (a sediment-transport curve for the site) or *SSL* derived from a streamgage with similar sediment characteristics using appropriate scaling factors, or (3) another technically supportable method. Regardless of the method or combination of methods used to estimate missing *SSL* data, the rationale should be fully explained in the station analysis or associated report.

Uncertainty estimates of long-term suspended-sediment load computed by summing retransformed *SSC* from SLR or MLR models with transformed response variables can be computed. Estimates of the mean squares errors are discussed in Gilroy and others (1990).

Model Validation and Maintenance of a Long-Term Suspended-Sediment Concentration Record

Once an acceptable regression model is developed, it can be used to compute *SSC* beyond the period of record used in model development with proper sample collection and analysis. Maintenance of a long-term *SSC* record requires ongoing collection of turbidity and streamflow time-series data and sample collection for reanalysis and verification of the current *SSC* regression model. The method for validating the regression model is affected by the frequency of calibration-sample collection and the purpose of the study. Regression models can be validated annually (or at some other frequency as needed on the basis of the nature of the monitored hydrologic system and its watershed, and the needs and constraints of the monitoring program) after sufficient applicable new data have been collected or on the basis of other valid criteria. A fundamental

characteristic of hydrology is variability, with periods of floods and periods of droughts. Additionally, watershed conditions can change seasonally or from other factors such as through changes in land use, implementation of best management practices, or by wildfire. Therefore, regression models to compute *SSC* at a site should never be considered static but rather considered to represent a set period in a continually dynamic system in which additional data will help verify any change in *SSL*, type, and source.

Validation of Suspended-Sediment Concentration Model

One approach to updating the regression model is to plot new observations with the original model-calibration data set and recompute the regression coefficient(s) and *y*-intercept. Typically, at least 4 to 10 *SSC* samples and associated turbidity and streamflow values representing a wide range of streamflows are collected annually, depending on the site and monitoring program, to validate the existing regression model. More such data may be needed. The additional data plotted along with the model-calibration data set for comparison should indicate any significant change in the turbidity-*SSC* relation that would signal the need for a completely revised regression model or additional and more frequent sample collection. A review of the scatter plot for the Little Arkansas River near Sedgwick, Kansas, suggests that there has been no significant change in the turbidity-*SSC* relation (fig. 16).

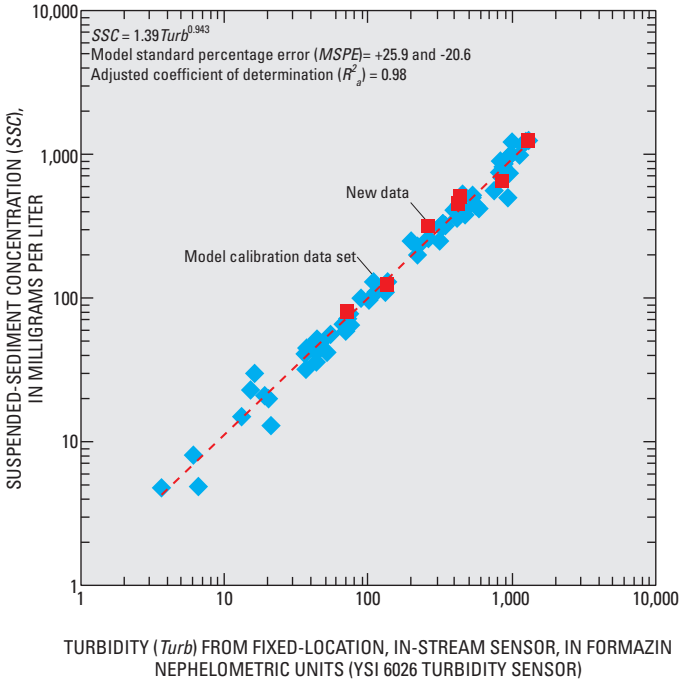

Figure 16. Model-calibration data set (water years 1999–2005) and new (water year 2006) turbidity and suspended-sediment concentration data for U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas.

A regression model developed from new measurements not used in previous model development should be compared to the existing regression model. Analysis of covariance (ANCOVA; see Helsel and Hirsch, 2002, p. 316) can be used to test (1) the regression model on the basis of the original model data and additional data, (2) the original regression model, and (3) the regression model solely on the basis of the additional data. ANCOVA will determine if the slope or *y* intercept of any of these models is significantly different, indicating a fundamental shift in the turbidity-*SSC* relation and the possible need to develop a new model. If a shift occurred, the hydrographer also will need to determine when it occurred and when to cease use of the existing model and begin use of a new model. A fundamental shift such as this should be accounted for by a major change in sediment source or transport processes in the watershed, such as those resulting from a substantial change in land use or land cover, construction or removal of an impoundment, wildfire, landslide, or a major flood. A more likely scenario is a gradual change over years that can be detected only by continued sample collection and analysis.

New data that do not significantly change the original regression should be added to the model-calibration data set to refine the regression model. The slope, *y* intercept, and the computed *SSC* values from the new model will not be significantly different from the old model, but the improved estimate of *RMSE* may reduce the prediction interval. The hydrographer has to determine when the refined model will take effect. If sample collection and analysis are considered on an annual basis, the new model should start at the beginning of the ensuing water year. An approved computed *SSC* time series should not be recomputed unless there is strong evidence that the turbidity-*SSC* relation changed during the approved period. The hydrographer in this case has determined that the revised model (fig. 16) will take effect at the beginning of water year 2006.

Sampling Plan

A sampling plan to obtain the requisite turbidity, streamflow, and *SSC* data should be devised to periodically validate and refine the existing regression model. Conditions or events that may cause variability in the turbidity-*SSC* relation also should be considered when devising a sampling plan for maintaining long-term *SSC* record. Sample values from the model-calibration data set may indicate periodic, seasonal, or other fluctuations that may induce variability in the current model. These fluctuations should be considered when collecting representative samples to facilitate adequate validation of an existing regression model. A prudent and affordable annual sampling plan for the Little Arkansas River near Sedgwick, Kansas, includes two to four spring stormwater runoff sample sets, two to four summer stormwater runoff or

base streamflow sample sets, and one to two winter base-flow sample sets.

Changes to Turbidity Sensor Model or Type

Different sensors can provide different turbidity readings for the same environmental sample (Landers, 2003). Manufacturers have made improvements and design changes to turbidity sensors over time. A change of sensor model or type most likely will require an adjustment to the historical values so that the equivalency of turbidity-sensor-response characteristics of historical and newly collected data is maximized. The hydrographer should compare turbidity measurements between differing sensors in a range of environmental samples. The difference between sensors cannot be identified in formazin standards (Hach; Loveland, Colo.) and may be reversed in polystyrene bead standards (APS Analytical Standards Inc.; Redwood City, Calif.; fig. 17).

Typically, turbidity data collected with an old sensor can be adjusted to an approximately equivalent reading for a new sensor by means of a conversion factor. The conversion factor is computed from a data set consisting of concurrent turbidity measurements collected by the old and new sensors arrayed adjacent to each other in the stream. Care should be taken to ensure that the range of the concurrent measurements spans the known range of turbidity values at the site. One way of achieving this is to operate both sensors in-stream, side-by-side, over a wide range of turbidity conditions. The resulting data set will provide a robust conversion factor for the monitoring site.

The site-specific turbidity conversion factor can be calculated several ways, such as from the mean or median of the instantaneous conversion factors or by means of an ordinary least squares (OLS) regression (if the relation is linear; fig. 18). The median conversion factor computed as the ratio, new sensor value/old sensor value, is the least likely to

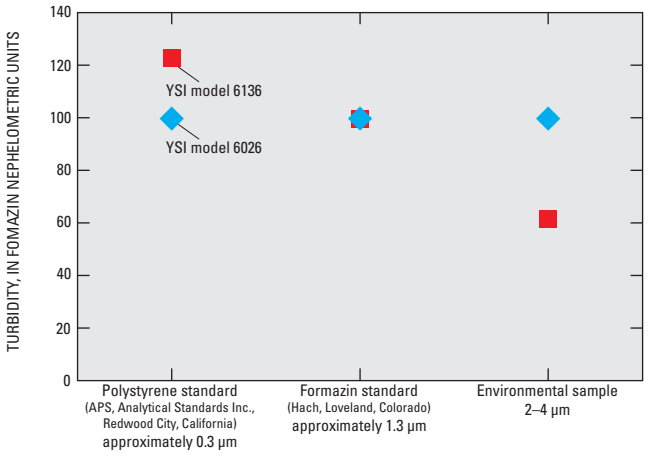

Figure 17. Comparison of turbidity measurements from YSI turbidity models 6026 and 6136 (YSI Incorporated, Yellow Springs, Ohio) in various solutions.

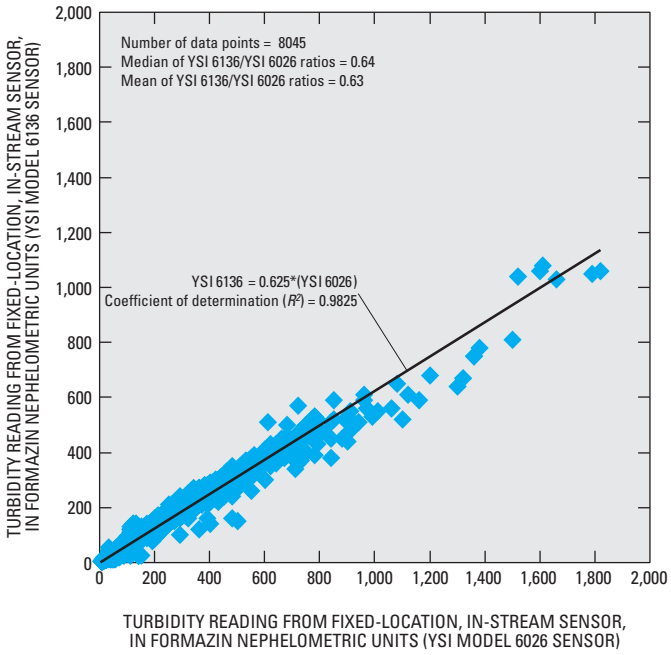

Figure 18. Relation between YSI 6026 and YSI 6136 turbidity sensor values, U.S. Geological Survey streamgage on Little Arkansas River near Sedgwick, Kansas, July 14, 2004, to August 26, 2005.

be affected by outliers and was selected for use. YSI Incorporated (2003) suggests a conversion factor of 0.65 for converting turbidity measurements made with sensor model 6026 to comparable measurements made with sensor model 6136. The conversion factor for the Little Arkansas River near Sedgwick, Kansas, was 0.64, which was obtained by taking the median of the instantaneous conversion factors from several months of concurrent in-stream turbidity measurements with both sensors (fig. 18).

The model-calibration data set can be adjusted using the conversion factor, and new regression model coefficients can be computed for the historical turbidity data. Each historical turbidity value in the model-calibration data set is multiplied by an empirically derived (or, lacking that, manufacturer-specified) conversion factor. Thus, the converted historical data are normalized with respect to the non-model data so that either sensor would provide the same value under identical environmental conditions. The adjusted model-calibration data then are used to recompute the regression model for computing *SSC* following the same steps used to develop the original model. The revised regression model then can be used to compute *SSC* on the basis of measurements from the new turbidity sensor. Historical *SSC* and turbidity time-series data with the ADAPS aging status of "approved" should not be recalculated or deleted. The hydrographer should plot the time series of historical *SSC* values that overlap with the time series from the new *SSC* regression model to ensure that the new and old equations are comparable.

Factors Affecting Relation Between Turbidity and Suspended-Sediment Concentration

The hydrographer should be mindful of factors other than *SSC* that can affect turbidity measurements. Particle size, shape, and color all affect the amount of light scattered, the important parameter for turbidity (Sutherland and others, 2000). Light is absorbed and scattered as it travels from a light source, to suspended particles, and is reflected back to a detector. When particle sizes larger than about 90 µm (very fine sand) are in suspension, the turbidity-*SSC* relation will be negatively biased, and that bias will increase as particle size increases (Anderson, 2005). Particle shape affects the scatter intensity. Darker or more black-colored (Munsell Color Co., 2000) particles also have been shown to substantially affect turbidity measurements by imparting a negative bias in measurements (Sutherland and others, 2000). Insights as to the potential effects of these and other factors might be gained from having particle-size and color analyses performed on selected water-sediment samples. Other factors affecting the turbidity-*SSC* relation are measurement error (including *SSC* sample collection and analysis) and natural variability caused by processes not evaluated in the regression model. Turbidity resulting from the presence of suspended microorganisms–principally phytoplankton–can result in increased uncertainty in the *SSC* determination. Hence, caution should be used when inferring *SSC* from turbidity or turbidity and streamflow values in water with substantial microbiological activity.

Summary

Collection, computation, and publication of suspended-sediment and related environmental data are a necessary part of investigations to evaluate effects of fluvial sediment and sediment-associated constituents on water resources. In-stream continuous turbidity data, or continuous turbidity and streamflow data, calibrated with measured suspended-sediment concentration (*SSC*) data, can be used to compute a time series of *SSC* and suspended-sediment load (*SSL*). Development of a simple linear regression model between turbidity and measured *SSC* data is the first step in computing a *SSC* time series. If the model standard percentage error (*MSPE*) simple linear regression model meets an established minimum criterion, this model can be used to compute a time series of *SSC*. If the simple regression model does not meet the acceptability criterion, a multiple linear regression model using paired instantaneous turbidity and streamflow data is developed. If the addition of streamflow is statistically significant and the uncertainty associated with the multiple regression model results in an improvement over that for the simple linear model and is ultimately acceptable, it is used as the basis for computing a time series of *SSC*. The computed *SSC* time series is subsequently used with its paired streamflow time series to compute a time series of *SSL* by standard U.S. Geological Survey techniques. Time-series *SSC* and *SSL* data can be used to better describe variability in suspended-sediment conditions, to evaluate *SSC* relative to numerical water-quality criteria and management goals, and to make watershed comparisons.

Once an acceptable regression model is developed, it can be used to compute *SSC* beyond the period of record used in model development with proper sample collection and analysis. Maintenance of a long-term *SSC* record requires ongoing collection of turbidity and streamflow time-series data and calibration-sample collection for reanalysis and verification of the current *SSC* regression model. The method for validating the regression model is affected by the frequency of sample collection and the purpose of the study. Regression models can be validated annually (or at some other frequency as needed on the basis of the nature of the monitored hydrologic system and its watershed, and the needs and constraints of the monitoring program) after sufficient new data have been collected or on the basis of other valid criteria. Regression models to compute *SSC* are generally site specific and should never be considered static but rather considered to represent a set period in a continually dynamic system in which additional data will help verify any change in *SSL*, type, and source.

Acknowledgments

This report was prepared by the USGS Kansas Water Science Center (WSC), Lawrence, Kansas, and the Offices of Surface Water and Water Quality, Reston, Virginia. USGS personnel in the California, Kansas, Oregon, and Pennsylvania WSCs provided astute technical advice and assistance. Information, discussion, comments, and suggestions from Teresa J. Rasmussen (Kansas WSC) and USGS colleague reviewers Paul A. Buchanan (California WSC), Elizabeth A. Hittle (Pennsylvania WSC), Gregory F. Koltun (Ohio WSC), David K. Mueller (Central Region), and Mark A. Uhrich (Oregon WSC) resulted in substantial improvements to this document. Trudy Bennett was responsible for oversight and data collection at the Little Arkansas River near Sedgwick, KS site.

Appendixes

Appendix 1. Examples of Suspended-Sediment Concentration Models from Kansas, Oregon, Florida, and California

Turbidity and *SSC* data and models from rivers in four States are presented to illustrate turbidity-*SSC* applications at a variety of geographic locations, drainage areas, and freshwater/saltwater conditions. Examples are courtesy of Heather Bragg and Mark Uhrich of the Oregon WSC (2007), Paul Buchanan of the California WSC (2004), A.C. Lietz (retired), and Elizabeth Hittle of the Pennsylvania WSC (2005).

U.S. Geological streamgages used for examples of turbidity and suspended-sediment concentration (SSC) data and regression models.

Example	Station number	Station name	Turbidity instrument make and model	Fresh- or saltwater	Drainage area (square miles)
1	07144100	Little Arkansas River near Sedgwick, Kansas	YSI model 6026	Freshwater	1,239
2	14178000	North Santiam River below Boulder Creek, Oregon	YSI model 6026	Freshwater	216
3	02279000	C-51 Canal, Palm Beach County, Florida	YSI model 6026	Freshwater	Not applicable
4	11458370	Mare Island Causeway, San Pablo Bay, California	D and A OBS	Saltwater	Not applicable

Example 1. Complete Review Package for Little Arkansas River near Sedgwick, Kansas

WATER-QUALITY MONITOR STATION ANALYSIS
2005 WATER YEAR
SUSPENDED-SEDIMENT RECORD
07144100
Little Arkansas River near Sedgwick, Kansas

MODEL-CALIBRATION DATA SET—All data were collected using USGS protocols and are stored in USGS NWIS databases. The regression model is based on 68 concurrent measurements of turbidity and streamflow and *SSC* samples collected from November 1998 through June 2005. Samples were collected throughout the range of continuously observed hydrologic and turbidity conditions. Turbidity and streamflow values are time-averaged approved unit values corresponding with the duration of sample collection. A comparison of cross-section mean and corresponding time-series monitor readings is provided. Water-quality data were collected using an YSI 6600 monitor with a 6026 turbidity sensor (FNU). Selected data values used to develop the regression models were removed on the basis of sample evaluation. Five *SSC* values were removed from the data set because of transcription errors, sampling errors, and a sample compromised during shipping. Three data values were affected by sensor limitations (within 10 percent of the sensor maxima) and, therefore, were removed from the data set. Summary statistics and the complete model-calibration data set are provided.

MODEL DEVELOPMENT—Initially, data plots of the response variable (*SSC*) and possible explanatory variables turbidity and streamflow indicate both are correlated to *SSC*. Regression analysis was done using S-Plus software, and the final output is provided. Turbidity and streamflow were examined together as explanatory variables for estimating *SSC*, but the p-values for streamflow were larger than 0.025. Different combinations of untransformed and $\log_{10}$-transformed data were evaluated. Log_{10}-transformed turbidity and *SSC* were selected as the best model on the basis of residual plots, *MSPE*, and p-value for streamflow. Residual plots for evaluating variance, normality, homoscedasticity, and curvature are provided. For $\log_{10}$-transformed models, estimated values were multiplied by a calculated retransformation bias correction factor (Duan, 1983). Ninety-percent prediction intervals are provided for evaluating uncertainty of the estimates.

MODEL SUMMARY—Summary of final regression analysis for suspended-sediment concentration at Little Arkansas River near Sedgwick, Kansas.

$$\log_{10}(SSC) = 0.943 \log_{10}(Turb) + 0.130,$$

where

SSC = Suspended-sediment concentration, in milligrams per liter; and
Turb = Turbidity (YSI 6026), in formazin nephelometric units.

Model information:

Number of measurements = **68**,
root-mean-squared error (*RMSE*) = **0.10**,
model standard percentage error (*MSPE*) = **+25.9 and -20.6 percent**
90-percent prediction intervals = **± 41 percent**,
adjusted coefficient of determination (R^2_a) = **0.98**,
PRESS = **0.663**.
Duan's bias correction factor = **1.03.**

Coefficients:

	Coefficient	Standard error	t-statistic	p-value
Intercept	0.130	0.041	3.02	0.0035
$\log_{10}(Turb)$	0.943	0.018	50.9	1.13E-54

Correlation matrix of coefficients:

	Intercept	$\log_{10}$(*Turb*)
Intercept	1	
$\log_{10}$(*Turb*)	-0.9588	1

***SSC* RECORD**—The record is computed using a regression model and ADAPS software. Data are computed at 15-minute intervals. The record is complete for the year except as noted. The turbidity monitor was removed for a short period in December-February to avoid ice damage.

Daily values for partial days were updated where data existed during the expected time for the occurrence of the maximum or minimum, if at least 12 hours of values were available for the day, and if values were present adjacent to the extreme for the day.

312 days of record out of 365 days (85 percent) will be published.

REMARKS—

- A new turbidity sensor, YSI model 6136, was installed to collected concurrent turbidity measurements. These measurements will be used to convert YSI model 6136 values to the YSI model 6026 to compute *SSC* with the new 6136 sensor.
- T.B. Bennett collected field data.
- Cross-section survey results can be retrieved from NWIS, database 02.
- The Excel® "Field Measurement Summary" spreadsheet for this site and water year summarizes the number of site visits, calibration results, and calculations of the magnitude of fouling and calibration drift.

Appendix 2. Computation, Storage, and Real-Time Display of Time-Series Suspended-Sediment Concentration and Load in National Water Information System

In some cases, ADAPS, a subsystem of NWIS, can compute *SSC* unit values (UVs) and *SSL* daily values (DVs). *SSC* UVs can only be computed in NWIS if turbidity is the sole explanatory variable in the regression model. Currently (2009), NWIS cannot compute *SSC* values if:

1. The model includes computed UVs, such as streamflow, for an explanatory variable, or
2. The model is a MLR model.

For *SSC* models that NWIS cannot compute, the hydrographer should refer to the Graphical Constituent Loading Analysis System (GCLAS; Koltun and others, 2006) or a spreadsheet application. The time series of computed *SSC* unit values then can be loaded to ADAPS using Device Conversion and Delivery System (DECODES) (U.S. Geological Survey, 2003).

SSL DVs are computed using mean daily *SSC* and streamflow. The resulting *SSL* DV is correct only if the *SSC* and streamflow are correlated in time. Typically, this is not the case and results in erroneous *SSL* DVs. Hydrographers should instead use GCLAS or a spreadsheet application to compute *SSL* UVs and DVs. The time series of computed *SSL* unit values then can be loaded to ADAPS using DECODES (U.S. Geological Survey, 2003).

The following presents the general methods for computation, storage, and real-time display of *SSC* unit values and *SSL* daily values using NWIS. For complete instructions, refer to U.S. Geological Survey (2003), *http://pubs.usgs.gov/of/2003/ofr03123/*. NOTE: The user must have a user class of "adba" or "syst" to have access to perform several of the following steps (U.S. Geological Survey, 2003).

In ADAPS, the site must have a data descriptor (DD) for computed:

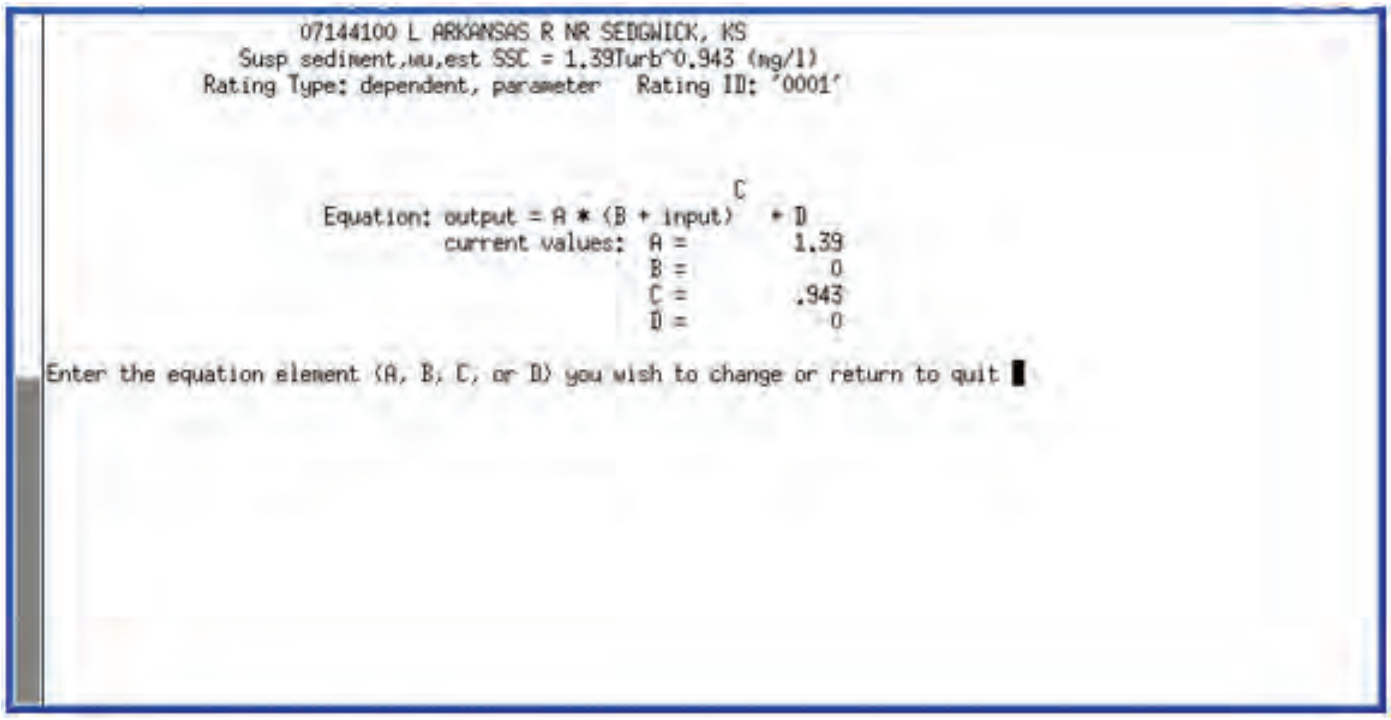
- *SSC* unit values (NWIS parameter code 99409—suspended-sediment concentration, water, unfiltered, estimated by regression equation, milligrams per liter) and
- *SSL* unit values (NWIS parameter code 80295—sediment suspended sediment load, water, unfiltered, estimated by regression equation, pounds per second, 80296–sediment suspended sediment load, water, unfiltered, estimated by regression equation, tons per second, 80297–suspended sediment load, water, unfiltered, computed, the product of regression-computed suspended sediment concentration and streamflow, tons per day, or 80298–suspended sediment load, water, unfiltered, regression computed, turbidity and streamflow as regressors, tons per day).

The DD setup for *SSC* and *SSL* should include:

1. Adding a DD optional description (30 characters maximum).

   SSC—Add the SLR model (example, "*SSC* = 1.39*Turb*^0.943")
   SSL—example, "by regression using turbidity DD##," where DD## is the turbidity data descriptor number.
2. The processor for the *SSC* DD needs to be identified as a "standard rating computation" and have the turbidity DD identified as the input DD.
3. The rating values of measured turbidity and estimated *SSC* should be calculated outside of ADAPS using the SLR model and the BCF and entered as a "dependent, parameter" rating. The proper "rating expansion type" for Little Arkansas River near Sedgwick, Kansas example is "equation."

   - The rating "Remarks" (99 characters maximum) should include the SLR model, the BCF, and the turbidity sensor's manufacturer and model number and (or) the parameter and method codes. (example, *SSC* = 1.39*Turb*^0.943, *turb* = YSI 6026 = DD##, parameter 63680, method TS086).
   - The *SSC* values for Little Arkansas River near Sedgwick, Kansas, are computed using equation 7, where the BCF is incorporated into the model.
   - When *SSC* model coefficients change due to addition of samples, the rating, rating remarks, and start and end dates need to be updated.



4. Primary computation must be performed on the *SSC* DD to compute the *SSC* UVs.

   - In ADAPS, select menu options:
     "PR—Primary Data Processing,"
     "7—Primary Computations,"
     select the desired site number, DD, and dates,
     <Enter>
     select the desired options, and
     <Enter> .
   - Enter Hydra to compare *SSC* UVs with turbidity UVs;
     select "PR—Primary Data Processing,"
     select "2—Edit Time-Series Data using Hydra,"
     select "3. COMPUTED UNIT VALUES,"
     select the desired site number, DD, and dates, and
     add a reference curve for the turbidity DD.
   - View the plot of the two curves and verify that the data look correct. For instance, for the Little Arkansas River near Sedgwick, Kansas, the *SSC* and turbidity are nearly identical at values less than 400. For *SSC* values larger than 400, the difference increases as *SSC* increases so that turbidity is larger than *SSC*.

5. Currently (2009), ADAPS computes mean daily *SSL* from mean daily *SSC* and streamflow and the appropriate conversion factor. The resulting *SSL* DV is only correct if *SSC* and streamflow are highly correlated ($r > 0.95$). In most cases, they are not highly correlated, and therefore, ADAPS should not be used to compute *SSL*. The hydrographer should use either GCLAS or a spreadsheet application for the computation of *SSL* UVs or DVs. If the hydrographer can verify that the *SSC* and streamflow for their site is highly correlated ($r > 0.95$), then the following instructions can be used to compute *SSL* DVs in ADAPS.

   Primary computations must be performed on the *SSL* DD to compute *SSL* DVs.

   - Compute *SSL* DVs using DV_MANIP in ADAPS. From the ADAPS prompt:
     type DV_MANIP (or "PR 9"),
     select "A" to write the DVs to ADAPS,
     select the desired site number, dates, and the *SSL* DD,
     <Enter>,
     select option (8) compute load from streamflow and concentration,
     select "A,"
     select the desired site number, dates, and the streamflow DD,
     <Enter>,
     select "A,"
     select the desired site number, dates, and the *SSC* DD,
     select "e" (edited or estimated) to set the DV remark code, and
     select "s" to store the data in ADAPS.

6. Plot to *SSL* DVs, *SSC* UVs, and streamflow UVs in either Hydra or Tkg2 for comparison.

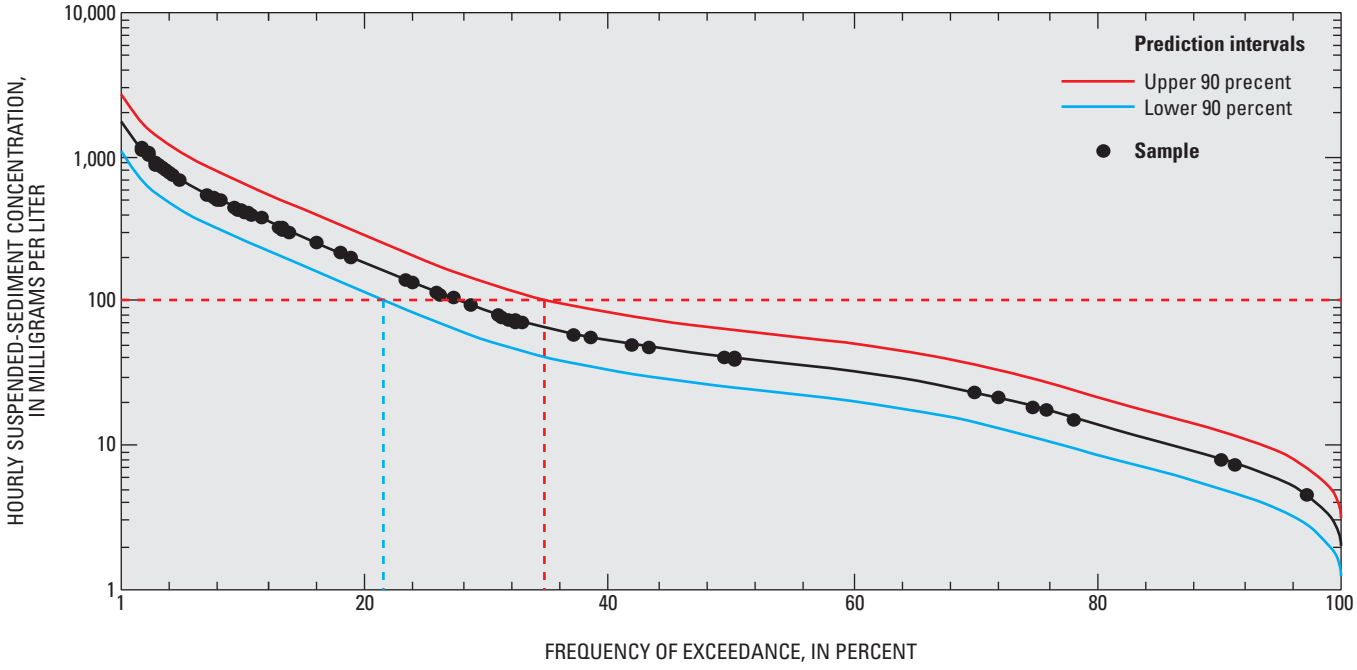
7. NWISWeb can be configured to display up to 60 days of *SSC* unit values, all available daily values, daily, monthly, and annual statistics for turbidity, streamflow, *SSC*, and *SSL* and *SSC* values from discrete sample collection.

Appendix 3. Comparison of Computed Suspended-Sediment Concentrations with Water-Quality Criteria

Currently (2009), there are no State criteria for *SSC*. Five States (Hawaii, Nevada, New Jersey, South Dakota, and Utah) have numeric criteria for total suspended solids (*TSS*), which range from a minimum concentration of 35 milligrams per liter (mg/L) in Utah to a maximum of 158 mg/L in South Dakota (U.S. Environmental Protection Agency, 2001). The differences between values of *SSC* and *TSS* as metrics for the suspended solid-phase content of surface waters are discussed in Gray and others (2000). *SSC* remains one of the most cited water-quality impairments in the United States even with the lack of State criteria. The *SSC* values computed using SLR methods have a quantifiable uncertainty that allows for several methods of comparison with criteria. In the following examples, 100 mg/L is an assumed *SSC* water-quality criterion for comparison.

Continuous *SSC* can be used, for example, to construct cumulative frequency distribution (duration) curves to determine percentage of time that computed concentrations exceed water-quality criteria. Computed concentration duration curves can be used to evaluate current water-quality conditions and to estimate the duration and magnitude of potential water-quality degradation. Without *SSC* water-quality criteria, water-resource managers can use duration curves to assess how frequent a potential water-quality criterion may be exceeded. When OLS regression is used to generate estimates for which probability statements are made, such as with duration curves and probability of exceeding criteria, values at the upper end likely are underestimated, and values at the lower end may be overestimated (Helsel and Hirsch, 2002).

In the example below, 28 percent of the hourly computed *SSC* values exceeded 100 mg/L for the period October 1999 through September 2005. The 90-percent prediction interval indicates that 100 mg/L could be exceeded 22 to 36 percent of the time. Simple linear regression (SLR) was used to compute the values plotted in figure 20 after SLR was determined to be the most appropriate regression technique. Like all regression techniques, the true relation of the response and explanatory variables is unknown, and the regression model is only an estimate of this relation. Other regression techniques might yield different models and, therefore, different duration curves. The differences between regression techniques typically are within the 90-percent prediction interval of the SLR regression.



Duration curve and 90-percent prediction intervals for computed hourly suspended-sediment concentrations in Little Arkansas River near Sedgwick, Kansas, October 1999–September 2005.

Although prediction intervals are approximate indicators of uncertainty, a range of values is not very useful for comparing the water quality of a stream to water-quality criteria. Probability of exceedance provides water managers with a single hourly value for decisionmaking. Probabilities of exceeding designated water-quality criteria or other values of interest for a $\log_{10}$ transformed model can be determined as follows:

$$\Pr\left(SSC \le Criterion\right) = 1 - D\left[\frac{\log_{10}\left(SSC\right) - \log_{10}\left(Criterion\right)}{RMSE}\right]$$

where

Pr is the probability that the criterion has been exceeded ($0 < Pr < 1$),

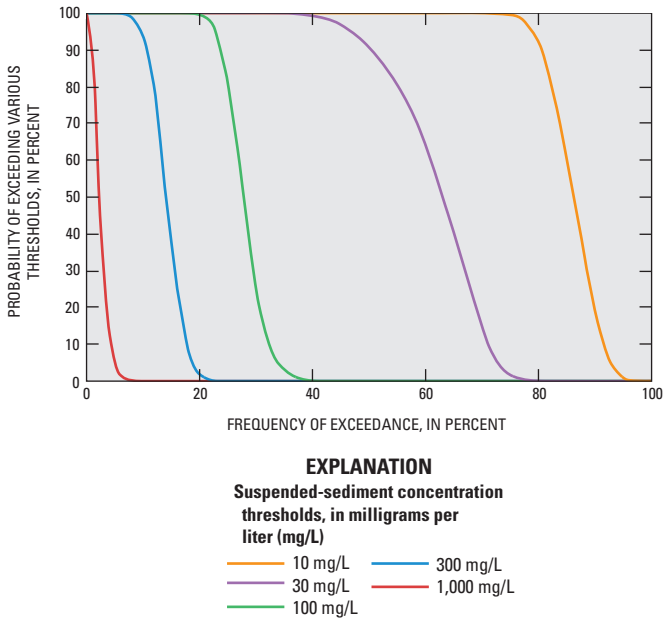
D is the cumulative distribution function for the standard normal curve—values for it are obtained from tables in statistics textbooks or equations that approximate the exact values,

SC is the BCF-corrected, regression-computed *SSC* value;

Criterion assumed 100 mg/L [if *RMSE* is in $\log_{10}$ space, then criterion is $\log_{10}(100)$]; and

RMSE is root-mean-squared error, or standard error of the regression, or standard deviation of the residuals.

The probability of hourly *SSC* also can be displayed as probability curves. Each curve represents an *SSC* and is plotted using frequency of exceedance (x axis) and the probability that the actual *SSC* is equal to the given threshold (y axis). The figures can be used to estimate the frequency of exceedance for 5 values of *SSC*. For instance, 20 percent of all hourly values of *SSC* for Little Arkansas River at Sedgwick have a 99-percent chance of exceeding 100 mg/L. Two percent of all hourly *SSC* values have a 50-percent chance of exceeding 1,000 mg/L for Little Arkansas River at Sedgwick.



Cumulative frequency curves showing probability of exceedance of suspended-sediment concentration thresholds of 10, 30, 100, 300, and 1,000 milligrams per liter, Little Arkansas River near Sedgwick, Kansas, 1999–2005.

Correlations of Turbidity to Suspended-Sediment Concentration in the Toutle River Basin, near Mount St. Helens, Washington, 2010–11

By Mark A. Uhrich, Jasna Kolasinac[2], Pamela L. Booth[3], Robert L. Fountain[2], Kurt R. Spicer[1], and Adam R. Mosbrucker[1]

Abstract

Researchers at the U.S. Geological Survey, Cascades Volcano Observatory, investigated alternative methods for the traditional sample-based sediment record procedure in determining suspended-sediment concentration (SSC) and discharge. One such sediment-surrogate technique was developed using turbidity and discharge to estimate SSC for two gaging stations in the Toutle River Basin near Mount St. Helens, Washington. To provide context for the study, methods for collecting sediment data and monitoring turbidity are discussed. Statistical methods used include the development of ordinary least squares regression models for each gaging station. Issues of time-related autocorrelation also are evaluated. Addition of lagged explanatory variables was used to account for autocorrelation in the turbidity, discharge, and SSC data. Final regression model equations and plots are presented for the two gaging stations. The regression models support near-real-time estimates of SSC and improved suspended-sediment discharge records by incorporating continuous instream turbidity. Future use of such models may potentially lower the costs of sediment monitoring by reducing time it takes to collect and process samples and to derive a sediment-discharge record.

Introduction

Suspended-sediment transport throughout the Toutle River Basin has been monitored and studied since 1980–81, following the eruption of Mount St. Helens on May 18, 1980. This study used standard U.S. Geological Survey (USGS) methods to compute sediment-discharge for gaging stations in the basin (Porterfield, 1977), along with standard laboratory and field procedures (Guy, 1977; Edwards and Glysson, 1999). Streamflow and suspended-sediment concentration (SSC) have been measured, and suspended-sediment discharge (SSQ) has been computed, in several drainages in the Toutle River Basin (Dinehart, 1998). SSC data are collected by pump sample most days and by depth-integrated methods on infrequent days. This report uses data from two long-term gaging stations on the North Forth Toutle River and main-stem Toutle River. Daily, monthly, and annual SSC and SSQ data are available online.

In recent years, technology improvements have spawned efforts to develop innovative and improved methods of generating time-series records of SSC and SSQ. Traditionally, sample-based methods require lengthy evaluation and review before sediment records are finalized, although interactive software referred to as Graphical Constituent Loading Analysis System (GCLAS) has improved this processing (Koltun and others, 2006). Using recently approved methods (Rasmussen and others, 2009); this study examines turbidity as an alternative or surrogate for SSC with the intention of better defining SSQ, streamlining record computations, and possibly lowering costs. Additionally, land, water, fish, and wildlife resource planners need real-time estimations of SSC and SSQ to more effectively respond to changes and disturbances in basins under their management. These techniques, which compute SSC from turbidity and streamflow, coupled with a gaging-station telemetry system, potentially would allow delivery of near real-time SSC and SSQ data. Because real-time SSQ estimates are considered provisional owing to sensor and sampling uncertainty, regression-based SSQ records would be finalized annually following approval of turbidity and streamflow data. Use of a regression model to compute sediment records may improve accuracy by incorporating high-frequency measurements of explanatory variables, and also may lower costs by reducing record processing time and the number of samples collected and analyzed. The sediment-sample collection, turbidity monitoring, and regression analysis for this study were conducted in cooperation with the U.S. Army Corps of Engineers, Portland District.

Purpose and Scope

- The primary objective of this study is to test the feasibility and application of instream turbidity sensors at two sites in the Toutle River Basin and to demonstrate the use of these sensors as a surrogate for SSC, and document the results.
- Turbidity and streamflow data from April 2010 to September 2011 are used to generate regression models for estimating SSC. Such models can be updated as new turbidity, streamflow, and sampled SSC data become available.
- Regression equations are provided for both streamgages and could be used to provide near-real-time estimates of SSC and SSQ. The proof of concept is shown and regression-based estimates for the time-series data could be finalized if they were deemed beneficial. Future projections of SSC also could be made available as an online data series.
- Finally, we make a preliminary assessment as to whether using such a regression approach would provide a better-quality SSQ estimate and would reduce effort and expense compared to previous methods.

Study Area

The number and location of streamflow-gaging and sediment-monitoring stations in the Toutle River Basin have evolved since their establishment in 1980–81. Current (2014) gaging stations shown in figure 1 include North Fork Toutle River below Sediment Retention Structure near Kid Valley, Washington (NF Toutle-SRS, 14240525); and Toutle River at Tower Road near Silver Lake, Washington (Toutle-Tower, 14242580). A third gaging station, South Fork Toutle River at Toutle, Washington (SF Toutle, 14241500), was discontinued in 2013. For the 6 water years (WYs 2007–12)

the reported NF Toutle-SRS total SSQ was more than 18 million tons (units in short tons), constituting more than 67 percent of the total SSQ of nearly 27 million tons computed for Toutle-Tower. For the 20-year period, WYs 1993–2012, the reported total SSQ for Toutle-Tower was more than 60 million tons, an annual average of 3 million tons. For the 1.5-year (April 2010–September 2011) period of data in this report, the Toutle-Tower SSQ totaled nearly 2.9 million tons, slightly less than the yearly average (*http://wdr.water.usgs.gov/*).

The Toutle-Tower gaging station, at 160-ft in elevation, is about 7 river miles (RMs) upstream of the confluence of the Toutle and Cowlitz Rivers and has a drainage area of 496 mi^2. The NF Toutle-SRS gaging station, at RM 12 of the North Fork Toutle River, drains 175 mi^2, and is about 30 RMs upstream of the Toutle-Tower gaging station (fig. 1). The NF Toutle-SRS station, at 700-ft elevation, is less than 2 RMs downstream of the Sediment Retention Structure (SRS). The SRS was completed in 1989 to retain and avert sediment eroded from the Mount St. Helens debris-avalanche deposit from being transported to the lower basin and eventually the Cowlitz and Columbia Rivers. Through 2012, the SRS has trapped about 115 million yd^3, representing about 3.5 percent of the total sand and gravel deposited after the 1980 eruption (Major and Spicer, 2003; Gibson and others, 2010). Nonetheless, a large volume of fluvial sediment passing the SRS is deposited downstream and is aggrading channel beds, thereby increasing the threat of flood inundation to the surrounding communities, as well as posing a hazard to river navigation and economically important commerce, drinking-water supplies, and migrating fish.

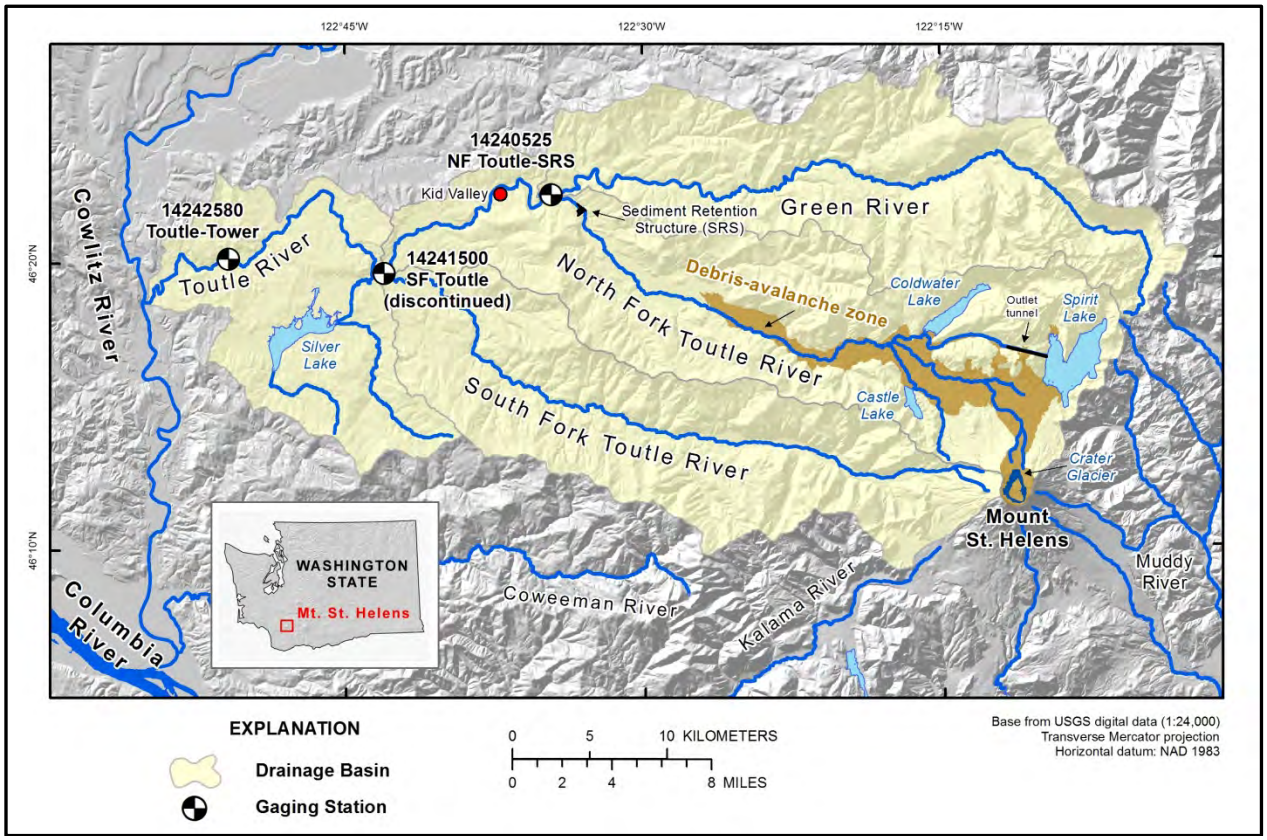

Figure 1. Map showing Toutle River Basin study area, drainage basins, and U.S. Geological Survey (USGS) gaging station locations, near Mount St. Helens, Washington.

Data Collection and Analysis Methods

To achieve the objectives in the section, "Purpose and Scope," we installed instream turbidity sensors at two gaging stations, NF Toutle-SRS and Toutle-Tower. Fifteen-minute unit-value turbidity and discharge data and periodic suspended-sediment samples were collected at both gaging stations (U.S. Geological Survey, 2010, 2011).

Matched pairs of turbidity and discharge with SSC were used as the explanatory and response variables, respectively, in a multi-linear regression using ordinary least squares (OLS) methods. Separate regression models were generated for each station. The resulting equations can be used to estimate 15-minute unit values of SSC from associated turbidity and water discharge unit values. Finally, the regression results, including accompanying uncertainty estimates, can be compared with previous sample-based sediment records computed for these stations in the Toutle River Basin in order to evaluate the relative utility of the traditional and surrogate methods.

Several established USGS methods were used to collect and process the suspended-sediment samples and to check, review, and publish the turbidity data.

Suspended-Sediment Sampling

This study started in April and May 2010 for the Toutle-Tower and NF Toutle-SRS streamgages, respectively, when turbidity calibrations and data collection began (figs. 2 and 3). Suspended-sediment samples were collected routinely in WYs 2010 and 2011, with an emphasis on storm, high-streamflow, and high-turbidity events.

Figure 2. Photographs showing suspended-sediment sampling, March 12, 2010 (large photograph), and servicing sensors, April 20, 2012 (inset), at North Fork Toutle River below Sediment Retention Structure near Kid Valley, Washington. Photographs taken by Kurt Spicer, USGS, Cascades Volcano Observatory.

Figure 3. Photographs showing suspended-sediment sampling at Toutle River at Tower Road near Silver Lake, Washington, December 13, 2012. Photographs taken by Kurt Spicer, USGS, Cascades Volcano Observatory.

Cross-Sectional, Depth-Integrated Sediment Samples

Manual suspended-sediment samples were collected at both gaging stations using standard USGS depth-integrated, equal-discharge-increment (EDI) and equal-width-increment (EWI) methods, (figs. 2 and 3; Edwards and Glysson, 1999). These sampling procedures have been used consistently at the NF Toutle-SRS and Toutle-Tower gaging stations since sampling began in the early 1980s. EDI and EWI sampling methods are the accepted procedures for providing representative cross-sectional SSCs.

Two sets of manual EDI/EWI samples (sets "A" and "B") usually were collected nearly simultaneously for each sampling visit and can be used independently or averaged to produce a single concentration and to better capture sample uncertainty (Topping and others, 2011). Manual data in this study used sample A and B sets so that each individual concentration could be used to better populate and define the regression model.

Point Samples

Automatic pumping samplers on the bank at each site were used to augment the EDI/EWI cross-sectional samples for periods between the manual collections. A single pump sample per day usually was collected in addition to multiple samples during high-flow events. Autosamplers draw water from a single point in depth and cross section, and, therefore, differ from the EDI/EWI methods that capture spatial variability throughout the stream width and water column. Autosampler concentrations nearest in

time to EDI/EWI samples were evaluated to determine if an adjustment or shift in the autosampler concentration was necessary. These point-sample correction adjustments or coefficients are used to shift autosampler concentrations to better reflect the mean cross-section concentration defined by manual EDI/EWI samples.

Autosampler concentrations typically are less than or equal to manual-sample concentrations (Glysson, 2008). To establish a correction coefficient, a pumping sample normally is manually triggered before and after an EDI/EWI cross-section sample set. Generally, if the pump and EDI/EWI sample concentrations agree to within 5 percent, no correction is applied and the coefficient is 1.0. If the difference is greater than 5 percent, the autosampler concentrations are adjusted to the manual concentration with a shift usually greater than 1.0. The shift is applied across time, either by relation to flow or by linear proration, until the next measured pumping sample coefficient. The corrections are defined by a manual cross-sectional sample or by a particular streamflow or turbidity event that may have altered the pumping efficiency or indicated a change in stream-channel dynamics (Guy, 1977; Guy, 1978; Porterfield, 1977; Bent and others, 2000). Finally, as in any sample collection program, there is a delay in acquiring the concentration data because of shipment time and laboratory processing, so that pump and manual sample results are not available in real time.

Turbidity Measurement and Data Processing

Turbidity data were collected and processed using established USGS procedures for continuous water-quality monitoring (Wagner and others, 2006). Continuous turbidity data were collected at NF Toutle-SRS and Toutle-Tower using a DTS-12 sensor™, manufactured by Forest Technology Systems, Victoria, Canada (*http://www.ftsenvironmental.com/products/sensors/dts12/*). The sensor has a large optical face that allows for a relatively wide water column area to be measured by the lens and detector. The probe has a large and durable wiper that virtually eliminates the need for cleaning corrections because debris buildup on the optics is removed at each reading. The head of the sensor is angled at 45 degrees to lessen the formation of air bubbles, which can interfere with the optics and cause false readings. The sensor head must be oriented facing down and into the main water body for correct turbidity readings. The DTS-12 sensor™ turbidity readings are reported in Formazin Nephelometric Units (FNU) (Anderson, 2005).

Suspended-sediment concentrations in the Toutle River Basin typically range from 10–50 milligrams per liter (mg/L) during extended periods of low flow, to 10,000–20,000 mg/L during storm runoff. Such sediment-laden waters can negatively affect instream electronic instrumentation. The DTS-12 sensors™ have worked consistently through these harsh conditions, requiring only routine cleanings with calibration checks every 3 to 6 months. The DTS-12 sensor™ takes 20 readings per second over 5 seconds and provides several parameters for those 100 readings. These parameters include mean, median, minimum, and maximum turbidity, and water temperature. Two variance parameters also are included to help with quality assurance for the other parameters. Near real-time median turbidity readings are reported on the USGS National Water Information System Web site (*http://waterdata.usgs.gov/wa/nwis/current/?type=flow*) in 15-minute intervals, and are used in the regression analyses. Daily median, minimum, and maximum turbidity for the two gaging stations are published in the Washington Annual Data Report (U.S. Geological Survey, 2010, 2011). Approved instantaneous turbidity and discharge data for NF-Toutle-SRS and Toutle-Tower used in this analysis are shown in figure 4.

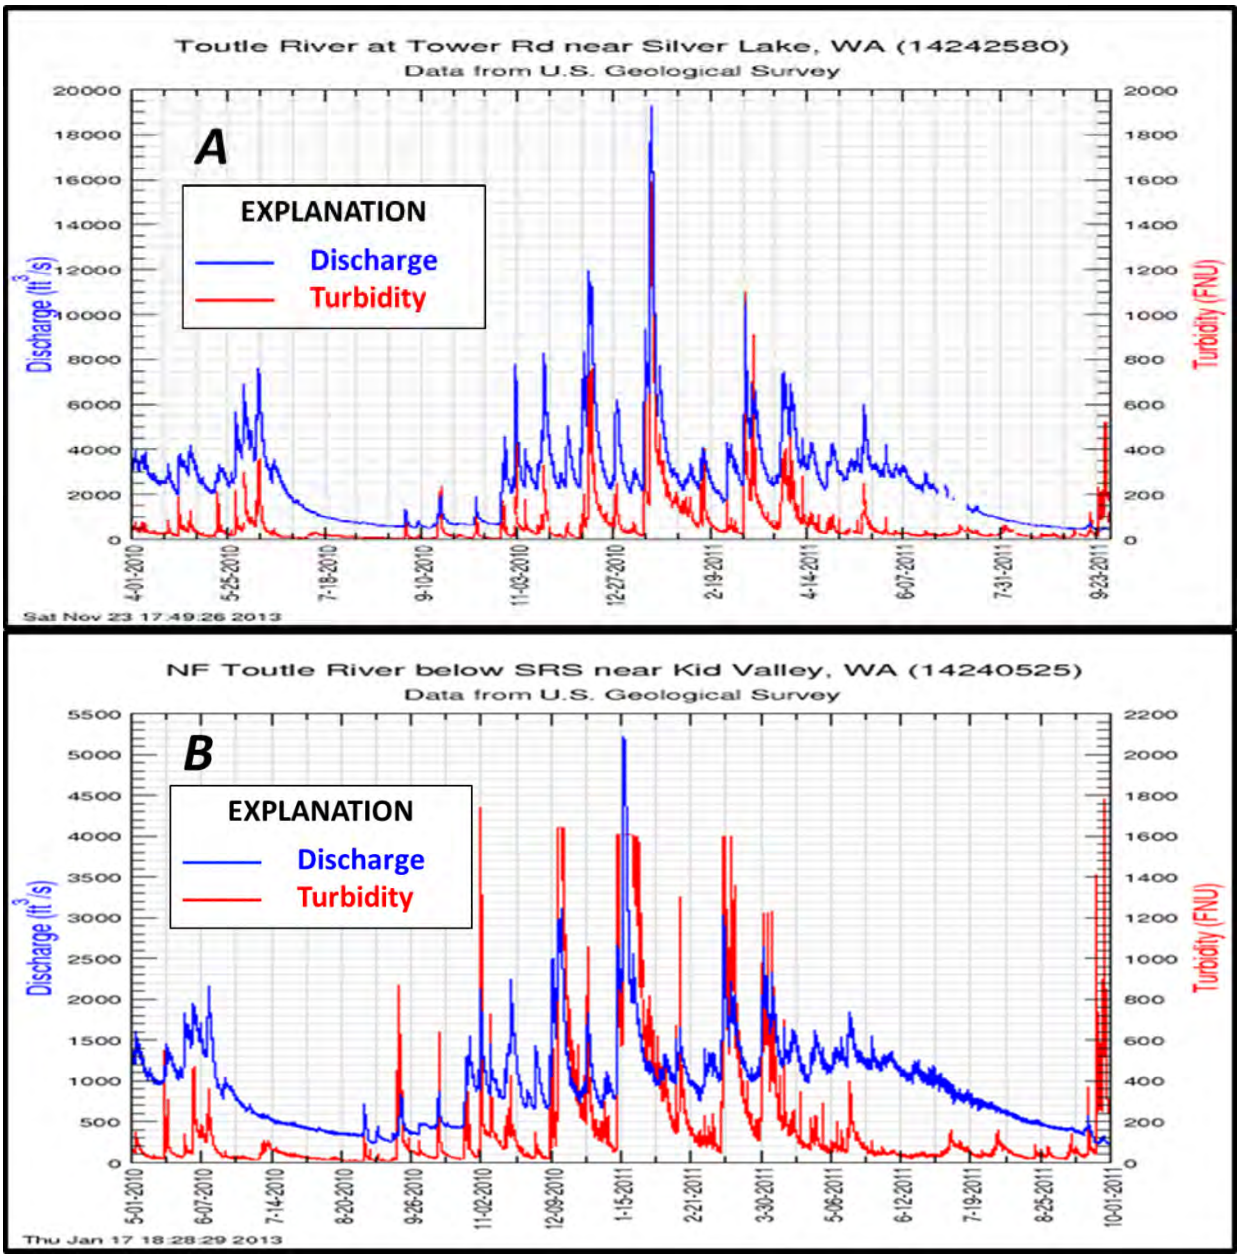

Figure 4. Graphs showing stream discharge and turbidity at two streamgages in Toutle River Basin, Washington, 2010–11. (*A*) April 1, 2010–September 30, 2011 and (*B*) May 1, 2010–September 30, 2011. (ft^3/s, cubic foot per second; FNU, Formazin Nephelometric Units.)

Turbidity Greater than Instrument Limits

All instream turbidity sensors have a maximum, instrument-specific reading. If turbidity surpasses that threshold, the sensor produces a false reading wherein the maximum value is reported repeatedly throughout the event. When graphed, this turbidity threshold displays as a horizontal line. After turbidity decreases to less than this threshold, the sensor again records valid measurements within the range of the probe.

The DTS-12 sensor™ threshold varies from sensor to sensor and ranges from about 1,600 to 2,100 FNU. Turbidity at NF Toutle-SRS reached the sensor threshold in December 2010, and in January and March 2011, with each threshold reading lasting from several hours to as long as 5 days. Turbidity at Toutle-Tower exceeded the sensor threshold on January 16, 2011, for 3 hours. Sediment samples collected during these turbidity sensor thresholds were not included in the regression models, as the true turbidity for the samples was unknown.

Existing alternative turbidity sensors suitable for instream monitoring that measure values greater than the DTS-12 sensor™ threshold potentially could provide a more consistent and complete turbidity record through peak events. Such a turbidity sensor was tested and routinely calibrated at NF Toutle-SRS, although the records for that sensor have not yet been approved. Data from this alternative sensor could be used to supplement periods when the DTS-12 sensor™ recorded threshold values and flat-lined. It then would be possible to run the regression models using these secondary values. The high-end turbidity values, if estimated or measured for missing or greater-than-threshold periods, also could be used to compute more complete and continuous model-generated SSC and SSQ values, which would be valuable given that these often are the periods of the greatest sediment transport. However, processing the high-end turbidity data would require further examination and review. Because the development of turbidity-surrogate regressions for this report was considered a proof of concept for the Toutle River gaging stations, processing high-end turbidity data was beyond the scope of this report; we, therefore, used only existing turbidity data that was approved and published. The potential utility of the high-turbidity data for refining the existing load estimates is considered in the section, "Discussion and Future Studies."

Selection of Turbidity and Sediment Concentration Data for Regression Analysis

Approved turbidity and SSC data were paired by matching the autosampler and EDI concentration to the closest-in-time turbidity value. If the EDI sample took more than 30 minutes to collect, the 15-minute turbidity values were averaged for the necessary time period in order to obtain a single value. Turbidity and sediment-sample data used for this report constitute roughly one-half of WY 2010 and the entire WY 2011 (April or May 2010–September 2011) for the Toutle-Tower and NF Toutle-SRS gaging stations, respectively. This provided a base dataset to begin construction of the regression models (appendix A). These relations can be evaluated from year to year, and can be compared with turbidity and SSC data collected in later years to determine any shift in turbidity-discharge to SSC relations and (or) transport regime.

To maintain consistency with the previously published sediment records for these periods (*http://wdr.water.usgs.gov/*), the identical sample concentrations (both EDIs and pumping samples) used in the sediment records were used in the regression analysis, except for turbidity and sample concentrations deleted from the analysis dataset when turbidity readings were at maximum threshold. The total number of EDI and pumping samples available for each gaging station collected from April or May 2010 through September 2011 are shown in table 1.

NF Toutle-SRS and Toutle-Tower discharge and turbidity with EDI samples collected from May 1 or April 1, 2010, through September 30, 2011, are shown in figure 5. Two EWI samples were collected, but neither sample was used because of contamination from the streambed.

Gaging station and sample dates	Equal-Discharge-Increment samples collected	Pumping samples collected
NF Toutle-SRS, May 2010–September 2011	48	605
Toutle-Tower, April 2010–September 2011	9	696

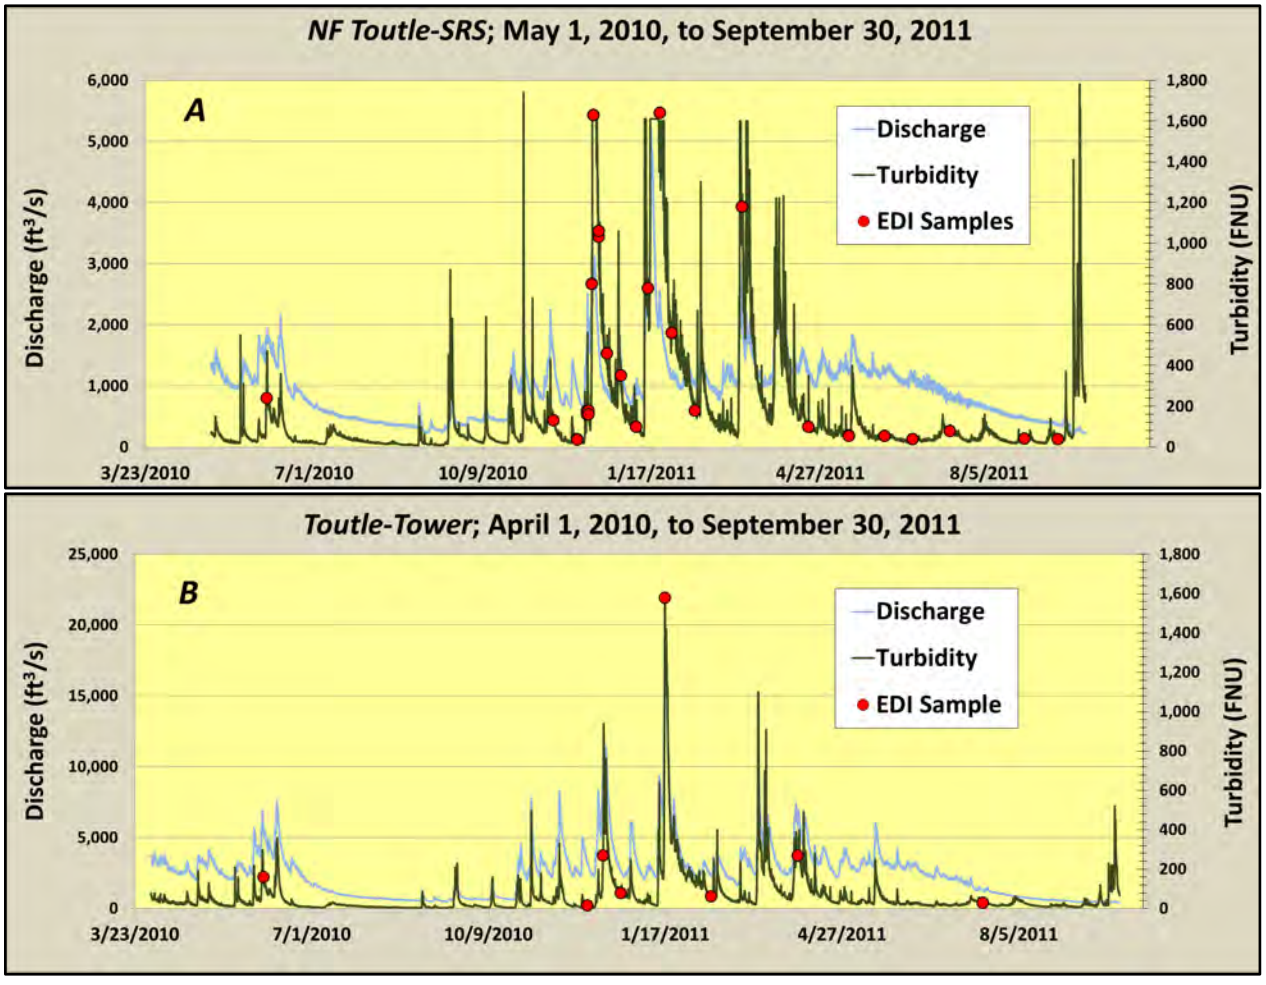

Figure 5. Graphs showing stream discharge and turbidity with time of equal-discharge-increment samples collected overlaid on turbidity, at (*A*) North Fork Toutle River below Sediment Retention Structure near Kid Valley (NF Toutle-SRS), May 1, 2010–September 30, 2011, and (*B*) Toutle River at Tower Road near Silver Lake (Toutle-Tower), April 1, 2010–September 30, 2011, Toutle River Basin, Washington. Discharge is measured in cubic feet per second (ft^3/s) and turbidity is measured in Formazin Nephelometric Units (FNU). Not all points are visible because of overlap of set A and B sample points collected close in time to each other.

These two sample sets indicate a strong reliance on autosamples, as is the normal routine in working a sample-based sediment-discharge record. As mentioned in the "Suspended-Sediment Sampling; Point Samples" section, autosamples, by nature of their position and orientation along the side of a channel cross section and as single-point samples, may not typically represent a concentration equal to the manual depth-integrated, cross-sectional samples. Therefore, a regression-based approach ideally would rely more on EDI/EWI samples than on pumping samples because of the differences in uncorrected concentrations between the two sample types.

Discharge Data

Water discharge values used for this analysis were computed from a stage-discharge rating developed from current-meter measurements and a 15-minute, time-series stage record, using established USGS techniques (Buchanan and Somers, 1976; Rantz and others, 1983). Streamflow measurements typically, but not always, accompanied cross-section EDI and EWI samples. Current-meter instruments were used exclusively for discharge data in this report. According to Sauer and Meyer (1992), the standard errors associated with individual discharge measurements can range from 2 to 20 percent, although most standard errors range from 3 to 6 percent. Discharge data for the Toutle River sites are available at *http://wdr.water.usgs.gov/*.

Statistical Methods

Regression Models Applied

We used OLS linear regression (Helsel and Hirsch, 2002) with turbidity and discharge as explanatory variables and the EDI/EWI and auto-sampled SSC data as the response variable. Regression model development for SSC is covered extensively in Rasmussen and others (2009), including various correlation and data transformation measures and use of available explanatory variables. We selected the best candidate model on the basis of supportive diagnostic statistics, the fit of the explanatory and response variables, and hydrographer knowledge of sediment dynamics and data collection at the individual sites.

Following visual and statistical analysis of the SSC, turbidity, and discharge datasets, as well as examination of the residuals from preliminary OLS models, we log-transformed the datasets of both streamgages to improve distributional normality. We also tried natural log, square, and cube root transformations. The log transformation worked best overall by compressing tailings and outliers, as well as addressing possible heteroscedasticity, thereby improving the fit of the regression (Helsel and Hirsch, 2002). We also tested using a univariate model with turbidity as the sole explanatory variable. Finally, the addition of discharge statistically improved the sum of squares error (SSE) and coefficient of determination (R^2) and, therefore, was used in a multiple linear regression (MLR). However, the log transformation and MLR did not alleviate time-related auto-correlation, as indicated by low Durban-Watson statistics (Helsel and Hirsch, 2002). Although this transformation improved overall model fit by decreasing the SSE and normalizing the residuals, autocorrelation was still a concern.

One method to address autocorrelation and to increase accuracy in the regression model was the inclusion of time lags of turbidity and discharge as additional explanatory variables. The final MLR used a single lag of turbidity as a third variable. The inclusion and importance of lagged turbidity is explained in the section, "Accounting for Autocorrelation."

Statistical Diagnostics and Analysis of Variance

Analysis of Variance (ANOVA) statistics generated for each gaging station regression are shown in tables 2 and 3. The structure of the ANOVA is written from left to right, with each column broadening the understanding and role that each "Source" statistic contributes to the development and significance of the final regression model. A base understanding of the terminology and structure of the statistics is necessary to better interpret the results.

The Sequential Sum of Squares (Seq. SS) consists of the decomposition of the sum of the squared difference between the individual observed value of the log of SSC and the mean of log of SSC into the "*Regression*" part and the "*Error*" part. The *Regression* part is the sum of the squared difference between the predicted value and the overall mean of log of SSC, whereas the *Error* part is the difference between the observed value and the predicted value. Because there are multiple values for each day, the *Error* is further decomposed into *Lack-of-Fit* (sum of square of difference between local average and fitted) and *Pure Error* (sum of square of difference between observed and local average). These SS values then are corrected for bias by their respective degrees of freedom (df) with the unbiased estimation value under Sequential Mean Square (Seq. MS). The Seq. MS functions as the value for the estimations of variance for the distributions of the *Regression* and the *Error*.

Table 2. Final Analysis of Variance (ANOVA) for logSSC compared to LogT, logT-lag, logQ, for North Fork Toutle River below Sediment Retention Structure near Kid Valley, Washington. [See text for explanation of statistical terms].

In testing the significance or statistical fit of the regression equation for the NF Toutle-SRS and Toutle-Tower gaging stations, the ANOVA F-statistic from tables 2 and 3 indicates a significant relation between log of turbidity and log of SSC with a 1-percent probability of a type I error or the probability of incorrectly rejecting a true null hypothesis. The significance is determined by comparison to a critical F* value on the F-distribution with 3, and 649 or 701 df for the NF Toutle-SRS and Toutle-Tower sites, respectively, as determined by the numerator ($MS_{regression}$ = *Regression**SS***/*Regression**df***) and the denominator ($MS_E = Error\boldsymbol{SS}/Error\boldsymbol{df}$). This F-statistic is formed through the ratio of two probability distributions: the explained regression to the unexplained errors. The resulting ratio is an indicator of the overall fit of the regression model without involving units of measure or implying multiplicative effects.

The F-statistics for both regressions indicated that a significant proportion of the variation in log (SSC) was explained by the relation with log T (Turbidity) and log Q (Discharge) relative to the unexplained variation in log (SSC). Because the variance estimator Seq. ME (or MS_E from the ANOVA table) is expressed as *SSE* divided by df of the error, focusing on minimizing *SSE* was important for minimizing the estimate of the variance and standard deviation ($\sqrt{MS_E}$) of the model. The ANOVA tables 2 and 3 also included a "*Lack-of-Fit*" statistic that for both regressions was significant, indicating a poor overall fit. The discrepancy between the F and Lack-of-Fit statistics indicates a high variation within the data, including the possibility of autocorrelation of the errors observed through the distribution of the residuals, as reflected in the low Durban-Watson scores.

One of the best methods for determining the quality of a regression is the *PRESS* or prediction sum of squares. In general terms, the *PRESS* is a cross-validation calculation that provides a regression-fit summary that measures how well the model will perform in predicting new data. *PRESS* values were included and evaluated so that the best candidate model would have the lowest *PRESS*, and, thus, the best structure.

The Variance Inflation Factors (VIFs) in tables 4 and 5 also help determine the quality of a regression; VIFs measure the extent to which multicollinearity was present between the explanatory variables. Multicollinearity occurs when two or more variables are linear combinations of the other variables. A VIF greater than 5 is cause for concern, whereas a VIF greater than 10 is a major sign of colinearity, indicating that the predictors are highly correlated. Also provided in tables 2 and 3 are Mallow's Cp statistics, which are designed to minimize bias and standard error by keeping the number of coefficients low and in balance. Too few model variables cause bias, whereas too many predictors result in an imprecise model. Mallow's Cp is used so that the precision and bias of the full MLR is compared to the best subsets of predictors. The desired Mallow's Cp is a value that is close to the number of beta or explanatory variable coefficients plus the constant or y-intercept. This provides a model that is relatively precise and unbiased in estimating the correct regression coefficients, as well as predicting future responses or SSCs. Overall, the ANOVA results in tables 2 and 3 indicate that the final regressions between log SSC and the log transformed turbidity and discharge data are significant, with these variables explaining much of the variation in SSC. However, the strength of these relations is lessened because of the presence of significant autocorrelation.

Autocorrelation

The large number of daily and sub-daily pumping samples and paired EDI A and B sets, collected close in time to each other and available for this analysis, opened the dataset to potential problems associated with autocorrelation, or the serial correlation of a variable such as turbidity and (or) suspended-sediment concentration with itself over successive time intervals. When a variable indicates autocorrelation, one observation is related to another observation such that both observations will change together to some extent. In this case, the individual values of SSC, turbidity, or discharge are essentially similar to their previous value in the time series, such as during a storm event, and, therefore, do not represent random or independent occurrences. This presents a problem because statistically sound OLS regression models are assumed to have independent and normally distributed errors. When the errors, as observed through the residuals, show autocorrelation, the OLS method tends to underestimate the standard errors and coefficients of the model, thereby producing erroneously narrow confidence and prediction interval bands. These patterns typically can be identified through graphical analysis. For instance, if several samples are collected during a particular event, such as on the rising or falling limb of a hydrograph, the residuals may appear grouped together for that event in a non-random pattern.

Initial attempts to minimize the effects of autocorrelation led to averaging EDI-paired A and B sample sets, as well as randomly subsampling the autosamples. These smaller datasets then were tested by applying different regressions on the reduced number of autosamples and EDIs as suggested by Helsel and Hirsch (2002). Although these attempts reduced the potential for autocorrelation, the resulting graphical and statistical analysis showed minimal reduction. Therefore, additional methods were used to develop a model using all data (EDIs and autosamples), while also reducing the autocorrelation and *SSE*.

Evaluating Autocorrelation

The Durbin-Watson statistic (DW) (tables 2 and 3) essentially is the measure of the Sum of Error generated from the difference between a residual at index i and index i-1 taken over all residuals. A DW statistic between 0 and 1.6 generally indicates a positive auto-correlation for large sample sizes, especially when DW is less than 1. Because the DWs for both regressions were close to 0, there is a strong indication that positive autocorrelation was present. Because there was reason to be concerned about the variability of the residuals, a closer analysis of residual graphs for normality was warranted.

The normal probability graphs for the NF Toutle-SRS and Toutle-Tower gaging stations (figs. 6*A* and 7*A*) showed no strong deviation from a normal distribution of residuals. However, a comparison of the histogram (figs. 6*B* and 7*B*) and the "fitted values" against their residuals (figs. 6*C* and 7*C*) showed some abnormal grouping and tailing. Collectively, these three graphs show no reason for concern; for each station, the graphs of residuals against "observation order" (figs. 6*D* and 7*D*) showed that the residuals were related to each other across time, substantiating the DW statistic.

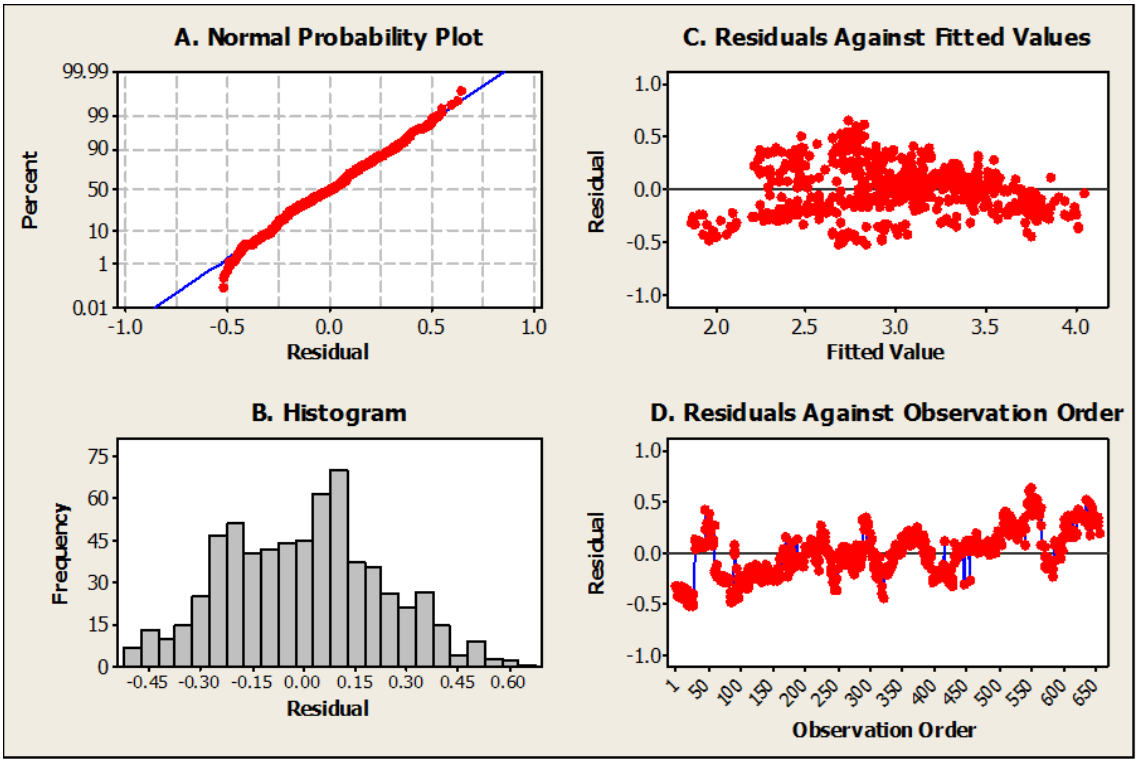

Figure 6. Graphs showing (*A*) normal probability distribution of residuals; (*B*) frequency distribution of residuals; (*C*) comparison of residuals with fitted values; and (*D*) comparison of residuals with observation order, for a multivariate regression of log(SSC) against log(T), log(Tlag), and log(Q), for North Fork Toutle River below Sediment Retention Structure near Kid Valley, Washington. Figure made from Minitab® software as 4-in-1 plots (*www.minitab.com*).

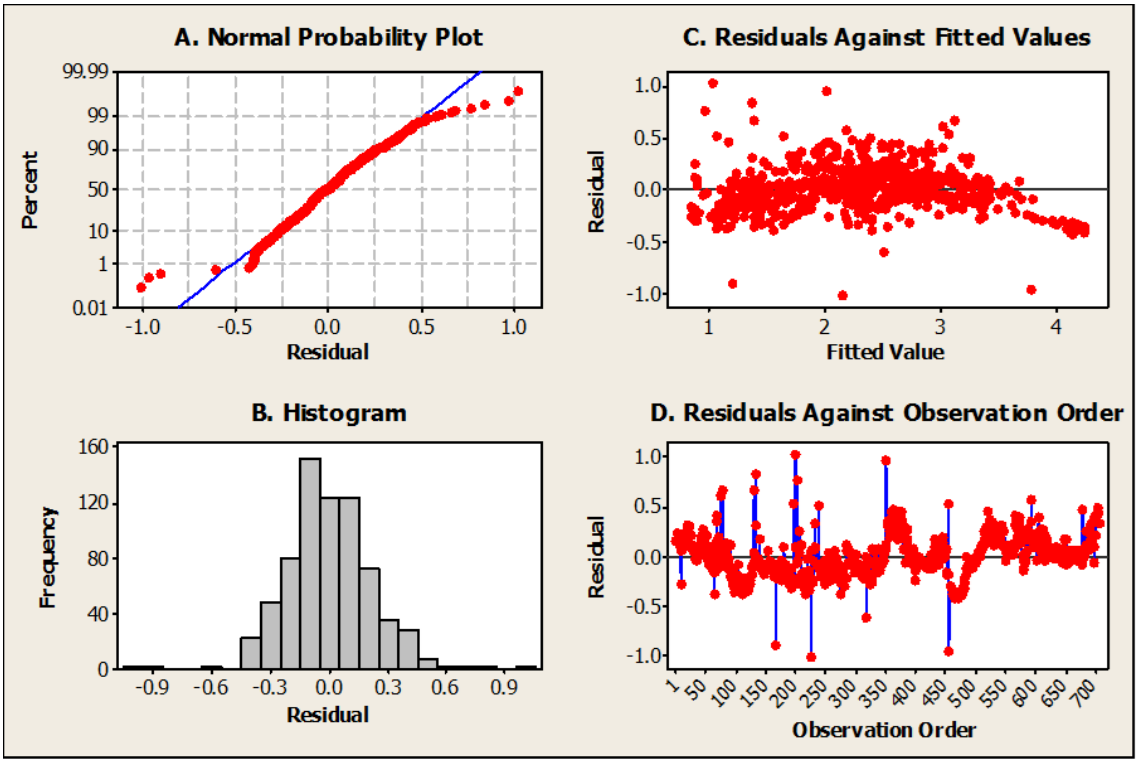

Figure 7. Graphs showing (*A*) normal probability distribution of residuals; (*B*) frequency distribution of residuals; (*C*) comparison of residuals with fitted values; and (*D*) comparison of residuals with observation order, for a multivariate regression of log(SSC) against log(T), log(Tlag), and log(Q), for Toutle River at Tower Road near Silver Lake, Washington. Figure made from Minitab® software as 4-in-1 plots (*www.minitab.com*).

Accounting for Autocorrelation

There are various options to account for time-related autocorrelation, including Auto-Regressive Moving Average (ARMA) modeling (Box and Jenkins, 1976); state-space modeling (SSM) using a Kalman filter (Harvey, 1989); and variable lagging, among others. Because this particular application was for real-time estimation and not for future forecasting, more extensive autocorrelation modeling techniques such as ARMA and SSM were not used. Additionally, the collection time difference between paired observations reduced the necessity for more extensive modeling as described in "Autocorrelations Die Out." Thus, regressions were run adding lag values of discharge and turbidity to account for some of the autocorrelation. The inclusion of lags increased R^2, lowered the standard error (*SSE*), and improved the DW statistic. The final R^2 and *SSE* are listed with tables 2 and 3.

Autocorrelations Die Out

Although this analysis indicated that autocorrelation was present in the datasets, use of more extensive time-series modeling was impractical for real-time application given that the correlation of logSSC with the most recent observed value of SSC died out after about 30 days. That is, the daily statistical dependence or strength of the relation between the 96 values of 15-minute logSSC variables decreases to near zero in about 1 month, such that the change in one 15-minute SSC will correspond to a change in another 15-minute SSC for only about 30 days. Because it normally takes more than 30 days for a sample concentration to become available from the laboratory and accessible for analysis, and because this dataset contained breaks in pump and manual sample collection that were longer than 30 days, this model used lagged values instead of a time-series component to increase accuracy in the regression model. Given these conditions, the regression developed using 2010–11 data worked adequately because the SSC correlations went to zero in such a relatively short time. In other words, the 30-day die out and the availability of new SSC sample data will almost never overlap, making the value of time-series models negligible in real-time estimation of SSC. If SSC were to be predicted into the future, a time-series model would be necessary.

Lagging Turbidity and Discharge

Regressions using lagged values of turbidity and discharge were tested for significance and improvement over the non-lagged MLR. A lag is a past value of the variable; a turbidity lag of 1would use the previous 15-minute value, a turbidity lag of 2 would use the previous 30-minute value, and so on. In our case, we evaluated using 1 lag of turbidity and 1 lag of water discharge by adding these values as third and fourth explanatory variables. On the basis of the regression diagnostics and ANOVA, we decided to use a single turbidity lag of 1, without using lags of discharge.

Robustness Checks

The term “robustness” here refers to statistics with good performance with the data, such that the coefficients are resistant to errors in the results and not unduly influenced by outliers. Robustness checks look for consistency of coefficient estimates by subsampling the original dataset and then estimating the model with out-of-sample data, along with other means of testing the validity of regression results.

The consistency of the OLS regression coefficient estimates for each streamgage was checked using the following methodology: Data for each streamgage first was condensed to a single matched pair per day. Days with only one value were automatically included. On days with multiple observations, one observation per day was randomly selected. For NF Toutle-SRS, the 653 observations came from 341 days, and for Toutle-Tower, the 705 observations came from 355 days.

This condensed dataset of 341 and 355 observations, respectively, was further subsampled. Each observation was given a random number and then sorted by that number from highest to lowest. The top 90 percent of the data with the highest random number were selected for use in generating the five potential OLS regression models. The five sets of explanatory variables included (1) logT; (2) logT and logT-lag; (3) LogT and logQ; (4) LogT, logT-lag, logQ; and (5) logT, logT-lag, logQ, logQ-lag. The remaining 10 percent of the data were used as out-of-sample or sequestered data and input to the 90-percent regression equation. That is, the turbidity, lagged turbidity, and discharge values from the 10-percent group were input to the 90-percent subsampled regression equation. The estimated SSC results and associated *SSE* were compared between the 90- and 10-percent datasets. For NF Toutle-SRS, 307 observations were used for the 90-percent regression and 34 observations were used for comparison. For Toutle-Tower, 320 observations were used for the 90-percent regression and 35 observations were used for the 10-percent comparison (appendix B).

OLS regressions were run on the 90-percent subsampled data for each of the five models for each gaging station. In using the 90-percent subsampled data for each model, two means of comparison were used. First, the coefficient estimates and standard errors were compared to their full data counterparts for consistency. Second, SSC was estimated and *SSE* was calculated using the 10-percent sequestered data. The model with the smallest *SSE* and most consistent estimates was considered the best model. If the 90-percent OLS estimates were grossly different and (or) had different signs from the full dataset OLS, then this model would not be the best to use.

Across models, although there was some deviation in the magnitude of the lagged turbidity estimate, the positive or negative sign remained the same and estimates for turbidity and discharge fluctuated within reason. Testing the subsample models on the 10-percent sequestered data showed that the ideal model using turbidity, lagged turbidity, and discharge (number 4 in the explanatory variable list) as explanatory variables had the lowest out-of-sample *SSE*. These results support the use of the final model and coefficient estimates.

Final Regression Models

Regression Model Coefficients

The log-log regression model analysis of SSC (response variable) with turbidity, turbidity-lag, and discharge (predictor variables) for the NF Toutle-SRS and Toutle-Tower gaging stations provided the output shown in tables 4 and 5. The coefficients are used to generate the regression equations listed as equations 1 and 2. The ANOVA statistics in tables 2 and 3 apply to these equations.

Table 4. Regression coefficients for North Fork Toutle River below Sediment Retention Structure near Kid Valley, Washington.

Parameter	Coefficient	SE	t-statistic	P-value	VIF
logT	0.1854	0.2882	0.64	0.52	322.304
logT lag	0.3545	0.2897	1.22	0.221	321.817
logQ	0.89518	0.04497	19.91	0	1.601
Constant	-0.8054	0.1135	-7.10	0	

$$\log_t SSC = -0.8054 + 0.1854 \log_t T + 0.3545 \log_t Tlag + 0.8952 \log_t Q \quad (1)$$

where

T	is turbidity,
Q	is discharge,
$Tlag$	is lag turbidity value for the previous 15-minute period, and
t	is the 15-minute interval time.

Table 5. Regression coefficients for Toutle River at Tower Road near Silver Lake, Washington..

Parameter	Coefficient	SE	t-statistic	P-value	VIF
logT	0.5676	0.1456	3.90	0	115.711
logT lag	0.1612	0.1449	1.11	0.266	112.942
logQ	0.9101	0.03587	25.37	0	3.149
Constant	-1.99049	0.09096	-21.88	0	

$$\log_t SSC = -1.9905 + 0.5676 \log_t T + 0.1612 \log_t Tlag + 0.9101 \log_t Q \quad (2)$$

Selecting the Predictor Variables for Model

Using the coefficients from the $\log_t SSC$ to $\log_t T$, $\log_t Tlag$, and $\log_t Q$ regression model, the unlogged or untransformed final equations became:

NF Toutle-SRS:
Equation (1) is converted to power form as equation 3,

$$SSC_t = 0.156531 * T_t^{0.1854} * Tlag_t^{0.3545} * Q_t^{0.8952} \quad (3)$$

Toutle-Tower:
Equation (2) is converted to power form as equation 4,

$$SSC_t = 0.010221 * T_t^{0.5676} * Tlag_t^{0.1612} * Q_t^{0.9101} \quad (4)$$

Applying the Bias Correction Factor

Because regressions were conducted on log-transformed variables, a bias was introduced that distorts the estimated SSC when the log values are converted back to their original linear form. Duan's smearing bias correction factor (BCF) was computed using the average of the unlogged residuals, as a best estimate of this introduced bias (Helsel and Hirsch, 2002; Rasmussen and others, 2009; Uhrich and Bragg, 2003). The BCF result for each station is computed as:

Bias Correction Factor (BCF): $\frac{\sum_i^n 10^{r_i}}{N} = 1.1491573\ and\ 1.14909$,

for **NF Toutle-SRS** and **Toutle-Tower**, respectively, and where r = logged residual values.

The right side of the regressions (equations 3 and 4) then are multiplied by the BCF to obtain the final equation:

NF Toutle-SRS:

$$SSC_t = 0.179879 * T_t^{0.1854} * Tlag_t^{0.3545} * Q_t^{0.8952} \quad (5)$$

Toutle-Tower:

$$SSC_t = 0.011745 * T_t^{0.5676} * Tlag_t^{0.1612} * Q_t^{0.9101} \quad (6)$$

Equations 5 and 6 are considered the general regression analysis (GRA) in this report and can be used normally to estimate SSC, with no further derivations.

The BCF accounts only for model error with no corrections for sample error, or error arising when estimating regression coefficients from a more finite dataset. That is, if one wanted to calculate the daily mean turbidity and averaged just three 15-minute values for that day, the sample error would be higher than if the mean turbidity was averaged using all ninety-six 15-minute values available for that day. Hence, larger sample sets, such as those used in this analysis, will tend to have a lower or negligible sample error. Although the BCF for model error increases SSC, the sample error correction has the inverse effect. Smaller sample sets without a sample error correction tend to overestimate the SSC. Because sample error was negligible in this analysis, no correction was applied.

Applying the Regression Models to Future Data

As new turbidity and discharge data are collected, they can be added to the original 15-minute turbidity and discharge datasets or kept separate as their own unique dataset. This distinction depends on the new GRA assembled from the additional SSC samples, which are paired with a turbidity and discharge value at the specific time of each sample. Analysis of covariance or ANCOVA can be used to test the significance of the original regression against future data added to the dataset. This would help determine if a change in the turbidity-SSC relation warrants developing a model for the new dataset (Helsel and Hirsch, 2002, p. 316). Rasmussen and others (2009) suggest that each water year be worked separately, and that the data from that water year then be compared to the data from the previous water year. If there is no significant difference in the slope and y-intercept between water years, the data could be joined together to refine the model and to generate a single multi-water year GRA. As a potential benefit, the refined model may have a lower *SSE* and reduced prediction interval. If the difference in regression models is significant, then a new GRA equation must be developed, using the methods described in this section, for the additional water year and (or) period of record. The new GRA equation then would be used until the analysis is reiterated using data from subsequent water years.

Final Regression Model Graphs

Graphs of the logSSC (measured) against logSSC (estimated) from final GRA equations for both gaging stations are shown in figures 8 and 9. The OLS lines in figures 8 and 9 represent the GRA relation defined by equations 5 and 6. The 95-percent prediction and confidence intervals are shown in figures 8 and 9, as provided by the statistical package used (*www.minitab.com*). A prediction interval is always wider than a confidence interval because it must account for both the uncertainty of the population mean and data scatter, also described as the model and sampling uncertainty. The distinction is that prediction intervals provide information on the distribution of values and not the uncertainty in determining the population mean, whereas confidence intervals provide information on how well the population mean was determined. The key point here is that confidence intervals provide information on the true population parameter, whereas prediction intervals represent ranges of values within which there is a 95-percent certainty (in this case) that the true population (SSC) occurs.

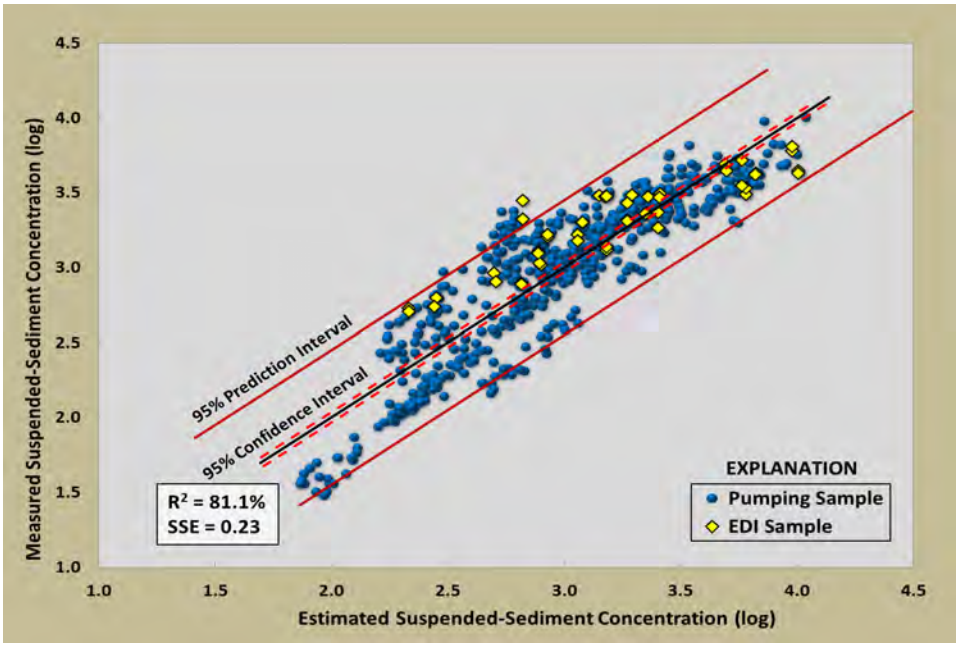

Figure 8. Final multiple linear regression model showing the general regression analysis line (equation 5) superimposed over measured and estimated suspended-sediment concentrations for pump and equal discharge increment samples, for North Fork Toutle River below Sediment Retention Structure near Kid Valley, Washington, water years 2010–11. Graph also shows 95-percent prediction and confidence intervals.

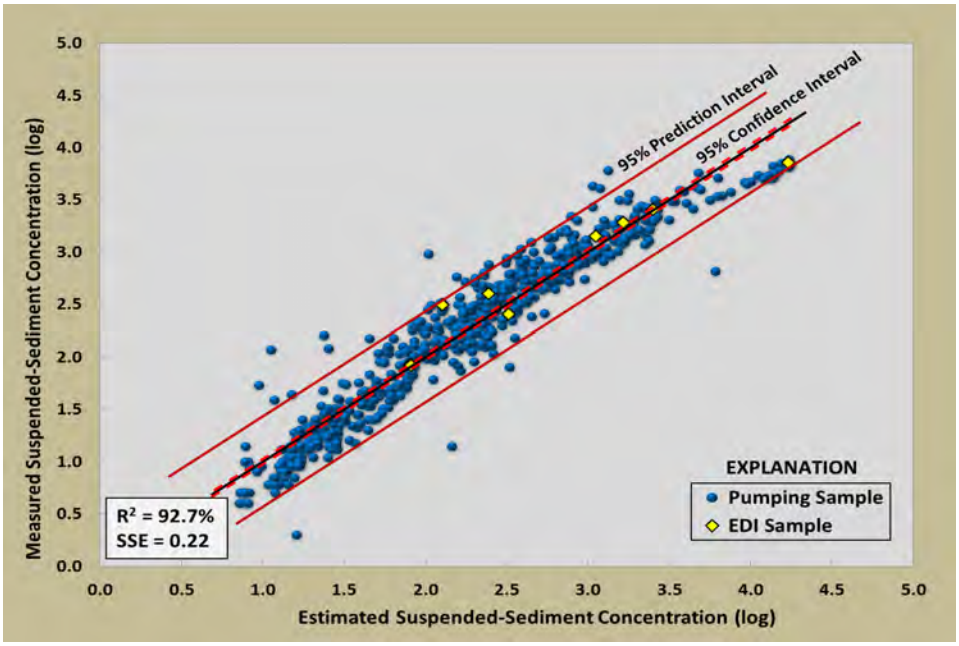

Figure 9. Final multiple linear regression model showing the general regression analysis line (equation 6) superimposed over measured and estimated suspended-sediment concentrations for pump and equal discharge increment samples, for Toutle River at Tower Road near Silver Lake, Washington, water years 2010–11. Graph also shows 95-percent prediction and confidence intervals.

Discussion and Future Studies

The use of surrogates for high-density measurements in real time offers many opportunities for improved understanding of hydrologic processes, along with well-characterized and reduced uncertainty, and ultimately better informed decision-making. In this study, we used turbidity as a surrogate for SSC in the sand-dominated Toutle River Basin; as a proof-of-concept approach to evaluate the feasibility of improving estimates of sediment loading and transport in the drainage basin; and possibly to reduce costs, compared to historical, manual techniques. The results of the study indicate that the potential for such improvements is high, with relatively robust regressions developed at both the NF-Toutle-SRS and Toutle-Tower sites. Although beyond the scope of this report, use of these regressions, together with discharge data from the two gaging stations, could be used to calculate 15-minute and daily concentrations and loads from the WYs 2010–11 dataset. The calculations also could be extended through WY 2012, with each computation being a relatively straightforward exercise. Future refinement and other uses of these regression techniques, beyond calculation of concentration and load, could provide additional information for understanding changes over time in sediment sources, transport, and deposition. Additionally, there remain some limitations and criteria to the regressions obtained in this report and to the overall use of surrogate technologies, which must be considered when using these results for decision-making.

Appropriate Uses of Turbidity-SSC Surrogate Regressions

Development of turbidity-SSC regressions are not conventionally universal across all water systems and riverine environments. The models developed herein can be used solely for the Toutle River Basin and cannot be transferred to other drainage basins. In addition, some waterways do not lend themselves to this type of analysis because of variability in the sediment-water matrix, as well as unacceptable monitoring conditions. From a monitoring standpoint, the turbidity-SSC surrogate regressions generally assume a consistent amount of light scattering by particles in transport over the range of the regression data. However, sediment grain-size distributions usually change during events or by season, based on the energy of the stream and the sediment sources, which can add uncertainty to the regression-based estimates of concentration or load. Based on past sediment events, it may be advantageous to subdivide the data by seasonal time frames or by increasing or decreasing streamflow and (or) turbidity components. This might produce a suite of regression models that could be used in conjunction with each other, each invoked by assessing in real time the sequential changes in turbidity and (or) discharge to determine which model to use, and thereby improve the estimates of sediment concentration.

By using these refined models, potential future work could compare results from the single regression model developed in this report to such a combined seasonal or event model approach. The combined approach likely would provide a tighter fit with a near-zero covariance between the residuals. The Toutle River Basin is a complex fluvial system that, upon further analysis, might lend itself to this type of event-based sediment-transport regime. Seasonal or event models may better estimate sediment-transport events that are unrelated to streamflow, which show up as tailings outside the confidence interval of the single regression line. Examples include volcanic- or glacial-influenced events from the Mount St. Helens crater, as well as landslides or localized streambank sloughing. These types of studies would provide insight into how the Mount St. Helens sediment-source terrain and depositional areas evolve over time, along with insight into management of sedimentation in the lower Toutle River Basin.

It also would be informative to test the comparability, cross-sectional representation, and cost effectiveness of a sampling regime that emphasizes more pump samples, as used for this study, compared to one composed of a greater number of manual EDIs. Such an evaluation could bolster the cost-effectiveness and usability of the data-collection program by assuring samples would be collected at the appropriate time and frequency. Additionally, the autosample sediment-size mixture of coarse and fine sediment can differ greatly from the EDIs and EWIs because of various pipe-hose lengths and configurations, hydraulic head required to pump and disperse the sample, and variable stream velocity and bed movement near the autosampler intake. Many of the pumping samples collected and used in this study were targeted to capture the full range of suspended sediment during peak discharge and turbidity events, when manual samples could not be collected. These samples provided valuable confirmation at critical sediment flux periods that otherwise would not have been possible. Regardless of this, if the surrogate-regression based approach is used, the number of pump samples collected and analyzed in the future could be decreased without significantly increasing manual EDI samples.

As a reasonable next step in processing these data, future work could include SSC as an online near-real-time parameter, using the regressions shown in this report with the ongoing continuous turbidity values. SSC could be added to the parameters of turbidity, stage, and discharge for each station, and also could be used as a comparison to the previous sample-based, sediment-record results.

As mentioned in the section, "Turbidity Greater than Instrument Limits," when the turbidity sensors are at their flat-line threshold, the data are not used in turbidity-discharge to SSC model development, as well as in any continuous SSC estimation. This is the most critical limitation to this study, as sediment transport is highest during these episodes and, therefore, is most vital in quantifying the sediment flux. Future work could include estimates through these peak periods or use alternative high-end turbidity sensors to provide a complete record of model-estimated SSC and SSQ. However, the high-end turbidity sensors would need to have their own instrument- and site-specific regressions generated. This prerequisite is owing to differences in light scattering and detection between a high-end sensor and the DTS-12 sensor™ used in this study (Rasmussen and others, 2009). One such high-end sensor initially was deployed at the NF Toutle-SRS site in 2011; therefore, a dataset with paired SSC sample results already is available, and can be used as the starting point from which to begin this work.

Finally, no inferences were drawn with respect to the sediment-size data. All manual samples and many of the autosamples include size-fraction data; however, none of these data were taken into account for this study. Regression models could be constructed for the individual sand/silt fraction, such that concentration and load for coarse- or fine-grain sizes could be determined separately. Additional work could use the size-fraction data to suggest source areas and to develop a synopsis of how specific areas have eroded and evolved over time, as well as to estimate the volumes of different size classes transported downstream past the NF Toutle-SRS gaging station to the main-stem Toutle and Cowlitz Rivers.

Updating Existing Regressions

The regression models in this report use data only from April 2010 to September 2011, as the time frame and scope for this work coincided with WYs 2010–11 approved and published turbidity and SSC records. The regression models and equations can easily be applied to or updated to include later water years. Inclusion of additional manual and pumping samples, the data for which already are available for WYs 2012–13, would better define the turbidity-discharge to SSC relation and improve the regression development and structure. By periodically evaluating the latest, finalized turbidity and discharge data, by water year, major changes in the sediment-transport system could be documented.

Trends and Use of State-Space Models

Sediment flux in the Toutle River Basin at both gaging stations responds to regional hydrology, but also responds to localized events and patterns. Specific erosional events from the Mount St. Helens crater and debris avalanche, and areas directly upstream of the SRS have all caused spikes and anomalies that are outside the typical sediment-transport pattern. These types of events can produce a hysteresis or differential pattern between sediment concentration and turbidity or discharge over varying parts of the event hydrograph. These patterns could reveal source or process information that, with closer evaluation, could be used to more effectively understand and manage sediment transport throughout the Toutle River Basin. The debris-avalanche deposit and braided channels formed through the entire valley, upstream and downstream of the SRS, also have implications for other environmental factors, such as fish survival and migration, along with the health and restoration of other aquatic species and habitats. Additional explanatory variables that weigh supplementary factors (such as seasonality, specific events, antecedent conditions, water temperature, and other water-quality parameters) could be incorporated in the model to help understand these wide-ranging ecological conditions.

In working within the 30-day autocorrelation die-off period, if SSC sample results, including laboratory analysis and database entry, could be routinely performed on a more real-time, continuous basis, such that SSC values were provided in less than 30 days, then autocorrelation modeling with a time-series component would be relevant to the results and should be applied. Realistically, however, most processing of sediment samples takes more than 30 days to generate an SSC value. One benefit of more real-time SSC data would be improved event-based estimation. Additionally, understanding and correcting for time-series properties of SSC would be most useful when interpolating between missing values of observed SSC. However, to apply these types of time-series corrections would require all SSC samples to be in an even time-step (Jones, 1986); although adjustments could be made using SSMs to alleviate this concern. Other time-series components, such as an ARMA model, also might be required, along with smoothing techniques to estimate intermediate values of SSC, such as using a Kalman filter in a SSM.

Such sophisticated techniques as ARMA processing and SSMs, if employed, would better simulate the trends in observed SSC by incorporating seasonality and rise/fall hysteresis variables. One possible parameter to better define rise/fall dynamics in fluvial constituent studies is use of the square of streamflow (Cohn and others, 1992). Particularly powerful are SSMs that use dynamic optimization techniques to define the best "path" through a deterministic or stochastic dataset. One such data-fusion procedure is a Kalman filter, which works by smoothing linear data and then estimating missing SSC in a feed-forward and feed-back manner by minimizing the mean square error of the estimated SSC (Maybeck, 1979). For instance, noisy, erratic data could be smoothed and estimates made in past, present, and future states. The Kalman filter works much like GCLAS by melding the observed sampled SSCs with estimated SSCs and interpolating missing values, although the two methods have their distinctions. GCLAS by its design is a human-based, more time-dependent interactive process, whereas SSM with a Kalman filter can be entirely automated. The distinct advantages of the SSM method are its reproducibility and reduced processing time, as well as the ability to estimate error metrics of the interpolated values. Thus, the more frequently samples are collected, the less the error estimate. After turbidity and discharge records are available, a sediment discharge record could be generated automatically with a defined uncertainty.

High-End Turbidity Sensor

As mentioned in the "Turbidity Greater Than Instrument Limits" section, a high-end turbidity sensor capable of monitoring suspended-sediment at levels at least one order of magnitude higher than the current turbidity sensor is in operation, on a trial basis, at NF Toutle-SRS. Future work could include this high-end sensor as part of the normal turbidity calibration and records-processing work, which could be published as a second turbidity parameter. Separate regressions for the high-end sensor also would need to be developed. See figure 10 for comparison of instream DTS-12 sensor™ and high-end sensor readings.

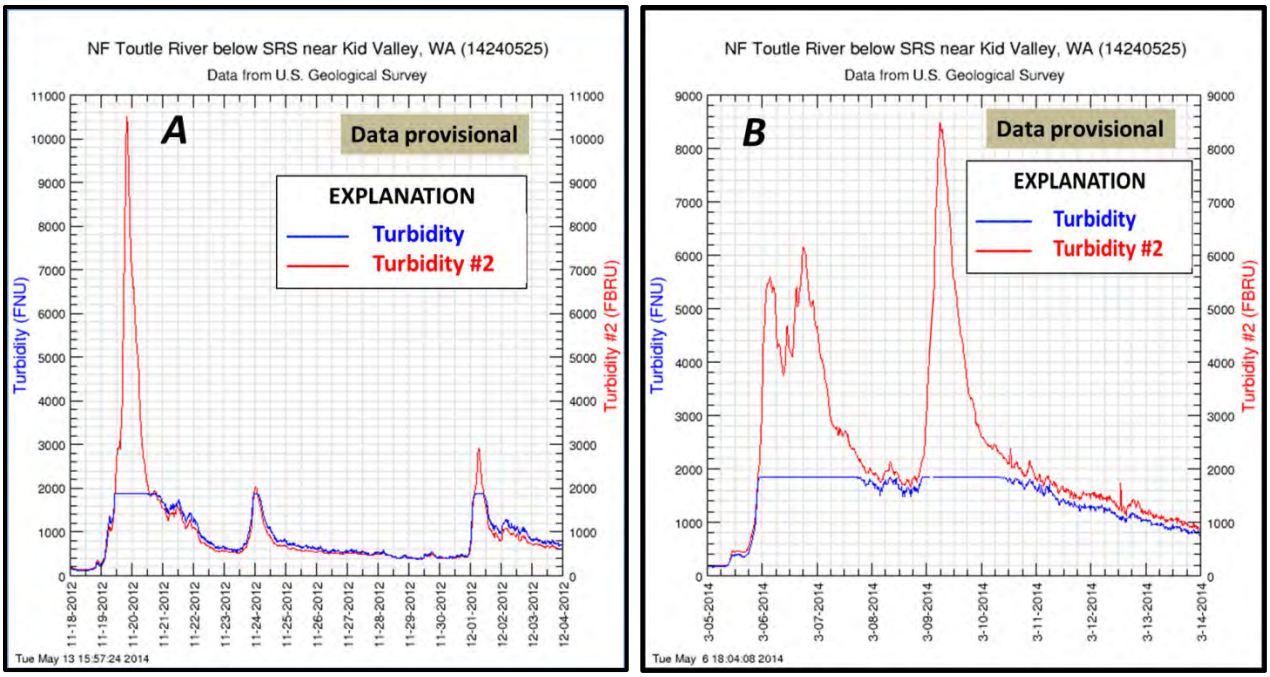

Figure 10. Graphs showing turbidity at North Fork Toutle River below Sediment Retention Structure near Kid Valley, Toutle River Basin, Washington, 2012 and 2014. Graph in blue shows how *NF Toutle-SRS* turbidity, for (*A*) November 18–December 4, 2012, and (*B*) March 5–March 14, 2014, reached the sensor maximum at near 2000 FNU. Graph in red shows, for the same time period and scale, how a high-end sensor (Turbidity #2) recorded turbidity (in formazin backscatter ratio units, FBRU) beyond the threshold level in blue.

Expected Effects of Raising SRS-Spillway

The SRS spillway was raised in elevation by 7 ft in September–October 2012, (back cover photograph; U.S. Army Corps of Engineers, 2012). The effects of this higher spillway on sediment transport and downstream channel morphology are not yet quantified. Additional analysis could integrate future turbidity and streamflow data into the established regression model, and also serve as a contrast to previous turbidity-discharge to SSC relations. For example, data directly preceding and following the spillway construction, such as data for WYs 2012 and 2013, could be compared. Any change in this relation would help to define and quantify new trends in sediment transport affected and (or) caused by this spillway raise. Similarly, future longer-term modifications to the SRS could be evaluated for any changes to the turbidity-SSC, turbidity-streamflow, and turbidity plus streamflow-SSC relation. Finally, the spillway raise may have affected the sediment-size fraction transported downstream past the SRS; one possible effect would be that relatively more coarse sediment is retained upstream of the SRS, with relatively more fine material transported downstream. Existing data on both size fractions and the nature of the turbidity-SSC regression could shed light on the degree to which these changes have occurred. The suspended-sediment loads could be computed with the percentage of certain size classes quantified by volume and compared year-to-year.

Conclusions

Despite the more than 30 years since the eruption of Mount St. Helens, sediment management in the Toutle River remains a daunting task. To help improve estimates of sediment transport and to reduce costs, the feasibility of instream turbidity measurement as a surrogate for suspended-sediment concentration (SSC) was tested in the Toutle River Basin. The results indicate that turbidity can be used reliably to augment the existing SSC sample collection, and possibly to improve the final estimates, as well as to reduce future data collection costs. The Toutle River at Tower Road (Toutle-Tower) near Silver Lake, Washington, and North Fork Toutle River below Sediment Retention Structure (NF Toutle-SRS) near Kid Valley, Washington, gaging stations each had sensors installed and data collected for the periods April 1 and May 1, 2010, through September 30, 2011, respectively. Multiple linear regression models using ordinary least square methods were generated and equations were provided for both gaging stations that use the instream turbidity and discharge data to enable prediction of real-time SSC. The equations to calculate SSC were corrected for bias using a smearing estimator.

The turbidity-SSC regressions were relatively successful, and could be improved in the future by employing sensors that have a higher maximum range. The use of pump samplers also could be optimized by finding a balance between cost savings from their unattended sampling capabilities, and the uncertainty they introduce. Uncertainty from pump samplers occurred because the sample represented a single point rather than a cross section, and the large number (as used herein) contributed to autocorrelation. Scheduling manual equal-discharge-increment sampling for times providing the most desirable and broadest range in streamflow and turbidity levels also could help to streamline the data-collection program.

In addition to the regression statistics, other tests and improvement measures were applied, such as the Durbin-Watson statistic to test for serial correlation and the use of lagged turbidity and discharge variables. The regression with the best supportive diagnostic statistics and best fit of the explanatory and response variables, along with minimal serial correlation, was selected as the final model and equation. The final regression equation used logged values of turbidity, discharge, and a single 15-minute lag of turbidity as explanatory variables in estimating SSC.

The dataset used in this study was confined to roughly 1.5 years of turbidity and SSC; however, additional years of data were made available after this data analysis was underway. Future water years could readily be added to better define and fine-tune these correlations. Sediment-size data were not used in this analysis, which prevented any inferences regarding sediment transport of various size fractions. Future models could be constructed for separate fine- or coarse-grain sediment transport.

Despite these limitations, the proof of concept described in the initial study objectives has shown that, even in a high sand-transport environment, rugged in-stream turbidity instrumentation, robust measuring technology, and appropriate statistical modeling methods may produce a more efficient and less costly alternative to conventional sample-based, sediment-record methods currently (2014) in use. More sophisticated statistical analysis would be useful for this dataset and future Toutle-Tower and NF Toutle-SRS datasets, as this would broaden the understanding of turbidity-discharge to SSC correlations by incorporating seasonality, trends, and rise/fall hysteresis terms. Future use of an Auto-Regressive Moving Average component and State-Space Models using a Kalman filter also would automate sediment-discharge computations, deliver reproducibility, and provide an error measurement of the load estimate.

Acknowledgments

We would like to recognize the scientific and financial support received from the U.S. Army Corps of Engineers (COE) in making this project possible. The COE Portland District personnel were staunch and consistent supporters of this research, particularly Chris Nygaard and Paul Sclafani of the Mount St. Helens Long-Term Sediment Management Team (*http://www.nwp.usace.army.mil/Missions/Currentprojects/MountStHelensEIS.aspx*).

We would like to extend our appreciation to Greg Schwarz of the USGS headquarters office in Reston, Virginia, for his statistical evaluation, suggestions, and insight which greatly enhanced the quality, usability, and extent of this work.

A special thanks to Tami Christianson, of the USGS Cascades Volcano Observatory, for her diligent work in collecting sediment samples, often under challenging conditions, and for checking and providing the turbidity and streamflow data. Finally, we would like to acknowledge Dennis Saunders, Arlene Sondergaard, and Katherine Norton, all from the USGS Cascades Volcano Observatory, for checking, processing, and disseminating our sediment concentration data.

Appendix A. Suspended-Sediment Sample, Discharge, and Turbidity Data

Suspended-sediment sample data are presented for the discharge and turbidity monitoring gaging stations North Fork Toutle River below Sediment Retention Structure near Kid Valley, Washington (NF Toutle-SRS; U.S. Geological Survey [USGS] gaging station No. 14240525) and Toutle River at Tower Road near Silver Lake, Washington (Toutle-Tower; USGS gaging station No. 14242580). The data were used for regression model calibration and consist of the total suspended-sediment concentration and the corresponding discharge and turbidity recorded at the monitoring station during sample collection. When available, sample concentrations with fine suspended-sediment data are presented for particle sizes less than 0.0625 millimeters. Separate bar plot worksheets also are included that depict the number of samples collected at each gaging station. Each bar plot is differentiated by sample type as Equal-Discharge-Increment or pump sample, and by nine different ranges in turbidity that span the entire sensor measurement scale.

[Appendix A is a Microsoft© Excel file and can be downloaded at *http://pubs.usgs.gov/ofr/2014/1204/*.]

Appendix B. Robustness Check Data

Data used in checking for robustness is presented as two separate worksheets for each station in an Excel spreadsheet. Included are the sampled suspended-sediment concentration (SSC) data, and adjoining discharge (Q), turbidity (T) and lagged turbidity (T-lag) values for the 90- and 10-percent subsampled and sequestered out-of-sample data, respectively. Samples were randomly selected for the 90-percent group. One sample was randomly selected for days with more than one sample. The remaining samples were used for the 10-percent sequestered data. For NF Toutle-SRS, 653 samples were reduced to 307 and 34 samples for the 90- and 10-percent groups, respectively. For Toutle-Tower, 705 samples were reduced to 320 and 35 samples for the 90- and 10-percent groups, respectively.

TECHNIQUES OF WATER-RESOURCES INVESTIGATIONS OF THE U.S. GEOLOGICAL SURVEY

The U.S. Geological Survey publishes a series of manuals describing procedures for planning and conducting specialized work in water-resources investigations. The material is grouped under major subject headings called books and is further divided into sections and chapters. For example, Section A of Book 3 (Applications of Hydraulics) pertains to surface water. The chapter, the unit of publication, is limited to a narrow field of subject matter. This format permits flexibility in revision and publication as the need arises.

The reports listed below are for sale by the **U.S. Geological Survey, Information Services, Box 25286, Federal Center, Denver, Colorado 80225** (authorized agent of the Superintendent of Documents, Government Printing Office). Prepayment is required. Remittance should be sent by check or money order payable to the U.S. Geological Survey. Prices are not included because they are subject to change. **Current prices can be obtained by writing to the above address.** When ordering or inquiring about prices for any of these publications, please give the title, book number, chapter number, and "U.S. Geological Survey Techniques of Water-Resources Investigations."

when the ratio of weight of sediment to weight of water-sediment mixture is between 0 and 15,900. If this ratio is greater than 15,900, the investigator is referred to Guy (1969, table 1, p. 4) for the correct conversion factor to be used in the formula.

FIELD METHODS FOR MEASUREMENT OF FLUVIAL SEDIMENT

By Thomas K. Edwards and G. Douglas Glysson

Abstract

This chapter describes equipment and procedures for collection and measurement of fluvial sediment. The complexity of the hydrologic and physical environments and man's ever-increasing data needs make it essential for those responsible for the collection of sediment data to be aware of basic concepts involved in processes of erosion, transport, deposition of sediment, and equipment and procedures necessary to representatively collect sediment data.

In addition to an introduction, the chapter has two major sections. The "Sediment-Sampling Equipment" section encompasses discussions of characteristics and limitations of various models of depth- and point-integrating samplers, single-stage samplers, bed-material samplers, bedload samplers, automatic pumping samplers, and support equipment. The "Sediment-Sampling Techniques" section includes discussions of representative sampling criteria, characteristics of sampling sites, equipment selection relative to the sampling conditions and needs, depth- and point-integration techniques, surface and dip sampling, determination of transit rates, sampling programs and related data, cold-weather sampling, bed-material and bedload sampling, measuring total sediment discharge, and measuring reservoir sedimentation rates.

INTRODUCTION

Perspective

Knowledge of the erosion, transport, and deposition of sediment relative to land surface, streams, reservoirs, and other bodies of water is important to those involved directly or indirectly in the development and management of water and land resources. It also is becoming more important that such development and management be carried out in a manner that yields or conforms to a socially acceptable environment. The need for a clear understanding of hydrogeomorphologic processes associated with sediment requires the measurement of suspended and bed sediments for a wide range of hydrologic environments. The complex phenomena of fluvial sedimentation cause the required measurements and related analyses of sediment data to be relatively expensive in comparison with other kinds of hydrologic data. Accordingly, the purpose of this manual is to help standardize and improve efficiency in the techniques used to obtain sediment data, so the quantity and quality of the data can be maximized for a given investment of labor and resource.

Sediment data needs are of practical concern. Some of the general categories include:

1. The evaluation of sediment yield with respect to different natural environmental conditions—geology, soils, climate, runoff, topography, ground cover, and size of drainage area.
2. The evaluation of sediment yield with respect to different kinds of land use.
3. The time distribution of sediment concentration and transport rate in streams.
4. The evaluation of erosion and deposition in channel systems.
5. The amount and size characteristics of sediment delivered to a body of water.
6. The characteristics of sediment deposits as related to particle size and flow conditions.
7. The relations between sediment chemistry, water quality, and biota.

The scope of these requirements indicates that a wide variety of measurements are needed on streams and other bodies of water, ranging from large river basins to very small tributaries that drain areas such as parcels of land under urban development.

The equipment and methods discussed in this report for the collection of a suspended-sediment sample are designed to yield a representative sample of the water

sediment mixture. This representative sample may be analyzed for sediment concentration, particle-size distribution, or, if collected with the proper type sampler, any other dissolved, suspended, or total water-quality constituent. Therefore, the equipment and methods described in this report should be used to collect a representative sample for water-quality analysis.

Sediment Characteristics, Source, and Transport

Sediment is fragmental material transported by, suspended in, or deposited by water or air, or accumulated in beds by other natural agents. Sediment particles range in size from large boulders to colloidal-size fragments and vary in shape from rounded to angular. They also vary in mineral composition and specific gravity, the predominant mineral being quartz and the representative specific gravity being 2.65.

Sediment is derived from any parent material subjected to erosional processes by which particles are detached and transported by gravity, wind, water, or a combination of these agents. When the transporting agent is water, the sediment is termed "fluvial sediment." The U.S. Geological Survey (USGS) defines fluvial sediment as fragmentary material that originates mostly from weathering of rocks and is transported by, suspended in, or deposited from water (Federal Inter-Agency Sedimentation Project, 1963b); it includes chemical and biological precipitates and decomposed organic material, such as humus.

Erosion by water is classified as either sheet or channel erosion, with no distinct division between the two. Sheet erosion occurs when sediments are removed from a surface in a sheet of relatively uniform thickness by raindrop splash and sheet flow. Sediment-particle movement and the energy of the raindrops compact and partially seal the soil surface, effectively decreasing the infiltration rate and increasing the amount of flow available to erode and transport the sediment. The amount of material removed by sheet erosion is a function of surface slope, erodibility, and precipitation intensity and drop size.

Land-surface irregularities inhibit continuous sheet flow over large areas. This inhibition serves to concentrate the flow into small rills or channels and streams, which increase in size as they join together downstream. Within these channels, eroded material from the banks or bed of the stream is contributed to the flow until, in theory, the stream is transporting as much sediment as the energy of the stream will allow. Such channel erosion may be general or local along the stream but is primarily local in nature.

Some sediment is carried to streams by wind, but direct contribution to the stream channel by this conveyance usually accounts for only a small part of the total fluvial sediments. Aside from bank caving as a result of stream erosion or processes of mass wasting (Thornbury, 1969), gravitational transfer of sediments occurs toward and into streams. Conveyance by gravitational means ranges from slow creep to rapid landslide. Other significant sources of local sediments are glacial-melt outwash, volcanic activity, mining, earth movement, construction, or additional land-disturbance activities by man.

The stream usually transports sediment by maintaining the finer particles in suspension with turbulent currents and by rolling or skipping the coarser particles along the streambed. Generally, the finer sediments move downstream at about the same velocity as the water, whereas the coarsest sediments may move only occasionally and remain at rest much of the time.

Vertical distributions of suspended-sediment particle sizes may vary among streams and among cross sections within a stream. However, as a general rule, the finer particles are uniformly distributed throughout the vertical, and the coarser particles are concentrated near the streambed. Occasionally, coarse particles may reach the water surface, generally carried by turbulent flow or as a result of dispersive grain stress (Leopold and others, 1964). Thus, with use of the depth- or point-integrating suspended-sediment samplers described here, the sample obtained generally contains a range of particle sizes representative of the suspended-sediment discharge at the sampled vertical. The vertical is divided into two zones, as illustrated by figure 1. This separation is due to the design of the sampler, which limits the effective sampled depth. Sampling the entire depth is not possible because the physical location of the sampler nozzle relative to the bottom of the sampler prevents the nozzle from passing through the zone close to the bed. This portion of the depth is termed the unsampled zone and characteristically carries the higher concentration and coarser particles. The unsampled suspended sediment moving within this zone may or

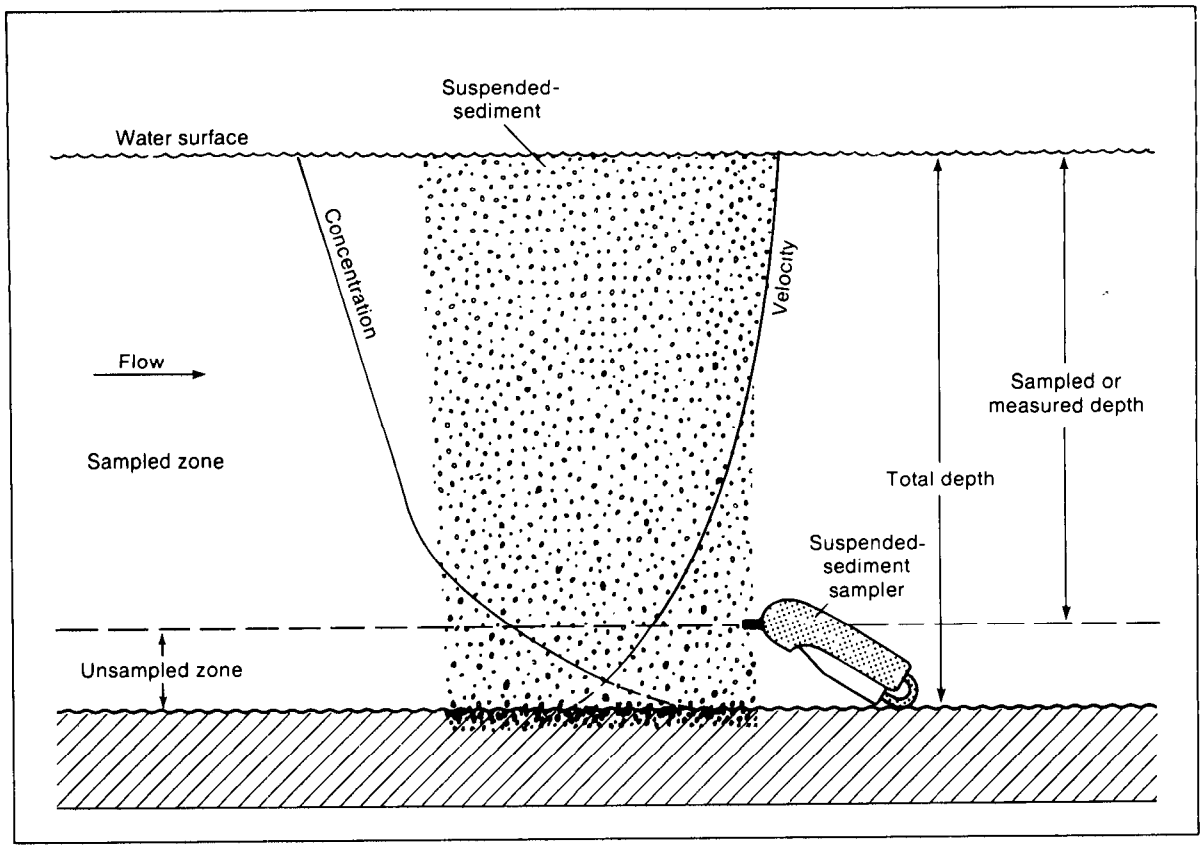

Figure 1. Sampled and unsampled zones in a stream sampling vertical, with respect to velocity of flow and sediment concentration.

may not account for a large part of the total suspended sediment, depending upon the depth, velocity, and turbulence of the flow through the vertical. The measured sediment discharge is nearly equal to the total sediment discharge if the velocity and turbulence conditions within the sampled vertical overcome the tractive force transporting the bedload in the unmeasured zone and effectively disperse all of the sediment being transported into suspension throughout the total depth.

The preceding discussion illustrates the complexity of the study of fluvial sediment transport and some of the many variables involved. The interested reader is directed to more detailed works concerning fluvial-sediment concepts and geomorphic processes, such as the contributions by Colby (1963), Leopold and others (1964), Guy (1970), and Vanoni (1975). The investigator also can obtain pertinent information on the subject by contacting the Federal Inter-Agency Sedimentation Project (F.I.S.P.), Waterways Experiment Station, Vicksburg, Mississippi.

Data Needs

No matter how precise the theoretical prediction of sedimentation processes becomes, it is inevitable that man's activities will continue to cause changes in the many variables affecting sediment erosion, transportation, and deposition; thus, there will be an increasing need for direct and indirect measurement of fluvial-sediment movement and its characteristics. Because of the rapid advances in technology, it seems of little value to list the many specific kinds of sediment problems and the kinds of sediment data required to solve such problems. However, some general areas of concern may be of interest. Sediment data are useful in coping with problems and goals related to water utilization. Many industries require sediment-free water in their processes. A knowledge of the amount and characteristics of sediment in the water resource is needed so that the sediment may be removed as economically as possible before the water is allowed to enter a distribution system. Information on sediment

movement and particle-size characteristics is needed in the design of hydraulic structures, such as dams, canals, and irrigation works. Streams and reservoirs that are free of sediment are highly regarded for recreation. Data on sediment movement and particle characteristics are needed to determine and understand how radionuclides, pesticides, and many organic materials are absorbed and concentrated by sediments, thus causing potential health hazards in some streams, estuaries, and water-storage areas. Knowledge concerning the effect of natural and man-made changes in drainage basins on the amount and characteristics of sediment yielded from the drainage basins is useful in helping to predict the stream environment when future basin changes are made. Knowledge about present fluvial-sediment conditions is being used to help establish criteria for water-quality standards and goals.

These data needs require sediment programs that will provide (1) comprehensive information on a national network basis, (2) special information about specific problem areas for water management, and (3) a description and understanding of the relations between water, sediment, and the environment (basic research). The reader is referred to Book 3, Chapter C1 of this series (Guy, 1970, p. 47) for a description of the kinds of sediment records commonly obtained at stream sites. Briefly, the records are of (1) the continuous or daily-record type, where sampling is sufficiently comprehensive to permit computation of daily loads, (2) the partial-record type, where a daily record is obtained for only a part of the year, and (3) the periodic-record type, where samples are taken periodically or intermittently. Usually a series of reconnaissance measurements is made prior to implementing any of these three programs. Even after a specific program is started, it is possible that adjustments may be necessary with respect to equipment, sample timing, or even measurement location. Realignment of efforts in this manner can be avoided in many instances by carefully applying design criteria to adequately meet the objectives of the project.

SEDIMENT-SAMPLING EQUIPMENT

General

In the early days of fluvial-sediment investigations, each investigator, or at least each agency concerned with sediment, developed methods and equipment individually as needed. It soon became apparent that consistent data could not be obtained unless equipment, data collection, and analytical methods were standardized. To overcome this difficulty, representatives of several Federal agencies (the Corps of Engineers of the Department of the Army, the Flood Control Coordinating Committee of the Department of Agriculture, the U.S. Geological Survey, the Bureau of Reclamation, the Office of Indian Affairs of the Department of the Interior, and the Tennessee Valley Authority) met in 1939 to form an interdepartmental committee, with the expressed purpose of standardizing sediment data-collection equipment, methods, and analytical techniques. The test facility for this work was initially located at the Iowa University Hydraulics Laboratory, in Iowa City, Iowa, and remained there for 9 years. In 1946, the committee became known as the Subcommittee on Sedimentation of the Federal Inter-Agency River Basin Committee. In 1948, the subcommittee moved the test facility to the St. Anthony Falls Hydraulic Laboratory, University of Minnesota, in Minneapolis, Minnesota. The subcommittee reorganized the project in 1956 to its present structure as the Federal Inter-Agency Sedimentation Project (F.I.S.P.). In 1992, F.I.S.P. was moved to its present location at the Waterways Experiment Station in Vicksburg, Mississippi. The project is sponsored by a technical committee composed of representatives of the U.S. Army Corps of Engineers, U.S. Geological Survey, Bureau of Reclamation, Agricultural Research Service, U.S. Forest Service, and Bureau of Land Management, working under a formal Guidance Memorandum describing the project's objectives and organization. The F.I.S.P. is overseen by the Technical Committee of the Subcommittee on Sedimentation of the Interagency Advisory Committee on Water Data.

Since its initiation in 1939, approximately 50 reports, dealing with nearly all aspects of measurement and analysis of fluvial sediment movement, have been published by F.I.S.P. The intent of this chapter is not to replace the Inter-Agency Project reports, but to condense and combine their information regarding sediment measurements. The interested reader should contact F.I.S.P. for a listing of individual reports presenting further background material and details on the standard samplers. Sampling equipment is available for purchase by any interested investigator from the F.I.S.P., 3909 Halls Ferry Road, Vicksburg, MS 39180-6199.

The samplers developed by the F.I.S.P. are designated by the following codes: US, United States standard sampler. (In the following discussions this code will appear in the initial reference but will be dropped from succeeding references to the sampler designations.)

D, depth integrating

P, point integrating

H, hand-held by rod or line. (This code is placed after the primary letter designation and is omitted when referring to cable- and reel-suspended samplers.)

BM, bed material

BP, battery pack

BL, bedload sampler

U or SS, single stage

PS or CS, pumping-type sampler

Year, last two digits of the year in which the sampler was developed.

Sediment samplers available from F.I.S.P. or Hydrologic Instrumentation Facility (HIF) include suites of depth-integrating suspended-sediment samplers, point-integrating suspended-sediment samplers, pumping samplers, bed-material samplers, and a bedload sampler. In addition, an array of instruments has been developed to fulfill the need for collecting samples during unpredictable high-flow events. One sampler of particular interest for use in the future is a suspended-sediment sampler that utilizes bags as sample containers to overcome the depth limits of standard samplers due to container size, nozzle diameter, and stream velocity (Federal Inter-Agency Sedimentation Project, 1982b).

Suspended-Sediment Samplers

The purpose of a suspended-sediment sampler is to obtain a representative sample of the water-sediment mixture moving in the stream in the vicinity of the sampler. The F.I.S.P. committee set up several criteria for the design and construction of suspended-sediment samplers:

1. To allow water to enter the nozzle isokinetically. (In isokinetic sampling, water approaching the nozzle undergoes no change in speed or direction as it enters the orifice.)
2. To permit the sampler nozzle to reach a point as close to the streambed as physically possible. (This varies from 3 to 7 inches, depending on the sampler.)
3. To minimize disturbance to the flow pattern of the stream, especially at the nozzle.
4. To be adaptable to support equipment already in use for streamflow measurement.
5. To be as simple and maintenance-free as possible.
6. To accommodate a standard bottle size [that is, 1-pint (473 mL) glass milk bottle, 1-quart (946 mL) glass, 1-liter (1,000 mL) plastic, 2-liter (2,000 mL) plastic, or 3-liter (3,000 mL) plastic, as listed in table 1].

When a suspended-sediment sampler is submerged with the nozzle pointing directly into the flow, a part of the streamflow enters the sampler container through the nozzle as air in the container exhausts under the combined effect of three forces:

1. The positive dynamic head at the nozzle entrance, due to the flow.
2. A negative head at the end of the air-exhaust tube, due to flow separation.
3. A positive pressure due to a difference in elevation between the nozzle entrance and the air-exhaust tube.

When the sample in the container reaches the level of the air exhaust, the flow rate drops, and circulation of the streamflow in through the nozzle and out through the air-exhaust tube occurs. Because the velocity of the water flowing through the bottle is less than the stream velocity, the coarser particles settle out, causing the concentration of coarse particles in the bottle to gradually increase.

Table 1. Sampler designations and characteristics

[Epoxy-coated versions of all samplers are available for collecting trace metal samples; US, United States; in., inches; lbs., pounds; ft/s, feet per second; cd, cadmium, do., ditto; X, type of sampler container size used; --, type of sampler container size not used]

Depth- and Point-Integrating Samplers

A depth-integrating sampler is designed to isokinetically and continuously accumulate a representative sample from a stream vertical while transiting the vertical at a uniform rate (Federal Inter-Agency Sedimentation Project, 1952, p. 22). The simple depth-integrating sampler collects and accumulates a velocity or discharge-weighted sample as it is lowered to the bottom of the stream and raised back to the surface.

The point-integrating sampler, on the other hand, uses an electrically activated valve, enabling the operator to isokinetically sample points or portions of a given vertical. For stream cross sections less than 30 feet deep, the full depth can be traversed in one direction at a time by opening the valve and depth integrating either from surface to bottom or vice versa. Stream cross sections deeper than 30 feet can be integrated in segments of 30 feet or less by collecting integrated-sample pairs consisting of a downward

integration and a corresponding upward integration in separate containers.

To eliminate confusion and more adequately differentiate between depth- and point-integrating samplers, a direct reference to Inter-Agency Report 14 (Federal Inter-Agency Sedimentation Project, 1963b, p. 60) is presented here to describe the characteristics of the point-integrating samplers that make them useful in conditions beyond the limits of the simpler depth-integrating samplers.

> Point-integrating samplers are more versatile than the simpler depth-integrating types. They can be used to collect a suspended-sediment sample representing the mean sediment concentration at any point from the surface of a stream to within a few inches of the bed, as well as to integrate over a range in depth. These samplers were designed for depth integration of streams too deep (or too swift) to be sampled in a continuous round-trip integration. When depth integrating, sampling can begin at any depth and proceed either upward or downward from that initial point through a maximum vertical distance of 30 feet.

A point-integrating sampler uses a 3/16-inch nozzle oriented parallel to the streamflow with the cross-sectional area exposed to approaching particles. The air is exhausted from the sample container and directed downstream away from the nozzle area as the sample enters. The intake and exhaust passages are controlled by a valve that can be activated on demand. When the valve is activated (opened to the sampling position), the sampling procedure is identical to that used for depth-integrating samplers. The increased effective depth to which a point-integrating sampler can be used, as compared to the maximum sampling depth to which a depth-integrating sampler is limited, is made possible by a pressure-equalizing chamber (diving-bell principle) enclosed in the sampler body. This chamber equalizes the air pressure in the sample container with the external hydrostatic head near the intake nozzle at all depths to alleviate the inrush of sample water, which would otherwise occur when the intake and air exhaust are opened at depth.

Hand-held samplers—US DH-81, US DH-75, US DH-48, US DH-59, and US DH-76

Where streams are wadable or access can be obtained from a low bridge span or cableway, a choice of five lightweight samplers can be used to obtain suspended-sediment samples via a wading rod or handline.

The DH-81 (fig. 2) consists of a DH-81A adapter and D-77 cap and nozzle. All parts are autoclavable. This construction enables the sampler to be used for collection of depth-integrated samples for bacterial analysis. The DH-81 can be used with 1/8-inch, 3/16-inch, or 1/4-inch nozzles and is suspended from a rod. Any bottle having standard mason jar threads can be used with this sampler. Obviously, the height of the unmeasured zone will vary depending on the size of

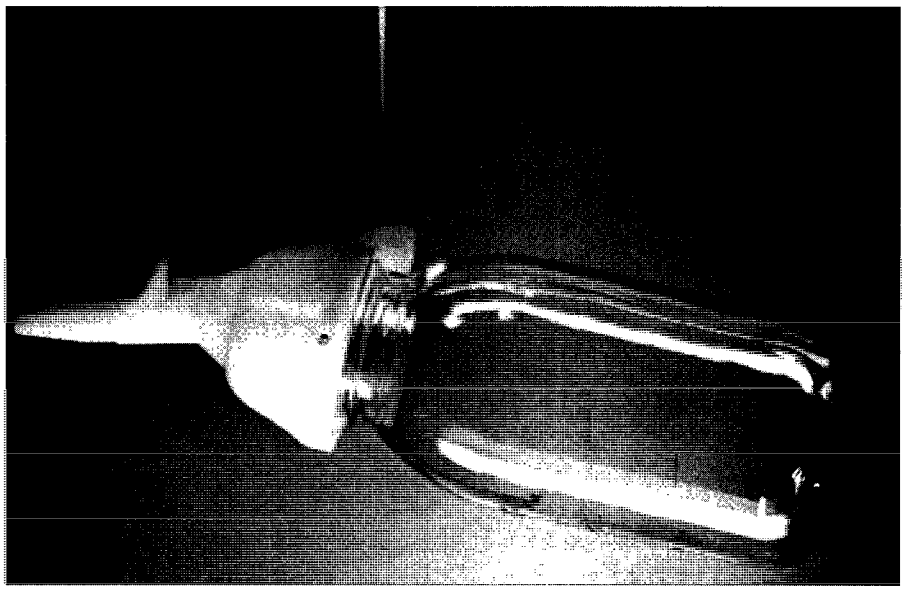

Figure 2. US DH-81 suspended-sediment sampler shown with a US DH-81A adapter, D-77 cap and nozzle, wading rod handle, and quart glass bottle.

bottle used. The DH-81 should be useful for sampling during cold weather because the plastic sampler head and nozzle attach directly to the bottle, eliminating a metal body (which would more rapidly conduct heat away from the nozzle, air exhaust, and bottle and create a more severe sampler-freezeup condition).

The DH-75 (fig. 3) weighs 0.9 pound and is available in two versions, the DH-75P and DH-75Q, which accept plastic containers of pint and quart volumes, respectively. The sampler consists of a cadmium-plated sheet-steel body 9 1/4 inches long, excluding the nozzle and sample container, with a retainer piece and shock cord assembly to hold the sample container against a cast silicone stopper through which the 3/16-inch nozzle and 180-degree air-exhaust tube pass to the mouth of the bottle. The DH-75 was developed as a freeze-resistant sampler. This sampler is not recommended for use as a general purpose depth-integrating suspended-sediment sampler.

The DH-48 sampler (fig. 4) features a streamlined aluminum casting 13 inches long that partly encloses the sample container. The container, usually a round pint glass milk bottle, is sealed against a gasket recessed in the head cavity of the sampler by a hand-operated spring-tensioned pull-rod assembly at the tail of the sampler. A modified version of this sampler is available to accommodate square pint milk bottles also. The sample enters the container through the intake nozzle as the air from the container is displaced and exhausted downstream through the air exhaust. The sampler, including container, weighs 4 1/2 pounds and can sample to within 3 1/2 inches of the streambed. This instrument is calibrated with an intake nozzle 1/4 inch in diameter, but may be used with a 3/16-inch nozzle in high-flow velocity situations (Federal Inter-Agency Sedimentation Project, 1963b, p. 57–60).

Two lightweight (24 and 25 pounds) handline samplers designated "DH-59" and "DH-76" (figs. 5 and 6) are designed for use in shallow unwadable streams with flow velocities up to 5 ft/s (feet per second). These samplers feature streamlined bronze castings 15 and 17 inches in length for the DH-59 and DH-76, respectively. The DH-59 accommodates a round pint sample bottle, while the DH-76, a more recent version of the sampler, is designed to take a quart container. The tail assembly extends below the body of the casting to ensure sampler alignment parallel to the flow direction with the intake nozzle entrance oriented upstream. Intake nozzles of 1/8-inch, 3/16-inch, and 1/4-inch diameters are calibrated for use with these samplers and may be interchanged as necessary when varying flow conditions are encountered from stream to stream. Suspended sediment can be collected to within 4 1/2 inches of the streambed with the DH-59, while the DH-76 can sample to within about 3 inches from the bottom.

These lightweight hand samplers are the most commonly used for sediment sampling during normal flow in small- and, perhaps, intermediate-sized streams. Because they are small, light, durable, and adaptable, they are preferred by hired observers and field people on routine or reconnaissance measurement trips. At many locations, a heavier sampler will be needed only for high-flow periods. It is often desirable, however, to require the observer to use a heavier sampler installed at a fixed location. The small size of the hand samplers also enables the person taking a sample in cold weather to warm the sampler readily if water freezes in the nozzle or air exhaust.

Cable-and-Reel Samplers—US D-74, US D-77, US P-61, US P-63, and US P-72

When streams cannot be waded, but are shallower than about 15 feet, depth-integrating samplers designated "D-74" and "D-77" can be used to obtain suspended-sediment samples. Forerunners of these samplers were the US D-43 and US D-49 samplers, both of which are no longer manufactured. These latter two are only mentioned here because many of these earlier designed instruments are still used at some locations. Sampling techniques for using the older samplers are identical to those presented later in this text relative to operation of the newer D-74 and D-77 samplers.

The D-74 (fig. 7) is a 62-pound sampler (approximately 40 pounds for the aluminum version) designed to be suspended from a bridge crane or cableway by means of a standard hanger bar and cable-and-reel system. This sampler replaces the earlier D-49, which replaced the D-43 for general use. The D-74 has a streamlined cast bronze (or aluminum) body 24 inches long that completely encloses the sample container. This sampler accommodates a round quart bottle, or with addition of an adapter sleeve, a standard pint milk bottle may be used. The sampler head is hinged at the bottom and swings downward to provide access to the sample-container chamber. In this manner, sample containers can be changed during the normal sampling

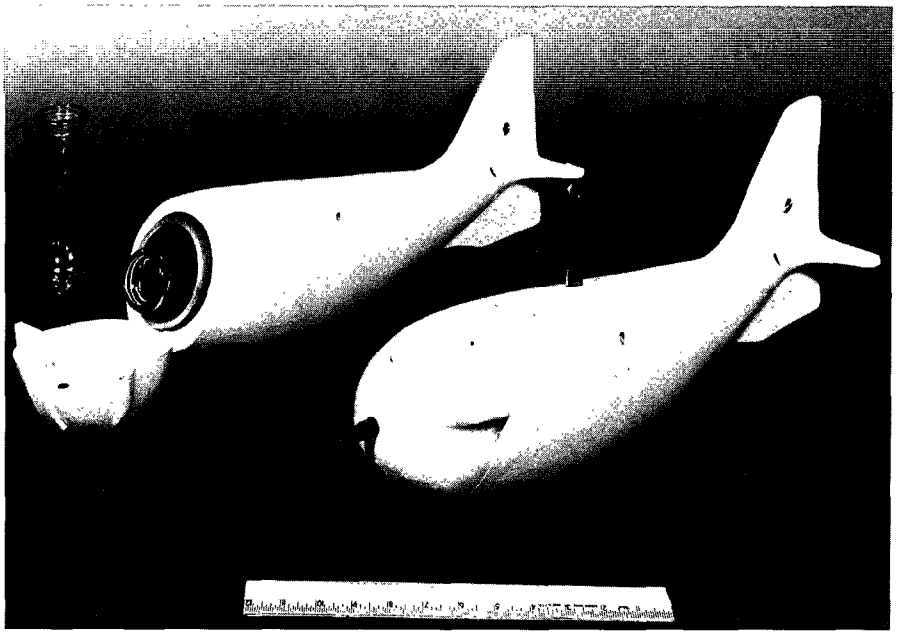

Figure 7. US D-74 suspended-sediment sampler.

routine. The body includes tail vanes that serve to align the sampler and the intake nozzle with the flow. Intake nozzles of 1/8-inch, 3/16-inch, and 1/4-inch diameters are available for use with the sampler and can be interchanged as varying flow conditions dictate. The sample container fills as a filament of water passes through the intake nozzle and displaces air from the container. The air is expelled in the downstream direction through an air-exhaust port in the side of the sampler head. The intake nozzle can be lowered to within about 4 inches of the streambed during sampling (approximately 4 1/3 inches for the aluminum version).

The D-77 is a dramatically different design (fig. 8) as compared to the design configuration of the D-74 and its predecessors. The sampler is 29 inches long and weighs 75 pounds; it has a bronze casting attached to a tail cone with four sheet-metal vanes welded in place to provide a means of orienting the intake nozzle into the flow. The casting is structured to accommodate a 3-liter autoclavable sample container that slides into the sample container chamber and is held in place by means of a spring clip on the bottom of the chamber. This sampler is constructed without a head assembly to cover the mouth of the container and facilitate attachment of the intake nozzle. Instead, a cap, nozzle, and air-exhaust assembly, constructed of autoclavable plastic, is screwed onto the mouth of the sample container, which is entirely exposed at the front of the sampler. This configuration was purposely chosen to allow collection of a large volume (2,700 mL), depth-integrated biological or chemical sample at near- or below-freezing temperatures. Although 1/8-inch, 1/4-inch, 3/16-inch, and 5/16-inch nozzles are available, only 5/16-inch nozzles are recommended for use with this sampler. The distance between the nozzle and sampler bottom is 7 inches.

A version of the D-77 sampler was tested by F.I.S.P. to eliminate the depth-range limit dictated by sample container size, nozzle size, and stream velocity (Federal Inter-Agency Sedimentation Project, 1982b). This version, commonly referred to as a "bag sampler," incorporates a sample bag inside a special rigid container. Information about this sampler and other bag samplers can be obtained from F.I.S.P.

Point-integrating samplers currently manufactured and widely used are the P-61, P-63, and P-72. Forerunners of these samplers were the P-46 and P-50 samplers, which are no longer manufactured but are mentioned here because several of these instruments are still used. The sampling techniques used for obtaining a sample with these older samplers are the same as for the newer samplers. The primary differences between these old and new versions are valve mechanisms and cost. The new versions have a simpler valve and are less expensive.

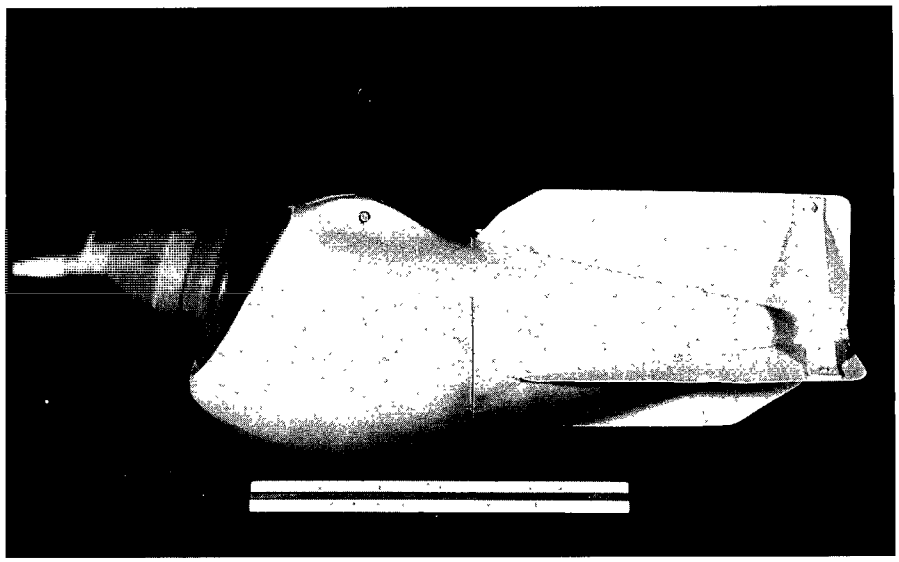

Figure 8. US D-77 suspended-sediment sampler.

The 105-pound P-61 (fig. 9) can be used for depth integration as well as for point integration to a maximum stream depth of 180 feet. The sampler valve for the P-61 has two positions. When the solenoid is not energized, the valve is in the nonsampling position, in which the intake and air-exhaust passages are closed, the air chamber in the body is connected to the cavity in the sampler head, and the head cavity is connected through the valve to the sample container. When the solenoid is energized, the valve is in the sampling position, in which the intake and air exhaust are open, and the connection from the sample container to the head cavity is closed. A P-61 sampler that has been modified to accommodate a quart bottle is illustrated in figure 9. When the ordinary pint bottle is used, the cylindrical adapter must be inserted into the bottle cavity. The maximum sampling depth is about 120 feet when the quart container is used.

The P-63 (fig. 10) is a 200-pound point-integrating suspended-sediment sampler and is better adapted to high velocities. The solenoid head is basically the same as that on the P-61. The P-63 differs from the P-61 mainly in size and weight. The P-63 is cast bronze, is 34 inches long, and has the capacity for a quart-sized round mayonnaise bottle. An adapter is furnished so that a round pint-sized milk bottle can be used. The maximum sampling depth is the same as for the P-61, about 180 feet with a pint sample container and about 120 feet with a quart container.

The 41-pound P-72 is a light-weight version of the P-61. It features a streamlined cast-aluminum shell rather than the bronze used to construct the P-61. The outward appearance of the P-72, the 3/16-inch intake nozzle, the solenoid head, and the accommodation for pint- and quart-sized containers are similar to the P-61. However, the listed maximum stream velocity at which the P-72 is recommended for use is 5.3 ft/s, as opposed to 6.6 ft/s for the P-61, and the depth limit to which this sampler should be used is about 72 feet using the pint container and 51 feet with the quart container. These depths are less than one-half of the maximum usable depths for the P-61 with the same container sizes.

All the point samplers are designed for suspension with a steel cable having an insulated inner conductor core. By pressing a switch located at the operator's station, the operating current may be supplied through the cable to the solenoid in the sampler head by storage batteries connected in series to produce 24 to 48 volts. If the suspension cable is longer than 100 feet, a higher voltage may be desirable. The US BP-76 battery pack has been designed as a portable power source for activating the P-61, P-63, and P-72 samplers and is available from the F.I.S.P. and HIF.

Because of the complex nature of point-integrating samplers, the user may find it necessary to seek additional information given in the Inter-Agency reports (Federal Inter-Agency Sedimentation Project, 1952, 1963b, and 1966).

Sampler Accessories

Nozzles

Each suspended-sediment sampler is equipped with a set of nozzles specifically designed for the particular sampler. These nozzles are cut and shaped externally and internally to ensure that the velocity of water after entering the nozzle is within 8 percent of the ambient stream velocity when the stream velocity is greater than 1 ft/s. It has been found that a deviation in intake velocity from the stream velocity at the sampling point causes an error in the sediment concentration of the sample, especially for sand-sized particles. For example, a plus-10-percent error in sediment concentration is likely for particles of sediment 0.45 mm in diameter, when the intake velocity is 0.75 of the stream velocity (Federal Inter-Agency Sedimentation Project, 1941, p. 38–41). The relation between intake-velocity deviation and errors in concentration resulting from collecting a sample enriched or deficient in sand-size particles (greater than 0.062 mm) is illustrated by figure 11. When sand-size particles are entrained in

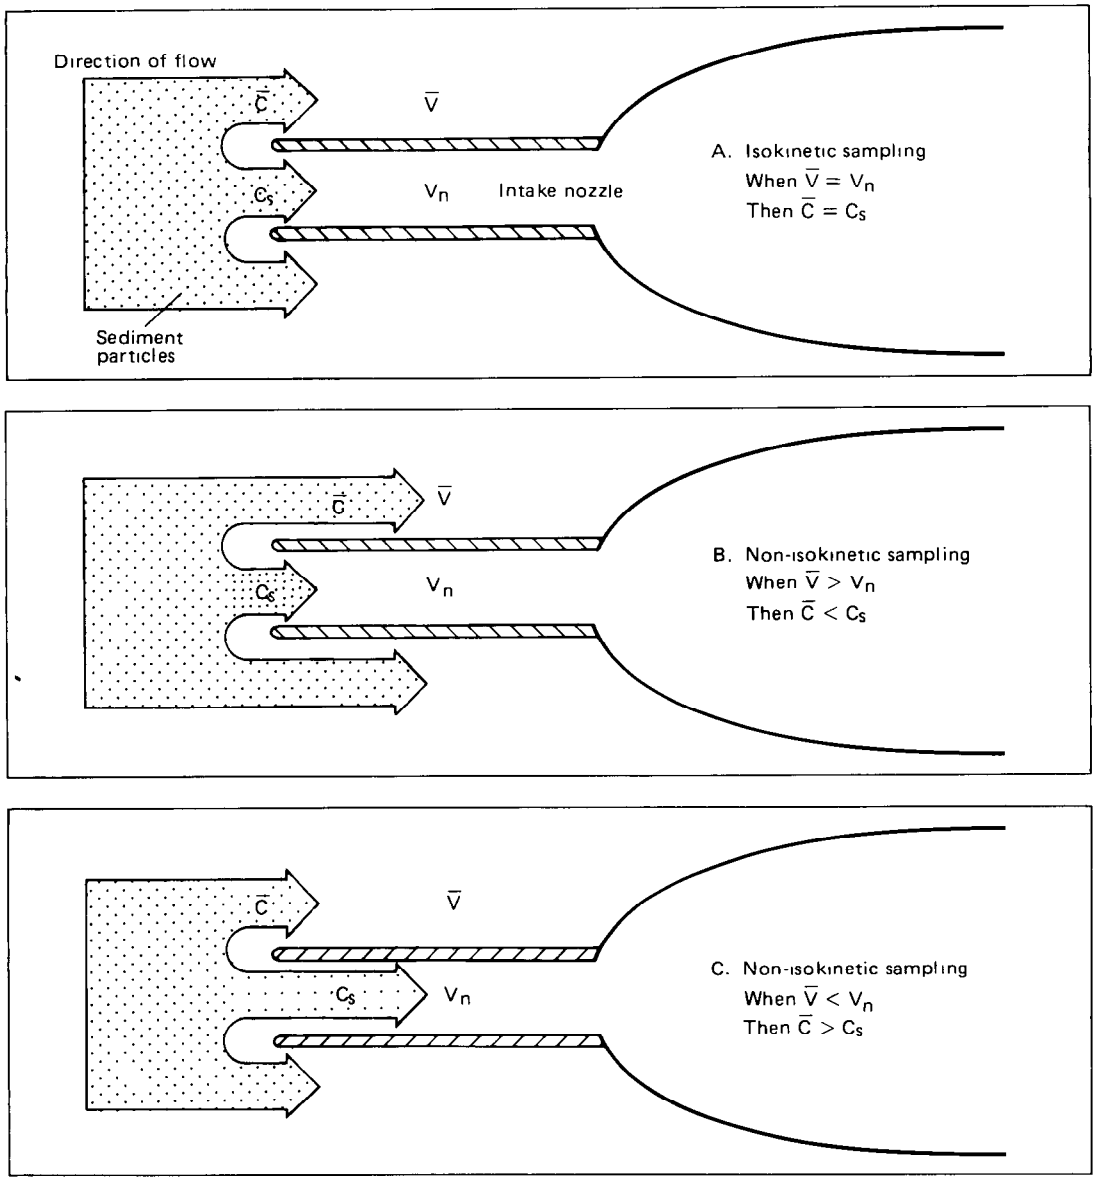

Figure 11. Relation between intake velocity and sample concentration for (*A*) isokinetic and (*B*, *C*) non-isokinetic sample collection of particles greater than 0.062 mm. When $\bar{V}$ = mean stream velocity, V_n = velocity in the sampler nozzle, $\bar{C}$ = mean sediment concentration in the stream, and C_s = sample sediment concentration.

the flow, the intake velocity within the sampler nozzle must be equal to the ambient stream velocity (isokinetic), in order to collect a sample representative of the mean discharge-weighted sediment concentration (fig. 11*A*). The resulting sediment concentration of the sample will be equal to the average discharge-weighted sediment concentration of the approaching flow. However, when the velocity in the nozzle is less than the stream velocity (non-isokinetic, fig. 11*B*), some water that should flow into the nozzle now curves to the side and flows around it. Inertia resists the curving flow and forces the approaching particles (greater than 0.062 mm) to follow straight-line paths into the nozzle. This combination of curved and straight-line movement increases the concentration of coarse particles in the sample. As a result, the sediment concentration in the sample is greater than the concentration in the approaching flow. Likewise, when the velocity in the nozzle is greater than the stream velocity (non-isokinetic, fig. 11*C*), some water that should flow past the nozzle curves to the side and flows into it. Again, inertia resists the curving flow and forces the particles (greater than 0.062 mm) to follow straight-line paths and flow past the nozzle. The result of this combination of curved and straight-line movement is a decrease in the sample concentration relative to the concentration of the approaching flow.

Because, in general, each sampler nozzle is designed for a particular series of samplers, it must be emphasized that a nozzle for one series of samplers should not be used in another series of samplers. However, there are two exceptions to this rule—the same nozzle can be used in the P-61, P-63, and P-72 series, and a nozzle can be interchanged between the D-49 and D-74. To ensure against incorrectly matching samplers and nozzles, all nozzles are color coded to specific sampler designs (table 1).

The reasons for the differences between the nozzles of different series are that (1) the length of flow paths for water and air are different, resulting in differences of flow resistance; and (2) the differential heads between the nozzle entrance and the air exhaust are different. Thus, interchanging nozzles among samplers of various series results generally in an incorrect intake velocity and, thus, incorrect sediment concentration and particle-size distribution in the sample. Therefore, when a nozzle is bent or broken, be certain to use a correct replacement nozzle.

If extra nozzles are needed for a sampler, they can be ordered from the F.I.S.P. at the address in the latest Inter-Agency report. The order must indicate the sampler series. If the exhaust tubes, tail fins, or any other part of a sampler are damaged, the entire sampler should be sent to the F.I.S.P. for repair and recalibration.

Three nozzle diameters—1/4 inch, 3/16 inch, and 1/8 inch—are available for use with all depth-integrating samplers, except for the DH-48, DH-75, D-77, and the point-integrating samplers. The D-77 sampler is the only depth-integrating sampler that uses a 5/16-inch nozzle. Although a nozzle may physically fit a sampler, the match may not be correct. For example, it is possible, but incorrect, to interchange any one of the 1/4-inch, 3/16-inch, and 1/8-inch nozzles listed in table 1 among the depth-integrating or point-integrating samplers. For instance, it is possible, but incorrect, to put DH-48 nozzles in DH-59 samplers. One exception is the D-77, which will not accept any nozzle other than the correct one. To help prevent the incorrect interchange of color-coded nozzles among samplers, new samplers ordered from F.I.S.P. are delivered with a color-coded plastic screw in the tail vane assembly, which indicates the correct color of nozzle to be used with the sampler (for example, DH-59 has a red screw and uses a red nozzle).

The reason for different size nozzles is that stream velocities and depths occur that will cause the sample bottle to overfill for a specific transit rate when using the largest nozzle. More specifically, for depth-integrating samplers with a pint bottle, the maximum theoretical sampling depths for round-trip integration are about 9 feet for the 1/4-inch, and 15 feet with both the 3/16-inch, and 1/8-inch nozzles. Therefore, to reduce the quantity of sample entering the bottle at depths over 9 feet, use a smaller bore nozzle in combination with a pint sample bottle. For a given situation, the largest nozzle should be used to reduce the chance of excluding large sand particles that may be in suspension.

Possible errors caused by using too small a nozzle are usually minor when dealing with fine material (less than 0.062 mm), but tend to increase in importance with increasing particle size. Small nozzles also are more likely than large ones to plug with organic material, sediment, and ice particles. This means that problems with nozzles can exist even when sampling streams transporting mostly fine material.

Point-integrating samplers are supplied only with a 3/16-inch nozzle to match the opening through the valve mechanism.

Gaskets

Of equal importance to using the correct nozzle in the instrument is the necessity for using the proper gasket to seal the bottle mouth sufficiently. Gaskets for this purpose are made of a sponge-like neoprene that deteriorates somewhat with use and time. When samples are being collected for water quality, such as for trace metal analysis, the gasket should be made of silicone rubber to avoid biasing the sample chemistry.

To check the gasket for adequate seal, insert a bottle in the proper position in the sampler; then block the air-exhaust port and force air into the sampler nozzle. **CAUTION**: A field person should never force air into the sampler by placing the mouth directly in contact with the nozzle—due to the possibility of questionable water quality at the site or the likelihood of receiving an electrical shock (if a brass nozzle is in use) upon activating the solenoid of a point-integrating sampler when opening the intake. A safe procedure to perform this check would be to block the air exhaust with a finger and place a short length of clean plastic or rubber tubing snugly over the nozzle and then apply air pressure by blowing into the tubing to force air through the nozzle. If air escapes around the bottle mouth, replace the gasket. If the problem persists, check the spring that pushes the bottle against the gasket. Each sampler series uses a different size or shape of gasket, so it is necessary to have spares for each series in use. Appropriate gaskets may be obtained from the F.I.S.P. (address can be obtained from the latest Inter-Agency report). Gaskets in the "P" series samplers also may be tested by lowering the sampler, with sample bottle in place, into the stream without opening the solenoid. After a minute or so, raise the sampler to the surface and inspect the sample bottle. If the gasket is sealing properly, less than a few milliliters of water should be present in the bottle.

Bottles

Depth- and point-integrating samplers accommodate different bottle sizes and types (fig. 12). Many field people still use pint glass milk bottles, which have been used for many years and can be adapted to every sampler series with the exception of the DH-81 and D-77. Quart-sized glass mayonnaise bottles (Owens-Illinois #6762) are increasing in general use because versions of all samplers, except the DH-48 and D-77, use this size sample container. The D-77

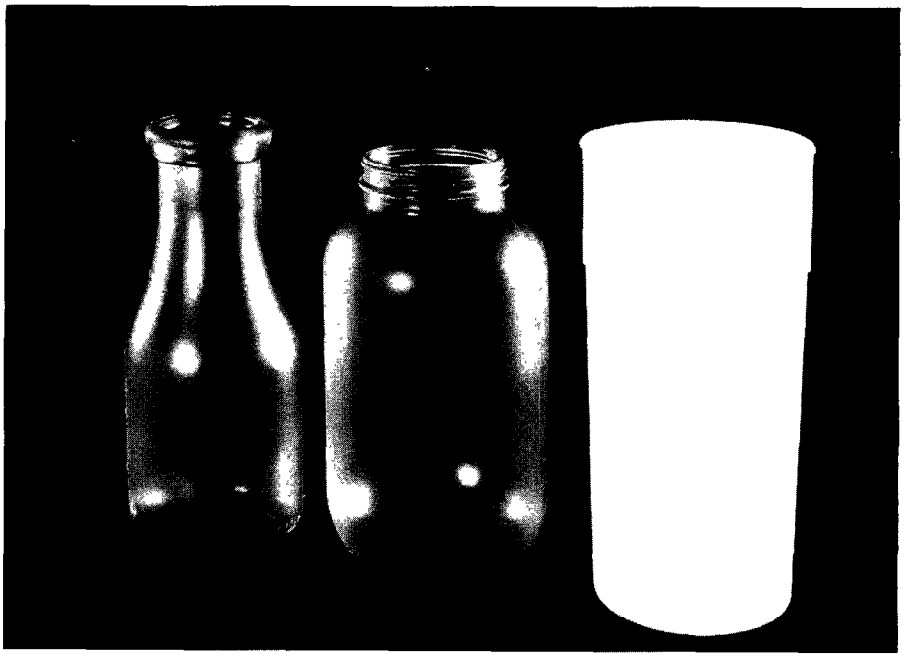

Figure 12. Sample containers to fit PS-69 pumping sampler (left to right): pint glass milk bottle, quart glass mayonnaise bottle, and quart plastic container to fit the PS-69 pumping sampler.

sampler holds a 3-liter plastic autoclavable bottle with standard mason jar threads (Nalge 2115-3000); the DH-81 holds any bottle with standard mason jar threads; and the DH-75 holds a plastic bottle (Bel-Art #F-10906, 1,000 mL) and a variety of other quart/liter bottles. Ideally, each type of glass bottle should have an etched surface to provide a labeling area to accommodate a record of pertinent information concerning each sample. Hydrofluoric acid has been used for this purpose, but care must be exercised when handling and storing this substance. In the past, commercial etching agents have been available for general use. However, the authors do not know of any such agent that is available at this time. This etched labeling surface should easily accept medium-soft blue or black pencil markings of sufficient durability to withstand handling and yet be easily removed during cleaning. Plastic bottles also require an area for labeling. However, this is less of a problem because a grease pencil or other marker that is not readily soluble in water, but that can be removed using a solvent, can be used to write on the side of the bottle.

The practice of using plain bottles with attached tags or marked caps for recording purposes should be avoided whenever possible. These labeling areas are generally small and provide little writing space. Additionally, the use of these labeling devices can result in tags being torn off during transport or in bottles being mislabeled by interchanging caps.

Plastic and teflon bottles are increasing in use throughout the Water Resources Division of the USGS. Several samplers have been designed to use plastic sample containers (the DH-75 series, the DH-81 and D-77 samplers). Compared to glass, these bottles are lightweight, strong, and useful when sampling for certain chemicals.

During depth integration, a collapsible bottle or bag would be the ideal arrangement to eliminate the problem of depth limitation due to the size of the sample container. Depth-integrating samplers incorporating this collapsible sample bag/bottle concept, are currently under development by F.I.S.P.

Bottles are usually stored and transported in wire, wooden, fiberboard, or plastic cases holding 12 to 30 bottles each. In the field, a small bottle carrier, which holds 6, 8, or 10 bottles, is more convenient; eliminates the need to handle the heavier 12- to 30-bottle cases while making a measurement; and provides a neat, convenient, and relatively safe place to set the bottles. When making wading measurements, both hands can be free to operate the sampler if the bottle carrier is suspended from the shoulder with a strap or rope.

Single-Stage Samplers

The single-stage samplers, US U-59 (fig. 13), also designated US SS-59, and US U-73, were designed and tested by the F.I.S.P. to meet the needs for instruments useful in obtaining sediment data on streams where remoteness of site location and rapid changes in stage make it impractical to use a conventional depth-integrating sampler.

The U-59 (SS-59) consists of a pint milk bottle or other sample container, a 3/16-inch inside diameter air exhaust, and 3/16-inch or 1/4-inch inside diameter intake constructed of copper tubing. Each tube is bent to an appropriate shape and inserted through a stopper

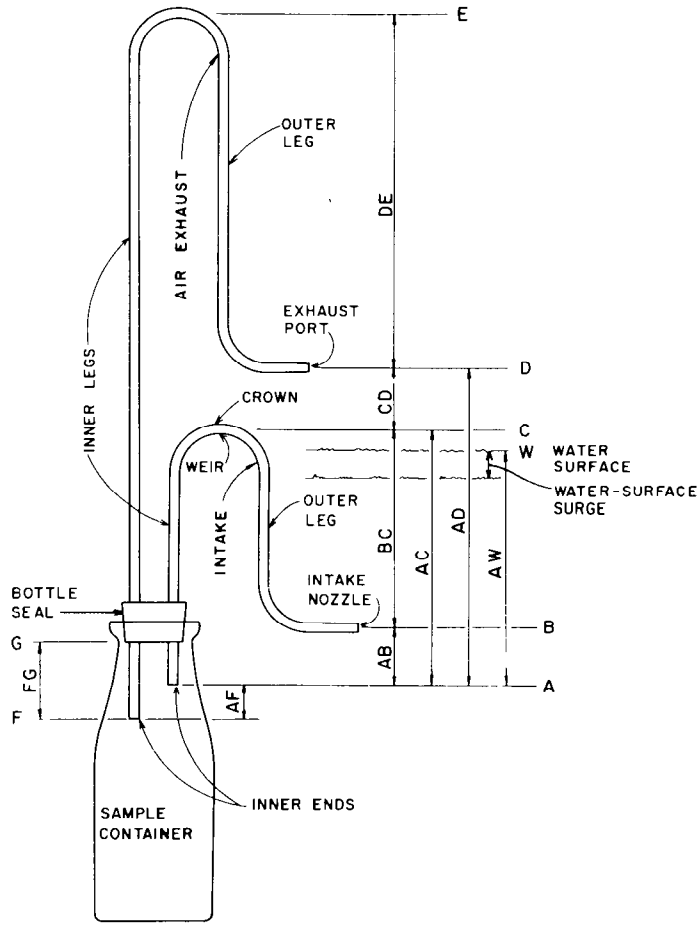

Figure 13. US U-59 single-stage suspended-sediment sampler. Sampling operation using designated letters is described in text (see also Federal Inter-Agency Sedimentation Project, 1961).

sized to fit and seal the mouth of the sample container. There are two general types of this sampler, one with a vertical intake and the other with a horizontal intake. The horizontal-intake type is further divided into three versions, each distinguished from the others by the height of the intake and air-exhaust tubes. Under some conditions either type could be used, but the two are not always interchangeable.

The vertical-intake sampler is used to sample streams carrying sediments finer than 0.062 mm. The vertical-intake sampler has the advantage of somewhat less tendency to fouling by debris and deposits of sediment in the intake nozzle than does the horizontal type of intake. Conversely, the horizontal-intake sampler should be used to sample streams carrying a considerable amount of sediment coarser than 0.062 mm.

The basic sampling operation of the instrument when velocities and turbulences are small is described by F.I.S.P. (1961, p. 17):

> When the stream surface rises to B, the elevation of the intake nozzle, the water-sediment mixture enters; and as the water surface continues to rise in the stream, it also rises in the intake. (The general elevation and dimensions are expressed without regard to the inside diameter of the tube or without distinction between the weir and the crown of the siphon.) When the water-surface elevation W reaches C, flow starts over the weir of the siphon, primes the siphon, and begins to fill the sample bottle under the head AC.
>
> Filling continues until the sample rises to F in the bottle, and water is forced up the air exhaust to the elevation W. Actually the momentum of flow in the tubes causes a momentary rise above W in the air exhaust. Water drains out of the inner leg of the intake. When the stream rises to D, air is trapped in the air exhaust. As long as sufficient air remains in the tubes, no flow can pass through to alter the original sample unless a differential head that exceeds the height of invert is built up. (If the legs of an invert are not symmetrical, the inverts have different effective air-trap heights resisting flow into and out of the bottle.) For conditions without significant surge and velocity effects at the intake nozzle or exhaust port, the heights BC and DE may be small.
>
> If, after the normal time of sampling, the depth of submergence over the sample bottle increases, the air in the bottle is compressed, and a small additional sample enters the bottle. This additional sample will enter through the tube having the smallest height of invert. Under variable submergence, the entrance of water will compress the air in the bottle on rising stages, and some expanding air will escape on falling stages; thus the quantity of air in the bottle becomes less and less, and the water rises in the bottle.

The sampling operation just described is somewhat idealistic because, in reality, the operation is affected by the flow velocity and turbulence, which alter the effective pressure at the nozzle entrance.

The U-59 has many limitations with respect to good sampling objectives. It must be considered a type of point sampler because it samples a single point in the stream at whatever stage the intake nozzle is positioned before a flow event occurs. Its primary purpose is to collect a sample automatically, and it is used at stations on flashy streams or other locations where extreme difficulty is encountered in trying to reach a station to manually collect samples. Besides being automatic, it is inexpensive; a "battery" of them can be used to obtain a sample at several elevations or times during the rising hydrograph. However, despite these seemingly important advantages, the U-59 has many limitations. Following are the most important:

1. Samples are collected at or near the stream surface, so that, in the analysis of the data, theoretical adjustments for vertical distribution of sediment concentration or size are necessary.
2. Samples are usually obtained near the edge of the stream or near a pier or abutment; therefore, theoretical adjustments for lateral variations in sediment distribution are required.
3. Even though several combinations of size, shape, and orientation of intake and air-exhaust tubes are available, the installed system may not result in intake ratios sufficiently close to unity to sample sands accurately for a specific runoff event.
4. Covers or other protection from trash, drift, and vandalism often create unnatural flow lines at the point of sampling.
5. Water from condensation may accumulate in the sample container prior to sampling.
6. Sometimes the sediment content of the sample changes during subsequent submergence.
7. The device is not adapted to sampling on falling stages or on secondary rises.
8. No specific sampler design is best for all stream conditions.
9. The time and gage height at which a sample was taken may be uncertain.
10. Under high velocities, circulation of flow into the intake nozzle and out the air exhaust can occur. This will increase the concentration of coarse material in the sample and can make the sample concentration several orders of magnitude higher than stream concentration.

To cover a wide range of operating conditions, four "standard" models of the U-59 are available. The many specific details of these are further described in F.I.S.P. (1961).

Before a bank of the U-59 samplers can be designed and installed, it is necessary to have some knowledge of the seasonal stage characteristics of the stream so that several samples can be obtained for a given storm event and throughout the season. The stream stage and flow-velocity characteristics not only affect the design with respect to the vertical spacing of the samplers, but also the support necessary for the bank of samplers.

The U-73 (fig. 14) is a more sophisticated single-stage sampling device. The sampler's design configuration solves several of the problems characteristic of the U-59. Specifically, this sampler (1) can be used to sample either a rising or falling stage, (2) has no problem of condensation in the sample container before the spring-loaded stoppers are tripped, and (3) features an exterior design that allows for a degree of protection from trash or drift without additional covers or deflection shields. Aside from these few advantages, the U-73 has the same limitations and should be used under the same conditions as the U-59.

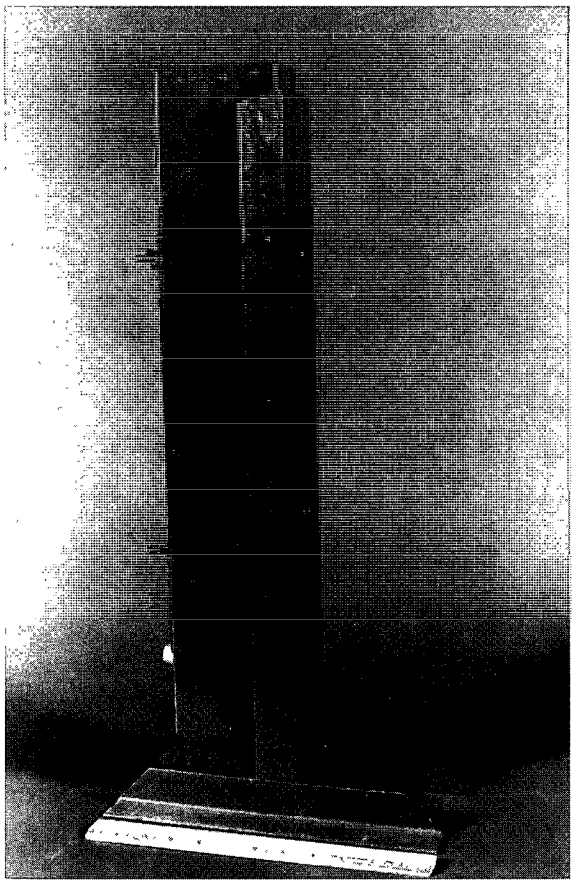

Figure 14. US U-73 single-stage suspended-sediment sampler.

The investigator using either the U-59 or U-73 may find protective measures necessary to avoid blockage of intakes or air exhausts due to nesting insects. In freezing climates, precaution may be warranted against sample-container breakage due to expansion of a freezing sample. Samples for water-quality analysis can be collected using the U-73-TM version of the U-73. However, do not use insecticides or antifreeze solutions if samples are to be analyzed for water quality because these will obviously contaminate the sample.

Bed-Material Samplers

Limitations

To properly sample bed material for interpretation, it is first necessary to establish what constitutes bed material and understand its relation to transported load, especially to bedload. Bedload is best defined as sediment that moves by sliding, rolling, or bouncing along on or near the streambed (Hubbell, 1964; Leopold and others, 1964; Emmett, 1980a). Bed material, on the other hand, is best defined in the Office of Water Data Coordination (1978) National Handbook, chapter 3, p. 3–5, which describes bed material as "the sediment mixture of which the bed is composed." In alluvial streams, bed-material particles are likely to be moved at any moment or during some future flow conditions. From the perspective of Leopold and others (1964), the streambed is composed of two elements, distinguished one from the other by particle size and their reaction to stream velocity. The first element consists of particles frequently transported as part of the suspended load or bedload, but considered as bed material when at rest. The second element consists of particles and aggregates of particles that compose definite structures on the streambed and reside there indefinitely or at least for long periods of time. The size fractions comprising the second element may only be moved by the most extreme flow events during which streambed erosion and scour occur.

The samplers described in this section can only accommodate bed material consisting of particles finer than about 30 or 40 mm in diameter. These bed-material samplers cannot accurately collect representative samples of particles larger than 16 mm, however. As noted in the description of individual samplers, there also may be limitations with respect to some very fine sediments because of poor sealing of the sampler after collection. This limits bed-material sampling, with standard US type samplers, to fine material that might be transported in suspension or as bedload at higher flows. The collection and analysis of material larger than coarse gravel are more difficult and costly because other techniques are required to handle heavy samples. Due to this difficulty in collecting large particle sizes, little information regarding bed-material size distribution is available for streams having gravel, cobble, and boulder beds. Therefore, much of the equipment for measurement of large bed material is of an experimental nature, and standard equipment for sampling large particles is unavailable. The interested investigator is directed to several references on direct and indirect methods of sampling and analysis of coarse bed materials, however, and is encouraged to contact Chief, Office of Surface Water, Reston, Virginia, or the F.I.S.P. for information (Lane and Carlson, 1953; Kellerhals, 1967; Wolman, 1954).

Hand-Held Samplers—US BMH-53, US BMH-60, and US BMH-80

Three types of instruments for hand sampling of bed material finer than medium gravel have been developed for general use. The BMH-53 (fig. 15) is designed to sample bed material in wadable streams. The instrument is 46 inches long and is made of corrosion-resistant materials. The sample container is a stainless-steel thin-walled cylinder 2 inches in diameter and 8 inches long with a tight-fitting brass piston. The piston is held in position by a rod that passes through the handle to the opposite end. The piston creates a partial vacuum above the material being sampled. This vacuum aids in overcoming the frictional resistance required to force the sampler into the bed. When sampling fine-grained material, this partial vacuum also aids in retaining the shallow core in the cylinder when the sampler is removed from the bed. The piston then serves to remove the sample from the cylinder by forcing it downward toward the bottom of the cylinder. In soft cohesive beds, this technique generally provides shallow cores with a minimum of distortion, from which sediment variations with depth and subsamples can be obtained. (See Federal Inter-Agency Sedimentation Project, 1963b and 1966, for more detailed information.) A version of this sampler, developed by the F.I.S.P. incorporates a "core catcher"

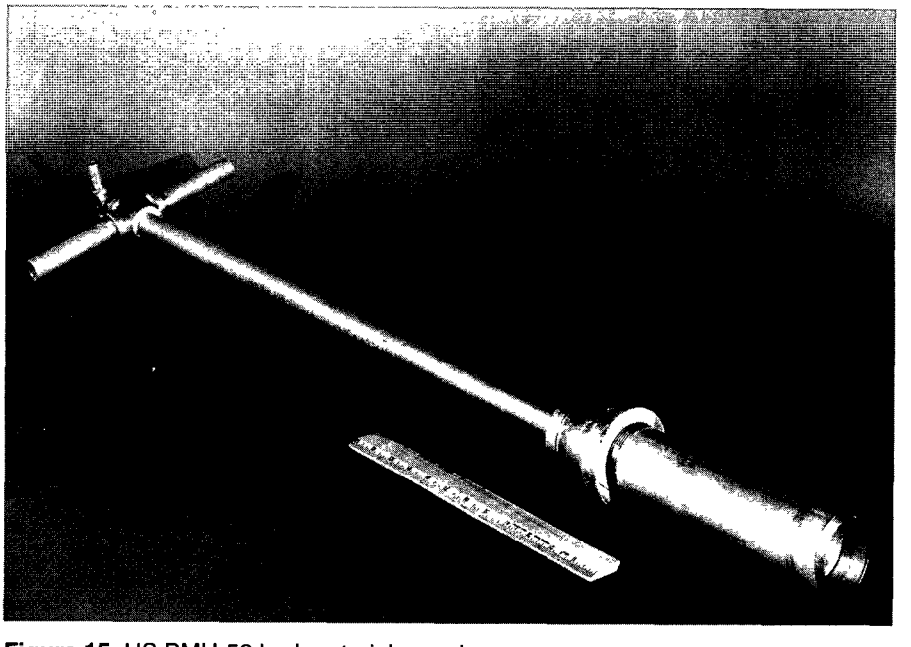

Figure 15. US BMH-53 bed-material sampler.

mechanism in the cylinder to retain samples containing a high percentage of sand.

The bed material of some wadable streams or lakes can be sampled with the US BMH-60 (fig. 16). This handline sampler is about 22 inches long, is made of cast aluminum, and weighs 30 pounds. Because of its light weight, it is useful only in streams of moderate depths and velocities. The bed material must be moderately firm and contain little or no gravel.

The sampler mechanism of the US BMH-60 consists of a scoop or bucket driven by a constant-torque spring that rotates the bucket from front to back. The scoop, when activated by release of tension on the hanger rod, can penetrate into the bed about 1.7 inches and can hold approximately 175 cubic centimeters of material. The scoop is aided in penetration of the bed by extra weight in the sampler nose. To cock the bucket into an open position for sampling (that is, retract it into the body), the sampler must first be supported by the handline, then the bucket can be rotated (back to front) with an allen wrench to an open cocked position.

The hanger rod to which the handline is attached is grooved so that a safety yoke can be placed in position to maintain tension on the hanger rod assembly. **CAUTION**: At no time should the hand or fingers be placed in the bucket opening because the bucket may accidentally close with sufficient force to cause permanent injury! A piece of wood or a brush can be used to remove any material adhering to the inside of the sample bucket. (See Federal Inter-Agency Sedimentation Project, 1963b and 1966, for more detailed information.)

After the safety yoke is removed, the bucket closes when tension on the handline is released, which occurs as the sampler strikes the streambed. A gasket on the closure plate prevents sampled material from being contaminated or being washed from the bucket.

Another bed-material hand-sampling instrument available for general use is designated BMH-80 (fig. 17). This sampler is 56 inches in total length and is used to sample the bed of wadable streams. The sampling mechanism is a semi-cylindrical bucket, resembling the BMH-60 bucket assembly, which is operated by positioning the lever on the handle to open or close the bucket. When the bucket is closed and a sample volume of approximately 175 cubic centimeters of bed material is captured, the closure is sufficiently sealed to prevent erosion of the sample while the instrument is lifted through the water column.

An additional handline sampler, used successfully for bed-material chemistry sampling on the Willamette and Columbia Rivers in Oregon, is the Ponar sampler.

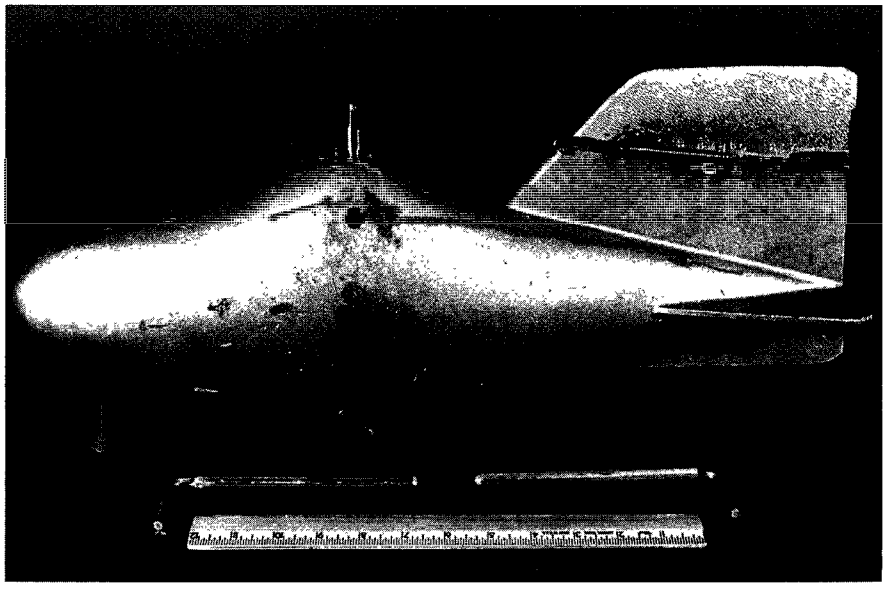

Figure 16. US BMH-60 bed-material sampler.

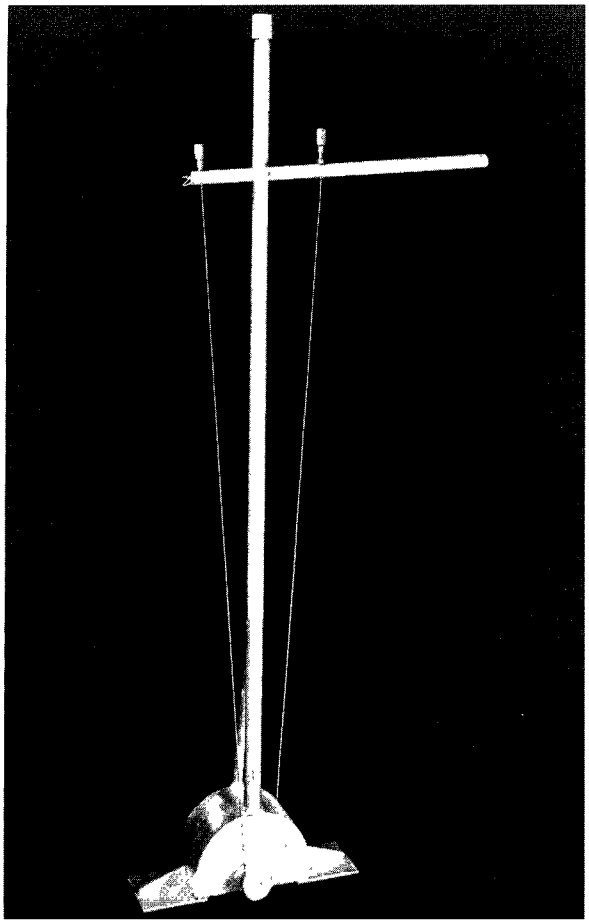

A

This is a clam-shell type sampler, consisting of two quarter-cylinder sections hinged together at the top. The sampler, which is constructed of galvanized or stainless steel, weighs about 25 pounds and can be suspended on a handline. The jaws of the instrument are held in the open position by a system of solid-notched bars and by the downward force created by the weight of the sampler on the suspension line. Gravity provides the necessary force for bottom penetration during sampling. The solid-notched bars holding the sampler jaws open are released when the downward force of the sampler's weight is released from the suspension line as the sampler strikes the bed. The sampler then closes as an upward force is applied to lift the sampler with the captured sediment. This sampler is particularly effective where bottom sediments consist of unconsolidated fines with no armoring present. Under these conditions, bottom penetration is 6 to 8 inches, resulting in a sample volume range of 8,000 cubic centimeters to 10,000 cubic centimeters of material. Some protection against erosion of the captured sediment is provided by an overlapping lip on the bottom and sides. However, a watertight seal does not exist, so care must be exercised when raising the sampler to the surface.

Cable-and-Reel Sampler—US BM-54

The 100-pound cable-and-reel suspended BM-54 sampler (fig. 18) can be used for sampling bed material of streams and lakes of any reasonable depth, except for streams with extremely high velocities. The body of the BM-54 is cast steel. Its physical configuration is similar to the cast aluminum BMH-60, 22 inches long and with tail vanes. Its operation also is similar to the BMH-60 in that it takes a sample when tension on the cable is released as the sampler touches the bed. The sampling mechanism externally looks similar to that of the BMH-60, but its operation is somewhat different.

The driving force of the bucket comes not from a constant-torque spring, but rather from a conventional coil-type spring. The tension on the spring is adjusted by the nut-and-bolt assembly protruding from the front of the sampler. The spring is powerful enough to obtain a sample from a bed of very compacted sand. It is suggested that the tension on the spring be released during extended periods of idleness even though the bucket is closed. Maximum tension need be used only when the streambed is very firm. Unlike the BMH-60, the spring and cable assembly rotates the bucket from the back to the front of the sampler. The trapped sample is kept from washing out by a rubber gasket. (See Federal Inter-Agency Sedimentation Project, 1963b, 1964, and 1966, for more complete description and details.)

BM-54 samplers obtained after 1956 are equipped with a safety mechanism similar to the safety yoke used on the BMH-60. This safety bar can be rotated over the cutting edge of the sample bucket when cocked into the open position. The bar keeps the bucket open when in the safety position, even if there is no tension on the hanger bar. As with the BMH-60, the cable tension on the catch mechanism holds the bucket open while the sampler is lowered. Safety bars can be obtained from F.I.S.P. and should be installed on any unit that does not have one. Again, personnel operating these samplers are cautioned to KEEP ONE'S HANDS AWAY FROM THE BUCKET CAVITY EVEN IF A SAFETY BAR IS IN USE. The power of the bucket is demonstrated by the fact that upon release, it has been observed to lift the 100-pound sampler from a hard surface.

A bed-material sampler incorporating the heavy streamlined body of the P-61 sampler and the spring-driven bucket of the BM-54 has been developed (C.W. O'Neal, Federal Inter-Agency Sedimentation Project, written commun., 1998). This sampler, the BM-84, is intended for use in large, swift rivers.

Prych and Hubbell (1966) developed a core sampler for use in deep flowing water in studies of the Columbia River estuary. This cable-suspended

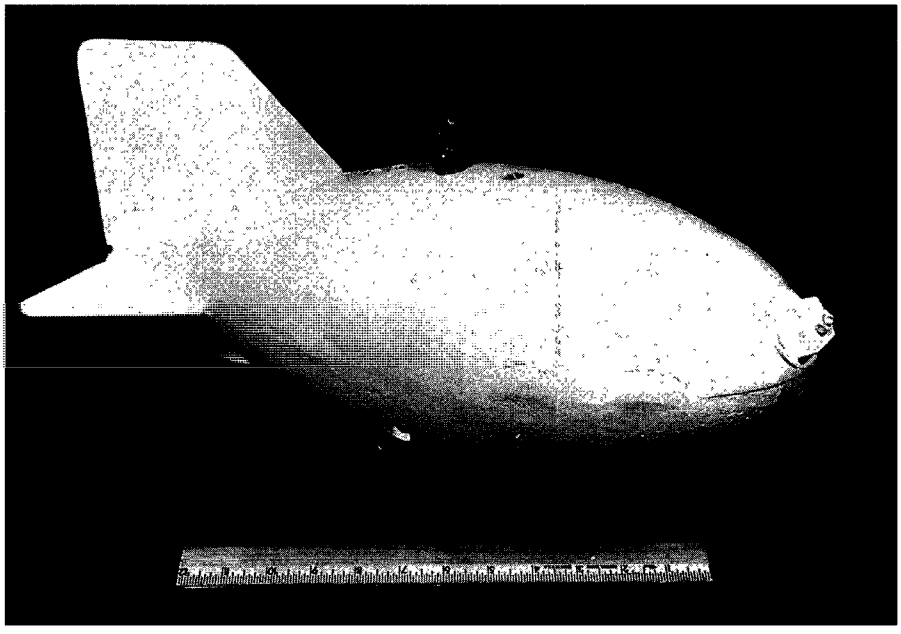

Figure 18. US BM-54 bed-material sampler.

sampler (fig. 19) is used to collect a 1 7/8-inch diameter by 6-foot-long core, by means of the combined action of vibration, suction, and an axial force derived through cables connected to a 250-pound streamlined stabilizing weight that rests on the streambed.

Smaller estuaries along the Oregon coast and other places have been successfully sampled using the Gravity Corer available from Benthos, Inc. This sampler is allowed to plunge to the bottom where, under the force of the gravitational pull on the sampler coupled with the momentum of its 250-pound total weight, it can penetrate up to 5 feet deep in soft bed material. However, much less penetration can be expected if the bed material consists of sand or gravel. The sampler is retrieved from the bed using a cable-reel boom assembly. The 2 5/8-inch diameter by 5-foot long core is retained in a core liner held in place by a core catcher at the bottom and protected against sample washout by a watertight valve at the top. The length of core and depth of penetration depend upon the degree of hardness of the bed being sampled. Other slightly more crude devices have been used with some success to sample bed material and thus deserve mention here. The two most notable of these devices are (1) the pipe dredge, which is lowered to the streambed and dragged a short distance to collect a sample; and (2) the "can on a stick" sampler, consisting of a rod with a scoop connected to the end, which can be used in wadable streams by lowering it to the streambed and scooping bed material from the bottom.

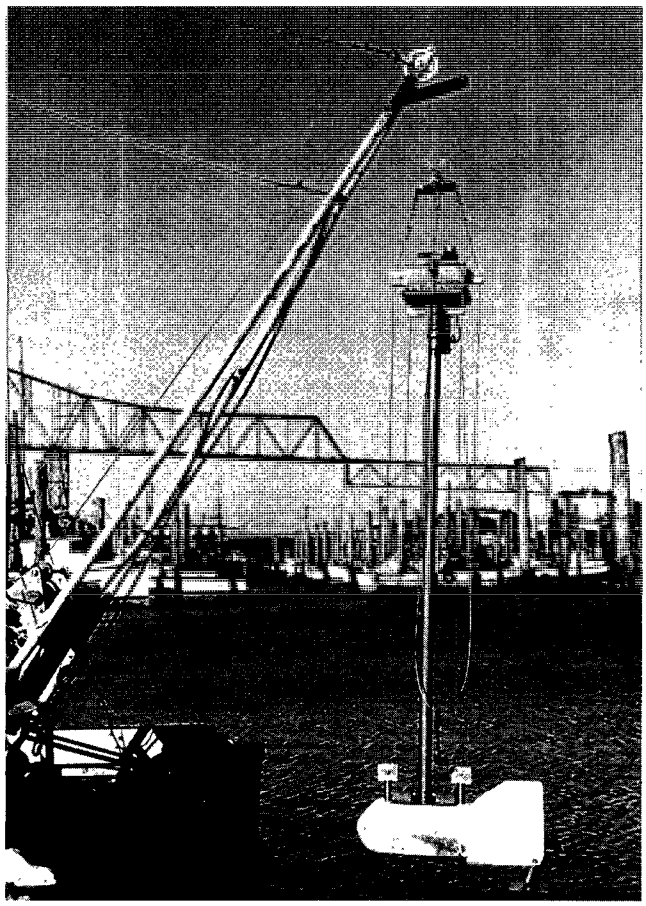

Figure 19. Vibra-core sampler prepared for coring (barrel approximately 5 feet long). From Prych and Hubbell (1966, plate 1).

Bedload Samplers

At this time, the reader should note the difference between bedload and unmeasured sediment. Remember from the bed-material section that bedload is the sediment that moves by sliding, rolling, or bouncing along on or very near the streambed. Unsampled sediment is comprised of bedload particles and particles in suspension in the flow below the sampling zone of the suspended-sediment samplers (fig. 1).

Bedload is difficult to measure for several reasons. Any device placed on or near the bed may disturb the flow and rate of bedload movement. More importantly, bedload transport rate and the velocity of water close to the bed vary considerably with respect to both space and time. Therefore, any sample obtained at a given point may not be representative of the mean transport rate for a reasonable interval of time because the bed particles move intermittently at a mean velocity much less than that of the water. Thus, a bedload sampler must be able to representatively sample, directly or indirectly, the mass or volume of particles moving along the bed through a given width in a specified period of time if bedload discharge is to be accurately determined.

Prior to 1940, most bedload was measured using some type of direct-collecting sampler. Bedload samplers developed during this era can be grouped into four categories: (1) box or basket, (2) pan or tray, (3) pressure difference, and (4) slot or pit samplers (Hubbell, 1964). Essentially, box or basket samplers consist of a heavy open-front box or basket apparatus, which is lowered to the streambed and positioned to allow collection of bedload particles as they migrate

downstream. The basket type, displaying various sampling efficiencies, has been used preferentially over box types. Pan or tray samplers consist of an entrance ramp leading to a slotted or partitioned box. These samplers also have varying sampling efficiencies. Pressure-difference samplers are designed to create a pressure drop at the sampler's exit and thus maintain entrance velocities approximately equal to the ambient stream velocity. Sampling efficiencies may be higher with this type of sampler than with others, and the deposition of sediments at the sampler entrance, inherent with basket or tray samplers, is eliminated. The best known early pressure-difference sampler is probably the Arnhem or Dutch sampler, after which the Helley-Smith bedload sampler is designed. Ideally, the best measurement of bedload would occur when all of the bedload moving through a given width during a specific time period was measured. The category of samplers that most closely meet this ideal is the slot or pit sampler. This type of sampler has efficiencies close to 100 percent. The slot openings of these pits are 100- to 200-grain diameters wide to ensure the high sampling efficiency. However, samples collected in the pits are removed only with great difficulty or by use of an elaborate conveyor device. A variation of this technique, consisting of a collection trough accessed by a series of hydraulically operated gates, extends from bank to bank at a site on the East Fork River, near Pinedale, Wyoming (Emmett, 1980a). Sediment trapped in the trough during sampling is removed by means of a continuous conveyor belt, which carries the sample to a weighing station on the stream bank.

The original Helley-Smith bedload sampler, introduced in 1971, was a variation of the Arnhem pressure-difference sampler. This sampler consists of an expanding nozzle, sample bag, and frame (fig. 20). The sampler design enables collection of particle sizes less than 76 mm at mean velocities to 9.8 ft/s. The sampler has a 3-inch by 3-inch square entrance nozzle, an area ratio (ratio of nozzle exit to entrance area) of 3.22, and a 295-square-inch polyester mesh sample bag that is 18 inches long with mesh openings of varying sizes (0.25 mm most commonly used), attached to the rear of the nozzle assembly with a rubber "O" ring. The total weight of the original sampler design is 66 pounds, requiring the use of a cable-reel suspension system. However, a lighter version incorporating a wading rod assembly also is available. Heavier versions weighing 99 pounds, 165 pounds, and 550 pounds (used on the Amazon River) have been used by USGS personnel (Emmett, 1980a). A scaled-up version of the sampler having a 6-inch by 6-inch square entrance has been used to sample streams with large particle sizes.

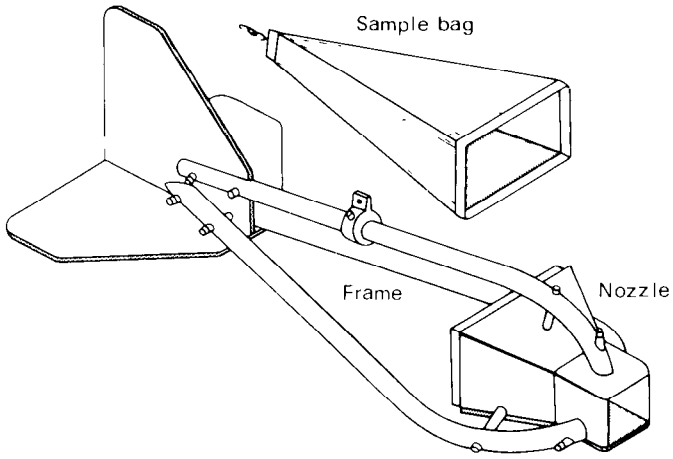

Figure 20. Helley-Smith bedload sampler. From Emmett (1980a, p. 2).

The standard 3-inch by 3-inch sampler has been calibrated in two different laboratory studies and in an extensive field study. Results of one laboratory study (Helley and Smith, 1971) indicated an average sampling efficiency of about 160 percent. Emmett (1980a) concluded from his field study that the overall sampling efficiency was close to 100 percent. A laboratory investigation (Hubbell and others, 1985) of varying bed materials and a range of transport rates indicates that the sampling efficiency of the standard 3-inch by 3-inch sampler varies with particle size and transport rate, displaying an approximate efficiency of 150 percent for sand and small gravel and close to 100 percent for coarse gravel. The standard 6-inch by 6-inch sampler had generally higher efficiencies. Tests of a Helley-Smith type sampler, which has a 3-inch by 3-inch nozzle with less expansion than the standard nozzle (an area ratio of 1.40), resulted in fairly constant efficiencies close to 100 percent for all transport rates and particle sizes. In May 1985, the 1.40 nozzle was approved by the Technical Committee on Sediment as a provisional standard sampler for use by U.S. Federal agencies. After some modifications to the frame, the 3-inch by 3-inch nozzle with 1.40-area-expansion ratio was designated the BL-84 sampler. The Water Resources Division of the USGS endorses the use of this new sampler with the 1.40-area-ratio nozzle; however, until additional testing is done, data obtained using the original 3.22-area-ratio Helley-Smith sampler will continue to be accepted.

Automatic Pumping-Type Samplers

Development and Design

Some sediment studies require frequent collection of suspended sediment at a site. Site location, flow conditions, frequency of collection, and operational costs frequently make collection of sediment data by manual methods impractical. For these reasons, F.I.S.P. and USGS personnel have developed and evaluated several models of automatic pumping-type samplers. The US PS-69 sampler is probably the best known of these samplers to be designed, tested, and used by USGS personnel. The US CS-77 (designed and tested by the Agricultural Research Service in Durant, Oklahoma) and the US PS-82 (Federal Inter-Agency Sedimentation Project, 1983) have been used. A number of automatic pumping-type samplers also have been designed by and are available through commercial sources. The Manning S-4050 and the ISCO 1680 are common commercially used samplers. (Manning Corp. is no longer in business.)

Automatic pumping-type samplers generally consist of (1) a pump to draw a suspended-sediment sample from the streamflow and, in some cases, to provide a back flush to clear the sampler plumbing before or after each sampling cycle; (2) a sample-container unit to hold sample bottles in position for filling; (3) a sample distribution system to divert a pumped sample to the correct bottle; (4) an activation system that starts and stops the sampling cycle, either at some regular time interval or in response to a rise or fall in streamflow (gage height); and (5) an intake system through which samples are drawn from a point in the sampled cross section. Ideally, this combination of components should be designed to meet the 17 optimum criteria as set forth by W.F. Curtis and C.A. Onions (U.S. Geological Survey, written commun., 1982).

1. Stream velocity and sampler intake velocity should be equal to allow for isokinetic sample collection if the intake is aligned with the approaching flow.
2. A suspended-sediment sample should be delivered from stream to sample container without a change in sediment concentration and particle-size distribution.
3. Cross contamination of sample caused by sediment carryover in the system between sample-collection periods should be prevented.
4. The sampler should be capable of sediment collection when concentrations approach 50,000 milligrams per liter and particle diameters reach 0.250 millimeter.
5. Sample-container volumes should be at least 350 milliliters.
6. The intake inside diameter should be 3/8 or 3/4 inch, depending upon the size of the sampler used.
7. The mean velocity within the sampler plumbing should be great enough to exceed the fall velocity of the largest particle sampled.
8. The sampler should be capable of vertical pumping lifts to 35 feet from intake to sample container.
9. The sampler should be capable of collecting a reasonable number of samples, dependent upon the purpose of sample collection and the flow conditions.
10. Some provision should be made for protection against freezing, evaporation, and dust contamination.
11. The sample-container unit should be constructed to facilitate removal and transport as a unit.
12. The sampling cycle should be initiated in response to a timing device or stage change.
13. The capability of recording the sample-collection date and time should exist.
14. The provision for operation using DC battery power or 110-volt AC power should exist.
15. The weight of the entire sampler or any one of its principal components should not exceed 100 pounds.
16. The maximum dimensions of the entire sampler or any one of its components should not exceed 35 inches in width or 79 inches in height.
17. The required floor area for the fully assembled sampler should not exceed 9 square feet (3 feet by 3 feet).

Installation and Use Criteria

The decision to use a pumping sampler for collection of sediment samples is usually based on both physical and fiscal criteria. These are real considerations; yet it should be understood that automatic

pumping samplers can be as labor intensive and costly as the manual sediment-data collection they were designed to supplement. Installation of an automatic pumping sampler requires intensive planning before installation, including careful selection of the sampler-site location and detailed background data, to ensure the collection of useful pumped sample data.

Before installation of an automatic pumping-type sampler, many of the problems associated with installing stream-gaging equipment must be dealt with. In addition, much data concerning the sediment-transport characteristics at the proposed sampling site must be obtained and evaluated prior to emplacement of the sampler and location of the intake within the streamflow. Logistically, the sample site must be evaluated as to ease of access, availability of electrical power, location of a bridge or cableway relative to the site, normal range of ambient air temperatures inherent with local weather conditions, and the availability of a local observer to collect periodic reference samples. The sediment-transport characteristics should include detailed information on the distribution of concentrations and particle sizes throughout the sampled cross section over a range of discharges.

Placement of Sampler Intake

The primary concept to consider when placing a sampler intake in the streamflow at a sample cross section is that only one point in the flow is being sampled. Therefore, to yield reliable and representative data, the intake should be placed at the point where the concentration approximates the mean sediment concentration for the cross section across the full range of flows. This idealistic concept has great merit, but the mean cross-section concentration almost never exists at the same point under varying streamflow conditions. It is even less likely that specific guidelines for locating an intake under given stream conditions at one stage would produce the same intake location relative to the flow conditions at a different stage. These guidelines would have even less transfer value from cross section to cross section and stream to stream. For these reasons, some very generalized guidelines presented by W.F. Curtis and C.A. Onions (written commun., 1982) are outlined here and should be considered on a case-by-case basis when placing a sampler intake in the streamflow at any given cross section.

1. Select a stable cross section of reasonably uniform depth and width to maximize the stability of the relation between sediment concentration at a point and the mean sediment concentration in the cross section. This guideline is of primary importance in the decision to use a pumping sampler in a given situation; if a reasonably stable relation between the sample-point concentration and mean cross-section concentration cannot be attained by the following outlined steps, the sampler should not be installed and an alternate location considered.
2. Consider only the part of the vertical that could be sampled using a standard US depth- or point-integrating suspended-sediment sampler, excluding the unsampled zone, because data collected with a depth- or point-integrating sampler will be used to calibrate the pumping sampler.
3. Determine, if possible, the depth of the point of mean sediment concentration in each vertical for each size class of particles finer than 0.250 mm, from a series of carefully collected point-integrated samples.
4. Determine, if possible, the mean depth of occurrence of the mean sediment concentration in each vertical for all particles finer than 0.250 mm.
5. Use the mean depth of occurrence of the mean sediment concentration in the cross section as a reference depth for placement of the intake.
6. Adjust the depth location of the intake to avoid interference by dune migration or contamination by bed material.
7. Adjust the depth location of the intake to ensure submergence at all times.
8. Locate the intake laterally in the flow at a distance far enough from the bank to eliminate any possible bank effects.
9. Place the intake in a zone of high velocity and turbulence to improve sediment distribution by mixing, reduce possible deposition on or near the intake, and provide for rapid removal of any particles disturbed during the purge cycle.

Because of the generalized nature of these guidelines, it will often be impossible to satisfy them all when placing a pumping sampler intake into naturally occurring streamflows. The investigator is encouraged, however, to try to satisfy these guidelines or, at the very least, to satisfy as many as possible and to minimize the effects of those not satisfied.

Sampler Advantages and Disadvantages

Automatic pumping-type samplers are very useful for collecting suspended-sediment samples during periods of rapid stage changes caused by storm-runoff events and in reducing the manpower necessary to carry out intensive sediment-collection programs (Federal Inter-Agency Sedimentation Project, 1981b). However, it should be noted that pumping samplers quite often require more man-hours and cost more to operate than a conventional, observer-sampled type of station. Pumping samplers, because of their mechanical complexity, power requirements, and limited sample capacity, quite often require more frequent site visits by the field personnel than would be required at the conventional observer station. In addition, problems associated with collecting high-flow, cross-section samples are still present.

In streams with significant amounts of suspended-sand loads, the problems associated with using a pumping sampler are so great that two records may have to be calculated, one for the silt-clay size fraction load and one for the sand-size fraction load. This requires that most of the samples collected with the pumping sampler, as well as the samples collected manually, be subjected to a full particle-size analysis. Extensive laboratory work of this type increases the cost of analysis and computation of the sediment-discharge record. Another disadvantage is that the pumping lift for most samplers is relatively small and may be less than the normal fluctuations in stage at some sites. This is especially true on western rivers, where stage ranges may exceed 50 feet, making it necessary to locate the pump outside of the sampler's shelter in order to maintain a manageable pumping lift.

Intake Orientation

The orientation of the pumping sampler intake nozzle can drastically affect sampling efficiency. There are five ways in which an intake could be oriented to the flow (fig. 21): (1) normal and pointing directly upstream (fig. 21*A*), (2) normal and horizontal to flow (fig. 21*B*), (3) normal and vertical with the orifice up (fig. 21*C*), (4) normal and vertical with the orifice down (fig. 21*D*), and (5) normal and pointing directly downstream (fig. 21*E*). Of these five orientations, 1, 3, and 4 should be avoided because of high sampling errors and trash collection problems. Orientation 2, with the nozzle positioned normal and horizontal to the flow, is the most common alternative used. The major problem with this orientation is that sand-size particles may not be adequately sampled (see the following section on pumped-sample data analysis). Orientation 5, pointing directly downstream, appears to have an advantage over orientation 2 (Winterstein and Stefan, 1983). When the intake is pointing downstream, a small eddy is formed at the intake, which envelops the sand particles and thus allows the sampler to collect a more representative sample of the coarse load. Winterstein and Stefan (1983) also have demonstrated that nozzle orientations at angles to the flow other than those illustrated in figure 21 do not improve the resultant sample and, therefore, do not represent any useful advantage.

Data Analysis

A major concern when evaluating sediment data collected by automatic pumping-type samplers is the relation between the data and the true mean suspended-sediment concentration in transport at the time of sample collection. In order to determine this relation, concentrations determined from the pumping sampler must be compared with the corresponding concentrations determined from a complete depth-integrated cross-section sample over the full range of flow. This relation then is used to adjust the pumped sample data.

It must be remembered that samples collected by pumping samplers are taken from a single point in the flow. Although attempts are made to ensure that cross-sectional mean sediment concentrations are obtained, in reality this rarely happens. However, if a stable relation between the concentration at the sample point and the mean concentration in the cross section exists, the sample can be considered as representative as possible. In addition, pumping samplers do not collect samples isokinetically (as do standard US depth- or point-integrating samplers), due to the pumping rate and the orientation of the intake orifice. Not sampling isokinetically introduces concentration errors, particularly for particles greater than 0.062 mm.

Pumping samplers rely on pump speed to create a velocity in the intake tube greater than the settling velocity of particles in suspension. This higher velocity is necessary to deliver the sample to the sample container without reducing the concentration of coarser particles by depositing them within the sampler's plumbing. The pumping action at the intake

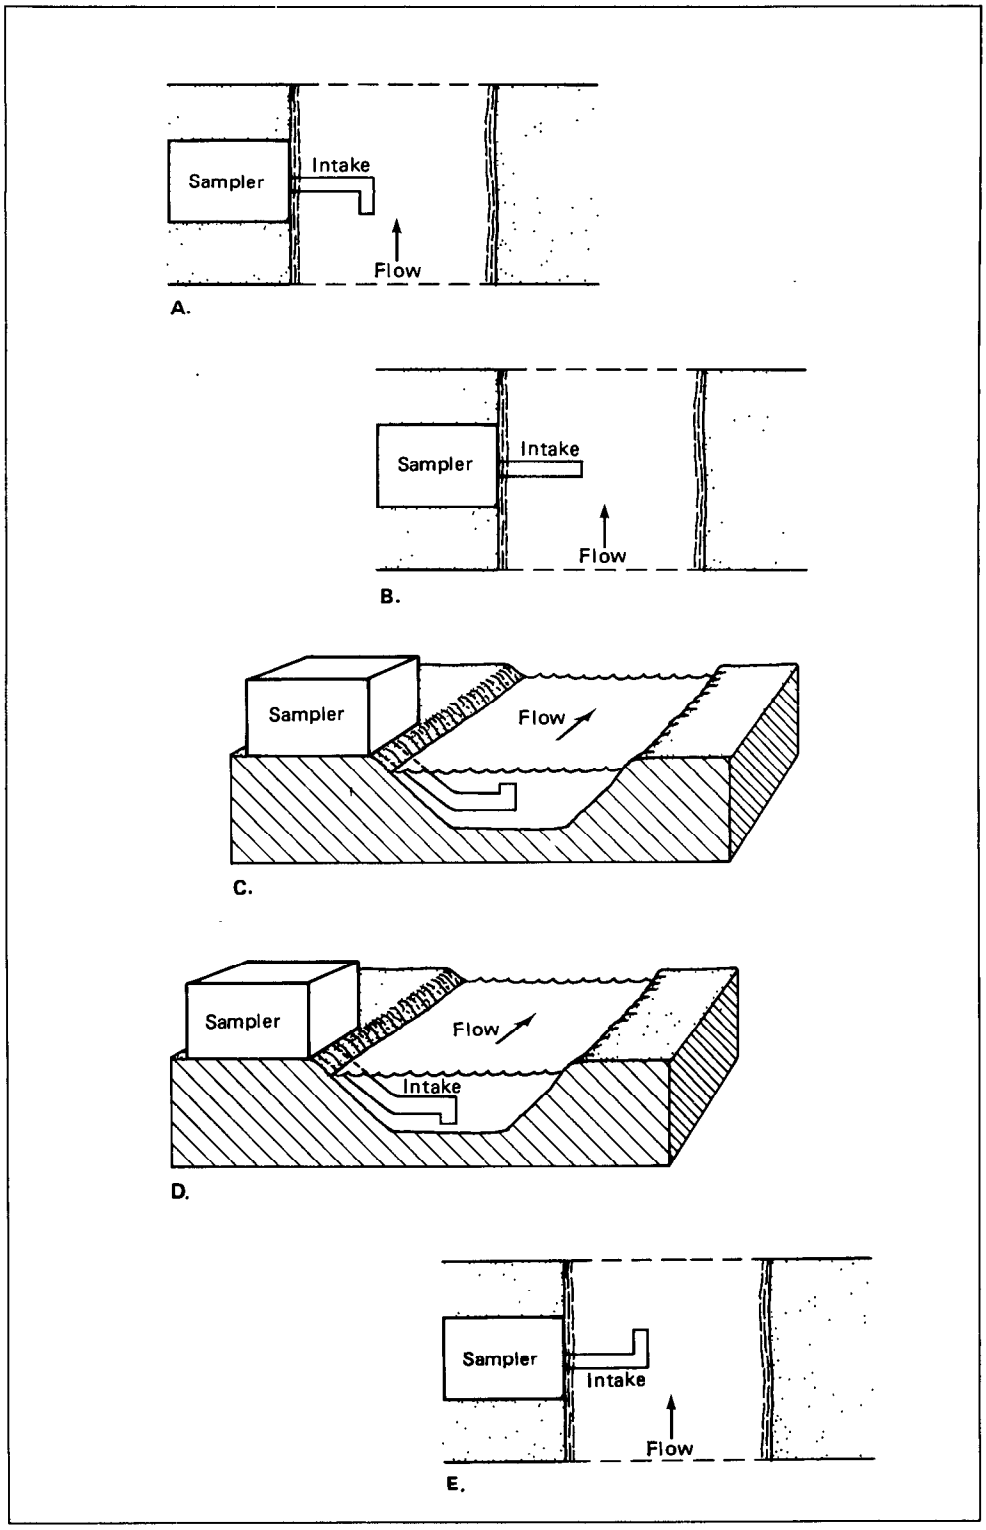

Figure 21. Examples of pumping-sampler intake orientations. *A*, Normal and pointing directly upstream. *B*, Normal and horizontal to flow. *C*, Normal and vertical with the orifice up. *D*, Normal and vertical with the orifice down. *E*, Normal and pointing directly downstream.

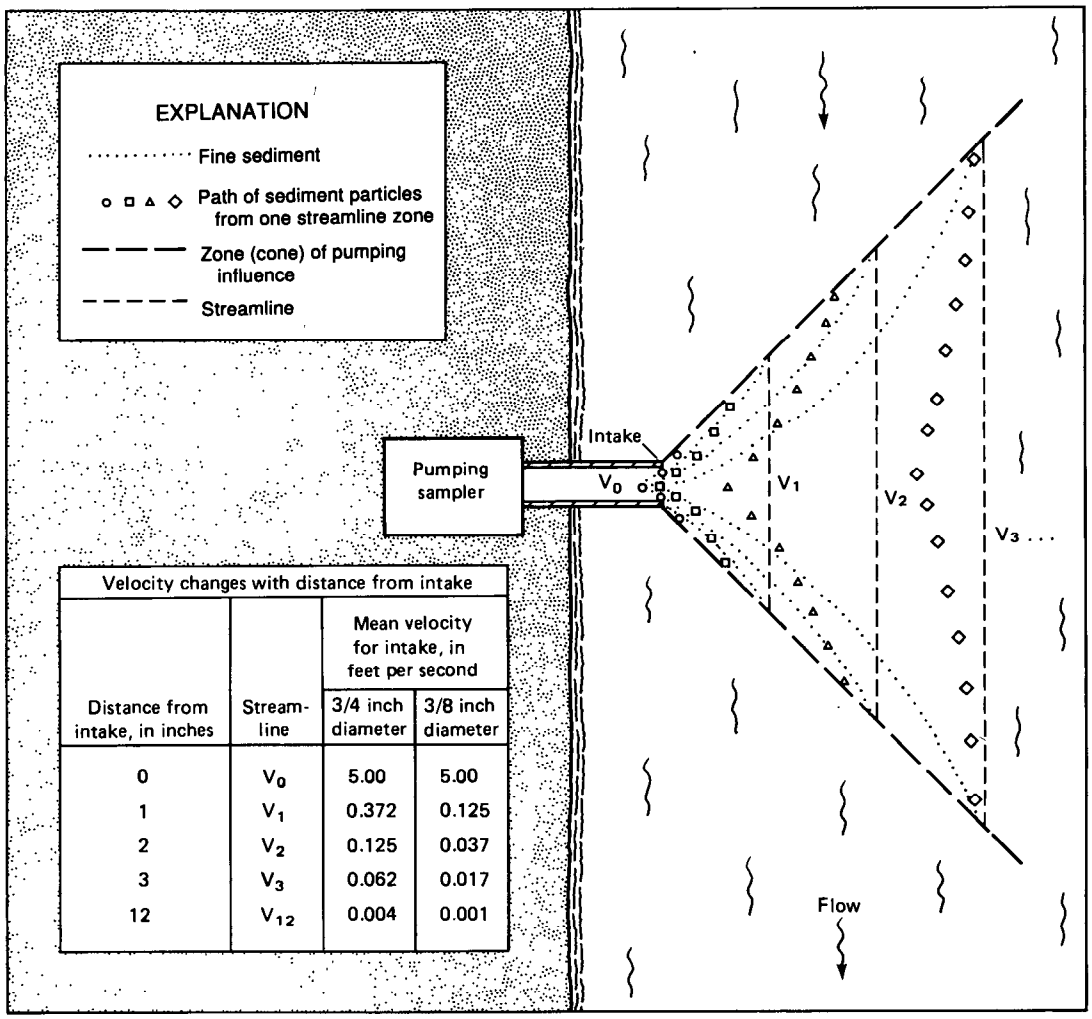
orifice bends the streamlines of sediment-laden flow as a sample is drawn into the intake and as particles are propelled through the sampler to the sample container. This force acts on particles carried past the orifice with varying results, dependent upon particle size and velocity (Federal Inter-Agency Sedimentation Project, 1941). That is, the pumping force attempts to pull particles laterally from their streamlines and accelerate them in the direction of the intake. At low stream velocities, when only fine silts and clays are being transported, this is not a problem. However, as stream velocity increases and particles larger than 0.062 mm begin to move in suspension, the pumping force must overcome the momentum of these larger particles, due to their mass and acceleration in the downstream direction, in order for a representative sample to be obtained. A decrease in sampling efficiency can result in a biased sample because fewer and fewer large particles are drawn into the intake as the distance from the intake increases (fig. 22). This figure shows that only those sediment particles passing directly in front of the intake, a short distance away, are greatly affected and subject to capture. It also should be realized that the zone (cone) of influence is an idealized concept, and pumping influence is much greater on sediments approaching the intake from upstream than on those sediments that have passed to the downstream side. As mentioned previously, this problem may be relieved somewhat by orienting the intake directly downstream.



Velocity changes with distance from intake

Distance from intake, in inches	Stream-line	Mean velocity for intake, in feet per second	
		3/4 inch diameter	3/8 inch diameter
0	V_0	5.00	5.00
1	V_1	0.372	0.125

Figure 22. Pumping effect on sediment streamlines within the zone (cone) of influence and velocity changes with distance from intake (cone) of influence and velocity changes with distance from the intake oriented normal and horizontal to the flow for 3/4-inch and 3/8-inch diameter intakes with pumped velocity of 5 feet per second (from Federal Inter-Agency Sedimentation Project, 1966; W.F. Curtis and C.A. Onions, written commun., 1982).

Intake Efficiency

To facilitate accurate interpretation of data collected by automatic pumping-type samplers, some comparison between sediment concentration of the pumped sample (C_p) and mean sediment concentration of the streamflow (C_s) must be made. This comparison is made in terms of intake efficiency, which is the ratio of the pumped-sample sediment concentration to the mean concentration of the stream at the intake sampling point (Federal Inter-Agency Sedimentation Project, 1966), or:

$$\frac{C_p}{C_s}(100) = \text{intake efficiency.}$$

In reality, this relation is based on comparison of the pumped sample to sediment concentration of a point sample collected as close to the intake sampling point as possible, using a standard US depth- or point-integrating sampler.

Intake efficiencies should be determined for pumping samplers as soon as possible after installation-related sediment disturbances have stabilized. Additional efficiency values should be established over a broad range of flow conditions to determine actual effects of variations in particle sizes at a given sample site. These data then can be used to evaluate the sediment concentration of pumped samples and check their credibility.

Cross-Section Coefficient

Determining the degree of efficiency with which a pumping sampler obtains a representative sample is one step in the interpretation of suspended-sediment concentration data. These data should be further assessed relative to the cross-sectional mean suspended-sediment concentration. A coefficient should be determined based on how well the pumping sampler's data represents the cross-sectional mean, and this coefficient should be applied to the pumping sampler data.

From previous discussion, it should be evident that sediment samples taken at a single point of flow within a cross section seldom represent the mean sediment concentration. Therefore, cross-section coefficients must be determined to relate pumped-sample sediment concentration to the mean sediment concentration in the cross section. Because no theoretical relation exists between these parameters, an empirical comparison must be made between concentrations obtained from pumped samples and concentrations obtained from depth-integrated, cross-sectional samples collected at the same time. Obviously, it is impossible to collect an entire cross-sectional sample in the length of time it takes to cycle the pumping sampler to collect a single sample. Therefore, it is recommended that a sample collected with the pumping sampler be taken immediately before and after the cross-section sample. This procedure will help bracket any changes in concentration that might occur during the time period necessary to collect the cross-section sample. If it is suspected that the concentration is changing rapidly during the collection of the cross-section sample, try to collect one or more samples with the pumping sampler during the time that the cross-section sample is being collected. These data will help in the development of the cross-section coefficient. Collection and comparison of these check samples should be repeated during each station visit, as well as during rising and falling stages, and at peak flows for all seasonal periods (snowmelt runoff, thunderstorms, and so on). A more detailed discussion on development of cross-section coefficients is available to the interested reader in Guy (1970) and Porterfield (1972).

Description of Automatic Pumping-Type Samplers—US PS-69, US CS-77, US PS-82, Manning S-4050, and ISCO 1680

The US PS-69 pumping sampler (fig. 23) is a time- or stage-activated, electrically driven, suspended-sediment sampler capable of collecting up to 72 samples at volumes to 1,000 mL. Standard pumping lifts are to 17 feet vertically, but repositioning the pump or using multiple pumps in series can increase lift capabilities for extreme situations. This sampler must be placed in a shelter and protected against inclement weather and temperature extremes.

Particle sizes sampled range to 0.250 millimeter with some decrease in sampling efficiency for the larger particles. Sediment concentrations to 160,000 milligrams per liter have been sampled by USGS personnel in New Mexico, using an air-driven pump with the PS-69 (J.V. Skinner, written commun., 1985); extremely high concentrations also have been sampled in the vicinity of the Mount St. Helens volcano in Washington.

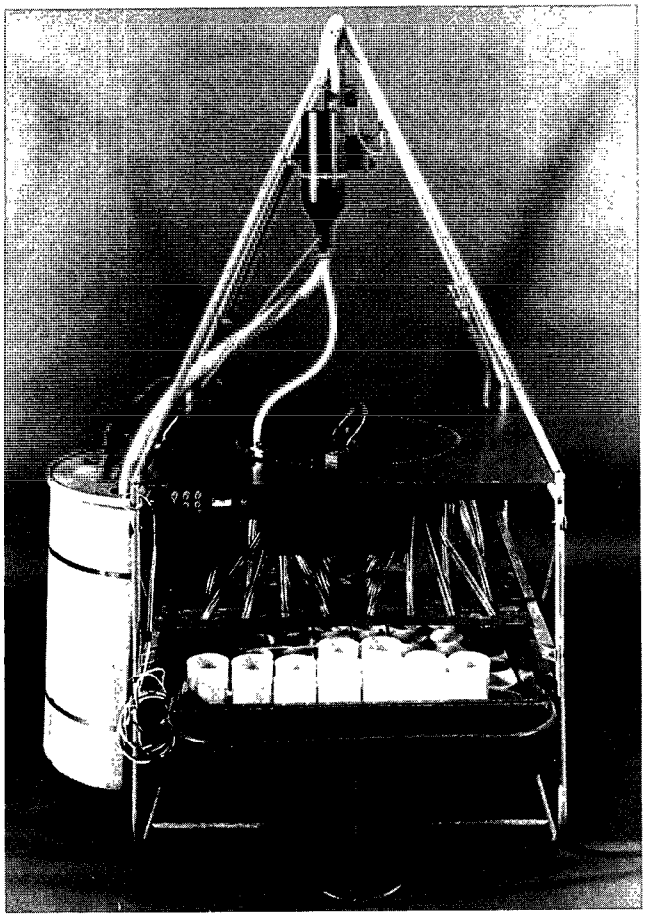

Figure 23. US PS-69 pumping sampler.

The PS-69 was evaluated by W.F. Curtis and C.A. Onions (written commun., 1982) by comparing the sampler's attributes to the 17 criteria previously listed. Results of this comparison are included in table 2.

The US CS-77, or Chickasha, sediment sampler (fig. 24) was designed and developed by the Agricultural Research Service, Durant, Oklahoma. This sampler was fashioned after an earlier design (US XPS-62, developed by F.I.S.P.) but has not been widely used by USGS personnel.

Like the PS-69, this sampler is time- or stage-activated to facilitate sampling on a predetermined schedule as well as during runoff events. Sampling times are recorded during the sampling procedure as part of the standard sampler's design of operation, in lieu of add-on modules and recording devices common to other samplers discussed here.

Table 2. Automatic pumping-type sampler evaluation

[A, US PS-69; B, US CS-77; C, US PS-82;D, Manning S-4050; E, ISCO 1680; mg/L, milligrams per liter; mL, milliliter; mm, millimeter; ≥, greater than or equal to; <, less than; >, greater than]

Evaluation criteria	Samplers meeting criteria
1. Sample collection isokinetic	None
2. Sediment concentration constant stream to sample container	A[1], B[2], C[2], D
3. Cross-contamination prevented	A, B, C, D
4. Collects concentrations to 50,000 mg/L and particles to 0.25 mm	A[1], B[2,1], C[1], D[1], E[2]
5. Sample volume >350 mL	A[3], B[3], C[3], D[3], E[3]
6. Intake diameter 3/4 inch	A
7. Mean velocity at intake and in internal plumbing great enough to ensure turbulent flow with a Reynolds number of 4,000	A[3], B[2], C[1], D[3], E[3]
8. Vertical pumping lift >35 feet	A[2], B[2], C[2]
9. Capable of collecting an adequate number of samples to accomplish the purpose of sampling	A[3], B[3], C[3], D, E
10. Sampler protected against freezing, evaporation, and dust	A[2], B[2], C, D[2], E[2]
11. Sample-container tray removable single unit	A, D, E
12. Sampling cycle activated by timer or stage change	A, B, C, D, E
13. Capable of recording sample date and time	A[2], B, C[2], D[2], E[2]
14. AC or DC power capability	A[2], B[2], C[2], D[2], E[2]
15. Sampler or principle components <100 pounds	A[2], B[2], C[3], D[3], E[3]
16. Sampler dimensions <35 inches wide by 79 inches high	A[2], B[2], C[3], D[3], E[3]
17. Required floor space <9 square feet (3 feet by 3 feet)	C[3], D[3], E[3]

[1]Sampler shows a reduction in capacity with particle sizes >0.250 mm.
[2]Sampler requires modification to meet criteria.
[3]Sampler exceeds criteria.

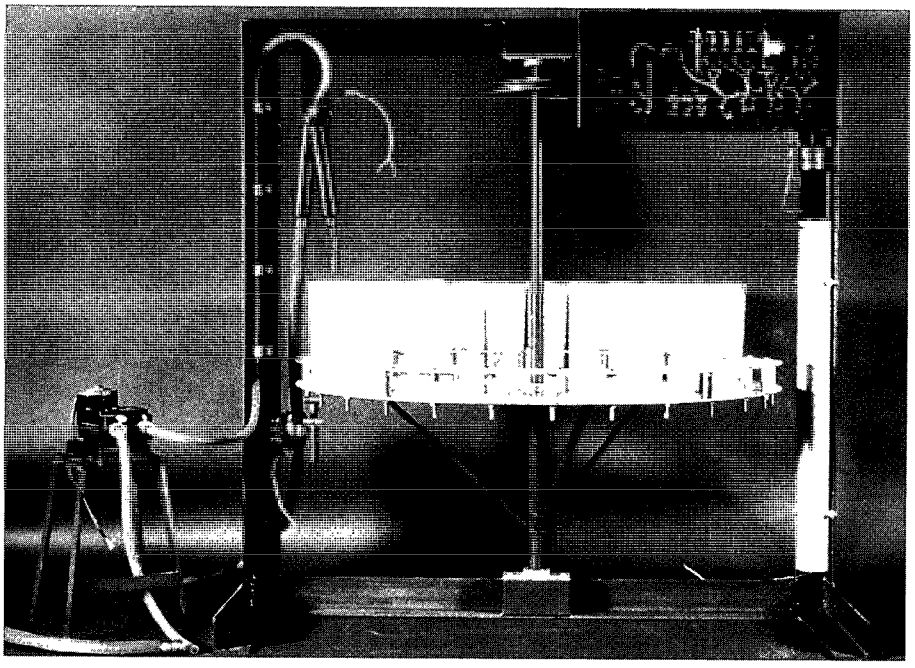

Figure 24. US CS-77 (Chickasha) pumping sampler.

Pumping lift attained by the standard CS-77 sampler configuration is 16 vertical feet; however, relocation of the pump unit to a lower elevation will establish a pull-push sequence, enabling greater sample lifts.

Further modification is necessary to improve the sampling efficiency for high concentration flows carrying greater than 10 percent sand-sized material. Additional information regarding this sampler may be obtained from the evaluation in table 2 and by contacting personnel at the F.I.S.P.

The US PS-82 automatic pumping-type sampler (fig. 25) was made available in March 1984 from F.I.S.P., but it is not widely used under field conditions. The Federal Inter-Agency Sedimentation Project (1983) describes the PS-82 as a lightweight portable pumping sampler, driven by 12-volt battery power, which is used to sample streamflows transporting particles ranging to fine sand size. These samplers weigh 35 pounds and can be housed under a 55-gallon oil drum. An evaluation of this sampler is included in table 2. For more specific information concerning the technical aspects of this sampler and its availability, the interested reader should contact the F.I.S.P.

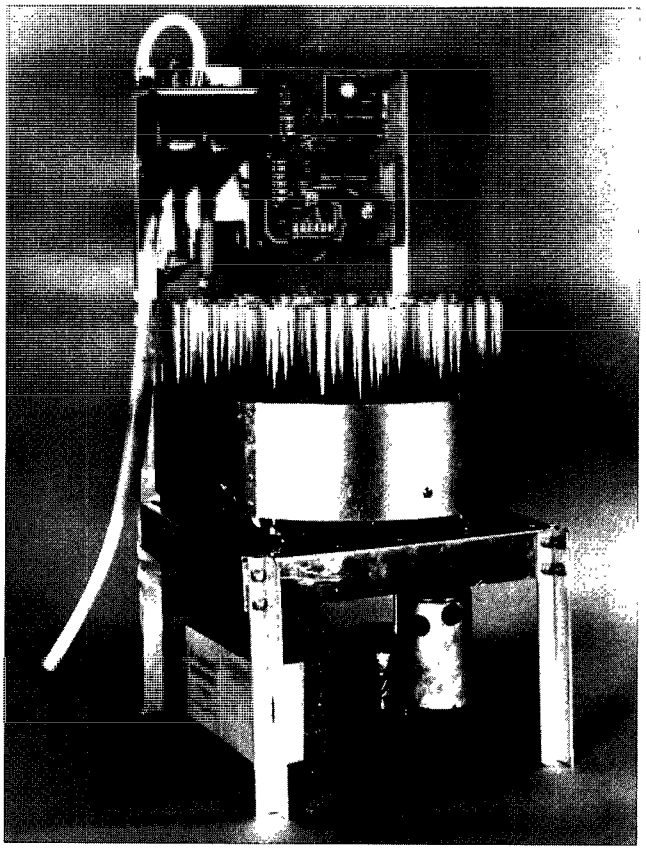

Figure 25. US PS-82 pumping sampler.

The aforementioned samplers were developed by Federal agencies concerned with the collection of suspended-sediment data in a timely, cost-effective manner and are available to the interested investigator from the F.I.S.P. at Waterways Experiment Station, 3909 Halls Ferry Road, Vicksburg, MS 39180-6199.

The following discussion is a description of the Manning S-4050 and ISCO 1680 automatic pumping-type samplers, which are not available through F.I.S.P., but may be obtained from the individual manufacturers. These samplers are described because they represent the types of samplers that are commonly available from commercial sources and used by the USGS.

The Manning S-4050 portable sampler was originally designed as a lightweight unit for sampling sewage. Modifications to this sampler have rendered it useful as a suspended-sediment sampler.

The sampler features a time- or stage-activated electric compressor, which purges the sample intake using the pressure side and draws a sample through the intake using the suction side to create a vacuum in the line, allowing atmospheric pressure to push the sample up to a maximum of 22 feet during the sampling mode. Particle suspension within the sampler is maintained by swirling action of the sample as it passes through the measuring chamber to the sample container.

Evaluation of this sampler in the same manner used for the previously discussed samplers indicates that this instrument is well suited to conditions where extreme pumping lifts are not necessary. Results of this evaluation are included in table 2.

The ISCO 1680, with a super-speed pump sampler, was originally developed as a sewage or wastewater sampler, like the Manning sampler. Normally, wastewater does not carry significant amounts of sediment. Therefore, representation of particle distribution was not a considered criteria during its design and testing stages. The sampler features an electrically driven peristaltic pump, which is activated on a predetermined schedule by an internal timer or in response to stage change. The intake tube is purged before and after each pumping period by automatic reversal of the pump.

The ISCO sampler demonstrates two major shortcomings regarding sediment collection: (1) continuity of sediment concentration from stream to sample container is not maintained efficiently, and (2) a possibility of cross contamination exists from sample to sample as a result of residue remaining in the system after the purge cycle. These problems can be minimized by the installation of a high output pump, available as an option with recent models. A sampler evaluation included in table 2 shows less than acceptable results for representative sediment-data collection.

Support Equipment

Sediment-sampling equipment has been designed by F.I.S.P. to facilitate the use of existing support equipment normally used in stream-gaging procedures. Other than wading rods and hand lines, support equipment is generally necessary for the proper operation of the heavier versions of sediment samplers. In general, support equipment consists of steel cable, hanger bars, reels, and cranes. However, specific conditions at a site may dictate modifications to these pieces of equipment to improve ease of handling in response to the local conditions. Modifications of support equipment necessary to facilitate the handling of samplers and improve safety are encouraged. Investigators are cautioned against alterations that might adversely affect sample collection, either by disturbing the streamflow in the cross section or by changing the sediment-trapping characteristics of the sampler. To ensure sample integrity, specialists should be consulted before any modifications of this type are made.

Commonly used support items include C-type hanger bars; type-A, type-B, and type-E reels; and portable cranes with 2-, 3-, and 4-wheel bases. The C-type hanger bars can be shortened to eliminate awkward and hazardous handling. Type-A reels can be used to suspend lightweight to medium-weight samplers and have been widely used at permanent single-vertical observer sites. Type-B and type-E reels are typically used with medium and heavy samplers. The type-B reel can be used manually or with an available power unit, allowing the sampler to be lowered by releasing the brake mechanism and letting it slip until the sampler reaches the water surface, then manually integrating the sampled vertical and raising the sampler, either manually or by activating the DC-powered motor to drive the reel. The type-E reel is a DC-powered reel that lends itself more readily to permanent installations where heavy sampling

equipment is required. Cranes are used to provide a mechanical advantage over hand-line or bridge-board suspended equipment, for more effective maneuvering of a sampler. The 2-, 3-, and 4-wheel base cranes are useful when sampling from a bridge deck; however, safety precautions should be taken to warn approaching traffic and to avoid blocking the roadway. Boom assemblies also are used in some instances, such as with truck- and boat-mounted installations. Reels, cranes, and powered hoists can be purchased from HIF. HIF can provide information on the availability, installation requirements, and operation of this equipment. Some additional information also may be obtained from the report "Discharge Measurements at Gaging Stations" (Buchanan and Somers, 1969).

SEDIMENT-SAMPLING TECHNIQUES

The sediment-sampling method and frequency of collection are dictated by the hydrologic and sediment characteristics of the stream, the required accuracy of the data, the funds available, and the proposed use of those data collected. When sampling sediment moving through a stream cross section, emphasis should be placed on the collection of a statistically representative population of the sediment particles in transit. To acquire a representative sample, one must first obtain a sample that adequately defines the concentration of particles over the full depth of the sampled vertical. Secondly, a sufficient number of verticals must be sampled to adequately define the horizontal variation in the cross section. The type of sampler used to collect the sample, the method of depth integration, the site at which the samples are collected, and the number of verticals needed to define the stream's concentration depend on the flow conditions at the time of sample collection, characteristics of the sediment being transported, the accuracy required of the data, and the objectives of the program for which the samples are being collected. The purpose of this section is to discuss site selection; equipment selection and maintenance; depth integration; sediment-discharge measurements; point integration; surface and dip sampling; transit rates; sample frequency, quantity, integrity, and identification; sediment-related data; cold-weather sampling; bed-material sampling; bedload sampling; total sediment discharge; and reservoir sedimentation. This section then deals with the decisions to be made and the instructions necessary to obtain the quantity and quality of samples required for computation and compilation of the desired sediment records.

Site Selection

The selection procedure for establishing a sampling location should emphasize the quest for a stream-data site. A stream-data site is best defined as a cross section displaying relatively stable hydrologic characteristics and uniform depths over a wide range of stream discharges, from which representative water-quality and sediment data can be obtained and related to a stage-discharge rating for the site. This is a rather idealized concept because the perfect site is rare at best. Therefore, it is necessary to note the limitations of the most suitable site available and build a program to minimize the disadvantages and maximize the advantages. Most often, sampling sites are located at or near existing gage sites, which may not always be well suited to water-quality and sediment-data collection. For this reason, future sites selected for stream gaging should be carefully assessed for suitability as a water-quality and sediment-sampling site.

As indicated, the site should be at or near a gaging station because of the obvious relation of sediment movement to the flow of the stream. If the sediment-measuring site is more than a few hundred feet from the water-stage recorder or at a site other than where the water-discharge measurement is made, it may be desirable to install a simple nonrecording stage indicator at the site so that a correlation of the flow conditions between the sediment and the distant water-measuring sites can be developed. The obvious difficulties with inflow between the sites from small tributaries also should be avoided where possible. Sites that may be affected by backwater conditions should be avoided whenever possible. Backwater affects both the stage-discharge and velocity-discharge relation at the site. Therefore, a given discharge may have varying stage and mean stream velocity and thus have varying sediment transport rates. If a site is affected by backwater, samples will have to be collected more frequently, and the cost in both man-hours and money will be significantly higher than for more "normal" sites.

A sediment-measuring site downstream from the confluence of two streams also may require extra sediment measurements. The downstream site may be adequate for water-discharge measurement, but could present problems if used as a sediment-measuring site due to incomplete mixing of the flows from the tributaries. Therefore, it might be desirable to move far enough downstream to ensure adequate mixing of the tributary flows. As indicated in Book 3, Chapter C1, "Fluvial Sediment Concepts" (Guy, 1970, p. 24), the distance downstream from a confluence that is required for complete mixing depends on the stream velocity, depth, and mixing width. If the flow at a sediment-measuring site is not mixed, extra samples will be required on a continuing basis because the relative flow quantity and sediment concentration from the two tributaries will change with time.

Aside from the confluence or tributary problem, the type of cross section for flow both in the channel and on the flood plain may affect the ease with which data can be obtained and the quality of the samples. The ratio of suspended load to total load and its variation with time can be greatly affected by the width-depth ratio, especially for sand-bed streams. For sites where the data are expected to be correlated with channel properties and the landforms of the region, a normal or average section should be used. When a fixed-routine sampling installation is used, a measuring section at a bend may provide a more stable thalweg and, hence, a more uniform adjustment coefficient with respect to time than one at a crossover. Sites in areas of active bank erosion should be avoided.

As a result of economic necessity, most sediment-measuring sites are located at highway bridges. These bridges are often constructed so that they restrict the flow width, or they may be located at a section where the channel is naturally restricted in width. Figure 26 (Culbertson and others, 1967) illustrates the conditions at several kinds of natural and artificially induced flow constrictions. As expected, the sand-bed type of stream causes the most serious flow problems with respect to scour in the vicinity of such constrictions. Even if the bridge abutments do not interfere with the natural width of the stream, the bridge may be supported by several midstream piers that can interfere with the streamflow lines and, thereby, reduce the effective cross-sectional area. As indicated in figure 26*F*, midstream piers can catch debris and, thereby, interfere with effective sediment sampling.

Because sediment samples must be obtained more frequently during floods, it is imperative that a site be selected where obtaining data during times of flooding is feasible. That is, particular attention should be given to the ease of access to the water-stage recorder and to a usable bridge or cable during a flood. Because of the need to collect samples frequently during floods, many of which occur at night, sites accessible only by poorly maintained backroads or trails should be avoided. Sometimes the choice of a sediment-measuring site also must be determined by the availability of a suitable observer to collect the routine samples.

In choosing a sediment-measurement site, it should be emphasized that samples need to be collected at the same cross-section location throughout the period of record. Different sampling cross sections can be used, if absolutely necessary, during the low-water wading stage and the higher stages requiring the use of a bridge or cableway. Although the total sediment transported through the different cross sections is probably equal at a given flow stage, the percentage of that total load represented by suspended-sediment load may be drastically different from one cross section to the other, due to differences in hydraulic and sediment-transport characteristics. When data computations are performed, these differences must be considered because the data may not be compatible, and the usefulness of the data in answering the objectives of the sampling program could be threatened. Sites where highway or channel realignment or other construction is anticipated during the period of record should be avoided. Good photographs of proposed or selected sediment-measuring sites are necessary to help document such features as channel alignment, water-surface conditions at various stages, composition of bed and bank material (at low flow), and natural or man-made features, which could affect the water-discharge and (or) sediment-discharge relations. Such pictures and extensive field notes are particularly useful when deciding on alternatives among sites and in later consideration of environmental changes at the site(s).

Equipment Selection and Maintenance

Before departing on a field trip where sediment data are to be collected, a field person should assemble and check all equipment needed to collect the best samples and related measurements. For example, if data are

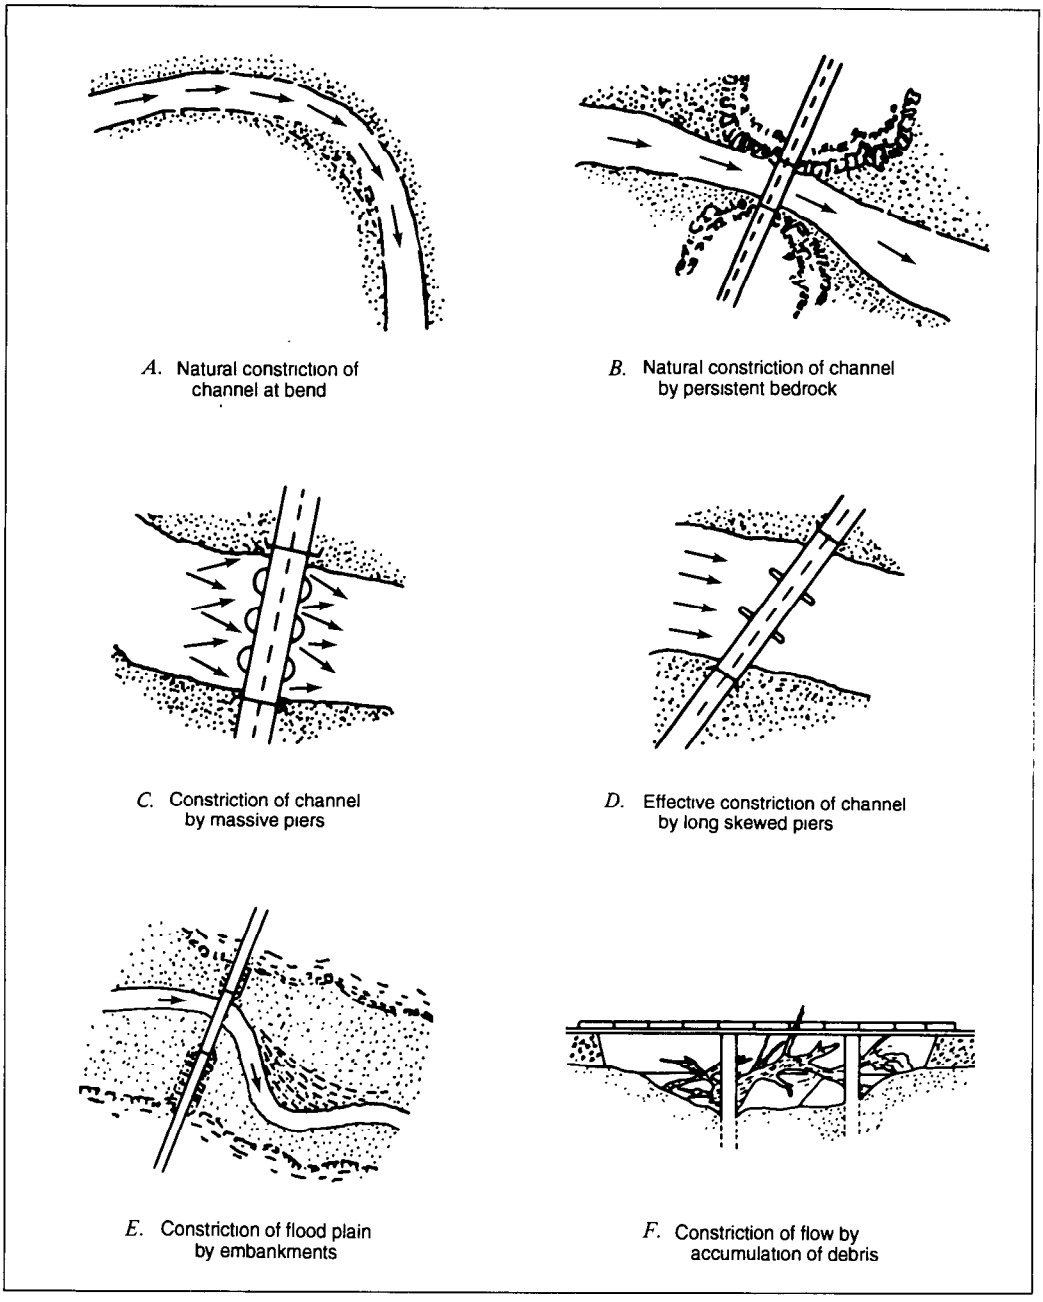

Figure 26. Examples of natural and artificially induced streamflow constrictions encountered at sediment-measurement sites. Modified from Culbertson and others (1967).

needed for total-load computation, equipment is needed for water-discharge measurement, suspended-sediment sampling, bedload sampling, and (or) bed-material sampling. If suspended-sediment concentration and particle-size profiles are required, point samplers and water-discharge-measuring equipment will be needed. Some of the special equipment used only at one location may be stored in the station gage house, with the observer, or in special storage shelters or boxes. However, a sampler or some support equipment could be damaged or stolen without the observer noticing or reporting the loss. Hence, it is necessary for field personnel to carry repair equipment, spare parts (including nozzles and gaskets), and perhaps even an extra sampler.

The streamflow conditions and sampling structures (bridge, cableway, or other) determine more specifically which sampler or samplers should be used at a

station. Stream depth determines whether hand samplers, such as the DH-48 or the BMH-53, or cable-suspended samplers, such as the D-74 or the P-61, should be used. Depths over 15 feet will require the use of point samplers as depth-integrating samplers to avoid overfilling or using too fast a transit rate. Stream velocity as well as depth are factors in determining whether or not a stream can be waded. A general rule is that when the product of depth in feet and velocity in feet per second equals 10 or greater, a stream's wadability is questionable. Application of this rule will vary considerably among field persons according to an individual's stature and the condition of the streambed. That is, if footing is good on the streambed, a heavier field person with a stocky build will generally wade more easily than will a lighter, thinner person when a stream depth-velocity product approaching 10 exists.

The depth-velocity product also affects the action of each sampler. The larger this product, the heavier and more stable the sampler must be to collect a good sample. At a new station or for inexperienced persons, considerable trial and error may be necessary to determine which sampler is best for a given stream condition.

All sampler nozzles, gaskets, and air exhausts, as well as the other necessary equipment, should be checked regularly and replaced or serviced if necessary. Sampler nozzles in particular should be checked to ensure that they are placed in the appropriate instrument or series. See the guidelines presented in table 1 to determine whether the nozzle is correct. The correct size of nozzle to use for a given situation must often be determined by trial. As mentioned in the previous section, it is best to use the largest nozzle possible that will permit depth integration without overfilling the sample bottle or exceeding the maximum transit rate (about 0.4 of the mean velocity in the sampled vertical for most samplers with pint containers).

If a sample bottle does not fill in the expected time, the nozzle or air-exhaust passages may be partly blocked. The flow system can be checked, as described in the section titled "Gaskets," by sliding a length of clean rubber or plastic tubing over the nozzle and blowing through the nozzle with a bottle in the sampler. This procedure should be performed carefully, avoiding direct contact with the nozzle, thus eliminating the possibility of ingesting any pollutant that might exist on the sampler. When air pressure is applied in this manner, circulation will occur freely through the nozzle, sample container, and out the air exhaust. Obstructions can be cleared by removing and cleaning the nozzle and (or) air exhaust, using a flexible piece of multistrand wire. This procedure should be adequate for most airway obstruction problems. However, if blockage results from accumulation of ice or from damage to the sampler, a heat source must be used to melt the ice or the sampler must be sent to the F.I.S.P. or HIF repair facility. Point samplers can be checked using the same technique, if the valve mechanism is placed in the sampling position while air is forced into the nozzle and through the air exhaust.

All support equipment required for sampling, such as cranes, waders, taglines, power sources, and current meters, should be examined periodically, and as used, to ensure an effective and safe working condition. For example, be certain that the supporting cable to the sampler or current meter is fastened securely in the connector; if worn or frayed places are noted, the cable should be replaced. Power equipment used with the heavier samplers and point samplers need a periodic operational check and battery charge. Point samplers should be checked immediately before use to determine, among other things, if the valve is opening and closing properly. By exercising such precautions, the field person will avoid unnecessary exposure to traffic on the bridge and will avoid lost sampling time should repairs and adjustments be required.

Maintenance of samplers and support equipment will be facilitated if a file of instructions for assembly, operation, and maintenance of equipment can be accumulated in the field office. Such a file could include F.I.S.P. reports as well as other pertinent information available from HIF.

Suspended-Sediment Sampling Methods

Sediment-Discharge Measurements

The usual purpose of sediment sampling is to determine the instantaneous mean discharge-weighted suspended-sediment concentration at a cross section. Such concentrations are combined with water discharge to compute the measured suspended-sediment discharge. A mean discharge-weighted suspended-sediment concentration for the entire cross

section is desired for this purpose and for the development of coefficients to adjust observer and automatic pumping-type sampler data.

Ideally, the best procedure for sampling any stream to determine the sediment discharge would be to collect the entire flow of the stream over a given time period, remove the water, and weigh the sediment. Obviously, this method is a physical impossibility in the majority of instances. Instead, the sediment concentration of the flow is determined by (1) collecting depth-integrated suspended-sediment samples that define the mean discharge-weighted concentration in the sample vertical and (2) collecting sufficient verticals to define the mean discharge-weighted concentration in the cross section.

Single Vertical

The objective of collecting a single-vertical sample is to obtain a sample that represents the mean discharge-weighted suspended-sediment concentration in the vertical being sampled at the time the sample was collected. The method used to do this depends on the flow conditions and particle size of the suspended sediment being transported. These conditions can be generalized to four types of situations: (1) low velocity ($v<2.0$ ft/s) when little or no sand is being transported in suspension; (2) high velocity ($2.0<v<12.0$ ft/s) when depths are less than 15 feet; (3) high velocity ($2.0<v<12.0$ ft/s) when depths are greater than 15 feet; and (4) very high velocities ($v>12.0$ ft/s).

First case.—In the first case, the velocity is low enough that no sand is being transported as suspended sediment. The distribution of sediment (silt and clay) is relatively uniform from the stream surface to bed (Guy, 1970, p. 15). The sampling error for this case, when only sediment particles less than 0.062 mm are in suspension, is small, even with intake velocities somewhat higher or lower than the ambient mean stream velocities. Therefore, it is not as important to collect the sample isokinetically with fines in suspension as it is when particles greater than 0.062 mm are in suspension. In shallow streams, a sample may be collected by submerging an open-mouthed bottle into the stream by hand. The mouth should be pointed upstream and the bottle held at approximately a 45-degree angle from the streambed. The bottle should be filled by moving it from the surface to the streambed and back. Care should be taken to avoid touching the mouth of the bottle to the streambed. An unsampled zone of about 3 inches should be maintained in order to obtain samples that are compatible with depth-integrated samples collected at higher velocities.

If the stream is not wadable, a weighted-bottle type sampler may be used. Remember that these samples are not discharge-weighted samples and that, if possible, their analytical results should be verified by or compared to data obtained using a standard sampler and sampling technique.

Second case.—In the second case, when $2.0<v<12.0$ ft/s and the depth is less than 15 feet, the standard depth-integrating samplers, such as DH-48, DH-75, DH-59, D-49, and D-74 may be used. The method of sample collection is basically the same for all these samplers, whether used while wading or from a bridge or cableway. Insert a clean sample bottle into the sampler and check to see that there are no obstructions in the nozzle or air-exhaust tube. Then lower the sampler to the water surface so that the nozzle is above the water, and the lower tail vane or back of the sampler is in the water for proper upstream-downstream orientation. After orientation of the sampler, depth integration is accomplished by traversing the full depth and returning to the surface with the sampler at a constant transit rate.

When the bottom of the sampler touches the streambed, immediately reverse the sampler direction and raise the sampler to clear the surface of the flow at a constant transit rate. The transit rate used in raising the sampler need not be the same as the one used in lowering, but both rates must be constant in order to obtain a velocity- or discharge-weighted sample. The rates should be such that the bottle fills to near its optimum level (approximately 3 inches below the top or 350 to 420 milliliters, for the pint milk bottle, or 2 inches below the top or 650 to 800 milliliters for the quart bottle).

For streams that transport heavy loads of sand, and perhaps for some other streams, at least two complete depth integrations of the sample vertical should be made as close together in time as possible, one bottle for each integration. Each bottle then constitutes a sample and can be analyzed separately or, for the purposes of computing the sediment record, concentrations from two or more bottles can be averaged, whereby they are called a set. This set then is a sample in time with respect to the record. Sample analyses from two or more individual bottles for a given

observation are useful for checking sediment variations among bottles—an obvious advantage in the event the sediment concentration in one bottle is quite different from the concentration in the other bottles for the same observation. Immediately after collection, every bottle or sample should be inspected visually by swirling the water in the bottle and observing the quantity of sand particles collected at the bottom. If there is an unusually large quantity or a difference in the quantity of sands between bottles, another sample from the same vertical should be taken immediately. The sample suspected of having too much sand should be discarded. If it is saved, an explanation such as "too much sand" should be clearly written on the bottle. If by chance, a bottle is overfilled or if a spurt of water is seen coming out of the nozzle when the sampler is raised past the water surface, the sample should be discarded. A clean bottle must be used to resample the vertical.

To help avoid the problem of striking the nozzle into a dune or settling the sampler too deeply into a soft bed, it is recommended that a slow downward integration be used, followed by a more rapid upward integration. Because most of the sand is transported near the bed, it is essential that the transit direction of the sampler be immediately reversed as the sampler touches the bed.

Pertinent information as shown in figure 27 must be available with each bottle for use in the laboratory and in compiling the record. Most districts provide bottles with an etched area on which a medium-soft lead (blue or black) or wax pencil can be used. Other districts use

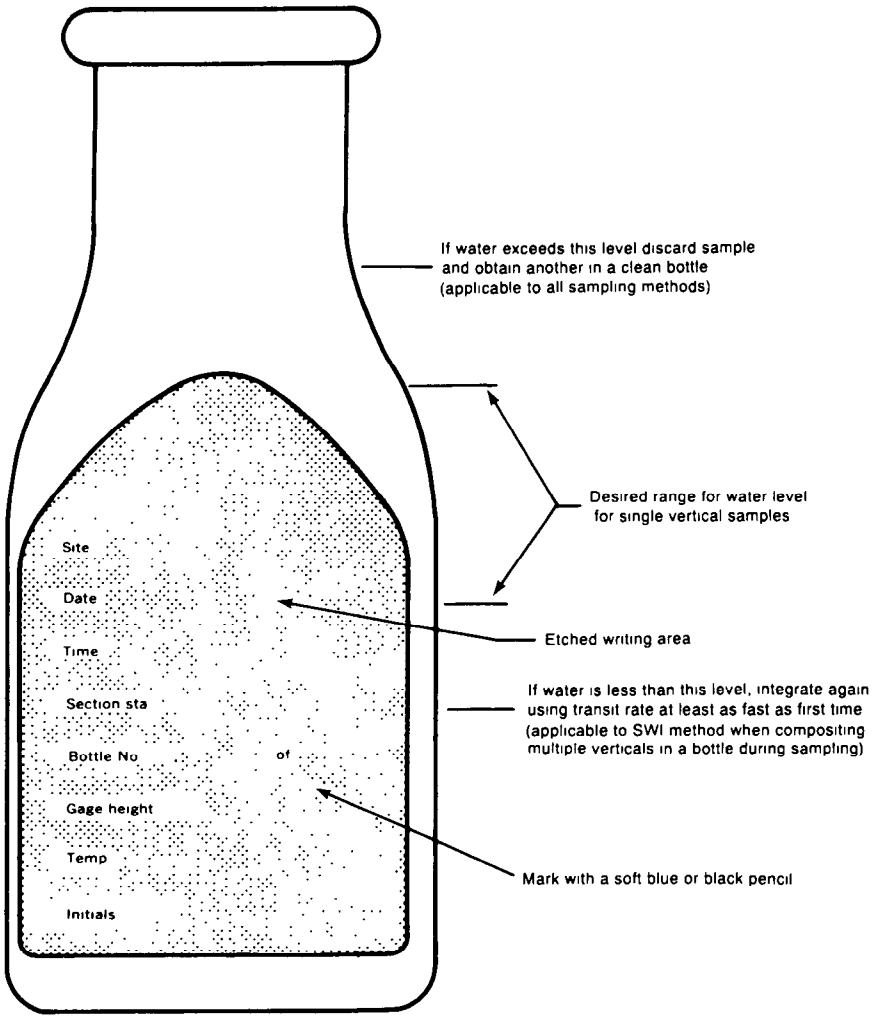

Figure 27. Sample bottle showing desired water levels for sampling methods indicated and essential record information applicable to all sampling methods.

plain bottles and attach tags for recording the required information. The required information may be recorded on the bottle cap if there are no other alternatives, but this should be avoided because of the small writing space and because of the possibility of putting the cap on the wrong bottle. Paper caps should not be used because they do not form as good a seal as do the plastic caps and may allow evaporation of the sample.

Third case.—In the third case, the depth-integrating samplers cannot be used because the depth exceeds the maximum allowable depth for these samplers. In this case, one of the point-integrating or bag-type samplers must be used. Because the bag sampler is still new and sufficient field data have not been collected to verify its sampling efficiency, USGS personnel who wish to use it must contact the Chief, Office of Surface Water, Reston, Virginia, and must set up a comparability sampling system to verify the sampler's efficiency under their specific conditions. The technique for collection of a sample using the bag-type sampler is similar to that used with the depth-integrating samplers.

The point samplers may be used to collect depth-integrated samples in verticals where the depth is greater than 15 feet. For streams with depths between 15 and 30 feet, the procedure is as follows:

1. Insert a clean bottle in the sampler and close the sampler head.
2. Lower the sampler to the streambed, keeping the solenoid closed and note the depth to the bed.
3. Start raising the sampler to the surface, using a constant transit rate. Open the solenoid at the same time the sampler begins the upward transit.
4. Keep the solenoid open until after the sampler has cleared the water surface. Close the solenoid.
5. Remove the bottle containing the sample, check the volume of the sample, and mark the appropriate information on the bottle. (If the sample volume exceeds allowable limits, discard the sample and repeat depth integration at a slightly higher transit rate.)
6. Insert another clean bottle into the sampler and close the sampler head.
7. Lower the sampler until the lower tail vane is touching the water, allowing the sampler to align itself with the flow.
8. Open the solenoid and lower the sampler at a constant transit rate until the sampler touches the bed.
9. Close the solenoid the instant the sampler touches the bed. (By noting the depth to the streambed in step 2 above, the operator will know when the sampler is approaching the bed.)

The transit rate used when collecting the sample in the upward direction need not be the same as that used in the downward direction, If the stream depth is greater than 30 feet, the process is similar, except that the upward and downward integrations are broken into segments no greater than 30 feet. Figure 28 illustrates the procedure for sampling a stream with a depth of 60 feet. Note the transit rate used in the upward direction (RT_3 and RT_4) is not equal to the transit rate in the downward direction (RT_1 and RT_2), but $RT_1 = RT_2$ and $RT_3 = RT_4$. Samples collected by this technique are composited for each vertical, and a single mean concentration is computed for the vertical. In addition to the usual information (fig. 27), the label on each bottle should indicate the segment or range of depth sampled and whether it was taken on a descending or ascending trip.

Samples **must** be obtained at a given vertical for both the downward and upward directions. Tests in the Colorado River (Federal Inter-Agency Sedimentation Project, 1951, p. 34) have shown an increase in the intake ratio of about 4 percent when descending versus a decrease in the intake ratio of about 4 percent on ascent.

Surface and Dip Sampling

Fourth case.—In the fourth case, circumstances are often such that surface or dip sampling is necessary. When the velocities are too high to use the depth- or point-integrating samplers or when debris makes normal sample collection dangerous or impossible, surface or dip samples may be collected.

A surface sample is one taken on or near the surface of the water, with or without a standard sampler. At some locations, stream velocities are so great that even the heaviest samplers will not reach the streambed while attempting to integrate the sampled vertical. Under such conditions, it can be expected that all, except the largest, particles of sediment will be thoroughly mixed within the flow; and, therefore, a sample near the surface is representative of the entire vertical. Extreme care should be used, however, because often such high velocities occur during floods when large debris is moving, especially on the rising part of the hydrograph. This debris may strike or

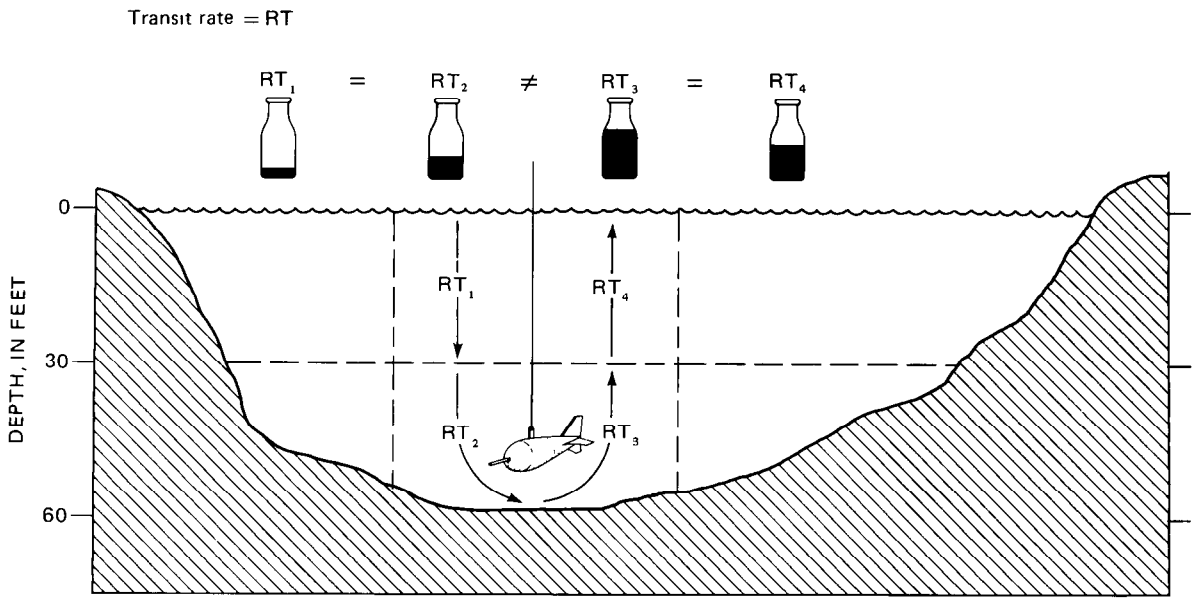

Figure 28. Uses of point-integrating sampler for depth integration of deep streams. RT, transit rate.

become entangled with the sampler and, thereby, damage the sampler, break the sampler cable, or injure the field person. Of course, a full explanation of sampling conditions should be noted on the bottle and in the field notes in order that special handling may be given the samples in the laboratory and in computing the records. The amount of debris in the flow may decrease considerably after the flood crest; even the velocity might decrease somewhat.

Because of the many problems associated with surface and dip sampling, these samples should be correlated to regular depth-integrated samples collected under more normal flow conditions, as soon as possible after the high flow recedes. Along with the depth-integrated sample, a sample should be collected in a manner duplicating the sampling procedure used to collect the surface or dip sample. These samples will be used to adjust the analytical results of the surface or dip sample collected during the higher flow, if necessary, to facilitate the use of these data in sediment-discharge computations and data analyses.

Multivertical

A depth-integrated sample collected using the procedures outlined in the previous section will accurately represent the discharge-weighted suspended-sediment concentration along the vertical at the time of the sample collection. As mentioned before, the purpose of collecting sediment samples is to determine the instantaneous sediment concentration at a cross section. The question now becomes, how do we locate the verticals in the cross section so that the end result will be a sample that is representative of the mean discharge-weighted sediment concentration?

The USGS uses two basic methods to define the location or spacing of the verticals. One is based on equal increments of water discharge; the second is based on equal increments of stream or channel width.

The Equal-Discharge-Increment Method

With the equal-discharge-increment method (EDI), samples are obtained from the centroids of equal-discharge increments (fig. 29). This method requires some knowledge of the distribution of streamflow in the cross section, based on a long period of discharge record or on a discharge measurement made immediately prior to selecting sampling verticals. If such knowledge can be obtained, the EDI method can save time and labor (compared to the equal-width-increment method, discussed in the next section), especially on the larger streams, because fewer verticals are required (Hubbell and others, 1956).

To use the EDI method without the benefit of previous knowledge of the flow distribution in the sampling cross section, first measure the discharge of the stream and determine the flow distribution across the channel at the sampling cross section prior to sampling. From the discharge measurement preceding the sampling (fig. 30) or from historic discharge-measurement records, equal-discharge increments can

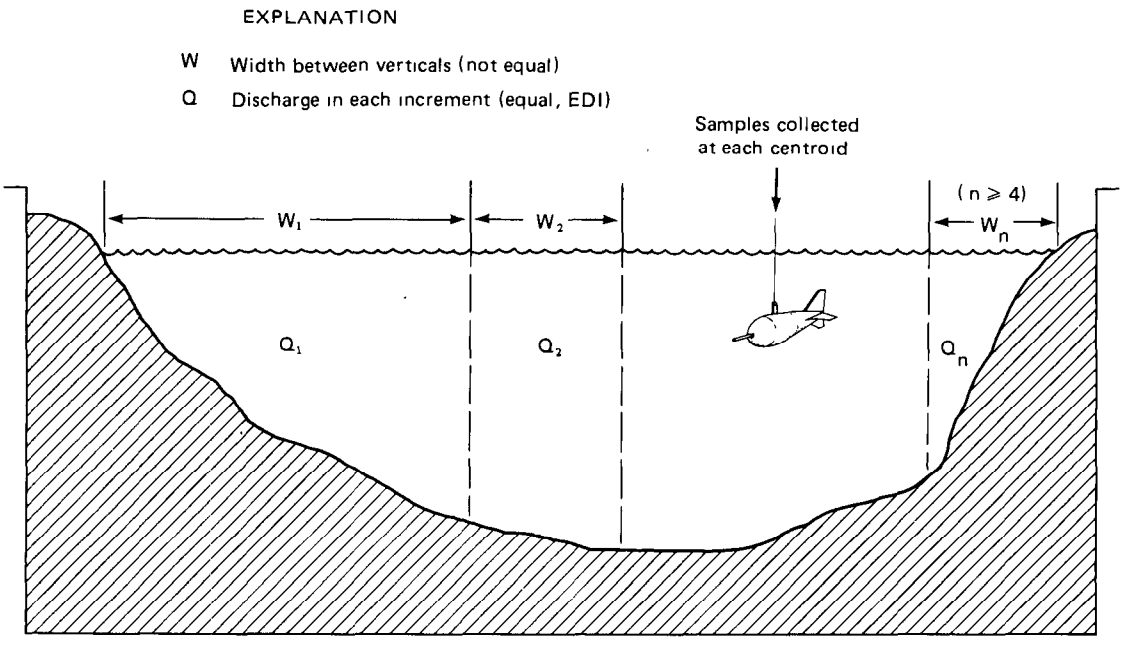

Figure 29. Example of equal-discharge-increment (EDI) sampling technique. Samples are collected at the centroids of flow of each increment.

be determined and centroids at which samples are to be collected can be located. In this example, the total discharge is equal to 166 ft^3/s (cubic feet per second). For illustration purposes, it was determined, by methods to be discussed later, that five verticals would be sampled. The equal increments of discharge (EDI's) then are computed by dividing the total discharge by the number of verticals (166 divided by 5 = 33.2 ft^3/s). The first vertical (A) is located at the centroid of the initial EDI or at a point where the cumulative discharge from the left edge of water (LEW) is one-half of the EDI, in this case 33.2 divided by 2 = 16.6 ft^3/s.

Subsequent centroids (B, C, and so on) are located by adding the increment discharge to the discharge at the previously sampled centroid; in this example, A = 16.6 ft^3/s, B = A + 33.2 ft^3/s, C = B + 33.2 ft^3/s, and so on. Samples are, therefore, collected at points where the cumulative discharge relative to the LEW is 16.6, 49.8, 83.0, 116.2, and 149.4 ft^3/s.

A minimum of four and a maximum of nine verticals should be used when using the EDI method. This method assumes that the sample collected at the centroid represents the mean concentration for the subsection.

To determine the stationing of the centroids, the field person must include a cumulative discharge column (ΣQ) on the discharge-measurement notes by adding the discharges shown in the "discharge" column and keeping a running total as shown in figure 31. The next step is to estimate the stationing of the above centroids. Each centroid is located at the station in the cross section corresponding to the occurrence of its computed cumulative discharge. As shown in figure 31, the cumulative discharge at station 26 equals 8.32 ft^3/s, while station 34 corresponds to 18.5 ft^3/s. Actually, the cumulative discharge is computed to the point midway between stations (far midpoint, fig. 31). Therefore, the point where the cumulative discharge equals 8.32 ft^3/s is located halfway between stations 26 and 34, at station 30. In like manner, the cumulative discharge of 18.5 ft^3/s occurs at the far mid-point between stations 34 and 42, at station 38. The first centroid then would be located between stations 30 and 38. Interpolating between these stations, the centroid discharge of 16.6 ft^3/s would be located at a station closer to station 38, where 18.5 ft^3/s occurs, in this case near station 37. Using the same procedure, estimates of centroid stationing yield stations 60, 83, 109, and 144 for the four remaining centroids.

If the cross section at the measurement site is stable and the control governing the stage at the measurement cross section also is stable, previous measure-

Figure 31. Discharge-measurement notes used to estimate the equal-discharge-increment centroid locations based on cumulative discharge and far-midpoint stationing.

ments may be used to determine centroids of equal increments of discharge.

By plotting the cumulative discharge versus stations for our example (fig. 32), the stations of the centroids may be read directly from the curve. Their values are 36, 59, 82, 110, and 146 ft^3/s, which correspond nicely with our previously estimated values.

A number of these measurements may be plotted on the same sheet (fig. 33) and carried into the field. For discharges that fall between those plotted, the field person can estimate the locations of the centroids by interpolating between the curves.

An alternate method of estimation is to plot cumulative percent of total discharge on the y-axis, instead of cumulative discharge (fig. 34). This method entails one additional step, in that the cumulative percent must be calculated; however, it does have the advantage of showing the variation in stations for the same percentage of flow for different discharges. For example, figure 34 shows that for discharges 86 to 200 ft^3/s, the 10-percent centroid (the centroid of the first 20 percent of flow) can range from station 20 to station 50.

The transit rate used in traversing the distance from water surface to streambed and back to water surface need not be the same in both directions and can vary among centroids. This technique should facilitate collection of approximately equal sample volumes from each centroid (fig. 35).

Individual bottles collected as part of an EDI sample set can be analyzed for concentration separately and their concentrations averaged to give the mean discharge-weighted concentration for the set. The advantage of this method is that data describing the cross-sectional variation in concentration are produced. Additionally, a bottle containing an abnormally high concentration compared to others in the set (due to recirculation or to digging the nozzle into the bed) could be excluded from the concentration calculation where it might seriously affect the results. If approximately equal volumes of sample are collected at each vertical, the samples may be composited prior to analysis.

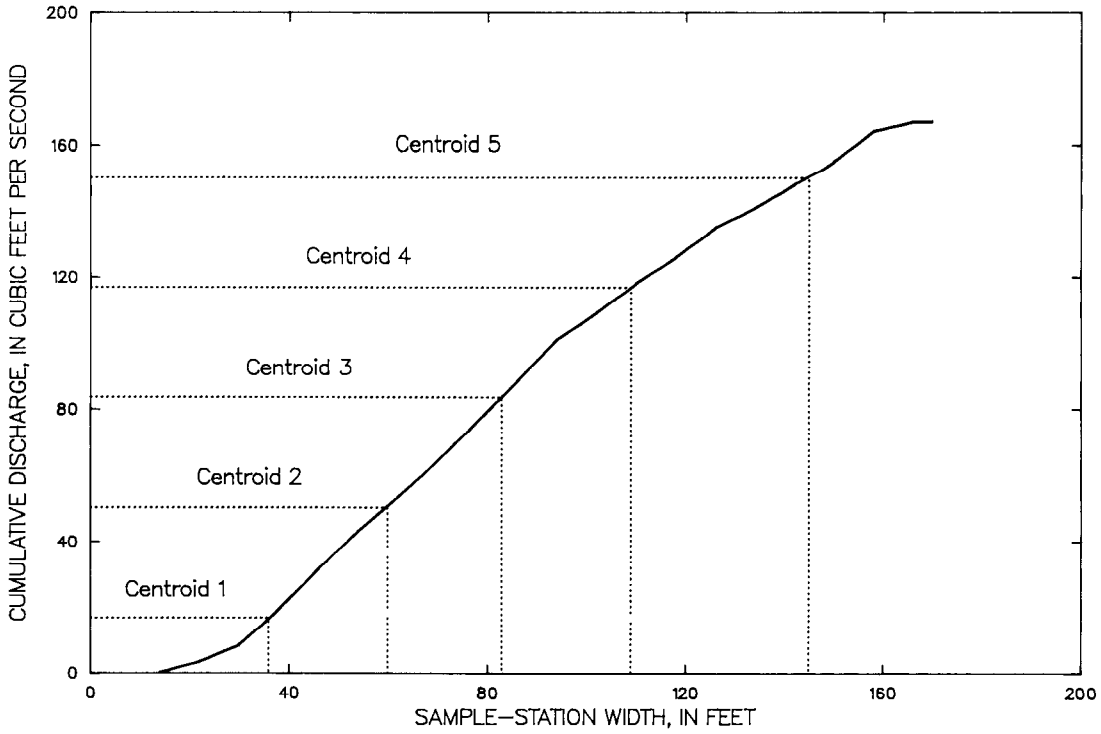

Figure 32. Cumulative discharge versus sample-station widths for determining equal-discharge-increment centroid locations.

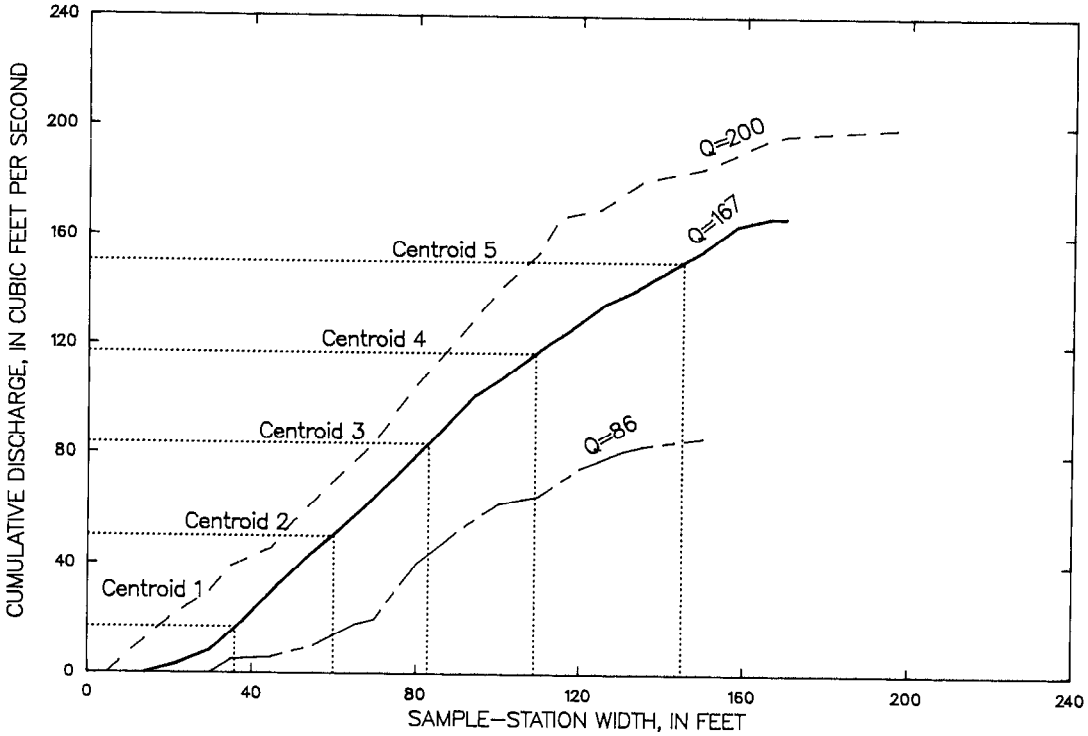

Figure 33. Cumulative discharge versus sample-station widths for determining equal-discharge-increment centroid locations. Multiple discharge-measurement plots allow users to estimate centroid locations by interpolating between curves.

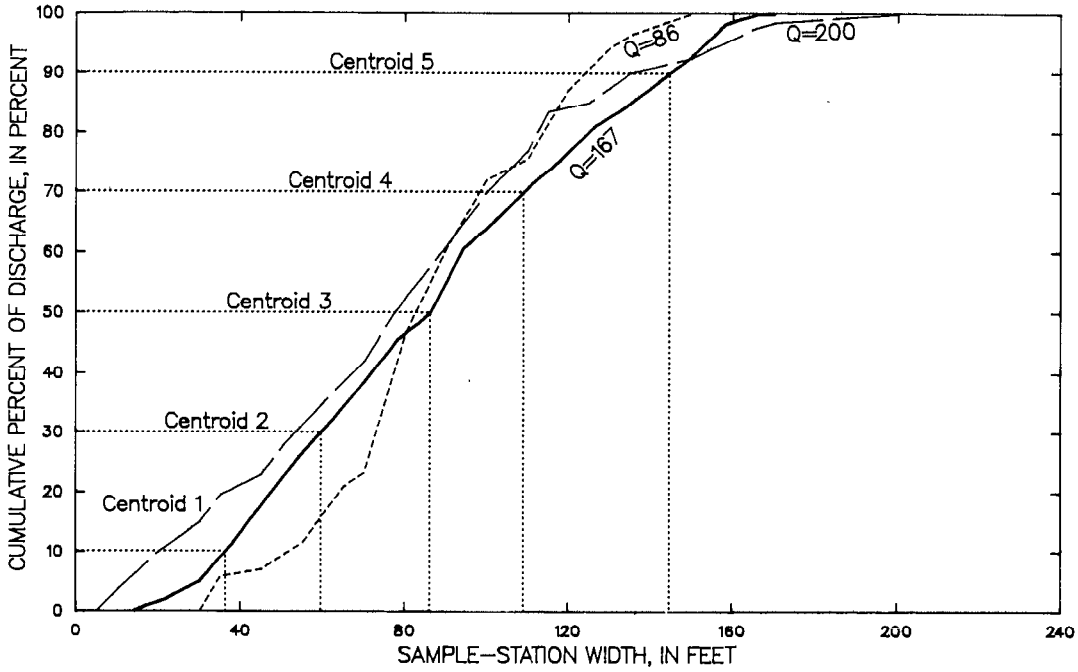

Figure 34. Cumulative percent of discharge versus sample-station widths for determining equal-discharge-increment centroid locations.

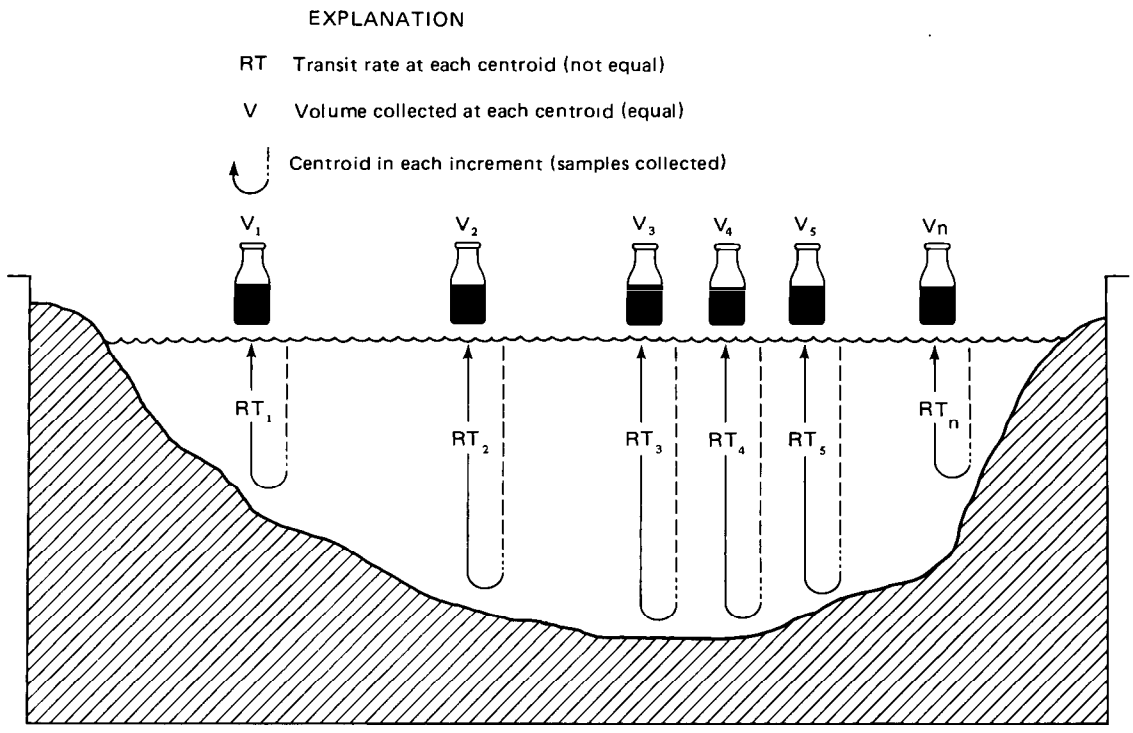

Figure 35. Vertical transit rate relative to sample volume collected at each equal-discharge-increment centroid.

The streambed of a sand-bed stream characteristically shifts radically, at single points and across segments of the width, over a period of weeks or in a matter of hours. This not only makes it impossible to establish cumulative discharge or cumulative percentage of discharge versus station curves applicable from one visit to the next, but also makes it impossible to be certain the discharge distribution does not change between the water-discharge measurement and the sediment sampling (see Guy, 1970, fig. 15).

The Equal-Width-Increment Method

A cross-sectional suspended-sediment sample obtained by the equal-width-increment (EWI) method requires a sample volume proportional to the amount of flow at each of several equally spaced verticals in the cross section. This equal spacing between the verticals (EWI) across the stream and sampling at an equal transit rate at all verticals yields a gross sample volume proportional to the total streamflow. It is important, obviously, to keep the same size nozzle in the sampler for a given measurement. This method was first used by B.C. Colby in 1946 (Federal Inter-Agency Sedimentation Project, 1963b, p. 41) and is used most often in shallow, wadable streams and (or) sand-bed streams where the distribution of water discharge in the cross section is not stable. It also is useful in streams where tributary flow has not completely mixed with the main-stem flow.

The number of verticals required for an EWI sediment-discharge measurement depends on the distribution of concentration and flow in the cross section at the time of sampling, as well as on the desired accuracy of the result. On many streams, both statistical approaches and experience are needed to determine the desirable number of verticals. Until such experience is gained, the number of verticals used should be greater than necessary. In all cases, a minimum of 10 verticals should be used for streams over 5 feet wide. For streams less than 5 feet wide, as many verticals as possible should be used, as long as they are spaced a minimum of 3 inches apart, to allow for discrete sampling of each vertical and to avoid overlaps. Through general experience with similar streams, field personnel can estimate the required minimum number of verticals to yield a desired level

of accuracy. For all but the very wide and shallow streams, a maximum of 20 verticals is usually ample.

The width of the increments to be sampled, or the distance between verticals, is determined by dividing the stream width by the number of verticals necessary to collect a discharge-weighted suspended-sediment sample representative of the sediment concentration of the flow in the cross section (fig 36). For example, if the stream width determined from the tagline, cableway, or bridge-rail markings at the sample cross section is 160 feet, and the number of verticals necessary is 10, then the width (W) of each sampled increment would be 16 feet. The sample station within each width increment is located at the center of the increment (W/2), beginning at a location of 8 feet from the bank nearest the initial point for width measurement. The verticals then are spaced 16 feet apart, resulting in sample stationing at 8, 24, 40, 56, 72, 88, 104, 120, 136, and 152 feet of width. However, in the event the width increment results in a fractional measurement, the width can be rounded to the nearest integer that will yield a whole numbered station for the initial sample vertical. That is, if the increment computation yields a width of 15.5 feet, the nearest integer width would be 16 feet, and the initial vertical would be located at 8 feet from the bank; the stationing would be similar to the previous example. Results of samples obtained using this nonideal stationing will not be measurably affected because alterations in width occur in the increments nearest the streambank, where flow velocity is low compared to midstream increments.

The EWI sampling method requires that all verticals be traversed using the transit rate (fig. 37) established at the deepest and fastest vertical in the cross section. The descending and ascending transit rates must be equal during the sampling traverse of each vertical, and they must be the same at all verticals. By using this equal-transit-rate technique with a standard depth- or point-integrating sampler at each vertical, a volume of water proportional to the flow in the vertical will be collected (fig. 37).

It is often difficult to maintain an equal transit rate when collecting samples while wading. The authors have found the following procedure to be effective in alleviating this difficulty. The field person should hold the sampler at a reference point on the body (for example, the hip), at which level the downward and upward integration is started and finished (even though part of the traverse is in air). The same reference point should be used at each vertical, allowing the same amount of time to elapse during the round trip traverse of the sampler (regardless of the stream depth encountered). In this manner, the transit rate will remain constant for the entire cross section. It should be remembered that the reference point at which the sampler traverse is started and stopped must be located above the water surface at the deepest vertical sampled and must be the same for each vertical.

Because the maximum transit rate must not exceed 0.4 v_m (v_m equals the mean ambient velocity in the sampled vertical) and because the minimum rate must be sufficiently fast to keep from overfilling any of the sample bottles, it is evident that the transit rate to be used for all verticals is limited by conditions at the vertical containing the largest discharge per foot of width (largest product of depth times velocity). A discharge measurement can be made to determine where this vertical is located, but generally, it is estimated by sounding for depth and acquiring a feel for the relative velocity with an empty sampler or wading rod. The transit rate required at the maximum discharge vertical then must be used at all other verticals in the cross section and is usually set to fill a bottle to the maximum sample volume in a round trip. It is possible to sample at two or more verticals using the same bottle if the bottle is not overfilled. If a bottle is overfilled, it must be discarded, and all verticals previously sampled using that bottle must be resampled, using a sufficient number of bottles to avoid overfilling. Note: a sample bottle is overfilled when the water surface in the bottle is above the nozzle or air exhaust with the sampler held level.

Advantages and Disadvantages of Equal-Discharge-Increment and Equal-Width-Increment Methods

Some advantages and disadvantages of both the EDI and EWI methods have been mentioned in the previous discussion. It must be remembered, however, that both methods, if properly used, yield the same results. The advantages of the EDI method are—

1. Fewer verticals are necessary, resulting in a shortened collection time.
2. Sampling during rapidly changing stages is facilitated by the shorter sampling time.
3. Bottles comprising a sample set may be composited for laboratory analysis when equal volumes of sample are collected from each vertical.

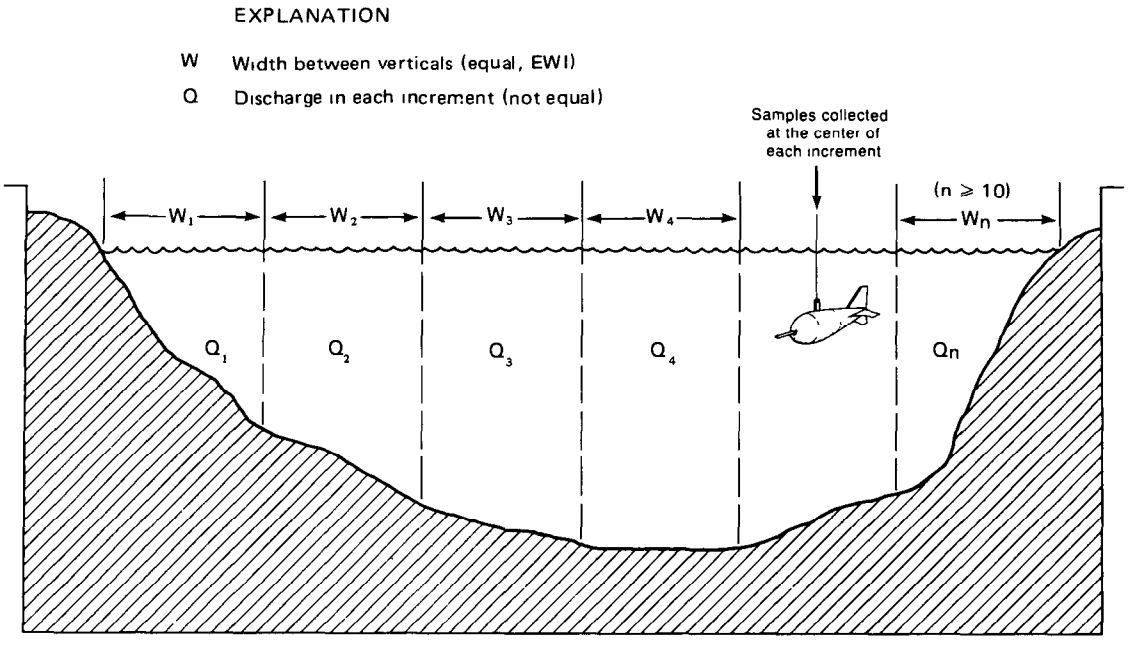

Figure 36. Equal-width-increment sampling technique.

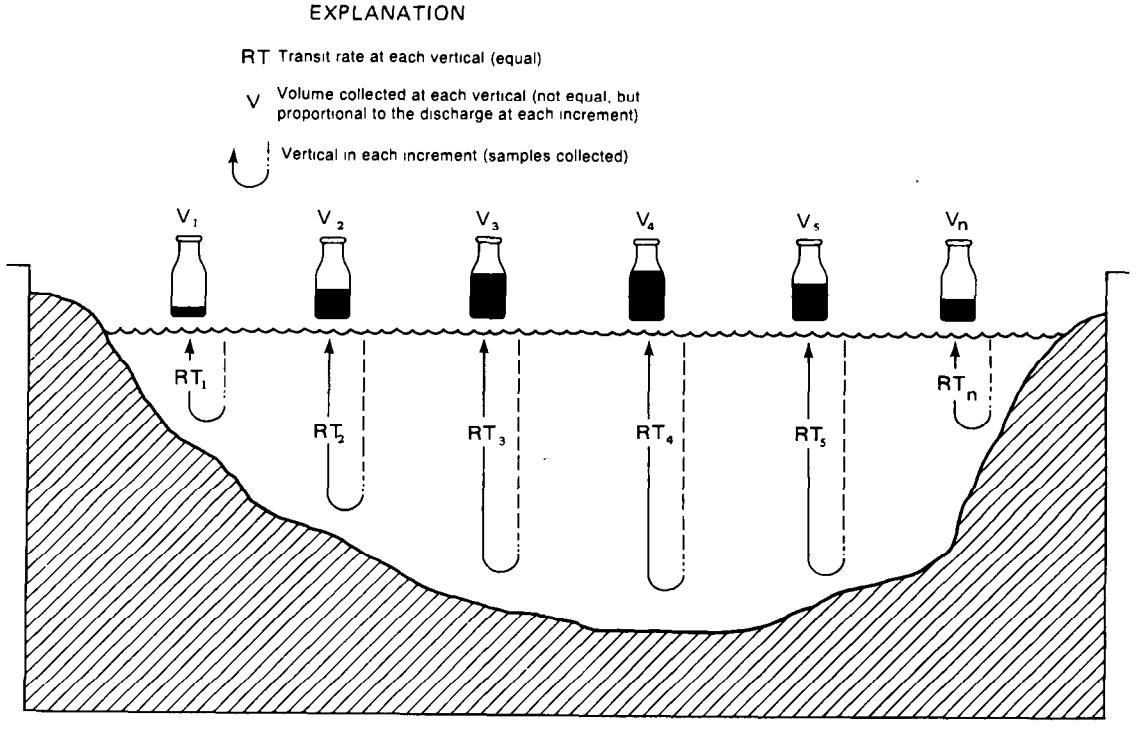

Figure 37. Equal-width-increment vertical transit rate relative to sample volume, which is proportional to water discharge at each vertical.

4. The cross-sectional variation in concentration can be determined if sample bottles are analyzed individually.
5. Duplicate cross-section samples can be collected simultaneously.
6. A variable transit rate can be used among verticals.

The advantages of the EWI method are—

1. Previous knowledge of flow distribution in the cross section is not required.
2. Variations in the distribution of concentration in the cross section may be better defined, due to the greater number of verticals sampled.
3. Analytical time is reduced as sample bottles are composited for laboratory analysis.
4. This method is easily taught to and used by observers because the spacing of sample verticals is based on the easily obtained stream width, instead of on discharge.
5. Generally less total time is required on site, if no discharge measurement is deemed necessary and the cross section is stable.

From the previous discussion it is obvious that, while both methods have definite advantages, the advantages of one method are, in many cases, the disadvantages of the other. One major disadvantage of the EWI method that should be noted is the inability to adequately distinguish obviously bad samples in the sample set, as illustrated by the following:

Example:

Vertical/bottle	1	2	3	4	5	6
Weight of sediment (g)	0.053	0.036	0.699	0.053	0.047	0.036
Weight of water sediment mixture (g)	350	300	325	330	360	355
Concentration (mg/L)	151	120	2,150	161	131	101

Mean concentration

EWI and EDI methods (composited) = 457 mg/L

EDI method (individual bottles analyzed, concentration averaged) = 469 mg/L

EDI method (individual bottles analyzed excluding bottle 3, concentration averaged) = 133 mg/L

As this example shows, if the sample were an EWI sample and composited for analysis, the computed mean concentration is 457 mg/L, which also is the mean concentration if the sample were considered as an EDI sample similarly composited for analysis. If, in the case of the EDI sample, the individual bottles were analyzed, normal computation would result in a mean concentration of 469 mg/L. From the data, bottle 3 appears to have been enriched and is not consistent with the other data points for this cross section. By exercising the flexibility of the EDI method and eliminating the number 3 bottle, the mean concentration of the remaining five bottles is computed to be 133 mg/L, which is probably more consistent with the actual mean concentration in the cross section.

Point Samples

A point sample is a sample of the water-sediment mixture collected from a single point in the cross section. It may be collected using a point-integrating sampler.

Point-integrated samples may be collected using one of the point-integrating samplers previously discussed. Data obtained in this manner may be used to define the distribution of sediment in a single vertical, such as the observer's fixed station, the vertical and horizontal distribution of sediment in a cross section, and the mean spatial sediment concentration.

The purpose for which point samples are to be collected determines the collection method to be used. If samples are collected for the purpose of defining the horizontal and vertical distribution of concentration and (or) particle size, samples collected at numerous points in the cross section, with any of the "P" type samplers, will be sufficient. Normally, 5 to 10 verticals are sufficient for horizontal definition. Vertical distribution can be adequately defined by obtaining samples from a number of points in each sample vertical. Specifically, samples should be taken at the surface, from 1 foot above the bed point, with the sampler touching the bed, and from 6 to 10 additional points in the vertical above the 1-foot-above-bed point. Each individual point sample should be analyzed separately. The results then can be plotted on a cross section relative to their instream location.

If point samples are collected to define the mean concentration in a vertical, 5 to 10 samples should be collected from the vertical. The sampling time for each sample (the time the nozzle is open) must be equal.

This will ensure that samples collected are proportional to the flow at the point of collection. These samples then are composited for laboratory analysis. If the EDI method is used to define the stationing of the verticals, the sampling time may be varied among verticals. If the EWI method is used to determine the location of verticals, a constant sampling time for samples from all verticals must be used.

Number of Verticals

The number of suspended-sediment sampling verticals at a measuring site may depend on the kind of information needed in relation to the physical aspects of the river. For example, to determine the distribution of sediment concentration or particle size across the stream, it is necessary to sample at several verticals. The number of verticals necessary to define such a cross-sectional distribution depends on the accuracy being sought and on the systematic variation of sediment concentration at different verticals across the stream.

As noted previously, suspended-sediment samplers are designed to accumulate a sample that is directly proportional to the stream discharge or velocity. The accumulated sample may be from a point in the stream cross section, a vertical line between the surface and streambed, or several such vertical lines across the entire stream cross section. Such a sample then can be considered to be representative of some element of cross-sectional flow, whether it be a few square feet adjacent to the point sample, a few square feet adjacent to both sides of a vertical line, or the area of the entire flow summed by several vertical lines. The number of verticals sampled must be adequate to represent the cross section in the sample. The number of sample bottles to be collected will depend on the kind of analysis to be made in the laboratory, and the location of the sampling verticals will depend on the concentration and size distribution of sediment moving through the stream cross section.

Both EDI and EWI methods of sediment-discharge measurement obtain a water-discharge weighted sample at each vertical. The volumetric sum from all verticals yields a sample volume proportional to the water discharge for the stream. Remember that all or nearly all of the concentration variations at different verticals across the stream may be the result of non-uniform distribution of sand-sized material and that finer sediments are generally more uniformly dispersed throughout the section. If the section is close to a tributary, mixing of main stream and tributary flows may not be complete. Therefore, locating sampling sections downstream from tributary inflows should be avoided.

Colby (1964) showed that the discharge of sand is approximately proportional to the third power of the mean velocity, with constant temperature and a given particle-size distribution for a range of velocity from about 2 to 5 ft/s and within some reasonable range of depths. Thus, $Q_s = k_1 v^3$, in which Q_s is the discharge of sand per unit width; k_1 is a constant for a given depth, particle size, and temperature; and v is the mean velocity. The sand discharge can be written as $Q_s = k_2 cvd$, in which k_2 is another constant, c is the mean discharge-weighted concentration in the sampled vertical, and d is the total sampled depth. Solving for c gives

$$c = \frac{k_1}{k_2} \frac{v^2}{d}$$

Thus, the variability of concentration at different sampling verticals should be closely related to the variability of v^2/d. In order to have a v^2/d index useful for comparison among all streams, the compound ratio

$$\frac{v^2 d_{(max)}}{v^2 d} \text{ is suggested,}$$

where $[v^2/d_{(max)}]$ is the ratio from the vertical having the maximum v^2/d, and v^2/d is the ratio of the mean velocity squared to the mean depth of the whole stream cross section. The mean velocity and mean depth are computed and available from water-discharge measurements.

Based on the v^2/d index concepts of variability, P.R. Jordan used data from Hubbell and others (1956) to prepare a nomograph (fig. 38) that indicates the number of sampling verticals required for a desired maximum acceptable relative standard error (sampling error) based on the percentage of sand and the v^2/d index. In the example illustrated by figure 38, the acceptable relative standard error is 15 percent, the sample is 100-percent sand, the v^2/d index is 2.0, and the required number of verticals is seven. Notice that if the sediment were 50-percent sand, the same results

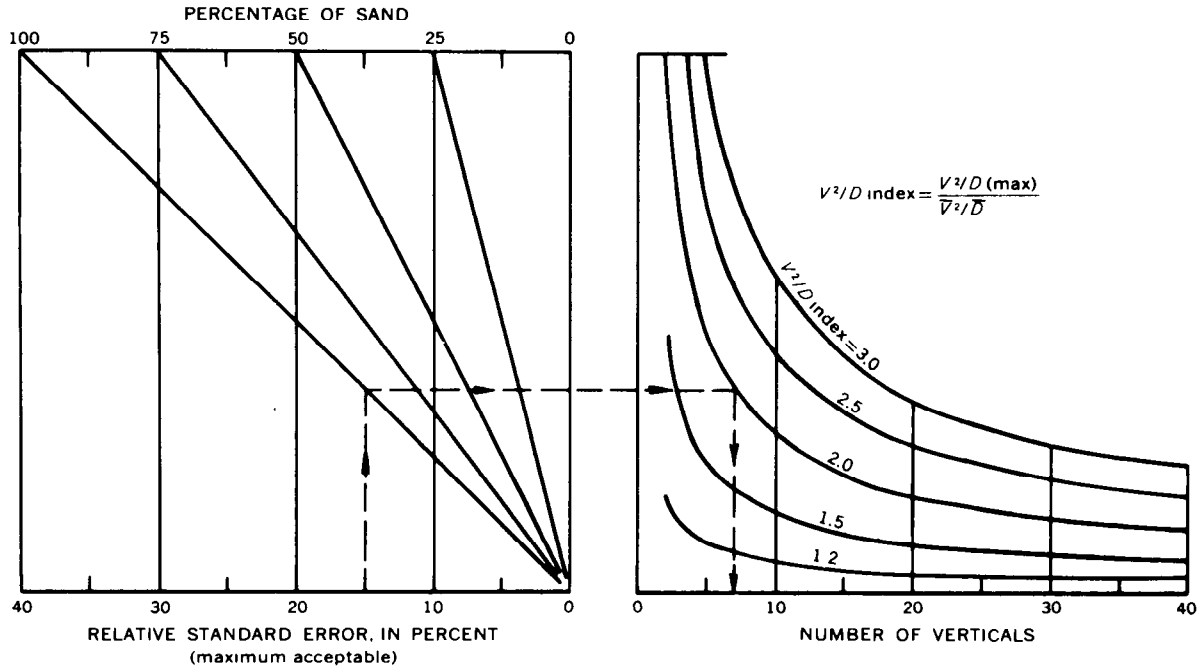

Figure 38. Nomograph to determine number of sampling verticals required to obtain results within an acceptable relative standard error.

could be obtained with three verticals; or, if seven verticals were used with 50-percent sand, the relative standard error would be about 8 percent. When the discharge of sand-sized particles is of primary interest, the 100-percent line should be used regardless of the amount of fines in the sample.

Transit Rates for Suspended-Sediment Sampling

The sample obtained by passing the sampler throughout the full depth of a stream is quantitatively weighted according to the velocity through which it passes. Therefore, if the sampling vertical represents a specific width of flow, the sample is considered to be discharge weighted because, with a uniform transit rate, suspended sediment carried by the discharge throughout the sampled vertical is given equal time to enter the sampler. In previous writings, the point was made to keep the transit rate of the samplers constant throughout at least a single direction of travel.

The maximum transit rate used with any depth-integrating sampler must be regulated to ensure the collection of representative samples. If the transit rate is too fast, the rate of air-volume reduction in the sample container is less than the rate of increase in hydrostatic pressure surrounding the sampler, and water may be forced into the intake or air exhaust. Additionally, an excessive transit rate can result in intake velocities less than the stream velocity at the intake, due to a large entrance angle between the nozzle and streamflow lines caused by the vertical movement of the sampler in the flow (Federal Inter-Agency Sedimentation Project, 1952). To alleviate these problems, transit rates should never exceed 0.4 of the mean velocity (0.4 v_m) in a vertical. Figures 39, 40, and 41 can be used to determine the appropriate transit rate to be used with a given nozzle-size/sample-container-size combination. These figures show that maximum transit rates vary from about 0.1 v_m to the approach angle limit of 0.4 v_m, previously noted. This variation is a function of both nozzle size and sample-container size. The smaller nozzle (1/8 inch) is greatly affected by approach angle intake velocity reductions; figures 39 and 40 show that the transit rate decreases directly with nozzle size. Also, by comparison of figures 39 and 40, it is obvious that transit rates are inversely affected by sample-container size because an increase in sampler container size produces a decrease in allowable transit rate due to the effects of hydrostatic pressure compressing the air within the container during the downward transit. Figures 39, 40, and 41 were constructed using procedures from F.I.S.P. (1952), Report 6, Section 8, as contained in the

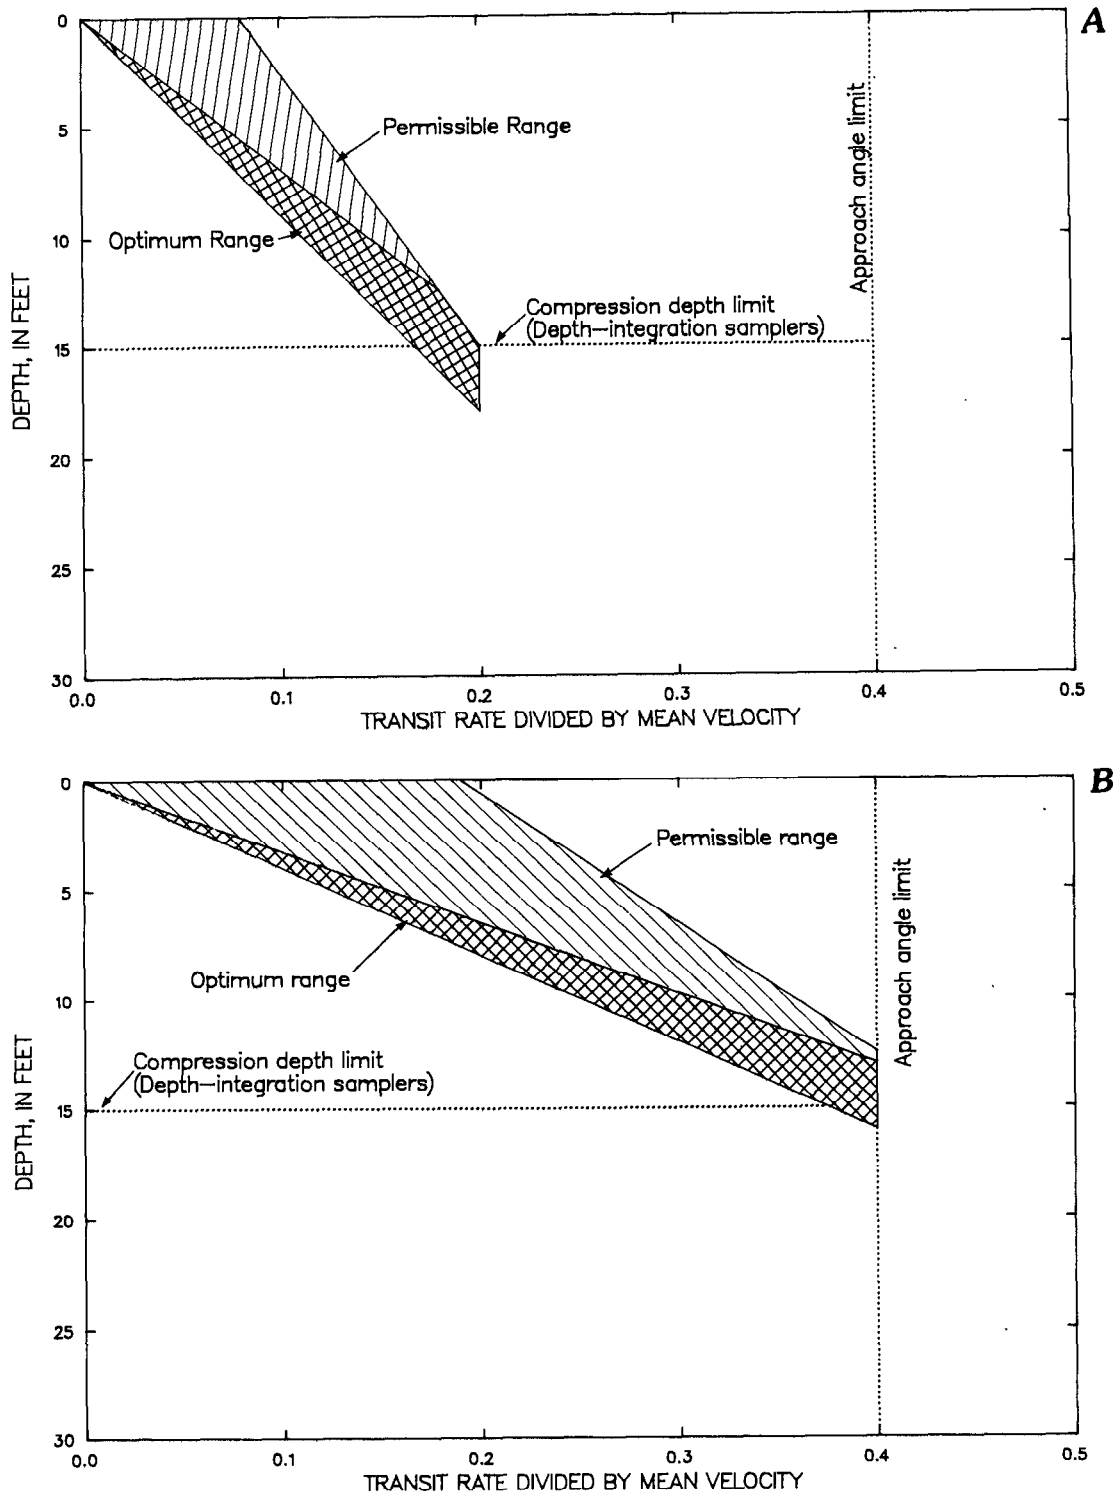

Figure 39. Variation of range of transit rate to mean velocity ratio versus depth relative to nozzle size for pint-size sample container. *A*, 1/8-inch nozzle. *B*, 3/16-inch nozzle. *C*, 1/4-inch nozzle.

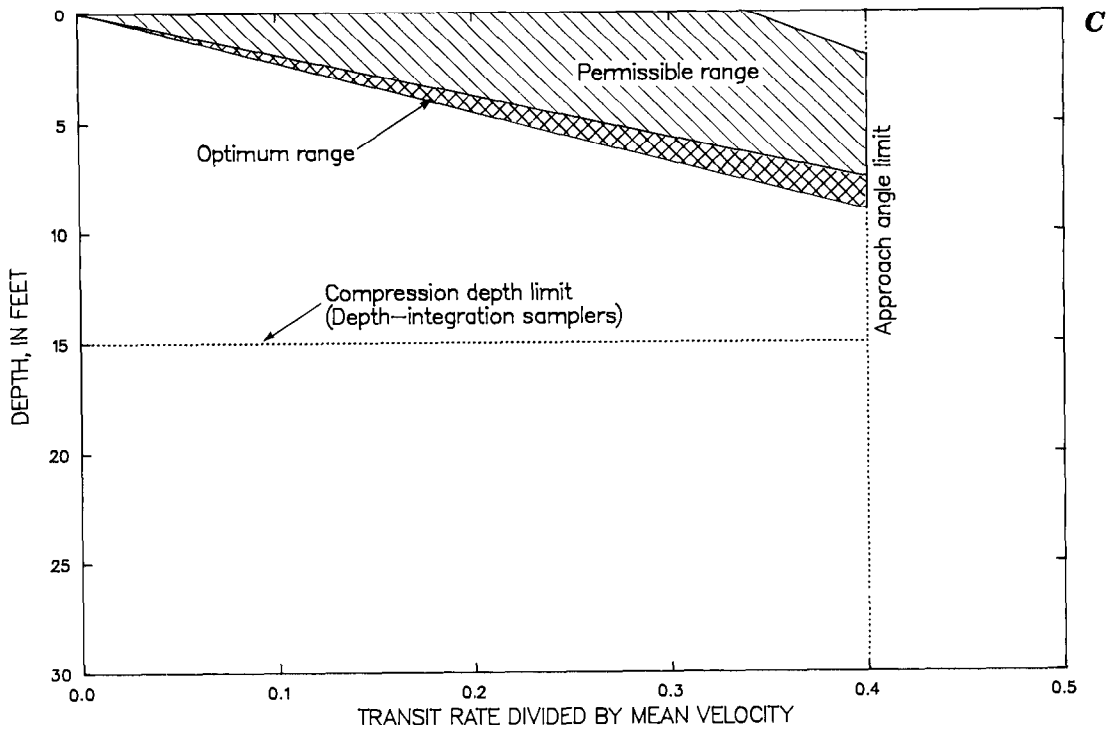

Figure 39. Variation of range of transit rate to mean velocity ratio versus depth relative to nozzle size for pint-size sample container. *A*, 1/8-inch nozzle. *B*, 3/16-inch nozzle. *C*, 1/4-inch nozzle—Continued.

sampling instructions for the D-74 depth-integrating sampler.

Figure 42 is a graphic presentation of the procedure to be followed when constructing transit-rate graphs similar to those presented in figures 39, 40, and 41, using the following nomenclature and equations:

A_n = Area of intake nozzle at entrance; square feet 1/8 inch = 8.52×10^{-5}, 3/16 inch = 19.2×10^{-5}, 1/4 inch = 34.1×10^{-5}, and 5/16 inch = 53.3×10^{-5}

d_c = Stream depth where bottom compression limit equals surface compression; feet

h_1 = Atmospheric pressure at water surface = 34 feet at sea level

Q_{max} = Maximum sample volume; cubic feet (pint bottle, 420 mL = 0.015 ft^3; quart bottle, 800 mL = 0.028 ft^3; 3-liter bottle, 2,700 mL = 0.095 ft^3)

Q_{min} = Minimum sample volume; cubic feet (pint bottle, 300 mL = 0.011 ft^3; quart bottle, 650 mL = 0.023 ft^3; 3-liter bottle, 2,000 mL = 0.071 ft^3)

r_b = Relative velocity near stream bottom; feet per second

RT = Transit rate of sampler; feet per second (rising rate equals lowering rate for EWI method)

r_s = Relative velocity at stream surface; feet per second

V_1 = Volume of container; cubic feet 1 pint = 0.01671 ft^3, 1 quart = 0.03342 ft^3, and 3-liter bottle = 0.105 ft^3

V_m = Mean stream velocity in vertical; feet per second

$$\text{Point 1}\quad \frac{RT}{V_m} = \frac{A_n r_b h_1}{V_1}$$

$$\text{Point 2}\quad \frac{RT}{V_m} = \frac{A_n h_s h_1}{V_1}$$

$$\text{Point 3}\quad d_c = \frac{h_1(r_s - r_b)}{r_{b+1}} =$$

15 feet, for assumed velocity profile in figure 42.

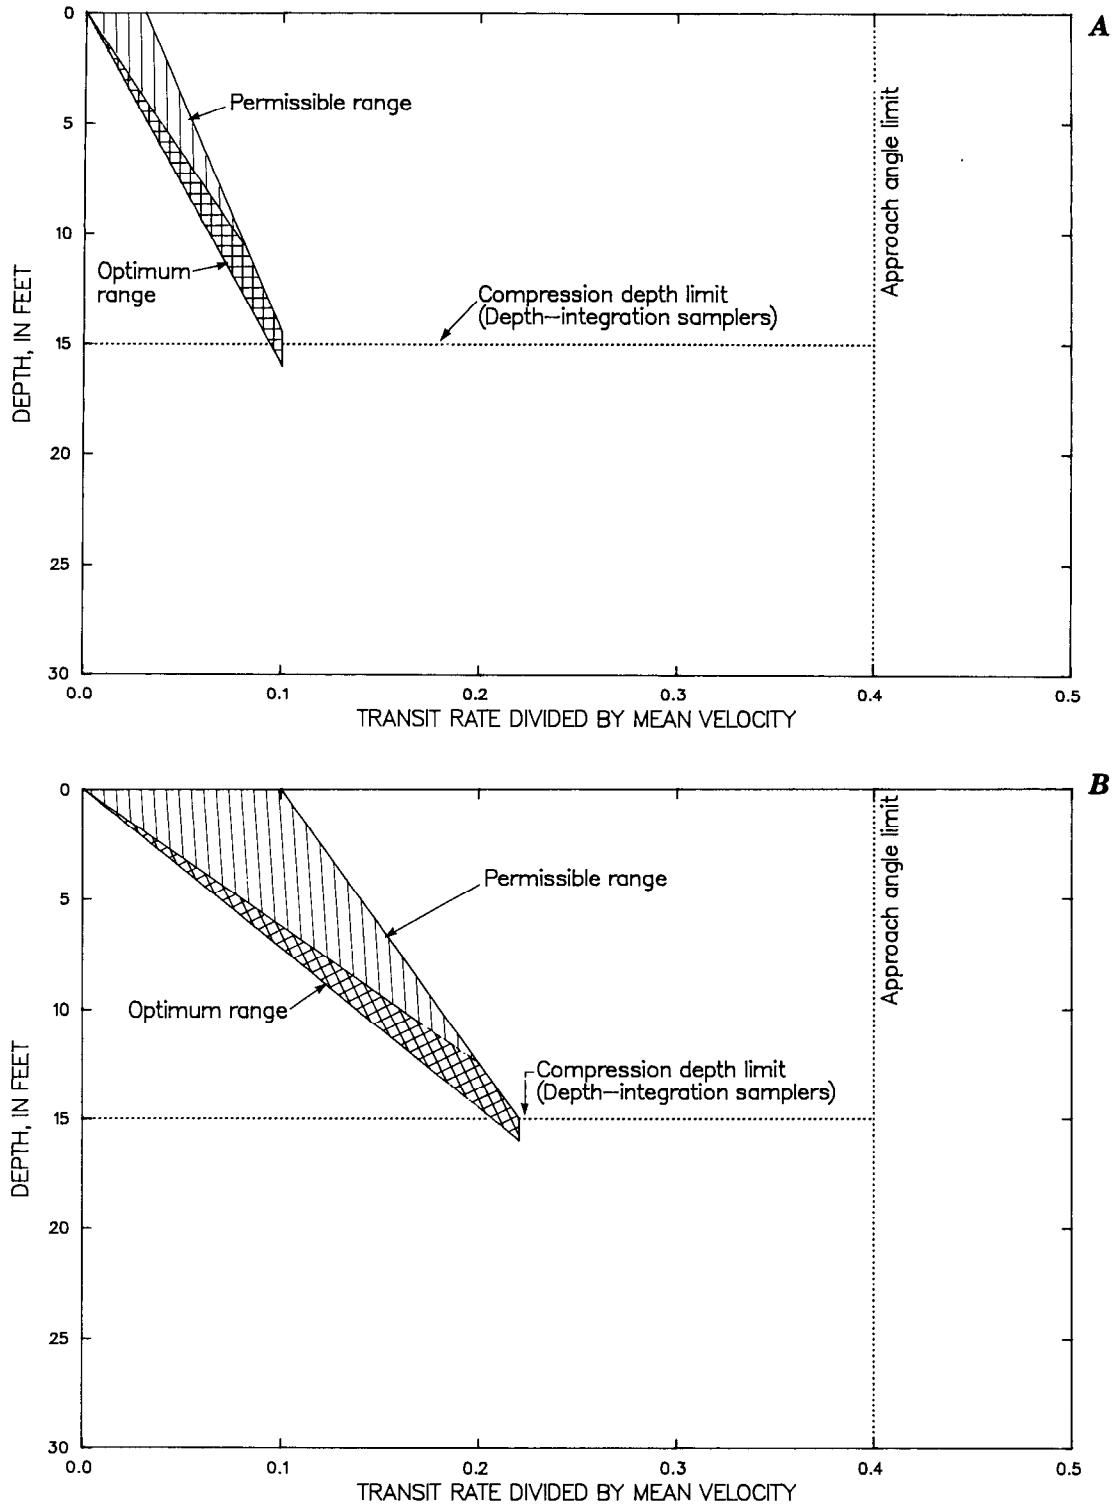

Figure 40. Variation of range of transit rate to mean velocity ratio versus depth relative to nozzle size for quart-size sample container. *A*, 1/8-inch nozzle. *B*, 3/16-inch nozzle. *C*, 1/4-inch nozzle.

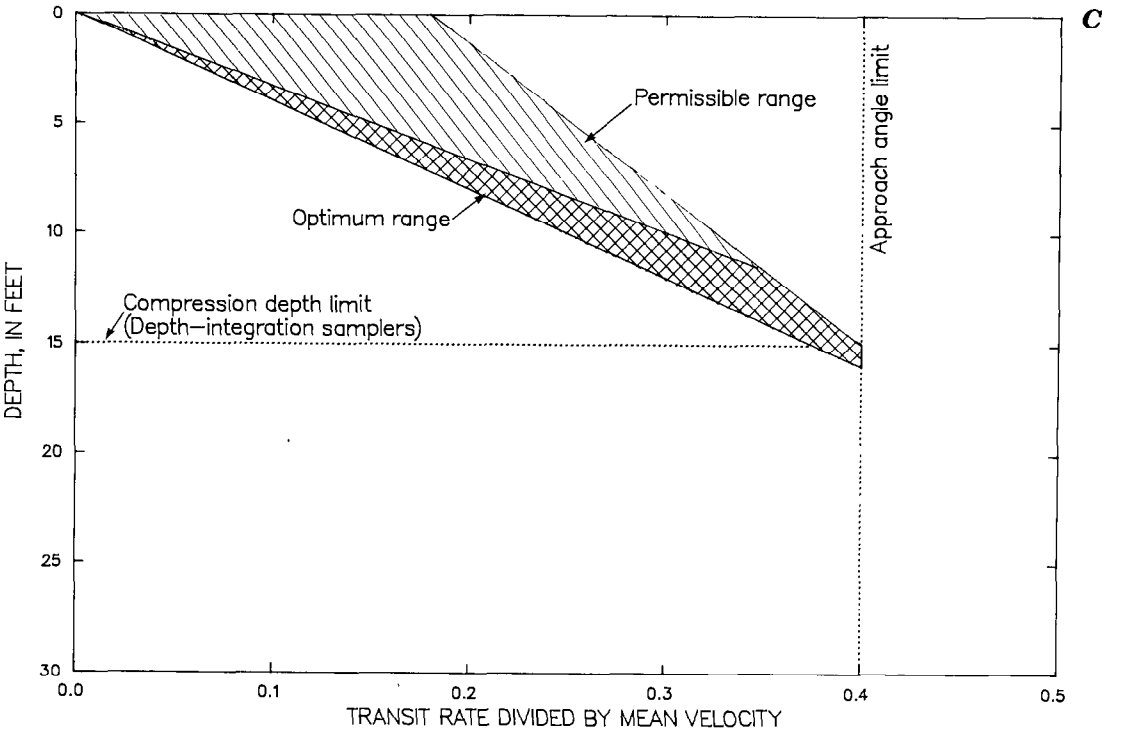

Figure 40. Variation of range of transit rate to mean velocity ratio versus depth relative to nozzle size for quart-size sample container. A, 1/8-inch nozzle B, 3/16-inch nozzle. C, 1/4-inch nozzle—Continued.

$$\text{Point 4}\ \frac{RT}{V_m} = \frac{20\ A_n}{Q_{max}}$$

$$\text{Point 5}\ \frac{RT}{V_m} = \frac{20\ A_n}{Q_{min}}$$

For points 4 and 5, the depth is arbitrarily taken at 10 feet to facilitate plotting. Also, the following sample vertical velocity profile is assumed:

Relative depth	*Velocity/ mean velocity in vertical*
surface	1.16
.1	1.17
.2	1.16
.3	1.15
.4	1.10
.5	1.05
.6	1.0
.7	.94
.8	.84
.9	.67
1.0 bottom	.5

The technique for use of figures 39, 40, and 41 to determine the transit rate to be used in a given situation depends upon (1) the depth of the sample vertical, (2) the mean velocity of the vertical, (3) the nozzle size being used, and (4) the sample-bottle size used in the sampler. An example of transit-rate determination is presented in figure 43. The nozzle size and sample-bottle size must be known so the proper figure can be selected. In this case, a 3 /16-inch nozzle and 1-pint bottle will be used. The depth and mean velocity of the sample vertical also must be known. For this example, a depth of 10 feet and mean velocity of 2 ft/s are assumed. To determine transit rate for this example (1) select the depth of the sample vertical (10 feet); (2) draw a line perpendicular to the depth on the vertical scale that terminates at the center of the optimum range; (3) read the value of RT/V_m from the horizontal scale corresponding to this point (0.28); and (4) multiply the RT/V_m value by the mean velocity (V_m = 2 ft/s) to determine the transit rate (RT = 0.56 ft/s). Note that, if the same nozzle, depth, and mean velocity were used with a quart sample container in lieu of the pint container (fig. 40*B*), an RT value of 0.30 ft/s would be used, reducing the transit rate by almost one-half.

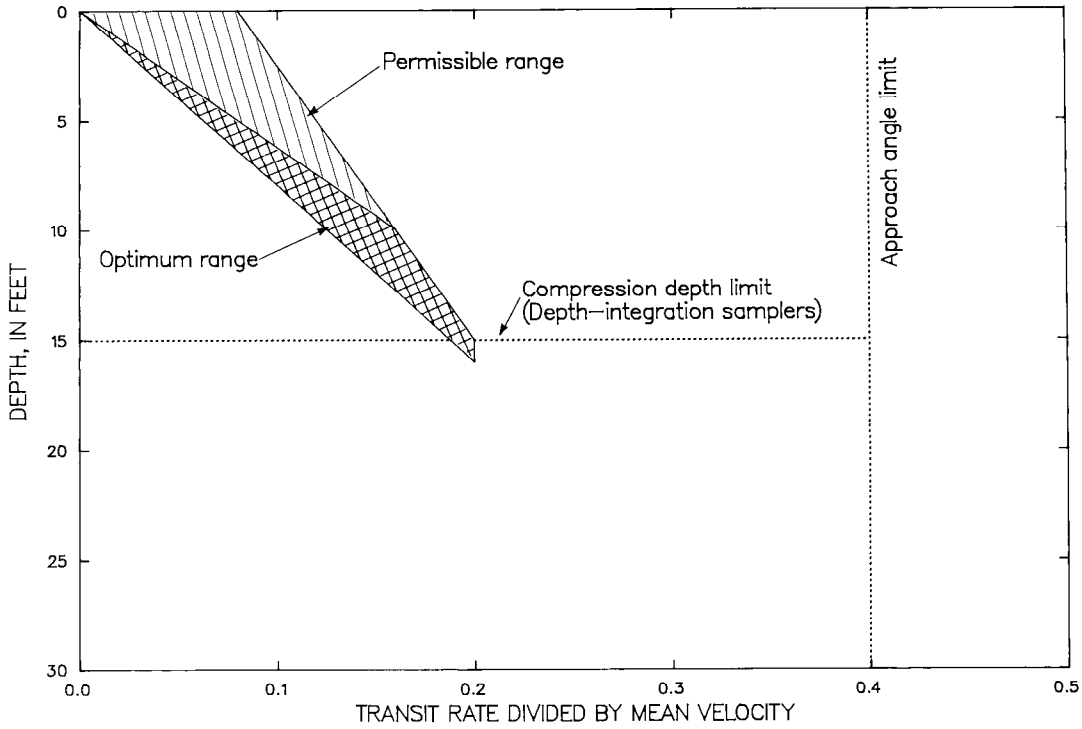

Figure 41. Range of transit rate to mean velocity ratio versus depth for 5/16-inch nozzle on a 3-liter sample bottle.

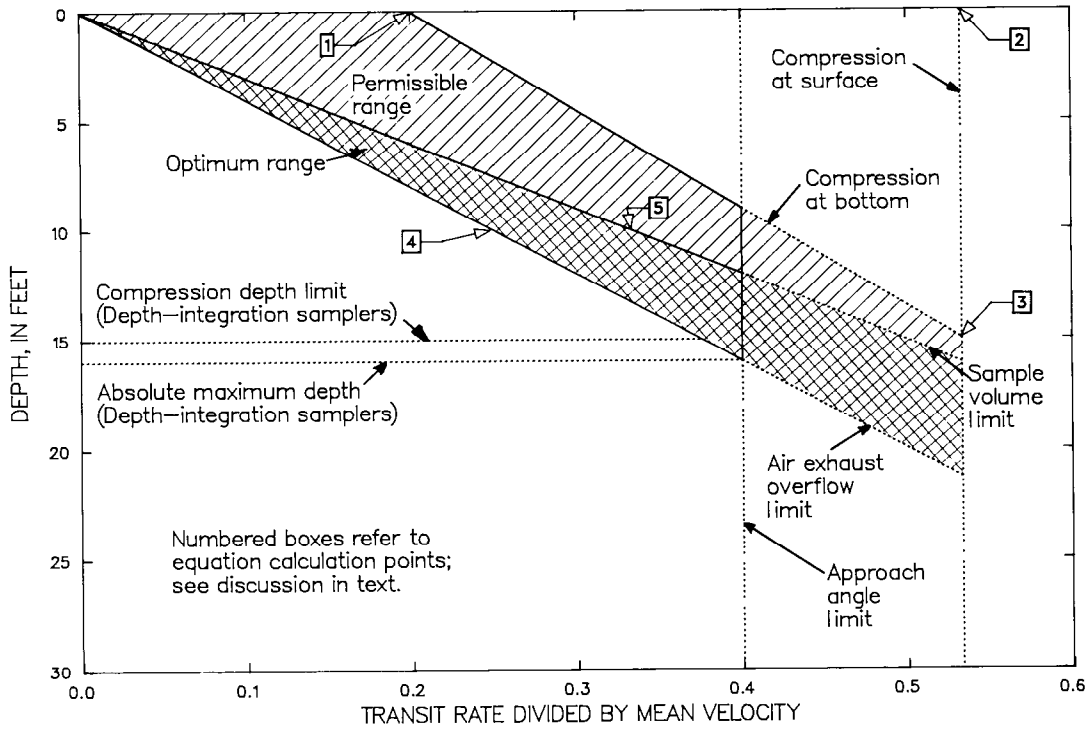

Figure 42. Construction of a transit-rate determination graph (see text for explanation of numbered points).

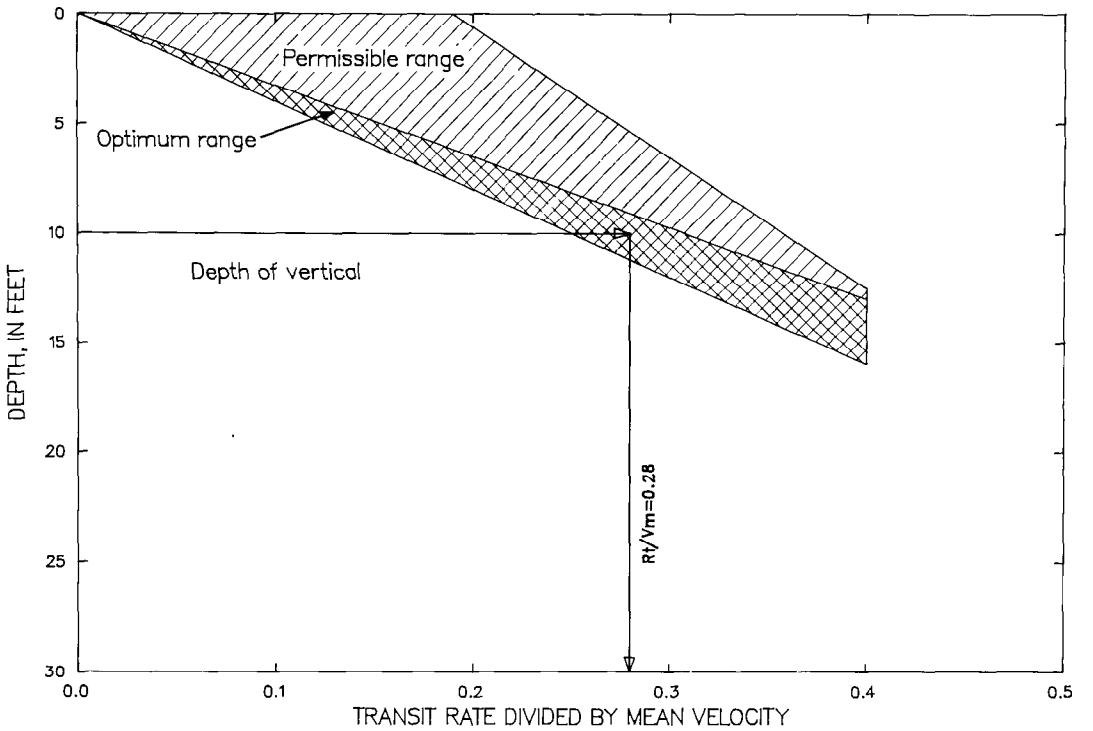

Figure 43. Example of transit rate determination using graph developed for 3/16-inch nozzle and a 1-pint sample container (see text for discussion).

Use of transit rates determined from the optimum range of figures 39, 40, or 41 will yield a representative sample of adequate volume to provide for laboratory analysis and avoid overfilling. In some instances, however, sampler operation within the optimum range is not possible. Under these conditions, operation using a transit rate determined from the permissible range is acceptable. In these cases, it should be realized that a representative sample can still be obtained, but the sample volume may be less than adequate for laboratory purposes and, therefore, more integrations may be required at each vertical to obtain the necessary volume of sample.

Additional explanation and qualifications with respect to the transit rate for depth-integrated suspended-sediment sampling include the following:

1. For cable-suspended samplers, the instantaneous actual transit rate, RT_a, may differ considerably from the computed rate, RT, if V_m exceeds about 6 ft/s and if the sampler is suspended from more than 20 feet above the water surface. Under such conditions, the sampler is dragged downstream, and the indicated depth is greater than the true depth. Corrections for indicated depth are given by Buchanan and Somers (1969, p. 50–56) for various angles and lengths of sounding line used for suspension of a weight in deep, swift water. The correct depth then would be used to enter in figures 39, 40, and 41 to determine the appropriate transit rate.

2. In theory, the allowable RT may be greater than 0.4 V_m, and sampling depth thereby increased if the sampler is cable suspended and capable of being tilted somewhat in the direction of vertical movement (that is, nozzle is slightly down when sampler is lowered and slightly up when sampler is raised, due to the effect of vertical forces on the horizontal tail-fin stabilizer). On the other hand, if the sampler cannot be tilted, the velocity at the bottom of the vertical is much less than V_m, and there is a heavy concentration of suspended sand near the bed, the use of an RT value near the 0.4 V_m limitation may cause RT to approach or even exceed the actual velocity near the bed and thus cause an excessive error in the collection of sand particles. The approach-angle theoretical depth limits will, of course, be less if either the downward or the upward transit rates, RT_d or RT_u, are different from RT. However, determining the attitude of the sampler during actual use is difficult at best and impossible under turbid flow conditions. For this reason, varying either RT or sampling beyond recommended limits is

not advisable and probably not necessary because small errors during descent will probably be cancelled during ascent.

3. The air-compression lower limit is based on the assumption that a uniform velocity distribution exists throughout the vertical. Actually, the velocity varies with the depth throughout the vertical. Therefore, where the velocity is considerably greater than the mean in the upper part of the vertical, the lower limit could be increased somewhat. In theory, the air-compression lower limit could be effectively increased by using a downward transit rate, RT_d, where RT_d is less than RT, and compensating for the extra filling of the bottle on the downward trip by using an upward transit rate, RT_u, where $RT_u = RT + (RT - RT_d)$. Note: this brief discussion is presented here as an interesting concept and should not be practiced in actual field conditions, where channel configuration and velocity profiles may not represent the ideal flow conditions found in a controlled flume environment.

4. Because of possible greater deviation from the ideal relation of intake velocity to stream velocity of 1.0, the 1/8-inch nozzle should not be used if there are significant quantities of sand larger than 0.25 mm in suspension. The 1/8-inch nozzle also is less reliable than the larger nozzles where small roots and other organic fibers are suspended in the flow.

5. In the event the sampler accommodates other than a pint-sized sample container, the RT should be carefully determined because RT for a quart container may be nearly one-half of that acceptable for a pint container with a given nozzle size. The use of a sample container larger than 1 pint does not, however, increase the sample depth range, due to the air-compression depth limit. Therefore, samples should not be taken from greater than about 15 feet with a depth-integrating sampler.

Observer Samples

At many sites, collection of suspended-sediment data is required on a frequent basis. To define the sediment-discharge trends, these data could be required once daily or more often (in the case of high-flow events). Frequent suspended-sediment data collection can put extreme pressure on a project's fiscal resources as well as on the personnel involved. In order to save money, travel time and, most importantly, to ensure timely collection of data on a regular basis and during extreme events, local residents are often contracted to work as observers.

Observers usually lack technical background, but can be trained to collect cross-section samples using either the EDI or EWI method. However, due to the complexities involved in computing centroids and a lack of expertise in obtaining the stream discharge for the EDI method, this technique is not recommended for observer-operated sites. Observers most often collect samples from an established single vertical in the cross section, as previously mentioned. The best location in the cross section for a single-vertical sediment sample is determined by data collection. Generally, each new sediment-record site is carefully investigated by means of several detailed sediment-discharge measurements to determine the concentration of sediment across the stream at different discharges. These sediment data can be collected using either the EDI or EWI method.

If the single vertical is used to obtain observer-collected samples, these data must be treated much the same as point-sample data collected with a pumping sampler. That is, cross-section samples must be taken occasionally for comparison with the observer samples in order to establish adjustment coefficients. Samples should be collected at the observer's single-vertical using the observer's equipment, both before and after each cross-section sample is taken. These samples then form the basis for a coefficient that can be used to adjust the concentration of the single-vertical samples. This adjustment coefficient, or comparison of the routine single vertical with the cross section, is determined by computing the ratio of the average concentration of cross-section samples to the average concentration of single-vertical samples. This ratio then can be applied to the daily samples taken between sediment-discharge measurements. If the coefficient is consistently above or below unity, it may be desirable to change the position of the fixed routine sampling installation to a location where the coefficient would be at or near unity. Generally, if the coefficients are within 5 percent of unity, a coefficient of 1.0 is applied, unless they are consistently high or low for long periods of time. Guy (1968) illustrated methods for determining the quality of the coefficient and the number of samples needed in a sample set. Porterfield (1972) gave further details on how coefficients are used in the computation of sediment records.

During high flows, when the depth of the single vertical exceeds the theoretical 15-foot compression

depth limit of the depth-integrating sampler, the observer should try to obtain a sample by altering the technique to collect the most representative sample possible. The best collection technique under these conditions would be to depth integrate 0.2 of the vertical depth (0.2*d*), or a 10-foot portion of the vertical. These samples then can be checked and verified by collecting a set of reference samples with a point-integrating sampler. By reducing the sampled depth during periods of high flow, the transit rate can be maintained at 0.4 V_m or less in the vertical, and a partial sample can be collected without overfilling the sample container, even under conditions of higher velocities that usually accompany increases in discharge.

Sampling Frequency, Sediment Quantity, Sample Integrity, and Identification

Sampling Frequency

When should suspended-sediment samples be taken? How close can samples be spaced in time and still be meaningful? How many extra samples are required during a flood period? These are some questions that must be answered because timing of sample observations is as important to record computations (see Porterfield, 1972) as is the technique for taking them. Answering such questions is relatively easy for those who compute and assemble the records because they have the historical record before them and can easily see what is needed. However, the field person frequently does not have this record and certainly cannot know what the conditions will be in the future.

Observers should be shown typical hydrographs or recorder charts of their stations or of nearby stations to help them understand the importance of timing their samples so that each sample yields maximum information. The desirable time distribution for samples depends on many factors, such as the season of the year, the runoff characteristics of the basin, the adequacy of coverage of previous events, and the accuracy of information desired or dictated by the purpose for which the data are collected.

For many streams, the largest concentrations and 70 to 90 percent of the annual sediment load occur during spring runoff; on other streams, the most important part of the sediment record may occur during the period of the summer thunderstorms or during winter storms. The frequency of suspended-sediment sampling should be much greater during these periods than during the low-flow periods. During some parts of these critical periods, hourly or more frequent sampling may be required to accurately define the trend of sediment concentration. During the remainder of the year, the sampling frequency can be stretched out to daily or even weekly sampling for adequate definition of concentration. Hurricane or thunderstorm events during the summer or fall require frequent samples during short periods of time. Streams having long periods of low or intermittent flow should be sampled frequently during each storm event because most of the annual sediment transport occurs during these few events.

During long periods of rather constant or gradually varying flow, most streams have concentrations and quantities of sediment that vary slowly and may, therefore, be adequately sampled every 2 or 3 days; in some streams, one sampling a week may be adequate. Several samplings a day may occasionally be needed to define the diurnal fluctuation in sediment concentration. Fluctuations in power generation and evapotranspiration can cause diurnal fluctuations. Sometimes diurnal temperature fluctuations result in a snow and ice freeze/thaw cycle causing an accompanying fall and rise in stage. Diurnal fluctuations also have been noted in sand-bed streams when water-temperature changes cause a change in flow regime and a drastic change in bed roughness (Simons and Richardson, 1965).

The temporal shape of the hydrograph is an indicator of how a stream should be sampled. Sampling twice a day may be sufficient on the rising stage if it takes a day or more for a stream to reach a peak rate of discharge. During the peak, samples every few hours may be needed. During the recession, sampling can be reduced gradually until normal sampling intervals are sufficient.

The sediment-concentration peak may occur at any time relative to the water discharge; it may coincide with the water-discharge peak or occur several days prior to or after it. Hydrographs for large rivers, especially in the Midwest, typically show water-discharge peaks occurring several days after a storm event. If the sediment concentration has its source locally, the sediment peak can occur a day or more prior to the water-discharge peak. In this case, the receding limb of the sediment-concentration curve will nearly coincide with the lagging water-discharge peak. In this event, intensive sampling logically should

be done prior to the water-discharge peak. Detailed sampling of hydrograph peaks during the initial stages of a monitoring program will help determine when the sediment-sampling frequency should be increased and decreased in order to optimize the sediment-sampling effort relative to peak-flow conditions.

Intermittent and ephemeral streams usually have hydrograph traces in which the stage goes from a base flow or zero flow to the maximum stage in a matter of a few minutes or hours, and the person responsible for obtaining the samples frequently does not know when such an event is to occur. A sampling scheme should be designed to define the sediment discharge by taking samples during the rising stage, then the peak stage and the recession. Generally, adequate coverage of the peak is obtained if samples on the rising limb are four times as frequent as samples collected during the recession. For example, if the recession is best sampled on a bi-hourly basis, the rising limb should be sampled every one-half hour.

Elaborate and intensive sampling schedules are not required for each and all events on small streams that drain basins of rather uniform geologic and soil conditions because similar runoff conditions will yield similar concentrations of sediment for the different runoff events. Once a concentration pattern is established, samples collected once or twice daily may suffice, even during a storm period (Porterfield, 1972).

Streams draining basins with a wide variety of soils and geologic conditions and receiving uneven distributions of precipitation cannot be adequately sampled by a rigid, predetermined schedule. Sediment concentration in the stream depends not only on the time of year, but also on the source of the runoff in the basin. Thus, each storm or changing flow event should be covered as thoroughly as possible, in a manner similar to that described for intermittent and ephemeral streams.

The accuracy needed in the sediment information also dictates how often a stream should be sampled. The greater the required accuracy and the more complicated the flow system, the more frequently it will be necessary to obtain samples. This increase in sampling frequency—with the added costs of laboratory analysis—greatly increases the cost of obtaining the desired sediment information. Often, however, the record may actually cost less when adequate samples are collected than when correlation and other synthetic means must be used to compute segments of a record because of inadequate sampling.

Stream-sediment stations may be operated or sampled on a daily, weekly, monthly, or on an intermittent or miscellaneous schedule. Usually, those operated on a daily basis are considered adequate to yield the continuous record. One should be mindful that each sample at a specific station costs about the same amount of money, but the amount of additional information obtained often decreases with each succeeding sample after the first few samples are taken. Sometimes samples obtained on a monthly basis yield more information for the money than those from a daily station, although there is a danger that too little information may be of no value or may even be misleading. For a given kind of record, the optimum number of samples should be a balance between the cost of collecting additional samples and the cost of a less precise record.

The frequency of collection of bed-material samples depends upon the stability of the streambed at the sample site. In many cases, seasonal samples may be adequate to characterize the distribution among particles comprising the bed. However, samples should be obtained whenever possible during high-flow events in order to describe the composition of bed material as compared to its composition during periods of normal or low flow. Particularly important is the collection of bed-material samples following high flows that have inundated the flood plain and greatly altered the streambed configuration.

Sediment Quantity

Previous sections discussed the number of sampling verticals required at a station to obtain a reliable sediment-discharge measurement or a sample of the cross-sectional concentration. The number of cross-sectional samples required to define the mean concentration within specific limits also has been discussed. The requirements in terms of quantity of sediment for use in the laboratory to determine particle-size gradation may at times exceed the other requirements for concentration. The size range and quantity of sediment needed for the several kinds of sediment analyses in the laboratory are given in table 3. The desirable minimum quantity of sediment for exchange capacity and mineralogical analyses is based on the requirements for radioactive cesium techniques described by Beetem and others (1962).

To estimate visually the quantity of sediment entrained in a sample or series of sample bottles

Table 3. The desired quantity of suspended sediment required for various sediment analyses

[mm, millimeter; g, gram]

Analysis	Size range (mm)	Desirable minimum quantity of sediment (g)
Size:		
Sieves:		
Fine	0.062–0.5	0.07
Medium	0.25–2	.5
Coarse	1.0–16	20
Visual accumulation tube:		
Smallest	0.062–0.5	.05
Largest	0.062–2	5
Pipette	0.002–0.062	[1].8
Bottom withdrawal tube	0.002–0.062	[1].5
Exchange capacity:		
Fine	0.002	1
Medium	0.002–0.062	2
Coarse	0.062–2	10
Mineralogical:		
Fine	0.002	1
Medium	0.002–0.062	2
Coarse	0.062–2	5

[1]Double the quantities shown if both native and dispersed media are required.

requires considerable experience. It also is difficult to determine what portion of the total sample is sands (greater than 0.062 mm) because the proportion can be different from stream to stream and from time to time in the same stream. To aid in estimating such sediment quantities, it is helpful to have, in the office or laboratory, reference bottles with various known quantities and concentrations for visual inspection. The number of bottles of sample, the amount of sand, and sample concentration needed for a given kind of analysis are shown in figure 44 (G. Porterfield, written commun., 1968).

Although it is possible to conduct the laboratory operation for particle-size analysis in a manner that also will give the sediment concentration, it is best to obtain separate samples for size analysis and concentration analysis. Such "special" samples should be plainly labeled. Generally, it is desirable to instruct the observer to collect additional samples for particle-size analysis.

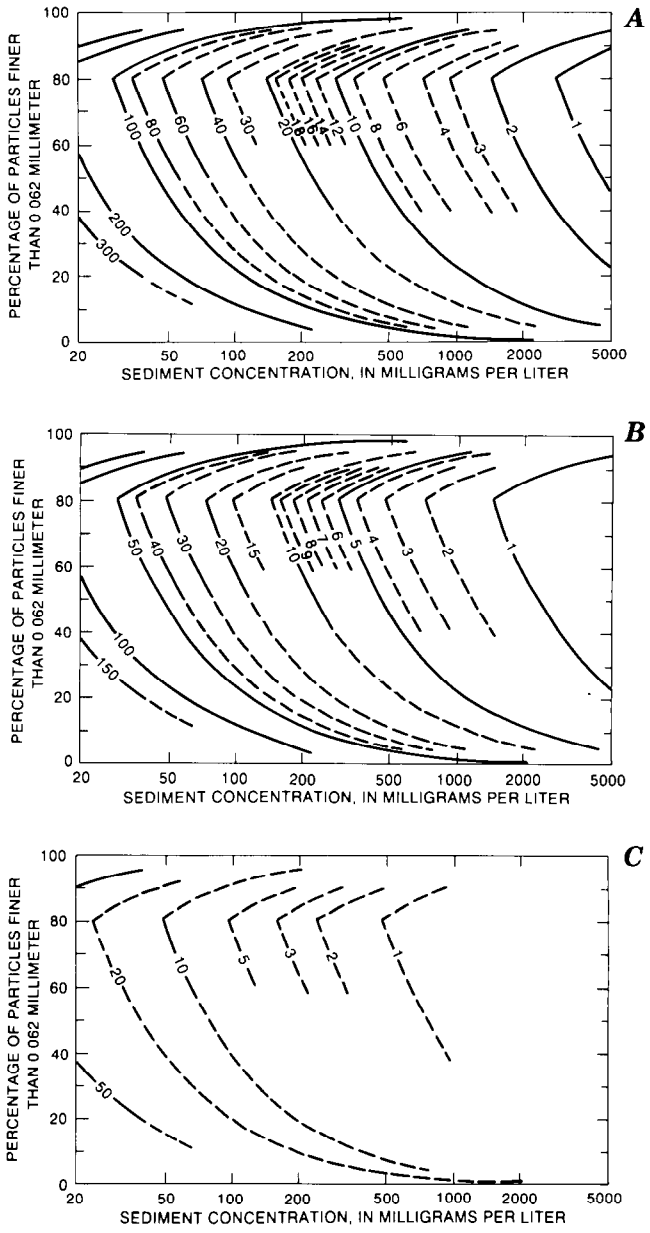

Figure 44. Minimum number of bottles containing optimum sample volume needed to yield sufficient sediment for size analysis (from Porterfield, 1972). *A*, Pint bottles each containing 400 milliliters with 1.0 gram of sediment. *B*, Quart bottles each containing 800 milliliters with 2.0 grams of sediment. *C*, Three-liter bottles each containing 2,400 milliliters with 3.0 grams of sediment.

Sample Integrity

Every sample taken by a field person should be, as previously indicated, the best sample possible considering the stream conditions, the available equipment, and the time available for sampling. Because sampling errors on sand-bed streams frequently occur in the dune regime where the nozzle of the sampler can

accidentally pick up sand from the downstream side of a dune, each sample bottle must be inspected in the field immediately after removing it from the sampler. The cost of the field and laboratory work, to say nothing of the embarrassment of a bad record, is sufficient incentive to make this simple check and, if necessary, to collect another sample.

After the first bottle is taken, it can be checked by swirling the contents of the bottle, then holding the bottle where the sand on the bottom can be seen moving. A mental note is made of the quantity of sand contained in the bottle. The second and remaining bottles then can be examined and compared with the previous bottles. Any vertical or verticals where a bottle or bottles contain a significantly different quantity of medium and coarse sand should be carefully resampled. If the check sample also contains a noticeably different amount of sand in comparison to others in the set, retain both bottles and note that the high or low concentration of sand is consistent at the vertical or verticals in question. If the check sample contains a smaller or more representative amount of sand, or if the quantity of sand is different from the first but still not normal, it may be desirable to wait several minutes to take a third bottle on the assumption that the dune face would move beyond the sample vertical. This procedure is qualitative, however, and it must be noted that the extremely high errors are more likely to be detected by this method than are small errors.

A more subtle error in sample concentration may occur when a bottle is overfilled. This error also results in too high a concentration, possibly caused by overfilling the sample bottle. Such a sample should be discarded and another sample obtained using an increased transit rate. If the transit rate or the nozzle must be changed to avoid overfilling during an EWI measurement, then it is best to discard any previous samples and resample in clean bottles. The computations required to make use of an EWI measurement having two transit rates are more costly and error prone than the minor expense of discarding samples.

Sample Identification

Although most of the information needed on sample bottles is indicated by figure 27, other information may be helpful in the laboratory and in records processing. The field person will need to keep the requirements for such processing in mind so that other explanatory notes can be recorded on the sample or inspection sheets (fig. 45). Such notes, some of which have been mentioned previously, may include:

1. Time—Sometimes operations cross zone boundaries or the use of daylight time may cause confusion.
2. Method or location—Routine vertical, EDI, or EWI cross-section sample.
3. Stationing—Is it one location or sampling vertical, or is the sample an accumulation of several verticals at different locations?
4. Unusual sample conditions—Consistent sampling of sand at this location: surface sample or dip sample.
5. Variation of desired technique—Such as change of transit rate, change of sampling vertical location, depth somewhat beyond capacity of instrument, or transit rate may have exceeded 0.4 V_m.
6. Condition of stream—Such as boils noted on water surface, soft dune bed, swift smooth water, braided stream, sandbar in cross section, or slush ice present.
7. Location in the vertical—If a point sampler is used for one-way integration, mention which direction the sampler was moving, the depth dividing the integrated portions, and the total depth.
8. Gage height—Note if the inside or outside gage was used. Note any unusual conditions that may affect the reading.
9. Collector's name.

Sediment-Related Data

Water Temperature

Water-temperature data may seem unimportant in comparison with the sediment data. However, it has a growing list of uses besides the need to help evaluate the sediment-transport characteristics of the stream. The temperature or viscosity of the flow affects sediment suspension and deposition and may affect the roughness of a sand-bed stream.

The best or preferred method to obtain the correct water temperature is to submerge the thermometer while wading some distance out in the stream. The thermometer is held beneath the water for sufficient time (about one-half minute) to allow the temperature of the thermometer to equalize with the water temperature. The stem or the scale of the thermometer is raised out of the water and held so that the etched scale

Figure 45. Example of inspection sheet for use by field person to record the kinds of measurements made and the stream conditions observed during a visit to a sediment-measurement site.

on the stem is at right angles to the line of sight; the temperature then should be read to the nearest one-half degree. The bulb of the thermometer should always remain in the water until after the reading is obtained. The reading of a wet thermometer when exposed to the air may decrease several degrees in a matter of seconds because of evaporation, if the air is dry, or the wind is blowing. Be certain that the location in the stream where the temperature is taken is not affected by the inflow from a spring or tributary.

When it is not possible to wade out into a stream, the water temperature may be taken from a sample bottle. The thermometer should be inserted first into a bottle from near midstream to let the thermometer adjust to the approximate temperature. Then, immediately after removing the next bottle from the sampler, transfer the thermometer from the previous bottle and allow about 15 seconds for the temperature to stabilize. The thermometer should be read while the bulb of the thermometer is submerged. When removing the thermometer from a bottle, lift the thermometer about 2 inches from the bottom and shake slightly to remove sediment from the case of the thermometer. Most freshwaters freeze at 0°C; therefore, if a negative reading is obtained, an error is indicated. Brackish and brine waters freeze at temperatures somewhat less than 0°C, depending on the kind and concentration of ions present.

Stream Stage

As with temperature, stream-stage data may seem insignificant but in reality can be very important. The data may be used to construct missing gage-height records for periods of recorder failure or to verify time of sampling. Gage heights also may serve to indicate whether the observer actually obtained a sample at the time and in the manner indicated by available notes.

Remember that the gage height is defined as the water-surface elevation referred to some arbitrary gage datum. For the gage height to be considered correct, the observer or field person should always note which gage is read. The streamflow and sediment records are computed on the basis of the inside or recording gage. The observer is usually instructed to read only the outside or reference gage. Because of differences in location and the effect of velocity head, it is not expected that both gages will read the same at a given time, although some relation may exist between them as the stage changes (Buchanan and Somers, 1968; Carter and Davidian, 1968). The field person should record all stream-stage information on the inspection sheet (fig. 45).

The outside reference gage may be one of two types. The most common of those exposed continuously to the flowing stream are the staff gage and the slope gage. Under turbulent flow conditions, these exposed gages should be read by noting the average of several high and low readings made within a period of 10 or 15 seconds. It is necessary to make certain that the observers understand that the scale is divided into hundredths of a foot and not feet, inches, and fractions of an inch, and that they understand the divisions of the metric system if that is used. The other type of outside gage is the wire-weight gage or chain gage that is usually attached to a bridge railing. The weight from this type of gage is lowered so that its bottom breaks the water surface about one-half the time when there are water waves or ripples. For the wire-weight gage, the gage height is read on the scale of the drum at the pointer. For the chain gage, the reading is obtained by reference to the scale provided.

The inside gage height is usually referenced by tape from a float in a stilling well to a pointer. The stilling well is connected hydraulically to the flow of the stream. The inside reference gage should correspond to the gage height being recorded, but, as mentioned previously, it may vary somewhat from the outside gage. If the variance between inside and outside gages is unusually large and the inside gage is lagging the actual gage height of the stream, the intake should be flushed to remove any obstruction caused by sediment accumulation.

The field person should record the inside gage reading at least once each visit to ensure that the gage is working properly. Also, if the observer uses the outside gage, the field person should record the readings from both the outside and the inside gages.

Cold-Weather Sampling

Subfreezing temperatures can cause surface ice, frazil ice, and anchor ice to form on or in a stream and create many difficulties with regard to suspended-sediment sampling. The surface ice usually forms at the edges of the stream first and covers the midstream part last. If it is necessary to use surface ice for support to make holes for sampling, extreme caution should be exercised because the strength of such ice can be deceiving, especially if weakened during alternating

freezing and warm periods. If these auger holes are to be reused later, a cover of wood or some other low-cost insulating material can be used to protect them from refreezing. However, it should be realized that covers of this type may be lost if the weather warms sufficiently for the ice to break up. In some cases (to avoid walking out on the ice or if a warming trend is expected), it may be possible to prevent loss by attaching the cover to a line or to the sampler cable to allow its easy removal. If the sampler cable is used for this purpose, however, the sampler should be secured to or removed from the sampler shelter to avoid its loss by falling through the open bottom of the shelter. Suspended-sediment samplers should never be used to break through seemingly thin ice by dropping the sampler more than 3 or 4 inches because the sampler and nozzle can be damaged by the force of the drop. If the ice will not break by the sheer weight or very gentle drop of the sampler, a hole must be opened by some other means.

If the ice is too thin to safely support a person's weight, it is best not to obtain a sample for 1 or more days because winter samples are generally low in sediment concentration and are, therefore, most certainly not worth the chance of an accident. When the spring breakup occurs, the large slabs of floating ice can easily cause damage to the sampler or the support equipment or injure the operator. Under these conditions, a surface sample may be all that can be obtained between cakes of floating ice. Every effort should be made to obtain such a surface sample because the sediment concentration can, and usually does, change considerably under such conditions.

Frazil ice is composed of the small ice crystals formed at the surface in the turbulent part of the stream. The crystals are formed in a variety of shapes, from slender needles to flat flakes. They do not freeze together because of the swift current, but may bunch together to form a soft mass. This kind of ice may partly or completely clog the intake nozzle of the sampler. Sampling may be best accomplished by moving the sampler swiftly through the layer of frazil ice and then using a normal transit rate to sample the relatively ice-free region below. Often when such ice obstructs the nozzle, it will remove itself when the sampler is brought out of the water, and the only indication that the sample is in error would be that the quantity of water in the bottle is significantly less than would be expected under normal circumstances.

Anchor ice is formed on the bottom of shallow streams by radiation of heat during the colder nighttime hours. Incoming radiation and the warmer temperatures during the day allow this ice to break loose from the bottom and float to the top to mix with the frazil ice. Sometimes, when the nozzle contains frazil or small pieces of anchor ice as the sampler is brought out of the water, a subfreezing air temperature will cause the ice to freeze tight in the nozzle. If the ice freezes tight to the nozzle or if the sample bottle freezes to the sampler casing, it will be necessary to heat the sampler, by using the heater in the field vehicle, soaking the sampler in a container of warm water, or heating the nozzle and sampler head with a small propane torch. Care must be taken when employing the torch method because the gaskets in the sampler head and plastic nozzles can be damaged by the open flame. Some of these problems can be avoided by the use of two samplers; while one is thawing, the other can be used to sample.

If the sampler or samplers are kept beneath the heater in the field vehicle while the observer drives to the station or from one station to another, the first one or two verticals can be more easily sampled. The observer should be advised and encouraged to remove the nozzle from the sampler and leave the sampler head in the open position after completing the sampling. This will allow the gasket, nozzle, and air vent to dry more completely and may avoid a frozen sampler nozzle or sampler head frozen shut on the next visit.

Aside from the problems with plugged sampler nozzles, a very cold sampler may cause freezing of water between the sample bottle and the inside of the sampler. This problem can be minimized by removing the bottle as quickly as possible from the sampler after the integration is complete; otherwise, it may be necessary to heat the sampler as described above. It also should be obvious that samples in glass bottles must be protected from freezing after the measurement and during transport to the laboratory. Freezing itself does not harm a sample for sediment analysis, but a broken bottle will obviously result in loss of the sample.

If an extensive sampling program is to be carried out during the winter months in areas of extreme cold, it is advisable for the investigator to obtain DH-75 and D-77 samplers. These samplers are designed to be used in freezing conditions, as previously discussed. Several sample bottles and nozzle and cap assemblies can be taken to the site, where they can be easily changed if nozzle or air-exhaust freezeups occur during sampling.

Bed-Material Sampling

Data on the size of material making up the streambed (across the entire channel, including flood plains) are essential for the study of the long-range changes in channel conditions and for computations of unmeasured or total load.

Materials Finer Than Medium Gravel

Selection of a suitable bed-material sampler is dependent on the size of bed material to be sampled, and on stream depth and velocity. When a stream can be waded, the most practical of the standard samplers is the BMH-53 or BMH-80 (figs. 15 and 17). When sampling from a boat, these samplers can be used to depths of about 4 feet.

In use, the BMH-53 is placed in a vertical position on the streambed with the piston extended to the open end of the cylinder. The cylinder then is pushed a full 8 inches into the bed while the piston is held at the bed surface. Complete filling of the cylinder will help ensure a minimum of disturbance of the top 1 or 2 inches when the sampler is raised through the flow. When coarse sand or gravel material is being sampled, it is often necessary to pull on the piston rod while pushing on the cylinder. By pulling on the piston, a partial vacuum is created above the sample, which helps draw the sample into the cylinder. The sampler then is withdrawn from the bed and held in an inclined position above the water with the cylinder end highest. For most purposes, only the upper inch of material nearest the surface of the streambed is desired or needed in an analysis. This is obtained by pushing on the piston while the sampler is still inclined until only 1 inch of material remains in the tube. Any excess material is removed by smoothing off the end of the cylinder with a spatula or a straight pencil. The material left in the sampler is ejected into a container (usually a paper or plastic carton). An experienced field person can composite samples from the entire cross section into just a few cartons. The inexperienced field person would do well to use a separate container for each vertical. Before storing the sampler, it should be rinsed by stroking the piston a few times in the stream to remove sediment particles from the cylinder and piston seal.

The BMH-80 is used in a manner similar to that of the BMH-53. The sampler is extended to the streambed with the bucket in the open position. After the sampler contacts the bed material, the field person should keep a firm downward pressure on the sampler while closing the sample bucket, thus trapping a shallow sample of the streambed. This sampling procedure should be repeated until the streambed has been representatively sampled.

If the stream is too deep or swift for the BMH-53 or BMH-80, the BMH-60 or the BM-54 can be used. The 30-pound BMH-60 is easiest to use when stream velocities are under 2 or 3 ft/s and depths are less than about 10 feet. To use the BMH-60, suspend the entire weight of the sampler by the hanger rod and cock the bucket in the open position with the allen wrench provided. The energy thus imparted to the spring and the sharp edge of the bucket make it obvious that one must keep hands away from the bucket opening at all times. If necessary, the safety yoke may be fastened around the hanger bar while opening and cocking the bucket. After the safety yoke is removed and fastened to the tail, the sampler then can be lowered by hand or by cable and reel to the surface of the streambed. Any jerking motions made while lowering the sampler that would cause the cable to slack may release the catch and allow the bucket to close prematurely. This can happen if the water surface is struck too hard. After the cocked sampler touches the streambed and tension is released on the line, the sampler should be lifted slowly from the bed so the bucket will scoop a sample.

To remove the sample from the bucket, a carton or container is positioned under the sampler, and the bucket is opened with the allen wrench. The sampler need not be held by the hanger bar during sample removal unless considerable material is clinging to the flat plate within the bucket cavity. If removal of such material is required, the bucket should be cocked in the open position and the sample brushed into the container with a stick or small brush. When moving the sampler between verticals and when storing it in the vehicle, the bucket should be in the closed position to avoid an accidental closing and to reduce the tension on the spring. If the bucket is closed for transport as suggested, a stick, a piece of tire, or similar material should be used to cushion the force of the bucket when it is closed because the closing force is sometimes great enough to break welded joints in the mechanism (J.V. Skinner, Federal Inter-Agency Sedimentation Project, written commun., 1985).

The 100-pound BM-54 is used when velocities are greater than 2 or 3 ft/s and depths are greater than 10 feet. The BM-54 sampling action, described

previously, is similar to the BMH-60, except that the bucket opens front to back. It is used only with a cable-and-reel suspension and is rather awkward to handle when removing the sample. The techniques for taking a sample with the BM-54 are essentially the same as for the BMH-60. One important difference in operation is the use of a safety bar on the BM-54 to hold the bucket in an open position instead of the safety yoke as on the BMH-60. As noted earlier, the sampler should be stored with the bucket in a closed position and, if extended storage is anticipated, the tension on the spring should be further reduced.

A BM-54 can be used in extremely high velocities if a C-type weight is attached to the hanger bar above the sampler. If additional weights are required with the BM-54, extreme care should be taken to avoid bending and possibly breaking the hanger bar between the sampler and the C-type weight.

Personnel of F.I.S.P. have developed a heavy bed-material sampler (the BM-84, which weighs about 160 pounds). The P-61 point-integration sampler body is used to provide a large mass. The streamlined body configuration is fitted with a spring-driven sample scoop that is activated by a solenoid system similar to that used on point samplers. Otherwise, the sampler is similar to, and performs the same function as, the BM-54. The design is an attempt to cope with bed-material sampling problems encountered in the vicinity of Mount St. Helens volcano (J.V. Skinner, Federal Inter-Agency Sedimentation Project, oral commun., 1984). The weight of this configuration is increased by filling void space within the sampler body to increase the cross-sectional density of the sampler, thus increasing its stability in deep, high velocity conditions.

As previously discussed, other sampling equipment is available commercially—for example, the ponar sampler and core samplers, such as the vibra-core unit and gravity corer. These samplers can be very useful; however, careful planning of the proposed sampling project and analytical methods is essential to obtaining a representative sample and reliable data.

Materials Coarser Than Medium Gravel

Gravels in the 2- to 16-mm range can be analyzed by mechanical dry sieving; in order to obtain a representative particle-size distribution, the size of the sample to be collected must be increased with particle size. Large sediment sizes (>16 mm) are difficult both to collect and to analyze. The method now used for size determination of these very large particles involves a pebble count, in which at least 100 pebbles from a wadable streambed are manually collected and measured. A fixed grid pattern locating the sampling points can be paced, outlined by surveys, or designated by small floats. At the intersections of the fixed grid pattern, the pebble underlying the field person's toe is retrieved, and a measurement is made of the long, intermediate, or short diameters, or all three. The measurements are tabulated as to size interval, and the percentage of the total of each interval then is determined (Wolman, 1954).

Because the pebble-count method entails the measurement of the dimensions of randomly selected particles in the field, it is laborious and usually limits the number of particles counted. Too often this results in an inadequate sample of the population,

Another method for analyzing coarse particles involves the use of an instrument known as the Zeiss Particle Size Analyzer (Ritter and Helley, 1968). For the Zeiss technique, a photograph of the streambed is made during low flow with a 35-mm camera supported by a tripod about 2 meters above the streambed—the height depends on the size of the bed material. A reference scale, such as a steel tape or surveyor's rod, must appear near the center of the photograph to provide a size reference.

In the laboratory, particle diameters are registered cumulatively or individually on exponential or linear scales of size ranges (Guy, 1969). After the data are tabulated, the sizes registered on the counter of the particle-size analyzer must be multiplied by the reduction factor of the photograph, which is calculated from the reference scale in the photograph.

In nonwadable streams, a pipe dredge is useful in sampling these large particles. However, this method entails the use of equipment capable of handling extremely heavy loads and requires special attention to safety during operation.

Location and Number of Sampling Verticals

Bed-material samples are often collected in conjunction with a discharge measurement and (or) a set of suspended-sediment samples. If the discharge measurement and (or) the suspended samples are taken first, the bed-material samples should be collected at the same stations, but not necessarily from the same number of stations. By taking them at the same stationing points, any change in bed material or

radical change in discharge across the stream that would affect the sediment-discharge computations can be accounted for by subdividing the stream cross section at one or between two of the common verticals.

To avoid collection of bed-material samples from an excessively disturbed streambed, it is best to obtain the bed-material samples prior to making other measurements, especially in wadable streams. Also, by taking the bed material first, radical changes across the section in bed-material size and water discharge can be used as a basis for choosing desirable verticals for other measurements.

Most results from bed-material samples will not be noticeably affected, but it should be remembered that the sample taken with the BMH-53 or other core sampler is different from that taken with the BMH-60, BMH-80, and the BM-54. The cross section of the BMH-53 or other core sampler is constant with depth so that each increment of sample with depth is equally represented by volume. The curved buckets of the BMH-80, BMH-60, and BM-54 do not sample equal volumes of material with depth; instead, the bottom one-half inch of the 2-inch-deep bucket contains only 15 percent of the total sample, whereas the upper one-half inch contains 33 percent of the sample.

The number and location of bed-material samples required at a cross section must be adequate to provide a representative statistical population. This population should include samples collected from the entire cross section. To obtain this population, the logical procedure is to use the results from a rather detailed set of 10 to 20 uniformly spaced bed-material samples taken from the cross section. Some studies may require that flood-plain deposits be represented in the bed-material sampling scheme to get a representative population.

Sample Inspection and Labeling

As samples are obtained across the stream, the field person should visually check and compare each sample with the previous samples to see if the material varies considerably in size from one location to the next. Samples of different sizes and (or) weight should not be composited. If a given sample does contain considerable coarser or finer material, another sample should be obtained about a foot from the original location. If, after two or three tries in the vicinity of the first sample, no appreciable difference is noted, the first sample should be retained. Small deposits of material that are coarser or finer than most of the bed material are not considered representative of the bed-material size for the stream cross section.

Proper labeling of bed-material samples is not only necessary for future identification but also provides important information useful in the laboratory analysis and the preparation of records. Information desired on each bed-material sample carton should include:

Station Name
Date
Time
Gage height
Water temperature
Stationing number
Bed form and flow conditions
Carton number of the set
Kind of sampler used
Purpose of sample or special instructions for analysis and computations
Initials of field person

Bedload Sampling Technique

The sediment moving in the unsampled zone (see fig. 1) comprises suspended sediment and bedload. Bedload is the sediment that moves by sliding, rolling, or bouncing along on or within a few grain diameters of the streambed.

Although many investigations have provided extensive knowledge in the areas of how bedload moves in a channel and how pressure-differential bedload samplers operate, a great deal more work in these areas is needed. The following paragraph, taken from Hubbell (1964, p. 2), is still appropriate:

> In the past, attempts have been made to determine the bedload discharge in three general ways: by direct measurement with some type of apparatus, by definition of physical relations from which the bedload could be estimated, and by quantitative measurements of the results of some sedimentation process such as erosion or deposition. Unfortunately, direct-measuring apparatus have been useful for only a very limited range of sediment and hydraulic conditions; the definition of physical relations has not been complete enough to estimate precisely the bedload discharge; and the quantitative measurements have supplied information only on the characteristics of the reach that was studied. As a result, no single apparatus or procedure, whether theoretical or empirical, has been universally accepted as completely adequate for the determination of bedload discharge over the wide range of sediment and hydraulic conditions in nature.

Despite these difficulties, the hydrologist often is called upon to provide estimates of bedload transport from measurements. The purpose of this section is not only to outline instructions governing the collection of bedload samples, but also to present a discussion of variations in bedload-discharge rate, the problems involved in collecting samples, and considerations in the design and development of a sampling program to define bedload movement.

Bedload discharge can be extremely variable. Variations can occur both spatially and temporally during steady-flow conditions, as well as with changes in stream discharge. In order to collect a sample that represents the mean bedload-discharge rate, all variations must be taken into account.

Even for constant flow conditions, the temporal variation of bedload transport rates at a given point in a cross section is quite large. When dunes are present, bedload discharges are zero, or near zero, in the troughs, increase progressively along the upstream side of the dune, and are maximum at the crest. Even in streams with gravel beds, the bedload appears to move in cycles or slugs (Emmett, 1981). These variations have been measured in the laboratory flume by Hubbell and others (1981) and in the field by Emmett (1975) and Carey (1985) (fig. 46).

Temporal variation in sampled bedload rates collected at steady-flow conditions at a single vertical are primarily dependent on the ratio of sampling time to the time it takes one dune, cycle, or slug to pass by

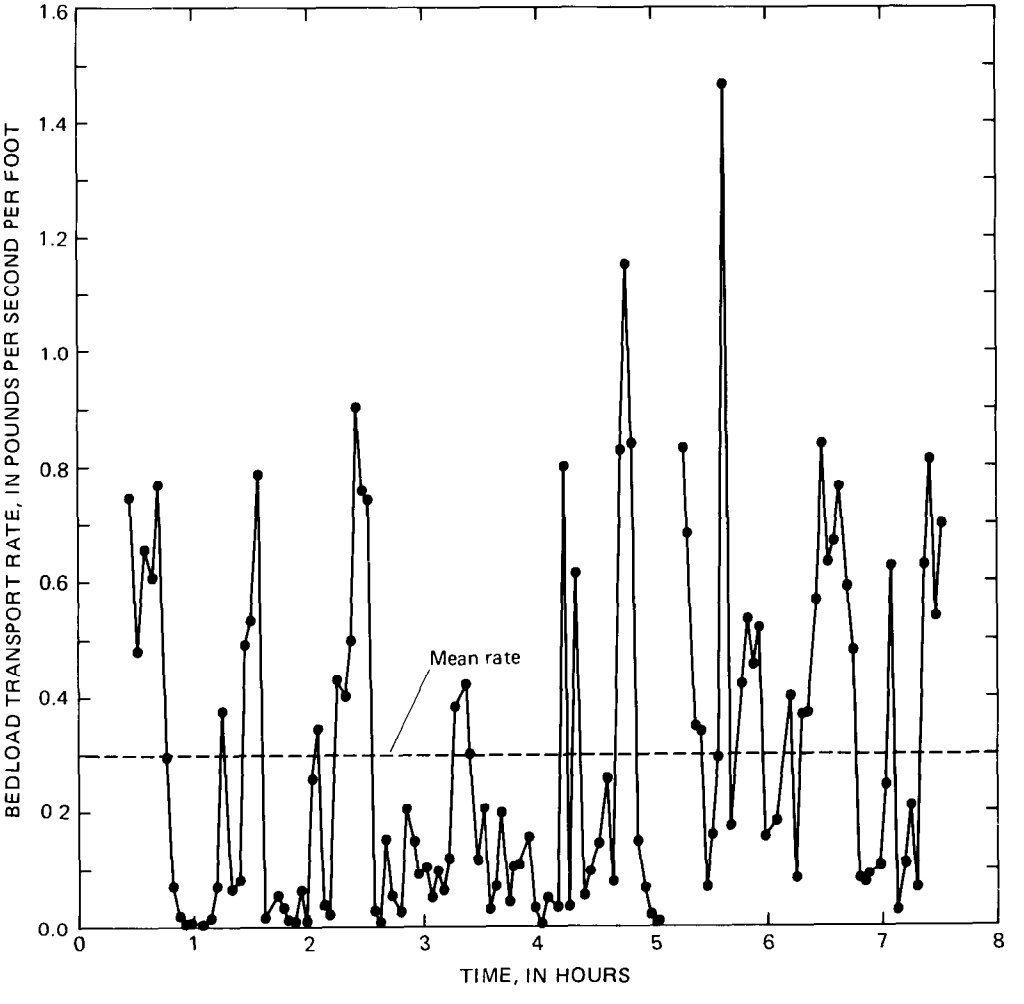

Figure 46. Temporal variation of bedload transport rates for 120 consecutive bedload samples from a stream with constant water discharge (Carey, 1985).

the sampling point. Obviously, if the sampling time were equal to the cycle period or several times greater than the cycle period, the temporal variation at a single sampling point would be small. However, as the sample time becomes less with respect to the cycle time, the temporal variation can become quite large.

Einstein (1937) and Hamamori (1962) both developed theoretical distributions to describe the temporal distribution of bedload transport rates at a vertical. Einstein based his distribution on the assumption that bedload particles move in a random series of steps and rests, with the particles generally resting a much longer period of time than they are moving. Hamamori's distribution was derived to define the temporal variation when dunes are present on the bed. Figure 47 shows a comparison of Einstein's and Hamamori's distributions. Einstein's T is defined as the nondimensional sampling time measured in terms of the average rest period. Einstein's T = 2 distribution (sample time equals the length of two average rest periods) and Hamamori's distribution are nearly identical. As T increases (sampling-time increases), the two theoretical distributions depart from one another, and Einstein's distribution indicates reduced variability.

The temporal variations in bedload transport rates measured by Carey (1985) at a single vertical in a sand-bed stream in Tennessee are shown in figure 46. The cumulative probability distribution of bedload discharges measured by Carey fit the theoretical distribution developed by Hamamori. As indicated in the figure, even for a constant flow condition, the rate determined from a sample taken from a single vertical at a point in time may differ considerably from the mean bedload discharge at that vertical. This extreme temporal variability in bedload transport rates has been known since at least 1931 (Hubbell, 1964).

The spatial or cross-channel variation in bedload discharge is usually significant. Typically, bedload transport rates vary from zero or small near banks through larger values toward midstream. The mean cross-channel distribution of bedload discharge may vary uniformly (fig. 48*A*), may be uniformly consistent (fig. 48*B*), may be erratic with varying tendencies (fig. 48*C*), or may be an unpredictable combination of varying tendencies (fig. 48*D*). Each river is likely to have a unique combination; adjacent reaches of the same river may have different configurations, and these configurations are likely to change

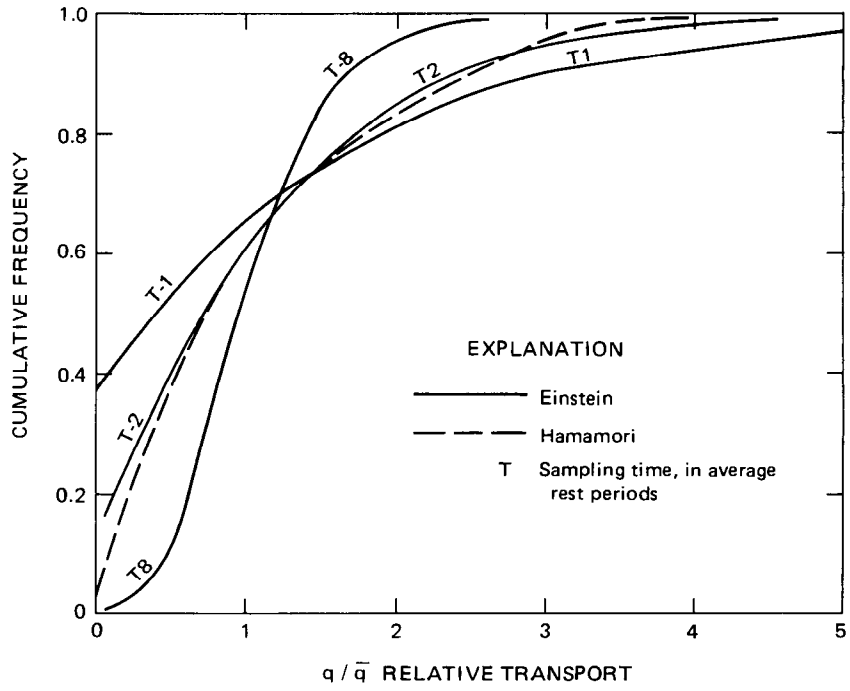

Figure 47. Comparison of cumulative probability distributions of bedload transport rates predicted by Einstein (1937) and Hamamori (1962) (D.G. McLean, University of British Columbia, written commun., 1986).

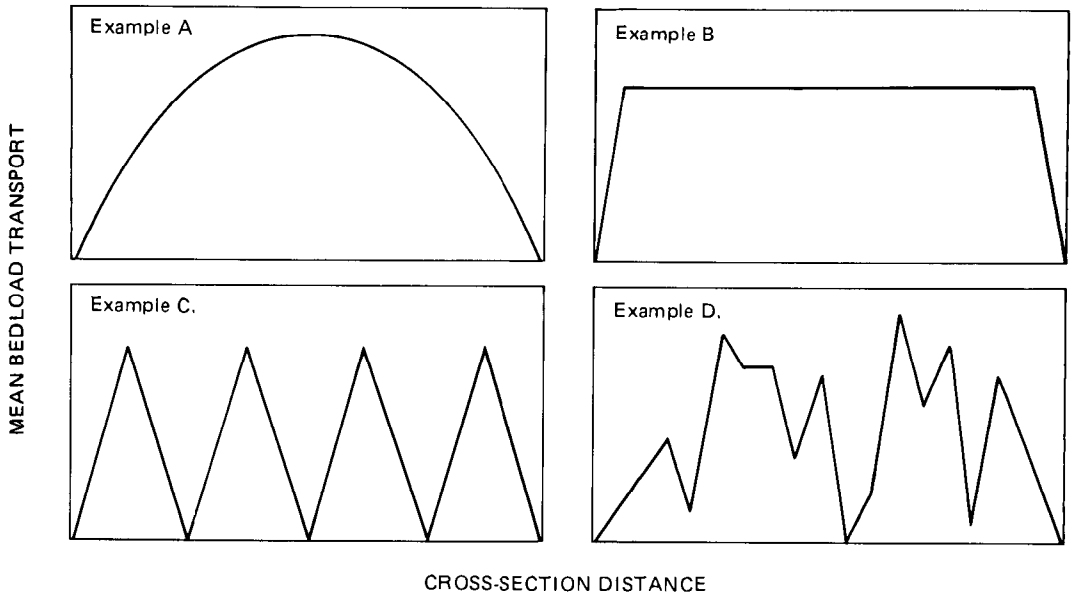

Figure 48. Examples of possible distribution of mean bedload transport rates in a cross section. *A*, Discharge varies uniformly. *B*, Discharge is uniformly consistent. *C*, Discharge is erratic with varying tendencies. *D*, Discharge is an unpredictable combination of varying tendencies.

with changing flow conditions (stages). There is little proven basis for predicting spatial variability.

The temporal and spatial variations in transport rates of bedload discharge that occur under steady-flow conditions are amplified when the stage changes rapidly. Because of these temporal and spatial variations, many samples have to be collected at many verticals in the cross section to ensure an accurate estimate of the mean bedload discharge. The samples also would have to be collected over a short enough period of time to avoid any change in transport rates due to changing stage. In most field sampling programs, the number of samples collected must represent and compromise between accuracy and economic or physical feasibility.

Another major problem encountered in bedload sampling is that of collecting a representative sample. To collect a representative sample, the sampler must (1) trap, during the sampling period, all bedload particles that would normally have passed through the width occupied by the sampler; and (2) reject all particles that normally would not have passed through the width during the same period. The degree to which this is accomplished is termed the "sampling efficiency," which is defined as the ratio of the mass of bedload collected to mass of bedload that would have passed through the sampler width in the same time period had the sampler not been there (Hubbell, 1964). For perfect representative sampling, the sampling efficiency should be 1.0 (or 100 percent) for all sizes of bedload particles in transport at the sampling point during the sampling period.

Currently, the most commonly used bedload sampler is the Helley-Smith sampler (see page 25 for discussion of recommended samplers). Over 3,000 of these samplers have been placed in use since the model was introduced in the early 1970's. It should be understood that the Helley-Smith is not a true bedload sampler because it collects some particles moving in suspension. As previously noted, bedload moves on or very near the streambed. Depending on the size of the unsampled zone, the Helley-Smith has the potential to collect a sample from the entire unsampled zone. Even if the Helley-Smith sampler has a sampling efficiency of 1.0, the total sediment discharge cannot necessarily be calculated by simply summing the measured suspended-sediment discharge and the measured bedload discharge. Figure 49 shows the percent error involved in computing total sediment discharge for a particular size range by summing the measured suspended-sediment discharge (Q_{sm}) and the bedload discharge measured with a Helley-Smith sampler (D) for that particular size range.

In order to make bedload sampling practical, methods must be used that minimize the number of samples required to obtain a reasonable estimate of the mean cross-sectional bedload discharge. Field

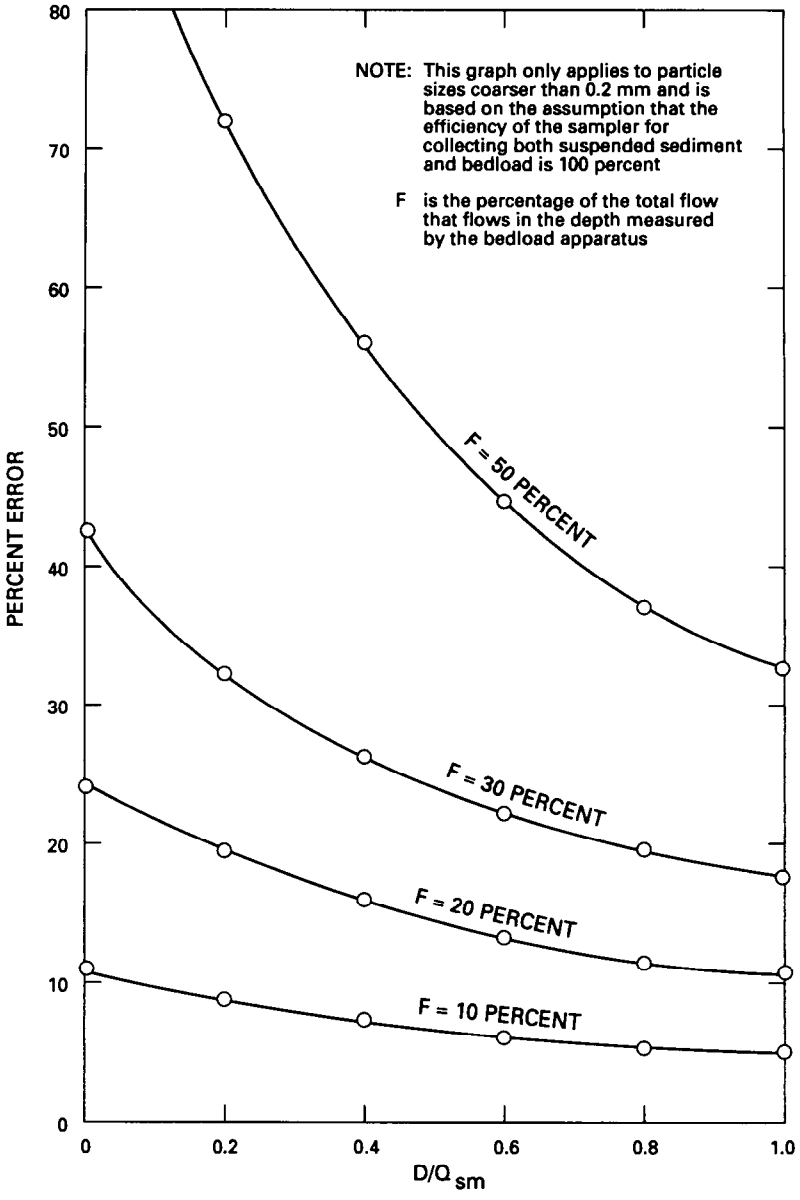

Figure 49. Percent error due to computing total sediment discharge of a size range by summing measured suspended-sediment discharge (Q_{sm}) and bedload discharge measured with a Helley-Smith sampler (D).

experience has shown that the collection of about 40 individual bedload transport rate measurements per cross-section sample is, in most cases, practical and economically feasible (Emmett, 1980a). The following general methods can be used to collect the samples.

(1) Starting at one bank and proceeding to the other, collect one sample per vertical at 20 evenly spaced verticals in the cross section, return to the bank, and repeat the process. We will refer to this method as the single equal-width-increment (SEWI) method (fig. 50). The time the sampler is left on the bottom should be equal for all verticals in a given cross section. The time the sampler is left on the bottom need not be the same for both cross sections collected. This procedure was first introduced by Emmett (1980a) and is widely used. The samples are collected at the midpoint of the evenly spaced increments. Samples collected in this manner can be composited for analytical purposes; however, a better understanding of the local bedload transport characteristics is gained if each vertical sample is analyzed individually.

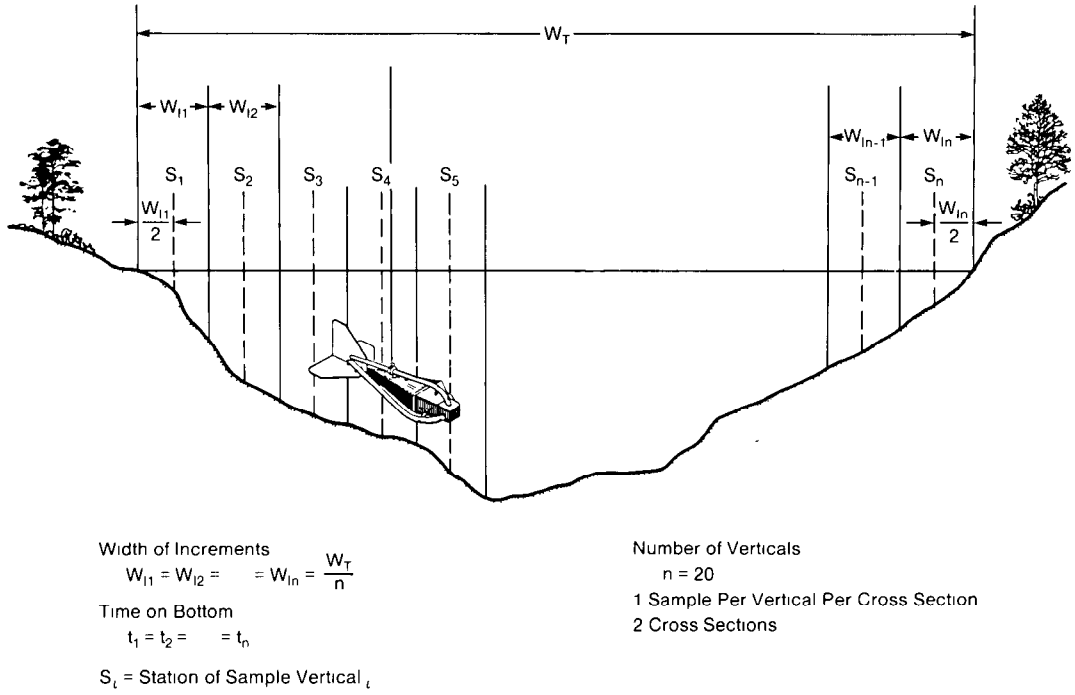

Figure 50. Single equal-width-increment bedload-sampling method.

(2) Starting at one bank and proceeding to the other, collect one sample at 4 or more evenly spaced verticals, return to the starting bank, and repeat the process multiple times until a total of 40 samples is collected. We will refer to this method as the multiple equal-width-increment (MEWI) method (fig. 51). If the sample collected at each vertical is bagged separately, the time the sampler is left on the bottom need not be equal at all verticals. If samples collected in a cross section are to be composited, sample times at each vertical in the cross section must be equal. As in the SEWI method, samples are collected at the midpoint of the evenly spaced increments.

(3) Starting at one bank and proceeding to the other, collect one sample from 4 or more unevenly spaced verticals, return to the starting bank, and repeat the process until a minimum of 40 samples is collected. We will refer to this method as the unequal-width-increment (UWI) method (fig. 52). This method requires some prior knowledge of the depths and velocities across the section. The selection of where to place the verticals in the UWI method depends, to a certain extent, on which method is to be used to calculate the bedload discharge. If the midsection method is used (see "Computation of Bedload-Discharge Measurements" section for explanation of calculation methods), the sampling verticals should be spaced unevenly in an attempt to delineate equal portions of the cross-section bedload discharge. To the extent possible, samples should be collected midway between breaks in the lateral bed slope and closer together in segments of high velocity and changing lateral bed slope. If the mean-section method is used to calculate the bedload discharge, sample verticals should be placed at the break points in the lateral cross-sectional distribution curve of mean bedload transport rate where the rate changes from one trend to another (that is, break in slope). At most sections, the lateral distribution in mean rates, once defined, can be related to velocity and lateral bed topography.

To quantify the approximate magnitude of sampling errors that could result from various sampling situations, Hubbell and Stevens (1986) developed a bedload transport simulation model. They used Hamamori's (1962) distribution to simulate temporal variations at the equally spaced sampling verticals and assumed that the sampler used had a 100-percent sampling efficiency. The results of test runs using two different spatial variations are shown in figure 53. In the first case, the lateral distribution of mean bedload transport rates is fairly uniform across the cross section and, in the second case, it is skewed. If these results were used to estimate maximum possible error for using the SEWI and MEWI methods, in the first

case, the MEWI method would give a lower maximum possible error (35 percent) than would the SEWI method (50 percent). In the second case, however, using the SEWI method would result in a maximum error of 80 percent and using the MEWI method would result in a maximum error of 120 percent. The maximum probable error with the UWI method cannot be evaluated from figure 53.

From the previous discussion, it is obvious that no one method works best in all situations and that no one standard sampling protocol can be used at all stations. This should come as no surprise. There are two acceptable methods for collecting suspended-sediment samples (EWI and EDI). Both work equally as well as the other but are better suited to different stream conditions and cross-sectional sediment distributions. Likewise, a unique sampling protocol must be derived for each site at which bedload-discharge data are to be collected. Probably the best way to start sampling at a site is to do multiple sets of complete SEWI and MEWI or UWI measurements each time the site is visited and over as many flow ranges as possible. Unfortunately, human resources and budget restrictions, as well as hydrologic conditions, may prevent multiple or even single SEWI, MEWI, or UWI type cross-sectional measurements. If it is not possible or feasible to collect full SEWI, MEWI, and (or) UWI type samples, the approach listed below can be used as a minimum protocol to follow when first starting to collect bedload data at a site. Caution should be used, however, because the modified SEWI, MEWI, or UWI methods will not supply as much information as would the complete method. Therefore, more sets of samples may be needed to acquire sufficient knowledge of the cross section to design an efficient sampling protocol. (Note: The SEWI method helps define cross-sectional variations in bedload transport rates, whereas the MEWI and UWI methods are more effective in defining temporal variations at individual verticals.)

(1) Using the SEWI method, collect samples at approximately 20 equally spaced verticals in the cross section. The spacing and location of the verticals should be determined by the sampling procedure used in the EWI method. For very wide sections, where large variations in bedload rates are suspected, sampling stations should not be spaced more than 50 feet apart. For narrow cross sections, sampling stations need not be closer than 1 foot apart.

(2) Lower the sampler to the streambed and use a stopwatch to measure the time interval during which the sampler is on the streambed. The sampling-time interval should be the same for each vertical sampled

in the cross section. The time required to collect a proper sample can vary from 5 seconds or less to several hours or more. Generally, a sampling time that does not exceed 60 seconds is preferred. Because of the temporal variations in bedload transport rates, there is no easy way to determine the appropriate sampling time. Several test samples (as many as 10 or more collected sequentially at a vertical with a suspected high transport rate) may be needed in order to estimate the proper sampling-time interval to be used. The sample time should be short enough to allow for the collection of a sample from the section with the highest transport rate, without filling the sample bag more than about 40 percent full. The sample bag may be filled to 40 percent full with sediment coarser than the mesh size of the bag without reducing the hydraulic efficiency of the sampler (Druffel and others, 1976). Sediment that is approximately equal to the mesh size may clog the bag and cause a change in the sampling efficiency of the sampler.

(3) One sample should be collected at each vertical, starting at one bank and proceeding to the other. It is recommended that, during this initial data gathering stage, a minimum of one transect using the SEWI method be used. The samples should be placed in separate bags for individual analysis and labeled with the vertical's station number. They may be composited into one or several sample bags for a composite analysis, but if composited, no information on cross-sectional variability can be obtained from the data.

(4) A second sample should be collected using the UWI or MEWI methods. Four or five verticals should be sampled four or five times each, obtaining a total of 20 samples. Samples should be collected using the same procedure as described in number 2 above, except that the sample time for each sample need not be the same. All samples should be bagged and tagged for separate analysis.

(5) The following data must be recorded on a field note sheet for each cross-section sample:

- Station name/number
- Date
- Cross-section sample starting and ending times
- Gage height at the start and end of sample collection
- Total width of the cross section, including stations on both banks
- Width between verticals (SEWI method)
- Number of verticals sampled (SEWI method)
- Station of verticals sampled (UWI or MEWI method)
- Time sampler was on the bottom at each vertical
- Type sampler used
- Name of person collecting sample

In addition, the following information should be recorded on each sample container:

- Station name
- Date
- Designation of cross-section sample to which the container belongs (that is, if two cross-section samples were collected, one would be "A" and the other "B")
- Number of containers for that cross section (for example, "1 of 2" or "2 of 2")
- Stations(s) of the vertical(s) the sample was collected from
- Time sampler was on the bottom and at the vertical station
- Clock time the sample was collected (start and finish if composite)
- Collector's initials

Analysis of the first transect (SEWI method) will give some indication of the cross-sectional variability if individual verticals are analyzed separately. Analysis of the second set of transects (UWI or MEWI method) will give some indication of temporal variability. As stated before, the procedure described above should be considered the minimum to be followed when first collecting bedload data at a site. Additional samples and transects will help define the temporal and spatial variation at the site for all flow ranges. After a cross section has been sampled several times at different flow ranges using the above procedure, it should be possible to develop a sampling protocol that fits the site better.

Computation of Bedload-Discharge Measurements

The bedload transport rate at a sample vertical may be computed by the equation

$$R_i = \frac{KM_i}{t_i} \qquad (1)$$

where

R_i = bedload transport rate, as measured by bedload sampler, at vertical i, in tons per day per foot;

M_i = mass of the sample collected at vertical i, in grams;

t_i = time the sampler was on the bottom at vertical i, in seconds; and

K = a conversion factor used to convert grams per second per foot into tons per day per foot. It is computed as

$$K = (86{,}400 \text{ seconds/day}) \frac{1 \text{ ton}}{(907{,}200 \text{ grams})} \frac{1 \text{ foot}}{(N_w)} \quad (2)$$

where

N_w is the width of sampler nozzle in feet. (For a 3-inch nozzle, $K = 0.381$; for a 6-inch nozzle, $K = 0.190$.)

The cross-sectional bedload discharge measured by the Helley-Smith sampler may be computed using the total cross-section, midsection, or mean-section method. The simplest method of calculating bedload discharge from a sample collected with a Helley-Smith type bedload sampler is the total cross-section method (fig. 54). This method should only be used if the following three conditions are met:

1. The sample times (t_i) at each vertical are equal.
2. The verticals were evenly spaced across the cross section (that is, SEWI or MEWI method used).
3. The first sample was collected at one-half the sample width from the starting bank.

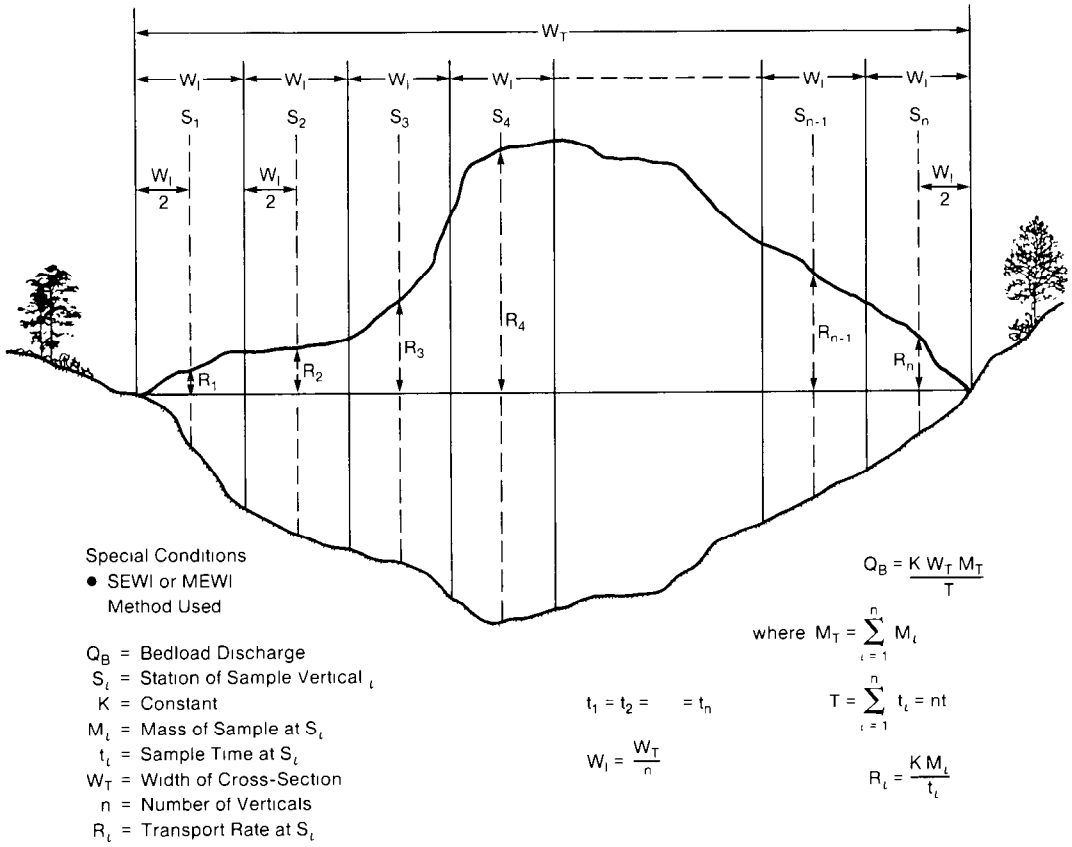

Figure 54. Total cross-section method for computing bedload discharge from samples collected with a Helley-Smith bedload sampler.

If these conditions are met, then

$$Q_B = K\frac{W_T}{t_T}M_T \qquad (3)$$

where

Q_B = bedload discharge, as measured by bedload sampler, in tons per day;

W_T = total width of steam from which samples were collected, in feet, and is equal to the increment width (W_i) times n (n = total number of vertical samples);

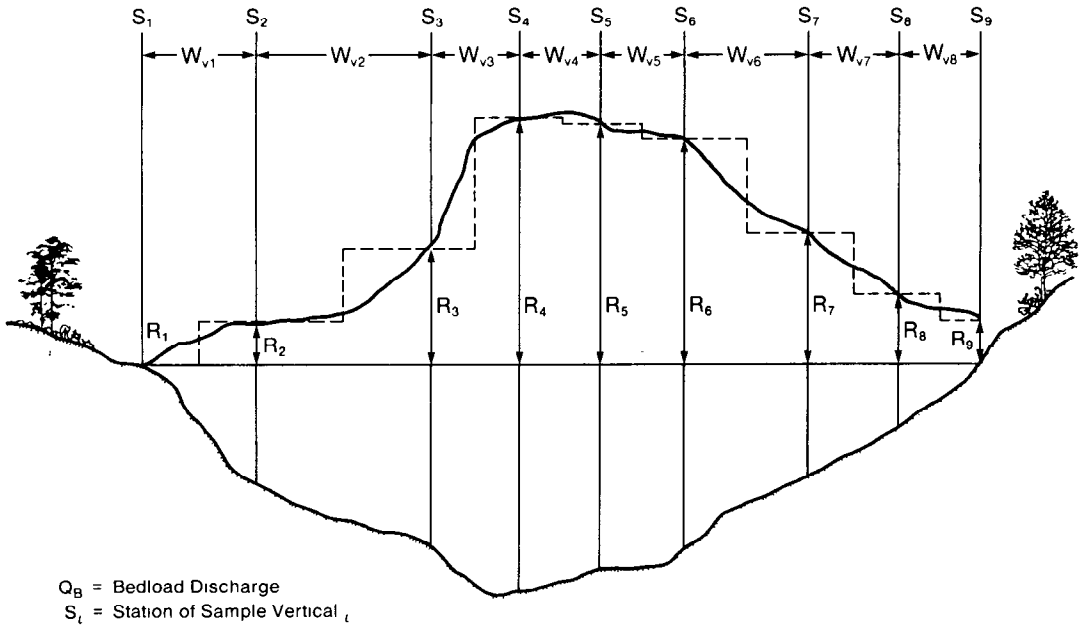
^tT = total time the sampler was on the bed, in seconds, computed by multiplying the individual sample time by n;

M_T = total mass of sample collected from all verticals sampled in the cross section, in grams; and

K = conversion factor as described in equation 2 above.

If any of the three conditions stated above are not met, then either the midsection or mean-section method should be used. Mathematically, the two methods, if used with no modifications, will produce identical answers. However, as indicated under the discussion of the UWI method, the placement of the sampling verticals with respect to breaks in the lateral cross-sectional distribution curve of mean bedload transport rate will somewhat dictate which method should be used. The midsection method (fig. 55) is computed using the following equation:

$$Q_B = \frac{R_1 W_1}{2} + \sum_{i=2}^{n-1} R_i\left[\frac{(S_i - S_{i-1})}{2} + \frac{(S_{i+1} - S_i)}{2}\right] + \frac{R_n W_{n-1}}{2} \qquad (4)$$



Q_B = Bedload Discharge
S_t = Station of Sample Vertical $_t$
R_t = Transport Rate at S_t
K = Constant
M_t = Mass of Sample Collected at S_t
t_t = Sample Time at S_t
n = Number of Verticals
W_{vt} = Width Between Verticals $_t$ and $_{t+1}$

$$Q_B = \frac{R_1 W_{v1}}{2} + \sum_{t=2}^{n-1} R_t\left[\frac{(S_t - S_{t-1})}{2} + \frac{(S_{t+1} - S_t)}{2}\right] + \frac{R_n W_{vn-1}}{2}$$

$$= \frac{K}{2}\left[\frac{M_1}{t_1}W_{v1} + \frac{M_n}{t_n}W_{vn-1} + \sum_{t=2}^{n-1}\frac{M_t}{t_t}(S_{t+1} - S_{t-1})\right]$$

Figure 55. Midsection method for computing bedload discharge from samples collected with a Helley-Smith bedload sampler.

where

W_i = width between sampling verticals i and $i+1$, in feet;

S_i = stations of the vertical (i) in the cross section measured from some arbitrary starting point, in feet; and

Q_B, n, R, and K have previously been defined,

You will note that equation 3 is very similar to the equation used to compute a surface-water discharge measurement. This method corresponds to the midpoint method currently used to compute surface-water discharge measurements (Buchanan and Somers, 1969). By combining equations 1 and 4 and rearranging terms:

$$Q_B = \frac{K}{2}\left[\frac{M_1 W_1}{t_1} + \frac{M_n W_{n-1}}{t_n} + \sum_{i=2}^{n-1} \frac{M_1}{t_i}(S_{i+1} - S_{i-1})\right] \quad (5)$$

One advantage to using the midsection method is that the distance W_1 need not necessarily be equal to the distance between sampling verticals. At times, it may become apparent, due to local conditions, that a particular R_1 should not be applied over a width equal to halfway back to the last station and halfway forward to the next, but applied to some other width. This width, sometimes referred to as the effective width, is decided on by the user. Bridge piers, large boulders, abrupt changes in velocity or lateral bed topography, or other conditions that may obstruct or cause sudden changes to bedload transport rate will affect the selection of the effective width.

The third method, the mean-section method (fig. 56), is computed using the following equation:

$$Q_B = \sum_{i=1}^{n-1} W_i \frac{(R_i + R_{i+1})}{2}, \quad (6)$$

which is equivalent to:

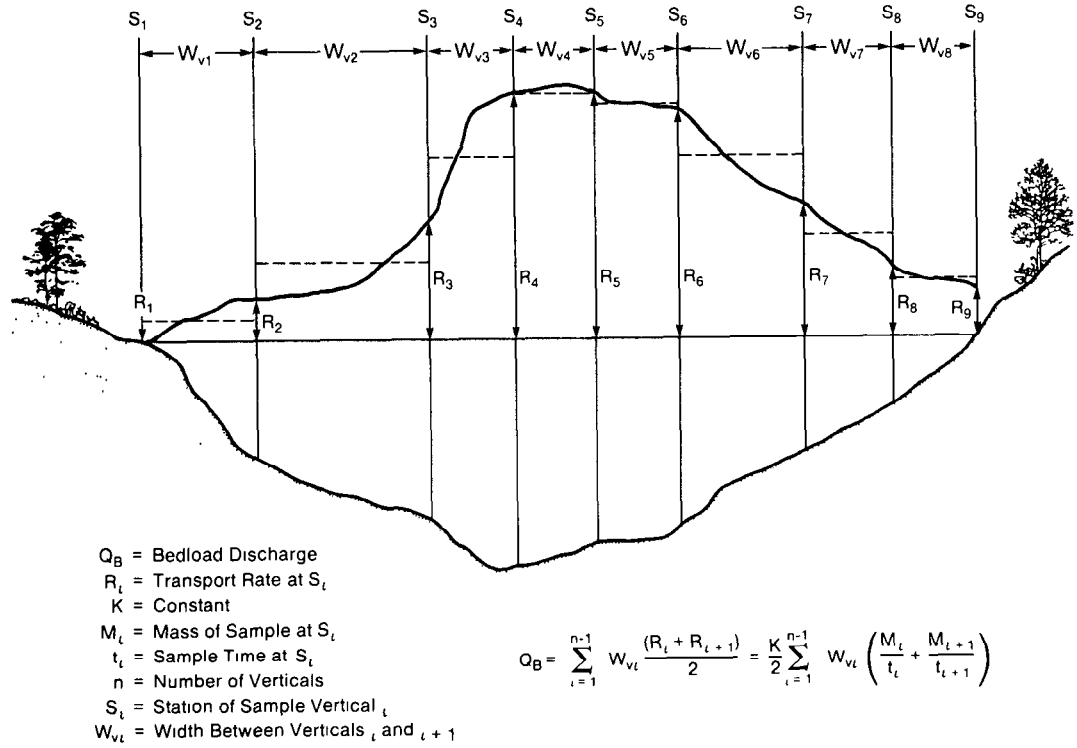


Figure 56. Mean-section method for computing bedload discharge from samples collected with a Helley-Smith bedload sampler.

$$Q_B = \frac{K}{2}\sum_{i=1}^{n-1} W_1\left(\frac{M_i}{t_i} + \frac{M_{i+1}}{t_{i+1}}\right) \quad (7)$$

All the above terms are the same as used in the midsection method. This method averages the two adjoining rates and applies the average rate over the distance between them. For this reason, it is important to try to place the sampling verticals at points where the trends in lateral mean bedload transport rate change. Under most field conditions, this might be difficult.

For situations where the total cross-section method cannot be used, it is recommended that the midsection method be used. This recommendation is made because of its similarity to the surface-water discharge-measurement method, which most field personnel are familiar with, and because of the flexibility in using the effective width concept.

Collecting bedload samples will generate 40 or more samples, creating a potential problem regarding transportation and analyses of so many samples. Carey (1984) adapted a procedure for measuring the submerged weight of bedload samples in the field and converting that measurement to dry weight from a laboratory procedure used by Hubbell and others (1981). The method uses the basic equation

$$W_{ds} = \frac{SG_s}{SG_s - 1} W_{ss} \quad (8)$$

where

W_{ds} = dry weight of the sediment;
SG_s = specific gravity of the sediment; and
W_{ss} = submerged weight of the sediment.

Measurements for Total Sediment Discharge

Total sediment discharge is the mass of all sediment moving past a given cross section in a unit of time. It can be defined as the sum of the (1) measured and unmeasured sediment discharges, (2) suspended-sediment discharge and bedload discharge, or (3) fine-material discharge (sometimes referred to as the washload) and coarse-material or bed-material discharge.

There are some sand-bed streams with sections so turbulent that nearly all sediment particles moving through the reach are in suspension. Sampling the suspended sediment in such sections with a standard suspended-sediment sampler represents very nearly the total load. Several streams with turbulent reaches are described in Benedict and Matejka (1953). Further discussion concerning total-load measurement also can be found in Inter-Agency Report 14 (Federal Inter-Agency Sedimentation Project, 1963b, p. 105–115). Turbulence flumes or special weirs can be used to bring the total load into suspension. Total load can usually be sampled with suspended-sediment samplers to a high degree of accuracy where the streambed consists of an erosion resisting material such as bedrock or a very cohesive clay. In such situations, most, if not all, the sediment being discharged is in suspension (or the bed would contain a deposit of sand).

Benedict and Matejka (1953) and Gonzales and others (1969) have described some structures used for artificial suspension of sediment to enable total-load sampling. However, most total-load sampling is usually accomplished at the crest of a small weir, dam, culvert outlet, or other place where the sampler nozzle integrates throughout the full depth of flow from the surface to the top of the weir.

Where such conditions or structures are not present, the unmeasured load must be computed by various formulas. The unmeasured load can be approximated by use of a bedload formula such as that of Meyer-Peter and Muller (1948), Einstein (1950), Colby and Hembree (1955), or Chang and others (1965). However, these computational procedures can give widely varying answers. The Colby and Hembree (1955) method [modified from Einstein (1950)] determines the total load in terms of the amount transported for different particle-size ranges. Colby and Hubbell (1961) later simplified the modified Einstein method to include the use of four nomographs in lieu of a major computational step. The essential data required for the Colby and Hubbell technique at a particular time and location are listed here:

1. Stream width, average depth, and mean velocity.
2. Average concentration of suspended sediment from depth-integrated samples.
3. Size analyses of the suspended sediment included in the average concentration.
4. Average depth of the verticals where the suspended-sediment samples were collected.

5. Size analyses of the bed material.
6. Water temperature.

Stevens (1985) has developed two computer programs for the computation of total sediment discharge by the modified Einstein procedure. One program is written in FORTRAN 77 for use on the PRIME computer; the other is in BASIC and can be used on most microcomputers.

Hubbell (1964) gives the following formula for determining the total sediment discharge of a given size range from the measured suspended-sediment discharge and the discharge measured with any type of bedload apparatus (see fig. 57).

$$Q_T = \frac{Q_D}{eff} + Q_{sm} + Q_{usm1} - FQ_{sm} + (1 - E/e)Q_{ts2} \quad (9)$$

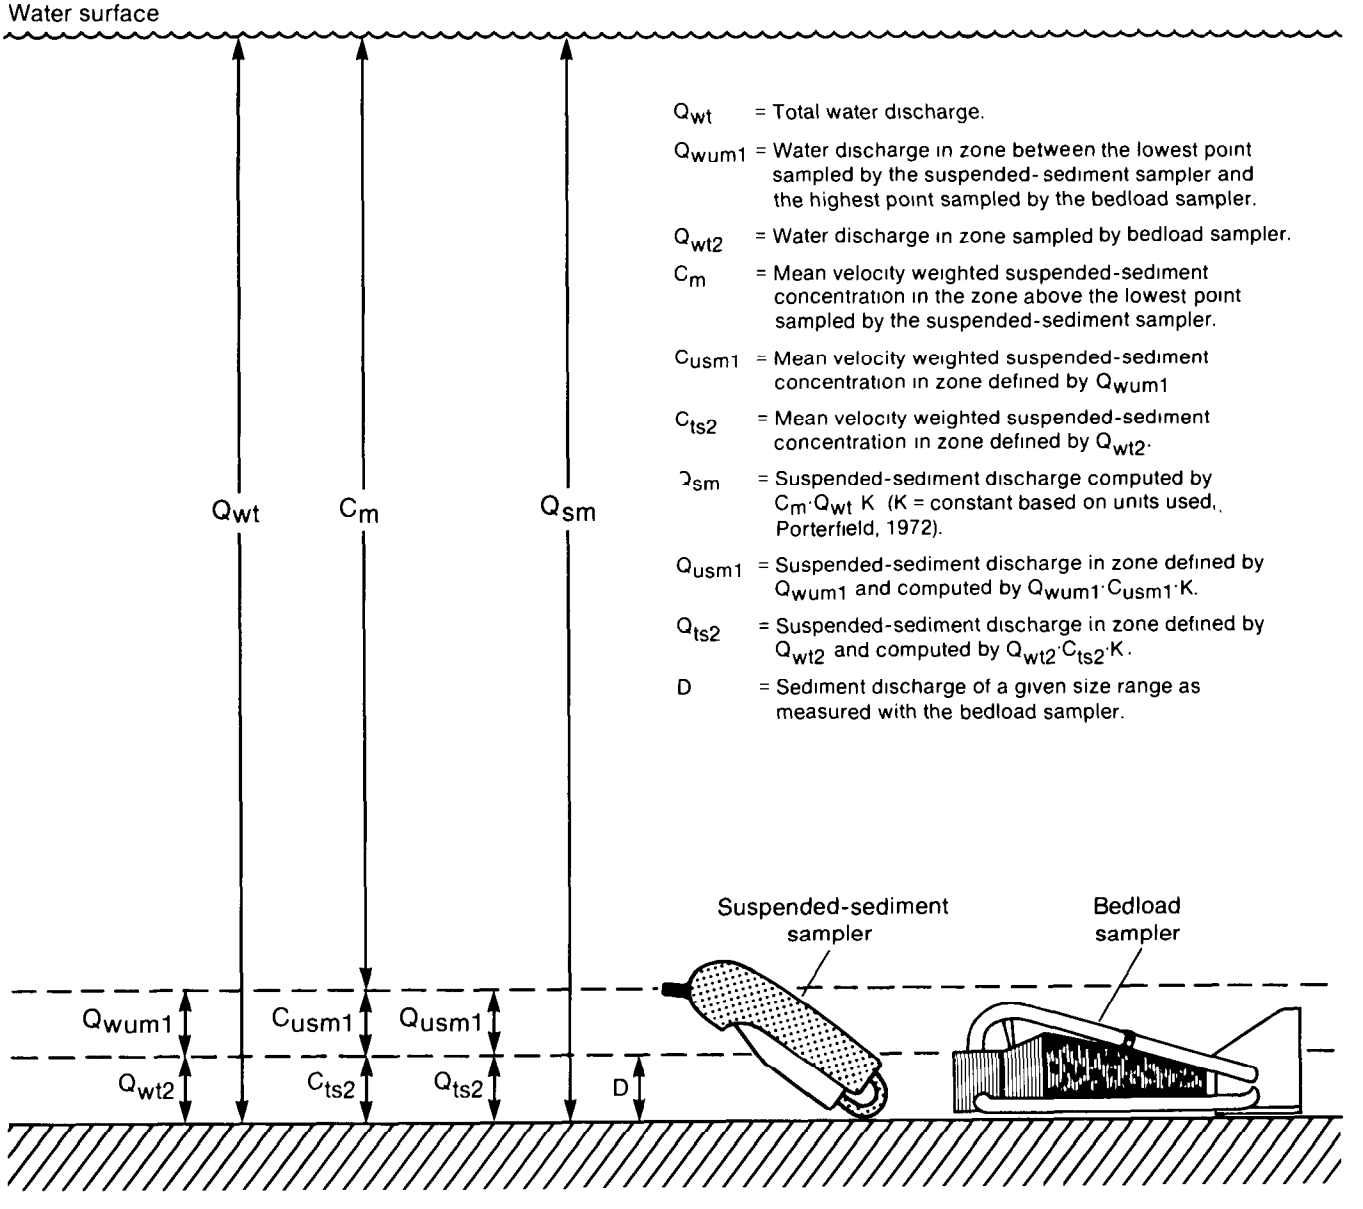

Figure 57. Zones sampled by suspended-sediment and bedload samplers and the unmeasured zone.

where

Q_T = total sediment discharge of the size range,

Q_D = discharge of the size range as measured with the bedload apparatus. If the apparatus measures more than the bedload discharge, as does the Helley-Smith, Q_D includes some of the suspended-sediment discharge,

e = efficiency of the bedload apparatus in measuring bedload discharge of the size range,

Q_{sm} = measured suspended-sediment discharge of the size range,

Q_{usm1} = unmeasured suspended-sediment discharge of the size range in the depth between the lowest point measured by the suspended-sediment sampler and the highest point measured by the bedload apparatus,

F = the fraction of the total depth represented by the flow in the depth measured by the bedload apparatus,

E = the efficiency of the bedload apparatus in measuring the suspended-sediment discharge of the size range transported through the vertical sampled by the apparatus, and

Q_{ts2} = total suspended-sediment discharge of the size range through the depth measured by the bedload apparatus.

A more detailed explanation of how to compute the total sediment discharge from measured suspended-sediment discharge and bedload discharge measured with a bedload measuring apparatus is given by Hubbell (1964, p. 7–9). If the efficiency of the bedload sampler is 100 percent for both bedload and suspended-sediment load and if the bedload sampler samples the entire unsampled zone, then the above equation is much simpler.

Reservoir-Trap Efficiency

The efficiency with which a reservoir traps sediment depends mostly on its size with respect to the rate of inflow. Other factors may include the reservoir shape, its operation, the water quality, and the size and kind of inflowing sediment. Except for small detentions with bottom outlets, all of the sand-sized and much of the silt-sized particles would be expected to be trapped. An evaluation of reservoir-trap efficiency must involve measurements of the quantity and size characteristics of the sediment entering and leaving the reservoir (Mundorff, 1964, 1966). Sometimes measurements of sediment accumulation in the reservoir plus the sediment output are used as a practical method of evaluating the sediment yield of the drainage basin.

Inflow Measurements

On many reservoirs, trap efficiency cannot be evaluated in sufficient detail from measurements of accumulation and sediment outflow. For such reservoirs, it is necessary to measure the sediment discharge and particle size entering the reservoirs. This measurement requires that stations be operated daily or continuously on streams feeding into the reservoir. Trap efficiency on a storm-event basis can be determined if several samples adequately define the concentration of the inflow and outflow hydrographs. For small detention reservoirs, it may be difficult or impractical to measure the inflow on a daily basis. If a continuous record is not possible, the objective should be to obtain observations sufficient to define the conditions for several inflow hydrographs so that a storm-event sediment rating curve can be constructed for use in estimating the sediment moved by the unsampled storms (Guy, 1965).

If it is impractical to obtain sufficient data to define the sediment content of several storm events, the least data for practical analysis should include 10 or 15 observations per year so that an instantaneous sediment rating curve can be constructed (Miller, 1951). It is expected that the instantaneous curve will yield less accurate results than the storm-event curve, which in turn will be less accurate than the continuous record. Each of the rating-curve methods may require data for a range of conditions so that adjustments can be determined for the effect of time of year, antecedent conditions, storm intensity, and possibly for the storm location in the basin (Colby, 1956; Jones, 1966).

As for most new sediment stations, particle-size analysis should be made on several of the inflow observations during the first year. These particle-size analyses will form a data base, which may make it possible to reduce the number of analyses required in future years.

Outflow Measurements

The outflow from a reservoir is drastically different from the inflow because of the attenuating effect of the

flow through the reservoir or because of possible willful control in the release of water (Carter and Godfrey, 1960; Mitchell, 1962). Logically, the smaller reservoirs, which are likely to have fixed outlets and the poorest trap efficiencies, require the most thorough outflow measurement schedules. If an inflow-outflow relation for sediment discharge can be constructed, such a relation may change considerably in the direction of greater sediment output (lower trap efficiency) as the reservoir fills with sediment.

Normally, the particle size of sediment outflow is expected to be finer than for the inflow; and, therefore, the concentration of outflowing sediment should not fluctuate as rapidly as that of the inflow. The normal slowly changing outflow concentration may not occur if the outflow is from the vicinity of the interface involving a density current.

A desirable sampling schedule for outflow may vary from once a week for the large reservoir to several observations during a storm event for a small reservoir. The need for outflow particle-size data also will depend on the scale of the stream and reservoir system, the trap efficiency, and how well the inflow is defined. With respect to quality control, if the trap efficiency of a reservoir is expected to be more than 95 percent and if the sediment inflow can only be measured to the nearest 10 or 15 percent of its expected true value, it is not necessary to measure the sediment outflow in great detail unless there is a need to accurately define the amount of sediment in the flow downstream from the reservoir.

Sediment Accumulation

The small reservoir or detention basin can be used—if trap efficiency can be estimated or measured—to provide a measure of the average annual sediment yield of a drainage basin. This method is useful in very small basins where the inflow is difficult to measure and where the amount of water-inflow and sediment-concentration data is not important.

For small catchment basins or reservoirs on ephemeral streams (those that are dry most of the time), the determination of sediment accumulation involves a detailed survey of the reservoir from which stage-capacity curves can be developed—usually 1-foot contours for the lower parts of the reservoirs and 2- to 5-foot contours for the upper parts, depending on the terrain and size of the reservoir (Peterson, 1962). The accretion of sediment then can be measured either by monumented range lines in the reservoir or by resurvey for a new stage-capacity curve.

For reservoirs not dry part of the time, the sediment accumulation is usually measured by sounding on several monumented range lines spaced to provide a representative indication of the sediment accumulation between measurements. Methods for reservoir surveys are described by Heinemann (1961), Porterfield and Dunnam (1964), and Vanoni (1975). A summary of reservoir sediment deposition surveys made in the United States through 1975 was compiled by Dendy and Champion (1978). The period from 1976 to 1980 has been covered by the Inter-Agency Advisory Committee on Water Data's Subcommittee on Sediment (1983).

In order to convert the measurements of sediment volume found in reservoirs to the usual expression of mass of sediment yield, it is necessary that the sedimentation surveys of reservoirs include information on the volume-mass of sediment. Heinemann (1964) reports that this was accomplished in Sebetha Lake, Kansas, using a gamma probe and a piston sampler. From his data, obtained at 41 locations, he found that the best equation for predicting volume-mass is

$$V_M = 1.688d - 0.888c + 98.8 \qquad (10)$$

where

V_M = the dry unit volume-mass, in pounds per cubic foot;

d = the depth of sample from the top of the deposit; and

c = the percentage of clay smaller than 0.002 mm.

On the basis of 1,316 reservoir deposit samples, Lara and Pemberton (1965) found the unit volume-mass to vary according to changes in reservoir operation and to the fraction of clay, silt, and sand. The Office of Water Data Coordination (1978) reported that refinements based on reservoir operation, sediment size, and compaction could be made to the estimates made by Lara and Pemberton (1965) and Lane and Koelzer (1943). The following formula, along with factors listed in table 4, may be used to estimate dry unit volume-mass:

$$V_M = V_{tc}P_c + V_{tm}P_m + V_{ts}P_s \qquad (11)$$

where

V_M = dry unit volume-mass, in pounds per cubic foot;
V_t = dry unit volume-mass as computed in equation 12, in pounds per cubic foot;
c = clay-size material;
m = silt-size material;
s = sand-size material;
P = percent of total sample, by weight, in size class (clay, silt, sand); and

$$V_t = V_i + 0.43K\left[\frac{T}{T-1}(\log T) - 1\right] \qquad (12)$$

where

V_i = initial unit volume-mass, in pounds per cubic foot from table 4;
K = Lane and Koelzer (1943) factors from table 4, in pounds per cubic foot; and
T = time after deposition, in years.

Table 4. Initial dry unit volume-mass (V_1) and K factors for computing dry unit volume-mass of sediment deposits in pounds per cubic foot (Office of Water Data Coordination, 1978)

Type of reservoir operation	V_1			K		
	Clay	Silt	Sand	Clay	Silt	Sand
1. Sediment submerged	26	70	97	16	5.7	0
2. Moderate to considerable annual drawdown	35	71	97	8.4	1.8	0
3. Normally empty	40	72	97	0	0	0
4. River sediment	60	73	97	0	0	0

OTHER SEDIMENT DATA-COLLECTION CONSIDERATIONS

In retrospect, it must be emphasized that field methods for fluvial-sediment measurements must be coordinated with methods for other hydrologic and environmental measurements. With the ever-increasing requirements of a thorough data-acquisition system, together with advances in technology, it must be expected that methods will continue to change in the future. For example, because there is a foreseeable need for increasing water-pollution surveillance studies with respect to stream-quality standards, it is apparent that a continuous recording of some indicator of sediment conditions is badly needed at a large number of sites. Consequently, the F.I.S.P. has undertaken the development of sensors and automatic pumping-type samplers with a view toward continuously recording the concentration of sediment that moves in streams. The development of such automatic equipment is likely to enhance rather than detract from the need for conventional manual observations.

The authors sincerely hope that the material regarding the equipment and techniques for sampling presented herein will stimulate the ongoing development of better equipment and techniques for the future and, at the same time, help to standardize and make more efficient the day-to-day operations.

The opportunity certainly exists at the field level for many innovations for improving the end product or the sediment record. Some field people, for example, may like to carry a copy of the station stage-discharge rating curve, on which all particle-size analyses are recorded, showing date and kind of sample for each measuring site. As communications and river forecasting become more sophisticated, it may be possible to have better dialogue between the office and the field people or local observers, who are trying to obtain the maximum information at many sampling sites. Such communication is especially critical during periods of flooding, when timely data are most important.

In addition to increasing coordination of sediment-data activities with other related measurements, it is important to stress that adequate notes be obtained (including pictures) so that those involved in the laboratory analysis of the samples, those responsible for preparing the record, and especially those responsible for interpreting the data can properly read what happened at the sample site. The amount of new information to be obtained from data interpretation is seriously affected by the quality of the information with respect to timing and representativeness of the sediment measurements.

The authors further emphasize the need for a concerted and continuing effort with respect to safety in the measurement program. Aside from the hazards of highway driving, the work usually involves the use of heavy equipment during floods or other unusual

natural events, often in darkness and under unpleasant weather conditions. Even though the hazards of working from highway bridges and cableways are mostly self-evident, there are many opportunities for the unusual to happen and, therefore, a great deal of effort must be expended to ensure safety. Such effort, of course, must be increased when it is necessary to accomplish the work in a limited amount of time and with a reduced work force.

PREFACE

The science and, in part, art of stream gaging has evolved through the years, largely from the collective experiences and innovations of its practitioners. The earliest truly comprehensive manual on stream-gaging procedures and equipment, based on techniques developed up to that time, was published in 1943 by the Geological Survey as Water-Supply Paper 888, "Stream-Gaging Procedures," by D. M. Corbett and others. That report was an instant classic; it was received enthusiastically by the hydraulic-engineering profession throughout the world and became a major training document for at least two generations of stream gagers, hydrologists, and hydraulic engineers, both in the United States and abroad.

The need for updating Water-Supply Paper 888 has been obvious for some time as a result of later developments in stream-gaging techniques and equipment. Furthermore, it has been felt for some time that the scope of that report should be expanded to cover not only the newer field techniques but also the office procedures required to produce a published annual record of stream discharge. In recognition of those needs, the Geological Survey has sporadically produced supplementary reports that update the description of specific techniques and equipment or that describe specific field or office procedures not covered by Water-Supply Paper 888. These reports—some administrative, some open-file, and others in the published series titled "Techniques of Water-Resources Investigations"—are fragmentary in the sense that they deal only with selected aspects of the broad subject of stream gaging. Similar, but less detailed, reports on selected topics have also been produced by international agencies in the form of Technical Notes by the World Meteorological Organization and in the form of Recommendations and Standards by the International Standards Organization.

The present report evolved from that background. Its two volumes provide a comprehensive compilation of time-tested techniques presented as an up-to-date (1980) standardized manual of stream-gaging procedures.

Acknowledgments.—The material presented in the manual is based on the work of many hydraulic engineers and technicians, each of whom has contributed to the current state-of-the-art in the measurement and computation of streamflow. Many of those who contributed directly to the manual are listed in the references appended to each chapter. However, the authors wish to acknowledge a special group of colleagues who have made major contributions to this manual in the form of written (cited) methods and techniques, significant suggestions for correction and revision of the manuscript and illus-

trations, and all-out efforts to bring about development and publication of the material. These colleagues include:

Harry H. Barnes, Jr.	Thomas J. Buchanan
Rolland W. Carter	Frederick A. Kilpatrick
George F. Smoot	Ernest D. Cobb
Howard F. Matthai	Manual A. Benson
Alvin F. Pendleton, Jr.	Tate Dalrymple
Harry Hulsing	Carl E. Kindsvater
G. Lawrence Bodhaine	Hubert J. Tracy
Jacob Davidian	James F. Wilson

The authors also wish to acknowledge with thanks the suggestions of their many other colleagues, who are too numerous to mention.

CONTENTS

[Article headings are listed in the table of contents only in the volume of the manual in which they occur, but all chapter titles for the two volumes are listed in both volumes A complete index covering both volumes of the manual appears in each volume]

VOLUME 1. MEASUREMENT OF STAGE AND DISCHARGE

Chapter 5.—Measurement of Discharge by Conventional Current-Meter Method

Chapter 6.—Measurement of Discharge by the Moving-Boat Method

Chapter 7.—Measurement of Discharge by Tracer Dilution

Chapter 8.—Measurement of Discharge by Miscellaneous Methods

Chapter 9.—Indirect Determination of Peak Discharge

VOLUME 2. COMPUTATION OF DISCHARGE

MEASUREMENT AND COMPUTATION OF STREAMFLOW

VOLUME 1. MEASUREMENT OF STAGE AND DISCHARGE

By S. E. RANTZ and others

CHAPTER 1.—INTRODUCTION

PURPOSE OF THE MANUAL

The purpose of this manual is to provide a comprehensive description of state-of-the-art standardized stream-gaging procedures, within the scope described below. The manual is intended for use as a training guide and reference text, primarily for hydraulic engineers and technicians in the U.S. Geological Survey, but the manual is also appropriate for use by other stream-gaging practitioners, both in the United States and elsewhere.

SCOPE OF THE MANUAL

The technical work involved in obtaining systematic records of streamflow is discussed, in two volumes, in accordance with the following six major topics:

Volume 1. Measurement of stage and discharge
- a. Selection of gaging-station sites
- b. Measurement of stage
- c. Measurement of discharge

Volume 2. Computation of discharge
- d. Computation of the stage-discharge relation
- e. Computation of daily-discharge records
- f. Presentation and publication of stream-gaging data

In order to make the text as broadly usable as possible, discussions of instrumentation and measurement are aimed at the technician, and discussions of computational procedure are aimed at the junior engineer who has a background in basic hydraulics.

Many of the procedures for determining discharge that are discussed in volume 2 require specialized instrumentation to obtain field data that supplement the observation of stage. The descriptions of such specialized equipment and associated observational techniques

are given in appropriate chapters in volume 2 so that the reader may have unified discussions of the methodologies applicable to each type of problem in determining discharge.

In general the authors have attempted to prepare a manual that will stand independently—references are given to supplementary published material, but the reader should find relatively few occasions when there is pressing need to consult those references. There are three notable exceptions to that statement.

1. The subject of indirect determination of peak discharge (v. 1, chap. 9) is treated here only in brief because of space limitations; the subject is treated fully in five reports in the Geological Survey report series, "Techniques of Water-Resources Investigations." The five reports are named in the reference section of chapter 9.
2. Among the methods discussed in this manual for computing the discharge of tidal streams are four mathematical techniques for evaluating the differential equations of unsteady flow (v. 2, chap. 13). The four techniques are given only cursory treatment because a detailed description of the complex mathematical techniques is considered to be beyond the scope of the manual.
3. The processing of streamflow records by digital computer (v. 2, chap. 15) is a subject that is given only generalized treatment here. It was not practicable to include a detailed description of each step in the sequence of operation of an automated computing system because of space limitations, and also because the particulars of each step are somewhat in a state of flux in response to continual improvement in storage and access procedures.

STREAMFLOW RECORDS

Streamflow serves man in many ways. It supplies water for domestic, commercial, and industrial use; irrigation water for crops; dilution and transport for removal of wastes; energy for hydroelectric power generation; transport channels for commerce; and a medium for recreation. Records of streamflow are the basic data used in developing reliable surface-water supplies because the records provide information on the availability of streamflow and its variability in time and space. The records are therefore used in the planning and design of surface-water related projects, and they are also used in the management or operation of such projects after the projects have been built or activated.

Streamflow, when it occurs in excess, can create a hazard—floods cause extensive damage and hardship. Records of flood events obtained at gaging stations serve as the basis for the design of bridges, culverts, dams, and flood-control reservoirs, and for flood-plain delineation and flood-warning systems.

The streamflow records referred to above are primarily continuous records of discharge at stream-gaging stations, a gaging station being a stream-site installation so instrumented and operated that a continuous record of stage and discharge can be obtained. Networks of stream-gaging stations are designed to meet the various demands for streamflow information, including inventory of the total water resource. The networks of continuous-record stations, however, are often augmented by auxiliary networks of partial-record stations to fill a particular need for streamflow information at relatively low cost. For example, an auxiliary network of sites, instrumented and operated to provide only instantaneous peak-discharge data, is often established to obtain basic information for use in regional flood-frequency studies. An auxiliary network of uninstrumented sites for measuring low flow only is often established to provide basic data for use in regional studies of drought and of fish and wildlife maintenance or enhancement.

GENERAL STREAM-GAGING PROCEDURES

After the general location of a gaging station has been determined from a consideration of the need for streamflow data, its precise location is so selected as to take advantage of the best locally available conditions for stage and discharge measurement and for developing a stable stage-discharge relation.

A continuous record of stage is obtained by installing instruments that sense and record the water-surface elevation in the stream. Discharge measurements are initially made at various stages to define the relation between stage and discharge. Discharge measurements are then made at periodic intervals, usually monthly, to verify the stage-discharge relation or to define any change in the relation caused by changes in channel geometry and (or) channel roughness. At many sites the discharge is not a unique function of stage; variables other than stage must also be continuously measured to obtain a discharge record. For example, stream slope is measured by the installation of a downstream auxiliary stage gage at stations where variable backwater occurs. At other sites a continuous measure of stream velocity at a point in the cross section is obtained and used as an additional variable in the discharge rating. The rate of change of stage can be an important variable where flow is unsteady and channel slopes are flat.

Artificial controls such as low weirs or flumes are constructed at some stations to stabilize the stage-discharge relations in the low-flow range. These control structures are calibrated by stage and discharge measurements in the field.

The data obtained at the gaging station are reviewed and analyzed

by engineering personnel at the end of the water year. Discharge ratings are established, and the gage-height record is reduced to mean values for selected time periods. The mean discharge for each day and extremes of discharge for the year are computed. The data are then prepared for publication.

CHAPTER 2.—SELECTION OF GAGING-STATION SITES

INTRODUCTION

The general location of a gaging station is dependent on the specific purpose of the streamflow record. If the streamflow record is needed for the design or operation of a water project, such as a dam and reservoir, the general location of the gaging station obviously will be in the vicinity of the water project. The selection of a gaging-station site becomes complicated, however, when the station is to be one of a network of stations whose records are required for study of the general hydrology of a region. Such studies are used to inventory the regional water resource and formulate long-range water-development plans. In that situation, attention to hydrologic principles is required in selecting the general locations of the individual stations in the network to ensure that optimum information is obtained for the money spent in data collection.

A discussion of the design of gaging-station networks is beyond the scope of this manual and for the purpose of this chapter we will assume that the general location of a proposed gaging station has been determined. The discussion that follows will be concerned with the hydraulic considerations that enter into the selection of the precise location of the gage to obtain the best locally available conditions for the measurement of stage and discharge and for the development of a stable discharge rating.

CONSIDERATIONS IN SPECIFIC SITE SELECTION

After the general location of a gaging station has been determined, a specific site for its installation must be selected. For example, if the outflow from a reservoir is to be gaged to provide the streamflow data needed for managing reservoir releases, the general location of the gaging station will be along the stretch of stream channel between the dam and the first stream confluence of significant size

downstream from the dam. From the standpoint of convenience alone, the station should be established close to the dam, but it should be far enough downstream from the outlet gates and spillway outlet to allow the flow to become uniformly established across the entire width of the stream. On the other hand the gage should not be located so far downstream that the stage of the gaged stream may be affected by the stage of the confluent stream. Between those upstream and downstream limits for locating the gage, the hydraulic features should be investigated to obtain a site that presents the best possible conditions for stage and discharge measurement and for developing a stable stage-discharge relation. If the proposed gaging station is to be established for purely hydrologic purposes, unconnected with the design or operation of a project, the general location for the gage will be the stretch of channel between two large tributary or confluent streams. The same consideration will apply in the sense that the gage should be far enough downstream from the upper tributary so that flow is fairly uniformly established across the entire width of stream, and far enough upstream from the lower stream confluence to avoid variable backwater effect. Those limits often provide a reach of channel of several miles whose hydraulic features must be considered in selecting a specific site for the gage installation.

The ideal gage site satisfies the following criteria:

1. The general course of the stream is straight for about 300 ft (approx. 100 m) upstream and downstream from the gage site.
2. The total flow is confined to one channel at all stages, and no flow bypasses the site as subsurface flow.
3. The streambed is not subject to scour and fill and is free of aquatic growth.
4. Banks are permanent, high enough to contain floods, and are free of brush.
5. Unchanging natural controls are present in the form of a bedrock outcrop or other stable riffle for low flow and a channel constriction for high flow—or a falls or cascade that is unsubmerged at all stages (chap. 3).
6. A pool is present upstream from the control at extremely low stages to ensure a recording of stage at extremely low flow, and to avoid high velocities at the streamward end of gaging-station intakes during periods of high flow.
7. The gage site is far enough upstream from the confluence with another stream or from tidal effect to avoid any variable influence the other stream or the tide may have on the stage at the gage site.
8. A satisfactory reach for measuring discharge at all stages is available within reasonable proximity of the gage site. (It is not nec-

essary that low and high flows be measured at the same stream cross section.)

9. The site is readily accessible for ease in installation and operation of the gaging station.

Rarely will an ideal site be found for a gaging station and judgment must be exercised in choosing between adequate sites, each of which has some shortcomings. Often, too, adverse conditions exist at all possible sites for installing a needed gaging station, and a poor site must be accepted. For example, all streams in a given region may have unstable beds and banks, which result in continually changing stage-discharge relations.

The reconnaissance for a gaging site properly starts in the office where the general area for the gage site is examined on topographic, geologic, and other maps. Reaches having the following pertinent characteristics should be noted: straight alinement, exposed consolidated rock as opposed to alluvium, banks subject to overflow, steep banks for confined flow, divided channels, possible variable backwater effect from a tributary or confluent stream or from a reservoir, and potential sites for discharge measurement by current meter. The more favorable sites will be given critical field examination; they should be marked on the map, access roads should be noted, and an overall route for field reconnaissance should be selected.

In the field reconnaissance the features discussed earlier are investigated. With regard to low flow, a stable well-defined low-water control section is sought. In the absence of such a control, the feasibility of building an artificial low-water control is investigated. If a site on a stream with a movable bed must be accepted—for example, a sand-channel stream—it is best to locate the gage in as uniform a reach as possible, away from obstructions in the channel, such as bridges, which tend to intensify scour and fill. (See page 377.) Possible backwater resulting from aquatic growth in the channel should also be investigated. If the gage is to be located at a canyon mouth where the stream leaves the mountains or foothills to flow onto an alluvial plain or fan, reconnaissance current-meter measurements of discharge should be made during a low-flow period to determine where the seepage of water into the alluvium becomes significant. The station should be located upstream from the area of water seepage in order to gage as much of the surface flow as possible; the subsurface flow or underflow that results from channel seepage is not "lost" water, but is part of the total water resource.

With regard to high stages, high-water marks from major floods of the past are sought and local residents are questioned concerning historic flood heights. Such information is used by the engineer in making a judgment decision on the elevation at which the stage-

recorder must be placed to be above any floods that are likely to occur in the future. The recorder shelter should be so located as to be sheltered from waterborne debris during major floods. Evidence is also sought concerning major channel changes, including scour and deposition at streambanks, that occurred during notable floods of the past. That evidence, if found, gives some indication of changes that might be expected from major floods of the future.

The availability of adequate cross sections for current-meter measurement of discharge should also be investigated. Ideally, the measurement cross section should be of fairly uniform depth, and flow lines should be parallel and fairly uniform in velocity throughout the cross section. The measurement section should be in reasonable proximity to the gage to avoid the need for adjusting measured discharge for change in storage, if the stage should change rapidly during a discharge measurement. However a distance of as much as 0.5 mi (approx. 1 km) between gage and measuring section is acceptable if such a distance is necessary to provide both a good stage-measurement site and a good discharge-measurement site. Low-flow discharge measurements of all but the very large streams are made by wading. For flows that cannot be safely waded, the current meter is operated from a bridge, cableway, or boat. It is most economical to use an existing bridge for that purpose, but in the absence of a bridge, or if the measuring section at a bridge site is poor, a suitable site should be selected for constructing a cableway. If construction of a cableway is not feasible because of excessive width of the river, high-water measurements will be made by boat when safe to do so. The cross section used for measuring high flows is rarely suitable for measuring low flows, and wading measurements are therefore made wherever measuring conditions are most favorable.

Consideration should be given to the possibility of variable backwater effect from a stream confluence or reservoir downstream from the general location of the required gaging station. Without knowledge of stage and discharge at a potential gage site and of concurrent stage at the stream confluence or reservoir, the engineer can only conjecture concerning the location on the stream where backwater effect disappears for various combinations of discharge and stage. A safe rule is the following: Given a choice of several acceptable gaging sites on a stream, the gaging site selected should be the one farthest upstream from the possible source of variable backwater. If it is necessary to accept a site where variable backwater occurs, a uniform reach for measurement of slope should be sought, along with a site for the installation of an auxiliary gage. If a gaging station must be placed in a tide-affected reach, the unsteady flow that must be gaged will also require an auxiliary gage, but in addition line

power must be available to insure the synchronized recording of stage at the two gages. The availability of line power or telephone lines is also a consideration, where needed for special instrumentation or for the telemetering units that are often used in flood-forecasting and flood-warning systems.

In cold regions the formation of ice always presents a problem in obtaining reliable winter records of streamflow. However in regions that are only moderately cold, and therefore subject to only moderate ice buildup, forethought in the selection of gage sites may result in streamflow records that are free of ice effect. Gage sites that are desirable from that standpoint are as follows:

1. Below an industrial plant, such as a paper mill, steel mill, thermal powerplant, or coal mine. "Waste" heat may warm the water sufficiently or impurities in the water may lower the freezing point to the extent that open-water conditions always prevail.
2. Immediately downstream from a dam with outlet gages. Because the density of water is maximum at a temperature of 4°C, the water at the bottom of a reservoir is commonly at or near that temperature in winter. Most outlet gates are placed near the bottom of the dam, and the water released is therefore approximately 4°C above freezing. It would take some time for that water to lose enough heat to freeze.
3. On a long fairly deep pool just upstream from a riffle. A deep pool will be a tranquil one. Sheet ice will form readily over a still pool, but the weather must be extremely cold to give complete cover on the riffle. At the first cold snap, ice will form over the pool and act as an insulating blanket between water and air. Under ice cover the temperature of the streambed is generally slightly above the freezing point and may, by conduction and convection, raise the water temperature slightly above freezing, even though water enters the pool at 0°C. That rise in temperature will often be sufficient to prevent ice formation on the riffle.

After the many considerations discussed on the preceding pages have been weighed, the precise sites for the recording stage gage and for the cableway for discharge measurements (if needed) are selected. Their locations in the field are clearly marked and referenced. The maximum stage at which the low-water control will be effective should be estimated; the intakes to the stage recorder should be located upstream from the low-water control, a distance equal to at least three times the depth of water on the control at that estimated maximum stage. If the intakes are located any closer than that to the control, they may lie in a region where the streamlines have vertical curvature; intake location in that region is hydraulically undesirable.

The gaging station on the Kaskaskia River at Bondville, Ill., shown

in figure 1, satisfies most of the requirements discussed in this chapter. Low-flow measurements are made by wading upstream from the control. The bridge site provides accessibility, convenience to power lines, and a good location for an outside reference gage, which is shown on the downstream parapet wall of the bridge.

Up to this point there has been no discussion of specific site location for crest-stage gages. Those gages provide peak-discharge data only. Where possible they should be installed upstream from road culverts, which act as high-water controls. The specific site for a gage is at a distance of one culvert width upstream from the culvert inlet. In the absence of such control structures, the crest-stage gage should be installed in a straight reach of channel that can be utilized in computing peak discharge by the slope-area method (chap. 9).

CHAPTER 3.—GAGING-STATION CONTROLS

TYPES OF CONTROL

The conversion of a record of stage to a record of discharge is made by the use of a stage-discharge relation. The physical element or combination of elements that controls the relation is known as a control. The major classification of controls differentiates between section controls and channel controls. Another classification differentiates between natural and artificial controls. (Artificial controls are structures built for the specific purpose of controlling the stage-discharge relation; a highway bridge or paved floodway channel that serves incidentally as a control is not classed as an artificial control.) A third classification differentiates between complete, partial, and compound controls.

Section control exists when the geometry of a single cross section a short distance downstream from the gage is such as to constrict the channel, or when a downward break in bed slope occurs at the cross section. The constriction may result from a local rise in the streambed, as at a natural riffle or rock ledge outcrop, or at a constructed weir or dam; or it may result from a local constriction in width, which may occur naturally or be caused by some manmade channel encroachment, such as a bridge whose waterway opening is considerably narrower than the width of the natural channel. Examples of a downward break in bed slope are the head of a cascade or the brink of a falls.

Channel control exists when the geometry and roughness of a long reach of channel downstream from the gaging station are the elements that control the relation between stage and discharge. The length of channel that is effective as a control increases with discharge. Generally speaking, the flatter the stream gradient, the longer the reach of channel control.

A complete control is one that governs the stage-discharge relation throughout the entire range of stage experienced at the gaging station. More commonly, however, no single control is effective for the entire range of stage, and so the result is a compound control for the gaging station. A common example of a compound control is the situation where a section control is the control for low stages and channel control is effective at high stages. The compound control sometimes includes two section controls, as well as channel control. In that situation the upstream section control is effective for the very low stages, a section control farther downstream is effective for intermediate stages, and channel control is effective at the high stages.

With regard to complete controls, a section control may be a complete control if the section control is a weir, dam, cascade, or falls

of such height that it does not become submerged at high discharges. A channel control may be a complete control if a section control is absent, as in a sand channel that is free of riffles or bars, or in an artificial channel such as a concrete-lined floodway.

A partial control is a control that acts in concert with another control in governing the stage-discharge relation. That situation exists over a limited range in stage whenever a compound control is present. As an example consider the common situation where a section control is the sole control for low stages and channel control is solely operative at high stages. At intermediate stages there is a transition from one control to the other, during which time submergence is "drowning out" the section control. During that transition period the two controls act in concert, each as a partial control. In effect we have a dam (low-flow control) being submerged by tailwater; before complete submergence (channel control), the upstream stage for the particular discharge is dependent both on the elevation of the dam and on the tailwater elevation. Where the compound control includes two section controls, the degree of submergence of the upstream section control will be governed by the downstream section control, during a limited range in stage. When that occurs, each of the section controls is acting as a partial control. A constriction in channel width, unless unusually severe, usually acts as a partial control, the upstream stage being affected also by the stage downstream from the constriction.

ATTRIBUTES OF A SATISFACTORY CONTROL

The two attributes of a satisfactory control are permanence (stability) and sensitivity. If the control is stable, the stage-discharge relation will be stable. If the control is subject to change, the stage-discharge relation is likewise subject to change, and frequent discharge measurements are required for the continual recalibration of the stage-discharge relation. That not only increases the operating cost of a gaging station, but results in impairment of the accuracy of the streamflow record.

The primary cause of changes in natural controls is the high velocity associated with high discharge. Of the natural section controls, a rock ledge outcrop will be unaffected by high velocities, but boulder, gravel, and sand-bar riffles are likely to shift, boulder riffles being the most resistant to movement and sand bars the least resistant. Of the natural channel controls those with unstable bed and banks, as found in sand-channel streams, are the most likely to change as a result of velocity-induced scour and deposition.

Another cause of changes in natural controls is vegetal growth. The growth of aquatic vegetation on section controls increases the stage

for a given discharge, particularly in the low-flow range. Vegetal growth on the bed and banks of channel controls also affects the stage-discharge relation by reducing velocity and the effective waterway area. In the temperate climates, accumulations of water-logged fallen leaves on section controls each autumn clog the interstices of alluvial riffles and raise the effective elevation of all natural section controls. The first ensuing stream rise of any significance usually clears the control of fallen leaves.

Controls, particularly those for low flow, should be sensitive; that is, a small change in discharge should be reflected by a signficant change in stage. To meet that requirement it is necessary that the width of flow at the control be greatly constricted at low stages. In a natural low-water control such constriction occurs if the control is in effect notched, or if the controlling cross section roughly has a flat V-shape or a flat parabolic shape. Those shapes will ensure that the width of flow over the control decreases as discharge decreases. Generally speaking, a low-water control is considered to be sensitive if a change of no more than 2 percent of the total discharge is represented by a change of one unit of recorded stage. For example, in the U.S.A., stage is recorded in units of hundredths of a foot; therefore, for the low-water control to be regarded as sensitive, a change in stage of 0.01 ft (0.003 m) should represent a change of no more than about 2 percent of the total discharge.

In the interest of economy a gaging station should be located upstream from a suitable natural control (fig. 2). However, where natural conditions do not provide the stability or the sensitivity required, artificial controls should be considered. The artificial controls are all section controls; it is not feasible to pave or otherwise improve a long reach of channel solely for the purpose of stabilizing the stage-discharge relation.

ARTIFICIAL CONTROLS

An artificial control is a structure built in a stream channel to stabilize and constrict the channel at a section, and thereby simplify the procedure of obtaining accurate records of discharge. The artificial controls built in natural streams are usually broad-crested weirs that conform to the general shape and height of the streambed. (The term "broad-crested weir," as used in this manual, refers to any type of weir other than a thin-plate weir.) In canals and drains, where the range of discharge is limited, thin-plate weirs and flumes are the controls commonly built. Thin-plate weirs are built in those channels whose flow is sediment free and whose banks are high enough to accommodate the increase in stage (backwater) caused by the installation of a weir (fig. 3). Flumes are largely self cleaning and can

therefore be used in channels whose flow is sediment laden, but their principal advantage in canals and drains is that they cause relatively little backwater (head loss) and can therefore be used in channels whose banks are relatively low. Flumes are generally more costly to build than weirs.

Flumes may be categorized with respect to the flow regime that principally controls the measured stage; that is, a flume is classed as either a critical-flow flume or a supercritical-flow flume. The Parshall flume (fig. 4) is the type of critical-flow flume most widely used. Supercritical-flow flumes are used in streams that transport heavy loads of sediment that include rocks that are too large to pass through a critical-flow flume without being deposited in the structure. Of those flumes the trapezoidal supercritical-flow flume (fig. 5) is the most widely used by the U.S. Geological Survey.

Artificial controls eliminate or alleviate many of the undesirable characteristics of natural section controls. Not only are they physically stable, but they are not subject to the cyclic or progressive growth of aquatic vegetation other than algae. Algal slimes that sometimes form on artificial controls can be removed with a wire brush, and the controls are self cleaning with regard to fallen leaves. In moderately cold climates artificial controls are less likely to be affected by the formation of winter ice than are natural controls. The artificial control can, of course, be designed to attain the degree of sensitivity required for the gaging station. In addition, an artificial

FIGURE 2.—Gage and natural control, Little Spokane River at Elk, Wash.

control may often provide an improved discharge-measurement section upstream from the control by straightening the original angularity of flow lines in that cross section.

In canals or drains, where the range of discharge is limited, artificial controls are usually built to function as complete controls throughout the entire range in stage. In natural channels it is generally impractical to build the control high enough to avoid submergence at high discharges, and the broad-crested weirs that are usually built are effective only for low, or for low and medium, discharges. Figures 6 and 7 illustrate broad-crested weirs of two different shapes; the crests of both have a flat upward slope from the center of the stream to the banks, but in addition, the weir in figure 7 has a shallow V-notch in the center for greater sensitivity.

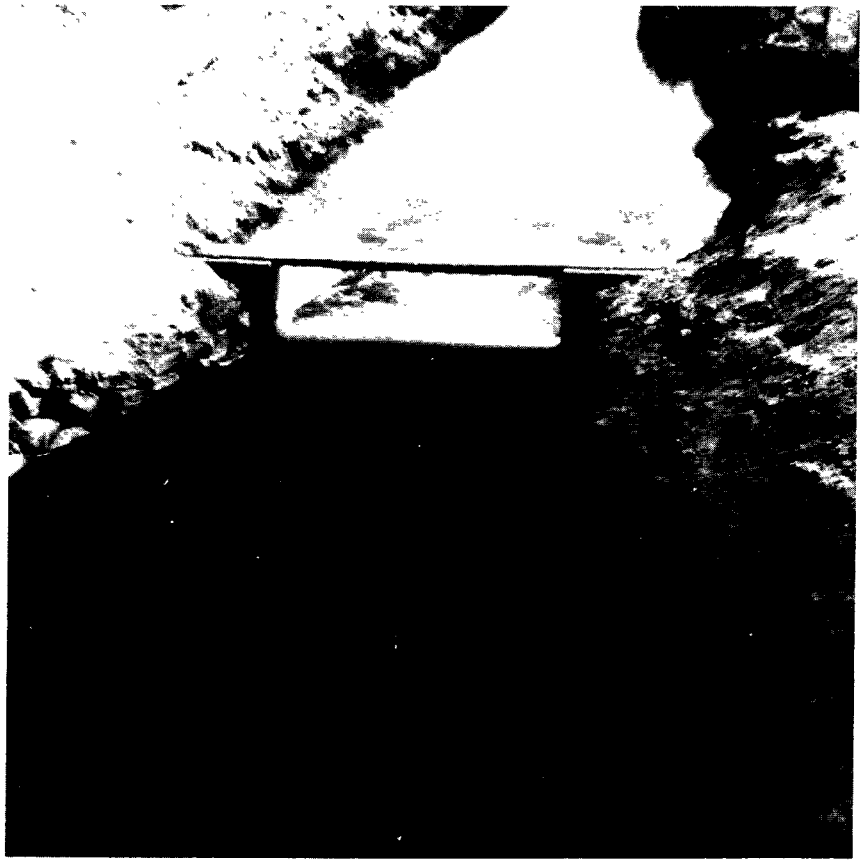

FIGURE 3.—Rectangular weir on Trifolium Drain 23 of Imperial Irrigation District, near Westmorland, Calif. (View looking downstream.)

The attributes desired in an artificial control include the following:

1. The control should have structural stability and should be permanent. The possibility of excessive seepage under and around the control should be considered, and the necessary precautions should be taken for the prevention of seepage by means of sheet piling or concrete cut-off walls and adequate abutments.
2. The crest of the control should be as high as practicable to possibly eliminate the effects of variable downstream conditions or to limit those effects to high stages only.
3. The profile of the crest of the control should be designed so that a small change in discharge at low stages will cause a measurable change in stage. If the control is intended to be effective at all stages, the profile of the crest should be designed to give a stage-discharge relation (rating curve) of such shape that it can be extrapolated to peak stages without serious error.
4. The shape of the control structure should be such that the passage of water creates no undesirable disturbances in the channel upstream or downstream from the control.

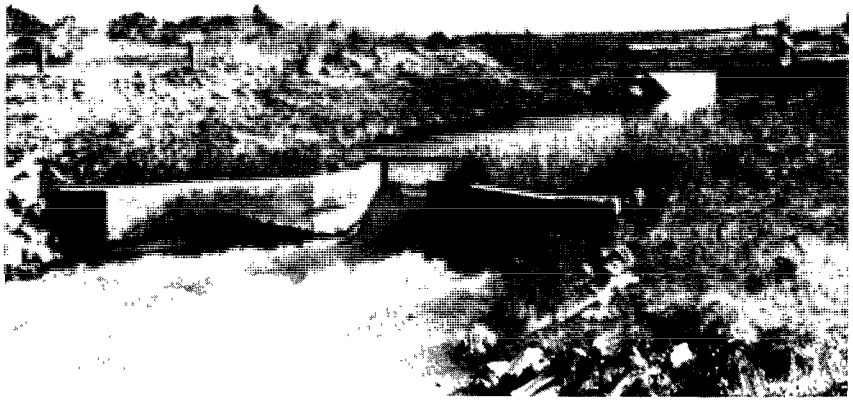

FIGURE 4.—Four-foot Parshall flume discharging 62 ft^3/s (1.76 m^3/s) under free-flow conditions. Scour protection is required with this height of fall. (Courtesy U.S. Bureau of Reclamation.)

5. If the stream carries a heavy sediment load, the artificial control should be designed to be self-cleaning. Flumes have that attribute; broad-crested weirs can often be made self-cleaning by a design modification in which the vertical upstream face of the weir is replaced by an upstream apron that slopes gently from the streambed to the weir crest.

Artificial controls are often built in conformance with the dimensions of laboratory-rated or field-rated weirs or flumes. The question arises whether to use the precalibrated rating or to calibrate in place each new installation. There are two schools of thought on the subject. In many countries, the precalibrated rating is accepted, and discharge measurements by current meter or by other means are made only periodically to determine if any statistically significant changes in the rating have occurred. If a change is detected, the new rating is defined by as many discharge measurements as are deemed neces-

FIGURE 5.—Flow through a 3-ft trapezoidal supercritical-flow flume showing transition from subcritical to supercritical flow.

sary. In other countries, including the U.S.A., the position is taken that it is seldom desirable to accept the rating curve prepared for the model structure without checking the entire rating of the prototype structure in the field by current-meter measurements, or by other methods of measuring discharge. The experience in the U.S.A. and elsewhere has been that differences between model and prototype invariably exist, if only in approach-channel conditions, and these differences are sufficient to require complete in place calibration of the prototype structure. In place calibration is sometimes dispensed with where the artificial control is a standard thin-plate weir having negligible velocity of approach.

CHOICE OF AN ARTIFICIAL CONTROL

Cost is usually the major factor in deciding whether or not an artificial control is to be built to replace an inferior natural control. The cost of the structure is affected most by the width of the stream and by the type or condition of bed and bank material. Stream width governs the size of the structure, and bed and bank material govern the type of construction that must be used to minimize leakage under and around the structure.

If an artificial control is to be used, the type and shape of the structure to be built is dependent upon channel characteristics, flow conditions, range of discharge to be gaged, sensitivity desired, and the maximum allowable head loss (backwater).

FIGURE 6.—Concrete artificial control on Mill Creek near Coshocton, Ohio.

CHOICE BETWEEN WEIR AND FLUME

As a general rule a weir is more advantageous for use as a control structure than a flume for the following reasons.

1. Weirs are usually cheaper to build than flumes.
2. A weir can be designed to have greater sensitivity at low flows with less sacrifice of range of discharge that can be accommodated, than is possible with a flume. Sensitivity is increased for a weir by notching the crest or by shaping the longitudinal profile of the crest in the form of a flat V or catenary. Sensitivity at low flow for a flume is usually attained by narrowing the effective width (converging sidewalls), or by using a trapezoidal cross section (narrower width at low stages), or by doing both; those measures significantly reduce the capacity of the flume.
3. The high water end of the stage-discharge relation for a weir can be extended beyond the stages at which the weir is effective as a control, with more confidence than can be done for a flume. In other words the stage-discharge relation for a flume becomes completely uncertain when any part of the structure upstream from the stage-measurement site is overtopped; the stage-discharge relation for a weir becomes completely uncertain only when the bank or abutment is overtopped and flow occurs around the end(s) of the weir.

If a flume is installed with the expectation that it will be overtop-

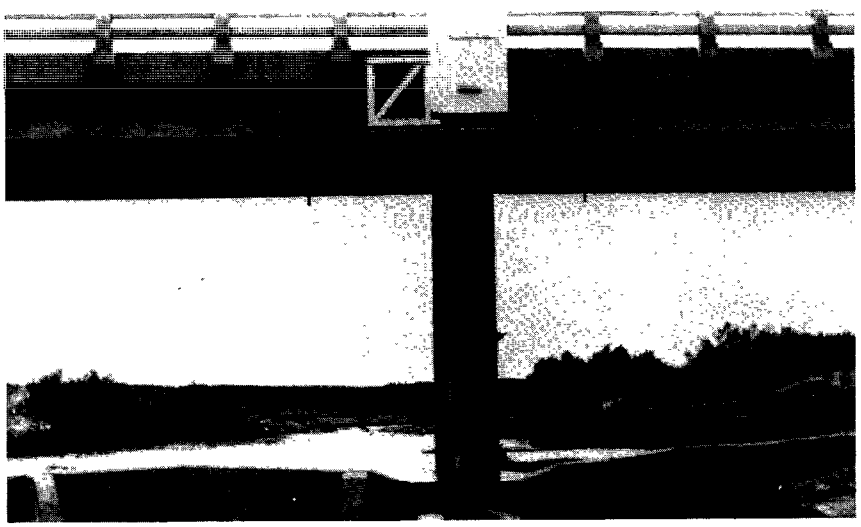

FIGURE 7.—Artificial control on Delaware River near Red Bluff, New Mex., with shallow V notch in the broad-crested weir.

ped by floodflows, it is advisable to install a nonrecording stage gage in a straight reach of channel, upstream or downstream from the flume but beyond the influence of the flume structure. Simultaneous observations of stage at the flume and in the unobstructed channel can be used to obtain a relation between the two stage gages. A stage-discharge relation for the site of the nonrecording gage can thus be derived from the flume rating, up to the discharge at which overflow starts at the flume. If for some reason, such as one of those discussed on page 273, high-flow discharge measurements are not available, the stage-discharge relation for the nonrecording gage can be extrapolated to flood stages; that extrapolation can then be used with the stage relation to define the overflow portion of the discharge rating for the flume.

However, in the following situations the use of a flume is more advantageous than the use of a weir.

1. If a heavy sediment load is carried by the stream, a weir will trap the sediment; accumulation of the sediment in the approach reach will alter the stage-discharge relation by changing the velocity of approach. Flumes however are usually self cleaning by virtue of their converging sidewalls and (or) steep floor. They therefore are more likely to maintain an unchanging stage-discharge relation. However, if the size of the sediment is not large, it is often possible to make a broad-crested weir self cleaning by including in its design an upstream apron that slopes downward from crest. An apron slope of 1 vertical to 5 horizontal will usually result in the transport of small sediment over the weir.
2. Weirs are usually not suitable for use in steep channels where the Froude number ($V/\sqrt{gd}$) is greater than about 0.75. Best results are obtained with weirs where the velocity head is a very minor part of the total head, and that is not the case in steep channels where the velocity head becomes excessively large. Furthermore, as explained above, weirs act as sediment traps on steep streams.
3. Flumes create less backwater for a given discharge than do weirs. Consequently it is more advantageous to use a flume if the channel has low banks. However for most natural streams it is impractical to design any type of structure to act solely as a metering device for the entire range of stage that may be experienced. In other words, for most natural streams sporadic overbank flooding is to be expected, with or without a control structure in the stream. Consequently the advantage of reduced backwater for a flume is usually realized only where the flow can be controlled to give some preassigned value of maximum dis-

charge. That situation occurs only in diversion canals or in natural streams having a bypass floodway.

CHOICE BETWEEN CRITICAL-FLOW FLUME AND SUPERCRITICAL-FLOW FLUME

After it has been decided for a particular site that the use of a flume is more desirable than the use of a weir, a decision must be made as to whether to use a critical-flow flume or a supercritical-flow flume.

Both types of flume will transport debris of considerable size without deposition in the structure, but if the transported rocks are excessively large, they may be deposited at or immediately upstream from the critical-depth section of a critical-flow flume. That will cause a change in the discharge rating of the flume. Therefore where that situation is likely to occur, a supercritical-flow flume should be selected for use.

If a critical-flow flume will pass the transported sediment load, that type of flume should be selected for use because the discharge rating for a critical-flow flume is more sensitive than that for a supercritical-flow flume.

SUMMARY

The artificial controls recommended for natural streams are as follows:

Sediment-transport characteristics	*Recommended structure*
Light load, small-size sediment	Weir.
Medium load, medium-size sediment	Parshall flume.
Heavy load, large-size sediment	Trapezoidal supercritical-flow flume.

The adjectives used above—light, medium, heavy, small, and large—are relative. Observation of both the study site and of the operation of control structures installed in an environment similar to that of the study site will provide the principle basis for the selection of the optimum type of control for use. In short, do not use a flume where a weir will do; if the use of a flume is indicated, do not use a supercritical-flow flume where a critical-flow flume (Parshall flume) will do.

The above recommendations also apply to canals or natural channels whose flow is controlled to limit the maximum discharge to some preassigned value. However, there is one exception; if the banks have little freeboard at the maximum discharge before the installation of an artificial control, a flume installation is generally preferable to a weir, in order to minimize the backwater caused by the structure.

DESIGN OF AN ARTIFICIAL CONTROL

Having decided on the type of artifical control to be used—weir, Parshall flume, or trapezoidal supercritical-flow flume—the next step is to design the structure. A standard design will usually be used, although channel conditions may make it necessary to make minor modification of the standard dimensions of the structure selected. The four factors—channel characteristics, range of discharge to be gaged, sensitivity desired, and maximum allowable head loss (backwater)—must be considered simultaneously in the precise determination of the shape, dimensions, and crest elevation of the control structure. However, two preliminary steps are necessary.

First, the head-discharge relations for various artificial controls of standard shape and of the type selected are assembled. Several such relations are to be found in hydraulics handbooks (King and Brater, 1963; World Meterological Organization, 1971). In addition, head-discharge relations for artificial controls that were field calibrated will usually be available in the files of water-resources agencies in the area—some are given in chapter 10. The head-discharge relations that are assembled need only be approximately correct, because channel conditions at the site of the proposed control will seldom match those for the model control.

The second preliminary step is to determine an approximate stage-discharge relation for the anticipated range in stage in the unobstructed channel at the site of the proposed control. That may be done by the use of an open-channel discharge equation, such as the Manning equation, in which uniform flow is assumed for the site and a value of the roughness coefficient is estimated. The reliability of the computed stage-discharge relation will be improved if one or more discharge measurements are made to verify the value of the roughness coefficient used in the computations. The purpose of the computations is to determine the tailwater elevation that is applicable to any given discharge after an artificial control is installed.

The next step is to consider the lower discharges that will be gaged. The tailwater elevations corresponding to those discharges are used to determine the minimum crest elevation permissible for the proposed artificial control at the lower discharges, under conditions of free flow or allowable percentage of submergence. If a flume is to be installed, the throat section should be narrow enough to ensure sensitivity at low discharges. If a weir is to be installed and the stream is of such width that a horizontal crest will be insensitive at low discharges, the use of a flat V crest is recommended—for example, one whose sides have a slope of 1 vertical to 10 horizontal. The sensitivity desired is usually such that the discharge changes no more than 2 percent for each change in stage of 0.01 ft (0.003 m). For a weir or

critical-flow flume (Parshall flume) it is also desirable that the minimum discharge to be gaged have a head of at least 0.2 ft (0.06 m) to eliminate the effects of surface tension and viscosity.

Stage-discharge relations for the several controls under consideration are next prepared for the anticipated range in discharge. A structure is then selected that best meets the demands of the site in acting as a control for as much of the range as possible, without exceeding the maximum allowable backwater (head loss) at the higher stages and with minor submergence effect and acceptable sensitivity at lower stages. In other words, a high crest elevation minimizes submergence but maximizes backwater effect which may cause or aggravate flooding; a low crest elevation maximizes submergence but minimizes backwater effect; and where flumes are concerned, the attainment of the desired range of discharge may require some sacrifice of sensitivity at extremely low discharges. The engineer must use judgment in selecting a control design that is optimum for the local conditions. For example, to design a flume whose throat is sufficiently wide to accommodate the desired range of discharge, it may be necessary to relax the 2-percent sensitivity criterion at extremely low flows; in that situation the engineer may accept a sensitivity such that a change in stage of 0.01 ft (0.003 m) results in as much as a 5-percent change in discharge.

From a practical viewpoint the use of artificial controls is limited to streams with stable channels. Artificial controls seldom operate satisfactorily in sand channels having highly mobile beds. The transport of sediment as bedload continually changes the characteristics of the approach channel, and the control itself may be buried or partially buried by the movement of sand dunes.

CHAPTER 4.—MEASUREMENT OF STAGE

GENERAL

The stage of a stream or lake is the height of the water surface above an established datum plane. The water-surface elevation re-

ferred to some arbitrary or predetermined gage datum is called the "gage height." Gage height is often used interchangeably with the more general term "stage," although gage height is more appropriate when used to indicate a reading on a gage. Stage or gage height is usually expressed in feet and hundredths of a foot, or in meters and hundredths or thousandths of a meter.

Records of gage height are used with a stage-discharge relation in computing records of stream discharge. The reliability of the discharge record is therefore dependent on the reliability of the gage-height record as well as on the accuracy of the stage-discharge relation. Records of stream stage are also useful in themselves for such purposes as the design of structures affected by stream elevation and the planning of flood-plain use. The gage-height record of a lake or reservoir provides, in addition to elevations, indexes of surface area and volume of the water body.

A record of stage may be obtained by systematic observations of a nonrecording gage or by means of a water-stage recorder. Special-purpose gages that do not give a complete record of stage are discussed on pages 74–78. The advantages of the nonrecording gage are the low initial cost and the ease of installation. The disadvantages are the need for an observer and the lack of accuracy of the estimated continuous-stage graph drawn through the plotted points of observed stage. For long-term operation the advantages of the recording gage far outweigh those of the nonrecording gage, and therefore the use of the nonrecording gage as a base gage is not recommended. However, at a recording-gage station, one or more nonrecording gages should be maintained as auxiliary gages for the operation of the station (p. 53–54). Telemetering systems are often used to transmit gage-height information to points distant from the gaging station (p. 54–59).

DATUM OF GAGE

The datum of the gage may be a recognized datum, such as mean sea level, or an arbitrary datum plane chosen for convenience. An arbitrary datum plane is selected for the convenience of using relatively low numbers for gage heights. To eliminate the possibility of minus values of gage height, the datum selected for operating purposes is below the elevation of zero flow on a natural control. Where an artificial control is used, the gage datum is usually set at the elevation of zero flow.

As a general rule a permanent datum should be maintained so that only one datum for the gage-height record is used for the life of the station. An exception occurs at gage sites where excessive streambed scour, after installation of the station, results in low-flow stages having a negative gage height. In that situation a change in gage datum

to eliminate the negative numbers is recommended, to avoid possible confusion involving the algebraic sign of the gage heights. Another exception occurs when channel changes at a station make it impractical to maintain the station at the existing site. It may then be necessary to move the station a distance, such that there is significant fall in the water-surface elevation between the old and new sites, even though discharges at the two sites are equivalent. In that situation there is generally little to be gained by establishing the datum at the new site at the same sea-level elevation as the datum at the original site. That is especially true if the station is moved downstream a distance such that negative gage heights would result from use of the original datum. When datum changes are made for whatever reason, a record of the change should be a part of the published station description.

In any event, when a station is established, it should be assumed that a permanent datum will be maintained at the site. To maintain a permanent datum, each gaging station requires at least two or three reference marks; that is, permanent points of known gage-height elevation that are independent of the gage structure. The datum at each gaging station is periodically checked by running levels from the reference marks to the gages at the station.

If an arbitrary datum plane is used, it is desirable that it be referred by levels to a bench mark of known elevation above mean sea level, so that the arbitrary datum may be recovered if the gage and reference marks are destroyed.

NONRECORDING STREAM-GAGING STATIONS

On page 23 it was mentioned that a record of stage could be obtained by systematic observation of a nonrecording gage. The advantages (low initial cost) and disadvantages (need for an observer, lack of accuracy) of a nonrecording gaging station were briefly discussed. On pages 53–54 the use of nonrecording gages as auxiliary and as reference (base) gages at recording-gaging stations will be discussed. Chapter 15 (p. 559–560) will describe the manner in which an observer's gage readings are used to compute a record of stage at a nonrecording gaging station. This section of the manual describes the various types of nonrecording gages.

Of the five types to be described, the two most generally used at nonrecording stations are either the staff or wire-weight gage. At such stations the nonrecording gage is usually read twice daily by an observer, and additional readings are made during periods of rapidly changing stage. The observer systematically records and reports his readings to headquarters. The record book and report cards shown in

figure 8 are used by the U.S. Geological Survey, the book being the permanent record of nonrecording-gage readings. The weekly report card serves as an interim report of the observations made. The weekly report cards are read promptly on their arrival at the headquarters office so that any problems or difficulties that arise can be handled without delay.

On each routine visit to a nonrecording stream-gaging station, the hydrographer also visits the observer to enter in the stage-record book the gage reading(s) that the hydrographer has made. At that time he also inspects the record book to check for discrepancies in the observer's readings. Such visits by the hydrographer are important; if they are not made the observer tends to feel that no one pays any attention to his work, and he may become less conscientious about his gage readings.

Descriptions of five types of nonrecording stage gages follow. The special-purpose crest-stage gage and its use as an adjunct to the nonrecording gaging station are described on pages 77–78.

FIGURE 8.—Cover of book and weekly report card for recording manual gage observations.

STAFF GAGE

Staff gages are either vertical or inclined. The standard Geological Survey vertical staff gage consists of porcelain-enameled iron sections, each 4 in (0.1 m) wide, 3.4 ft (1.04 m) long, and graduated every 0.02 ft (0.0067 m). (See fig. 9.) The vertical staff gage is used in stilling wells as an inside reference gage, or in the stream as an outside gage.

An inclined staff gage is usually a graduated heavy timber securely attached to permanent foundation piers. Inclined gages built flush with the streambank are less likely to be damaged by floods, floating ice, or drift than are projecting vertical staff gages. Copper barrelhoop staples and bronze numerals are generally used for the graduations. Inclined gages are used only as outside gages.

WIRE-WEIGHT GAGE

The wire-weight gage used in the U.S.A. is known as the type A wire-weight gage. It consists of a drum wound with a single layer of cable, a bronze weight attached to the end of the cable, a graduated disc, and a Veeder counter, all within a cast-aluminum box. (See fig. 10.) The disc is graduated in tenths and hundredths of a foot and is permanently connected to the counter and to the shaft of the drum. The cable is made of 0.045-in-diameter stainless-steel wire and is guided to its position on the drum by a threading sheave. The reel is equipped with a pawl and ratchet for holding the weight at any desired elevation. The diameter of the drum of the reel is such that each complete turn represents a 1-ft (0.305 m) movement of the weight. A horizontal checking bar is mounted at the lower edge of the instrument so that when it is moved to the forward position the bottom of the weight will rest on it. The gage is set so that when the bottom of the weight is at the water surface, the gage height is indicated by the combined readings of the counter and the graduated disc. The type A wire-weight gage is commonly mounted on a bridge handrail, parapet wall, or pier for use as an outside gage.

FLOAT-TAPE GAGE

A float-type gage consists of float, graduated steel tape, counterweight, and pulley. (See fig. 11.) The float pulley is usually 6 in (0.152 m) in diameter, grooved on the circumference to accommodate the tape, and mounted in a standard. An arm extends from the standard to a point slightly beyond the tape to carry an adjustable index. The tape is connected to the float by a clamp that also may be used for making adjustments to the tape reading if the adjustments necessary are too

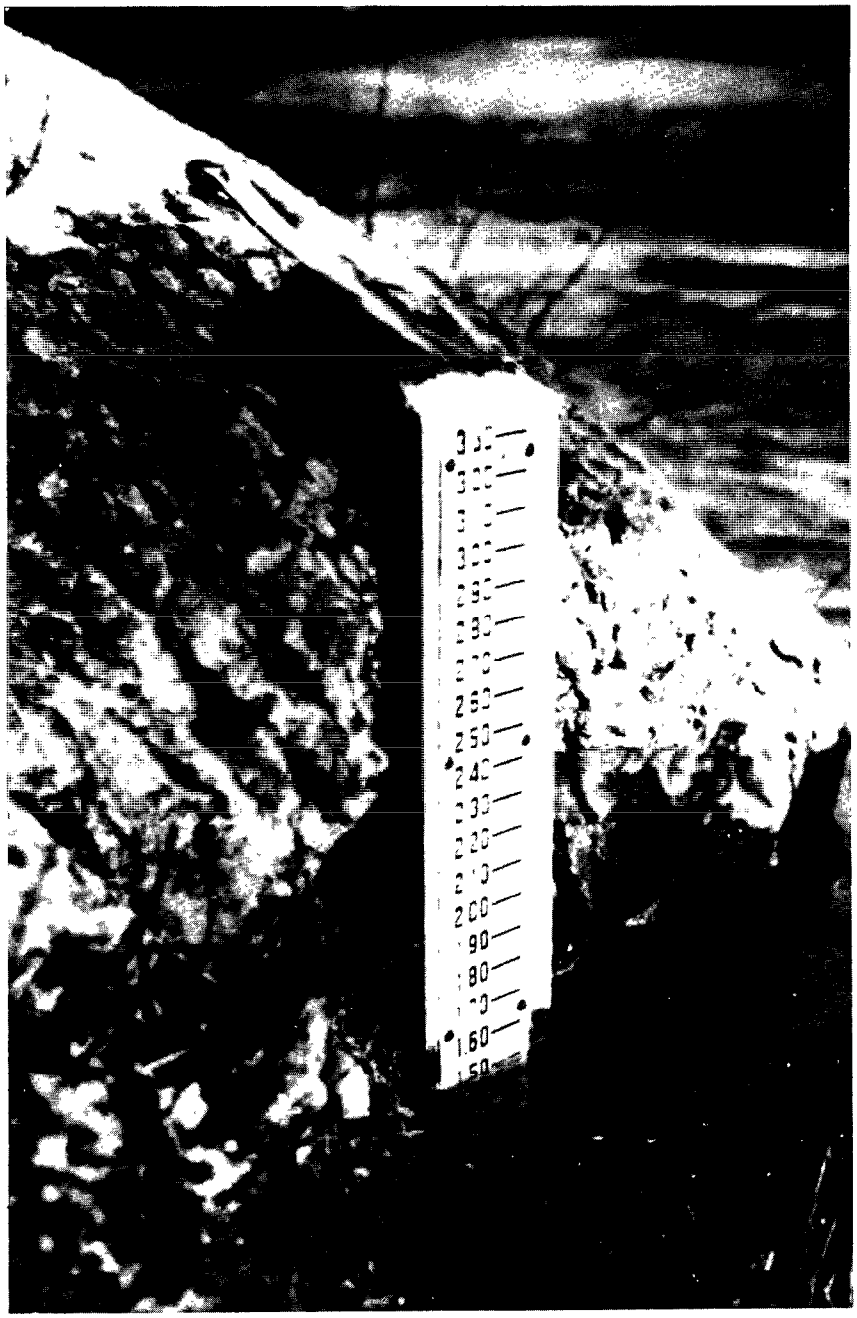

FIGURE 9.—Vertical staff gage.

large to be accommodated by the adjustable index. A 10-in (0.25 m)-diameter copper float and a 2-lb (0.9 kg) lead counterweight are normally used. The float-type gage is used chiefly in stilling wells as an inside reference or auxiliary gage.

ELECTRIC-TAPE GAGE

The electric-tape gage consists of a steel tape graduated in feet and hundredths of a foot, to which is fastened a cylindrical weight, a reel in a frame for the tape, a 4½-volt battery, and a voltmeter. (See fig. 12.) One terminal of the battery is attached to a ground connection, and the other to one terminal of the voltmeter. The other terminal of the voltmeter is connected through the frame, reel, and tape, to the weight. The weight is lowered until it contacts the water surface; this contact completes the electric circuit and produces a signal on the voltmeter. With the weight held in the position of first contact, the tape reading is observed at the index provided on the reel mounting. The electric-tape gage is used as an inside reference gage and occasionally as an outside gage. If oil is floating on the water surface, the gage will give the gage height of the interface, because oil is a dielectric. In some electric-tape gages a light or audible signal is substituted for the voltmeter.

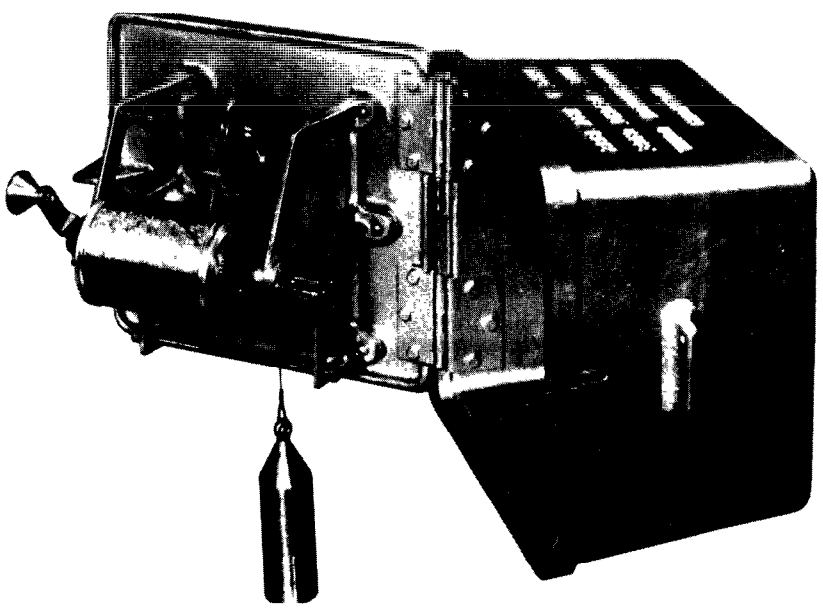

FIGURE 10.—Type A wire-weight gage.

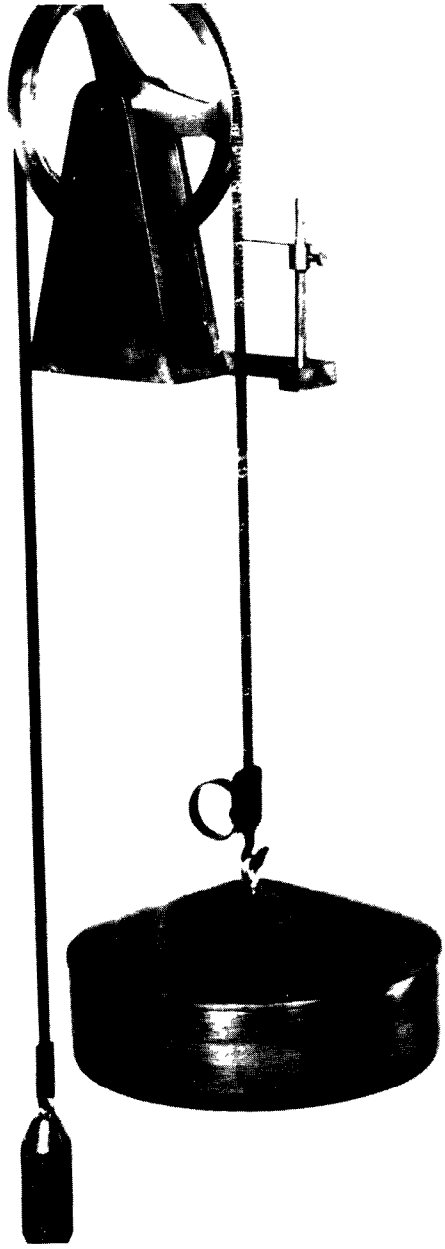

FIGURE 11.—Float-tape gage.

FIGURE 12.—Electric-tape gage.

CHAIN GAGE

A chain gage (fig. 13) is used where outside staff gages are difficult to maintain and where a bridge, dock, or other structure over the water is not available for the installation of a wire-weight gage. The chain gage can be mounted on a cantilevered arm which extends out over the stream, or which is made in such a way that it can be tilted to extend over the stream.

The chain gage consists of the cantilevered arm, one or more enamelled gage sections mounted horizontally on the cantilever, and a heavy sash chain that runs over a pulley on the streamward end of the cantilever. (See figure 13.) The chain is mounted so that it moves along the gage sections. A weight is attached to the streamward end of the chain, and an index marker (*M* in fig. 13) is attached near the other end at a distance from the weight that is appropriate for reading the gage height of low flows. Additional index markers can be attached to the chain at appropriate intervals to read gage heights greater than those directly obtainable from the mounted gage sections.

Stage is determined by lowering the weight until the bottom of the

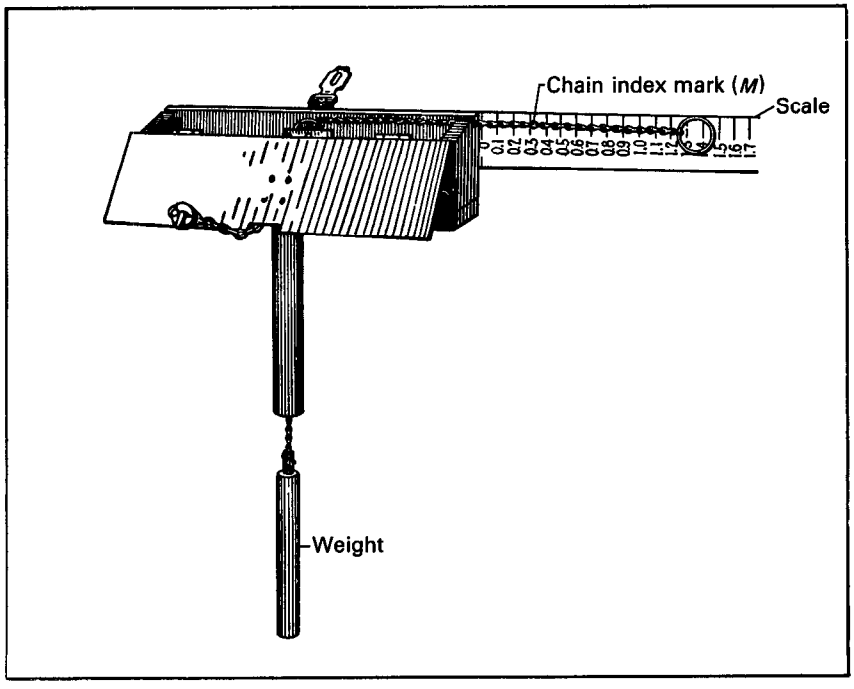

FIGURE 13.—Chain gage (cantilevered mount not shown).

weight just touches the water surface. The gage height then is read from the mounted gage plate at the location of the appropriate chain index marker.

RECORDING STREAM-GAGING STATIONS

METHODS OF SENSING STAGE FOR AUTOMATIC RECORDING

Stage is sensed for automatic recording by a float in a stilling well, or by a gas-purge system that transmits the pressure head of water in a stream to a manometer. The latter system, which does not require a stilling well, is known as a bubble gage.

FLOAT SENSOR

The float sensor consists of a tape or cable passing over a pulley, with a float in a stilling well attached to one end of the tape or cable and a counterweight attached to the other end. (See fig. 11.) The float follows the rise and fall of the water level, and the water level can be read by using an index and graduated tape, or the pulley can be attached to a water-stage recorder to transmit the water level to the recorder.

BUBBLE-GAGE SENSOR

The bubble-gage sensor (Barron, 1963) consists of a gas-purge system, a servomanometer assembly, and a servocontrol unit. (See fig. 14.) The gas-purge system transmits the pressure head of water in the stream to the manometer location. A gas, usually nitrogen, is fed through a tube and bubbled freely into the stream through an orifice at a fixed elevation in the stream. The gas pressure in the tube is equal to the piezometric head on the bubble orifice at any gage height.

The servomanometer converts the pressure in the gas-purge system to a shaft rotation for driving a water-stage recorder. Mercury is used as the manometer liquid to keep the overall manometer length to a minimum. The manometer has a sensitivity of 0.005 ft (0.0015 m) of water and can be built to record ranges in gage height in excess of 120 ft (36 m). The use of mercury in the manometer permits positioning of the pressure reservoir to maintain the float-switch contacts in null position. In this position, the vertical distance between mercury surfaces will be 1/13.6 times the head of water. A change in pressure at the reservoir displaces the mercury which in turn activates the float switch. This causes movement of the pressure reservoir until the distance of head of water divided by 13.6 is again maintained. This motion, in turn, is translated to the recorder.

The servocontrol unit provides the relay action necessary to permit the sensitive float switch to control the operation of the servomotor;

the unit also provides an appropriate time delay between the closing of the float switch and the starting of the motor.

Several bubble-gage sensors, differing in minor detail from that described above, are commercially available. Also commercially available is another type of bubble-gage sensor in which the nitrogen bubble tubing transmits the river-stage pressure to a bellows; the bellows, through a mechanical linkage, actuates a recording pen.

The proper placement of the orifice is essential for an accurate stage record. The orifice should be located where the weight of water above it represents the stage in the river. If the orifice is partly buried in sand or mud, the recorded stage will be greater than that in the river. An orifice preferably should not be installed in swift currents. If this is unavoidable, the orifice must be kept at right angles to the direction of flow. A recommended mounting for high-velocity flow is one in which the orifice is installed flush with the wall of the mounting structure. Care should also be taken to keep the orifice out of highly turbulent flow.

In unstable streambeds it is sometimes advantageous to place the bubble orifice in a vented well point driven into the unstable bottom.

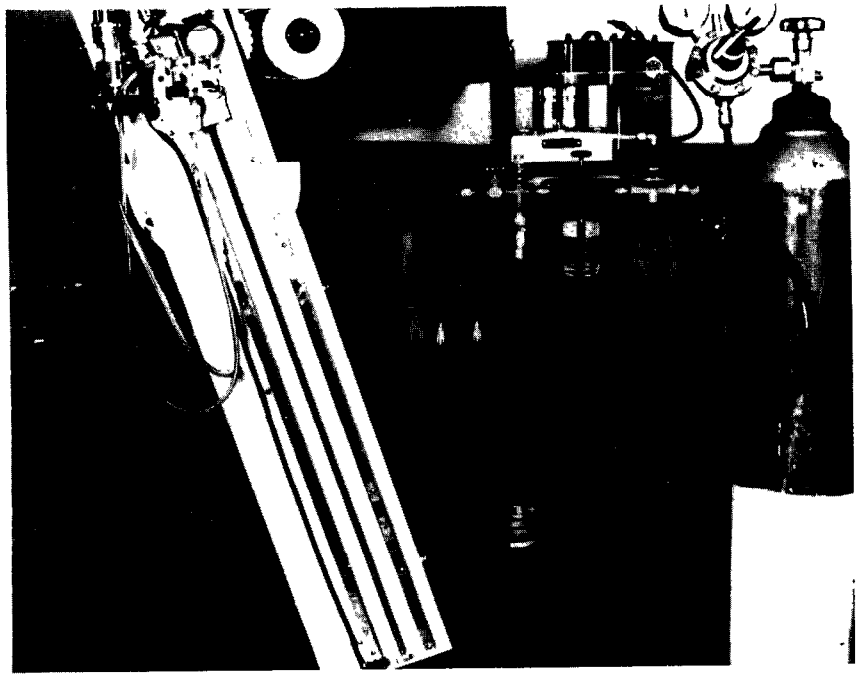

FIGURE 14.—Major units of the bubble gage.

If oil (generally kerosene) is to be added to prevent freezing in the vent pipe, the top of the well screen should be a sufficient distance below the minimum expected stream stage to retain the required depth of oil (fig. 15). To prevent variations in the depth of oil from affecting the manometer reading, the bubble orifice should be below the top of the screen so that the bubbles emerge into the water.

It is emphasized that for satisfactory operation of the well point the streambed material should not be so finely grained as to unduly impede the passage of river water to the well point and thereby cause lag in the recorded stage. To prevent clogging of the well-point screen, the screen should be made of material that will inhibit chemical reaction with substances in the water and (or) in the bed material. A stainless-steel screen set 1 to 3 ft (0.3 to 1.0 m) below the streambed is recommended.

The bubble gage is used primarily at sites where it would be expensive to install a stilling well. It is also used on sand-channel streams because the gas tends to keep the orifice from being covered with sand and the tube may be easily extended to follow a stream channel that shifts its location. However, the float stilling-well installation is cheaper to install at many sites, and its performance is usually more reliable than that of the bubble gage. The two systems have about the same accuracy—±0.01 ft (0.003 m). The choice of systems thus depends on the characteristics of the gage site.

WATER-STAGE RECORDERS

A water-stage recorder is an instrument for producing a graphic or punched-tape record of the rise and fall of a water surface with respect to time. It consists of a time element and a gage-height element which, when operating together, produce on a chart or on a tape a record of the fluctuations of the water surface. The time element is controlled by a clock that is driven by a spring, by a weight, or by electricity. The gage-height element is actuated by a float or a bubble gage.

If a float sensor is used, the float pulley is attached to the recorder. The float and counterweight are suspended on a perforated steel tape or on a plain or beaded cable. Cone-shaped protrusions on the circumference of the float-tape pulley match performations in the tape. As the float rises or falls the float pulley rotates in proportion to the change in stage; the rotation of the pulley is transmitted to the recorder and the appropriate gage height is thereby recorded. A copper float 10 in (0.25 m) in diameter is normally used, but other sizes are also used depending on the type of recorder, gage-height scale, and accuracy requirements.

If a bubble-gage sensor is used, the stage is translated to the recorder by a chain and sprocket arrangement. (See fig. 14.)

Stage recorders are either digital or graphic. Both types may be

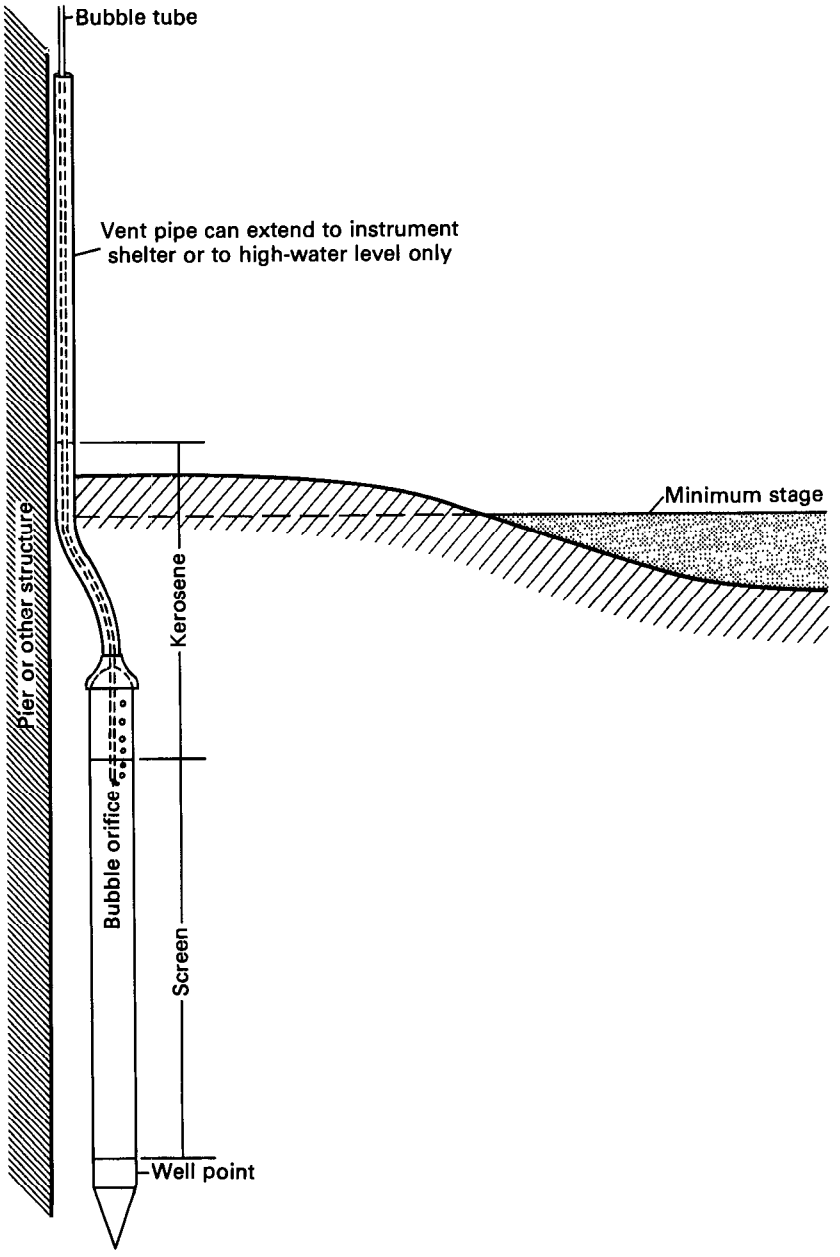

FIGURE 15.—Installation of bubble orifice in unstable streambed.

used with the float or bubble gage. Digital recorders are gradually replacing strip-chart (graphic) recorders at gaging stations in the United States. The two recorders are about equal in accuracy, reliability, and cost, but the digital recorder is compatible with the use of electronic computers in computing discharge records. This automated system offers greater economy and flexibility in the computation-publication process than do manual methods associated with graphic recording. However, the use of graphic recorders should be continued at those sites where a graphic record is necessary to detect ice effects, backwater, or frequent malfunctions of the recording system.

DIGITAL RECORDER

The digital recorder used by the U.S. Geological Survey (Isherwood, 1963) is a battery-operated slow-speed paper-tape punch which re-

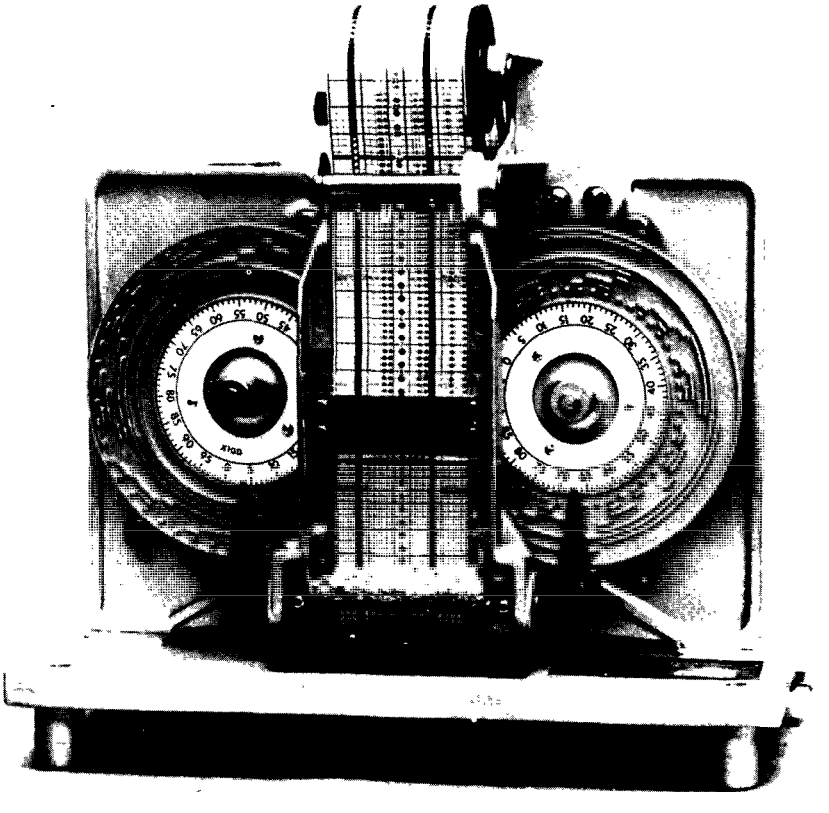

FIGURE 16.—Digital recorder.

cords a 4-digit number on a 16-channel paper tape at preselected time intervals. (See fig. 16.)

Stage is recorded by the instrument in increments of a hundredth of a foot from zero to 99.99 ft (30.5 m) and is transmitted to the instrument by rotation of the input shaft. Shaft rotation is converted by the instrument into a coded punch-tape record that is simple enough to be read directly from the tape. The code consists of four groups of four punches each. In each group, the first punch represents "1," the second "2," the third "4," and the fourth "8." Thus a combination of up to three punches in a group represents digits from 1 to 9, with a blank space for 0, and the four groups of punches represent all numbers from 1 to 9,999. (See fig. 17.)

Coding is done by means of two discs containing raised ridges in accordance with the punch code outlined above. One disc is mounted directly on the input shaft. The second code disc is connected to the first by a 100:1 worm gear so that one hundred revolutions of the input shaft rotate the second, or high-order disc, one complete revolution. A paper tape is moved upward through a punch block which is mounted on a movable arm hinged at the base of the recorder. The punch block contains a single row of 18 pins, 16 pins for the information punches and 2 for punching feed holes.

The tape is punched when the punch block with its protruding pins is forced against the code discs by spring action. Those pins, which strike the raised ridges of the discs, punch through the paper tape and record the position of the discs at that instant. The readout cycle begins with an impulse from the timer that causes a 6-volt motor to turn a sequencing camshaft. The sequence of operations for one reading includes punching the paper, advancing the paper, and compressing the punch spring for the next readout cycle.

The timers (fig. 18) used on the digital recorders are electromechanical timing devices that are powered by the same 7½-volt battery that operates the 6-volt motor. The timers provide contact closure for actuating the digital recorder at preselected time intervals of 5, 15, 30, or 60 minutes by using a different cam for each different time interval.

The cam on the timer corresponds to the minute hand on a clock; that is, it makes one revolution per hour in a clockwise direction. If the cam has one dropoff point, the recorder will punch hourly; if it has two dropoff points, it will punch every 30 minutes; and if it has four dropoff points, it will punch every 15 minutes. The timer in figure 18 has four dropoff points. The arm positioned by the cam operates a single-pole double-throw switch. When the cam dropoff point passes the arm, the switch initiates the major part of the readout cycle which includes punching of the tape. A preset action returns the switch to

the initial position prior to the next readout cycle. Alternating-current timers can be used with the digital recorders at places where

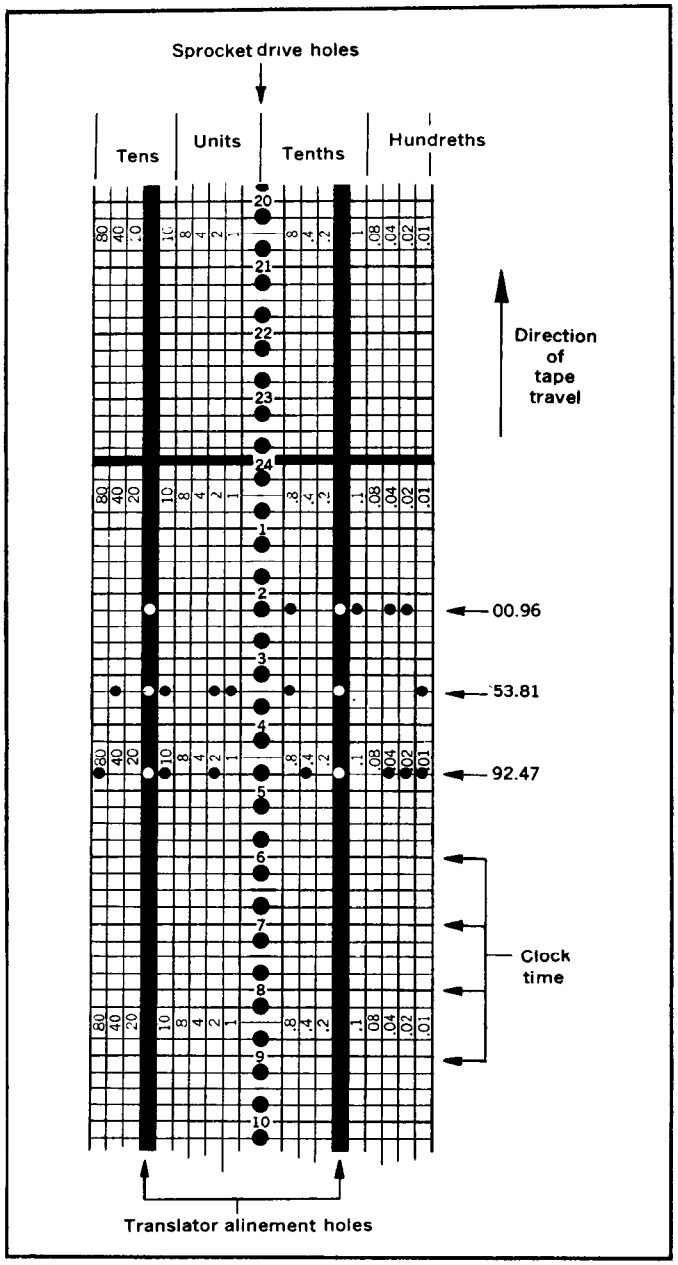

FIGURE 17.—Sample digital-recorder tape.

reliable alternating-current power is available.

Digital recorders may miss the absolute peak stage especially on flashy streams. However, a measure of the maximum peak that occurs between inspections of the recorder can be obtained by attaching a wire clip (similar to a paper clip) or small magnet to the float tape just below the instrument shelf in such a manner that it will slide along the tape as the stage rises but remain in a fixed position as the stage declines. (See p. 60–61).

Mechanically punched tape is the most practical for field use under widely varying conditions of temperature and moisture. Electronic translators are used to convert the 16-channel punch-tape records to a tape suitable for input into a digital computer for computation of a daily mean gage height and daily mean discharge.

In the metric version of the digital recorder, stage is recorded in increments of 1 millimeter from 0 to 9.999 m.

GRAPHIC RECORDER

The graphic, or analog, recorder furnishes a continuous trace of water stage, with respect to time, on a chart. Usually the gage-height element moves the pen or pencil stylus and the time element moves the chart, but in some recorders those actions are reversed. In the U.S.A. the common range of available gage-height scales is from 10 in=1 ft (10:12) to 10 in=20 ft (1:24). The width of strip charts is usually 10 in (0.25 m). The range of available time scales is from 0.3 to 9.6 in (0.0076 m to 0.244 m) per day. Normally the gage-height

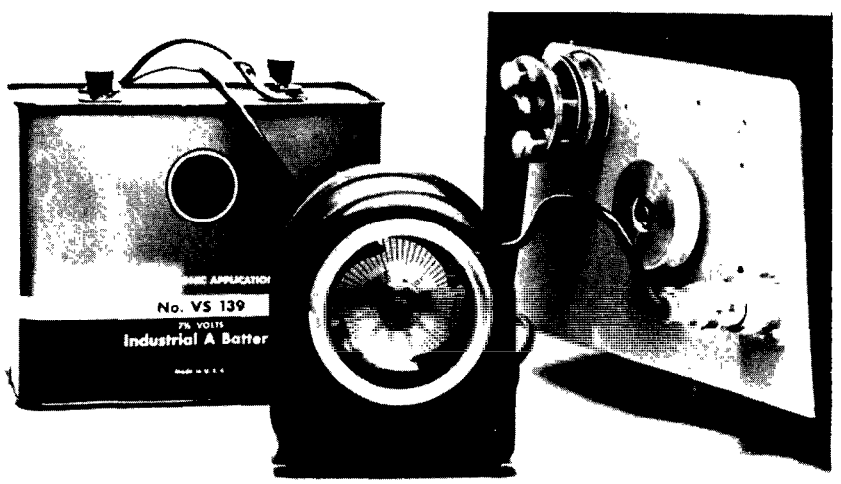

FIGURE 18.—Digital-recorder timer.

scale of 10 in=5 ft (1:6) or 10 in=10 ft (1:12) is used with a time scale of 1.2, 2.4, or 4.8 in per day.

Most graphic recorders can record an unlimited range in stage by a stylus-reversing device or by unlimited rotation of the drum.

Most strip-chart recorders will operate for several months without servicing. Drum recorders require attention at weekly intervals. Figure 19 shows a commonly used continuous strip-chart graphic recorder, and figure 20 a horizontal-drum recorder that must be serviced at weekly intervals. Attachments are available for the recorder

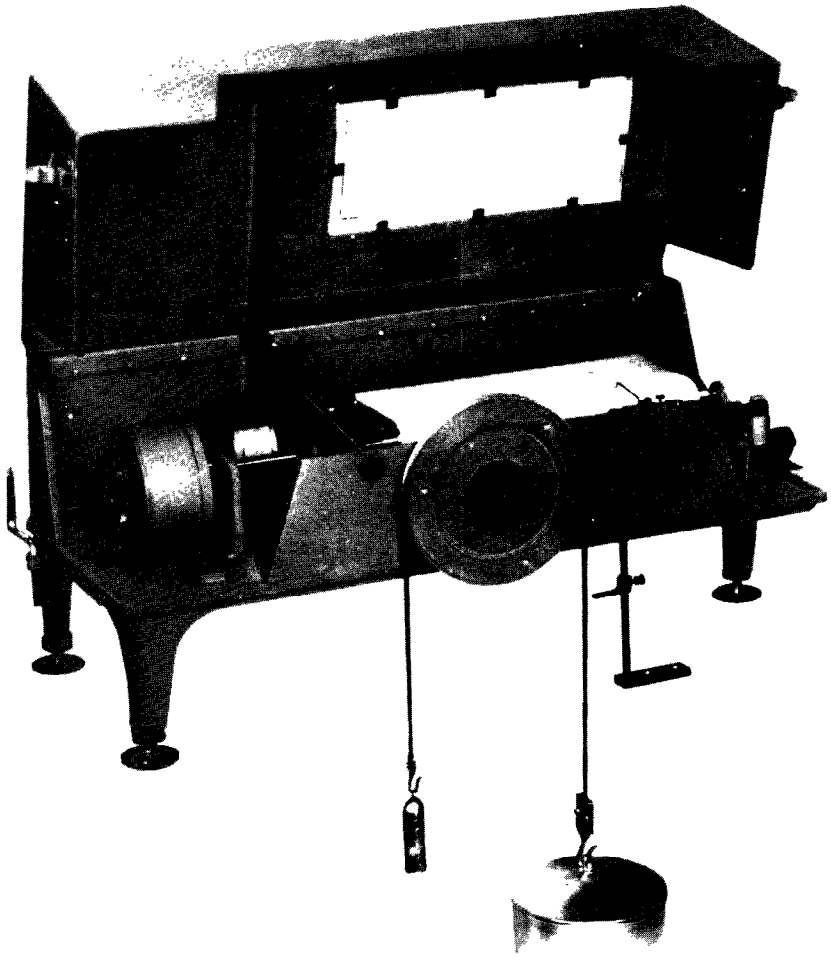

FIGURE 19.—Continuous strip-chart recorder.

shown in figure 19 to record water temperature or rainfall on the same chart with stage. Figure 21 is a section of a typical strip chart whose gage-height scale is 5:12 and whose time scale is 4.8 in per day.

STILLING WELLS

The stilling well protects the float and dampens the water-surface fluctuations in the stream caused by wind and turbulence. Stilling wells are made of concrete, reinforced concrete block, concrete pipe, steel pipe, and occasionally wood. They are usually placed in the bank of the stream (figs. 22–26), but often are placed directly in the stream and attached to bridge piers or abutments. (See figs. 27 and 28.) The

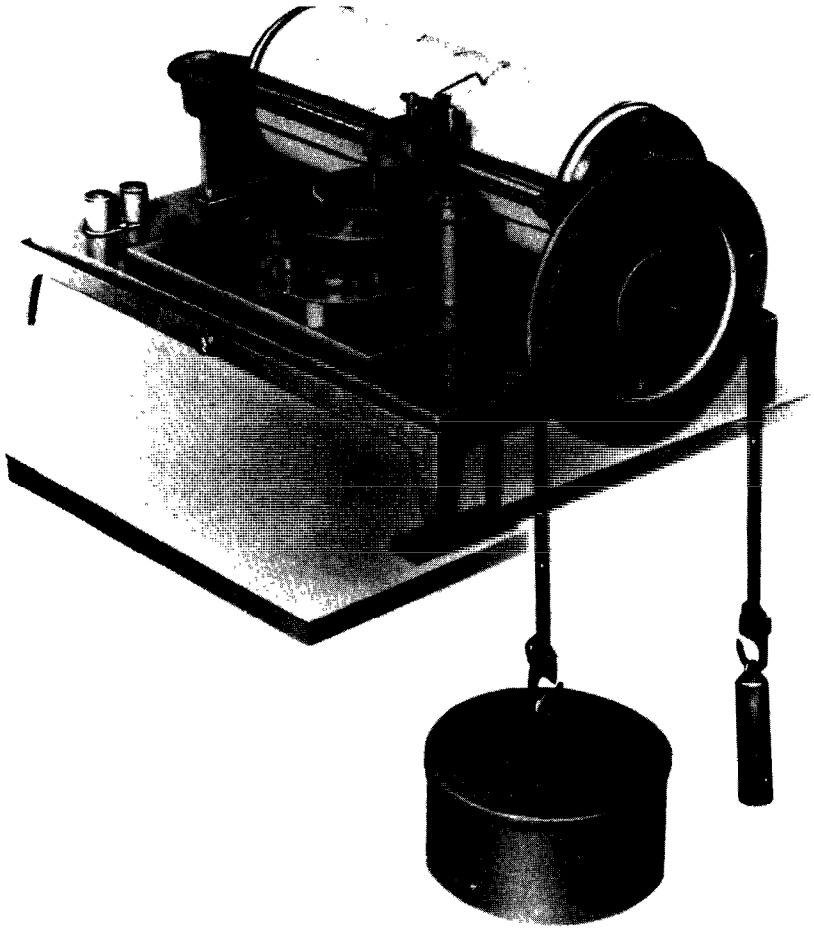

FIGURE 20.—Horizontal-drum recorder.

stilling well should be long enough for its bottom to be at least 1 ft (0.3 m) below the minimum stage anticipated, and its top preferably should be high enough so that the recording instrument will be above the level of the 100-year flood.

The inside of the well should be large enough to permit free operation of all the equipment to be installed. Usually a pipe 4 ft (1.2 m) in diameter or a well with inside dimensions 4 by 4 ft (1.2 by 1.2 m) is of satisfactory size, but pipes 1.5 ft (0.5 m) in diameter have been used for temporary installations where a conventional water-stage recorder was the only equipment to be installed. The 4 by 4 ft well provides ample space for the hydrographer to enter the well to clean it or to repair equipment. The smaller metal wells and the deep wells

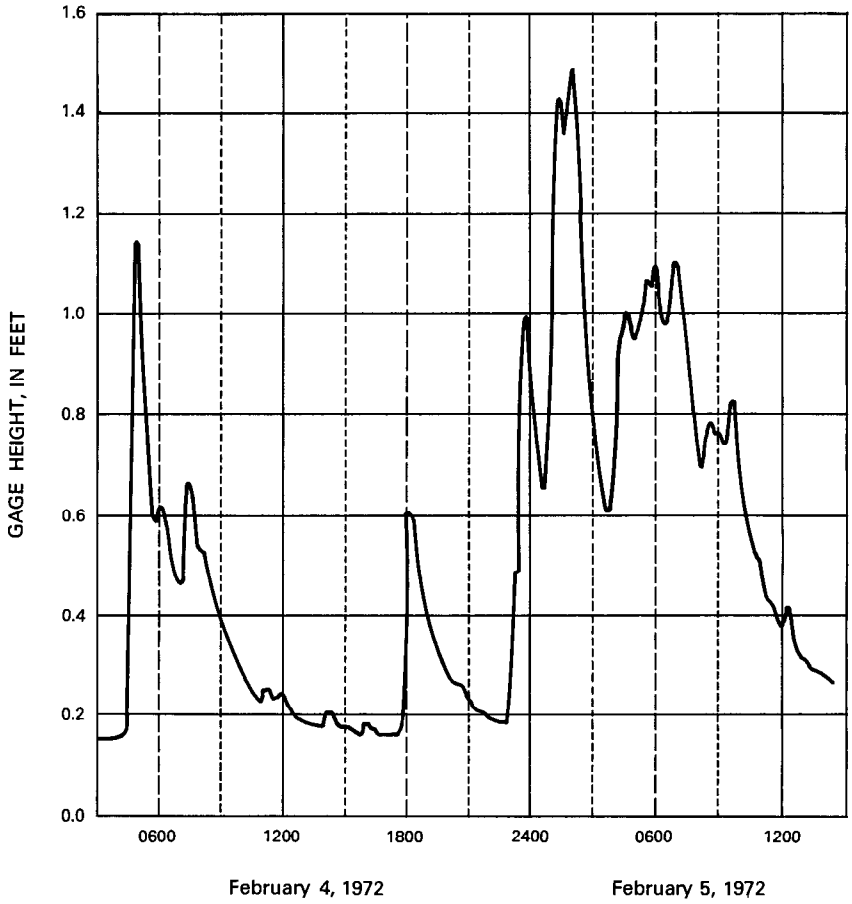

FIGURE 21.—Section of a typical strip chart.

should have doors at various elevations to facilitate cleaning and repairing. (See figs. 22 and 25.)

When placed in the bank of the stream the stilling well should have a sealed bottom so that ground water cannot seep into it nor stream water leak out.

Water from the stream enters and leaves the stilling well through the intake so that the water in the well is at the same elevation as the water in the stream. If the stilling well is in the bank of the stream, the intake consists of a length of pipe connecting the stilling well and the stream. The intake should be at an elevation at least 0.5 ft (0.15 m) lower than the lowest expected stage in the stream, and at least 0.5 ft above the bottom of the stilling well to prevent silt buildup from plugging the intake. In cold climates the intake should be below the

FIGURE 22.—Reinforced concrete well and shelter. (Note clean-out door.)

frostline. If the well is placed in the stream, holes drilled in the stilling well may act as an intake, taking the place of a length of pipe. Some wells placed in the stream have a cone-shaped hopper bottom that serves as an intake and is self cleaning.

Two or more pipe intakes are commonly installed at vertical intervals of about 1 ft (0.3 m). During high water, silt may cover the streamward end of the lower intakes while the higher ones will continue to operate. The intakes should be properly located and sized to minimize surge.

Most stations that have intakes subject to clogging are provided with flushing systems (see fig. 29) whereby water under several feet of head can be applied to the gage-well end of an intake. Ordinarily a pump raises water from the well to an elevated tank. The water is then released through the intake by the operation of a valve. Intakes without flushing systems may be cleaned with a plumber's snake or rod, or by building up a head of water in the well with a portable pump to force an obstruction out of the intakes.

The intakes for stations placed in the bank of the stream are usually galvanized-steel pipe. The most common size used is 2-in (0.05 m)-diameter pipe, but for some wells pipe diameters as large as 4 in (0.1 m) are used. After the size and location of the well have been decided upon, the size and number of intakes should be determined.

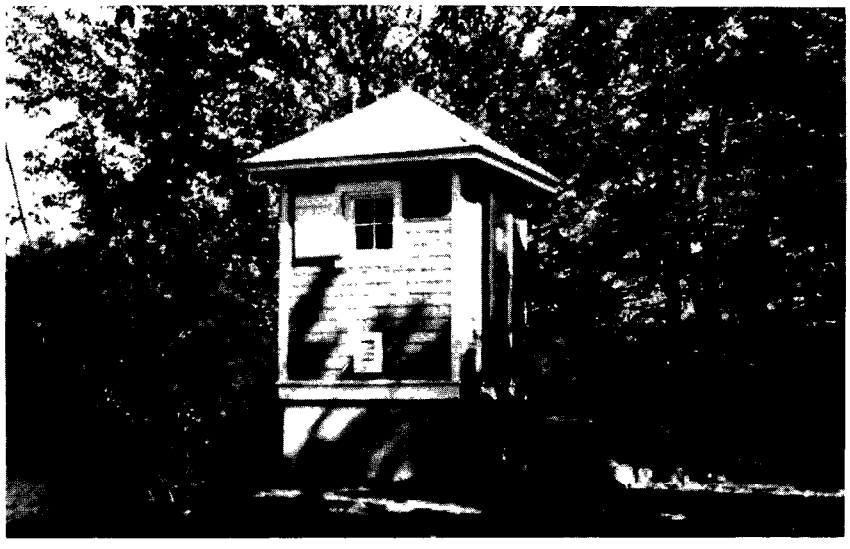

FIGURE 23.—Concrete well and wooden shelter with asphalt-shingle siding.

The intake pipe should be large enough for the water in the well to follow the rise and fall of stage without significant delay. The follow-

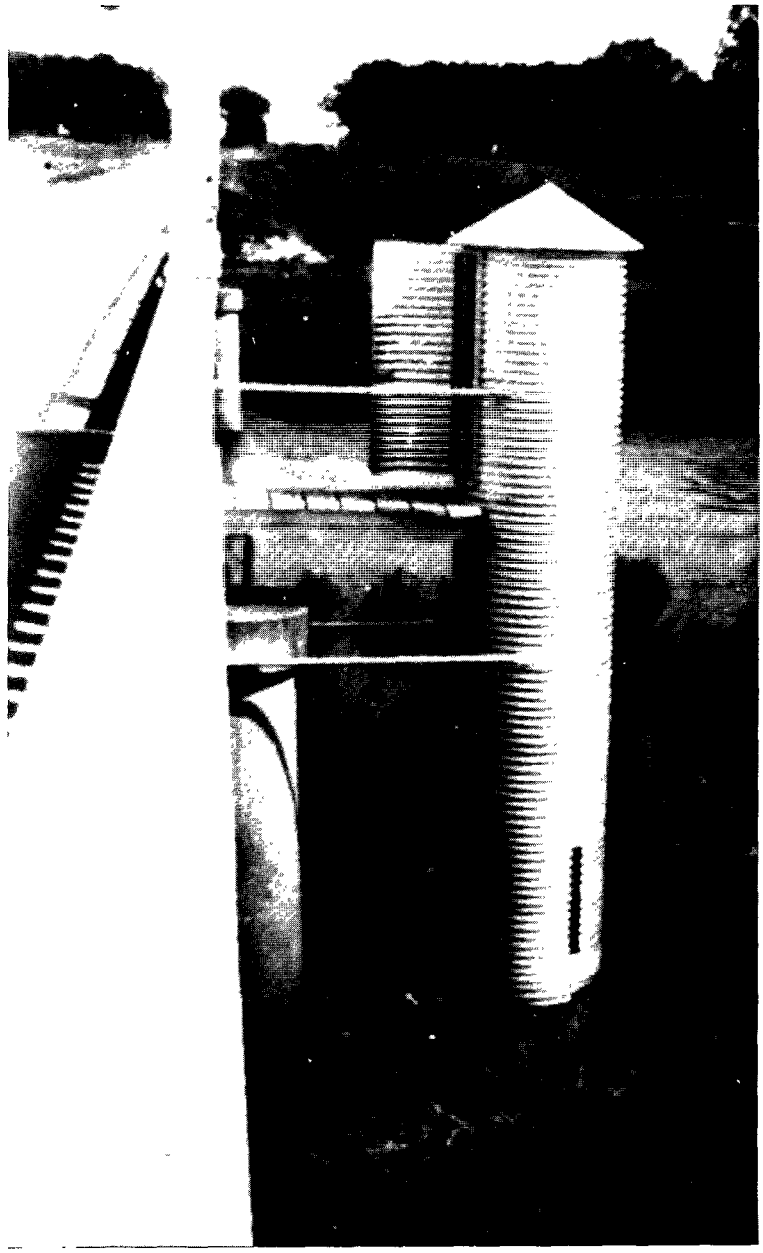

FIGURE 24.—Corrugated-galvanized-steel-pipe well and shelter.

ing relation may be used to predict the lag for an intake pipe for a given rate of change of stage:

$$\Delta h = \frac{0.01}{g} \frac{L}{D} \left(\frac{A_w}{A_p}\right)^2 \left(\frac{dh}{dt}\right)^2$$

in which

Δh = lag, in feet (or meters),

g = acceleration of gravity, in feet (or meters) per second per second,

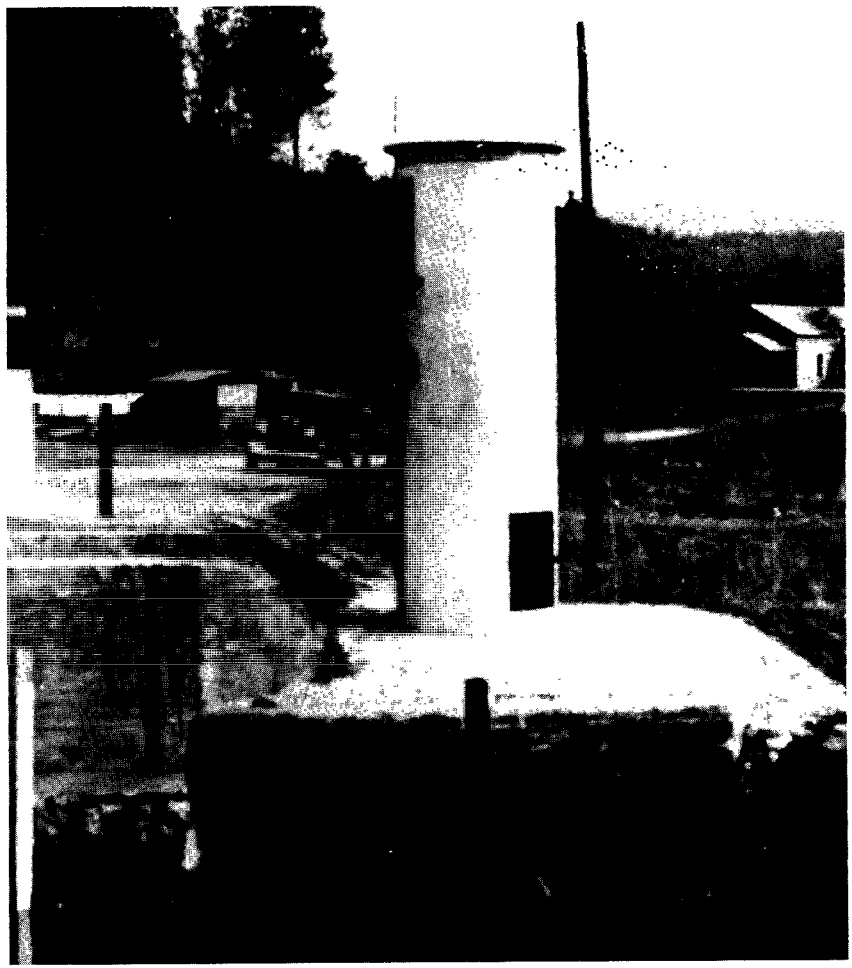

FIGURE 25.—Concrete-pipe well and shelter. (Note clean-out door, staff gage, and upper intake pipe.)

L = intake length in feet (or meters),
D = intake diameter, in feet (or meters),
A_w = area of stilling well, in square feet (or square meters),
A_p = area of intake pipe, in square feet (or square meters), and
$\frac{dh}{dt}$ = rate of change of stage, in feet (or meters) per second.

Smith, Hanson, and Cruff (1965) have studied intake lag in stilling-well systems, relating it to the rate of change of stage of the stream and to the various types and sizes of components used in the stilling-well intake system.

The intake pipe should be placed at right angles to the direction of flow, and it should be level. If the stream velocity at the end of the intake is high, either drawdown or pileup may affect the water level in the stilling well, depending on the angle of the flow at the intake opening. Drawdown causes the water level in the stilling well to be lower than that in the stream; pileup has the opposite effect. Drawdown commonly occurs at high velocities even when the intake pipe is at an angle of 90° with the flow. To reduce or possibly eliminate drawdown or pileup, a static tube should be attached to the streamward end of the intake pipe. A static tube is a short length of pipe attached to an elbow or tee on the end of the intake pipe and extending horizontally downstream. (See fig. 30.) The end of the static tube is capped, and water enters or leaves through holes drilled in the tube.

The usual means of preventing the formation of ice in the well

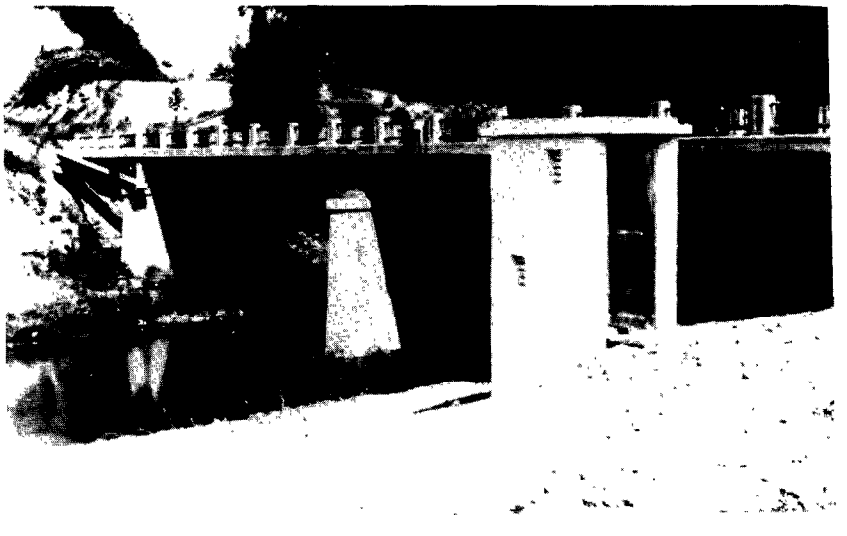

FIGURE 26.—Concrete-block shelter.

during cold weather are: (1) subfloors, (2) heaters, and (3) oil. Subfloors are effective if the station is placed in the bank and has plenty of fill around it. If the subfloor is built in the well below the frostline in the ground, ice will seldom form in the well as long as the stage remains below the subfloor. Holes are cut in the subfloor for the recorder float and weights to pass through, and removable covers are placed over the holes. Subfloors prevent air circulation in the well and the attendant heat loss.

An electric heater or heat lamps with reflectors may be used to keep the well free of ice. The cost of operation and the availability of electric service at the gaging station are governing factors. Heating cables are often placed in intake pipes to prevent ice from forming.

Oil is used in two ways: (1) Where the well is small and leakproof, the oil may be poured into the well; and (2) where the well is large or not leakproof, the oil—usually kerosene, fuel oil, or diesel oil—is poured into an oil tube. The oil tube, which is open ended and of sufficiently large diameter to accommodate the recorder float, is supported in the well in a vertical position with its lower end just above

FIGURE 27.—Steel-pipe well and look-in shelter attached to bridge abutment.

FIGURE 28.—Corrugated-steel-pipe well and wooden shelter attached to bridge pier.

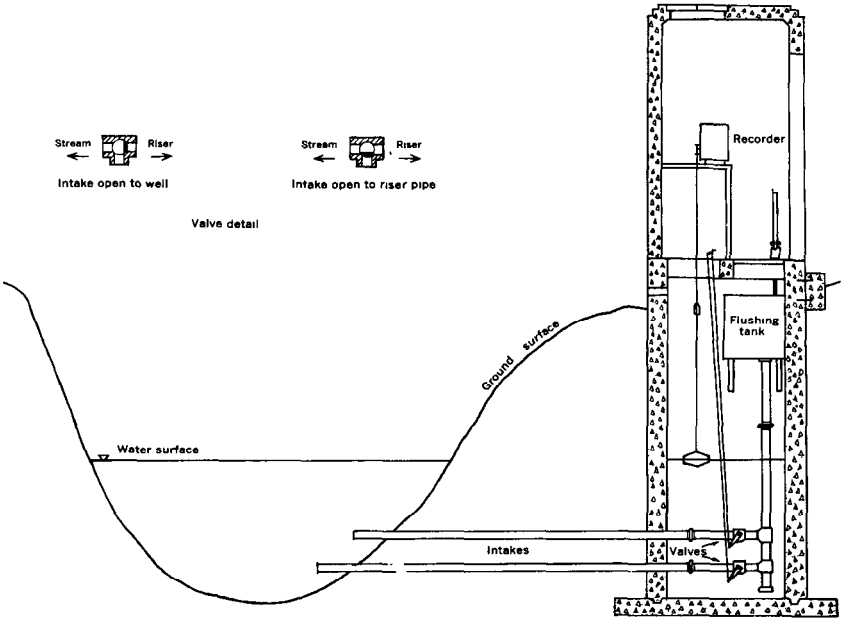

FIGURE 29.—Flushing system for intakes.

FIGURE 30.—Static tube for intakes. (Note outside reference gage.)

the floor of the well. The oil tube should be long enough to contain the oil throughout the range in stage expected during the winter. When oil is put in a well, the oil surface stands higher than the water surface in the stream. A correction must therefore be made to obtain the true river stage. The depth of oil required usually ranges from 0.5 to 2.0 ft (0.15 to 0.6 m) depending on the severity of the climate and the exposure of the well.

Stilling wells often fill with sediment, expecially those located in arid or semiarid regions. If a well is located on a stream carrying heavy sediment loads, it must be cleaned often to maintain a continuous record of stage. In those locations sediment traps are helpful in reducing the frequency and labor of sediment removal. A sediment trap is a large boxlike structure that occupies a gap in the lower intake line, streamward from the stilling well. The bottom of the sediment trap is usually about 3 ft (1.0 m) below the elevation of the intake. Inside the trap are one or more baffles to cause suspended sediment to settle in the trap, rather than pass into the well. A removable top to the trap provides access to the interior of the trap for the removal of trapped sediment.

The operation of type of recording stream-gaging station requires the installation of one or more nonrecording gages for use as auxiliary or reference gages. Reference gages are discussed on pages 53–54.

INSTRUMENT SHELTERS

Shelters are made of almost every building material available and in various sizes depending on local custom and conditions. (See figs. 22–28.) The most convenient type of shelter is one that the hydrographer can enter standing. A shelter with inside dimensions 4 by 4 ft (1.2 by 1.2 m) and with ceiling height 7 ft (2.2 m) above the floor is usually of adequate size, unless the shelter is also to be used to store sediment-sampling equipment and (or) house telemetry equipment (p. 54–59). Look-in shelters (fig. 27) are also used at sites where a limited amount of equipment is to be installed and a portable and inexpensive shelter is desired.

In humid climates, shelters are well ventilated and have a tight floor to prevent entry of water vapor from the well. Screening and other barriers are used over ventilators and other open places in the well or shelter to prevent the entry of insects, rodents, and reptiles.

The bubble gage does not require a stilling well. The instrument shelter for a bubble gage may be installed at any convenient location above the reach of floodwaters. This gage may be used to take advantage of existing natural or artificial features in a stream without costly excavation for well or intake and without need for any external

structural support. The bubble gage is especially well suited for short-term installations because the entire station is readily dismantled and relocated with practically no loss of investment.

A shelter with inside dimensions 4 by 4 by 7 ft (1.2 by 1.2 by 2.2m) is needed to accommodate the equipment for a bubble gage. Shelters similar to those in figures 22, 23, and 26 would be adequate. The shelter can be placed on a concrete slab or other suitable foundation. The bubble orifice is placed at least 0.5 ft (0.15 m) below the lowest expected stage in the stream. The plastic tube connecting the orifice and the instrument is encased in metal pipe or conduit, or buried to protect it from the elements, animals, and vandalism. A typical bubble-gage installation is shown in figure 31. The streamward end of the metal pipe should be flush with the streamward face of the pier shown in figure 31 to prevent disturbance of the streamlines of river flow in the vicinity of the orifice. The streamward end of the orifice line should also have a downward slope, as shown in the figure. It has been found that if the end of the orifice line is installed in a horizontal position, water tends to run up the bubble tube after each bubble is formed, and the induced surge is recorded by the stage recorder.

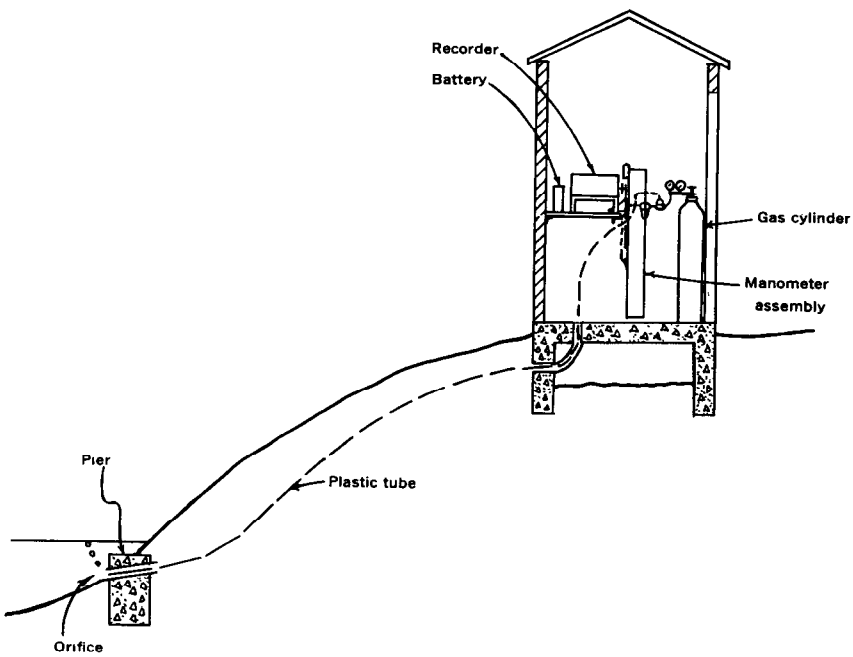

FIGURE 31.—Typical bubble-gage installation.

REFERENCE AND AUXILIARY GAGES AT RECORDING GAGING STATIONS

Nonrecording gages, which were discussed on pages 24–32, are used both as reference and auxiliary gages at recording stream-gaging stations. As used in this manual a reference gage is the gage to which the recording instrument is set; it is the base gage for the recording station. All other nonrecording gages at the recording station are considered to be auxiliary gages. A detailed discussion follows.

Outside gage—At bubble-gage stations a nonrecording gage, established in close proximity to the bubble orifice, acts as the base or reference gage for checking and resetting the gage height indicated by the water-stage recorder.

At stations equipped with a stilling well for the operation of a float-operated stage recorder, there is always the possibility that the stage in the stilling well may not be representative of the stage of the stream. For example, intakes can become plugged, floats can spring a leak, or oil can leak out of wells or oil tubes. Consequently, a nonrecording auxiliary gage is installed outside the stilling well so that the water level of the stream can be determined directly for comparison with the stage in the stilling well. It is not necessary that the two observed stages agree precisely; hydraulic conditions at the station may be such that precise agreement is not possible. If a reading of the outside auxiliary gage indicates that an unsatisfactory record is being obtained by the recording gage, the trouble is rectified immediately. If immediate repairs are not feasible, or if there has been an instrument failure, the outside auxiliary gage is used as a temporary substitute for the recording gage. The outside auxiliary gage can be read as needed by a local observer to continue the record of stage until the malfunction of the recording station is rectified.

Staff or wire-weight gages are usually used as outside auxiliary gages. Outside staff gages located in the pools near the gage structures are visible in figures 5, 6, 22, 25, and 30; a wire-weight auxiliary gage on the parapet wall of the bridge is visible in figure 1, and another is seen in figure 27.

Inside gage—At gaging stations equipped with a stilling well a nonrecording gage inside the structure is used to indicate the water-surface elevation in the stilling well. Readings on this inside gage are compared with readings on the outside auxiliary gage to assure that the stilling-well intakes are functioning properly. If the intakes are functioning properly, the inside gage is used for checking and resetting the gage height indicated by the water-stage recorder. In short, the inside gage is the base or reference gage for the station. Float- or electric-tape gages, or vertical staff gages, are the inside reference gages most commonly used in stilling wells.

On occasion a reference mark or reference point of known elevation, with respect to gage datum, is used in place of either a reference or auxiliary gage. The stage is then determined by measuring from the reference mark or point down to the water surface either in the stream or in the stilling well, as the case may be. While the practice of using a reference mark or point is acceptable, it is not nearly as convenient as the practice of using a standard nonrecording gage. (The distinction between a reference mark and reference point should be noted here: Both have elevations that are known, but a reference point is a point on the gage structure itself; a reference mark is a point that is not on the gage structure, and whose elevation is therefore unaffected by any movement of the gage structure.)

The practice described above of using the inside gage, rather than the outside gage, as the reference or base gage for a recorder equipped with a stilling well is followed in the U.S.A. and in many other countries. The reasoning behind that practice is that recorded (inside) gage heights will be used to determine discharge, and if differences exist between inside and outside stages, those differences will be known only for those times when both gages are read. If the outside gage is used as the base gage, corrections, known or assumed, must be applied to all recorded gage heights to convert them to outside stages. Furthermore, outside gages are often difficult to read with precision because of the action of wind and waves. In other countries the outside gage is used as the reference gage for the reasons that (1) river stage is often as important as discharge to the user of the record and (2) a stage-discharge relation is dependent on river stage, rather than on the stage inside a stilling well. The validity of both those reasons is recognized in the U.S.A. Therefore outside high-water marks are obtained for each flood event, and where the elevation of the marks differs significantly from the peak inside stage, both inside and outside stages are published. Also, where there is significant difference between inside and outside gage readings, the stage-discharge relation is first developed on the basis of outside-gage readings observed at the times when discharge is measured. The relation is then adjusted to correspond with inside-gage readings observed at the times of discharge measurement.

TELEMETERING SYSTEMS

Telemetering systems are used when current information on stream stage is needed at frequent intervals and it is impractical to visit the gaging station each time the current stage is needed. Current stage information is usually necessary for reservoir operation, flood forecasting, prediction of flows, and for current-data reporting. The types of telemetering systems are:

1. Those that continuously indicate or record stage at a distance from the gage site. Examples of this type are the position-motor and impulse telemetering systems.
2. Those that report instantaneous gage readings on call or at predetermined intervals. Examples of this type are the Telemark and resistance telemetering systems, and the experimental satellite data-collection systems.

POSITION-MOTOR SYSTEM

The position-motor system provides remote registering of water levels on graphic recorders or on counter or dial indicators over distances up to 15 mi (25 km). This system employs a pair of self-synchronizing motors—one on the transmitter, whose rotor is actuated by a float-tape gage or a bubble gage, and the other on the receiving unit, whose rotor follows the rotary motion of the transmitting motor to which it is electrically connected. Alternating current is used to operate the system, and a five-wire transmission line is required—two excitation wires and three line wires.

IMPULSE SYSTEM

The impulse system provides remote registering of water levels on graphic recorders or on counter and dial indicators over longer distances than does the position-motor system. This system will operate over leased telephone lines or other metallic circuits. The impulse sender at the gaging station is actuated by a float-tape gage or a bubble gage and sends electrical impulses over the line connecting it to the receiver. This system usually has a battery for the power source at the sender and alternating current at the receiver, though direct current or alternating current may be used at both ends. The advantage of this system over the position-motor system is that it will operate over long distances.

TELEMARK SYSTEM

The Telemark system codes instantaneous stage and signals this information either audibly over telephone circuits or by coded pulses for transmission by radio. The distance of transmission is unlimited because signals can be sent over long-distance telephone circuits or by radio. Telemark response to a telephone ring is automatic. When used in radio transmission, the signals are started by a timing device set for a predetermined broadcast schedule, or the Telemark may be interrogated by radio channel to start the signal.

The Telemark consists of (1) the positioning element which is actuated by a float-tape gage or a bubble gage (fig. 32) and (2) the signaling element which, when signaled, drives a contact across the

signaling drums that are positioned in correspondence with the stage. The Telemark may be operated by either alternating current or by batteries.

A Telemark that operates directly off a digital recorder is available and will probably be increasingly used. This Telemark does not need its own stage sensor; it uses that of the digital recorder. A memory system is used so that when the Telemark is signaled, the last gage height recorded on the digital recorder is transmitted.

Telemarks for radio reporting are equipped with an auxiliary switch and coding bar for transmitting identifying radio station call letters and numbers in international Morse code, in addition to transmitting the stage.

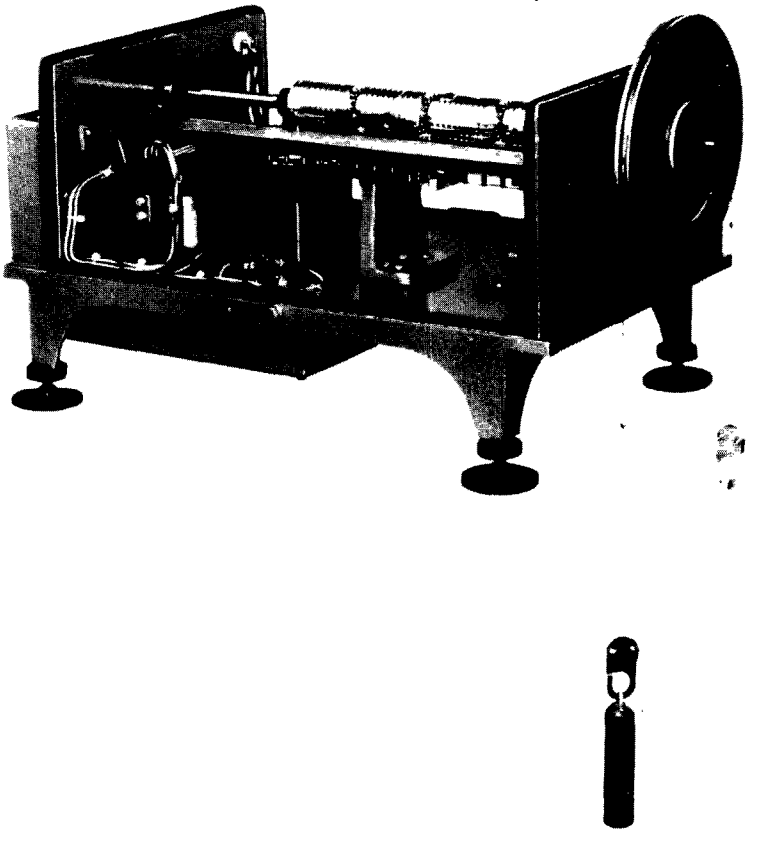

FIGURE 32.—Telemark gage.

RESISTANCE SYSTEM

The resistance system, as used in the U.S.A., was developed by the U.S. Weather Bureau. It provides remote indications of water level for distances up to about 40 mi (about 65 km). Two models are available, one for distances of about a mile (1.6 km) and the other for longer distances. The system consists of two potentiometers in a wheatstone-bridge circuit with a microammeter null indicator. One of the potentiometers is located in the gage house and is actuated by a float and pulley assembly. (See fig. 33.) The other potentiometer and the null indicator are housed at the observation site. (See fig. 34.) By adjusting this potentiometer for a null balance on the meter, the gage height can be read directly to tenths of a foot from a dial coupled to the potentiometer shaft. This system operates on batteries, and three wires connect the unit.

SATELLITE DATA-COLLECTION SYSTEM

The U.S. Geological Survey has been experimenting for several years with the collection of stream-stage data by use of an orbiting satellite which receives radio transmissions of stage and transmits

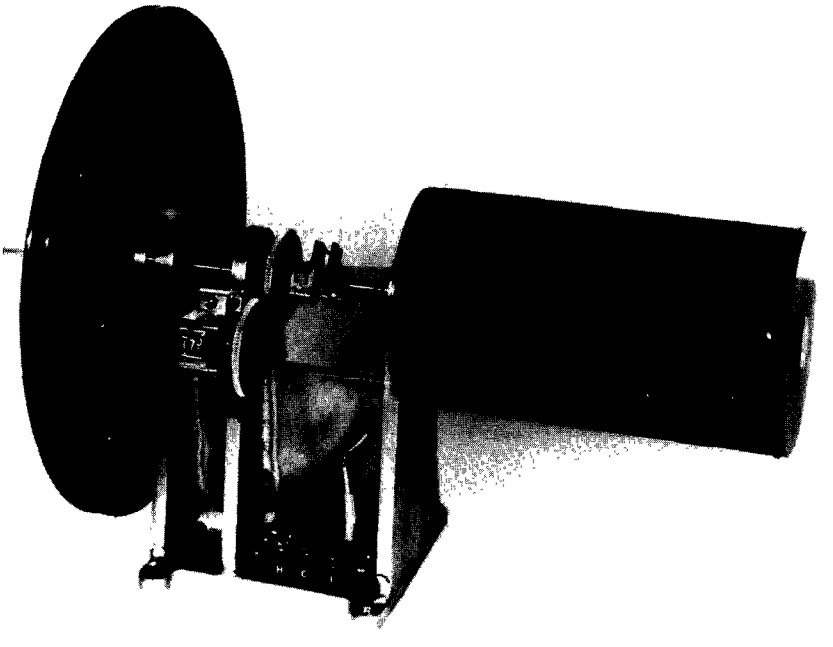

FIGURE 33.—Resistance system transmitter unit.

the data to central receiving stations. An operational system of that kind would make stage data continuously available for use by the managers of water projects who require current ("real time") information for project operation. Because the system is still in the experimental stage it will be described only briefly.

Experimental work on the system began soon after the launch of the Earth Resources Technology Satellite (ERTS) in July 1972. At numerous stream-gaging stations that are dispersed over a wide geographic area, inexpensive battery-operated radios, called data-collection platforms (DCP), are used to transmit stage data through ERTS to the National Aeronautics and Space Administration (NASA) receiving stations at Goldstone, California, and at Greenbelt, Maryland. The data are processed and distributed to experimenters from the ERTS Operations and Control Center in Greenbelt.

Data can be provided to a DCP either directly from a digital water-stage recorder or through an intermediate memory device. In the

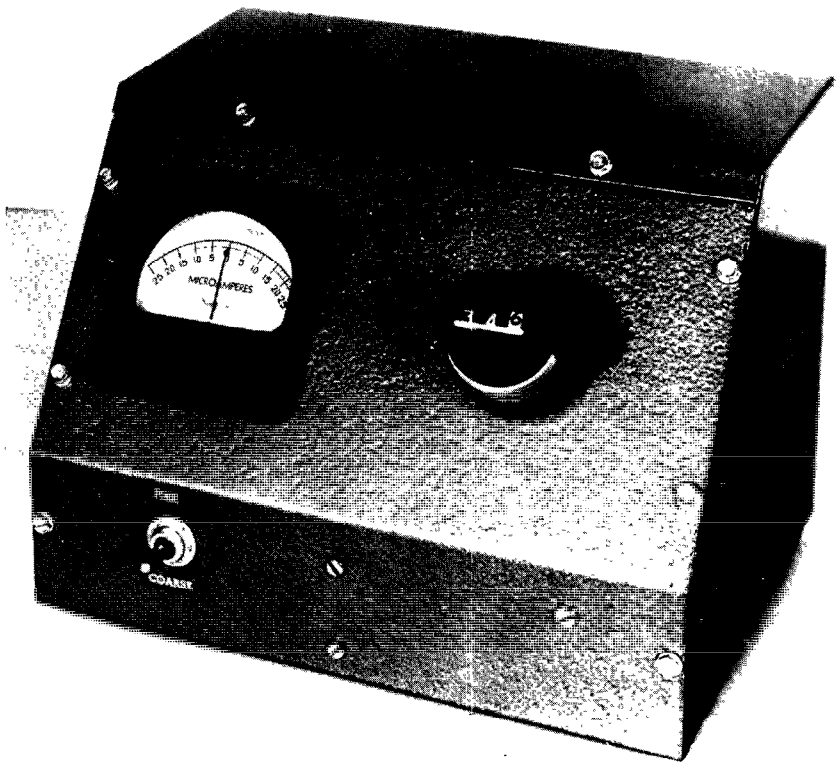

FIGURE 34.—Resistance system indicator unit.

direct communication the most recently recorded digital stream stage is continuously available to the DCP for inclusion in a 0.038-second radio message that is transmitted every 3 minutes. Several times daily the ERTS passes within 1,800 mi of the DCP, and the data are at that time relayed to the receiving stations. Where the intermediate memory device is used, the data are formatted efficiently in the device for inclusion in the periodic DCP message. By use of the memory device virtually all 24 of the hourly stream stages collected daily at North American stream-gaging stations can be accumulated and relayed, as opposed to the 5 or 6 hourly stages that are relayed daily when the DCP is directly connected to the digital-stage recorder. Tests of the satellite data-collection system have been successful to date (1980) and indicate that the satellite relay of environmental data from widely dispersed and remotely located gaging stations can be effectively and reliably performed.

OPERATION OF A RECORDING STREAM-GAGING STATION

Strip-chart or digital recorders are designed to give a continuous record of stage, but careful attention to details is necessary at each visit to the station to ensure a reliable and uninterrupted record during the period (commonly 4–6 weeks) that usually elapses between such visits. This section of the manual presents only general instructions for servicing recording stream-gaging stations. It is not practical to attempt to provide detailed instructions here for servicing stage-recorders because of the large numbers of such instruments of varying design that are available. For detailed instructions concerning any particular stage-recorder, it is necessary that the hydrographer consult the service manual prepared by the manufacturer of the instrument or prepared by the stream-gaging agencies that use the particular instrument.

The first thing done by the hydrographer on his visit to the recording station is to determine if the clock or timer is running. If it is a strip-chart recorder that is being serviced, the point at which the pen or pencil is resting is then circled; if it is a digital recorder that is being serviced, the instrument is caused to punch the digital tape and the set of punched holes is circled. The time by the hydrographer's watch is noted and the base nonrecording reference gage is read. Those observations are written on the chart or digital tape in proximity to the circled gage height. The hydrographer then reads all gages and notes the chart position or digital-tape position, with respect to time and gage height, of the circled pen mark or punched holes. All that information is also written on the chart or digital tape.

The various gage readings and the recorded gage heights are compared to determine if intakes are functioning properly or if there is a

malfunction in the gas-purge system of the bubble gage. The time indicated by the chart or digital tape is compared with the time indicated by the hydrographer's watch to determine if the instrument clock or timer is operating satisfactorily. The section of chart or digital tape bearing the gage-height record is next removed and is examined to determine if there has been any recorder malfunction since the previous servicing of the station.

The clock is then wound, or if the clock is battery driven, the battery voltage is checked and the chart or digital tape is rethreaded into the take-up roll. The pen or punch mechanism is next set to agree with the gage height indicated by the base reference gage, and the chart or digital tape is advanced to give agreement with the hydrographer's watch time. By resetting the recorder at this point, before completing his inspection of the station facilities, the hydrographer gives himself another opportunity to check the operation of the recorder after his work is completed and the instrument has been operating for a period of time.

If the station has a float-operated recorder, the hydrographer inspects the float to determine if it leaks and checks the float-clamp screw to make sure there can be no slippage of the float tape where it joins the float. He also checks the stilling well to be sure there is no unduly large accumulation of sediment in the well. If the well is equipped with an oil tube for winter operation he uses a point on the top of the tube to measure down to the oil surface within the tube and to the water surface outside the tube. The differential between the two measurements, when divided by a value equal to 1.0 minus the specific gravity of the oil, equals the depth of oil in the oil tube. The hydrographer can decide from that computation whether oil has leaked from the tube and the additional amount of oil, if any, to be added. If the stilling well is equipped with a flushing device, the intakes should be flushed as a matter of course. If no flushing device has been provided, and there are indications that the intakes are lagging, the intakes should be cleaned by forcing a plumber's snake through them.

If a high discharge has occurred since the previous visit to a stilling-well-equipped station, high-water marks should be sought both in the stilling well and outside the well, as a check on the peak stage shown by the stage recorder. After making that check, the high-water mark should be cleaned from the inside of the well to prevent confusion with high-water marks that will be left by subsequent peak discharges.

Another means of checking recorded peak stages is by having a wire clip (similar to a paper clip) or magnet attached to the float tape immediately below the shelf through which the tape passes. As the

stage rises, the wire clip or magnet, being too large to pass through the hole in the shelf, retains its position at the bottom of the shelf, and the moving float tape slides past it. When the stage recedes, the clip or magnet remains attached to the tape and moves downward as the float moves downward. Any one of several alternative methods may be used to determine the peak stage that had been attained. In one method the peak stage is obtained by subtracting a correction constant from the tape reading at the top of the wire clip. That correction constant is equal to the difference in elevation between the index pointer for the float gage and the bottom of the shelf. In a second method the visiting hydrographer computes the difference between readings on the float tape at the bottom of the shelf and at the top of the wire clip or magnet. He adds that difference to the current gage height to obtain the peak stage attained. A third method of determining the peak stage is to raise the float until the wire clip or magnet is at the bottom of the shelf; the corresponding tape-gage reading is the peak stage that had been attained. Regardless of the method used, after determining the peak stage the wire clip or magnet should be moved back to the bottom of the shelf for subsequent indication of peak stage.

If an indicator of minimum stage is desired, a similar device—wire clip or magnet—can be attached to the float tape immediately below the instrument shelf, but on the counterweight side of the float sheave. The operation of the minimum-stage indicator is similar to that described above for the peak-stage indicator.

If the station has a bubble-gage sensor, the bubble orifice should be inspected to make sure that it has not been buried by a deposit of sediment. A log of gas-feed rate, gas consumption, and gas-cylinder replacement (fig. 35) should be kept to insure a continuous supply of gas and to help in checking for leakage in the system. There can be no serious leak in the gas-purge system if (1) the manometer operates to indicate stage correctly and (2) the gas consumption based on the average bubble rate over a period of time corresponds with the gas consumption computed from the decrease in cylinder pressure. If a gas leak is evident, its location can be determined by isolating various parts of the gas-purge system by the sequential closing of valves in the system. If a high discharge has occurred since a previous visit to the station, a high-water mark should be sought in the vicinity of the base reference gage, as a check on the peak stage shown by the stage recorder.

After the hydrographer has completed his inspection of the station facilities, he returns to the stage recorder and repeats the first steps he had taken in servicing the recorder. He determines that the clock or timer is running; circles the point at which the pen is resting on the

BUBBLE GAGE LOG SHEET Station: Double Trouble Creek near Dry Bone, Ky.

Date	Time	Gage height			Air temp. °F	Pressure, psi		Bubbles per min.	Ft^3 of gas	Delay	Remarks
		Outside	Counter	Pen		Cylinder	Feed				
10-2-58	9:30a	1.31	1.32	1.32	75	1500	34	46	90	On	
11-1-58	1:00p	6.30	6.31	6.31	40	1275	36	44	88	On	Installed new batteries

FIGURE 35.—Sample log sheet for bubble gage.

strip chart; observes his watch time; reads all gages, and writes his observations on the strip chart or digital tape. He does not leave the station without assuring himself that: the recorded gage height and time agree with the gage height of the base reference gage and his watch time; the clock is running; all necessary valves are open; the float wheel (if any) is engaged; the pen (if any) is marking.

A few generalities may be stated concerning the maintenance of recording stream-gaging stations to increase the accuracy and improve the continuity of the stage record. Malfunctions of the recorder can be reduced by the periodic cleaning and oiling of the recorder and clock or timer. Each year intakes, stilling wells, and sediment traps should be thoroughly cleaned. Excessive humidity and temperatures in the gage house should be reduced to a minimum by proper ventilation, and if feasible, extremely cold temperatures in the gage house should be modified by the use of heating units or insulation. Humidity and temperature control reduce the errors associated with paper expansion and contraction. Experience in the U.S.A. has shown that a program of careful inspection and maintenance will result in a complete gage-height record about 98 percent of the time.

FACTORS AFFECTING THE ACCURACY OF THE STAGE RECORD

Continuous records of discharge at a gaging station are computed from the record of stage and the stage-discharge relation. For that purpose stage records having an accuracy of ±0.01 ft (±0.003 m) are generally required. That accuracy can usually be attained by use of the continuous stage-recording systems previously described. The record obtained by sketching a continuous-stage graph through the plotted points representing periodic observations of a nonrecording gage cannot attain such accuracy, of course, but with care the individual gage observations can usually have an accuracy within ±0.01 ft.

In the discussions that follow, nonrecording gages will be treated first and then recording gages will be discussed. A remark appropriate to a discussion of the accuracy of any gage concerns the maintenance of the gage datum to the accuracy criterion of 0.01 ft. That is achieved by running levels to reference marks for the gage (p. 24) and, if necessary, adjusting the gage to restore the original datum. Levels should be run at least once every 2–3 years, and oftener if conditions are known to be unstable. If a nonrecording gage is used only as an outside auxiliary gage for a stilling well, a larger error in gage datum may be tolerated, and adjustment to the gage need not be

made for datum discrepancies that do not exceed 0.02 ft (0.006 m). That is so because seldom will inside and outside gages agree exactly even when both are set precisely to the same datum. The inside reference gage, as explained earlier (p. 54) is the base gage for the station; the primary purpose of the outside gage at a station equipped with a stilling well is to indicate whether or not the intakes are operating properly. (As mentioned on page 54, in some countries the outside gage is used as the reference or base gage.)

NONRECORDING GAGES

STAFF GAGE

Settlement or uplift of the structure(s) supporting the staff gage may disturb the gage datum. Where levels from a reference mark show that the datum of an inclined staff gage (p. 26) has been disturbed, the gage is recalibrated by removing the staples used for the graduations and replacing them at the proper elevations. Vertical staff gages are usually made up of several porcelain-enameled iron sections, each about 3.4 ft (1.04 m) long and bearing permanent graduations. Where levels from a reference mark show disturbance of the datum of a vertical staff gage, it is necessary to reset the individual gage sections. The graduations of the manufactured gage plates often have minor discrepancies, and therefore if the gage plates must be reset, they should be reset so that a graduation near the center of each gage plate is at the proper datum.

It is often difficult to accurately detect the water line when making staff-gage observations under the conditions of poor light and (or) clear water. Under those conditions it is helpful to float a matchstick or some similar floatable material against the gage and thereby define the water line. When the water surface is surging rapidly as a result of wave action, the stage to be recorded is the mean of the elevations of the peak and trough of the waves.

WIRE-WEIGHT GAGE

Wire-weight gages (p. 26) are usually mounted on bridges, and changes in gage datum often result from the settlement of bridge abutments or piers, or from changes in the deflection of the bridges resulting either from differences in traffic loading at the times of observation or from seasonal changes in air temperature. In addition to errors attributable to datum changes, erroneous readings of the type A wire-weight gage may also be caused by slippage of the graduated disc of the gage; that slippage results from insecure tightening of the disc screws. The latter condition can be detected if a

reading of the gage height of the horizontal checking bar is always made prior to lowering the weight to the water surface.

In checking the datum of the type A wire-weight gage by levels from a reference mark, the elevation of the horizontal checking bar and that of the bottom of the weight at various heights above the water surface are compared with gage readings. When necessary, adjustment of the gage to give accurate readings is made by loosening the graduated disc, rotating the disc to the true gage height of the bottom of the weight as determined from levels, and then retightening the disc screws.

Reliable observations are difficult to obtain by wire-weight gage when the water surface is disturbed by waves; the stage sought under those circumstances is the mean of the elevations of the peak and trough of the waves. On the other hand, it is also difficult to sense the water surface from a high bridge when the water is quiescent. The ideal condition for sensing the water surface occurs when a slow-moving water current is present under the weight. When observations are made on a windy day, the wire that supports the weight will bow rather than hang vertically, thereby causing the gage to underregister. The error introduced will depend on the intensity of the wind and on the height of the gage above the water surface. The combination of a high wind and high bridge may cause appreciable underregistration of the gage.

Another source of error, and one that also increases with height above the water surface, is in the tendency of the weight to rotate about its vertical axis as the weight is being lowered. The rotation twists the wire, and sequences of untwisting and twisting of the wire follow. During each period of twisting the wire shortens and the weight ascends; during each period of untwisting the wire lengthens to its full length and the weight descends. Observation of the gage height of the water surface should not be made until the weight has ceased to rotate.

FLOAT-TAPE GAGE

Change in the datum of a float-tape gage (p. 26) may result from movement of the structure supporting the gage or from slippage of the adjustable index. A float-tape gage will also read incorrectly if the tape has slipped in the clamp connecting the tape and float (gage will overregister) or if the float has sprung a leak and has taken in water (gage will underregister). The first steps in checking a float-tape gage therefore are to make sure that the clamp screw bears tightly on the tape and to shake the float for indications of water sloshing within the float.

Where levels from a reference mark show the elevation of the adjustable index to be in error, the screw holding the index is loosened, the index is raised or lowered to its proper position, and the index screw is retightened. The elevation of the water surface in the stilling well is next obtained by measuring with a steel tape to the water surface from the index or other suitable point of known elevation. Any further adjustment that is needed to make the gage height agree with the water-surface elevation is made by adjusting the length of tape at the float clamp. After all adjustments are complete, a record should be made for future reference of the tape graduation at which the tape enters the tape clamp. If the stage of the stream is changing, the valves on the stilling-well intakes should be closed while adjustments to the float-tape gage are being made in order to maintain a constant water level in the stilling well.

ELECTRIC-TAPE GAGE

Change in the datum of an electric-tape gage (p. 28) can only result from movement of the structure supporting the gage, because the position of the index of the gage is permanent with respect to the instrument. An electric-tape gage may also read incorrectly (overregister) if the tape and weight are insecurely clamped together and slippage of the tape has occurred. Where levels from a reference mark show the gage index to be in error, nothing can be done about moving the index, but its new (and true) gage height is made a matter of record. The original datum of the gage can be maintained, however, by adjusting the effective length of the tape, that is, by changing the length of tape that is inserted and clamped in the gage weight (fig.12). In other words, when the tape is unreeled so that the bottom of the weight is, for example, 1.00 ft (0.3 m) below the index, the tape gage should read 1.00 ft (0.3 m) less than the gage height of the index. After the adjustment is completed, a record should be made, for future reference, of the tape graduation at which the tape enters the weight. If the stage of the stream is changing rapidly at the time a reading is to be taken in the stilling well, it is helpful to close the valves on the stilling-well intakes in order to obtain a constant water level in the stilling well.

Use of the electric-tape gage as the inside reference gage is practically a necessity where a small diameter stilling well is used in a cold climate. In that situation oil must be added to prevent freezing, and because the stilling well is too small to accommodate an oil tube (p. 48), the oil must be added in the well itself. Because the oil is lighter than water, the surface of the floating oil in the stilling well will be higher than the water level at the streamward end of the stilling-well

intakes. It is the gage height of the water level (*GH*) that is sought, and it may be computed by either of two equations:

$$GH = [\text{gage height of oil surface}] - [(1.0 - \text{specific gravity of oil}) \times (\text{depth of oil})] \quad (1)$$

or

$$GH = [\text{gage height of interface of oil and water}] + [(\text{specific gravity of oil}) \times (\text{depth of oil})]. \quad (2)$$

Use of an electric-tape gage makes it a simple matter to measure the distances needed in equation 2. That part of the tape above the weight is rubbed with carpenter's chalk for a distance of about 1.5 ft (0.5 m) above the weight, and the weight is then lowered until a signal is received on the voltmeter. At that point the electric-tape gage reading obtained will be that of the oil-water interface (p. 28). The tape is then reeled up and the lower end inspected. The oil will have wetted the chalk on the tape leaving a sharp demarcation between the wet and dry lengths of tape. The depth of oil is equal to the distance between the demarcation line and the bottom of the weight. If the depth of the oil is less than the length of the weight, the oil will not reach the tape. In that event, the weight is lowered a known distance below the oil-water interface—say, 1.0 ft (0.3 m)—and the apparent oil depth that is determined is reduced by 1.0 ft (0.3 m), the additional distance that the weight was lowered. The computed oil depth and the observed gage height of the oil-water interface are used in equation 2 to compute the true gage height.

CHAIN GAGE

Change in the datum of a chain gage (p. 31) can result from movement of the structure on which the gage is mounted, but there are many other sources of error. They include stretching of the chain, foreign material between chain links, wear of the chain links, and wear of the pulley wheel. For that reason the chain length between the bottom of the weight and the chain index markers should be measured at each visit by the hydrographer, using a 4-lb (2-kg) pull on the chain. A small spring balance is usually used to put the proper tension on the chain when measuring its length. If the chain length differs by more than 0.02 ft (0.006 m) from the "true" value established the last time the datum was checked by levels, the length of the chain is adjusted at the point where the chain is attached to the weight. The adjustment is easily made because the chain and weight are attached by means of a cotter pin through one of a series of holes

in the neck of the weight, the spacing between holes being about 0.02 ft (0.006 m).

In checking the gage datum by levels from a reference mark, the gage height of a point of known elevation on the supporting structure (reference point) is first checked. Next, the elevation of the bottom of the weight at one or more heights above the water surface, as determined by levels from a reference mark, is compared with gage readings. When necessary, adjustment of the chain length to give accurate gage readings is made in the manner indicated above. The length of the chain is measured and recorded before and after the adjustment.

The reliability of gage readings of the water surface is affected by wind, waves, and water current, in a manner similar to that discussed for the wire-weight gage (p. 65). There is no tendency, however, for the weight to rotate when lowered, as described in the discussion of the wire-weight gage.

ACCURACY OF FLOAT-OPERATED RECORDERS

This section of the report discusses the inaccuracies inherent in any float-operated instrument; the discussion is not concerned with such sources of error as datum changes, faulty intake operation, float leakage, float-tape slippage, and paper expansion, which were discussed in the preceding sections. The principal sources of error inherent in a float-operated instrument are float lag, line shift, and submergence of the counterweight (Stevens, 1921). With regard to the algebraic sign of the errors discussed below, a positive (+) sign indicates that the instrument shows a stage higher than the true stage, and a negative (−) sign indicates that the instrument underregisters.

Float lag.—If the float-operated recorder is set to the true water level while the water level is rising, it will thereafter show the correct water level, as far as float lag is concerned, for all rising stages. For falling stages, however, the recorded stage will be above the true water level (positive error) by the amount of float lag or change in flotation depth of the float. A reverse effect occurs if the original gage setting is made when the water level is falling. Float lag varies directly with the force (F) required to move the mechanism of the recorder and inversely as the square of the float diameter (D). F commonly ranges from 1 to 5 oz (0.03 to 0.15 kg) depending on the type and condition of the instrument.

The equation for maximum float-lag error ($MFLE$) is

$$MFLE = 0.37\, F/D^2 \text{ (English units)}, \qquad (3)$$

where $MFLE$ is expressed in feet, D is expressed in inches, and F is expressed in ounces. The equation is

$$MFLE = (0.00256)\, F/D^2 \text{ (metric units)}, \quad (4)$$

where $MFLE$ and D are expressed in meters, and F is expressed in kilograms.

If we assume a value of 3 oz (0.08 kg) for F and a value of 8 in (0.2 m) for D, $MFLE$ equals 0.017 ft (0.005 m). If the recorder was set to the true water level while the float was rising, the record on a falling stage will be in error by +0.017 ft. If however, the index were set at the true level at a stationary stage—that is, at the peak or trough of a changing stage, or when the valves in a stilling well were closed—then the error will be halved on a changing stage. The error will be +0.0085 ft for falling stages and −0.0085 for rising stages.

Line shift.—With every change of stage a part of the float tape passes from one side of the float pulley to the other, and the change in weight changes the depth of flotation of the float. The magnitude of change depends on the change in stage (ΔH) since the last correct setting of the recorder, the unit weight (U) of the tape, and the float diameter (D). The error will be positive (+) for a rising stage and a negative (−) for a falling stage.

The equation for line-shift error (LSE) is

$$LSE = 0.37 \left(\frac{U}{D^2}\right) \Delta H \text{ (English units)}, \quad (5)$$

where U is expressed in ounces per foot, D is in inches, and LSE and ΔH are in feet.

The equation is

$$LSE = (0.00256) \left(\frac{U}{D^2}\right) \Delta H \text{ (metric units)}, \quad (6)$$

where U is expressed in kilograms per meter, and LSE, D, and ΔH are expressed in meters.

If we assume a value of 0.14 oz/ft (0.013 kg/m) for U, a value of 50 ft (15 m) for ΔH, and a value of 8 in (0.2 m) for D, LSE equals 0.04 ft (0.012 m).

Submergence of the counterweight.—When the counterweight and any part of the float line become submerged as the stage rises, the pull on the float is reduced and its depth of flotation is increased. The converse is true when the submerged counterweight emerges from the water on a falling stage. Thus, the error caused by submergence or emergence is opposite to that of the line-shift error and tends to

compensate for the line-shift error. The submergence error is dependent on the weight of the counterweight (c) and the float diameter (D).

The equation for submergence error (SE) is

$$SE = 0.017 \frac{c}{D^2} \text{(English units)}, \tag{7}$$

where SE is expressed in feet, c is in ounces, and D is in inches.

The equation is

$$SE = (0.000118) \frac{c}{D^2} \text{(metric units)}, \tag{8}$$

where SE and D are expressed in meters and c is expressed in kilograms.

If we assume a value of 1.25 lb (0.57 kg) for c and a value of 8 in (0.2 m) for D, SE = 0.0053 ft (0.0016 m).

Although not related to errors inherent in a float-operated stage recorder, it might be mentioned here that error in recorded stage may be caused by expansion or contraction of the stilling well of a tall gage structure that is exposed to large temperature changes. For example, a steel well 80 ft (24 m) high, exposed to an increase in temperature of 40°C, will have its instrument shelf raised 0.04 ft (0.012 m), assuming, of course, that the instrument shelter is attached to the well.

Summary.—The errors inherent in a float-operated stage recorder will affect computed discharges. The effect of float lag can be reduced to any desired level by the use of an appropriately large float, and that accuracy level may then be maintained by keeping the instrument cleaned and oiled to reduce friction. The recorder should be set to the gage height in the stilling well when the stage in the well is constant, because the float-lag error in subsequent recorded gage-height will then be only half as large as it would be if the recorder setting were made during a period of changing stage in the stilling well. Even if the stage of the stream is changing, the stage in the well may be kept constant by keeping the intake valves closed while the recorder is being set.

The error resulting from counterweight submergence is a constant function of stage and becomes an integral part of the stage-discharge relation. The same would be true of line-shift error if the recorder settings were made only when the stage is low, but that practice is usually impractical. Line shift can be a significant source of error only at gaging stations that experience a wide range of stage.

ACCURACY OF BUBBLE-GAGE RECORDERS

This section of the report discusses the inaccuracies inherent in any bubble-gage system for sensing stage; the discussion is not concerned with such sources of error as datum corrections, sediment deposition on the bubble orifice, and leaks in the system, which were discussed in the preceding sections. The principal sources of error inherent in a bubble-gage recorder are variation in gas friction, variation in required bubble-feed rate with rate of increase in stage, and variation in weight of gas column with stage.

Variation in gas friction.—Friction created by the flow of gas through the bubble tubing results in the pressure at the manometer being slightly higher than that at the orifice. If the bubble-feed rate could be kept constant and temperature did not vary, the friction would remain constant and the accuracy of the gage would be unaffected, because the manometer is always set to agree with the water-surface elevation. However, changes in gas-feed rates cause variation in the friction of the gas flowing through the tube, and where long bubble tubes are used, the variation in friction can produce significant error in recorded gage height.

Inaccuracies due to variation in gas friction can be eliminated by using two gas tubes—one to feed gas to the bubble orifice, the other to act as a static pressure tube to transmit pressure from a point at or near the orifice back to the manometer.

As a conservative criterion for determining when the use of dual tubing is desirable, it is suggested that variations in gas friction be limited to 0.01 ft (0.003 m). If, for a given length of orifice line, an error no greater than 0.01 ft results from a 100 percent increase in bubble rate, a single bubble tube will be satisfactory. Figure 36, based on laboratory tests using the standard U.S. Geological Survey bubble gage shows the relation between the length of bubble tubing and a 100-percent variation in bubble rate for a gas-friction error of 0.01 ft. To illustrate the use of figure 36, assume that a 100-percent variation in bubble rate represents a change from 40 bubbles per minute to 80 bubbles per minute. The corresponding length of bubble tubing indicated by the diagram is 370 ft (113 m). Thus any length of single tubing up to 370 ft could be used in this particular case without introducing a friction error in excess of 0.01 ft. If more than 370 ft of tubing is required at this particular site, and a gage-height error greater than 0.01 ft cannot be tolerated, two gas tubes should be used. When two tubes are used, they should be joined at a T-connector, from whose vertical leg a single tube extends to the orifice. The T-connector should be located above the normal high-water elevation to prevent the entry of water into both legs of the system if pressure

loss occurs. Additional valves must also be provided so that the static pressure tube can be separately purged, if necessary.

Variation in required bubble-feed rate with rate of increase in stage.—During rapid rises in stage the instrument will lag if the

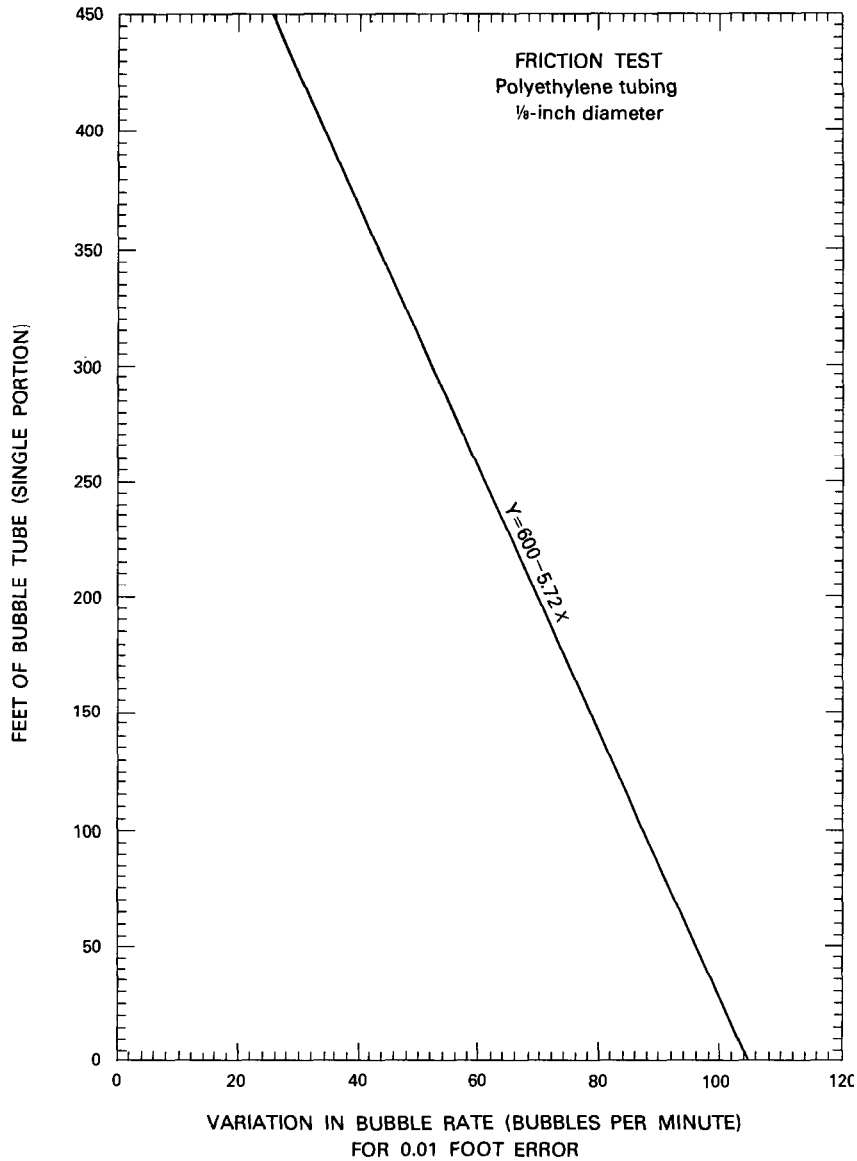

FIGURE 36.—Diagram for determining allowable length of bubble tubing for maximum friction error of 0.01 ft.

bubble-feed rate is too low. Laboratory tests on the standard U.S. Geological Survey bubble gage indicate that figure 37 may be used to

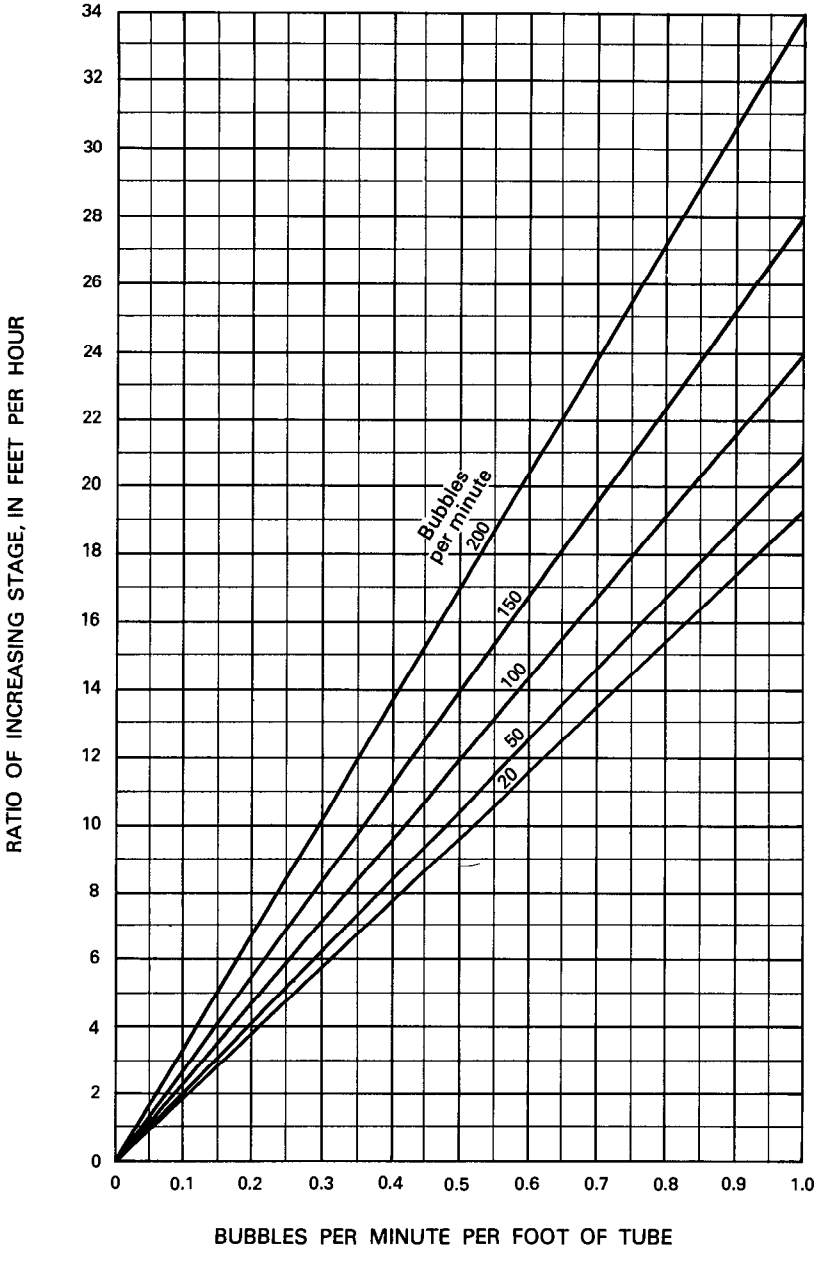

FIGURE 37.—Diagram for determining required bubble rate.

determine the bubble rate required for the maximum expected rate of increase of stage, where the minimum expected stage above the orifice will be less than 10 ft (3.0 m) for long periods of time. For periods when a minimum stage of more than 10 ft is expected to prevail, a lower bubble rate should be used to conserve gas, because the rate of increase of stage that a given bubble rate will support increases directly with stage. It was found that for installations where the minimum stage will continuously be higher than 10 ft, the maximum expected rate of increase of stage should be divided by $\frac{H_{(min)} + 33}{33}$ before entering figure 37. ($H_{(min)}$ is the minimum expected stage above the orifice.) For example, for a given expected rate of increasing stage, the adequate bubble rate for a minimum stage of 100 ft (30.0m) will be one-fourth of that for a minimum stage of 10 ft—the factor $\frac{100 + 33}{33}$ equals 4.

Variation in weight of gas column with stage.—At installations where the manometer is high above the bubble orifice, and large fluctuations in stage occur, the variation in weight of the gas column with stage will cause the manometer to read low (underregister) at high stages. The error varies almost linearly with stage and for that reason the manometer readout in that situation can be corrected without too much difficulty. Depending on the type of instrument used, either the inclination of the manometer is adjusted or a change is made in the gearing between the servosystem and the recording equipment.

As a matter of fact any source of error that varies linearly with stage—for example, the density of the water may increase with stage as a result of increased sediment load—may be compensated for by the adjustments mentioned above. Changes in temperature are usually a negligible source of error, except in high-head installations having large fluctuations in stage. In that situation it is recommended that the bubble-gage system be equipped with a temperature-compensated servomanometer to minimize the error attributable to temperature changes.

SPECIAL PURPOSE GAGES

MODEL T RECORDER

The model T recorder (fig. 38) is a graphic recorder that has a 1:6 gage-height scale and a time scale of 2.4 in. per day. Use of the recorder is limited to a 3-ft (0.9 m) range in stage and it should be serviced weekly, although it will record more than one trace on the 7-day chart. The model T recorder is operated by a motor-wound spring-

driven timer, and power is supplied to the timer by a 4½-volt battery. A timer is also available that operates on a 1½-volt battery. The housing of the recorder is designed to fit on the top of a vertical 3-in (0.076 m)-diameter pipe that can be used as the stilling well. This recorder is much cheaper and more compact than the conventional graphic recorders and is well suited for temporary installations for low-flow studies, particularly those concerned with diurnal fluctuation in discharge during low-flow periods. The model T recorder is not used at continuous-record gaging stations.

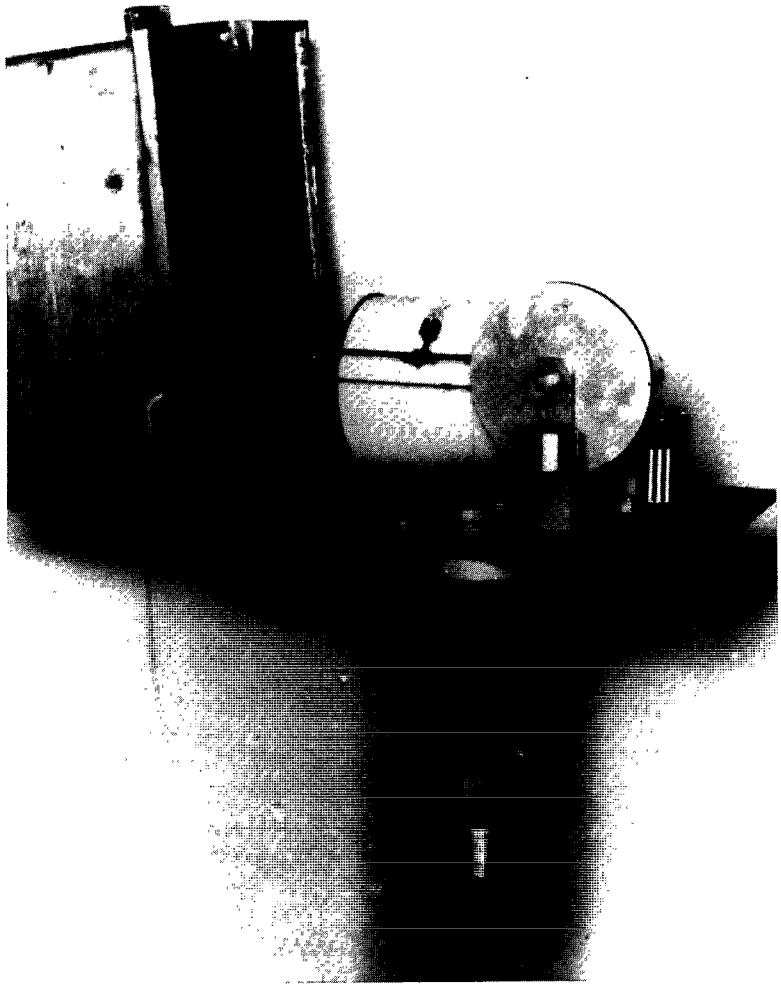

FIGURE 38.—Model T recorder.

SR RECORDER

The model SR recorder (fig. 39) is a graphic recorder that records flood stages and rainfall. A 5-in (0.127m)-diameter flat circular disc is rotated by a battery-wound clock. The power source is a 1½-volt battery. The chart is circular and turns one revolution in 24 hr. Three ranges in stage are available for the effective chart width of 2 in (0.05 m): 5, 10, or 20 ft. The recorder sits on a 2-in-diameter pipe that serves as the stilling well (similar to that for the model T). Five inches of rainfall can also be recorded on the effective width of the chart, but the rainfall reservoir can be equipped with a siphon that will allow an unlimited amount of rainfall to be recorded. The rainfall reservoir is a separate 2-in-diameter pipe that fills at the rate of 1 ft (0.3 m) for each 1 in (0.025 m) of rainfall. After the pipe has filled to a height of 5 ft (1.52 m), the siphon is tripped to empty the pipe.

The SR recorder is much cheaper and more compact than the conventional graphic recorders and is used for studying rainfall-runoff

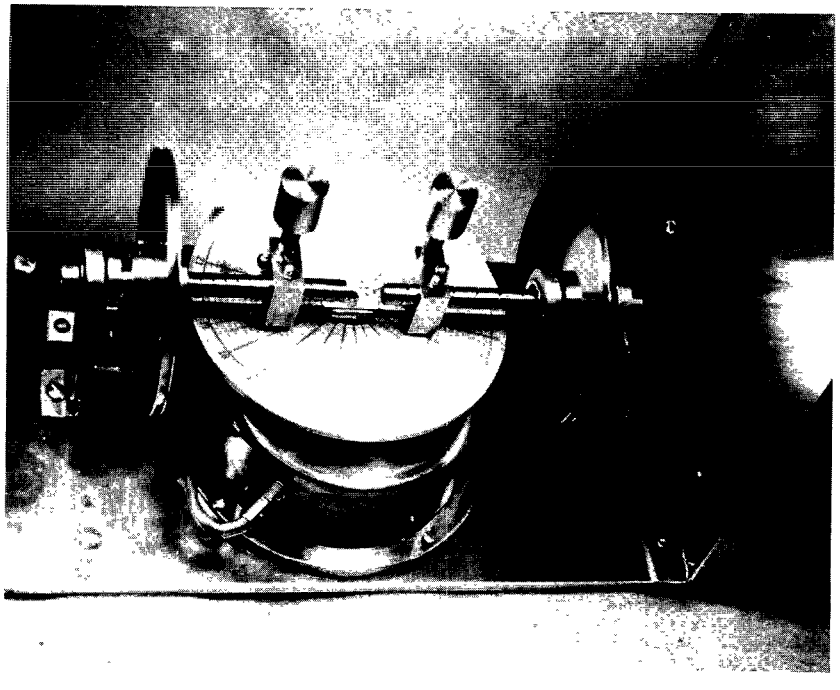

FIGURE 39.—Model SR recorder.

relations for isolated storms on small watersheds. The SR recorder is not used at continuous-record gaging stations.

A word of caution is in order at this point. The SR recorder has not proven to be an unqualified success, although it has performed satisfactorily at many installations. Its use is therefore recommended reservedly.

CREST-STAGE GAGE

The crest-stage gage is a device for obtaining the elevation of the flood crest of streams. The gage is widely used in the U.S.A. because it is simple, economical, reliable, and easily installed. Because of those attributes the crest-stage gage has become a basic instrument in regional studies of flood frequency. For such studies the network of standard gaging stations is augmented by a network of crest-stage gages, thereby providing flood-peak information at a great many sites in the region at reasonable cost.

A crest-stage gage is also a valuable adjunct to the nonrecording gage at nonrecording gaging stations. It provides a record of the peak stages of stream rises, and those stages can be used with the observer's routine readings when sketching the estimated continuous-stage graph through the plotted points of observed stage.

Many different types of crest-stage gages have been tested by the U.S. Geological Survey. (See, for example, Friday, 1965, and Carter and Gamble, 1963.) The one found most satisfactory is a vertical piece of 2-in (0.05 m) galvanized pipe containing a wood or aluminum staff held in a fixed position with relation to a datum reference. (See fig. 40.) The bottom cap has six intake holes located as shown in figure 40 to minimize nonhydrostatic drawdown or superelevation inside the pipe. Tests have shown this arrangement of intake holes to be effective with velocities up to 10 ft/s (3 m/s) and at angles up to 30 degrees with the direction of flow. The top cap contains one small vent hole.

The bottom cap, or a perforated tin cup or copper screening in cup shape attached to the lower end of the staff, contains regranulated cork. As the water rises inside the pipe the cork floats on the water surface. When the water reaches its peak and starts to recede the cork adheres to the staff inside the pipe, thereby retaining the crest stage of the flood. The gage height of a peak is obtained by measuring the interval on the staff between the reference point and the floodmark. Scaling can be simplified by graduating the staff. The cork should be cleaned from the staff before replacing the staff in the pipe to prevent confusion with high-water marks that will be left by subsequent peak discharges.

The datum of the gage should be checked by levels run from a reference mark to the top of the staff, the graduated staff being of

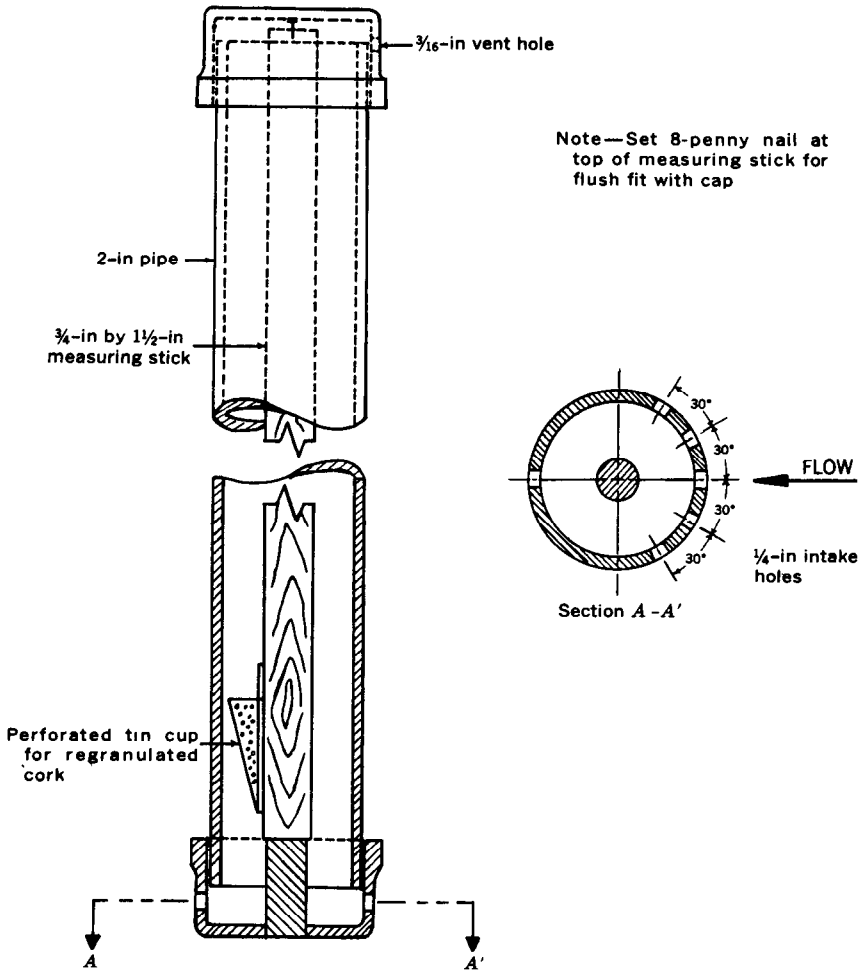

FIGURE 40.—Crest-stage gage.

known length. The gage itself should be serviced on a regular basis. However, the staff should not be removed from the pipe for any reason when the stage is high. If, after such removal, the staff is reinserted when water stands high in the pipe, the resulting surge of the water displaced by the staff will leave an artificial "high-water mark" on the staff.

CHAPTER 5.—MEASUREMENT OF DISCHARGE BY CONVENTIONAL CURRENT-METER METHOD

INTRODUCTION

Streamflow, or discharge, is defined as the volume rate of flow of water, including any substances suspended or dissolved in the water. Discharge is usually expressed in cubic feet per second or cubic meters per second.

Discharge measurements are made at each gaging station to determine the discharge rating for the site. The discharge rating may be a simple relation between stage and discharge or a more complex relation in which discharge is a function of stage, slope, rate of change of stage, or other factors. Initially the discharge measurements are made with the frequency necessary to define the station rating, as early as possible, over a wide range of stage. Measurements are then made at periodic intervals, usually monthly, to verify the rating or to define any changes in the rating caused by changes in stream-channel conditions.

Discharge measurements may be made by any one of the methods discussed in chapters 5–8. However, the conventional current-meter method is most commonly used in gaging streams. When using this

method, observations of width, depth, and velocity are taken at intervals in a cross section of the stream, while the hydrographer is wading or supported by a cableway, bridge, ice cover, or boat. A current meter is used to measure velocity. This chapter describes the conventional current-meter method.

GENERAL DESCRIPTION OF A CONVENTIONAL CURRENT-METER MEASUREMENT OF DISCHARGE

A current-meter measurement is the summation of the products of the subsection areas of the stream cross section and their respective average velocities. The formula

$$Q = \Sigma(a\ v) \tag{9}$$

represents the computation, where Q is total discharge, a is an individual subsection area, and v is the corresponding mean velocity of the flow normal to the subsection.

In the midsection method of computing a current-meter measurement, it is assumed that the velocity sample at each vertical represents the mean velocity in a rectangular subsection. The subsection area extends laterally from half the distance from the preceding observation vertical to half the distance to the next, and vertically from the water surface to the sounded depth. (See fig. 41.)

The cross section is defined by depths at verticals 1, 2, 3, 4, . . . n. At each vertical the velocities are sampled by current meter to obtain the mean velocity for each subsection. The subsection discharge is then computed for any subsection at vertical x by use of the equation,

$$q_x = v_x \left[\frac{(b_x - b_{(x-1)})}{2} + \frac{(b_{(x+1)} - b_x)}{2}\right] d_x$$

$$= v_x \left[\frac{b_{(x+1)} - b_{(x-1)}}{2}\right] d_x \tag{10}$$

where

q_x = discharge through subsection x,
v_x = mean velocity at vertical x,
b_x = distance from initial point to vertical x,
$b_{(x-1)}$ = distance from initial point to preceding vertical,
$b_{(x+1)}$ = distance from initial point to next vertical, and
d_x = depth of water at vertical x.

Thus, for example, the discharge through subsection 4 (heavily outlined in fig. 41) is

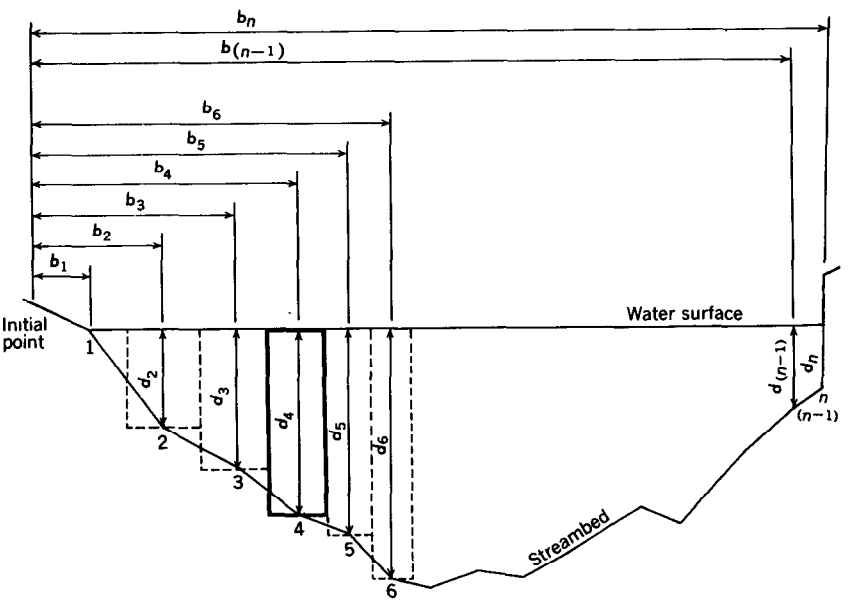
$$q_4 = v_4 \left[\frac{b_5 - b_3}{2}\right] d_4.$$

The procedure is similar when x is at an end section. The "preceding vertical" at the beginning of the cross section is considered coincident with vertical 1; the "next vertical" at the end of the cross section is considered coincident with vertical n. Thus,

$$q_1 = v_1 \left[\frac{b_2 - b_1}{2}\right] d_1$$

and

$$q_n = v_n \left[\frac{b_n - b_{(n-1)}}{2}\right] d_n.$$



EXPLANATION

1, 2, 3 ..... n	Observation verticals
$b_1, b_2, b_3, \ldots . b_n$	Distance, in feet or meters, from the initial point to the observation vertical
$d_1, d_2, d_3, \ldots . d_n$	Depth of water, in feet or meters, at the observation vertical
Dashed lines	Boundaries of subsections; one heavily outlined is discussed in text

FIGURE 41.—Definition sketch of midsection method of computing cross-section area for discharge measurements.

For the example shown in figure 41, q_1 is zero because the depth at observation point 1 is zero. However, when the cross-section boundary is a vertical line at the edge of the water as at vertical n, the depth is not zero and velocity at the end vertical may or may not be zero. The formula for q_1 or q_n is used whenever there is water only on one side of an observation vertical such as at piers, abutments, and islands. It is necessary to estimate the velocity at an end vertical, usually as some percentage of the adjacent vertical, because it is impossible to measure the velocity accurately with the current meter close to a boundary. There is also the possibility of damage to the equipment if the flow is turbulent. Laboratory data suggest that the mean vertical velocity in the vicinity of a smooth sidewall of a rectangular channel can be related to the mean vertical velocity at a distance from the wall equal to the depth. The tabulation below gives values that define the relation.

Distance from wall, as a ratio of the depth	*Mean vertical velocity, as related to* V_n
0.00	$0.65V_n$
.25	$.90V_n$
.50	$.95V_n$
1.00	$1.00V_n$

NOTE—V_n is the mean vertical velocity at a distance from the vertical wall equal to the depth.

The summation of the discharges for all the subsections—usually 25 to 30 in number—is the total discharge of the stream. An example of the measurement notes used by the U.S. Geological Survey is shown in figure 42.

The mean-section method, used by the U.S. Geological Survey prior to 1950, differs from the midsection method, described above, in computation procedure. In the older method discharges are computed for subsections between successive observation verticals. The velocities and depths at successive verticals are each averaged, and each subsection extends laterally from one observation vertical to the next. Subsection discharge is the product of the average of two mean velocities, the average of two depths, and the distance between observation verticals. In both methods total discharge is the sum of the subsection discharges. A study by Young (1950) concluded that the midsection method is simpler to compute and is a slightly more accurate procedure than the mean-section method.

Current-meter meaurements are usually classified in terms of the means used to cross the stream during the measurement, such as wading, cableway, bridge, boat, or ice cover.

INSTRUMENTS AND EQUIPMENT

Current meters, timers, and a means of counting meter revolutions are needed for the measurement of discharge, along with additional

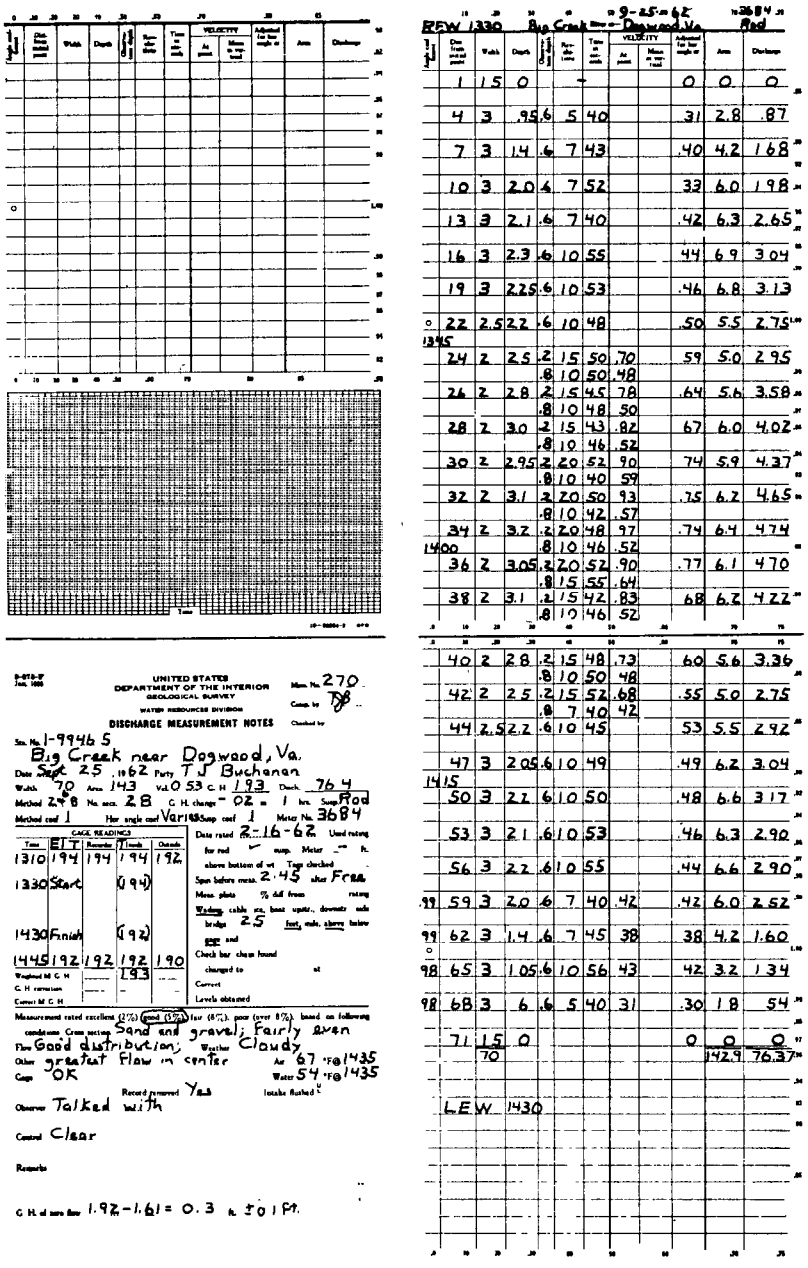


FIGURE 42.—Computation notes of a current-meter measurement by the midsection method.

equipment that depends on the manner in which the measurement is to be made—that is, whether by wading, cableway, bridge, boat, or from ice cover. Instruments and equipment used in making the current-meter measurements are described in this section of the manual under the following categories: current meters, sounding equipment, width-measuring equipment, equipment assemblies, and miscellaneous equipment.

CURRENT METERS

A current meter is an instrument used to measure the velocity of flowing water. The principle of operation is based on the proportionality between the velocity of the water and the resulting angular velocity of the meter rotor. By placing a current meter at a point in a stream and counting the number of revolutions of the rotor during a measured interval of time, the velocity of water at that point is determined.

The number of revolutions of the rotor is obtained by an electrical circuit through the contact chamber. Contact points in the chamber are designed to complete an electrical circuit at selected frequencies of revolution. Contact chambers can be selected having contact points that will complete the circuit twice per revolution, once per revolution, or once per five revolutions. The electrical impulse produces an audible click in a headphone or registers a unit on a counting device. The intervals during which meter revolutions are counted are timed with a stopwatch. A discussion of the required time interval follows.

Turbulent flow, which is ordinarily found in natural streams and in artificial channels, is always accompanied by local eddying, which results in pulsations in the velocity at any point. Figure 43, taken from a study by Pierce (1941), shows the pulsations observed in a laboratory flume for two different mean velocities. The greater magnitude of the pulsations, relative to the mean, at the lower velocity explains why current-meter observations at a point should cover a longer period when low velocities are being measured than when higher velocities are being measured. At high velocities, pulsations have only minor effect on the current-meter observations. In the U.S.A. it is customary to observe velocity at a point by current meter for a period that ranges from 40 to 70 s. It is recognized that the use of a period of from 40 to 70 s is not long enough to insure the accuracy of a single point-observation of velocity. However, because the pulsations are random and because velocity observations during a discharge measurement are made at 25 to 30 verticals, usually with two observations being made in each vertical, there is little likelihood that the pulsations will bias the total measured discharge of a stream. (See p. 181–182.) Longer periods of current-meter observation at a

point are not used, because it is desirable to complete a discharge measurement before the stage changes significantly and because the use of longer observation periods may add significantly to the operating cost of a large number of gaging stations.

Current meters generally can be classified with respect to two main types: those meters having vertical-axis rotors and those having horizontal-axis rotors. The comparative characteristics of these two types are summarized below:

1. Vertical-axis rotor with cups or vanes.
   a. Operates in lower velocities than do horizontal-axis meters.
   b. Bearings are well protected from silty water.
   c. Rotor is repairable in the field without adversely affecting the rating.
   d. Single rotor serves for the entire range of velocities.
2. Horizontal-axis rotor with vanes.
   a. Rotor disturbs flow less than do vertical-axis rotors because of axial symmetry with flow direction.
   b. Rotor is less likely to be entangled by debris than are vertical-axis rotors.
   c. Bearing friction is less than for vertical-axis rotors because bending moments on the rotor are eliminated.

VERTICAL-AXIS CURRENT METERS

A common type of vertical-axis current meter is the Price meter, type AA. (See fig. 44.) This meter is used extensively by the U.S. Geological Survey. The standard Price meter has a rotor 5 in (0.127

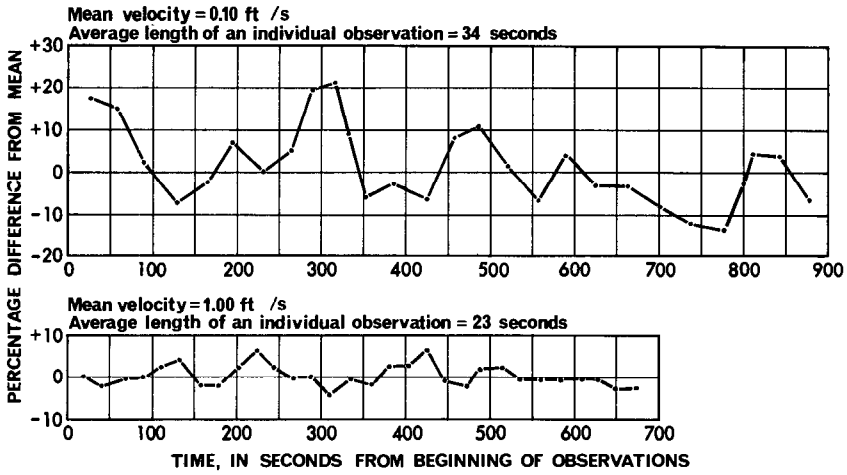

FIGURE 43.—Comparison of pulsations for two different mean velocities measured in a laboratory flume, 12 ft wide.

m) in diameter and 2 in (0.05 m) high with six cone-shaped cups mounted on a stainless-steel shaft. A pivot bearing supports the rotor shaft. The contact chamber houses both the upper part of the shaft and a slender bronze wire (cat's whisker) attached to a binding post. With each revolution an eccentric contact on the shaft makes contact with a bead of solder at the end of the cat's whisker. A separate reduction gear (pentagear), wire, and binding post provide a contact each time the rotor makes five revolutions. A tailpiece keeps the meter pointing into the current.

In addition to the standard type AA meter for general use there is a type AA meter for low velocities. No pentagear is provided. This modification reduces friction. The shaft usually has two eccentrics making two contacts per revolution. The low-velocity meter normally is rated from 0.2 to 2.5 ft/s (0.06 to 0.76 m/s) and is recommended for use when the mean velocity at a cross section is less than 1 ft/s (0.3 m/s).

In addition to the type AA meters, the U.S. Geological Survey uses a Price pygmy meter in shallow depths. (See fig. 44.) The pygmy meter is scaled two-fifths as large as the standard meter and has neither a tailpiece nor a pentagear. The contact chamber is an integral part of the yoke of the meter. The pygmy meter makes one contact per revolution and is used only with rod suspension.

The U.S. Geological Survey has recently developed a four-vane vertical-axis meter. (See fig. 45.) This meter is useful for measurements under ice cover because the vanes are less likely to fill with slush ice and because it requires a much smaller hole for passage through the ice. One yoke of the vane meter is made to be suspended at the end of a rod and will fit holes made by an ice drill. Another yoke

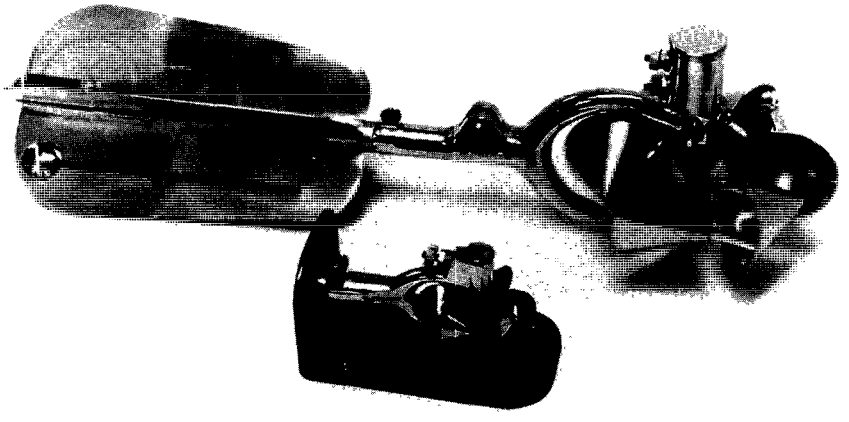

FIGURE 44.—Price type AA meter, top; Price pygmy meter, bottom.

is made for regular cable or rod suspension. (See fig. 45.) The vane meter has the disadvantage of not responding as well as the Price type AA meter at velocities less than 0.5 ft/s (0.15 m/s).

A new contact chamber has been designed by the U.S. Geological Survey to replace the wiper contact of the type AA and vane meters. The new contact chamber contains a magnetic switch, glass enclosed in a hydrogen atmosphere and hermetically sealed. The switch assembly is rigidly fixed in the top of the meter head just above the tip of the shaft. The switch is operated by a small permanent magnet rigidly fastened to the shaft. The switch quickly closes when the magnet is alined with it and then promptly opens when the magnet moves away. The magnet is properly balanced on the shaft. Any type AA meter can have a magnetic switch added by replacing the shaft and the contact chamber. The magnetic switch is placed in the special contact chamber through the tapped hole for the binding post. The rating of the meter is not altered by the change. An automatic counter (p. 130) is used with the magnetic-switch contact chamber. If a headphone is used, arcing may weld the contacts.

A Price meter accessory that indicates the direction of flow is described on page 129.

Vertical-axis current meters do not register velocities accurately when placed close to a vertical wall. A Price meter held close to a right-bank vertical wall will underregister because the slower water velocities near the wall strike the effective (concave) face of the cups. The converse is true at a left-bank vertical wall. (The terms "left bank" and "right bank" designate direction from the center of a stream for an observer facing downstream.) The Price meter also

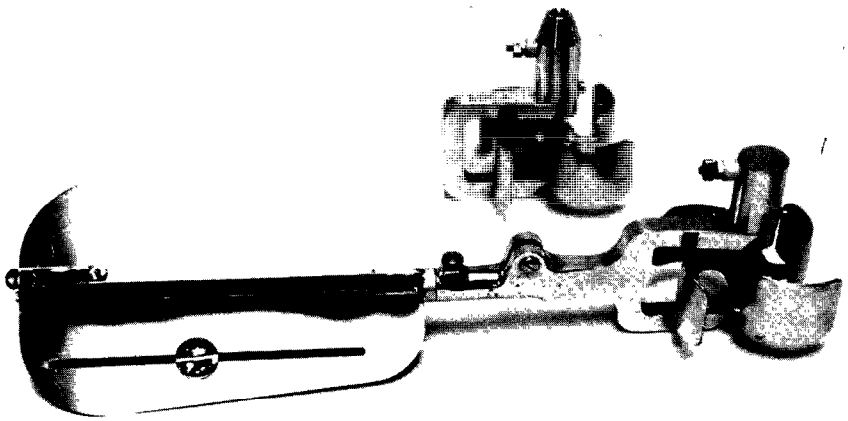

FIGURE 45.—Vane ice meter, top; vane meter with cable suspension yoke, bottom.

underregisters when positioned close to the water surface or close to the streambed.

HORIZONTAL-AXIS CURRENT METERS

The types of horizontal-axis meters most commonly used are the Ott, Neyrpic, Haskell, Hoff, and Braystoke. The Ott meter is made in Germany, the Neyrpic meter in France, and both are used extensively in Europe. The Haskell and Hoff meters were developed in the United States, where they are used to a limited extent. The Braystoke meter is used extensively in the United Kingdom. The Ott meter (fig. 46) is a precision instrument but is not widely used in the U.S.A. because it is not as durable as the Price meter under extreme conditions. The makers of the Ott meter have developed a component propeller that in oblique currents automatically registers the velocity component at right angles to the measuring section for angles as great as 45° and

FIGURE 46.—Ott current meter.

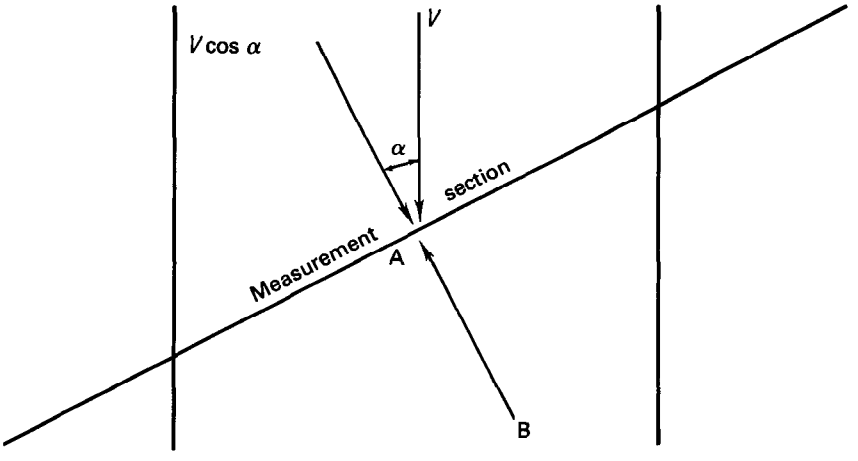

FIGURE 47.—Velocity components measured by Ott and Price current meters.

for velocities as great as 8 ft/s (2.4 m/s). For example, if this component propeller were held in the position AB in figure 47 it would register $V \cos \alpha$ rather than V, which the Price meter would register.

The Neyrpic meter is used rarely in the U.S.A. for the same reason that the Ott meter is rarely used there.

The Haskell meter has been used by the U.S. Lake Survey, Corps of Engineers, in streams that are deep, swift, and clear. By using propellers with a variety of screw pitches, a considerable range of velocity can be measured. The Haskell meter is more durable than most other horizontal-axis current meters.

The Hoff meter (fig. 48) is another current meter used in the U.S.A. The lightweight propeller has three or four vanes of hard rubber. The meter is suited for the measurement of low velocities but is not suited for rugged use.

COMPARISON OF PERFORMANCE OF VERTICAL-AXIS AND HORIZONTAL-AXIS CURRENT METERS

Comparative tests of the performance of vertical-axis and horizontal-axis current meters, under favorable measuring conditions, indicate virtually identical results from use of the two types of meter. That was the conclusion reached in 1958 by the U.S. Lake Survey, Corps of Engineers, after tests made with the Price, Ott, and Neyrpic current meters (Townsend and Blust, 1960). The results of one of their tests is shown in figure 49.

Between the years 1958 and 1960, the U.S. Geological Survey made 19 simultaneous discharge measurements on the Mississippi River using Price and Ott meters. The average difference in discharge between results from the two meters was -0.15 percent, using the measurements made with the Price meter as the standard for comparison. The maximum differences in discharge measured by the two meters was -2.76 and $+1.53$ percent.

OPTICAL CURRENT METER

In recent years the U.S. Geological Survey has developed an optical current meter (fig. 50). The meter and its use have been described by Chandler and Smith (1971). The optical current meter is designed to measure surface velocities in open channels without immersing equipment in the stream. However, because it measures only surface velocity, the optical meter is not considered a substitute for conventional equipment in those situations where good measurements can be made by standard techniques. It is a device that has extended the capability of making discharge measurements to a range of situations under which standard current-meter techniques cannot be used. Those situations include flood velocities that are too high to be measured by conventional meter—for example, supercritical velocities in floodways—or the presence of a debris load during flood periods that makes it hazardous to immerse a current meter.

Basically, the meter is a stroboscopic device consisting of a low-power telescope, a single oscillating mirror driven by a cam, a variable-speed battery-operated motor, and a tachometer. The water surface is viewed from above through the meter, while gradually changing the speed of the motor to bring about synchronization of the

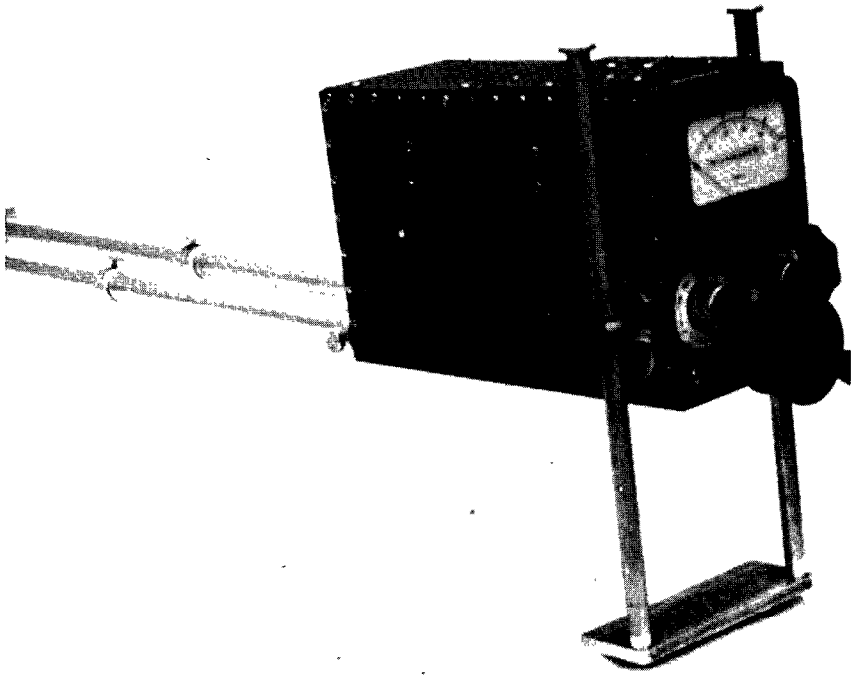

FIGURE 50.—Optical current meter.

angular velocity of the mirror and the surface velocity of the water. Synchronization is achieved when the motion of drift or disturbances on the water surface, as viewed through the meter, is stopped. A reading of the tachometer and height of the meter above the water surface are the only elements needed to compute the surface velocity.

The velocity measurement may be made from any bridge, walkway, or other structure that will support the optical meter. The vertical axis of the meter must be perpendicular to the water surface. Surface velocity (V_s) is computed from the equation

$$V_s = KRD,$$

where K is the constant for the meter, R is the readout from the tachometer, and D is the distance to the water surface in feet. The tachometer is scaled to produce a value of K equal to 1.00. The surface velocity computed from the above equation must be corrected by an appropriate coefficient to obtain the mean velocity in the vertical. The precise coefficient applicable is, of course, unique to the particular stream and to the location of the vertical in the stream cross section. However, data abstracted from conventional current-meter measurements show that application of a coefficient of 0.90 will not introduce errors of more than ±5 percent in concrete-lined channels. For natural channels a coefficient of 0.85 has been used.

A unique feature of the optical current meter is the automatic correction that is made for variations in the direction of the streamlines of flow. If the flow approaches the cross section at an angle other than the perpendicular, and if the axis of the oscillating mirror in the meter is parallel to the cross section, then at the null point of observation, the water will appear to move laterally across the field of view. The meter measures only the velocity vector normal to the cross section, and there is no need to apply horizontal angle corrections.

The range of velocities that can be measured with the optical current meter is limited at the lower end by the accuracy of the tachometer and at the upper end by the physical limitations of the human eye. Table 1 shows the range of velocities that can be meas-

TABLE 1.—*Range of velocities that can be measured with optical current meter*

Observation height (D)		Maximum velocity		Minimum velocity for ±5 percent resolution	
(ft)	(m)	(ft/s)	(m/s)	(ft/s)	(m/s)
5	1.52	25	7.62	1.6	0.49
10	3.05	50	15.2	3.2	.98
15	4.57	75	22.9	4.8	1.46
20	6.10	100	30.5	6.4	1.95

ured from various heights above the water surface with the U.S. Geological Survey model of the meter. The minimum velocities shown in column 3 of the table can be measured with an error of ±5 percent; the higher velocities at the various observation heights will be measured with lesser error.

CARE OF THE CURRENT METER

To insure reliable observations of velocity it is necessary that the current meter be kept in good condition. The care of conventional meters will be discussed first.

Before and after each discharge measurement the meter cups or vanes, pivot and bearing, and shaft should be examined for damage, wear, or faulty alinement. Before using the meter its balance on the cable-suspension hanger should be checked, the alinement of the rotor when the meter is on the hanger or wading rod should also be checked, and the conductor wire should be adjusted to prevent interference with meter balance and rotor spin. During measurements, the meter should periodically be observed when it is out of the water to be sure that the rotor spins freely.

Meters should be cleaned and oiled daily when in use. If measurements are made in sediment-laden water, the meter should be cleaned immediately after each measurement. For vertical-axis meters the surfaces to be cleaned and oiled are the pivot bearing, pentagear teeth and shaft, cylindrical shaft bearing, and thrust bearing at the cap.

After oiling, the rotor should be spun to make sure that it operates freely. If the rotor stops abruptly, the cause of the trouble should be sought and corrected before using the meter. The duration of spin should be recorded on the field notes for the discharge measurement. A significant decrease in the duration of spin indicates that the bearings require attention. In vertical-axis current meters the pivot requires replacement more often than other meter parts, and it therefore should be examined after each measurement. The pivot and pivot bearing should be kept separated, except during measurements, by use of the raising nut provided in the Price meter or by replacing the pivot with a brass plug in the pygmy meter. Fractured, worn, or rough pivots should be replaced.

Meter repairs by the hydrographer should be limited to minor damage only. That is particularly true of the rotor, where small changes in shape can significantly affect the meter rating. In vertical-axis meters, minor dents in the cups can often be straightened to restore the original shape of the cups, but in case of doubt, the entire rotor should be replaced with a new one. Badly sprung yokes, bent yoke stems, misalined bearings and tailpieces

should be reconditioned in shops equipped with the specialized facilities needed.

There are only few details connected with care of the optical current meter. The meter should be transported in a shock-proof carrying case and the battery should be checked periodically. Field performance of the tachometer should also be checked periodically. Three steps are involved in the checking process. First, a cam speed is measured by counting and timing mirror oscillations with a stopwatch, and the corresponding dial reading of the tachometer is observed. Next, a tachometer dial readout is computed from the measured cam speed and the known scale factor of the tachometer dial. In the final step the observed dial reading and the computed dial readout are compared.

RATING OF CURRENT METERS

To determine the velocity of the water from the revolutions of the rotor of a conventional current meter, a relation must be established between the angular velocity of the rotor and the velocity of the water that spins the rotor. That relation is known as the rating of the current meter. The rating is established by first towing the meter at a constant velocity through a long water-filled trough, and then relating the linear and rotational velocities of the current meter. The following paragraphs describe the rating of meters by the U.S. Geological Survey at the Hydrologic Instrumentation Facility in Mississippi.

The rating trough used is a sheltered concrete tank 450 ft (137 m) long, 12 ft (3.7 m) wide, and 12 ft (3.7 m) deep. An electrically driven car rides on rails extending the length of the tank. The car carries the current meter at a constant rate through the still water in the basin. Although the rate of travel can be accurately adjusted by means of an electronic regulating gear, the average velocity of the moving car is determined for each run by making an independent measurement of the distance it travels during the time that the revolutions of the rotor are electrically counted. Eight pairs of runs are usually made for each current meter. A pair of runs consists of two traverses of the basin, one in each direction, at the same speed. Practical considerations usually limit the ratings to velocities ranging from 0.1 to about 15 ft/s (0.03 to about 4.6 m/s), although the car can be operated at lower speeds. Unless a special request is made for a more extensive rating, the lowest velocity used in the rating is about 0.2 ft/s (0.06 m/s), and the highest is about 8.0 ft/s (2.5 m/s).

For convenience in field use, the data from the current-meter ratings are reproduced in tables, a sample of which is shown in figure 51.

FIGURE 51.—Current-meter rating table.

The velocities corresponding to a range of 3 to 350 revolutions of the rotor within a period of 40 to 70 s are listed in the tables. This range in revolution and time has been found to cover general field requirements. To provide the necessary information for extending a table for the few instances where extensions are required, the equations of the rating table are shown in the spaces provided in the heading. The term, R, in the equations refers to revolutions of the rotor per second. The equation to the left of the figure in parentheses (2.20 in fig. 51) is the equation for velocities less than 2.20 ft/s (0.67 m/s), and the equation to the right is for velocities greater than 2.20 ft/s. The velocity 2.20 ft/s is common to both equations.

It should be noted that the equations given are those of the rating table and not necessarily those of the actual rating. If a rating table already on file matches a rating within close tolerances, that table is selected in preference to preparing a new one. The tolerances are listed below:

Revolutions of rotor per second (R)	*Tolerance, in percent*
Less than 1.0	1.0
1.0 and greater	.5

Because of the rigid control in the manufacture of the Price meter, virtually identical meters are now being produced, and their rating equations tend to be identical. Therefore, the U.S. Geological Survey now feels no need to calibrate the meters individually. Instead, an average standard rating is established by calibrating a large number of meters that have been constructed to U.S. Geological Survey specifications, and that rating is then supplied with each meter. To insure that all meters are virtually identical, the dies and fixtures for the construction of Price meters are supplied to the manufacturer.

Price meters that have been first rated using a wading-rod suspension, and then rated using a cable suspension with U.S. Geological Survey Columbus-type weights and hangers, have not shown significant differences in rating. Therefore, no suspension coefficients are needed, and none should be used, if Columbus-type weights and hangers are properly used. Tests that compared meters were discussed on pages 89–90. In those tests Columbus-type weights were used with all meters. The close agreement of results for all meters indicate that no suspension coefficients are required when horizontal-axis current meters are used with Columbus-type weights.

The rating of the optical current meter is relatively simple. Its operation is based on precise mathematical principles, and, given an accurate tachometer, meter accuracy is dependent only on the configuration of the cam that oscillates the mirror. A master cam is used in

the manufacture of the individual meter cams. The meter is rated by observation of a long endless belt driven at constant speed. That known belt speed is checked against the speed computed by multiplying the height of the meter above the belt by the tachometer reading. If the comparison of known and computed speeds shows a lack of agreement, the tachometer scaling is changed to bring about agreement.

SOUNDING EQUIPMENT

Sounding (determination of depth) is usually done mechanically, the equipment used being dependent on the type of measurement being made. Depth and position in the vertical are measured by a rigid rod or by use of a sounding weight suspended from a cable. The cable length is controlled either by a reel or by a handline. A sonic sounder is also available, but it is usually used in conjunction with a reel and a sounding weight.

Sounding equipment used by the U.S. Geological Survey is described in the following categories: wading rods, sounding weights, sounding reels, handlines, and sonic sounder.

WADING RODS

The two types of wading rods commonly used are the top-setting rod and the round rod. The top-setting rod is preferred because of the convenience in setting the meter at the proper depth and because the hydrographer can keep his hands dry in the process. The round rod can be used in making ice measurements as well as wading measurements and has the advantage that it can be disassembled to 1-ft (0.3-m) lengths for storing and transporting.

The top-setting wading rod has a 1/2-in (12.7-mm) hexagonal main rod for measuring depth and a 3/8-in (9.5-mm) diameter round rod for setting the position of the current meter (fig. 52).

The rod is placed in the stream so the base plate rests on the streambed, and the depth of water is read on the graduated main rod. When the setting rod is adjusted to read the depth of water, the meter is positioned automatically for the 0.6-depth method. (See p. 134.) The 0.6-depth setting might also be described as the 0.4-depth position measured up from the streambed. When the depth of water is divided by 2 and this new value is set, the meter will be at the 0.2 depth position measured up from the streambed. When the depth of water is multiplied by 2 and this value is set, the meter will be at the 0.8-depth position measured up from the streambed. These two positions represent the conventional 0.2- and 0.8-depth positions. (See p. 134.)

The round wading rod consists of a base plate, lower section, three or four intermediate sections, sliding support, and a rod end (not essential). The parts are assembled as shown in figure 53. The meter

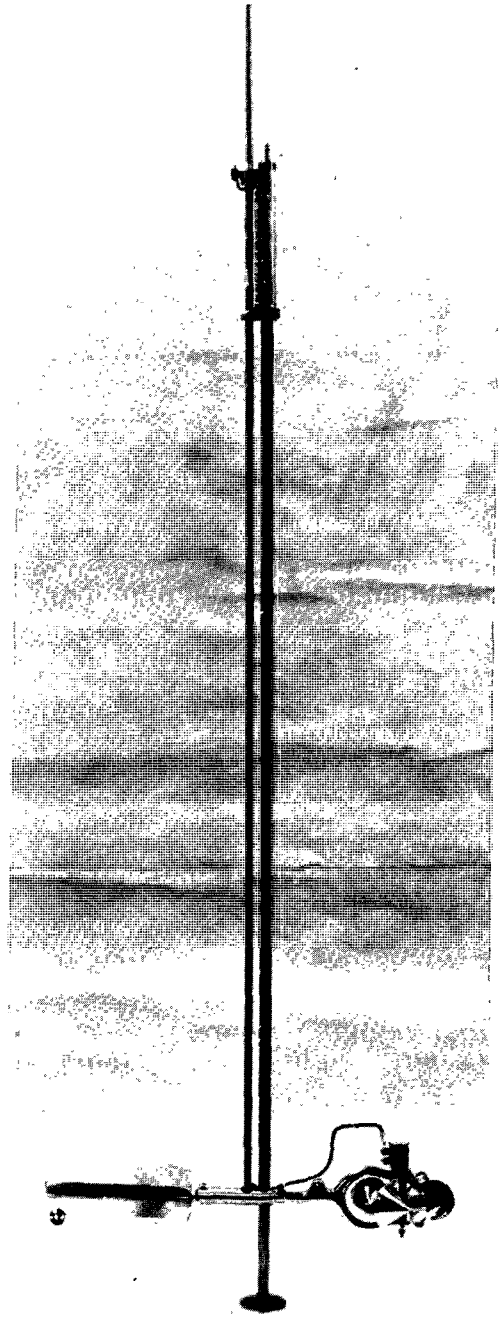

FIGURE 52.—Top-setting wading rod with meter attached.

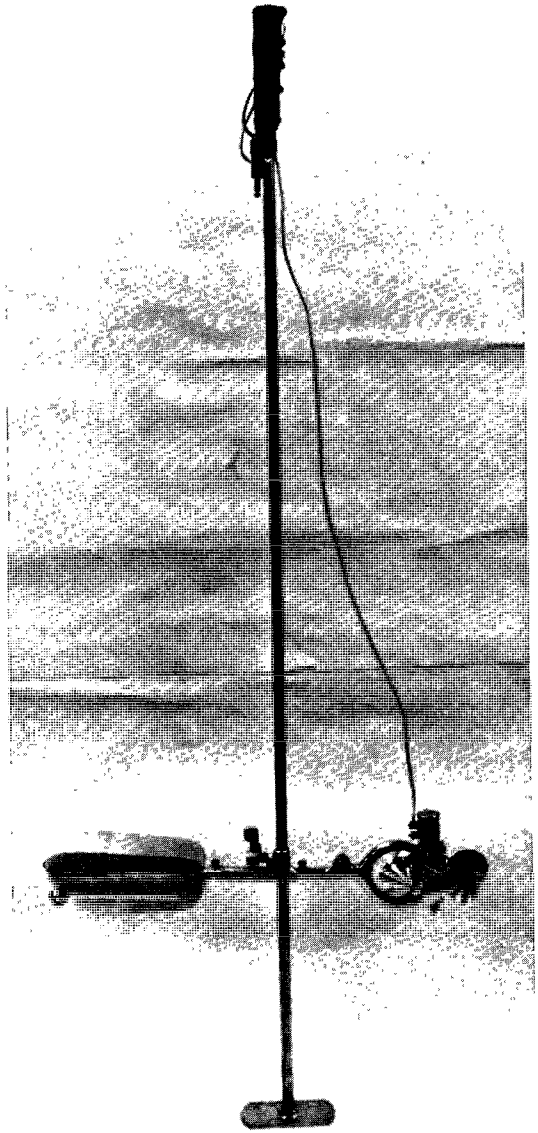

FIGURE 53.—Round wading rod with meter attached.

is mounted on the sliding support and is set at the desired position on the rod by sliding the support.

The round rod is also used in making ice measurements. Intermediate sections of the round rod are screwed together to make an ice

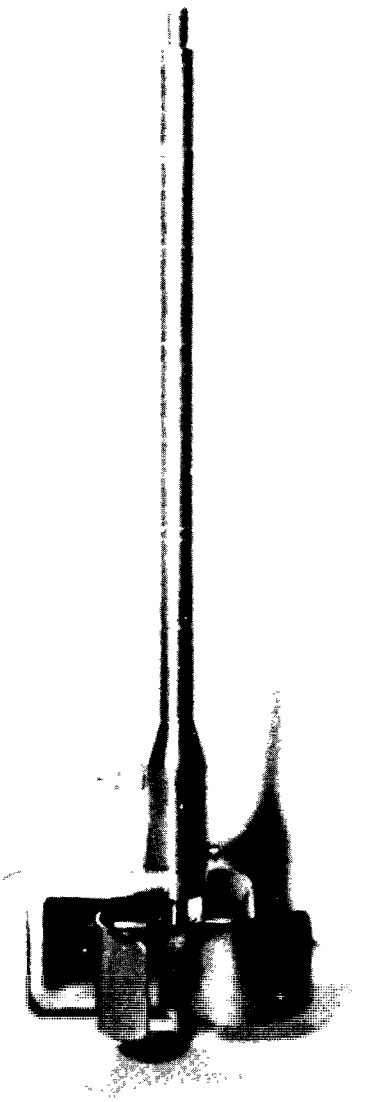

FIGURE 54.—Lower section of ice rod for use with vane ice meter.

rod of desired length (fig. 54). The most convenient length for an ice rod is about 3 ft (1 m) longer than the maximum depth of water to be found in a cross section. About 12 ft (4 m) is the maximum practical length for an ice rod; depths greater than 10 ft (3 m) are usually measured with a sounding weight and reel. The base plate, sliding support, and lower section are not used on an ice rod. Instead, a special lower section is screwed directly into the top of the contact chamber of the vane ice meter. (See fig. 54.) If a Price meter is used under ice cover, another special lower section is used to hold the meter by means of the hanger screw. (See fig. 55.) All lower sections for ice rods are now made so that the center of the vanes or cups is at the 0-ft point on the rod.

SOUNDING WEIGHTS AND ACCESSORIES

If a stream is too deep or too swift to wade, the current meter is suspended in the water by cable from a boat, bridge, or cableway. A sounding weight is suspended below the current meter to keep it

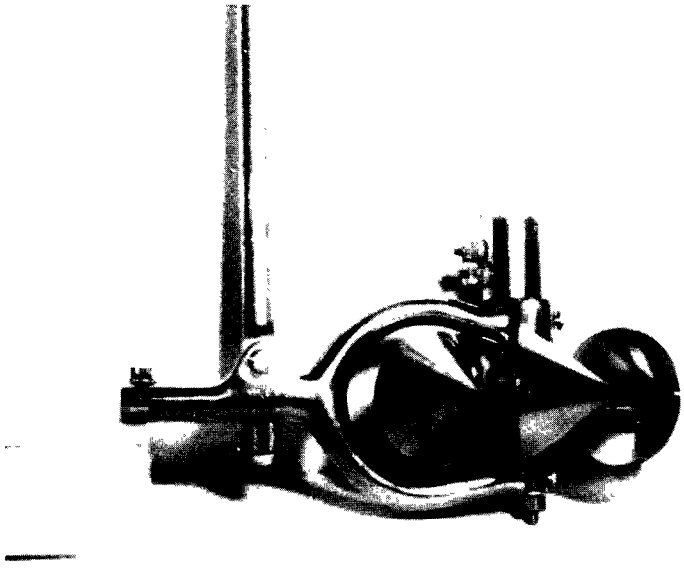

FIGURE 55.—Lower section of ice rod for use with Price meter.

stationary in the water. The weight also prevents damage to the meter when the assembly is lowered to the streambed.

The sounding weights now used in the U.S.A. are the Columbus weights, commonly called the C type. (See fig. 56.) The weights are streamlined to offer minimum resistance to flowing water. Each weight has a vertical slot and a drilled horizontal hole to accommodate a weight hanger and securing pin.

The weight hanger (fig. 57) is attached to the end of the sounding line by a connector. The current meter is attached beneath the connector, and the sounding weight is attached to the lower end of the hanger by means of the hanger pin.

In addition to the weights shown in figure 56, weights of 150, 200 and 300 lb (68, 91, and 136 kg) are used for measuring the discharge of deep, swift rivers. The sounding-weight hangers shown in figure 57 are designed to accommodate the weights of the various sizes. The height of the meter rotor above the bottom of the sounding weight must be considered in calculations to position the meter for velocity observations at various percentages of the stream depth.

SOUNDING REELS

A sounding reel has a drum for winding the sounding cable, a crank and ratchet assembly for raising and lowering the weight or holding it in any desired position, and a depth indicator. The U.S. Geological Survey has five types or sizes of sounding reel in common use, the choice of reel being dependent on the depth of water to be measured and on the weight required for sounding. The lightest of the reels, known as the Canfield reel (fig. 58), can be used with either single- or two-conductor cable; the other four reels use two-conductor cable, whose diameter ranges from 0.084 in to 0.125 in (2.13 to 3.18 mm),

FIGURE 56.—Columbus 15-, 30-, 50-, 75-, and 100-lb sounding weights.

depending on the weight to be handled. The three smaller reels have a hand crank for raising and lowering the meter and weight (fig. 58);

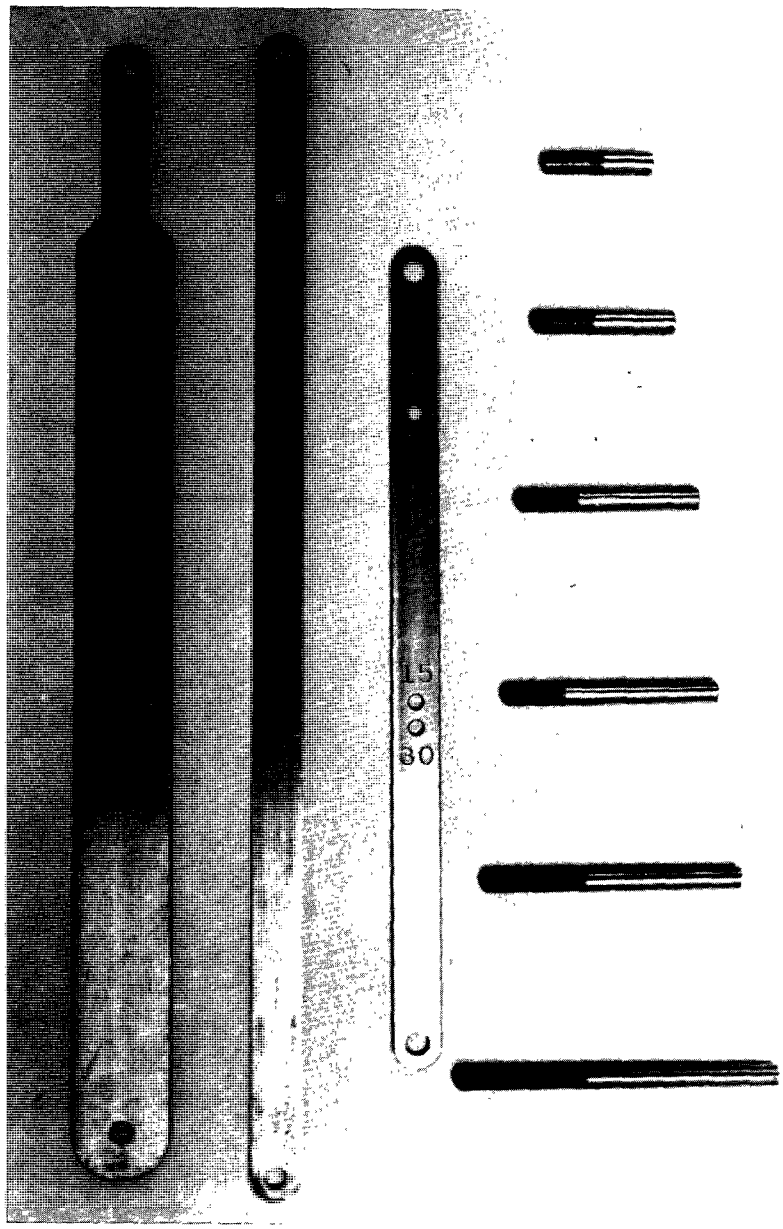

FIGURE 57.—Sounding-weight hangers and hanger pins.

the largest of the five reels is operated by a battery-powered unit but has a handcrank for emergency use; the second largest reel (fig. 59) may be operated either by a hand crank or a power unit. Specially designed connectors are used to join the end of the reel cable to the sounding-weight hanger.

The two smaller reels (Canfield and A-pack reels) are equipped with counters for indicating depth (fig. 58); the three larger reels are equipped with computing depth indicators (figs. 59 and 60). On the computing depth indicator, depth is indicated by a pointer. Tens of feet are read on a numbered dial through an aperture near the top of the main dial. The main dial also has a graduated spiral to indicate directly the 0.8-depth position (p. 134) for depths up to 30 ft (9.15 m).

HANDLINES

When discharge measurements that are to be made from a bridge require light sounding weights—15 or 30 lb (6.8 or 13.6 kg)—the weight and meter are often suspended on a handline (figs. 61 and 62). Handlines can also be used from cable cars, but they seldom are because a sounding reel mounted on the cable car is much more convenient to use.

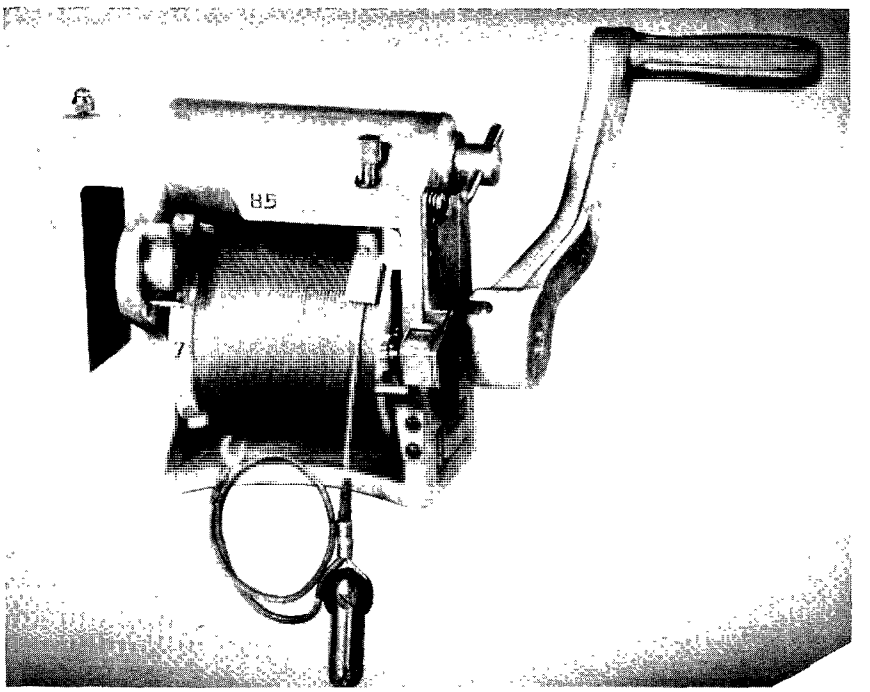

FIGURE 58.—Canfield reel.

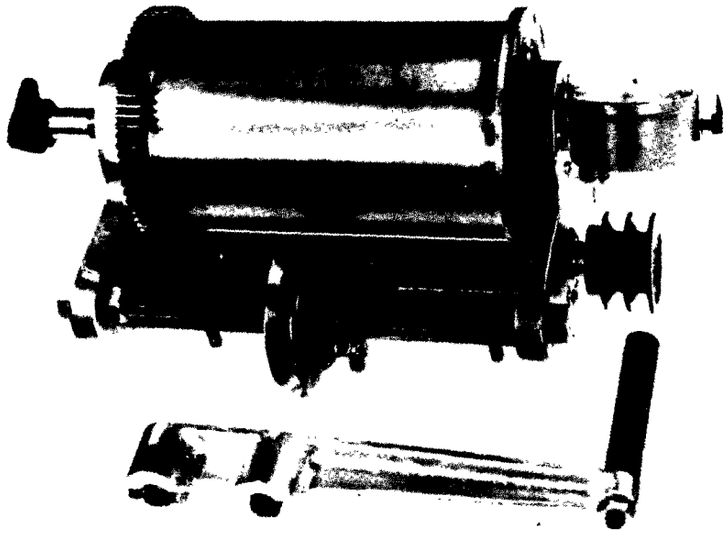

FIGURE 59.—B–56 reel.

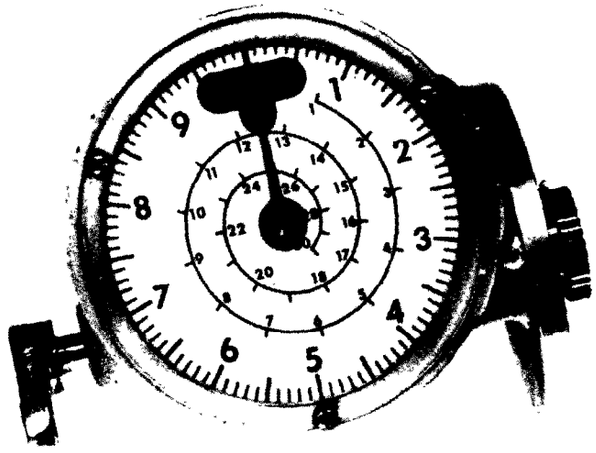

FIGURE 60.—Computing depth indicator.

The handline is made up of two separate cables that are electrically connected at a reel (fig. 63). The upper or hand cable is that part of the handline that is used above the water surface. It is a heavy-duty two-conductor electric cable, whose thick rubber protective covering makes the cable comfortable to handle. At its upper end is a connection for the headphone. The lower or sounding cable is a light reverse-lay steel cable with an insulated core. A connector joins the lower end of the sounding cable to the hanger that is used as a mount for the current meter and sounding weight. Sounding cable in excess of the length needed to sound the stream being measured is wound on

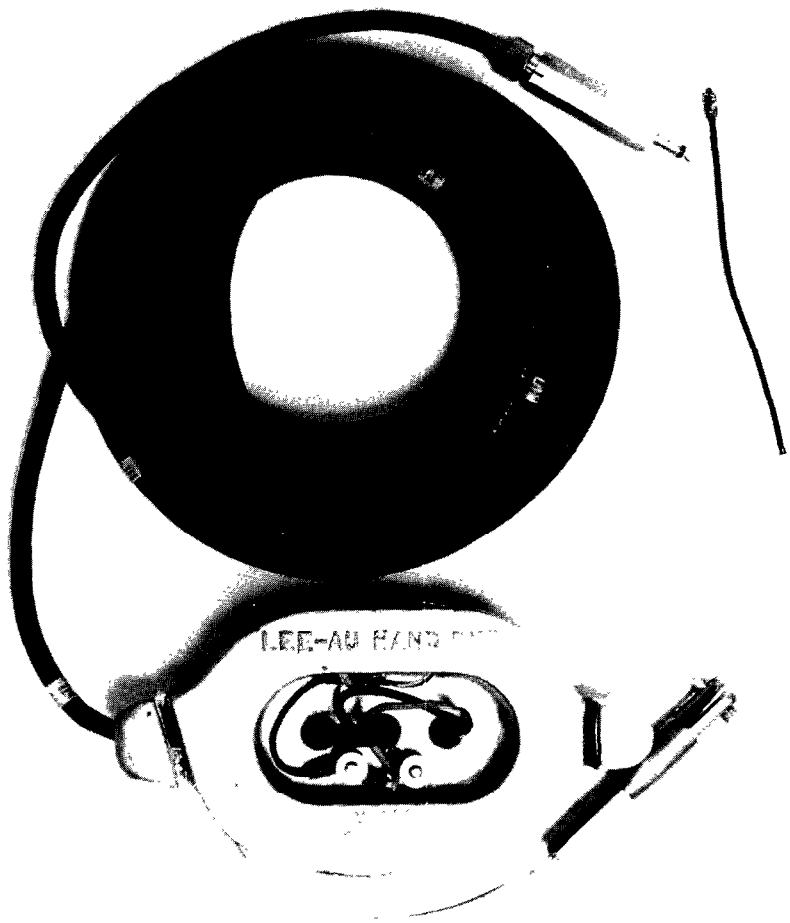

FIGURE 61.—Handline.

the reel. The sounding cable is tagged at convenient intervals with streamers of different colored binding tapes, each colored streamer being a known distance above the current-meter rotor. The use of these tags in determining depth is described on page 150.

The advantages of the handline are ease in assembling the equipment for a discharge measurement and relative ease in making discharge measurements from certain types of bridges, particularly truss bridges that do not have cantilevered sidewalks. The disadvantages of the handline are a lesser degree of accuracy in depth determination than that obtained with a sounding reel, more physical exertion is required in making the discharge measurement, and the handline can seldom be used for high-water measurements of large

FIGURE 62.—Handline in use from a bridge.

streams because of the heavy sounding weights needed for such measurements.

SONIC SOUNDER

A commercial, compact, portable sonic sounder has been adopted by the U.S. Geological Survey to measure stream depth. (See figs. 64 and 65.)

The sounder is powered by either a 6- or 12-volt storage battery and will operate continuously for 10 hr on a single battery charge. Three recording speeds are available, 36, 90, or 180 in (0.91, 2.29,4.57 m) per hr. Four operating ranges, 0–60, 60–120, 120–180, and 180–240 ft (0–18.3, 18.3–36.6, 36.6–54.9, and 54.9–73.2 m) allow intervals of 60 ft (18.3 m) of depth to be recorded. The sounder is portable, weighing only 46 lb (20.9 kg). The transducer has a narrow beam angle of 6° which minimizes errors on inclined streambeds and allows the hydrographer to work close to piers or other obstructions.

In swift debris-laden streams measurements can be made with this equipment without lowering the meter and weight to the streambed. As soon as the weight is in the water, the depth will be recorded. The meter can then be set at the 0.2 depth or just below the water surface for a velocity observation. The observed velocity can be converted to mean velocity in the vertical by applying an appropriate coefficient. (See p. 135–137.)

FIGURE 63.—Handline reels; Lee-Au (top) and Morgan (bottom).

Temperature change affects the sound-propagation velocity, but error from that source is limited to about ±2 percent in fresh water. That error can be eliminated completely by adjusting the sounder to

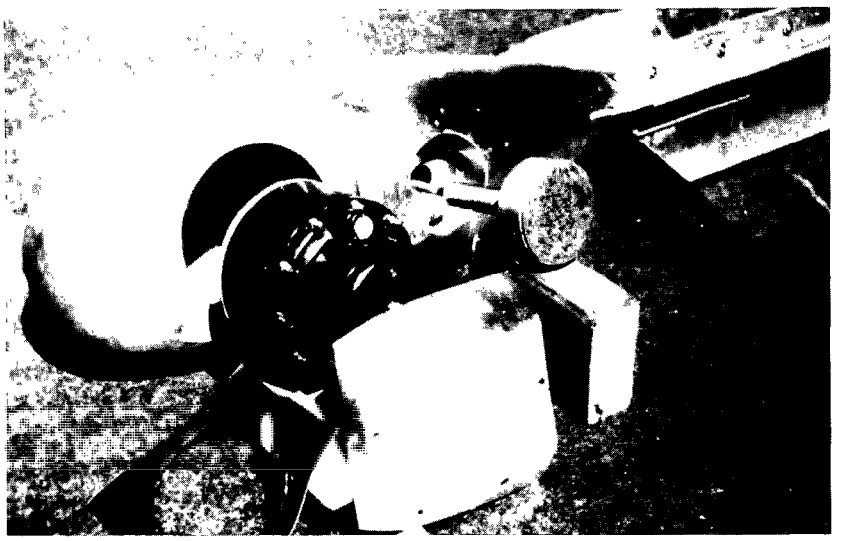

FIGURE 64.—Sounding weight with compass and sonic transducer ready for assembly.

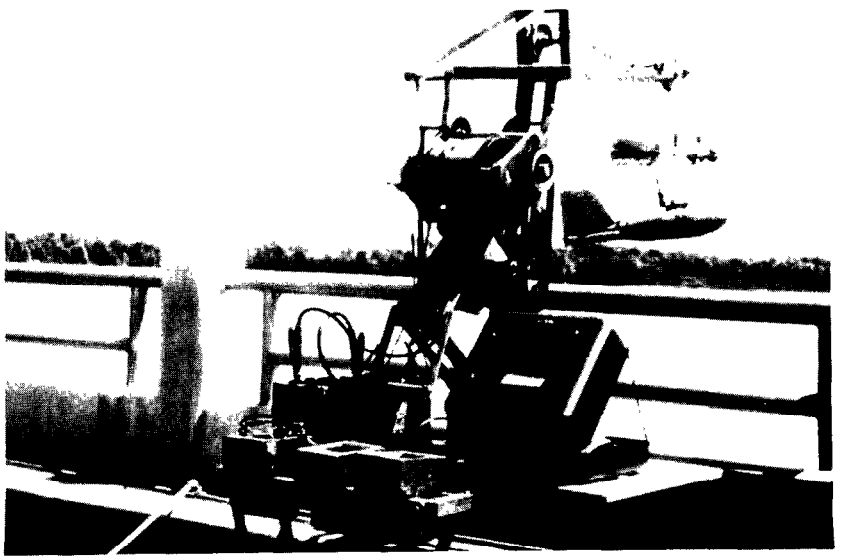

FIGURE 65.—Sonic measuring assembly.

read correctly at an appropriate average depth determined by other means.

WIDTH-MEASURING EQUIPMENT

The distance to any point in a cross section is measured from an initial point on the bank. Cableways and bridges used regularly for making discharge measurements are commonly marked at 2-, 5-, 10-, or 20-ft (0.61-, 1.52-, 3.05-, or 6.10-m) intervals by paint marks. Distance between markings is estimated, or measured with a rule or pocket tape.

For measurements made by wading, from boats, or from unmarked bridges, steel or metallic tapes or tag lines are used. Tag lines are made of 1/32-, 1/16-, 3/32-, or 1/8-in (0.79-, 1.59-, 2.38-, or 3.18-mm)-diameter galvanized steel aircraft cord having solder beads at measured intervals to indicate distances. The standard arrangement of solder beads or tags used by the U.S. Geological Survey is as follows:

one tag every 2 ft for the first 50 ft of tag line;
one tag every 5 ft for stations between 50 and 150 ft on the tag line;
one tag every 10 ft for stations between 150 ft and the end of the tag line.

For identifying the stationing of the tags, an additional tag (total of two tags) is used at stations 0, 10, 20, 30, 40, 50, 150, 250, 350, and 450 ft. Two additional tags (total of three tags) are used at stations 100, 200, 300, 400, and 500 ft.

The standard lengths of tag line are 300, 400 and 500 ft (91.4, 122, and 152m), but other sizes are available.

Three types of tag-line reels in use are Lee-Au, Pakron, and Columbus type A (fig. 66). Larger reels designed particularly for use with boats are described on page 120. It is practically impossible to string a tag line for discharge measurements from a boat when the width of the stream is greater than 2,500 ft (750 m). The methods used to determine width at such sites are described on pages 156–157.

EQUIPMENT ASSEMBLIES

Special equipment is necessary for each type of current-meter measurement. The meters, weights, and reels used have already been described. The additional equipment needed is described in this section.

The special equipment assemblies have been divided into five basic groups: cableway, bridge, boat, ice, and velocity-azimuth-depth assembly (VADA) equipment.

CABLEWAY EQUIPMENT

The cableway provides a track for the operation of a cable car from which the hydrographer makes a current-meter measurement. Cable

cars also support the sounding reel and other necessary equipment. Both sitdown and standup types of cable cars are used in stream gaging. (See figs. 67 and 68). Pierce (1947) describes plans for both types. Normally, sitdown cars are used for cableway spans less than 400 ft (122 m) and for those spans where the lighter sounding weights are used. The standup car is used on the longer spans and where heavy sounding weights are needed.

The cars are moved from one point to another on the cableway by means of cable-car pullers. (See fig. 69.) The standard car puller is a cast aluminum piece with a snub attached to act as a brake. The snub, usually four-ply belting, is placed between one of the car sheaves and the cable to prevent movement of the car along the cable. A second-type puller is used when a car is equipped with a follower brake (fig. 69). A third type, the Colorado River cable-car puller, is the same in principle as the puller used on cars equipped with a follower brake.

Power-operated cable cars are available for extremely long spans or other special situations. (See fig. 70.)

Sitdown cable cars have a variety of means of supporting the sounding reel. A-pack and Canfield reels are designed to clamp on the side of the car (fig. 71). Permanent or portable reel seats are attached to the cable cars for larger reels. (See figs. 67 and 72.)

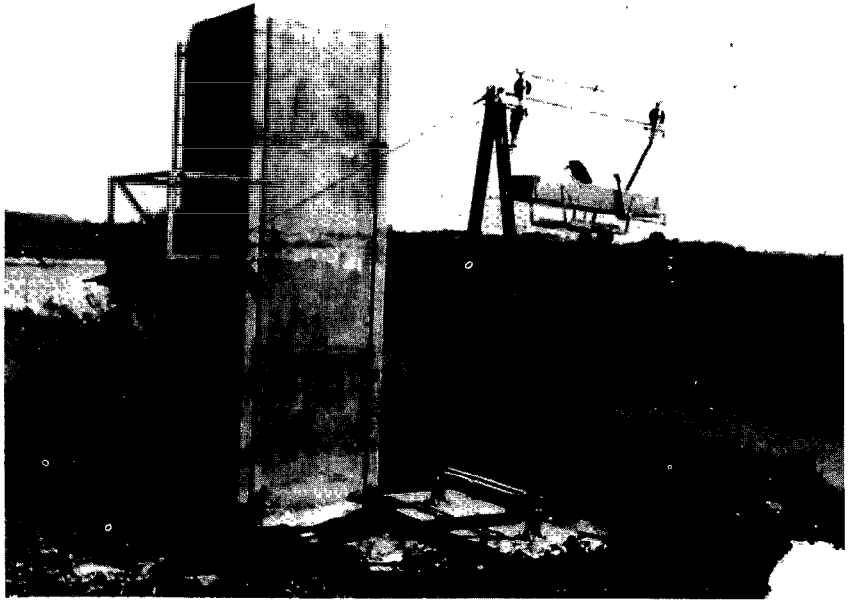

FIGURE 67.—Sitdown cable car.

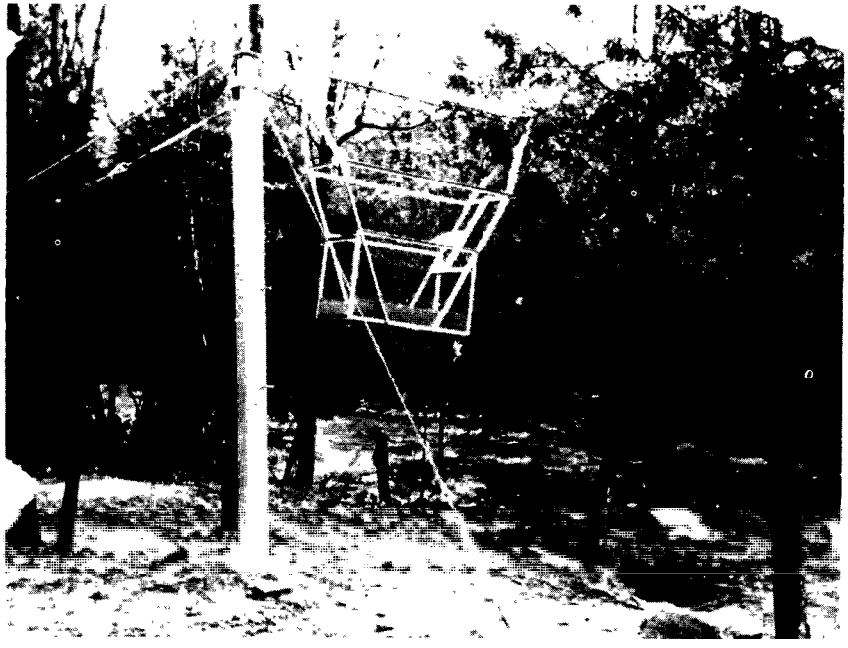

FIGURE 68.—Standup cable car.

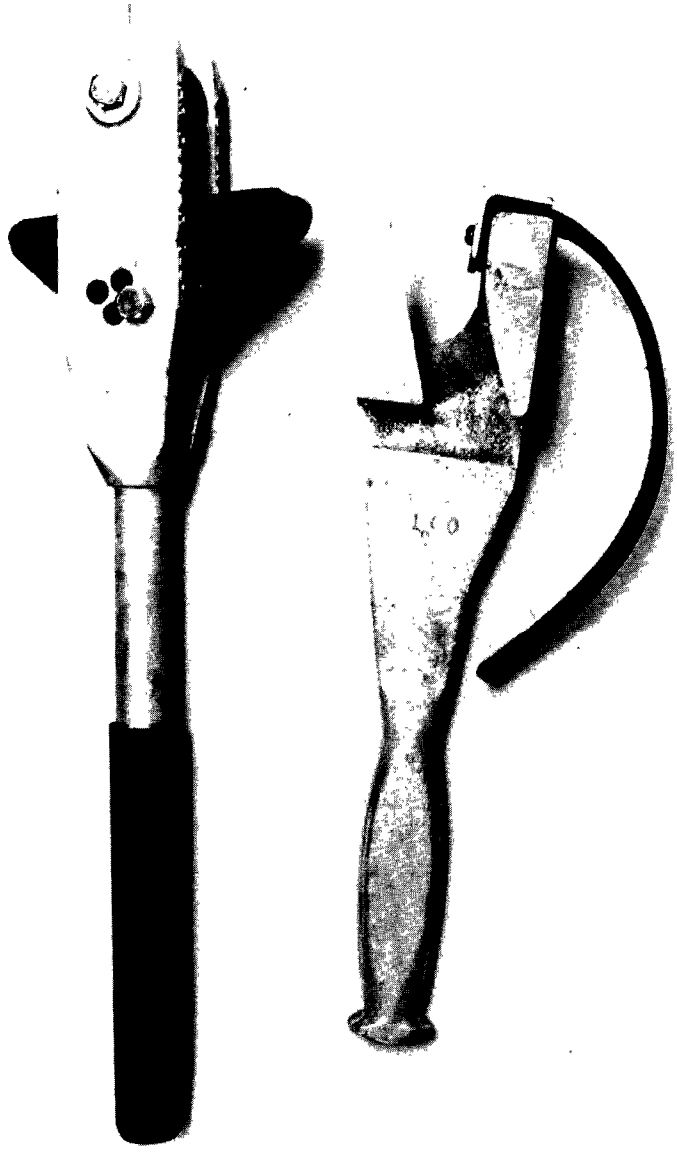

FIGURE 69.—Cable-car puller for follower-brake cable cars, left; for standard cars, right.

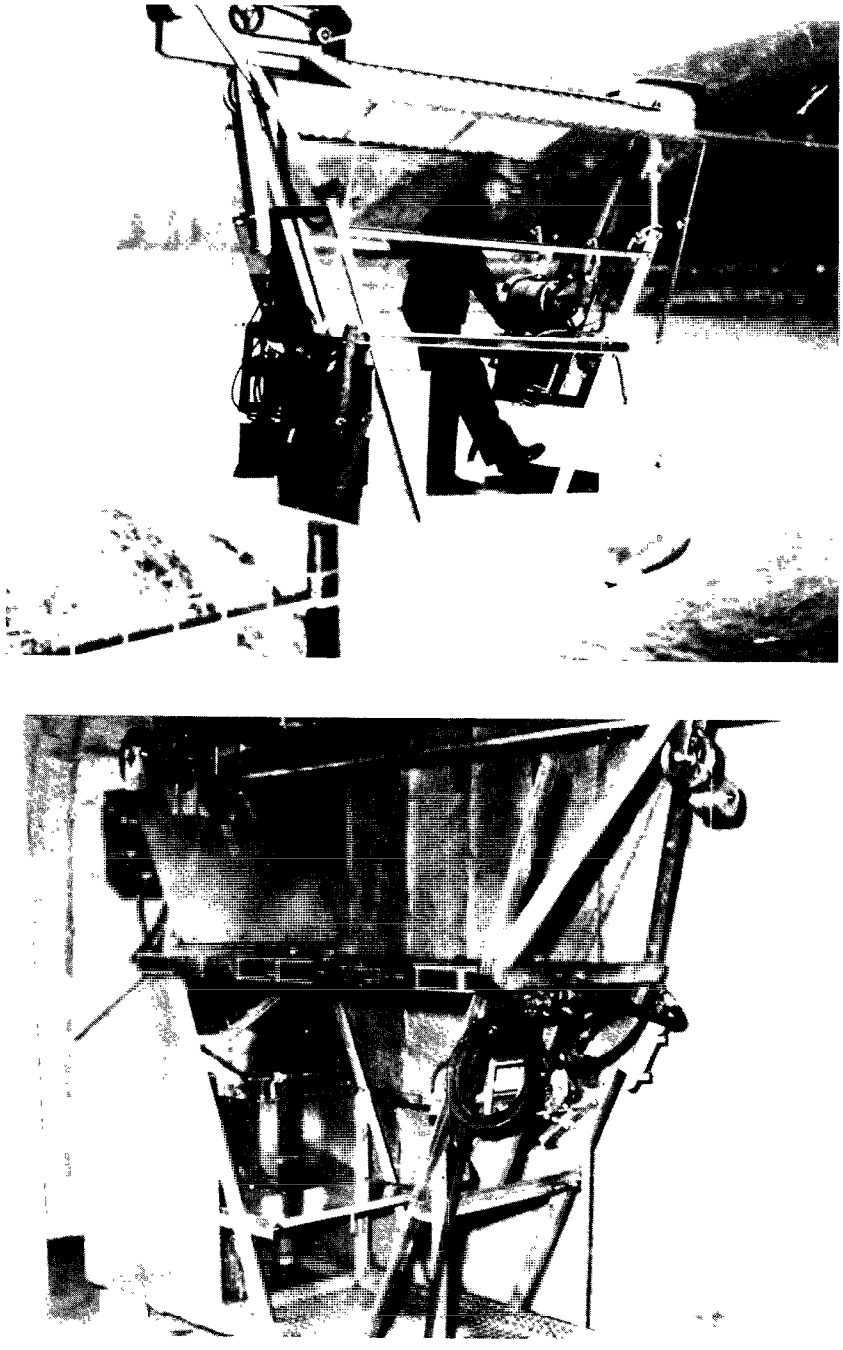

FIGURE 70.—Power-operated cable cars. (*A*) battery-powered car; (*B*) gasoline-powered car.

Standup cable cars have reel seats attached to the structural members of the car (fig. 68). A sheave attached to the structural members carries the sounding line so that the sounding weight and current meter will clear the bottom of the car. Power reels can also be used on standup cable cars.

Carrier cableways are sometimes used on the smaller streams for measuring discharge as well as for sediment sampling. They are used in areas where it is impossible to wade, where no bridges are avail-

FIGURE 71.—Sitdown cable car with Canfield reel clamped to side of car.

able, and where it has been impractical to build a complete cableway. The assembly is operated from the shore (fig. 73). Carrier cables are

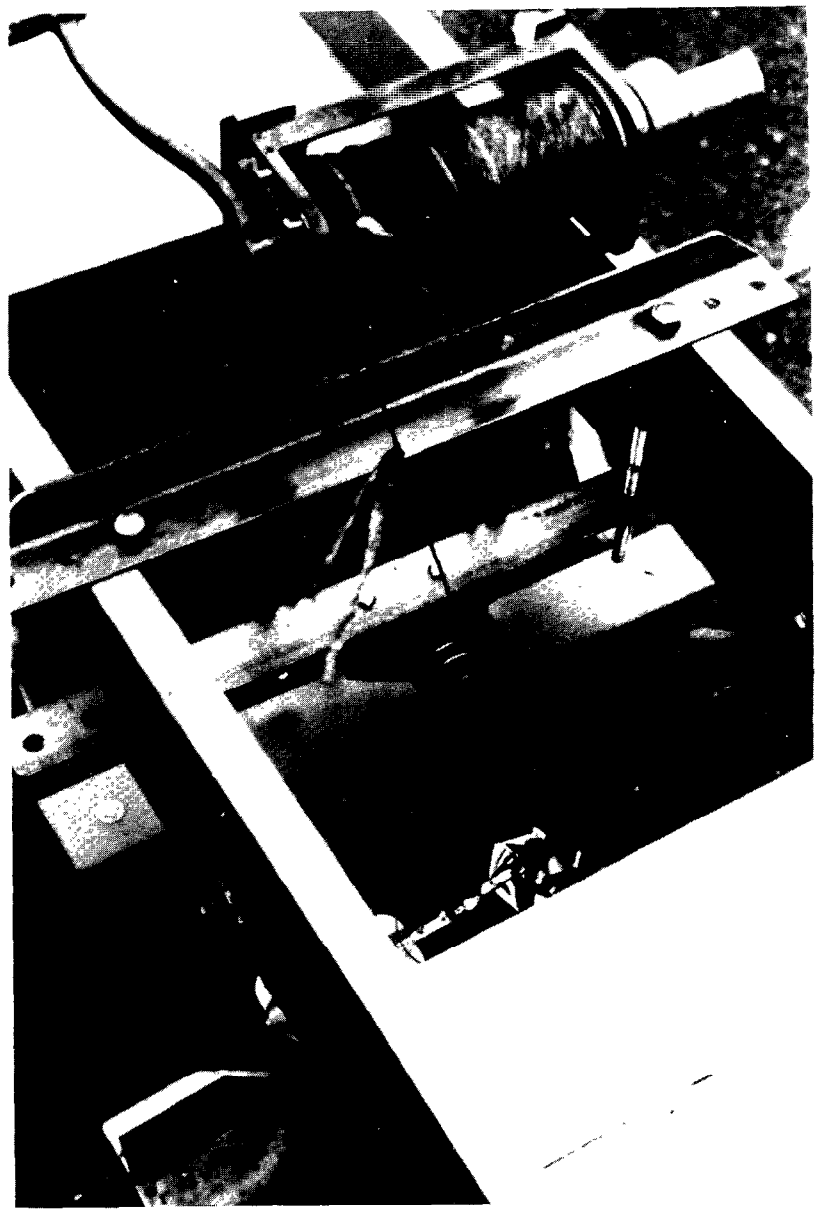

FIGURE 72.—Portable reel seat on sitdown-type cable car. (Note tags on sounding cable.)

more widely used in Europe, particularly in the United Kingdom, than they are in the U.S.A.

BRIDGE EQUIPMENT

When one measures from a bridge, the meter and sounding weight can be supported by a handline, or by a sounding reel mounted on a crane, or by a bridge board. The handline has been described on pages 104–108.

Two types of hand-operated portable cranes are the type A (figs. 74 and 75) for use with weights up to 100 lb (45.4 kg) and the type E for heavier weights.

All cranes are designed so that the superstructure can be tilted

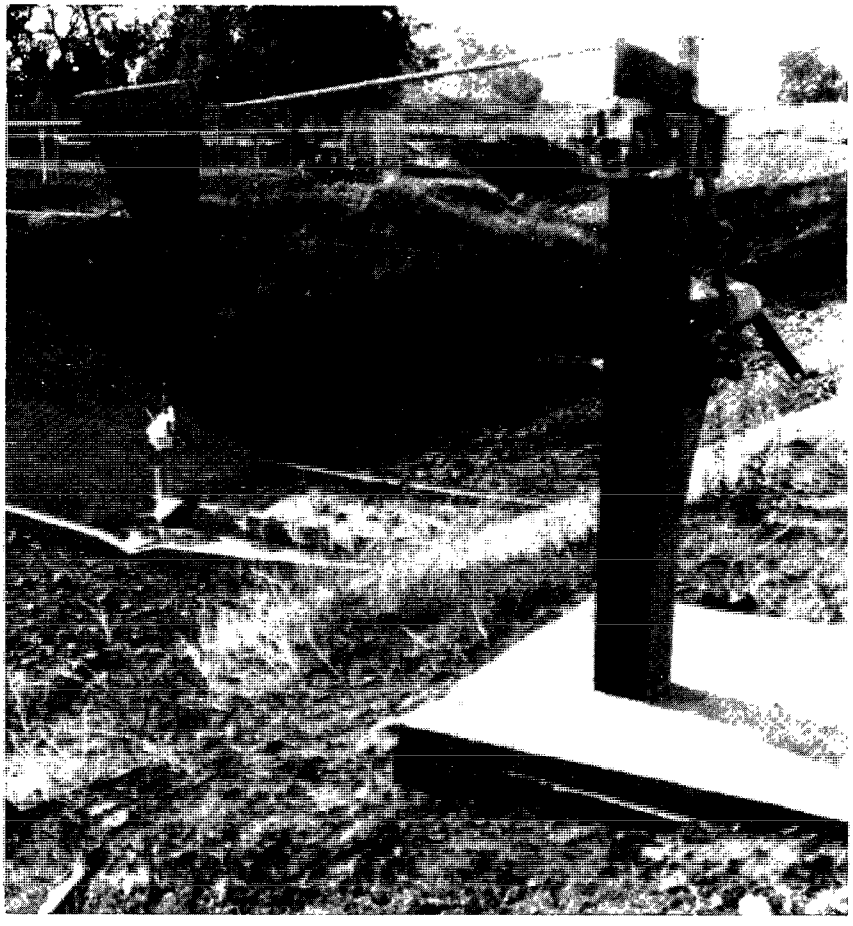

FIGURE 73.—Carrier (bank-operated) cableway. Two reels are used; one moves the meter assembly laterally, and the other moves the current meter vertically.

forward over the bridge rail far enough for the meter and weight to clear most rails. Where bridge members obstruct the movement of the crane from one vertical to the next, the weight and meter can be brought up, and the superstructure can be tilted back to pass by the obstruction. (See figs. 74 and 75.)

Cast-iron counterweights weighing 60 lb (27.2 kg) each are used with four-wheel-base cranes. (See fig. 75.) The number of such weights needed depends upon the size of the sounding weight being supported, the depth and velocity of the stream, and the amount of debris being carried by the stream.

A protractor is used on cranes to measure the angle the sounding line makes with the vertical when the weight and meter are dragged downstream by the water. The protractor is a graduated circle clamped to an aluminum plate. A plastic tube, partly filled with colored antifreeze, fitted in a groove between the graduated circle and

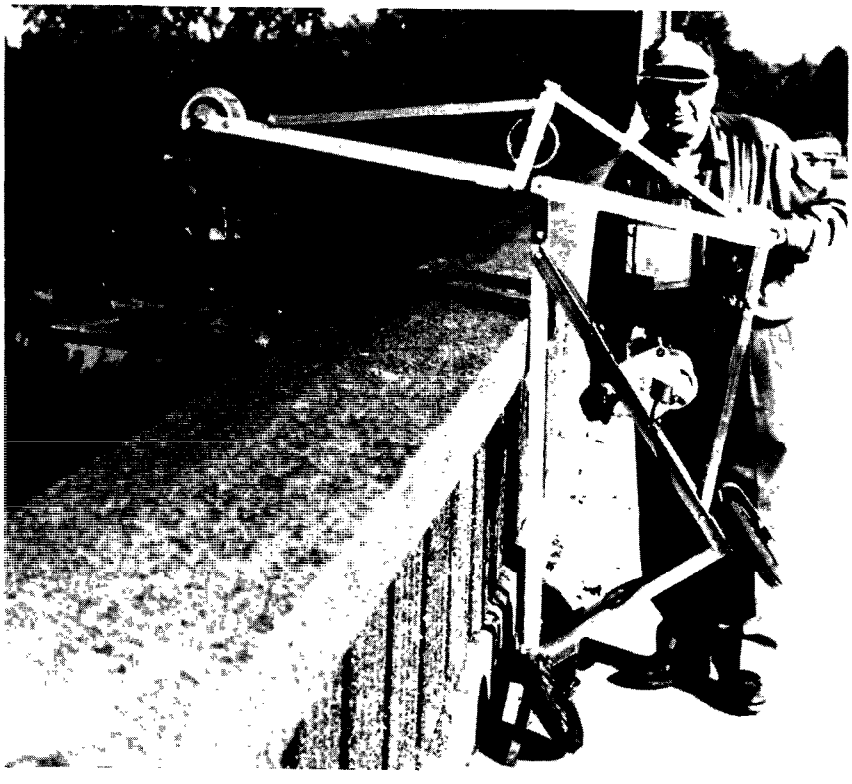

FIGURE 74.—Type-A crane with three-wheel base. (During soundings and velocity observations the crane is tilted against the bridge rail. An A–55 reel is mounted on the crane.)

the plate, is the protractor index. A stainless-steel rod is attached to the lower end of the plate to ride against the downstream side of the sounding cable. The protractor will measure vertical angles from −25° to +90°. The cranes in figures 74 and 75 are equipped with protractors at the outer end of the boom.

Bridge boards may be used with an A-pack or A-55 sounding reel and with weights up to 50 lb (22.7 kg). A bridge board is usually a plank about 6 to 8 ft (1.8 to 2.4 m) long with a sheave at one end over which the meter cable passes and a reel seat near the other end. The board is placed on the bridge rail so that the force exerted by the sounding weight suspended from the reel cable is counterbalanced by the weight of the sounding reel (fig. 76). The bridge board may be hinged near the middle to allow one end to be placed on the sidewalk or roadway.

Many special arrangements for measuring from bridges have been

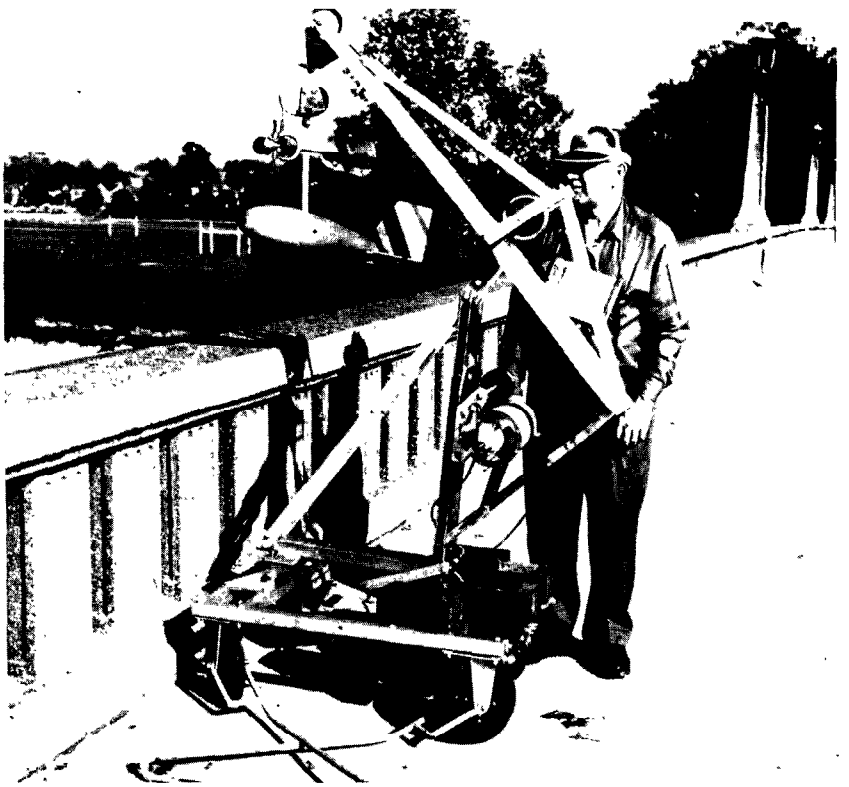

FIGURE 75.—Type-A crane with four-wheel base with boom in retracted position. (A B–56 reel is mounted on crane. Note fluid protractor on outer end of boom.)

devised to suit particular purposes. Truck-mounted cranes are often used for measuring from bridges over the larger rivers. (See fig. 77.) Monorail stream-gaging cars have been developed for large rivers. The car is suspended from the substructure of the bridge by means of an I-beam. The car is attached to the I-beam track by trolleys and is propelled by a forklift motor having a wheel in contact with the bottom of the beam. The drive mechanism and sounding equipment are powered by a 430-ampere-hour, 450-lb (204-kg), 12-volt battery.

BOAT EQUIPMENT

Measurements made from boats require special equipment not used for other types of measurement. Extra-large tag-line reels are used on wide streams. Three different tag-line reels are used by the U.S. Geological Survey for boat measurements:

1. A heavy duty horizontal-axis reel without a brake and with a capacity of 2,000 ft (610 m) of ⅛-in (3.18-mm)-diameter cable (fig. 78).

FIGURE 76.—Bridge board in use.

2. A heavy-duty horizontal-axis reel with a brake and with a capacity of 3,000 ft (914 m) of ⅛-in-diameter cable (fig. 79).
3. A vertical-axis reel without a brake and with a capacity of 800 ft (244 m) of ⅛-in-diameter cable (fig. 80).

A utility line of 30 ft (9 m) of 3/32-in (2.38-mm)-diameter cable with a harness snap at one end and a pelican hook at the other is connected to the free end of the boat tag line and fastened around a tree or post, thereby preventing damage to the tag line. After the tag line is strung across the stream, the reel is usually bolted to a plank and chained to a tree. The tag line has station markers at appropriate intervals.

Special equipment is necessary to suspend the meter from the boat when the depths are such that a rod suspension cannot be used. A crosspiece reaching across the boat is clamped to the sides of the boat and a boom attached to the center of the cross piece extends out over the bow. (See fig. 81.) The crosspiece is equipped with a guide sheave and clamp arrangement at each end to attach the boat to the tag line and make it possible to slide the boat along the tag line from one station to the next. A small rope can be attached to these clamps so

FIGURE 77.—Truck-mounted crane used on the Mississippi River.

that in an emergency a tug on the rope will release the boat from the tag line. The crosspiece also has a clamp that prevents lateral movement of the boat along the tag line when readings are being made. The boom consists of two structural aluminum channels, one telescoped within the other to permit adjustments in length. The boom is equipped with a reel plate on one end; on the other end is a sheave over which the meter cable passes. The sheave end of the boom is designed so that by adding a cable clip to the sounding cable, a short distance above the connector, the sheave end of the boom can be retracted when the meter is to be raised out of the water. The raised

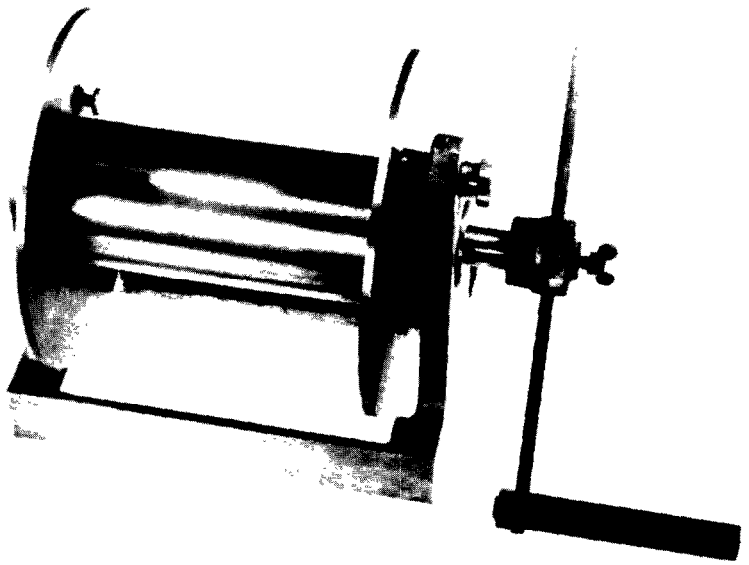

FIGURE 78.—Horizontal-axis boat tag-line reel without a brake.

meter is easy to clean and is in a convenient position when not being operated.

All sounding reels fit the boat boom except the A-pack and the Canfield reels, which can be made to fit by drilling additional holes in the reel plate on the boom.

In addition to the equipment already mentioned, the following items are needed when making boat measurements:

1. A stable boat big enough to support the hydrographers and equipment.
2. A motor that can move the boat with ease against the maximum current in the stream.
3. A pair of oars for standby use.
4. A life preserver for each hydrographer.
5. A bailing device.

Figure 82 shows the equipment assembled in a boat.

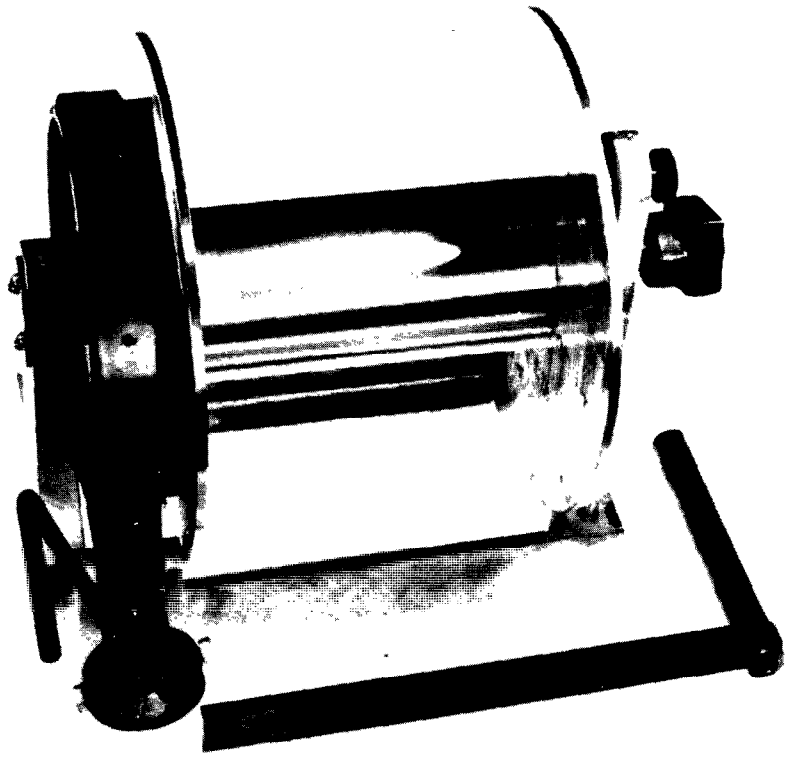

FIGURE 79.—Horizontal-axis boat tag-line reel with a brake.

ICE EQUIPMENT

Current-meter measurements made under ice cover require special equipment for cutting holes in the ice through which to suspend the meter.

Cutting holes through the ice on streams to make discharge measurements has long been a laborious and time-consuming job. The development of power ice drills, however, has eliminated many of the difficulties and has reduced considerably the time required to cut the holes. Holes are often cut with a commercial ice drill that cuts a 6-in (0.15-m) diameter hole (fig. 83). The drill weighs about 30 lb (13.6

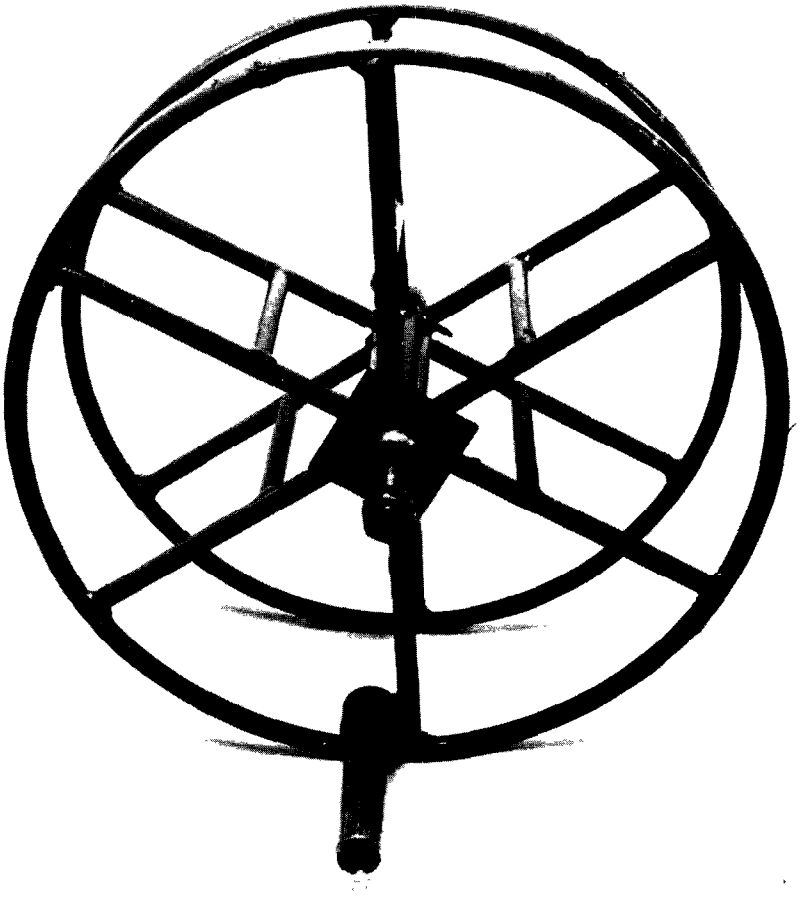

FIGURE 80.—Vertical-axis boat tag-line reel (when in use the axis of the reel is vertical).

kg) and under good conditions will cut through 2 ft (0.6 m) of ice in about a minute.

Where it is impractical to use the ice drill, ice chisels are used to cut the holes. Ice chisels used are usually 4 or 4½ ft (about 1.3 m) long and weigh about 12 lb (5.5 kg). The ice chisel is used when first crossing an ice-covered stream to determine whether the ice is strong enough to support the hydrographer. If a solid blow of the chisel blade does not penetrate the ice, it is safe to walk on the ice, providing the ice is in contact with the water.

Some hydrographers supplement the ice chisel with a Swedish ice auger. The cutting blade of this auger is a spadelike tool of hardened steel that cuts a hole 6–8 in (0.15–0.20 m) in diameter. The auger is operated by turning a bracelike arrangement on top of the shaft.

When holes are cut in the ice the water, which is usually under pressure because of the weight of the ice, rises in the hole. To determine the effective depth of the stream (p. 153–154), ice-measuring sticks are used to measure the distance from the water surface to the

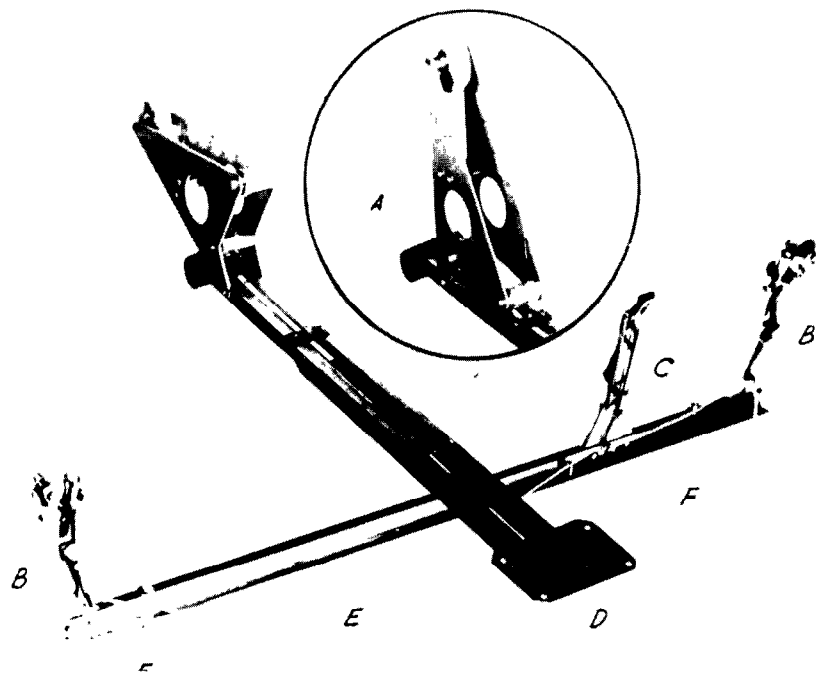

FIGURE 81.—Boom and crosspiece for use on boats. (*A*, retractable end of boom; *B*, guide sheave and clamp for attaching to tag line; *C*, clamp to prevent movement of the boat along the tag line; *D*, plate to accomodate reel; *E*, rope to release clamps (*B*) to free boat from tag line; and *F*, clamps to attach crosspiece to boat.)

bottom of the ice. This is done with a bar about 4 ft long (1.2 m), made of strap steel or wood, which is graduated in feet and tenths of a foot and has an L-shaped projection at the lower end. The horizontal part of the L is held on the underside of the ice, and the depth to that point

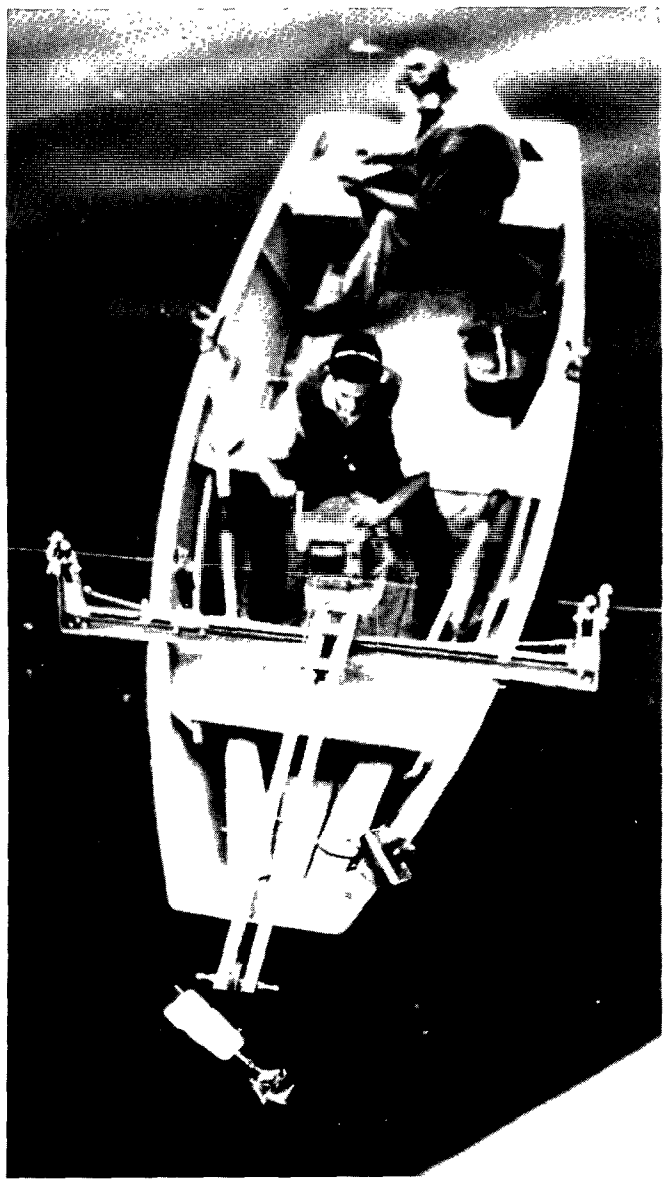

FIGURE 82.—Measuring equipment set up in a boat.

is read at the water surface on the graduated part of the stick. The horizontal part of the L is at least 4 in (0.1 m) long so that it may

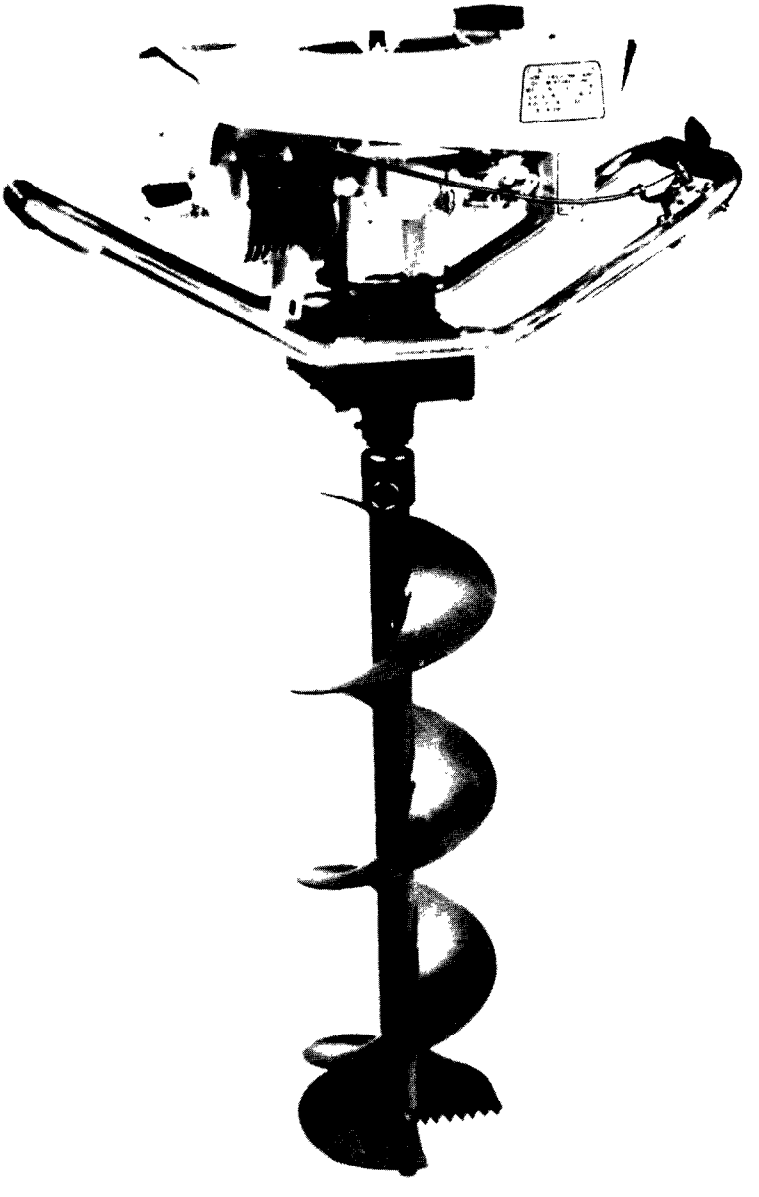

FIGURE 83.—Gasoline-powered ice drill. (Photograph by permission of General Equipment Co.)

extend beyond any irregularities on the underside of the ice.

When the total depth of water under ice cover is greater than 10 or 12 ft (3.0 or 3.6 m), a sounding reel or handline is usually used. The sounding reel is mounted on a collapsible support set on runners. (See fig. 84.)

A special ice-weight assembly is used for sounding under ice be-

FIGURE 84.—Collapsible reel support and ice-weight assembly.

cause a regular sounding weight will not fit through the hole cut by the ice drill (fig. 84). The weights and meter are placed in a framework that will pass through the drilled hole.

VELOCITY-AZIMUTH-DEPTH ASSEMBLY

The velocity-azimuth-depth assembly, commonly called VADA, combines a sonic sounder with a remote-indicating compass and Price current meter to record depth, indicate the direction of flow, and permit observations of velocity at any point.

In figure 85, the azimuth-indicating unit is shown mounted on a four-wheel crane. Incorporated within the remote-indicator box is the battery for the current-meter circuit, the headphone jacks, and the two-conductor jack for the sonic sounder. A switch allows the remote-indicating unit to be used separately or in conjunction with the sonic sounder. The sonic sounder is described on page 108. This assembly is useful in tidal investigations and in other special studies, as well as at regular gaging stations, where it is desirable to determine the

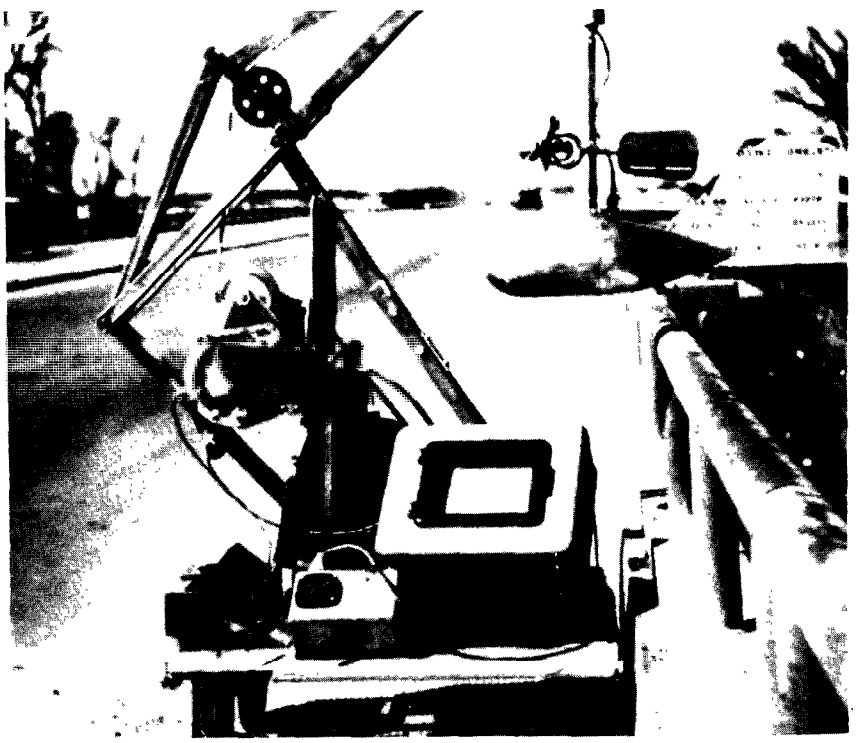

FIGURE 85.—Velocity-azimuth-depth assembly.

direction of flow beneath the water surface, because of the possibility that it may differ from that at the surface.

MISCELLANEOUS EQUIPMENT

Several miscellaneous items that have not been described are necessary when current-meter measurements are made. Three classifications of this equipment are timers, counting equipment, and waders and boots.

In order to determine the velocity at a point with a current meter, it is necessary to count the revolutions of the rotor in a measured interval of time, usually 40–70 s. The velocity is then obtained from the meter-rating table (fig. 51). The time interval is measured to the nearest second with a stopwatch.

The revolutions of the meter rotor during the observation of velocity are counted by an electric circuit that is closed each time the contact wire touches the single or penta eccentric of the current meter. A battery and headphone are part of the electrical circuit, and a click is heard in the headphone each time the contact wire touches. (See fig. 86.) Compact, comfortable hearing-aid phones have been adapted by some to replace the headphones.

A magnetic-switch contact chamber has been developed to replace the contact-wire chamber (p. 87). An automatic electric counter has also been developed for use with the magnetic contact chamber (fig. 86). The counter can register up to 999 and has a reset button. A metal clip is attached to the counter so that it may be easily carried on the hydrographer's belt. The electric counter should not be used with the contact-wire chamber, because at low velocities the contact wire wipes irregularly thereby sending several signals to the counter for each revolution.

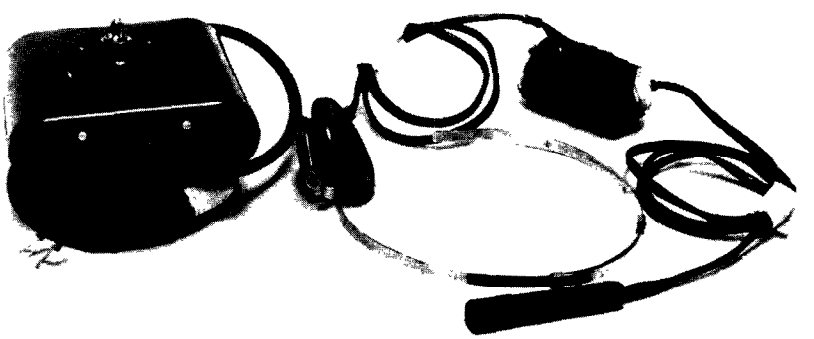

FIGURE 86.—Automatic counter (left) and headphone (right).

Waders or boots are needed when wading measurements are made. Waders should be loose fitting even after allowance has been made for heavy winter clothing. Ice creepers strapped on the shoe of boots or waders should be used on steep or icy streambanks and on rocky or smooth and slippery streambeds. (See fig. 87.)

MEASUREMENT OF VELOCITY

The current meter measures velocity at a point. The method of making discharge measurements at a cross section requires determination of the mean velocity in each of the selected verticals. The mean velocity in a vertical is obtained from velocity observations at many points in that vertical, but it can be approximated by making a few velocity observations and using a known relation between those velocities and the mean in the vertical. The more commonly used methods of determining mean vertical velocity are:

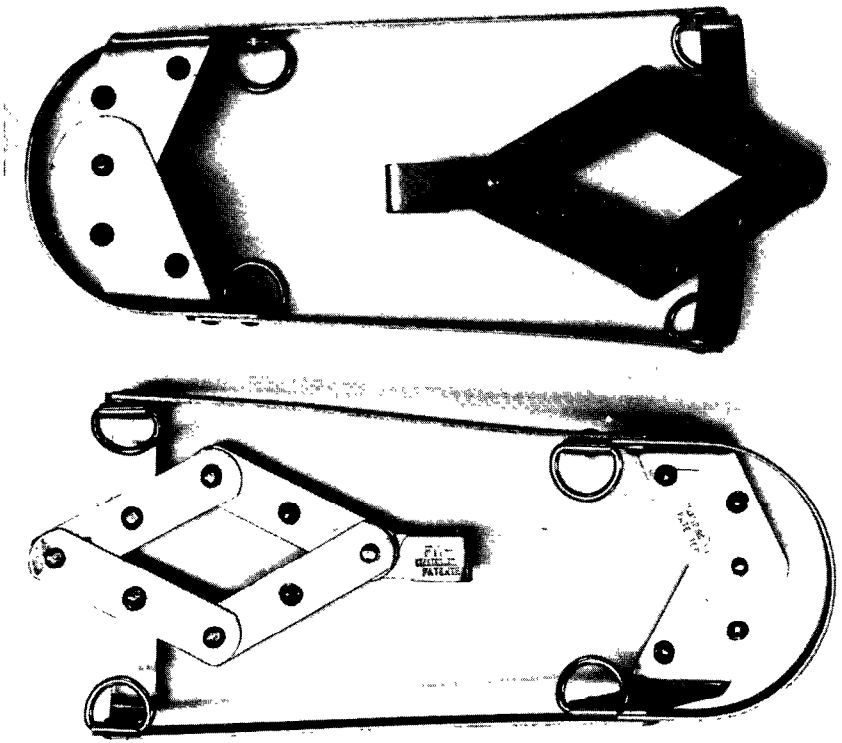

FIGURE 87.—Ice creepers for boots and waders.

1. Vertical-velocity curve.
2. Two-point.
3. Six-tenths-depth.
4. Three-point.
5. Two-tenths depth.
6. Subsurface-velocity.
7. Surface-velocity.
8. Integration.

Less commonly used are the following multipoint methods of determining mean vertical velocity:

9. Five-point.
10. Six-point.

VERTICAL-VELOCITY CURVE METHOD

In the vertical-velocity curve method a series of velocity observations at points well distributed between the water surface and the streambed are made at each of the verticals. If there is considerable curvature in the lower part of the vertical-velocity curve, it is advisable to space the observations more closely in that part of the depth. Normally, the observations are taken at 0.1-depth increments between 0.1 and 0.9 of the depth. Observations are always taken at 0.2, 0.6, and 0.8 of the depth so that the results obtained by the vertical-velocity curve method may be compared with those obtained by the more commonly used methods of velocity observation. Observations are made at least 0.5 ft (0.15m) below the water surface and above the streambed when the Price AA meter or the vane meter is used and are made at least 0.3 ft (0.09 m) from those boundaries when the Price pygmy meter is used; those meters underregister velocity when placed closer to the water surface or streambed.

The vertical-velocity curve for each vertical is based on observed velocities plotted against depth (fig. 88). In order that vertical-velocity curves at different verticals may be readily compared, it is customary to plot depths as proportional parts of the total depth. The mean velocity in the vertical is obtained by measuring the area between the curve and the ordinate axis with a planimeter, or by other means, and dividing the area by the length of the ordinate axis.

The vertical-velocity curve method is valuable in determining coefficients for application to the results obtained by other methods but is not generally adapted to routine discharge measurements because of the extra time required to collect field data and to compute the mean velocity.

Intensive investigation of vertical-velocity curves by Hulsing, Smith, and Cobb (1966) resulted in table 2 which shows average ordinates of the vertical-velocity curve.

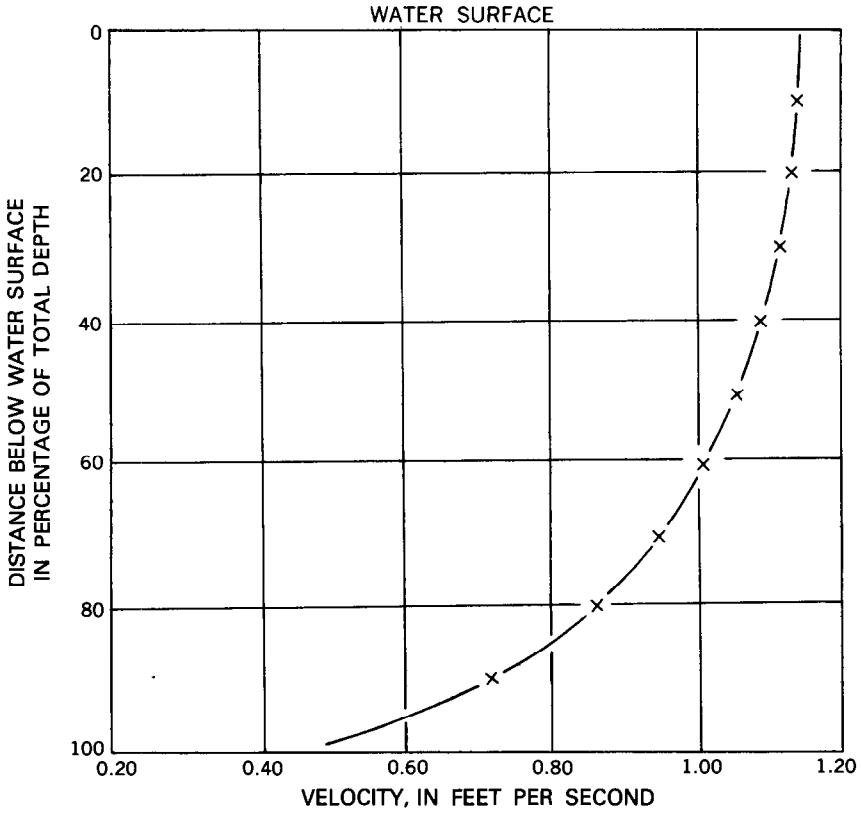

FIGURE 88.—Typical vertical-velocity curve.

TWO-POINT METHOD

In the two-point method of measuring velocities, observations are made in each vertical at 0.2 and 0.8 of the depth below the surface. The average of those two observations is taken as the mean velocity in the vertical. This method is based on many studies involving actual observation and mathematical theory. Experience has shown that this method gives more consistent and accurate results than any of the other methods listed, other than the five-point, six-point, and vertical-velocity curve methods. The two-point method is the one generally used by the U.S. Geological Survey. Table 2 indicates that the two-point method, on the average, gives results that are within 1 percent of the true mean velocity in the vertical.

The two-point method is not used at depths less than 2.5 ft (0.76 m) when measuring with a Price current meter, because the meter would then be too close to the water surface and to the streambed to give dependable results.

The vertical-velocity curve will be distorted by overhanging vegetation that is in contact with the water or by submerged objects, such as large rocks and aquatic growth, if those elements are in close proximity, either in the upstream or downstream direction, to the vertical in which velocity is being measured. Where that occurs the two-point method will not give a reliable value of the mean velocity in the vertical, and an additional velocity observation at 0.6 of the depth should be made. The three observed velocities should then be used in the three-point method (p. 135). A rough test of whether or not the velocities at the 0.2 and 0.8 depths are sufficient for determining mean vertical velocity is given in the following criterion: the 0.2-depth velocity should be greater than the 0.8-depth velocity but less than twice as great.

SIX-TENTHS DEPTH METHOD

In the 0.6-depth method, an observation of velocity made in the vertical at 0.6 of the depth below the surface is used as the mean velocity in the vertical. Actual observation and mathematical theory have shown that the 0.6-depth method gives reliable results. (See table 2.) The U.S. Geological Survey uses the 0.6-depth method under the following conditions:

1. Whenever the depth is between 0.3 ft (0.09 m) and 1.5 ft (0.46 m) and a Price pygmy meter is being used, or between 1.5 ft (0.46 m) and 2.5 ft (0.76 m) and a Price type AA (or type A) meter is being used. (See table 3 for depth and velocity limitations of each meter.)
2. When large amounts of slush ice or debris make it impossible to

observe the velocity accurately at the 0.2 depth. That condition prevents the use of the two-point method.

3. When the distance between the meter and the sounding weight is too great to permit placing the meter at the 0.8 depth. That circumstance prevents the use of the two-point method.
4. When the stage in a stream is changing rapidly and a measurement must be made quickly.

Although, the preceding paragraph states that the 0.6-depth method may be used with a pygmy meter when water depths are as shallow as 0.3 ft (0.09 m), strictly speaking, the 0.6-depth method should not be used when depths are less than 0.75 ft (0.23 m). This follows from the fact that the pygmy meter underregisters when set closer to the streambed than 0.3 ft (p. 132). From a practical standpoint, however, when it is necessary to measure velocities where water depths are as shallow as 0.3 ft, the 0.6-depth method is used. It is recognized, however, that the results obtained in that situation are only approximate values that underestimate the true velocity. Efforts made to date to define shallow-depth coefficients for natural streams have been unsuccessful.

THREE-POINT METHOD

In the three-point method velocities are observed at 0.2, 0.6, and 0.8 of the depth, thereby combining the two-point and 0.6-depth methods. The mean velocity is computed by averaging the 0.2- and 0.8-depth observations and then averaging that result with the 0.6-depth observation. When more weight to the 0.2- and 0.8-depth observations is desired, the arithmetical mean of the three observations may be used. The first procedure is usually followed, however.

The three-point method is used when the velocities in the vertical are abnormally distributed, as explained on page 134. When a Price type AA (or type A) current meter is used, the three-point method cannot be applied unless the depths are greater than 2.5 ft (0.76 m). (See table 3.)

TWO-TENTHS-DEPTH METHOD

In the 0.2-depth method the velocity is observed at 0.2 of the depth below the surface and a coefficient is applied to the observed velocity to obtain the mean in the vertical. The method is principally used for measuring flows of such high velocity that it is not possible to obtain depth soundings or to position the meter at the 0.8 or 0.6 depth.

A standard cross section or a general knowledge of the cross section at a site is used to compute the 0.2 depth when it is impossible to obtain soundings. A sizable error in an assumed 0.2 depth is not critical in the determination of velocity because the slope of the

vertical-velocity curve at this point is usually nearly vertical. (See fig. 88.) The 0.2 depth is also used in conjunction with the sonic sounder for flood measurements. (See p. 108.)

The measurement made by the 0.2-depth method is normally computed by using the 0.2-depth velocity observations without coefficients, as though each observation were a mean in the vertical. The approximate discharge thus obtained divided by the area of the measuring section gives the weighted mean value of the 0.2-depth velocity. Studies of many measurements made by the two-point method show that for a given measuring section the relation between the mean 0.2-depth velocity and the true mean velocity either remains constant or varies uniformly with stage. In either circumstance, this relation may be determined for a particular 0.2-depth measurement by recomputing measurements made at the site by the two-point method using only the 0.2-depth velocity observation as the mean in the vertical. The plotting of the true mean velocity versus the mean 0.2-depth velocity for each measurement will give a velocity-relation curve for use in adjusting the mean velocity for measurements made by the 0.2-depth method.

If at a site too few measurements have been made by the two-point method to establish a velocity-relation curve, vertical-velocity curves are needed to establish a relation between the mean velocity and the 0.2-depth velocity. The usual coefficient to adjust the 0.2-depth velocity to the mean velocity is about 0.87. (See table 2.)

The 0.2-depth method is not as reliable as either the two-point method or the 0.6-depth method when conditions are equally favorable for a current-meter measurement by any of the three methods.

SUBSURFACE-VELOCITY METHOD

In the subsurface-velocity method the velocity is observed at some arbitrary distance below the water surface. That distance should be at least 2 ft (0.6 m), and preferably more for deep swift streams to avoid the effect of surface disturbances. The subsurface-velocity method is used, in the absence of an optical current meter, when it is impossible to obtain soundings and the depths cannot be estimated with sufficient reliability to even approximate a 0.2-depth setting for a conventional current-meter measurement. Coefficients are necessary to convert the velocities observed by the subsurface-velocity method to the mean velocity in the vertical. A prerequisite in obtaining those coefficients is to determine the depths during the measurement from soundings made after the stage has receded enough for that purpose. Those depths are used with the known setting of the current meter below the water surface to compute ratios of depth of observation to total depth during the measurement. The coefficients

to be used with the subsurface-velocity observations can then be computed either by use of the data in table 2 or by obtaining vertical-velocity curves at the reduced stage of the stream.

SURFACE-VELOCITY METHOD

If an optical current meter (p. 91–93) is available, the surface-velocity method is used in preference to the subsurface-velocity method described above. In a natural channel a surface-velocity coefficient of 0.85 or 0.86 is used to compute mean velocity on the basis of the data in table 2. In a smooth artificial channel a surface-velocity coefficient of 0.90 is used. If the artificial channel has smooth vertical walls, the coefficients shown in figure 89 are used in the vicinity of the walls. Figure 89 is based on data obtained in a laboratory study. The fact that the coefficients close to the wall are greater than unity is explained by the fact that the secondary currents that form near

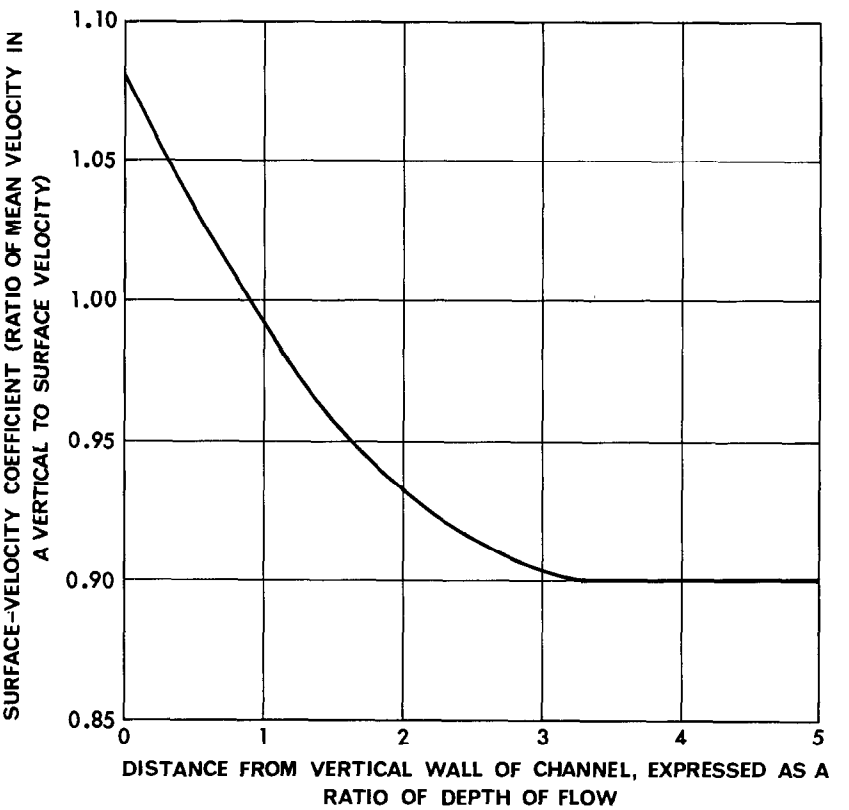

FIGURE 89.—Relation of surface-velocity coefficient to distance from vertical wall of a smooth rectangular channel.

the walls depress the position of the filaments of maximum velocity; that is, the maximum velocity in a vertical close to the wall does not occur at the water surface.

INTEGRATION METHOD

In the integration method the meter is lowered in the vertical to the bed of the stream and then raised to the surface at a uniform rate. During this passage of the meter the total number of revolutions and the total elapsed time are used with the current-meter rating table to obtain the mean velocity in the vertical. The integration method cannot be used with a vertical-axis current meter because the vertical movement of the meter affects the motion of the rotor; consequently, the method is not used in the U.S.A., where the Price meter is the standard current meter. However, the integration method is used to a degree in European countries where horizontal-axis meters are the standard current meters. The accuracy of the measurement is dependent on the skill of the hydrographer in maintaining a uniform rate of movement of the meter. A disadvantage of the method is the inability of the meter to measure streambed velocities because the meter cannot be placed that low. Coefficients smaller than unity are therefore required to correct the observed integrated velocity.

FIVE-POINT METHOD

The five-point method is rarely used in the U.S.A. Velocity observations are made in each vertical at 0.2, 0.6, and 0.8 of the depth below the surface, and as close to the surface and to the streambed as practical. The European criteria for surface and bottom observations state that the horizontal axis of the current meter should not be situated at a distance less than 1½ times the rotor height from the water surface, nor should it be situated at a distance less than 3 times the rotor height from the streambed. In addition, no part of the meter should break the surface of the water.

The velocity observations at the five meter positions are plotted in graphical form, and the mean velocity in the vertical is determined by the use of a planimeter, as explained on page 132. As an alternative, the mean velocity may be computed from the equation

$$V_{\text{mean}} = 0.1(V_{\text{surface}} + 3V_{0\,2} + 3V_{0.6} + 2V_{0.8} + V_{\text{bed}}).$$

SIX-POINT METHOD

The six-point method is rarely used in the U.S.A., but is sometimes used in European countries in situations where the existence of a distorted vertical-velocity distribution is known or suspected; for example, in the presence of aquatic growth or under ice cover. Veloc-

ity observations are made in each vertical at 0.2, 0.4, 0.6, and 0.8 of the depth below the surface, and also close to the surface and to the streambed. The criteria for surface and streambed observations are those given in the discussion above.

The velocity observations at the six meter positions are plotted in graphical form and the mean velocity in the vertical is determined by planimetering the area bounded by the vertical-velocity curve and the ordinate axis, as explained on page 132. The mean velocity may also be computed mathematically from the equation,

$$V_{mean} = 0.1(V_{surface} + 2V_{0.2} + 2V_{0.4} + 2V_{0.6} + 2V_{0.8} + V_{bed}).$$

PROCEDURE FOR CONVENTIONAL CURRENT-METER MEASUREMENT OF DISCHARGE

The first step in making a conventional current-meter measurement of discharge is to select a measurement cross section of desirable qualities. If the stream cannot be waded, and high-water measurements are made from a bridge or cableway, the hydrographer has no choice with regard to selection of a measurement cross section. If the stream can be waded, the hydrographer looks for a cross section of channel with the following qualities:

1. Cross section lies within a straight reach, and streamlines are parallel to each other.
2. Velocities are greater than 0.5 ft/s (0.15 m/s) and depths are greater than 0.5 ft (0.15 m).
3. Streambed is relatively uniform and free of numerous boulders and heavy aquatic growth.
4. Flow is relatively uniform and free of eddies, slack water, and excessive turbulence.
5. Measurement section is relatively close to the gaging-station control to avoid the effect of tributary inflow between the measurement section and control and to avoid the effect of storage between the measurement section and control during periods of rapidly changing stage.

It will often be impossible to meet all of the above criteria, and when that is the case, the hydrographer must exercise judgment in selecting the best of the sites available for making the discharge measurement.

If the stream cannot be waded and the measurement must be made from a boat, the measurement section selected should have the attributes listed above, except for those listed in item 2 concerning depth and velocity. Depth is no consideration in a boat measurement; if the stream is too shallow to float a boat, the stream can usually be waded. However, velocity in the measurement section is an important con-

sideration. If velocities are too slow, meter registration may be affected by an oscillatory movement of the boat, in which the boat, even though fastened to the tag line, moves upstream and downstream as a result of wind action; or, where a vertical-axis meter is used, meter registration may be affected by vertical movement of the boat as a result of wave action (p. 180–181). If velocities are too fast, it becomes difficult to string the tag line across the stream.

Regardless of the type of measurement that is to be made, if the gaging station is downstream from a hydroelectric powerplant, the stage will be changing too rapidly, most of the time, to assure a satisfactory discharge measurement. The hydrographer should obtain a schedule of operations from the powerplant operator, or determine the operating schedule from the gage-height chart, and plan to make his discharge measurements near the crest or trough of the stage hydrograph, or during periods of near-constant discharge from the powerplant.

After the cross section has been selected, the width of the stream is determined. A tag line or measuring tape is strung across the measurement section for measurements made by wading, from a boat, from ice cover, or from an unmarked bridge. Except where a bridge is used, the line is strung at right angles to the direction of flow to avoid horizontal angles in the cross section. For cableway or bridge measurements, use is made of the graduations painted on the cable or bridge rail as described on page 110. Next the spacing of the verticals is determined to provide about 25 to 30 subsections. If previous discharge measurements at the site have shown uniformity of both the cross section and the velocity distribution, fewer verticals may be used. The verticals should be so spaced that no subsection has more than 10 percent of the total discharge. The ideal measurement is one in which no subsection has more than 5 percent of the total discharge, but that is seldom achieved when 25 subsections are used. (The discharge measurement notes in figure 42 show that the subsection with the greatest discharge had 6.2 percent of the total discharge.) It is not recommended that all observation verticals be spaced equally unless the discharge is evenly distributed across the stream. The spacing between verticals should be closer in those parts of the cross section that have the greater depths and velocities.

After the stationing of the observation verticals has been determined, the appropriate equipment for the current-meter measurement is assembled and the measurement note sheets for recording observations are prepared. (See fig. 42.) The following information will be recorded for each discharge measurement:

1. Name of stream and location to correctly identify the established gaging station; or name of stream and exact location of site for a miscellaneous measurement.

2. Date, party, type of meter suspension, and meter number.
3. Time measurement was started using military time (24-hr clock system).
4. Bank of stream that was the starting point.
5. Control conditions.
6. Gage heights and corresponding times.
7. Water temperature.
8. Other pertinent information regarding the accuracy of the discharge measurement and conditions which might affect the stage-discharge relation.

The streambank is identified by the letters LEW or REW (left edge of water or right edge of water, respectively, when facing downstream). The time is recorded periodically in the notes during the course of the measurement. If the gaging station is equipped with a digital recorder it is advantageous to synchronize the time observations with the punch cycle of the recorder. (See fig. 42.) The time observations are important for computing the mean gage height of the discharge measurement, if the measurement is made during a period of appreciable change in stage. (See p. 170–173.) When the discharge measurement is completed, the time is recorded along with the streambank (LEW or REW) where the measurement ended.

We have digressed somewhat in discussing the measurement notes and now return to the details of the discharge measurement. After the note sheet is readied, the meter assembly is checked. The meter should balance on the hanger used and should spin freely; the electric circuit through the meter should operate satisfactorily; and the stopwatch should check satisfactorily in a comparison with the hydrographer's watch. After recording on the note sheet the station (distance from initial point) of the edge of water, the actual measurement is ready to be started.

Depth (if any) at the edge of water is measured and recorded. The depth determines the method of velocity measurement to be used, normally the two-point method (p. 134) or the 0.6-depth method (p. 134). The setting of the meter for the particular method to be used is then computed, and the meter position is recorded, using a designation such as 0.8 or 0.6 or 0.2, as the case may be. After the meter is placed at the proper depth and pointed into the current, the rotation of the rotor is permitted to become adjusted to the speed of the current before the velocity observation is started. The time required for such adjustment is usually only a few seconds if velocities are greater than 1 ft/s (0.3 m/s), but for slower velocities, particularly if the current meter is suspended on a cable, a longer period of adjustment is needed. After the meter has become adjusted to the current, the number of revolutions made by the rotor is counted for a period of 40 to 70 s. The stopwatch is started simultaneously with the first signal

or click, which is counted as "zero," and not "one." The count is ended on a convenient number coinciding with one of those given in the column headings of the meter rating table. The stopwatch is stopped on that count and is read to the nearest second or to the nearest even second if the hand of the stopwatch is on a half-second mark. That number of seconds and the number of revolutions are then recorded.

If the velocity is to be observed at more than one point in the vertical, the meter setting for the additional observation is determined, the revolutions are timed, and the data are recorded. The hydrographer moves to each of the observation verticals and repeats the above procedure until the entire cross section has been traversed. For each vertical he records distance from initial point, water depth, meter-position depth, revolutions of the meter, and the time interval associated with those revolutions (fig. 42).

Consideration must be given to the direction of flow, because it is the component of velocity normal to the measurement section that must be determined. The discussion that follows concerns currents that approach the measurement section obliquely, at angle α (fig. 47). If, in a wading measurement, the meter used is a horizontal-axis meter with a component propellor, such as the Ott meter, the propellor should be pointed upstream at right angles to the cross section, but only if α is less than 45°. Such a meter will register the desired component of velocity normal to the cross section, when α is less than 45°. If α is greater than 45°, the component meter should be pointed into the current. All other meters on a wading-rod suspension should likewise be pointed into the current. Any meter on a cable suspension, as is used for the higher stages, will automatically point into the current because of the effect of the meter vanes. When the meter is pointed into an oblique current the measured velocity must be multiplied by the cosine of the angle (α) between the current and a perpendicular to the measurement section in order to obtain the desired normal component of the velocity.

In the U.S.A., either of two methods is used to obtain cosine α (fig. 47). In the first method, use is made of the field notes which have a point of origin (o) printed on the left margin and cosine values on the right margin (fig. 42). The cosine of the angle of the current is measured by holding the note sheet in a horizontal position with the point of origin on the tag line, bridge rail, cable rail, or any other feature parallel to the cross section (fig. 90). With the long side of the note sheet parallel to the direction of flow, the tag line or bridge rail will intersect the value of cosine α on the top, bottom, or right edge of the note sheet. The direction of the current will be apparent from the direction of movement of floating particles. If the water is clear of floating material, small bits of floating material are thrown into the

stream and the edge of the note sheet is alined parallel to the direction of movement. If no such material is available, the inelegant, but time-honored method of spitting into the stream is used to obtain an indicator of the direction of flow. The measured velocity is multiplied by the cosine of the angle to determine the velocity component normal to the measurement section.

The second, and more reliable, method of obtaining cosine α involves the use of a folding foot-rule. These rules, which are either 3 or 6 ft long, are graduated in hundreths of a foot and are jointed every half foot. The first 2 ft of the rule is extended, the 2.00-ft marker is placed on the tag line or bridge rail (fig. 91), and the rule is alined with the direction of the current. The rule is folded at the 1-ft mark so that the first foot of the rule is normal to the tag line or bridge rail. That reading, subtracted from 1.00, is cosine α. For example, if the reading on the rule is 0.09 ft, cosine α equals 0.91.

Details peculiar to each of the various types of current-meter measurement are described in the sections of the manual that follow.

CURRENT-METER MEASUREMENT BY WADING

Current–meter measurements are best made by wading, if conditions permit. (See fig. 92.) Wading measurements have a distinct advantage over measurements made from cableways or bridges in that it is usually possible to select the best of several available cross sections for the measurement. The type AA or pygmy meter is used for wading measurements in the U.S.A. Table 3 lists the type of meter and velocity method to be used for wading measurements at various depths.

Some departure from table 3 is permissible. For example, if a type

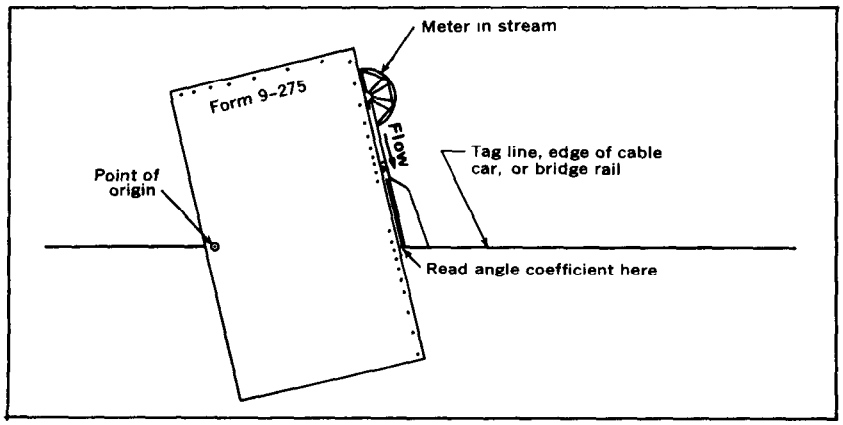

FIGURE 90.—Measurement of horizontal angle with measurement-note sheet.

AA meter is being used in a measurement section that has almost all its depths greater than 1.5 ft (0.46 m), the pygmy meter should not be substituted for the few depths that are less than 1.5 ft, or vice versa. With regard to the use of the type AA meter in depths less than 1.5 ft, strictly speaking, that meter should not be used in depths less than 1.25 ft (0.38 m). A depth of 1.25 ft will accommodate the 0.6-depth method without causing the meter to be set closer than 0.5 ft from the streambed; if the meter is set any closer to the streambed it will underregister the velocity (p. 132). However, if the hydrographer is using the type AA meter in a measurement section that has only few verticals shallower than 1.25 ft, he may use that meter for depths that are even as shallow as 0.5 ft (0.15 m) without changing to a pygmy meter. The hydrographer must make a judgment decision. He knows that his meter is underregistering the velocity by some unknown percentage in the depths shallower than 1.25 ft, but if that shallow-depth flow represents less than 10 percent of the total discharge, his total measured discharge should not be too greatly in error.

Neither the type AA meter nor the pygmy meter should be used for measuring velocities slower than 0.2 ft/s, unless absolutely necessary.

If depths or velocities under natural conditions are too low for a dependable current-meter measurement, the cross section should be modified, if practical, to provide acceptable conditions. It is often pos-

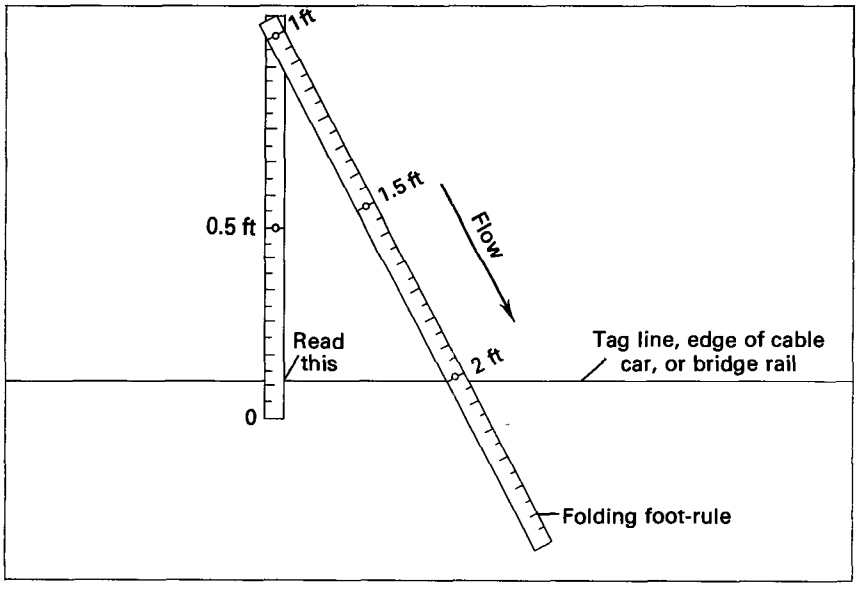

FIGURE 91.—Measurement of horizontal angle with folding foot-rule.

sible to build temporary dikes to eliminate slack water or shallow depths in a cross section, or to improve the cross section by removing rocks and debris within the section and in the reach of channel im-

FIGURE 92.—Wading measurement using top-setting rod.

TABLE 3.—*Current-meter and velocity-measurement method for various depths (wading measurement)*

Depth		Meter	Velocity method
(ft)	(m)		
2.5 or more	0.76 or more	Type AA (or type A)	0.2 and 0.8
1.5–2.5	0.46–0.76	---- do ----	.6
.3–1.5	.09– .46	Pygmy[1]	.6

[1]Used when velocities are less than 2 5 ft/s (0 76 m/s)

mediately upstream and downstream from the section. After the cross section has been modified, the flow should be allowed to stabilize before starting the discharge measurement.

The hydrographer should stand in a position that least affects the velocity of the water passing the current meter. That position is usually obtained by facing the bank so that the water flows against the side of the leg. The wading rod is held at the tag line by the hydrographer who stands about 3 in (0.07 m) downstream from the tag line and at least 1.5 ft (0.46 m) from the wading rod. He should avoid standing in the water if his feet and legs occupy a significantly large percentage of a narrow cross section. In small streams where the width permits, the hydrographer stands on an elevated plank or other support, rather than in the water.

The wading rod should be held in a vertical position with the meter parallel to the direction of flow while the velocity is being observed. If the flow is not at right angles to the tag line, the angle coefficient should be carefully measured (figs. 90 and 91).

When measuring streams having shifting beds, the soundings or velocities can be affected by the scoured depressions left by the hydrographer's feet. For such streams, the meter should be placed ahead of and upstream from the feet. For such streams, too, the hydrographer's notes should accurately describe the configuration of the streambed and water surface. (See p. 376–379.)

A measurement should be made of the depth of water over the lowest point of the control, either before or after the discharge measurement. The gage height corresponding to this lowest point (gage height of zero flow) is very useful in analyzing the stage-discharge relation for the gaging station. (See p. 333–334).

When the flow is too low for a reliable measurement of discharge by current meter, the discharge is determined by use of (1) a volumetric method of measurement, (2) a portable Parshall flume, or (3) a portable weir plate. Those three methods of discharge determination are discussed in chapter 8.

CURRENT-METER MEASUREMENTS FROM CABLEWAYS

The equipment assemblies for use on cableways are described on pages 110–117.

The size of the sounding weight used in current-meter measurements depends on the depth and velocity in the measurement cross section. A rule of thumb generally used is that the size of the weight (lb) should be greater than the maximum product of velocity (ft/s) and depth (ft) in the cross section. If insufficient weight is used, the meter assembly will be dragged downstream. If debris or ice is flowing or if the stream is shallow and swift, the weight used should

be appreciably heavier than that indicated by the above rule. The rule is not rigid, but it does provide a starting point for deciding on the size of weight required at various stages.

The Price type AA current meter is generally used in the U.S.A. when making discharge measurements from a cableway. The depth is measured by use of a sounding reel, and the velocity is measured by setting the meter at the proper position in the vertical. (See table 4.) Table 4 is designed so that no velocity observations will be made with the meter closer than 0.5 ft (0.15 m) to the water surface. In the zone from the water surface to a depth of 0.5 ft, the current meter is known to give erroneous results.

Some sounding reels are equipped with a computing depth indicator. To use the computing spiral, the indicator is set at zero when the center of the current-meter rotor is at the water surface. The sounding weight and meter are then lowered until the weight touches the streambed. If, for example, a 30 C .5 (see table 4) suspension is used and if the indicator reads 18.5 ft when the sounding weight touches the bottom, the depth would be 19.0 ft (18.5 ft + 0.5 ft). To move the meter to the 0.8-depth position (0.8×19.0 ft), the weight and meter are raised until the hand on the indicator is over the 19-ft mark on the graduated spiral (fig. 60); the hand will then be pointing to 15.2 on the main dial. To set the meter at the 0.2-depth position (0.2×19.0 ft), the weight and meter are raised until the hand on the indicator is pointing to 3.8 ft on the main dial.

One problem found in observing velocities from a cableway is that movement of the cable car from one station to the next causes the car to oscillate for a short time after coming to a stop. The hydrographer should wait until this oscillation has been dampened to the extent that it is negligible before counting meter revolutions.

Tags can be placed on the sounding line at known distances above the center of the meter cups as an aid in determining depths. Furthermore, the use of tags allows the meter to be kept submerged throughout the discharge measurement to prevent freezing in cold air during the winter measurements. The tags, which are usually streamers of different colored binding tape, are fastened to the sounding line by solder beads or by small cable clips. Tags are used for determining depth in either of two ways.

1. In the procedure that is usually preferred, a tag is set at the water surface, after which the depth indicator is set at the distance between that particular tag and the center of the meter cups. This is equivalent to setting the indicator at zero when the center of the meter rotor is at the water surface, and the hydrographer then proceeds with his depth settings as described in a preceding paragraph. If debris or ice is flowing, this method prevents damage to the meter.

TABLE 4.—*Velocity-measurement method for various meter suspensions and depths*

Suspension[1]	Minimum depth			
	0.6 method		0.2 and 0.8 method	
	(ft)	(m)	(ft)	(m)
15 C .5, 30 C .5	1.2	0.37	2.5	0.76
50 C .55	1.4	.43	2.8	.85
50 C .9	2.2	.67	4.5	1.37
75 C 1.0, 100 C 1.0, 150 C 1.0	2.5	.76	5.0	1.52
200 C 1.5, 300 C 1.5	[2]3.8	1.16	7.5	2.29

[1]Suspensions shown indicate the size of the sounding weight and the distance from the bottom of the weight to the current-meter axis. Thus "50 C .9" refers to a 50-pound Columbus-type weight, the suspension for which puts the meter 0.9 ft above the bottom of the weight.

[2]Use 0.2-depth method for depths between 2.5 and 3.7 ft, and apply appropriate coefficient (usually 0.87 from table 2).

2. In the second method the sounding weight is first lowered to the streambed, and the depth is then determined by raising the weight until the first tag below the water surface appears at the surface. The total depth is then sum of (a) the distance the weight was raised to bring the tag to the water surface, (b) the distance the tag is above the center of the meter cups, and (c) the distance from the bottom of the weight to the center of the cups. This method is usually used with handlines, and it is also used to simplify the measurement of deep, swift streams (p. 159–163).

If large quantities of debris are carried by the stream, the meter should be periodically raised to the cable car for inspection during the measurement to be certain that the pivot and rotor of the meter are free of debris. However, the meter should be kept in the water during the measurement if the air temperature is well below freezing. The hydrographer should carry a pair of lineman's side-cutter pliers when making measurements from a cableway. These can be used to cut the sounding line to insure safety if the weight and meter become caught on a submerged object or on heavy floating debris and it is impossible to release them. Sometimes the cable car can be pulled to the edge of the water where the entangling debris can be removed.

When a measurement of a deep, swift stream is made from a cableway, the meter and weight do not hang vertically but are dragged downstream. The vertical angle, that is, the angle between the meter-suspension cable and the vertical, should be measured by protractor in order to correct the soundings to give the actual vertical depth. The procedure used to correct soundings is described on pages 159–168.

If a handline is used to suspend the current meter and sounding weight, the measurement procedure to be followed is that described in the section on bridge measurements (p. 150–151).

CURRENT-METER MEASUREMENTS FROM BRIDGES

Bridges are often used for making discharge measurements of streams that cannot be waded. Measurement cross sections under bridges are often satisfactory for current-meter measurements, but cableway sections are usually superior.

No set rule can be given for choosing between the upstream or downstream side of the bridge for making a discharge measurement. The advantages of using the upstream side of the bridge are:

1. Hydraulic characteristics at the upstream side of bridge openings usually are more favorable.
2. Approaching drift can be seen and thus can be more easily avoided.
3. The streambed at the upstream side of the bridge is not likely to be scoured as badly as the downstream side.

The advantages of using the downstream side of the bridge are:

1. Vertical angles are more easily measured because the sounding line will move away from the bridge.
2. The flow lines of the stream may be straightened by passing through a bridge opening with piers.

Whether to use the upstream side or the downstream side of a bridge for a current-meter measurement should be decided individually for each bridge after considering the above factors. Other pertinent factors relate to physical conditions at the bridge, such as location of the walkway, traffic hazards, and accumulation of trash on pilings and piers.

In making the discharge measurement either a handline, or a sounding reel supported by a bridge board or by a portable crane, is used to suspend the current meter and sounding weight from the bridge. The velocity is measured by setting the meter at positions in the vertical as indicated in table 4. If velocities are high, the equipment is used no closer than several feet from piers and abutments. In that situation depths and velocities at the pier or abutments are estimated on the basis of observations in the vertical nearest the pier. (See p. 82.)

Where piers are in the measuring section, it is usually necessary to use more than 25–30 subsections to obtain results as reliable as those obtained with a similar measuring section that has no piers. Piers not only affect the horizontal distribution of velocities, but they frequently affect the direction of the current, causing horizontal angles that must be carefully measured.

Whether or not to exclude the area of a bridge pier from the area of the measurement cross section depends primarily on the relative locations of the measurement section and the end of the pier. If meas-

urements are made from the upstream side of the bridge, it is the relative location of the upstream end (nose) of the pier that is relevant; for measurements made from the downstream side it is the location of the downstream end (tail) of the pier that is relevant. If any part of the pier extends into the measurement cross section, the area of the pier is excluded. However, bridges quite commonly have cantilevered walkways from which discharge measurements are made. In that case the measurement cross section lies beyond the end of the pier—upstream from the nose or downstream from the tail, depending on which side of the bridge is used. In that situation it is the position and direction of the streamlines that determines whether or not the pier area is to be excluded. The hydrographer, if he had not previously noted the stationing of the sides of the pier when projected to the measurement cross section, does so now. If there is negligible or no downstream flow in that width interval (pier subsection)—that is, if only stagnation and (or) eddying exists upstream from the nose or downstream from the tail, whichever is relevant—the area of the pier is excluded. If there is significant downstream flow in the pier subsection, the area of the pier is included in the area of the measurement cross section. The horizontal angles of the streamlines in and near the pier subsection will usually be quite large in that circumstance.

Footbridges are sometimes used for measuring the discharge of canals, tailraces, and small streams. Often a rod suspension can be used for the meter when measuring from a footbridge. In low velocities the procedure for determining depth when using a rod suspension is the same as that used for wading measurements. For higher velocities depth is obtained from the difference in readings at an index point on the bridge when the base plate of the rod is at the water surface and when it is on the streambed. The measurement of depth by that method eliminates errors in reading the depth caused by the fast-moving water piling up on the upstream face of the rod. Handlines, bridge cranes, and bridge boards are also used from footbridges.

When using a sounding reel, depths and velocities are measured by the methods described in the preceding section of the manual on cableway measurements (p. 146–148). When using a handline, depth is determined by first lowering the sounding weight to the streambed and then raising the weight until one of the tags is at the water surface. The distance that the weight is raised is measured along the rubber-covered cable (p. 106) with either a steel or metallic tape, a folding foot-rule, or a graduated rod. The total depth of water is then the summation of (1) the distance the particular tag is above the meter cups, (2) the measured distance the meter and weight were raised, and (3) the distance from the bottom of the weight to the meter cups.

Another, less widely used, method of determining depth requires that the meter cups be set at the water surface, after which the sounding weight is lowered to the streambed while measuring, with tape or rule, the length of line that is let out. This measured distance, plus the distance from the bottom of the sounding weight to the meter cups, is the depth of water.

When using a handline, enough cable is unwound from the handline reel to keep the reel out of water when the sounding weight is on the streambed at the deepest part of the measuring section. That prevents submergence of the reel and thick rubber-covered cable and attendant drag on the equipment in high-velocity flow, and unless the bridge is relatively close to the water surface, it still permits the hydrographer to raise and lower the meter by means of the rubber-covered cable rather than the bare-steel cable. When the meter is set for a velocity observation, the hydrographer stands on the rubber-covered cable or ties it to the handrail to hold the meter in place. By doing so his hands are free to operate the stopwatch and record the data.

If the bridge has vertical truss members in the plane of the measurement cross section, the handline can be disconnected from the headphone wire and passed around the truss member with the sounding weight on the bottom. This eliminates the need for raising the weight and meter to the bridge each time a move is made from one vertical to another and is the principal advantage of a handline.

CURRENT-METER MEASUREMENTS FROM ICE-COVER

Discharge measurements under ice cover (fig. 93) are usually made under conditions that range from uncomfortable to severe, but it is extremely important that they be made, because the reliability of a large part of the computed discharge record for a winter period may depend on one such measurement.

Cross sections for possible use for measuring under ice cover should be selected during the open-water season when channel conditions can be observed and evaluated. Commonly the most desirable measurement section will be just upstream from a riffle because slush ice that collects under the ice cover is usually thickest at the upstream end of the pools created by riffles. The equipment used for cutting or drilling holes in the ice was described on pages 124–129.

The danger of working on ice-covered streams should never be underestimated. When crossing the stream, the hydrographer should test the strength of the ice with solid blows using a sharp ice chisel. Ice thickness may be irregular, especially late in the season when a thick snow cover may act as an insulator. Water just above freezing can slowly melt the underside of the ice, creating thin spots. Ice

FIGURE 93.—Ice rod being used to support current meter for a discharge measurement, top; ice drill being used to cut holes, bottom.

bridged above the water may be weak, even though relatively thick.

At the cross section selected for measurement three holes, one at each quarter point of the width, are cut to check on the possible presence of slush ice or possible maldistribution of flow. If poor conditions are found, other cross sections are similarly investigated to find one that is free of slush ice and has a favorable horizontal distribution of flow. After finding a favorable cross section, at least 20 holes are cut for the current-meter measurement of discharge. The holes should be spaced so that no subsection carries more than 10 percent of the total discharge. On narrow streams it may be simpler to remove all the ice in the cross section.

The effective depth of the water (fig. 94) is the total depth of water minus the distance from the water surface to the bottom of the ice. The vertical pulsation of water in the holes in the ice sometimes causes difficulty in determining the depths. The total depth of water is usually measured with an ice rod or with a sounding weight and reel, depending on the depth.

The distance from the water surface to the bottom of the ice is measured with an ice-measuring stick (p. 125), unless slush is present at the hole. In that situation the effective depth is the total depth

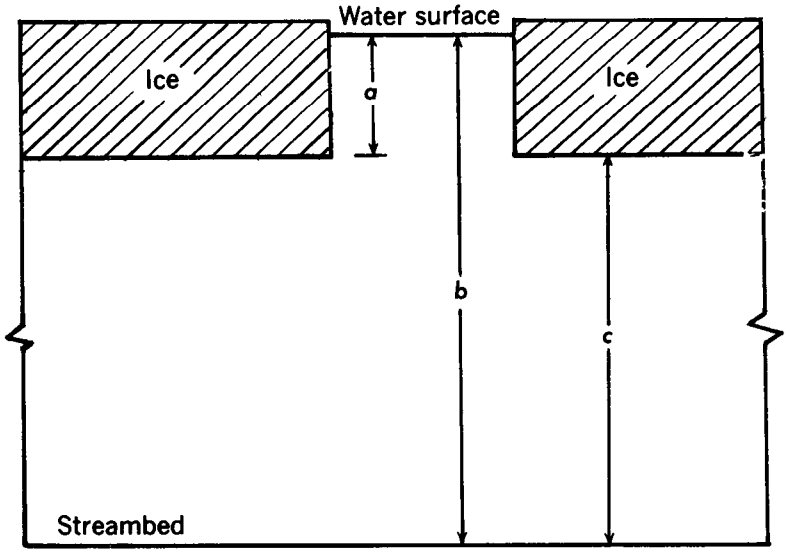

FIGURE 94.—Method of computing meter settings for measurements under ice cover.

minus the distance from the water surface to the interface between water and slush. To locate that interface, the current meter is suspended at a depth below the slush ice where the meter rotor turns freely. The meter is then slowly raised until the rotor stops; that point is considered the interface, and its depth below the water surface is measured for determining the effective depth. The effective depth is then used to compute the proper position of the meter in the vertical.

The vane ice meter is recommended for use under ice cover because (1) the vanes do not become filled with slush ice as the cups of the Price meter often do, (2) the yoke of the vane meter will fit in the hole made by the ice drill, and (3) the yoke and ice rod can serve as an ice-measuring stick. The contact chamber of the vane meter can be rotated to any position; its binding post is therefore placed perpendicular to the axis of the yoke to avoid interference when using the top of the yoke as the horizontal leg of an ice-measuring stick.

Because of the roughness of the underside of the ice cover, the location of the filament of maximum velocity is some distance below the underside of the ice. Figure 95 shows a typical vertical-velocity

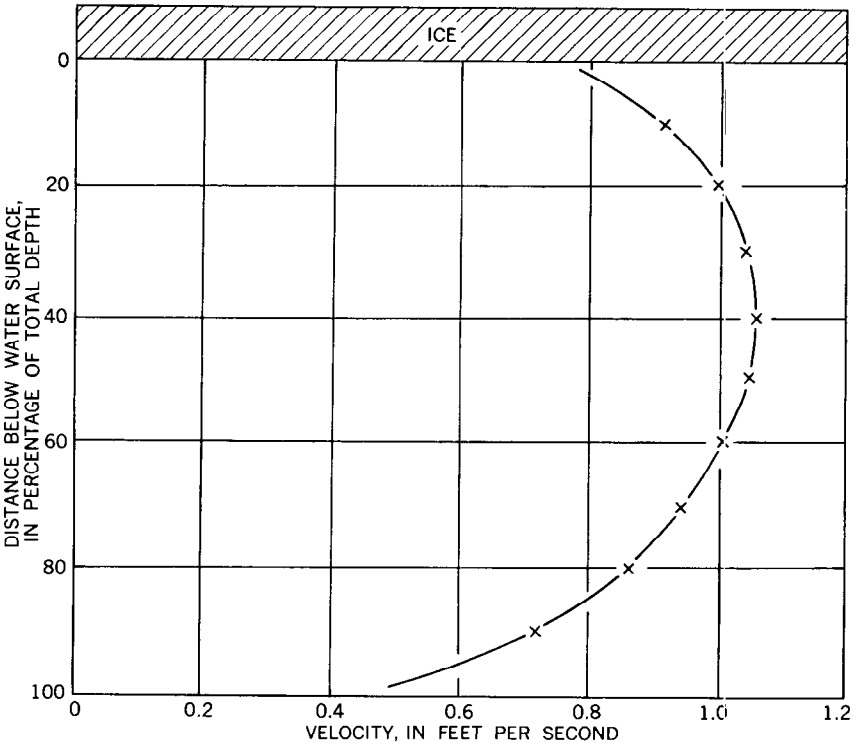

FIGURE 95.—Typical vertical-velocity curve under ice cover.

curve under ice cover. In making a discharge measurement the 0.2- and 0.8-depth method is recommended in the U.S.A. for effective depths equal to or greater than 2.5 ft, and the 0.6-depth method for effective depths less than 2.5 ft. It is also recommended that two vertical-velocity curves be defined when ice measurements are made to determine whether any coefficients are necessary to convert the velocity obtained by the 0.2- and 0.8-depth method, or by the 0.6-depth method, to the mean velocity. Normally the average of the velocities obtained by the 0.2- and 0.8-depth method gives the mean velocity, but a coefficient of about 0.92 usually is applicable to the velocity obtained by the 0.6-depth method. In Europe a three-point method is commonly used in which velocity observations are made at 0.15, 0.5, and 0.85 of the effective depth.

When measuring the velocity, the meter is kept as far upstream as possible to minimize any effect that the vertical pulsation of water in the hole might have on the meter registration. The meter is exposed as little as possible to the cold air so that its operation will not be impaired by the formation of ice on exposed parts.

If there is only partial ice cover on the measuring section, the procedure described above is used for the ice-covered observation verticals, and open-water methods are used for the open-water verticals.

A sample sheet of discharge-measurement notes for a measurement made under ice cover is shown in figure 96. Vertical-velocity curves that had been defined for that measurement had indicated that mean velocity in a vertical was given by the 0.2- and 0.8-depth method, and that the 0.6-depth method required a coefficient of 0.92.

CURRENT-METER MEASUREMENTS FROM BOATS

Discharge measurements are made from boats where no cableways or suitable bridges are available and where streams are too deep to wade. Personal safety is the limiting factor in the use of boats on streams having high velocities.

In making a boat measurement the tag line is first strung across the measurement section by unreeling the line as the boat moves across the stream. Some tag-line reels are equipped with brakes (fig. 79) to control the line tension during the unreeling. If a tag line whose reel is unequipped with a brake has been strung across a stream, the slack is taken up by means of a block and tackle attached to the reel and to an anchored support on the bank. If there is traffic on the river, one man must be stationed on the bank to lower and raise the tag line to allow river traffic to pass. Streamers should be attached to the tag line so that it may be seen by boat pilots. The method of positioning the boat for measuring depths and velocities, by sliding the boat along the tag line from one observation vertical to another, was described on page 121.

If the flow of traffic on the river is continual or if the width of the river is too great for a tag line to be used, other means are needed to position the boat. One method that dispenses with the tag line involves keeping the boat lined up with flags positioned on each end of

FIGURE 96.—Part of notes for discharge measurement under ice cover.

the measurement cross section. Flags on one bank would suffice, but it is better to have them on both banks. The position of the boat in the cross section can be determined by means of a transit on the shore and a stadia rod held in the boat (fig. 97). Another method of determining the position of the boat is by setting a transit on one bank at a convenient measured distance from, and at right angles to, the cross section. The position of the boat is computed by measuring the angle to the boat, as shown in figure 98. A third method of determining the position of the boat requires a sextant in the boat. The sextant is used to read the angle between a flag at the end of the cross section and another at a known distance perpendicular to the cross section (fig. 98). The boat position can be computed from the measured angle and the known distance between the flags on the shore. Unless anchoring is more convenient, the boat must be held stationary by its motor when readings are being taken.

Boat measurements are not recommended where velocities are

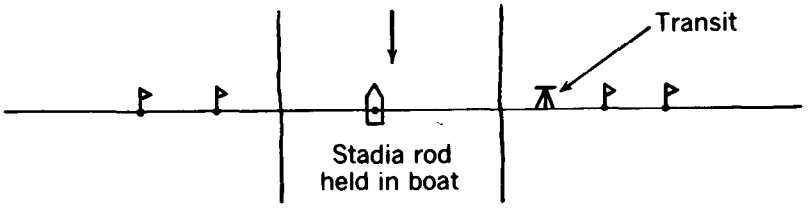

FIGURE 97.—Determining position in the cross section, stadia method.

FIGURE 98.—Determining position in the cross section, angular method.

slower than 1 ft/s (0.3 m/s) when the boat is subject to the action of wind and waves. (See p. 180–181.) If the maximum depth in the cross section is less than 10 ft (3 m) and the velocity is low, a rod is usually used for measuring the depth and supporting the current meter. For greater depths and velocities, a cable suspension with reel, boat boom, and sounding weight is used. The procedure for measuring discharge from a boat using the boat boom and crosspiece (p. 122–123) is the same as that for measuring from a bridge or cableway, once the special equipment has been set up and the method of positioning the boat has been established.

A special method of measuring discharge from a boat without stopping the boat at observation stations—the moving-boat method—is described in detail in chapter 6.

NETWORKS OF CURRENT METERS

Occasional special measurements require the simultaneous determination of velocities at several points in a cross section, distributed either laterally or vertically. For example, it may be necessary to measure a vertical-velocity profile quickly in unsteady flows and to check it frequently in order to determine the changes in shape of the vertical profile as well as the rates of those changes. Another example is the measurement of tide-affected streams where it is desirable to measure the total discharge continously during at least a full tidal cycle (approximately 13 hr). The need for so many simultaneous velocity determinations (one at each vertical in the cross section) for so long a period can be an expensive and laborious process using conventional techniques of discharge measurement.

A grouping of 21 current meters and special supplemental instrumentation has been used by the U.S. Geological Survey to facilitate measurements of the types just described. Only a few persons are required to operate the system. The 21 meters are connected so that the spacing between any two adjacent meters can be varied to distances as great as 200 ft (61 m). Furthermore, each meter has sufficient handline cable to be suspended vertically from a bridge for as much as 200 ft. The meters have a standard calibration. Revolutions of the rotors are recorded by electronic counters that are grouped compactly in one box at the center of the bank of meters. The operator, by flipping one switch, starts all 21 counters simultaneously and, after an interval of several minutes, stops all counters. The indicated number of revolutions for the elapsed time interval is converted to a velocity for each meter. The distance between meters is known; a record of stage is maintained to evaluate depth; prior information at the site is obtained to convert point velocities in the verticals to mean velocities in those verticals. All of the information necessary to compute discharge in the cross section is therefore available

and is tabulated for easy conversion to discharge.

Other countries have developed similar equipment; for example, a grouping of 40 meters is used in the United Kingdom.

SPECIAL PROBLEMS IN CONVENTIONAL CURRENT-METER MEASUREMENTS

MEASUREMENT OF DEEP, SWIFT STREAMS

The measurement of deep, swift streams by current meter usually presents no serious problems when adequate sounding weights are used and when floating ice or drift is not excessive. Normal procedures must sometimes be altered, however, when measuring streams under particularly adverse conditions, the four most common situations of that kind being represented by the following cases:

Case A. Possible to sound, but weight and meter drift downstream.

Case B. Not possible to sound, but a standard cross section is available.

Case C. Not possible to sound, and no standard cross section is available.

Case D. Not possible to submerge the meter in the water.

Procedures are described below for discharge measurements made under those adverse conditions. The procedures for cases B, C, and D are actually applicable only where channel conditions in the measurement cross section or reach are stable, meaning that no significant scour or deposition occurs.

CASE A. DEPTH CAN BE SOUNDED

Where it is possible to sound the depth but the weight and meter drift drownstream, the depths as measured by the usual methods will be in error, being too large (fig. 99). The correction for the error has two parts, the air correction and the wet-line correction. The air correction is shown in figure 99 as the distance *cd*. The wet-line correction in figure 99 is shown as the difference betwen the wet-line depth *de* and the vertical depth *dg*.

As shown in figure 99, the air correction depends on the vertical angle *P* and the distance *ab*. The correction is computed as follows:

$$ab=ac$$

$$\cos P=\frac{ab}{ad}=\frac{ab}{ac+cd}=\frac{ab}{ab+cd}$$

$$ab+cd=\frac{ab}{\cos P}$$

$$cd=\frac{ab}{\cos P}-ab=ab\left[\frac{1}{\cos P}-1\right]. \qquad (11)$$

The air correction for even-numbered angles between 4° and 36° and for vertical lengths between 10 and 100 ft is shown in table 5. The correction is applied to the nearest tenth of a foot; hundredths are given to aid in interpolation. Table 6 is a similar table in metric units.

The air correction may be nearly eliminated by using tags at

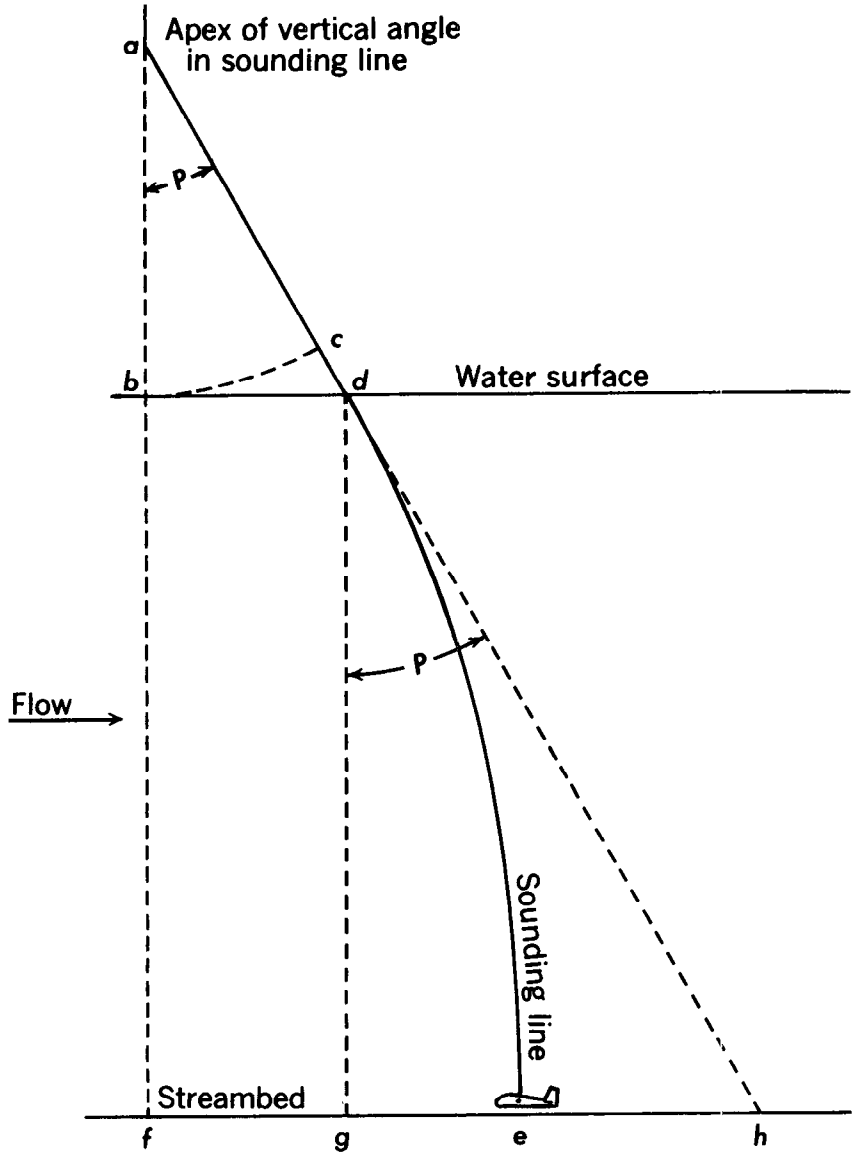

FIGURE 99.—Position of sounding weight and line in deep, swift water.

selected intervals on the sounding line, and then using the tags to reference the water surface. This practice is almost equivalent to moving the reel to a position just above the water surface.

The correction for excess length of line below the water surface is obtained by using an elementary principle of mechanics. If a known horizontal force is applied to a weight suspended on a cord, the cord takes a position of rest at some angle with the vertical, and the tangent of the vertical angle of the cord is equal to the horizontal force divided by the vertical force of the weight. If several additional horizontal and vertical forces are applied to the cord, the tangent of the angle in the cord above any point is equal to a summation of the horizontal forces below that point, divided by the summation of the vertical forces below the point.

The distribution of total horizontal drag on the sounding line is in accordance with the variation of velocity with depth. The excess in length of the curved line over the vertical depth is the sum of the products of each tenth of depth and the function $(1/\cos P)-1$ of the corresponding angles; the function is derived for each tenth of depth by means of the tangent relation of the forces acting below any point.

The wet-line correction for even-numbered angles between 4° and 36° and for wet-line depths between 10 and 100 ft is shown in table 7. (Table 8 is a similar table in metric units.) The correction is applied to the nearest tenth of a foot. The wet-line correction cannot be determined until the air correction has been deducted from the observed depth.

The following assumptions were used in deriving the wet-line correction tables:

1. The weight will go to the bottom despite the force of the current.
2. The sounding is made when the weight is at the bottom but entirely supported by the line.
3. Drag on the streamlined weight in the sounding position is neglected.
4. The table is general and can be used for any size sounding weight or line that is designed to offer little resistance to the current.

If the direction of flow is not perpendicular to the measuring section, the angle of the measuring line as indicated by the protractor will be less than the true angle of the line. The air correction and wet-line correction will then be too small. To correct for this it is necessary to either measure by protractor the horizontal angle between the direction of flow and a perpendicular to the measurement section, or determine the horizontal-angle coefficient by the methods described on pages 142–143.

If the horizontal angle of the direction of flow is called H, the measured vertical angle P, and the true vertical angle X, the relation

between the angles is expressed by the equation

$$\tan X = \frac{\tan P}{\cos H} \text{ (fig. 100).} \qquad (12)$$

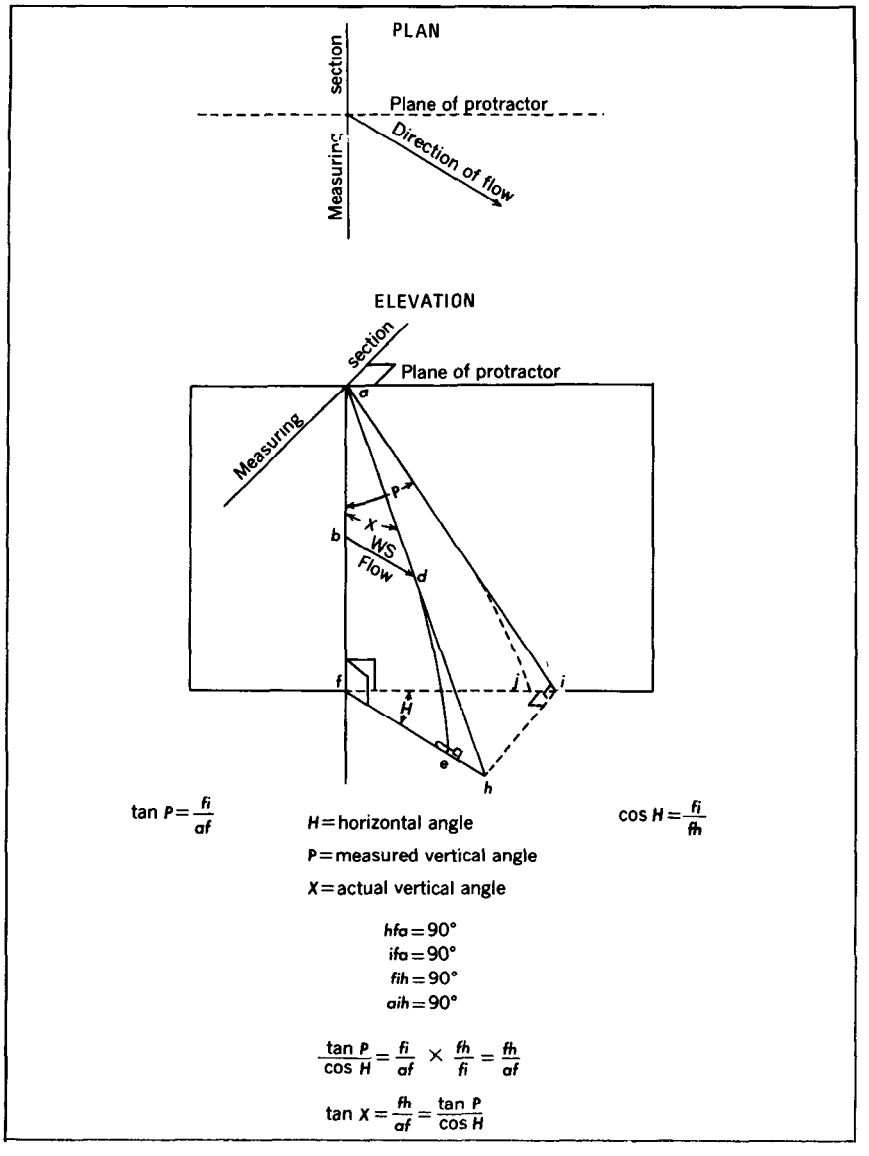

FIGURE 100.—Sketch of geometry of relation of actual to measured vertical angle when flow direction is not normal to measurement section.

Table 9 gives the quantities in tenths of degrees, to be added to observed vertical angles to obtain the true vertical angles for a range of horizontal angles between 8° and 28°.

The conditions that cause error in sounding the depth also cause error in setting the meter at selected depths. The correction tables are not strictly applicable to the problem of setting the meter for velocity observations because of the increased horizontal force on the sounding weight caused by higher velocities when the weight is raised from the streambed. A meter placed in deep, swift water by the ordinary methods for observations at selected percentages of the depth will be too high in the water. The use of tables 5–9 will tend to eliminate this error in the placement of the meter, and although not strictly applicable, their use for this purpose has become general.

For the 0.2-depth position, the curvature of the wet line is assumed to be negligible, and the length of sounding line from the apex of the vertical angle to the weight is considered a straight line. The method used to place the meter at the 0.2-depth position is as follows:

1. Compute the 0.2 value of the vertical depth.
2. Lower the meter this depth into the water and read the vertical angle.
3. Obtain the air correction from table 5 or 6. The vertical length used to obtain the air correction is the sum of (a) 0.2 of the vertical depth, (b) the distance from the water surface to the apex of the angle, and (c) the distance from the bottom of the weight to the meter.
4. Let out an additional amount of line equal to the air correction.
5. If the angle increases appreciably when the additional line is let out, let out more line until the total additional line, the angle, and the vertical distance are in agreement with figures in the air-correction table.

To set the meter at the 0.8-depth position, a correction to the amount of line reeled in must be made for the difference, if any, between the

TABLE 9.—*Degrees to be added to observed vertical angles to obtain actual vertical angles when flow direction is not normal to measurement section*

Observed vertical angle	Horizontal angle					
	8° cos=0.99	12° cos=0 98	16° cos=0 96	20° cos=0 94	24° cos=0 91	28° cos=0.88

12°	.1	.3	.5	.8	1.1	1.5
16°	.1	.4	.6	1.0	1.4	2.0
20°	.2	.4	.7	1.2	1.7	2.4
24°	.2	.5	.8	1.4	2.0	2.8
28°	.2	.5	1.0	1.5	2.2	3.0
32°	.2	.6	1.0	1.6	2.4	3.3
36°	.2	.6	1.1	1.7	2.5	3.4

air correction for the sounding position and that for the 0.8-depth position. This difference is designated as m in table 10. If the angle increases for the 0.8-depth position, the meter must be lowered; if the angle decreases the meter must be raised.

In setting the 0.8-depth position of the meter, the wet-line correction may require consideration if the depths are more than 40 ft and if the change in vertical angle is more than 5 percent. If the vertical angle remains the same or decreases, the wet-line correction (table 7 or 8) for the 0.8-depth position is less than the wet-line correction for the sounding position by some difference designated as n in table 10. If the vertical angle increases, the difference in correction n deminishes until the increase in angle is about 10 percent; for greater increases in angle, the difference between corrections also increases. Table 10 summarizes the effect on air- and wet-line corrections caused by raising the meter from the sounding position to the 0.8-depth position.

For slight changes in the vertical angle, because of the differences m and n in the air- and wet-line corrections, the adjustments to the wet-line length of the 0.8-depth position are generally small and usually can be ignored. Table 10 indicates, however, that the meter may be placed a little too low if the adjustments are not made. Because of this possibility, the wet-line depth instead of the vertical depth is sometimes used as the basis for computing the 0.8-depth position, and no adjustments are made for the differences m and n.

CASE B. DEPTH CANNOT BE SOUNDED BUT STANDARD CROSS SECTION IS AVAILABLE

On occasion it is not possible to sound the bottom, but a standard measurement cross section at the bridge or cableway may be available from previous measurements that were made. Such a cross section

TABLE 10.—*Summary table for setting the meter at 0.8-depth position in deep, swift streams*

Change in vertical angle	Air correction		Wet-line correction	
	Direction of change	Correction to meter position	Direction of change	Correction to meter position
None	None	None	Decrease	Raise meter the distance n.
Decrease	Decrease	Raise meter the distance m.	do	Do.
Increase	Increase	Lower meter the distance m.	Decrease, then increase.	[1]

[1] Raise meter the distance n unless the increase in angle is greater than about 10 percent, then it is necessary to lower the meter the distance n.

will be useful only if all discharge measurements use the same permanent initial point for the stationing of verticals across the width of the stream, and if there is an outside reference gage or reference point on the bank or bridge to which the water-surface elevation at the measurement cross section may be referred. In the situation described above, the following procedure is used:

1. Determine depths at the observation verticals from the standard cross section and the known water-surface elevation at the measurement cross section.
2. Measure the velocity at 0.2 of the depth.
3. Compute the measurement in the normal manner using the measured velocities as though they were the mean velocities in the vertical, and using the depths from step 1.
4. Determine the coefficient to adjust the 0.2-depth velocity to mean velocity in the cross section, as explained on pages 135–136.
5. Apply the coefficient from step 4 to the computed discharge from step 3.

CASE C. DEPTH CANNOT BE SOUNDED AND NO STANDARD CROSS SECTION IS AVAILABLE

When it is not possible to sound the depth and a standard cross section is not available, the following procedure is used:

1. Refer the water-surface elevation before and after the measurement to an elevation reference point on a bridge, on a driven stake, or on a tree at the water's edge. (It is assumed here that no outside reference gage is available at the measurement cross section.)
2. Estimate the depth and observe the velocity at 0.2 of the estimated depth. The meter should be at least 2.0 ft (0.6 m) below the water surface. Record in the notes the actual depth the meter was placed below the water surface. If an estimate of the depth is impossible, place the meter 2.0 ft below the water surface and observe the velocity there.
3. Make a complete measurement at a lower stage and include some vertical-velocity curves.
4. Use the complete measurement and difference in stage between the two measurements to determine the cross section of the first measurement. To determine whether the streambed has shifted, the cross section should be compared with one obtained in a previous measurement at that site.
5. Use vertical-velocity curves, or the relationship between mean velocity and 0.2-depth velocity, to adjust the velocities observed in step 2 to mean velocity.
6. Compute the measurement in the normal manner using the depths from step 4 and the velocities from step 5.

CASE D. METER CANNOT BE SUBMERGED

If it is impossible to keep the meter and weight in the water because of high velocities and (or) floating drift, use the following procedure:

1. Obtain depths at the measurement verticals by the method explained for case B if a standard cross section is available, or by the method explained above for case C if no standard cross section is available.
2. Measure surface velocities with an optical current meter, as explained on pages 91–93, 137–138.
3. Compute the measurement in the normal manner using the surface velocities as though they were the mean velocities in the vertical, and using the depths from step 1.
4. Apply the appropriate velocity coefficient to the discharge computed in step 3; use a coefficient of 0.86 for a natural channel and 0.90 for an artificial channel.

If an optical current meter is not available, time floating drift over a measured course. (See p. 261–262.)

It should be noted here that the amount of floating drift or ice is usually greatly reduced just after the crest of a rise in stage. It may be possible at that time to obtain velocity observations with a standard current meter.

COMPUTATION OF MEAN GAGE HEIGHT OF A DISCHARGE MEASUREMENT

The mean gage height of a discharge measurement represents the mean stage of the stream during the measurement period. Because the mean gage height for a discharge measurement is one of the coordinates used in plotting the measurements to establish the stage-discharge relation, an accurate determination of the mean gage height is as important as an accurate measurement of the discharge. The computation of the mean gage height presents no problem when the change in stage is uniform and no greater than about 0.15 ft (0.05 m), for then the mean may be obtained by averaging the stage at the beginning and end of the measurement. However, measurements must often be made during periods when the change of stage is neither uniform nor slight.

As a prerequisite for obtaining an accurate mean gage height, the clock time at the beginning and end of the measurement should be recorded on the measurement notes, and additional readings of the clock time should be recorded on the notes at intervals of 15 to 20 min during the measurement. After the discharge measurement has been completed, the recorder chart should be read, and breaks in the slope of the gage-height graph that occurred during the measurement should be noted The breaks in slope are useful in themselves and are

also used to determine the gage height corresponding to the clock times noted during the measurement. If the station is equipped with a digital recorder, the gage-height readings punched during the measurement are to be read. At nonrecording stations the only way to obtain intermediate readings is for the stream gager to stop a few times during the measurement to read the gage, or to have someone else do this for him.

If the change in stage is greater than 0.15 ft (0.05 m) or if the change in stage has not been uniform, the mean gage height is obtained by weighting the gage heights corresponding to the clock-time observations. The weighting is done by using either partial discharge or time as the weighting factor. In the past the weighting in the U.S.A. was always done on the basis of partial discharges, but recent study indicates that discharge-weighting usually tends to overestimate the mean gage height, whereas time-weighting usually tends to underestimate the mean gage height. On the basis of the present state of our knowledge, it is suggested that the mean gage height for a discharge measurement be computed by both methods, after which the two results are averaged. A description of the two methods follows.

In the discharge-weighting process, the partial discharges measured between clock observations of gage height are used with the mean gage heights for the periods when the partial discharges were measured. The formula used to compute mean gage height is

$$H = \frac{q_1h_1 + q_2h_2 + q_3h_3 \ldots\ldots\ldots + q_nh_n}{Q}, \qquad (13)$$

in which

H = mean gage height (ft or m),

Q = total discharge measured (ft^3/s or m^3/s) = $q_1 + q_2 + q_3 \ldots . + q_n$,

where

$q_1, q_2, q_3, \ldots . q_n$ = discharge (ft^3/s or m^3/s) measured during time interval 1, 2, 3, ... n and

$h_1, h_2, h_3, \ldots . h_n$ = average gage height (ft or m) during time interval 1, 2, 3, ... n.

Figure 101 shows the computation of a discharge-weighted mean gage height. The graph at the bottom of figure 101 is a reproduction of the gage-height graph during the discharge measurement. The discharges are taken from the current-meter measurement notes shown in figure 42. The upper computation of the mean gage height in figure 101 shows the computation using equation 13. The lower computation has been made by a shortcut method to eliminate the multiplication

of large numbers. In that method, after the average gage height for each time interval has been computed, a base gage height, which is usually equal to the lowest average gage height, is chosen. Then, the

Angle coef. factor	Dist. from initial point (1)	Width (2)	Depth (3)	Observation depth	Revolutions (4)	Time in seconds	VELOCITY: At point	VELOCITY: Mean in vertical	Adjusted for hor. angle or	Area	Discharge

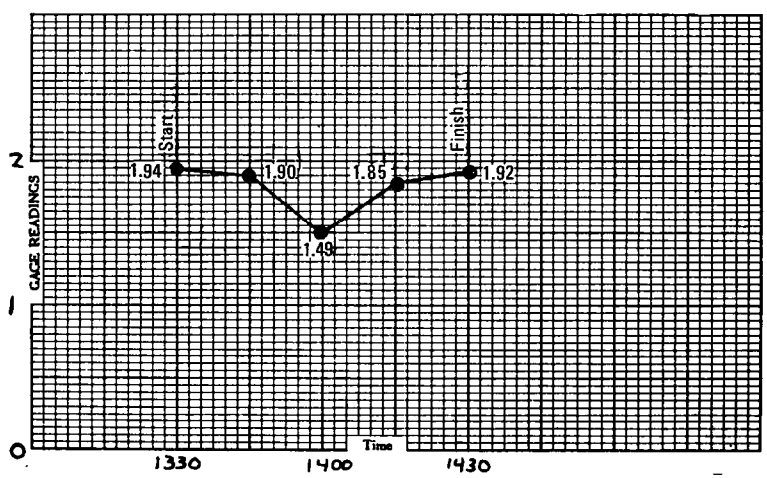

FIGURE 101.—Computation of discharge-weighted mean gage height.

differences between the base gage height and the average gage heights are used to weight the discharges. When the mean difference has been computed, the base gage height is added to it.

In the time-weighting process, the arithmetic mean gage height for time intervals between breaks in the slope of the gage-height graph are used with the duration of those time periods. The formula used to compute mean gage height is

$$H = \frac{t_1h_1 + t_2h_2 + t_3h_3 \ldots\ldots + t_nh_n}{T} \qquad (14)$$

in which

H = mean gage height, in feet or meters,

T = total time for the measurement, in minutes = $t_1 + t_2 + t_3 \ldots\ldots t_n$,

$t_1, t_2, t_3 \ldots\ldots t_n$ = duration of time intervals between breaks in slope of the gage-height graph, in minutes, and

$h_1, h_2, h_3 \ldots\ldots h_n$ = average gage height, in feet or meters, during time interval 1, 2, 3, ... n.

Using the data from figure 101, the computation of the time-weighted mean gage height is as follows:

Average gage height (*h*)	*Time interval* (*t*)	*h* × *t*
1.92	15	28.80
1.70	15	25.50
1.67	15	25.05
1.88	15	28.20
Total	60	107.55

Mean gage height = 107.55/60 = 1.79 ft

In the example used above there is little difference between the discharge-weighted mean gage height (1.77 ft) and the time-weighted mean gage height (1.79 ft); the average of the two values, 1.78 ft, is the preferred mean gage height for the discharge measurement.

When extremely rapid changes in stage occur during a measurement, the weighted mean gage height is not truly applicable to the discharge measured. To reduce the range in stage during the measurement, measurements under those conditions should be made more rapidly than those made under constant or slowly changing stage. It should be realized, however, that shortcuts in the measurement procedure usually reduce the accuracy of the measured discharge. Therefore measurement procedures during rapidly changing stage must be optimized to produce a minimal combined error in measured discharge and computed mean gage height.

MEASUREMENT PROCEDURES DURING RAPIDLY CHANGING STAGE

The preceding discussion on computing the mean gage height of discharge measurements demonstrated that under conditions of rapidly changing stage, measurement procedures must be streamlined, even at the expense of some accuracy. The reduction in measurement time makes it possible to obtain a gage-height value that is representative of the measured discharge. Where streams are uncontrolled, flood rises are more rapid on small streams than on large streams, because small streams are subject to flash floods that may rise and fall with sufficient rapidity to produce peak flows of almost momentary duration. Consequently the discussion that follows distinguishes between the procedures to be followed for measuring large streams and those for small streams, during periods of rapidly changing stage. The procedure to be followed for measuring streams whose flow is controlled by hydroelectric powerplants was discussed on page 140.

CASE A. LARGE STREAMS

During periods of rapidly changing stage on large streams, the time consumed in making a discharge measurement may be reduced by modifying the standard measurement procedure in the following manner:

1. Use the 0.6-depth method (p. 134). The 0.2-depth method (p. 135) or the subsurface method (p. 136) may be used if placing the meter at the 0.6-depth creates vertical angles requiring time-consuming corrections, or if the vertical angle increases because of drift collecting on the sounding line.
2. Reduce the velocity-observation time to about 20–30 s.
3. Reduce the number of sections taken to about 15–18.

By incorporating all three of the above practices a measurement can be made in 15–20 min. If the subsurface method of observing velocities is used, some vertical-velocity curves will be needed later to establish coefficients to convert observed velocity to mean velocity.

Carter and Anderson (1963) have shown that discharge measurements having 30 verticals, for which the two-point method of observation was used with a 45-s period of observation, will have a standard error of 2.2 percent (see p. 181–183). That means that two-thirds of the measurements made using standard procedures would be in error by 2.2 percent or less. They have also shown that the standard error for a 25-s period of observation, using the 0.6-depth method with depth and velocity observed at 16 verticals, is 4.2 percent. The error caused by using the shortcut method is generally less than the error to be expected as a result of the shifting flow patterns that commonly

occur during periods of rapidly changing stage, and in addition, uncertainty concerning the appropriate mean gage height for the measurement is eliminated.

CASE B. SMALL STREAMS

The discussion that follows deals with the measurement of flash floods on small streams. Flash floods begin and end with such abruptness that if the flow is to be measured, the hydrographer must have advance warning of the occurrence of such an event. The warning will enable him to reach the measuring site and make all necessary preparations for current-meter measurements before the stream starts to rise at the site. Once the rise begins it is essential that the many point observations required be made as rapidly as possible because of the rapidly changing discharge.

After arriving at the measuring site where the flash flood is expected, the hydrographer first marks the location of the observation verticals he intends to use. These marks are placed on the bridge rail or cableway that is used for discharge measurements. He then determines the elevation of the streambed, referred to gage datum, at those verticals. That is done both to save time during the actual discharge measurement and because he may be unable to sound the streambed when the flood is in progress. An auxiliary staff gage that can be read from the measuring bridge or cableway should be part of the gaging equipment.

In measuring the discharge during a flash flood, the procedure differs in the following ways from that used in making a conventional current-meter discharge measurement.

1. *Use 6 to 10 observation verticals in the measurement cross section.*—The actual number of verticals used will depend on the width and uniformity of the cross section. Current-meter observations are started when the stage starts to rise and are continued until the flow recedes to normal, or near-normal stage. After completing one traverse of the cross section, the next traverse is started immediately in the opposite direction, and observations continue to be made back and forth across the stream.

2. *Time is saved by making a single velocity observation at each observation vertical.*—If depths, velocities, and the absence of floating drift permit, the 0.6-depth method (p. 134) or 0.2-depth method (p. 135) is used. Otherwise, an optical current meter is used in the surface-velocity method (p. 137).

3. *Readings of the auxiliary staff gage are made at every third velocity observation and clock time is also recorded.*—That is done because the rapid change in stage will commonly make it impossible to later obtain accurate stages, corresponding to the time of each velocity

observation, from the automatic gaging-station record. Furthermore, during periods of rapidly changing stage, a staff-gage record is usually more reliable than an automatic-gage record because of "drawdown" at the intake or because of well or intake lag. Moreover if the gaging station is equipped with a digital recorder, the frequency of punches will seldom be adequate for a flash flood.

After the stream has receded, determinations of streambed elevation at the observation verticals are again made to learn if scour or fill has occurred. If there has been a change in streambed elevation, the change is prorated with time, or in accordance with the best judgment of the hydrographer, to provide the values of depth needed to compute discharge. The most reliable discharge results are obtained, of course, where the streambed is stable or relatively so, leaving no serious uncertainty about stream depths during the measurement.

4. *Computation procedure*—Normally, the discharge of a stream is computed for each current-meter traverse of the measurement cross section, using observed velocities, depths, and incremental channel widths. Because of the rapid change of stage that occurs during the course of a velocity-observation traverse, that conventional computation procedure should not be used when measuring the discharge of flash floods. If the conventional procedure is used there is great uncertainty as to the stage that applies to the computed discharge value. The recommended computation procedure for a flash flood is as follows.

The first step is to construct an individual relation of mean velocity to stage for each observation vertical. The mean velocity, it will be recalled, is obtained by applying an appropriate coefficient to each observed value of surface or subsurface velocity. For each vertical, mean velocity is plotted against stage, and each point is identified by clock time. A single smooth curve is usually fitted to the points, but the scatter of the points may indicate the need for two curves—one for the rising limb of the hydrograph and the other for the falling limb.

In either event, all the data needed are now available for constructing the stage-discharge relation for the entire cross section. The distance between observation verticals (incremental width) is known, and for any selected stage the corresponding depth and mean velocity at each observation vertical are likewise known. Those data are then used, in the conventional manner, to compute the total discharge corresponding to the selected stage. By repeating that operation for several stages, one obtains a stage-discharge relation for the entire range of stage, or, if necessary, two such relations—one for the rising limb of the hydrograph and one for the falling limb. As a final step, the stage-discharge relation(s) is applied to the stage hydrograph to compute the discharge hydrograph. In the absence of a reliable au-

tomatic stage record, the numerous visually observed values of stage provide the stage hydrograph.

CORRECTION OF DISCHARGE FOR STORAGE DURING MEASUREMENT

If a discharge measurement is made at a significant distance from the gage during a change in stage, the discharge passing the gage during the measurement will not be the same as the discharge at the measurement section because of the effect of channel storage between the measurement section and the gage.

Adjustment is made for channel storage by applying to the measured discharge a quantity obtained by multiplying the channel surface area by the average rate of change in stage in the reach. The equation used is

$$Q_G = Q_m \pm WL \frac{\Delta h}{\Delta t}, \tag{15}$$

where

Q_G = discharge passing the gage control (ft^3/s or m^3/s),
Q_m = measured discharge (ft^3/s or m^3/s),
W = average width of stream between measurement section and control (ft or m),
L = length of reach between measurement section and control (ft or m),
Δh = average change in stage in the reach L during the measurement (ft or m), and
Δt = elapsed time during measurement (s).

A reference point or a temporary gage is set at the measurement cross section if channel storage is likely to be significant. The water-surface elevations at the section and at the gage are determined before and after the measurement to compute Δh. If the measurement is made upstream from the control, the adjustment will be plus for falling stages and minus for rising stages; if made downstream from the control, the adjustment will be minus for falling stages and plus for rising stages.

Figure 102 shows the front sheet of a measurement that has been made 0.6 mi upstream from the control during a period of changing stage. The computation of the adjustment for storage for the measurement shown in figure 102 follows:

Measurement made 0.6 mi upstream, L = 3,170 ft.
Average width (W) between measurement section and control = 150 ft.
Change in stage at control, 5.84 to 6.74 ft = +0.90 ft.
Change in stage at measurement section, 12.72 to 13.74 = +1.02 ft. (Readings taken at measurement section from a reference point before and after measurement.)

Average change in stage (Δh) = (0.90 + 1.02) ÷ 2 = 0.96 ft.
Elapsed time during measurement = 1¼ hr = 4,500 s.
Measured discharge Q_m = 8,494 ft³/s.

$$Q_G = 8{,}494 - 150\,(3{,}170)\,\frac{0.96}{4{,}500} = 8{,}494 - 101 = 8{,}393 \text{ ft}^3/\text{s}.$$ Use 8,390 ft³/s.

FIGURE 102.—Discharge-measurement notes with discharge adjusted for channel storage.

The adjusted discharge figure is the one used for defining the stage-discharge relation.

The adjustment of measured discharge for storage during a period of changing discharge is a separate and distinct problem from that of making adjustments for variable slope caused by changing discharge. (See p. 418–421.) Regardless of whether or not the discharge is to be adjusted later for variable slope, the storage adjustment to discharge is made immediately after completion of the discharge measurement.

SUMMARY OF FACTORS AFFECTING THE ACCURACY OF A DISCHARGE MEASUREMENT

The factors that affect the accuracy of a discharge measurement have been discussed in appropriate sections of the preceding text. This section provides a brief recapitulation of those factors.

1. *Equipment.*—Accurate measurement requires that measurement equipment be properly assembled and maintained in good condition. To avoid damage in transport, the equipment should be packed in appropriate containers or compartments of the vehicle used by the hydrographer. Current meters are especially susceptible to damage when in use, because measurements must often be made when drift or floating ice is present in a stream.

2. *Characteristics of the measurement section.*—The basic characteristics of the measurement section affect measurement accuracy. The attributes desired in a measurement section are those listed on page 139. If possible, the section should be deep enough to permit use of the two-point method of measuring velocity. The presence of bridge piers in or near the measurement section adversely affects the distribution of velocities. Piers also tend to induce local bed scour which affects the uniformity of depth. Those adverse effects are increased if the bridge piers tend to collect drift on their upstream faces.

3. *Spacing of observation verticals.*—The spacing of observation verticals in the measurement section can affect the accuracy of the measurement. Twenty-five to 30 verticals should normally be used, and the verticals should be spaced so that each subsection will have approximately equal discharge. However, a measurement vertical should be located fairly close to each bank and at "breaks" in depth. The spacing of the verticals should also be reduced in the vicinity of bridge piers. If many bridge piers are present in the section or if the streambed is nonuniform, more verticals than the recommended 25–30 should be used.

4. *Rapidly changing stage.*—When the stage changes rapidly during a discharge measurement, the computed discharge figure loses some of its significance, and there is uncertainty as to the appropriate gage height to apply to that discharge figure. Consequently, the standard procedure for making discharge measurements should be

shortened when the stage is changing rapidly, as explained on pages 174–177, even at the expense of some accuracy. The reduction in measurement time makes it possible to obtain a mean gage height that is representative of the measured discharge.

5. *Measurement of depth and velocity.*—Inaccuracies in sounding and in the placement of the current meter are most likely to occur in those sections having great depths and velocities. Heavy sounding weights should be used to reduce the vertical angle made by the sounding line, and where vertical angles exist, tags and (or) correction tables should be used in determining vertical distances. Where velocities are not perpendicular to the measurement section, the cosine of the angle between the perpendicular and the direction of the current must be determined. If a velocity-azimuth-depth assembly (p. 129–130) is not used, it is necessary to assume that the angle of the surface current prevails throughout the vertical; that assumption may be erroneous.

6. *Ice in the measuring section.*—Reliable measurements may usually be made when measuring from ice cover if the measurement verticals are free of slush ice. Slush ice interferes with the operation of the current-meter rotor and also causes difficulty in determining the effective depth of water. If the effective depth is considered to be that portion of the depth in which the current meter indicates velocity, the assumed effective depth may be too small if slush ice is interfering with free operation of the rotor. Collections of slush ice are generally thickest near the upstream end of ice-covered pools, and those areas should therefore be given little consideration as measurement sections. If the ice cover is layered so that there is water flowing between ice layers, it is almost impossible to obtain a reliable discharge measurement, particularly if the water layers are too thin to permit insertion of the meter between ice layers. The exposure of a wet current meter to subfreezing air temperatures may cause serious underregistration of the current meter as a result of ice forming in the meter bearings and contact chamber. Therefore, once the measurement is started, the current meter should be kept in the water as much as possible to avoid exposure to the cold air.

7. *Wind.*—Wind may affect the accuracy of a discharge measurement by obscuring the angle of the current, by creating waves that make it difficult to sense the water surface prior to sounding the depth, and by affecting the velocity at 0.2-depth in shallow streams, thereby distorting the vertical-velocity distribution. When making boat measurements, the wind-caused waves may induce vertical motion in a cable-suspended meter, or the wind may cause an oscillatory horizontal movement of the boat against the tag line; either movement may affect the operation of the current meter. Table 11 sum-

marizes the results of an investigation (Kallio, 1966) on the effect of vertical motion on the operation of Price, vane-type, and Ott (cosine rotor 8646–A) current meters. The plus signs in table 11 indicate overregistration by the meter; the minus signs indicate underregistration.

ACCURACY OF A DISCHARGE MEASUREMENT MADE UNDER AVERAGE CONDITIONS

Carter and Anderson (1963) made a statistical analysis of the error in discharge measurements made in natural streams under average measuring conditions. They tested the following four assumptions on which the computation of discharge measurements is based:

1. The rating of the current meter is applicable to the conditions of the measurement.
2. The velocity observed at a point is a true time-averaged velocity.
3. The ratio is known between the velocity of selected points in the vertical and the mean velocity in the vertical.

TABLE 11.—*Registration errors, in percentage of stream velocity, caused by vertical motion of current meter*

4. The depth measurements are correct, and the velocity and depth vary linearly with distance between verticals.

Assumption 1 was tested by comparing the ratings obtained for Price current meters when rated in flumes of different sizes. It was found that the ratings can be repeated within a fraction of 1 percent. When a Price meter was tested in a wind tunnel under differing degrees of turbulence, its performance was not affected by increased turbulence. The similarity of results using the Price, Ott, and Neyrpic current meters has already been discussed on page 89. It was therefore assumed that the standard deviation (S_{R_i}) of the error ratio between measurement results obtained with different current meters equals 1 percent.

Assumption 2 was tested in 23 different rivers where velocities for consecutive time periods of 15, 30, 45, 90, 120, and 240 s were observed for a 1-hr period at points corresponding to 0.2, 0.4, 0.6, and 0.8 depth. The measurement verticals ranged in depth from 2.4 to 26.7 ft (0.7 to 8.1 m), and velocities ranged from 0.43 to 7.9 ft/s (0.13 to 2.4 m/s). Statistical analysis showed that velocity fluctuations were randomly distributed in time and space and that if 45-s observations were taken at the 0.2- and 0.8-depth positions in 30 verticals, the standard deviation (S_{R_t}) of the error ratio between observed and true point velocity was 0.8 percent.

Assumption 3 was tested using more than 100 stream sites. The standard deviation (S_{R_s}) of the error ratio between the mean velocity obtained from 0.2- and 0.8-depth observations and the true vertical velocity, using 30 verticals for the discharge measurement, was 1.15 percent.

Assumption 4 was tested using discharge measurements made at 127 stream sites, in which more than 100 verticals were measured in each cross section. The discharge for each site was again computed using the data for 1/2, 1/4, 1/5, 1/7, and 1/10 of the total number of verticals in each cross section. Error ratios between those computed discharges and the discharges computed using all observation verticals were determined. When 30 observation verticals were used, the standard deviation (S_N) of the error ratios was 1.6 percent.

The standard error of a discharge measurement (S_T) was computed from the equation

$$S_T = \sqrt{(S_{R_i})^2 + (S_{R_t})^2 + (S_{R_s})^2 + (S_N)^2}. \quad (16)$$

For a measurement using velocity observations of 45 s at the 0.2- and 0.8-depth positions in each of 30 verticals, S_T equaled 2.2 percent. That means that if single discharge measurements were made at a number of gaging sites using the standard method recommended in

this manual, the errors of two-thirds of the measured discharges would be less than 2.2 percent.

CHAPTER 6.—MEASUREMENT OF DISCHARGE BY THE MOVING-BOAT METHOD

INTRODUCTION

On large streams and estuaries the conventional methods of measuring discharge by current meter are frequently impractical and involve costly and tedious procedures. There may be no suitable facilities at remote sites. Where suitable facilities do exist, they may be inundated or inaccessible during floods. At some sites, unsteady flow conditions require that measurements be made as rapidly as possible. Measurements on tide-affected rivers must not only be made rapidly, but often continually, throughout a tidal cycle. The moving-

boat technique is a method of rapidly measuring the discharge of large streams. It requires no fixed facilities, and it lends itself to the use of alternate sites if conditions make this desirable.

The moving-boat technique is similar to the conventional current-meter measurement in that both use the velocity-area approach in determining discharge. (See chapter 5.) In each method, a measurement is the summation of the products of the subsections of the stream cross section and their respective average velocities. Both techniques require that the following information be obtained:

1. Location of sampling verticals 1, 2, 3,. . .n across the stream in reference to the distance from an initial point.
2. Stream depth, d, at each observation vertical.
3. Stream velocity, V, perpendicular to the cross section at each observation vertical.

During a traverse of the boat across the stream, a sonic sounder records the profile of the cross section, and a continuously operating current meter senses the combined stream and boat velocities. A vertical vane alines itself in a direction parallel to the movement of water past it, and an angle indicator attached to the vane assembly indicates the angle between the direction of the vane and the true course of the boat. The data from these instruments provide the information necessary for computing the discharge for the cross section. Normally, data are collected at 30 to 40 observation points in the cross section for each run. Experience has shown that discharges determined by the moving-boat technique match, within 5 percent, discharges determined by conventional means.

The principal difference between the conventional measurement and the moving-boat measurement lies in the method of data collection. The standard current-meter method of measurement uses what might be called a static approach in its manner of sampling; that is, the data are collected at each observation point in the cross section while the observer is in a stationary position. This is in contrast to the dynamic approach to data collection utilized in the moving-boat method. Here, data are collected at each observation point while the observer is aboard a boat that is rapidly traversing the cross section.

THEORY OF THE MOVING-BOAT METHOD

The moving-boat measurement is made by traversing the stream along a preselected path that is normal to the streamflow. The traverse is made without stopping, and data are collected at intervals along the path. During a traverse of the cross section, the boat operator maintains course by "crabbing" into the direction of the flow sufficiently to remain on line (fig. 103). The velocity, V_b, of the boat

with respect to the stream-bed along the selected cross-section path is the velocity at which the current meter is being pushed through the water by the boat. The force exerted on the current meter, then, is a combination of two forces acting simultaneously: one force resulting from the movement of the boat through the water along the cross-section path and the other a consequence of the natural streamflow normal to that path.

The velocity measurement taken at each of the sampling points in the cross section is a vector quantity that represents the relative velocity of water past the vane and meter. This velocity, V_V, is the vector sum of V, the component of stream velocity normal to the cross section at the sampling point, and V_b, the velocity of the boat with respect to the streambed along the selected path. The vector diagram in figure 104 depicts this relation.

The sampling data recorded at each observation point provide the necessary information to define V_V. The pulses-per-second reading from the rate-indicator unit is used in conjunction with a rating table to obtain the vector magnitude, V_V, while the angle reading, α, representing the angle the vane makes with the cross-section path, defines the direction of the vector.

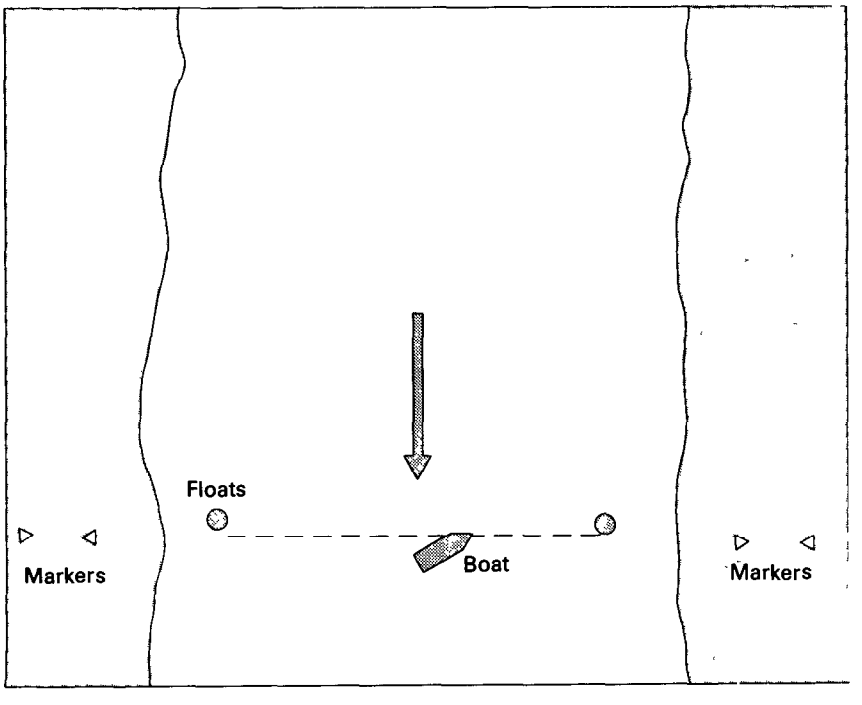

FIGURE 103.—Sketch of stream with markers.

Stream velocity, V, perpendicular to the boat path (true course) at each sampling point, 2, 3, 4, . . . $(n-1)$, can be determined from the relation

$$V = V_V \sin \alpha. \tag{17}$$

The solution of the above equation yields an answer which represents that component of the stream velocity that is perpendicular to the true course even though the direction of flow may not be perpendicular. This is the desired component.

From the same vector diagram, it can be seen that

$$L_b = \int V_V \cos \alpha \, dt, \tag{18}$$

where L_b is the distance that the boat has traveled along the true course between two consecutive observation points, provided the stream velocity is perpendicular to the path. Where the velocity is not perpendicular, an adjustment is required as explained on pages 207–208, where the adjustment of total width and area is discussed.

If one assumes that α is approximately uniform over the relatively short distance that makes up any one increment, then α may be treated as a constant. Therefore, equation 18 becomes

$$L_b \approx \cos \alpha \int V_V \, dt. \tag{19}$$

However,

$$\int V_V \, dt = L_V, \tag{20}$$

where L_V is the relative distance through the water between two consecutive observation points as represented by the output from the rate indicator and counter. Therefore,

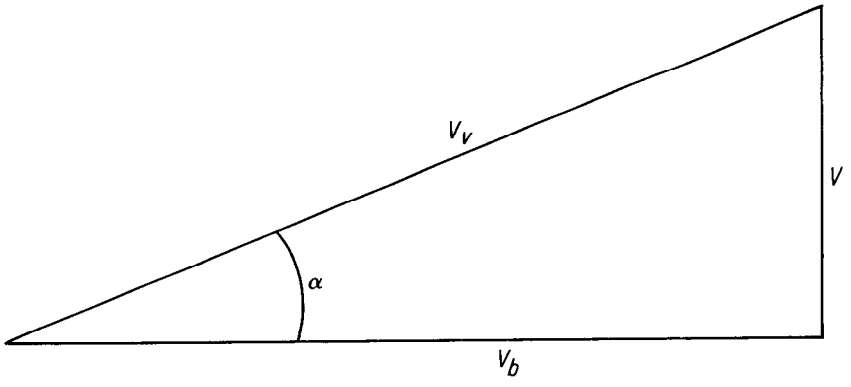

FIGURE 104.—Diagram of velocity vectors.

$$L_b \approx L_V \cos \alpha. \quad (21)$$

Finally, d, stream depth at each observation point, is obtained by adding the transducer depth to the depth obtained from the sonic-sounder chart. Upon determining V, L_b, and d for each vertical, the midsection method of computing a discharge measurement is used. (See p. 80–82.)

Much of the accuracy of a moving-boat discharge measurement depends upon the skill of the boat operator in maintaining a true course. Although even the most experienced pilot cannot be expected to keep the boat absolutely on course for an entire run, it is still extremely important that the measurement begin and end on line and that any deviations from the true course be kept as few in number and as small in magnitude as possible.

If velocity readings are taken while the boat is moving off course in an upstream direction, those readings will be greater than the true velocities; if the readings happen to be taken when the movement is toward the downstream direction, then the sampled velocity readings will be less than the true velocities. Thus, if one assumes the equal likelihood of overregistering or underregistering the stream velocities because of deviations from the true course, the errors can be considered compensating in nature. However, to further insure the reliability of the measurement, it is recommended that the results of at least six individual runs, each with from 30 to 40 observation points, be averaged to obtain the discharge when steady-flow conditions exist. This is practicable because of the ease and speed with which the extra runs can be made.

For unsteady-flow conditions on tidal streams, it will usually be desirable not to average the results from a series of runs but rather to keep them separate so as to better define the discharge cycle.

EQUIPMENT

Specialized instrumentation consisting of a sonic sounder, a vane with indicator, a special current meter with its associated electronic equipment, and an easily maneuverable small boat with some modifications, provide the capability needed for a moving-boat measurement.

VANE AND ANGLE INDICATOR

A vane with an indicating mechanism is mounted on the bow of the boat, with the vane centered approximately 3 to 4 ft (0.9 to 1.2 m) below the water surface (fig. 105). This assembly consists of a vertical, stainless-steel shaft with a pointer connected to its upper end and a thin vertical aluminum fin, 1-ft (0.3 m) high and 1½-ft (0.46m) long,

attached to its lower end. The shaft is housed in an aluminum bearing tube and is mounted with ball bearings at the upper end and a teflon bearing (no lubrication needed) in the lower end of the tube so that the assembly (vane, shaft, pointer) is free to rotate as a unit. The vertical vane alines itself in a direction parallel to the movement of the water past it. The pointer is attached to the shaft so that it will be in line with the vane, pointing directly into the flow past the vane. The angle between the direction of the vane and the true course of the boat (the line of the cross section) is indicated on a dial by the pointer. The circular dial, calibrated in degrees on either side of an index point, swivels freely about the upper end of the vertical shaft, just below the pointer. A sighting device attached to the dial provides a means of alining the index point on the dial with the true course. In positive (downstream) streamflow the pointer above the dial will always point to the upstream side of the true course. Because the upstream side may be to the left or right side, depending on the direction in which the boat is traveling, and also because of possible negative velocities, the dial is calibrated in degrees (from 0 to 90) on both sides of its index point.

CURRENT METER

The current meter used by the U.S. Geological Survey is a component propeller type with a custom body made for mounting on the leading edge of the vane (fig. 105). The component propeller is less susceptible than are other types of meters to vertical components of velocity and was chosen to minimize errors created by the bobbing of the boat.

A 24-toothed gear passing in the proximity of a magnetic field is

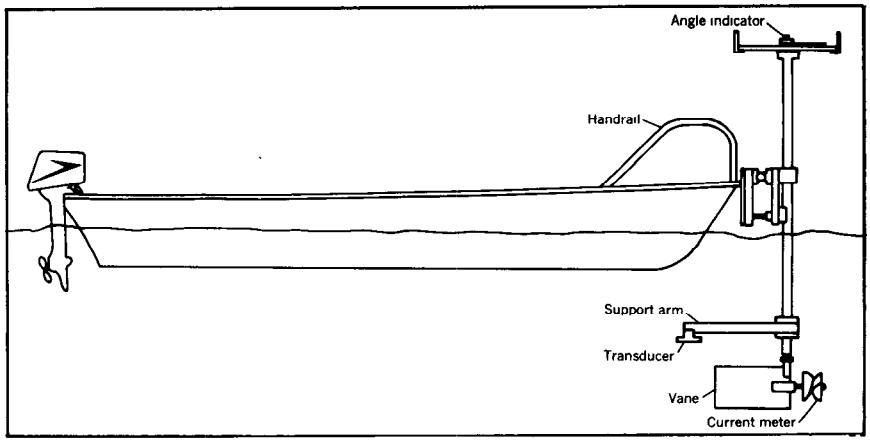

FIGURE 105.—Sketch of boat showing equipment.

used to generate 24 pulses per revolution of the propeller. The large number of pulses for each revolution facilitates the conversion of the pulse rate to an analog readout. An electronic pickup assembly registers these pulses and feeds them into a frequency-to-voltage converter, and they are then displayed as a reading on an electrical meter.

At one end of the meter cable is a metallic probe that is screwed into the meter body at the opening just behind the propeller nut (fig. 106). The probe is a permanent magnet that provides the magnetic field necessary for pulse generation. To function properly, the probe tip must be positioned within a few thousandths of an inch of the 24-toothed gear located within the meter. Adjustment of the probe position, which is seldom required, should be done with care to prevent damage to the probe tip.

Before the meter is used, the cup within the hub of the current-meter propeller should be filled with thin oil (Ott propeller oil) as shown in figure 106. The bearing assembly is then inserted into the hub, and the propeller nut is tightened. After the conclusion of a series of measurements, the cup should be emptied completely and cleaned before storage.

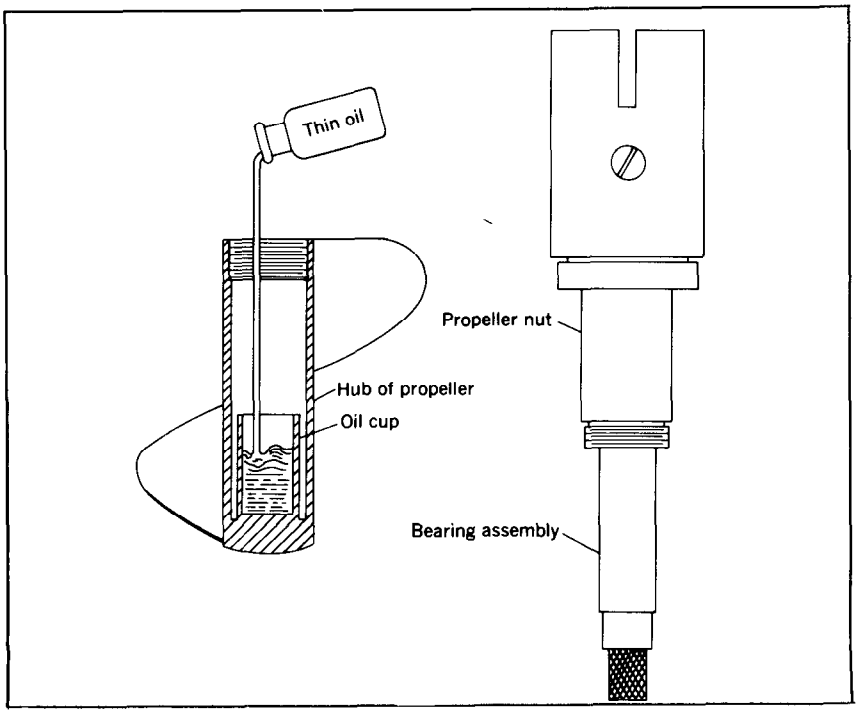

FIGURE 106.—Component propeller-type meter.

RATE INDICATOR AND COUNTER

One of the principal functions of the rate indicator and counter is to register the pulses received from the current meter, feed them into a frequency-to-voltage converter, and then display them as a reading on its electrical meter (fig. 107). These pulses are received through the current-meter cable which is plugged into the marked receptacle provided in the front panel of the unit. The current meter generating the pulses is calibrated so that the reading on the electrical meter in pulses per second can be converted to a particular velocity in feet per second through the use of a rating table (fig. 108). The value read from the electrical meter at any particular instant represents an instantaneous readout of velocity.

Two scale selections are available for the rate-indicator unit. If the switch is set at the "500" selection, the readout is taken from the lower scale of the panel meter; at the 1,000 setting, the upper scale is used. The 500 scale is the more sensitive of the two, and therefore its use is recommended during those measurements in which the velocity of the water past the meter is not great enough to give readings that exceed 500 pulses per second.

In addition to serving as a pulse-rate indicator from which velocity determinations can be made, this unit has also been designed to provide a method of automatically selecting measurement points in a section at regular intervals of travel distance. This design makes use of the fact that each revolution of the meter propeller generates 24

FIGURE 108.—Sample tables of meter rating, L_b, and sine α.

evenly spaced pulses, and that from the calibration of the meter it can be determined that one pulse is equal to some fraction of a foot of meter travel through the water, or of water travel past the meter. By using a set of frequency-dividing modules, provision is made for these pulses to be electronically counted to a preset number, at which time an audible signal is generated and the sounder chart is automatically marked. The counter then automatically resets itself, and the process is repeated. The purpose of the audible signal is to let the boat crew know when a sampling location is reached. At this point they will take an angle reading from the pointer and a readout from the electrical meter. The markings on the sounder chart are automatically triggered by an electrical impulse transmitted to the depth-sounder unit by a relay in the meter electronics. The relay cable from the counter to the sounder should be plugged into the appropriately marked receptacle on the front panel of both units. The markings on the sounder chart locate observation points in the cross section and thus show where depth readings should be taken.

Preset intervals that are available on each unit are as follows:

Range selection	*Pulse counts*	*Distance, in feet*
1	1,024	18.75
2	2,048	37.5
3	4,096	75
4	8,192	150
5	16,384	300

The distances listed above are typical; exact ones depend upon the calibration of the particular current meter used. If possible, the pulse-selector switch should be set for a distance that will divide the measured width between the two floats into from 30 to 40 increments. For example, if the distance between floats is 500 ft (150 m), range 1 should be selected; for a distance of 1,000 ft (300 m), range 2 should be used, and so on. Each distance listed in the table above represents L_V, the relative distance through the water, and it will be somewhat larger than the corresponding L_b value, the distance along the true course that the boat has traveled. L_b is the distance one should use to determine the number of observation points that will be taken in a given cross section. However, the listed L_V values can be used to estimate roughly the number of observation points—the estimated number will always be less than the actual number of observation points.

The rate indicator and counter has two internal power supply packs, each consisting of a set of nickel-cadmium rechargeable batteries. A battery test switch located on the front panel of the unit can be used to test the condition of either the 3.6-volt or the 12-volt power supply (fig. 107). Testing should be done with both the main

power and the marker switches off. A reading of the panel meter above the test switch will indicate the degree of charge. A needle deflection greater than the battery testline mark indicates a satisfactory charge level for most measurement requirements. A fully charged battery pack will operate satisfactorily from 12 to 16 hr. A marginal reading, with needle deflection just to the test mark, indicates approximately 4 to 8 hr of useful battery operation remaining. A reading below the mark serves as a warning that a battery charge is needed.

BATTERY CHARGER

The battery charger serves as a dual unit for charging either one of the two battery supply packs located within the rate indicator and counter unit. Its charge plug is inserted into the charge receptacle located on the panel of the rate indicator and counter. The other plug should be connected to a 115-volt, 60-cycle line power supply. With proper care the batteries should provide many years of service.

SONIC SOUNDER

A portable sonic sounder (fig. 109) is used to provide a continuous strip-chart record of the depth of the stream, that is, a profile of the cross section between the two floats. Its transducer releases bursts of ultrasonic energy at fixed intervals. The instrument measures the time required for these pulses of energy to travel to the streambed, to be reflected, and to return to the transducer. With a known propagation velocity of sound in water, the sounder computes and records the depth. Accuracy of the recording depth sounder is approximately ± 0.5 ft (0.15 m). The sounder used in this application is a commercially available model with a minor modification for automatically marking the chart at each observation point in response to an electrical pulse from the meter electronics. The sounder is powered by a standard lead-acid battery of 6 or 12 volts, depending on the model of the sounder.

One minor modification to the sonic sounder is the installation of a receptacle on its front panel into which is plugged the relay cable from the rate indicator and counter. The purpose of this relay connection is to transmit the electrical pulses from the counter unit that will automatically trigger the vertical-line markings on the sounder chart. This provision for automatically marking the sounder chart at regular intervals of distance traveled eliminates the need for the manually operated "mark" switch, except in the event that the relay cable is damaged or missing. Then, as an expedient measure, the chart is marked at each observation point by manually pulling the switch at each tone signal sounded by the counter unit.

Three paper-feed speeds are provided with the unit. The small lever

in the lower left-hand corner of the recorder chassis is the control. The set of speeds available will vary according to the model. Some models

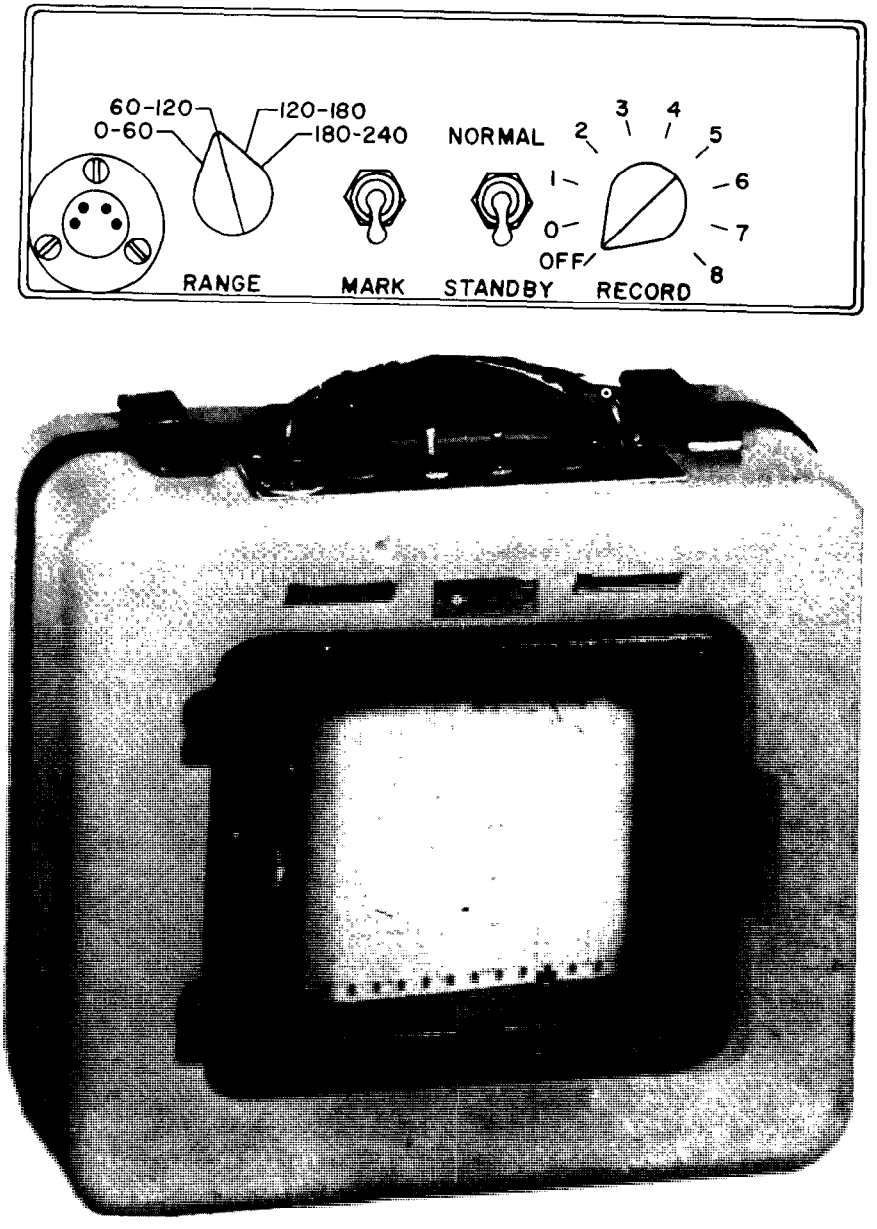

FIGURE 109.—Sonic sounder and control panel.

provide choices of 12, 30, and 60 in/hr (0.30, 0.76, and 1.52 m/hr), and others 36, 90, and 180 in/hr (0.91, 2.29, and 4.57 m/hr). A suitable chart speed is one that results in a spacing of approximately 0.25 in between the vertical-line markings that are set on the chart during the measurement. Spacing wider than that needlessly wastes chart paper, whereas much narrower spacing results in poor resolution of the streambed trace. Narrow spacing also causes difficulty in determining the fractional part of a full spacing that should be assigned to the final width increment. Width of spacing is dependent upon the range setting on the counter unit, the current-meter velocity, and the chart speed. Table 12, computed for a current-meter velocity of 5 ft/s (1.52m/s), provides an example of typical spacing distances expected for various combinations of chart speed and range distance.

BOAT

Any easily maneuverable small boat that is sufficiently stable for the stream on which it is to be used is adequate for a moving-boat measurement. A photograph of a boat with the vane assembly mounted is shown in figure 110.

Preparation of the boat.—A 12×12×¼-in steel plate should be so attached that it is centered on the bow of the boat, perpendicular to the centerline of the boat, and as nearly vertical as possible. This plate must be securely anchored because at high velocities great force will be exerted on it. It may be necessary, depending on the style of boat being used, to erect handrails on the forward part of the boat, similar to those shown in figure 105. This is done for the safety of the angle reader who must stand in the bow.

Mounting of the equipment.—The 12×12-in aluminum plate on the vane assembly is attached to the 12×12-in steel plate on the bow of the boat. It is necessary to clamp these two plates together and drill four holes for accepting bolts to permanently fasten the plates together. The general location of the bolt holes should be near the four corners, but exact placement is not critical.

The two cap screws in the depth adjustment clamp that hold the aluminum bearing tube of the assembly (fig. 111) can be loosened so

TABLE 12.—*Spacing of vertical-line markings, in inches, on the sonic-sounder chart for various combinations of chart speed and range distance*

[Computed for a current-meter velocity of 5 ft/s]

Chart speed	Range distance				
	18 75 ft	37.5 ft	75 ft	150 ft	300 ft
36 in/hr	0.04	0.08	0.16	0.32	0.64
90 in/hr	.10	.20	.40	.80	1.6
180 in/hr	.20	.40	.80	1.6	3.2

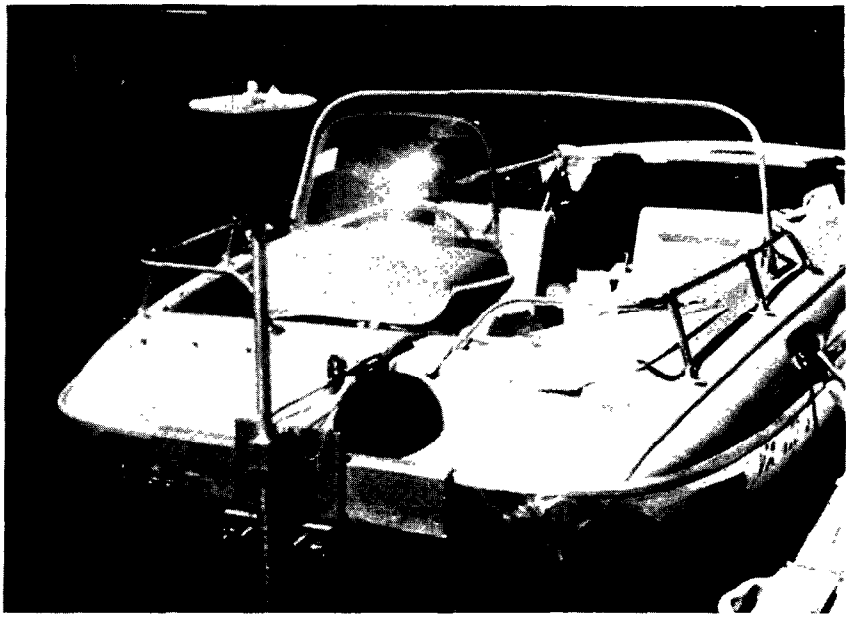

FIGURE 110.—Boat with mounted vane assembly.

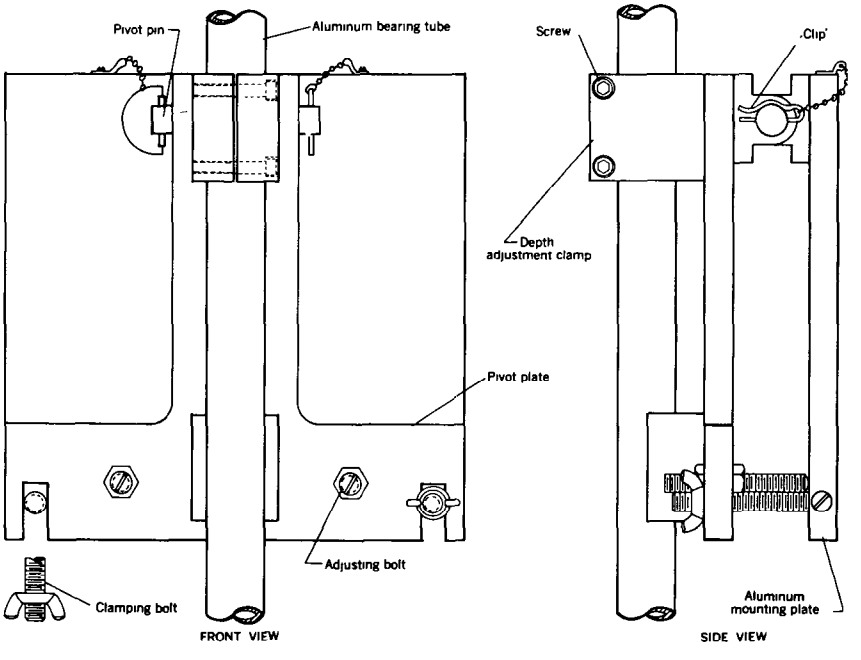

FIGURE 111.—Detailed view of vane-mounting assembly.

that the tube may be either raised or lowered in order to position the meter at the desired depth. This depth should preferably be at least 3 ft (0.91 m) to avoid the effect of surface disturbances and not greater than 4 ft (1.22 m) to avoid the danger of too great a torque being exerted at high velocities. Caution should be exercised to avoid high boat speeds, for the drag on the vane assembly is proportional to the square of the velocity of the water past the vane and therefore increases very rapidly with speed.

The sonic-sounder transducer is mounted on a support arm at a depth of either 2 or 3 ft (0.61 or 0.91m). It can be positioned by first loosening the two cap screws that secure the support arm to the aluminum bearing tube of the vane assembly and then moving the arm either up or down to the desired depth.

Because the vane assembly is mounted perpendicular to the centerline of the boat, it will change slightly from its original vertical position as a result of the raising of the bow of the boat during the moving-boat measurement. To offset this change and thus allow for vertical positioning of the assembly during normal boat operation, the mounting assembly provides for a compensating angle adjustment to be accomplished through the use of two adjusting bolts and a pivot plate (fig. 111). By screwing these bolts either inward or outward, the lower portion of the assembly can be pivoted toward or away from the boat. If the adjusting bolts are touching the aluminum plate when the assembly is in a vertical position, they must be screwed away from the plate so that the lower portion of the assembly can then be pivoted toward the boat and secured in position by use of two clamping bolts. The degree of adjustment would depend upon the operating velocity of the boat during the measurement.

Removal of the equipment.—After the measurements are completed, the vane assembly can be removed while leaving the aluminum plate bolted to the steel plate on the bow of the boat. This is accomplished by first loosening the wing nuts on the two clamping bolts of the plate and then removing the clip and sliding out the pivot pin that secures the assembly to the aluminum plate (fig. 111). Prior to doing this, the meter and the transducer cables should be disconnected from the rate indicator and the sonic sounder, respectively.

MEASUREMENT PROCEDURES

Procedures for a moving-boat measurement include selection and preparation of a suitable measuring site, preparation and assembly of the equipment used for the measurement, and a selection of settings for the instruments used to collect the data.

SELECTION AND PREPARATION OF THE MEASUREMENT SITE

Some preparation is required at the site prior to starting a series of

moving-boat measurements. First, a path for the boat to travel is selected, it being as nearly perpendicular to the flow direction as possible. Then, two clearly visible range markers are placed on each bank in line with this path. The color of these markers should contrast sharply with the background. Spacing between the markers is dependent upon the length of the path, the longer paths requiring greater spacing. Approximately 100 ft (30 m) of spacing is needed for each 1,000 ft (300 m) of path length. Next, anchored floats are placed in the stream 40 to 50 ft (12 to 15 m) from each shore along the selected path (fig. 103). In making a traverse, this distance is needed for maneuvering the boat when entering or leaving the path. The floats should be placed so that the depth of water in their vicinity is always greater than 3 to 4 ft (0.9 to 1.2 m), which is vane depth. Large plastic bleach containers are suitable for use as floats; styrofoam cubes can also be used. It is preferable not to place the floats directly in the boat path but rather 10 to 20 ft (3 to 6 m) upstream. Their purpose is to mark the beginning and ending points of the boat measurement, and by offsetting them upstream they can serve that purpose without being in the way as the boat approaches along the selected path. Finally, the width of the stream is measured by triangulation, stadia, or other methods, and the exact locations of the floats are determined. Because the floats are close to the bank, a tape measure can be used to determine the distance from edge of water to each float. These distances should be recorded in the spaces provided on the front page of the discharge-measurement notes, for they will be used in the computation of the measurement.

If a station is to serve as a site for moving-boat discharge measurements on a continuing basis, it will probably be desirable to construct permanent range markers. Such markers would serve two useful purposes. First, determination of stream width would become a relatively simple procedure because of the availability of the constant distance between the markers once this distance has been established. A tape measure could be used to obtain the horizontal distance from the nearest marker to the water's edge on each bank. Subtracting these two distances from the established distance between the two streamward markers would provide the width of the stream. A second advantage would be that if the need arose, the markers could serve as permanent initial points from which cross-section profiles of the measurement section could be constructed.

PREPARATION OF THE EQUIPMENT

The special equipment and instruments necessary for a moving-boat measurement have been described in some detail on pages 187–197 under the general heading "Equipment." The purpose of this

section of the manual is to summarize, for the convenience of the boat crew, the steps involved in the assembly of the equipment and in the selection of the instrument settings.

ASSEMBLY OF THE EQUIPMENT

The steps listed below should be followed in assembling the equipment:

1. Permanently mount a steel plate to the bow of the boat (p. 195) and then attach the aluminum plate of the vane assembly to it (p. 197). Both of these steps are "one time" operations that should be completed in advance of the trip.
2. Several days prior to the trip, check the batteries in the rate-indicator and counter unit and the storage battery for the sonic sounder to see that they are adequately charged. This will provide time to charge the batteries, if necessary, before the start of the trip.
3. Attach the sonic-sounder transducer to its support arm on the vane assembly (fig. 105).
4. Attach the current meter to the leading edge of the vane (fig. 105).
5. Use the pivot pin and clip and the two clamping bolts of the aluminum plate to secure the vane assembly to the plate (fig. 111).
6. Position the current meter at the desired depth (3 to 4 ft). This is done by loosening the two cap screws in the depth adjustment clamp and then raising or lowering the aluminum bearing tube to the proper position before retightening the screws. Measure the meter depth and record it in the measurement notes once positioning is completed.
7. Route the current-meter cable up the vane assembly and plug it into the marked receptacle on the rate indicator and counter unit. To prevent entanglement, the cable should be taped to the aluminum bearing tube in several places. It is necessary to provide some slack in the cable at its lower end to allow for the movement of the meter as the vane rotates during the measurement.
8. Position the sonic-sounder transducer at a depth of 2 or 3 ft. This is accomplished by first loosening the two cap screws that secure the support arm to the aluminum tube and then sliding the arm either up or down the tube to the proper position before tightening the screws. Measure the transducer depth and record it in the measurement notes at this time.
9. Route the transducer cable up the vane assembly, securing it by tape to the aluminum bearing tube; feed it through the hole

provided near the hinge of the sonic-sounder case; and then plug it into the marked receptacle at the back of the dividing plate.

10. Insert the battery cable of the sonic sounder into the marked receptacle at the back of the dividing plate of the unit. It can be fed through one of the holes provided near the hinge. A standard 6- or 12-volt storage battery, depending on the sonic-sounder model used, should be used as a power supply (p. 193).
11. Plug the relay cable from the counter unit to the sonic sounder into the marked receptacle on the front of each unit.
12. Use the two adjusting screws (fig. 111) to provide for the compensating angle adjustment of the vane assembly as described on page 197.

SELECTION OF THE INSTRUMENT SETTINGS

The notekeeper is responsible for the functioning of the rate indicator and counter and the recording depth sounder. To assure proper operation of the equipment, it is necessary that he make several preliminary instrument settings for each unit prior to the measurement. The following is a list of the steps involved in obtaining these settings:

Sonic sounder:

1. Check to see that the pulleys turn smoothly and that the stylus enters the track easily.
2. Set the operation switch to "stand by" position.
3. Turn on the unit by rotating the "record" switch clockwise to some low-numbered position and wait a few minutes for the tubes to warm up.
4. Set the depth-range selection at phase 1 (0–60 ft) and advance the gain control to obtain the "zero mark" near the top of the sounder chart.
5. Set the "zero mark" on the zero line of the recorder paper through use of the zero adjustment screw located behind the top pulley.
6. Continue to advance the gain until the "echo mark" appears somewhere below the "zero mark." If no echo appears when the gain is opened, switch the range control to the next phase (60–120 ft) and so on until the bottom is found.
7. Determine the optimum chart speed through use of table 12; then use the small lever in the lower left-hand corner of the recorder chassis to make this selection.
8. Change the operating switch from "stand by" to "normal" position several minutes before the measurement begins. This will start

the chart recording and provide an opportunity for a final check of instrument operation before the measurement begins.

Rate indicator and counter:

1. Select the desired scale for the rate-indicator meter located on the panel.
2. Check both battery packs with the battery test switch. This final check will have been preceded by a test several days before the measurement date in order to provide time to charge the batteries if needed (p. 199).
3. Set the rate-indicator switch to "on" position.
4. Set the marker switch to "on" position. (The actual marking will not begin until the "start" button is depressed.)
5. Select a range setting that will provide between 30 to 40 observation points. Because of the scale settings available, this may not always be possible, in which case choose that comprise setting that will come closest to meeting this provision.

After all the control settings are completed, the instruments are ready for use. The "start" and "stop" buttons on the panel of the counter unit are used to begin and end instrument operation at the precise moments the bow of the boat reaches the first and second floats, respectively. The operation of these button controls in regard to the starting and stopping procedure is described in the section of the manual that immediately follows.

FUNCTION OF THE CREW MEMBERS

Three crew members are necessary for making a moving-boat discharge measurement. They include a boat operator, an angle observer, and a notekeeper. Before crew members begin making discharge measurements by the moving-boat method, it is important that they develop a high degree of proficiency in all phases of the technique. This can be done by making practice measurements at a site where the discharge is known and then comparing the moving-boat discharge with the rated discharge. If there is no suitable site available for that purpose, the boat crew should make a series of moving-boat measurements at a single location and compare results for repeatability.

BOAT OPERATOR

Before the measurement begins, the boat operator should become thoroughly familiar with the sampling site. In tidal streams the operator should be familiar with conditions during all phases of the tidal cycle. This will help him avoid running the boat aground in shallow depths and damaging the submerged equipment. While man-

euvering the boat, it is necessary to avoid sudden sharp turns that might result in damage to the meter cable by causing it to be wrapped around the vane assembly.

The operator should select an approach path for the boat that will allow it to be properly maneuvered into position prior to passing the first float. The path should begin from a downstream position as close to the riverbank as depth considerations permit. From such a starting point the boat can be accelerated to near its normal operating speed and the turn into the measuring section can be completed before the measurement begins. By attaining both the proper speed and alinement prior to reaching the float, the instrument readings will have time to stabilize before the initial sample is taken.

During a traverse the only function of the boat operator is to pilot the boat. He maintains course by "crabbing" into the direction of flow sufficiently to remain on line throughout the run. As varying stream velocities are encountered in the cross section, he should rely more upon steering adjustments to keep the proper alinement than upon acceleration or deceleration of the boat. Alinement is determined by sighting on the shore which is being approached. Much of the accuracy of the measurement depends on the skill of the boat operator in maintaining a true course with the boat.

Because the stream velocity is calculated as a sine function of angle alpha (fig. 104, eq. 17), small angles should be avoided whenever possible. It is desirable to maintain angle alpha at approximately 45°. The reason for this is that an error of several degrees in reading angle alpha would be more significant at small angle readings than the same error at larger angle readings. In order to maintain an angle of 45°, the velocity of the boat must be equal to that of the stream. This can be done if the stream velocity is greater than 2.5 ft/s (0.75 m/s); however, control of the boat is difficult to maintain below that velocity. For example, in tidal streams the stream velocity will often vary from 0 to several feet per second; therefore, it is not always possible to maintain an angle as large as 45°, and the measurement must be made using smaller angles.

ANGLE OBSERVER

A second man alines the dial of the vane indicator through its sighting device and, upon receiving the audible signal from the pulse counter, he reads the angle formed by the vane with respect to the true course. He reports the angle to the notekeeper who then records it. If the boat has strayed from the true path, the angle reader should sight parallel to the cross-section markers rather than at the markers themselves.

NOTEKEEPER

The notekeeper has several functions to perform. Prior to the measurement it is his responsibility to see that the preparation of all equipment pertaining to the rate indicator and counter and to the sonic sounder is completed satisfactorily. That includes not only equipment assembly but also selection of appropriate instrument settings.

The accuracy of the sonic sounder varies with changes in the velocity of sound in water, which in turn varies slightly with temperature, dissolved solids, and other variables. Thus sounder output should be compared to a known depth. Any significant error detected in the comparison can be expressed as a percentage of the known depth, and this percentage would be applicable to all depths determined by the sonic sounder. Consequently, this percentage correction should be applied to the total area and total discharge.

A check to determine that the current meter and rate indicator are functioning properly is also desirable. Such a check can be made by comparing the indicated velocity to a velocity determined by the Price current meter. This test is intended to determine proper operation only and is not intended for calibration purposes.

It is the notekeeper's responsibility to operate the controls provided on the equipment for starting and stopping the counter. It is important to the accuracy of the measurement that this unit promptly begin and end its operation at the first and second floats, respectively. This is accomplished by operating the "start" and "stop" buttons on the panel of the counter in the following manner:

1. Approximately 1 s before the boat reaches the first float, the "start" button is depressed; then it is released at the moment of passing. This marks the sounder chart, resets the counter, and starts it.

Marking of the sounder chart and sounding of the beeper (tone signal) will be automatic during the measurement. This will occur at regular intervals as determined by the setting of the range switch on the panel of the counter unit.

2. At the moment the bow of the boat reaches the second float, the "stop" button is depressed for 1 s and then released. This marks the sounder chart, signifying the end of the measurement, and stops the counter.

During the measurement the notekeeper records the angle reading at each signal as it is called out by the angle reader. He also reads and records the instantaneous "velocity" from the rate indicator meter at the same time. Readings are taken at all observation points as defined by the tone signals, including the two float positions.

If the time between consecutive measurements is short, it is desira-

ble to leave the operating switch of the sonic sounder in the "normal" position until the measurement series is concluded. In this way the chart continues to advance between measurements, but there are no vertical line markings. This absence of vertical lines provides a gap on the chart that clearly sets off one measurement from another.

COMPUTATION OF THE DISCHARGE MEASUREMENT

COMPUTATION OF UNADJUSTED DISCHARGE

The method of computing discharge measured by the moving-boat technique is basically similar to the computation method used for conventional current-meter discharge measurements. (See p. 80–82). The discharge in a subsection, q, is the product of the subsection area of the stream cross section and the average velocity in the subsection. The midsection method of computation is used in which it is assumed that the average velocity at the observation vertical is the average velocity for a rectangular subsection. The rectangular subsection extends laterally from half the distance from the preceding observation vertical to half the distance to the following observation vertical and extends vertically from the water surface to the sounded depth (fig. 112). The summation of the discharges of the subsections, $q_1, q_2, q_3, \ldots q_n$, is the total unadjusted discharge of the stream. A step-by-step outline of the computation procedure, which refers to the sample measurement notes shown in figure 113, is given here as a guide to the hydrographer who computes the discharge from the field observations.

1. The data in the first column of figure 113 are the angle readings recorded by the notekeeper during the measurement. Because these readings begin and end at the float positions (there are no edge-of-water readings), they represent the values observed at locations 2, 3, 4, . . . $(n-1)$.

2. Each value in column 2 represents an incremental distance the boat has traveled along the cross-section path between two consecutive observation points. For example, α_x (col. 1) represents the angle reading at location x, and L_{b_x} (col. 2) is the incremental distance the boat has traveled along the true course, extending from the previous observation point, $x-1$, to the location x where the reading was taken.

The values in column 2 can be read directly from a table (fig. 108) by using the angle values recorded in column 1 and the range number as determined by the range selection on the counter unit. Two exceptions are the first and last values in the column, representing the distance to each float from its nearest edge of water. They are deter-

mined by direct measurement prior to the actual run. This is necessary because the actual boat run does not begin and end at the edge-of-water positions and thus is not set up to measure those distances. Therefore, the beginning angle reading, α_2, at the first float is not used for obtaining distance from the edge of water to that float. It should also be noted that L_{b_3} is always recorded as one-half of the value found in the table. This is necessary because the counter unit has been programed to signal at a "half-count" on its first count routine. All remaining values can be recorded directly from the table of L_b values, without any changes, with the possible exception of the one determined from the last angle reading which was made at the second float. This angle reading may or may not have been made at

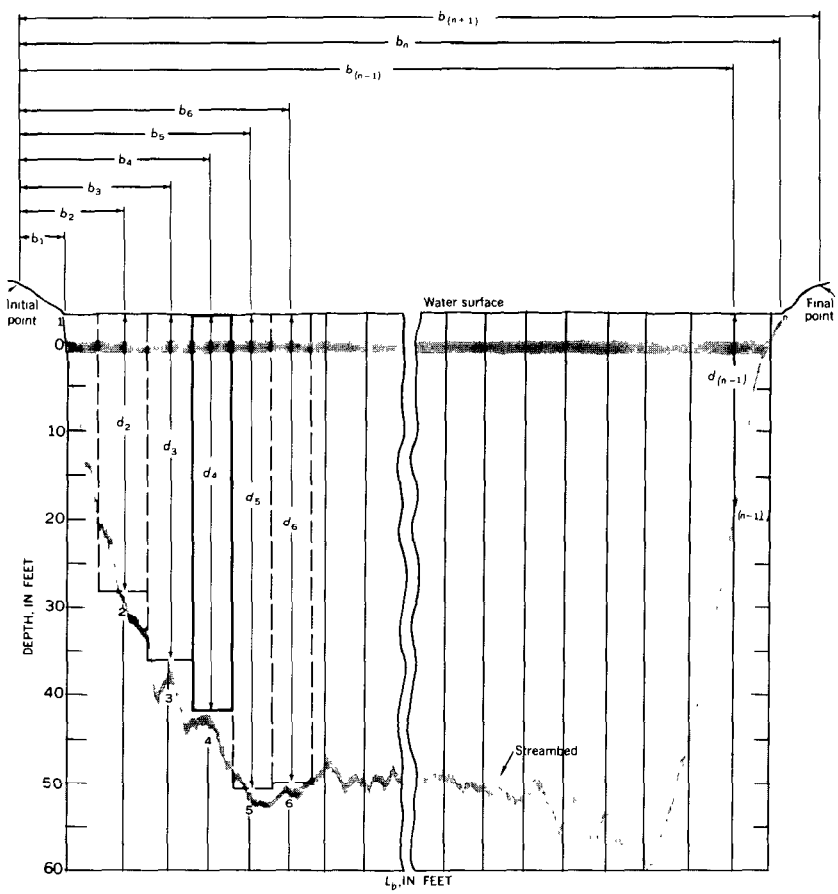

FIGURE 112.—Definition sketch of midsection method of computation superimposed on a facsimile of a sonic-sounder chart.

the end of a full count by the counter unit. In the sample measurement the value recorded was three-fourths of that in the table because the sounder chart distance between the last two vertical markings was approximately three-fourths of the normal spacing.

3. Each value recorded in column 3 represents the distance from the initial point (marker) to the observation point where the data were collected. The data in column 2, together with the "distance to float" and the "distance to marker" values recorded on the front sheet of the discharge measurement notes (fig. 113) are used to obtain these cumulative distances. For a moving-boat measurement, these distances are defined as follows:

b_1 = distance from initial point (marker) to edge of water

$b_2 = b_1$ + measured distance to float from edge of water

$b_3 = b_2 + L_{b_3}$

$b_4 = b_3 + L_{b_4}$

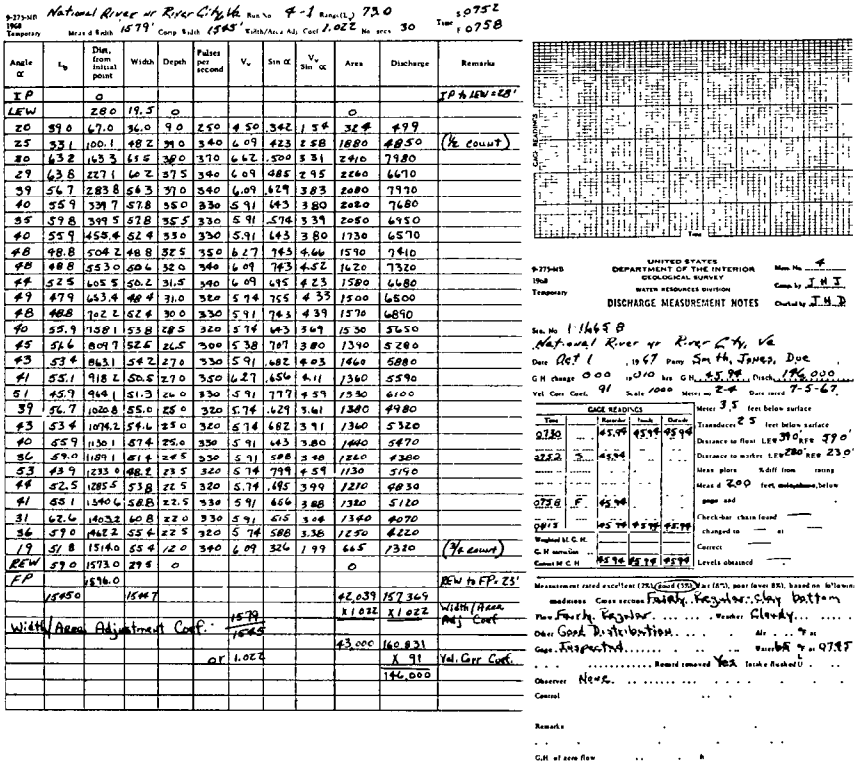

FIGURE 113.—Sample computation notes of a moving-boat measurement.

. . . . . .

$b_{(n-1)} = b_{(n-2)} + L_{b_{(n-1)}}$

$b_n = b_{(n-1)}$ + measured distance from float to edge of water

$b_{(n+1)} = b_n$ + distance to final point (marker).

4. Each of the incremental widths in column 4 represents the distance that extends laterally from half the distance from the preceding meter location $(x-1)$, to half the distance to the next, $(x+1)$. These values are obtained by using the distances in column 3.

5. Each of the values in column 5 represents the stream depth at a sampling point in the cross section. These values are obtained by adding the transducer depth to each of the depth readings recorded on the sounder chart at the sampling locations.

6. The data in column 6 are the pulses-per-second readings recorded by the notekeeper during the measurement.

7. The values recorded in column 7 represent the instantaneous velocity of the water past the vane at each observation point. They are read directly from the meter-rating table (fig. 108), using the pulses-per-second values of column 6.

8. The data in column 8 are the sine function values of the angle readings in column 1. These values may be obtained from the sine table in figure 108, using the angle readings of the first column.

9. Each of the values in column 9 represents the stream velocity normal to the cross section at that particular sampling point.. To obtain these values, it is necessary to multiply each V_V value in column 7 by the corresponding sin α value in column 8.

10. The values in column 10 represent the individual subsection areas for the measurement. They are obtained by multiplying the widths of column 4 by their corresponding depths in column 5. The incremental areas are then summed to provide the total unadjusted area for the measurement.

11. Each quantity in column 11 represents the unadjusted discharge through one of the subsections of the discharge measurement. These values are summed to provide the total unadjusted discharge of the measurement.

12. This column is used for recording any descriptive remarks pertaining to the measurement.

ADJUSTMENT OF TOTAL WIDTH AND AREA

As explained on page 186, the relation expressed by the equation $L_b \approx L_V \cos \alpha$ is used to obtain the incremental widths across the stream. This equation is based on the assumption that a right-triangle relationship exists among the velocity vectors involved. If the flow is not normal to the cross section, that assumed situation does not exist and the use of the equation can result in a computed width that is too

large or too small (fig. 114), depending on whether the vector quantity representing the oblique flow has a horizontal component that is opposed to, or in the direction of, that of the boat path. Thus in figure 114 the computed width would be AB' of the right triangle $AB'C$ rather than the true width AB of oblique triangle ABC. In this case the computed width is too large, whereas the computed width DE' of right triangle $DE'F$ is less than the actual width DE of oblique triangle DEF.

Ideally the correction for error in the computed width would be applied to that particular increment in the cross section where the error occurred. However, in practice only the overall width is directly measured, and thus only the total width is available for comparison with the computed quantities. Therefore, if the sum of the computed incremental widths does not equal the total measured width of the cross section, it is assumed that each increment requires a proportionate adjustment.

The moving-boat method uses the relation between the measured and computed widths of the cross section to determine a width/area adjustment factor. To obtain that coefficient, the measured width of the cross section is divided by its computed width, that is

$$k_B = \frac{B_m}{B_c} \tag{22}$$

where

k_B = width/area adjustment factor,
B_m = measured width of cross section, and
B_c = computed width of cross section.

The coefficient (k_B) is then used to adjust both total area and total discharge of the measurement, on the basis of the previously mentioned assumption that the error in width is evenly distributed, on a percentage basis, across each width increment of the cross section.

The computation notes in figure 113 provide an example of the application of a width/area adjustment coefficient.

ADJUSTMENT OF MEAN VELOCITY AND TOTAL DISCHARGE

During a moving-boat discharge measurement, the current meter is set at a predetermined fixed depth of from 3 to 4 ft (0.9 to 1.2 m) below the water surface. In other words, this technique uses the subsurface method of measuring velocity. (See page 136.) The measurement is computed by using constant-depth subsurface velocity observations without adjustment coefficients, as though each observed velocity were a mean in the vertical. In adjusting the computed discharge, each measured velocity should ideally be multiplied by a coefficient to adjust it to the mean velocity in its vertical. However, it

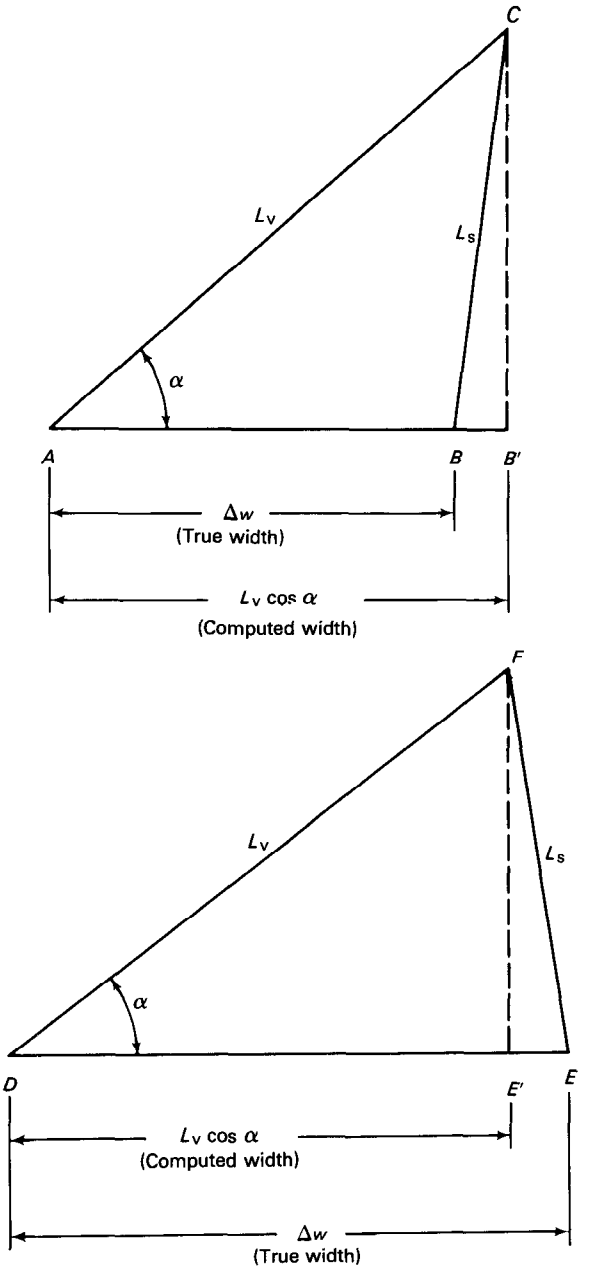

FIGURE 114.—Comparison of actual and computed values of incremental widths.

is assumed that in the larger streams where the moving-boat technique would be applicable, these coefficients would be fairly uniform across a section, thus permitting the application of an average velocity coefficient to the total discharge. Information obtained from several vertical-veolocity curves, well distributed across the measurement section, would be needed to determine a representative velocity coefficient for the total cross section.

DETERMINATION OF VERTICAL-VELOCITY ADJUSTMENT FACTOR

Vertical-velocity curves (p. 132–133) are constructed by plotting observed velocities against depth. The vertical-velocity curve method calls for a series of velocity observations (by conventional methods) at points well distributed between the water surface and the streambed. Normally these points are chosen at 0.1-depth increments between 0.1 and 0.9 of the depth. Observation should also be made at least 0.5 ft (0.15 m) from the water surface and 0.5 ft (0.15 m) from the streambed; for this particular application, a velocity reading should be made at the moving-boat sampling depth of from 3 to 4 ft (0.9 to 1.2 m) below the water surface. Once the velocity curve has been constructed, the mean velocity for the vertical can be obtained by measuring the area between the curve and the ordinate axis with a planimeter, or by other means, and then dividing this area by the length of the ordinate axis.

To obtain a velocity-correction coefficient at location x in the cross section, the mean velocity in the vertical is divided by the observed velocity at the measured depth, that is,

$$k_V = \frac{\overline{V}}{V}, \tag{23}$$

where

k_V = vertical-velocity adjustment factor,
$\overline{V}$ = mean velocity in the vertical, and
V = observed velocity (3- or 4-ft depth).

To arrive at a representative average coefficient, coefficients should be determined at several strategically located verticals that are representative of the main portion of the streamflow. Once an average coefficient has been determined, it should not be necessary to redetermine it each time when making future discharge measurements at the same site. However, it would be necessary to test its validity at several widely varying stages and, in estuaries, at widely different parts of the tidal cycle.

Investigations on the Mississippi River at both Vicksburg and St. Louis, on the Hudson River at Poughkeepsie, and on the Delaware

River at Delaware Memorial Bridge all indicated coefficients that lie in the narrow range of 0.90 to 0.92 for adjusting the subsurface velocity to the mean velocity. Carter and Anderson (1963) present a table of velocity ratios and standard deviations for various relative depths. That table indicates that for depths of 10 ft (3 m) or more, an average coefficient of 0.90 is satisfactory for adjusting velocities obtained 4 ft (1.2 m) below the surface to mean velocity. The sample from which the data in that table were obtained consisted of 100 stream sites at each of which 25 to 30 verticals had been used. Similar conclusions concerning subsurface velocity coefficients can be drawn from table 2 (p. 132).

APPLICATION OF VELOCITY ADJUSTMENT TO COMPUTED DISCHARGE

Application of the vertical-velocity adjustment factor is made immediately after the width-area adjustment has been applied to the computed discharge. In other words, after the computed discharge has been multiplied by the width-area adjustment factor, the resulting product is multiplied by the vertical-velocity adjustment factor. The final product is the adjusted, or "true," discharge for the measurement. (See fig. 113.)

CHAPTER 7.—MEASUREMENT OF DISCHARGE BY TRACER DILUTION

GENERAL

The measurement of stream discharge by dilution methods depends on the determination of the degree to which an added tracer is diluted by the flowing water. Any substance can be used as a tracer if it meets the following criteria:

1. It dissolves readily in water at ordinary temperatures.
2. It is either absent in the water of the stream or present only in very low concentrations.
3. It is not decomposed in the water of the stream and is not retained or absorbed in significant quantity by sediments, plants, or other organisms.
4. It can be detected in extremely low concentrations by simple methods.

5. It is harmless to man and animals in the concentration it assumes in the stream.

Until recent years chemical salts, primarily common salt (NaCl), were usually used as the tracers injected into the streams. The use of salt tracers, on all but the smallest streams, was limited, however, to the sudden-injection method, because of the difficulty of handling the large quantities of salt solution required by the usually more accurate constant-rate-injection method. In recent years, and particularly in the U.S.A., the use of dye tracers in the constant-rate-injection method has become the most popular method of discharge measurement by tracer dilution. That has resulted from the development of fluorescent dyes and fluorometers that can detect those dyes at very low concentrations. The use of fluorescent dyes is not as popular in Europe as in the U.S.A. There, colorimetric analysis, using sodium dichromate as the tracer dye, is the most widely used means of measuring discharge by the constant-rate-injection method. However, where the sudden-injection method is to be used, the use of common salt as a tracer is still preferred, particularly on the smaller streams, because of the greater ease in handling salt and in determining concentrations. Radioactive elements, such as gold 198 and sodium 24, have also been used in recent years as the tracers in the sudden-injection method, but the use of such elements is still (1980) considered experimental.

The tracer-dilution methods of measuring discharge are more difficult to use than the conventional current-meter method, and under most conditions the results are less reliable. Dilution methods should therefore not be used when conditions are favorable for a current-meter measurement of discharge. Tracer-dilution methods of measuring discharge in open channels can be used advantageously in rough channels that carry highly turbulent flow.

THEORY OF TRACER-DILUTION METHODS

In the tracer-dilution methods of measuring discharge, a tracer solution is injected into the stream to be diluted by the discharge of the stream. From measurements of the rate of injection, the concentration of the tracer in the injected solution, and the concentrations of the tracer at a sampling cross section downstream from the injection site, the stream discharge can be computed.

Either of two methods may be used for determining the discharge of a stream by tracer dilution. The first method, the constant-rate-injection method, requires that the tracer solution be injected into the stream at a constant flow rate for a period sufficiently long to achieve a constant concentration of the tracer in the streamflow at the downstream sampling cross section. The second method, the sudden-

injection method, requires the instantaneous injection of a slug of tracer solution and an accounting of the total mass of tracer at the sampling cross section. Another use is often made of the sudden-injection method that is not concerned with degree of dilution. Where the cross-sectional area of the flow is constant, as in pressure conduit, the sudden-injection method may be used to determine the velocity of flow; discharge can then be computed by using that velocity and the known cross-sectional area. (See p. 533.)

THEORY OF THE CONSTANT-RATE-INJECTION METHOD

A constant-rate-injection system is shown schematically in figure 115. If the tracer is injected for a sufficiently long period, sampling of the stream at the downstream sampling cross section will produce a concentration-time curve similar to that shown in figure 116. The stream discharge is computed from the equation for the conservation of mass, which follows:

$$QC_b + qC_1 = (Q + q)C_2 \tag{24}$$

or

$$Q = \left[\frac{C_1 - C_2}{C_2 - C_b}\right] q,$$

where

q is the rate of flow of the injected tracer solution,
Q is the discharge of the stream,
C_b is the background concentration of the stream,
C_1 is the concentration of the tracer solution injected into the stream, and
C_2 is the measured concentration of the plateau of the concentration-time curve (fig. 116).

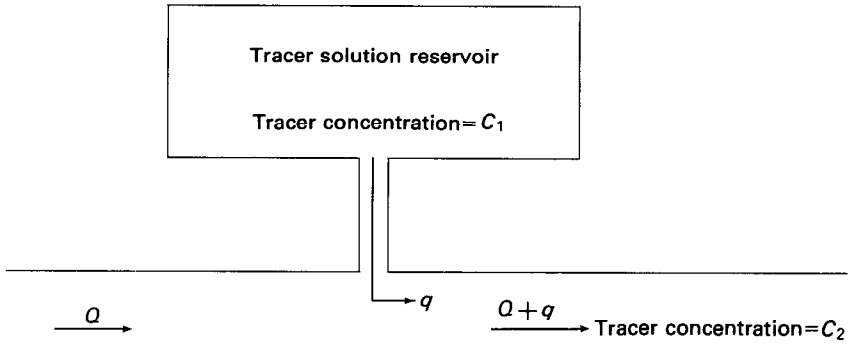

FIGURE 115.—Constant-rate-injection system.

THEORY OF THE SUDDEN-INJECTION METHOD

If a slug of tracer solution is instantaneously injected into a stream, sampling of the stream at the downstream sampling cross section will produce a concentration-time curve similar to that shown in figure 117. The equation for computing stream discharge, which is again based on the principle of the conservation of mass, is

$$Q = \frac{V_1 C_1}{\int_0^\infty (C - C_b) dt}, \tag{25}$$

where

Q is the discharge of the stream,
V_1 is the volume of the tracer solution introduced into the stream,
C_1 is the concentration of the tracer solution injected into the stream,
C is the measured tracer concentration at a given time at the downstream sampling site,
C_b is the background concentration of the stream, and
t is time.

The term $\int_0^\infty (C - C_b)\, dt$ is the total area under the concentration-time curve. In practice the term $\int_0^\infty (C - C_b) dt$ can be approximated by the term

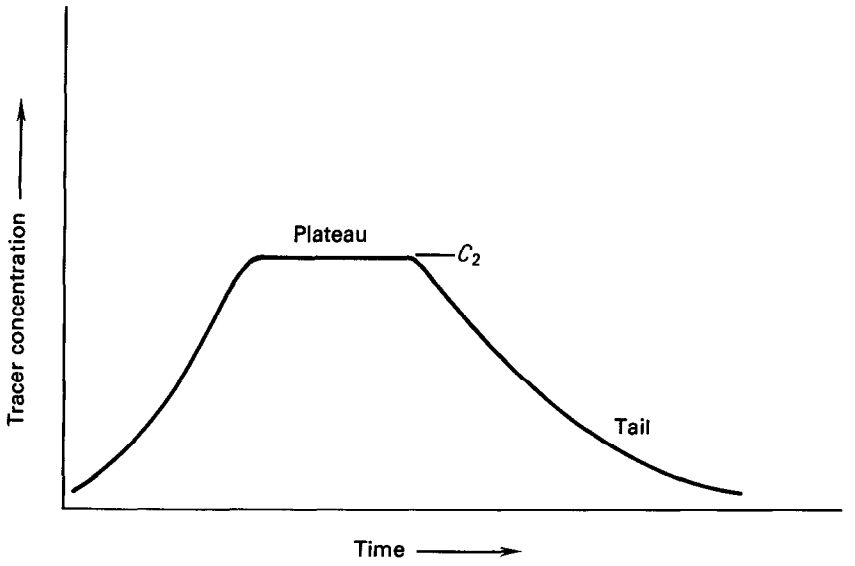

FIGURE 116.—Concentration-time curve at downstream sampling site for constant-rate injection.

$$\sum_{i=1}^{N} (C_i - C_b)(t_{i+1} - t_{i-1})/2,$$

where

i is the sequence number of a sample,
N is the total number of samples, and
t_i is time when a sample, C_i, is obtained.

FACTORS AFFECTING THE ACCURACY OF TRACER-DILUTION METHODS

Even if it is assumed that measurements of concentrations and of the injection rate are error free, there still remain three factors that affect the accuracy of tracer-dilution methods of measuring discharge. Those factors are stream turbidity, loss of tracer between the injection site and the downstream sampling site, and incomplete mixing throughout the stream cross section before the downstream sampling section is reached.

TURBIDITY

Turbidity may either increase or decrease the recorded tracer fluorescence depending upon the relative concentrations of tracer and turbidity (Feuerstein and Selleck, 1963). To minimize the effect of turbidity, samples should be permitted to stand long enough to allow

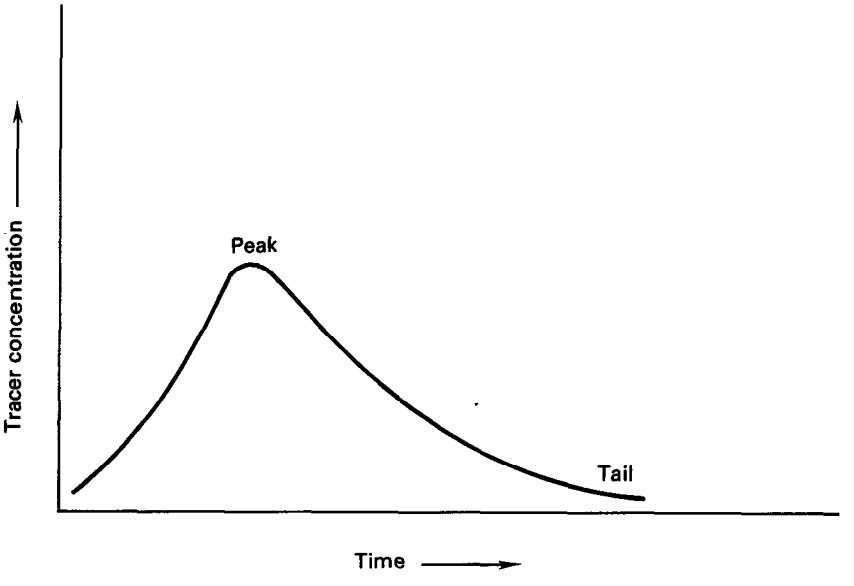

FIGURE 117.—Concentration-time curve at downstream sampling site for sudden injection.

suspended solids to settle prior to fluorometric analysis (p. 231, 240). Use of a centrifuge for the purpose of separating the suspended solids is even more effective, but a centrifuge is seldom used for that purpose in stream-gaging work.

LOSS OF TRACER

The computation of stream discharge, as mentioned earlier, is based on equations for the conservation of mass. Consequently, the accuracy of the computed discharge will be adversely affected if some of the tracer is lost in the reach of channel between the injection site and the downstream sampling site. Tracer losses are primarily due to sorption and chemical reaction between the tracer and one or more of the following: streambed material, suspended sediments, dissolved material in the river water, plants, and other organisms. For most of the tracers used, chemical reaction is a minor factor in comparison with sorption. The degree of tracer loss by sorption for a particular tracer varies primarily with the type and concentration of suspended and dissolved solids in the water. In routine stream gaging by the tracer-dilution method no attempt is made to quantify tracer loss by sorption; instead, the "best" tracer available from the standpoint of being least affected by sorption is used.

Photochemical decay is also a source of tracer loss which varies with the tracer material used and its residence time in direct sunlight. Loss from that source is usually negligible, even with fluorescent dyes, if the proper dye is used and if residence time in direct sunlight is limited to only a few hours, as it usually is in stream-gaging work.

Equations 24 and 25 show that loss of tracer will result in a computed discharge that exceeds the true stream discharge.

CRITERIA FOR SATISFACTORY MIXING

Tracer-dilution measurements require complete vertical and lateral mixing at the sampling site. Vertical mixing is usually accomplished very rapidly compared to lateral mixing; therefore, the distance required for lateral mixing is the primary consideration. Frequently, long reaches are needed for complete lateral mixing of the tracer. The mixing distance will vary with the hydraulic characteristics of the reach. Engmann and Kellerhals (1974) have demonstrated that ice cover significantly reduces the mixing capacity of a reach of river.

When the constant-rate-injection method is used, complete mixing is known to have occured when the concentration C_2, shown in figure 116, has the same value at all points in the downstream sampling cross section. When the sudden-injection method is used, complete

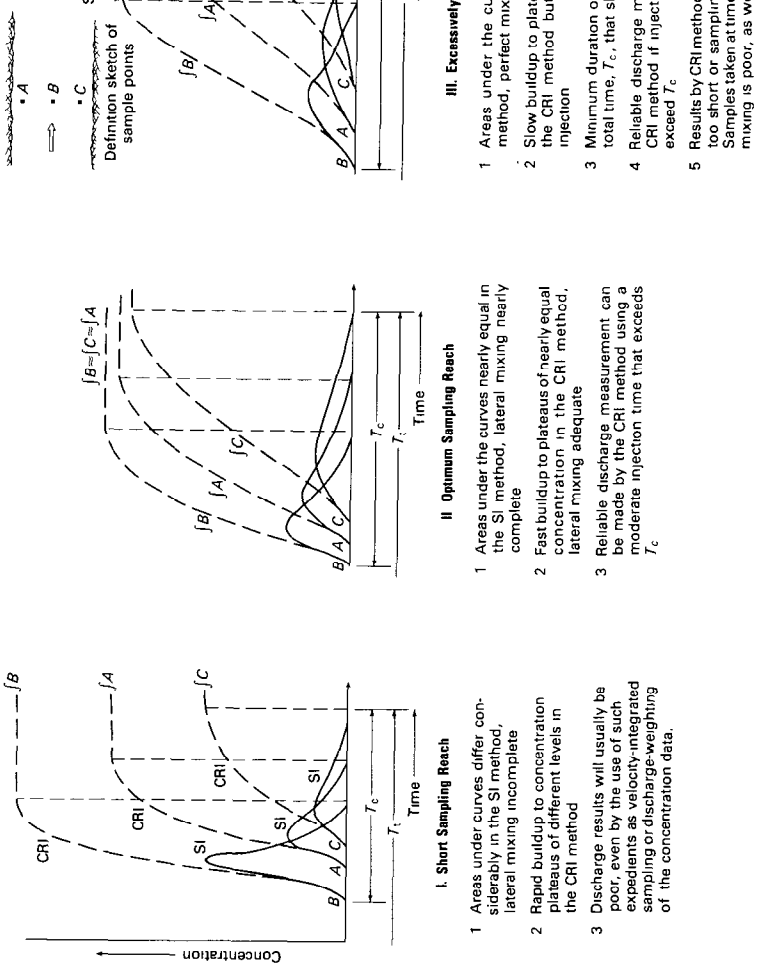
mixing is considered to have occurred when the area under the concentration-time curve, shown in figure 117, has the same value at all points in the downstream sampling section.

For a reach of channel of given geometry and stream discharge, the length of reach required for adequate mixing of the tracer is the same for either of the two methods of tracer injection. Several formulas are available for estimating the required mixing length for a particular set of conditions, but these formulas, while useful as guides, are too simplistic to give adequate consideration to the degree of mixing desired. Perfect mixing is seldom the optimum goal (see below) because perfect mixing usually requires an extremely long reach of channel, along with a correspondingly long period of injection in the constant-rate-injection (CRI) method and a correspondingly long period of sampling in the sudden-injection (SI) method.

Figures 116 and 117 are only rudimentary illustrations of the two methods. For either method to be successful an understanding is needed of the interrelations among mixing length and injection and sampling times. Figure 118 attempts to illustrate those interrelations for both types of injection. It is important to realize that unless adequate mixing is known to exist at a given sampling site, the tracer cloud in the SI method must be sampled for its entire time of passage at several locations laterally in the channel, such as at A, B, and C in figure 118. Similarly, in the CRI method the plateau concentration must be sampled at several locations laterally in the channel. Experience indicates that regardless of method or stream size, at least three lateral sampling points should be used at each sampling site.

Figure 118 indicates that there is an optimum mixing length for a given stream reach and discharge. Use of too short a distance will result in an inaccurate accounting of the tracer mass passing the sampling site. Use of too great a distance will yield excellent results, but only if it is feasible to inject the tracer for a long enough period (CRI method) or to sample for a long enough period (SI method). An optimum mixing length is one that produces mixing adequate for an accurate discharge measurement but does not require an excessively long duration of injection or sampling.

As mentioned earlier, figure 118 shows that the tracer cloud resulting from a sudden injection must be sampled at the sampling site from the time of its first appearance there until the time (T_t) of its disappearance at all points in the sampling cross section. For the same mixing reach and discharge, if the CRI method is used, a plateau will first be reached at all points in the sampling cross section at time T_t after injection starts at the injection site. Thus, it is seen that for the CRI method the duration of injection must at least be equal to T_t and injection should continue long enough thereafter to



I. Short Sampling Reach

1. Areas under curves differ considerably in the SI method, lateral mixing incomplete
2. Rapid buildup to concentration plateaus of different levels in the CRI method
3. Discharge results will usually be poor, even by the use of such expedients as velocity-integrated sampling or discharge-weighting of the concentration data.

II Optimum Sampling Reach

1. Areas under the curves nearly equal in the SI method, lateral mixing nearly complete
2. Fast buildup to plateaus of nearly equal concentration in the CRI method, lateral mixing adequate
3. Reliable discharge measurement can be made by the CRI method using a moderate injection time that exceeds T_c

III. Excessively Long Sampling Reach

1. Areas under the curves are identical in the SI method, perfect mixing
2. Slow buildup to plateaus of equal concentration in the CRI method but only after a long period of injection
3. Minimum duration of constant injection is equal to total time, T_c, that slug dye cloud is present
4. Reliable discharge measurement can be made by CRI method if injection period is long enough to exceed T_c
5. Results by CRI method will be poor if injection time is too short or sampling is discontinued too soon Samples taken at time S would give impression that mixing is poor, as well as suggesting loss of dye

FIGURE 118.—Comparison of concentration-time curves obtained by SI and CRI methods, observed at three points in sampling cross section, for sampling reaches of three different lengths.

insure adequate sampling of the plateau. It should be noted that a stable condition of mixing is usually first attained in midchannel. Tracer lag along the streambanks will generally prolong the time required for complete lateral mixing.

The CRI method has become increasingly popular because reliable injection apparatus is available and the sampling process is relatively simple. If an injection period well in excess of T_c is used, the sampling can be done leisurely at several points in the sampling cross section. In the SI method the injection is simple, but the sampling process is much more demanding. More reliable results are usually obtained by the CRI method.

Figure 118 indicates that a satisfactory discharge measurement requires "nearly equal" areas under the concentration-time curves for the sampling points in the SI method and "nearly equal" concentration plateaus for the sampling points in the CRI method. A numerical criterion—P_m, the percentage of mixing—is often used as a quantitative index of the consistency of sampling results for the sampling cross section. A satisfactory discharge measurement can usually be obtained if the value of P_m is 95 percent or greater. The computation of P_m is discussed in the paragraphs that follow.

Percentage of mixing, P_m, is defined in this manual by the equation

$$P_m = 100 - \{|X_A - X_m|Q_A + |X_B - X_m|Q_B + |X_C - X_m|Q_C + \ldots\}\frac{50}{X_m Q}, \quad (26)$$

where

$X_A, X_B, X_C, \ldots$ are the areas under the concentration-time curves or, for constant-rate injection, the C_2 concentrations at the points A, B, C, . . . across the sampling section;

X_m is the mean area under the concentration-time curves or, for constant-rate injection, the mean C_2 concentration for points A, B, C, . . . across the sampling section;

$Q_A, Q_B, Q_C, \ldots$ are the subsection discharges applicable to the points, A, B, C, . . .;

Q is the total stream discharge.

If the distribution of discharge is unknown at the sampling section, the cross-sectional subareas applicable to each point should be used in place of Q_A, Q_B, Q_C; total cross-sectional area should be used in place of Q. If both discharge and area distribution are unknown, as will often be the case, the appropriate widths may be used. Terms $|X_A - X_m|$, $|X_B - X_m|$, $|X_C - X_m|$, . . . are absolute values.

The percentage of mixing can also be determined graphically, as shown in figure 119. Values of C_2 or $\int_0^\infty (C - C_b)dt$, depending on the

injection method used, are plotted for each sampling point against the distance from an initial point at water's edge. The mean value C_2 or $\int_0^\infty (C - C_b)dt$ is determined by dividing the area under the distribution curve for C_2 or $\int_0^\infty (C - C_b)dt$ by the total width of the section. The percentage of mixing, P_m, is then given as

$$P_m = \left(\frac{A}{A + B}\right) 100 \tag{27}$$

where

A is the area under the C_2 distribution and mean C_2 curves, or the area under the $\int_0^\infty (C - C_b)dt$ distribution and mean $\int_0^\infty (C - C_b)dt$ curves;

B is the area above the C_2 distribution and under the mean C_2 curves or the area above the $\int_0^\infty (C - C_b)dt$ distribution and under the mean $\int_0^\infty (C - C_b)dt$ curves.

The graphical technique illustrated in figure 119 can also be used if the distribution of discharge or area is known. The only change in the procedure that is required is a change in the abscissa of figure 119. In place of "distance from edge of water" either cumulative discharge or cumulative area from edge of water is substituted.

CALIBRATION OF MEASUREMENT REACH

Several theoretical studies have been made by the U.S. Geological Survey (for example, Yotsukura and Cobb, 1972) in which equations have been derived for determining the length of measurement reach required for satisfactory or complete mixing. However, the derived equations cannot be applied in the field without detailed information

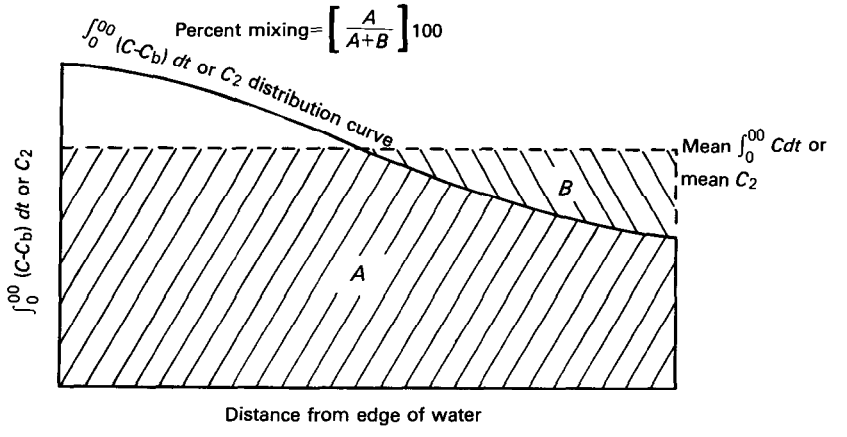


FIGURE 119.—Concentration-distribution curve illustrating the graphical method of determining the percentage of mixing.

on channel geometry and velocity distribution for the reach of channel. Consequently several gross formulas have been developed from the theoretical equations strictly for use as guides in determining a satisfactory length of measurement reach. Some of the simplified formulas follow:

a. Point injection at midchannel (English units)—

1. $$L=0.25\frac{V}{(gDS)^{1/2}}\frac{W^2}{D}, \tag{28}$$

where

L is distance downstream from the injection point,
V is mean velocity,
g is acceleration of gravity,
D is mean depth,
S is gradient of water surface or streambed, and
W is stream width.

2. $$L=0.6\frac{R^{1/6}}{ng^{1/2}}\frac{W^2}{D}, \tag{29}$$

where R is the hydraulic radius and n is the Manning roughness coefficient.

3. $$L=2V\ \frac{(W^2)}{D}\cdot \tag{30}$$

b. Point injection at bankside (English units)—

$$L=8V\frac{W^2}{D}. \tag{31}$$

Studies indicate that if more than one injection point is used, the mixing distance will vary inversely with the square of the number of injection points, provided that the injection points are located so that the dye will disperse equal distances both to the left and right of the injection points. This statement may seldom hold true for natural stream conditions, but it does indicate that the mixing length may be shortened considerably by using additional injection points.

In Europe the formula commonly used as a guide for determining the required length, L, between the injection site and sampling section is

$$L=0.13C\ \frac{(0.7C+6)}{g}\ \frac{b^2}{h}\text{(metric units)}, \tag{32}$$

where

b is the average width of the wetted cross section,
h is the average depth of flow,
C is the Chezy coefficient for the reach ($15<C<50$), and
g is acceleration of gravity.

Equation 32 is intended for use where injection is made at a single point in midstream.

Before making a discharge measurement by the tracer-dilution method, the proposed measurement reach should be calibrated to determine the length required for adequate mixing and the possibility of significant tracer loss. If repeated tracer-dilution measurements of the stream are to be made, it will be especially advantageous to make the calibration study comprehensive. One of the equations, 28 to 32, may be used as a guide in selecting a length of reach for the calibration tests; the quantity of tracer to be used for any given discharge is discussed later on pages 235–237. Instructions for calibration testing follow.

Select an injection site on the stream, and on the basis of one of the equations, 28 to 32, select several downstream sampling sites. Inject the tracer and then sample the water at three or more points in the cross section at each of the selected sampling sites. Take adequate samples at each point to define the plateau of the concentration-time curve if the constant-rate-injection method is used, or to define the entire concentration-time curve if the sudden-injection method is used. Analyze the samples and determine the percentage of mixing by use of equation 26. As mentioned earlier, for a satisfactory measurement of discharge the percentage of mixing should be at least 95. Mixing distances and losses may vary with discharge, and the reach may therefore have to be calibrated at more than one discharge. The quantity of tracer lost, if any, between successive sampling sites can be determined by a comparison of the values of C_2 (constant-rate-injection method) or of $\int_o^\infty (C - C_b)dt$ (sudden-injection method) obtained at each site. That determination provides a basis for the final selection of a sampling site from the several sites tested.

EFFECT OF INFLOW OR OUTFLOW BETWEEN INJECTION AND SAMPLING SITES

A satisfactory tracer-dilution measurement of discharge made in a reach that has no inflow or outflow between the injection and sampling sites will give the discharge occurring at all cross sections in the reach.

If tributary inflow enters the reach and if the tributary inflow is well mixed with the water in the main stream, the discharge measured will be that at the sampling site. If the tributary inflow is not well mixed, that fact may be evident from the difference in concentrations at the various sampling points in the sampling cross section; a low percentage of mixing would indicate that the particular sampling site could not be used for a satisfactory measurement of discharge.

If outflow occurs between the injection and sampling sites and if the tracer becomes completely mixed anywhere upstream from the outflow channel, the discharge measured at the sampling site will be that for the reach upstream from the outflow channel. If the tracer does not become completely mixed upstream from the outflow channel, the discharge measured at the sampling site will be indeterminate; the magnitude of the "measured" discharge will be dependent on the quantities of both tracer and water that are carried off in the outflow.

MEASUREMENT OF DISCHARGE BY FLUORESCENT DYE DILUTION

As mentioned earlier, the most popular type of tracer for the measurement of streamflow in the U.S.A. is fluorescent dye. The cost of the dye is relatively small because the quantity of dye needed for a discharge measurement is small; modern fluorometers are capable of accurately measuring dye concentrations of less than 1 μg/L (microgram per liter) and can detect concentrations as low as 0.02 μg/L.

FLUORESCENT DYES

Fluorescence occurs when a substance absorbs light at one wavelength and emits it at another, and usually longer, wavelength. The dyes commonly used as tracers are strongly fluorescent. They are organic dyes of the rhodamine family and are commercially available.

Dyes selected for use as tracers should (1) have a high detectability range, (2) have little effect on flora or fauna, (3) have a low sorption tendency, (4) have a low photochemical decay rate, (5) be soluble and disperse readily in water, (6) be chemically stable, (7) be inexpensive, (8) be easily separated from common background fluorescence, and (9) be easy to handle.

On the basis of recent studies in the U.S.A. on the adsorption potential and detectability of dyes, Rhodamine WT dye is recommended as the best dye available for use in dye-dilution measurements of discharge. Formerly used at times, but no longer recommended are Rhodamine B, BA, and Fluorescein.

FLUOROMETER

The fluorometer is an instrument that gives a measure of the strength of the light emitted by a fluorescent substance. Figure 120 is a schematic diagram of a fluorometer. The flurometer briefly described in this manual is the Turner model 111 fluorometer, and it is discussed because it is the instrument that is in general use by the U.S. Geological Survey. However, there are many satisfactory fluorometers that are commercially available, and for detailed in-

structions concerning any particular fluorometer it is necessary that the hydrographer consult the service manual prepared by the manufacturer of that instrument. The fluorometry techniques described in this manual are oriented toward use of the Turner fluorometer, but those techniques are applicable to most types of fluorometer. (Note.—The use of brand names in this manual is for identification purposes only and does not imply endorsement by the U.S. Geological Survey.)

DESCRIPTION OF FLUOROMETER

The principle of the operation of the Turner model 111 fluorometer is described in the operating manual (1963, p. 12) as follows:

This fluorometer is basically an optical bridge which is analogous to the accurate Wheatstone Bridge used in measuring electrical resistance. The optical bridge measures the difference between light emitted by the sample and that from a calibrated rear light path. A single photomultiplier surrounded by a mechanical light interrupter sees light alternately from the sample and the rear light path. Photomultiplier output is alternating current, permitting a drift-free A–C amplifier to be used for the first electronic stages. The second stage is a phase-sensitive detector whose output is either positive or negative, depending on whether there is an excess of light in the forward (sample) or rear light path, respectively. Output of the phase detector drives a servo amplifier which is in turn connected to a servo motor. The servo motor drives the light cam (and the "fluorescence" dial) until equal amounts of light reach the photomultiplier from the sample and from the rear light path. The quantity of light required in the rear path to balance that from the sample is indicated by the "fluorescence" dial. Each of this dial's 100 divisions add equal increments of light to the rear path by means of a light cam.

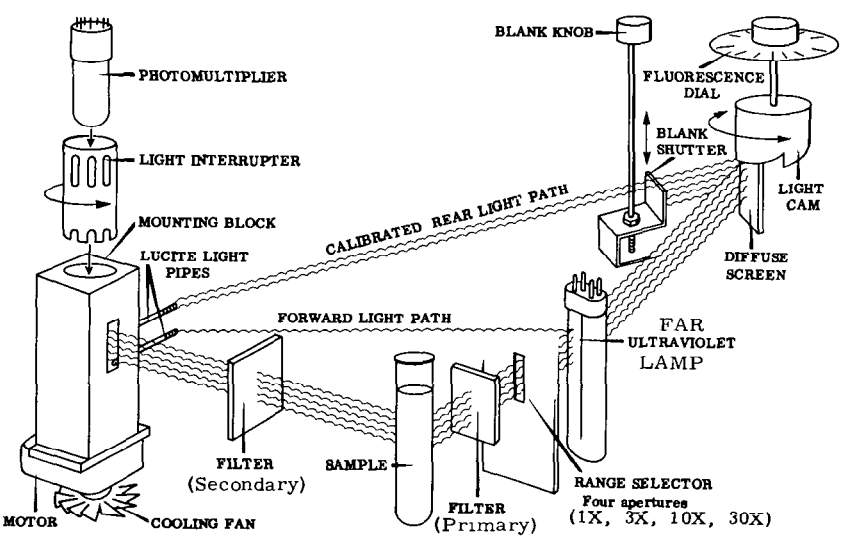

FIGURE 120.—Schematic diagram of the fluorometer (from G. K. Turner Associates, 1963, p.13).

Lamps.—At least three different lamps can be used as a light source for the fluorometer when the fluorescence of rhodamine dyes is tested. They are the general purpose ultraviolet lamp, the far ultraviolet lamp, and the green T–5 lamp. Although all three lamps work well, the far ultraviolet and green T–5 lamps are recommended as a light source because their outputs are compatible with the fluorescent properties of the dyes. Sensitivity of the fluorometer is increased approximately twofold to tenfold when the far ultraviolet and green T–5 lamps, respectively, are substituted for the general purpose ultraviolet lamp.

Filters.—The sensitivity of the fluorometer is directly related to the filter system employed. Light having undesirable wavelengths may be screened out by placing filters at two points in the fluorometer: (1) between the source light and the water sample and (2) between the water sample and the photomultiplier.

The filter (primary) recommended for use with rhodamine dyes for the absorbed light has a peak color specification of 546 mμ (millimicrons); that is, the greatest amount of light passed through the filter is at a wavelength of 546 mμ. Light at other wavelengths is subdued or eliminated. The recommended filter (secondary) for the emitted light has a peak color specification of 590 mμ. The peak color specifications for these filters are near the peak excitation and emittance wavelengths of the rhodamine dyes and will eliminate most natural background fluorescence. The filters may be used regardless of the type of lamp that is installed.

Doors.—Three main types of doors available for use with the fluorometer are the standard-cuvette (test tube) door, the temperature-stabilizing door, and flow-through door. All three doors are easily interchanged.

The standard-cuvette door is the easiest to use in the field for intermittent sampling and should be used with the green T–5 lamp. If the far ultraviolet lamp is used, a high-sensitivity kit should be installed on this door because it will increase the overall sensitivity of the fluorometer about tenfold. It is important to note that excessive sensitivity will be obtained if the high-sensitivity kit and green T–5 lamp are used together.

The temperature-stabilizing door is recommended for the final testing of samples. This door is similar to the standard-cuvette door with the high sensitivity kit but has, in addition, a water-cooled, copper block that surrounds the cuvette. Cooling water may be pumped or tap water of constant, or near-constant, temperature may be run through the door to stablize the sample temperature. Only round 12×75-mm cuvettes can be used with this door.

The flow through door permits continuous sampling which can be

recorded. A pump is used to circulate water from the stream through the cuvette in the door. The results may be recorded on any recorder with a 0 to 1 milliamp or 0 to 10 millivolt readout. The intake hose used with the flow-through door should be made of plastic or other nonabsorptive material. Different fittings and cuvette sizes are available for this door. The sensitivity of the flow-through door is about the same as that of the standard-cuvette door with the high sensitivity kit. That is so because of the larger cuvette used in the flow-through door.

Normally dye concentrations are not determined in the field because it is difficult to attain sufficient accuracy under such conditions. The flow-through door arrangement may be used for preliminary calibration of a reach, however. As a rule, bottle samples are collected and transferred to the laboratory for accurate fluorometric analysis.

EFFECT OF TEMPERATURE ON FLUOROMETRY

Accurate dilution discharge measurements require accurate fluorometry, and accurate fluorometry can only be attained in the laboratory where operating conditions are favorable. Temperature has a significant effect upon the fluorescence intensity of dyes. Fluorescence decreases with increasing temperature. This characteristic of the dyes has been investigated by several researchers, among them Feuerstein and Selleck (1963). For best results, all samples, including background and standard solutions, should be placed in a laboratory temperature bath and kept at constant temperature prior to fluorometric analysis. If the same temperature is used for all samples, no temperature corrections will be needed. If temperatures cannot be held constant, temperature corrections, as given in table 13 for Rhodamine WT dye, should be applied to dial readings or to concentrations.

Dunn and Vaupel (1965) point out the need for corrections to fluorometer dial readings as a result of changing compartment temperatures. However, tests by the U.S. Geological Survey showed that these corrections were needed only during the warmup period. A 1½-to 2-hr warmup will usually eliminate the need for this type of correction, although minor changes may still be observed thereafter. The warmup characteristics of each fluorometer should be determined. If possible, the fluorometer should not be operated where large temperature changes can occur rapidly.

CALIBRATION CHARACTERISTICS OF THE FLUOROMETER

Most fluorometers have a linear calibration ratio, meaning that dye concentration is directly proportional to the dial reading on the fluorometer and is related by the equation

TABLE 13.—*Temperature-correction coefficients for Rhodamine WT dye*

Temperature difference ($T_s - T$)[1]		Temperature-correction coefficient

[1] T_s is the standard cuvette-sample temperature and T is the cuvette-sample temperature at the time the sample was tested in the fluorometer.

$$C = aD, \tag{33}$$

where

C is the dye concentration of the sample tested,

a is a coefficient, and

D is the fluorometer dial reading for the sample tested.

Solutions of known concentration are tested with the fluorometer, and the relation between concentration and dial reading is determined from equation 33.

Some fluorometers, however, do not have linear calibration ratios, and it is therefore necessary to determine the nature of the relation between concentration and dial reading by testing with standard solutions over a wide range of concentrations. A plot of concentration versus fluorometer-dial reading will give the shape of the calibration relation for the particular fluorometer. Experience to date indicates that nonlinear response occurs more frequently and to a greater degree at the low end of the curve; special effort should be made, therefore, to define that part of the curve.

If a fluorometer is found to have a nonlinear calibration relation, the instrument should be returned to the manufacturer for replace-

ment of parts or adjustment. Before an instrument is returned, one should be certain that the relation is truly nonlinear and not the result of an error in calibration. Inadequate instrument warmup is frequently the cause of a nonlinear calibration. If the instrument has to be used and the calibration is nonlinear, the derived nonlinear calibration curve should be used.

It is recommended that, if possible, dial readings of less than 10 be avoided, because the normal instrument error inherent in fluorometer operation can result in relatively large percentage errors for low dial readings. Low dial readings can be avoided by use of the proper fluorometer aperture. For example, the Turner fluorometer has four apertures, each designed to allow the passage of a different amount of light (fig. 120). The amount of light passed at each scale is approximately proportional to scale number; that is, the 30× scale will pass about 30 times as much light as the 1× scale. The relation between scales, for any fluorometer used, should be determined by testing each of several samples of different dye concentrations on more than one scale. A plot of dial readings for one scale against corresponding dial readings on another scale will give the desired relation. It should be mentioned here that low dial readings are unavoidable when testing the background (natural) fluorescence of river water. (See p. 231.)

PREPARATION OF STANDARD DYE SOLUTIONS FOR FLUOROMETER CALIBRATION

In calibrating the fluorometer it is necessary to first prepare samples of dye solution of known relative concentration, then test the samples in the fluorometer, and finally relate the readings on the fluorometer dial to the known relative concentrations. This matter of relative concentrations should be explained at this point. The accurate determination of stream discharge depends on the measurement of concentrations relative to each other; the absolute values of the concentrations are of no importance as long as the values of the concentrations are all determined in the same manner and all bear the same ratio to the absolute or true concentrations. Where the term "concentration" is used in this manual, it refers to "relative concentration"; the two terms are used here interchangeably. The calibration characteristics of the fluorometer were discussed in the preceding section of this manual. This section explains the preparation of standard dye solutions of various concentrations for use in the calibration process.

Standard dye solutions are prepared by diluting, with known amounts of water, the dye solution furnished by the manufacturer of the dye. The relative concentration of the furnished solution is the value given by the manufacturer. For example, if the manufacturer's

20-percent dye solution is used, its relative concentration is 200,000,000 $\mu g/l$. If the relative concentration of that solution differs from the true or absolute concentration by some small percentage, all diluted samples that are prepared from that batch of dye solution will have relative concentrations that differ from their absolute values by that same small percentage. Chlorinated tapwater should not be used in the dilution, because the chlorine present in the water quenches the fluorescence of rhodamine dyes.

The equipment and materials needed to make the dilutions are listed below. Where glass is specified for the equipment, other nonabsorptive materials may also be used.

1. Volumetric flasks (glass) of 100, 250, 500, 1,000, and 2,000 mL capacity.
2. Volumetric pipettes (glass) in an assortment of sizes.
3. Beakers (glass), or 1-gal (3.75 mL) glass jars.
4. Wash bottles (polyethylene).
5. Sample bottles (glass).
6. Masking tape and pen.
7. Distilled water. River or chlorinated tap water should not be used; however, tap water exposed to the air for 24 hr will lose its chlorine.

The dilution process is performed in steps, as illustrated in the example shown below. The relative concentration at each step is computed from the equation

$$C_n = \frac{C_i V_i}{V_a + V_i} , \tag{34}$$

where

C_n is the new concentration,
C_i is the initial concentration,
V_i is the volume of initial concentration, and
V_a is the added volume of water.

A flow chart similar to that shown in the example below is recommended when making the dilute solutions.

Example.—The original dye solution, as obtained from the manufacturer, is a 20-percent solution of Rhodamine WT. In making the solutions of known relative concentration, the process will be checked by duplicating the procedure for each of two samples. In other words, two samples of equal size of the original solution, are diluted in precisely the same manner. The resulting two dilute solutions are each diluted further in the same manner, and so on. As a result we will have two independent sets of standard solutions for use in calibrating the fluorometer.

To get back to the dilution process, 20 mL of the original 20-percent

solution is diluted to 2,000 mL with pure water. The concentration of the resulting solution is computed by use of equation 34. The process is repeated twice, each time using the solution last obtained, as indicated in the following flow chart:

$$C_n = \frac{\text{20 mL of } (200\times10^6)\ \mu\text{g/L dye solution}}{\text{2,000 mL total solution}} = \frac{1}{100}(200\times10^6) = 2\times10^6\ \mu\text{g/L}$$

$$\downarrow$$

$$\frac{\text{20 mL of } (2\times10^6)\ \mu\text{g/L solution}}{\text{2,000 mL total solution}} = \frac{1}{100}(2\times10^6) = 20{,}000\ \mu\text{g/L}$$

$$\downarrow$$

$$\frac{\text{20 mL of 20,000}\ \mu\text{g/L solution}}{\text{2,000 mL total solution}} = \frac{1}{100}(20{,}000) = 200\ \mu\text{g/L}$$

The solution obtained, with concentration equal to 200 μg/L, is referred to in this manual as a working standard solution because any lesser concentration that may be desired can be prepared from it by one additional serial dilution. For example, a dilution ratio of 1/200 will provide a solution with a concentration as low as 1 μg/L. No dilution ratios of less than 1/200 should ever be used. The working standard solution should be stored for future use. Experience has indicated that standard solutions of 200 or more μg/L when properly stored in hard glass dark bottles out of direct light will keep for periods of at least 6 months. There is evidence, though not conclusive, to indicate that very weak standard solutions tend to deteriorate or to adhere slightly to the bottles in which they are stored.

The stored working standard solution may be used for periodically checking the fluorometer calibration to determine if changes in the calibration have occurred, and enough of the standard solution should be retained for future use if the same dye lot from the manufacturer is to be used for discharge measurements. New sets of standard solutions should be prepared after 6 months to avoid the risk of decay of fluorescence in the stored standard solutions. In addition, new sets should also be prepared when new batches of dye are to be used for discharge measurements because the dyes received from the manufacturer may vary from batch to batch.

If the fluorometer calibration is known to be linear, from previous tests using standard solutions made with distilled or unchlorinated tap water, only a limited few concentrations need be prepared and tested for the discharge-measurement calibration of the fluorometer. The concentrations prepared should approximate the plateau concentration expected in stream samples that will be taken during the discharge measurement.

OPERATION OF THE FLUOROMETER

The U.S. Geological Survey uses the Turner model 111 fluorometer. The fluorometer is operated in accordance with the following instructions.

Allow a warmup period of 1½ to 2 hr before any tests are made. This warmup period will permit the instrument temperature to stabilize. If possible, have all samples, including standard and background solutions, at the same temperature. Establish the zero point on the fluorometer by inserting the dummy cuvette in the cuvette holder, after which the dial is adjusted to zero with the blank knob. To test a standard solution, fill the cuvette with that solution, but before putting the cuvette into the fluorometer, wipe the outside of the cuvette dry with laboratory-grade paper tissue. That prevents distortion from droplets on the glass or contamination of the fluorometer, and possible erroneous readings when testing other samples. After wiping, insert the cuvette in the holder and close the fluorometer door. After the fluorometer dial reaches a stable reading, record the reading. As mentioned earlier, test each pair of several standard solutions of different concentrations on more than one fluorometer scale for calibration of the instrument. An alternate, and perhaps more desirable, course of action is to first test all field samples on one fluorometer scale. If that scale accommodates all field samples, calibrate only that one scale in the range found pertinent.

If a water sample from a discharge measurement is being tested, first rinse the cuvette with tap water and then, after shaking out excess droplets, rinse the cuvette with the sample being tested. The cuvette may then be filled. It is important that any sediment in the sample be allowed to settle and that any oxygen bubbles be removed. (Cold samples taken from streams with a high dissolved-oxygen content will often have bubbles form on the sides of the cuvette.) If the samples have been allowed to sit in a temperature bath overnight, the sediment will have settled and the oxygen bubbles will usually have been released. If the oxygen bubbles have not been eliminated by allowing the samples to warm up before testing, they can usually be removed by tapping the cuvette before testing.

The blank and background samples should be tested at intervals during the fluorometer operation as a check against possible instrument malfunction or change in instrument calibration. Background samples are water samples used to define the natural fluorescence of the stream. Natural fluorescence should be determined for any dye-dilution measurement. Always correct water-sample concentrations for this background effect.

The frequency of testing known relative concentrations will depend primarily on the number of stream samples. Known relative concentrations are ordinarily tested before and after the stream samples, but more frequent testing is desirable where numerous samples are involved

Sample bottles made of polyethylene, glass, or similar nonabsorptive material can be used repeatedly for sampling. After each measurement all sample bottles should be thoroughly rinsed and drained. The bottles, if stored, should be well separated from any dye-contaminated equipment.

Whatever the equipment used, care should be taken at every step in the discharge determination to prevent contamination of stream samples, standard solutions, and the equipment used for measurement and analysis. A sample can be contaminated, from the standpoint of concentration, by the addition of pure water as well as by the addition of minute quantities of dye from the analyst's hands or other source.

DYE-INJECTION APPARATUS

Apparatus for the injection of dye solution at a constant rate is of three types: mariotte vessel, floating siphon, and pressure tank.

MARIOTTE VESSEL

The features of the mariotte vessel, shown in figure 121 are (1) an

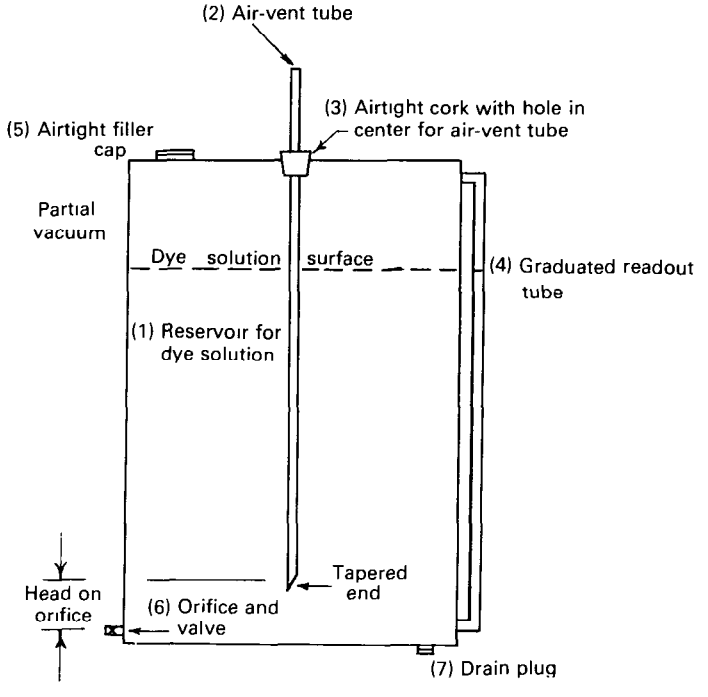

FIGURE 121.—Mariotte vessel (constant-head device).

airtight tank that holds the dye solution, (2) an air-vent pipe inserted into the tank through (3) a rubber stopper that will form an airtight seal both on the tank and the vent pipe, (4) a plastic or glass readout tube for determining the level of the liquid in the tank, (5) a filling plug that must be airtight, (6) a discharge orifice and valve, and (7) a flushing orifice and valve.

The lower tip of the air-vent pipe should be tapered to prevent the tip from being placed directly on the bottom of the tank and thereby obstructing the air flow. Discharge at more than one point may be obtained by installing the desired number of orifices in the tank.

The operation of the vessel is as follows. When the discharge valve (6) is opened, the level of the dye solution in the tank (1) will drop, creating a partial vacuum above the liquid (the top of the tank must be airtight). As the level of the liquid continues to drop, the vacuum increases causing the level of liquid in the air vent (2), which is open to the atmosphere, to drop until it reaches the bottom of the vent. As the solution continues to be discharged, air will enter the tank through the vent causing an equilibrium between the partial vacuum formed above the liquid surface and the weight of the liquid above the bottom of the air vent. When this equilibrium has been reached, a constant discharge will have been attained and will continue until the liquid in the tank drops to the bottom of the air vent. The acting head is the different in elevation between the bottom of the air vent and the orifice.

FLOATING SIPHON

Constant injection of a dye solution is possible through the use of the floating siphon device shown in figure 122. The device is designed to discharge at a constant rate by maintaining a fixed head on the orifice. The features of the floating siphon are (1) a tank that holds the solution, (2) a float with siphon tube and guide assembly, and (3) priming valves that can be used in activating the siphon. The discharge tube with orifice is permanently attached to the float in the position shown. Note that regardless of the position of the float within the reservoir, the operating head on the orifice remains the same. Stable, uniform movement of the float and siphon assembly is possible through the use of guides and a balance counterweight. When the siphon is effective, the float and assembly will drop with the water surface but at the same time maintain a constant discharge because of the steady head operating on the orifice.

The mariotte vessel and the floating siphon can both be equipped with readout gages that are used to calibrate the reservoirs volumetrically. These gages can be read at selected time intervals during the injection period to determine the constant-flow rate. The flow rate can

also be determined by volumetrically measuring the discharge from the orifice for a given period of time.

PRESSURE TANK

A constant-rate injection of dye solution may be obtained by use of a pressure tank in combination with a flow regulator (fig. 123). The flow regulator maintains a constant pressure differential across a valve in the regulator, thus giving a constant flow rate at any setting of the regulator. A pressure differential of a few pounds per square inch must be maintained for the flow regulator to function properly.

The solution to be injected is poured into the pressure tank, and the tank is sealed. Air is then pumped into the tank, providing the necessary pressure for the regulator. The solution is forced from the tank, by the pressure, through the regulator and to the injection lines.

Most commercially available flow regulators have a purge meter

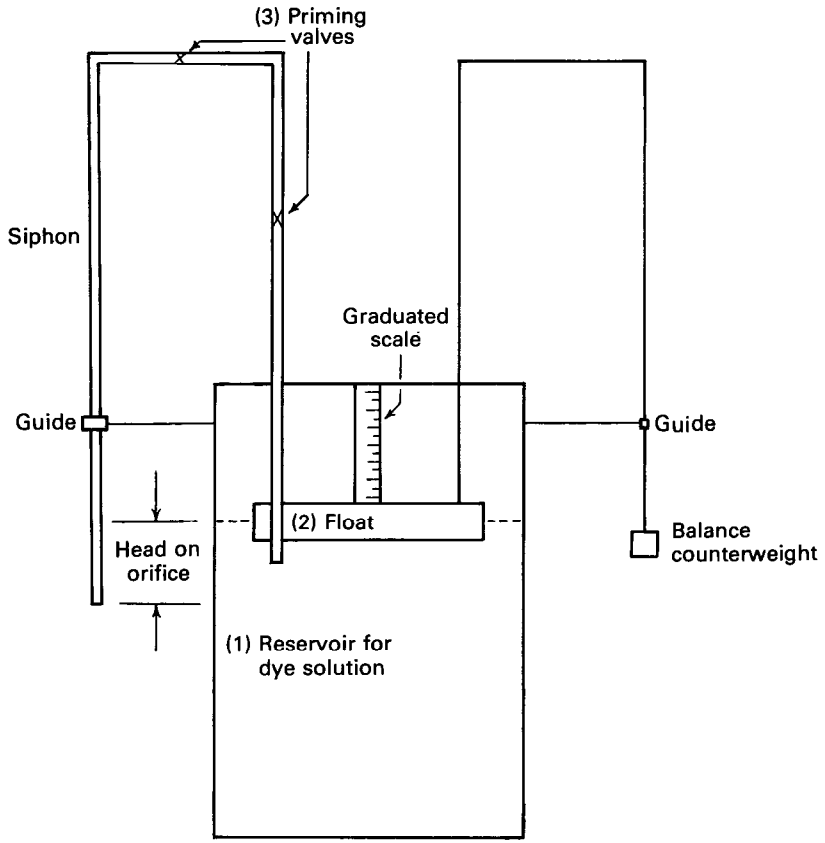

FIGURE 122.—Floating siphon (constant-head device).

attached to them. These meters may be used to obtain the approximate desired flow rate. The flow rate used in the computations should be determined from a volumetric measurement of the tank discharge.

Pressure tank and flow regulator systems are commercially available. These systems are as light as 8 lb (3.6 kg), when empty, for an operating-pressure tank capacity of about 2 gal (7.5 L). Flow regulators may be obtained for flow rates between 0.012 and 4 gal/hr or more. Flow rates once established will be maintained within ±2 percent.

DETERMINATION OF QUANTITIES OF FLUORESCENT DYE FOR MEASURING DISCHARGE

QUANTITY OF DYE NEEDED FOR MEASUREMENT BY THE CONSTANT-RATE-INJECTION METHOD

The volume of dye required to make a discharge measurement

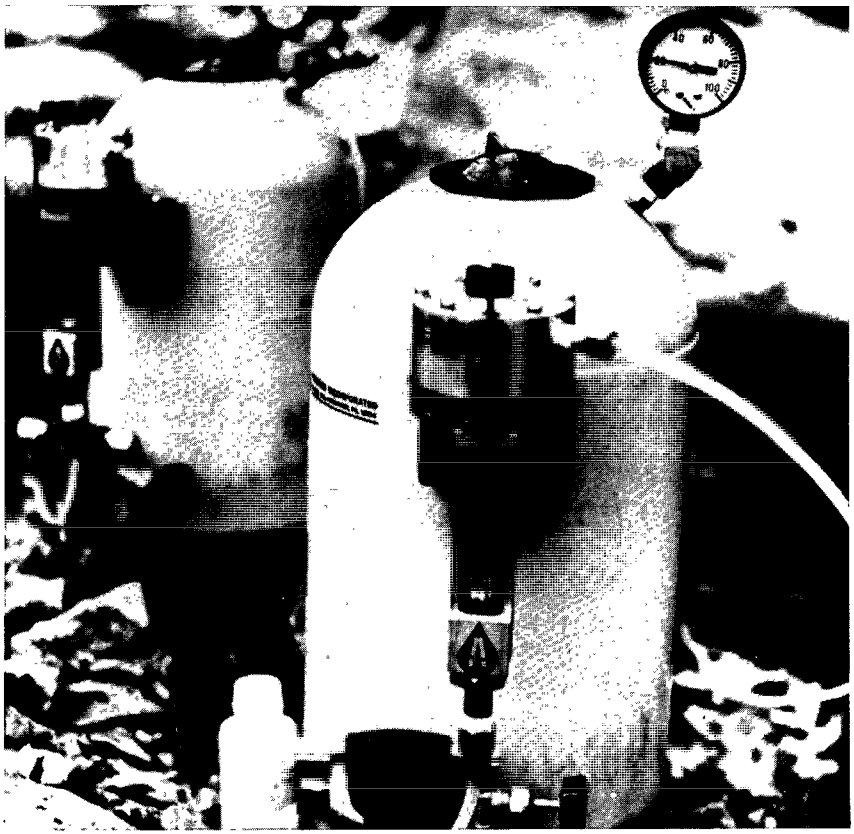

FIGURE 123.—Pressurized constant-rate injection tanks for injection of dye into streams.

using the constant-rate-injection method will depend on the discharge of the stream and on the total injection time. That volume can be estimated using the equation

$$V_d = 1.02 \times 10^8 \left(\frac{C_2}{C_d}\right) Q\, t_t, \tag{35}$$

where

V_d is the volume, in milliliters, of dye solution to be added to the water in the injection tank,

C_d is the concentration, in micrograms per liter, of the dye solution added to the water in the injection tank. If a 20 percent dye solution is added, the concentration of C_d is considered to be 200,000,000 μg/L. (See p. 228–229 for a discussion of relative and absolute concentration values.)

C_2 is the plateau concentration, in micrograms per liter, desired at the sampling site,

Q is the estimated stream discharge, in cubic feet per second, and

t_t is the total injection time, in hours.

The value of 1.02×10^8 is a combination of conversion factors. A concentration value for C_2 of 5 μg/L is recommended for Rhodamine WT.

The volume of tracer solution injected, which consists of the volume dye solution (V_d) plus added water, and the rate of injection are mutually dependent. Their limiting values are based on the size and characteristics of the dye-injection apparatus that is used. The capacity or volume of the apparatus divided by t_t gives the upper limiting value of the rate of injection, q. Any paired values of q and volume (qt_t) that are within the capability of the apparatus are satisfactory. However, it is recommended that no value of q less than 2×10^{-5} ft^3/s (0.57 mL/s) be used, because low injection rates are difficult to measure accurately. It is further recommended that V_d be diluted sufficiently to give the injection solution a concentration of no more than 25×10^6 μg/L, because more highly concentrated solutions tend to clog the injection apparatus.

QUANTITY OF DYE NEEDED FOR MEASUREMENT BY THE SUDDEN-INJECTION METHOD

If discharge is to be measured by the sudden-injection method, it is recommended that common salt be used as the tracer, rather than dye. (See p. 250–256.) However, as a matter of general interest, an equation is given here for computing the quantity of dye required for a discharge measurement of that type.

The volume of dye required to make a discharge measurement by the sudden-injection method can be estimated using the following

empirical equation:

$$V'_d = 3\times10^7 \left(\frac{C_p}{C'_d}\right) Qt_p, \tag{36}$$

where

V'_d is the volume, in milliliters, of dye solution of concentration C'_d to be introduced into the stream,

C_p is the peak dye concentration, in micrograms per liter desired at the sampling site,

Q is the estimated stream discharge, in cubic feet per second, and

t_p is the estimated time, in hours, for the dye peak to travel from the injection site to the sampling site.

The value of 3×10^7 is a combination of empirical equation constants and conversion factors. A concentration value for C_p of 10 μg/L is recommended for Rhodamine WT.

PROCEDURES FOR MEASURING DISCHARGE BY THE DYE-DILUTION METHOD

The only dye-dilution method that will be discussed here is the constant-rate-injection method. The sudden-injection method is not considered here because not only is it usually a less accurate method, but it is extremely laborious when dye is used and it can be applied with less effort by using common salt as a tracer. As mentioned earlier, the sudden-injection method requires that the entire concentration-time curve be defined, and for that purpose it is desirable to sample the stream concentration at intervals of less than a minute during periods of rapidly changing concentration. If the dye-dilution technique is used, it means that within a minute or so, grab samples must be obtained at all three sampling points in the sampling cross section. Furthermore, because it is recommended that at least 20 samples be taken at each sampling point to define the concentration-time curve, it means that a minimum of 60 stream samples must be analyzed by fluorometer, along with calibration and background samples. In short, it is not practical to use dye as a tracer in the sudden-injection method. Although recording fluorometers with flow-through doors are available, they seldom provide the precision required for a discharge measurement. When salt is used as the tracer, conductivity readings can be obtained at a point in a matter of a few seconds, by using a temperature-compensated probe and portable meter. (See p. 252–255.)

FIELD PROCEDURES

The following field procedures are recommended for determining

stream discharge by the dye-dilution method:

1. Select and calibrate the measurement reach (p. 220–222).

2. Select exact locations for the injection and sampling sites. Data obtained from the calibration tests are used in making the site selections, and consideration should be given to accessibility and convenience for conducting field operations. Bridges are often excellent for the purpose. The injection site for either single- or multiple-point injection should be one where the injection system can be readily observed and, if necessary, serviced. Select sampling sites where sampling is possible anywhere in the cross section. Locate a minimum of three sampling points in the cross section so that the section can be checked for lateral mixing.

The best location for a single-point injection is normally at the center of the cross section. A center injection generally produces the minimum possible mixing length if the dye is to be introduced at only one point. Space the injection points for a multiple-point injection so that each dye injection diffuses equal lateral distances.

3. Prepare the sample bottles. Show the following information on each bottle:

a. The sampling site (may be abbreviated).
b. Location of the sampling point in the cross section.
c. Sample number (if desired).
d. Sample time (use military time, that is, 24-hr clock system).
e. Date.

Make these notes with a ballpoint pen using masking tape for labels on the bottles. Note the time (sample time) when the sample is obtained.

4. Determine the amount of dye needed for injection from equation 35. The total injection time used in equation 35 includes the time required for the concentration plateau to have been reached at the sampling section and sufficient time to permit at least 15 min of sampling of the plateau.

5. Prepare the dye solution and injection equipment. Make certain that the solution is thoroughly mixed. Exercise caution in transporting the dye and do not carry excessive quantities of it on field trips. Dye in solution can be easily removed from containers by the use of pipettes. Adverse weather conditions, particularly high wind or rain, create serious problems in handling the dyes. Prepackaging of specific quantities of dye will facilitate operations in the field. River water taken at the site may be used in preparing the injection solution, but do not obtain river water immediately below a sewage outfall or at sites where chlorine is injected into the river system.

6. Obtain several background samples upstream from the injec-

tion site. Do this before handling the dye.

7. Obtain three samples of injection solution. These samples, each of about 2 oz (60 mL), may be taken immediately before or after the solution is injected into the stream.

8. Inject the diluted dye solution. Determine the actual rate of dye injection by timed observations of volume depletion in the injection tank. If a mariotte vessel is used for injection, check the fittings for air leakage before and during injection. Discharge will become constant within a few seconds after the orifice is opened if the tank is airtight. The sound of air bubbling from the air vent through the solution can be heard when the vessel is operating properly.

9. Do not inject the highly concentrated dye solution near the streambed; otherwise, the bed may be stained by the dye and excessive dye loss will result.

10. The time of arrival of the concentration plateau can be estimated from data obtained when the reach was calibrated. It is usually desirable to start sampling a little before the estimated time of arrival of the concentration plateau. Define the plateau with at least five samples at each of the three sampling points in the sampling cross section. If a fluorometer is available, the arrival and passage of the dye can be determined by using the flow-through door and recorder accessory, or by periodically testing individual samples using the standard door. Do not mistake a possible temporary leveling of the concentration-time curve as being the actual plateau. A short time should elapse between the taking of samples to minimize the effect of nonrepresentative surges of high or low concentration.

11. In obtaining stream samples at the sampling site, take samples just below the water surface and far enough from the banks to avoid areas of slack water. If possible, the sampling site should be at a contracted section of the stream or at one where velocities are fairly uniform across the entire section. The following equipment is needed for grab sampling:

a. Sampling device and line (for sampling from a structure).
b. Boots or waders (for sampling by wading).
c. Boat, motor, paddle, gasoline can, life jacket (for sampling by boat).
d. Bottles (glass or plastic, 4-oz, wide-mouth bottles are recommended).
e. Masking tape (for labeling samples).
f. Ballpoint pens (for making identifying notations on sample labels).
g. Watch.

12. Contamination of stream samples is always a possibility. When handling any dye, keep hands and clothes clean as a safeguard

against accidental contamination. Rinse bottles at least three times in stream water immediately before sampling. This precaution is necessary because bottles are used repeatedly and some may have had high concentrations of dye in them previously. Dye from stained hands can contaminate samples, resulting in erroneous concentration determinations; therefore, keep hands away from the uncapped mouths of bottles and out of the sample water.

13. Clean the injection and mixing equipment.

14. Store and carry sample bottles in an upright position to prevent leakage and to allow sediment to settle.

ANALYSIS AND COMPUTATIONS

Fluorometer analysis should not begin until the standard concentration solutions have been prepared. Place all samples, including background samples and standard concentration solutions, in a constant-temperature bath. By keeping the samples in the bath overnight, any sediment present will have an opportunity to settle, and any oxygen bubbles present will usually be released. After fluorometer warmup, all samples may be analyzed. Use of a constant-temperature bath will eliminate the need for temperature corrections. However, if for any reason a temperature bath was not used, the first step in the analysis procedure that follows is to make temperature corrections.

1. Correct each fluorometer reading for the effect of temperature by the following method. A standard cuvette-sample temperature is selected. This may be the mean, median, mode, or any other convenient cuvette-sample temperature recorded while testing the samples. The difference between each recorded cuvette-sample temperature and the standard temperature is used to select the appropriate coefficient from table 13. Temperature-correction coefficients are usually prorated with respect to time between temperature observations. Multiply the fluorometer dial-readings by the coefficients to obtain adjusted dial readings.

2. Next correct the dial readings, or temperature-adjusted dial readings if such adjustment had been necessary, for the effect of background fluorescence, as determined from the background samples. This background correction is applied to each water sample and to each sample of standard concentration.

Usually all fluorometer testing will be done using a single fluorometer aperture. If more than one aperature is used, obtain a background reading for each aperature and use a mean background value for correcting the dial readings. Do not use a mean background value if a definite change in background has been noted. A change in background fluorescence may result from a variety of causes such as

unstable fluorometer operation, increased suspended-sediment load, and the presence of sewage or industrial wastes. Enter the background readings in the notes. Subtract the background readings from the adjusted dial readings from step 1 above to obtain the final corrected dial readings.

3. Use the final corrected dial readings for the standard solution of known relative concentration to compute the fluorometer coefficient, a, in equation 33 (p. 227). When this standard solution is tested several times during a period of sample testing, the value of the coefficient is normally prorated, with respect to time, between testings.

4. Determine the relative concentrations of samples by multiplying the corrected dial readings, from step 2 above, by the coefficient, a.

5. Compute the stream discharge by use of equation 24. Because the background concentrations have already been subtracted from the stream sample concentrations, equation 24 becomes

$$Q = \left[\frac{C_1}{C_2} - 1 \right] q,$$

which can be simplified, without significant loss of precision, to

$$Q = \left(\frac{C_1}{C_2} \right) q. \tag{37}$$

An average value of C_2 is used in the computations. If the individual C_2 values show little variation among them, use the arithmetic mean. If the variation is significant, obtain the mean value of C_2 by weighting the mean plateau concentrations for each sampling point by the percentage of discharge associated with the sampling point. If the discharge distribution is unknown, but the area distribution is known, obtain the mean value of C_2 by weighting the plateau concentrations for each sampling point by the percentage of area associated with each sampling point. If both the discharge and area distributions are unknown, as will usually be the case, compute the mean value of C_2 by using percentage of width as the weighting factor.

6. Determine the percentage of mixing by using equation 26, or by use of the graphical procedure described on page 219–220. Reliable results are generally obtained when the percentage of mixing is 95 or more. Reliable results are also possible for flow conditions where the percentage of mixing is less than 95 if the discharge distribution at the sampling section is uniform or known.

SAMPLE COMPUTATION—CONSTANT-RATE-INJECTION METHOD

A sample computation of the constant-rate-injection method is

presented here based on data obtained on March 25, 1965, at Little Seneca Creek near Boyds, Md., in the course of a detailed investigation of dye-dilution methods of measuring discharge. The average width of Little Seneca Creek at the time of the measurement was 30–35 ft (9–10 m). Depths averaged between 1 and 2 ft (0.3 and 0.6 m). The streambed was composed mostly of gravel, with some rock outcrops. Flow in the measuring reach passed through several bends.

Calibration of the measurement reach at about the stage to be measured had indicated that a measuring reach of 1,800 ft (550 m) was satisfactory for adequate mixing when the dye was injected at three points across the stream. The calibration further indicated that the time required for the concentration plateau to arrive at the sampling site was about 45 min. Three sampling points, designated A, B, and C, respectively, were to be used at the sampling site. Grab-samples were taken immediately before and during the passage of the concentration plateau.

1. The required volume of dye (V_d), to be supplied from a mariotte vessel, was computed from equation 35,

$$V_d = (1.02\times10^8)\,\frac{C_2}{C_d}\,Qt_t\ .$$

The approximate value of the plateau concentration (C_2) desired at the sampling site was 5 μg/L. The estimated value of stream discharge (Q) was 50 ft^3/s. The total injection time (t_t) was estimated to be 80 min (1.33 hr)—45 min for traveltime and 35 min to insure a concentration plateau of adequate duration. The dye to be used was Rhodamine WT, 20-percent solution, and C_d was therefore equal to 2×10^8 μg/L. Consequently,

$$V_d = (1.02\times10^8)\quad\left(\frac{5}{2\times10^8}\right)(50)\,(1.33) = 170\text{ mL.}$$

2. The discharge rate of diluted dye solution (q) from the injection vessel that was selected was 1.50×10^{-4} ft^3/s. The volume of solution needed in the injection tank was equal to qt_t, where t_t was 1.33 hr, or 4,800 s. That volume was therefore

$$(1.50\times10^{-4})\,(4800) = 0.72\text{ ft}^3\text{, or approximately 20,000 mL.}$$

The 170 mL of dye solution was mixed with sufficient stream water to give an injection solution of 20,000 mL.

3. The concentration of the solution in the injection tank (C_n) was computed from equation 34,

$$C_n = \frac{C_i V_i}{V_a + V_i}$$

$$= \frac{(200{,}000{,}000)\ (170)}{20{,}000}$$

$$= 1{,}700{,}000\ \mu g/L.$$

4. Timed observations of the change in the level of the dye solution in the injection tank showed the actual rate of outflow to be 1.51×10^{-4} ft^3/s.

The steps that follow were taken in the office to complete the measurement.

1. A working standard solution of concentration 200 $\mu g/L$ had previously been prepared (p. 229–230). A dilution ratio of 1/40 was applied to that solution to obtain two standard sample solutions whose concentration was 5.00 $\mu g/L$.

Standard solutions of 5.00 $\mu g/L$ were used for calibration of the fluorometer because that was the expected value of the plateau concentration of the stream. (The concentration of the standard solutions should approximate the concentrations of the stream samples that will be used to compute stream discharge.)

2. A form for keeping notes was prepared as shown in figure 124. Column 1 of figure 124 shows the time when the sample was obtained in the field, and column 2 shows the time when the sample was tested in the fluorometer.

3. The samples had not been placed in a constant-temperature bath, and consequently temperature corrections were necessary. The samples, including those for background testing (stream water untouched by dye) and for fluorometer calibration (5.00 $\mu g/L$), were tested in the fluorometer. Columns 3 and 4 of figure 124 show dial readings on the fluorometer aperture that was used. Column 5 shows two temperature readings. The upper reading is the temperature of the water being circulated through the fluorometer door. The lower reading is the temperature of the fluorometer compartment. Obtain that temperature from a thermometer that can be taped to the compartment side at the left of the secondary filter. Column 6 shows the temperature of the cuvette sample. That temperature is taken immediately after the fluorometer dial is read by removing part of the water from the cuvette, inserting the thermometer in the cuvette, and replacing the cuvette in the door. Allow the thermometer to stabilize before reading. Compute temperature-correction coefficients from the observed cuvette-sample temperatures.

4. A standard cuvette sample temperature of 82°F (27.8°C) was selected for use. Temperature coefficients from table 13, correspond-

ing to the differences between 82°F and the observed cuvette-sample temperatures in column 6 of figure 124, were then obtained and recorded in column 7.

FIGURE 124.—Sample analysis sheet used for computing discharge by the constant-rate-injection method of dye dilution.

5. The adjusted dial readings in column 8 were obtained by multiplying the values in either column 3 or column 4 by the temperature coefficients in column 7.

6. The average temperature-adjusted fluorometer reading for background fluorescence, obtained by testing the unaffected stream water, was recorded in column 9. Its value, 1.2 in this test, was then subtracted from all temperature-adjusted readings in column 8, and the corrected dial readings were recorded in column 10.

7. The fluorometer coefficient, a, in column 11, was obtained as the average of the ratios of the known concentration of the two background samples (5.00 μg/L) to their corrected dial readings. The background samples were tested at the beginning and end of the fluorometer analysis, and the fluorometer coefficients obtained were prorated with time for use in the analysis.

8. The concentrations of the samples listed in column 12 were obtained by multiplying the fluorometer coefficients in column 11 by the corrected dial readings in column 10.

9. The concentrations obtained for each sampling point are normally plotted against sampling time to determine the average concentration of the plateau C_2 at each of the three sampling points, A, B, and C. In this example, no plots were made; instead, C_2 for each sampling point was computed, in column 12 of figure 124, as the mean of the last five values obtained, it being evident that those values were plateau values.

10. Because the three sampling points, A, B, and C, were evenly spaced across the stream, each of the three values of C_2 from step 9 were given equal weight in computing the mean value of C_2 for the entire sampling section:

$$\text{mean } C_2 = \frac{5.62+5.50+5.33}{3} = 5.48 \ \mu\text{g/L}.$$

11. The discharge was computed from the simplified form of equation 24 that is shown as equation 37 on page 241.

$$Q = \frac{C_1}{C_2} q$$

$$= \left(\frac{170\times10^4}{5.48}\right)(1.51\times10^{-4}) = 46.8 \text{ ft}^3/\text{s}.$$

12. Mixing percentage (P_m) was computed, using appropriate widths in equation 26:

$$P_m = 100 - \frac{\left[|X_A - X_m|W_A + |X_B - X_m|W_B + |X_C - X_m|W_C\right]\times 50}{(W_{total})(X_m)}$$

Because the sampling points were evenly spaced, W_A, W_B, and W_C may each be replaced by 1, and W_{total} may be replaced by 3. Then

$$P_m = 100 - \frac{[|5.62-5.48| + |5.50-5.48| + |5.33-5.48|]\times 50}{3(5.48)}$$

$$= 100 - \frac{(0.31)\times 50}{16.44}$$

$$= 99 \text{ percent (satisfactory)}$$

In the original study of Little Seneca Creek, the discharge had been measured by current meter for a comparison with the discharge obtained by the dye-dilution method. The current-meter discharge was 47.3 ft^3/s, whereas the dye-dilution discharge was 46.8 ft^3/s. The two values differ by 1 percent.

SIMPLIFIED PROCEDURES FOR MAKING NUMEROUS DYE-DILUTION MEASUREMENTS OF DISCHARGE

The preceding description of the method of measuring discharge by the constant-rate-injection method was highly detailed to give complete understanding of the procedure. It should be apparent that there are many details to be considered in collecting and analyzing the samples. If only an occasional dye-dilution measurement is to be made, the procedures described above should be followed. If numerous dye-dilution measurements are to be made on a routine basis, "mass production" methods may be instituted to simplify and speed the procedure.

The first simplifying step is the laboratory production of two batches of solution, each of which represents a working standard concentration. Bulk production of the two concentrations will considerably reduce the amount of time that would otherwise be required later for serial dilutions and for calibrating the fluorometer. The standard concentration that is needed for fluorometer calibration is one that closely approximates the C_2 (plateau) concentrations that will be obtained in the discharge measurements. The value of C_2 will usually approximate 5 $\mu g/L$. Consequently one working standard solution of 200$\mu g/L$ should be produced in adequate quantity from the stock of 20-percent Rhodamine WT dye. The concentration of 200 $\mu g/L$ is high enough to permit storage of the solution for at least 6 months with little danger of deterioration and is still low enough to produce, with a single dilution, concentrations that approximate any C_2 values that may be obtained in a discharge measurement.

The other solution of working standard concentration that should be produced in bulk is one that can be used as the injection solution in a discharge measurement without further dilution. By way of background explanation we examine figure 125, the basis of which is equation 37. Figure 125 shows the relation among Q, q, and C_1 for a constant value of C_2. The constant value of C_2 that is used is 5 μg/L, which is the optimum value of the plateau concentration in the constant-rate-injection method. Concentration values of C_1 ranging from 0.05 percent (0.5×10^6 μg/L) to 2.5 percent (25×10^6 μg/L) are shown in the diagonal lines of figure 125. To produce a C_1 solution of, say 0.4 percent, 8 L of water is added to the parenthetical quantity of 137.2 mL of 20-percent Rhodamine WT dye. Examination of figure 125 shows that with a given injection concentration (C_1) a wide range of discharges may be measured by merely changing the injection rate (q). For example, a C_1 concentration of 0.4 percent (4×10^6 μg/L) permits the measurement of stream discharges from 15 ft^3/s to almost 300 ft^3/s, while still creating a plateau concentration (C_2) of 5 μg/L. Even those discharge limits may be exceeded by allowing C_2 to vary from its value of 5 μg/L. By using figure 125 with a knowledge of the range of discharges to be measured, a suitable value of C_1 can be selected for use as a working standard concentration.

To recapitulate what has been said up to this point, two working standard concentrations should be used for laboratory production of bulk solutions.

1. A concentration (C_1) of 4×10^6 μg/L, or one more suitable for the range of discharges to be measured, should be used for one solution. That solution will be used, without further dilution, as the injection solution for discharge measurements.

2. A concentration of 200 μg/L should be used for the second solution. A single dilution of that solution will provide standard solutions for calibrating the fluorometer at concentration C_2 (usually about 5 μg/L). Both solutions must be made from the same batch of 20-percent Rhodamine WT dye that is received from the manufacturer.

The discharge measurements will be made in the manner described in the earlier sections of this chapter, but before analysis by fluorometer, all samples and standard solutions should be allowed to sit overnight in a laboratory temperature bath. That will eliminate the need for temperature corrections to fluorometer dial readings.

As the hydrographer gains experience with the dye-dilution method, he will find that he can dispense with the computation of percentage of mixing (P_m) at the conclusion of his fluorometer analysis. By visual inspection of the computed individual plateau concentrations, he will be able to judge whether or not satisfactory mixing had been attained at the site of his sampling

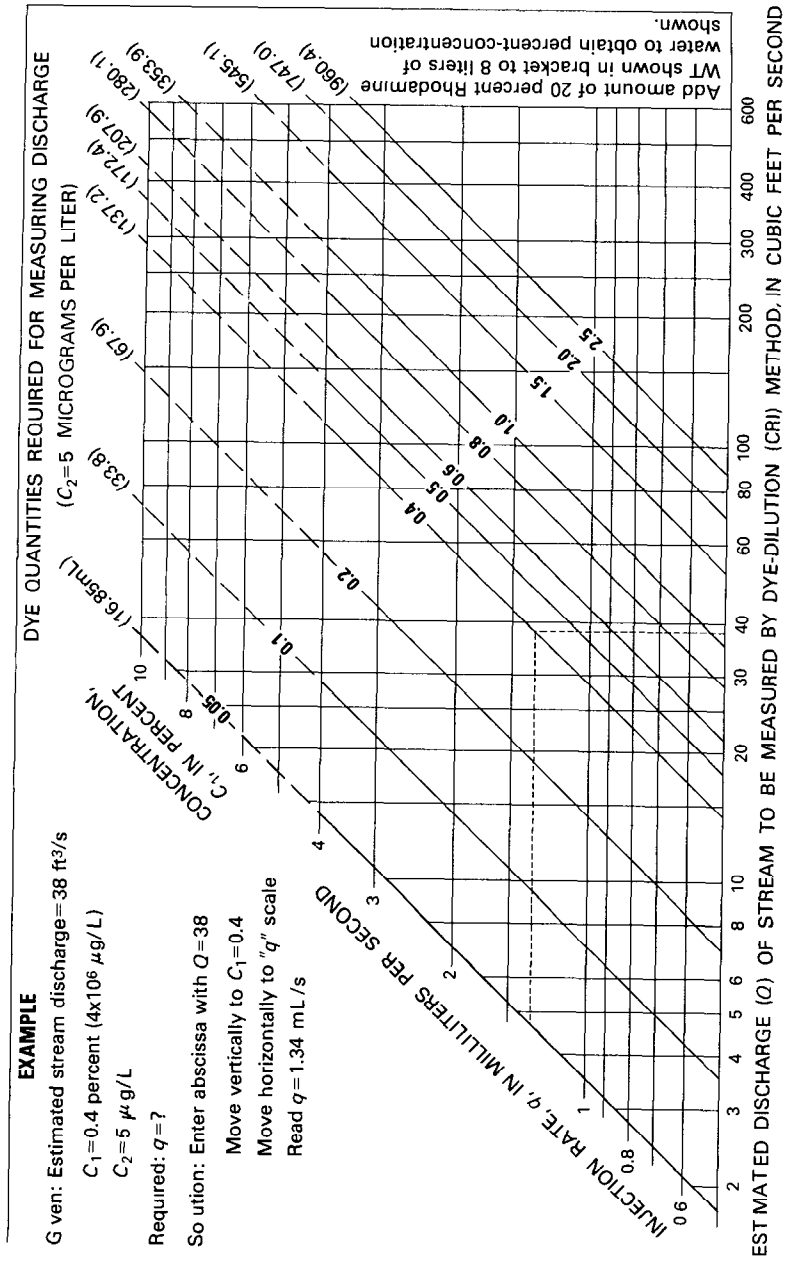

FIGURE 125.—Dye-injection rate of various stock dye concentrations related to estimated stream discharge.

MEASUREMENT OF DISCHARGE BY SODIUM DICHROMATE DILUTION

GENERAL

In Europe colorimetric analysis, using sodium dichromate ($Na_2Cr_2O_7 \cdot 2H_2O$) as the tracer, is the most widely used means of measuring discharge by the constant-rate-injection method. Because colorimetric analysis is rarely used in the U.S.A., the method will be described here only in brief; detailed descriptions are available in a report by the International Standards Organization (1973) and in a paper by Hosegood, Sanderson, and Bridle (1969).

The solubility of sodium dichromate is relatively high—the stock solution commonly used has a concentration of 600 g/L—and the salt satisfies most of the requirements for a tracer that are listed on page 211. Complications resulting from the presence of chromium ions in the water being gaged seldom occur, because natural waters generally contain few such ions. However, the nature and quantity of suspended sediment in the natural water can seriously affect the accuracy of analysis because of the possibility of sorption of sodium dichromate by the sediment. Another consideration in the use of sodium dichromate as a tracer is its potential toxicity to aquatic life, particularly in localized areas of high concentration; drinking-water standards in the U.S.A., for example, recommend a limiting concentration of 0.05 mg/L for chromium ions (Environmental Protection Agency, Environmental Studies Board, 1972, p. 62).

The factors that enter into the selection of a reach of channel for a measurement of discharge by sodium dichromate dilution are identical with those discussed earlier on pages 215–223. The types of apparatus for constant-rate-injection—mariotte vessel, floating siphon, and pressure tank—were described on pages 232–235.

The method of sampling for a discharge measurement by the constant-rate-injection method is similar to that described for fluorescent dyes (p. 237–240).

PRINCIPLE OF COLORIMETRIC ANALYSIS

Colorimetric analysis permits the measurement of extremely low concentrations of sodium dichromate. In that type of analysis a colorimeter is used to compare (1) the natural dilution of stream samples after tracer injection with (2) the known dilution of a stock solution of the salt. The comparison is based on differences in the absorption of light by the solutions after a reagent has been added to each of them.

The colorimeter is calibrated by the use of standard solutions, and it is recommended that the colorimeter used be one that gives a linear

relation between color intensity (concentration) and meter reading. The colorimeter coefficient is then equal to the known concentration of the standard solutions divided by the average of the colorimeter readings.

METHOD OF ANALYSIS BY COLORIMETER

As mentioned earlier, the stock solution commonly used for discharge measurements contains 600 g of sodium dichromate in each liter of solution. The injection rate of this stock solution depends on the estimated river discharge and the desired increase or rise in concentration of chromium ions (Cr^6) corresponding to the plateau concentration. That rise in concentration, $(C_2 - C_b)$ in the equation that follows, is generally in the range of 0.04 to 0.08 mg/L.

Discharge is computed by use of the equation

$$Q = \left[\frac{C_1}{C_2 - C_b}\right] q, \tag{38}$$

where

Q is stream discharge (m^3/s),
q is rate of flow of injected solution (m^3/s or $mL/s \times 10^{-6}$),
C_1 is concentration of the injected solution (mg/L),
C_2 is concentration of the plateau of the concentration-time curve shown in fig. 116 (mg/L), and
C_b is background concentration of the stream (mg/L).

MEASUREMENT OF DISCHARGE BY SALT DILUTION

GENERAL

As mentioned earlier, when salt is the tracer used in measuring discharge by the tracer-dilution technique, the sudden-injection method is generally used. Although the sudden-injection method is usually less accurate than the constant-rate-injection method, the difficulty of handling the large quantities of salt solution required by the constant-rate-injection method make the method impractical. Common salt (NaCl) is the salt tracer generally used because it is relatively cheap and it meets all the criteria for a tracer that are listed on page 211.

The basic principles behind the salt-dilution method are as follows. The ion concentration of a dilute salt solution, such as natural river water, increases as the salt content increases. Consequently, the easily measured electrical conductivity (conductance) of the solution is an index of the salt concentration. Furthermore, over a wide range of concentrations the conductance is directly proportional to salt concentration. Therefore, after injection of a concentrated salt solution

into a stream, the discharge can be computed by use of the ratios of the conductances of the injected and sampled salt solutions, instead of the ratios of the salt concentrations themselves. The procedure followed in the salt-dilution method is analogous to that used in the dye-dilution method in that relative conductance values are used rather than absolute values.

The factors that enter into the selection of the reach of channel for a salt-dilution measurement of discharge are identical with those discussed earlier on pages 215–223. Although loss of salt in the measurement reach by sorption is a negligible concern, reaches that have areas of slack water should be avoided, if possible, because the storage and slow release of tracer from those areas greatly prolongs the time required for the entire salt cloud to pass the sampling site. The sampling site should be free of excessive turbulence because the operation of the electrode cell that is placed in the stream to measure relative conductance is adversely affected by the presence of air bubbles.

The salt-dilution method of measuring discharge in open channels is littled used in the U.S.A. but is popular elsewhere, as in the U.S.S.R. The description of the salt-dilution technique that follows, and the sample computation that concludes the discussion, have been taken from a description of salt-dilution technique that follows, and the sample computation that concludes the discussion, have been taken from a description of salt-dilution stream gaging in the U.S.S.R. (World Meteorological Organization, 1962, p. 47–49). The subject is discussed under the following three headings:

1. Preparation and injection of the concentrated salt solution.
2. Measurement of relative conductance at the sampling site.
3. Computation of discharge.

PREPARATION AND INJECTION OF THE CONCENTRATED SALT SOLUTION

The following equipment is needed for the preparation and injection of the concentrated salt solution at the injection site:

1. Two tanks, each having a capacity of 60–70 L; one tank is used for preparation of the solution and the other for injection of the solution.
2. A measuring vessel of 10-L capacity, having a mark showing the exact level for 10 L of liquid.
3. A wooden or aluminum paddle for mixing the solution.
4. A vessel having a capacity of 0.3–0.5 L for adding small volumes of solution to the 10-L measuring tank.
5. A glass flask with a ground glass stopper, having a capacity of 20–30 mL, in which a sample of the solution is retained.

The quantity of salt (NaCl) required for injection depends on the

discharge to be measured; 1–2 kg of salt is needed for each cubic meter per second of stream discharge. The smaller unit quantity of salt is used for streams having a low natural concentration of dissolved material. In estimating the quantity of salt to be brought to the injection site, consideration should also be given to the possibility that the discharge measurement will have to be repeated.

The preparation and measurement of the injection solution takes place at the injection site, but at a distance from the river to avoid any accidental spill of salt or salt solution into the river. An accident of that kind could affect the results of the discharge measurement. To prepare the injection solution, the quantity of salt needed is first determined from an estimate of the discharge and the natural concentration of dissolved materials in the stream. The computed quantity of salt is then placed in one of the large tanks, and river water is added to the tank at the rate of 10 L to each 3 kg of salt. The mixture is then stirred to obtain a saturated salt solution. After the larger undissolved crystals have settled to the bottom of the tank, the solution is transferred to the second large tank, and its volume is carefully measured in the process, the transfer being made by means of the 10-L measuring vessel. An additional amount of river water sufficient to fill the small glass flask (20–30 mL) to its brim is then added to the measured solution in the second large tank. The flask and stopper are carefully rinsed in that tank, after which the contents of the tank are thoroughly stirred once more. The small glass flask is then filled with the solution, tightly stoppered, and is delivered to the sampling site downstream for later use there. The large tank now holds the volume of salt solution that was originally measured into it. The large tank is then moved to the river, and at a signal from the sampling site that all is in readiness there, the tank is overturned to spill its contents almost instantaneously into midstream. That act completes the work to be done at the injection site.

MEASUREMENT OF RELATIVE CONDUCTANCE AT THE SAMPLING SITE

A conductance meter (fig. 126) that is a modification of a Wheatstone bridge is set up at the sampling site. The principal elements of the meter are a rheochord, a 10,000-ohm resistance chamber, and an electrode cell immersed in the stream, well away from the bank. The resistance chamber is used to compensate for the natural conductance of the water in the stream so that the needle of the galvanometer reads zero. The indicator on the rheochord is also set at zero. When this has been done, the signal to inject the salt solution is sent to the injection site.

After the solution has been poured into the stream at the injection

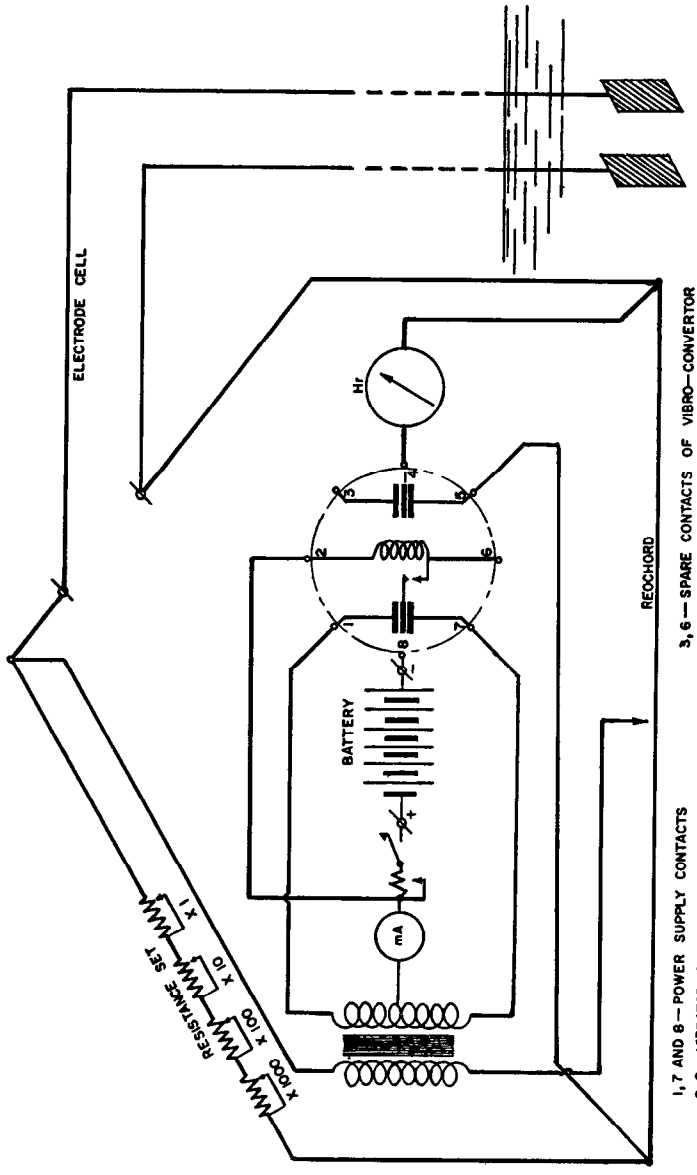

FIGURE 126.—Schematic diagram of conductance meter used in salt-dilution method of measuring discharge. (From World Meteorological Organization, 1962, p. 47.)

site, the current is switched on in the conductance meter, and the stability of the compensation for natural conductance is checked. If the galvanometer needle has deviated from zero, it is returned to zero by changing the resistance. Constant observation of the needle then begins. When the needle begins a perceptible movement to the right, it is a sign that the solution, or ionic wave, is approaching, and the stopwatch is started. From that time on, the galvanometer needle is maintained in a position approximating the zero reading by turning the rheochord handle. Every 15 s the needle is returned exactly to zero and the indicator position on the rheochord scale is read. That reading represents relative conductance (P) expressed in tenths of a percent (0/00):

$$P_W = 1{,}000 \left[\frac{(EC)_W - (EC)_o}{(EC)_o} \right], \tag{39}$$

where EC is conductance (electrical conductivity), subscript W refers to the ionic wave, and subscript o refers to the natural water in the stream. (Note.—Conductance is the reciprocal of resistance.)

As the ionic wave passes the sampling site, relative conductance increases rapidly at first, reaches a peak, and then recedes slowly to zero or to a constant value slightly above or below zero. When the rheochord readings remain constant for 5 or 6 readings (1½ min) near the zero value, the measurement is terminated. Immediately thereafter the determination of the relative conductance of the injection solution begins, using the sample in the small flask obtained at the injection site just before the measurement began. For this determination the following equipment is needed:

1. A 10-L measuring vessel.
2. A jug for adding water to the measuring vessel.
3. A wooden or aluminum paddle for mixing the solution.
4. A 1-mL glass pipette.

The measuring vessel is rinsed three or four times with river water. It is then filled with river water to the 10-L mark, and the electrode cell of the conductance meter is immersed in it. The rheochord needle is set to zero, the current is switched on, and the resistance is adjusted to set the galvanometer needle to zero. The pipette is next rinsed in the injection solution that had been delivered in the small flask, and the pipette is used to add 1 mL of that solution to the 10 L of river water in the measuring vessel. The pipette is then rinsed three times in the vessel to insure that all of the extremely small volume of salt in the 1 mL of solution is introduced into the vessel. The contents of the vessel are then thoroughly mixed, and the relative conductance of the greatly diluted injection solution is measured with the meter, using the technique described for measuring relative conductance in the

ionic wave. The ratio of dilution for the sample of injection solution is 1:10,000, because 1 mL of injection solution was mixed with 10 L of river water.

COMPUTATION OF DISCHARGE

The simplest way to describe the computation of discharge from salt-dilution data is by means of an example. Assume that in the preceding discussion of methodology, the stream discharge had been estimated to be about 4.5 m^3/s. The unit quantity of salt to be used was 2 $kg/m^3/s$ of discharge; consequently about 9 kg of salt was prepared. Water was added to the salt at the rate of 10 L per 3 kg of salt. As a result, 30 L (0.03 m^3) of injection solution was prepared. This value is shown on line 1 on the left-hand side of the computation sheet in figure 127. At the sampling site, 10 L of river water (line 2) was mixed with 1 mL of injection solution (line 3), giving a dilution ratio of 10,000 (line 4). The resistance of the river water was found to be 969 ohms (lines 5 and 6), and the resistance of the sample of diluted (1:10,000) injection solution was found to be 691 ohms (line 7). The relative conductance of that sample, as read on the rheochord in tenths of a percent, was 402 (line 8). On line 9, the rheochord reading for the dilute sample of injection solution is checked mathematically by use of the measured resistances. The equation used on line 9 is identical with equation 39. On line 10 the relative conductance of the injected solution is computed by multiplying the relative conductance of the diluted injection sample by the dilution ratio.

On the right-hand side of figure 127 are shown the relative conductance values read on the rheochord scale at 15-s intervals during the 15-min passage of the ionic wave. Subtotals are shown for the three columns of relative conductance values; the grand total is 1,933. The data are presented graphically in figure 128, where relative conductance is plotted against time.

Discharge is computed from equation 40, the denominator of which is the area under the curve of relative conductance versus time:

$$Q = \frac{V_1 P_p}{F \pm \Delta F}, \tag{40}$$

where

- Q is discharge, in cubic meters per second,
- V_1 is volume of the injected solution, in cubic meters,
- P_p is relative conductance of the injected solution, in tenths of a percent,
- F is the product of the sampling interval, in seconds, multiplied by the sum of the observed values of relative conductance, and
- ΔF is a correction factor for any change in reading of the rela-

tive conductance of the natural river water between the start and end of the measurement:

$$\Delta F = \frac{P_{start} - P_{end}}{2}(t_n - t_1),$$ where $t_n - t_1$ is the time, in seconds, that elapsed during the measurement.

The discharge is computed in lines 11–16 on the left-hand side of figure 127. Line 11 shows the sampling interval—15 s; line 12 shows the sum of the observed relative conductances of the ionic wave—1,933; line 13 shows the computation of F—28,995; line 14 shows the computation of ΔF—there was no change in natural relative conductance during the 900 s that elapsed during the measurement. The value of the denominator of equation 40 is shown on line 15. The discharge, computed in accordance with equation 40, is shown on line 16.

MEASUREMENT OF DISCHARGE BY DILUTION OF RADIOACTIVE TRACERS

GENERAL

The use of radioactive material for measuring discharge by tracer

dilution will not be described in detail, because the method is still (1980) considered to be in the experimental stage. Radioactive tracers should be ideal for the dilution method because concentrations as low as 10^{-9} ci/L may be accurately determined with a counter or count-rate meter whose sensing probe is immersed in the stream.

The radioactive element that has been most commonly used is gold 198, which has a half-life of 2.7 d. Tests have also been made using sodium 24, which has a half-life of 14.9 hr. It is necessary that the radioactive tracer have a short half-life so that the radioactivity introduced into the stream will decay to an insignificant level in a short

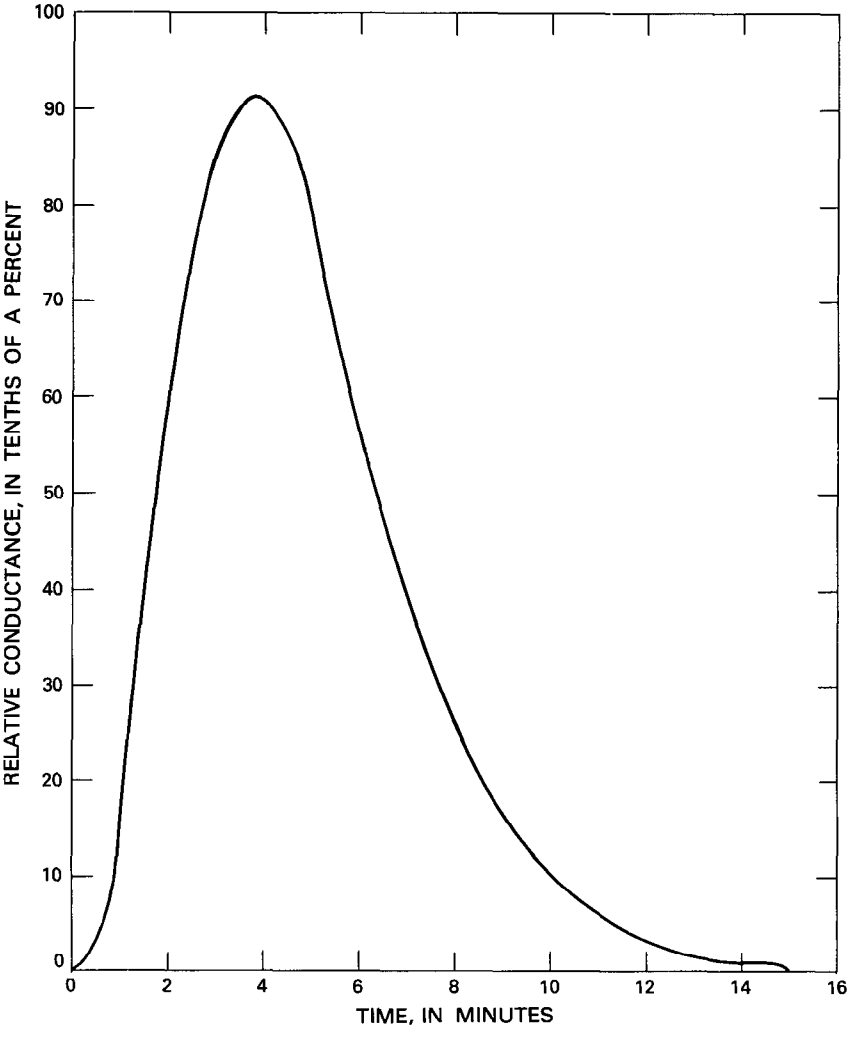

FIGURE 128.—Curve of relative conductance versus time for the ionic wave in the sample problem. (From World Meteorological Organization, 1962, p. 48.)

time. That requirement introduces a problem in logistics, in that the radioactive element must arrive from the nuclear plant and be used at the measurement site at the scheduled time, so that excessive decay of the radiation does not occur before the discharge measurement is made. Another factor that tends to discourage the use of radioactive tracers is the requirement of a government license merely to handle the material; radiation shielding must be provided while shipping and handling the material because of the potential threat to public health. In addition, approval must usually be obtained at all government levels, including the local level, before the radioisotope can be used in a stream, and local fear of radioactive pollution is often difficult to overcome.

METHODOLOGY

A measurement reach of channel is selected, using one of the equations, 28 to 32 (p. 221–222), as a guide in determining the length of reach needed for satisfactory mixing. Before the measurement is started, the instrument for counting gamma-ray emissions—Geiger or scintillation counter—is calibrated, taking into account the exact conditions under which the counter will be used.

A measured quantity of the radioisotope is introduced into the stream at the injection site by being quickly poured out of a bottle; or more frequently, a glass bottle containing the radioisotope is placed in a wire-screen container that is then lowered into the stream, after which the glass bottle is shattered to release the isotope for mixing in the streamflow. At the sampling site downstream, where the probe of the Geiger or scintillation counter is immersed in the stream, gamma-ray emissions are continuously counted. The counters are started well before the arrival of the isotope-stream mixture so that the counts received from natural (background) radiation sources may be measured. The counters continue to count throughout the passage of the isotope-stream mixture until the count returns to the background level. The total net count (N) is equal to the gross count obtained minus the background count accumulated during the period of the gross count.

The discharge is computed from the equation

$$Q = \frac{FA}{N}, \tag{41}$$

where

Q = stream discharge (volume per unit time),
F = a calibration factor for the probe and counting system,
A = total quantity of radioactivity introduced into the stream, and
N = total net count recorded by the counter.

CHAPTER 8. MEASUREMENT OF DISCHARGE BY MISCELLANEOUS METHODS

GENERAL

This chapter deals with the measurement of discharge when conditions are such that it is not feasible to use either a velocity meter or tracer-dilution equipment. The situations and methodologies discussed include the following:

A. High flow
   1. Timed observation of floats
B. Low flow
   1. Volumetric measurement
   2. Use of a calibrated portable weir plate
   3. Use of a calibrated portable Parshall flume
C. Unstable flow—roll waves or slug flow
   1. Use of photographic techniques

Not discussed here is the practice followed in many countries, other than the U.S.A., in which discharge is measured by observing the head on gaging-station controls that are built in conformity with laboratory-rated weirs or flumes. The transfer of a laboratory discharge rating to a structure in the field requires the existence, and maintenance, of similitude between laboratory model and prototype, not only with regard to the structure, but also with regard to the approach channel. For example, scour and (or) fill in the approach channel will change the head-discharge relation, as will algal growth on the control structure. Both the structure and the approach channel must be kept free from accumulations of debris, sediment, and vegetal growth. Flow conditions downstream from the structure are significant only to the extent that they control the tailwater elevation, which may influence the operation of structures designed for free-flow conditions.

The existence or development of conditions that differ from laboratory conditions will necessitate in place calibration of the control to establish the extent of departure from the laboratory discharge ratings. In place calibration requires the measurement of discharge by current meter or by other means, as described in chapters 5 through 9. Because experience in the U.S.A. has indicated that departure from laboratory conditions is the norm, rather than the exception, gaging-station controls are always calibrated in place by the U.S. Geological Survey.

The reader who is interested in the measurement of discharge by the use of precalibrated controls is referred to publications by the World Meteorological Organization (1971) and the International Standards Organization (1969).

FLOATS

Floats are seldom used in stream gaging but are useful in an emergency for measuring high discharges under the following circumstances:

1. No conventional or optical current meter is available.
2. A current meter is available but the measurement structure—bridge or cableway—has been destroyed, and equipment for measuring from a boat is unavailable.
3. A conventional current meter is available, but floating ice or drift make it impossible to use the meter.

Surface floats are used in those situations, and they may be almost any distinguishable article that floats, such as wooden disks; bottles partly filled with either water, soil, or stones; or oranges. Floating ice cakes or distinguishable pieces of drift may be used if they are present in the stream.

Two cross sections are selected along a reach of straight channel for a float measurement. The cross sections should be far enough apart so that the time the float takes to pass from one cross section to the other can be measured accurately. A traveltime of at least 20 s is recommended, but a shorter time may be used for streams with such high velocities that it is not possible to find a straight reach of channel having adequate length. The water-surface elevation should be referenced to stakes along the bank at each cross section and at one or more intermediate sites. Those elevations will be used at a later date, when conditions permit, to survey cross sections of the measurement reach, and the end stakes will be used to obtain the length of the reach. The surveyed cross sections will then be used to derive an average cross section for the reach.

In making a float measurement a number of floats are distributed uniformly across the stream width, and the position of each with respect to distance from the bank is noted. The floats should be introduced a short distance upstream from the upstream cross section so that they will be traveling at the speed of the current when they reach the upstream section. A stopwatch is used to time their travel between the end cross sections of the reach. The estimated position of each float with respect to the bank is also noted at the downstream cross section.

If there is no bridge or cableway from which to introduce the floats in the stream, the floats will have to be tossed in from the streambank. If that is the situation that exists at a wide stream, it may be impossible to position any floats in the central core of the stream where most of the flow occurs. A float measurement of discharge made under those conditions would be meaningless. However, the difficulty of introducing floats at intervals across the entire width

of a wide stream can be overcome if a boat can be obtained for the purpose.

The velocity of a float is equal to the distance between the end cross sections divided by the time of travel. The mean velocity in the vertical is equal to the float velocity multiplied by a coefficient whose value is dependent on the shape of the vertical-velocity profile of the stream and on the depth of immersion of the float with respect to stream depth. A coefficient of 0.85 is commonly used to convert the velocity of a surface float to mean velocity in the vertical.

The procedure for computing the discharge is similar to that used in computing the discharge for a conventional current-meter measurement. (See chapter 5.) The discharge in each subsection of the average cross section is computed by multiplying the area of the subsection by the mean vertical velocity for that subsection. The total discharge is equal to the sum of the discharges for all subsections.

Float measurements of discharge that are carefully made under favorable conditions may be accurate to within ±10 percent. Wind may adversely affect the accuracy of the computed discharge by its effect on the velocity of the floats. If a nonuniform reach is selected and few floats are used in the cross section, measurement results may be in error by as much as 25 percent.

VOLUMETRIC MEASUREMENT

The volumetric measurement of discharge is only applicable to small discharges, but it is the most accurate method of measuring such flows. In that method the hydrographer observes the time required to fill a container of known capacity, or the time required to partly fill a calibrated container to a known volume. The only equipment required, other than the calibrated container, is a stopwatch.

The container is calibrated in either of two ways. In the first method, water is added to the container by known increments of volume, and the depth of water in the container is noted after the addition of each increment. In the second method, the empty container is placed on a weighing scales, and its weight is noted. Water is added to the container in increments, and after each addition the total weight of container and water is noted, along with the depth of water in the container. The equation used to determine the volume corresponding to a depth that was read is

$$V = \frac{W_2 - W_1}{w}, \tag{42}$$

where

V = volume of water in container, in cubic feet or cubic meters,

W_2 = weight of water and container, in pounds or kilograms,

W_1 = weight of empty container, in pounds or kilograms, and
w = unit weight of water, 62.4 lb/ft^3 or 1,000 kg/m^3.

Volumetric measurements are usually made where the flow is concentrated in a narrow stream, or can be so concentrated, so that all the flow may be diverted into a container. Examples of sites presenting the opportunity for volumetric measurement of discharge are a V-notch weir; an artificial control where all the flow is confined to a notch or to a narrow width of catenary-shaped weir crest; and a cross section of natural channel where a temporary earth dam can be built over a pipe of small diameter, through which the entire flow is directed. Sometimes it is necessary to place a trough against the artificial control to carry the water from the control to the calibrated container. If a small temporary dam is built, the stage behind the dam should be allowed to stabilize before the measurement is begun. The measurement is made three or four times to be certain no errors have been made and to be sure the results are consistent.

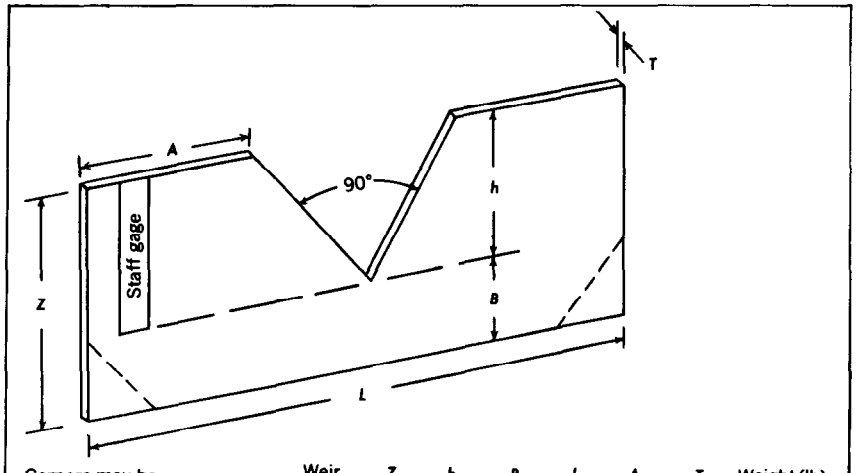
Volumetric measurements have also been made under particular circumstances when no other type of measurement was feasible. One such circumstance involved a small stream that was in actuality a series of deep pools behind broad-crested weirs that acted as drop structures to dissipate the energy of the stream. At low flows the depth of water on the weir crest was too shallow to be measured by current meter, and the velocity in the pools was too slow for such measurement. To measure the discharge a large container of known volume was placed on a raft held close to the downstream weir face by ropes operated from the banks. A sharp-edged rectangular spout of known width was held so that one end butted tightly against the downstream face of the weir, the base of the spout being held just below the weir crest. The other end of the spout led to the container of known volume. Timed samples of the flow, sufficient to fill the container, were taken at a number of locations along the downstream face of the weir, the raft being moved laterally across the stream, from location to location, by the ropes. The procedure was analogous to making a conventional current-meter discharge measurement. Instead of measuring depth and velocity at a series of observation sites in the cross section, as is done in a current-meter measurement, the discharge per width of spout opening was measured at a series of observation sites. The discharge measured at each site was multiplied by the ratio of subsection width to spout width to obtain the discharge for the subsection. The total discharge of the stream was the summation of the discharges computed for each subsection.

PORTABLE WEIR PLATE

A portable weir plate is a useful device for determining discharge

when depths are too shallow and velocities too low for a reliable current-meter measurement of discharge. A 90° V-notch weir is particularly suitable because of its sensitivity at low flows. Three different sizes of weir plate are commonly used by the U.S. Geological Survey; their recommended dimensions are given in figure 129.

The weir plate is made of galvanized sheet iron, using 10- to 16-gauge metal. The 90° V-notch that is cut in the plate is not beveled but is left with flat, even edges. The larger weir plates are made of thinner material than the smaller weir plates, but the medium and large plates are given additional rigidity by being framed with small angle irons fastened to the downstream face. A staff gage, attached to the upstream side of the weir plate with its zero at the elevation of the bottom of the notch, is used to read the head on the weir. The staff gage should be installed far enough from the notch to be outside the region of drawdown of water going through the notch. Drawdown becomes negligible at a distance from the vertex of the notch that is equal to twice the head on the notch. Consequently, if the weir plate has the dimensions recommended in figure 129, the staff gage should be installed near one end of the plate.



Corners may be trimmed if desired

Weir	Z	h	B	L	A	T	Weight (lb)
Large	1.75	1.00	0.75	4.0	1.0	16 ga.	24
Medium	1.25	.80	.45	3.0	.7	14 ga.	17
Small	.75	.47	.28	2.0	.53	10 ga.	8

All dimensions, other than T, are in feet

FIGURE 129.—Portable weir-plate sizes.

To install the weir, the weir plate is pushed into the streambed. A pick or shovel may be necessary to remove stones or rocks that prevent even penetration of the plate. A carpenter's level is usually used to insure that the top of the plate is horizontal and that the face of the plate is vertical. Another means of leveling the weir plate is by the use of a staff gage or level bubble attached at each end of the plate. The weir plate is then leveled by adjusting it until both staff gages give identical readings of the water surface or until the level bubbles are centered. Through eyebolts that are attached to the plate, rods are driven into the streambed to maintain the weir in a vertical position. Soil or streambed material is packed around the weir plate to prevent leakage under and around it. Canvas is placed immediately downstream from the weir to prevent undercutting of the bed by the falling jet. It ordinarily requires only one man to make the installation.

A large weir plate of the dimensions shown in figure 129 can measure discharges in the range from 0.02 to 2.0 ft^3/s (0.00057 to 0.057 m^3/s) with an accuracy of ±3 percent, if the weir is not submerged. A weir is not submerged when there is free circulation of air on all sides of the nappe. The general equation for flow over a sharp-edged 90° V-notch weir is

$$Q = Ch^{5/2}, \tag{43}$$

where

Q = discharge, in cubic feet per second or cubic meters per second,
h = static head above the bottom of the notch, in feet or meters, and
C = coefficient of discharge.

Each weir should be rated by volumetrically measuring the discharge corresponding to various values of head. In the absence of such a rating, a value of 2.47 may be used for C in equation 43 when English units are used, or 1.36 when metric units are used.

When the weir is installed it will cause a pool to form on the upstream side of the plate. No readings of head on the notch should be recorded until the pool has risen to a stable elevation. The head should then be read at half-minute intervals for about 3 min, and the mean value of those readings should be the head used in equation 43 to compute discharge. After the completion of the measurement the weir plate is removed.

PORTABLE PARSHALL FLUME

A portable Parshall flume is another device for determining discharge when depths are too shallow and velocities too low for a current-meter measurement of discharge. The portable flume used by the U.S. Geological Survey is a modified form of the standard Par-

shall flume (p.314–319) having a 3-in (0.076 m) throat. The modification consists, primarily, of the removal of the downstream diverging section of the standard flume. The purpose of the modification is to reduce the weight of the flume and to make it easier to install. Because the portable Parshall flume has no downstream diverging section, it cannot be used for measuring flows when the submergence ratio exceeds 0.6. The submergence ratio is the ratio of the downstream head on the throat to the upstream head on the throat. Although a submergence ratio of 0.6 can be tolerated without affecting the rating of the portable flume, in practice the flume is usually installed so that the flow passing the throat has virtually free fall. That is usually accomplished by building up the streambed a couple of inches under the level converging floor of the flume. (See fig. 130.)

Figure 130 shows the plan and elevation of the portable Parshall flume. The gage height or upstream head on the throat is read in the small stilling well that is hydraulically connected to the flow by a ⅜-in hole. The rating for the flume is given in table 14.

When the flume is installed in the channel, the floor of the converging section is set in a level position by using the level bubble that is attached to one of the braces (fig. 130). A carpenter's level can be used for that purpose if the flume is not equipped with a level bubble. Soil or streambed material is then packed around the flume to prevent leakage under and around it. Figure 131 shows a typical field installation. After the flume is installed, water will pool upstream from structure. No gage-height readings should be recorded until the pool has risen to a stable level. As with the portable weir, after stabilization of the pool level, gage-height readings should be taken at half-

TABLE 14.—*Rating table for 3-in modified Parshall flume*

minute intervals for about 3 min. The mean value of those readings is the stage used in table 14 to obtain the discharge. A carefully made measurement should have an accuracy of ±2 or 3 percent. After completion of the measurement, the portable flume is removed.

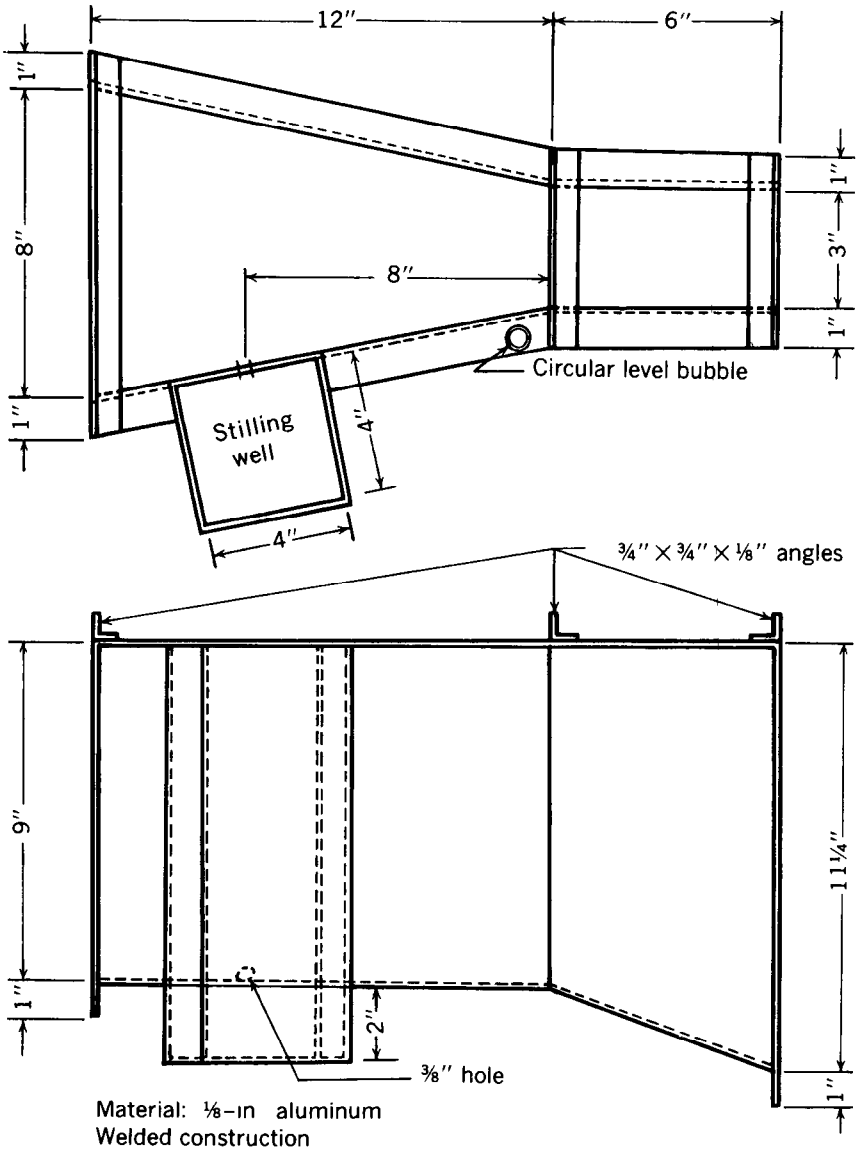

FIGURE 130.—Working drawing of modified 3-in Parshall flume.

MEASUREMENT OF UNSTABLE FLOW—ROLL WAVES OR SLUG FLOW

CHARACTERISTICS OF UNSTABLE FLOW

Unstable or pulsating flow often occurs during flash floods in arid areas. In pulsating flow the longitudinal profile is marked by a series of abrupt translatory waves (fig. 132) that rapidly move downstream. Translatory waves, commonly called roll waves or slug flow, can only develop in steep channels of supercritical slope and, therefore, are a matter of concern to the designer of steep-gradient channels. Channels are usually designed for stable flow. Should pulsating flow occur at high stages in a channel so designed, the channel capacity may be inadequate at a discharge much smaller than the design flow. Furthermore, if the overriding translatory wave carries an appreciable part of the total flow, conventional stream-gaging methods cannot be used to determine the discharge. Conventional water-stage recorders

FIGURE 131.—Modified 3-in Parshall flume installed for measuring discharge.

of either the float or pressure-sensing type do not react quickly enough to record the rapidly fluctuating stage; depths and velocities change too rapidly to permit discharge measurement by current meter; no stage-discharge relation exists for pulsating flow; and the commonly used formulas for computing stable open-channel discharge are not applicable.

DETERMINATION OF DISCHARGE

In brief, the method of determining the discharge of pulsating flow requires (1) computation of the discharge (Q_w) in the overriding waves and (2) computation of the discharge (Q_1) in the shallow-depth, or overrun, part of the flow. The sum of the two discharges is the total discharge at the time of observation.

To compute the discharge (Q_w) in an overriding wave, which is usually wedge shaped (fig. 132), the dimensions of the wave are observed, and the volume of the wave is divided by the elapsed time between the arrival of waves. For example, if the wedge-shaped wave in a train of waves has a volume of 200 ft^3 (5.67 m^3) and a wave arrives every 10 s, the discharge in the overriding wave is 200/10, or 20 ft^3/s (0.57 m^3/s). Average values are usually used in the computation—for example, the average volumes of five consecutive waves and the average time interval between the arrival of those consecutive waves. It should be mentioned at this point that the longitudinal profile of the wave is actually slightly concave upward and the wave front, while extremely steep, is not vertical. However, to simplify the computation of discharge, the waves are assumed to have a simple wedge shape.

To compute the discharge (Q_1) in the shallow-depth, or overrun, part of the flow, the cross-sectional area of the shallow-depth flow is

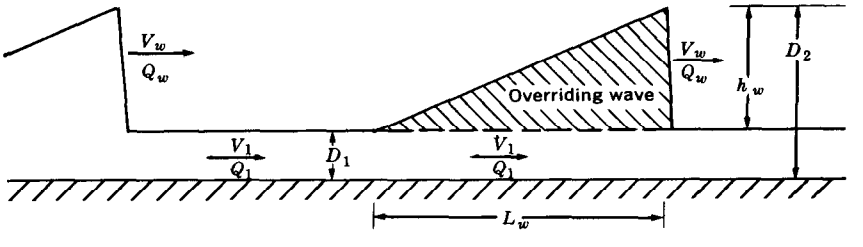

FIGURE 132.—Schematic sketch of longitudinal water-surface profile during pulsating flow.

observed (D_1 × channel width), and that area is multiplied by its velocity, V_1. Seldom will there be time enough between waves to obtain velocity observations of V_1 with a conventional current meter. V_1 may be computed by some stable-flow equation, such as the Manning equation, but preferably the surface velocity of shallow-depth flow should be measured by optical current meter. (See p. 91–93.) The surface velocity can then be multiplied by an appropriate coefficient—0.9 or 0.85, for example—to give the mean velocity, V_1. The final step is to compute the total discharge at the time of observation by adding Q_w and Q_1.

EXAMPLES OF DISCHARGE DETERMINATION

This section briefly describes two examples of discharge determinations made under conditions of pulsating flow in southern California.

Holmes (1936) obtained photographic documentation of a train of translatory waves in a steep stormflow channel. The rectangular channel was 43 ft (13.10 m) wide, 8 ft (2.44 m) high, and had a slope of 0.02. The waves themselves lapped at the top of the manmade channel giving them a height (D_2) of 8 ft, and their length (L_w) was about 600 ft (180 m). The average distance between wave crests was about 1,200 ft (360 m), and the average time interval between arrival of the waves (T_p) was 51 s. The channel between waves was dry or nearly so ($D_1=0$), meaning that the entire discharge was transported in the waves. The average discharge over the time T_p, computed from the equation

$$Q = (\text{volume})/T_p = \tfrac{1}{2}\,(W)\,(h_w)\,(L_w)/(T_p), \tag{44}$$

was therefore about 2,000 ft^3/s (56 m^3/s). The channel had been designed for stable-flow conditions and, according to the Manning equation, had a capacity of about 16,000 ft^3/s (405 m^3/s). We see then, that under the observed conditions of unstable flow the channel could accommodate only one-eighth of the design discharge.

Thompson (1968) described the experimental measurement of pulsating flow in the rectangular stormflow channel of Santa Anita Wash in Arcadia, California. The concrete channel was 28 ft (8.5 m) wide and had a slope of 0.0251. On the infrequent occasions when the channel had carried storm runoff in the past, the flow had been observed to be pulsating. For the test, water was released into the channel from an upstream reservoir at controlled rates of approximately 100 ft^3/s (2.8 m^3/s), 200 ft^3/s (5.6 m^3/s), 300 ft^3/s (8.5 m^3/s). Unstable flow did not develop until the flow came out of a bend in the steep storm channel and entered a straight reach of the channel. In other words, the released flow was stable upstream from the bend and pulsating downstream from the bend. During the release of water, dis-

charge measurements were made continuously by current meter in the stable flow upstream from the bend. The discharge hydrograph based on those measurements is shown by solid line in figure 133. Downstream from the bend a simultaneous attempt was made to measure the unstable flow by the method described in this paper, for the purpose of verifying the method.

At the test site, about 3,300 ft (1,000 m) downstream from the bend, the equivalent of a series of staff gages, in the form of a grid, was painted on one of the vertical channel walls so that water-surface

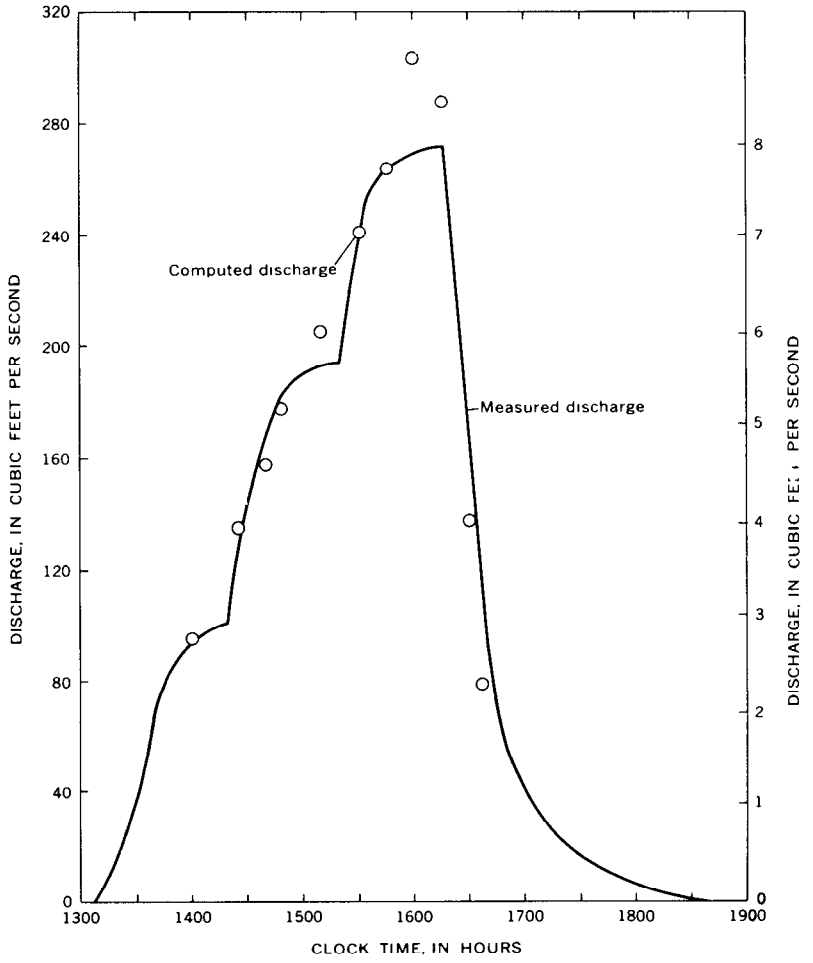

FIGURE 133.—Discharge hydrograph at Santa Anita Wash above Sierra Madre Wash, Calif., April 16, 1965, and plot of discharges computed from observations of flow.

elevations could easily be read by a crew of observers. Some of the observers were equipped with both still- and motion-picture cameras to document the observations; others were equipped with stopwatches to time wave velocity over a measured course of 102 ft (31 m) and to obtain the elapsed time between the arrival of waves. The waves were not evenly spaced and occasionally one wave would overtake another, but in general the waves were fairly uniform in size, maintained their spacing, and underwent little attenuation in the 3,300-ft reach above the test site. For computation purposes the average volumes of five consecutive waves and their average elapsed time between arrivals (T_p) were used, and discharges were computed at 15 min intervals using the procedure described earlier. For example, at the time of greatest discharge, the average value of T_p was 9.6 s, and the average wave dimensions were $D_1 = 0.42$ ft (0.13 m), $h_w = 0.66$ ft (0.20 m), and $L_w = 158$ ft (48.2 m). The computed value of Q_w equaled 152 ft^3/s (4.30 m^3/s). No optical current meter was available at the time, and Q_1 was therefore computed by the Manning equation. The computed value of Q_1 also equaled 152 ft^3/s (4.30 m^3/s), giving a computed total discharge 304 ft^3/s (8.60 m^3/s) at the time of observation. The values of discharge that were computed at 15-min intervals are plotted as open circles in figure 133 and show satisfactory agreement with the "true" discharge hydrograph. The field test of the method was therefore considered a success.

PROPOSED INSTRUMENTATION

There is as yet no instrumentation that is operational for automatically recording the data required to compute discharge under conditions of pulsating flow. Thompson concluded the above-cited report (1968) by describing three types of automatic instrumentation—photographic, depth sensing, and dye dilution—that might be developed for that purpose.

CHAPTER 9.—INDIRECT DETERMINATION OF PEAK DISCHARGE

INTRODUCTION

During floods, it is frequently impossible or impractical to measure the peak discharges when they occur because of conditions beyond control. Roads may be impassable; structures from which current-meter measurements might have been made may be nonexistent, not suitably located, or destroyed; knowledge of the flood rise may not be available sufficiently in advance to permit reaching the site near the time of the peak; the peak may be so sharp that a satisfactory current-meter measurement could not be made even with an engineer present at the time; the flow of debris or ice may be such as to prevent use of a current meter; or limitations of personnel might make it impossible to obtain direct measurements of high-stage discharge at numerous locations during a short flood period. Consequently, many peak discharges must be determined after the passage of the flood by indirect methods such as slope-area, contracted opening, flow-over-dam, or flow-through-culvert.

Indirect determinations of discharge make use of the energy equation for computing streamflow. The specific equations differ for different types of flow, such as unobstructed open-channel flow, flow over dams, and flow through culverts. However, all the methods involve these general factors:

1. Physical characteristics of the channel; that is dimensions and conformation of the channel within the reach used and boundary conditions.
2. Water-surface elevations at time of peak stage to define the upper limit of the cross-sectional areas and the difference in elevation between two or more significant cross sections.
3. Hydraulic factors based on physical characteristics, water-surface elevations, and discharge, such as roughness coefficients and discharge coefficients.

This chapter provides only a brief general discussion of the procedures used in collecting field data and in computing discharge by the various indirect methods. That highly specialized subject is treated in detail in the several manuals of the series "Techniques of Water-Resources Investigations of the United States Geological Survey" that are listed as references at the end of this chapter.

It should be remembered that the discharge that is determined by either direct measurement or by indirect methods includes not only the water but also any substances suspended or dissolved in the water (p. 79).

COLLECTION OF FIELD DATA

The data required for the computation of discharge by indirect methods are obtained in a field survey of a reach of channel. The survey includes the elevation and location of high-water marks corresponding to the peak stage; cross sections of the channel along the reach; selection of a roughness coefficient; and description of the geometry of dams, culverts, or bridges, depending on the type of peak-discharge determination to be made. The selection of a suitable site is a most important element in the application of the indirect method of discharge determination.

It is recommended that a transit be used to make a "transit-stadia" survey of the selected site. That method combines vertical and horizontal control surveys in one operation and is accurate, simple, and speedy.

Selection of a roughness coefficient remains essentially an "art" that is developed through experience. The factors that exert the greatest influence on the coefficient of roughness are the character of the streambed material, cross section irregularity, the presence of vegetation, and the alinement of the channel. In the Manning equation the roughness coefficient, n, ranges from as low as 0.012 for a concrete-lined channel in excellent condition or for a smooth sand channel of regular geometry to more than 0.1 for overbank areas having a heavy cover of brush.

SLOPE-AREA METHOD

The slope-area method is the most commonly used technique of indirect discharge determination. In the slope-area method, discharge is computed on the basis of a uniform-flow equation involving channel characteristics, water-surface profiles, and a roughness or retardation coefficient. The drop in water-surface profile for a uniform reach of channel represents energy losses caused by bed and bank roughness.

In applying the slope-area method, any one of the well-known variations of the Chezy equation may be used. However the Manning equation is preferred in most countries, including the U.S.A., because it is simple to apply, and the many years of experience in its use have shown that it produces reliable results.

The Manning equation, written in terms of discharge, is

$$Q = \frac{1.486}{n} AR^{2/3}S^{1/2}, \quad \text{(in English units), or} \qquad (45)$$

$$Q = \frac{AR^{2/3}S^{1/2}}{n} \quad \text{(in metric units),} \qquad (45a)$$

where

Q = discharge,
A = cross-sectional area,
R = hydraulic radius,
S = friction slope, and
n = roughness coefficient.

The Manning equation was developed for conditions of uniform flow in which the water-surface profile and energy gradient are parallel to the streambed and the area, hydraulic radius, and depth remain constant throughout the reach. For lack of a better solution, it is assumed that the equation is also valid for the nonuniform reaches that are invariably encountered in natural channels, if the water-surface gradient is modified by the difference in velocity-head between cross sections. The energy equation for a reach of nonuniform channel between cross section 1 and cross section 2 shown in figure 134 is

$$(h_1 + h_{v_1}) = (h_2 + h_{v_2}) + (h_f)_{1-2} + k(\Delta h_v)_{1-2}, \qquad (46)$$

where

h = elevation of the water surface at the respective cross sections above a common datum,
h_v = velocity head at the respective cross sections = $\alpha V^2/2g$, where α = velocity-head coefficient,
h_f = energy loss due to boundary friction in the reach,
Δh_v = upstream velocity head minus the downstream velocity head, used as a criterion for expansion or contraction of reach, and
$k(\Delta h_v)$ = energy loss due to acceleration or deceleration in a contracting or expanding reach, where
k = energy loss coefficient.

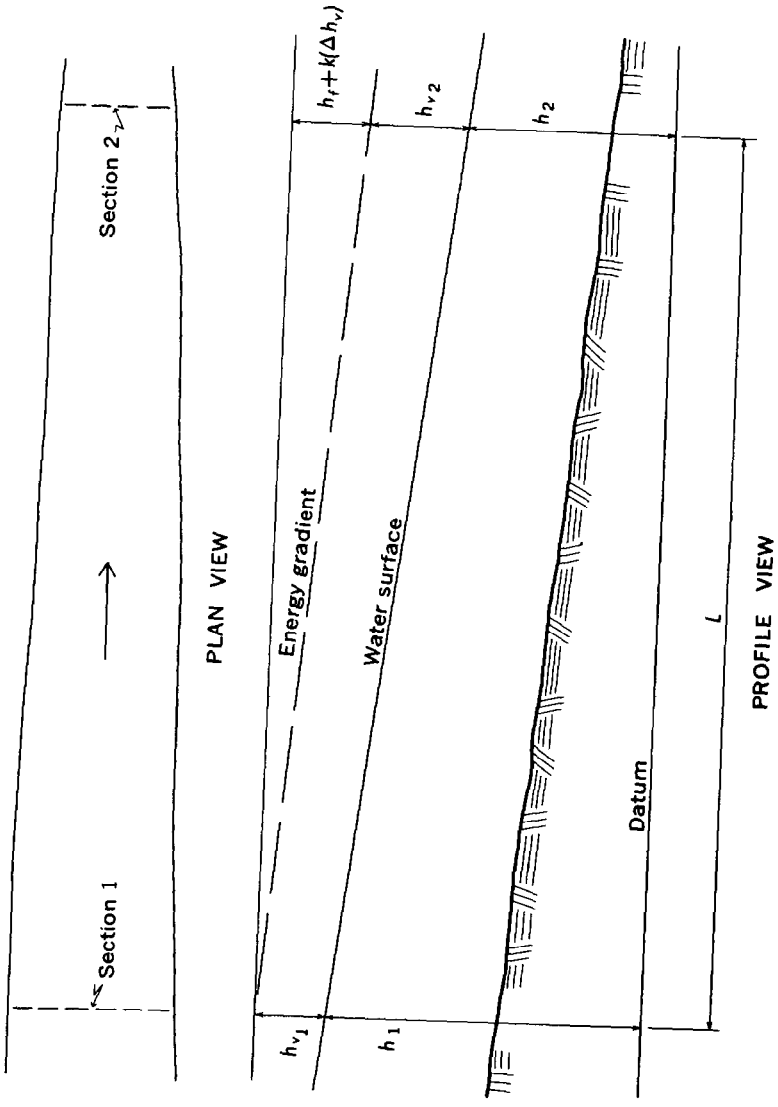

FIGURE 134.—Definition sketch of a slope-area reach.

The friction slope (S) to be used in the Manning equation is thus defined as

$$S = \frac{h_f}{L} = \frac{\Delta h + \Delta h_v - k(\Delta h_v)}{L}, \tag{47}$$

where Δh is the difference in water-surface elevation at the two sections and L is the length of the reach.

In using the Manning equation the conveyance, K, is computed for each cross section as $(1.486/n)AR^{2/3}$ in English units, or $(1/n)AR^{2/3}$ in metric units. The mean conveyance in the reach is then computed as the geometric mean of the conveyance at the two sections. This procedure is based on the assumption that the conveyance varies uniformly between sections. The discharge is computed by use of the equation

$$Q = \sqrt{K_1 K_2 S}, \tag{48}$$

where S is the friction slope as previously defined.

CONTRACTED-OPENING METHOD

The contraction of a stream channel by a roadway crossing creates an abrupt drop in water-surface elevation between an approach section and the contracted section under the bridge. The contracted section framed by the bridge abutments and the channel bed is in a sense a discharge meter that can be utilized to compute floodflows. The head on the contracted section is defined by high-water marks, and the geometry of the channel and bridge is defined by field surveys.

In computations of peak discharge at a contraction, the drop in water-surface level between an upstream section and a contracted section is related to the corresponding change in velocity. The discharge equation results from writing the energy and continuity equations for the reach between these two sections, designated as sections 1 and 3 in figure 135.

The discharge equation is

$$Q = CA_3\sqrt{2g\left(\Delta h + \alpha_1 \frac{V_1^2}{2g} - h_f\right)}, \tag{49}$$

in which

Q = discharge,
g = acceleration of gravity,
C = coefficient of discharge based on the geometry of the bridge and embankment,
A_3 = gross area of section 3; this is the minimum section parallel to the constriction between the abutments, and it is not

necessarily located at the downstream side of the bridge,

Δh = difference in elevation of the water surface between sections 1 and 3,

$\alpha_1 \frac{V_1^2}{2g}$ = weighted average velocity head at section 1, where V_1 is the average velocity, Q/A_1, and α_1 is coefficient that takes into account the variation in velocity in that section, and

h_f = the head loss caused by friction between sections 1 and 3.

The friction loss, h_f, as computed by the Manning equation, is only

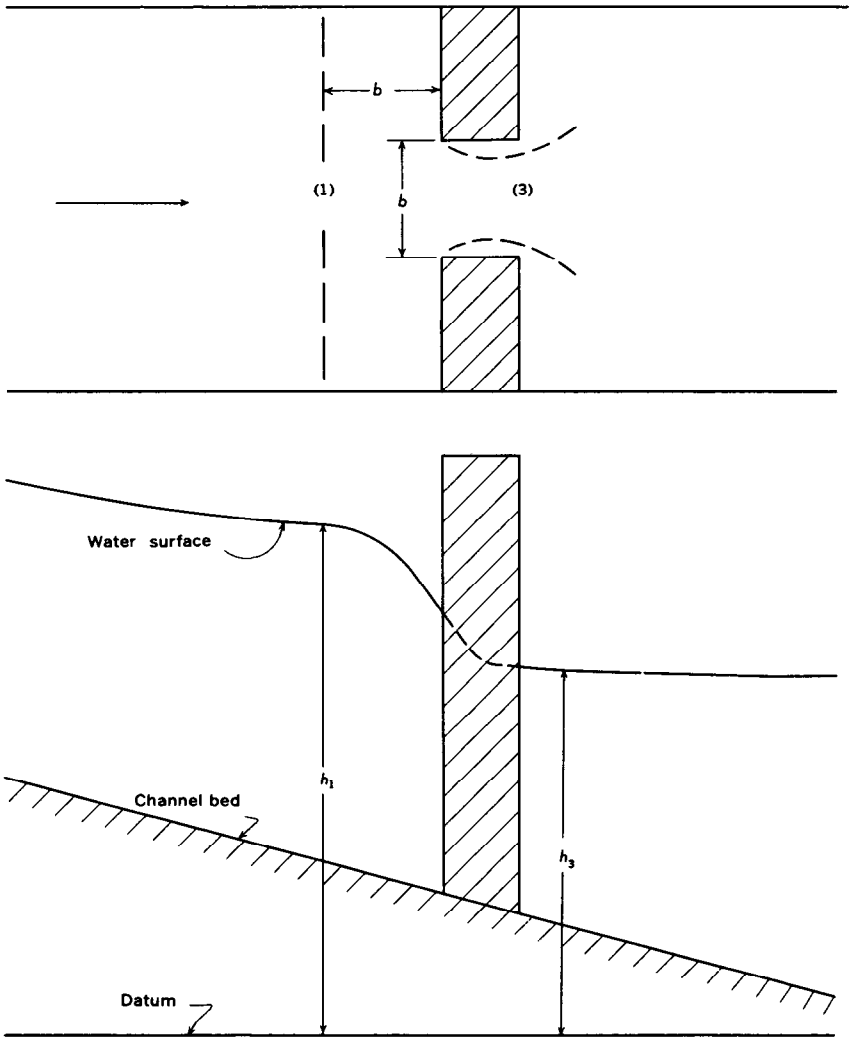

FIGURE 135.—Definition sketch of an open-channel contraction.

an approximation of the actual loss because of the rapid change in velocity from section 1 to section 3. Therefore, satisfactory results are attainable only if the term "h_f" is small relative to the difference in head, Δh.

FLOW OVER DAMS AND WEIRS

The term "dams," as used here, also includes highway and railway embankments that act as broad-crested dams during floods. The peak discharge over a dam or weir can be determined on the basis of a field survey of high-water marks and the geometry of the particular structure. (The terms "dam" and "weir" are used interchangeably.)

The basic equation for flow over a dam is

$$Q = CbH^{3/2}, \tag{50}$$

where

Q = discharge,
C = a coefficient of discharge having the dimensions of the square root of the acceleration of gravity,
b = width of the dam normal to the flow, excluding the width of piers, if any, and
H = total energy head ($h + V_a^2/2g$) referred to the crest of the dam, where h = static head, and V_a = mean velocity at the approach section to the dam.

It is apparent from equation 50 that the reliability of a computation of flow over a dam is dependent primarily on using the correct dam coefficient, C. Values of C vary with the geometry of the dam and with the degree of submergence of the dam crest by tailwater. One of the manuals referred to on page 273 (Hulsing, 1967) treats in detail the coefficients associated with sharp-crested (thin-plate) weirs, broad-crested weirs, round-crested weirs, and weirs of unusual shape. Because the technical details in that manual cannot be readily summarized here, the reader is referred to the Hulsing report.

FLOW THROUGH CULVERTS

The peak discharge through culverts can be determined from high-water marks that define the headwater and tailwater elevations. This indirect method is used extensively to measure flood discharges from small drainage areas.

The placement of a roadway fill and culvert in a stream channel causes an abrupt change in the character of flow. This channel transition results in rapidly varied flow in which acceleration, rather than boundary friction, plays the primary role. The flow in the approach channel to the culvert is usually tranquil and fairly uniform. However, within the culvert the flow may be tranquil, critical, or rapid if the culvert is partially filled, or the culvert may flow full under pressure.

The physical features associated with culvert flow are illustrated in figure 136. They are the cross section in the approach channel located upstream from the culvert entrance at a distance that is equivalent to the width of the culvert opening; the culvert entrance; the culvert barrel; the culvert outlet; the farthest downstream section of the barrel; and the tailwater downstream from the culvert barrel.

The change in the water-surface profile in the approach channel reflects the effect of acceleration that results from the contraction of cross sectional area. Loss of energy near the entrance is related to the sudden contraction and subsequent expansion of the live stream within the barrel, and entrance geometry has an important influence on this loss. The important features that control the stage-discharge relation at the approach section can be the occurrence of critical depth in the culvert, the elevation of the tailwater, the entrance or barrel geometry, or a combination of these elements.

The peak discharge through a culvert is determined by application of the continuity equation and the energy equation between the approach section and a section within the culvert barrel. The location of the downstream section depends on the state of flow in the culvert barrel. For example, if critical flow occurs at the culvert entrance, the headwater elevation is not a function of either the barrel friction loss or the tailwater elevation, and the terminal section is located at the upstream end of the culvert.

Information obtained in the field survey includes the peak elevation of the water surface upstream and downstream from the culvert and the geometry of the culvert and approach channel. Reliable high-water marks can rarely be found in the culvert barrel; therefore, the type of flow that occurred during the peak flow cannot always be determined directly from field data, and classification becomes a trial-and-error procedure.

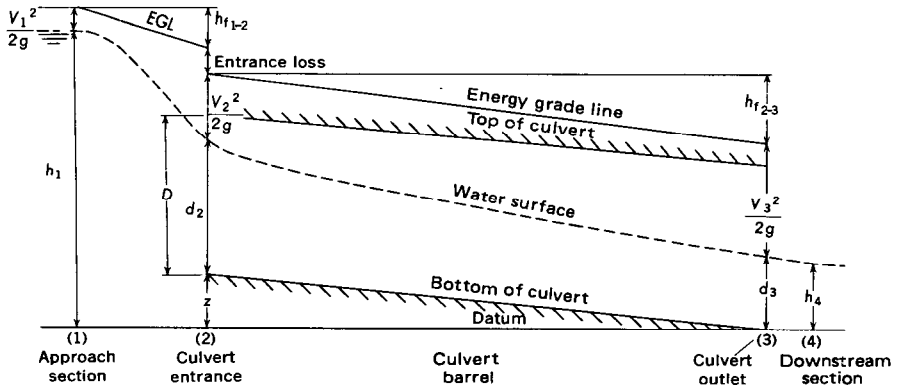

FIGURE 136.—Graphical presentation of the Bernoulli equation in culvert flow.

GENERAL CLASSIFICATION OF FLOW

For convenience in computation, culvert flow has been classified into six types on the basis of the location of the control section and the relative heights of the headwater and tailwater elevations. The six types of flow are illustrated in figure 137, and pertinent characteristics of each type are given in table 15. From that information the general classification of types of flow can be made.

1. If h_4/D is equal to or less than 1.0 and $(h_1 - z)/D$ is less than 1.5, only types I, II, and III flow are possible.
2. If h_4/D is greater than 1.0, only type IV flow is possible.
3. If h_4/D is equal to or less than 1.0 and $(h_1 - z)/D$ is equal to or greater than 1.5, only types V and VI flow are possible.

A manual by Bodhaine (1968) discusses trial-and-error procedures for further identification of the type of culvert flow and for the computation of discharge.

ESTIMATING DISCHARGE FROM SUPERELEVATION IN BENDS

Situations exist where none of the four methods previously described for determining peak discharge can be reliably applied. For example, in a highly sinuous, steep canyon stream, there may be no straight reaches of sufficient length for reliable application of the slope-area method; no abrupt area contractions may exist; and no manmade structures, such as dams or culverts, may have been built. In the above situation the peak discharge may sometimes be estimated from the superelevation in a bend of the stream (Apmann, 1973). The discharge should be estimated at each of several bends, after which the several estimated discharges are averaged.

A fundamental characteristic of open channel flow is the deformation of the free surface in a bend because of the action of centrifugal force. The water surface rises on the concave or outside bank of the

TABLE 15.—*Characteristics of types of culvert flow*

Flow type	Barrel flow	Location of terminal section	Kind of control	Culvert slope	$\frac{h_1-z}{D}$	$\frac{h_4}{h_c}$	$\frac{h_4}{D}$
I	Partly full	Inlet	Critical depth.	Steep	<1.5	<1.0	≤1.0
II	do	Outlet	do	Mild	<1.5	<1.0	≤1.0
III	do	do	Backwater	do	<1.5	>1.0	≤1.0
IV	Full	do	do	Any	>1.0	–	>1.0
V	Partly full	Inlet	Entrance geometry.	do	≥1.5	–	≤1.0
VI	Full	Outlet	Entrance and barrel geometry.	do	≥1.5	–	≤1.0

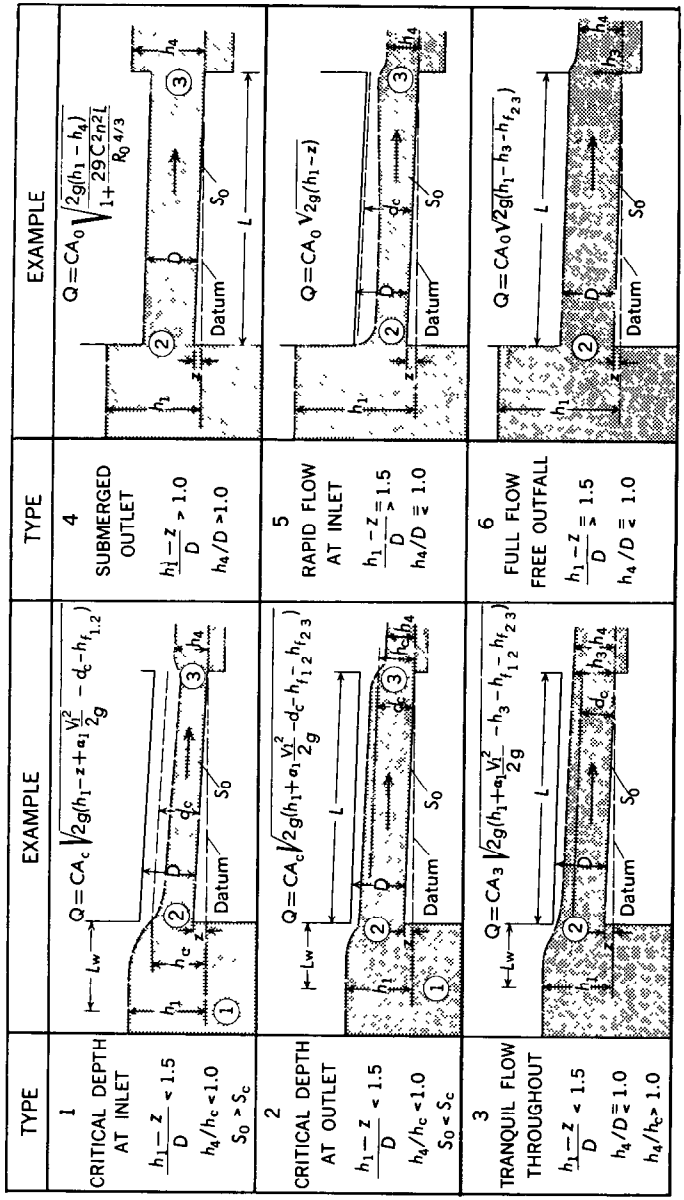

FIGURE 137.—Classification of culvert flow.

bend and lowers along the convex or inside bank of the bend. The difference in water-surface elevation between the banks is the superelevation. Superelevation varies with angular distance in the bend because of acceleration of the fluid entering and leaving the curve and because of the varying curvature of streamlines within the bend.

The discharge equation given by Apmann (1973) is

$$Q = A\sqrt{\frac{gh}{K}} \tag{51}$$

where

Q = discharge,
A = average radial cross section in the bend,
g = acceleration of gravity,
h = superelevation, that is, the maximum difference in water-surface elevation, measured along a radius of the bend, between inner and outer banks of the bend, and
K = superelevation coefficient.

The value of K is determined from the equation

$$K = \frac{5}{4}\tanh\left(\frac{r_c\Theta}{b}\right)\ln\left(\frac{r_o}{r_i}\right). \tag{52}$$

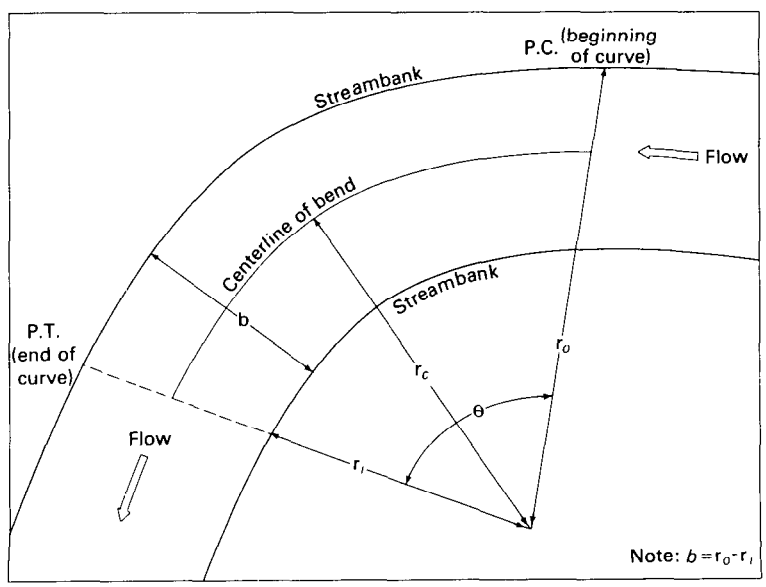

FIGURE 138.—Idealized sketch of a bend (plan view).

(NOTE.—tanh is the hyperbolic tangent)

The symbols in equation 52 are shown in the sketch in figure 138.

The method described applies only to bends having no overbank flow. The limited amount of work that has been done with the method indicates that it should not be applied where superelevations are less than 0.25 ft (0.076 m) because of uncertainties regarding the elevations of high-water marks at the banks. These uncertainties result from wave action and from the thickness of the bank-deposited debris that is often used as a high-water mark.

MEASUREMENT AND COMPUTATION OF STREAMFLOW

VOLUME 2. COMPUTATION OF DISCHARGE

By S. E. RANTZ and others

CHAPTER 10.—DISCHARGE RATINGS USING SIMPLE STAGE-DISCHARGE RELATIONS

INTRODUCTION

Continuous records of discharge at gaging stations are computed by applying the discharge rating for the stream to records of stage. Discharge ratings may be simple or complex, depending on the number of variables needed to define the stage-discharge relation. This chapter is concerned with ratings in which the discharge can be related to stage alone. (The terms "rating," "rating curve," "stage rating," and "stage-discharge relation" are synonymous and are used here interchangeably.)

Discharge ratings for gaging stations are usually determined empirically by means of periodic measurements of discharge and stage. The discharge measurements are usually made by current meter. Measured discharge is then plotted against concurrent stage on graph paper to define the rating curve. At a new station many discharge measurements are needed to define the stage-discharge relation throughout the entire range of stage. Periodic measurements are needed thereafter to either confirm the permanence of the rating or to follow changes (shifts) in the rating. A minimum of 10 discharge measurements per year is recommended, unless it has been demonstrated that the stage-discharge relation is unvarying with time. In that event the frequency of measurements may be reduced. It is of prime importance that the stage-discharge relation be defined for flood conditions and for periods when the rating is subject to shifts as a result of ice formation (see section titled, "Effect of Ice Formation on Discharge Ratings") or as a result of the variable channel and control conditions discussed in the section titled, "Shifts in the Discharge Rating." It is essential that the stream-gaging program have sufficient flexibility to provide for the nonroutine scheduling of additional measurements of discharge at those times.

If the discharge measurements cover the entire range of stage experienced during a period of time when the stage-discharge relation is stable, there is little problem in defining the discharge rating for that

period. On the other hand, if, as is usually the case, discharge measurements are lacking to define the upper end of the rating, the defined lower part of the rating curve must be extrapolated to the highest stage experienced. Such extrapolations are always subject to error, but the error may be reduced if the analyst has a knowledge of the principles that govern the shape of rating curves. Much of the material in this chapter is directed toward a discussion of those principles, so that when the hydrographer is faced with the problem of extending the high-water end of a rating curve he can decide whether the extrapolation should be a straight line, or whether it should be concave upward or concave downward.

The problem of extrapolation can be circumvented, of course, if the unmeasured peak discharge is determined by use of the indirect methods discussed in chapter 9. In the absence of such peak-discharge determinations, some of the uncertainty in extrapolating the rating may be reduced by the use of one or more of several methods of estimating the discharge corresponding to high values of stage. Four such methods are discussed in the section titled "High-flow Extrapolation."

In the discussions that follow it was generally impractical to use both English and metric units, except where basic equations are given. Consequently English units are used throughout, unless otherwise noted.

STAGE-DISCHARGE CONTROLS

The subject of stage-discharge controls was discussed in detail in chapter 3, but a brief summary at this point is appropriate.

The relation of stage to discharge is usually controlled by a section or reach of channel downstream from the gage that is known as the station control. A section control may be natural or manmade; it may be a ledge of rock across the channel, a boulder-covered riffle, an overflow dam, or any other physical feature capable of maintaining a fairly stable relation between stage and discharge. Section controls are often effective only at low discharges and are completely submerged by channel control at medium and high discharges. Channel control consists of all the physical features of the channel that determine the stage of the river at a given point for a given rate of flow. These features include the size, slope, roughness, alinement, constrictions and expansions, and shape of the channel. The reach of channel that acts as the control may lengthen as the discharge increases, introducing new features that affect the stage-discharge relation.

Knowledge of the channel features that control the stage-discharge relation is important. The development of stage-discharge curves where more than one control is effective, and where the number of

measurements is limited, usually requires judgment in interpolating between measurements and in extrapolating beyond the highest measurements. That is particularly true where the controls are not permanent and the various discharge measurements are representative of changes in the positioning of segments of the stage-discharge curve.

GRAPHICAL PLOTTING OF RATING CURVES

Stage-discharge relations are usually developed from a graphical analysis of the discharge measurements plotted on either rectangular-coordinate or logarithmic plotting paper. In a preliminary step the discharge measurements available for analysis are tabulated and summarized on a form such as that shown in figure 139. Discharge is then plotted as the abscissa, corresponding gage height is plotted as the ordinate, and a curve or line is fitted by eye to the plotted points. The plotted points carry the identifying measurement numbers given in figure 139; the discharge measurements are numbered consecutively in chronological order so that time trends can be identified.

At recording-gage stations that use stilling wells, systematic and significantly large differences between inside (recorded) gage heights and outside gage heights often occur during periods of high stage, usually as a result of intake drawdown (see section in chapter 4 titled, "Stilling Wells"). For stations where such differences occur, both inside and outside gage heights for high-water discharge measurements are recorded on the form shown in figure 139, and in plotting the measurements for rating analysis, the outside gage readings are used first. The stage-discharge relation is drawn through the outside gage readings of the high-water discharge measurements and is extended to the stage of the outside high-water marks that are observed for each flood event. The stage-discharge relation is next transposed to correspond with the inside gage heights obtained from the stage-recorder at the times of discharge measurement and at flood peaks. It is this transposed stage-discharge relation that is used with recorded stages to compute the discharge.

The rationale behind the above procedure is as follows. The outside gage readings are used for developing the rating because the hydraulic principles on which the rating is based require the use of the true stage of the stream. The transposition of the rating to inside (recorded) stages is then made because the recorded stages will be used with the rating to determine discharge. The recorded stages are used for discharge determination because if differences exist between inside and outside gage readings, those differences will be known only for those times when the two gages are read concurrently. If the

FIGURE 139.—Example of form used for tabulating and summarizing current-meter discharge measurements.

outside gage heights were used with the rating to determine discharge, variable corrections, either known or assumed, would have to be applied to recorded gage heights to convert them to outside stages. We have digressed here to discuss differences between inside and outside gage heights, because in the discussions that follow no distinction between the two gages will be made.

The use of logarithmic plotting paper is usually preferred for graphical analysis of the rating because in the usual situation of compound controls, changes in the slope of the logarithmically plotted rating identify the range in stage for which the individual controls are effective. Furthermore, the portion of the rating curve that is applicable to any particular control may be linearized for rational extrapolation or interpolation. A discussion of the characteristics of logarithmic plotting follows.

The measured distance between any two ordinates or abscissas on logarithmic graph paper, whose values are printed or indicated on the sheet by the manufacturer of the paper, represents the difference between the logarithms of those values. Consequently, the measured distance is related to the ratio of the two values. Therefore, the distance between pairs of numbers such as 1 and 2, 2 and 4, 3 and 6, 5 and 10, are all equal because the ratios of the various pairs are identical. Thus the logarithmic scale of either the ordinates or the abscissas is maintained if all printed numbers on the scale are multiplied or divided by a constant. This property of the paper has practical value. For example, assume that the logarithmic plotting paper available has two cycles (fig. 140), and that ordinates ranging from 0.3 to 15.0 are to be plotted. If the printed scale of ordinates is used and the bottom line is called 0.1, the top line of the paper becomes 10.0, and values between 10.0 and 15.0 cannot be accommodated. However, the logarithmic scale will not be distorted if all values are multiplied by a constant. For this particular problem, 2 is the constant used in figure 140, and now the desired range of 0.3 to 15.0 can be accommodated. Examination of figure 140 shows that the change in scale has not changed the distance between any given pair of ordinates; the position of the ordinate scale has merely been transposed.

We turn now to a theoretical discussion of rating curves plotted on logarithmic graph paper. A rating curve, or a segment of a rating curve, that plots as a straight line of logarithmic paper has the equation,

$$Q = p(G - e)^{\backslash}, \tag{53}$$

where

Q is discharge;

$(G - e)$ is head or depth of water on the control—this value is indicated by the ordinate scale printed by the manufacturer or

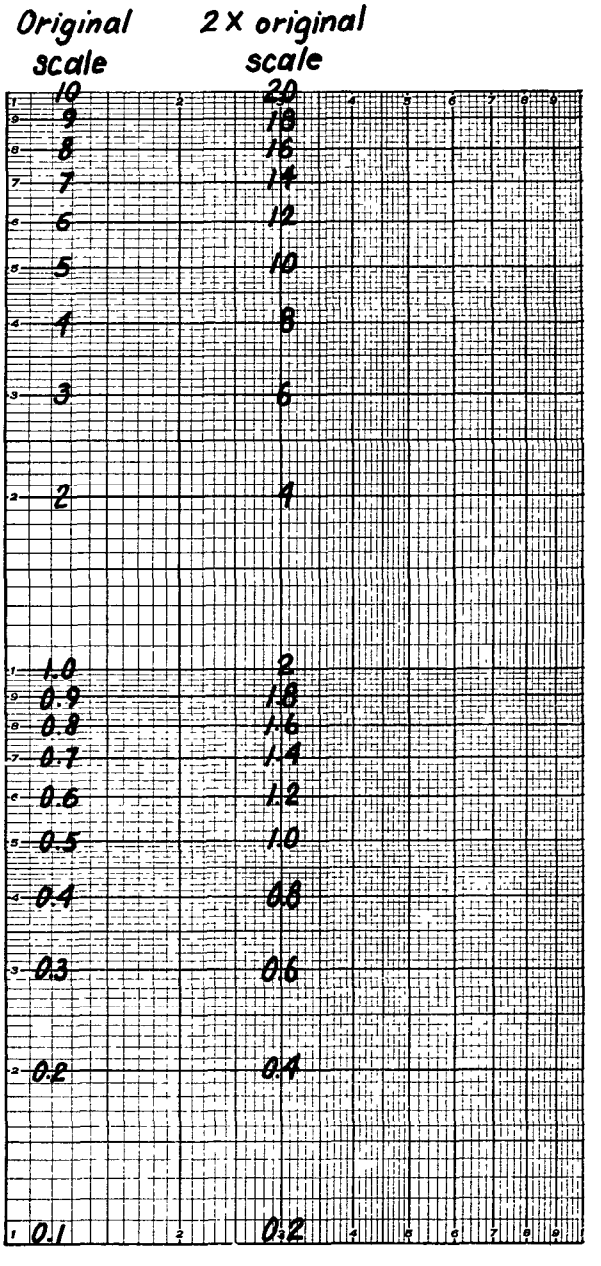

FIGURE 140.—Example showing how the logarithmic scale of graph paper may be transposed.

by the ordinate scale that has been transposed, as explained in the preceding paragraph;

G is gage height of the water surface;

e is gage height of zero flow for a section control of regular shape, or the gage height of effective zero flow for a channel control or a section control of irregular shape;

p is a constant that is numerically equal to the discharge when the head $(G - e)$ equals 1.0 ft or 1.0 m, depending on whether English or metric units are used; and

N is slope of the rating curve. (Slope in equation 53 is the ratio of the horizontal distance to the vertical distance. This unconventional way of measuring slope is necessary because the dependent variable Q is always plotted as the abscissa.)

We assume now that a segment of an established logarithmic rating is linear, and we examine the effect on the rating of changes to the control. If the width of the control increases, p increases and the new rating will be parallel to and to the right of the original rating. If the width of the control decreases, the opposite effect occurs; p decreases and the new rating will be parallel to and to the left of the original rating. If the control scours, e decreases and the depth $(G - e)$ for a given gage height increases; the new rating moves to the right and will no longer be a straight line but will be a curve that is concave downward. If the control becomes built up by deposition, e increases and the depth $(G - e)$ for a given gage height decreases; the new rating moves to the left and is no longer linear but is a curve that is concave upward.

When discharge measurements are originally plotted on logarithmic paper, no consideration is given to values of e. The gage height of each measurement is plotted using the ordinate scale provided by the manufacturer or, if necessary, an ordinate scale that has been transposed as illustrated in figure 140. We refer now to figure 141. The inside scale $(e = 0)$ is the scale printed by the paper manufacturer. Assume that the discharge measurements have been plotted to that scale and that they define the curvilinear relation between gage height (G) and discharge (Q) that is shown in the topmost curve. For the purpose of extrapolating the relation, a value of e is sought, which when applied to G, will result in a linear relation between $(G - e)$ and Q. If we are dealing with a section control of regular shape, the value of e will be known; it will be the gage height of the lowest point of the control (point of zero flow). If we are dealing with a channel control or section control of irregular shape, the value of e is the gage height of *effective* zero flow. The gage height of effective zero flow is not the gage height of some identifiable feature on the irregular section control or in the channel but is actually a mathematical constant

that is considered as a gage height to preserve the concept of a logarithmically linear head-discharge relation. Effective zero flow is usually determined by a method of successive approximations.

In successive trials, the ordinate scale in figure 141 is varied for e values of 1, 2 and 3 ft, each of which results in a different curve, but each new curve still represents the same rating as the top curve. For example, a discharge of 30 ft^3/s corresponds to a gage height (G) of 5.5 ft on all four curves. The true value of e is 2 ft, and thus the rating plots as a straight line if the ordinate scale numbers are increased by that value. In other words, while even on the new scale a discharge of 30 ft^3/s corresponds to a gage height (G) of 5.5 ft, the head or depth on the control for a discharge of 30 ft^3/s is $(G-e)$, or 3.5 ft; the linear rating marked $e = 2$ crosses the ordinate for 30 ft^3/s at 5.5 ft on the new scale and at 3.5 ft on the manufacturer's, or inside, scale. If values of e smaller than the true value of 2 ft are used, the rating curve will be concave upward, if values of e greater than 2 ft are used, the curve will be concave downward. The value of e to be used for a rating curve, or for a segment of a rating curve, can thus be determined by adding or subtracting trial values of e to the numbered scales on the logarithmic plotting paper until a value is found that results in a straight-line plot of the rating. It is important to note that if the logarithmic ordinate scale must be transposed by multiplication or division to accommodate the range of stage to be plotted, that transposition must be made before the ordinate scale is manipulated for values of e.

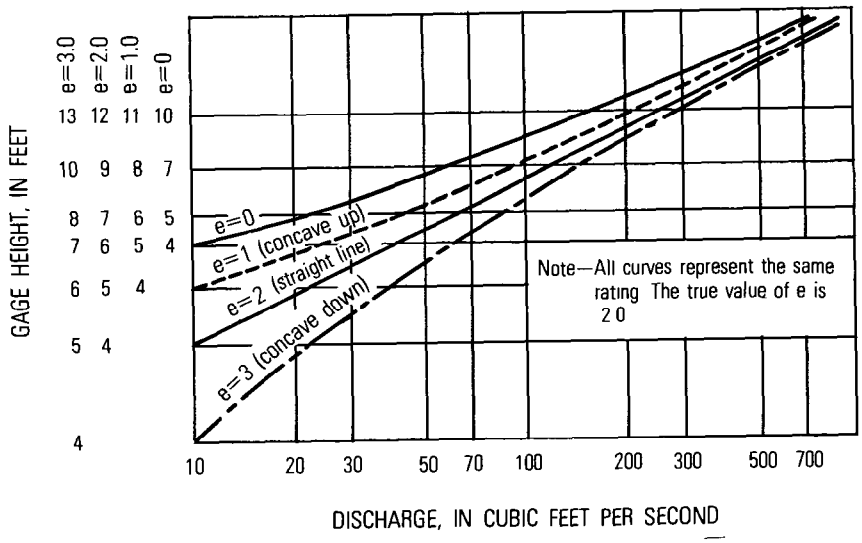

FIGURE 141.—Rating-curve shapes resulting from the use of differing values of effective zero flow.

A more direct solution for e, as described by Johnson (1952) is illustrated in figure 142. A plot of G versus Q has resulted in the solid-line curve which is to be linearized by subtracting a value of e from each value of G. The part of the rating between points 1 and 2 is chosen, and values of G_1, G_2, Q_1 and Q_2 are picked from the coordinate scales. A value of Q_3 is next computed, such that

$$Q^2_3 = Q_1 Q_2.$$

From the solid-line curve, the value of G_3 that corresponds to Q_3 is picked. In accordance with the properties of a straight line on logarithmic plotting paper,

$$(G_3 - e)^2 = (G_1 - e)(G_2 - e). \tag{54}$$

Expansion of terms in equation 54 leads to equation 55 which provides a direct solution for e.

$$e = \frac{G_1 G_2 - G_3^2}{G_1 + G_2 - 2G_3} \tag{55}$$

A logarithmic rating curve is seldom a straight line or a gentle curve for the entire range in stage. Even where a single cross section of the channel is the control for all stages, a sharp break in the

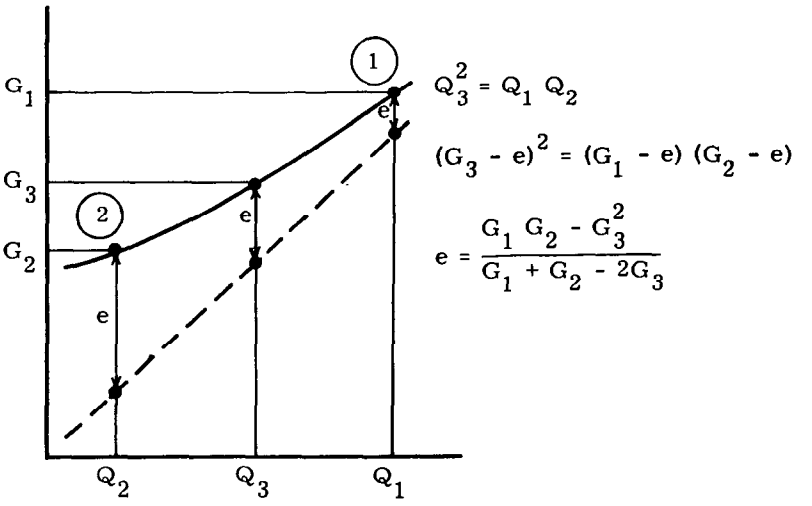

FIGURE 142.—Schematic representation of the linearization of a curve on logarithmic graph paper.

contour of the cross section, such as an overflow plain, will cause a break in the slope of the rating curve. Commonly, however, a break in slope is due to the low-water control being drowned out by a downstream section control becoming effective or by channel control becoming effective.

The use of rectangular-coordinate paper for rating analysis has certain advantages, particularly in the study of the pattern of shifts in the lower part of the rating. A change in the low-flow rating at many sites results from a change in the elevation of effective zero flow (e), which means a constant shift in gage height. A shift of that kind is more easily visualized on rectangular-coordinate paper because on that paper the shift curve is parallel to the original rating curve, the two curves being separated by a vertical distance equal to the change in the value of e. On logarithmic paper the two curves will be separated by a variable distance which decreases as stage increases. A further advantage of rectangular-coordinate paper is the fact that the point of zero flow can be plotted directly on rectangular-coordinate paper, thereby facilitating extrapolation of the low-water end of the rating curve. That cannot be done on logarithmic paper because zero values cannot be shown on that type of paper.

As a general rule logarithmic plotting should be used initially in developing the general shape of the rating. The final curve may be displayed on either type of graph paper and used as a base curve for the analysis of shifts. A combination of the two types of graph paper is frequently used with the lower part of the rating plotted on an inset of rectangular-coordinate paper or on a separate sheet of rectangular-coordinate paper.

SECTION CONTROLS

ARTIFICIAL CONTROLS

At this point we digress from the subject of logarithmic rating curves to discuss the ratings for artificial section controls. A knowledge of the rating characteristics of controls of standard shape is necessary for an understanding of the rating characteristics of natural controls, almost all of which have irregular shapes. On pages that follow we first discuss thin-plate weirs, then broad-crested weirs, and finally flumes.

Thin-plate weirs are generally used in small clear-flowing streams, particularly where high accuracy is desired and adequate maintenance can be provided, as in small research watersheds. Flumes are preferred for use in small streams and canals that carry sediment and debris, and in other situations where the head loss (backwater) associated with a thin-plate weir is unacceptable. Most types of flume may also be used under conditions of submergence, as opposed to free-flow

conditions, thereby permitting them to operate with even smaller head loss but with some loss of accuracy of the stage-discharge relation. The broad-crested weirs are commonly used in the larger streams.

TRANSFERABILITY OF LABORATORY RATINGS

Standard shapes or dimensions are commonly used in building artificial controls, and many of these standard structures have been rated in laboratory model studies (World Meteorological Organization, 1971). The transfer of a laboratory discharge rating to a structure in the field requires the existence, and maintenance, of similitude between laboratory model and prototype, not only with regard to the structure, but also with regard to the approach channel. For example, scour and (or) fill in the approach channel will change the head-discharge relation, as will algal growth on the control structure. Both the structure and the approach channel must be kept free from accumulations of debris, sediment, and vegetal growth. Flow conditions downstream from the structure are significant only to the extent that they control the tailwater elevation, which may influence the operation of structures designed for free-flow conditions.

Because of the likelihood of the existence or development of conditions that differ from those specified in a laboratory model study, the policy of the Geological Survey is to calibrate the prototype control in the field by discharge measurements for the entire range of stage that is experienced. (See section in chapter 3 titled, "Artificial Controls.") In-place calibration is sometimes dispensed with where the artificial control is a standard thin-plate weir having negligible velocity of approach.

THIN-PLATE WEIRS

The surface of the weir over which the water flows is the crest of the weir. A thin-plate weir has its crest beveled to a chisel edge and is always installed with the beveled face on the downstream side. The crest of a thin-plate weir is highly susceptible to damage from floating debris, and therefore such weirs are used as control structures almost solely in canals whose flow is free of floating debris. Thin-plate weirs are not satisfactory for use in canals carrying sediment-laden water because they trap sediment and thereby cause the gage pool to fill with sediment, sometimes to a level above the weir crest. The banks of the canal must also be high enough to accommodate the increase in stage (backwater) caused by the installation of the weir, the weir plate being an impedance to flow in the canal. The commonly used shapes for thin-plate weirs are rectangular, trapezoidal, and triangular or V-notch.

The information needed to compute the discharge over a thin-plate weir is as follows:

1. Static head (h), which is the difference in elevation between the weir crest and the water surface at the approach section; the approach section is located upstream from the weir face a distance equal to about $3h$ or more. (See section in chapter 2 titled, "Considerations in Specific Site Selection" for discussion of location of gage intakes.)
2. Length of crest of weir (b) if weir is rectangular or trapezoidal.
3. Width of channel in the plane of the weir face (B).
4. Angle of side slopes if weir is triangular or trapezoidal.
5. Average depth of streambed below elevation of weir crest (P). P is measured in the approach section.

RECTANGULAR THIN-PLATE WEIR

Flow over a rectangular thin-plate weir is illustrated in figure 143. The discharge equation for this type of weir is:

$$Q = Cbh^{3/2}, \tag{56}$$

where

Q = discharge,
C = discharge coefficient,
b = length of weir crest normal to flow, and
h = static or piezometric head on a weir, referred to the weir crest.

Information on discharge coefficients for rectangular thin-plate weirs is available from the investigations of Kindsvater and Carter (1959) and others, and is given in the previously cited WMO Technical Note No. 117 (1971). Those investigations show that the coefficient for free discharge is a function of certain dimensionless ratios which describe the geometry of the channel and the weir;

$$C = f\left(\frac{h}{P}, \frac{b}{B}, E\right), \tag{57}$$

where E is the slope of the weir face; the other variables are depicted in figure 143.

The relation between C, h/P and E for weirs with no side contraction ($b/B = 1.0$) is shown in figure 144, where each of the four curves corresponds to a particular value of E. The coefficient is defined in the range of h/P from 0 to 5. The value of the coefficient becomes uncertain at high values of h/P. The greater the value of h/P, the greater the velocity of approach, and therefore the greater the coefficient. The coefficients in figure 144 are for use with English units, where all

linear measurements are expressed in feet and discharge is in cubic feet per second. If linear measurements are expressed in meters and discharge is in cubic meters per second, all values of C must be multiplied by the factor 0.552.

Side contractions reduce the effective length of the weir crest. That effect is accounted for by multiplying the value of C from figure 144 by a correction factor that is a function of b/B, h/P, and the degree of rounding of the upstream vertical edge of the weir-notch abutments. Rounding is a factor only in the situation where the horizontal weir crest is set between vertical abutments. For a rectangular thin-plate weir with sharp-edged entry, the correction factor is k_c; appropriate values of k_c are obtained from the curves in figure 145. For a

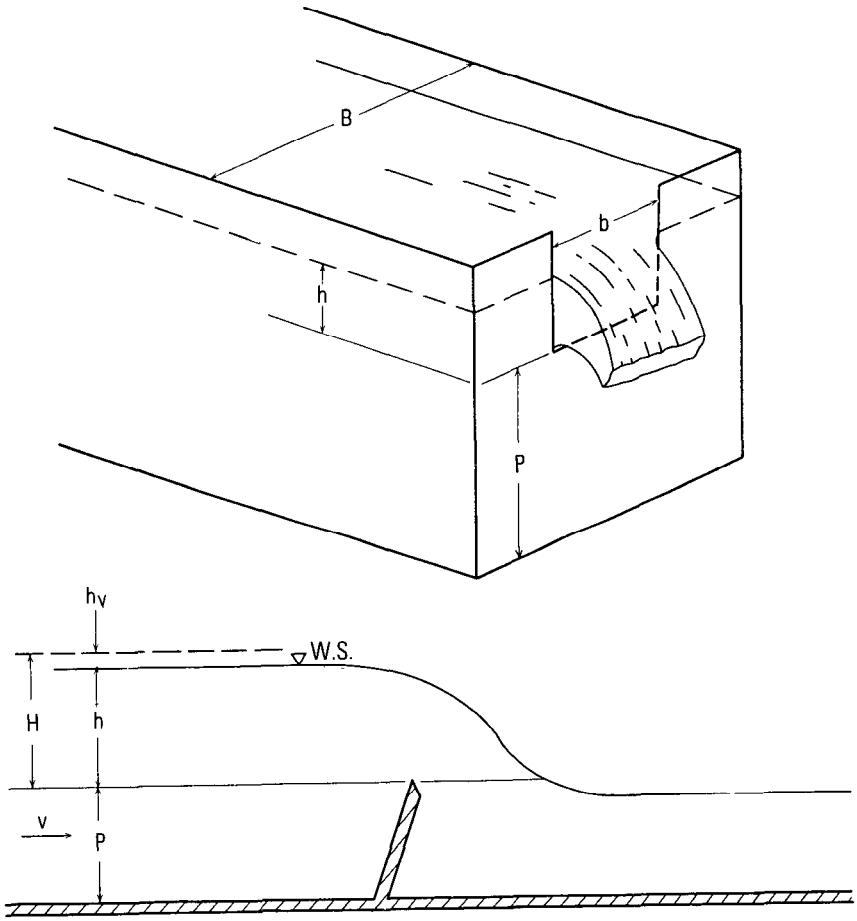

FIGURE 143.—Definition sketch of a rectangular thin-plate weir.

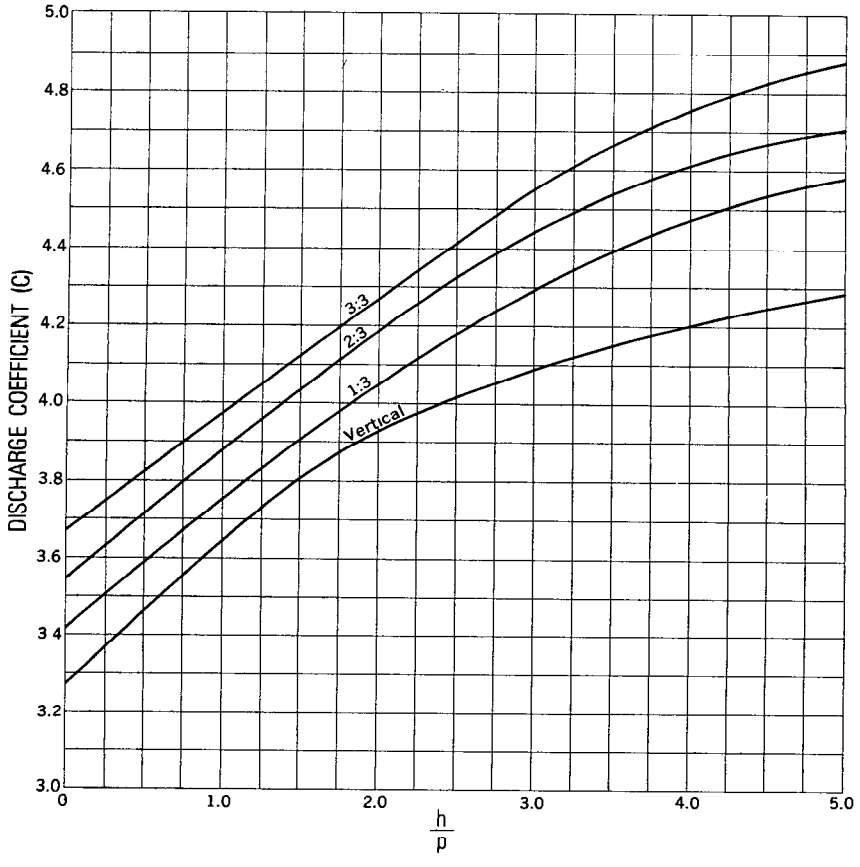

FIGURE 144.—Discharge coefficients for full-width, vertical and inclined, rectangular thin-plate weirs.

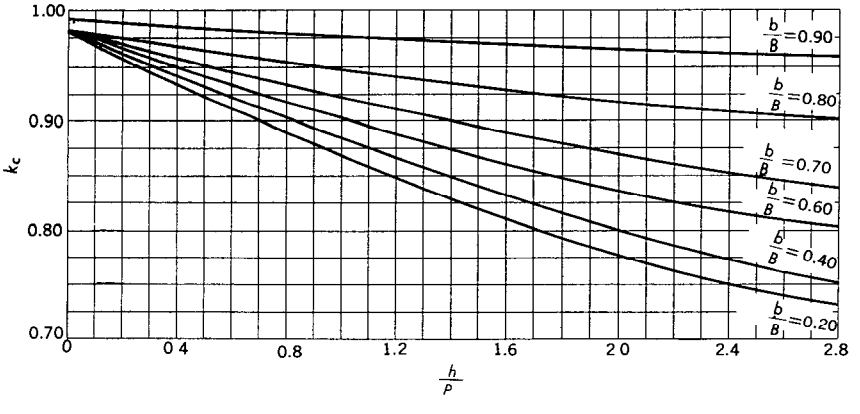

FIGURE 145.—Definition of adjustment factor, k_c, for contracted rectangular thin-plate weirs.

rectangular thin-plate weir having vertical abutments rounded with radius r, the correction factor, when $r/b \geq 0.12$, is assumed to equal $(1 + k_c)/2$, where again k_c is read from figure 145. For rounded abutments having a lesser value of r/b, the correction factor is obtained by interpolating between the appropriate k_c value from figure 145 and the value $(1 + k_c)/2$. In other words, for given values of b/B, h/P, and r/b between 0 and 0.12, we interpolate linearly between the value of k_c (corresponds to $r/b=0$) and the value of $(1 + k_c)/2$ (corresponds to $r/b = 0.12$).

We will now prepare the rating for a hypothetical rectangular thin-plate weir for the purpose of examining the implications of a logarithmic plot of the rating. The discharges corresponding to various stages will be computed by use of the theoretical equation for a rectangular weir, using figures 144 and 145 to obtain the constant in the equation. We will assume that the computed discharges represent the results of carefully made discharge measurements.

Assume that we have a rectangular thin-plate weir, with vertical face, and that discharge measurements (computations) have been made at heads ranging from 0.1 ft to 7.0 ft. The dimensions of the weir using the symbols in figure 142 are given in table 16. The data and computations are also shown in table 16 and should be self-explanatory. The weir constant is actually equal to $C(k_c)$. The stages and corresponding discharges are plotted on logarithmic graph paper and fitted with a curve by eye in figure 146.

Figure 146 shows that a tangent can be fitted to the plotted points at heads greater than 0.3 ft ($G=1.3$ ft). The intercept (p) of the tangent at $G - e=1.0$ ft is 67 ft^3/s and the measured slope of the tangent is 1.55. (Note that the slope of the rating curve Q/h is the ratio of the horizontal distance to the vertical distance.) In accordance with equation 53, the equation of the tangent is therefore $Q=67h^{1.55}$ However, the equation for discharge over a rectangular weir is $Q=(Ck_cb)h^{1.50}$. Therefore (Ck_cb) must vary with stage, as we know it does, and $Ck_cb=67h^{0.05}$; the exponent 0.05 is obtained by subtracting the theoretical exponent 1.50 from the empirical exponent 1.55. Because b has a constant value of 20 ft, $Ck_c=3.35h^{0.05}$; the coefficient 3.35 is obtained by dividing the original coefficient (67) by the value of b (20 ft). We can extrapolate the tangent in figure 146 with some confidence. If we wish to determine the discharge from the curve for a gage height of 11 ft ($h=10$ ft), the extrapolated value of Q is 2,380 ft^3/s; that is, if a value of 10 ft is substituted in the equation $Q=67h^{1.55}$, Q will equal 2,380 ft^3/s. That value matches the true value computed on the bottom line of table 16 for a gage height of 11 ft.

TRAPEZOIDAL THIN-PLATE WEIR

Few experimental data are available for determining the discharge

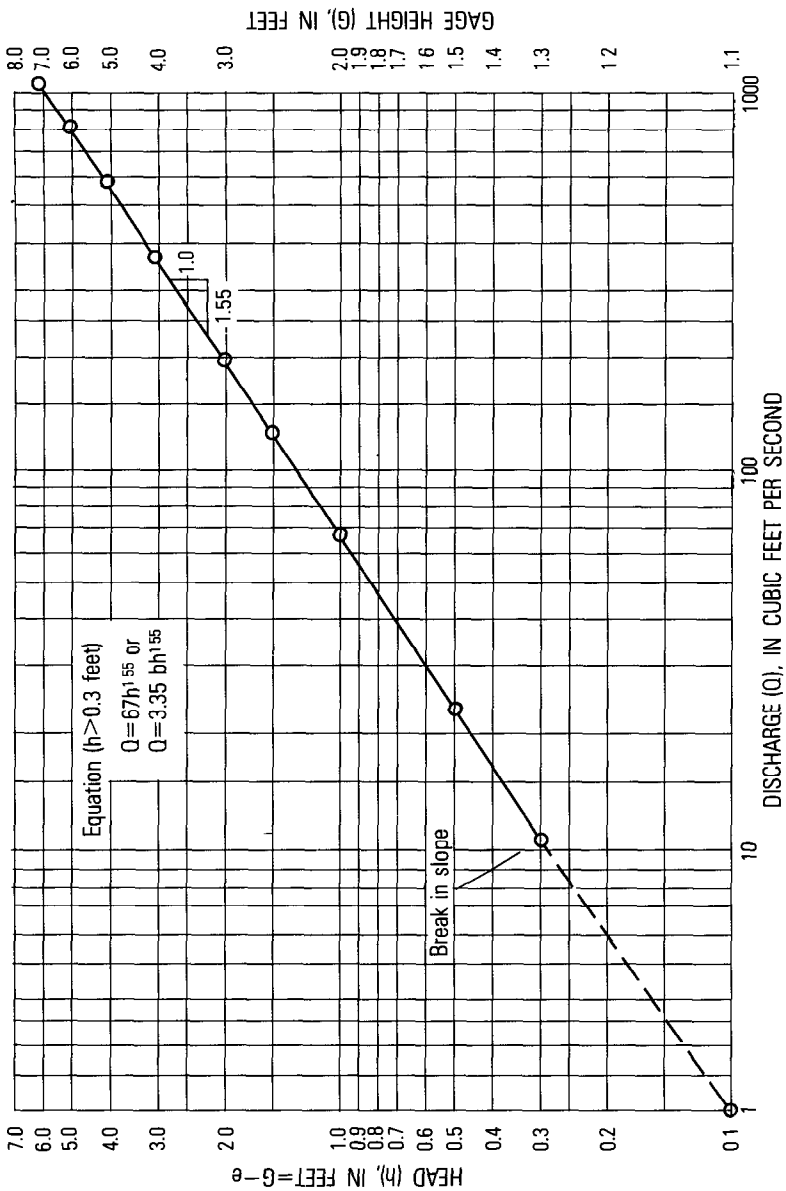

FIGURE 146.—Rating curve for hypothetical rectangular thin-plate weir.

coefficients of trapezoidal weirs (fig. 147). One exception is the vertical Cippoletti weir, which is a sharp-crested trapezoidal weir whose sides have a slope of 1 horizontal (x) to 4 vertical (y). The slope of the sides is approximately that required to obtain a discharge through the two triangular parts of the weir opening that equals the decrease in discharge resulting from end contractions. In other words, the Cippoletti weir acts as a rectangular thin-plate weir whose crest length is equal to b and whose contraction coefficient, k_c, is equal to 1.0. The dimension B (fig. 147) for a Cippoletti weir has little bearing on the discharge. The equation used to compute discharge is again

$$Q=Cbh^{3/2}, \tag{56}$$

and close approximations of values of C are obtained from figure 144. The head, h, and height of notch, P, are both measured in the approach section.

If we compute the discharge for a vertical thin-plate Cippoletti weir whose value of b is 20 ft and whose value of P is 2.0 ft, similar to the dimensions used in computing the hypothetical rating shown in table 16, the rating will approximate that obtained for the thin-plate rectangular weir of table 16. The only difference in discharge will be that attributable to the fact that the value of k_c is 1.00 for all values of head for the Cippoletti weir. A logarithmic plot of the rating (not shown here) indicates that the equation for all but the very small values of head is

$$Q=69h^{1.58}, \text{ (English units)}$$

meaning that $C=3.45h^{0.08}$.

For trapezoidal weirs other than Cippoletti weirs, the general empirical equation for discharge is

$$Q=Cb(h+h_v)^{\gamma}, \tag{58}$$

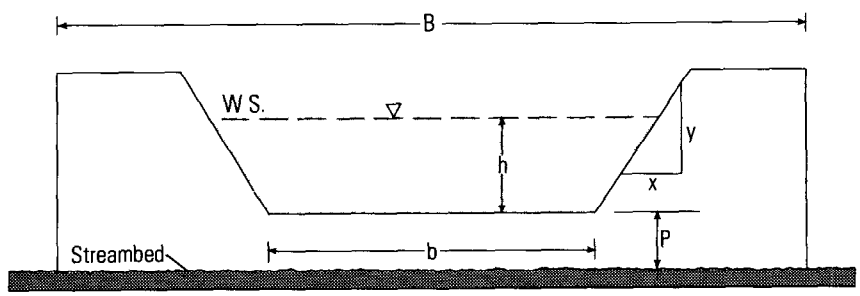

FIGURE 147.—Sketch of upstream face of a trapezoidal weir.

where h_v, the velocity head at the approach section, is equal to $V_a^2/2g$, V_a being the mean velocity in the approach section and g being the acceleration of gravity. The coefficient C and exponent N must be determined from current-meter discharge measurements that cover the entire range of stage that is experienced. If discharge measurements are not available for the highest stage experienced, a rating curve is obtained by plotting on logarithmic paper the head $(G-e)$ against discharge (Q) for the measurements that have been obtained, and then fitting a curve to the plotted points. The upper end of that curve should be a tangent, or possibly an extremely flat curve, that can be extrapolated to the highest stage experienced. Because the limiting shapes of a trapezoid are a rectangle at one extreme and a triangle at the other, the slope of the tangent will lie somewhere between 1.5, which is the theoretical slope for a rectangular weir, and 2.5 which is the theoretical slope for a triangular weir. The closer the shape is to a rectangle, the closer the slope will be to 1.5; the closer the shape is to a triangle, the closer the slope will be to 2.5.

The reader will note the difference in form between equations 56 and 58. Equation 56 uses static head (h), whereas equation 58 uses total head $(h+h_v)$. Velocity head is a factor in any discharge equation for a weir. In the more modern laboratory studies of weir discharge, the static-head term is used in the discharge equation, and velocity head, as indicated by a term h/P, is used directly as a variable in the determination of C. (See equation 57.) In older laboratory investigations, a more empirical approach for determining C was followed in that the total-head term was used in the discharge equation and the values of C that were determined do not vary directly with change in velocity head. Both forms of the weir-discharge equations will be found in this manual; the older type of equation is shown wherever it has not been superseded by later laboratory studies.

TRIANGULAR OR V-NOTCH THIN-PLATE WEIR

Triangular or V-notch thin-plate weirs (fig. 148) are installed at sites where low discharges occur; they are highly sensitive to low flows but have less capacity than rectangular or trapezoidal weirs. Because the area of the notch is invariably small compared to the cross-sectional area of the channel, water is pooled upstream from the weir and the approach velocity is necessarily low. The approach velocity head can usually be neglected in computing the discharge for a 90° V-notch weir ($\Theta=90°$ in fig. 148). Actually, for values of Θ equal to or less than 90°, it has been specified that velocity of approach is negligible if h/P is less than 0.4 and h/B is less than 0.2 (WMO Tech. Note 117, 1971). Whether or not the velocity head can be ignored in computing discharges for V-notch weirs having central angles greater

than 90° depends on the relative size of the areas occupied by the water in the notch and the water in the approach section. Virtually no experimental work has been done with triangular weirs having significant velocity of approach, and all equations discussed below are for installations where the velocity of approach can be neglected. Furthermore the equations are applicable only for thin-plate V-notch weirs whose faces are vertical.

Both the cross-sectional area of the flow in the notch and its velocity in the notch are functions of the head (h). Consequently, the general equation for a triangular thin-plate weir is $Q=Ch^{\backprime}$, and the constants in that equation do not vary greatly from those in the following equations:

$$Q=2.5(\tan \Theta/2)h^{5/2},$$

where h is in feet and Q is in cubic feet per second; or

$$Q=1.38(\tan \Theta/2)h^{5/2},$$

where h is in meters and Q is in cubic meters per second.
The head is measured in the approach section, a distance about $3h$ upstream from the weir face. From an earlier discussion it is apparent that the above equations will plot as straight lines on logarithmic graph paper. The slope of the ratings will be 2.5, and the intercept, where $h=1$, will be either 2.5 tan $\Theta/2$ or 1.38 tan $\Theta/2$, depending on whether English or metric units are used.

V-notch weirs are most commonly built with a central angle of 90°. Much experimental work has been done with thin-plate 90°

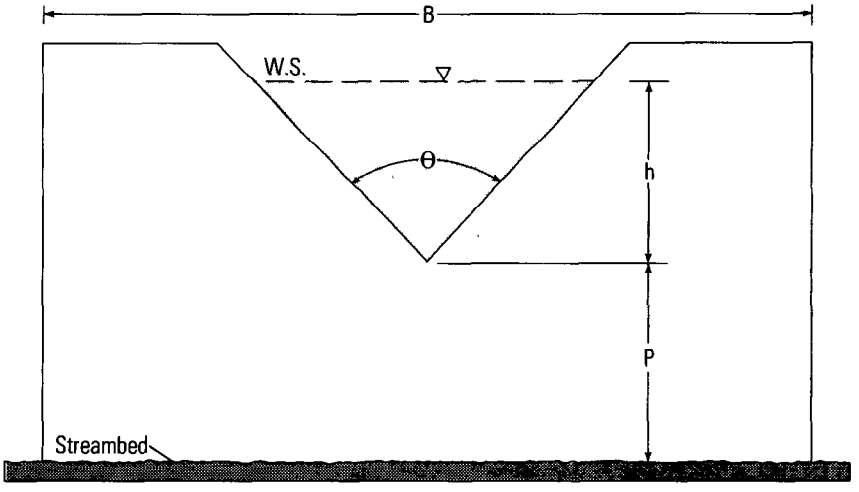

FIGURE 148.—Sketch of upstream face of a triangular or V-notch weir.

V-notches, and the discharge equation usually recommended in the U.S.A. is

$$Q=2.47h^{2.50} \text{ (English units).}$$

More precise values of the weir coefficient, which vary with h, are given for use with metric units in WMO Technical Note No. 117.

The only other central angle that is commonly used in the U.S.A. for V-notch weirs is 120°. The recommended discharge equation is

$$Q=4.35h^{2.50} \text{ (English units).}$$

SUBMERGED THIN-PLATE WEIRS

Submergence occurs at a weir when the elevation of the downstream water surface (tailwater) exceeds the elevation of the weir crest (fig. 149). The tailwater elevation is measured downstream from the turbulence that occurs in the immediate vicinity of the downstream face of the weir. The degree of submergence is expressed by the ratio h_t/h. For any given head h, submergence has the effect of reducing the discharge that would occur under the condition of free flow; the greater the submergence ratio h_t/h, the greater the reduction in discharge. Villemonte (1947) combined the results of his tests with those of several other investigators to produce the generalized relation shown in figure 150. Figure 150 is applicable to all shapes of vertical thin-plate weirs. In that figure, the abscissa is the submergence ratio raised to a power N, where N is the exponent in the free-flow discharge equation; for example, $N=1.5$ for a rectangular weir and $N=2.5$ for a triangular weir. The ordinate in figure 150 is the ratio of discharge under the submerged condition (Q_s) to free-flow discharge (Q). The relation shown in figure 150 agrees reasonably with the individual results obtained by the various investigators of submerged-weir discharge. However, if great accuracy is essential, it

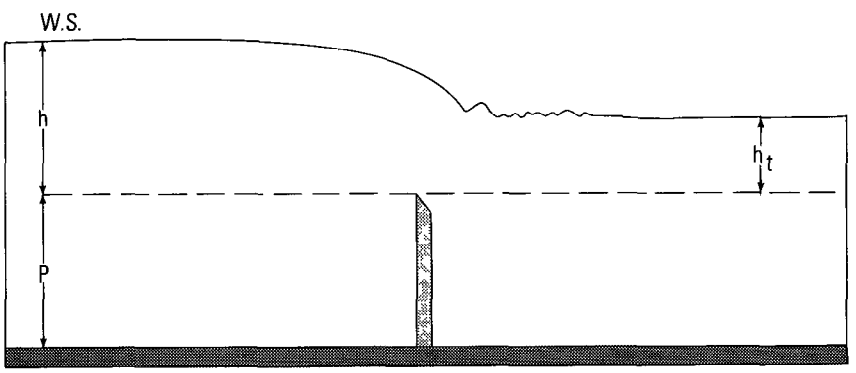

FIGURE 149.—Sketch showing submergence of a weir.

is recommended that the particular weir be calibrated in the field or in a laboratory under conditions similar to field conditions.

BROAD-CRESTED WEIRS

The term "broad-crested weir", as used here, refers to any weir that is not of the thin-plate type. The most common type of artificial control built in natural channels is the broad-crested weir. A structure of that type has the necessary strength and durability to withstand possible damage by floating debris. When installed in a stream channel that carries sediment-laden water, the weir is often built with a gently sloping upstream apron (slope: 1 vertical to 5 horizontal) so that there is no abrupt impedance to the flow and sediment is carried over the weir and not deposited in the gage pool. Because the

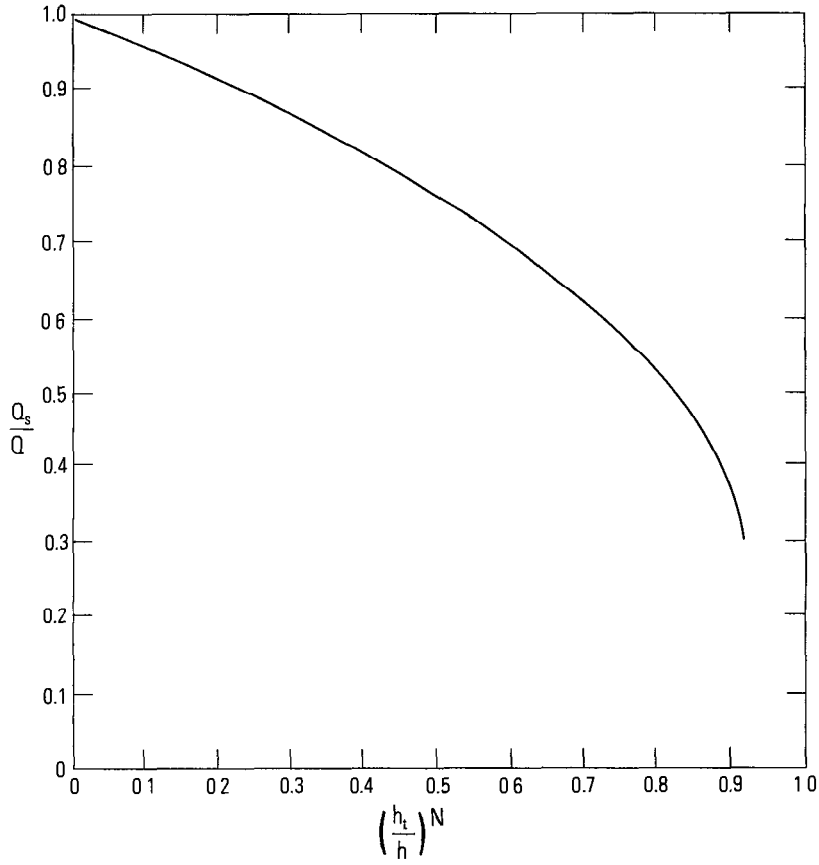

FIGURE 150.—Generalized relation of discharge ratio to submergence ratio for vertical thin-plate weirs. (After Villemonte, 1947.)

backwater caused by a high weir can aggravate flood problems along a stream, broad-crested weirs are usually built low to act as low-water controls and they become submerged at intermediate and high stages.

There are a myriad of crest shapes that can be used for broad-crested weirs, and there will be no attempt to describe the characteristics of the rating curve for each. Much of the material for such a discussion can be found in WMO Technical Note No. 117 (1971), in a report by Hulsing (1967), and in a textbook by King and Brater (1963). Instead, this section of the report will present a discussion of general principles as they apply to the definition of the discharge rating and will present the approximate ratings for broad-crested weirs commonly used as gaging-station controls in the U.S.A. The weirs are all intended to be field calibrated by current-meter discharge measurements.

Before proceeding to the discussion of broad-crested weirs commonly used in the U.S.A., it might be mentioned in passing that perhaps the most popular weir for use as a gaging-station control in Europe, and particularly in the United Kingdom, is the Crump weir (World Meteorological Organization, 1971). The Crump weir is triangular in cross section; the *upstream* face has a slope of 1 (vertical) to 2 (horizontal) and the *downstream* face has a slope of 1 (vertical) to 5 (horizontal). The crest, or apex of the triangular cross section, is usually horizontal over its entire length (b), but for greater sensitivity the crest may be given the shape of a flat Vee, the sides of which often have a slope of 1 (vertical) to 10 (horizontal). The basic equation for the Crump weir with horizontal crest is,

$$Q = Cb\,(h + h_v)^{3/2},$$

where C equals about 3.55 when English units are used and 1.96 when metric units are used.

FLAT-CRESTED RECTANGULAR WEIR

The simplest type of broad-crested weir is one that is rectangular in cross section and whose crest is horizontal over its entire length, b. The basic discharge equation for that weir is $Q = Cb(h + h_v)^{1.5}$, where h_v is the head attributable to velocity of approach. The coefficient C will increase with stage in the manner shown in figure 151, and h_v will also increase with stage as a result of the velocity of approach increasing with stage. (Figure 151 also shows the relation of C to stage for flat-crested weirs with sloping faces.) The rating curve for a flat-crested rectangular weir, when plotted on logarithmic graph paper, will be a straight line except for extremely low stages. The equation

of the line will be of the form $Q=p(G-e)^N$, where the slope of the line, N, will have a value greater than 1.5 because both the weir coefficient and the velocity head increase with stage.

Most flat-crested rectangular weirs are not sufficiently sensitive at low flows. To increase the low-flow sensitivity, the crest is often modified as shown in figure 152. Instead of the crest being horizontal over its entire length, b, the crest is given a gentle slope from one streambank to the other, or the crest is given the shape of an extremely flat Vee or catenary. As a result of this modification, the area of flow over the weir is triangular, or nearly so, at low flows and approximately rectangular at high flows. In other words, the length of weir crest that is utilized by the flow varies with stage until the stage rises high enough to flow over the entire length of the crest (b in fig. 152). In the general equation for the weir discharge, $Q=Cb(h+h_v)^{1.5}$, not only do C and h_v increase with stage, but length of weir crest, b, also increases with stage, as stated in the preceding sentence. Consequently if the weir rating plots as a straight line on logarithmic graph paper in accordance with equation, $Q=p(G-e)^N$, the slope of the line, N, will be considerably greater than 1.5, and invariably will be greater than 2.0.

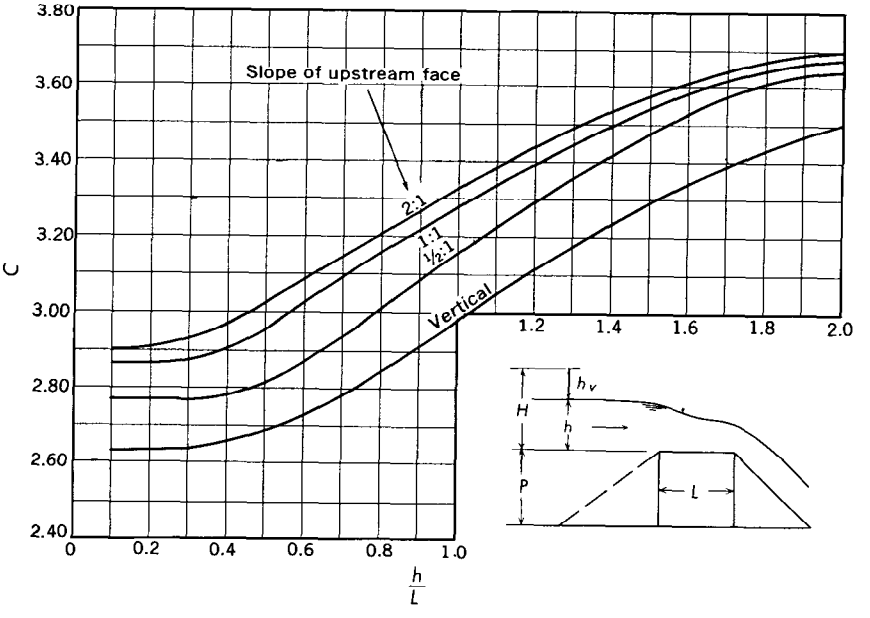

FIGURE 151.—Coefficients of discharge for full-width, broad-crested weirs with downstream slope ≤ 1:1 and various upstream slopes. (Slope is the ratio of horizontal to vertical distance.)

NOTCHED FLAT-CRESTED RECTANGULAR WEIR

Figure 153 shows the notched flat-crested rectangular weir that is the control for a gaging station on Great Trough Creek near Markles-burg, Pa.

Because there is a sharp break in the cross section at gage height 1.4 ft, a break occurs in the slope of the rating curve at that stage. The gage-height of zero flow for stages between 0.0 and 1.4 ft is 0.0 ft; for stages above 1.4 ft, the effective zero flow is at some gage height between 0.0 and 1.4 ft. If the low end of the rating is made a tangent, the gage height of zero flow (e) is 0.0 ft, and the slope of this tangent turns out to be 2.5, which, as now expected, is greater than the theoretical slope of 1.5. The upper part of this rating curve is concave upward because the value of e used (0.0 ft) is lower than the effective value of zero flow for high stages.

If the upper end of the rating is made a tangent, it is found that the value of e, or effective zero flow, must be increased to 0.6 foot. Because we have raised the value of e, the low-water end of the curve will be concave downward. The high-water tangent of the curve, principally because of increased rate of change of velocity of approach, will have a

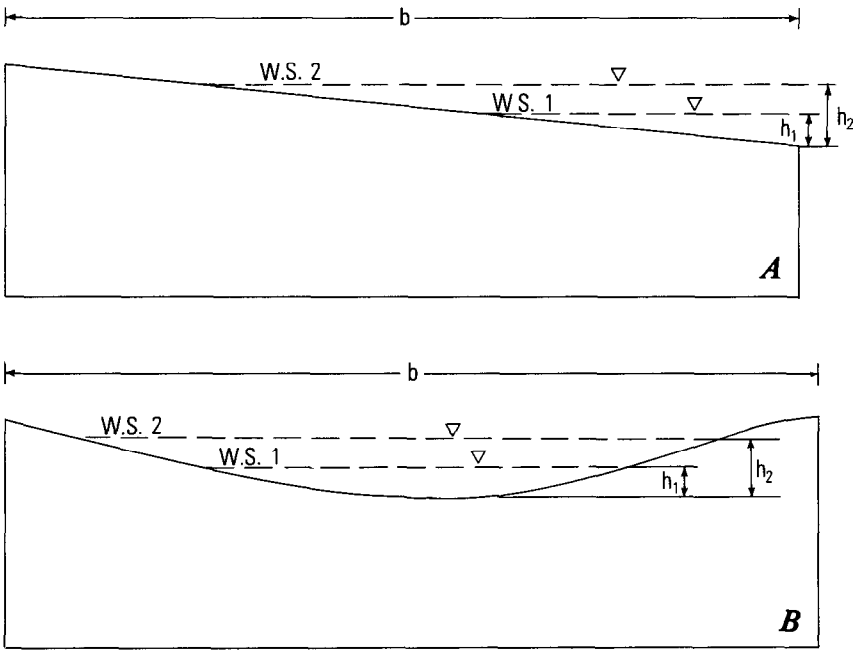

FIGURE 152.—Sketch of upstream face of flat-crested weir with (A) sloping crest and (B) catenary crest.

slope that is greater than that of the low-water tangent of the curve previously described; its slope is found to have a value of 3.0.

The low-water tangent for the notched control, which is defined by discharge measurements, warrants further discussion. Its slope of 2.5 is higher than one would normally expect for a simple flat-crested rectangular notch. One reason for the steep slope is the fact that the range of stage involved, 0.0 ft to 1.4 ft, is one in which the theoretical weir coefficient C increases very rapidly with stage. A more important reason is the geometric complexity of the notch which is not indicated in figure 153. At the downstream edge of the notch is a sharp-edged plate; its elevation is at 0.0 ft, but the sharp edge is about 0.1 ft higher than the concrete base of the notch. The details of the notch are not important to this discussion; they are mentioned here only to warn the reader not to expect a slope as great as 2.5 in the rating for a simple flat-crested rectangular notch. In fact, the sole purpose here of discussing the low-water tangent of the rating curve is to demonstrate the effect exerted on the curve by varying the applied values of e. The low-water end of a rating curve is usually well defined by discharge measurements, and if it is necessary to

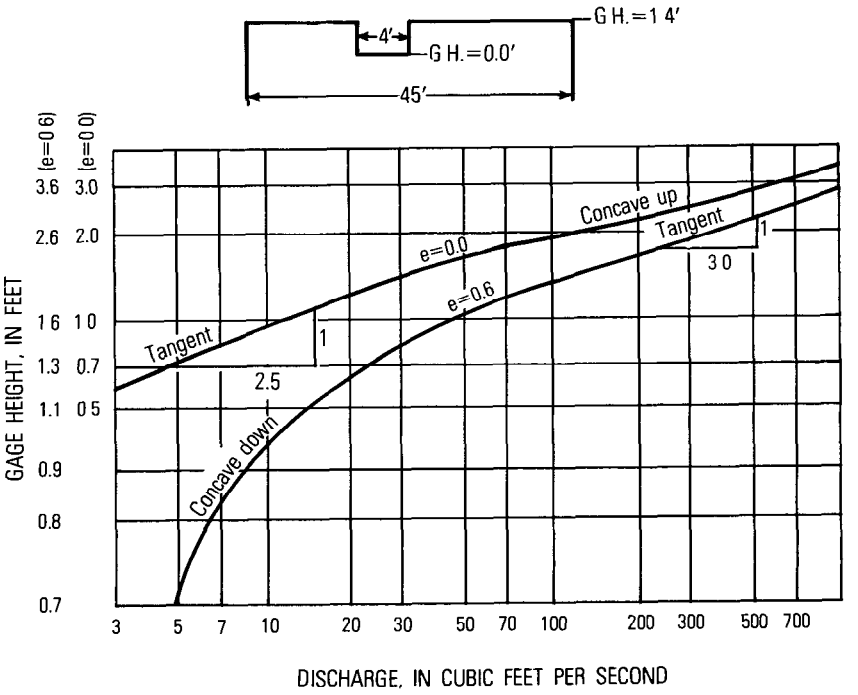

FIGURE 153.—Rating curve for a notched broad-crested control at Great Trough Creek near Marklesburg, Pa.

extrapolate the rating downward, it is best done by replotting the low-water end of the curve on rectangular-coordinate graph paper, and extrapolating the curve down to the point of zero discharge. (See section titled, "Low-Flow Extrapolation.")

TRENTON-TYPE CONTROL

The so-called Trenton-type control is a concrete weir that is frequently used in the U.S.A. The dimensions of the cross section of the crest are shown in figure 154. The crest may be constructed so as to be horizontal for its entire length across the stream, or for increased low-flow sensitivity the crest may be given the shape of an extremely flat Vee. For a horizontal crest, the equation of the stage-discharge relation, as obtained from a logarithmic plot of the discharge measurements, is commonly on the order of $Q=3.5bh^{1.65}$(English units). The precise values of the constants will vary with the height of the weir above the streambed, because that height affects the velocity of approach. The constants of the equation are greater than those for a flat-crested rectangular weir (see section titled, "Flat-crested Rectangular Weir") because the cross-sectional shape of the Trenton-type control is more efficient than a rectangle with regard to the flow of water.

When the Trenton-type control is built with its crest in the shape of a flat Vee, the exponent of h in the discharge equation is usually 2.5 or more, as expected for a triangular notch where velocity of approach

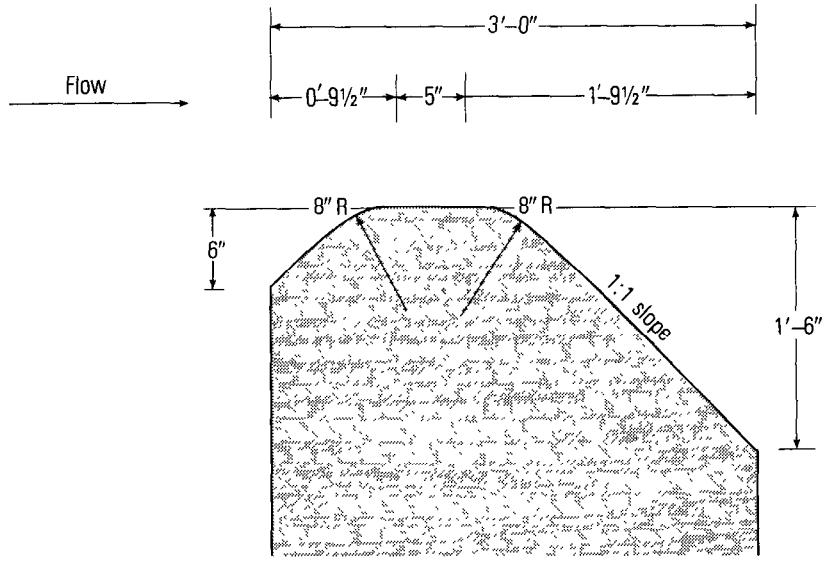

FIGURE 154.—Cross section of Trenton-type control.

is significant. Again, the precise values of the constants in the discharge equation are dependent on the geometry of the installation.

COLUMBUS-TYPE CONTROL

One of the most widely used controls in the U.S.A. is the Columbus-type control. This control is a concrete weir with a parabolic notch that is designed to give accurate measurement of a wide range of flows (fig. 155). The notch accommodates low flows; the main section, whose crest has a flat upward slope away from the notch, accommodates higher flows. The throat of the notch is convex along the axis of flow to permit the passage of debris. For stages above a head of 0.7 ft, which is the elevation of the top of the notch, the elevation of effective zero flow is 0.2 ft, and the equation of discharge is approximately,

$$Q = 8.5(h - 0.2)^{3.3} \text{ (English units)}$$

The precise values of the constants in the equation will vary with conditions for each installation. The shape of the crest above a stage of 0.7 ft is essentially a flat Vee for which the theoretical exponent of head is 2.5 in the discharge equation. However, the actual value of the exponent is greater than 2.5 principally because of the increase of velocity of approach with stage.

SUBMERGED BROAD-CRESTED WEIRS

Weir submergence was defined earlier in the section titled, "Submerged Thin-Plate Weirs." As in the case of thin-plate weirs, for a given static head (h) the discharge decreases as the submergence ratio (h_t/h) increases. Little quantitative data are available to define the relation of discharge ratio to submergence ratio for the many types of broad-crested weir. However, it is known that for horizontal crests the submergence ratio must be appreciable before any significant reduction in discharge occurs. This threshold value of the submergence ratio at which the discharge is first affected ranges from about 0.65 to 0.85, depending on the cross-sectional shape of the weir crest.

FLUMES

Flumes commonly utilize a contraction in channel width and free fall or a steepening of bed slope to produce critical or supercritical flow in the throat of the flume. The relation between stage measured at some standard cross section and discharge is thus a function only of the characteristics of the flume and can be determined, on an interim basis at least, prior to installation.

In the section in chapter 3 titled, "Artificial Controls," it was mentioned that flumes may be categorized with respect to the flow regime

that principally controls the measured stage; that is, a flume may be classed as either a critical-flow flume or a supercritical-flow flume. The most commonly used critical-flow flume is the Parshall flume, and it is the only one of that type that will be described here. The

supercritical-flow flume is less widely used, but fills a definite need. (See section in chapter 3 titled "Choice of an Artificial Control.") Of that type of flume, the trapezoidal supercritical-flow is preferred by the Geological Survey; it too will be described here.

PARSHALL FLUME

The principal feature of the Parshall flume is an approach reach having converging sidewalls and a level floor, the downstream end of which is a critical-depth cross section. Critical flow is established in the vicinity of that cross section by having a sharp downward break in the bed slope of the flume. In other words, the bed slope downstream from the level approach section is supercritical. The primary stage measurement is made in the approach reach at some standard distance upstream from the critical-depth cross section.

The general design of the Parshall flume is shown in figure 156. Table 17 gives the dimensions corresponding to the letters in figure 156 for various sizes of flumes. The flumes are designated by the width (W) of the throat. Flumes having throat widths from 3 in. to 8 ft have a rounded entrance whose floor slope is 25 percent. The smaller

Note: Flume sizes 3 inches through 8 feet have approach aprons rising at a 1:4 slope and the following entrance roundings: 3 through 9 inches, radius =1.33 feet; 1 through 3 feet, radius=1 67 feet, 4 through 8 feet, radius=2 00 feet

and larger flumes do not have that feature, but it is doubtful whether the performance of any of the flumes is significantly affected by the presence or absence of the entrance feature as long as approach conditions are satisfactory.

Parshall flumes have provision for stage measurements both in the approach reach and in the throat reach, but the downstream gage is required only when submerged-flow conditions exist. The datum for both gages is the level floor in the approach. The raised floor, length G in figure 156, in the downstream diverging reach is designed to reduce scour downstream and to produce more consistent stage-discharge relations under conditions of submergence. The percentage of submergence for Parshall flumes is computed by the formula,

$$\frac{h_B}{h_A} \times 100.$$

Where free-flow conditions exist for all flows, the downstream gage, h_B, may be omitted and the entire diverging reach may be dispensed with if desired. That simplification has been used in the design of small portable Parshall measuring flumes. (See section in chapter 8 titled, "Portable Parshall Flume.")

Tables 18 and 19 summarize the relation of discharge to stage at h_A under conditions of free flow (low stage at h_B) for flumes of the various sizes. Although the free-flow stage-discharge relations for the various flumes were derived experimentally, all relations can be expressed closely by the following equation, (Davis, 1963),

$$Y_0 + \frac{Q_0^2}{2Y_0^2\,(1 + 0.4X_0)^2} = 1.351\,Q_0^{\,0.645} \text{ (English units)} \qquad (59)$$

in which

Y_0 = nondimensional depth, y_1/b
Q_0 = nondimensional discharge, $Q/g^{1/2}b^{5/2}$
X_0 = nondimensional distance, x/b
y_1 = depth at measuring section
b = channel width at throat
Q = discharge
g = acceleration of gravity
x = distance from throat crest to measuring section.

For flumes with throat widths no greater than 6 ft, the following simplified form of the above equation (Dodge, 1963) can be used:

$$Y_0 = 1.19 Q_0^{\,0.645} X_0^{\,0.0494} \qquad (60)$$

When the stage h_B is relatively high, the free-flow discharge corresponding to any given value of h_A is reduced. The percentage of submergence, or value of $[(h_B/h_A)\times 100]$, at which the free-flow discharge is first affected, varies with the size of flume. For flumes whose throat width is less than 1 ft, the submergence must exceed 50 percent before there is any backwater effect; for flumes with throat width from 1 to 8 ft, the threshold submergence is 70 percent; for flumes with throat width greater than 10 ft, the threshold submergence is 80 percent. Figure 157 shows the discharge ratings for Parshall flumes, from 2 inches to 9 inches, under both free-flow and submergence conditions. Figure 158 shows the correction in discharge, which is always negative, that is to be applied to free-flow discharges for various percentages of submergence and various values of h_A, for flumes having throat widths between 1 and 50 feet. The appropriate correction factor (k_s) for flume size is applied to the corrections read from the graphs. In other words,

$$Q_s = Q_f - k_s Q_c,$$

where

Q_s = discharge under submergence conditions,
Q_f = discharge under free-flow conditions, and
Q_c = discharge correction unadjusted for flume size.

The stage-discharge relations, both for free-flow and submergence conditions, given in the preceding tables and graphs, should be used only as guides or as preliminary ratings for Parshall flumes built in the field. Those installations should be field-calibrated because the structural differences that invariably occur between model and prototype flume usually cause the discharge rating for the field structure to differ from the experimental ratings given in this manual.

Note· Available data indicates that extension of the above ratings to greater heads is reliable

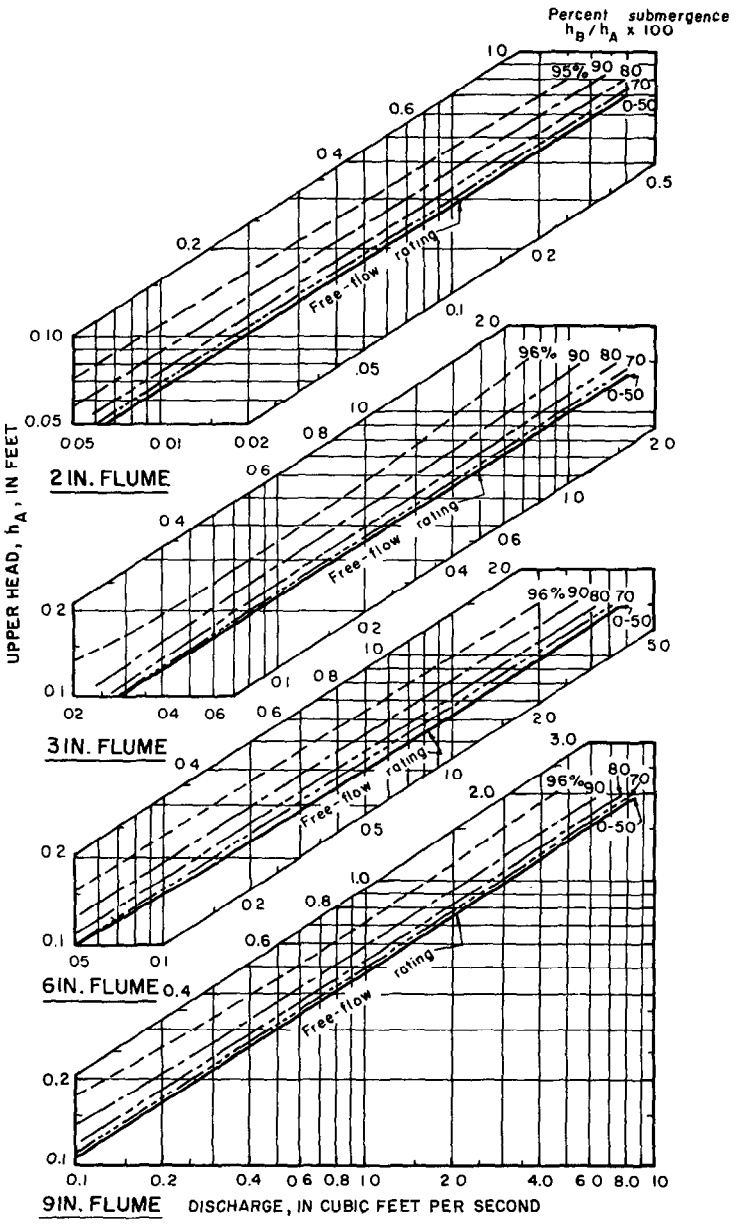

FIGURE 157.—Discharge ratings for "inch" Parshall flumes for both free-flow and submergence conditions.

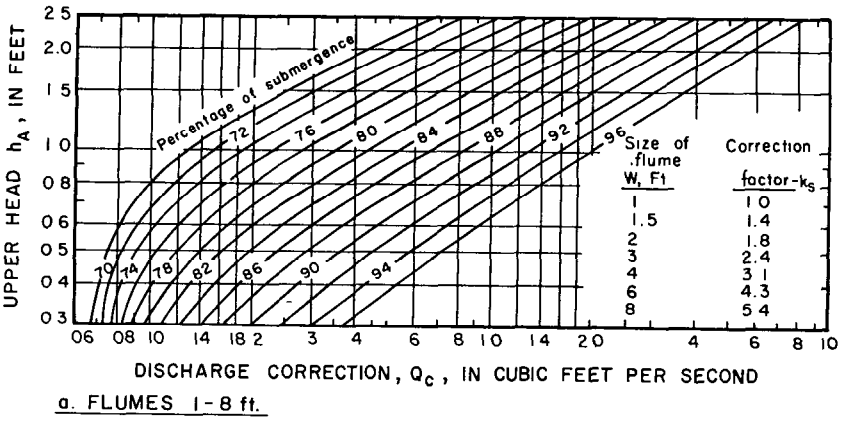
TRAPEZOIDAL SUPERCRITICAL-FLOW FLUME

The principal feature of the trapezoidal supercritical-flow flume is a reach of flume (throat) whose bed has supercritical slope, upstream from which is a critical-depth cross section. The general design of the flume and the dimensions for the flumes of three throat widths that have been installed by the Geological Survey are shown in figure 159. The purpose of having the flume trapezoidal in cross section is to increase the sensitivity of the stage-discharge relation, particularly at low flows. Wide latitude exists with regard to the height (E) of the



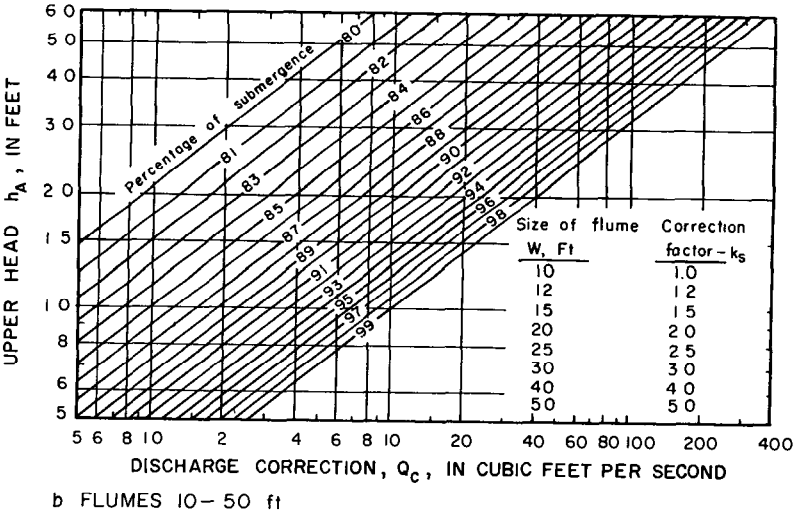


FIGURE 158.—Correction factors for submerged flow through 1- to 50-ft Parshall flumes.

sidewalls that can be used, and thus the range of discharge that can be accommodated by a supercritical-flow flume of any particular throat width is quite flexible. Stage (vertical depth of flow) is measured at a cross section at midlength of the throat reach, gage datum being the floor of the flume at the stage-measurement site. The measurement of stage must be precise because the stage-discharge relation for supercritical flow is extremely insensitive—a small change in stage corresponds to a large change in discharge.

Were it not for the severe width constriction at the downstream end of the converging reach, critical flow would occur at the break in floor slope at the downstream end of the approach reach and flow would be supercritical at all cross sections downstream from the approach reach. However for all but extremely low flows, the sharp constriction in width resulting from the use of a convergence angle (ϕ) of 21.8° (fig.159) causes backwater that extends upstream into the approach

Note—Height of wall (E) is dependent on magnitude of maximum discharge to be gaged

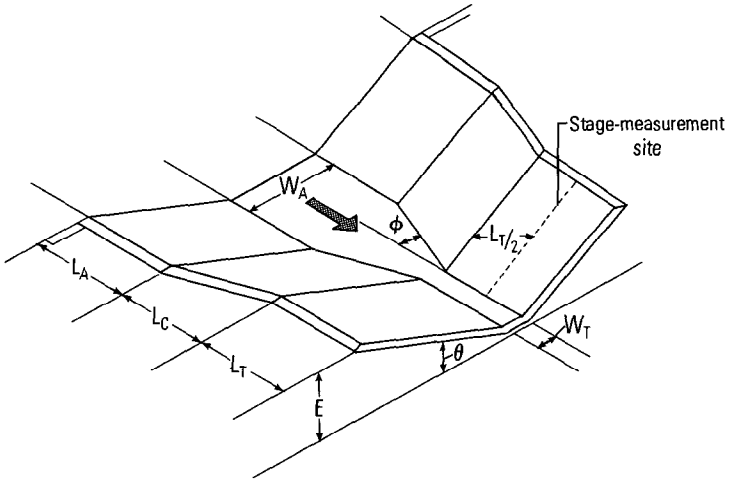

FIGURE 159.—Configuration and dimensions of trapezoidal supercritical-flow flumes of three throat widths.

reach. As a result critical depth occurs at the most constricted cross section in the converging reach, the flow being subcritical in the approach and converging reaches and supercritical in the throat reach. That is seen in figure 5 (chap. 3) which is a photograph of a 3-foot trapezoidal flume in Owl Creek in Wyoming. The purpose of the converging reach is to obtain an increased velocity at the critical-depth cross section and thereby reduce the likelihood of debris deposition at that cross section; such deposition could affect the stage-discharge relation in the throat of the flume.

The measured stage corresponding to any discharge is a function of the stage of critical depth at the head of the throat reach and the geometry of the throat reach upstream from the stage-measurement cross section. Consequently a theoretical rating for all but the smallest discharges can be computed by use of the Bernoulli or total-energy equation for the length of throat reach upstream from the stage-measurement site (fig. 160). By equating total energy at the critical-depth cross section (c) at the head of the throat reach to total energy at the stage-measurement cross section (m), we have,

$$\frac{V_c^2}{2g} + h_c + z_c = \frac{V_m^2}{2g} + h_m + z_m + h_f, \tag{61}$$

where

V is mean velocity,
g is acceleration of gravity,
h is vertical depth,
z is elevation of flume floor above any arbitrary datum plane, and
h_f is friction loss.

We make the assumption that the friction loss h_f in the short reach is negligible and may be ignored. Then by substituting, in equation 61 values from the two equations

$$Q = A_c V_c = A_m V_m \quad \text{and} \quad \Delta Z = Z_c - Z_m,$$

we obtain

$$\frac{Q^2}{2gA^2_c} + h_c + \Delta z = \frac{Q^2}{2gA^2_m} + h_m. \tag{62}$$

From the properties of critical-depth flow (Chow, 1959, p. 64), the critical-section factor (J) is computed by the formula

$$J = A_c \sqrt{\frac{A_c}{T_c}} \tag{63}$$

where A_c is the area and T_c is the top width at the critical-depth cross section. The discharge (Q) at the critical-depth cross section is

$$Q = J\sqrt{g} \tag{64}$$

By assuming a depth (h_c) at the critical-depth cross section, we can compute Q and A_c, and thus the values of all terms on the left side of equation 62 will be known for any chosen value of h_c. Because h_m is uniquely related to A_m, equation 62 can be solved by trial and error to obtain the depth (stage) at the measurement cross section corresponding to the value of Q that was computed earlier.

The entire procedure is repeated for other selected values of h_c to provide a discharge rating curve for the entire range of discharge. The value of h_c corresponding to the maximum discharge to be gaged represents the height to which the sidewalls of the throat section must be built to contain that discharge. An additional height of at least 0.5 ft should be added for freeboard to accommodate surge and wave action.

The computed discharge rating should be used only until the rating can be checked by current-meter discharge measurements. The sources of error in the computed rating are uncertainty as to the exact location of the critical-depth cross section for any given discharge and neglect of the small friction loss (h_f). However, the general shape of the discharge rating curve will have been defined by the computed values, and relatively few discharge measurements should be required for any needed modification of the rating.

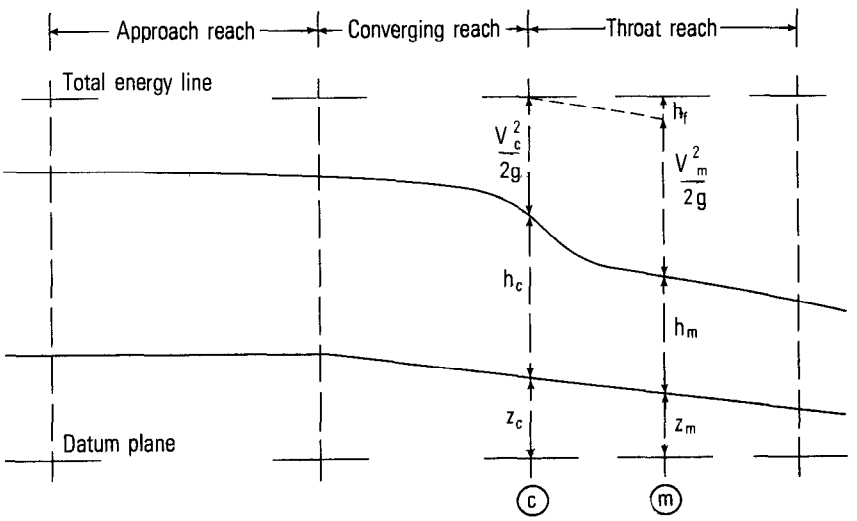

FIGURE 160.—Sketch illustrating use of the total-energy (Bernoulli) equation.

The total-energy equation (eq. 61) should also be applied to the converging reach to obtain the required height of the sidewalls at the upper end of the converging reach. The height plus an additional freeboard height of at least 0.5 ft should be used for the sidewalls in the approach reach. In applying equation 61 to the converging reach, the value of discharge used is the maximum discharge that is to be gaged, and the depth used at the lower end of the converging reach is the corresponding critical depth (h_c) that was computed earlier for the throat reach.

The solid-line curves on figures 161–163 are the theoretical discharge rating curves for the flumes of the three throat widths that have been field tested. The agreement between measured and theoretical discharges has generally been good except at extremely low stages. Nevertheless the theoretical curves should be considered as interim rating curves for newly built flumes until later measurements either corroborate the ratings or show the need for modification of the ratings. It is expected that the stage-discharge relation will not be affected by submergence, as long as submergence percentages do not exceed 80 percent. (Percentage of submergence for a given discharge is defined as the ratio, expressed as a percentage, of the stage in the natural channel immediately downstream from the throat reach to the stage at the stage-measurement site, both stages being referred to the floor elevation of the flume at the stage-measurement site.)

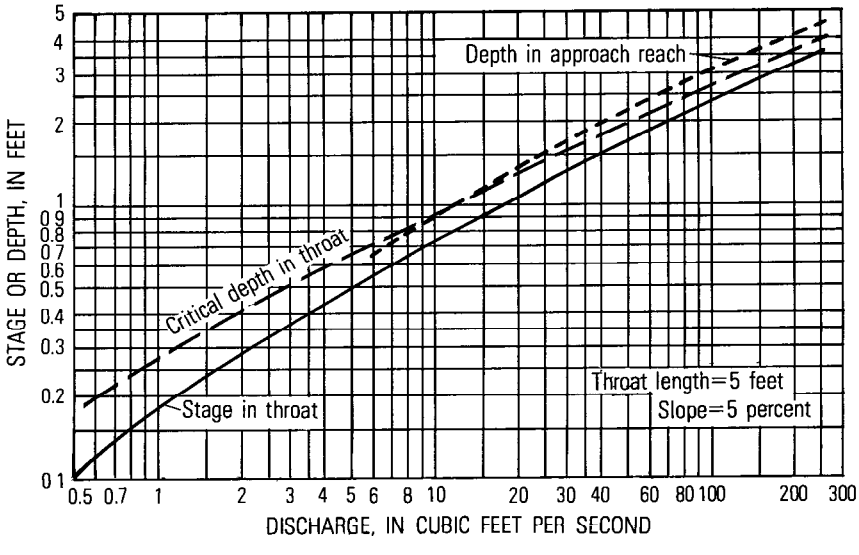

FIGURE 161.—Stage-discharge relation and significant depth-discharge relations for 1-ft trapezoidal supercritical-flow flume.

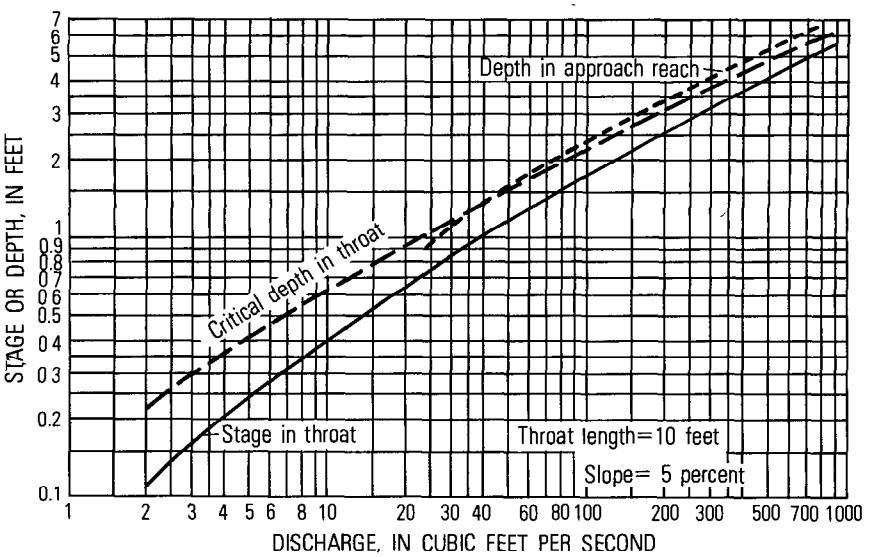

FIGURE 162.—Stage-discharge relation and significant depth-discharge relations for 3-ft trapezoidal supercritical-flow flume.

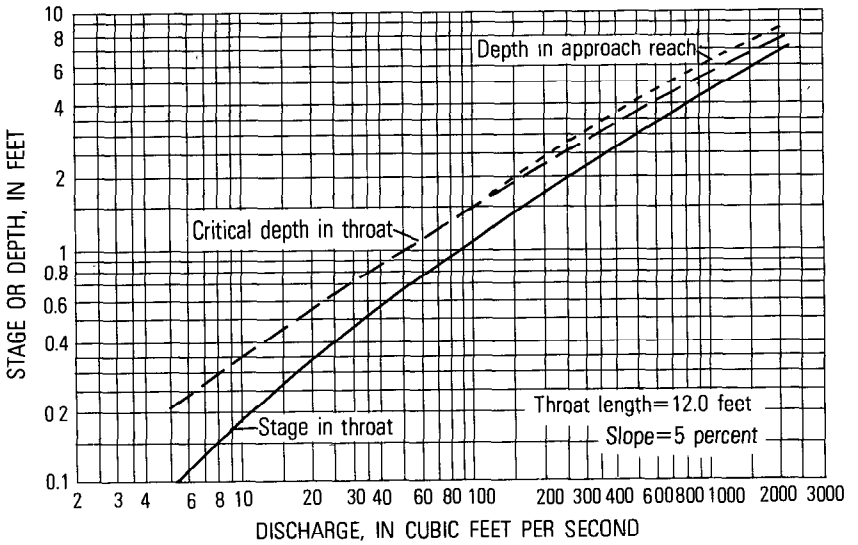

FIGURE 163.—Stage-discharge relation and significant depth-discharge relations for 8-ft trapezoidal supercritical-flow flume.

Also shown on each of the three rating-curve graphs are curves labeled "critical depth in throat" and "depth in approach reach." These curves are used to obtain the heights of sidewalls required to

contain the maximum discharge for which the flume is designed. For example, let us assume that an 8-ft flume is to be built to gage a range of discharges whose maximum value is 1200 ft^3/s. Figure 163 shows that the theoretical stage for that discharge is 5.2 ft; the height of the throat sidewall (critical depth) is shown to be 6.0 ft and the height of the approach sidewall is 6.8 ft. To those sidewall heights will be added at least 0.5 ft of freeboard, and the top of the sidewalls in the converging reach will be sloped uniformly to join the tops of the sidewalls of the approach and throat reaches.

Up to this point little has been said concerning the approach reach. Its sidewalls are extended upstream from the converging reach by means of rock fill or concrete to meet the natural channel banks. As long as the approach reach provides a smooth transition from the natural channel to the converging reach, its actual geometry will have no effect on the theoretical rating. The level floor of the approach reach will provide a site for current-meter measurements of discharge and will also induce the deposition of large debris, thereby helping to keep the more vital parts of the flume structure free of sediment deposition.

NATURAL SECTION CONTROLS

Natural section controls, listed in order of permanence, are usually a rock ledge outcrop across the channel, or a riffle composed of loose rock, cobbles, and gravel, or a gravel bar. Less commonly, the section control is a natural constriction in width of the channel, or is a sharp break in channel slope, as at the head of a cascade or brink of a falls.

Where the control is a rock outcrop, riffle, or gravel bar, the stage-discharge relation, when plotted on logarithmic paper, conforms to the general principles discussed for broad-crested artificial controls. If the natural control is essentially horizontal for the entire width of the control, the head on the control is the difference between the gage heights of the water surface and the crest of the control. The exponent (N) of the head in the equation of discharge,

$$Q = p(G - e)^N \tag{53}$$

will be greater than the theoretical value 1.5, primarily because of the increase in velocity of approach with stage. If the crest of the control has a roughly parabolic profile, as most natural controls have (greater depths on the control near midstream), the exponent N will be even larger because of the increase in width of the stream with stage, as well as the increase in velocity of approach with stage. The value of N will almost always exceed 2.0. If the control is irregularly

notched, as is often the case, the gage height of effective zero flow (e) for all but the lowest stages, will be somewhat greater than that for the lowest point in the notch. (The method of determining values of e was explained in the section titled, "Graphical Plotting of Rating Curves.")

The above principles are also roughly applicable to the discharge equations for an abrupt width contraction or an abrupt steepening of bed slope. The exponent N and the gage height of effective zero flow are influenced, as described above, by the transverse profile of the streambed at the control cross section.

An example of natural section control is treated in the following discussion.

COMPOUND SECTION CONTROLS

Where the control section is a local rise in the streambed, as at a rock outcrop, riffle, or gravel bar, that cross section is invariably a control only for low flows. The gaging station in that circumstance has a compound control, the high flows being subject to channel control. Occasionally there is a second outcrop or riffle, downstream from the low-water riffle, that acts as a section control for flows of intermediate magnitude. When the control for intermediate stages is effective it causes submergence of the low-water control. At high flows the section control for intermediate stages is in turn submerged when channel control becomes effective. An example of a compound control involving two section controls follows; an example of a compound control involving a section control that is submerged when channel control becomes effective is described in the section titled, "Compound Controls Involving Channel Control."

Figure 164 shows the rating for the compound section control at the gaging station on Muncy Creek near Sonestown, Pa. The control consists of two rock-ledge riffles, effective zero flow (e) for very low stages being at gage height 1.3 feet and for higher stages at gage height 1.2 feet. If the low end of the rating is made a tangent, it means that too large a value of e is used for the high end of the rating (1.3 ft vs 1.2 ft), and the high-water end of the curve becomes concave downward. Conversely, if the high end of the curve is made a tangent, the low-water end of the curve becomes concave upward. The high-water tangent of the curve has a greater value of exponent N than the low-water tangent of the other curve. This difference in the values of N reflects the effect of differences in the geometries of the two controls as well as the effect of increased rate of change of approach velocities at the higher stages. The slopes of the two tangents are 2.9 and 2.2, both values being greater than the theoretical slope of 1.5.

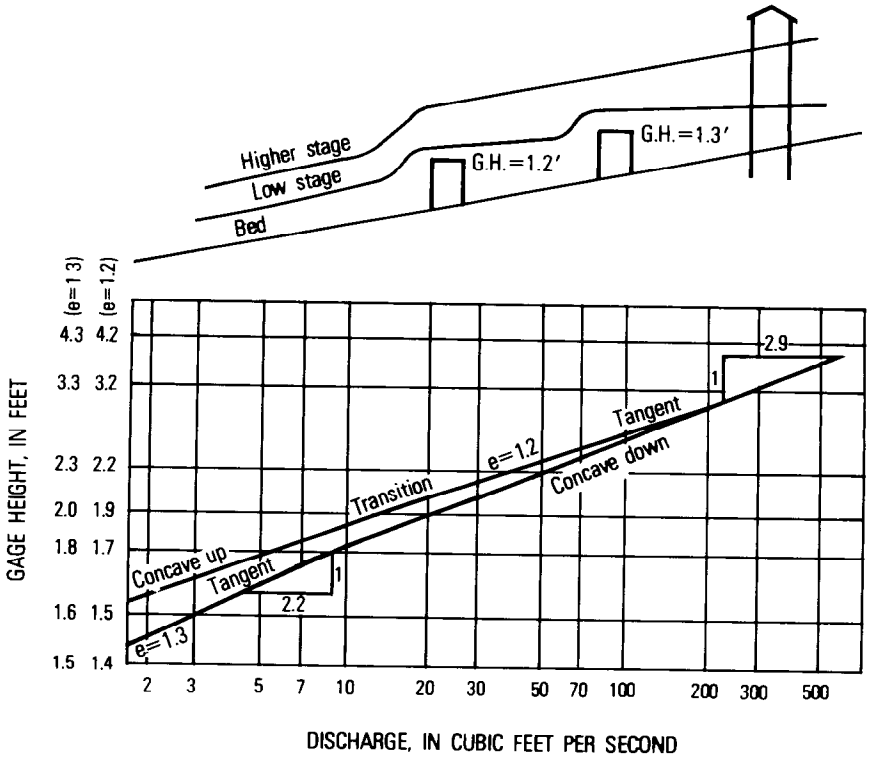

FIGURE 164.—Rating curve for a compound section control at Muncy Creek near Sonestown, Pa.

CHANNEL CONTROL

CHANNEL CONTROL FOR STABLE CHANNELS

The term "stable channels," as used in this report, is a relative term. Virtually all natural channels are subject to at least occasional change as a result of scour, deposition, or the growth of vegetation, but some alluvial channels, notably those whose bed and banks are composed of sand, have movable boundaries that change almost continuously, as do their stage-discharge relations. For the purpose of this manual, stable channels include all but sand channels. Sand channels are discussed in the section titled, "Sand-Channel Streams."

Almost all streams that are unregulated by man have channel control at the higher stages, and among those with stable channels, all but the largest rivers have section control at low stages. Because this section of the manual discusses only stable channels that have channel control for the entire range of stage experienced, the discussion is limited to the natural channels of extremely large rivers and

to artificial channels constructed without section controls. The artificial channels may be concrete-lined, partly lined or rip-rapped, or unlined. Streams that have compound controls involving channel control are discussed in the section titled, "Compound Controls Involving Channel Control."

The Manning discharge equation for the condition of channel control, as discussed in chapter 9, under the heading, "Slope-Area Method," is

$$Q = \frac{1.486}{n} AR^{2/3}S^{1/2} \text{ (English units)}, \tag{65}$$

or

$$Q = \frac{1}{n} AR^{2/3}S^{1/2} \text{ (metric units)} \tag{66}$$

In analyzing an artificial channel of regular shape, whose dimensions are fixed, flow at the gage is first assumed to be at uniform depth. Consequently, for any stage all dimensions on the right side of the equations are known except n. A value of n can be computed from a single discharge measurement, or an average value of n can be computed from a pair of discharge measurements, and thus a preliminary rating curve for the artificial channel can be computed for the entire range of stage from the results of a pair of discharge measurements. If subsequent discharge measurements depart from the computed rating curve, it is likely that the original assumption of flow at uniform depth was erroneous. That means that the energy slope, S, is not parallel to the bed slope, but varies with stage, and that the value of n, which was computed on the basis of bed slope, is also in error. The rating curve must be revised to fit the plotted discharge measurements, but the preliminary rating curve may be used as a guide in shaping the required extrapolation of the rating curve. The extrapolation should also be checked by application of the conveyance-slope method of rating extrapolation, which is described in the section titled, "Conveyance-Slope Method."

To understand the principles that underlie the stage-discharge relation for channel control in a natural channel of irregular shape we return to the Manning equation and make some simplifying assumptions in that equation. We assume, not unreasonably, that at the higher stages n is a constant and that the energy slope (S) tends to become constant. Furthermore, area (A) is approximately equal to depth (D) times width (W). We make the substitution for A in equation 65 or 66, and by expressing $S^{1/2}/n$ as a constant, C_1, we obtain

$$Q = C_1 (D) (W) R^{2/3}. \text{ (approx.)}$$

If the hydraulic radius (R) is considered equal to D, and W is considered a constant, the equation becomes

$$Q = CD^{1.67} = C(G-e)^{1.67} \text{ (approx.)} \quad (67)$$

However, unless the stream is exceptionally wide, R is appreciably smaller than D. This has the effect of reducing the exponent in the last equation although this reduction may be offset by an increase of S or W with discharge. Changes in roughness with stage will also affect the value of the exponent. The net result of all these factors is a discharge equation of the form

$$Q = C\,(G-e)^N$$

where N will commonly vary between 1.3 and 1.8 and practically never reach a value as high as 2.0.

An example of a discharge rating for channel control in a natural stream is given in the following section, where compound controls that involve channel control are discussed.

COMPOUND CONTROLS INVOLVING CHANNEL CONTROL

In the preceding section mention was made of the fact that compound control of the stage-discharge relation usually exists in natural channels, section control being effective for the lower stages and channel control being effective for the higher stages. An example of that situation is shown in figure 165, the rating curve for the Susquehanna River at Harrisburg, Pa. The low-water control is a low weir with zero flow at gage height 2.2 feet. At a stage of 3.9 feet this control starts to drown out and channel control becomes effective. If the low end of the rating is made a tangent, a value of $e = 2.2$ ft must be used. Because the value of e for the upper end of the rating is something less than 2.2 feet, the high end becomes concave downward. If the high end of the curve is made a tangent, the effective value of e is found to be 0.0 ft. This being too low a value of e for the lower end of the curve, the low end becomes concave upward.

If the rating for a section control (low end of the curve) is a tangent, the value of the exponent N is expected to be greater than 2.0. In this example, $N = 2.3$. If the rating for a channel control (high end of the curve) is a tangent, the value of N is expected to be less than 2.0, and probably between 1.3 and 1.8. In this example $N = 1.3$. Should overbank flow occur the rating curve will bend to the right.

It can be demonstrated, nonrigorously, that straight-line rating curves for section control almost always have a slope greater than 2.0 and that those for channel control have a slope less than 2.0. It has

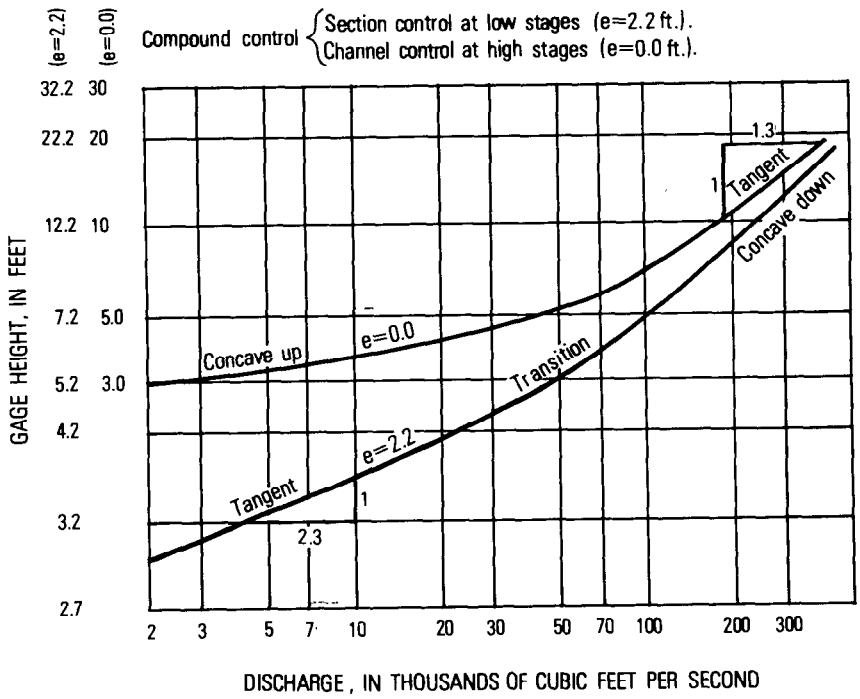

FIGURE 165.—Rating curve for a compound control at Susquehanna River at Harrisburg, Pa.

been shown that the equation for a straight-line rating on log paper is $Q = CH^N$, where N is the slope of the line. The first derivative of this equation is a measure of the change in discharge per tenth of a foot change in stage. The first derivative is:

$$\frac{dQ}{dH} = CNH^{N-1}.$$

Second differences are obtained by differentiating again. The second derivative is:

$$\frac{d^2Q}{dH^2} = CN\ (N-1)H^{N-2}.$$

Examination of the second derivative shows that second differences increase with stage when N is greater than 2.0 and decrease with stage when N is less than 2.0.

The hypothetical rating for a compound control is shown in table 20. This rating represents the condition of section control at the lower

TABLE 20.—*Hypothetical stage-discharge rating for a compound control*

stages and channel control at the higher stages. If two values of discharge are shown for an item in the rating table, the figure in parenthesis is the exact value and the figure without a parenthesis is the "rounded" value that normally would be used in the rating table. Experienced hydrographers will recognize the progression of discharge values in this table as being typical. Inspection of the second difference column shows the second differences to be increasing at the low-water end (section control, $N > 2$) and decreasing at the high-water end (channel control, $N < 2$). These are the results that one would predict from the discussion in the preceding paragraph.

EXTRAPOLATION OF RATING CURVES

Rating curves, more often than not, must be extrapolated beyond the range of measured discharges. The preceding material in this

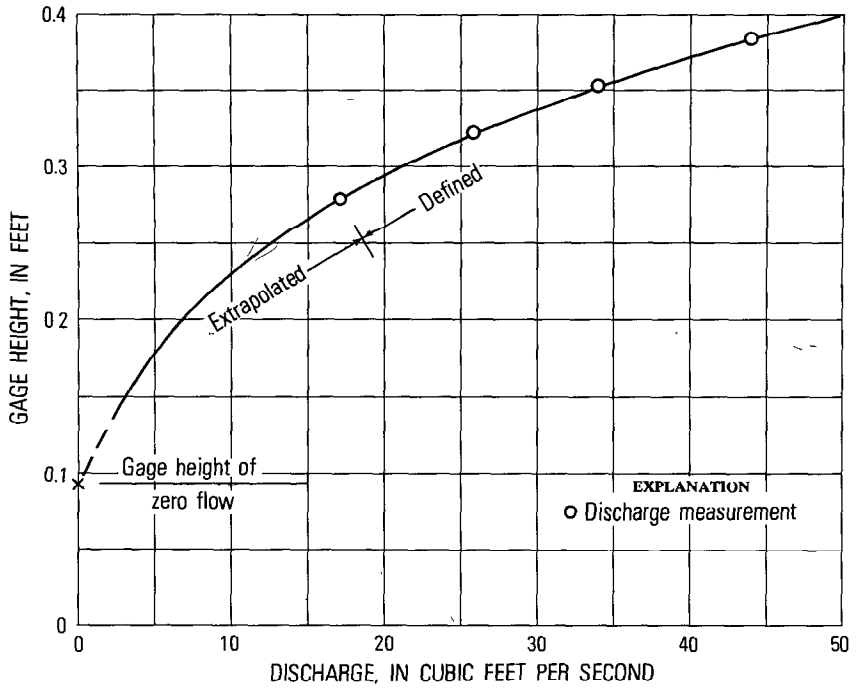

FIGURE 166.—Example of low-flow extrapolation on rectangular-coordinate graph paper.

chapter explained the principles governing the shape of logarithmic rating curves to guide the hydrographer in shaping the extrapolated segment of a rating. However, even with a knowledge of those principles, a large element of uncertainty exists in the extrapolation process. The purpose of this section of the manual is to describe methods of analysis that will reduce the degree of uncertainty.

LOW-FLOW EXTRAPOLATION

Low-flow extrapolation is best performed on rectangular-coordinate graph paper because the coordinates of zero flow can be plotted on such paper. (Zero discharge cannot be plotted on logarithmic graph paper.) An example of such an extrapolation is shown in figure 166, where the circled points represent discharge measurements plotted on the coordinate scales of gage height versus discharge. The rating in the example is defined by the measurements down to a gage height of 0.28 ft, but an extrapolation to a gage height of 0.14 ft is required. Field observation has shown the low point on the control (point of zero flow) to be at gage height 0.09 ft.

The method of extrapolation in figure 166 is self-evident. A curve

has been drawn between the plotted points at gage heights 0.09 ft and 0.28 ft to merge smoothly with the rating curve above 0.28 ft. There is no assurance that the extrapolation is precise—low-flow discharge measurements are required for that assurance—but the extrapolation shown is a reasonable one.

HIGH-FLOW EXTRAPOLATION

As mentioned in the "Introduction" of this chapter, the problem of high-flow extrapolation can be avoided if the unmeasured peak discharge for the rating is determined by the use of the indirect methods discussed in chapter 9. In the absence of such peak-discharge determinations, estimates of the discharges corresponding to high values of stage may be made by using one or more of the following four techniques:

1. conveyance-slope method,
2. areal comparison of peak-runoff rates,
3. step-backwater method, and
4. flood routing.

As a matter of fact, only as a last resort should the rating curve be extrapolated beyond a discharge value equal to twice the greatest measured discharge. If a greater extrapolation is required, the hydrologist should first try to define the upper end of the rating by use of one of the indirect peak-discharge determination methods of chapter 9. If for some reason, that course of action is not feasible, he should then use at least one of the four techniques listed above.

The knowledgeable reader of this manual may notice the absence from the above list of two techniques that used to be standard practice—the velocity-area method and the Q vs $Ad^{1/2}$ method. The Q vs $Ad^{1/2}$ method was superior to the velocity-area method and largely supplanted it; similarly, the conveyance-slope method, because of its superiority, has, in the last two decades, largely supplanted the Q vs $Ad^{1/2}$ method. Of the three somewhat similar methods, only the conveyance-slope method is described here, because a description of the two earlier methods (Corbett and others, 1943, p. 91–92) would have only academic, rather than practical, value.

CONVEYANCE-SLOPE METHOD

The conveyance-slope method is based on equations of steady flow, such as the Manning equation. In the Manning equation,

$$Q = KS^{1/2}. \tag{68}$$

The conveyance, K, equals $\frac{1.486}{n} AR^{2/3}$ when English units are used,

and $K=\frac{1}{n}AR^{2/3}$ when metric units are used. Values of A and R corresponding to any stage can be obtained from a field survey of the discharge-measurement cross section, and values of the coefficient n can be estimated in the field. Thus, the value of K, embodying all the elements that can be measured or estimated, can be computed for any given stage. (We shall soon see that errors in estimating n are usually not critical.) Values of gage height vs K, covering the complete range of stage up to the required peak gage height, are computed and plotted on rectangular graph paper. A smooth curve is fitted to the plotted points.

Values of slope, S, which is actually the energy gradient, are usually not available even for measured discharges. However, for the measured discharges, $S^{1/2}$ can be computed by dividing each measured discharge by its corresponding K value; S is then obtained by squaring the resulting value of $S^{1/2}$. Values of gage height vs S for the measured discharges are plotted on rectangular graph paper, a curve is fitted to the plotted points, and the curve is extrapolated to the required peak gage height. The extrapolation is guided by the knowledge that S tends to become constant at the higher stages. That constant slope is the "normal" slope, or slope of the streambed. If the upper end of the defined part of the curve of gage height vs S indicates that a constant or near-constant value of S has been attained, the extrapolation of the curve can be made with confidence. The discharge for any particular gage height will be obtained by multiplying the corresponding value of K from the K curve by the square root of the corresponding value of S from the S curve. We see that errors in estimating n will have minor effect because the resulting percentage error in computing K is compensated by a similar percentage error in the opposite direction in computing $S^{1/2}$. In other words, the constancy of S is unaffected, but if K is, say, 10 percent high, $S^{1/2}$ will be 10 percent low, and the two discrepancies are canceled when multiplication is performed. However, if the upper end of the defined part of the curve of gage height vs S has not reached the stage where S has a near-constant value, the extrapolation of the curve will be subject to uncertainty. In that situation the general slope of the streambed, as determined from a topographic map, provides a guide to the probable constant value of S that should be attained at high stages.

As mentioned in the preceding paragraph, the discharge for any particular gage height is obtained by the multiplication of appropriate values of K and $S^{1/2}$, and in that manner the upper end of the stage-discharge relation is constructed.

Figure 167 provides an example of the conveyance-slope method, as used for rating-curve extrapolation at the gaging station on Klamath River at Somes Bar, Calif. The conveyance curve is based on

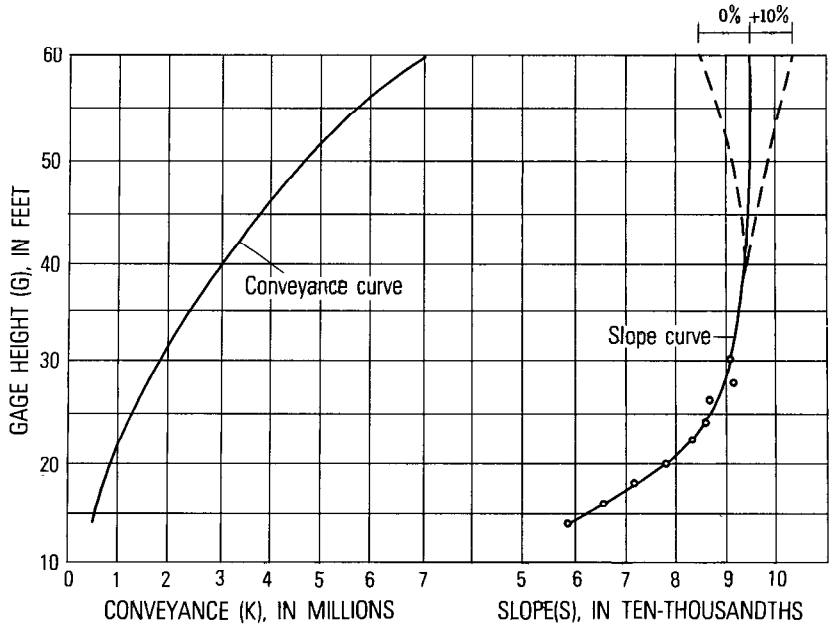

FIGURE 167.—High-flow extrapolation by use of conveyance-slope method—Klamath River at Somes Bar, Calif.

values of K computed from the geometry of the measurement cross section. The slope curve is defined to a gage height of 30 ft by discharge measurements (circled points), and extrapolated as the solid line to the peak gage height of 60 ft. It appears highly unlikely that the slope curve at a gage height of 60 ft will fall outside the limiting dashed curves shown in figure 167; in other words, it appears unlikely that the value of S at 60 ft (0.00095) is in error by more than ± 10 percent. If that is true, when the square root of S is computed and then used in a computation of peak discharge, the error for both $S^{1/2}$ and Q reduces to ± 5 percent. Although the attainment of so high an accuracy is highly improbable, the fact remains that one can place considerable confidence in the discharge computed for a gage height of 60 ft in this example. It should be mentioned here that the likelihood of a decrease in slope at high stages, as shown by the dashed curve on the left of the slope curve, is greatest when overbank flows occur.

In the above example conditions were ideal for application of the conveyance-slope method, and the example in figure 167 may therefore be misleading with regard to the general accuracy of the method. The conveyance-slope method assumes first that the geometry of the cross-section used for discharge measurements is fairly representa-

tive of that of a long reach of downstream channel. The need to meet this assumption immediately eliminates from consideration those gaging stations where discharge measurements are made at constricted cross sections, such as occur at many bridge- and cableway-measurement sections.

The conveyance-slope method also assumes that slope tends to become constant (uniform flow) at the higher stages. That is strictly true only for long, straight channels of uniform cross section, but natural channels that meet that description are virtually nonexistent. Consequently, the slope-stage relation may be anything but a vertical line at the upper stages. In the example in figure 167, a judgment decision, based on a knowledge of the channel characteristics, was made concerning the "probable" limiting positions of the stage-slope relation—the dashed lines on the graph—to give some idea of the "probable" error of the discharge computation. However, even given that knowledge of channel characteristics, if the two highest discharge measurements (two highest circles on the slope curve) had not been available it would have been impossible to position the upper end of the slope curve with any confidence. Fortunately there is a mitigating factor; an error of even as much as 40 percent in the value of slope at the upper end of the slope curve would give an error in discharge of either +18 percent ($\sqrt{1.40}-1.0=0.18$) or −23 percent ($1.0-\sqrt{0.60}=0.23$), depending on whether the estimate of slope was high or low.

In summary, the conveyance-slope method is a helpful adjunct in extrapolating rating curves, but its limitations must be understood so that it is not misused.

AREAL COMPARISON OF PEAK-RUNOFF RATES

When flood stages are produced over a large area by an intense general storm, the peak discharges can often be estimated, at gaging stations where they are lacking, from the known peak discharges at surrounding stations. Usually each known peak discharge is converted to peak discharge per unit of drainage area before making the analysis. In other words, peak discharge is expressed in terms of cubic feet per second per square mile or cubic meters per second per square kilometer.

If there has been relatively little difference in storm intensity over the area affected, peak discharge per unit area may be correlated with drainage area alone. If storm intensity has been variable, as in mountainous terrain, the correlation will require the use of some index of storm intensity as a third variable. Figure 168 illustrates a multiple correlation of that type where the independent variables

used were drainage area and maximum 24-hour basinwide precipitation during the storm of December 1964 in north coastal California.

The peak discharges estimated by the above method should be used only as a guide in extrapolating the rating curve at a gaging station. The basic principles underlying the extrapolation of logarithmic rating curves are not to be violated to accommodate peak-discharge values that are relatively gross estimates, but the estimated discharges should properly be given consideration in the extrapolation process.

STEP-BACKWATER METHOD

The step-backwater method is a technique in which water-surface profiles for selected discharges are computed by successive approximations. The computations start at a cross section where the stage-discharge relation is known or assumed, and they proceed to the gage site whose rating requires extrapolation. If flow is in the subcritical regime, as it usually is in natural streams, the computations must proceed in the upstream direction; computations proceed in the downstream direction if flow is in the supercritical regime. In the discussion that follows, the usual situation of subcritical flow will be assumed.

Under conditions of subcritical flow, water-surface profiles converge upstream to a common profile. For example, the stage for a given discharge at a gated dam may have a wide range of values depending on the position of the gates. At a gaging station far enough upstream to be beyond the influence of the dam, the stage for that discharge will be unaffected by the gate operations. Consequently, when the water-surface profile is computed for a given discharge in the reach between the dam and the gaging station, the segment of the computed profile in the vicinity of the gage will be unaffected by the value of stage that exists at the dam. However, it will be necessary that the computations start at the dam and proceed upstream, subreach by subreach (in "steps"). It follows, therefore, that if an initial cross section for the computation of the water-surface profile is selected far enough downstream from the gage, the computed water-surface elevation at the gage, corresponding to any given discharge, will have a single value regardless of the stage selected for the initial site.

A guide for determining the required distance (L) between gaging station and initial section is found in the dimensionless graph in figure 169. The graph, (Bailey and Ray, 1966), has for its equation,

---

DRAINAGE AREA (A), IN SQUARE MILES

$$\frac{LS_o}{\bar{d}} = 0.86 - 0.64\left(\frac{S_o C^2}{g}\right) \tag{69}$$

where

L is the distance required for convergence,
S_o is bed slope,
$\bar{d}$ is mean depth for the smallest discharge to be considered,
g is the acceleration of gravity, and
C is the Chezy coefficient.

If a rated cross section is available downstream from the gage, that cross section would be used as the initial section, of course, and there would be no need to be concerned with the above computation of L.

After the initial site is selected, the next step is to divide the study reach, that is, the reach between the initial section and the gaging station, into subreaches. That is done by selecting cross sections where major breaks in the high-water profile would be expected to occur because of changes in channel geometry or roughness. Those cross sections are the end sections of the subreaches. The cross sections are surveyed and roughness coefficients are selected for each subreach. That completes the field work for the study.

The first step in the computations is to select a discharge, Q, for study, and obtain a stage at the initial section for use with that value of discharge. If the initial section is a rated cross section, that stage will be known. If the initial section is not a rated cross section, an estimated stage there is computed from the estimated mean depth ($\bar{d}$) for discharge Q; $\bar{d}$ in turn is estimated by cut-and-try computations from a variation of the Chezy equation,

$$\bar{d} = \frac{Q^2}{(CA)^2 S_o} \tag{70}$$

where

C is the Chezy coefficient,
A is the cross-sectional area corresponding to $\bar{d}$, and
S_o is the bed slope (or water-surface slope).

Step-backwater computations are then applied to the subreach farthest downstream. We have a known or estimated stage at the downstream cross section for the value of Q being considered; the object of the computations is to determine the stage at the upstream end of the subreach that is compatible with that value of Q. The computation for each subreach is based on a steady-flow equation, such as the Chezy or Manning equation, after the equation has been modified for nonuniformity in the subreach by use of the difference in velocity head at the end cross sections. (See section in chapter 9 titled,

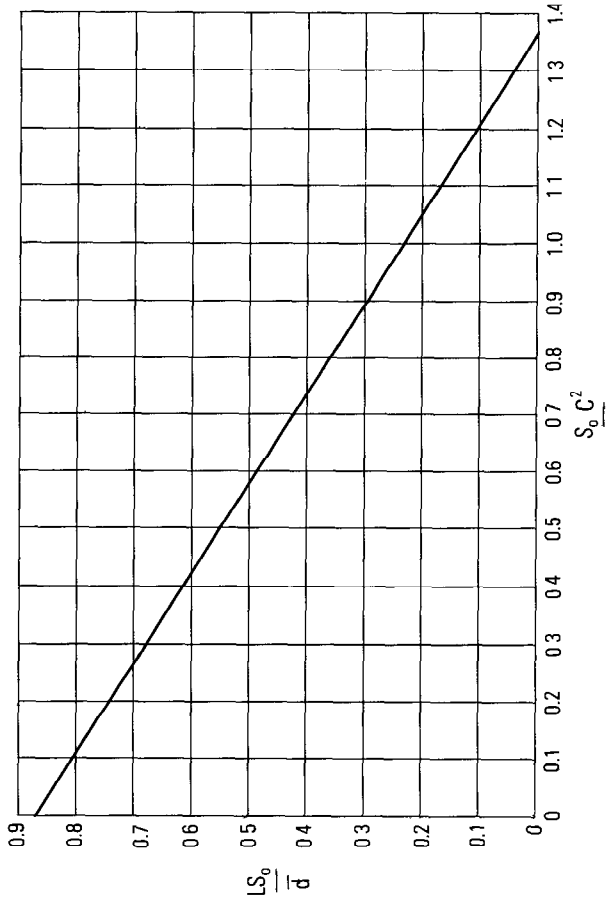

FIGURE 169.—Dimensionless relation for determining distance required for backwater profiles to converge.

"Slope-Area Method.") It will be recalled that the Chezy equation is related to the Manning equation by the formulas,

$$C = \frac{1.486}{n} R^{1/6} \text{ (English units)} \tag{71}$$

or

$$C = \frac{1}{n} R^{1/6} \text{ (metric units)} \tag{71a}$$

where n is the Manning roughness coefficient and R is the hydraulic radius.

By shifting terms in the modified Chezy equation, the following equation is obtained for the difference in water-surface elevation (Δh) between the upstream (subscript 1) and downstream (subscript 2) cross sections.

$$\Delta h = h_1 - h_2 = \frac{(\Delta L) V_1 V_2}{C^2 R_1^{1/2} R_2^{1/2}} + \frac{(\alpha_2 V_2^2 - \alpha_1 V_1^2)}{2g} (1+k), \tag{72}$$

where

h is stage;

ΔL is the length of the subreach;

V is average velocity in the cross section;

g is the acceleration of gravity;

k is a constant whose value is zero when $\alpha_2 V_2^2 > \alpha_1 V_1^2$; and whose value is 0.5 when $\alpha_2 V_2^2 < \alpha_1 V_1^2$; and

α is the velocity-head coefficient whose value is dependent on the velocity distribution in the cross section.

As for α, in many countries its value is assumed to be 1.1; in the U.S.A. its value is assumed to be 1.0 for cross sections of simple shape, but its value is computed for cross sections of complex shape that require subdivision. The equation used for that purpose is

$$\alpha = \frac{\Sigma (K_i^3/a_i^2)}{K_T^3/A_T^2}, \tag{73}$$

where the subscript i refers to the conveyance (K) or area (a) of the individual subsections, and the subscript T refers to the conveyance (K) or area (A) of the entire cross section. With regard to conveyance, K,

$$K_i = C a_i R_i^{1/2}, \text{ and } K_T = \Sigma K_i$$

We return to our computations for the downstream subreach. A trial value of stage for discharge Q is selected for the upstream cross

section, and values of A, V, and R are computed for the upstream and downstream cross sections. Those values are substituted in equations 72 and 73 and after solving for Δh, the computed value of Δh is compared with the difference between the trial value of stage at the upstream cross section and the known or assumed stage at the downstream cross section. Seldom will the two values agree after a single trial computation; if they do not agree, a second trial value of stage is selected for the upstream cross section. The computational procedure is repeated and the newly computed value of Δh is compared with its corresponding trial value. The computations are repeated as many times as are necessary to obtain agreement between the computed Δh and the difference between the trial stage at the upstream cross section and the known or assumed stage at the downstream cross section.

After a satisfactory value of stage has been determined for the upstream cross section, that cross section becomes the downstream cross section for the next subreach upstream. Computations similar to those described in the preceding paragraph are repeated for that subreach, and for each succeeding subreach, to provide a water-surface profile extending to the gaging station that is applicable to the discharge value (Q) being studied.

If the stage corresponding to discharge Q at the initial cross section was known, the stage computed for the gage is satisfactory. If the stage at the initial cross section was estimated from equation 70, it is necessary to repeat the above computations twice using other values of stage at the initial cross section for the same discharge Q. That is done to assure convergence of the water-surface profiles at the gage. The computations are repeated, first using an initial stage about 0.5 to 1.0 ft (0.15 to 0.30 m) higher than that originally used, and then using an initial stage about 0.5 to 1.0 ft lower than that originally used. All three sets of computations for discharge should result in almost identical values of stage at the gaging station for discharge Q. If they do not, the initial cross section for the step-backwater computation should be moved farther downstream, and all computations previously described must be repeated. If the three sets of computations give water-surface profiles that converge at a common stage at the gage, the entire procedure is repeated for other discharges until enough data are obtained to define the high-water rating for the gaging station.

From the preceding discussion it should be evident that the computations will be expedited if, in a preliminary step, the three relations of stage versus area (A), hydraulic radius (R), and conveyance (K), are computed for each cross section. Even then, the computations will be laborious and the use of a digital computer is therefore recommended.

The step-backwater method can be used to prepare a preliminary rating for a gaging station before a single discharge measurement is made. A smooth curve is fitted to the logarithmic plot of the discharge values that are studied. The preliminary rating can be revised, as necessary, when subsequent discharge measurements indicate the need for such revision. If the step-backwater method is used to define the high-water end of an existing rating curve, the discharge values investigated should include one or more of the highest discharges previously measured. By doing so, selected roughness coefficients can be verified, or can be modified so that step-backwater computations for the measured discharges provide stages at the gaging station that are in agreement with those observed. The computations for the high-water end of the rating can then be made with more confidence, in the knowledge that reasonable values of the roughness coefficients are being used. There will also be assurance of continuity between the defined lower part of the rating and the computed upper part.

FLOOD ROUTING

Flood-routing techniques may be used to test and improve the overall consistency of records of discharge during major floods in a river basin. The number of direct observations of discharge during such flood periods is generally limited by the short duration of the flood and the inaccessibility of certain stream sites. Through the use of flood-routing techniques, all observations of discharge and other hydrologic events in a river basin may be combined and used to evaluate the discharge hydrograph at a single site. The resulting discharge hydrograph can then be used with the stage hydrograph for that gage site to construct the stage-discharge relation for the site; or, if only a peak stage is available at the site, the peak stage may be used with the peak discharge computed for the hydrograph to provide the end point for a rating-curve extrapolation.

Flood-routing techniques, of which there are many, are based on the principle of the conservation of mass—inflow plus or minus change in storage equals outflow. It is beyond the scope of a stream-gaging manual to treat the subject of flood routing; it is discussed in most standard hydrology texts (for example, Linsley, Kohler, and Paulhus, 1949, p. 485–541).

SHIFTS IN THE DISCHARGE RATING

Shifts in the discharge rating reflect the fact that stage-discharge relations are not permanent but vary from time to time, either gradually or abruptly, because of changes in the physical features that form the control for the station. If a specific change in the rating

stabilizes to the extent of lasting for more than a month or two, a new rating curve is usually prepared for the period of time during which the new stage-discharge relation is effective. If the effective period of a specific rating change is of shorter duration, the original rating curve is usually kept in effect, but during that period shifts or adjustments are applied to the recorded stage, so that the "new" discharge corresponding to a recorded stage is equal to the discharge from the original rating that corresponds to the adjusted stage. For example, assume that vegetal growth on the control has shifted the rating curve to the left (minus shift), so that in a particular range of discharge, stages are 0.05 ft higher than they originally had been. To obtain the discharge corresponding to a recorded stage of, say, 1.30 ft, the original rating is entered with a stage of 1.25 ft (1.30−0.05) and the corresponding discharge is read. The period of time during which such stage adjustments are used is known as a period of shifting control.

Frequent discharge measurements should be made during a period of shifting control to define the stage-discharge relation, or magnitude(s) of shifts, during that period. However, even with infrequent discharge measurements the stage-discharge relation can be estimated during the period of shifting control if the few available measurements are supplemented with a knowledge of shifting-control behavior. This section of the report discusses such behavior. That part of the discussion that deals with channel-control shifts does not include alluvial channels, such as sand channels, whose boundaries change almost continuously; sand channels are discussed in the section titled, "Sand-Channel Streams."

The formation of ice in the stream and on section controls causes shifts in the discharge rating, but ice effect is not discussed here; it is discussed separately in the section titled. "Effect of Ice Formation on Discharge Ratings."

DETECTION OF SHIFTS IN THE RATING

Stage-discharge relations are usually subject to minor random fluctuations resulting from the dynamic force of moving water, and because it is virtually impossible to sort out those minor fluctuations, a rating curve that averages the measured discharges within close limits is considered adequate. Furthermore, it is recognized that discharge measurements are not error-free, and consequently an average curve drawn to fit a group of measurements is probably more accurate than any single measurement that is used to define the average curve. If a group of consecutive measurements subsequently plot to the right or left of the average rating curve, it is usually clearly evident that a shift in the rating has occurred. (An exception to that

statement occurs where the rating curve is poorly defined or undefined in the range of discharge covered by the subsequent measurements; in that circumstance the indication is that the original rating curve was in error and requires revision.) If, however, only one or two measurements depart significantly from a defined segment of the rating curve, there may be no unanimity of opinion on whether a shift in the rating has actually occurred, or whether the departure of the measurement (s) results from random error that is to be expected occasionally in measurements.

Two schools of thought exist with regard to identifying periods of shifting control. In the U.S.A. and many other countries, a pragmatic approach is taken that is based on certain guidelines and on the judgment of the analyst. In other countries, notably the United Kingdom, the approach used is based on statistical theory. (It is reiterated that the discussion that follows excludes the constantly shifting alluvial channels that are discussed in the section on "Sand-Channel Streams.")

In the U.S.A., if the random departure of a discharge measurement from a defined segment of the rating curve is within ±5 percent of the discharge value indicated by the rating, the measurement is considered to be a verification of the rating curve. If several consecutive measurements meet the 5-percent criterion, but they all plot on the same side of the defined segment of the rating curve, they may be considered to define a period of shifting control. It should be mentioned that when a discharge measurement is made, the measurement is computed before the hydrographer leaves the gaging station and the result is plotted on a rating curve that shows all previous discharge measurements. If the discharge measurement does not check a defined segment of the rating curve by 5 percent or less, or if the discharge measurement does not check the trend of departures shown by recent measurements, the hydrographer is normally expected to make a second discharge measurement to check his original measurement. However, at many stations the 5-percent criterion may be too stringent for low-flow measurements because of control insensitivity. At those installations departures in excess of 5 percent are generally acceptable if the indicated shift does not exceed 0.02 ft.

In making a check measurement, the possibility of systematic error is eliminated by changing the measurement conditions as much as possible. The meter and stopwatch are changed, or the stopwatch is checked against the movement of the second hand of a standard watch. If the measurements are being made from a bridge, boat, or cableway, the measurement verticals are changed by measuring at verticals between those originally used; if wading measurements are being made, a new measurement section is sought, or the meas-

urement verticals in the original section are changed. If the check measurement checks the original rating curve or current rating trend by 5 percent or less, the original discharge measurement will be given no consideration in the rating although it is still entered in the records. If the check measurement checks, by 5 percent or less, the original discharge measurement or the trend of that measurement if the stage has changed, the two measurements are considered to be reliable evidence of a new shift in the stage-discharge relation. If the check measurement fails to check anything that has gone before, a second check measurement is made and the most consistent two of the three measurements are used for rating analysis. The need for a second check measurement is a rarity, but it may possibly occur.

Thus, in the U.S.A., a single discharge measurement and its check measurement, even if unsupported by later measurements, may mark a period of shifting control. The engineer who analyzes the rating does have the responsibility of explaining the reason for the short-lived shift—it can often be explained as having started as a result of fill (or scour) on a preceding stream rise and as having ended as a result of scour (or fill) on the recession or on a following rise.

In the United Kingdom, the analysis of the rating starts in the usual way; the chronologically numbered discharge measurements are plotted on logarithmic graph paper and are fitted by eye with a smooth curve. Where compound controls exist, there may be one or more points of inflection in the curve. In the statistical analysis that follows, each segment of the rating curve between inflection points is treated separately. The standard deviation ($S_{//}$) of the plotted points, in percent, is computed for each segment, using the standard statistical equation,

$$S_{//} = \sqrt{\frac{\Sigma d^2}{N-1}} \quad , \tag{74}$$

where

d is the departure of a discharge measurement from the rating curve, in percent, and

N is the number of measurements used to define the segment of the rating curve.

Use of the standard deviation ($S_{//}$) in detecting rating shifts is explained as follows in ISO Recommendation R 1100 (1969, p. 15). On the average, 19 out of 20 measurements should depart from the particular segment of the rating curve by no more than $2S_{//}$ percent. Any subsequent discharge measurement that departs by a much greater percentage—say, $3S_{//}$ percent—can be regarded as the result of faulty measurement, except in those cases where two or more consecutive measurements, either chronologically or over a range of stage, appear to be well on one side of the $\pm 2S_{//}$ limit. Where that occurs, a change

in the stage-discharge relation is required—either in the form of a reconstruction of the original relation using the additional discharge measurements, or in the form of a new stage-discharge relation because a shift in the control is indicated.

In the United Kingdom, additional statistical tests are given the rating to assure that : (1) the discharge measurements show no preponderance of either plus or minus departures from the rating curve; (2) the number of "runs" of successive plus or minus departures from the rating, examined in ascending order of stage, are neither excessively large nor excessively small, and (3) the average percentage departure of all measurements from the rating curve does not differ significantly from zero.

In the U.S.A. the above statistical approach is not favored for several reasons. First, it is felt that the limiting criteria of $2S_p$ percent will usually exceed the 5 percent criteria preferred in the U.S.A. Second, any statistical approach gives equal weight to all discharge measurements used in the analysis. In the U.S.A. hydrographers rate the probable accuracy of the measurements they make on the basis of measuring conditions at the time, without reference to how closely the measurements plot on the rating curve. The feeling in the U.S.A. is that more weight in the analysis should be given to measurements rated good to excellent than to measurements rated fair to poor. Third, while it is agreed that in general an average curve drawn to fit a group of measurements is probably more accurate than any single measurement that is used to define the average curve, it is also felt in the U.S.A. that any subsequent measurement that is verified by a check measurement is more accurate than the rating-curve value of discharge, particularly at a station that is historically known to have rating-curve shifts.

RATING SHIFTS FOR ARTIFICIAL CONTROLS

Weirs.—Artificial controls are not subject to scour and fill by high flows, but the streambed immediately upstream from the weir may be so affected. If scour occurs in the pool formed by the weir, the pool is deepened and velocity of approach decreases. The net result is a smaller discharge for a given stage than under pre-scour conditions; that is, the rating curve for the period of scour will shift to the left of the rating curve for pre-scour conditions. The converse occurs if the weir pool has been subjected to deposition or fill.

The effect of such scour and fill on the stage-discharge relation is usually relatively minor, and usually can be expressed by a parallel shift of most of the section-control portion of the rating curve that is plotted as a straight line on logarithmic graph paper. If only a single discharge measurement is available for defining the parallel shift

curve, the shift curve is drawn to pass through that measurement. If more than one discharge measurement is available, and there is no evidence of a progressive rating shift with time, the parallel shift curve is drawn to average the discharge measurements. If the discharge measurements indicate a progressive rating shift with time, shifts are prorated with time. However, what may appear to be a gradually progressive shift, may in fact be several discrete shifts caused by individual peak flows whose occurrences are not widely separated in time. The shift in stage to be applied to recorded gage heights during the period of shifting control is determined from the vertical spacing between the original rating curve and the shift curve.

The shift, if attributable to fill, is considered to start after the peak discharge of a stream rise that preceded the first of the variant discharge measurements. Shift adjustments are therefore started on the recession of that rise. The shift, if attributable to scour, is considered to start during the high stages of a stream rise that preceded the first of the variant discharge measurements. Because those high stages generally occur when the section control is "drowned out" by channel control, the shift in the section-control segment of the rating is again commonly first applied after the peak discharge of the rise. The shifts are ended on a stream rise that follows the last variant discharge measurement, using the general principle that scour in the gage pool usually occurs during high stages and fill usually occurs during the recession of a stream rise.

The parallel shift discussed in a preceding paragraph requires some elaboration. A parallel shift of the rating curve on logarithmic graph paper indicates that for all stages the discharge changes by a fixed percentage, and that the difference in stage between the two lines increases with stage. However, it is not quite true that the discharge changes by a fixed percentage when the weir pool has scoured or filled. At extremely low flows there will be no effect because velocity of approach is negligible; that section of the original rating has a break in slope (see fig. 146; $G = 1.3$ ft), and the lower end of the parallel shift curve above the break in slope should be warped to join the extreme low-water curve. The effect of scour or fill on the percentage change in discharge increases rapidly with stage to a maximum value and then slowly decreases to a percent change that does not differ greatly from the maximum percentage. The parallel shift drawn through the available discharge measurement(s) will adequately fit those relatively large percentage changes in discharge at the higher stages; the warped section of the shift curve at the lower stages will adequately fit the rapidly increasing percentage change in discharge at those lower stages. Figure 170 illustrates the above discussion; the

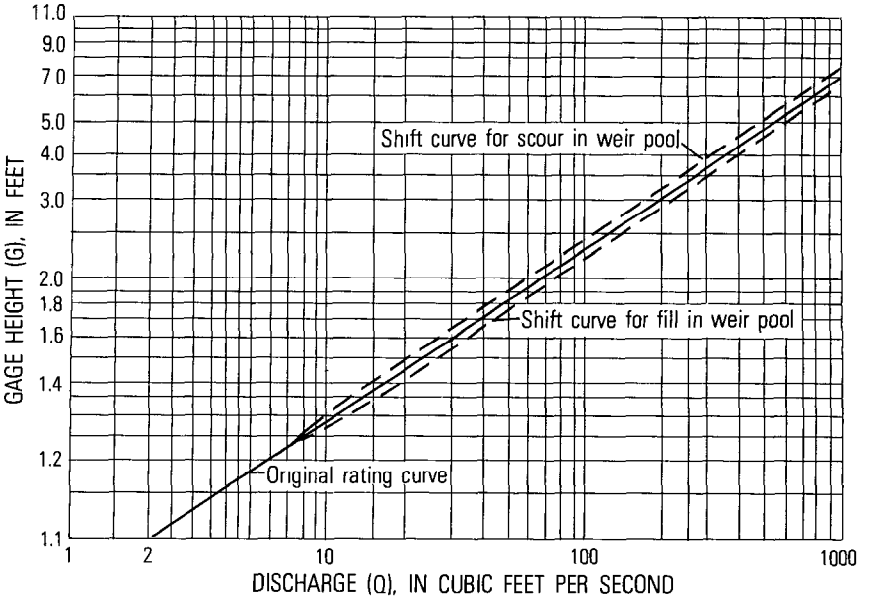

FIGURE 170.—Rating curve for hypothetical rectangular thin-plate weir, with shift curves for scour and fill in the weir pool.

original rating curve shown is a reproduction of that given in figure 146.

It has been mentioned frequently in this manual that section controls are usually submerged at high stages as a result of channel control becoming effective. The parallel shift curve described above should be extended to the stage where it either intersects the actual rating for channel control (in the case of scour in the weir pool) or can be warped into the rating for channel control (in the case of fill in the weir pool). If a shift has occurred simultaneously in the channel control (see section titled, "Rating Shifts for Channel Control"), the shift curves for the section-control and channel-control segments of the rating are drawn to form a continuous curve.

Up to now we have discussed changes in the velocity of approach that are caused only by scour and fill in the weir pool. The velocity of approach may also be affected by aquatic vegetation growing in the weir pool. Usually such an occurrence will reduce the velocity of approach by greatly increasing the friction loss, and the rating curve will shift to the left. However, the shift will not be abrupt, but will gradually increase as the growing season progresses. The aquatic growth in the pool may also encroach on the weir to the extent that the effective length (b) of the weir is reduced. The effect of a reduction in effective length of the weir is a parallel shift of the rating to the left

when plotted on logarithmic graph paper. At all stages the discharge will be reduced by a percentage that is equal to the percentage change in effective length of the weir. The shift will either decrease gradually as the vegetation dies in the dormant season, or the shift may terminate abruptly if the vegetation is washed out by a stream rise.

Moss or algal growth may sometimes attach itself to a weir crest and thereby reduce the head on the weir for any given gage height (G). The head will be reduced by a constant value that is equal to the thickness of the growth. In other words, in the equation, head$=G-e$, the value of e is increased by the thickness of the growth. The reduction in head causes the rating to shift to the left, it being displaced vertically by an amount equal to the thickness of the growth. If the shift rating is plotted on rectangular-coordinate graph paper, it will be parallel to the original rating. If the shift rating is plotted on logarithmic graph paper, it will be a curve that is concave upward and asymptotic to the original linear rating curve at the higher stages. The growth of algae or moss on the weir should be removed with a wire brush before it becomes heavy enough to affect the stage-discharge relation. The effect of the shift caused by the algal growth disappears during stages when channel control becomes effective.

Flumes.—Shifts in the stage-discharge relation for flumes are most commonly caused by changes in the approach section—either in the channel immediately upstream from the flume or in the contracting section of the flume upstream from the throat. In either event the change is caused by the deposition of rocks and cobbles that are too large to pass through the flume; the flume is self-cleaning with regard to sediment of smaller size. Manual removal of the large debris should restore the original discharge rating of the flume.

The deposition of rocks and debris upstream from the flume may divert most of the flow to the gage-side of the flume and the build-up of water at the gage will result in a shift of the discharge rating to the left. Conversely, if most of the flow is diverted to the side of the flume opposite the gage, the discharge rating will shift to the right. In the above situation, the shift curve is usually drawn parallel to the original rating curve on logarithmic graph paper in much the same manner as was described earlier for shifts resulting from scour and fill in the pool behind the weir.

If rocks and cobbles are deposited at the entrance to the throat of the flume, they will cause the discharge rating to shift to the left because the stage at the gage will be raised higher than normal for any given discharge. A similar backwater effect will result from the growth of algae at the entrance to the throat.

The backwater effect, or decrease in head for a given gage height

caused by deposition or algal growth at the entrance to the throat of the flume, has the effect of increasing the value of e in a linear logarithmic plot of the rating. The shift rating on logarithmic graph paper will be a curve that is concave upward and asymptotic to the original linear rating curve at the higher stages. The deposition of rocks and debris will be associated with a high-water event; the growth of algae will increase gradually with time.

Large rocks driven by high-velocity flow through the flume may erode the walls and floor of a concrete flume. The resulting increase in roughness and decrease in elevation of the concrete may cause shifts in the stage-discharge relation. The two effects tend to be compensating; an increase in roughness will shift the discharge rating to the left, and a decrease in elevation of the concrete surface will shift the discharge rating to the right. However, the latter effect usually predominates, particularly in supercritical-flow flumes.

RATING SHIFTS FOR NATURAL SECTION CONTROLS

The primary cause of changes in natural section controls is the high velocity associated with high discharge. Of those controls, a rock ledge outcrop will be unaffected by high velocities, but boulder, gravel, and sand-bar riffles are likely to shift, boulder riffles being the most resistant to movement and sand bars the least resistant. After a flood the riffles are often altered so drastically as to bear no resemblance to their pre-flood state, and a new stage-discharge relation must be defined. Minor stream rises usually move and sort the materials composing the riffle, and from the standpoint of the rating curve, the greatest effect is usually a change in the gage height of effective zero flow (e). The shift curve ideally should be defined by current-meter discharge measurements. However, if only one or two measurements are available for the purpose, they are examined and the gage-height shift that they indicate is applied to the section-control segment of the original rating curve. If the shift rating is plotted on rectangular paper, it will tend to be parallel to the original rating. The extreme low-water end of the curve can be extrapolated to the actual point of zero flow, as determined in the field when low-water discharge measurements are made. If the shift rating is plotted on logarithmic graph paper, it will be a curve that is either concave upward or downward, depending on whether the shift is to the left (increase in e) or the right (decrease in e). The shift curve will tend to be asymptotic to the linear rating at the higher stages of section control, but its precise slope in the range of stage where channel control is beginning to exert an effect, will depend on whether or not a shift has occurred in the channel-control segment of the rating curve.

(See section titled, "Rating Shifts for Channel Control.")

Vegetal growth in the approach channel of the control or on the control itself will affect the stage-discharge relation in the manner described on preceding pages, where rating shifts for weirs were discussed. Aquatic vegetation in the approach channel will affect the velocity of approach, and if the channel growth encroaches on the control, it may reduce the effective length of the control. Aquatic growth on the control itself will reduce the discharge corresponding to any given stage by reducing the head on the control and increasing the resistance to flow, and (or) by reducing the effective length of the control. The shifts associated with vegetal growth are cyclic and therefore change with time. The growth increases as the growing season progresses and declines during the dormant season, but shifts may terminate abruptly if the vegetation is washed out by a stream rise.

In temperate climates, accumulations of water-logged fallen leaves on section controls each autumn clog the interstices and raise the effective elevation of all section controls. The effect of an increase in the gage height of effective zero flow (e) is explained on a preceding page in the discussion of moss and algal growth on weirs. The build-up of water-logged leaves is progressive starting with the first killing frost (usually in October in the Northern Hemisphere) and reaching a maximum when the trees are bare of leaves. The first ensuing stream rise of any significance usually clears the control of fallen leaves.

Two other causes of backwater (increased gage height for a given discharge), unassociated with hydrologic events, also warrant discussion. Vacationers in the summer often use the gage pool for swimming, and they will often pile rocks on the control to create a deeper pool. This change in the height of the control manifests itself in the record of stage as an abrupt increase in gage height, usually during a rainless period, without any corresponding decline in stage that would be associated with the passage of a stream rise. The abrupt rise in stage fixes the time when the shift in the rating occurred; the magnitude of the change in stage is a measure of the change in the value of e. In some regions another cause of backwater is the construction of dams by beavers. These dams are built of boughs, logs, stones, and mud to create a pool that is part of the beavers' habitats. Again, the time of occurrence and the effect on the stage of the stream can be detected in the gage-height record which will show a gradual rise, usually over a period of a few days as the dam is being built, without the corresponding decline in stage that would be associated with a stream rise. The beaver dams usually remain in place until washed out by a high discharge.

RATING SHIFTS FOR CHANNEL CONTROL

As mentioned earlier, most natural streams have compound controls—section control for low-stages and channel control for high stages. The shifts in section control that were described on the preceding pages are commonly accompanied by shifts in channel control.

The most common cause of a shifting channel control, in a relatively stable channel, is scour or fill of the streambed caused by high-velocity flow. The scour usually occurs during a stream rise and fill usually occurs on the recession, but that statement is an oversimplification of the highly complex process of sediment transport. The degree of scour in a reach is dependent not only on the magnitude of the discharge and velocity, but also on the sediment load coming into the reach. On some streams it has been found that when scour is occurring in a pool at a meander bend there is simultaneous filling on the bar or riffle at the crossover, or point of inflection between successive meander bends; on other streams scour has been found to take place simultaneously through relatively long reaches of channel, both in pools and over bars. A further complication is the fact that the length of channel that is effective as a control is not constant, but increases with discharge.

From the preceding discussion it should be apparent that there is no really satisfactory substitute for discharge measurements in defining shifts in the channel-control segment of the rating; of particular importance are measurements made at or near the peak stage that occurs during periods of shifting control. However, in the usual situation a few (or less) measurements made at medium stages are the only ones available for analyzing channel-control shifts, and the shifts must be extrapolated to peak stages. The assumptions usually made in the rating analysis are those discussed below. The results are accepted unless they are shown to be invalid by a determination of peak discharge as described in chapter 9, or are shown to be invalid by use of one or more of the methods of rating-curve extrapolation as described in the section on "High-flow Extrapolation."

If a single predominantly large stream rise occurred shortly before the first measurement that indicated a shift, the shifts are assumed to have been caused solely by that rise. If more than one large stream rise occurred shortly before the first shift measurement, the shift curve may be prorated between rises. For example, if two rises of almost equal magnitude occurred just before the first shift measurement, and if the shift curve indicates a shift of 0.30 ft at a given stage, the shift to be used during the period between the two rises would be 0.15 ft at the given stage. It is often helpful to plot the shifts indicated by the discharge measurements against the observed stage of those measurements to obtain the trend of the shifts.

The pattern of scour and fill in the control channel determines whether the shift will increase with stage, decrease with stage, or be relatively constant at all stages. Figure 171 (graph *A*) illustrates a common situation where the shifts, either plus in the case of scour or minus in the case of fill, increase in absolute value as stage decreases. The highest value of the shift is assumed to be only slightly greater than the maximum value observed in order to avoid "overcorrecting" the original rating. Graph *B* of figure 171 shows the shift ratings corresponding to measurements nos. 1 and 2. The ratings have been plotted on rectangular-coordinate graph paper because the shifts are more easily visualized, at least by the inexperienced hydrographer, on that type of plotting paper. The stage-shift curve is usually plotted on rectangular-coordinate paper, but the rating curves are usually plotted on logarithmic graph paper. On logarithmic paper the shift curves in this example would converge more rapidly toward the original rating curve at high stages. The shift curves at low stages would be shaped to join smoothly with the shift curve for section control. The period for applying the shifts would be terminated on the stream rise following the last shift measurement; the original rating would be used on the recession from that rise.

In analyzing shifts there is no substitute for experience with a given stream because the shift pattern can often be interpreted logically in more than one way. For example, refer to the shift curve for channel fill in graph *B* of figure 171. Assume that measurements nos. 1 and 2 were made on a stream recession, and the measurement no. 1 was made a few days before measurement no. 2. Measurement no. 2 shows the effect of greater fill than measurement no. 1; fill usually occurs on a recession; therefore it is possible that the shifts should have been made to vary with time or to vary with time and stage, rather than with stage alone as shown in figure 171*A*. In the absence of additional knowledge the simplest interpretation is generally made, as was done here. Given more discharge measurements or a better knowledge of the behavior of the particular stream, a more accurate analysis can be made.

Figure 172 (graph *A*) illustrates a less common situation where the shifts increase as stage increases. Again the highest value of shift is assumed to be only slightly greater than the maximum value observed in order to prevent "overcorrecting" the original rating. Graph *B* of figure 172 shows the shift ratings corresponding to measurements nos. 1 and 2. The period for applying shifting-control corrections would be terminated on the stream rise following the last shift measurement; the original rating would be used on the rising limb of that rise. As in the case of figure 171, in the absence of additional knowledge, more than one interpretation can be given to

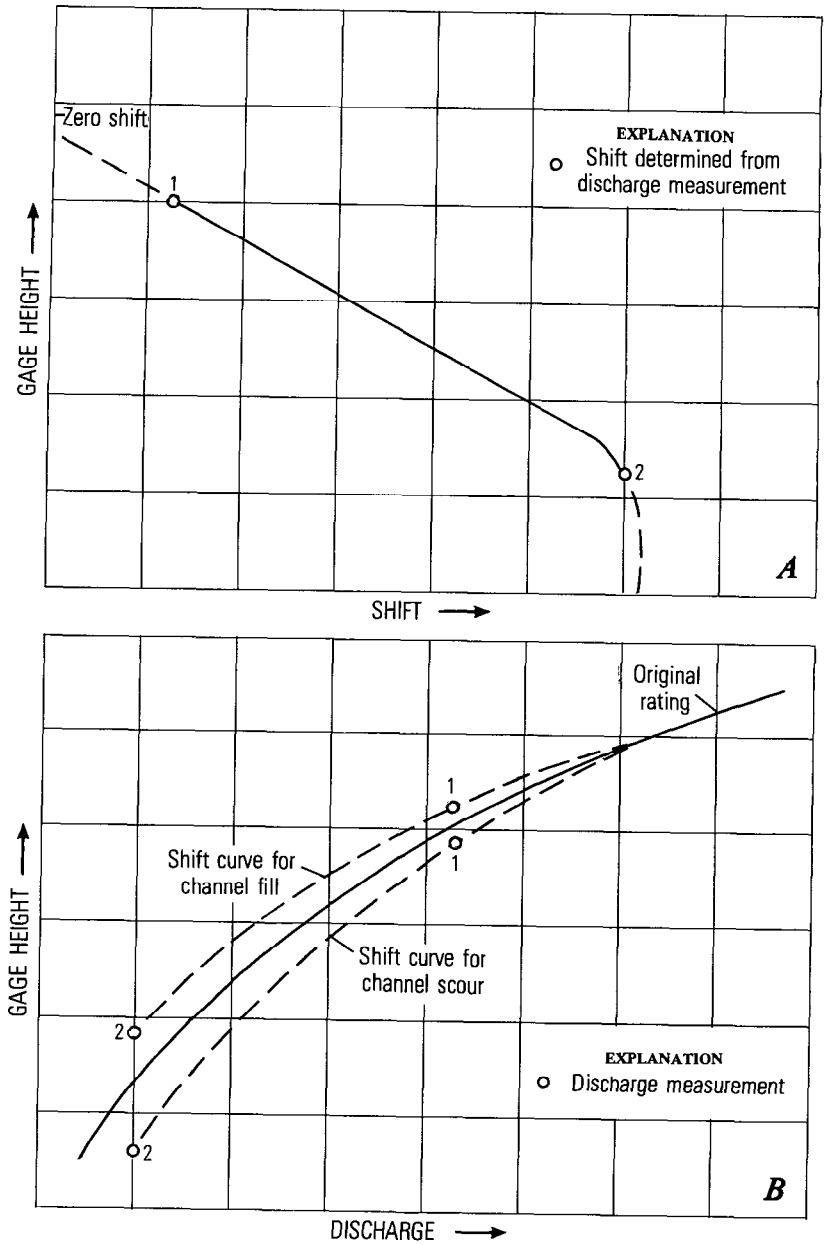

FIGURE 171.—First example of a stage-shift relation and the corresponding stage-discharge relation caused by scour or fill in the control channel.

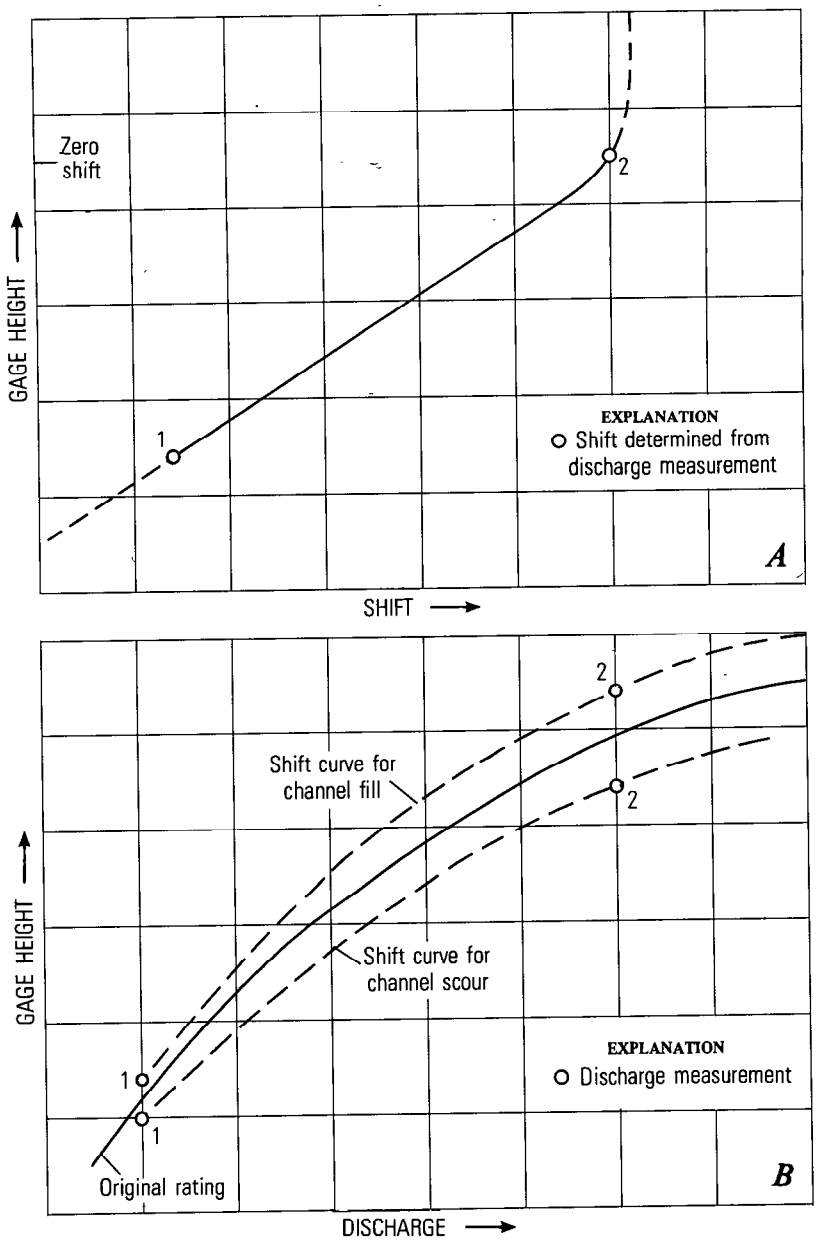

FIGURE 172.—Second example of a stage-shift relation and the corresponding stage-discharge relation caused by scour or fill in the control channel.

shifts shown by measurements nos. 1 and 2, depending on the relative times when the measurements were made and the fact that scour generally occurs on stream rises and fill generally occurs on stream recessions.

If there had been an additional major rise, one that occurred between the pairs of measurements shown in figures 171 and 172, other courses of action would be available. If the analyst had no additional data on which to base a judgment, he could assume that two separate shift events occurred, each attributable to the rise that preceded a discharge measurement. For each shift period, he could use a constant shift, equal to that shown by the discharge measurement made during that shift period. If, however, the analyst has had experience in the past with shifting control at the station caused by scour and fill in the control channel and if that experience had shown that shifts tend to vary with stage, another course of action would suggest itself. For each of the stage periods, the analyst could use a stage-shift relation of average shape that passed through the shift value shown by the appropriate discharge measurement. The above discussion would also apply to the situation of a single shift period and the availability of only a single discharge measurement made during that period. (It is assumed that the single discharge measurement would be accompanied by a check measurement to verify its accuracy, as discussed in the section on "Detection of Shifts in the Rating.")

If, during a period of shifting control, several measurements had been made but few of them could be fitted with a smooth shift curve, it would then be necessary to prorate the shifts with both time and stage, or possibly with time alone, based on the average shape of a stage-shift relation.

As mentioned earlier, scour in the control channel causes a plus shift because depth, and therefore discharge, is increased for a given gage height. Deposition or fill in the control channel causes a minus shift, because depth, and therefore discharge, is decreased for a given gage height. Thus the effect on the discharge of scour or fill in a channel control is opposite to that of scour and fill in a weir pool, which affects only the velocity of approach. Therefore, if a permanent weir is part of a compound control, scour in both the weir pool and in the channel control will cause a minus shift in the rating for section control and a plus shift in the rating for channel control. The converse is true when fill occurs in both the weir pool and the channel control. That situation is compatible with the stage-shift relation shown in figure 172, where a further decrease in stage would change the sign of the shifts. If the section control is a natural riffle, that riffle is likely to scour when the channel scours and fill when the channel fills, a situation that is compatible with the stage-shift relation shown in

figure 171. In any event, the shift curves for low stages of channel control should be shaped to join smoothly with the shift curves for high stages of section control where a compound control exists.

Up to now the discussion of channel-control shifts has been confined to shifts caused by streambed scour and deposition. Shifts may also be caused by changes in the width of the channel. Even in a relatively stable channel the width of the channel may be increased during intense floods by widespread bank-cutting, and in some areas (for example, north coastal California) channel widths may be constricted by widespread landslides that occur when steep streambanks are undercut. In meandering streams changes in channel width occur as point bars are built up by deposition and later eroded by flood flows. The effect of a change in channel width on the stage-discharge relation, unaccompanied by a change in streambed elevation, is to change the discharge, for a given gage height, by a fixed percentage. When the original rating curve for channel control is plotted linearly on logarithmic graph paper, in accordance with the equation,

$$Q = p(G-e)^{\backslash}, \tag{53}$$

the value of p increases with an increase in width and decreases with a decrease in width. The shift curve for a change in width alone will therefore plot on logarithmic graph paper as a straight line that is parallel to the original linear rating curve. Under those conditions a single discharge measurement is sufficient for constructing a shift curve for channel control.

When a change in channel width occurs concurrently with a change in streambed elevation, the effects of the two changes are compounded. The resulting shift curve is complex and requires at least several discharge measurements for its definition.

The growth of vegetation in a stream channel will affect the stage-discharge relation by reducing the discharge for a given gage height. The shift rating will therefore plot to the left (minus shift) of the original rating. The vegetation will increase the roughness coefficient of the channel and will tend to constrict the effective or unobstructed width of the channel. Both those factors reduce the value of p in equation 53, and if the changes in roughness coefficient and effective width are unvarying with stage, the shift curve will be parallel to, and to the left of, the original rating curve that has been plotted linearly on logarithmic graph paper. Usually, however the changes are not independent of stage. If the growth consists of aquatic weeds, the weeds will be overtopped and bent over by high water; if the growth consists of alders and willows, the backwater effect will be greater at higher stages when the tree crowns as well as when the tree trunks are submerged. The rating shift caused by channel vege-

tation is, of course, variable with time as the growth spreads and increases in size.

EFFECT OF ICE FORMATION ON DISCHARGE RATINGS

GENERAL

The formation of ice in stream channels or on section controls affects the stage-discharge relation by causing backwater that varies in effect with the quantity and nature of the ice, as well as with the discharge. Because of the variability of the backwater effect, discharge measurements should be made as frequently as is feasible when the stream is under ice cover, particularly during periods of freeze-up and thaw when flow is highly variable. (Procedures for making measurements under ice cover are described in the section in chapter 5 titled, "Current-Meter Measurements from Ice Cover.") In midwinter the frequency of measurements will depend on climate, accessibility, size of stream, winter runoff characteristics, and required accuracy of the discharge record. As a general rule, two measurements per month is the recommended frequency. At stations below powerplants that carry a variable load, it may be necessary to make two measurements during each winter visit—one at the high stage of the regulated flow and the other at the low stage. The backwater effects may be markedly different at the two stages. In very cold climates where winter ice-cover persists and winter discharge shows a relatively smooth recession, fewer winter measurements are needed than in a climate that promotes the alternate freezing and thawing of river ice.

Knowledge of the three types of ice formation—frazil, anchor, and surface ice—and their possible effects, is helpful in analyzing streamflow records for ice-affected periods. With regard to the type of stage recorder that is preferred for use at ice-affected stations, the graphic recorder, described under that heading in Chapter 4, is by far the best because the recorder graph generally provides dependable evidence of the presence and type of ice formation.

FRAZIL

Frazil is ice in the form of fine elongated needles, thin sheets, or cubical crystals, formed at the surface of turbulent water, as at riffles. The turbulence prevents the ice crystals from coalescing to form sheet ice. The crystals may form in sufficient numbers to give the water a milky appearance. When the crystals float into slower water they come together to coalesce into masses of floating slush. When the current carries slush ice under a sheet of downstream surface ice, the slush may become attached to the underside of the surface ice, thereby increasing the effective depth of the surface ice. Most of the slush that adheres to the surface ice does so near the upstream end of the ice sheet.

Frazil or floating slush has no effect on the stage-discharge relation, but it may interfere with the operation of a current meter. It is particularly troublesome to operators of hydroelectric plants; by adhering and building up on trash racks the ice may effectively reduce the flow to the turbines.

ANCHOR ICE

Anchor ice is an accumulation of spongy ice or slush adhering to the rocks of a streambed. In former years the theory was held that the ice resulted from loss of heat by longwave radiation from streambed to outer space, because anchor ice generally formed on clear cold nights on the streambeds of open reaches of river. This theory has been shown to be invalid, because all of the long-wave radiation that can be lost from the bed of a stream at 0°C would be absorbed in less than 1 cm of water. Anchor ice is now commonly believed to be either (1) frazil that turbulent currents have carried to the streambed where the ice adhered to the rocks, or (2) ice that formed as the result of supercooled water finding nucleating agents on the streambed on which to crystallize. The ice crystals first formed on the rocks act as a nucleating agents for the continued growth of the ice mass.

Regardless of how anchor ice forms, it cannot form or exist when the rocks are warmed by shortwave radiation from the sun which penetrates the water. When the morning sun strikes anchor ice that had formed the night before and the streambed is warmed by the incoming solar radiation, the anchor ice is released and floats to the surface, often carrying small stones that it has picked up from the bed. For the next few hours the stream will be full of floating slush released in a similar manner upstream.

Anchor ice on the streambed or on the section control may build up the bed and (or) control to the extent that a higher than normal stage results from a given discharge. The solid-line graph in figure 173 shows a typical effect of anchor ice on a water-stage recorder graph. The rise starts in late evening or early morning, many hours after the sun has set, when ice begins to adhere to the rocks and raise the water level. By 10 a.m. the sun has warmed the streambed sufficiently to release the ice and the stage starts to fall. The distinguishing feature of the "anchor-ice hump" is that the rise is slow compared to the fall, whereas an actual increase in streamflow would occur in the opposite sequence, or at least the rise would be as rapid as the fall.

The small rises in actual discharge in the late afternoon, shown by the short-dashed lines in figure 173, probably result from water being released from channel storage when anchor ice upstream goes out. There may also be some runoff from the melting of snow and ice during the warmer part of the day.

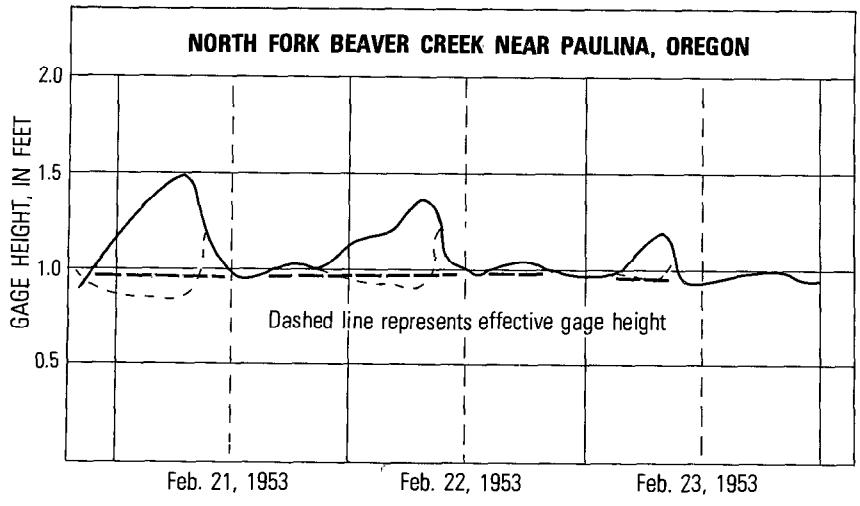

FIGURE 173.—Typical anchor-ice rises. (After Moore, 1957.)

SURFACE ICE

FORMATION OF ICE COVER

As the name implies, surface ice forms on the surface, first as a fringe of shore ice, which then, if the stream is not too turbulent, spreads to form a continuous ice cover spanning the stream from bank to bank. A description of the formation of surface ice follows.

With the onset of cold weather, the water in a stream is gradually cooled. Along the banks where the water is quiescent, temperature stratification occurs as in a lake. Because depths near the bank are usually very shallow, temperatures reach the freezing point more quickly there; ice crystals form and adhere to the banks, twigs, and projecting rocks, and a thin ice sheet forms. In the open part of the channel, temperature stratification is generally absent because of turbulent mixing, and the entire water body must reach 0°C before any freezing will occur. In the absence of nuclei or foreign material on which the ice crystals may form, there may be slight supercooling of the surface layer before any ice crystals are produced.

The ice sheet builds out from the shore as supercooled water, or water carrying ice crystals, impinges on the already-formed shore ice, and the transported or newly formed ice crystals adhere to the sheet. In the center of the stream, turbulence prevents coalescence of the ice crystals (frazil) that form. In the less turbulent areas, groups of crystals coalesce to form small pans of floating slush. These pans and (or) individual ice crystals are carried by the currents until they too impinge and adhere to existing ice sheets. In this manner an ice sheet finally forms across the entire stream. The ensuing increase in thick-

ness of the ice sheet occurs almost entirely at the interface of ice and water.

On a fairly wide stream there is no great buildup of pressure as a result of the ice cover because the ice is, to a large degree, in floatation. Ice is weak in tension. If the stage rises or if the ice thickens considerably, the increased upward force of the water causes tension cracks to appear at the banks. The ice floats up to a position in equilibrium with the water, and water fills the tension cracks and freezes. The result is again a solid sheet in equilibrium with the river. If the stage drops, the unsupported weight of the ice again causes tension cracks, especially at the banks, and the ice drops to an equilibrium position with respect to the water. Water again fills the tension cracks, freezes, and again a solid sheet of ice results.

On narrow streams the ice may be in floatation, bridged, or under pressure. If the stream is so narrow or the ice so thick that the ice can resist the tensile stress placed on it by changes in stage, the ice will not change position regardless of change in stage. At high stages the stream, in effect, will be flowing in a pressure conduit; at low stages the ice sheet will be bridged so that it makes no contact with the water. This is particularly true when there are large boulders in the stream to which the ice is frozen, thereby reducing the length of the unsupported free span.

EFFECT OF SURFACE ICE ON STREAM HYDRAULICS

Surface ice when in contact with the stream may, in effect, change streamflow from open-channel flow to closed-conduit flow. Frictional resistance is increased because a water-ice interface replaces the water-air interface, hydraulic radius is decreased because of the additional wetted perimeter of the ice, and the cross-sectional area is decreased to a degree by the thickness of the ice. The stage will therefore increase for a given discharge. Figure 174 shows the water-stage recorder graph for a gaging station as the formation of surface ice begins to cause backwater effect. In this example, daily mean discharge remained about the same as before the freezeup, although the discharge undoubtedly fluctuated somewhat during each day. It can be seen from figure 174 that surface ice can cause much uncertainty regarding the discharge because the stage-discharge relation becomes indeterminate. It is evident in figure 174 that backwater effect exists and is increasing, because the rise looks very unnatural, but the amount of backwater effect cannot be determined directly from the recorder chart.

Surface ice can also cause siphon action when it forms on a section control, but that effect is not very common. In figure 175 when water filled the entire space between control and ice, siphon action began

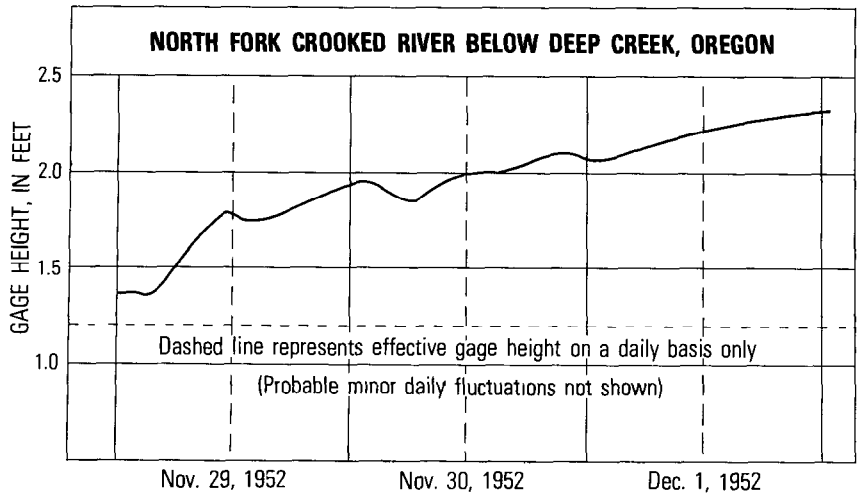

FIGURE 174.—Typical rise as complete ice cover forms. (After Moore, 1957.)

and water flowed over the control faster than it entered the gage pool. The gage pool was pulled down 0.3 ft below the point of zero flow before air entered the system and broke up the siphon action. Discharge ceased and then became a trickle while the inflow again filled the gage pool. When the entire space between control and ice was filled once more, siphon action began again. Siphon action is easily recognizable from the rapid fluctuations of the stage record. If the gaging station is visited at that time, the discharge measurement should be made far enough upstream from the gage pool to be beyond the effect of the fluctuating pool level.

If the section control is open and the gage is not too far removed from the control, there will probably be no backwater effect even though the entire pool is ice covered. The only effect of the ice cover will be to slow up the velocity of approach, and this effect will probably be minor. If the gage, however, is a considerable distance upstream from the riffle, surface ice on the pool may cause backwater as the covered reach of pool becomes a partial channel control.

Ice forming below an open-section control may jam and raise the water level sufficiently to introduce backwater effect at the control.

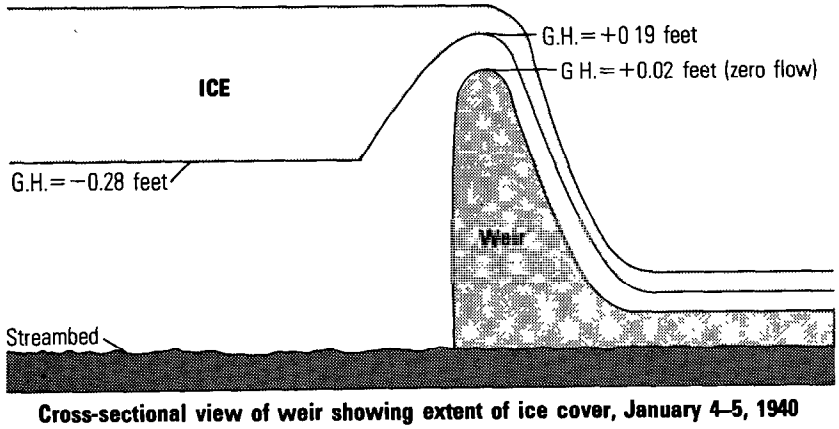
COMPUTATION OF DISCHARGE DURING PERIODS OF BACKWATER FROM ANCHOR ICE

Discharge measurements are usually not made when anchor ice is present for the following reasons. First, adjustment of the stage record for the effect of anchor ice can be made quickly and reliably. Second, a discharge measurement made at that time is of little help in

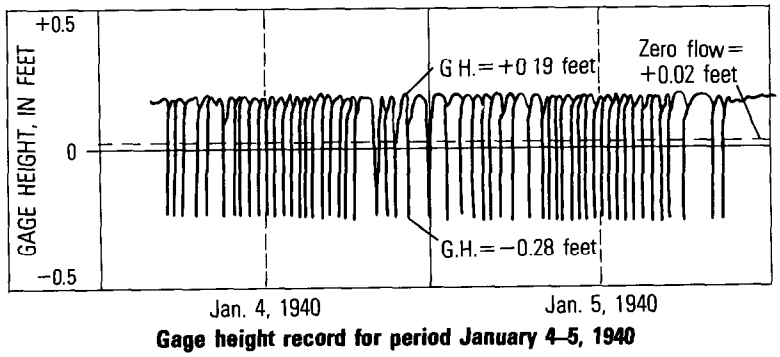
the analysis because discharge is highly variable with time as a result of water entering or leaving channel storage.

Anchor-ice rises are clearly recognizable on the recorder chart. In computing discharge for periods of anchor-ice effect, adjustments to gage-height are made directly on the gage-height graph. In figure 173 the long-dashed line connecting the low points of the "anchor-ice hump" is the effective gage height to use during the hours when the hump was recorded. Actually, the true effective gage height is shown by the short-dashed line. As the anchor ice builds up, the flow decreases faster than the normal recession shown by the long-dashed line, because some of the flow is going into storage as a result of the increased stage.

When the anchor ice goes out at about 9 or 10 a.m., a slug of water is released from storage and the true effective gage height rises. It can be seen however, that the areas formed by the short-dashed lines



Cross-sectional view of weir showing extent of ice cover, January 4–5, 1940



Gage height record for period January 4–5, 1940

FIGURE 175.—Effect of siphon action at artificial control in Sugar Run at Pymatuning, Pa., January 4–5, 1940.

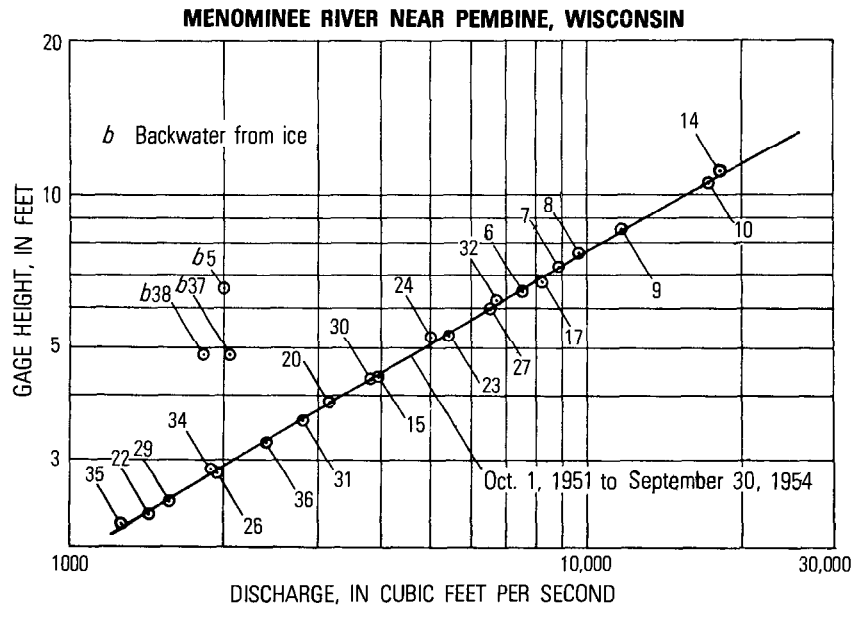


FIGURE 176.—Rating curve for Menominee River near Pembine, Wis. (After Moore, 1957.)

above and below the long-dashed line balance, and we would get identical daily mean values from use of either of the dashed lines. The rule then for obtaining effective gage height during anchor-ice periods is to cut off the hump with a straight line connecting the low points of the gage-height graph.

COMPUTATION OF DISCHARGE DURING PERIODS OF BACKWATER FROM SURFACE ICE

Figure 176 is an example of how discharge measurements (nos. 5, 37, 38), made during periods of ice effect, plot on a rating curve. Figure 174 is an example of a gage-height graph as complete ice cover forms. It is apparent from figure 174 that the backwater effect from surface ice cannot be determined directly from the recorder chart. The recorder chart is very helpful, however, in determining which periods during the winter are affected by ice. Complete notes describing ice conditions at the times the station was visited are also very valuable. Most important of all are discharge measurements made during ice-affected periods. A discharge measurement gives a definite point on a hydrograph plot of daily mean discharge versus date (fig. 177) through which the graph of estimated true daily discharge must pass. If little change in stage occurred during the day the discharge measurement was made, the measured discharge is considered to be the daily mean discharge. If a significant change in stage occurred that

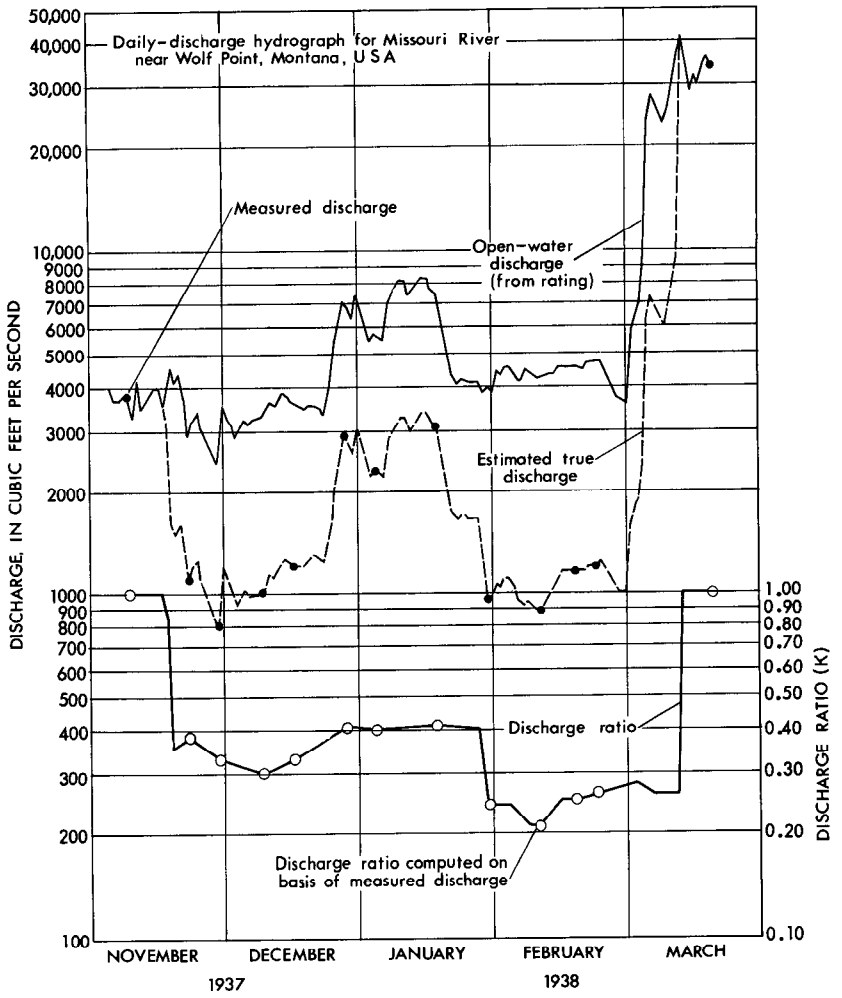

FIGURE 177.—Example of discharge-ratio method for correcting discharge record for ice effect.

day, the daily mean discharge (Q) is computed from the formula,

$$Q = Q_a \left(\frac{Q_m}{Q_r} \right), \tag{75}$$

where

Q_a is the discharge from the open-water (ice-free) rating curve corresponding to the daily mean gage height,

Q_m is the measured discharge and

Q_r is the discharge from the open-water rating curve corresponding to the gage height of the discharge measurement.

Three methods of correcting open-water discharge for ice effect are in use. (The term "open-water discharge", as used in this section of the manual, refers to the discharge for ice-free conditions obtained by applying the gage height record to the rating or shift curve that was in use immediately before the start of the ice-affected period.) The three methods are:

1. discharge-ratio method (sometimes known in the U.S.A. as the Lithuanian method),
2. shifting-control method or Stout method, and
3. hydrographic-and climatic-comparison method.

The reliability of each of the methods varies almost directly with the number of discharge measurements that were made during the ice-affected period that is being studied. Regardless of the method used, the corrected hydrograph of daily discharge, if possible, should be checked for consistency with other records. If the station being studied is on a stream that carries natural flow (flow not significantly affected by manmade development), its corrected record is compared with those for nearby streams that likewise carry natural flow. Particularly useful for that purpose are the hydrographs of streams that are unaffected by ice. If the station being studied is on a regulated stream, its corrected hydrograph is compared with the record of upstream reservoir releases or upstream hydroelectric generation, expressed either in units of discharge or in units of power output.

DISCHARGE-RATIO METHOD

In the discharge-ratio method which is used in many European countries, the open-water daily mean discharge is multiplied by a variable factor K to give the corrected discharge during periods of ice cover. A value of K is computed for each discharge measurement as the ratio of measured discharge (Q_m) to the open-water discharge (Q_i). Because K varies during the winter with time, as changes occur in the ice cover, the value of K for use on any given day is obtained by interpolation, on the basis of time, between K values computed for consecutive discharge measurements. Meteorological data are generally used to modify the simple interpolation between K values for consecutive discharge measurements; for example, during a period of extremely low temperatures the values of K indicated by simple interpolation would be reduced because the discharge usually decreases sharply at such times. The dates on which ice effect begins and ends are based on the observed or deduced beginning and end of ice cover.

An example of the discharge-ratio method is shown in figure 177. Note that discharge is plotted on a logarithmic scale. The upper daily hydrograph shows open-water discharges and the solid circles are

discharge measurements; the lower graph shows the K values obtained from discharge measurements (open circles) and the interpolation between those values; the middle graph is the hydrograph of estimated true daily discharges, obtained by multiplying concurrent values from the upper and lower graphs. The nonlinear interpolations for K values during the periods November 9–23, January 18 to February 19, and February 24 to March 20, were based on the observer's notes concerning ice conditions and on temperature and precipitation records (not shown in fig. 177).

SHIFTING-CONTROL METHOD

The shifting-control method, at one time the standard method used in the U.S.A., is seldom used here now, but it is still used in other countries. In the shifting-control method, recorded gage heights are reduced by a variable backwater value to obtain the effective daily gage heights. The effective gage heights are then applied to the open-water rating to obtain estimated true daily discharges. The backwater correction on days when discharge measurements are made is computed as the difference between the actual gage height and the effective gage height—effective gage height being the gage height from the open-water rating that corresponds to the measured discharge. The backwater correction for use on any given day is obtained by interpolation, on the basis of time, between the backwater corrections computed for consecutive discharge measurements. As in the discharge-ratio method, the interpolation is subject to modification on the basis of meteorological records, and the dates on which ice effect begins and ends are based on the observed or deduced beginning and end of ice cover.

An example of the shifting-control method is shown in figure 178. The method is applied to the same gaging station used in the example in figure 177. Note that a natural (not logarithmic) scale is used in figure 178. The upper daily hydrograph in figure 178 shows recorded gage heights and the solid circles are the effective gage heights for discharge measurements; the lower graph shows the backwater corrections obtained from discharge measurements (open circles) and the interpolation between those values; the middle graph is the hydrograph of effective gage height, obtained by subtracting values on the lower graph from concurrent values on the upper graph. The nonlinear interpolations for backwater corrections during various periods were based on the observer's notes concerning ice conditions and on temperature and precipitation records (not shown in fig. 178). As mentioned in the preceding paragraph, the effective gage heights (middle graph) are applied to the rating curve to obtain estimated true daily discharges.

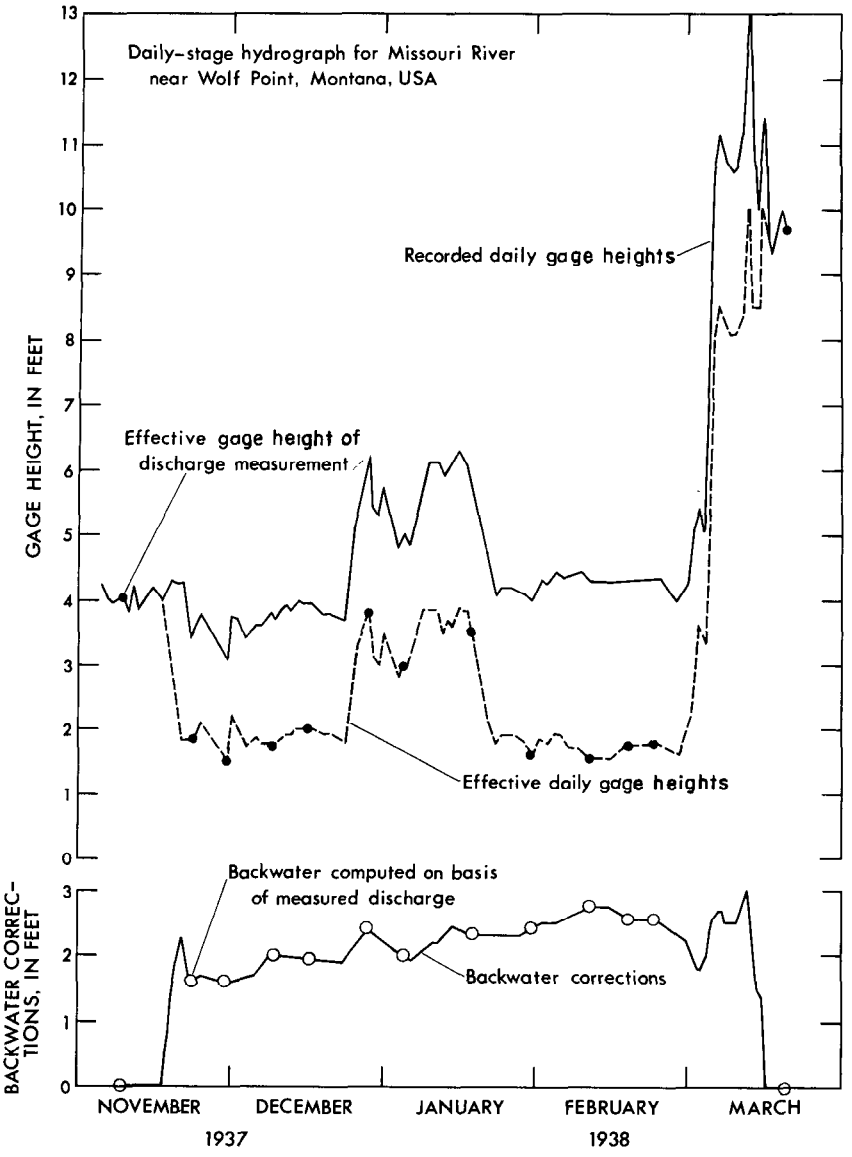

FIGURE 178.—Example of shifting-control method for adjusting stage record for ice effect.

HYDROGRAPHIC- AND CLIMATIC-COMPARISON METHOD

The method of hydrographic and climatic comparison has been favored in the U.S.A. for the last 30 years. The mechanics of the method differ from those of the discharge-ratio method, but both methods

basically correct the daily open-water discharge by a variable percentage.

The first step is to compute the station discharge record for the entire year as though there were no ice effect at any time. The daily hydrograph of open-water discharge and the discharge measurements are then plotted, using a logarithmic discharge scale, and notes concerning ice conditions are entered on the graph. At this point the hydrograph sheet resembles the upper graph in figure 177. If a measurement of ice-affected discharge is not representative of the daily mean discharge because of changing stage during the day, the daily mean discharge, as computed by equation 75, is also plotted. All is then in readiness for estimating the true daily discharge directly on the hydrograph sheet, and that is done on the basis of three comparisons:

1. comparison with records for nearby gaging stations,
2. comparison with weather records, and
3. comparison with the base-flow recession curve for the gaging station that is being studied.

Comparison with records for nearby gaging stations

Comparison with other discharge records is the most important basis for determining the probable discharge for periods between discharge measurements. Even though the record used for comparison may also have been corrected for ice effect, its use provides an additional independent set of basic data—another stage record and another set of current-meter measurements. Without a nearby record that compares well with the record being studied, the accuracy of the daily discharges estimated between the dates of discharge measurements may be greatly reduced. However, hydrographic comparisons are not infallible because the relation between the flow of two streams may vary significantly during the year; hence the importance of making many discharge measurements during ice-affected periods.

In making the hydrographic comparison, the nearby station with the most reliable winter streamflow record is selected for use as a reference station. The reliability of the reference station may have been established by the fact that its discharge is unaffected by ice or is affected by ice for only a relatively short period, or by the fact that many winter measurements have been made at the station and the true discharge between the dates of measurement can be estimated from weather records. (See discussion below on use of weather records.) A hydrograph of daily discharge, corrected for ice effect if necessary, is prepared for the reference station on a separate sheet of

graph paper, similar to that used for plotting the daily hydrograph for the station being studied.

A light table is used in comparing the two hydrographs. A light table is a glass-topped table that is illuminated by light from below the glass top, so that when one hydrograph is superposed on the other on the table top, both hydrographs can be viewed simultaneously. The hydrograph for the reference station is taped to the top of the light table. The hydrograph for the study station is then superposed on that of the reference station and positioned laterally so that the date lines of the two hydrographs coincide. The period preceding the first measurement (no. 1) that showed ice effect at the study station is the period first selected for consideration. The hydrograph for the study station is positioned vertically so that hydrographs for the two stations roughly coincide for the period immediately preceding the day or days when the start of ice effect is suspected. A comparison of the hydrographs and an inspection of the weather records should fix the date when ice effect started. That date will be preceded by a period of subfreezing weather, and on that date—usually a rainless day—the hydrograph for the study station will start a gradual rise not shown by the hydrograph for the reference station. For an appreciable period thereafter the hydrograph for the study station will remain above that of the reference station.

After the starting date (*A*) of ice-effect at the study station has been selected, the vertical position of the hydrograph for the study station is changed slightly, if necessary, to make the two hydrographs coincide on that date. If that positioning causes measurement no. 1 to fall directly on the hydrograph for the reference station, the hydrograph for the reference station between date *A* and measurement no. 1 is traced with dashed lines on the hydrograph sheet for the study station. The daily discharges indicated by the dashed lines are the estimated true discharges at the study station during the period between date *A* and measurement no. 1.

However, only rarely does measurement no. 1 coincide with the reference hydrograph when discharges at the two stations are made to coincide on date *A*; measurement no. 1 will usually lie above or below the hydrograph for the reference station. In that situation, as discharges from the reference hydrograph are being transferred to the sheet bearing the study hydrograph, the study sheet will in effect be moved up or down, as the case may be, so that when the transfer of discharge points reaches measurement no. 1, measurement no. 1 will coincide exactly with the reference hydrograph. If the temperature record shows no great fluctuation from day to day during the period between date *A* and measurement no. 1, the vertical displacement of the sheet bearing the study hydrograph will be made uniformly dur-

ing the transfer process. If the temperature record does fluctuate from day to day during the period, the vertical displacement will be made at a variable rate to reflect the fact that the ratio of true discharge to open-water discharge usually decreases during sharp drops in temperature; the ratio increases during sharp rises in temperature. In other words, the vertical distance between open-water discharge and true discharge increases on the study-hydrograph sheet during sharp drops in temperature; the vertical distance decreases during sharp rises in temperature. Observer's notes concerning major changes in the ice cover, particularly where complete cover is intermittent during the winter, are also very helpful in estimating the degree of ice effect.

After correcting the discharge between date *A* and measurement no. 1, the process is repeated for the period between discharge measurement no. 1 and the next successive discharge measurement (no. 2). The two hydrographs are made to coincide at measurement no. 1 and the transfer of discharge points to the study hydrograph proceeds to measurement no. 2. In that manner the open-water discharge for the study station is corrected until the date is reached when ice effect ceases.

Comparison with weather records

Records of air temperature and precipitation are a most valuable aid in making corrections for ice effect. The temperature record helps the engineer decide whether the precipitation is rain or snow—snow will have no immediate effect on the runoff. The temperature record also helps the engineer decide whether ice cover is forming, increasing, or dissipating. For stations for which there are no nearby discharge records for comparison and for which the recorder chart does not provide dependable clues to the fluctuation of discharge, it may be necessary to correct open-water discharges for ice effect almost solely on the basis of weather records and available measurements of discharge. Discharge usually follows closely the "ups-and-downs" of the air temperature record, and the discharge measurements help fix, within reasonable limits, the estimated rises and falls of the "true" discharge hydrograph. An exception to that statement is found in regions of extreme cold, such as the Arctic, that become blanketed with a heavy snow cover. The snow acts as an insulator for the underlying ground, and it then requires a prolonged change in temperature to significantly change the slow uniform recession of streamflow during the winter.

It should be mentioned here that a water-temperature recorder is a helpful adjunct to a gaging station. When the water temperature is above the freezing level, there is little likelihood of ice effect.

Comparison with base-flow recession curves

During periods of subfreezing weather, virtually all the flow in a stream is base flow; that is, water that comes out of ground-water storage to sustain the flow of the stream during periods when there is no surface runoff. It will often be found that during cold ice-affected periods, the flow of the stream will be declining at a rate similar to the rate of recession shown by that stream during ice-free periods. Thus if we have a known discharge of say, 20 ft^3/s, on some day during the ice-affected period and we wish to estimate daily discharge during the next 10 days, all of which were free of rain or snowmelt, we look for an ice-free period elsewhere in the record for the study station when there was no surface runoff, and choose a day whose discharge is 20 ft^3/s. We then note the receding values of discharge for the following 10 days, and use those same discharges for the 10 days to be estimated. The ice-free period that is used for an index should preferably be in the nongrowing season because the use of water by vegetation affects the rate of base-flow recession.

It is possible that daily discharges estimated from the base-flow recession for a warmer period may be somewhat high because extremely cold weather reduces the rate at which water percolates through the ground, and because some of the water that does reach the stream may go into storage behind ice dams. Nevertheless a standard base-flow recession curve provides a valuable guide to the probable flow during recession periods when the stream is ice-covered. Because the discharge during periods of base flow originates as ground water, a record of the fluctuations of ground-water levels of wells in the area can be useful as an index for estimating the true discharge during those periods.

An example of the application of the hydrographic- and climatic-comparisons method is illustrated in figures 179 and 180. Figure 179 shows a portion of a plotted hydrograph of daily mean discharge for the gaging station on North Fork John Day River at Monument, Oreg. The solid line represents open-water discharge obtained by applying recorded gage heights to the rating curve, and the X on January 26 represents the open-water discharge corresponding to the gage height of discharge measurement C made on that date. The open-water discharge is almost 10 times as great as the measured discharge on January 26. The dashed line on figure 179 represents the estimated true daily discharge obtained by comparison with the hydrograph of daily mean discharge for John Day River at Service Creek, Oreg. and by comparison with the record of daily maximum and minimum temperature at Dayville, Oreg. The reference hydrograph and temperature record used for the comparison are shown in figure 180. Actually the precipitation record at Dayville was also

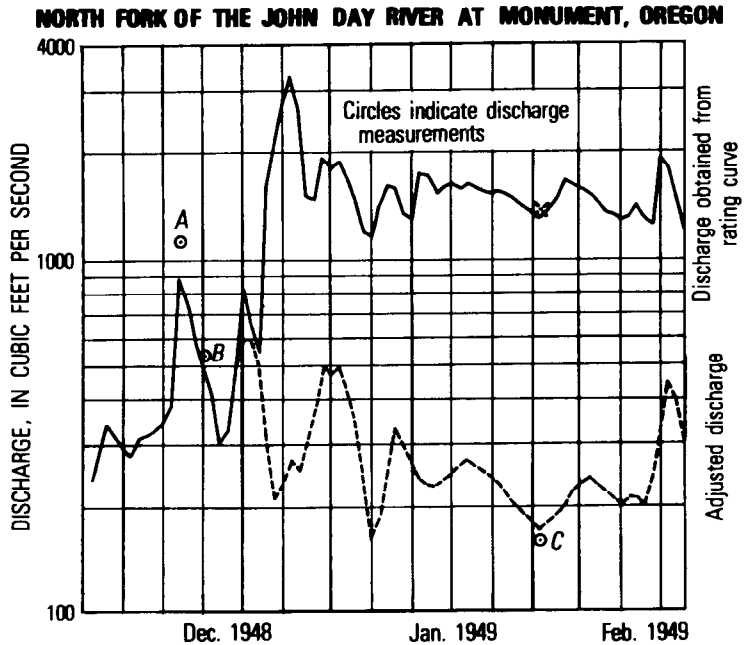

FIGURE 179.—Daily hydrographs for open-water discharge and for discharge corrected for ice effect. (After Moore, 1957.)

considered, but because all precipitation during the study period occurred as snow and therefore had no immediate effect on the runoff, the precipitation record is not shown in figure 180.

Also shown on figure 180 is the corrected hydrograph for the study station on North Fork John Day River at Monument; the hydrograph of open-water discharge at that station has been omitted to reduce clutter in the illustration. The discharge for the reference station on John Day River at Service Creek was unaffected by ice. The shapes of the two hydrographs are not identical, but useful comparison between the hydrographs for two stations does not require that their shapes be identical, as long as their discharge trends are similar. It can be seen on figure 180 that both hydrographs respond to the effect of air-temperature fluctuations during the winter period.

In applying the method of hydrographic and climatic comparison, the hydrograph of "true" daily discharge, plotted on a logarithmic scale, was displaced from the open-water hydrograph by a variable vertical distance. That means, in effect, that discharge ratios, variable with time, were applied to the open-water discharges, and there-

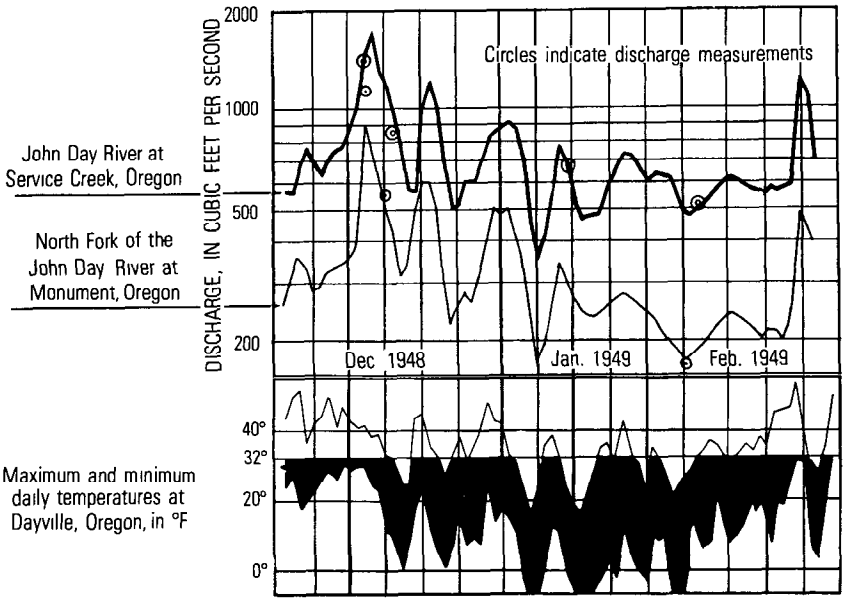

FIGURE 180.—Comparison of daily winter discharge at two gaging stations showing their response to air-temperature fluctuations. (After Moore, 1957.)

fore a basic similarity exists between the hydrographic-comparison method and the discharge-ratio method. It appears to the author that application of the hydrographic-comparison method would be greatly facilitated if the hydrograph of open-water discharge for the study station were first adjusted by the discharge-ratio method because application of that method is relatively simple. The adjusted hydrograph would then be refined by using it, rather than the open-water hydrograph, in the hydrographic-comparison method. It is much simpler to apply the hydrographic-comparison method for refining discharge estimates than it is to apply that method for making original discharge estimates.

SAND-CHANNEL STREAMS

In fixed channels, well-defined stage-discharge relations can usually be developed that show only minor shifting at low flow. In sand-channel streams, however, stage-discharge relations are continually changing with time because of scour and fill and because of changes in the configuration of the channel bed. These changes cause the shape and position of the stage-discharge relation to vary from time to time and from flood to flood, and it becomes very difficult to explain the apparent haphazard scatter of discharge measurements available to define the rating. Familiarity with the results of research

studies as reported by Colby (1960), Dawdy (1961), Simons and Richardson (1962), Beckman and Furness (1962), and Culbertson and Dawdy (1964) will greatly assist the analyst in defining the discharge rating.

For a stream with rigid boundaries, the best site for a stream-gaging station is upstream from a constriction because the constriction will provide a stable and sensitive control. An opposite effect occurs, however, at a constriction on a sand-channel stream; the rating will be unstable there because the constricted section will experience maximum streambed scour and fill. In fact, any contracting reach on a sand-channel stream is undesirable for use as a gaging-station site, and a straight uniform reach should be sought. Preferably both the gage and the cableway site for high-water discharge measurements should be located in a reach suitable for the determination of peak discharge by the slope-area method (chap. 9). This will permit the use of high-water current-meter measurements to verify computed peak discharges as well as develop the hydraulics of the stage-discharge relation. The fieldwork for a sand-channel stream should also include the collection of samples of bed materials at the stream-gaging site.

BED CONFIGURATION

On the basis of laboratory investigation, Simons and Richardson (1962) described the bed configuration of sand-channel streams as ripples, dunes, plane bed, standing waves, and antidunes. This sequence of bed configurations occurs with increasing discharge. When the dunes wash out, and the sand is rearranged to form a plane bed, there is a marked decrease in resistance to flow which may result in an abrupt discontinuity in the stage-discharge relation. The forms of bed roughness, as shown in figure 181 and described in table 21, are grouped according to the two separate conditions of depth-discharge relationship that are evident in a given channel. The sequence of configurations described in table 21 is developed by continually increasing discharge. The lower regime occurs with lower discharges; the upper regime with higher discharges; an unstable discontinuity in the depth-discharge relationship appears between these two more stable regimes.

The presence of fine sediment in the flow influences the configuration of the sand bed and thus the resistance to flow. It has been found by Simons and Richardson (1962, p. 4) that with concentrations on the order of 40,000 milligrams per liter of fine material, resistance to flow in the dune range is reduced as much as 40 percent. The effect is less pronounced in the upper regime, but fine sediment may change a standing-wave condition into a breaking antidune which will increase the resistance to flow. Thus the stage-discharge relation for a

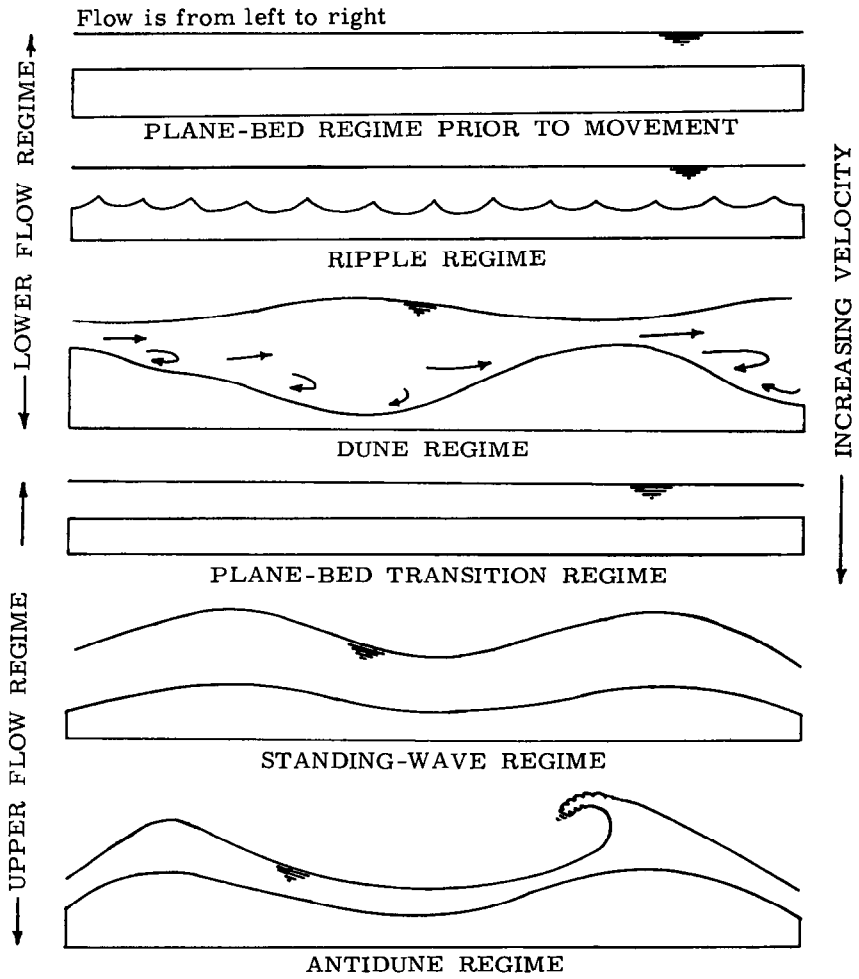

FIGURE 181.—Idealized diagram of bed and water-surface configuration of alluvial streams for various regimes of flow.

stream may vary with sediment concentration if the flow is heavily laden with fine sediment.

Changes in temperature can also alter the form of bed roughness, and, hence, the resistance to flow. Lowering the temperature increases the viscosity of the water and increases the mobility of the sand. If, for example, the form of bed roughness is in transition or nearly so, and if there is a reduction in the temperature of the water, the increased mobility of the sand may cause the dunes to wash out and the bed to become plane. This phenomenon is reversible.

Changes in bed forms do not occur instantaneously with increasing or decreasing discharge. The time lag between change in bed form

TABLE 21.—*Surface and bed descriptions for the various flow regimes*

Type of configuration	Description	
	Bed	Flow
Lower regime flow:		
Plane bed	Plane; no sediment movement.	Plane surface; little turbulence.
Ripples	Small uniform waves; no sediment movement.	Plane surface; little turbulence.
Dunes	Large, irregular, saw-toothed waves formed by sediment moving downstream; waves move slowly downstream.	Very turbulent; large boils.
Upper regime of flow:		
Plane bed	Dunes smoothed out to plane bed.	Plane surface; little turbulence.
Standing waves	Smooth sinusoidal waves in fixed position.	Standing sinusoidal waves in phase with bed waves; termed "sand waves."
Antidunes	Symmetrical sinusoidal waves progressing upstream and increasing in amplitude; suddenly collapse into suspension then gradually reform.	Symmetrical sand waves progressing upstream in phase with bed waves; amplitude increases until wave breaks, whole system collapses then gradually reforms.

and change in discharge may result in loop rating curves. For example, if bed configuration is initially dunes, the dunes will persist on rising stages to a discharge that is greater than the discharge at which the dunes will reform on falling stages. Thus at a given stage, the discharge may be greater when the stage is falling. Because the form of each loop curve depends on the initial condition of bed configuration and the rate of change of discharge, an infinite number of different loop curves, and even multiple-loop curves, may occur for a given reach of channel across the transition from dunes to plane bed. The stage-discharge relation within the transition band may be indeterminate. An example of a loop curve, typical of some channels, is shown in figure 182.

RELATION OF MEAN DEPTH TO DISCHARGE

A plot of stage against discharge in sand-channel streams often obscures any underlying hydraulic relationship because neither the bottom nor sides of these streams are fixed. Figure 183 shows as an extreme example the stage-discharge plot for Huerfano River near Undercliffe, Colo., for 1941 and 1942. The relation between stage and discharge is indeterminate. However, the underlying hydraulic relation may be revealed by a change in variables. The effect of variation in bottom elevation is eliminated by replacing stage by mean depth or hydraulic radius. The effect of variation in width is eliminated by

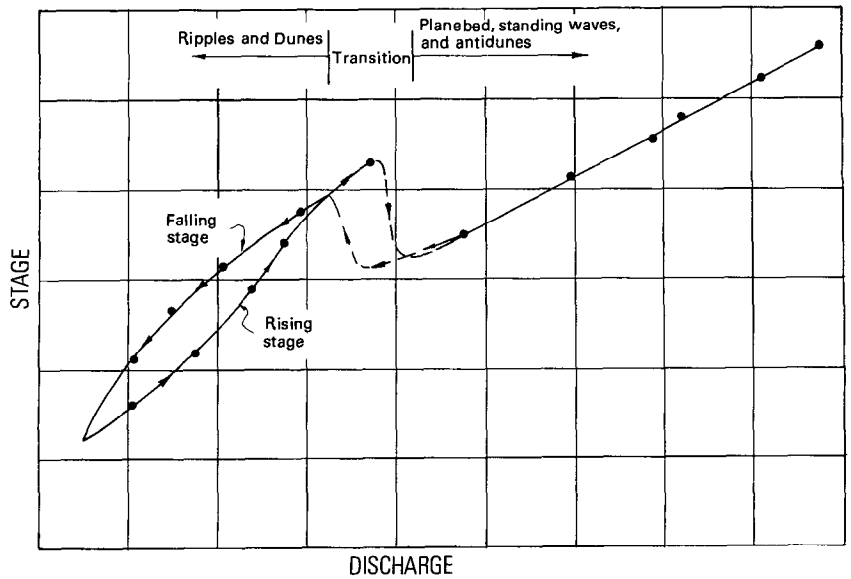

FIGURE 182.—Typical loop curve of stage versus discharge for a single flood event in a sand channel. (After Stepanich, Simons, and Richardson, 1964.)

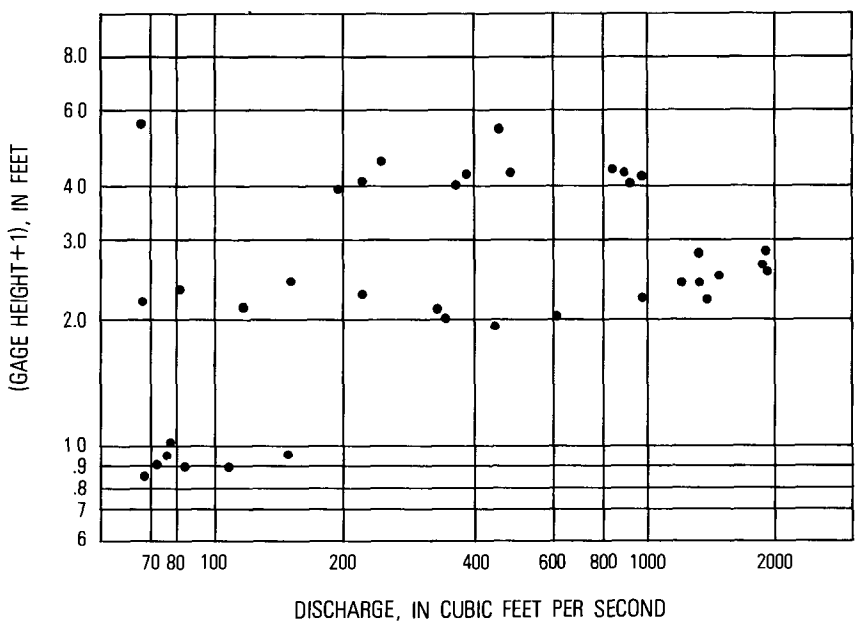

FIGURE 183.—Stage-discharge relation for Huerfano River near Undercliffe, Colo.

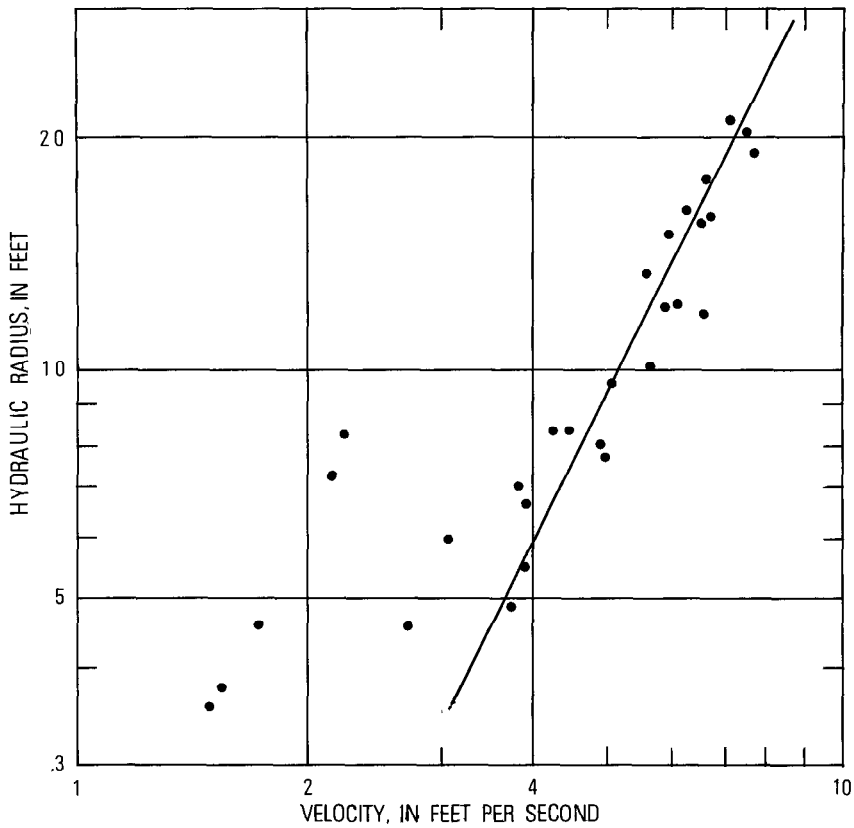

FIGURE 184.—Relation of velocity to hydraulic radius for Huerfano River near Undercliffe, Colo.

using mean velocity. Figure 184 shows most of the same measurements for Huerfano River that were plotted in figure 183, now replotted on the basis of velocity and hydraulic radius. Measurements for this stream with a hydraulic radius greater than one foot define a single curve with bed forms corresponding to the upper regime. Measurements in the transition range from dunes to plane bed scatter wildly as would be expected from the previous discussion.

The discontinuity in the depth-discharge relation is further illustrated in figure 185 which shows a plot of hydraulic radius against velocity for Rio Grande near Bernalillo, N. Mex. The measurements plotted on the left represent bed configurations of ripples and dunes and the curve on the right represents bed configurations of plane bed, standing waves, or antidunes.

According to Dawdy (1961), the curve representing the upper regime in a true sand-bed stream usually fits the following relation,

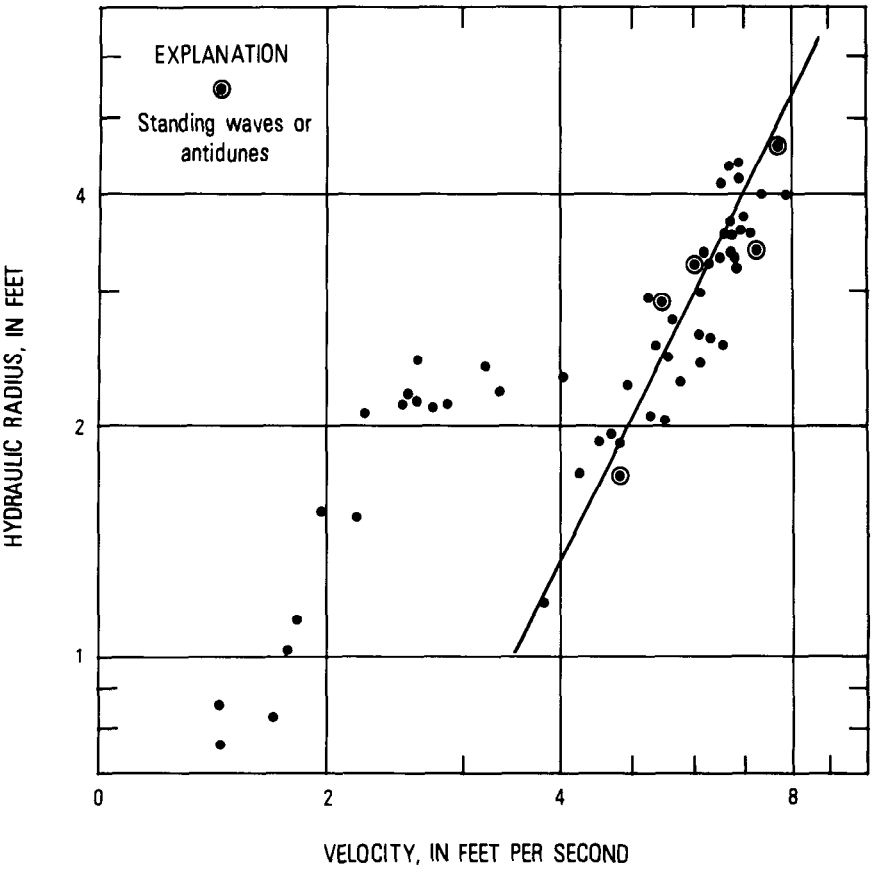

FIGURE 185.—Relation of velocity to hydraulic radius for Rio Grande near Bernalillo, N. Mex.

$$V = kR^{1/2},$$

where V is the mean velocity, k is a constant, and R is the hydraulic radius. He found this relation to be applicable for 26 of the 27 streams used in his study. More recent study has shown that the exponent of R ranges from ⅔, as in the Manning equation, to ½, the larger exponents being associated with the coarser grain sizes.

DEVELOPMENT OF DISCHARGE RATING

Plots of mean depth or hydraulic radius against mean velocity or discharge per foot of width are valuable in the analysis of stage-discharge relations. These plots clearly identify the regimes of bed configuration and assist in the identification of the conditions represented by individual discharge measurements. For example, only

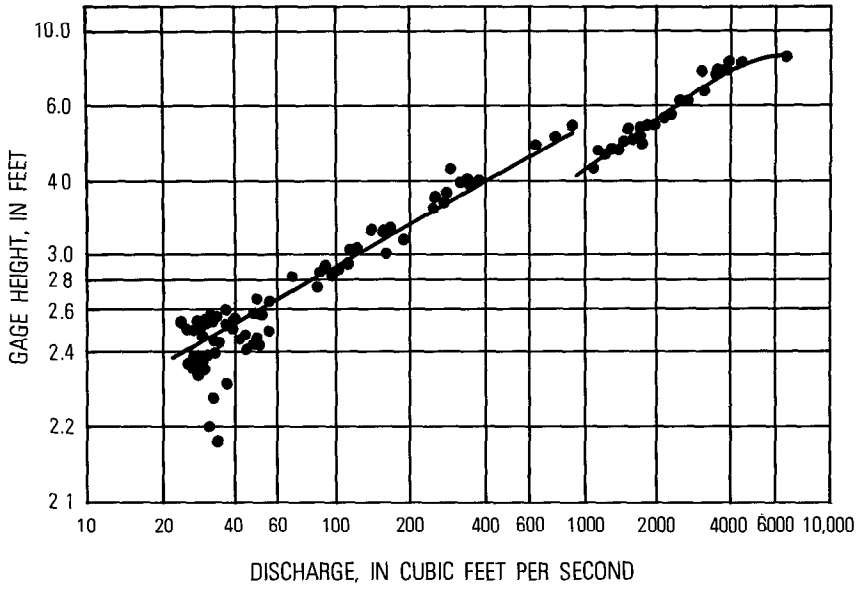

FIGURE 186.—Stage-discharge relation for station 34 on Pigeon Roost Creek, Miss. (After Colby, 1960.)

those measurements identified with the upper regime should be used to define the position and slope of the upper portion of the stage-discharge curve; similarly, only those measurements identified with the lower regime should be used to define the lower portion of the stage-discharge curve. Measurements made in the transition zone may be expected to scatter widely but do not necessarily represent shifts in more stable portions of the rating.

Plots of stage against mean depth and stage against width are also helpful in developing a mean stage-discharge relation and in analyzing the cause of shifts from the mean relation. In the upper regime the use of these plots in conjunction with the plot of velocity versus mean depth or hydraulic radius raised to the ½ to ⅔ power, depending on grain size, may be useful in establishing a reasonable slope to the upper part of the stage-discharge relation.

The stage-discharge relation developed by Colby (1960) for Pigeon Roost Creek, Miss., is shown in figure 186. This stream is about 75 ft wide, the banks are relatively stable, and the median size of the bed material is 0.4 mm. The mean elevation of the channel bed does not change appreciably with time or discharge. The discontinuity in the stage-discharge relation is very abrupt. Discharges from 900 to 1,800 ft^3/s may occur at a stage of 5.3 ft.

According to Colby (1960, p. 19, 20), stage-discharge relations may

be expected to have a discontinuity if the reach has all of the following characteristics:

1. a bed of uniform and readily shifting sediment that does not form distinct pools and riffles,
2. at some flows almost all of the stream-bed is covered with loose sand dunes,
3. at higher flows the bed of the stream is mostly plane or has antidunes,
4. the depth of flow at the point of discontinuity is sufficiently great so that changes in the stage-discharge relation at the discontinuity can be distinguished from changes caused by small local shifts of the channel bottom, and
5. the lateral distribution of depths and velocities is sufficiently uniform for the bed configuration to change across most of the streambed in a relatively short time.

The above conditions are very restrictive. Many streams with sand beds have well developed pools and riffles at the stage where the discontinuity might otherwise occur. Streams do not generally have uniform sediment sizes; many have large sorting coefficients. A few streams having suitable bed material may never show the discontinuity because dunes exist even at the highest flow rates. Others may have such high slopes that the lower regime cannot be defined by discharge measurements because of the shallow depths at which the discontinuity occurs. Winding streams seldom have uniform lateral distribution of velocity and depths. Some streams have such gradual or inconsistent transitions between dunes and plane bed that the discontinuity may be difficult, if not impossible, to define. Dunes may exist near the banks at the same time that a plane bed exists near the center of the stream. The transition in this case may occur so gradually with increasing stage that the discontinuity in rating is eliminated. However, at any station where dunes exist at low flows and a plane bed exists at higher flows, there is a major change in bed roughness. Knowledge of the bed forms that exist at each stage or discharge can be very helpful in developing the discharge rating.

EVIDENCES OF BED FORMS

Evidence of the bed forms that exist at a given time at a particular station can be obtained in several ways, a listing of which follows.

1. Visual observation of the water surface will reveal one of several conditions: large boils or eddies, which indicate dunes; a very smooth water surface, which indicates a plane bed; standing waves, which indicate smooth bed waves in phase with the surface waves; or breaking waves, which indicate antidunes. Visual observations of the water surface should be recorded on each discharge measurement.

2. Noting whether the sand in the bed is soft or firm. A soft bed often indicates lower regime conditions. The streambed during upper regime flow will usually be firm.

3. Measurements of bed elevations in a cross section will usually indicate the type of bed forms. A large variation in depth indicates dunes, and a small variation in depth a plane bed. The small variation in depths for a plane-bed (upper-regime) configuration should not be confused with small variations caused by ripples or by small dunes, both of which are definitely lower-regime configurations. A large variation in bed elevation at a particular point in the cross section during a series of discharge measurements indicates the movement of dunes.

4. The amount of surge on a recorder chart may also indicate the configuration of the channel bed. Medium surge may indicate dunes, little or no surge may indicate a plane bed, and violent surge may indicate standing waves or antidunes. The transition from plane bed to dunes during a discharge recession may cause a secondary hump on the gage-height trace if the transition occurs over a short time period.

5. Relations that define the occurrence of bed forms as a function of hydraulic radius (R), slope (S), mean velocity (V), and grain size (d), are useful in developing discharge ratings. A relation of that type, presented by Simons and Richardson (1962), is shown in figure 187. In that figure the dimension of R is feet; that of V is feet per second. Recent studies suggest that: the lower regime of bed forms will occur when the ratio,

$$\frac{V^4}{g^2 D^{1/2} d_{50}^{3/2}} , \tag{76}$$

is less than 1×10^3; the upper regime of bed forms will occur when the ratio is greater than 4×10^3; the bed will be in transition if the ratio is between those values. In the above ratio, V is the mean velocity in feet per second, g is the acceleration of gravity in feet per second per second, D is the mean depth in feet, and d_{50} is the median grain size of bed material in feet.

SHIFTING CONTROLS

The upper part of the stage-discharge relation is relatively stable if it represents the upper regime of bed forms. Rating shifts that occur in upper-regime flow can be analyzed in accordance with the methods or principles discussed in the section titled, "Rating Shifts for Channel Control." However, the shift ratings after minor stream rises will generally have a strong tendency to parallel the base rating when plotted on rectangular-coordinate graph paper; that is, the equation

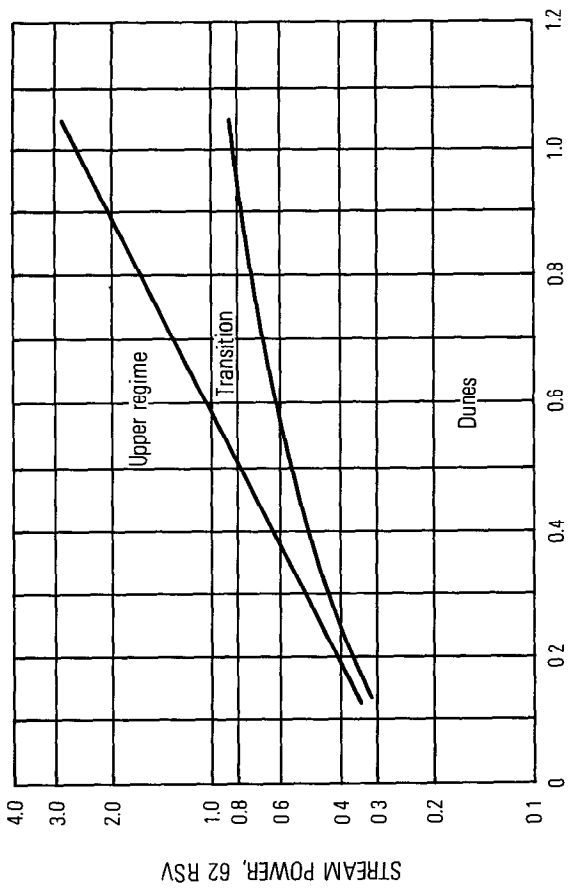

FIGURE 187.—Relation of stream power and median grain size to form of bed roughness.

for each shift curve will differ from that of the base rating by a change in the value of e in the basic equation,

$$Q=p(G-e)^N. \tag{53}$$

The shifts will change on stream rises and will often vary with time between rises. Major stream rises may also change the value of p in equation 53.

The lower part of the rating is usually in the dune regime and the stage-discharge relation varies almost randomly with time. Frequent discharge measurements are necessary to define the stage-discharge relation, and for some streams they are necessary to determine the variation of discharge with time in the absence of any usable relation between stage and discharge. In the U.S.A. a frequency of three discharge measurements per week is often recommended, but for some streams, even daily measurements barely suffice.

A mean curve for the lower regime is frequently used with shifts as defined by discharge measurements. In some instances the shift defined by a single discharge measurement represents only the temporary position of a dune moving over a partial section control. A series of discharge measurements made at short time intervals over the period of a day may define a pattern of shifts caused by dune movement. When discharge is constant but the stage fluctuates, the changing gage-height trace generally reflects dune movement.

Continuous definition of the stage-discharge relation in a sand channel stream at low flow is a very difficult problem. The installation of a control structure should be considered if at all feasible.

ARTIFICIAL CONTROLS FOR SAND CHANNELS

When conventional controls are installed in sand channels, they are seldom satisfactory, even those designed to be self-cleaning. The principal difficulty is that for such controls in a sand channel, discharge is dependent not only on water-surface elevation, but also on the bed elevation and flow regime upstream from the structure. A satisfactory control is one whose stage-discharge relation is unaffected by bed configuration. A few successful low-water controls have been designed for use in sand channels; one example is the weir designed for the gaging station on the Rio Grande conveyance channel near Bernardo, N. Mex. (Richardson and Harris, 1962). That structure will not be described here because generalizations concerning control shape are meaningless; each control structure must be individually designed for compatibility with channel and flow conditions that exist at the proposed site for the control. A laboratory model study involving a reach of channel is therefore needed for each

site investigated. Efforts continue to design low-water controls that are both relatively cheap and that have satisfactory operating characteristics when installed in sand channels (Stepanich and others, 1964).

CHAPTER 11—DISCHARGE RATINGS USING SLOPE AS A PARAMETER

GENERAL CONSIDERATIONS

If variable backwater or highly unsteady flow exists at a gaging station, the energy slope is variable at a given stage and the discharge rating cannot be defined by stage alone.

Variable backwater is most commonly caused by variable stage at a downstream confluence for a given discharge upstream or by the manipulation of gates at a downstream dam. The discharge under those conditions is a function of both stage and slope of the energy gradient. If the rate of change of stage is sufficiently great, the acceleration head must also be considered, but this chapter deals only with situations where the acceleration head has insignificant effect and can be neglected.

The unsteady-flow situation treated in this chapter is that of a natural flood wave, in which the flow maintains a stable wave profile as it moves down the channel. That type of wave is known as a uniformly progressive wave, and it often produces a loop rating at the gaging station; that is, for a given stage the discharge is greater when the stream is rising than it is when the stream is falling. The difference between the two discharges is significant only when the flow is highly unsteady. The term "highly unsteady", when associated only with the property of producing loop ratings, is a relative term, because channel slope is of equal importance in determining whether or not loop ratings will occur. A flood wave in a steep mountain channel will have a simple stage-discharge relation; that same flood wave in a flat valley channel may have a loop rating. The sections of this chapter that deal with unsteady flow are concerned only with loop ratings whose definition requires the use of slope, as well as stage, in a relation with discharge.

When a new gaging station is established, the need for a slope parameter in the rating can often be anticipated from the rating procedures used for existing stations nearby in a similar hydrologic and hydraulic environment. At other times the need for a slope parameter is not as evident. However, a plot of a series of discharge measurements made at medium and high stages will indicate the type of rating required for the station and will dictate whether or not an auxiliary gage is necessary to continuously measure water-surface slope.

If a pair of gages is needed, the locations of the base and auxiliary gage are based on the characteristics of the slope reach. The length of the reach should be such that ordinary errors that occur in the deter-

mination of gage heights at stage stations will cause no more than minor error in computing the fall in the reach. A fall of about 0.5 ft (0.15 m) is desirable but satisfactory records can often be obtained in reaches where the minimum fall is considerably less than 0.5 ft. Channel slope in the reach should be as uniform as possible. The reach should be as far upstream from the source of backwater as is practicable, and inflow between the two gages should be negligible. If possible, reaches with frequent or appreciable overbank flow should be avoided, as should reaches with sharp bends or unstable channel conditions. If the reach includes a natural control for low stages, the upstream (base) gage should be located just upstream from that control so that a simple stage-discharge relation will apply at low stages. Rarely will a slope reach be found that has all of the above attributes, but they should be considered in making a selection from the reaches that are available for slope measurement.

THEORETICAL CONSIDERATIONS

Variable slopes that affect flow in open channels are caused by variable backwater, by changing discharge, or by variable backwater in conjunction with changing discharge. The pair of differential equations given below provides a general solution to both gradually varied and unsteady flow.

$$\frac{Q^2}{K^2} = -\frac{\partial H}{\partial x} - \frac{1}{g}\frac{\partial V}{\partial t} \tag{77}$$

$$\frac{\partial Q}{\partial x} = -B\frac{\partial h}{\partial t} \tag{77a}$$

In the equations Q is the discharge, K is the conveyance of the cross section, H is the total energy head, x the distance along the channel, g the acceleration of gravity, V the mean velocity, t the time, B the top width of the channel, and h is the water-surface elevation. A solution to these equations in uniform channels may be obtained by approximate step methods after the conveyance term has been evaluated by discharge measurements.

In those practical problems of determining flow in open channels that require application of equation 77 the increment of slope due to the acceleration head $\frac{1}{g}\frac{\partial V}{\partial t}$ is, in general, so small with respect to the other two terms that its effect may be neglected. Thus, in equation 77 the terms that remain in addition to discharge (Q), are conveyance (K) which is a function of stage, and energy gradient ($\partial H/\partial x$) which is related to water-surface slope. At those sites where tidal action or

variation in power production cause the acceleration head to be large, approximate methods of integration of equations 77 and 77a are used in conjunction with an electronic computer. Those methods are described briefly in chapter 13 of this manual.

The discussion of stage-fall-discharge ratings presented in the present chapter draws heavily on previously published reports. The three primary references used are Corbett and others (1945), Eisenlohr (1964), and Mitchell (1954).

VARIABLE SLOPE CAUSED BY VARIABLE BACKWATER

The stage at a gaging station for a given discharge, under the usual subcritical flow conditions, is influenced by downstream control elements. A brief discussion of those elements is now in order.

Previous discussions of controls in this manual have dealt primarily with such elements as natural riffles, weirs and dams, flumes, and the physical properties of the stream channel. It had also been explained that a control may act independently for some range of stage or it may act in concert with one or more other controls. However, it had also been mentioned in appropriate places in this manual that the stage at downstream stream confluences may affect the stage-discharge relation at a gaging station. Where that occurs, the confluent stream must be classed as a control element that acts in concert (partial control) with the control(s) in the gaged stream. Furthermore, when a confluent stream acts as a control element, it usually does so as a variable element. That is, the stage at the gaging station will no longer be related solely to the discharge of the main stream, but will also vary with variation of the discharge in the confluent stream.

At gaging stations on tide-affected streams, the tide itself must be considered as a variable control element because of its effect on the stage-discharge relation at the gaging station. As mentioned earlier tide-affected stage-discharge relations are treated in chapter 13.

A less clear-cut situation with regard to control elements exists in many streams in southeastern United States. These streams have extremely wide flood plains that are crossed in places by highway embankments whose bridge openings locally constrict the flow severely. At high flow if water occupies the flood plain, the stage-discharge relation at the bridge is affected; for a given discharge through the bridge the corresponding stage will vary, depending on whether streamflow is entering the overbank areas as on a rising stage, or whether water is returning to the main channel from the overbank areas as on a falling stage. In that situation the overbank flow itself is acting as a variable control element in concert with the "more conventional" and more stable control elements, such the

geometry of the bridge opening and the geometry and roughness of the downstream main channel and overbank areas. The streamflow that is entering the overbank areas acts, in effect, as an extremely wide downstream distributary; the overbank flow that is returning to the stream acts, in effect, as an extremely wide downstream tributary. The streams usually have extremely flat gradients and the rating may possibly be complicated by the effect of changing discharge on streams of flat slope. However, as explained in the section titled, "Variable Slope Caused by a Combination of Variable Backwater and Changing Discharge," streams affected by both variable backwater and changing discharge are treated as though they were affected by variable backwater alone.

The control elements that affect the stage-discharge relation for a stream have now been identified and their descriptions have been amplified for the discussion of backwater that follows. At any given discharge the effect on the stage at the gaging station that is attributable to the operative control element(s) is known as backwater. As long as the control elements are unvarying, the backwater for a given discharge is unvarying, and the discharge is a function of stage only; the slope of the water surface at that stage is also unvarying. If some of the control elements are variable—for example, movable gates at a downstream dam or the varying stage at a downstream stream confluence—for any given discharge the stage at the station and the slope are likewise variable. In a preceeding discussion titled "Theoretical Considerations," it was demonstrated that for the above variable conditions, discharge can be related to stage and slope. Because the slope between two fixed points is measured by the fall between those points, it is more convenient to express discharge as a function of stage and fall.

Stage-fall-discharge ratings are usually determined empirically for observations of (1) discharge, (2) stage at the base gage, which is usually the upstream gage, and (3) the fall of the water surface between the base gage and an auxiliary gage. The general procedure used in developing the ratings is as follows:

1. A base relation between stage and discharge for uniform flow or for a fixed backwater condition is developed from the observations. The discharge from that relation is termed Q_r.
2. The corresponding relation between stages and the falls for conditions of uniform flow or fixed backwater is developed. Those falls are termed rating falls, F_r. Figure 188 shows schematically three forms the stage-fall relation may have.
3. The ratios of discharges Q_m, measured under conditions of variable backwater, to Q_r, are correlated with the ratios of the measured falls F_m to the rating falls F_r. Thus,

$$\frac{Q_m}{Q_r} = f\left(\frac{F_m}{F_r}\right). \tag{78}$$

The form of the relation depends primarily on the channel features that control the stage-discharge relation. The relation commonly takes the form,

$$\frac{Q_m}{Q_r} = \left(\frac{F_m}{F_r}\right)^N, \tag{78a}$$

where N varies from 0.4 to 0.6, the theoretical value of N being 0.5. Generally speaking, the stage-fall-discharge rating can be extrapolated with more confidence when the data are such that they fit equation 78a best when an N value of 0.5 is used.

The fall between the base and auxiliary gage sites, as determined from recorded stages at the two gages, may not provide a true representation of the slope of the water surface between the two sites. That situation may result from the channel and gaging conditions that are described below.

First, the water surface in any reach affected by backwater is not a plane surface between points in the reach, as sinuosity of the channel

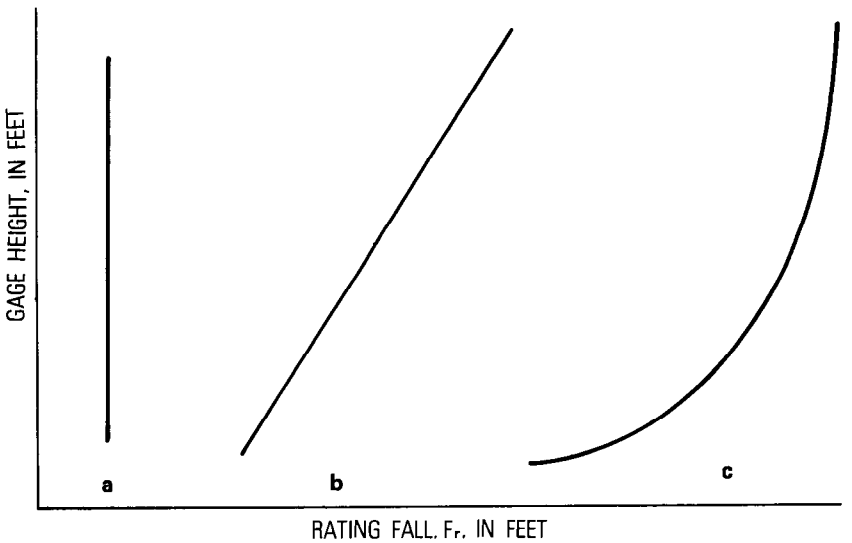

FIGURE 188.—Schematic representation of typical stage-fall relations. Curve (a), rating fall constant; curve (b), rating fall a linear function of stage; curve (c), rating fall a curvilinear function of stage.

will produce variations in the height of the water surface, both across and along the reach; variations in channel cross section and the effects of backwater also tend to produce curvature of the water surface. The slope determined from observed differences in stages is that of a chord connecting the water-surface elevations at points at the ends of a reach. It may not represent the slope of the water surface at either end of the reach but may be parallel to a line that is tangent to the water surface at some point in the reach.

Second, no reach of a natural stream selected for the determination of slope is completely uniform. The area of the cross section may vary considerably from point to point in the reach, but more important is the effect that shoals, riffles, rapids, or bends in the stream channel within the reach may have on the slope of the water surface, as well as on the energy gradient.

Third, the positions of the gages at the ends of the reach with respect to the physical features of the channel may have a material effect on the recorded gage heights and hence on the indicated slope. For example, if one gage is on the inside of a rather sharp bend and the other on the outside of a similar bend, the slope computed from records of stages at those gages may be widely different from the average slope of the water surface. Also, if differing drawdown effects exist at the intakes of the two gages, the two stage records obtained may not provide a true index of the water-surface slope.

Fourth, both gages may not be set to exactly the same datum, the difference in datum possibly being a large percentage of the total fall if the fall is small. The slope determined from gages not set to the same datum would not indicate the true water-surface slope because the computed slope would include the quantity y/L, where y is the difference in datum and L is the length of the reach.

Because of those conditions, theoretical relations between stage, fall, and discharge cannot be directly applied, and the relations must be empirically defined by discharge measurements made throughout the range of backwater conditions. Thus, the "best" value of the exponent of F_m/F_r in equation 78a will often be found to be in the range from 0.4 to 0.6, rather than having the theoretical value of 0.5; or, it may even be necessary to depart from a pure exponential curve in order to fit the plotted points satisfactorily. At other times the substitution of a term, $F+y$, for F values in equation 78a will improve the discharge relation. The use of a constant, y, whose best value is determined by trial computations, compensates in part for the inaccuracies in the value of F that were discussed above.

It is convenient to classify stage-fall-discharge ratings according to the types of relation that may be developed between stage and rating fall. The two types are:

1. *Rating fall constant.*—This type of relation (curve *a* in fig. 188) may be developed for channels that tend to be uniform in nature and for which the water-surface profile between gages does not have appreciable curvature.

2. *Rating fall a function of stage.*—This type of relation (curves *b* and *c* in fig. 188) may be developed if any of the following conditions exist:

   a. appreciable curvature occurs in the water-surface profile between gages;
   b. the reach is nonuniform;
   c. a submerged section control exists in the reach between gages, but the control does not become completely drowned by channel control even at high discharges; and
   d. a combination of some of the conditions listed above.

It is not uncommon for variable backwater to be effective for only part of the time. That follows from the two general principles that apply to backwater effect. The first states that for a given stage at the variable control element, backwater decreases at the base gage as discharge increases. For example, in a long gage reach of fairly steep slope, a given stage at the variable control element may cause significant backwater at the base gage when the discharge in the gaged stream is low but cause no backwater during periods when the discharge is high. The second principle states that for a given discharge, backwater decreases at the base gage as stage decreases at the variable control element. For example, at a given discharge in the gaged stream a high stage at the variable control element may cause significant backwater at the base gage, but a low stage at the variable control element may cause no backwater.

Other basic principles and detailed procedures used in defining stage-fall-discharge ratings are discussed on the pages that follow. The discussions are arranged in accordance with the preceding classification of stage-rating fall relations. A knowledge of the hydraulic principles applicable to a given slope reach is essential as a guide to the empirical analysis of the data.

RATING FALL CONSTANT

GENERAL DISCUSSION OF RATING PRINCIPLES

In uniform channels the water-surface profile is parallel to the bed; the slope, and therefore the fall, is the same for all discharges. The rating fall, F_r, for the condition of no variable backwater (uniform-flow conditions) would be the same at any stage. The stage-discharge relation with no backwater could be described by the Chezy equation,

$$Q_0 = CA_0\sqrt{R_0 S_0},$$

where the subscripts denote uniform flow; or by the equation,

$$Q_r = CA\sqrt{RF_r/L}, \tag{79}$$

where the subscripts denote the base rating conditions.

If variable backwater is imposed on the reach by a downstream tributary, the measured fall, F_m, and measured discharge, Q_m, would be less at a given stage than indicated by the uniform-flow rating. If the slope or fall as measured truly represents the slope at the base gage, those measurements would define, as shown in figure 189, a family of stage-discharge curves, each for a constant but different value of fall. The relation of each curve in the family to the curve for base rating conditions according to equation 79, is expressed by the equation,

$$\frac{Q}{Q_r} = \sqrt{\frac{F}{F_r}} \tag{80}$$

The discharge under variable backwater conditions may be computed as the product of (*a*) the discharge Q_r from the base rating and (*b*) the

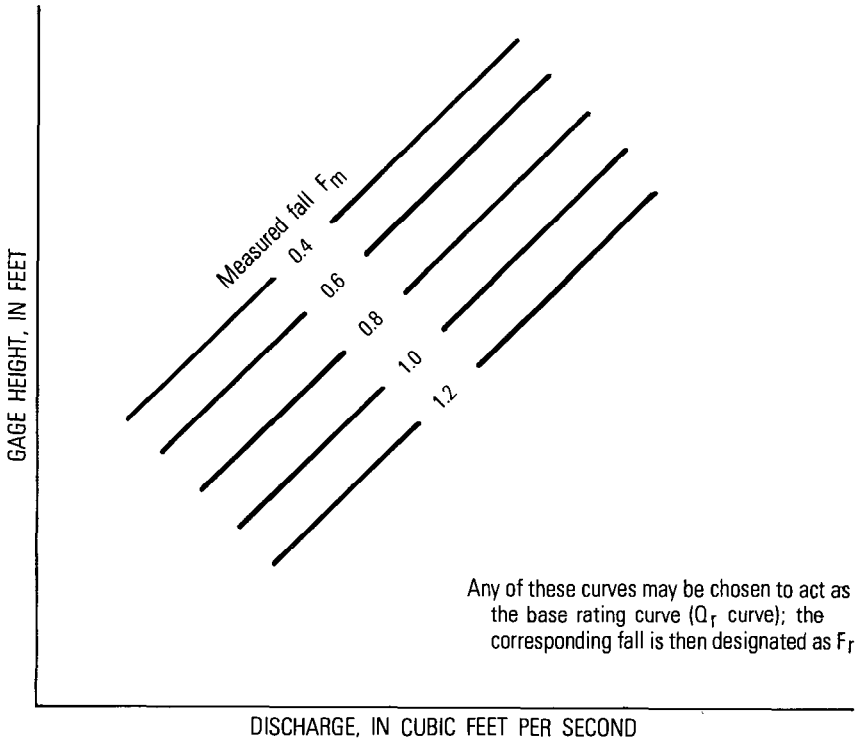

FIGURE 189.—Schematic representation of family of stage-discharge curves, each for a constant but different value of fall.

square root of the ratio of the measured fall to the constant-value rating fall.

A constant rating fall may also exist at sites where the base rating is controlled by a dam downstream from the reach in which fall is measured. If the curvature in the backwater profile is not significant, and if the channel is uniform, the water-surface profile will approximately parallel the channel-bed profile at all discharges. For example, the curve in figure 189 for a constant fall of 1.2 ft may be taken to represent the base stage-discharge relation for a fixed or stable control element. The curve for lesser falls that might result from variable submergence of the dam, are theoretically related to this base curve by the square root of the fall ratios, as described above. Quite commonly a constant value of 1.0 ft is used for F_r in equation 80. That special case of the constant rating-fall method, usually referred to as the unit-fall method, simplifies the computations because equation 80 then reduces to

$$Q_r = Q/\sqrt{F.} \tag{81}$$

A constant rating fall is not the usual case encountered in natural streams. However, if discharge measurements cover the entire range of flow conditions and if such measurements conform to a constant rating fall, there is no need to use a more complicated technique. If profile curvature and velocity-head increments are truly negligible, the relation between the discharge ratio and fall ratio should resolve into a single curve; otherwise the relation may be a family of curves with stage as a third variable.

PROCEDURE FOR ESTABLISHING THE RATING

The general procedure used in establishing a stage-fall-discharge rating with constant rating fall is outlined as follows:

1. Plot all discharge measurements using stages at the base gage as ordinates and discharges as abscissas, and note the measured fall (F_m) beside each plotted point. If the information on this plot indicates a family of curves, each corresponding to a constant value of fall (fig. 189), the use of a constant rating fall should be investigated.

2. The most satisfactory type of constant-fall rating, from the standpoint of high-water extrapolation, is one whose discharge ratio-fall ratio relation is a pure parabolic relation, as in equation 80, with the exponent equal to, or nearly equal to, 0.5. If such a relation fits the measured discharges, the results are unaffected by whatever value of constant fall (F_r) is used. For convenience, unit fall is used, as in equation 81.

3. For each discharge measurement (Q_m), compute Q_r by use of the equation $Q_r = Q_m/(F_m)^{0.5}$.

4. Plot values of gage height versus Q_r for each discharge measurement and fit a curve to the plotted points to obtain the Q_r discharges from the Q_r rating curve.

5. Compute and tabulate the percentage departures of the plotted Q_r discharges from the Q_r rating curve.

6. Repeat steps 3–5, using exponents of F_m other than, but close to, 0.5. Try exponents equal to 0.40, 0.45, 0.55, and 0.60.

7. Compare the five Q_r rating curves and select the curve that best fits the plotted points used to define it. In steps 8 and 9 that follow, the discharges from that "best" rating curve will be referred to as Q_{rd}, and the corresponding exponent of F_m will be referred to as d.

8. If the plotted discharges closely fit the Q_{rd} rating curve, that curve and the relation of (Q_m/Q_{rd}) to F_m are accepted for use.

9. If the plotted discharges do not closely fit the Q_{rd} rating curve repeat steps 3–5, using the exponent d but substituting the term (F_m+y) for F_m. Several values of y, a small quantity that may be either positive or negative, are tried to obtain a Q_r rating curve that closely fits the plotted discharge.

10. Compare the various Q_r rating curves obtained from step 9 and select the curve that best fits the plotted points used to define it. If the plotted discharges closely fit that Q_r rating curve, that rating curve and the corresponding relation of (Q_m/Q_r) to (F_m+y) are accepted for use. If the fit is not considered to be sufficiently close, the use of a pure parabolic relation, such as equation 81, is abandoned and the strictly empirical approach described in the following steps is used.

11. From the family of stage-discharge curves discussed in step 1, select one as the base Q_r curve and use the constant fall for this curve as F_r.

12. Compute the ratios Q_m/Q_r and F_m/F_r, plot the discharge ratios as ordinates and the fall ratios as abscissas, and draw an average curve through the plotted points that passes through the point whose coordinates are 1.0, 1.0.

13. Adjust each measured discharge by dividing it by the discharge ratio corresponding to the fall ratio on the above curve. Plot these computed values of Q_r against stage, and draw an average curve (Q_r curve) through the plotted points.

14. Repeat steps 11–13 using alternative constant values of F_r until the best relation between stage, fall, and discharge is established.

15. If the best relation derived from the application of steps 11–14 is still unsatisfactory, use the more flexible method described in the section titled, "Rating Fall a Function of Stage."

EXAMPLE OF RATING PROCEDURE

The stage-fall-discharge rating for Tennessee River at Guntersville, Ala. is presented in figure 190 as an example of a rating with constant rating fall. The upper gage is a water-stage recorder installed in a well attached to a pier of a highway bridge. The lower gage is a water-stage recorder installed on the right bank 43,700 ft below the upper gage and 3,300 ft above Guntersville Dam. The channel conditions in this reach are reasonably uniform. Variable backwater is caused by the operations at Guntersville Dam.

A satisfactory relation between stage, fall, and discharge could not be established for the upper (base) gage by use of the procedures for a pure parabolic fall-ratio curve that are described in steps 1–10. The empirical approach described in steps 11–14 was therefore used. The best rating was obtained by using a value of F_r equal to 1.5 ft. The fall-ratio curve in figure 190 approximately fits equation 80 for all fall ratios no greater than 1.0; for fall ratios greater than 1.0 the curve is flatter than a parabola defined by equation 80.

To plot, on the Q_i rating curve, a subsequent discharge measurement (Q_m) having a fall F_m, the fall ratio, F_m/F_r or $F_m/1.5$, is first computed. The fall-ratio curve is then entered with the computed fall ratio, and the discharge ratio, Q_m/Q_r, is read. Q_m is then divided by that value of the discharge ratio to give the value of Q_i to be plotted.

The method of obtaining the discharge corresponding to a given gage height and a given fall (F_m) is explained in the section titled, "Determination of Discharge from Relations for Variable Backwater."

RATING FALL A FUNCTION OF STAGE

GENERAL DISCUSSION OF RATING PRINCIPLES

Where variable backwater is a factor in the discharge rating, it will generally be found that fall is a function of stage. The average relation between fall and discharge may be linear, or fall may be a complex function of stage. Rating principles are best discussed by reference to examples.

The right-hand graph in figure 191 for the Columbia River at The Dalles, Oreg., is an example of a linear relation between stage and fall. The stage-discharge relation at the base gage is affected by reservoir operations at Bonneville Dam, more than 80 miles downstream. The auxiliary gage is located at Hood River bridge, 19 miles downstream from the base gage. Within the range of measured discharges, fall increases linearly with stage.

A much more complex stage-fall relation is shown in the right-hand graph in figure 192 for the Ohio River at Metropolis, Ill. At the downstream (auxiliary) gage, the stage-discharge relation is affected only at the lower stages by a constriction, the backwater from which causes fall to decrease with stage in the slope reach. At the higher

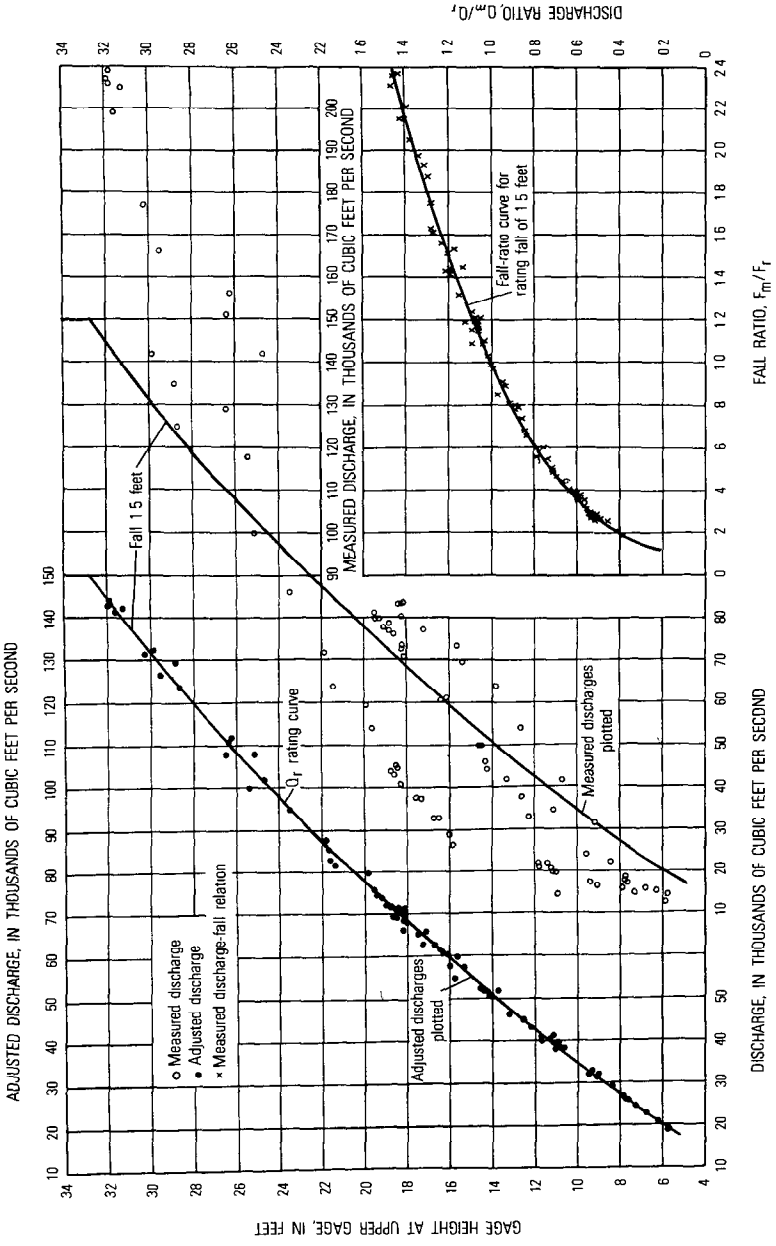

FIGURE 190.—Stage-fall-discharge relations for Tennessee River at Guntersville, Ala.

stages the constriction has little effect and fall increases with stage.

Another example of a complex stage-fall relation is shown in the right-hand graph in figure 193 for Kelly Bayou near Hosston, La. The base gage for this rating is about 2.7 miles upstream from the mouth of Kelly Bayou. The auxiliary gage is on Black Bayou, 4.2 miles downstream from the base gage. At low stages, fall increases with stage; at medium and high stages the backwater effect from Black Bayou is more pronounced and fall tends to assume a constant value.

Where a section control exists just downstream from the base gage, it is necessary to identify those situations when backwater effect is absent at the base gage. Obviously there will be no backwater when the tailwater at the section control is below the crest of the control. Most artificial controls are broad-crested, and submergence is generally effective only when tailwater rises to a height above the crest that is equal to or greater than 0.7 times the head on the control. Looked at another way, submergence is effective only when the fall between the upstream and downstream stages is equal to or less than 0.3 times the head on the control. Thus a straight line of initial submergence may be drawn on the curve of stage versus fall; the line passes through the coordinates representing the elevation of the control crest and zero fall, with a slope of 3 ft of stage per foot of fall.

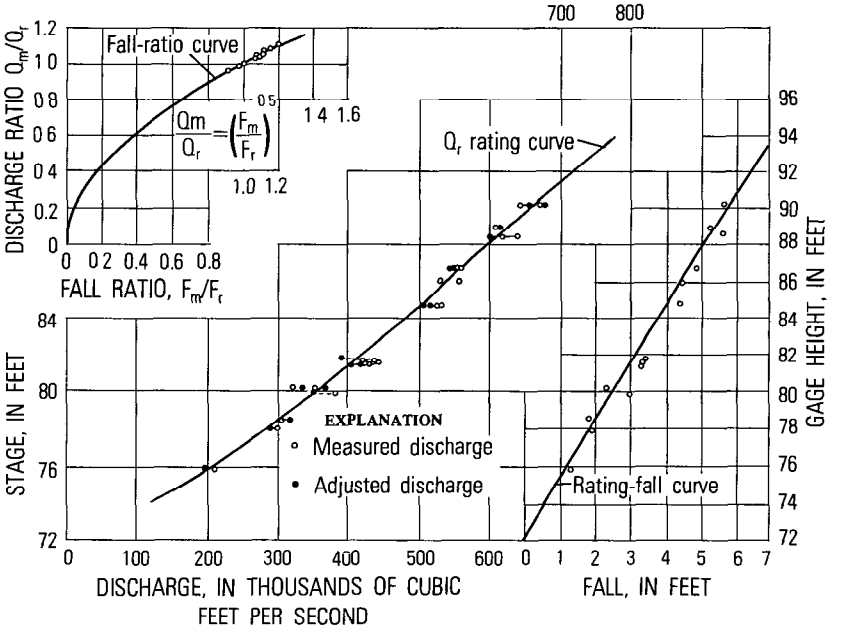

FIGURE 191.—Stage-fall-discharge relations for Columbia River at The Dalles, Oreg.

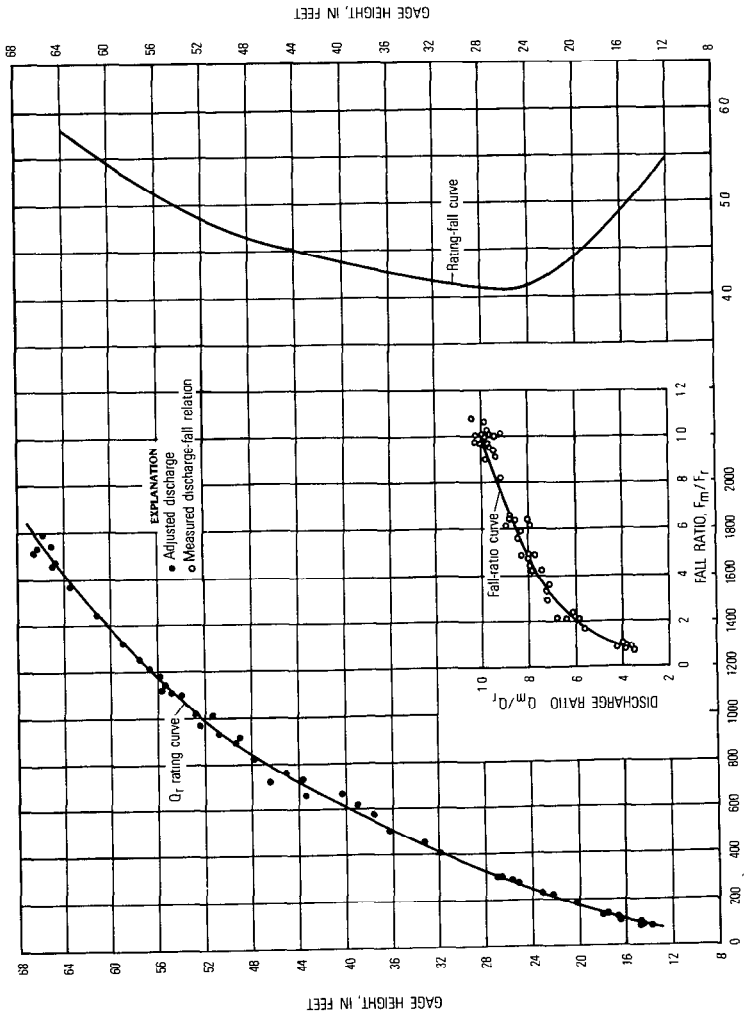

FIGURE 192.—Stage-fall-discharge relations for Ohio River at Metropolis, Ill.

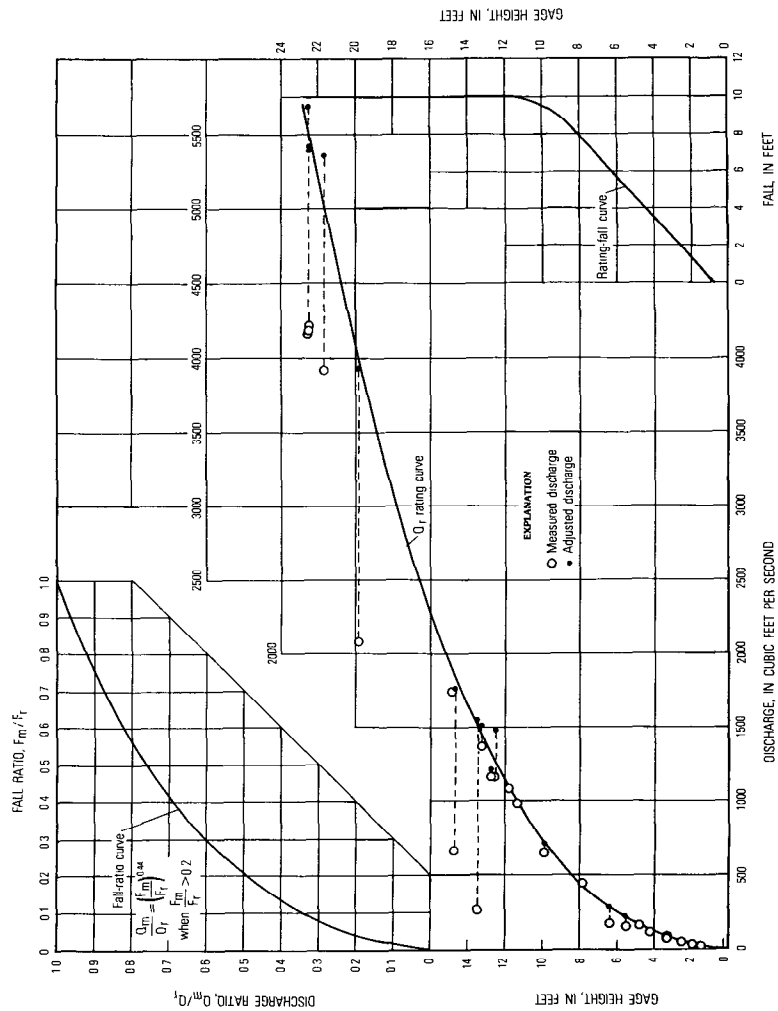

FIGURE 193.—Stage-fall-discharge relations for Kelly Bayou near Hosston, La.

The precise position and slope of the line will depend on the location of the downstream auxiliary gage with respect to the section control. If the auxiliary gage is immediately downstream from the control, the line of initial submergence will have the position and slope stated above. If the auxiliary gage is far downstream from the control, the line on the stage-fall graph will intersect the elevation of the control crest at a value of fall greater than zero, and the slope of the line will depend on the hydraulic features of the station; field observation will be necessary to define the graph coordinates of the line of initial submergence. All observed or recorded values of fall that lie below the line of initial submergence indicate free-fall discharge (discharge unaffected by the tailwater elevation); all observed or recorded values of fall that lie above the line of initial submergence indicate discharge affected by variable backwater. Furthermore, if the auxiliary (tailwater) gage is close to the control, the fall-ratio curve for discharges affected by backwater should closely fit the theoretical equation,

$$(Q_m/Q_r) = (F_m/F_r)^{0.5}.$$

If the auxiliary (tailwater) gage is distant from the control, the fall-ratio curve will depart from the theoretical equation.

The right-hand graph in figure 194 shows the stage-fall relation for Colusa Weir near Colusa, Calif. The base gage for the station is a short distance upstream from an ungated weir which acts as a section control, and the auxiliary gage is a short distance downstream from the control. There is no pool immediately upstream from Colusa Weir, the streambed being at the elevation of the weir crest; there is a drop of about 2 ft immediately downstream from the weir. The line of initial submergence shown crossing the lower part of the stage-fall relation has the theoretical position and slope discussed above. Colusa Weir is at the downstream end of a large natural detention basin along the left bank of the Sacramento River, and water that passes over the weir immediately enters the river. Because the river stage rises faster than the stage of the detention pool, fall decreases with stage at the base gage, as shown by the rating-fall curve.

The right-hand graph in figure 195 is a plot of stage versus fall for the Kootenay River at Grohman, B.C., Canada. The base gage for this station is on the west arm of Kootenay Lake about 2 miles upstream from Grohman Narrows. Downstream from the narrows is the forebay of the Corra Linn powerplant, and in the forebay is the auxiliary gage, about 8 miles downstream from the base gage. Grohman Narrows is the control for the base gage, but operations of Corra Linn Dam cause variable submergence of the control when the stage of the

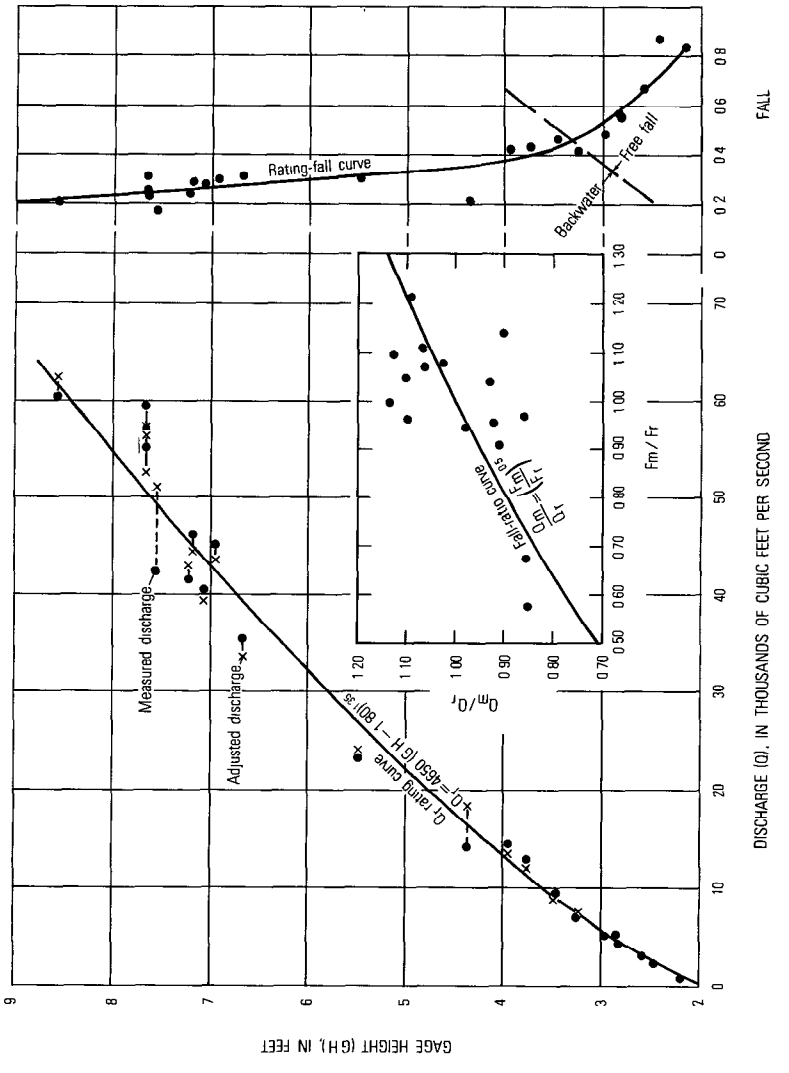

FIGURE 194.—Stage-fall-discharge relations for Colusa Weir near Colusa, Calif

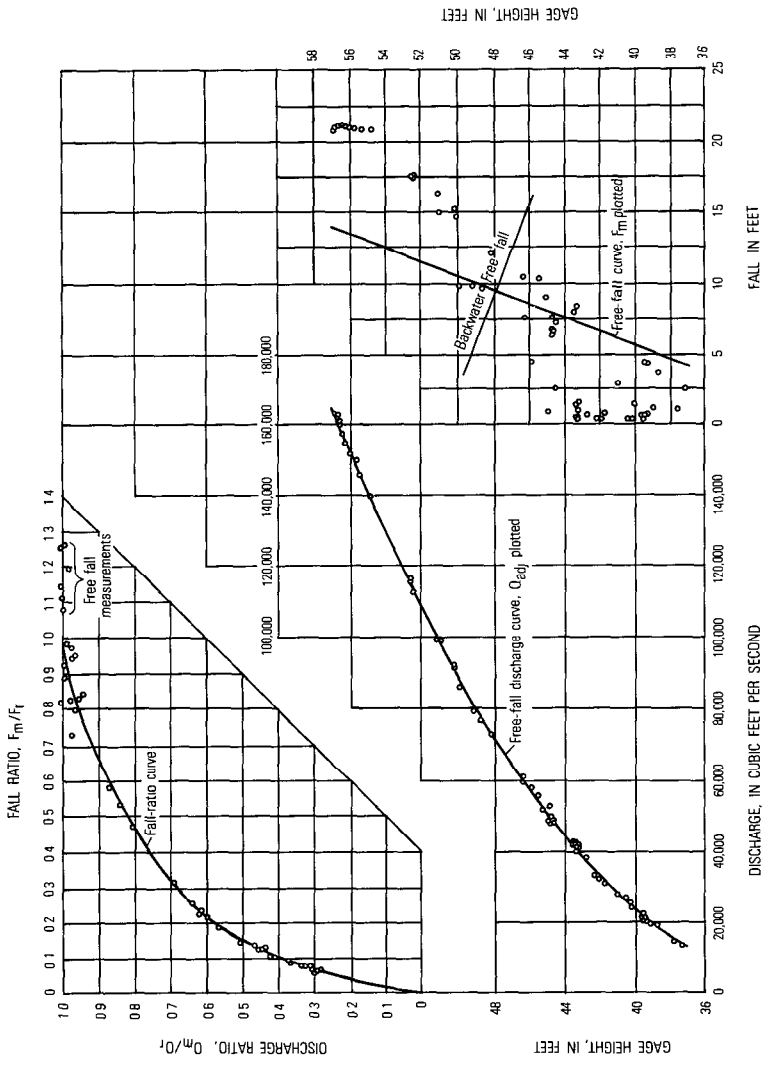

FIGURE 195.—Stage-fall-discharge relations for Kootenay River at Grohman, British Columbia, Canada. Measurements with falls less than 0.4 feet not plotted.

forebay is sufficiently high. The line of initial submergence, shown as the free-fall curve in figure 195, was determined from observation and discharge measurements. Discharge measurements whose values of fall plot below, or to the right of, the free-fall curve are unaffected by backwater and those discharges are therefore independent of fall. Discharge measurements whose values of fall plot above, or to the left of, the free-fall curve are affected by variable backwater. For those measurements the graph shows no apparent relation between stage and fall, and the free-fall curve (line of initial submergence) was used as the rating-fall curve for the measurements affected by variable backwater.

The rating for a gaging station whose base gage has no section control is analyzed in a manner similar to that previously described in the section on "Rating Fall Constant—Procedure for Establishing the Rating," the principal difference being that instead of using a constant value of rating fall, the rating fall for any stage is obtained from the rating-fall curve. The rating for a gaging station whose base gage has a section control is analyzed in two separate steps. The free-fall part of the rating (no variable backwater) is analyzed as explained in chapter 10, where simple stage-discharge relations are discussed. That part of the rating that is affected by variable backwater is analyzed as though no section control existed. It is not necessary to use the free-fall rating curve as the basis for establishing that part of the rating that is affected by variable backwater although that course of action is commonly followed.

Summary.—In view of the many different and complex situations that exist in natural channels, it is difficult to give general guidelines for establishing stage-fall-discharge relations. The analyst should make every effort to acquaint himself with the physical characteristics of the channel and the source of variable backwater. The best position of the relation curves that comprise the discharge rating must be determined by trial and error. The complexity of those relations determines, to a large degree, the number of discharge measurements necessary to define the discharge rating. Although the methods are empirical, experience has shown that there may be found a stage-discharge relation (the Q_r curve) which, taken in conjunction with its associated stage-fall relation (the rating-fall curve), will give close approximation to the true discharge under all possible combinations of stage and fall, by the application of a single-curve relation, Q_m/Q_r versus F_m/F_r. It is desirable, but not always possible, to have that relation take the theoretical form,

$$Q_m/Q_r = (F_m/F_r)^{0.5} \tag{80}$$

PROCEDURE FOR ESTABLISHING THE RATING

The general procedure used in establishing a stage-fall-discharge rating with variable fall is outlined as follows:

1. Plot all discharge measurements using stages at the base gage as ordinates and discharges (Q_m) as abscissas, and note the measured fall (F_m) beside each plotted point.

2. On another graph plot the measured fall (F_m) for each discharge measurement against stage at the base gage, using stage as the ordinate.

3. If the base gage has a section control, determine the position of the line of initial submergence on the plot of stage versus measured fall. Its position is based on discharge measurements known to have been made under conditions of free fall. Those measurements, plotted against stage on logarithmic graph paper, are fitted with a free-fall rating curve which is extrapolated in accordance with the principles discussed in chapter 10. The remaining measurements are added to the logarithmic rating plot; those measurements that plot to the left of the extrapolation are considered to be affected by backwater. That knowledge, along with a knowledge of the probable degree of submergence required to cause backwater effect, enables the analyst to fix the position of the line of initial submergence. Only those measurements that plot above, or to the left of, the line of initial submergence are used in the analysis of the rating for variable backwater that is discussed in the steps that follow.

4. Fit a curve, Q_r rating curve, to the stage-discharge plot in step 1, and another curve, F_r, or rating-fall curve, to the stage-fall plot in step 2.

5. From the curves in step 4 obtain values of Q_r and F_r corresponding to the stage of each discharge measurement.

6. Compute the ratios Q_m/Q_r and F_m/F_r for each discharge measurement.

7. Plot Q_m/Q_r as ordinate against F_m/F_r as abscissa, and on that graph draw the curve $Q_m/Q_r=(F_m/F_r)^{0.5}$.

8. On the basis of the scatter of the plotted points about the curve in step 7, adjust the Q_r and F_r curves (step 4) to obtain revised values of Q_r and F_r (step 5), such that the new ratios of Q_m/Q_r and F_m/F_r fit the curve in step 7 as closely as possible. The adjustments to the Q_r and F_r curve should not be so drastic that the adjusted curves are no longer smooth curves.

9. Repeat steps 4–8, using exponents of (F_m/F_r) other than, but close to 0.5. Try exponents equal to 0.40, 0.45, 0.55, and 0.60.

10. Compare the five plots of Q_m/Q_r versus F_m/F_r and select the one which shows the best fit between curve and plotted points. (The ratio of plotted values of Q_m/Q_r to curve values of Q_m/Q_r is identical with

the ratio of measured discharge to discharge obtained from the stage-fall-discharge relations.) In steps 11 and 12 that follow, the exponent of that best fall-ratio curve will be referred to as d.

11. If the plotted ratios closely fit the curve $(Q_m/Q_r) = (F_m/F_r)^d$, that curve and the corresponding Q_r and F_r curves are accepted for use.

12. If the plotted ratios do not closely fit the curve $(Q_m/Q_r) = (F_m/F_r)^d$, repeat steps 4–8, using the exponent d but substituting the terms $(F_m + y)$ for F_m and $(F_r + y)$ for F_r. Several values of y, a small quantity that may be either positive or negative, are tried to obtain a close fit between plotted points and the curve $(Q_m/Q_r) = \left[(F_m+y)/(F_r+y)\right]^d$.

13. Compare the various plots of the fall-ratio graph obtained from step 12 and select the one showing the best fit between curve and plotted points. If the fit is satisfactory, that curve and the corresponding Q_r and F_r curves are selected for use. If the fit is not considered to be sufficiently close, the use of a pure parabolic relation, such as

$$Q_m/Q_r = (F_m/F_r)^d \tag{82}$$

or

$$Q_m/Q_r = \left[(F_m+y)/(F_r+y)\right]^d \tag{83}$$

is abandoned and the strictly empirical approach described in the following steps is used.

14. Select one of the trial Q_r and F_r curves, such as were constructed in step 4, along with the corresponding values of Q_r, F_r, Q_m/Q_r, and F_m/F_r, such as were obtained in steps 5 and 6.

15. Plot the discharge ratios as ordinates and the fall ratios as abscissas, and draw an average curve through the plotted points that passes through the point whose coordinates are (1.0, 1.0).

16. On the basis of the scatter of the plotted points about the curve in step 15, adjust the Q_r and F_r curves (step 14), as well as the fall-ratio curve. Again, the reminder that the adjusted curves must remain smooth curves.

17. Repeat steps 14–16, using other trial curves of Q_r, F_r, and fall ratio versus discharge ratio, until the best relation is established between stage, fall, and discharge; in other words, until a close fit is obtained between plotted points and the fall-ratio curve.

18. After having obtained acceptable Q_r, F_r, and fall-ratio curves, plot adjusted values of the discharge measurements on the Q_r rating curve. The adjusted values are computed as follows: Given a measured discharge (Q_m) and a measured fall (F_m). Enter the F_r curve (stage-fall relation) with the gage height of the discharge measurement and read F_r. Next, compute the fall ratio, F_m/F_r, and enter

the fall-ratio curve to obtain the discharge ratio, Q_m/Q_r. Obtain the value Q_r to be plotted by dividing Q_m by (Q_m/Q_r).

The method of obtaining the discharge corresponding to a given gage height and a given fall (F_m) will be explained in the section titled, "Determination of Discharge from Relations for Variable Backwater."

EXAMPLES OF RATING PROCEDURE

Figures 191–195 are examples of stage-fall-discharge relations for slope stations where fall is a function of stage.

Figure 191 for a Columbia River station shows that excellent results were achieved in the range of discharge that was measured. The linear trend of fall increasing with stage is clearly evident, and the fall-ratio curve not only is represented by the theoretical equation 80, but is closely fitted by the plotted points. Where the rating-fall curve (stage versus fall) is so well defined, the first estimate of the Q_r curve is usually made by the use of equation 80, in which Q would represent the measured discharges. The computed Q_r values for the discharge measurements would then be plotted against stage, and a curve fitted to the plotted points would represent the first trial Q_r curve.

Figure 192 for an Ohio River station is an extremely complex example, as can be seen from the shape of the rating-fall curve. It is not surprising that the fall-ratio curve could not be expressed by a simple parabolic equation such as equation 82 or 83.

Figure 193 for a station on Kelly Bayou shows that there is relatively minor effect from variable backwater at low stages. At medium and high stages, the variable stage of Black Bayou causes variable backwater at the base gage. The rating-fall used during high-water periods has the constant value of 10.0 ft. The fall-ratio curve, for values of F_m/F_r greater than 0.2, has the equation

$$Q_m/Q_r = (F_m/F_r)^{0.44}.$$

Because the exponent 0.44 does not differ greatly from its theoretical value of 0.5, the Q_r rating curve can be extrapolated with some confidence.

Figure 194 for Colusa Weir is an example of the stage-fall-discharge relation for a station whose base gage has a section control. There is no variable backwater at low flow, as shown by the 6 discharge measurements that plot below the line of initial submergence on the graph of stage versus fall. The remaining 16 discharge measurements show the effect of variable backwater. While the fit of adjusted measured discharges to the Q_r rating curve is not completely satisfactory, there is some satisfaction to be derived from the facts that

the equation of the fall-ratio curve is theoretically correct and the fall-ratio curve balances the plotted points.

Figure 195 for a station on the Kootenay River is an example of the stage-fall-discharge relation for a station whose base gage has a control that is unsubmerged at high stages. Of the 59 discharge measurements shown, 23 were made under free-fall conditions; they plot below, or to the right of, the line of initial submergence on the graph of stage versus fall. The remaining 36 discharge measurements are affected by variable backwater and were used in the stage-fall-discharge analysis. Because the line of initial submergence was used as F_r in the analysis, the value of F_m for any measurement affected by backwater is less than F_r. Consequently the fall-ratio curve was fitted empirically to the plotted points and is not expressed by a simple parabolic equation such as equation 82 or 83.

DETERMINATION OF DISCHARGE FROM RELATIONS FOR VARIABLE BACKWATER

After the three necessary graphical relations are available—stage versus rating fall (F_r), stage versus rating discharge (Q_r), and Q_m/Q_r versus F_m/F_r—the graphs are converted to tables. The determination of discharge (Q_m) corresponding to a given stage and a given fall (F_m) proceeds as follows:

1) From the stage-fall table determine the rating fall, F_r, for the known stage.
2) Compute the ratio F_m/F_r.
3) From the table of discharge ratios, (Q_m/Q_r) and fall ratios (F_m/F_r), determine the value of the ratio Q_m/Q_r.
4) From the stage-discharge table, determine the rating discharge, Q_r, for the known stage.
5) Compute Q_m by multiplying the ratio Q_m/Q_r by the value of Q_r.

Much emphasis has been placed on obtaining a purely parabolic function, such as equation 82 or 83, for the relation between fall ratio and discharge ratio. Such a relation not only permits the analyst to extrapolate the Q_r curve with more confidence, but it also expedites the computation of discharge. For example equation 82 may be transposed to

$$Q_m = \left(\frac{Q_r}{F_r^{\alpha}}\right)\left(F_m^{\alpha}\right). \tag{82a}$$

Two tables can be prepared, one giving the values of the quantity (Q_r/F_r^{α}) corresponding to stage, and the other giving values of (F_m^{α}) corresponding to values of F_m. The discharge is then computed as the

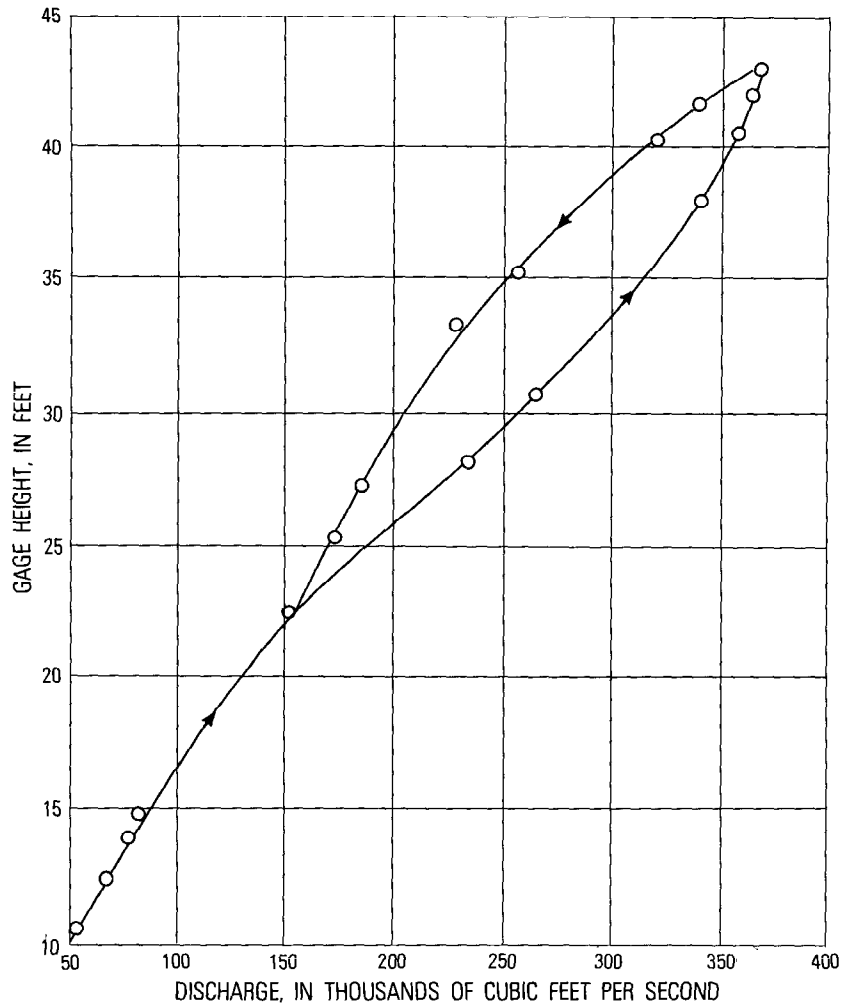

FIGURE 196.—Stage-discharge loop for the Ohio River at Wheeling, W. Va., during the flood of March 14–27, 1905.

product of the two values picked from the tables. Equation 83 may be transposed in a similar way.

VARIABLE SLOPE CAUSED BY CHANGING DISCHARGE

THEORETICAL CONSIDERATIONS

Where channel control is effective, the effect of changing discharge on a graph of the stage-discharge relation is such as to produce a loop curve (fig. 196), on which the discharge for a given stage is greater

when the stream is rising than it is when the stream is falling. In other words, given a simple stage-discharge relation for steady flow—that is, a rating that averages all discharge measurements—it will be found that the measurements made on a rising stage plot to the right of the curve and those made on a falling stage plot to the left. The discharge measurements for individual flood waves will commonly describe individual loops in the rating. The departure of measurements from the rating curve for steady flow is of significant magnitude only if the slope of the stream is relatively flat and the rate of change of discharge is rapid. For gaging stations where this scatter of discharge measurements does occur, the discharge rating must be developed by the application of adjustment factors that relate steady flow to unsteady flow. (Unsteady flow refers to discharge at a site that changes appreciably with time, as in the passage of a flood wave.)

The relation between the discharges for steady and unsteady conditions at the same stage can be derived from the general equations for unsteady flow (Rouse, 1950). A simplified equation shown below may also be derived by neglecting all terms representing change of velocity head or acceleration.

$$\frac{Q_m}{Q_c} = \sqrt{1 + \frac{1}{S_c\, v_w}\,\frac{dh}{dt}} \tag{84}$$

where Q_m is the discharge for unsteady flow, Q_c and S_c are the discharge and energy slope for steady flow at the same stage, v_w is the wave velocity, and dh/dt is the rate of change of stage with respect to time (dh is positive for rising stages).

Because equation 84 is basic to the methods commonly used for adjusting discharge ratings for the effect of changing discharge, it is appropriate to elaborate on its derivation. The ratio of the magnitudes of two discharges that occur at a given stage is equal to the ratio of the square roots of their energy slopes. That principle can be expressed in the following basic equation, which is similar to equation 80 that was used in preceding sections of the manual.

$$\frac{Q_m}{Q_c} = \frac{\sqrt{S_m}}{\sqrt{S_c}} \tag{85}$$

where S_m is the energy slope for unsteady flow at the time of Q_m; the remaining terms are defined above for equation 84.

During changing discharge, the slope of the water surface increases or decreases by an increment of slope (ΔS), where

$$\Delta S = \frac{1}{v_w} \frac{dh}{dt} \cdot \tag{86}$$

If we assume that the increment of slope by which the energy gradient changes is likewise equal to ΔS, then

$$S_m = S_c + \Delta S = S_c + \frac{1}{v_w} \frac{dh}{dt} \cdot \tag{87}$$

By combining equations 85 and 87,

$$\frac{Q_m}{Q_c} = \left(\frac{S_c + \frac{1}{v_w} \frac{dh}{dt}}{S_c} \right)^{1/2}, \tag{88}$$

or

$$\frac{Q_m}{Q_c} = \left(1 + \frac{1}{S_c v_w} \frac{dh}{dt} \right)^{1/2} \cdot \tag{84}$$

The wave velocity v_w in the above equations may be evaluated by the Seddon principle (Seddon, J. E., 1900).

$$v_w = \frac{1}{B} \frac{dQ}{dh},$$

where B is the width of the channel at the water surface, and dQ/dh is the slope of the stage-discharge curve for constant-flow conditions. From examination of formulas for mean velocity (V_m) in open channels, the ratio of wave velocity to mean velocity may be shown to vary as follows,

	Ratio v_w/V_m	
Channel Type	*Manning*	*Chezy*
Triangular	1.33	1.25
Wide rectangular	1.67	1.50
Wide parabolic	1.44	1.33

Experience seems to indicate that the most probable value of the ratio in natural channels is 1.3.

Equation 84 explains why the effect of changing discharge is significant only on flat streams during rapid changes in discharge; that combination is necessary to make the right-hand side of the

equation differ significantly from unity. During rapid changes in discharge, absolute values of dh/dt are large. On flat streams both energy slope (S_e) and wave velocity (v_w) are small. The combination of a large value of dh/dt and small values of S_e and v_w gives the right-hand side of the equation a value that is significantly larger than unity during a rising stage (dh/dt is positive) and significantly smaller than unity during a falling stage (dh/dt is negative).

METHODS OF RATING ADJUSTMENT FOR CHANGING DISCHARGE

The two methods used to adjust discharge for the effect of changing slope attributable to changing discharge are the Boyer method and the Wiggins method. Both methods are based on equation 84. The knowledgeable reader of this manual may notice that the Jones and Lewis methods are not included among the techniques for adjusting discharge. Those two methods have been supplanted by the somewhat similar Boyer method and therefore are not described here. For a description of the Jones and Lewis methods the interested reader is referred to the manual by Corbett (1943, p. 159–165).

BOYER METHOD

The Boyer method provides a solution of equation 84 without the necessity for individual evaluation of v_u and S_e. The method requires numerous discharge measurements made under the conditions of rising and falling stage. Measured discharge (Q_m) is plotted against stage in the usual manner, and beside each plotted point is noted the value of dh/dt for the measurement. For convenience dh/dt is expressed in feet or meters per hour and the algebraic sign of dh/dt is included in the notation—plus for a rising stage and minus for a falling stage. A trial Q_e rating curve, representing the steady-flow condition where dh/dt equals zero, is fitted to the plotted discharge measurements, its position being influenced by the values of dh/dt noted for the plotted points. Values of Q_e from the curve corresponding to the stage of each discharge measurement, are used in equation 84, along with the measured discharge (Q_m) and observed change in stage (dh/dt), to compute corresponding values of the adjustment factor, $1/S_e v_u$. The computed values of $1/S_e v_w$ are then plotted against stage and a smooth curve is fitted to the plotted points. If the plotted values of $1/S_e v_w$ scatter widely about the curve, the Q_e curve is modified to produce some new values of $1/S_e v_u$ that can be better fitted by a smooth curve. The modifications of the curves of Q_e and $1/S_e v_u$ should not be so drastic that the modified curves are no longer smooth curves, nor should the modified shape of the Q_e rating curve violate the principles underlying rating curves, as discussed in chap-

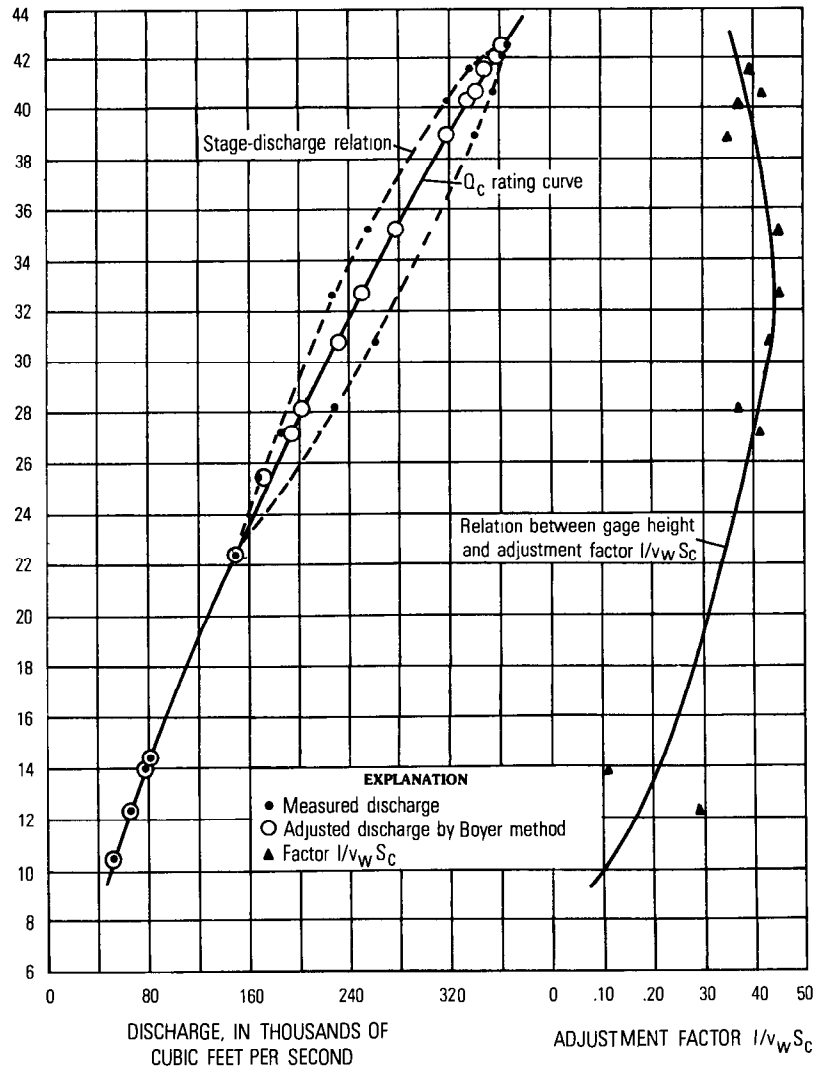

FIGURE 197.—Adjustment of discharge measurements for changing discharge, Ohio River at Wheeling, W. Va., during the period March 14–27, 1905.

ter 10. Construction of the two curves completes the rating analysis. Figure 197 is an example of such an analysis.

To adjust the value of subsequent discharge measurements for plotting on the Q_c rating curve, the adjustment-factor curve is first entered with the stage of the measurement to obtain the appropriate value of the factor, $1/S_c v_w$. Next, the observed value of dh/dt is used

with that factor to compute the term, $\left(1+\frac{1}{S_c v_w}\frac{dh}{dt}\right)^{0.5}$. That term is then divided into the measured discharge (Q_m) to obtain the required value of Q_c.

To determine discharge from the Q_c rating curve and adjustment-factor curve, during a period when the stage and rate of change of stage are known, the procedure described above is used to obtain the value of the term $\left(1+\frac{1}{S_c v_w}\frac{dh}{dt}\right)^{1/2}$. That term is then multiplied by Q_c, which is obtained by entering the Q_c rating curve with the known stage. The product is the required discharge (Q_m).

WIGGINS METHOD

The Wiggins method is convenient for adjusting measured discharge (Q_m) for the effect of changing discharge to obtain the corresponding steady-flow discharge (Q_c). However, the reverse procedure of computing discharge for unsteady flow (Q_m) from the steady-flow discharge rating is rather complicated. Consequently, the Wiggins method is used only for those stations where only occasional adjustment of measured discharge at high stages is required. If the discharge is affected by changing stage on numerous days each year, the more accurate Boyer method of discharge adjustment should be used. Unlike the Boyer method, application of the Wiggins method does not require numerous discharge measurements that have been made under conditions of both rising and falling stage.

The discharge measurement adjusted by the Wiggins method are used to define the steady-flow rating, and that rating is used directly with the gage-height record to obtain daily values of discharge. That course of action is justifiable for those streams whose discharge is affected by changing discharge on only a few days each year. For that type of stream, it will generally be found that the discharge adjustment is less than 10 percent. On the affected days, the discharge obtained from the steady flow rating will be underestimated by a small percentage when the discharge is rising rapidly, and overestimated by a small percentage when the discharge is falling rapidly. The discrepancies are compensating, and if only few days are involved, the streamflow record is not significantly impaired. The advantage of applying the adjustment to discharge measurements made under unsteady-flow conditions is that the scatter of discharge measurements on the rating curve is reduced, and the rating curve can therefore be more precisely defined.

Application of the Wiggins method has been simplified by the preparation of diagrams that eliminate much of the computational labor. Figures 198*A-D* are used to determine the value of the energy slope

(S_m) at the time of the discharge measurement (Q_m), for combinations of values of mean velocity (V_m) and hydraulic radius (R). The Manning equation was used in preparing the graphs, and each of the four sheets is applicable for a particular value of Mannings n, as shown in the following tabulation:

Figure 198A—n=0.025 Smooth bed and banks.
198B—n=0.035 Fairly smooth.
198C—n=0.050 Rough.
198D—n=0.080 Very rough.

Figure 199 is used to determine the increment of energy slope $\left(\frac{1}{v_w}\frac{dh}{dt}\right)$ attributable to changing discharge, for combinations of values of flood-wave velocity (v_w) and rate of change of stage (dh/dt). Flood-wave velocity is assumed to equal $1.3V_m$.

Figures 200*A* and *B* are used to determine the factor to apply to the measured discharge (Q_m) to obtain the steady-flow discharge (Q_c). The factor, which is equal to

$$\left[\frac{S_m-\left(\frac{1}{\bar{v}_u}\right)\left(\frac{dh}{dt}\right)}{S_m}\right]^{0.5},$$

is given for combinations of values of S_m from figure 198 and of $\left(\frac{1}{v_w}\frac{dh}{dt}\right)$ from figure 199. (Note that the factor differs from that given in equation 88, because S_m is used here as the base slope, rather than S_c as in equation 88.) Figure 200*A* is used for rising stages and figure 200*B* is used for falling stages.

An example of the use of the Wiggins diagrams follows.

Given: a discharge measurement with the following data for a stream with fairly smooth bed (n=0.035);

Q_m=23,000 ft^3/s
Area=53,900 ft^2
Width= 2,700 ft
V_m=4.27 ft/s
Change in stage=0.87 ft in 1.5 hours (rising)

Compute adjusted discharge to be plotted on rating curve.

First compute:

$$R = \frac{\text{Area}}{\text{Width}} = \frac{53{,}900}{2{,}700} = 20 \text{ ft}$$

$$v_u = 1.3\ V_m = 1.3 \times 4.27 = 5.55 \text{ ft/s}$$

$$\frac{dh}{dt} = \text{change in stage per hour} = \frac{0.87}{1.5} = 0.58 \text{ ft/hr}$$

Then: (a) Enter figure 198*B* with $V_m = 4.27$ and $R = 20$ and read $S_m = 0.00018$

(b) Enter figure 199 with $\frac{dh}{dt} = 0.58$ and $v_w = 5.55$ and read slope increment $(\frac{1}{v_w}\frac{dh}{dt}) = 0.000029$

(c) Enter figure 200*A* (rising stage) with $S_m = 0.00018$ and slope increment = 0.000029 and read factor = 0.915.

Adjusted discharge = 0.915 × 230,000 = 210,000 ft³/s.

Because the stage was rising, the unadjusted discharge would plot to the right of the rating curve. The computed adjustment moves the measurement to the left.

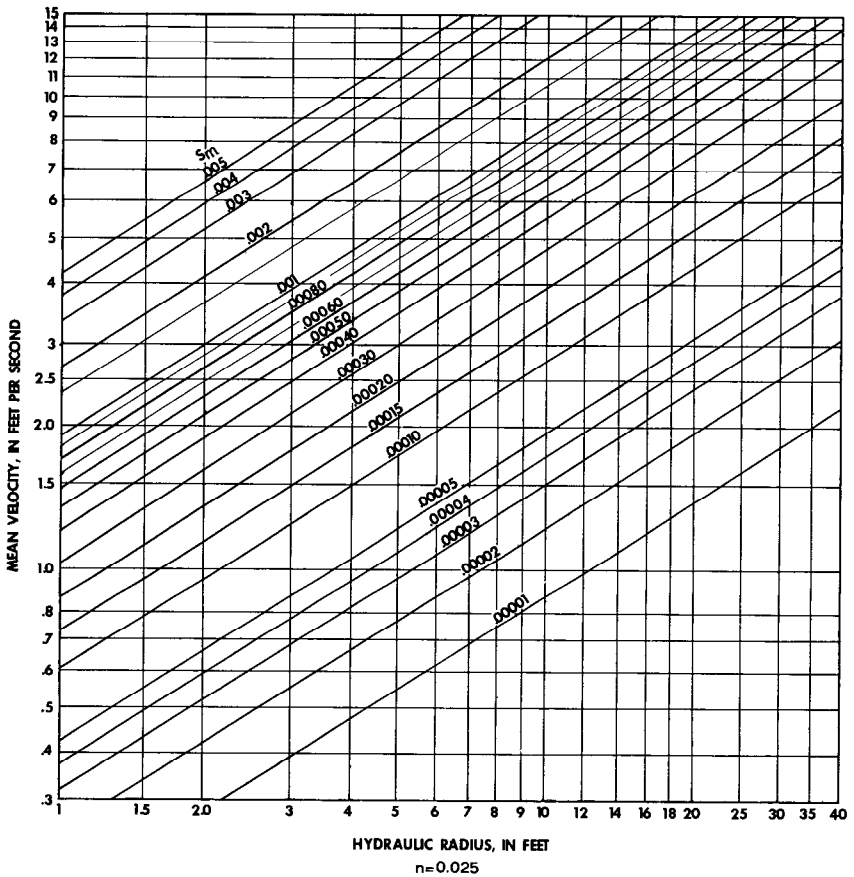

FIGURE 198*A*.—Diagram for solution of the Manning equation to determine S_m. Smooth bed and banks (n=0.025).

Both the measured (Q_m) and adjusted (Q_c) discharges are entered in the list of discharge measurements and both are plotted on the rating curve. Suitable symbols are used, however, to differentiate between the measured and adjusted discharges.

VARIABLE SLOPE CAUSED BY A COMBINATION OF VARIABLE BACKWATER AND CHANGING DISCHARGE

Where the rating for a gaging station is affected by a combination of variable backwater and changing discharge, the rating should be analyzed as though it were affected by variable backwater only, using the fall-rating methods described in the section titled, "Rating Fall a Function of Stage." The basic equation for variable-backwater adjustments (eq. 80) and that for changing-discharge adjustments (eq.

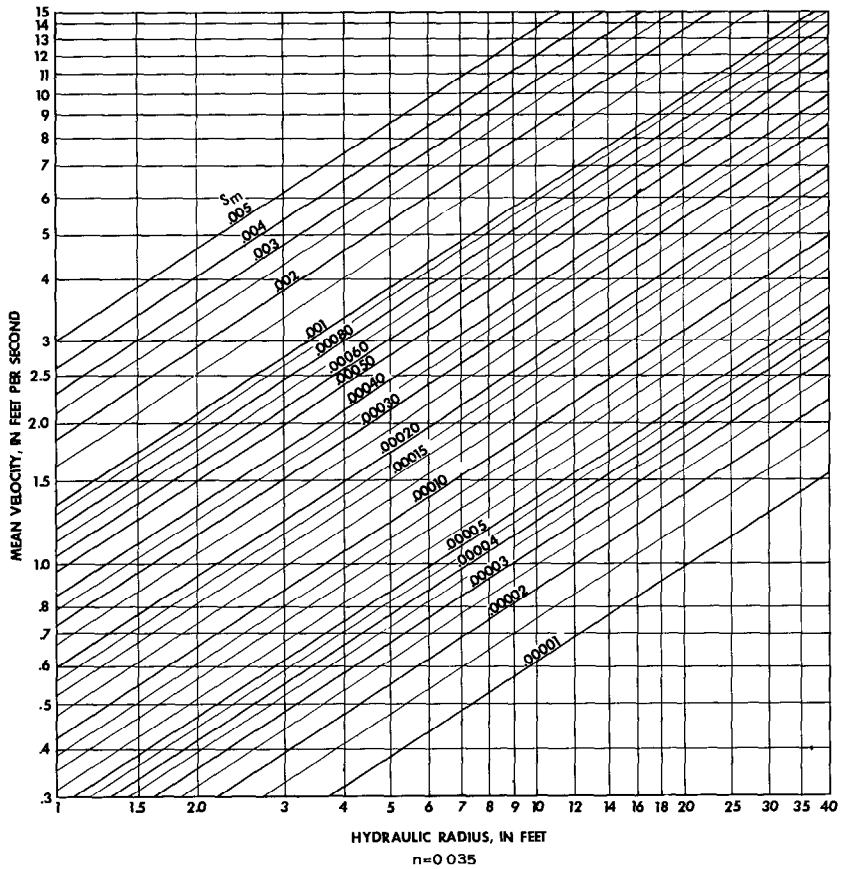

FIGURE 198*B*.—Diagram for solution of the Manning equation to determine S_m. Fairly smooth bed (n=0.035).

85) are similar, but only the fall-rating methods are versatile enough to handle the combined effect of the two factors.

SHIFTS IN DISCHARGE RATINGS WHERE SLOPE IS A FACTOR

Changes in channel geometry (scour or fill) and (or) changes in flow conditions (vegetal growth) will cause shifts in the discharge rating where slope is a factor, just as they cause shifts in simple stage-discharge relations. When discharge measurements indicate a shift in the rating for a slope station, the shifts should be applied to the Q_r rating curve if the station is affected by variable backwater, or to the Q_c rating curve if the station is affected by changing discharge. Extrapolation of the shift curves should be performed in accordance with the principles discussed in chapter 10 for shifts in simple stage-

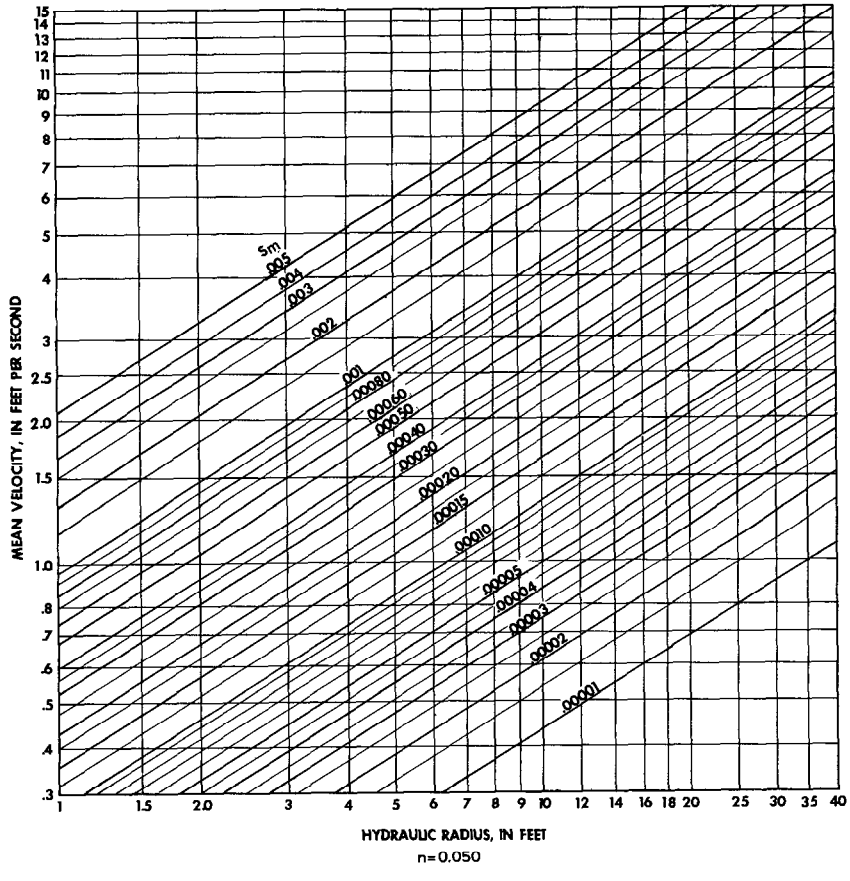

FIGURE 198*C*.—Diagram for solution of the Manning equation to determine S_m. Rough bed (n=0.050).

discharge relations. (See section in chapter 10 titled, "Shifts in the Discharge Rating.")

A SUGGESTED NEW APPROACH FOR COMPUTING DISCHARGE RECORDS FOR SLOPE STATIONS

Now that the use of electronic computers has become commonplace, it appears that a fresh approach might be tried with regard to computing streamflow records for gaging stations equipped with a stage-recorder at each end of a slope reach. Instead of using the various graphical empiricisms that were described in this chapter, a computer program could be written to compute discharge for the reach by the Manning equation or by some similar equation for open-channel flow. (It is assumed that acceleration head can be neglected.) Dis-

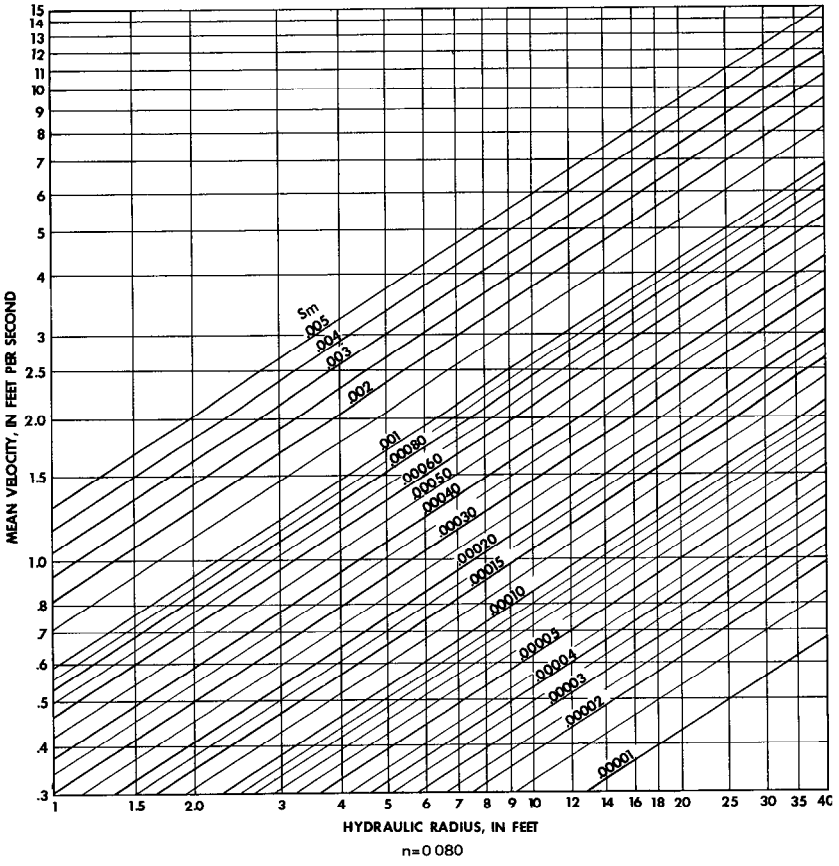

FIGURE 198*D*.—Diagram for solution of the Manning equation to determine S_m. Very rough bed (n=0.080).

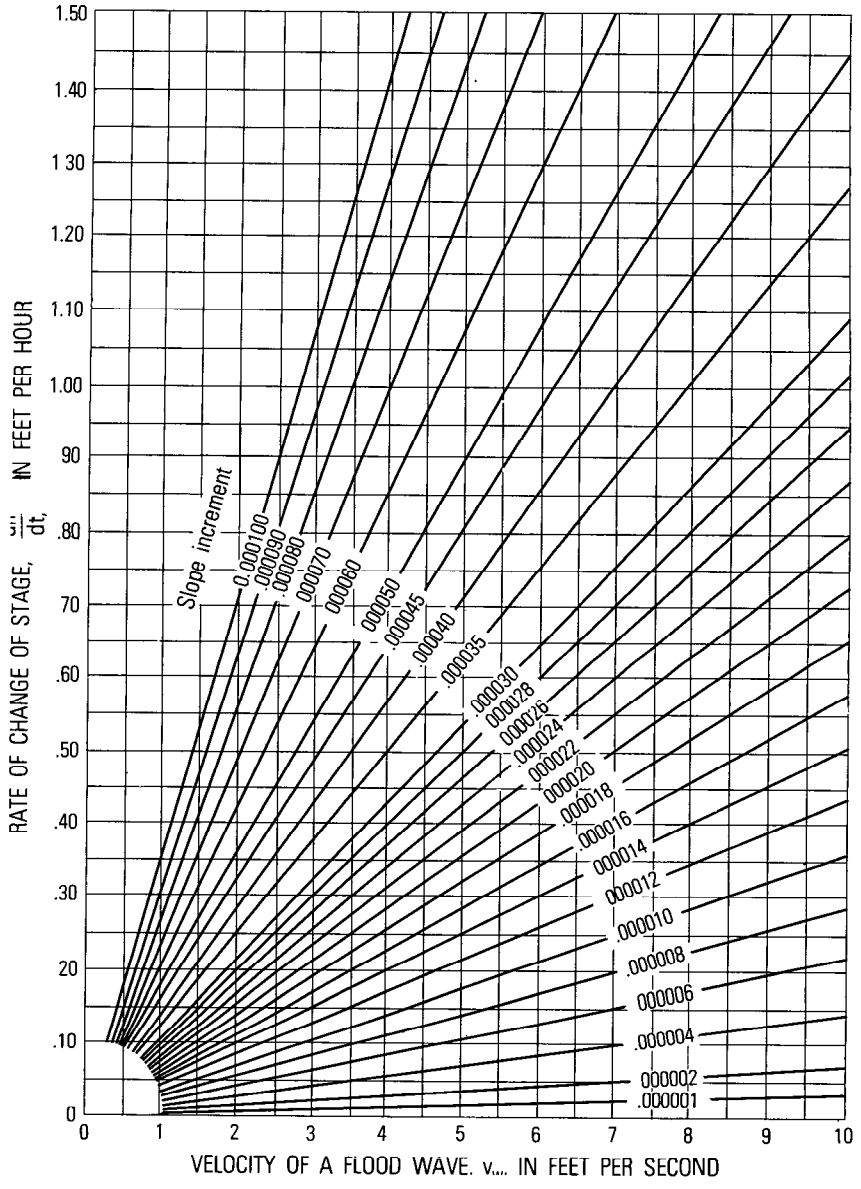

FIGURE 199.—Diagram for determining slope increment resulting from changing discharge.

charge measurements would be made solely for the purpose of determining the Manning roughness coefficient (n) from the measured discharge, thereby obtaining the only unkown factor needed to compute the conveyance (K) at each end of the slope reach.

The value of n computed from a discharge measurement usually would not represent the true value of the roughness coefficent but would actually be a "catchall" value that included the effect of error in the computed value of the energy slope in the reach. The computed values of n would likely vary with stage.

The discharge computations would proceed along the following lines. The basic form of the Manning equation is

$$Q = KS^{1/2} \tag{89}$$

where

Q is discharge;
K is conveyance, which is equal to $\frac{1.49}{n} AR^{2/3}$ (A is cross-sectional area and R is hydraulic radius); and
S is the energy gradient.

Equation 89 can be expanded to

$$Q = K_2 \sqrt{\frac{F}{\frac{K_2}{K_1} L + \frac{K_2^2}{2gA_2^2}\left[-\alpha_1\left(\frac{A_2}{A_1}\right)^2(1-k)+\alpha_2(1-k)\right]}} \tag{90}$$

where

F is fall in the reach,
L is length of reach,
g is the acceleration of gravity,
α is the velocity-head coefficient whose value is dependent on the velocity distribution in the cross section,
k is a coefficient of energy loss whose value is considered to be zero for contracting reaches and 0.5 for expanding reaches;
subscript 1 refers to the upstream cross section, and
subscript 2 refers to the downstream cross section.

For the cross section at each end of the slope reach, relations would be prepared between stage and each of the following three elements: K, A, and α. A computer program would be written to solve equation 90. Then, given the stage at each end of the reach, the computer would compute F, A, K, α, and finally, Q.

For those slope stations where the change in velocity head in the reach is so minor an item that it can be neglected, the conventional constant-fall method (see section titled, "Rating Fall Constant") could be continued in use; computer computation would be optional.

It is emphasized that the above method of computing discharge records is as yet untried, but it is suggested that it be tested.

CHAPTER 12—DISCHARGE RATINGS USING A VELOCITY INDEX AS A PARAMETER

INTRODUCTION

Chapter 11 discussed the use of a slope parameter for developing discharge ratings at gaging stations where the use of stage alone was inadequate for rating purposes. However, it is not feasible to use a slope parameter for all stations for which no simple stage-discharge relation can be developed. Often slopes are so flat that the available reach of channel for developing slope is too short to give sufficiently accurate values of fall in the reach. At other sites, as on tidal streams or on some streams used for hydroelectric power generation, the acceleration head (p. 391) in the equations of unsteady flow is of such magnitude that it cannot be ignored as was done in chapter 11. In those situations it is often possible to develop a discharge rating by using a velocity index in a stage-velocity-discharge relation.

The principle behind a stage-velocity-discharge relation is simple enough. A continuous stage record provides a means of obtaining a continuous record of cross-sectional area from a relation of area to stage. If a continuously recorded velocity index, at a point or in a transverse line, can be related to stage and mean velocity in the cross section, the product of cross sectional area and mean velocity gives the discharge at any time. The calibration of the velocity relation—that is, the relation of recorded index velocity to stage and mean velocity—requires discharge measurements for the determination of mean velocity. The discharge measurements also furnish the values of cross-sectional area to be used in the stage-area relation.

Four types of instrumentation have been used to provide an index of mean velocity in a measurement cross section. They are:

1. standard current meter,
2. deflection meter,
3. acoustic velocity meter, and
4. electromagnetic velocity meter.

The simplest instruments for recording velocity at a fixed point in the cross section are the standard current meter and the deflection meter. Their use is limited to the smaller streams and canals where the hazard of damage by boats or debris is minimal. The acoustic velocity meter integrates the velocity along a transverse line in the stream. It has been used in large rivers to provide an index to mean velocity in the measurement cross section. The use of an electromagnetic velocity meter is still (1980) in the experimental stage, and its use has been limited mostly to the smaller streams. Experimental work in the U.S.A. with the electromagnetic current meter has been largely in the use of the meter to obtain a continuous record of velocity at a point; in several European countries the experimental

work has been largely in the use of the meter to obtain a continuous record of an index value of integrated mean velocity in the entire measurement cross section.

STANDARD CURRENT-METER METHOD

The use of an unattended standard current meter, securely anchored in a fixed position in the stream below the minimum expected stage, is attractive because of the simplicity of the device. The most desirable location for the meter will be in the central core of the flow, away from the influence of the banks or any other impediment to flow, where streamlines are parallel and at right angles to the measurement cross section. For streams of irregular alignment or cross section, it may be necessary to experiment with meter location to determine the most suitable site for the meter.

Any of several schemes may be used for recording revolutions of the current meter. For example, one might use a modification of the system for recording velocity that was described earlier for the moving-boat method of measuring discharge (see section in chapter 6 titled, "Rate Indicator and Counter"). In that system a clock-activated moving chart is automatically marked after each occurrence of a predetermined number of meter revolutions. In another system that might be used, the current meter would be connected to a digital recorder and at predetermined time intervals—say, 15 minutes—the number of revolutions that occurred in the preceding 15 minutes would be punched. In either system the current-meter rating equation would be used to convert revolutions per time interval to average velocity during the time interval.

As mentioned earlier, discharge measurements would be used to calibrate the stage-velocity-discharge relation. The cross-sectional areas shown by the discharge measurements would be used with stage to define the stage-area relation, which could be extrapolated by the use of data obtained in a field survey. The mean velocities shown by the discharge measurements would be used in a graphical relation of mean velocity to stage and to the index velocities indicated by the fixed current meter. Extrapolation of that relation would be aided if a vertical-velocity curve were obtained at the site of the index current meter at the time of each discharge measurement, and if the mean velocity in the vertical at the index meter site, as computed from each vertical velocity curve, were related to mean velocity in the measurement cross section. The use of such relations is illustrated in the hypothetical example that follows where, for simplicity, it is assumed that the relations can be expressed mathematically.

Assume that the vertical-velocity curves at the index site can consistently be defined by the equation,

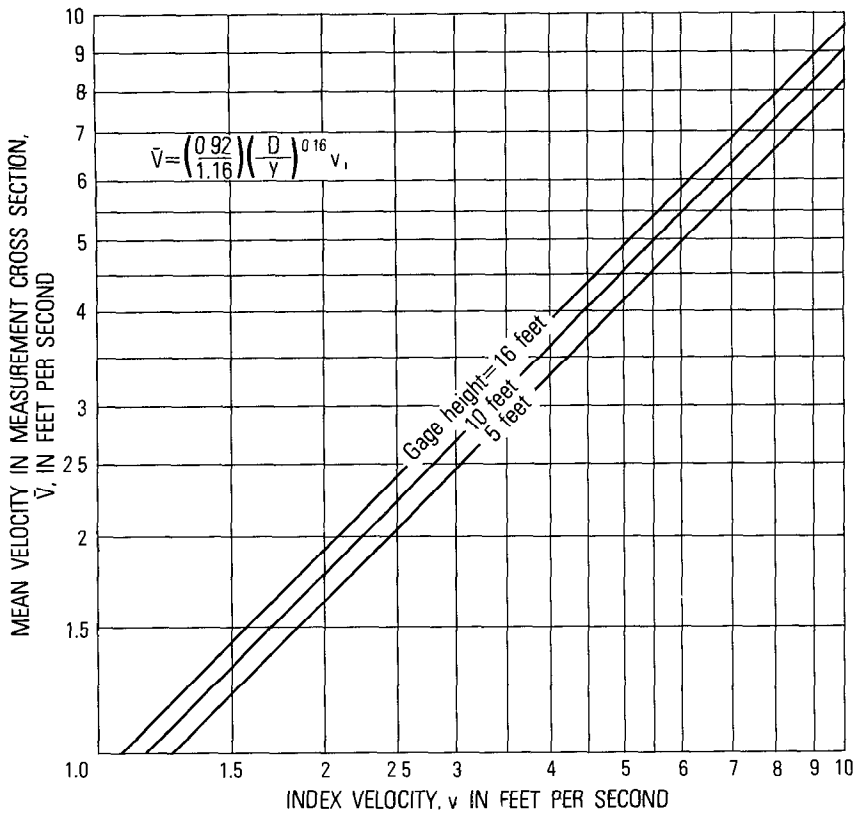

FIGURE 201.—Hypothetical relation of mean velocity in measurement cross section to stage and index velocity.

$$v_i = 1.16\ V_m\ (y/D)^{0.16},$$

where

V_m is the mean velocity in the vertical,

D is the depth, and

v_i is the velocity at a height, y, above the streambed.

Assume further that the ratio of mean velocity in the measurement cross section to mean velocity in the vertical at the index-meter site is consistently 0.92. It is also assumed that gage height and depth are equivalent, that stage is expected to range from 6 to 16 ft, and that the index meter is set at an elevation 5 ft above the streambed. Under those assumptions, the relation of mean velocity in the cross section to stage and index velocity would be that shown in figure 201. The mean velocity obtained by the use of figure 201 would be multiplied by the appropriate cross-sectional area to obtain the required discharge.

The utilization of a standard current meter to obtain an index of mean velocity has certain disadvantages that inhibit its use. The meter is susceptible to damage or impairment by submerged drift, but even where that hazard is negligible, there is a strong tendency for the meter to become fouled, after long immersion, by algae and other aquatic growth that becomes attached to the meter. Stoppage or impaired operation of the meter invariably results from the attachment of such growth, and constant servicing of the meter is usually a necessity. Suspended sediment in the stream also adversely affects the operation of an unattended current meter.

DEFLECTION-METER METHOD

GENERAL

Deflection meters are used to provide a velocity index in small canals and streams where no simple stage-discharge relation can be developed. The inability to develop a simple stage-discharge relation usually results from tide effect or from downstream gate operations to regulate the flow. At such gaging stations a recording stage-gage is operated in conjunction with the deflection meter.

The deflection meter has a submerged vane that is deflected by the force of the current. The amount of deflection, which is roughly proportional to the velocity of the current impinging on the vane, is transmitted either mechanically or electrically to a recorder. Values of the mean velocity of the stream are determined from discharge measurements, and mean velocity is then related to deflection and stage.

The ideal location for a deflection meter is in midchannel of a straight reach. However, it seldom is feasible to install the meter in midchannel; a site close to the bank of a straight reach is usually used.

Through the years, two basic types of deflection vane have evolved—the vertical-axis and the horizontal-axis types. The vertical-axis type has been most commonly used. Both types are described in the sections that follow.

VERTICAL-AXIS DEFLECTION VANE

The vertical-axis deflection vane is attached to a vertical shaft that is free to pivot about its vertical axis. Figure 202 shows two variations of the vertical-axis deflection vane. Vane A on the left is designed to sample a "point" or local velocity; vane B on the right is designed to integrate velocities throughout the greater part of a vertical. Vane B is used particularly in tidal streams where at times during a tidal cycle, stratification and density currents occur. At those times the denser salt water at the bottom of the channel flows upstream while fresh water in the upper zone starts to flow seaward.

Vane B extends from about 6 inches above the streambed to an elevation just below the water surface at low tide. While vane B is used in other circumstances, it cannot be used in a narrow channel where velocities are high, because a hydraulic jump may occur on the downstream side of the vane and affect the meter rating.

The force of the current acting on a vertical-axis vane turns the vertical shaft and the motion is transmitted to a graphic or digital

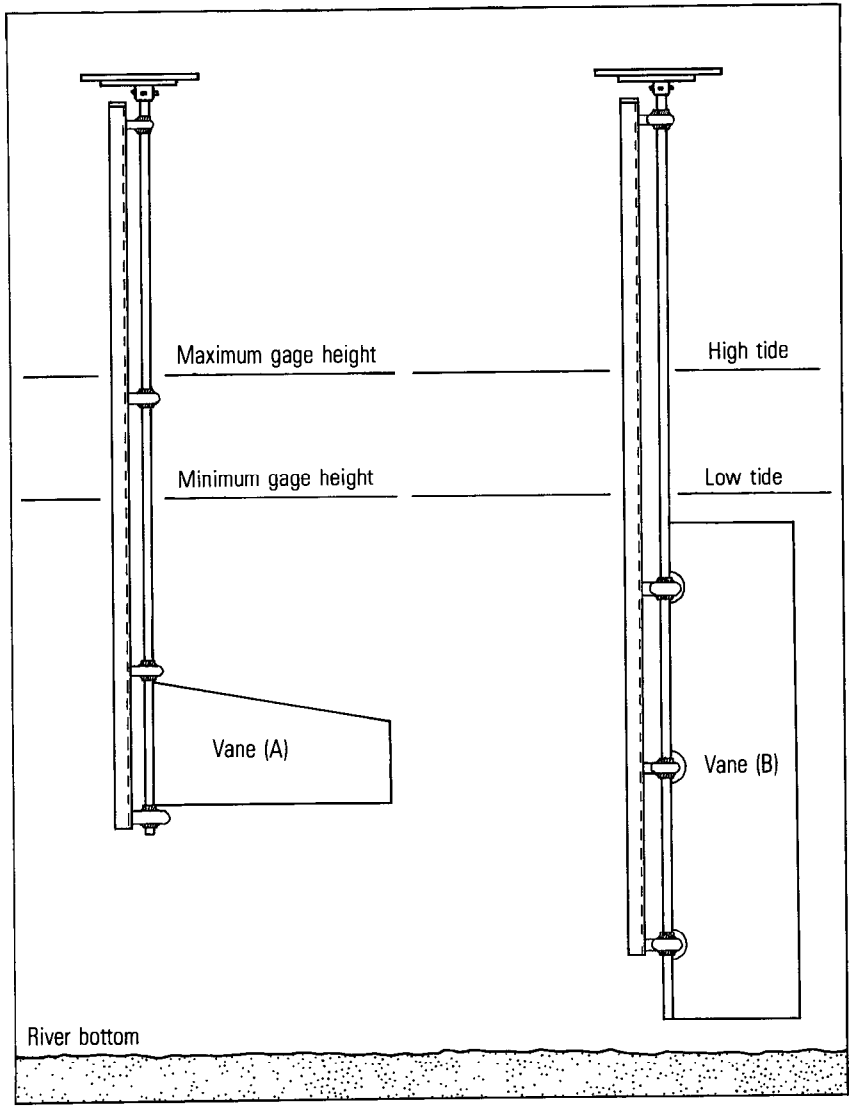

FIGURE 202.—Sketch of two types of vertical-axis deflection vanes.

recorder. A graphic recorder is shown in the system in figure 203. The vertical shaft also has an index plate fastened to it, and to the index plate is attached a counterweighted cable. When the velocity is zero, no lateral force is exerted on the vane and the counterweight will hold the vane in a position that is perpendicular to the direction of flow. A 15- to 20-pound counterweight is generally used with most vanes, but high velocities and (or) the use of a large vane may necessitate the use of a heavier counterweight in order to provide the counter-torque necessary to resist the rotary movement of the vane.

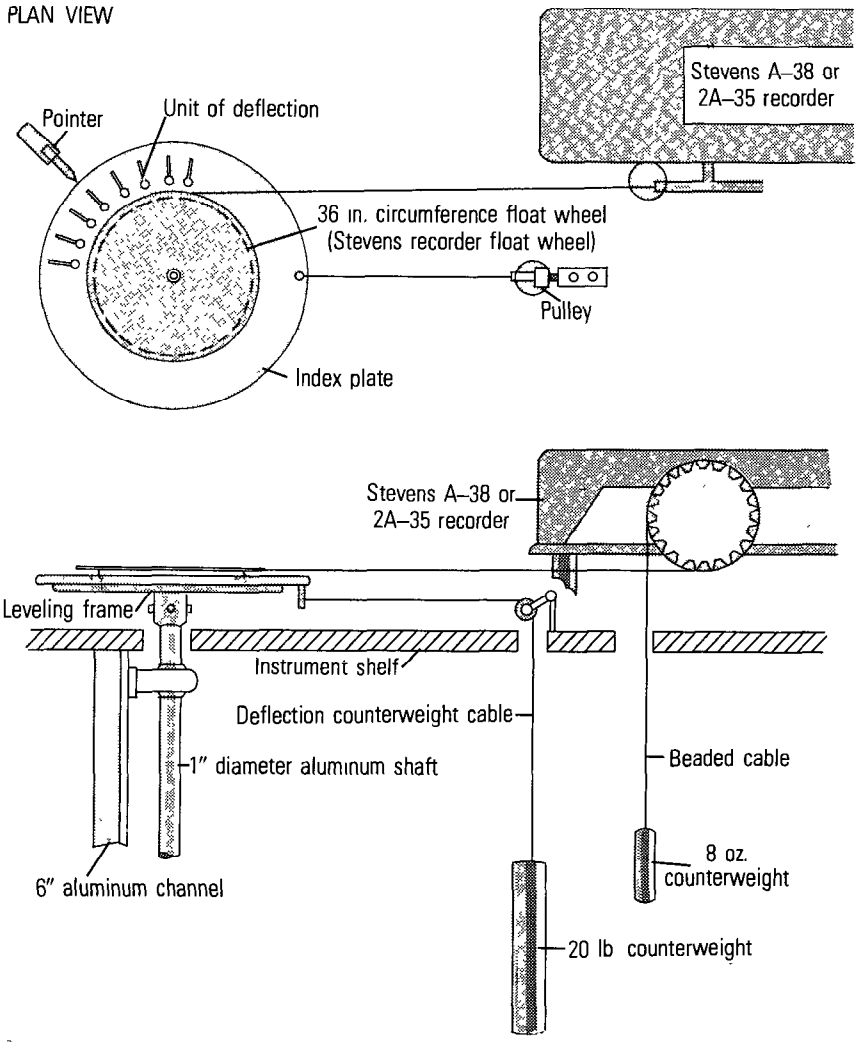

FIGURE 203.—Plan and front elevation views of a vertical-axis deflection meter attached to a graphic recorder.

A pointer for indicating the units of deflection on the index plate is attached to the instrument shelf. The index plate is calibrated by placing the recorder pen at zero position on the recorder and locking it there. The index plate is then scribed with a mark opposite the pointer. The index plate is rotated until the pen moves 1 inch on the recorder chart and another mark is scribed opposite the pointer. This process is repeated until marks for the full range of deflection have been scribed on the index plate and numbered. These units of deflection on the calibrated index plate are the reference marks for checking and resetting the recorder pen on future inspections of the deflection meter.

The vertical-axis deflection vane does have several drawbacks, the most serious of which is its tendency to collect floating debris which, in turn, affects the calibration of the vane. Another problem is the high degree of bearing friction resulting from the weight and bearing system of the vane assembly; the friction causes insensitivity at low velocities. In addition, removal of the vane for service and repair is difficult because of the weight involved. Furthermore, the projection of the vane assembly above the water surface makes it susceptible to damage by ice.

HORIZONTAL-AXIS DEFLECTION VANE

A recent development is the horizontal-axis or pendulum type deflection vane. This type is designed to overcome many of the difficulties mentioned in connection with the vertical-axis vane. For example, the pendulum vane can be installed with the mount totally submerged, thus reducing the possibility of collecting debris at or near the water surface where such debris is usually found. Its light weight and simplified bearing design greatly reduce the bearing friction, thus improving its low-velocity characteristics. Because no parts protrude from the water, there is little danger of damage by ice.

The pendulum-type vane consists of a flat triangular plate, suspended from above, that pivots about a horizontal axis located at the apex of the triangle (fig. 204). Interchangeable weights are available for attachment to the base of the triangular plate, thereby providing for optimum adjustment to the desired veolcity range. The location and design of the weights serve the additional purpose of reducing fluctuations caused by eddy shedding.

The force of the current acting on the horizontal-axis vane causes it to deflect. The angle formed by the vane itself and a small reference pendulum sealed within the pivot chamber is the angle of deflection. A potentiometer is positioned to generate an electrical signal that is proportional to the angle of deflection. The voltage that is generated is converted to a proportional shaft position for recording by a digital or graphic recorder.

It can be demonstrated that when the horizontal-axis vane is deflected by flowing water and the system is in mechanical equilibrium, the following relation exists between velocity of the water, angle of deflection, and the physical properties of the vane:

$$V^2 = \left(\frac{2WL_M}{\rho A L_A}\right)\left(\frac{\sin\Theta}{C_D\cos^2\Theta + C_L\sin^2\Theta}\right),$$

where V is horizontal velocity of the water,
W is weight of the pendulum in water,

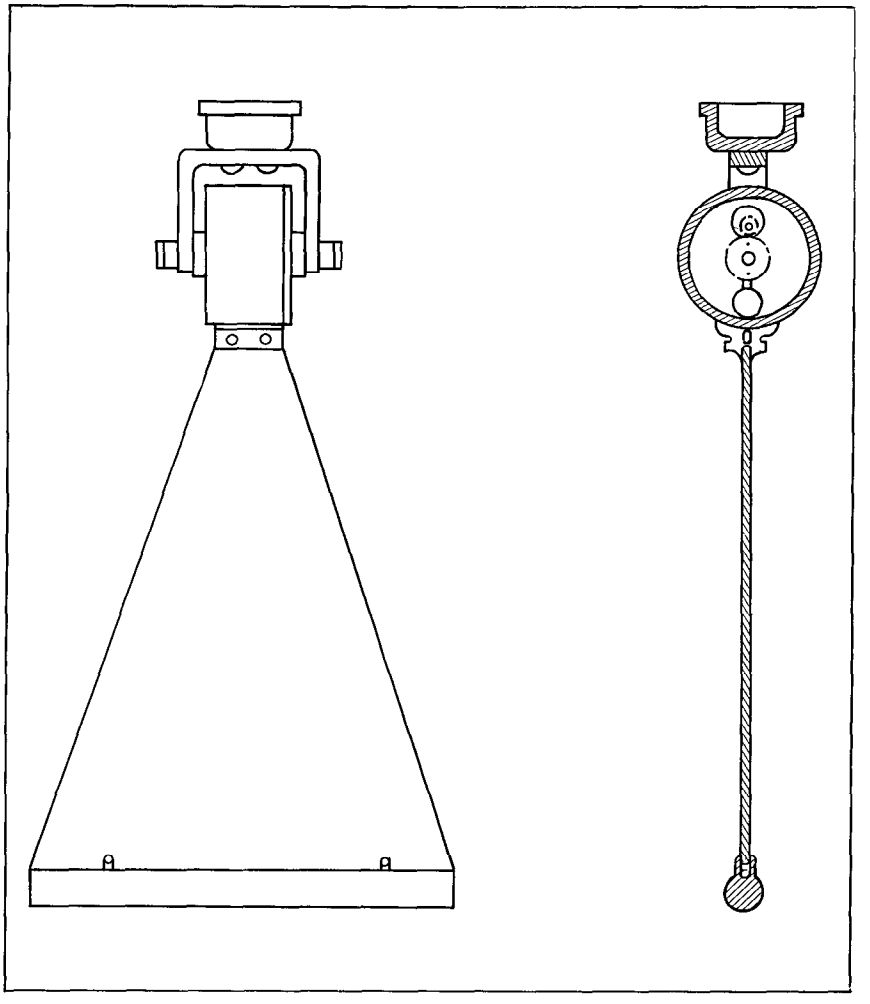

FIGURE 204.—Sketch of a pendulum-type deflection vane.

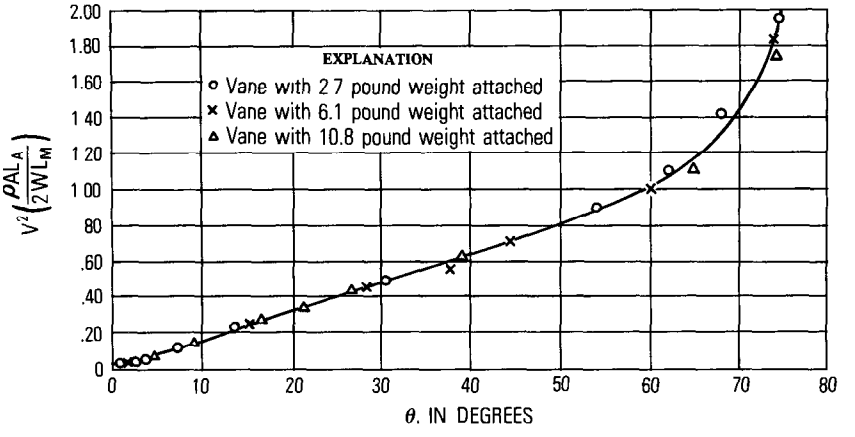

FIGURE 205.—Calibration curve for pendulum-type deflection vane.

ρ is the density of water,
A is the area of the vane,
L_M is the distance from the pivot point to the center of mass,
L_A is the distance from the pivot point to the center of the area,
Θ is the angle of deflection,
C_D is the coefficient of drag, and
C_L is the coefficient of lift.

Figure 205 is a graphical presentation of the above relation that can be used for selecting the weight needed for a given velocity range.

EXAMPLES OF STAGE-VELOCITY-DISCHARGE RELATIONS BASED ON DEFLECTION-METER OBSERVATIONS

Figure 206 shows a graphic-recorder chart for a gaging station in Florida where tidal flow reverses direction. The upper pen trace shows the stage at various times during the tide cycle for the period May 4–6, 1962. The lower pen trace shows the deflection units recorded during the same period. Zero flow is represented by a reading of four units on the deflection scale. Flow is in the seaward direction when the deflection is less than 4 units (hachured part of deflection graph in fig. 206); flow is in the inland direction when the deflection is greater than four units.

The rating curves shown in figure 207 were derived from discharge measurements. The units of deflection are indicative of velocity in a single vertical in the channel, having been obtained from a vertical-axis deflection meter equipped with vane B (fig. 202). The velocity curve shows the relation of deflection units to measured mean velocity in the channel; stage was not a factor in the relation because of the limited range (2 ft) in stage. For deflections of less than four units, velocity is negative, meaning that flow is in the seaward direction.

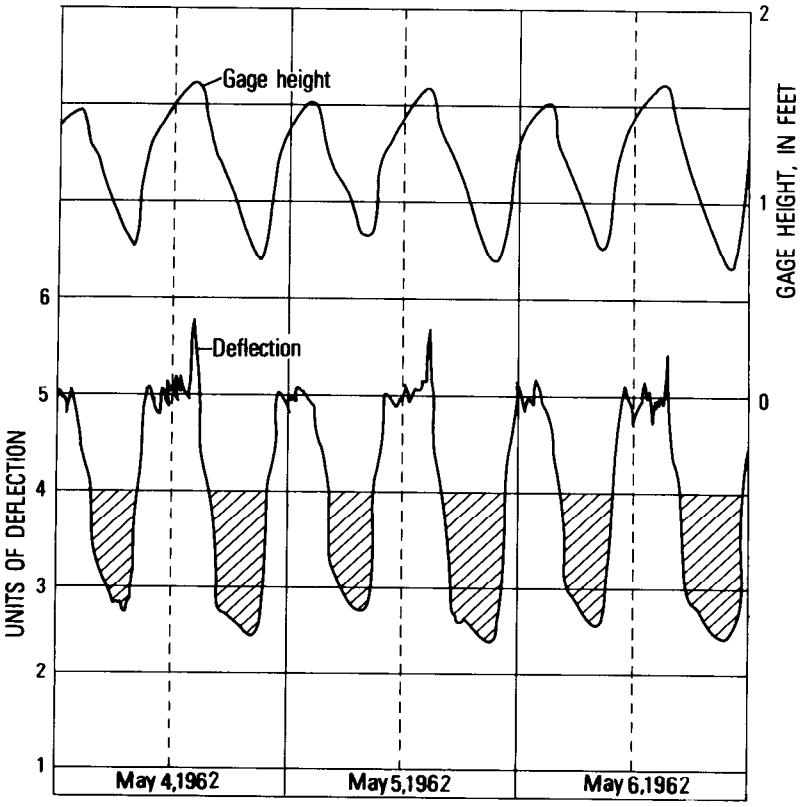

FIGURE 206.—Recorder chart for a deflection-meter gaging station on a tidal stream.

The stage at the time of discharge measurements was used to construct the area curve, which relates stage to cross-sectional area. Discharge is computed by multiplying area by mean velocity; negative values of discharge indicate seaward flow and positive values indicate inland flow.

Figure 208 shows the rating for a gaging station at the outlet of a large natural lake, immediately downstream from which are gates that regulate the flow for hydroelectric-power generation farther downstream. The deflection meter at the station is of the vertical-axis type and is equipped with vane A (fig. 202) to measure deflection at a "point" in the rectangular channel. Instead of deriving separate relations of stage versus cross-sectional area and deflection versus mean velocity, a single graphical relation, in the form of a family of curves, was derived for discharge versus stage and deflection. A preliminary study had shown that mean velocity was related to a combination of deflection and stage. The ratings for values of deflection other than

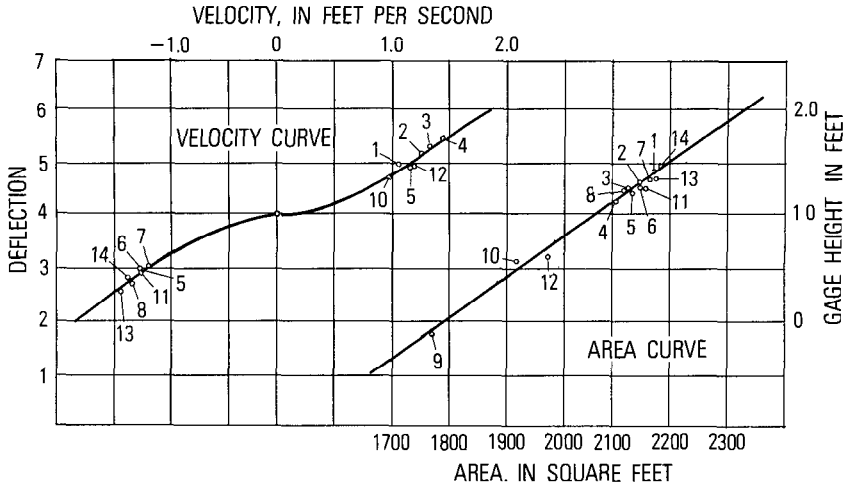

FIGURE 207.—Rating curves for a deflection-meter gaging station on a tidal stream.

those shown by the individual curves in figures 208 were obtained by interpolation between curves. Most of the 40 discharge measurements, which are shown by the small circles in figure 208, depart from the interpolated ratings by no more than 2 percent.

The use of separate relations for area and mean velocity is considered preferable to the use of a single compound relation for discharge, as was done in figure 208, because separate analysis of two components of discharge is simpler. Shifts in the discharge rating—that is, differences between measured and computed discharge—are also more easily analyzed when separate relations for area and mean velocity are prepared.

ACOUSTIC VELOCITY-METER METHOD

DESCRIPTION

Acoustic velocity meters are particularly advantageous in obtaining a continuous record of the discharge of large rivers in those situations where neither a simple stage-discharge relation nor a stage-fall-discharge relation can be applied satisfactorily. Those situations, as mentioned in the first section of this chapter, usually involve tidal flow or flow affected by hydroelectric-power generation, where the acceleration head in the equations of unsteady flow (p. 391) cannot be ignored. Acoustic velocity meters operate on the principle that the velocity of sound propagation through a fluid in motion is the algebraic sum of the fluid velocity and the acoustic propagation rate through the fluid. Thus acoustic pulses transmitted in the direction of flow will traverse a given path in shorter time than will acoustic pulses transmitted in opposition to the flow. The difference in transit

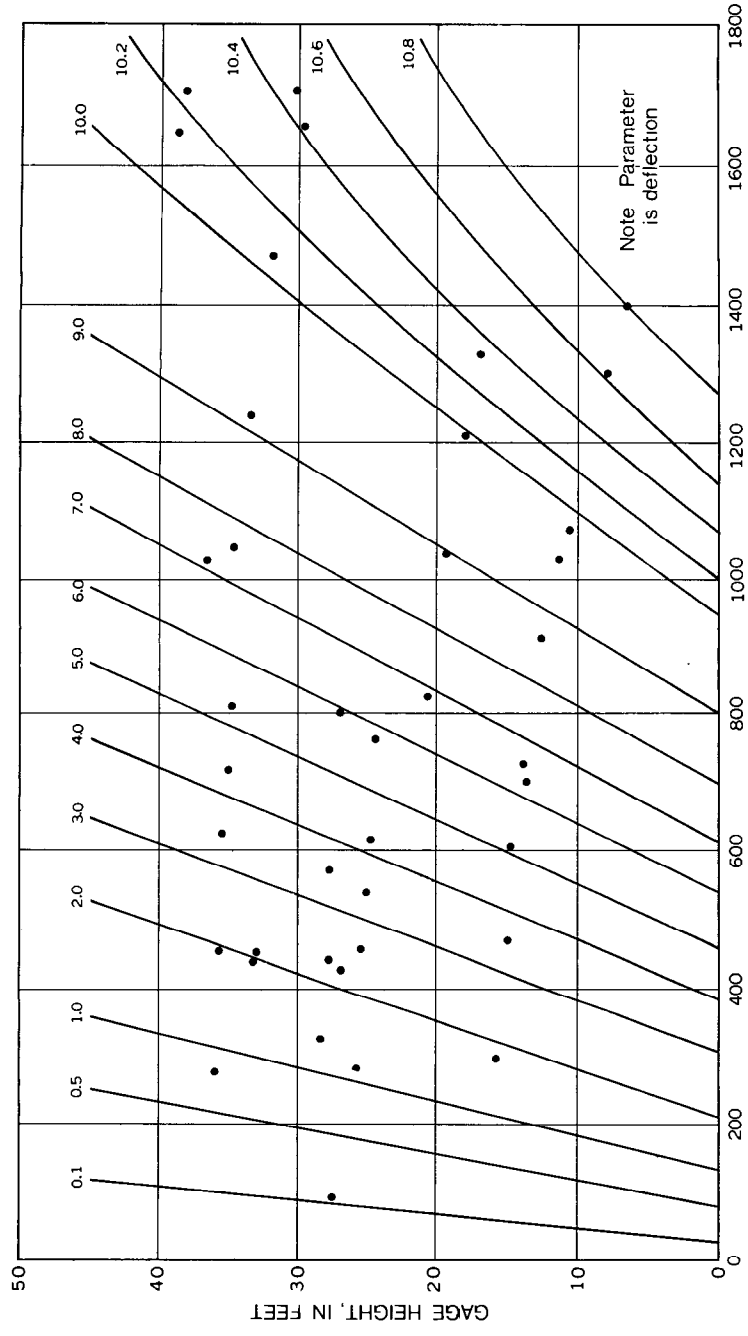

FIGURE 208.—Rating curves for a deflection-meter gaging station on Lake Winnipesaukee outlet at Lakeport, N.H.

times provides a measure of the line velocity—that is, the average value of the water velocity at the elevation of the acoustic path—and the line velocity is a satisfactory index of mean velocity in the channel. Because the transducers that transmit and receive the acoustic pulses are installed in the stream at a fixed elevation, the relation of line velocity to mean velocity varies with stage. The stage data required for the velocity relation are obtained from the stage recorder, which also provides an index of cross-sectional area.

Differences exist among the various acoustic-velocity metering systems that are commercially available, but the differences are not vital, and only one system will be briefly described. The major components of the acoustic monitoring system are two submerged transducers (fig. 209) and a console (fig. 210) housed on the streambank and electrically connected to both transducers. The two transducers, one on each side of the channel, are installed at the same elevation—an elevation that is below the lowest expected stage of the stream—on a diagonal path across the stream. The transducers convert electrical impulses generated in the console into sound pulses that travel through the water. They also convert the received sound pulses back into electrical signals. The console contains: the operating controls, the signal-generating and -receiving circuits (acoustic unit), the system clock that provides the basic timing pulses for the system and also furnishes the time-of-day readout, the digital processor (digital unit) that controls the transmission of acoustic pulses and performs the computations of the velocity index, and the velocity-index display. The velocity index is a measure of the line velocity. In the U.S.A., power for the system is usually furnished by a 110-volt alternating-current power supply.

Although acoustic-velocity meter systems are currently (1980) operational, the techniques and instrumentation are relatively new and are continually being improved. The cost of an acoustic-velocity meter installation is roughly 10 times that of a conventional gaging station. For that reason the acoustic-velocity method is limited to those sites where an accurate record of discharge is unattainable by the more conventional methods, but is of great value for water-management purposes.

THEORY

Measurement of the water velocity is possible because the velocity of a sound pulse in moving water is the algebraic sum of the acoustic propagation rate and the component of velocity parallel to the acoustic path. Reference is made to figure 211 in the following derivation of the mathematical relations of the system.

The traveltime of an acoustic pulse originating from a transducer at A and traveling in opposition to the flow of water along the path

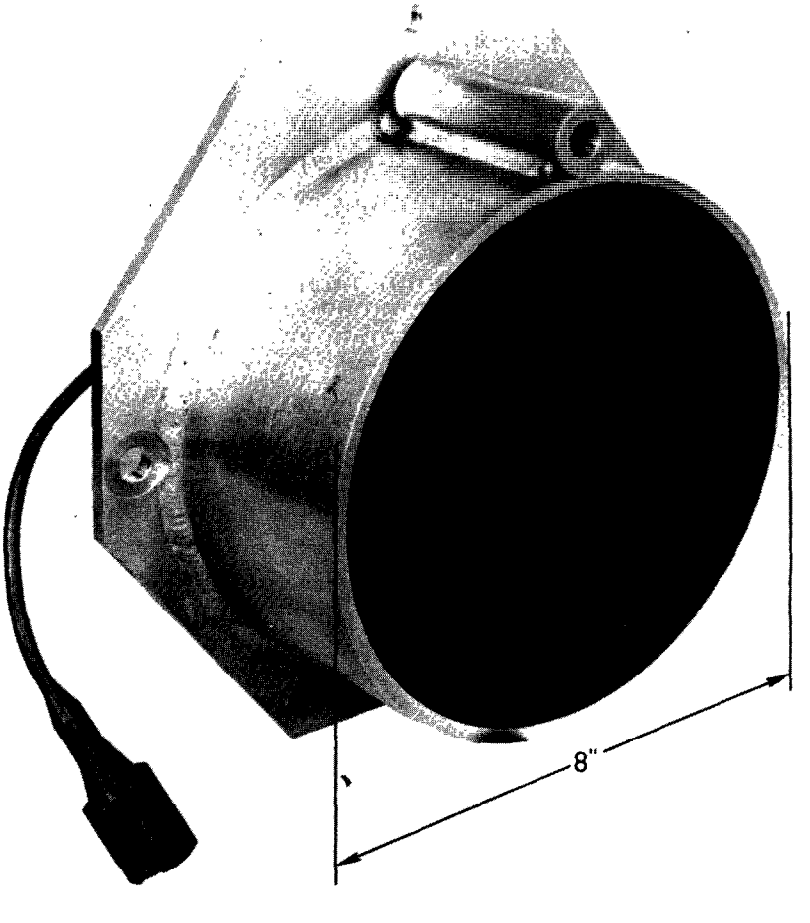

FIGURE 209.—Transducer.

A–C can be expressed as

$$T_{AC} = \frac{B}{c - V_P} \quad , \tag{91}$$

where

c is the propagation rate of sound in still water,
B is the length of the acoustic path from A to C,
T_{AC} is traveltime from A to C, and
V_P is average component of water velocity parallel to the acoustic path.

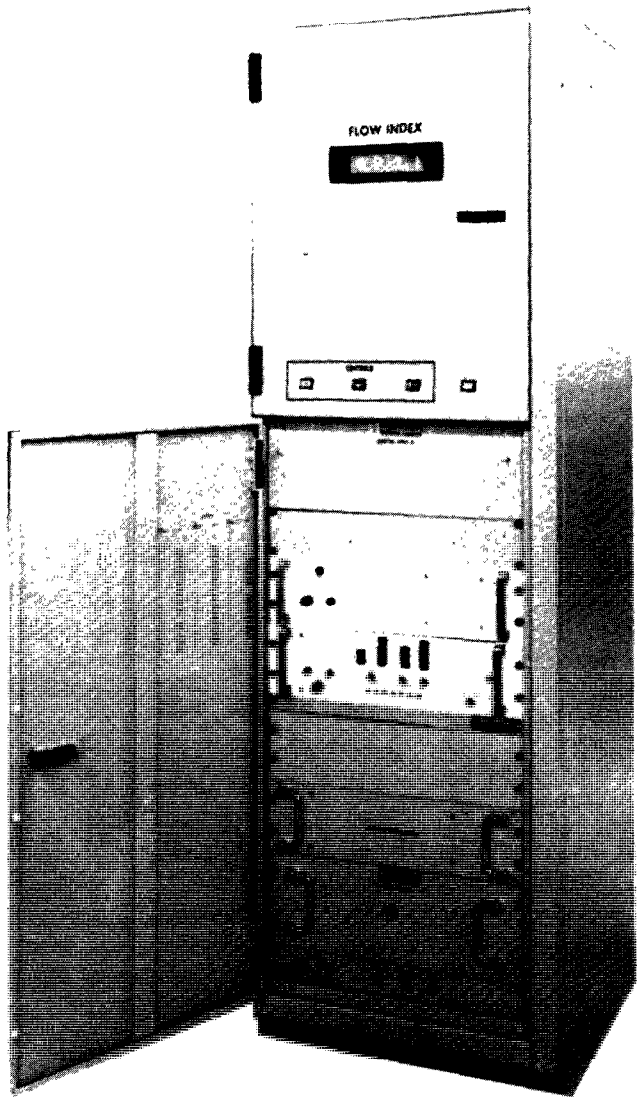

FIGURE 210.—Console.

Similarly, the traveltime for a pulse traveling with the current from C to A is

$$T_{CA} = \frac{B}{c + V_P} , \tag{92}$$

where T_{CA} is traveltime from C to A.

ΔT is the difference between T_{AC} and T_{CA}; therefore,

$$\Delta T = \frac{B}{c - V_P} - \frac{B}{c + V_P} = \frac{2BV_P}{c^2 - V_P{}^2} \quad ; \tag{93}$$

and since $V_P{}^2 <<< c^2$,

$$\Delta T \cong \frac{2BV_P}{c^2} \quad , \tag{94}$$

or

$$V_P \cong \frac{\Delta T c^2}{2B} \quad . \tag{95}$$

Both ΔT and c in equation 95 can be defined by measurement of the traveltimes of acoustic signals transmitted in each direction between transducers, c being computed by solving equations 91 and 92 simultaneously. The digital processor in the console can be scaled to produce a velocity index (I) that is equal to V_P. In some of the older systems used in the U.S.A. the velocity index was not scaled to equal V_P, but instead the velocity index was directly proportional to V_P, so that

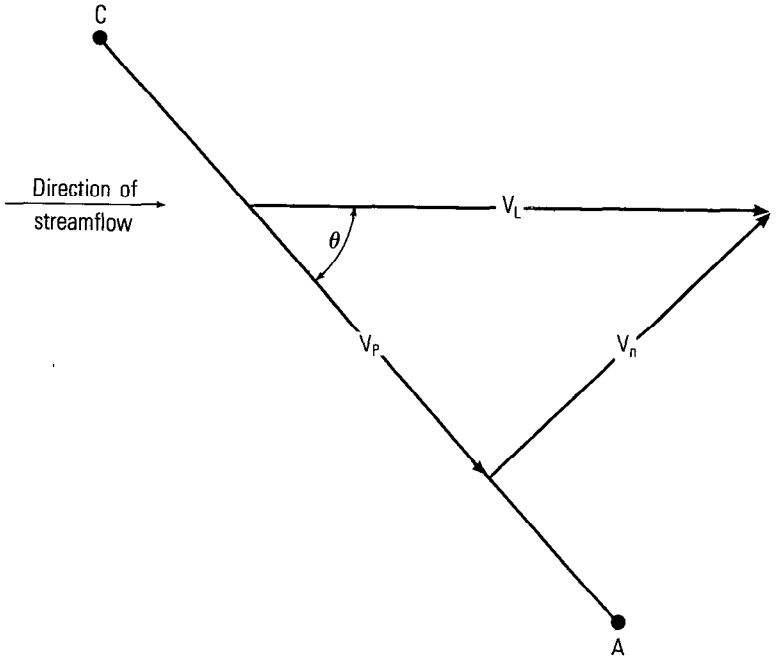

FIGURE 211.—Sketch to illustrate operating principles of the acoustic velocity meter.

$$V_P = C_1 I, \tag{96}$$

where C_1 is a constant of proportionality.
In the continuing discussion of "Theory", equation 96 will be used with the understanding that $C_1 = 1.00$ in some of the acoustic-velocity meter systems.

Figure 211 shows that

$$V_L = \frac{V_P}{\cos \Theta}, \tag{97}$$

where V_L is the average water velocity at the elevation of the acoustic path, and Θ is the acute angle between the streamline of flow and the acoustic path, AC.

By combining equations 96 and 97,

$$V_L = \left(\frac{C_1}{\cos\Theta}\right) I \tag{98}$$

Experimentation has shown V_L to be a stable index of $\overline{V}$, the mean velocity in the cross section at right angles to the streamlines of flow. The relation between V_L and $\overline{V}$ can be expected to vary with stage because V_L is a measure of the mean velocity along a line at a fixed elevation in the cross section. As the stage rises, the position of this line is moved downward in the cross section relative to the total depth, and resultant changes in the velocity distribution in the vertical column cause a change in the ratio between V_L and $\overline{V}$. Correlation of the ratio $V_L/\overline{V}$ with stage is accordingly necessary, and $\overline{V}$ can be expressed as follows:

$$\overline{V} = C_2 V_L, \tag{99}$$

where C_2 is a function of stage.

The basic equation for discharge (Q) is

$$Q = \overline{V} A, \tag{100}$$

where A is area of the cross section.

By substituting in equation 100, terms given in equations 98 and 99, the following equation is obtained:

$$Q = I\left(\frac{C_1 C_2}{\cos \Theta}\right) A. \tag{101}$$

When the symbol K is substituted for $\frac{(C_1 C_2)}{\cos \Theta}$ in equation 101, the result is

$$Q = KIA. \tag{102}$$

K varies with stage including, as it does, C_2 which is a function of stage.

To calibrate the system, discharge measurements are made to obtain measured values of A and $\overline{V}$. The measured values of A are correlated with stage to obtain a graphical stage-area relation. Measured values of $\overline{V}$ are divided by concurrent values of I, recorded by the console digital processor, to obtain concurrent values of K. Those values of K are correlated with stage to obtain an empirical graphical relation of K to stage. Such a relation is shown in figure 212.

To compute the discharge for any given value of I, the concurrent value of stage is first read. That value of stage is then used in the above graphical relations to obtain the corresponding values of A and K. In a final step the values of K, I, and A are multiplied together, in accordance with equation 102, to obtain the required value of discharge.

Newer acoustic-meter velocity systems that have been designed provide a readout of discharge after the calibration coefficients have been determined. The additional calibration coefficients needed are provided by substituting mathematical relations of A to stage and K to stage, in place of the graphical relations discussed above. The computation of discharge is based on the following two assumptions:

1. The relation between area (A) and stage (H) is stable and can be adequately defined by the second-order equation,

$$A = C_1 + C_2H + C_3H^2, \tag{103}$$

   where C_1, C_2, and C_3 are constants.

2. The ratio (K) between mean stream velocity ($\overline{V}$) and the velocity index (I), which is equal to, or linearly related to, the line velocity (V_p), can be defined by the second-order equation,

$$K = \overline{V}/I = C_4 + C_5H + C_6H^2, \tag{104}$$

   where C_4, C_5, and C_6 are constants.

If sufficient data from discharge measurements are available, the "best" values of C in equations 103 and 104 can be computed from a least-squares solution of each of the equations. Usually, however, the C values in the two equations are obtained from the graphical relations of A versus H and K versus H. That is done by first selecting the coordinates of three significant points on one of the graphical relations, and then substituting those values in the appropriate equation—equation 103 when the area relation is used. The three resulting simultaneous equations are solved to produce the required C values. The process is then repeated, using equation 104 for the K relation. The six C values so obtained are then entered in the program for computing discharge. Discharge is computed as before, in

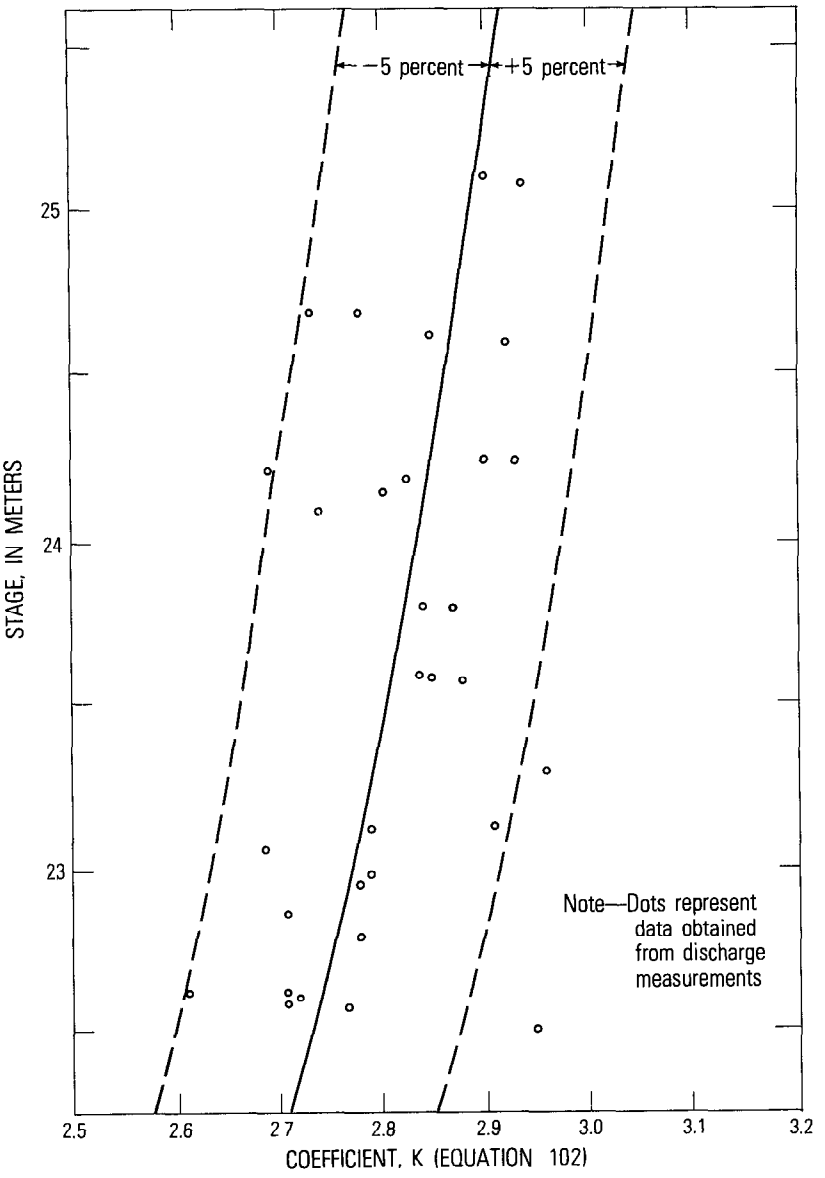

FIGURE 212.—Relation between stage and mean-velocity coefficient, K, for the acoustic-velocity meter (AVM) system, Columbia River at The Dalles, Oreg.

accordance with equation 102, except that the computations are performed in the console digital processor. The digital processor uses the C values, along with concurrent values of I and H, to make the required computations and provide a readout of K, I, A, H, and Q.

It would be simple, of course, to multiply I by the product of equations 103 and 104 and thereby obtain a single equation for Q. The result would be a fourth order equation of the form,

$$Q = I(k_1+k_2H+k_3H^2+k_4H^3+k_5H^4), \quad (105)$$

in which the k constants represented combinations of the C constants from equations 103 and 104. The "best" values of the constants could be obtained by a least-squares solution of equation 105, using measured values of Q and concurrent values of I and H. The use of equation 105 would simplify the computation of discharge, but the analyst would then lose much of his ability to analyze error sources in the calibration of shifts in the basic relations. It is therefore recommended that equations 103 and 104 be used rather than equation 105.

EFFECT OF TIDAL FLOW REVERSAL ON RELATION OF MEAN VELOCITY TO LINE VELOCITY

The value of C_2 in equation 99, $\overline{V} = C_2V_l$, varies only with stage in unidirectional flow. In streams where the direction of flow reverses in response to tide, the value of C_2 may vary not only with stage, but also with the four phases of the tide cycle. For such streams numerous discharge measurements, preferably by the moving-boat method (chap. 6), are required to evaluate C_2 for each of the tide phases. In using the moving-boat method of discharge measurement, it is necessary to determine a velocity coefficient for each individual discharge measurement and that is done by continuously defining the vertical-velocity distribution at several strategically located verticals that are representative of the main portion of streamflow. (See section in chapter 6 titled, "Adjustment of Mean Velocity and Total Discharge.")

The results of an evaluation of C_2 for a particular cross section in the Sacramento River in California are given in table 22 (Smith, 1969, p. 11–18). Column heading, $\overline{C_2}$, in table 22 refers to the mean values of C_2; column heading, s, refers to the standard deviations of C_2 values. Figure 213 is a plot of the data from columns headed, $\overline{V}$ and $\overline{C_2}$, in table 22.

ORIENTATION EFFECTS AT ACOUSTIC-VELOCITY METER INSTALLATIONS

EFFECT OF ACOUSTIC-PATH ORIENTATION ON ACCURACY OF COMPUTED LINE VELOCITY (V_l)

The basic accuracy or resolution of a given acoustic-velocity meter (*AVM*) system is controlled principally by the accuracy with which the arrival times of the acoustic pulses can be discriminated and by the accuracy of the timing circuitry used to measure elapsed times. A related factor that affects the accuracy of results obtained with a par-

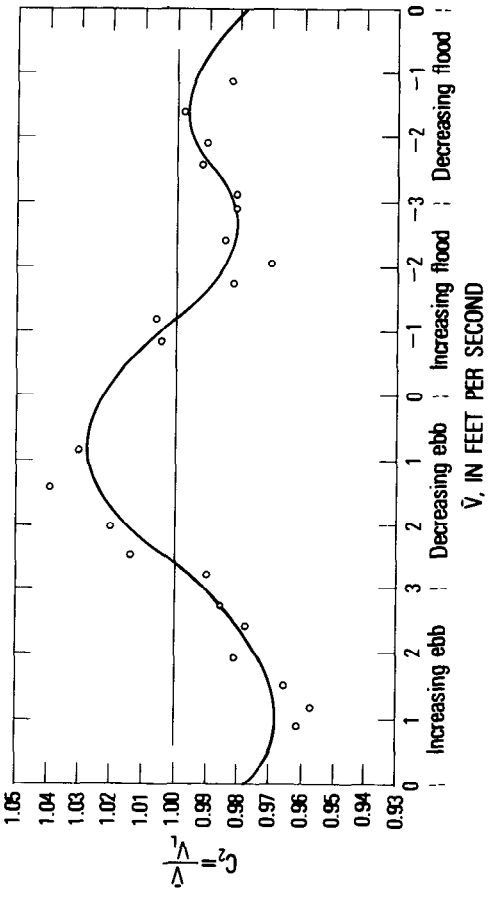

FIGURE 213.—Relation between C_2 and velocity and tide phase.

ticular *AVM* system is the orientation of the acoustic path with respect to the streamlines of flow. The effect of path orientation will now be examined for one of the *AVM* systems used in the U.S.A. It is assumed that no changes in the basic circuitry are made for operations over acoustic paths of various orientations, that the streamlines at all times and stages are parallel and their direction is invariant, and that acoustic performance is thoroughly reliable.

From figure 211

$$V_P = V_L \cos \Theta \tag{97a}$$

Insertion of the resolution error (R_e) for the system in equation 97a yields

$$V_P = V_L \cos \Theta \pm R_e$$

or,

$$V_L = \frac{V_p}{\cos \Theta} \pm \frac{R_e}{\cos \Theta} \cdot \tag{106}$$

The last term in equation 106 represents the error (E) in computed values of V_L, meaning that

$$E = \pm \frac{R_e}{\cos \Theta} \tag{107}$$

In other words, for a given *AVM* system, the error in computed values of V_L decreases as Θ decreases.

According to the claim of the manufacturer of the *AVM* system under discussion, inaccuracy (E) attributable to the resolution error is ± 0.05 ft/s when angle Θ is 45°. From equation 107, the implication is that the resolution error (R_e) equals $\pm 0.05 \cos \Theta$, or ± 0.035 ft/s. Table 23 was computed from equation 107 using the above value of R_e. Because the error in computed values of V_L is independent of the magnitude of V_L, the greatest percentage errors in computed velocity occur at low velocities for any given orientation of the acoustic path.

EFFECT OF VARIATION IN STREAMLINE ORIENTATION

If an *AVM* system were located a short distance downstream from the confluence of two streams, as shown in figure 214, the direction of

TABLE 23.—*Error in computed* V_L, *attributable to resolution error, for various acoustic-path orientations, for a given* AVM *system*

Path-orientation angle Θ, in degrees	Error in V_L, in ft/s
30	±0.04
45	± .05
60	± .07
70	± .10
80	± .20

the streamlines of flow at the gage site could be expected to vary with the proportion of total discharge contributed by the tributary stream. When the tributary flow is low, the angle between streamlines and acoustic path is Θ, V_L is the velocity normal to the cross section whose area is A, and a value of V_p is recorded by the AVM;

$$V_L = \frac{V_p}{\cos \Theta} \quad , \tag{108}$$

and

$$Q_{AVM} = AV_L \tag{109}$$

If stage and discharge remain constant, but the proportion of flow from the tributary increases significantly, the angle Θ between the streamlines of flow and the acoustic path will increase by an increment ϕ, but V_L will remain constant because the discharge and stage remain constant. A value of V'_p will now be recorded by the AVM, where

$$V'_p = V' \cos(\Theta+\phi) \tag{110}$$

But,

$$V' = \frac{V_L}{\cos \phi} \tag{111}$$

Therefore,

$$V'_p = \frac{V_L \cos (\Theta+\phi)}{\cos \phi} \tag{112}$$

However the discharge has not changed. If the AVM system had been calibrated under conditions where, for the given discharge and given stage, the angle between streamlines and acoustic path was Θ, the AVM system will be unaware of the increase in angle from Θ to $(\Theta+\phi)$, and the discharge will be computed as

$$Q'_{AVM} = \frac{AV'_p}{\cos \Theta} = \frac{AV_L \cos(\Theta+\phi)}{\cos \Theta \cos \phi} \tag{113}$$

But the true AVM discharge (line velocity times area) is that shown by equation 109. Therefore the ratio between computed AVM discharge for the condition of the angle being $(\Theta+\phi)$ and the true AVM discharge is,

$$\frac{Q'_{AVM}}{Q_{AVM}} = \frac{\left(\frac{AV_L \cos (\Theta+\phi)}{\cos \Theta \cos \phi}\right)}{AV_L} \tag{114}$$

$$= \frac{\cos (\Theta+\phi)}{\cos \Theta \cos \phi}$$

$$= 1 - \tan\Theta \tan\phi \tag{115}$$

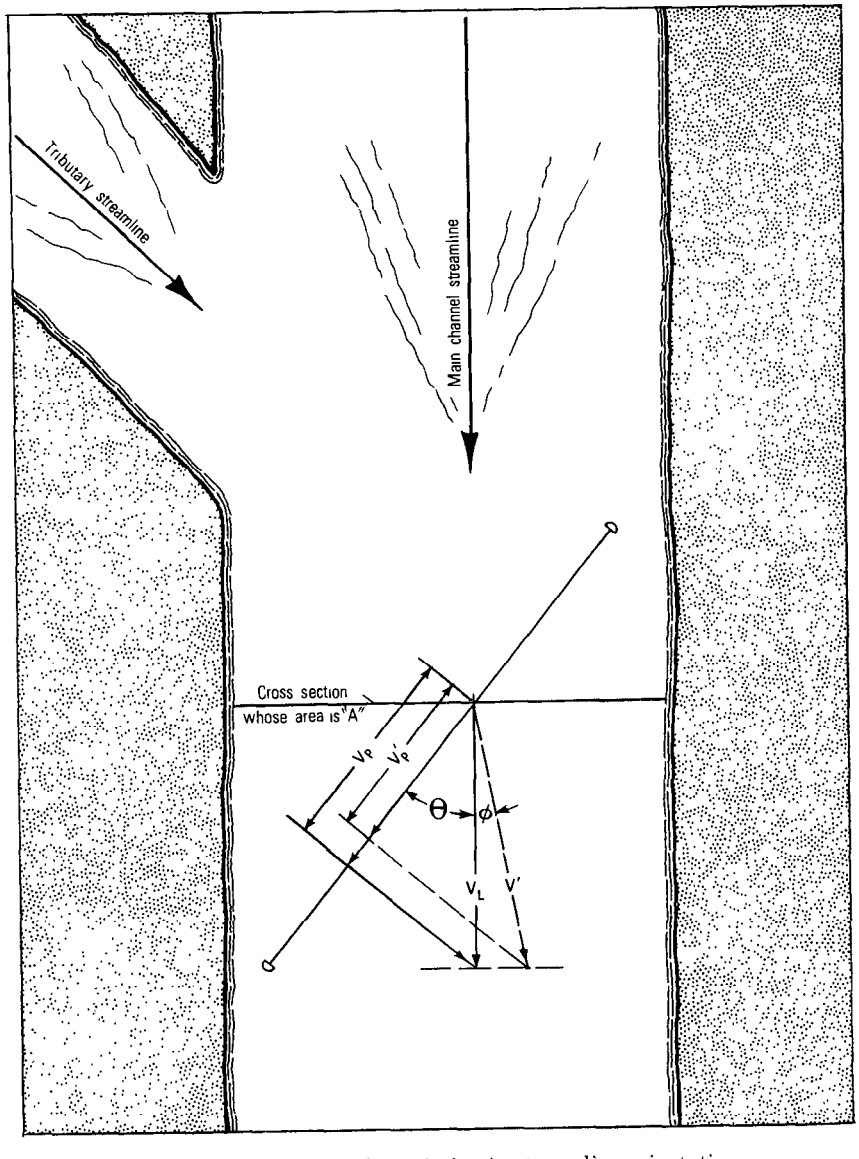

FIGURE 214.—Possible variation in streamline orientation.

Equation 115 is evaluated in table 24 for acoustic path orientations (Θ) ranging from 30° to 60°, and for streamline variations (ϕ) ranging from −4° to +4°.

As a general rule one should avoid installing an *AVM* system immediately downstream from the confluence of two streams. It is true

TABLE 24.—*Ratio of computed discharge to true discharge for various combinations of* Θ *and* ϕ

Θ	Ratios for the values of ϕ indicated below								
	−4°	−3°	−2°	−1°	0°	+1°	+2°	+3°	+4°
30°	1.040	1.030	1.020	1.010	1.000	0.990	0.980	0.970	0.960
45°	1.070	1.052	1.035	1.017	1.000	.983	.965	.948	.930
50°	1.083	1.062	1.042	1.021	1.000	.979	.958	.938	.917
60°	1.121	1.091	1.060	1.030	1.000	.970	.940	.909	.879

that calibration of the system will be unaffected if, for each value of total discharge, there exists a particular ratio of tributary discharge to mainstream discharge. However, if that ratio is not constant for a given total discharge, error will be introduced in the calibration of the system, and therefore, in the computation of discharge.

FACTORS AFFECTING ACOUSTIC-SIGNAL PROPAGATION

In the installation of an *AVM* system, consideration must be given to the factors that affect the propagation of the acoustic signal through the water. Refraction or reflection of the acoustic beam away from the selected path or attenuation of the acoustic signal may result from:

1. temperature gradients in the stream,
2. boundary proximity,
3. air entrainment,
4. sediment concentration, and
5. aquatic vegetation.

TEMPERATURE GRADIENTS

Periodic loss of signal at some *AVM* installations where the transducers were relatively close to the water surface of a deep stream have led engineers to theorize that the development of even extremely small temperature gradients in the water column may cause refraction of the acoustic signal. In streams where mixing is poor, changes in solar radiation and air temperature could conceivably cause such gradients to develop. It has been reasoned that location of the acoustic path near mid-depth of the stream should minimize temperature gradients caused by variations in temperature or possibly by heat exchange between the water and channel perimeter.

BOUNDARY PROXIMITY

When the acoustic path is located near the water surface or near the streambed, part of the acoustic signal will be reflected from the boundary (air-water interface or streambed). The reflected component may arrive at the receiving transducer almost simultaneously with, but out of phase with, the primary pulse. In extreme cases, signals may be almost completely blanked out. This phenomenon is related to

the ratio of path length to distance to a boundary and to the frequency of the transmitted signal.

The above considerations, combined with the possibility of the thermal effects discussed above, have led the designers of some *AVM* systems to develop the criteria curves for *AVM* site selection shown in figure 215. The curves indicate the performance that can probably be expected from some systems in a given channel geometry when the transducer elevation is set at mid-depth. The terms "excellent" and "acceptable" are relative, and their significance is dependent upon the reliability requirements at the site. The curves show that the depth of water required increases as the path length increases. For example, for a path length of 500 ft, excellent acoustic performance would be expected for depths greater than 18 ft and acceptable performance would be anticipated for depths between 10 and 18 ft, but for depths less than 10 ft, on-site investigation of the characteristics of acoustic transmission would be necessary. For a path length of 1,000 ft, these depth ranges change to 34 ft or more for excellent transmission and from 19 to 34 ft for acceptable transmission. On-site studies would be required for depths less than 19 ft. The curves in figure 215 should not be construed as providing all the information

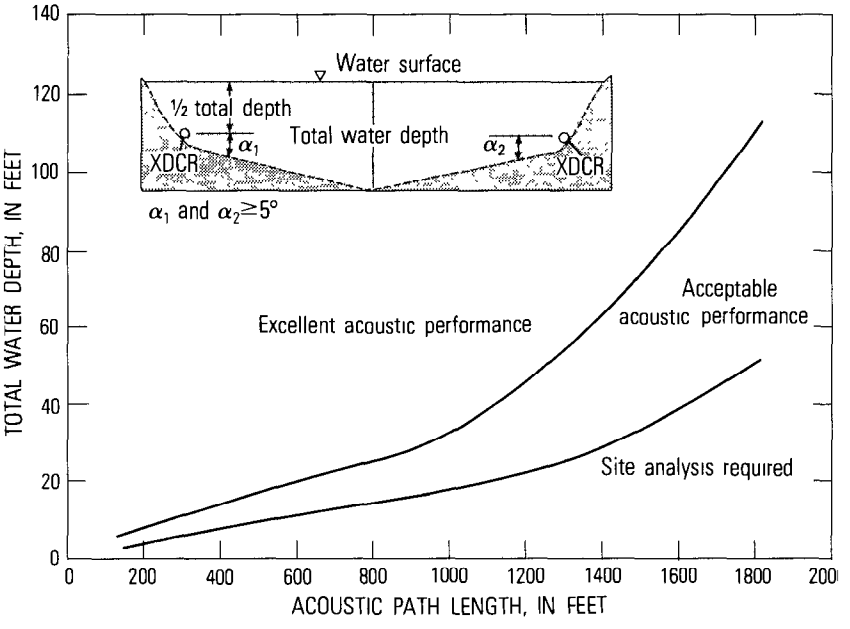

FIGURE 215 —Curves used as a preliminary guide for AVM site selection, based solely on consideration of channel geometry.

required for assessment of the potential for utilizing an *AVM* system. By these criteria, broad, shallow channels would seem to be questionable sites, but it is possible that further developments in transducer design and system characteristics may provide reliable performance in such channels also.

AIR ENTRAINMENT

Little quantitative information is available concerning the attenuation of acoustic signals by air bubbles entrained in the water, but the effect of air entrainment has been observed downstream from dams where the falling water becomes highly aerated. Bubbles formed at such sites may remain entrained in the water for a considerable distance downstream, and they absorb and reflect the acoustic signal much as fog absorbs and reflects a beam of light. The highly absorptive characteristics of water with entrained air precludes satisfactory operation of *AVM* systems, and locations close to spillways or other sources of air entrainment should consequently be avoided.

SEDIMENT CONCENTRATION

The degree of attenuation of signal strength caused by the reflection and scatter of the acoustic signals from sediment particles suspended in the stream has not been fully documented. The attenuation is influenced not only by suspended-sediment concentration, but also by the size of the sediment particles, water temperature, and length of the acoustic path. Equations given by Flammer (1962) for the evaluation of energy loss are:

$$E = E_0 10^{-0.1\alpha x}, \tag{116}$$

where

E = sound energy flux at a given point, if sediment is suspended in the transmitting fluid;

E_0 = sound-energy flux at the same point, if no sediment were present;

α = attenuation coefficient that is due to sediment alone, measured in decibels per inch; and

x = distance from the point of measurement to the sound source.

The attenuation coefficient α can be evaluated as

$$\alpha = C\left[\frac{K(\gamma-1)^2 S}{S^2+(\gamma+\tau)^2}+\frac{K^4 r^3}{6}\right]\frac{22.05}{2}, \tag{117}$$

where

C = concentration (1,000 mg/L = 0.001),

$K = 2\pi/\lambda$,

$\gamma = \rho_1/\rho_2$,

$S = [9/(4\beta r)]\,[1+1/(\beta r)]$,

$\tau = \frac{1}{2}+9/(4\beta\tau)$, and

r=particle radius, in centimeters;

in which

λ=wave length of sound in water, in centimeters; ρ_1 and ρ_2=densities of particle and fluid, respectively;

$\beta=\left[\omega/2\upsilon\right]^{1/2}$

$\omega=2\pi f$;

υ=kinematic viscosity of water, in stokes; and

f=frequency of sound wave.

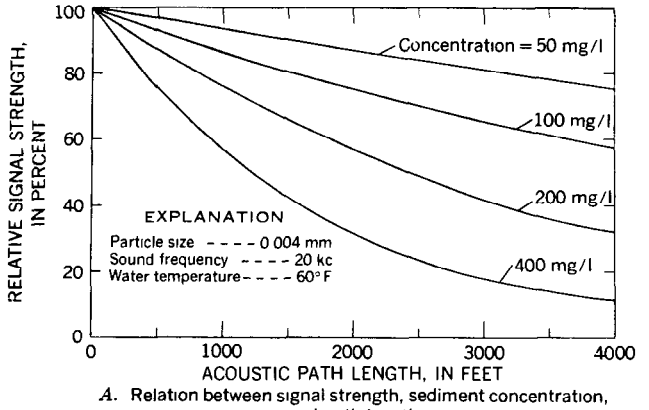
An example of the evaluation of equations 116 and 117 for an *AVM* site investigated in central California is shown in figure 216. Pertinent site and *AVM* characteristics were as follows:

Particle size—0.004 mm
Sediment concentration—20-100 mg/L
Water temperature—60°F(15.6°C)
Sonic-path length—4,000 ft (1219 m)
Sound frequency—20 kc

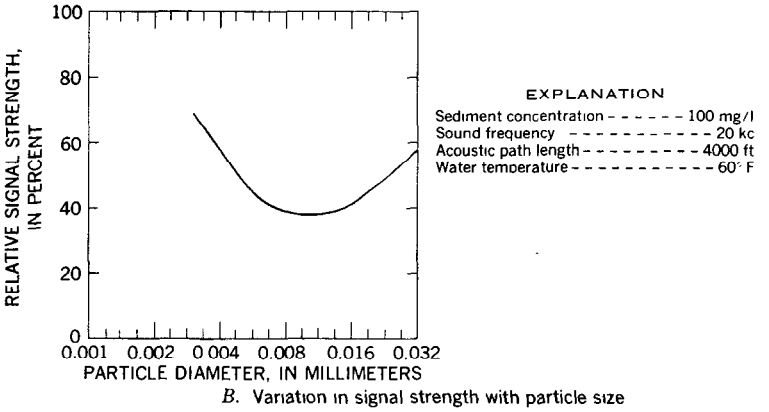
Figure 216*A* illustrates the general problem and shows the reduction in signal strength resulting from sediment concentrations ranging from 50 mg/L to 400 mg/L over acoustic paths as long as 4,000 ft. Figure 216*B* shows the signal loss for a given concentration and path length, as affected by particle size, and relates signal loss, for a path length of 4,000 ft, to sediment size when the sediment concentration is held constant at 100 mg/L. Figure 216*C* relates signal loss, for a path length of 4,000 ft, to sediment concentration when the sediment size is held constant at 0.004 mm. Figure 216*C* is of particular significance; it indicates that for the probable range in suspended-sediment concentrations at the site under consideration (20–100 mg/L), signal strength will vary from 90 to 56 percent of the levels possible in clear water. One of the requirements of an *AVM* designed for use at this site would be that no calibration changes should result from signal strength variations of that magnitude.

AQUATIC VEGETATION

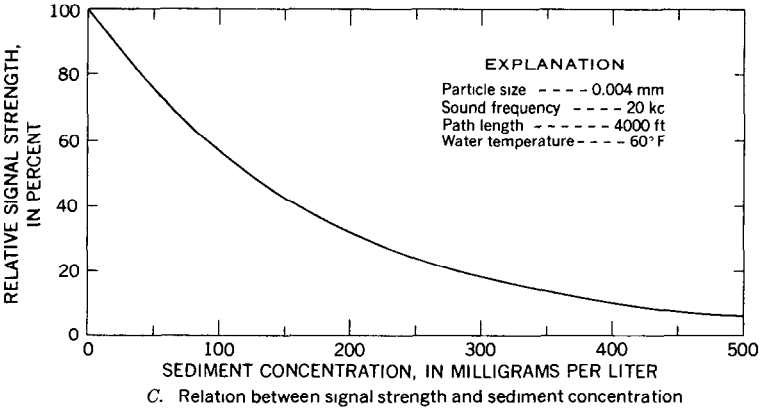
The effect of aquatic weeds in the acoustic path is variable, depending on the location and density of the weed growth. Dense growth may cause complete blockage of the signal. It has been found, in experiments in the United Kingdom, that the removal of only a small amount of weeds will increase the amplitude of the received signal. Further experimentation (Green and Ellis, 1974) has shown that weeds growing close to the transducer may actually cause the *AVM* system to overregister the velocity; the weeds reflect and scatter the wave train and the extra scattered signals are detected by the transducer. On the other hand, weeds in the midchannel result in a widely variable registration of velocity, in which the velocity is underestimated. In short, aquatic weeds in the acoustic path interfere with



A. Relation between signal strength, sediment concentration, and path length



B. Variation in signal strength with particle size



C. Relation between signal strength and sediment concentration

FIGURE 216.—Interrelation between signal strength, sediment concentration, particle size, and acoustic-path length.

the operation of an *AVM* system, but the quantitative results of experimentation with weed growths are not transferable from the experimental sites to other *AVM* sites.

It should also be noted that there has been no experimentation to relate attenuation caused by weed growth to sonic frequency. It appears probable that operation at a low frequency might reduce the attenuation; however, that would also reduce the basic accuracy of the *AVM* system.

SUMMARY OF CONSIDERATIONS FOR ACOUSTIC-VELOCITY METER INSTALLATIONS

The foregoing discussions of factors that influence *AVM* operation demonstrate that the interrelation of those factors must be considered in site selection of the acoustic path of an *AVM* system in a given stream. The most important consideration is to ensure reliable acoustic transmission and reception, and from that standpoint the acoustic path should be as short as possible to minimize acoustic refraction and attenuation losses. On the other hand, consideration of the hydraulic aspects of the system suggests use of a long path at a small angle of incidence (Θ in fig. 211) to the streamlines to achieve the best resolution of velocity and to reduce the effect of variations in streamline direction. These are opposing restraints on the system configuration, therefore compromise is often required. For most installations, the desired resolution can be attained by utilizing a path at the mid-depth position and at an angle of 45° to the streamlines. Narrow deep sections of a river are to be preferred over broad shallow sections, and locations influenced by tributary inflow should be avoided. On-site investigation of acoustic-propagation characteristics will be desirable at sites where the depth-to-path length criteria of figure 215 indicate possible problems.

Weed-covered sites and sites where air bubbles are entrained in the water should be avoided in selecting an acoustic path because of the likelihood of signal attenuation. For that same reason, the use of *AVM* systems may not be practical in streams that frequently carry large sediment loads.

ELECTROMAGNETIC VELOCITY-METER METHOD

GENERAL

The electromagnetic method of measuring velocity in streamgaging operations will be discussed only briefly because it is still (1980) in the experimental stage. Experimental work in the U.S.A. has been largely in the use of the electromagnetic meter to obtain a continuous record of velocity at a point. The observed point velocities

are then used as indexes of mean velocity in the stream, precisely as explained in earlier sections of this chapter, where the standard current meter and the deflection meter were the instruments used for continuously measuring point velocities. In several European countries, notably the United Kingdom, experimental work in electromagnetic stream-gaging has been largely in the use of an electromagnetic meter to obtain a continuous record of an index value of integrated mean velocity in the entire measurement cross section.

The operation of an electromagnetic velocity meter is based on the principle that an electromotive force, or voltage, is induced in an electrical conductor moving through a magnetic field. For a given field strength the magnitude of the induced voltage is proportional to the velocity of the conductor. In the electromagnetic velocity meter, the conductor is the flowing water whose velocity is to be measured. Although all devices for measuring water velocity electromagnetically are based on the above principle, the actual instrumentation for measuring point velocities differs greatly from that used for integrating the mean velocity in a cross section.

POINT-VELOCITY INDEX

INSTRUMENTATION

A variety of electromagnetic meters for measuring point velocity are available commercially. The meters differ in details of construction and performance, but essentially there are two general types.

One type of meter consists of the following elements: a nonmagnetic tube or pipe through which the water flows; two magnetic coils, one on each side of the pipe; electrodes in the walls of the pipe between the magnetic coils; and suitable electrical circuits to transform the induced voltage into a velocity indication on a meter dial. The other type of meter consists of a probe, or cylinder, containing an electromagnet internally and two pairs of external electrodes in contact with the water. Flow around the cylindrical probe intersects magnetic flux lines causing voltages to be generated that are detected by the electrodes. Electrical circuitry is provided to transform the induced voltage into a velocity indication on a meter dial.

For either type of meter, a source of electrical power is needed to activate the magnetic field and a transmitter is used to record the velocity signals on digital tape or to send the signals to desired stations. The meters used in the U.S.A. generally require an alternating-current source of 110 volts, but many are battery powered. The meters cause negligible head loss; accuracy claimed by the manufacturers is generally in the range of ± 2 to ± 3 percent or ± 0.005 to ± 0.007 ft/sec, whichever is larger. In other words, from a standpoint of percentage error, the higher velocities are more accu-

rately measured than low velocities.

At the gage site the unattended electromagnetic velocity meter is securely anchored in a fixed position in the stream below the minimum expected stage. The considerations governing the precise location of the meter in the stream are identical with those discussed for the standard current meter when it is used to provide a point-velocity index (see section titled "Standard Current-Meter Method"). A recording stage-gage is operated in conjunction with the velocity meter. Velocity and stage are usually recorded on digital tape.

ANALYSIS OF POINT-VELOCITY DATA

The point-velocity data from the electromagnetic meter are analyzed in the same manner as discussed earlier in this chapter for the fixed standard current meter. Mean velocity for the measurement cross section, as obtained from discharge measurements, is correlated with concurrent stage and point velocity. Cross-sectional area is related to stage. The product of mean velocity and cross-sectional area gives the required discharge. Experimentation in the U.S.A. in the use of an unattended electromagnetic meter as a point-velocity index for gaging open-channel flow had lagged, primarily because of problems in suppressing electrical noise and in preventing the contamination of electrodes, but experimentation has recently been renewed. A description of a gaging-station operation in which point-velocity data are being obtained from an electromagnetic probe follows.

The gaging site on the Alabama River near Montgomery, Ala. is at a pool formed by a dam 43 miles downstream. The river is 600 ft wide and 40 ft deep, and the flow is largely controlled by the operation of hydroelectric-power dams upstream. The flow of the river is thus highly unsteady and in addition the water-surface slope varies because of operations at the downstream dam. The discharge of the river could not be related to stage or to stage and slope. Consequently, an electromagnetic meter was installed to provide point-index velocities.

The meter is of the portable probe type, is battery powered, and features solid-state electronics in a durable field housing. The form and size of the probe are shown in figure 217. The electromagnetic probe is mounted on a structure attached to the upstream end of a bridge pier in the center of the stream. The probe was positioned to sense the velocity at a point 6 ft upstream from the nose of the pier and 6 ft below the minimum stage of the water surface. The recorder and electronic package are installed in the gage house on the pier, about 35 feet above the mean high-water stage. The Geological Survey developed the electronics necessary to average the continuously generated velocity signal over 30-minute intervals and to record this average velocity on a digital recorder.

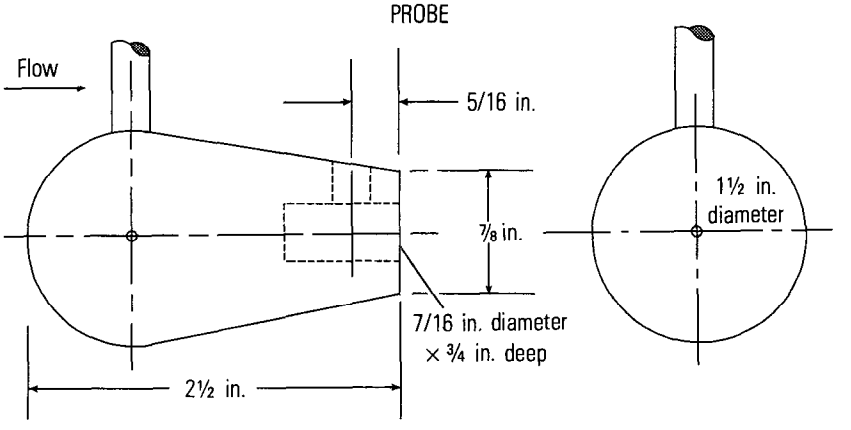


FIGURE 217.—Electromagnetic probe, model 201, Marsh-McBirney.

A series of current-meter discharge measurements was made to calibrate the relation of point velocity, as indicated by the probe, to the average velocity of the stream, as determined from the discharge measurements. Because of the unsteady flow, it was necessary that the discharge measurements be completed as quickly as possible. For that reason the measurements were made by defining the variation of velocity with time at a number of verticals in the stream-measurement cross section, as described in the section in chapter 5 titled, "Measurement Procedures During Rapidly Changing Stage—Case B. Small Streams." The relation between recorded point-index velocity and mean stream velocity determined from the discharge measurements is shown in figure 218. Although several of the plotted points scatter widely, the relation appears to be adequately defined over the range of velocity that was experienced. An attempt to improve the relation by the use of stage as an additional parameter, as in figure 201, was unsuccessful. A continuous record of discharge is computed at the gaging station by using the records of stage and point velocity, stage being an index of the cross-sectional area and point velocity an index of mean stream velocity.

Experience with the electromagnetic probe at the Alabama River gaging station has been very encouraging. The instrumentation appears to have wide application for gaging streams at sites where simpler rating methods such as stage-discharge or stage-slope-discharge are not adequate. The system has the sensitivity and accuracy required even at low velocities, is relatively inexpensive, has flexibility with regard to location because it is powered by dry-cell batteries, and can probably be used even at sites where the direction of flow reverses. The use of the system for gaging streams is consid-

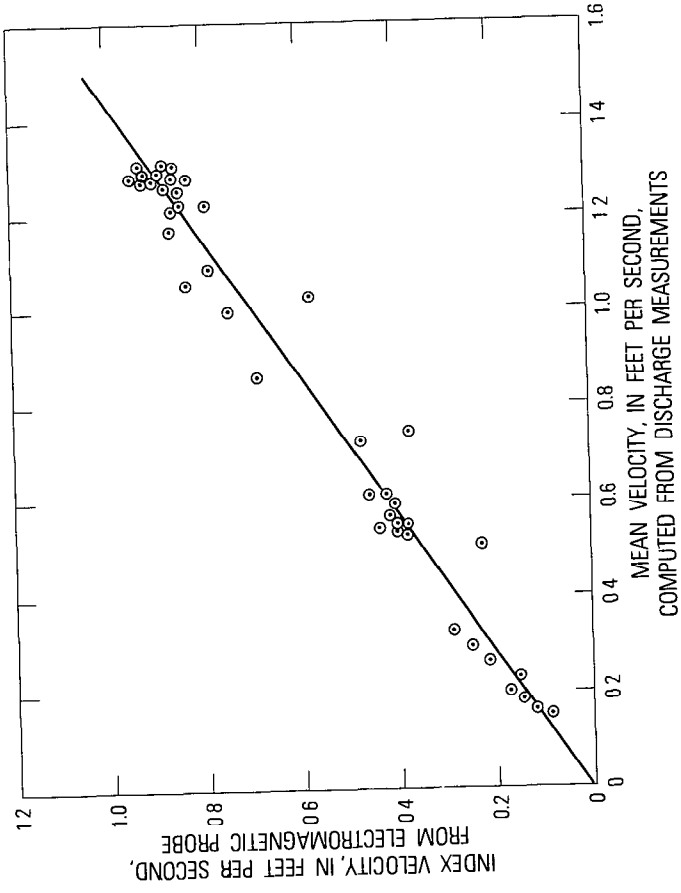

FIGURE 218.—Relation between point-index velocity and mean stream velocity for Alabama River near Montgomery, Ala.

ered to be in the experimental stage (1980), but it is hoped that further testing and development will result in the perfection of a reliable tool for gaging streams.

INTEGRATED-VELOCITY INDEX

THEORY

The discussions that follow have been extracted from British publications (Herschy and Newman, 1974; Newman, 1974; Plessey Radar, 1974).

If a conductor moves through a magnetic field, an electromotive force (voltage) is generated in the conductor. That principle can be applied to stream gaging. An electric current, flowing through a coil placed on a streambed at right angles to the flow, generates a magnetic field in the vertical direction. The flowing water is the conductor moving through the field, and the electromotive force (emf) generated in the water is at right angles to the flow. In accordance with Faraday's law of electromagnetic induction, the equation relating the length of the conductor moving in the magnetic field to the emf that is generated, is

$$E = HVb, \tag{118}$$

where

E is emf generated, in volts;
H is magnetic field intensity, in Tesla;
V is average velocity of the river water, in meters per second, and
b is river width, in meters.

In practice most streambeds will have some significant electrical conductivity that will allow electric currents to flow in the bed. The electric currents have the effect of attenuating the signal, predicted from equation 118, by a theoretically predictable factor called the conductivity-attenuation factor δ,

$$\delta = \frac{1}{1 + \left(\frac{b\sigma_0}{2h\sigma_1}\right)} \tag{119}$$

where

b is stream width,
h is stream depth,
σ_0 is streambed conductivity, and
σ_1 is river-water conductivity.

Equation 118 then becomes

$$E = HVb\delta \tag{120}$$

In an operational electromagnetic gaging station, the river and streambed conductivity should be continuously monitored and the output signal corrected accordingly.

When an electromagnetic gaging station uses an artificially produced magnetic field, that is, a magnetic field produced by a current-carrying coil, the field must, from practical considerations, be spatially limited. This means that electric currents flow in the areas outside the magnetic field, thereby reducing the output potential by a factor β, the end-shorting factor. That factor is a constant for a given coil size and configuration. Equation 120 now becomes

$$E = HVb\delta\beta. \tag{121}$$

For a given electromagnetic gaging station the magnetic-field intensity H, and the end-shorting factor β, are constants. The streambed resistivity attenuation factor, δ, is a function of the river-aspect ratio (the stage, if the river width is constant) and of the river-to-streambed conductivity ratio, σ_0/σ_1. Therefore, to insert the correct value of δ in equation 121 it is necessary to have measurements of the stage and the river-to-streambed conductivity ratio. The mean velocity of the river can then be computed. To obtain the discharge, the velocity is multiplied by the river cross-sectional area.

INSTRUMENTATION

An electromagnetic system for integrating stream velocity can be installed anywhere in a river or canal where the conductivity of the water is uniform but not necessarily constant. At present, installations have been confined to small streams. Measuring sections that are bounded by heavily reinforced concrete or by steel pilings are not suitable because of the relatively high electrical conductivity of those boundary elements. Although the signal-recovery techniques that are used make the system immune to ambient electrical noise, sites close to overhead or buried powerlines should be avoided if possible.

A description of one of the operational systems for integrating the stream velocity electromagnetically follows. In that system a large coil (fig. 219) is buried under the streambed and banks to a depth of about 0.5 m (1.5 ft, approx.). The trench in which the coil is laid roughly follows the contours of the bed and banks to minimize the effect of variation in the velocity profile. A magnetic field is produced by an electric current flowing through the coil.

Two signal probes placed in the magnetic field are fixed against the banks (fig. 219) or are driven vertically into the banks (fig. 220). The probes are used to detect the electromotive force induced in the moving water and to define precisely the cross section of the measurement area. The purpose of driving the signal probes vertically into the bank, as in figure 220, is to define a cross section whose area is rectangular. Such materials as aquatic vegetation and bed and bank sediments streamward from the probes are included in the size of the

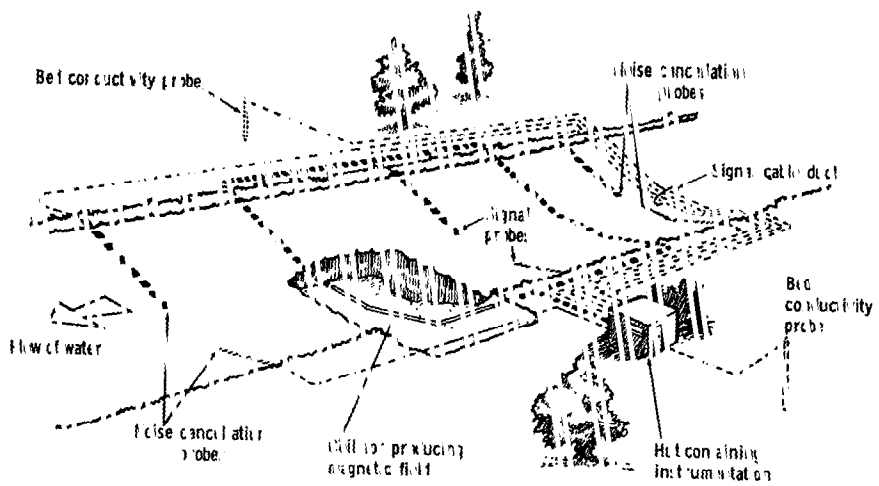

FIGURE 219.—Instrumentation for an electromagnetic stream-gaging station. (After Hershy and Newman, 1974.)

cross-sectional area the velocity of the extraneous material is zero and its effect on the system is therefore as innocuous as that of stagnant water.

Four noise-cancelation probes (fig. 219) outside the influence of the induced magnetic field are used to detect the ambient electrical noise which is later subtracted from the signal induced by the coil. These probes are mounted in a manner similar to the signal probes, with one pair upstream and one pair downstream from the measurement area.

Two bed-conductivity probes (fig. 219) are placed on each side of the stream, at a distance back from the bank that is approximately equal to the width of the stream. The probes and their cables may be buried sufficiently deep to avoid damage by agricultural work or other ground-disturbing activities. By the use of the bed-conductivity probes and the signal probes, the conductivity of the streambed is measured.

The power-supply unit provides a direct-current source that is connected to the coil through a switching unit. The switching unit in response to timing pulses from the data-processor unit described below reverses the direction of the current flowing through the coil at half-second intervals. This causes a synchronous change in the polarity of the electrical potential induced in the moving water by the magnetic field with the result that the signal can be detected by the signal probes in the presence of electrical noise. At the signal-recovery unit, the probe voltage is amplified, and after filtering and conversion, a digital signal is provided to the data-processor unit.

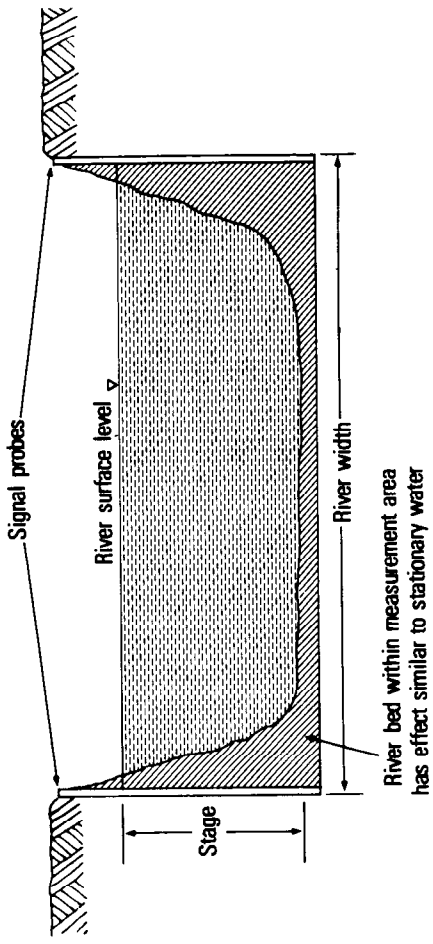

FIGURE 220.—Schematic diagram showing inclusion of bed and bank material in stream cross section. (After Herschy and Newman, 1974)

Additional instrumentation in the system includes a stage sensor and a power-operated pump that delivers continuous samples of water to a conventional conductivity sensor. The stage sensor, usually operating in a stilling well, provides a digital signal of stage to the data processor.

The block diagram in figure 221 shows the function of the data processor. In the data processor, the information from the probes is combined with that from the sensors for conductivities and stage. The latest information received is combined with similar prior information to provide a weighted average value. The weighted average value is then scaled, using preprogramed constants, to give an output of discharge in conventional units. The principles underlying the computation of discharge have been discussed in the subsection on theory of the integrated-velocity index. However, in the system described here, no separate computations of area and mean velocity are made. The two computations are easily combined because the cross-sectional area is a simple function of stage, the area bounded by the signal probes being a simple rectangle (fig. 220) or a trapezoid. The time constant in the process of averaging values is normally 15 minutes, which is also the time interval used in logging the data.

Information relating to discharge, stage, and water and streambed conductivities may be recorded locally on computer-compatible punched paper tape or on magnetic tape. Alternatively, the data may be transmitted to a control center over telephone lines or by a radio link. The transmission can be incorporated in a wider telemetry system for flood or pollution warning.

An initial field calibration, using discharge measurements, is required for the system. However, because the relation of electromagnetic output to discharge is linear, few discharge measurements are required to define the relation.

APPRAISAL OF METHOD

Studies to date (1980) indicate that the technique of electromagnetic stream gaging is feasible although there are still problems to be resolved. The method would probably have its principal use in gaging those streams that are not amenable to the more conventional methods of stream gaging—sand-channel streams with movable beds (see section in chapter 10 titled "Sand-Channel Streams,") and streams with profuse growths of aquatic weeds.

CHAPTER 13—DISCHARGE RATINGS FOR TIDAL STREAMS

GENERAL

A discharge rating can be obtained for a tidal or tide-affected stream if a velocity index is used as a parameter in the rating along with stage. If the stream is quite small, a deflection meter is a satisfactory device for obtaining a continuous record of velocity; the electromagnetic method of stream-gaging is still in the experimental stage. For the larger streams the acoustic velocity meter is a satisfactory device for obtaining an index of velocity. (The instrumentation and methodologies involved in the use of deflection meters, electromagnetic velocity meters, and acoustic velocity meters were described in Chapter 12.) In the absence of such devices, there are two general approaches for obtaining a continuous discharge record—the theoretical approach involving evaluation of the equations of unsteady flow for a tide-affected reach of channel, and the empirical approach involving empirical relations whose effectiveness generally varies inversely with the degree of importance of the acceleration head (see section in chapter 11, titled "Theoretical Considerations"). The theoretical approach is much preferred.

Either approach requires a recording stage gage at each end of a long reach of channel. The two gages must be synchronized so that simultaneous stages at the two sites can be obtained from the stage records. Either approach requires discharge measurements for calibrating the discharge model; the moving-boat method of measuring discharge (chap. 6) is recommended for the larger streams.

EVALUATION OF UNSTEADY-FLOW EQUATIONS

It is beyond the scope of this manual to treat in detail the various methods of evaluating the equations of unsteady flow. Basic to all methods is the solution, by approximate step procedures, of the following pair of differential equations:

$$\frac{Q^2}{K^2} = -\frac{\partial H}{\partial x} - \frac{1}{g}\frac{\partial V}{\partial t} \tag{122}$$

$$\frac{\partial Q}{\partial x} = -B\frac{\partial h}{\partial t}, \tag{122a}$$

where Q is the discharge, K is the conveyance of the cross section, H is the total energy head, x the distance along the channel, g the acceleration of gravity, V the mean velocity, t the time, B the top width of the

channel, and h is the water-surface elevation. Solution of the equations requires the use of a digital computer.

The four methods of equation evaluation that will be briefly discussed are:

1. power series,
2. method of characteristics,
3. implicit method, and
4. Fourier series.

For any of the four methods, it is necessary that a series of current-meter discharge measurements be made over several tidal cycles at either end of the reach. The measurements are needed to compute the resistance and conveyance properties of the reach and to serve as checks on the computed discharges. The series of measurements should include one series made at a time of low freshwater discharge and large tidal range, and another made when the freshwater discharge is high. These two series of measurements may be sufficient if the channel is stable with regard to scour and fill, but for an unstable alluvial channel, it is necessary that several additional series of discharge measurements be made. For meaningful results it is necessary that the channel either be stable (unchanging) or if subject to change, the channel changes must occur in the same way for each change in discharge during rises and subsequent recessions.

During a series of discharge measurements over a tidal cycle, enough measurements must be made to define the discharge hydrograph to an accuracy that will permit momentary discharges to be determined at 15-minute intervals for the duration of the cycle. The discharge measurements are commonly made at about hourly intervals and cover a few hours more than the duration of the tidal cycle.

The exact procedure used to measure the discharge in a tidal reach will vary with size of channel and flow conditions. For a small tide-affected stream, one or two field crews measuring continuously across the stream may be adequate for obtaining the data for an accurate definition of the discharge hydrograph. For a large tide-affected river, several measuring crews may be required, and it may be necessary to compute the hydrograph in the manner described for flash floods on small streams (see section in chapter 5 titled, "Measurement Procedures During Rapidly Changing Stage—Case B. Small Streams"). In that method a stage-mean velocity relation is first determined for each measurement vertical, and total stream discharge is then computed for selected stages. The preferred method of measuring discharge in a large tide-affected stream is, of course, the moving-boat method (chap. 6).

One of the basic assumptions of the methods to be presented is that the water in the tidal reach is substantially of homogeneous density,

thereby eliminating the possibility of density currents. Therefore, consideration should be limited to those portions of tidal reaches that are affected by the propagation of long, low-amplitude, translatory waves but in which salinity intrusion does not cause a saline wedge to form or cause distinct stratification of flow.

An important consideration in the choice of a reach is the availability of a 110-volt power supply at both ends to drive the digital stage recorders synchronously. Although standby DC units, equipped with DC to AC inverters, are available to take over immediately in the event of a power failure, standby units should be used for periods no longer than absolutely necessary; the use of standby units for long periods of time invariably results in loss of synchronization. Any loss of synchronization between the two clocks, even fractions of a minute, may cause significant error in the computation of discharge. Recent (1976) tests indicate that battery-operated electronic clocks may have the required accuracy and reliability, and if so, the availability of a 110-volt power supply will no longer be a requirement.

POWER SERIES

In solving the equations of unsteady flow by use of a power series—commonly a Taylor series—finite differences are used. Velocity and stage and all orders of their derivatives are continuous functions with respect to x and t. The value of Δx, or length of reach to be used, is generally 3 to 7 miles—there is a theoretical maximum length that depends on tidal wave length (hours) and mean channel depth. The value of Δt to be used is usually 15 minutes.

In the power-series method, tidal flow is considered to be one-dimensional unsteady flow in a prismatic channel. However, a natural reach of channel usually differs greatly from an idealized tidal reach that has an unvarying prismatic cross-section and a constant bottom slope. Consequently, it is necessary to determine a mean cross-section that is representative of the reach and whose dimensions are variable with stage. From such a representation, the geometric parameters required for the discharge computations can be obtained. The number of cross sections to be surveyed in the field in order to compute a representative mean cross-section depends on the length and degree of uniformity of the tidal reach. Usually ten or more cross sections, somewhat evenly spaced in the reach, are required.

Local inflow or outflow (diversions) to or from the tidal reach is considered in the solution, but the quantity of such flow must be small in comparison with the flow in the main channel. The local inflow or outflow is often assumed to be constant throughout a complete tidal cycle and is considered to enter or leave the main channel uniformly

along the entire length of reach; thus large concentrations of flow at a single point cannot be accommodated by the method.

A mathematical description of the mechanics of computing discharge in tidal reaches, by the use of a power series for solving the equations of unsteady flow, is beyond the scope of this manual. For such information the reader is referred to papers by Baltzer and Shen (1961, 1964) and by Davidian (1964).

METHOD OF CHARACTERISTICS

The method of characteristics is well adapted to the solution of partial differential equations in two variables, such as equations 122 and 122a. (All terms in those equations are related to velocity and (or) stage.) In the method, the basic partial differential equations are first transformed to characteristic equations and then to corresponding difference equations.

As in the power-series method, tidal flow is considered to be one-dimensional unsteady flow in a prismatic channel. In the finite-difference solution of the equations, computations are made at equal time intervals Δt (usually 15 minutes, or less) and at equal increments of distance x along the channel. The selected value of Δx must meet the criterion,

$$\Delta x \geq \Delta t \, (V + \sqrt{gd}), \tag{123}$$

where

V is mean velocity of flow at the starting cross section of increment Δx,

g is the acceleration of gravity, and

d is depth.

Both velocity and stage, as well as discharge, which is the product of velocity and area, can be obtained explicitly for each new step of Δt. Unlike the power-series method which provides the desired information for only one variable at a time—for example, the discharge at one end of the reach—the method of characteristics provides the desired information simultaneously for any selected points in the reach that lie at multiples of Δx from the end of the reach. However, it is possible to change the values of Δx and Δt during the computation, if that is desired, as long as the relation of Δt to Δx meets the criterion given in equation 123.

A single representative cross section is normally used for the entire reach, as in the power-series method. However, a multiple reach may also be used (Lai, 1967a). A long reach is divided into several subreaches, each with its own individual geometry and roughness coefficient. The basic method of characteristics is applied to each subreach, and additional boundary conditions are imposed at each junction be-

tween subreaches. Furthermore, the method of characteristics will accommodate the entrance of a large gaged tributary into the reach; the boundary conditions are then more involved, but there is no complication in principle.

The mathematical details of the method of characteristics are described by Lai (1965a, 1967a), Lister (1960), and Stoker (1953).

IMPLICIT METHOD

The implicit method is yet another finite-difference procedure for solving the basic partial differential equations for flows of homogeneous density in tidal reaches. The implicit method has one advantage over the method of characteristics in that the choice of Δt is less restricted; the stability of the solution is not limited by the criterion of equation 123.

The mathematical details of the implicit method are described by Lai (1965b, 1967b, 1968) and by O'Brien, Hyman, and Kaplan (1951).

FOURIER SERIES

The equations of unsteady flow have also been solved by a method of harmonics in which a Fourier series is used. The distinctive characteristic of a Fourier series is the periodicity of the trigonometric terms of which it is composed. The Fourier series lends itself well to the expression of periodic phenomena that are represented by linear differential functions; the equations of unsteady flow, however, are quasi-linear hyperbolic differential functions. Consequently, it is necessary to linearize the equation system when using a Fourier series. That distorts the equation system. An even more significant consideration is whether or not tidal flow can be described as a truly periodic phenomenon. The long translatory wave motion introduced into a tidal reach by the astronomical tide is periodic, but its periodicity is disturbed when the natural upland flow of a river system is superimposed on the tidal wave motion or when storm surges from the ocean occur.

Despite these drawbacks, Fourier series evaluation techniques for determining flow in tidal reaches have been developed (Dronkers, 1947, p. 127–137; Dronkers and Schönfeld, 1955, p.11–24; Schonfeld, 1951, p. 70–87 and 143–152). However this type of solution is the least suitable of the four methods that have been briefly described here for solving the differential equations of unsteady flow in tidal reaches.

EMPIRICAL METHODS

Four empirical methods of rating tidal reaches have been in use, all but one of which were developed before the use of digital computers became commonplace. Those techniques are:

1. method of cubatures,
2. rating-fall method,
3. tide-correction method, and
4. coaxial graphical-correlation method.

All the above methods have their shortcomings which are discussed, where appropriate, in the sections of the manual that follow.

METHOD OF CUBATURES

One of the oldest methods of computing discharge in tidal estuaries is the method of cubatures (Pillsbury, 1956). The method, still in use, is based on the equation of the conservation of mass;

Outflow at the study station = inflow ± change in storage.

The inflow term in the above equation is the freshwater discharge measured at a gaging station at or upstream from the head of tide—that is, a gaging station having a simple stage-discharge relation. The storage term refers to volume of water in the reach between the inflow gaging station and the study station on the estuary. Intermediate stage gages are usually needed for evaluating the storage term. The gages are spaced at such distances that no significant error is introduced in the computations by considering the water surfaces between gages as planes. That requirement ordinarily is met by stations some miles apart but suitably placed with regard to marked changes in the cross section of the waterway. The differences in the tidal ranges on the opposite shores of a wide estuary may usually be disregarded, but it may be necessary to establish tidal stations on any long tidal tributaries of the main waterway. For convenience in the computations, the tides at all stations should be reduced to the same horizontal datum, preferably taken low enough to make all stages positive.

If existing surveys do not afford reliable data on the areas of the water surfaces between the selected tidal stations, a survey to establish these surfaces is required. Usually such surface areas may be taken as increasing uniformly from low water to high water, but if there are any considerable tide flats that are exposed at the lower tidal stages, the area at the stage at which such flats are covered also should be found.

Freshwater inflow to the reach from tributary streams is estimated if the tributary flow is relatively small. If the tributary streams are large, they are gaged upstream from the head of tide to provide a continuous record of freshwater inflow, just as is done with the principal inflow stream.

A sample computation is shown in figure 222 for a 5.8 mile reach of the Delaware River between Trenton and Fieldsboro, N.J. This is the second reach in the estuary; the first reach extends upstream from

Time	Tidal stage			Mean stage during time interval	Water-surface area (A) at mean stage	Change in stage (Δy) during time interval	Change in storage			Outflow Q
	Upper station	Lower station	Mean (y)				In study reach $\Delta Q = A(\Delta y/\Delta t)$	In upstream reach	Total (upstream plus study reaches)	
(hr)	(ft)	(ft)	(ft)	(ft)	(1000's of ft^2)	(ft)	(ft^3/sec)	(ft^3/sec)	(ft^3/sec)	(ft^3/sec)
1	2	3	4	5	6	7	8	9	10	11

FIGURE 222.—Sample computation of tide-affected discharge by method of cubatures, using 30-minute time intervals. (After Pillsbury, 1956.)

Trenton to the Delaware River gaging station that is upstream from head of tide. Total freshwater inflow to the second reach is −12,200 ft^3/s, flow in the downstream (ebb) direction being considered negative in the computations. That inflow consists of 12,000 ft^3/s for the Delaware River mainstream and 200 ft^3/s for tributary inflow. The time interval (Δt) used in the computations is 30 minutes, or 1,800 seconds. The computations in the table in figure 222 are largely self-explanatory. The figures in column 9 were obtained from similar computations (not shown) for the reach upstream from the study reach. Column 10 is the sum of columns 8 and 9; column 11, the outflow from the study reach, is the sum of the total storage change (column 10) and the total freshwater inflow (−12,200 ft^3/s).

Figure 223 is the discharge hydrograph obtained by first plotting the outflow histogram (values from column 11 of fig. 222), and then drawing a smooth hydrograph to give balance between areas above and below the horizontal bars of the histogram.

The method of cubatures is not only cumbersome, but the discharge figures obtained are only rough approximations of the true values

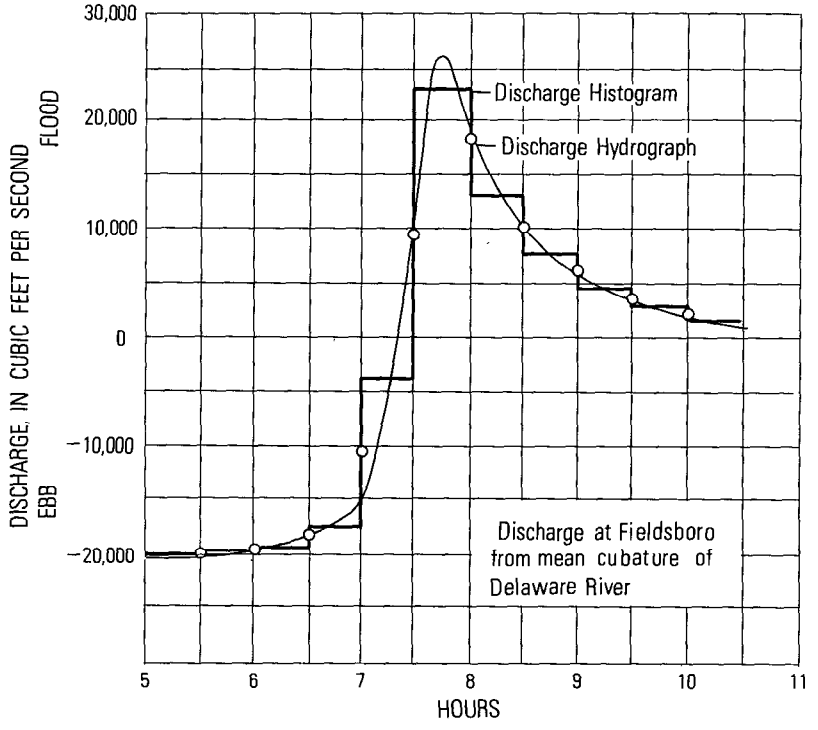

FIGURE 223.—Discharge hydrograph obtained for sample problem by method of cubatures. (After Pillsbury, 1956.)

because of the large errors inherent in computing the storage component of the continuity equation. When the method is used, the results, although approximate, should be checked for consistency—total computed outflow should approximate total inflow over some long-term period whose net change in storage is negligible.

RATING-FALL METHOD

Stage-fall-discharge relations have been used successfully for rating tide-affected streams where acceleration head is a minor factor. The rating-fall method that is discussed in detail in the section in chapter 11 titled, "Variable Slope Caused by Variable Backwater," is used for that purpose. Acceleration head is often a minor factor where the slope reach is located at the upper end of an estuary near the head of tide. Consequently, it is usually only at or near such locations that the rating-fall method can be used successfully.

TIDE-CORRECTION METHOD

The tide-correction method assumes that a direct proportionality exists between the cyclic range in stage observed at any two points within a tidal reach. On the basis of that assumption, a relation of mean discharge for a tidal cycle to mean stage for a tidal cycle is developed for the base-gage site. In calibrating that relation, the mean discharge for a tidal cycle, obtained by averaging several individual measurements made 1–2 hours apart throughout the cycle, is plotted against adjusted mean stage at the base gage. The adjustment applied to the mean stage at the base gage is determined from the difference, at the secondary gage, between observed mean stage and the stage that is presumed to exist under conditions of least tide fluctuation. That difference (D) is multiplied by the ratio of the stage range at the base gage to the stage range at the secondary gage; the product is the stage adjustment required at the base gage. In practice, the secondary stage observations are frequently made at a nearby ocean inlet. Mean sea level is assumed to represent the condition of least tidal fluctuation, and therefore, if all gages have their datums set to mean sea level, D is always equal to the mean stage for a tidal cycle at the secondary gage. Essentially the tide-correction method attempts to approximate the stage that would occur for a particular steady-flow discharge under a fixed backwater condition. An example of the tide-correction method (Parker and others, 1955) follows.

At Hialeah, Fla., the base gage is on the Miami Canal, 7.6 miles upstream from the ocean. A tide gage on the ocean is used as the secondary gage. Both gages have their datum at mean sea level. On a given date the following tidal-cycle data were obtained from the stage gages:

	Base gage	*Secondary gage*
Mean stage (ft)	2.64	1.61 = D
Maximum stage (ft)	3 18	2.74
Minimum stage (ft)	2.10	.48
Stage range (ft)	1.08	2.26

$$\text{Stage correction (base gage)} = D\left(\frac{\text{stage range at base gage}}{\text{stage range at secondary gage}}\right)$$

$$= 1.61\left(\frac{1.08}{2.26}\right)$$

$$= 0.77 \text{ ft}$$

The stage correction is always negative and therefore the stage at the base gage, to be applied to the mean discharge for the tidal cycle on that date, is

$$\text{Gage height} = 2.64 - 0.77 = 1.87 \text{ ft.}$$

The mean-cycle discharge, as determined from 20 sets of discharge measurements, was plotted against the actual mean-cycle gage height and also against the tide-corrected gage height, as indicated on figure 224. The rating curve shows the relation between the tide-corrected gage height and the mean tide-cycle discharge for the upper gage. The discharge, when plotted against actual mean-cycle gage height, shows a considerable scatter of the plotted points, but the discharge plotted against tide-corrected gage height shows a very

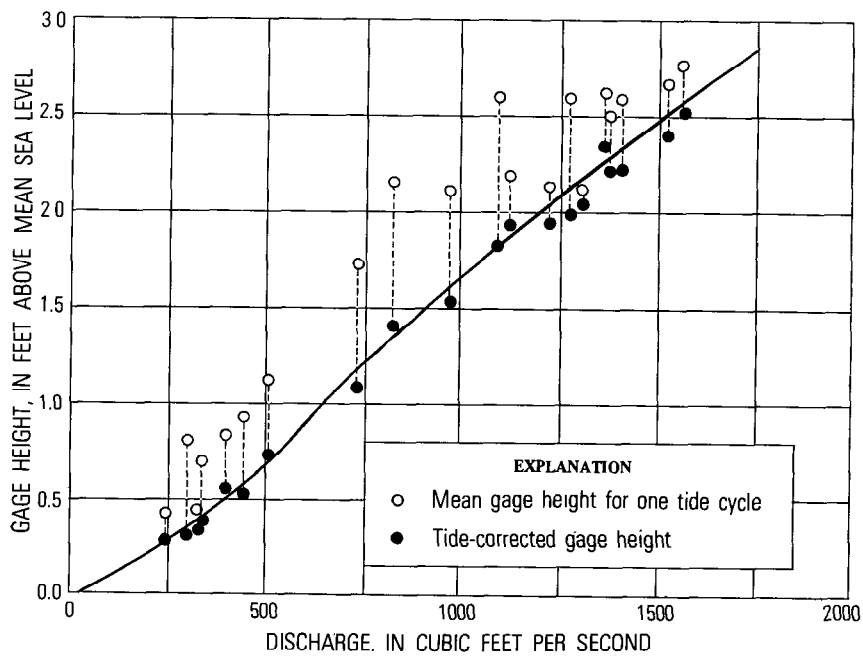

FIGURE 224.—Graph of relation between tide-corrected gage height and discharge for Miami Canal at Water Plant, Hialeah, Fla.

close agreement for the numerous measurements. The shape of the rating curve is characteristic of that for a stream having a large initial cross-sectional area at the point of zero flow.

The tide-correction method of rating a tide-affected stream may be used where reverse flows occur during a part of each tide cycle because the mean discharge for the cycle is the value used in the computation. It is also applicable to a reach of tidal waterway, on which both observation stations are upstream from the mouth of the waterway. Mean-cycle discharge obtained from the rating curve can be plotted against mean-cycle time on a hydrograph sheet, and after connecting the points by straight lines, the daily mean discharges can be determined.

The tide-correction method has been satisfactory, though cumbersome, for computing the daily discharge of tide-affected canals in Florida, but efforts to adopt the method for use elsewhere in the U.S.A. have generally been unsuccessful.

COAXIAL RATING-CURVE METHOD

The coaxial method of graphical correlation to determine discharge in a tidal reach was developed to fill the need for a simple method of making reasonably accurate "on-the-spot" determinations of streamflow. A method of this kind is required, for example, in the operation of a sewage plant discharging its effluent into a tide-affected stream. The method that was developed fills this need in that readings from a pair of stage gages can be used to determine momentary discharge directly from a set of rating curves.

The coaxial method is best described by an example. Coaxial rating curves were developed for the Sacramento River at Sacramento, Calif., on the basis of 302 discharge measurements made during the years 1957–60 (Rantz, 1963). Actually only 52 of the measurements were used to develop the curves; the remaining 250 discharge measurements were used to test the rating curves and refine them slightly. Measured discharges ranged from 4,060 ft^3/s (115 m^3/s) to 19,300 ft^3/s (547 m^3/s).

The streamflow-measurement section is at the site of the stage recorder in the city of Sacramento; the auxiliary stage recorder is 10.8 mi (17.4 km) downstream near the town of Freeport. Local inflow into the 10.8-mile reach of channel is negligible. The reach itself is located far enough upstream on the Sacramento River estuary so that no reversal of flow occurs. When upland flow (streamflow) into the estuary is less than about 30,000 ft^3/s (850 m^3/s), however, the discharge is affected by tidal action, and the flow in the reach is unsteady. The relative magnitude of the tidal effect in the reach increases with decrease in the upland flow and with increase in the range of elevation between high and low tides. The stages at Sacramento and

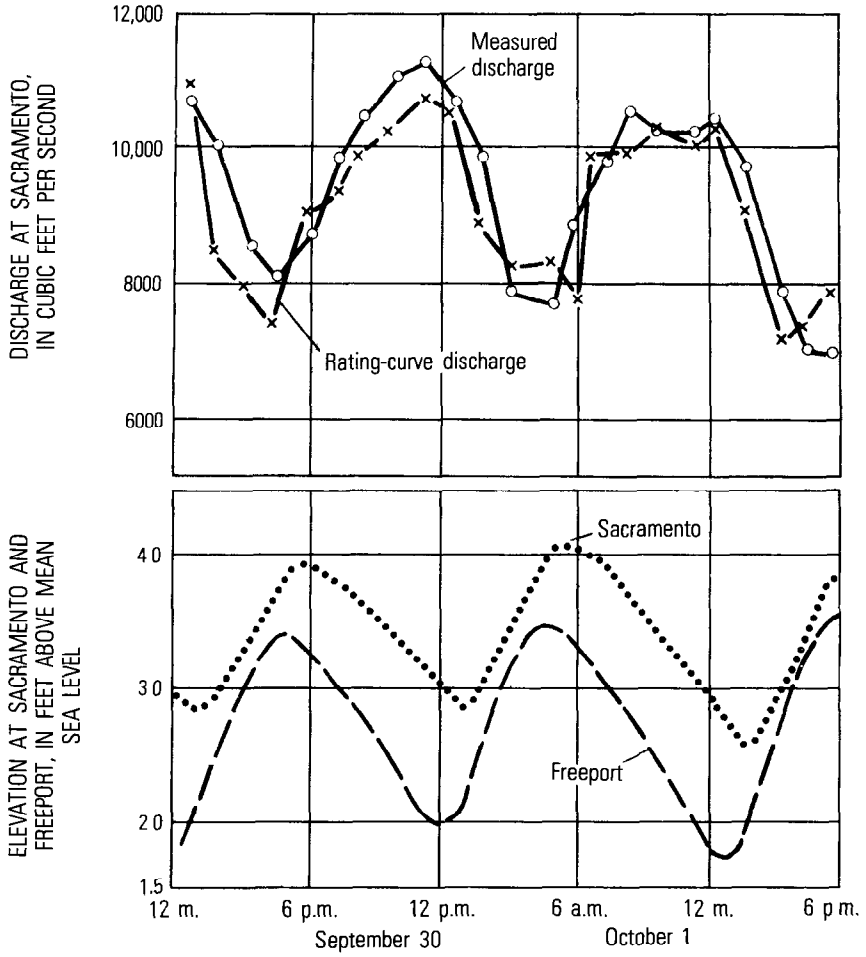

FIGURE 225.—Stage and discharge of the Sacramento River at Sacramento, Calif., Sept. 30 to Oct. 1, 1959.

Freeport during a 36-hour period and the fluctuation of discharge at Sacramento illustrate a typical low-flow condition (fig. 225). The upland flow above Sacramento was 9,300 ft/s (263 m^3/s). As a result of tidal effect, the discharge at Sacramento varied from 6,800 ft^3/s (193 m^3/s) to 11,300 ft^3/s (320 m^3/s).

The differential equations of unsteady flow were used to devise a graphical technique for determining discharge. The following parameters serve as indices of the terms that appear in these differential equations:

Dependent variable.—Measured discharge at Sacramento.

Independent variables.—(1) Stage at Sacramento, (2) fall in the

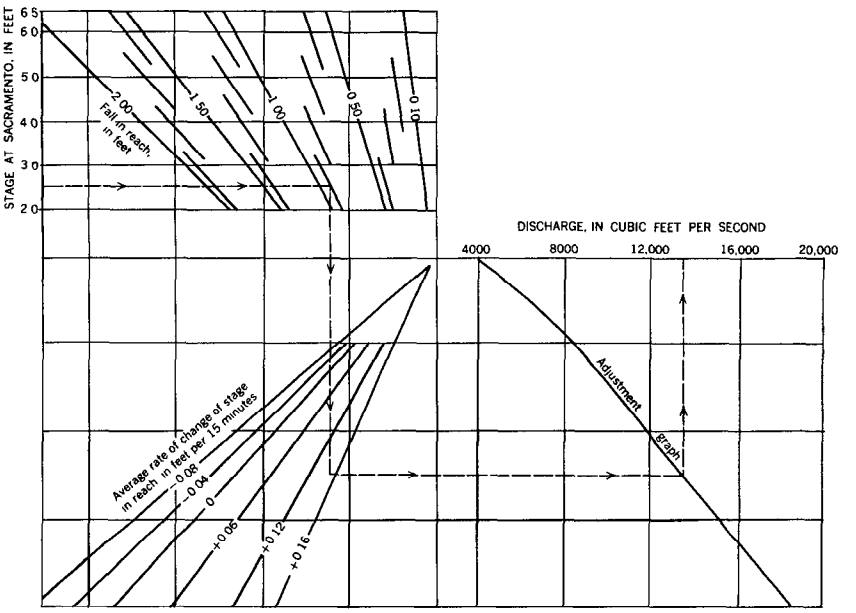

FIGURE 226.—Coaxial rating curves for the Sacramento River at Sacramento, Calif. (Dashed lines and arrows illustrate use of the curves.)

reach between Sacramento and Freeport, and (3) the algebraic average of the change in stage observed at Sacramento and Freeport during a 15-minute interval.

Because of the differential form of the equations of unsteady flow, there is no statistical model on which to base the relationship of these variables. A further complication arises from the fact that joint functions are involved, for interrelations among the independent variables affect the flow at Sacramento. The versatile statistical technique known as the coaxial method of graphical multiple correlation (Linsley and others, 1949, p. 650–655) was adopted for developing the rating curves for the Sacramento River.

The coaxial graphical correlation that was the end product of this study is shown in figure 226. In the interest of simplicity, only a few lines are shown in each family of curves. To use the graph, first, the curves in the upper left-hand group are entered with the stage at Sacramento and the fall in the reach; next, the curves in the lower left-hand group are entered with the average rate of change of stage in the reach; finally, the adjustment graph to the right is entered and the discharge is read. The adjustment graph was added to the correlation to introduce a necessary curvilinearity to the relationship. This curve may also serve another purpose—if the relation should change, as a result of channel dredging, for example, only the adjustment

graph need be revised, thereby eliminating the laborious task of revising the two families of curves.

Of the 305 discharge measurements, 268, or 89 percent of them, checked the rating within ±10%; 286 measurements, or 95 percent of the measurements, checked the rating within ±15%. The rating was weakest during periods of low upland flow, but for only a few hours of any day during those periods. Those hours coincided with times when the acceleration head in the equations of unsteady flow was of relatively major importance.

The coaxial rating-curve method fulfills its purpose of being useful for making "on-the-spot" estimates of tidal flow at Sacramento, but the method is too cumbersome for use in computing a continuous record of discharge for a gaging station. Solution of the theoretical equations of unsteady flow (see section on "Evaluation of Unsteady-Flow Equations") is much better for the latter purpose.

CHAPTER 14—DISCHARGE RATINGS FOR MISCELLANEOUS HYDRAULIC FACILITIES

INTRODUCTION

This chapter is a "catchall" for specialized problems in establishing discharge ratings for various hydraulic facilities, using techniques that are not specifically described in chapters 10–13. The hydraulic facilities are discussed under the following principal headings:

1. dams with movable gates,
2. navigation locks,
3. pressure conduits, and
4. urban storm drains.

DAMS WITH MOVABLE GATES

GENERAL

Dams are commonly equipped with movable gates for better control of pool stage and outflow. As a general rule the movable gates, as such, are not rated; instead, the channel downstream is rated by the most practicable method—simple stage-discharge relation (chap. 10), or stage-fall-discharge relation (chap. 11), or by use of a velocity index furnished, for example, by an acoustic velocity meter (chap. 12). However, in some situations none of those rating methods may be satisfactory. For example, consider a river controlled by a series of low navigation dams. In that situation, the river profile resembles a huge staircase—successive pools separated by dams. The movable dam crests negate the use of a simple stage-discharge relation; the slope of the water surface in the pools may be too flat for a stage-fall-discharge relation; and velocities may be too slow for accurate evaluation by an acoustic velocity meter. In that situation, the most practicable method of obtaining a continuous record of discharge is to calibrate the flow through or over the movable gates. If boat traffic is heavy and natural inflow is light, a significant part of the discharge may be the flow released through the navigation locks and the lockages must likewise be calibrated (see section on "Navigation Locks").

Calibration of the gates by discharge measurements during periods of light releases of water may be extremely difficult. If boat lockages are infrequent, standard current-meter measurements made downstream by boat, using a low-velocity meter, may be adequate. If boat lockages are frequent, the surges in discharge attributable to the lockages may cause unsteady and nonuniform flow conditions downstream; discharge measurements must then be made as rapidly as possible under conditions that are not conducive to accurate

results. A rapid discharge measurement may be made by the moving-boat method (chap. 6) or by use of a bank of current meters operated from a bridge (see section in chapter 5 titled, "Networks of Current Meters"). If velocities are too slow for accurate measurement by either of those two methods, and if only small quantities of water are being released under the dam-crest gates, the best course of action might be to use the volumetric method for measuring flow over a dam crest that is described in the section in chapter 8 titled, "Volumetric Measurement." In using the volumetric method, the barge carrying the calibration tank is kept in place not only by lines operated from the banks, but also by an outboard motor on the barge to keep the barge from drifting downstream. The difficulty of measuring low flow under the conditions described above is apparent. At those times it may also be difficult to determine the actual head on the gates because lockages often cause longitudinal seiche-like waves to traverse the gage pool, and those waves travel back and forth over the length of the pool for a considerable period of time.

The flow at movable dam-crest gates may be placed in two general categories—weir flow over the gate or dam crest and orifice flow under the gate. Each of those types of flow may be either free or submerged, depending on the relative elevations of headwater, tailwater, and pertinent elements of the dam crest or gate. Listed below are the crest gates that will be discussed.

1. Drum gates
2. Radial or Tainter gates
3. Vertical lift gates
4. Roller gates
5. Movable dams
    a. Bear-trap gates
    b. Hinged-leaf gates
    c. Wickets
    d. Inflatable dams
6. Flashboards
7. Stop logs and needles

A gated dam usually has several gates along its crest. The gates are installed in bays that are separated by piers. All other conditions being equal, the discharge through a single gate, when adjacent gates are open, will be about 5 percent greater than the discharge through that same gate when adjacent gates are closed. The various types of gates should be calibrated by discharge measurements, but as an aid to shaping the calibration curves, experimental ratings where available are given in the text that follows.

Discharge measurements for the purpose of determining gate coefficients will almost always be made in the downstream channel and

will include the flow for all the gates that are open. Furthermore, for given stages upstream and downstream from the gates, the gate coefficient will commonly vary with the gate position or opening. Consequently, if discharge is to be measured with more than one gate open, arrangements should be made, if possible, for all gates to be positioned identically. If the difference in the positioning of the gates are minor, and if the gate coefficient does not vary significantly with its positioning, a discharge measurement may be made; in the computation of the gate coefficient, an average gate position will be assumed for each of the bays carrying flow.

DRUM GATES

A drum gate consists of a segment of a cylinder which, in the open or lowered position, fits in a recess in the top of the spillway. When water is admitted to the recess, the hollow drum gate is forced upward to a closed position. One type of drum gate (fig. 227*A*) is a completely enclosed gate hinged at the upstream edge; buoyant forces aid in its lifting. That type of gate is adapted to automatic operation and also conforms closely to the shape of the ogee crest when lowered. A second type (fig. 227*B*) has no bottom plate and is raised by water pressure alone. Because of the large recess required by drum gates in the lowered position, they are not adapted to small dams.

With regard to its calibration, the drum gate resembles a thin-plate weir with a curved upstream face over the greater part of its travel. Given an adequate positioning indicator, the drum gate can serve as a satisfactory stream-gaging control. Its use for that purpose has been investigated by Bradley (1953), and the discussion that follows is taken almost verbatim from Bradley's paper dealing with a drum gate of the type shown in figure 227*A*.

When the drum gate simulates a thin-plate weir—that is, when a line drawn tangent to the downstream lip of the gate makes a positive angle with the horizontal, as shown in figure 228*A*—four principal factors are involved. These factors are H, the total head above the high point of the gate; Θ, the angle between the horizontal and a line

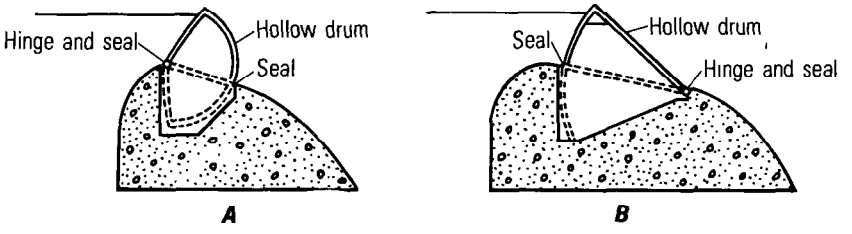

FIGURE 227.—Two types of drum gate.

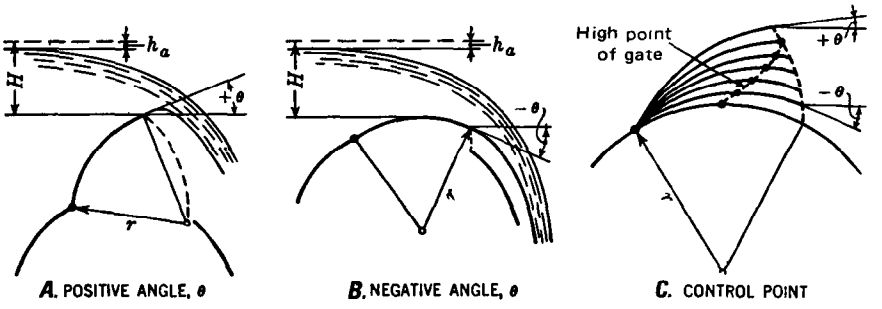

FIGURE 228.—Drum-gate positions. (After Bradley, 1953.)

drawn tangent to the downstream lip of the gate; r, the radius of the gate, or an equivalent radius if the shape of the gate is parabolic; and C_u, the coefficient of discharge in equation,

$$Q = C_u b H^{3/2}, \tag{124}$$

where

Q is discharge (ft^3/s), and

b is length of the gate (ft) normal to the discharge.

The velocity in the approach section was not included as a variable because the drum-gate installations studied were on high dams where approach effects were negligible. It has been shown that when the approach depth measured below the high point of the gate is equal to or greater than twice the head on the gate, a further increase in the approach depth produces little change in the coefficient of discharge. Most drum-gate installations are on dams that meet the above depth criterion, particularly when the gate is in a raised position. Therefore, in the usual case of adequate approach depth, the four variables, H, Θ, r, and C_u completely define the flow over this type of gate when angle Θ is positive (fig. 228*A*).

For negative values of Θ (fig. 228*B*), the downstream lip of the gate no longer controls the flow. In that situation the control point shifts upstream to the vicinity of the high point of the gate for each setting, as illustrated in figure 228*C*, and flow conditions gradually approach those of the free crest as the gate is lowered. Although other factors enter the problem, similitude in the computation exists down to an angle of about $-15°$.

Experimentation with eleven drum gates produced the family of curves for C_u shown in figure 229. The discharge coefficients in the region between $\Theta = -15°$ and the gate completely down are determined by graphical interpolation, a method that will be explained in the example that follows. The effect of submergence of the drum gate on C_u was not investigated because drum gates are invariably used on high dams, and the probability of submergence is negligible. The data

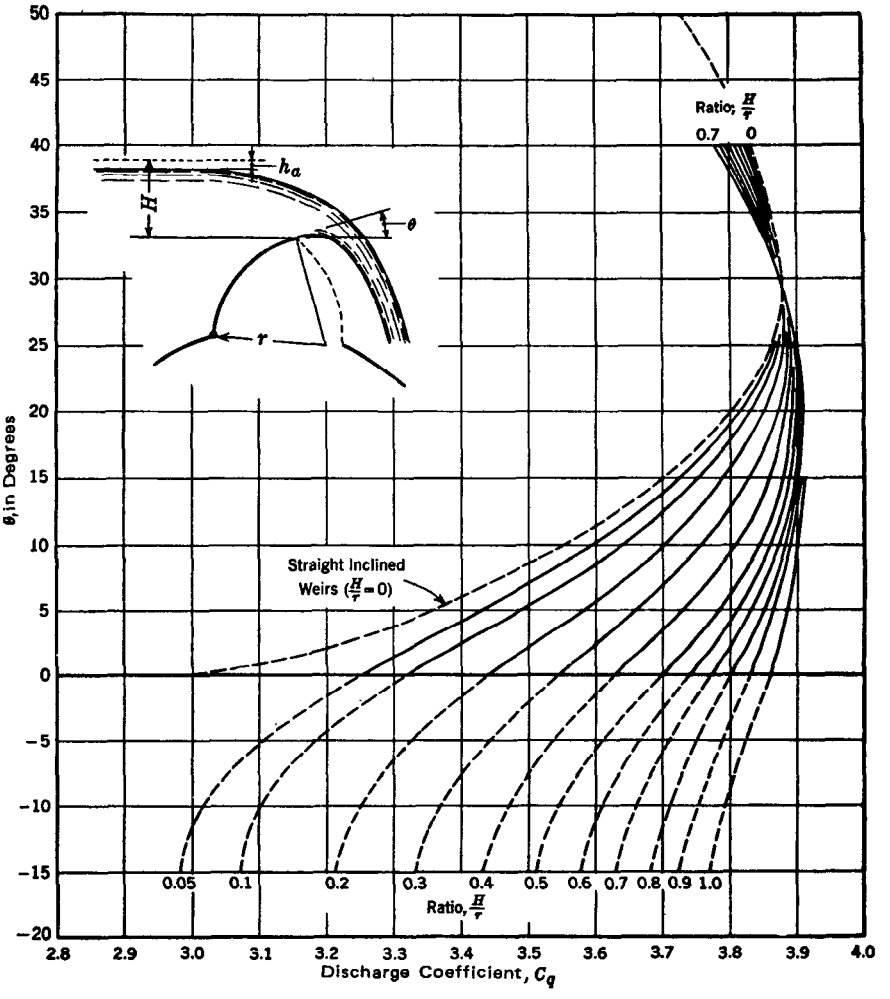

FIGURE 229.—General curves for the determination of discharge coefficients. (After Bradley, 1953.)

to be continuously recorded for computing discharge over rated drum gates are reservoir stage and the indication of drum-gate position for each gate.

The method of rating a drum gate on a round-crested weir will now be demonstrated using as an example the plan and spillway cross section of Black Canyon diversion dam in Idaho (figs. 230 and 231). The first step is the determination of the design head of the dam and the corresponding discharge coefficient for the free crest. That is done in accordance with the technique described under the heading "Nappe-fitting method" in the U.S.G.S. manual on computing peak

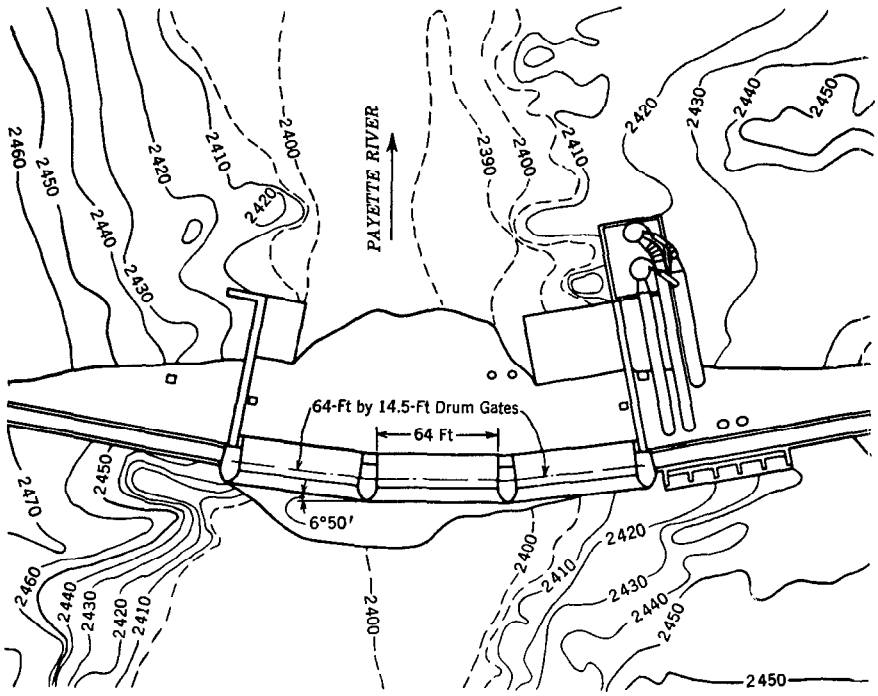

FIGURE 230.—Plan of Black Canyon Dam in Idaho. (After Bradley, 1953.)

discharge at dams (Hulsing, 1967, p. 13–23). If a discharge measurement has been made under the condition of flow over a free crest, the results of the measurement are used to check the value of design head and design-head coefficient, using the technique described under the heading "Index-measurement method" in the previously cited manual by Hulsing (1967, p. 23–24). The design head (H_0) of Black Canyon diversion dam was found to be 14.5 ft and the corresponding coefficient of discharge (C_0) was found to be 3.48.

With the coefficient of discharge known for free flow at the design head, the entire free-flow coefficient curve can be established by use of figure 232. The free-flow coefficient curve for the spillway of Black Canyon diversion dam (H_0 = 14.5 ft; C_0 = 3.48) is constructed by arbitrarily assuming several values of H/H_0 and reading the corresponding values of C/C_0 in figure 232. The method of computation is illustrated in table 25, and the head-coefficient curve for free flow (gate down) obtained in that manner is shown in figure 233.

Before considering the rating of the spillway with gates in raised positions, it is necessary to construct a diagram, such as that shown in figure 234, to relate gate elevation to the angle Θ for the Black

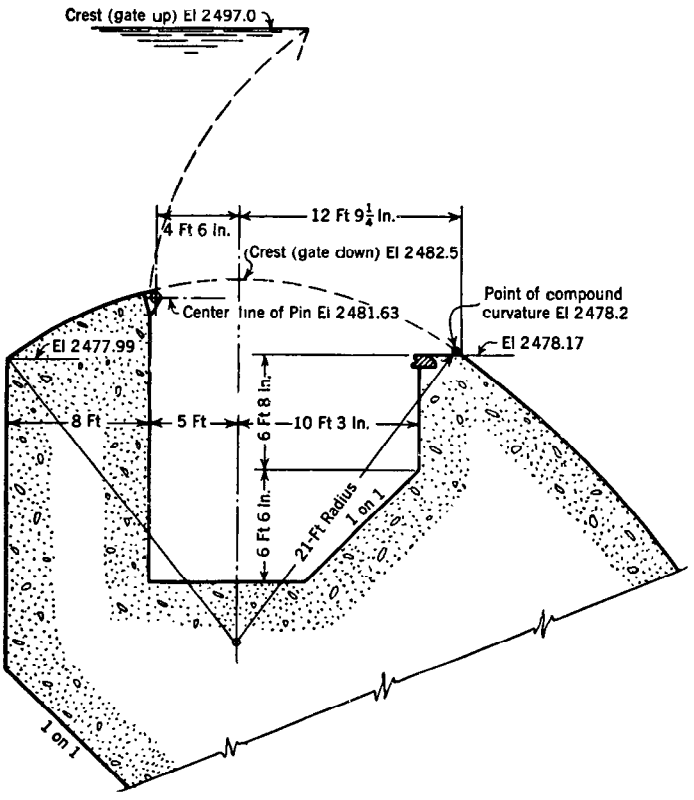

FIGURE 231.—Spillway crest detail, Black Canyon Dam, Idaho. (After Bradley, 1953.)

Canyon Dam gate. The tabulation in figure 234 shows the angle Θ for corresponding elevations of the downstream lip of the gate at intervals of 2 ft.

Beginning with the maximum positive angle of the gate, which is 34.883°, the computation may be started by choosing a representative number of reservoir elevations as indicated in column 2 of table 26. The difference between the reservoir elevation and the high point of the gate constitutes the total head on the gate, and values of head are recorded in column 3. Column 4 shows these same heads divided by the radius of the gate, which is 21.0 ft.

The discharge coefficients listed in column 5 (table 26) of the set of computations designated "A", are obtained by entering the curves in figure 229 with the values in column 4 for $\Theta = +34.883°$. The remainder of the procedure outlined in columns 6 and 7 of table 26, consists of computing the discharge for one gate from the equation,

$$Q = C_a\, bH^{3/2}. \tag{124}$$

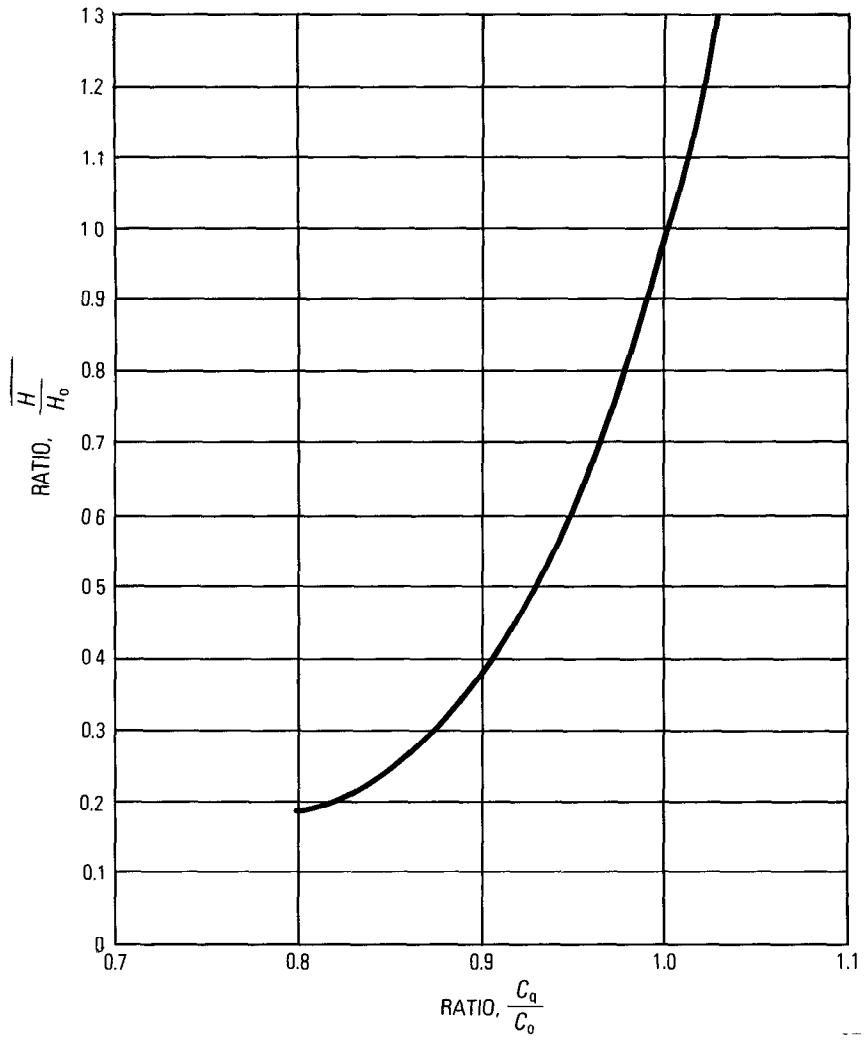

FIGURE 232.—Diagram for determining coefficients of discharge for heads other than the design head (After Bradley, 1953.)

A similar computation procedure is repeated for other positive angles of Θ, as in sets B, C, and D of table 26.

For positive values of angle Θ the high point of the gate is the downstream lip of the gate. As the angle Θ decreases to negative values, the high point of the gate is no longer the downstream lip. In determining the discharge for negative values of Θ between 0° and −15°, the procedure remains the same as was used for positive values

of Θ, but as mentioned above, the controlling difference between reservoir elevation and high point of the gate is no longer the head above the downstream lip. (See fig. 234.) Discharge computation for negative angles down to $-15.017°$ are tabulated in sets E, F, and G of table 26.

The plotting of values of discharge, reservoir elevation, and gate elevation from table 26, results in the seven curves in figure 235 that bear the plotted points, shown by closed circles. An eighth curve, the extreme lower curve, which bears plotted points shown by X's, represents the discharge of the free crest with the gate completely down; the plotted points represent values obtained from table 25.

The discharge values shown in figure 235 are for one gate only. When more than one gate is in operation, the discharges from the separate gates may be totaled, providing the gates are each raised the same amount. The experimental models used in this study had from one to eleven gates operating, so that a reasonable allowance for pier effect on the discharge is already present in the results.

The intervals between the eight curves in figure 235 that are identified by plotted points are too great for rating purposes, particularly the gap between gate elevations 2485.75 and 2482.5 ft. That deficiency is remedied by cross-plotting the eight curves for various constant values of discharge as shown in figure 236. Fortunately the result is a straight-line variation for any constant value of discharge. The lines in figure 236 are not quite parallel, and there is no assurance that they will be straight for every drum gate. Nevertheless, this uncertainty will not detract appreciably from the accuracy obtained. Interpolated information from figure 236 is then utilized to construct the additional curves in figure 235. Figure 235 now shows the rating

for the Black Canyon Dam spillway for gate intervals of 0.5 ft. For intermediate values, straight-line interpolation is permissible.

RADIAL OR TAINTER GATES

The damming face of a radial or Tainter gate is essentially a segment of a hollow steel cylinder spanning between piers on the dam crest. The cylindrical segment is supported on a steel framework that pivots on trunnions embedded in the downstream part of the piers. The gate is raised or lowered by hoisting cables that are attached to each end of the gate; the cables lead to winches on a platform above the gate. In its closed position, the lower lip of the gate rests on the dam crest.

[a]H is the total head on the gate. [b]The discharge for one gate: $Q = C_d b H^{3/2}$.

RADIAL GATES ON A HORIZONTAL SURFACE

Experimental work has been performed to determine discharge coefficients for radial gates that control flow along a horizontal surface (Toch, 1953). The results of those experiments are shown in figures 237 to 240. Figure 237 is a definition sketch for a radial gate on a horizontal surface. The discharge coefficient, C_d, is defined as

$$C_d = \frac{q}{b(2gh_v)^{1/2}} \tag{125}$$

where q is discharge per unit width of gate, g is acceleration of gravity, and h_v and b are elements shown in the definition sketch (fig. 237).

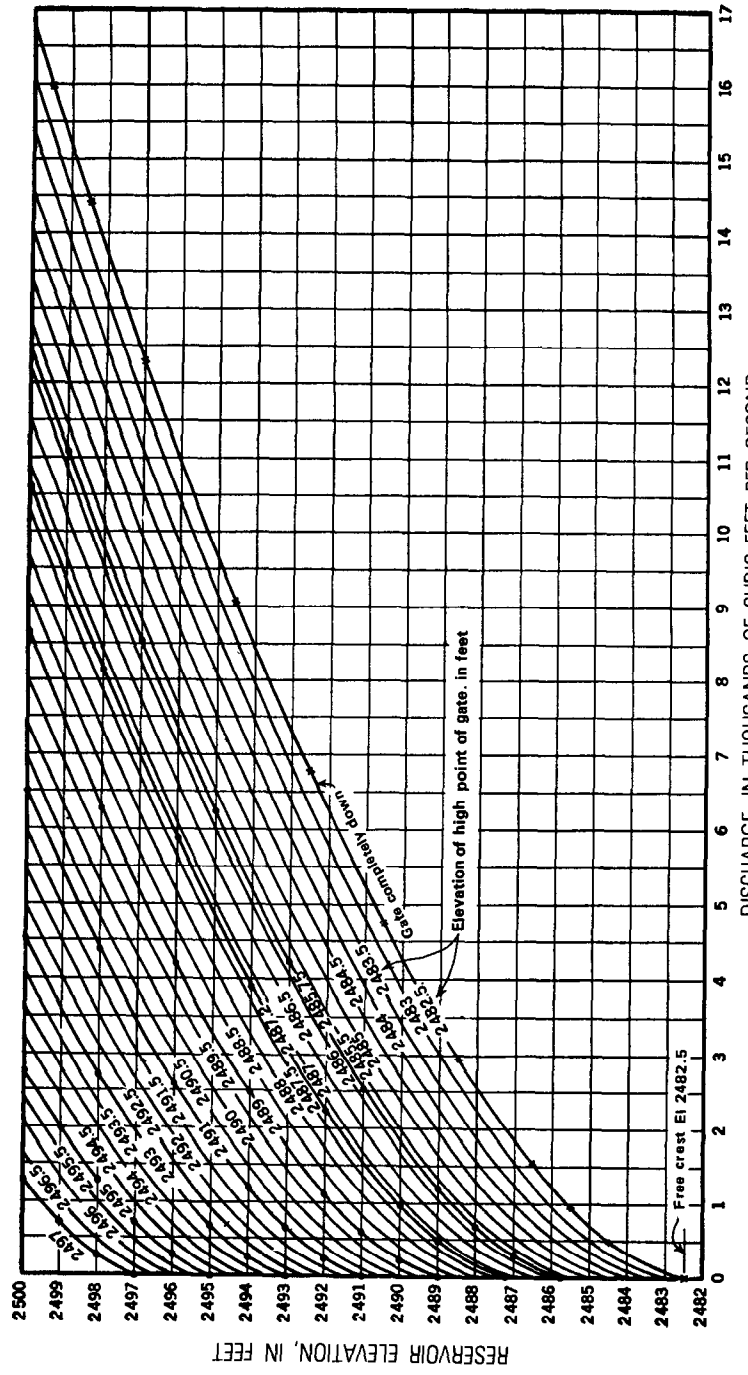

FIGURE 235.—Rating curves for drum-gate spillway of Black Canyon Dam, Idaho. (After Bradley, 1953.)

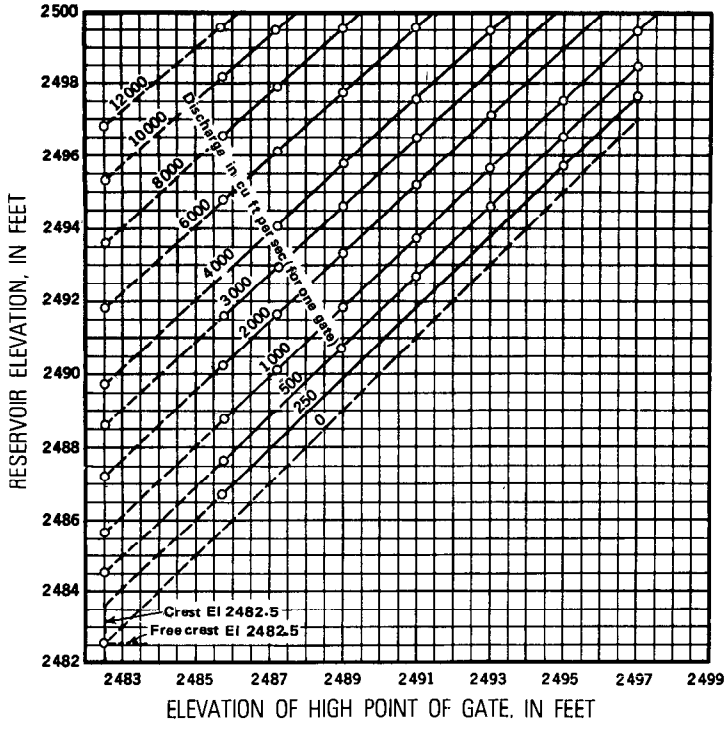

FIGURE 236.—Cross-plotting of values from initial rating curves, Black Canyon Dam, Idaho. (After Bradley, 1953.)

Figures 238 to 240 show values of C_d for three values of the ratio a/r, where a is trunnion elevation and r is gate radius. In the relations shown in the three figures, all pertinent elements have been made dimensionless by using gate radius, r, as a reference. Thus the relative headwater depth is h_1/r, the relative tailwater depth is h_2/r, the relative height of opening is b/r, and the relative trunnion height is a/r. Free efflux (flow) occurs when $h_2 < b$; submerged efflux occurs when $h_2 \geq b$. Each of the three graphs shows values of the coefficient of discharge for:

a. Free efflux for three values of b/r,
b. Submerged efflux for two values of b/r, when $h_2/r = 0.5$, and
c. Submerged efflux for three values of b/r, when $h_2/r = 0.7$.

RADIAL GATES ON A CURVED DAM CREST OR SILL

More commonly radial gates are used to control the flow over a curved dam crest or over a sill. The discharge coefficients determined for a radial gate on a horizontal surface cannot be transferred to a

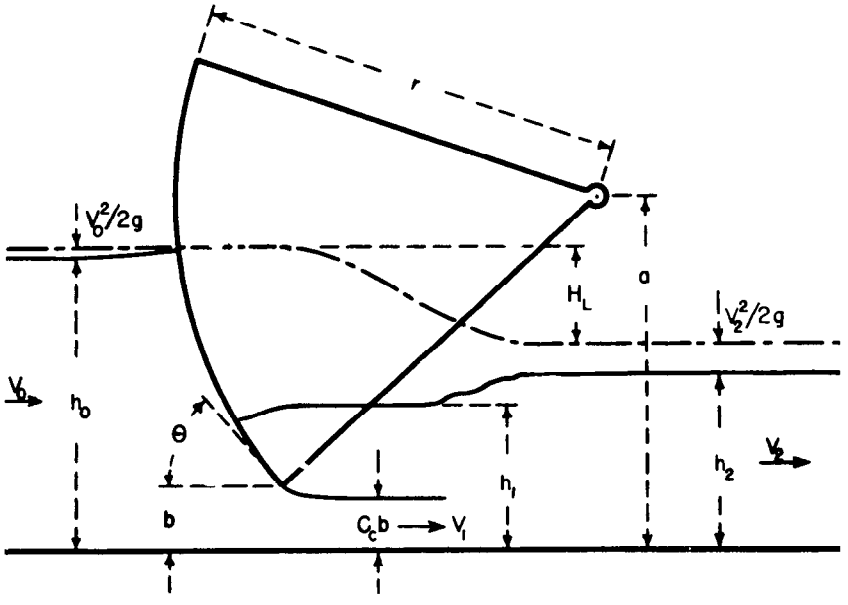

FIGURE 237.—Definition sketch of a radial gate on a horizontal surface. (After Toch, 1953.)

radial gate on a curved dam crest or sill because of differences in the pressure distribution. The flow under radial gates on a curved crest or sill is controlled by the geometry of three interrelated variables—the crest shape, the gate, and the gate setting. Major factors that influence the discharge relations are the position of the gate-seal point with respect to the highest point of the spillway crest and the curvature of the upstream face of the gate. Therefore, experimentally derived discharge coefficients for various prototype dams cannot be transferred to other installations unless the several variables involved are similar. Consequently, radial gates will invariably require rating by current-meter discharge measurements.

When radial gates control the flow over a sill or a curved dam crest, six flow regimes may occur, namely,

1. free orifice flow,
2. submerged orifice flow,
3. free weir flow,
4. submerged weir flow,
5. free flow over closed radial gate, and
6. submerged flow over closed radial gate.

Figure 241 is a definition sketch for the discussions that follow, all of which are concerned with only a single gate. As mentioned earlier in this discussion of movable gates, when discharge measurements for

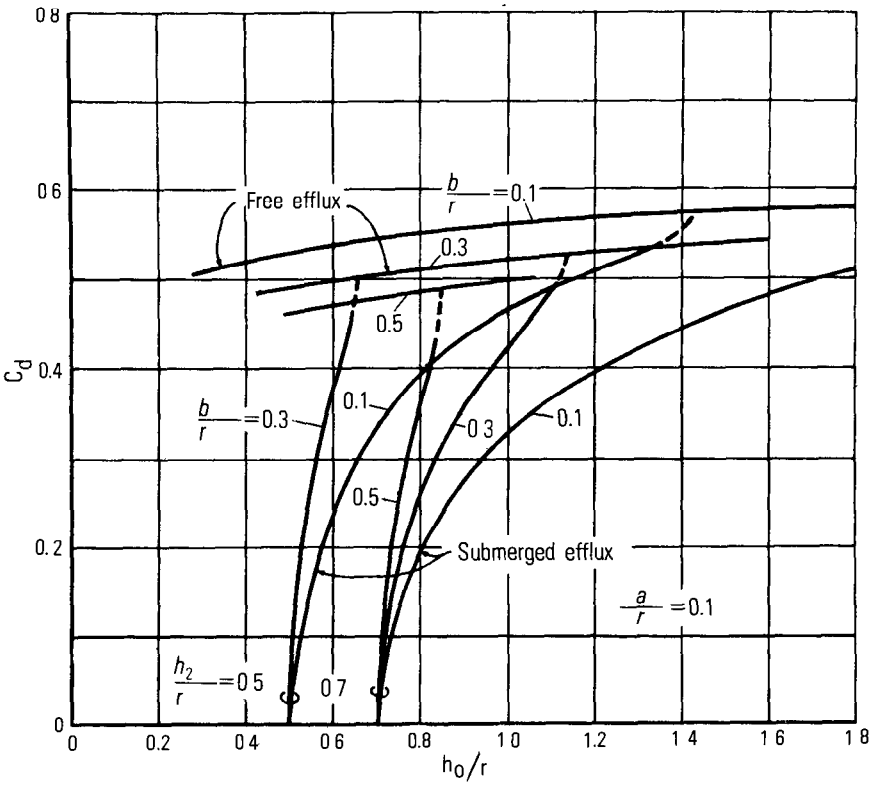

FIGURE 238.—Coefficient of discharge for free and submerged efflux, a/r = 0.1. (After Toch, 1953.)

calibration purposes are made with several gates open, it is highly desirable that all gate openings be identical, unless of course the gates are all raised sufficiently for their lower lips to be clear of the water. If gate openings are variable under the condition of orifice flow, it will be necessary to use an average gate opening in computing discharge coefficients for the gates from the measured discharge.

Free orifice flow.—Free orifice flow occurs when the lower lip of the raised gate is submerged by headwater but is above the elevation of tailwater. When the radial gate is on a sill, as in figure 241, free orifice flow occurs under the gate when h_g is less than $(2/3)h_1$, and h_3 is less than h_g. Discharge for that condition is computed from the equation,

$$Q = Ch_g b\ (2gh_1)^{1/2}, \tag{126}$$

where

Q = discharge for one gate,
c = discharge coefficient,

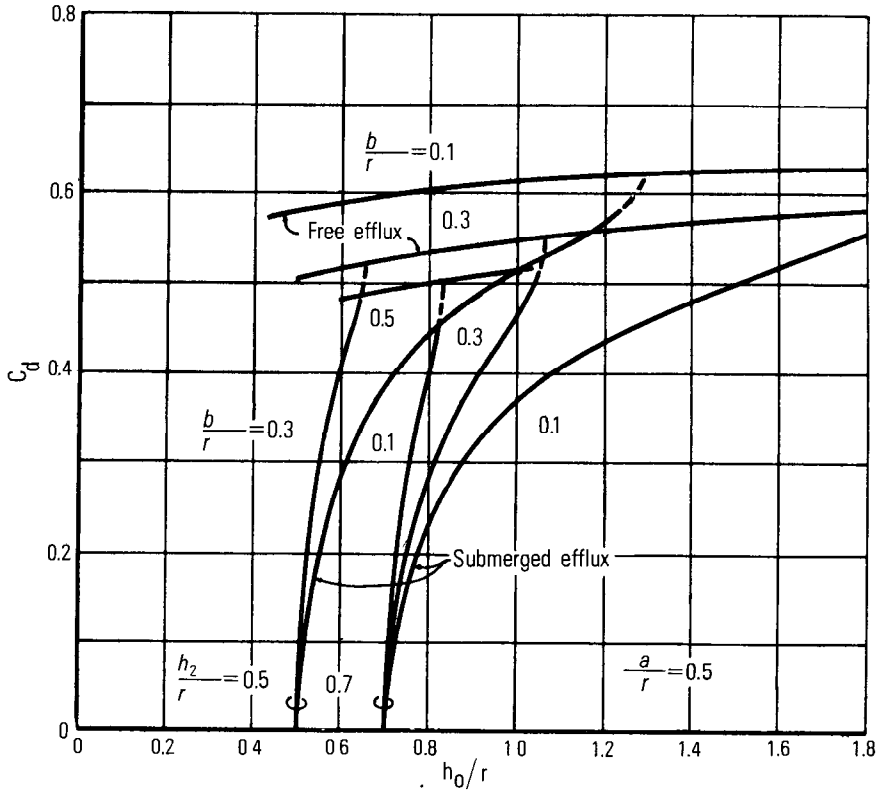

FIGURE 239.—Coefficient of discharge for free and submerged efflux, a/r = 0.5 (After Toch, 1953.)

b = lateral gate length (normal to flow), and
g = acceleration of gravity.

The remaining symbols in equation 126 are defined in figure 241. Values of C will vary inversely with h_a because the change in slope of the lower lip of the gate, as the gate is raised, progressively decreases the hydraulic efficiency of the orifice. There is also a tendency for C to increase with h_1, particularly at low stages, but that effect is usually minor compared to the effect of h_a. Consequently C can usually be related to h_a alone. In developing the relation, discharge measurements should be made throughout the expected range of h_a and h_1. Values of C are then plotted against h_g and the plotted points are fitted with a smooth curve. For convenience in later computations of discharge, the ordinates of the curve are put in tabular form.

The vertical gate opening, h_a, is computed from the following equation based on gate geometry and the position of the reference point at various gate settings:

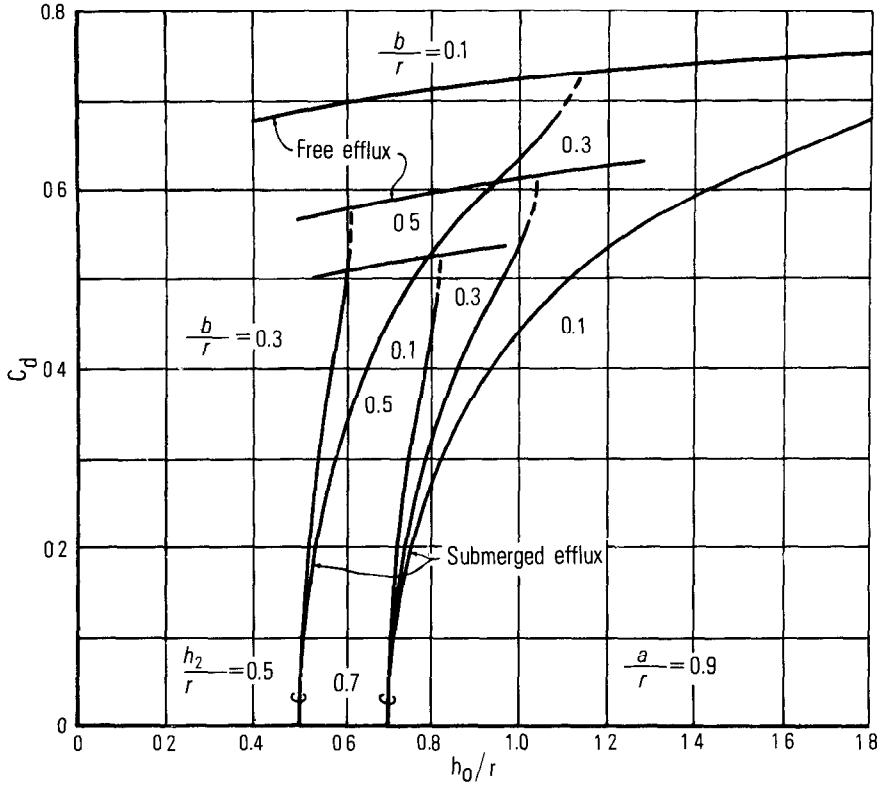

FIGURE 240.—Coefficient of discharge for free and submerged efflux, $a/r = 0.9$. (After Toch, 1953.)

$$h_u = R\cos\Theta\left(\frac{c-a}{r}\right) + a - R\sin\Theta\sqrt{1-\left(\frac{c-a}{r}\right)^2},$$

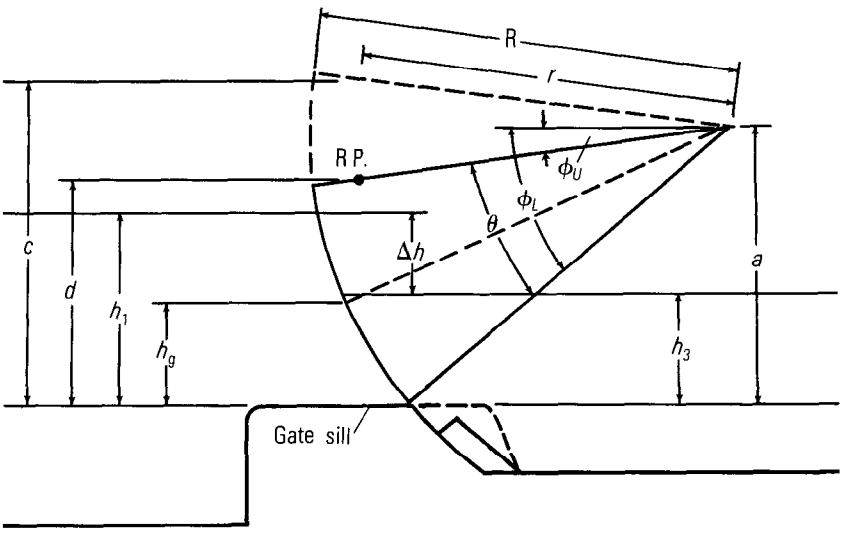
where

$$\Theta = \Phi_1 - \Phi_2 = \sin^{-1}\left(\frac{a}{R}\right) - \sin^{-1}\left(\frac{a-d}{r}\right).$$

Because C does not vary linearly with h_u it is highly desirable, and often necessary, that all gates be positioned identically during a discharge measurement to avoid the necessity of using an average value of h_u in the computation of C.

Submerged orifice flow.—Submerged orifice flow occurs when the lower lip of the raised gate is submerged by both headwater and tailwater. When the radial gate is on a sill, as in figure 241, submerged orifice flow occurs when h_3 is greater than h_u, and h_u is less than $(2/3)h_1$. The basic equation for computing discharge is

$$Q = C_u h_u b(2g\Delta h)^{1/2}, \qquad (127)$$



Definitions of symbols used in sketch are:

a = elevation difference, trunnion centerline to sill;
c = elevation difference, gate reference point (R.P.) to sill,
d = elevation difference, gate R.P to sill with the gate in a closed position;
h_1 = static headwater referenced to gate sill;
h_3 = static tailwater referenced to gate sill;
h_g = vertical gate opening,
r = radius from trunnion centerline to gate R.P.,
R = radius from trunnion centerline to upstream face of a Tainter gate;
R P = reference point used as indicator of gate position,
$\Delta h = h_1 - h_3$ = static head loss through structure;
θ = included angle between radial lines from the trunnion centerline through the R P. and through the lower lip of the gate,
ϕ_L = the angle measured from horizontal to the radial line from the trunnion centerline through the lower lip of the gate with the gate in a closed position, and
ϕ_U = the angle measured from horizontal to the radial line from the trunnion centerline through the gate R.P

FIGURE 241.—Definition sketch of a radial or Tainter gate on a sill

where C_{qs} is the coefficient of discharge for a submerged gate. The remaining symbols in equation 127 are defined either in figure 241 or in the preceding discussion of equation 126. Values of C_{qs} are determined from discharge measurements, and in addition, values of h_3/h_g and h_3/h_1 are computed for each measurement. For calibration purposes it is desirable to have measurements that cover the range of 1 to 100 for the ratio h_3/h_g, with several in the range of 1 to 2. The value of C_{qs} is a function of h_g, h_1, and h_3, and the complexity of that function

depends on the geometry of the hydraulic structure. The geometry may be such that all computed values of C_{gs} show little variation from a mean value, and when that occurs the mean value of C_{gs} is used in equation 127.

However, computed values of C_{gs} will often vary, particularly in the range of 1 to 2 for the ratio h_3/h_g. If that occurs, three relations involving C_{gs} are plotted graphically, and the one that best fits the plotted points is selected for use. The three relations are:

C_{gs} versus h_g,
C_{gs} versus h_3/h_1, and
C_{gs} versus h_3/h_g.

Quite often the last of the three relations will show the best fit. It will plot as a straight line on logarithmic graph paper and have the general equation,

$$C_{gs} = K(h_3/h_g)^B. \tag{128}$$

When equation 128 is substituted in equation 127, the result is

$$Q = K(h_3/h_g)^B h_g b(2g\Delta h)^{1/2}. \tag{129}$$

Ordinates of the relation indicated by equation 128 are put in tabular form for convenience in later computations of discharge. Because C_{gs} does not vary linearly with h_g, it is highly desirable, and often necessary, that all open gates be positioned identically during a discharge measurement to avoid the necessity of using an average value of h_g in the computation of C_{gs} from measured discharge.

Free weir flow.—Weir flow will occur when the lower lip of the gate is above the water surface. When the radial gate is on a sill, as in figure 241, weir flow will occur when h_g is greater than $(2/3)h_1$, because of drawdown of the water surface at the dam crest; the lower lip of the gate will then be above the water surface. Whether the weir flow is free or submerged will depend on the relative elevations of h_3 and h_1. Free weir flow will occur when the submergence ratio, h_3/h_1, is less than about 0.5–0.7, depending on the geometry of the weir crest. The discharge equation is,

$$Q = C_w b h_1^{3/2}, \tag{130}$$

where C_w is the coefficient of discharge for free weir flow. Values of C_w, which are dependent on the shape of the dam crest, are determined from discharge measurements, and the computed values are then plotted against h_1. Approach velocity head is usually negligible, but even where it is not, its effect is included in the variable coefficient, C_w. Measurements should be made at headwater (h_1) intervals of 1 to 2 feet throughout the expected headwater range to establish the functional relation between C_w and h_1. Information contained in a

previously cited report by Hulsing (1967) will usually be helpful as a guide to the probable shape of that relation.

Submerged weir flow.—As mentioned above, weir flow is submerged when the submergence ratio h_3/h_1 is greater than about 0.5–0.7, depending on the geometry of the weir crest. The discharge equation for that condition is

$$Q = C_w C_{ws} b h_1^{3/2}, \tag{131}$$

where C_w is the coefficient previously determined from equation 130. Values of C_{ws}, which is a submergence coefficient, must be determined from discharge measurements and expressed as a function of h_3/h_1. Satisfactory definition of the functional relation will probably require 10–12 discharge measurements well distributed over the range of h_3/h_1. Information contained in the Hulsing report (1967) will often be helpful in the analysis. If the submergence is greater than 0.95 for much of the time, it may be advisable to attempt to develop a relation of discharge to tailwater stage for use during periods of excessive submergence.

Flow over closed radial gate.—At extremely high flows, the closed radial gate may be overtopped, at which time the discharge over the gate is computed from the general weir equation,

$$Q = C b h^{3/2}, \tag{132}$$

where h is the head on the upper lip of the gate. The gate itself will act as a thin-plate weir. Values of the discharge coefficient C will vary primarily with the geometry of the gate and with h; the geometry of the dam crest or sill will have a lesser effect on the value of C. Discharge measurements will be required to define the rating for flow over the gate, both for unsubmerged flow (tailwater below the upper lip of the gate) and for submerged flow (tailwater above the upper lip of the gate).

Flow over a radial gate can also occur at low stages if the gate is of the submersible type. A submersible gate is designed to be lowered to allow flushing of upstream debris over the top of the gate. When so lowered, the bottom lip of the gate drops below the normal sill elevation. The upper surface of a submersible gate usually has an ogee or rounded crest.

Automated digital recording of elements for computing discharge.—To facilitate the computation of discharge, the Geological Survey has developed an automated digital system for the multiple recording of those elements that are required for discharge computation. The elements monitored are headwater, tailwater, and individual crest-gate positions. At navigation dams additional elements recorded include the number of lockages and, where supple-

mental hydroelectric power is produced, turbine pressure drops or commercial turbine monitor outputs. All of these elements are recorded on a digital recorder at preselected time intervals, usually hourly or bihourly. The recorded values of headwater, tailwater, and gate settings are the instantaneous values of those elements at the time of recording. The lockage count recorded is the number of lockages between the recordings. The turbine monitor integrates turbine pressure drops over the time interval between recordings.

All data at a site are recorded on paper punch tape in a preselected sequence by a master control console that queries the individual monitors in sequence. The punched tape is removed, usually once a month, and information from that tape is transferred to a magnetic tape. The magnetic tape is then used as input to a computer program for the computation of the streamflow record.

VERTICAL LIFT GATES

Vertical lift gates are simple rectangular gates of wood or steel spanning between piers on the dam crest. The gates move vertically in slots in the piers, and all but the smallest gates are mounted on rollers to reduce the friction caused by the hydrostatic force on the gate. The vertical lift gate, like the radial gate, must be hoisted at both ends, and the entire weight is suspended from the hoisting cables or chains (U.S. Army Corps of Engineers, 1952.) Piers must be extended to a considerable height above high water to provide guide slots for the gate in the fully raised position. To reduce the height of the piers required for operating large vertical lift gates, the large gates are often built in two horizontal sections, so that the upper section may be lifted and placed in another gate slot before raising the lower section. This design also reduces the load on the hoisting mechanism. Discharge may occur over either one or both sections of the gate or over the spillway crest. Discharge over the spillway crest may occur as weir flow if the gate is raised above the water surface, or as orifice flow if the raised gate does not clear the water surface.

The principles that govern the rating of radial gates likewise apply to vertical-lift gates. When the elevation of the lower edge of the raised gate is less than two-thirds of the upstream head, orifice flow occurs. The orifice flow is free if the tailwater is below the lower edge of the raised gate; the orifice flow is submerged if the tailwater is above the lower edge. General equations 126 and 127 apply to the discharge, and values of C and C_{qs} in those equations must be determined from discharge measurements.

If the elevation of the lower edge of a raised gate is greater than two-thirds of the upstream head, weir flow over the dam occurs. If the weir flow is free, equation 130 applies; if the elevation of the tailwater

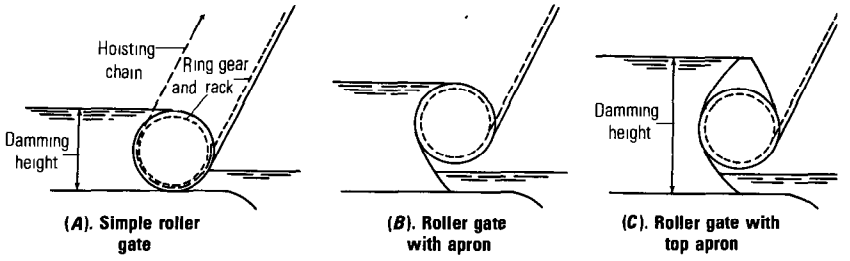


FIGURE 242.—Schematic sketches of roller gates. (U.S. Army Corps of Engineers, 1952.)

causes submergence effect, equation 131 applies. The coefficients in the two weir equations are primarily dependent on the shape of the weir crest. Values of the coefficients are determined from discharge measurements, but helpful information concerning them is found in a report by Hulsing (1967).

When a closed gate is overtopped by headwater, the upper edge of the gate acts as a weir and general equation 132 is applicable. The upper edge of a vertical-lift gate commonly has the shape of a modified horizontal broad-crested weir. Coefficients of discharge are determined from discharge measurements, but again, helpful information is to be found in the Hulsing report (1967).

ROLLER GATES

A roller (or rolling) gate (fig. 242) is a horizontal, internally braced, metal cylinder spanning between piers. Rings of gear teeth at the ends of the cylinder mesh with inclined metal racks supported by the piers, and when a pull is exerted on the hoisting cable or chain, the gate rolls up the rack (fig. 242*A*). The effective damming height of the cylinder can be increased by means of a projecting apron (fig. 242*B*) which rotates into contact with the dam crest as the gate rolls down the inclined racks (U.S. Army Corps of Engineers, 1952). A similar apron or rounded lip may be added to the top of the gate (fig. 242*C*).

As in the case of radial and vertical-lift gates, orifice flow will occur under partly raised rolling gates; weir flow over the dam will occur when the gates are raised sufficiently (⅔ or more of the headwater elevation) to be clear of the water surface, and weir flow over the gates will occur when the closed gates are overtopped by headwater. The principles of rating roller gates are similar to those discussed for radial gates and vertical-lift gates.

MOVABLE DAMS

A movable dam consists of a low concrete sill and a damming surface that can be raised above the water surface to maintain a desired

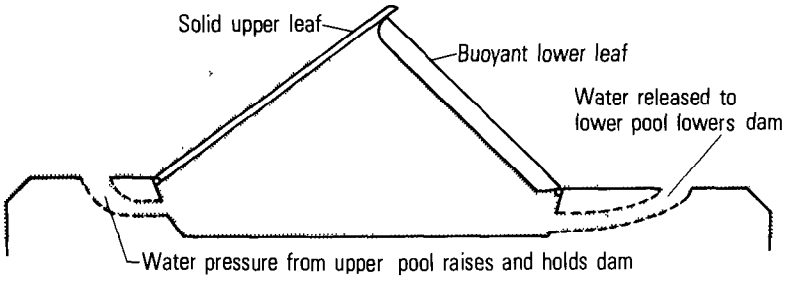

FIGURE 243.—Bear-trap gate. (U.S. Army Corps of Engineers, 1952.)

pool level, or lowered to the sill at higher discharges so as to offer no interference to the flow. The most commonly used gates or damming surfaces are bear-trap gates, hinged-leaf gates, wickets, and inflatable dams.

Bear-trap gate.—A bear-trap gate (fig. 243) consists of two leaves of timber or steel hinged and sealed to the dam or sill. When water is admitted to the space under the leaves, they are forced upward. The downstream leaf is hollow so that its buoyancy aids the lifting operation. When the dam is collapsed by the release of water from under the leaves, the leaves lie flat. (U.S. Army Corps of Engineers, 1952).

Hinged-leaf gate.—A hinged-leaf gate (fig. 244) is a rigid flat leaf hinged at bearings along its lower edge. In its raised position, the leaf slopes upward and downstream at an angle of between 20° and 30° from the vertical. When lowered, it lies approximately in a horizontal position. The position of the leaf is controlled by a mechanical hoist or by a counterweight device that causes the leaf to rise or fall automatically with slight incremental changes in headwater level.

Wickets.—A wicket is a shutter held in position against the water load by a metal prop (fig. 245*A*). It is not intended that water flow over the wicket at an appreciable depth, because the resultant water load will shift to a point above the prop and cause the wicket to overturn or vibrate violently (U.S. Army Corps of Engineers, 1952). The metal prop, hinged at midlength of the wicket, seats against a shoulder on a metal fixture ("hurter") embedded in the foundation. The wicket is raised by an upstream pull on a hoisting line attached to the bottom of the wicket. This causes the prop to fall into its seat after which the wicket is rotated into position against the sill (fig. 245*B*). The wicket is lowered by pulling upstream on a line attached to the top of the wicket; the base of the prop is pulled away from its seat and falls to one side into a groove in the hurter in which it can slide freely downstream. Wickets are raised and lowered by use of a boat operating on the upstream side of the dam. Figures 245*C* and

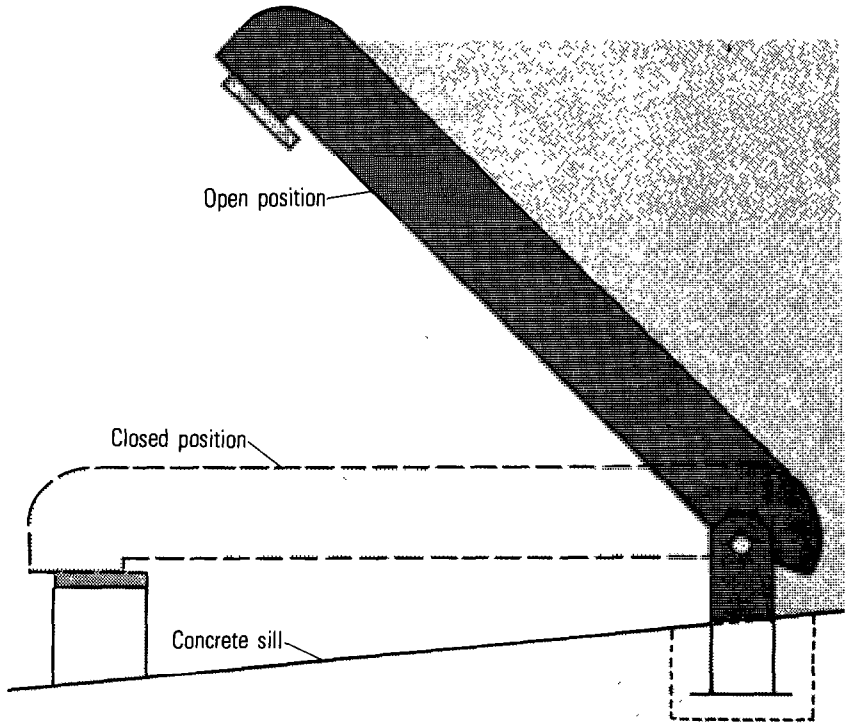

FIGURE 244.—Hinged-leaf gate.

245*D* show improved types of wickets. The Bebout wicket (fig. 245*D*) trips automatically to permit the passage of high flows.

Inflatable dams.—An inflatable dam, before activation, is a collapsed nylon-rubber bladder that occupies the full width of the stream and is attached to a concrete sill on the channel bottom. The dam is activated by pumping water into the bladder, thereby inflating it to form a barrier across the channel. The dam is deactivated by releasing water from inside the bladder. Inflatable dams are usually used on shallow streams to maintain a water level in the stream that is sufficiently high to submerge the intake of a diversion works. When the river stage is high, the dam is deflated. The inflation and deflation are often automatically controlled in response to the changing stage of the stream. Although it would probably be feasible to determine the rating for an inflatable dam by monitoring both the stream stage and the pressure within the dam bladder, inflatable dams have not been used as gaging-station controls. It is invariably simpler to operate a conventional gaging station on the stream either downstream from the inflatable dam or far enough upstream to be beyond the

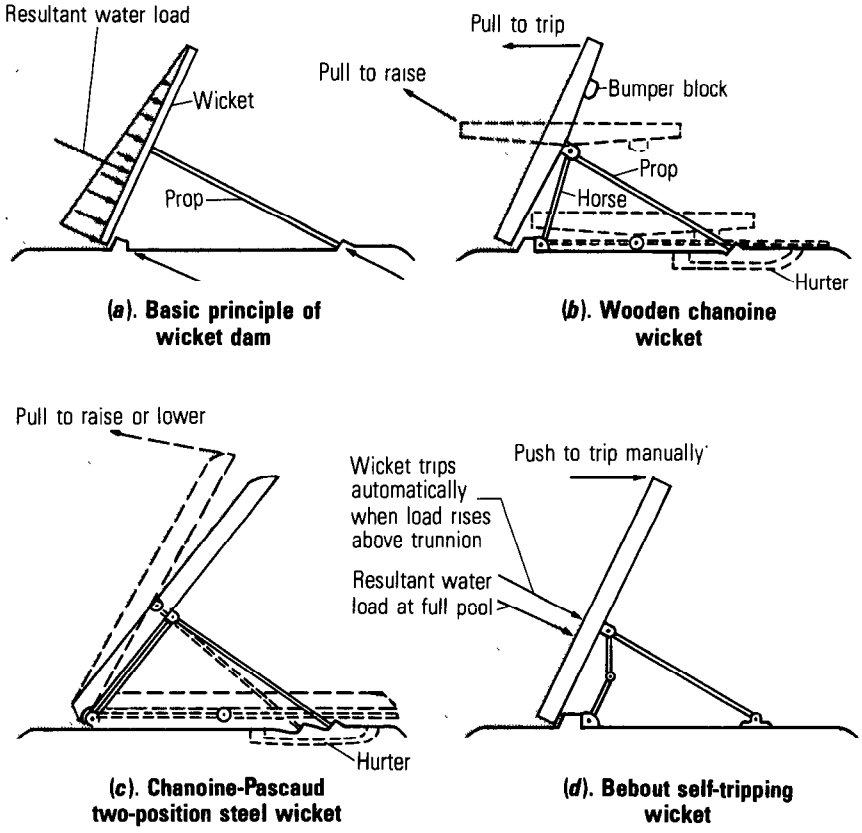

FIGURE 245.—Wickets. (U.S. Army Corp of Engineers, 1952.)

influence of backwater from the dam.

Discharge characteristics.—The discharge characteristics of bear-trap gates, hinged-leaf gates, and wickets are similar. In their lowered position they act as broad-crested weirs that control the stage-discharge relation over a limited range of low-water stage. The stage at which they become submerged depends primarily on the height of the sill on which they rest. Their discharge ratings in the lowered position will resemble that for a highway embankment (Hulsing, 1967, p. 26–27) whose general equation is

$$Q = CbH^{3/2}, \tag{133}$$

where

Q is discharge,
C is the coefficient of discharge,
b is the width normal to the flow, and
H is the total head.

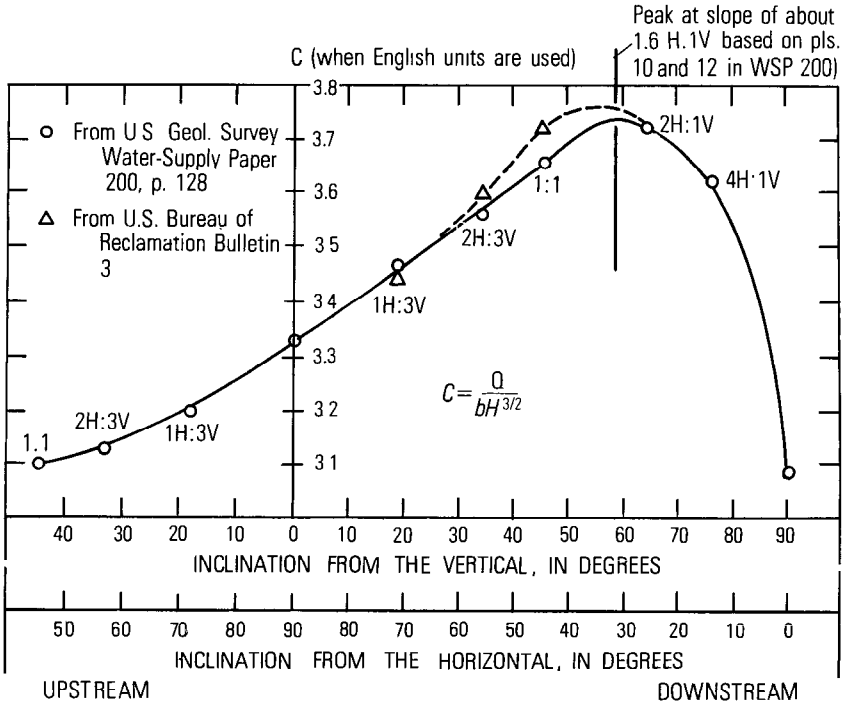

FIGURE 246.—Discharge coefficients for an inclined rectangular thin-plate weir.

The value of C will be dependent on the elevations of headwater and tailwater, the length of the crest in the direction of flow, and the geometry of the crest. For unsubmerged flow (tailwater $\leq$ 0.7 times headwater) C, when English units are used, can be expected to range from about 2.6 to 3.1, depending primarily on the ratio of static head (h) to length of sill in the direction of flow (L). For submerged flow, the free-flow value of C will be multiplied by a factor that ranges from almost zero to almost 1.00, depending on the degree of submergence.

When overtopped in their raised position by headwater, the three types of movable dam—bear-trap gate, hinged-leaf gate, and wickets—act as inclined thin-plate rectangular weirs. Figure 246 gives values of the discharge coefficient C in the general weir equation (eq. 133) for various angles of inclination of such weirs. If the upstream edge of the crest is rounded, the value of C may increase by 5–10 percent.

FLASHBOARDS

The usual flashboard installation consists of horizontal wooden panels supported by vertical pins placed on the crest of a spillway (fig. 247*A*). Such installations are temporary and are designed to fail

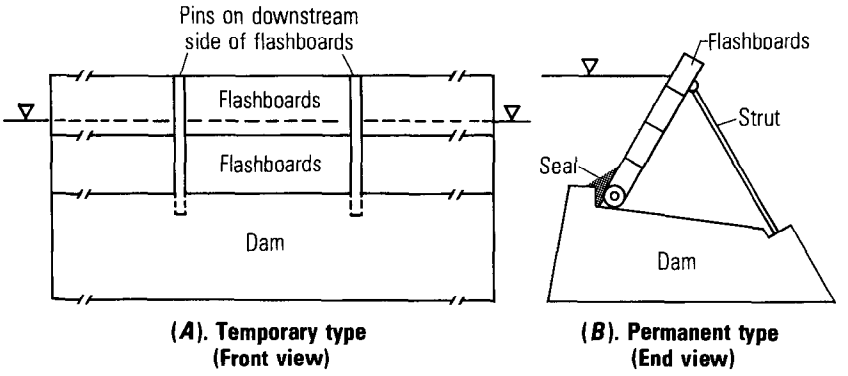

FIGURE 247.—Flashboards.

when the water surface in the reservoir reaches a predetermined level. A common design uses steel pipe or rod set loosely in sockets in the crest of the dam and designed to bend and release the flashboards at the desired water level. Temporary flashboards of this type have been used in heights up to 4 or 5 ft. Because temporary flashboards are lost each time the supports fail, permanent flashboards are more economical for large installations. Permanent flashboards usually consist of horizontal wooden panels that can be raised or lowered from an overhead cableway or bridge. The bottom edge of the panels is placed in a seat or hinge on the spillway crest, and the panels are supported in the raised position by struts (fig. 247*B*) or by attaching the top edge of the panels to the bridge.

To rate the vertical flashboards shown on figure 247*A*, a value of $C = 3.33$ (English units) is usually used in the general weir equation,

$$Q = CbH^{3/2} \tag{133}$$

As for the permanent flashboards in figure 247*B*, when the flashboards are lowered, the value of C that should be used is that for the free dam crest (no flashboards). The value of C to use when the flashboards are raised and supported by struts is determined from figure 248, which shows C values for various angles of inclination. If the raised flashboards are supported in an inclined position by a bridge so that the top edge of the flashboards is flush with the upstream edge of the bridge floor, we have in effect a flat-crested rectangular weir with inclined upstream face. The bridge floor acts as the flat weir crest and the flashboards act as the inclined upstream face of the weir. Discharge is computed by the use of equation 133; the value of C to be used in that equation can be obtained from figure 151 (chap. 10).

STOP LOGS AND NEEDLES

Stop logs consist of horizontal timbers, similar to flashboards, spanning between vertically slotted piers on the dam crest. The timbers may be inserted into, or removed, from the vertical slots by hand or with a hoist. There is usually considerable leakage between the timbers and considerable time may be required for their removal if they become jammed in the slots. Stop logs are ordinarily used only for small installations where the cost of more elaborate devices is not warranted or in situations where the removal or replacement of the stop logs is expected only at infrequent intervals.

Needles consist of timbers standing on end with their lower ends resting in a keyway in the spillway and their upper ends supported against the upstream edge of a bridge floor. Needles are easier to remove than stop logs but are difficult to place in flowing water. Consequently, they are used mainly for emergency bulkheads that are installed during periods of low flow.

The simple crest shape of stop logs and needles makes it easy to determine the theoretical value of the discharge coefficient C in the general weir equation 133. (See report by Hulsing (1967) on computing discharge over dams.) However, it is usually futile to rate stop logs or needles theoretically because of the appreciable leakage between them.

NAVIGATION LOCKS

Navigation locks are required for boat traffic to overcome the difference between headwater and tailwater elevations at a dam. The boat enters the open gate of the lock; the lock is closed behind the boat; valves are used for filling or emptying the locks, as the case may be, to bring the water level in the lock to that of the pool ahead of the boat; the other lock gate is opened and the boat proceeds on its journey. Various lock-filling and lock-emptying systems have been devised as a compromise between two conflicting demands: (1) that the filling time be short so as not to delay traffic, and (2) that the disturbances in the lock chamber not cause stresses in mooring hawsers which might cause the boat or barges to break loose and thereby damage either the boat or lock structure.

The flow through navigation locks is computed as the total volume of water released during a finite time interval, usually 1 day. The volume of water discharged for any one lockage is the product of the plan or water-surface area of the lock and the difference between headwater and tailwater at the time of lockage. These volumes are summed for the day and divided by 86,400, which is the number of seconds in a day, to obtain the average lockage flow in cubic feet per second or cubic meters per second. Usually it will be sufficiently accu-

rate to compute the daily average lockage discharge (Q_L) by use of the equation,

$$Q_L = \frac{N}{86{,}400} A(h_h - h_t), \tag{134}$$

where

N is the number of lockages in a day,
A is the plan or surface area of the lock,
h_h is the daily mean headwater elevation, and
h_t is the daily mean tailwater elevation.

If appreciable leakage through the lock occurs between boat lockages, the daily average leakage must be added to the daily average lockage discharge.

MEASUREMENT OF LEAKAGE THROUGH NAVIGATION LOCKS

If the leakage through the closed lock gates is great, it can be measured in the forebay with a low-velocity current meter. The leakage will seldom be that great, however, and it usually will have to be computed by a volumetric method.

If, for considerable periods of time between lockages, the lockmaster keeps the valves and lower gates closed and the upper gates open, leakage will occur through the lower gates, and it is that leakage (Q_{Lm}) that must be determined. If, instead, it is the valves and upper gates that are kept closed and the lower gates that are kept open, leakage will occur through the upper gates, and it is that leakage ($Q_{t\,m}$) that must be determined. If all valves and gates are kept closed, it is the equilibrium leakage (Q_{Le}) through the lower gate that must be determined.

Instructions for determining Q_{Lm}, $Q_{t\,m}$, and Q_{Le} follow. Figure 248 is a definition sketch of a lock.

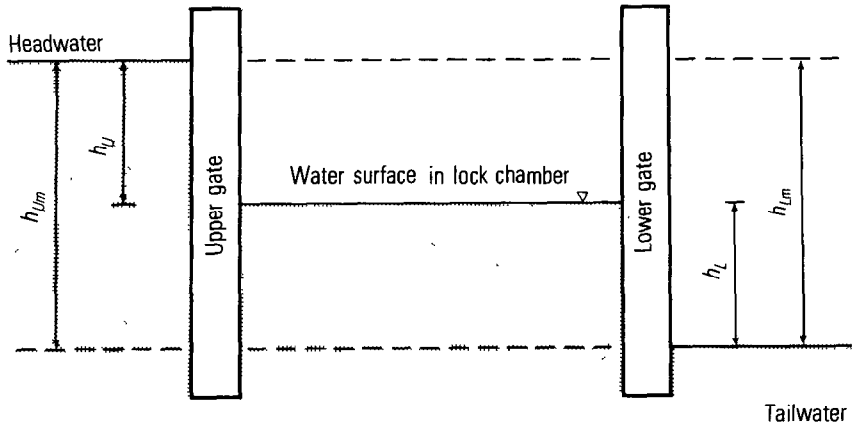
FIELD WORK

1. Close upper and lower lock gates and open the valve to fill the lock chamber. When the lock chamber is filled, close the valve and open one upper gate slightly.

2. Attach the zero end of a steel tape by a small staple to the middle of a long plank. Float the plank in a lock chamber against the lock wall after first setting a reference mark on top of the wall for use as an index for reading the tape. A portable electric-tape gage (see section in chapter 4 titled, "Electric-Tape Gage") is even more satisfactory for reading stages in the lock chamber.

3. Record gage heights in the upper pool and lower pool and the tape reading in the lock chamber.

4. Close the upper gate. Read the tape immediately after the gate is fully closed and seated, and start a stop watch. Thereafter, read the



Definitions

$h_{Um}=h_{Lm}$	Maximum head on upper or lower gates for given headwater and tailwater stages
h_U	Head on upper gate
h_L	Head on lower gate
Q_U	Leakage through upper gate produced by h_U
Q_{Um}	Leakage through upper gate produced by h_{Um}
Q_L	Leakage through lower gate produced by h_L
Q_{Lm}	Leakage through lower gate produced by h_{Lm}
Q_n	Rate of storage in lock with both gates closed=Q_L-Q_U. (When Q_n is negative, the water level rises in lock chamber, when Q_n *is positive, the water level falls in lock chamber.)*
h_{Ue}	Equilibrium head on upper gate when $Q_U=Q_L$
h_{Le}	Equilibrium head on lower gate when $Q_U=Q_L$
Q_{Le}	Leakage through lower gate produced by h_{Le}

$$h_U+h_L=h_{Um}=h_{Lm}$$
$$h_{Ue}+h_{Le}=h_{Um}=h_{Lm}$$

FIGURE 248.—Definition sketch of a lock.

tape and stop watch at intervals of about 0.5 ft as stage decreases in the chamber, or at 1-minute intervals, whichever comes first. Continue for about 10 minutes.

5. Empty the lock chamber by opening the lower gate, and then partly close the lower gate; that is, leave one lower gate slighty open.

6. Record gage heights in the upper pool and lower pool, and the tape reading in the lock chamber.

7. Close the lower gate. Read the tape immediately after the gate is fully closed and seated and start a stopwatch. Thereafter read the tape and stopwatch at intervals of about 0.5 foot as stage increases in the chamber, or at 1-minute intervals, whichever comes first. Continue for about 10 minutes.

8. Obtain dimensions of the lock chamber for use in computing

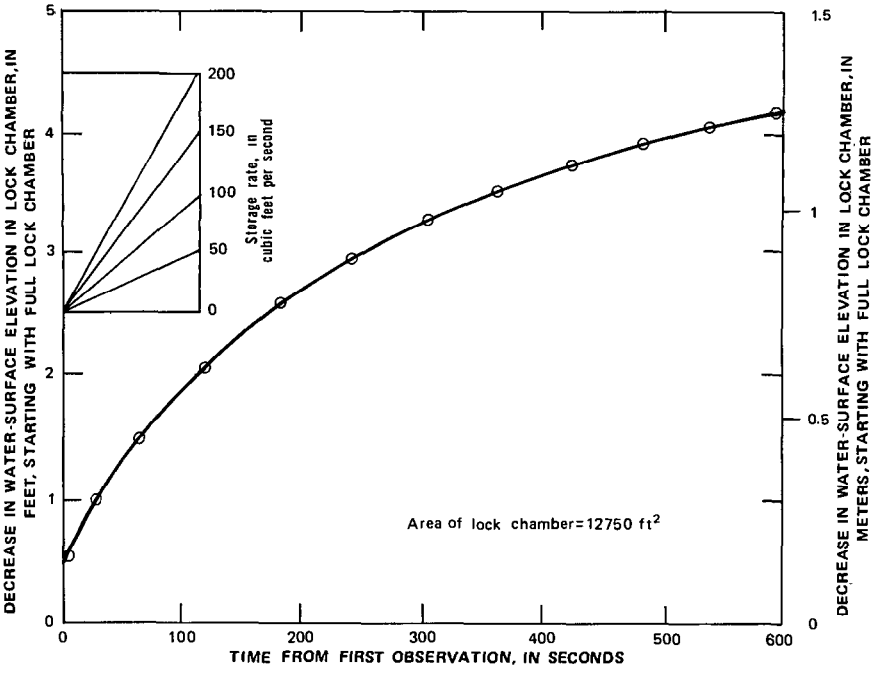


FIGURE 249.—Storage diagram starting with lock chamber full.

volumes of water involved in the leakage. That completes the field work.

COMPUTATIONS FOR Q_{Lm}

1. Use readings obtained when observations were started with a full lock chamber. Subtract initial tape reading (made with upper gate open slightly) from all tape readings.

2. Plot adjusted tape readings from step 1 against time in seconds. The first reading made after the upper gate was fully closed is plotted at zero seconds. Too much uncertainty usually exists as to when the gate actually seated to use the closure of the gate as the starting time for the graph. See figure 249. The plot should be made on a large sheet of graph paper.

3. Connect the plotted points with a smooth curve. A tangent to the curve at any value of the abscissa represents the rate of change of water-surface elevation at that instant. The rate of change multiplied by the surface area of the lock chamber gives the instantaneous rate of storage in the lock chamber; that is, the difference in rate of leakage out of the chamber through the lower gate and rate of leakage into the chamber through the upper gate.

At the instant the upper gate is closed, the leakage out of the chamber is at its maximum, Q_{Lm} (full head on the lower gate), and the

leakage into the chamber is zero (zero head on the upper gate). As the stage in the chamber falls, the leakage out of the chamber decreases because of the decreased head on the lower gate, and leakage into the chamber increases because of the increased head on the upper gate. Eventually leakage into the lock would equal the leakage out of the lock (Q_{Le}), and the stage in the chamber would remain constant.

4. In order to obtain the rate of storage at any instant from the tangent of the curve showing the decrease in lock stage with time, construct a diagram showing the storage rate (Q_n) for various tangential slopes.

The method of constructing the diagram is demonstrated in figure 249. The area of the lock chamber is 12,750 ft^2. If the stage in the chamber dropped 2 feet, the change in volume would be 2 × 12,750 or 25,500 ft^3. If Q_n were 200 ft^3/s, the time required for a 2 ft drop would be 127.5 seconds. A vertical line is drawn at 127.5 seconds on figure 249 and a diagonal line having a drop of 2 ft is drawn between the abscissa values of 0 and 127.5 seconds. A tangent to the storage curve having a similar slope would have a Q_n value of 200 ft^3/s. Diagonals representing other values of Q_n are added as shown.

5. Select two points on the storage curve, one near the origin (0 seconds) and the other no more than 1 ft lower in stage. Draw tangents to those points and use the slopes of those tangents with the tangential rate diagram to obtain the two values of Q_n. To obtain the tangential slope at a point on the curve, use a pair of dividers to lay off short equal distances on the curve on each side of the selected point. A chord connecting the equidistance points will have a slope approximately equal to that of the tangent.

6. The two values of Q_n obtained in the preceding step will be used to compute Q_{Lm}. No further use will be made of the leakage curve, except that it has value for making a rough check on the basic assumption that will be made in the computations that follow. That assumption is that the leakage through a gate can be treated as though it all occurred at an orifice at the bottom of the gate. In other words,

$$\frac{Q_L}{Q_{Lm}} = \left(\frac{h_L}{h_{Lm}}\right)^{1/2} \quad \text{and} \quad \frac{Q_{L'}}{Q_{L'm}} = \left(\frac{h_{L'}}{h_{L'm}}\right)^{1/2}$$

or

$$Q_L = Q_{Lm}\left(\frac{h_L}{h_{Lm}}\right)^{1/2} \quad \text{and} \quad Q_{L'} = Q_{L'm}\left(\frac{h_{L'}}{h_{L'm}}\right)^{1/2} \tag{135}$$

7. From figure 248 and equation 135.

$Q_n = Q_L - Q_l$

or
$$Q_n = Q_{Lm}\left(\frac{h_L}{h_{Lm}}\right)^{1/2} - Q_{Um}\left(\frac{h_U}{h_{Um}}\right)^{1/2} \tag{136}$$

For each of the two values of Q_n, all values in equation 136 are known, except for the values of Q_{Lm} and Q_{Um}. The known values can be substituted in equation 136 to give two simultaneous equations, which can then be solved for the desired value of Q_{Lm}.

8. In the preceding step, it would be a simple matter to solve for Q_{tm}, but we do not do so. Our basic assumption of orifice flow may not be strictly correct, and experience has shown that the desired value of Q_{tm} can be computed with much more accuracy by using the field data obtained when observations of leakage were started with an empty lock chamber.

9. Obtain values of leakage through the lower gate when the upper gate is open, for other values of total head. Use the following equation:
$$Q'_{Lm} = Q_{Lm}\left(\frac{h'_{Lm}}{h_{Lm}}\right)^{1/2} \tag{137}$$

where Q_{Lm} and h_{Lm} are values obtained from a leakage test as described above, and Q'_{Lm} is the leakage through the lower gate corresponding to any other value of total head, h'_{Lm}.

10. Prepare a rating table of Q_{Lm} versus h_{Lm}.

COMPUTATIONS FOR Q_{tm}

1. Use readings obtained when observations were started with an empty lock chamber. Subtract initial tape reading (made with lower gate slightly open) from all tape readings.

2. Plot adjusted tape readings from step 1 against time in seconds.

3. Proceed with computations in a manner analogous to that used in the computation of Q_{Lm}.

4. Obtain Q_n for two points on the leakage curve, one near the origin (0 seconds) and the other no more than 1 ft higher in stage.

5. Use equation 136 to solve for the desired value of Q_{tm}.

6. Obtain values of leakage through the upper gate when the lower gate is open, for other values of total head. Use the following equation:
$$Q'_{Um} = Q_{Um}\left(\frac{h'_{Um}}{h_{Um}}\right)^{1/2}, \tag{138}$$

where Q_{tm} and h_{tm} are values obtained from a leakage test as described above, and Q'_{tm} is the leakage through the upper gate corresponding to any other value of total head h'_{tm}.

7. Prepare a rating table of Q_{Um} versus h_{Um}.

COMPUTATIONS FOR Q_{Le}

1. Q_{Le} is the leakage through the lower gate when equilibrium exists; that is, the stage in the lock chamber is constant because $Q_U = Q_L$.

2. Starting with the equation, $Q_{Ue} = Q_{Le}$, it is a simple matter to transform the equation to

$$h_{Le} = h_{Lm} \Big/ \left[(Q^2_{Lm} / Q^2_{Um}) + 1 \right] \tag{139}$$

All values on the right-hand side of equation 139 are known because in preceding steps Q_{Lm} and Q_{Um} had been computed. Solve for h_{Le}.

3. Obtain the desired value of Q_{Le} from the equation

$$Q_{Le} = Q_{Lm} \left(\frac{h_{Le}}{h_{Lm}} \right)^{1/2}. \tag{140}$$

4. Use the rating tables for Q_{Lm} and Q_{Um} with equations 139 and 140, to prepare a rating table of Q_{Le} versus h_{Lm}.

PRESSURE CONDUITS

GENERAL

In one respect, the gaging of a pressure conduit is simple in that the cross-sectional area is constant for all discharges. The calibration of the metering device offers difficulty, however, because the discharge measurements require special instrumentation unless they can be made by current meter in the forebay or afterbay of the conduit where open-channel conditions exist.

The following are the metering devices used for pressure conduits:

1. Mechanical meters
   - a. Displacement meter
   - b. Inferential meter
   - c. Variable-area meter
2. Differential-head meters
   - a. Constriction meters
     - (1) Venturi meter
     - (2) Flow nozzle
     - (3) Orifice meter
   - b. Bend meter
   - c. Pressure differential in a reach of unaltered conduit
3. Electromagnetic velocity meter
4. Acoustic velocity meter
5. Laser flowmeter.

Changes in the rating of mechanical meters occur only as a result of wear on the moving parts of the meter. Changes in the rating of differential-head meters that are kept clean occur only as a result of changes in perimeter roughness of the conduit with time. The electromagnetic, acoustic, and laser velocity meters are complex electronic devices, and as such, they are subject to the occasional calibration drift that for various reasons affect such devices.

The various meters must be calibrated when first installed, and the calibration must be periodically checked thereafter. Methods of measuring discharge for that purpose include:

1. pitot-static tubes and pitometers,
2. salt-velocity method, and
3. Gibson method.

This section of the manual closes with a brief discussion of discharge ratings for turbines, pumps, gates, and valves, all of which are associated with pressure conduits.

METERING DEVICES FOR PRESSURE-CONDUIT FLOW

MECHANICAL METERS

Mechanical meters are widely used in water-distribution systems because of their low cost and small size, but they can only be used to measure a relatively narrow range of discharge. They are not suited for the measurement of very low flow rates because the liquid may pass the meter without moving the mechanical elements; they are seldom used to measure discharges greater than 10 ft^3/s (0.28 m^3/s) because of high head loss. A large variety of mechanical meters are commercially available, but only the three general types—displacement, inferential, and variable-area—will be described here (Howe, 1950, p. 210–212).

Displacement meters.—An elementary form of displacement meter consists of a single or multiple piston arrangement in which fluid passing through the meter moves a piston back and forth. The movement of the piston is readily registered upon a counting device calibrated in any desired units to give total volume of flow. Such meters can have a fairly large capacity and are accurate if no slippage occurs.

Another commonly used displacement meter is the disk meter which oscillates in a measuring chamber; for each oscillation a known volume of water passes the meter. The motion of the disk operates a gear train which in turn activates a counting mechanism, thereby furnishing a measure of the total volume of flow. When the disk is new, the meter is accurate to within 1 percent, but the meter may underregister significantly as the disk becomes worn.

Inferential meters.—Inferential meters are in effect small turbines and are called "inferential" because the rate of flow is inferred from

the speed of rotation of the propeller. An essential element of such meters is a set of guide vanes which may be adjusted to change the calibration of the meter. However, the calibration may inadvertently change if the surface of the propellor blades becomes worn or coated. Although inferential meters normally register only volume of flow, equipment may be added to the meter to indicate instantaneous rate of discharge.

Variable-area meter.—The variable-area meter consists of a vertical tapered tube containing a small plunger "float." In some instruments the plunger is completely immersed in a transparent, graduated tube; in others, a stem projects through the end of the conical tube and traverses a scale. In both types the plunger rises as the rate of flow increases, thereby increasing the area around it. By calibration, the position of the plunger can be related to the rate of flow. These instruments are restricted to the measurement of rather small discharges and will not accommodate any great change in viscosity without recalibration. Accuracy within 1 percent is possible.

DIFFERENTIAL-HEAD METERS

The flow of fluid through a constriction in a pressure conduit results in a lowering of pressure at the constriction. The drop in piezometric head in the reach between the undisturbed flow and the constriction is a function of the flow rate. The venturi meter, flow nozzle, and orifice meter (fig. 250) are constriction meters that make use of this principle. The difference in piezometric head may be measured with a differential manometer or pressure gages. In order that such an installation may function properly, a straight length of pipe at least 10 diameters long should precede the meter. Straightening vanes may also be installed in the conduit just upstream from the meter to suppress disturbances in the flow.

Venturi meters.—Venturi meters (fig. 250*A*) are highly accurate and efficient flow meters; they have no moving parts, require little maintenance, and cause little head loss (U.S. Bureau of Reclamation, 1971). They operate on the principle that flow in a given closed-conduit system moves more rapidly through areas of small cross section (D_2 in fig. 250*A*) than through areas of large cross section (D_1 in fig. 250*A*). The total energy in the flow, consisting primarily of velocity head and pressure head, is virtually the same at D_1 and D_2 within the meter. Thus the pressure must decrease in the constricted throat, D_2, where the velocity is higher; and conversely the pressure must be greater at D_1, upstream from the throat, where the velocity is lower. This reduction in pressure from the meter entrance to the meter throat is directly related to the rate of flow passing through the meter and is the measurement used to determine flow rate. Tables or dia-

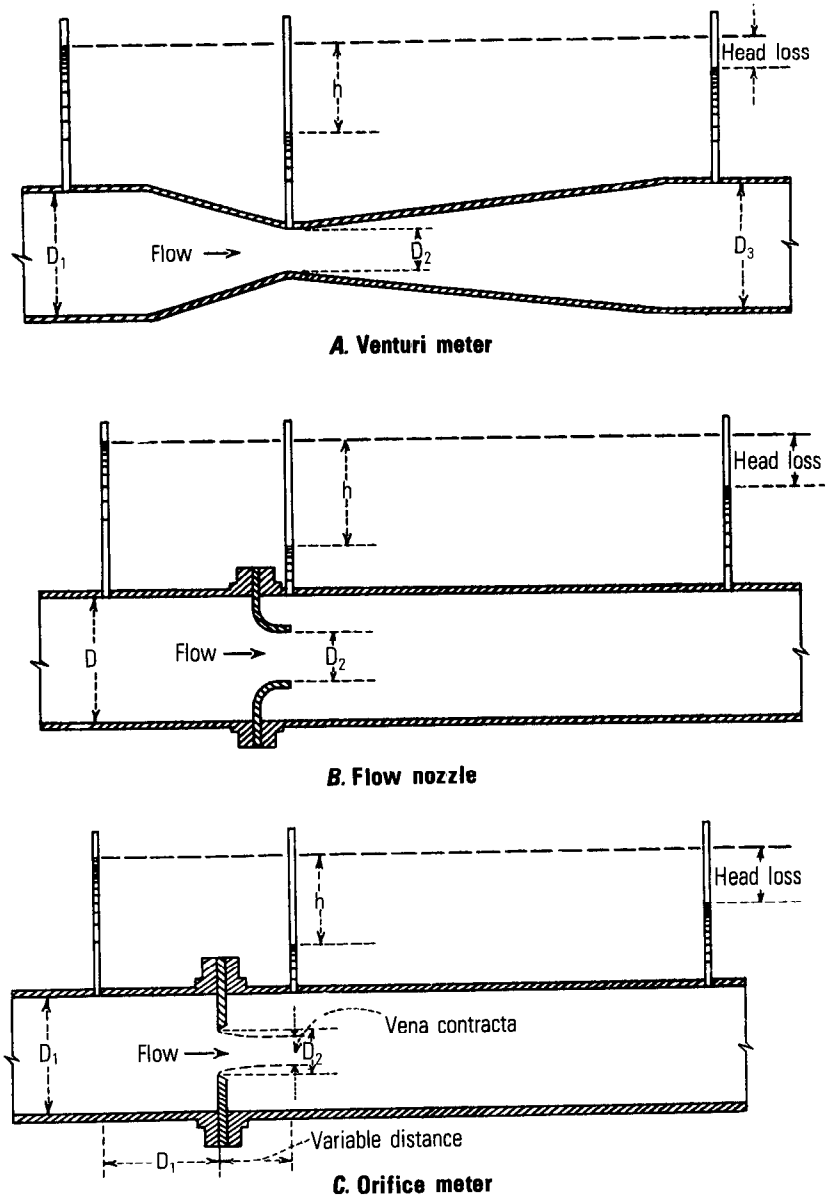

FIGURE 250.—Three types of constriction meter for pipe flow. (Courtesy of U.S. Bureau of Reclamation.)

grams of this head differential versus rate of flow may be prepared, and flow indicators or flow recorders may be used to display the differential or the rate of flow.

The relation of rate of flow, or discharge, to the head and dimensions of the meter is

$$Q = \frac{CA_2\sqrt{2gh}}{\sqrt{1 - r^4}}, \tag{141}$$

where

A_2 = cross-sectional area of the throat, in square feet,
h = difference in pressure head between upstream pressure-measurement section and the downstream pressure-measurement section, in feet,
g = 32.2 feet per second per second,
r = ratio of the throat diameter to pipe diameter = D_2/D_1, and
C = coefficient of discharge for the venturi meter.

The coefficient of discharge for the venturi meter varies with a Reynolds number that is based on the diameter and velocity at the throat and on the kinematic viscosity of the water; the kinematic viscosity of the water is in turn a function of the water temperature. The formula for computing the Reynolds number is

$$R = \frac{V_2 D_2}{\nu}, \tag{142}$$

where

R = Reynolds number (dimensionless),
V_2 = mean velocity in the throat (ft/s),
D_2 = throat diameter (ft), and
ν = kinematic viscosity (ft^2/s).

Table 27 gives values of kinematic viscosity corresponding to selected

TABLE 27.—*Values of kinematic viscosity corresponding to selected water temperatures*

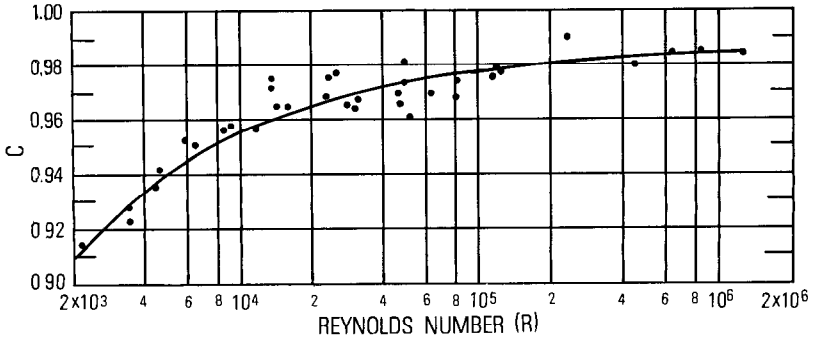

FIGURE 251.—Discharge coefficients for venturi meters as related to Reynolds number. (After Howe, 1950. Reprinted by permission of John Wiley & Sons, Inc.)

water temperatures. Figure 251 shows values of the discharge coefficient for venturi meters as related to the Reynolds number. Figure 251 is based on discharge data for meters having a diameter ratio (r) equal to 0.5, and although the discharge coefficient will vary slightly with the geometry of the venturi meter, the relation shown in the figure is considered accurate to within 1 percent for meters that are carefully maintained.

Flow nozzles.—Flow nozzles operate on the same basic principle as venturi meters. In effect, the flow nozzle is a venturi meter that has been simplified and shortened by omitting the long diffuser on the outlet side (fig. 250*B*). The streamlined entrance of the nozzle provides a straight cylindrical jet without contraction, so that the coefficient is similar, in considerable degree, to that for the venturi meter. In the flow nozzle, the jet is allowed to expand of its own accord, and the high degree of turbulence created downstream from the nozzle causes a greater loss of head than occurs in the venturi meter where the long diffuser suppresses turbulence.

The relation of rate of flow to the head and dimensions of the flow nozzle is

$$Q = \frac{CA_2\sqrt{2gh}}{\sqrt{1 - r^4}}, \tag{141a}$$

which is identical with equation (141) given above for the venturi meter. The symbols have the same meaning in both equations, except that C in equation 141a is the coefficient of discharge for the flow nozzle.

Specifications for the manufacture and installation of flow nozzles vary, and extensive research on the various types has resulted in the accumulation of a large body of data on discharge coefficients. Space limitations preclude detailed discussion of those coefficients, but it

may be stated that for the more popular types of design and in the usual range of operation the coefficients generally range from 0.96 to 0.99; for any type of flow nozzle, the discharge coefficients increase with Reynolds number and tend to become constant at Reynolds numbers greater than 10^6. A recommended source of data on discharge coefficients is a report of the American Society of Mechanical Engineers (1937).

The upstream pressure connection for measuring head is frequently made through a hole in the wall of the conduit at a distance of about 1 pipe diameter upstream from the starting point of the flare of the nozzle. The pressure observed is that of the stream before it has begun to turn inward in response to the inlet curvature of the nozzle. The downstream pressure connection may be made through the pipe wall opposite the end of the nozzle throat.

Orifice meters.—A thin-plate orifice inserted across a pipeline can be used for measuring flow in much the same manner as a flow nozzle (fig. 250*C*). The upstream pressure connection is often located at a distance of about 1 pipe diameter upstream from the orifice plate. The pressure of the jet ranges from a minimum at the vena contracta—the smallest cross section of the jet—to a maximum at about 4 or 5 conduit diameters downstream from the orifice plate. The downstream pressure connection—the center connection shown in figure 250*C*—is usually made at the vena contracta to obtain a large pressure differential across the orifice. The location of the vena contracta may be determined from data provided in standard hydraulic handbooks.

The relation of rate of flow to the head and dimensions of the metering section is

$$Q = \frac{CA_2\sqrt{2gh}}{\sqrt{1 - r^4}}, \tag{141b}$$

which is identical with equations 141 and 141a except that C in equation 141b is the coefficient of discharge for the orifice meter.

For pressure taps located 1 pipe diameter upstream from the orifice plate and at the vena contracta, the coefficient of discharge ranges from 0.599 for an r value of 0.20 to 0.620 for an r of 0.71, when the Reynolds number exceeds 2×10^5. The principal disadvantage of orifice meters, as compared to venturi meters or flow nozzles, is their greater loss of head. On the other hand, they are inexpensive and are capable of producing accurate flow measurements.

Bend meters.—Another type of differential head meter is the bend meter, which utilizes the pressure difference between the inside and outside of a pipe bend. The meter is simple and inexpensive. An elbow already in the line may be used without causing added head loss. For

best results a bend meter should be calibrated in place. The meter equation is

$$Q = CA\sqrt{2gh}\,, \tag{143}$$

where C is the coefficient of discharge, h is the difference in piezometric head between the outside and inside of the bend at the midsection, and A is the cross-sectional area of the pipe. For best results it is recommended that the lengths of straight pipe upstream and downstream from the bend be equal to at least 25 pipe diameters and 10 pipe diameters, respectively.

Lansford (1936) experimented with 90° bends, and he concluded that if calibration of a 90° bend is not feasible, results at moderate to high Reynolds numbers that are accurate to within 10 percent can be obtained from a simple formula for C, in which

$$C = \sqrt{r/(2D)}\,. \tag{143a}$$

In equation 143a, D is the pipe diameter and r is the centerline radius of the bend.

Pressure differential in a reach of unaltered conduit.—If a pressure-conduit system has high velocities and low pressures, it may not be practical to install a venturi meter in the line because cavitation will occur in the throat along with excessive vibration. In that situation the installation of a manometer between two piezometer taps in the conduit, several hundred feet apart, may be the most feasible method of metering the flow. One but preferably two discharge measurements would suffice to rate the manometer, and a third measurement could be made to check the rating equation which is,

$$Q = K\sqrt{\Delta h}\,, \tag{144}$$

where

Q = discharge,
K = a constant, and
Δh = head differential.

If two discharge measurements are used in the initial calibration, the two computed K values, which should agree closely, are averaged.

In the case of reaction turbines, the discharge may be metered by a manometer that measures the pressure drop in the scroll case. The scroll case of a reaction turbine has a decreasing diameter, being largest at its upstream end where it is joined to the penstock. A set of piezometer taps is installed at each end of the scroll case forming, in effect, a type of venturi section. Discharge is computed by use of equation 144, K being determined from discharge measurements, preferably made over the complete range of output, and simultaneous observations of the pressure drop. The calibration should remain constant as long as the turbine efficiency does not change.

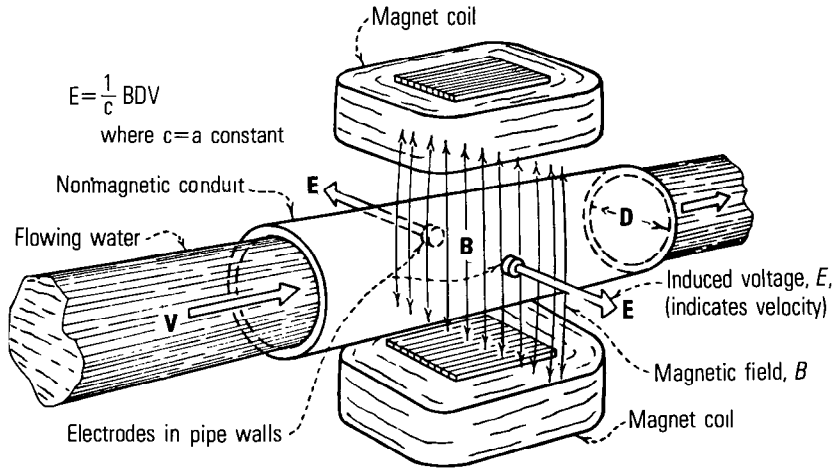

FIGURE 252.—Schematic view of one type of electromagnetic velocity meter. (Courtesy of U.S. Bureau of Reclamation.)

Summary.—Differential-head meters are very satisfactory metering devices as long as they are kept clean and the velocities in the conduit are high enough to give significant pressure differentials between the two piezometer taps.

ELECTROMAGNETIC VELOCITY METER

Electromagnetic velocity meters for measuring flow in pressure conduits are commercially available. The principle of the electromagnetic velocity meter was explained in the section in chapter 12 titled, "Electromagnetic Velocity-Meter Method"; but to repeat briefly, when a fluid which is an electric conductor moves across a magnetic field at 90°, as shown in figure 252, an electromotive force is produced in the fluid at right angles to both the flux of the magnetic field and the velocity of the fluid. The induced voltage is proportional to the average velocity of the fluid, V. If the pipe is a conductor, as it usually will be, an insulating liner must be installed in the metering section and the probes must contact the water. Two or more discharge measurements are required to calibrate the meter.

ACOUSTIC VELOCITY METER

Acoustic velocity meters for measuring flow in pressure conduits are commercially available. The principle of the acoustic velocity meter was explained in the section in Chapter 12 titled, "Acoustic Velocity-Meter Method," and will not be discussed further other than to state that better results are obtained with the transducers of the meter in direct contact with the fluid stream than are obtained with the transducers mounted on the outside of the conduit walls

(Schuster, 1975). The acoustic velocity meter should be calibrated by discharge measurements.

LASER FLOWMETER

Laser (light amplification by stimulated emission radiation) beams have been used for studying the turbulent characteristics of flowing liquids and for determining the velocity of fluid flow (Schuster, 1970). The Doppler principle, which involves a measurable shift in the frequency of the light rays under the influence of an external velocity imposed on the system, underlies the operation of the laser flowmeter. The flowing water scatters part of a beam of light (laser) directed through it. By comparing the frequencies of the scattered and unscattered rays, collected in receiving lenses on the opposite side of the stream, the velocity of the water (hence the discharge) can be calculated. In laboratory experiments, the instrument has measured fluid flows as slow as a fraction of an inch per second and as fast as 1,000 or more feet per second. The device is a valuable research tool, but it should also be considered a possible future device for measuring discharge in both open channels and pressure conduits.

DISCHARGE-MEASUREMENT METHODS FOR METER CALIBRATION

MEASUREMENT OF DISCHARGE BY PITOT-STATIC TUBES AND PITOMETERS

Pitot-static tubes and pitometers may be classed as differential-head meters, but they are seldom used for continuous-flow measurement. Instead, they are usually used for calibrating other metering devices in place and for intermittent measurements. Pitot tubes and pitometers indicate the velocity head at a point in the conduit cross section.

The operation of pitot-static tubes or pitometers is based on the principle that the increase in head at the mouth of a bent tube facing upstream is a measure of the velocity head of the oncoming flow. The most commonly used type of pitot-static tube (fig. 253*A*) consists of two separate parallel tubes, one for indicating total head, P_t (sum of static and velocity heads), and the other for indicating only static (pressure) head, P_s. Manometers are commonly used to measure these heads, the velocity head being the difference between the static head and the total head. A pressure transducer may also be used instead of the manometer for measuring the differential head. Where pitot-static tubes are used for continuous-flow measurement, oscillograph or digital recording of the electrical signal from the transducer provides a continuous record of the changes in head.

The general equation for pitot-static tubes and pitometers is

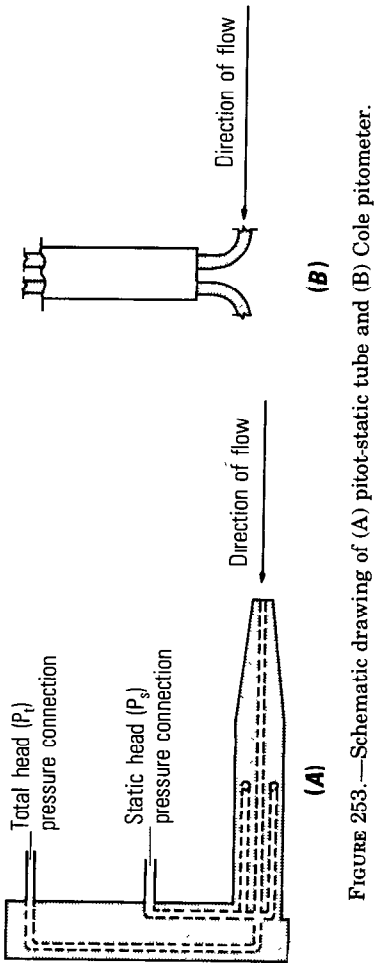

FIGURE 253.—Schematic drawing of (A) pitot-static tube and (B) Cole pitometer.

$$V = C_1\sqrt{2g\Delta h}, \tag{145}$$

where

V = velocity,
C_1 = coefficient,
g = acceleration of gravity, and
Δh = observed velocity-head differential.

The coefficient C_1 will vary with the dimensions and geometry of the meter, but the instruments are usually individually rated by the manufacturer in the manner that current meters are rated, and the value of C_1 is therefore known. For the pitot-static tube shown in figure 253*A* the value of C_1 usually ranges from 0.98 to 1.00.

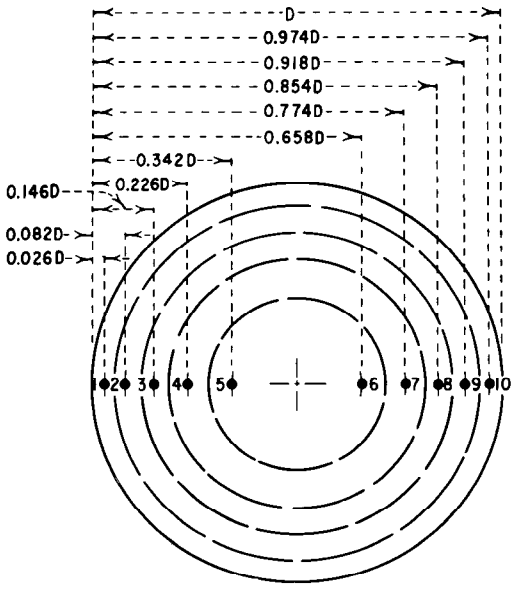
Another commonly used type of pitot device is the Cole pitometer (fig. 253*B*), which consists of two tubes headed in opposite directions. The tubes can be rotated so that the instrument may be inserted through a small bushing in a pipe. When in operating position, the downstream tube registers a negative pressure because its opening is in the wake of the instrument. The differential of the water columns is therefore considerably greater than $V^2/2g$. The value of C_1 in equation 145 usually ranges from 0.84 to 0.87.

Reinforced pitot tubes and pitometers have been used successfully in pipes up to five feet in diameter having flow velocities of 5–20 ft/s (U.S. Bureau of Reclamation, 1971). Even larger pipes can be traversed by pitometer by having access ports on both sides of the pipe and by probing to or past the conduit centerline from each side. The principal disadvantage encountered is that relatively large forces push on the tube when flow velocities are high, making positioning and securing of the instrument difficult. Dynamic instability may also occur, causing the tube to vibrate and produce erroneous readings. At moderate flow velocities the measurements are accurate.

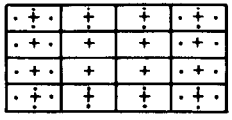
The most common pressure conduit is the circular pipe. For a constant rate of flow, the velocity varies from point to point across the stream, gradually increasing from the walls to the center of the pipe. The mean velocity is obtained by dividing the cross-sectional area of the pipe into a number of concentric equal-area rings and a central circle. The standard 10-point system is shown in figure 254*A*. More divisions may be used if large flow distortions or other unusual flow conditions exist. Observations are made at specific locations in these subareas (fig. 254*A*) and mean velocity is computed from the equation,

$$V_{\text{mean}} = C_1(\sqrt{2g})(\sqrt{\Delta h})_{\text{average}}. \tag{146}$$

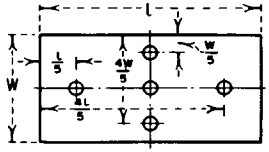
The mean velocity in rectangular ducts can be determined by first dividing the cross section into an even number—at least 16—of equal



(A). Ten-point system for circular conduits



(B). System for rectangular conduits, where at least 16 divisions must be used



(C). Additional points for data in areas around periphery of the rectangular conduit

FIGURE 254.—Locations for pitot-tube measurements in circular and rectangular conduits. (Reproduced from B.S. 1042, Flow Measurement (1943), by permission of the British Standards Institution.)

rectangles geometrically similar to the duct cross section, and then making a pitot-tube observation at the center of each subarea (fig. 254*B*). Additional readings should be taken in the areas along the periphery of the cross section in accordance with the diagram in figure 254*C*. Mean velocity is then computed from equation 146.

When using pitot-static tubes or pitometers, it must be remembered that at low velocities, head differentials are small and errors in reading head differentials will seriously affect the results. Also the openings in the tubes are small and foreign material in the water, such as sediment or trash, can plug the tubes.

MEASUREMENT OF DISCHARGE BY SALT-VELOCITY METHOD

Discharges in conduits flowing full may be determined from the known dimensions of the conduit and velocity observations made by the salt-velocity method. Basically, the method uses the increased conductivity of salt water as a means of timing the travel of a salt solution through a length of conduit. A concentrated solution of sodium chloride is suddenly injected into the conduit at an injection station. At two downstream stations, electrodes are connected to a recording ammeter. An increase in the recorded electric current occurs when the prism of water containing the salt passes the electrodes (fig. 255). The difference in time (t) between the centers of gravity of the recorded salt passage is obtained from the recorder chart as shown in figure 255. The discharge is equal to the volume of the conduit between the two electrodes—it is not necessary that the conduit be uniform—divided by time, t, in seconds.

The brine-injection system that is used is quite complex (figs. 256 and 257). A turbulence-creating device (turbulator) is also sometimes used to insure adequate mixing of the brine and water by the time the upstream electrode station is reached. The required equipment and techniques have been described in detail by Thomas and Dexter (1955).

MEASUREMENT OF DISCHARGE BY THE GIBSON METHOD

The Gibson method was developed for computing the discharge of a conduit or penstock controlled by a valve, turbine, or regulating device located at the downstream end. The pressure conduit must extend at least 25 feet, and preferably much more, upstream from the valve or regulating device, but the conduit need not be of uniform

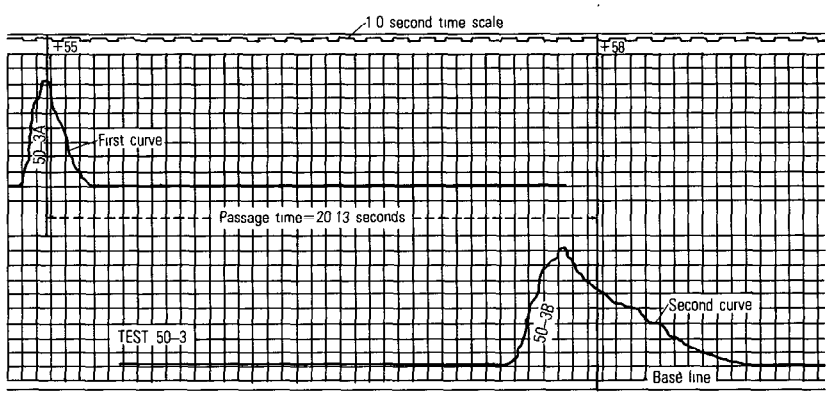


FIGURE 255.—Sample record of a salt cloud passing upstream and downstream electrodes in the salt-velocity method of measuring flows in pipelines. (Courtesy of U.S. Bureau of Reclamation.)

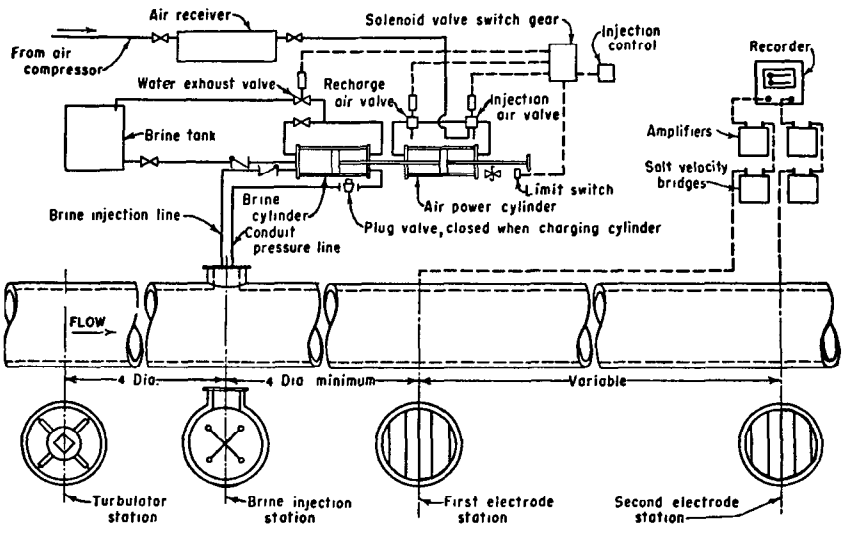

FIGURE 256.—General arrangement of salt-velocity equipment for pressure conduits. (Courtesy of U.S. Bureau of Reclamation.)

cross-sectional area. The underlying principle of the method is that the pressure rise that results from gradually shutting off the flow in a conduit is an indication of the original velocity of the water (Howe, 1950, p. 209–210).

The Gibson apparatus (fig. 258*A*) consists of: a mercury U-tube connected to the penstock just upstream from a gate; a light source behind the U-tube and a pendulum that swings in front of the box; and a narrow slit in the box directly behind the U-tube. Light shines through the U-tube and exposes a film on a rotating drum unless blocked by the pendulum or the mercury in the tube. During a test, the film therefore registers the fluctuation of the mercury column and the time intervals indicated by the pendulum (fig. 258*B*). The period of deceleration, T, terminates when the oscillations become symmetrical (point B, fig. 258*B*, where $t_1 = t_0$). An integration of the area $ABCA$ leads directly to the discharge through application of the equation,

$$Q = \left(\frac{\pi D^2}{4}\right)\left(\frac{g}{L}\right)(\text{area } ABCA), \tag{147}$$

in which Q is the discharge, D and L the diameter and length of conduit, and g the gravitational constant. The lower boundary of the area AC (practically a straight line) must be located by a trial-and-error process which is somewhat time-consuming but which nevertheless gives an accurate location of the line.

Equation 147 is applicable for a conduit of uniform cross section. If

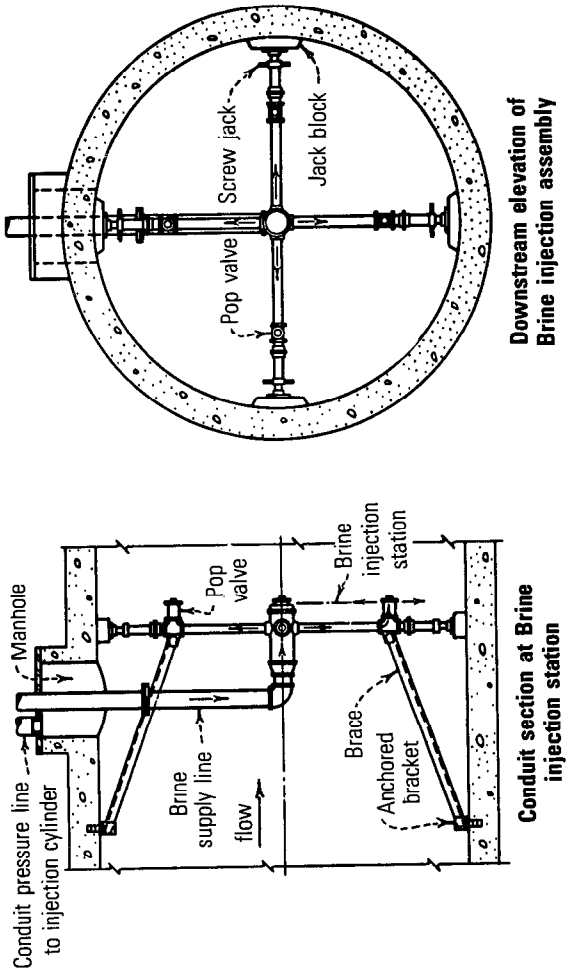

FIGURE 257.—Brine injection equipment in conduit. (Courtesy of U.S. Bureau of Reclamation.)

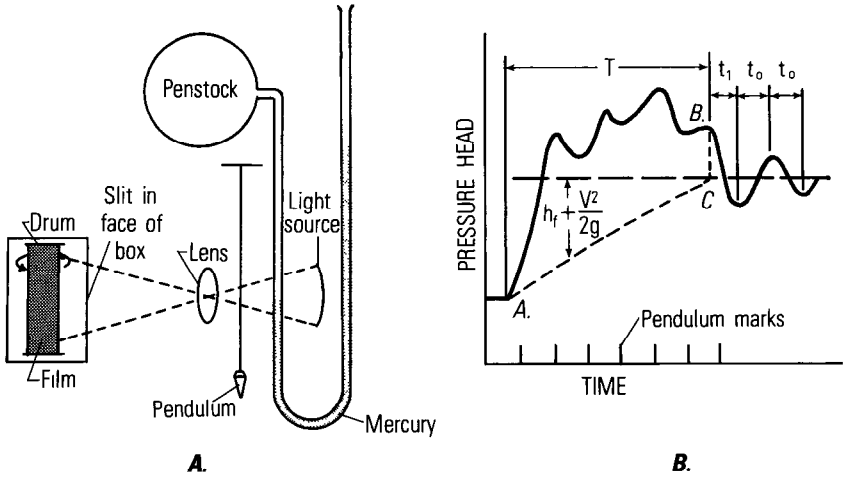

FIGURE 258.—Gibson apparatus and pressure-variation chart. (After Howe, 1950. Reprinted by permission of John Wiley & Sons, Inc.)

the conduit is not of uniform cross section throughout its length but is made up of a series of different sections of length l_1, l_2, l_3, etc. having cross-sectional areas a_1, a_2, a_3, etc., equation 147 must be modified. In that modification, we substitute the value $\Sigma(a/l)$ for the composite term $\left(\frac{\pi D^2}{4}\right)/L$; the value $\Sigma(a/l)$ is the sum of the quotients obtained by dividing the cross-sectional area of each conduit section by its respective length. The modified equation is therefore,

$$Q = g[\Sigma(a/l)]\ [\text{area } ABCA] \qquad (147a)$$

It is generally agreed that the Gibson method is very accurate. As an application of the momentum principle, this might be expected. The personnel requirements are not great, since only one operator is required to run the instrument. Neither is cost of the equipment excessive. A series of tests consumes a considerable time, however, because of the necessity for alternately shutting down the flow and bringing it back to a steady rate. Nevertheless, it must be concluded that the Gibson method offers a fairly simple and accurate approach to certain measurement problems that might otherwise be difficult.

CALIBRATION OF TURBINES, PUMPS, GATES, AND VALVES

The calibration of a reaction turbine by the measurement of pressure drop in the scroll case was discussed at the end of the section titled, "Differential-Head Meters." However, in some hydraulic systems it may be desirable, or perhaps necessary, to consider the turbine, pumps, gates, or valves themselves as flowmeters for the sys-

tem. To do that, it is required that the pertinent hydraulic element be calibrated. The calibration is often done in the laboratory using hydraulic models, but it is preferable that the hydraulic element be calibrated in place, or at least have its laboratory-derived calibration checked by field measurements of discharge. For field calibration, discharge measurements are made by one of the three methods discussed in the section on "Discharge-Measurement Methods for Meter Calibration," if they cannot be made by current meter in the forebay or afterbay of the system where open-channel conditions exist.

In the case of turbines or pumps, relations of discharge versus power are generally desired. They may be defined by observing the metered power output or input during periods when discharge measurements are made for various load conditions. Suitable curves or tables may be developed from these test data to show the discharge (Q) that occurs for specific types of operation. Curves or tables may also be prepared from model test data if the test data can be verified by a few discharge measurements. The calibration will change with time if there is a change in the efficiency of the turbine or pump resulting from long service or from other factors that cause deterioration.

If the range of operating conditions for a pump or turbine is narrow, the calibration is simplified. In such a situation—for example, where power input or output is metered—a simple relation of discharge versus power divided by head may be adequate. For a pump operated by an internal-combustion engine, where power was not metered but rotational speed was automatically recorded, the following calibration scheme has been used. For the most commonly used rotational speed, $(RPM)_r$, a base rating of discharge (Q_r) versus head was defined by current-meter discharge measurements. To obtain the discharge (Q_m) for other rotational speeds, $(RPM)_m$, an empirical adjustment relation of Q_m/Q_r versus $(RPM)_m/(RPM)_r$ was defined by the discharge measurements. (The method of defining the two relations is similar to that used in the constant-fall method of rating open-channel discharges, discussed in the section in chapter 11 titled, "Rating-Fall Constant." The use of head in the pump rating is analogous to the use of stage in the open-channel method; the use of rotational speed of the pump is analogous to the use of fall in the open-channel method.) After the two relations have been defined, to obtain the discharge (Q_m) for a given head and a given rotational speed, $(RPM)_m$, the ratio $(RPM)_m$ to $(RPM)_r$ is first computed. That ratio is then used in the adjustment relation to obtain the ratio Q_m/Q_r. The value Q_r is the discharge corresponding to the given head in the base rating. The desired discharge (Q_m) is then computed by multiplying Q_r by the ratio Q_m/Q_r.

For gates and valves, relations of discharge versus gate opening for various appropriate heads are desired. They may be defined by observing the gate or valve openings during periods when discharge measurements are made for various operating heads. Measurements made over the full range of gate openings and heads will provide the data for establishing the required curves or tables. Generally the relations are in the form of discharge (Q) for gate openings expressed as a percentage of full opening for pertinent operating heads. Curves or tables may also be prepared from model test data if the test data can be verified by a few discharge measurements. As with turbines and pumps, the calibrations for gates and valves are subject to change with time as wear or deterioration occurs.

URBAN STORM DRAINS

Quantitative studies of urban storm runoff have been handicapped by a lack of proper instrumentation for metering the flow in sewers. An ideal sewer flowmeter should have the following characteristics: (1) capability to operate under both open-channel and full-flow conditions, (2) a known accuracy throughout the range of measurement, (3) a minimum disturbance to the flow or reduction in pipe capacity, (4) a minimum requirement of field maintenance, (5) compatibility with real-time remote data-transmission, and (6) reasonable construction and installation costs.

Over the years many devices have been tested for use as sewer flowmeters. Wenzel (1968) has reviewed the methods and devices tested—weirs, depth measurement, depth and point-velocity measurements, dilution methods, and venturi flumes—and found that all have disadvantages of one kind or another. Of those devices, one of the most favorable was the flat-bottom venturi flume specifically designed for flow measurements in conduits by Palmer and Bowlus (1936). That flume has a throat of trapezoidal cross section, a flat bottom, and upstream and downstream side and bottom transitions. The flat bottom permits debris to flow smoothly through the throat and the transitions reduce the head loss substantially below that which would be caused by a weir, for example.

Wenzel (1968), in his study, concluded that further effort in designing some new modifications of a venturi flume offered the greatest promise of success in developing a more satisfactory flowmetering device for urban storm drains. Accordingly three new variations of a venturi section have been designed and laboratory tested in the U.S.A. The U.S.G.S. sewer flowmeter is now (1976) being field tested; the Wenzel asymmetrical and symmetrical sewer flowmeters are still awaiting installation in the field. The three types are briefly described below.

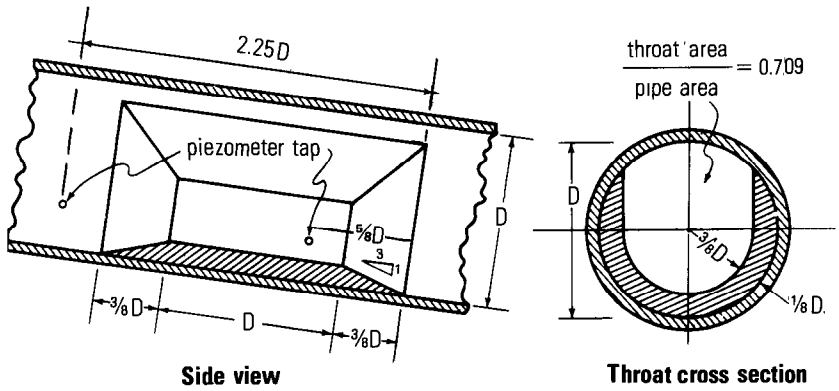

FIGURE 259.—Sketch of USGS flowmeter in a sewer.

U.S.G.S. sewer flowmeter.—The U.S.G.S. meter is a U-shaped constriction made to be inserted in a circular pipe (fig. 259). The symmetry of the design permits fabrication in two half sections for easy transportation and installation. Molds are available for fiberglass prototypes in standard pipe sizes from 24 to 60 in. (0.61 to 1.52 m).

The overall length from toe to heel is 1.75 pipe diameters. The throat length, equal to one pipe diameter, and the approach and getaway apron slopes of 1 on 3, resemble venturi meter specifications. The constriction, in fact, is a venturi flume for open channel flows; for pressure flows it may be considered to be a modified venturi meter.

For subcritical open-channel flows, the constriction dams up the flow, which then passes through critical depth as it spills through the throat. If the oncoming flow is supercritical, two conditions are possible: a hydraulic jump may be forced to form, which then spills through the throat and continues downstream as supercritical flow, or, on steeper slopes, the oncoming flow may remain supercritical throughout the entire constriction. As discharge increases, the water surface on the upstream side rises, touches the top of the pipe, and fills the upstream pipe, while the downstream side continues to flow part full. A discharge rating is available for each of these open-channel conditions.

Further increases in discharge trigger full-pipe conditions, which also are well rated. It is for these pressure-flow conditions that the question of head loss becomes of interest. Head loss, or backwater, is taken to be the increase in the upstream piezometric grade line caused by the presence of the constriction in the sewer line. For this constriction shape, the head loss is expressed as a function of the throat velocity head:

$$H_L = 0.04\frac{V^2_t}{2g}.$$

The constriction is considered to be self-cleaning. Inasmuch as sewers are generally laid to a self-scouring slope, any silting upstream from the constriction is expected to flush out on the next rise. The deposition of silt would have a negligible effect on the rating for small discharges, and no effect for high discharges.

The curved floor in the throat, parallel to the circumference of the pipe rather than being horizontal, retains some self-cleaning ability. It is a compromise between a V-notch base which would have great rating sensitivity for small discharges but a tendency to clog with small debris, and the other extreme, a horizontal floor as in a Palmer-Bowlus trapezoidal constriction. The floor thickness, one eighth of the pipe diameter, provides enough height to produce and maintain a stable hydraulic jump, and it also provides enough constriction (throat area is 0.709 of pipe area) to produce an adequate pressure drop for full-pipe flows. Yet, it is low enough to maintain open-channel flow for a larger range of discharge than would be maintained by a thicker constriction. By leaving the upper part of the pipe unconstricted, a quick transition from open-channel to full-pipe flow conditions is assured, and pressure build-up upstream from the constriction and head loss are minimized.

The pressures in the approach and in the throat of the constriction are measured remotely by pressure transducers. Dry nitrogen gas is bubbled at a constant rate through tubes to the two piezometer openings. The pressure at each opening is reflected to the head of the gas column where the transducer is located.

Data from the flowmeter are entered into the system and converted to two digital numbers proportional to the two pressures measured. The two transducer outputs are applied to a dual analog input amplifier that transforms them to analog voltage levels, which are then applied to analog-to-digital converters. Provisions are made so that one may compress, expand, or shift the range at the analog section.

The format under which data are recorded is dependent upon the conditions indicated by the system data inputs. The system logic inhibits data recordings during dry-weather, no-flow conditions. When flow begins in the sewer to be monitored by the system, the pressure at the approach tap will increase. During the period when this pressure exceeds a preset value, as indicated by the corresponding analog voltage exceeding a programed level, recordings will be continuous on a 1-minute cycle. The recordings are usually on on-site digital-punched paper tape, but variations have provided for analog recording as well as telemetry.

One or more recording precipitation gages and an automatic water sampler are included in the instrumentation for studying urban storm runoff.

It is desirable that the meter be calibrated in place by current-meter discharge measurements. However, as a guide to the probable meter rating and for use until field calibration is completed, the following laboratory discharge equations are presented. The coefficients shown are for use with English units.

A. *Pipe flowing full*

$$Q/D^{5/2} = 5.74\left(\frac{\Delta h}{D}\right)^{0.52}, \tag{148}$$

where

Q is discharge,

D is pipe diameter, and

Δh is the head differential between piezometer readings.

The constant 5.74 includes the constant for the acceleration of gravity. The exponent 0.52 fits the laboratory data better than the theoretical exponent 0.5.

B. *Open-channel flow*

1. *Supercritical regime*

$$Q/D^{5/2} = 5.58\,(h_1/D)^{1.58}, \tag{149}$$

where h_1 is the depth above pipe invert at the upstream piezometer.

2. *Subcritical regime—slope of culvert <0.020*

a. *For $h_1/D \geq 0.30$*

$$Q/D^{5/2} = 2.85\,(h_1/D - 0.191)^{1.76} \tag{150}$$

b. *For $h_1/D < 0.30$*

$$Q/D^{5/2} = 1.15\,(h_1/D - 0.177)^{1.38} \tag{151}$$

where h_2 is the depth above the flowmeter invert at the downstream piezometer.

Wenzel asymmetrical and symmetrical flowmeters.—A generalized drawing of the asymmetrical venturi section devised by Wenzel (1975) is shown in figure 260. The symmetrical venturi section differs from the asymmetrical type shown by having identical constrictions on either side of the vertical centerline of the pipe. The constriction

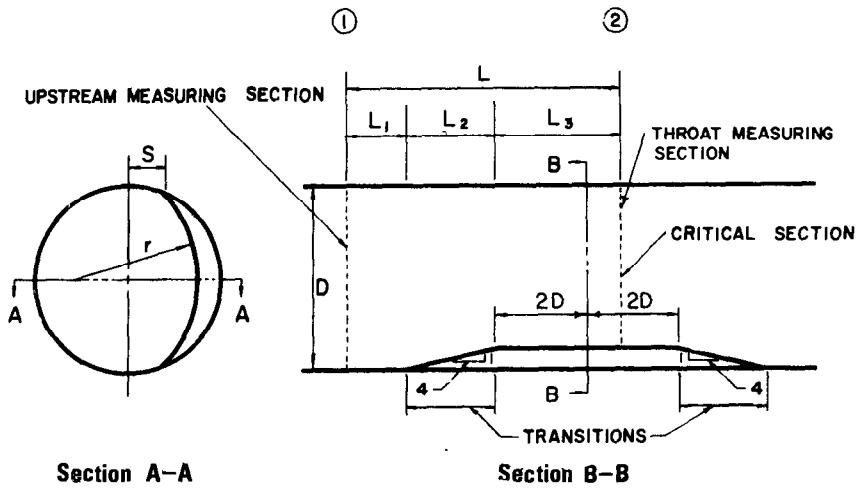

FIGURE 260.—Sketch of Wenzel asymmetrical flowmeter in a sewer. (After Wenzel, 1975.)

consists of a cylindrical section, whose radius is greater than that of the pipe, with entrance and exit transitions having a slope of 1 on 4. The cylindrical section intersects the pipe wall a distance S from the centerline, thereby maintaining the invert region free of obstruction so that self-cleaning is facilitated. In all laboratory tests, a constant value of 0.1 was maintained for S/D, but the ratio r/D was varied to provide various ratios of throat area to pipe area for testing. A throat length between $2.25D$ and $4.0D$ is recommended. The upstream piezometer tap is located approximately $D/3$ upstream from the beginning of the entrance transition; the downstream piezometer tap is located approximately at the center of the throat. As mentioned earlier, no information on the field performance of the Wenzel flowmeters is as yet available.

CHAPTER 15—COMPUTATION OF DISCHARGE RECORDS

GENERAL

Streamflow records for each gaging station are computed and published annually. The 12-month period used, which is known as the water year, usually does not coincide with the calendar year. In the U.S.A. the water year runs from October 1 to September 30 and is designated by the calendar year of the last 9 months—for example, the 1975 water year runs from October 1, 1974 to September 30, 1975. The following considerations govern the choice of the 12 months that will constitute the water year. The 12-month record is essentially an inventory of the water supply. As with any inventory, it should be made when the stock on hand (available water resource) is at a minimum. That is the case in most of the U.S.A. on September 30, at which time the growing season is at an end. Not only are groundwater, soil-moisture, and surface storage at or near a minimum on that date as a result of heavy water use during the preceding summer, but the replenishing rains of autumn have not yet begun and streamflow is also near minimal. In short, the 12-month period to be used as the water year is determined by the climatic regime of the region.

A daily record of discharge, along with momentary values of peak discharge and minimum flow, is computed for the water year from the record of stage and the discharge rating for the gaging station. The type of stage recorder used determines whether the computations are performed manually or by an electronic computer. In either system, the engineer must study the data and prepare what is termed a station analysis before the actual computation of discharge is begun.

STATION ANALYSIS

A station analysis, which documents the results of the study of the data, is prepared for each station for each water year. The study includes the following items, all of which are needed as a preliminary to computing the discharge record.

1. A review of field surveys of gage datum and a determination of the datum corrections, if any, to be applied to stage observations or recordings during the year.
2. A listing and review of discharge-measurement notes
3. An analysis of the discharge rating and the determination of the rating (or shift) applicable during each period of the year.
4. The preparation of tables that express the discharge rating, using the rating curves derived in the above item 3.

Documentation of items in the station analysis is made as the various steps in the analysis and computation of the discharge record are completed. The station-analysis document is described in detail later in this chapter after all items in the analysis and computation of discharge have been discussed. Examples of the methods of analysis and computation are interspersed in the discussions of methodology for illustrative purposes.

DATUM CORRECTIONS

The datum of the gaging station is the elevation of the zero point of the base or reference gage, preferably referred to mean sea level. (For a discussion of reference and auxiliary gages see the section so-titled in chapter 4. The base gage or reference gage is the gage to which the recording instrument is set; at a nonrecording station it is the gage whose daily readings are recorded by the observer.) Levels are run periodically to all bench marks, reference marks, reference points, and gages at each station for the purpose of determining if any datum changes have occurred as a result of settlement or other movement of any of the gages or of the bubble orifice. If significant movement is indicated by the levels, the gage or bubble orifice is reset to its original datum.

Figure 261 is a typical set of level notes obtained in checking the datum of a recording stage-gage of the float-sensor type; the base gage is a vertical staff gage in the stilling well immediately below a reference point (RP1). Where a vertical staff gage consists of a number of standard USGS porcelain-enameled gage plates, each 3.4 ft long, the elevation of one of the central graduations on each plate should be checked. This is usually done by measuring to each plate with a steel tape whose zero end is held at a reference point of known elevation; the reference point, as mentioned, is established directly above the staff gage. The level notes in figure 261 for the inside staff gage (IG) show that the above procedure was followed.

The level notes are checked in the field for mathematical errors before the field party leaves the gaging station.

If a change in datum has occurred, it is necessary to determine the effective date of the change. In the absence of any evidence indicating the date when the datum change occurred, the change is assumed to have occurred gradually from the time the last levels were run, and the change is prorated with time. On the station-analysis document there would be entered the date(s) when levels were run, the period(s) and magnitude(s) of the datum correction(s) required, and the date and time when the original datum was restored to eliminate the need for corrections. If no datum corrections were required, as indicated, for example, in the level notes of figure 261, that fact would be entered in the station–analysis document.

File No. 10-2450

LEVEL NOTES
(First sheet, to be completed in the field)

Station Clear Creek near Utopia, Calif.

Date Oct 6, 1965 Party Patch & Sweet ϕ

Date level adjusted: Oct 6, 1965

Object of these levels:

To check gage datum

Conclusions

Elevations of RM's and RP checked within 0.002 ft.
Outside staff-gage datum checked within 0.01 ft.
Inside staff-gage datum checked within 0.003 ft.

Changes made:
To inside staff gage, out staff gage, tape gage, or R.M.'s.
No changes required; none made.

Remarks

Data to be added to, or changed on, Station Description (9-197) as a result of these levels.
No changes or additions to be made.

REVIEW OF DISCHARGE MEASUREMENTS

The first step in the review of discharge measurements is to check the mathematics of the measurements. It is usually considered expedient, however, to accept, without checking, the results of a discharge measurement made by an experienced hydrographer if the measurement checks the rating curve within ±5 percent and if the measured discharge does not exceed all previously measured discharges. The discharge measurements (fig. 42), including indirect determinations of discharge (chap. 9), are then arranged in chronological order and numbered consecutively. The measurements are next compared with the gage-height record to ensure that all discharge measurements are at hand—the inspection notes on the stage record should indicate whether or not a discharge measurement had been made—and also to check the gage heights shown on the measurement sheet. If a datum correction is applicable, it is applied to the mean gage height for the measurement.

The measurements are then tabulated on a special form (USGS form 9-207 in fig. 262). Most of the column headings in figure 262 are self-explanatory. Those on the right half of the table supply information that is helpful to the analyst in appraising the comparative accuracy of the discharge measurements, in case he should find it necessary to give more weight to one measurement than to another in developing the discharge rating. The hydrographer's field appraisal of the probable accuracy of his measurement is shown in the column headed "Meas. rated," where E is excellent, G is good, F is fair, and P is poor. For example, measurements nos. 31, 32, 34–35A, and 44 are rated "poor" because the depths were too shallow or the velocities too low to obtain reliable discharges. In addition, only a few sections (verticals) were used for measurement nos. 32, 34, and 44. The gage-height change during the time required for the measurement is also listed because a rapidly changing stage would adversely affect the adequacy of the measurement. The outside gage reading is listed to provide the analyst with information as to whether or not the gage-well intakes were functioning properly. (Small differences between the readings of the base gage and of the outside auxiliary gage are often the norm because of the difference in location between intakes and outside gage.) The two columns headed "Rating. . . ." are discussed in the section titled, "Rating-Curve Analysis."

The "Remarks" column is most important to the analyst. If a measurement was made by any means other than wading, the method and the sounding weight used are indicated. Measurements made from a bridge or cableway are directly comparable for studying changes in the measurement cross section because the same cross section is used for all discharge measurements. With regard to noting the

FIGURE 262.—List of discharge measurements.

sounding-weight size, the measured discharge tends to be greater than the true discharge if too light a weight is used in high-velocity flow because depth soundings tend to be erroneously high and the meter also tends to rise to a higher (and faster) level than intended when positioned at the desired depth for a velocity observation.

The condition of the control—whether clear, ice-covered, or debris-covered—is also noted in the "Remarks" column, along with the gage height of zero flow on the control at the time of low-flow measurements. (Zero flow equals gage-height minus depth of water over the lowest point on the control.) The stability of the rating is dependent on control conditions; the elevation of zero flow is highly important for extrapolating the low-water end of the rating.

In the case of an indirect discharge determination (no. 39), the gage-height of the outside high-water mark is noted in the "Remarks" column, along with the Froude number and roughness coefficient. The equation for computing the Froude number (F) is $F=V/\sqrt{gd}$, where V is mean velocity in the measurement section, g is the acceleration of gravity, and d is mean depth in the measurement section; d is computed by dividing the area of the measurement section by its width. A Froude number close to unity casts some doubt on the indirect determination because it indicates the probability of unstable flow conditions. As for the roughness coefficient, more reliability is generally attached to indirect determinations for smooth channels (low roughness coefficient) than to such measurements for rough channels (high roughness coefficient).

If the gaging station is on an intermittent stream—one that goes dry for periods during the year—the list of discharge measurements should also list chronologically the dates when the hydrographer actually observed that there was no flow in the stream.

STATION RATING—SIMPLE STAGE-DISCHARGE RELATION

The rating curve for a gaging station is a graphical depiction of the relation between stage and discharge. Additional parameters such as fall or velocity index may be required in the rating (see section titled, "Stage Rating—Three-Parameter Discharge Relation"), but this section of the manual deals only with simple stage-discharge relations. Each station rating curve presents individual problems based on the control characteristics for the station, a knowledge of which is a prerequisite for the rating analysis. The principles underlying simple stage-discharge relations were discussed in chapter 10; this section deals only with the mechanics of computing and preparing the station rating.

PLOTTING OF DISCHARGE MEASUREMENTS

Rating curves and discharge measurements should be plotted on

logarithmic graph paper, and it is often advantageous to have an additional plot of the low-flow data on rectangular-coordinate graph paper so that the point of zero flow may be plotted. If a new station is being analyzed, the scales selected should be such as to accommodate the ranges of stage and discharge that are expected. If the station is not new, all measurements made since the analysis of the preceding year should be plotted on the prints of the last-used rating curve. Each plotted measurement is tagged with its identifying number, and if the "Remarks" column of the list of measurements indicates that a measurement was made under altered control conditions, that fact should be temporarily indicated alongside the measurement number. Measurements that are affected by ice (nos. 35 and 35A in fig. 262) are not plotted because they serve no purpose in defining the rating. (The use of ice-affected discharge measurements is discussed in the section titled "Rating-Curve Analysis" that follows.) The measurements listed in figure 262 are plotted on the logarithmic rating-curve sheet used during the preceding year (fig. 263). In actual practice, the rating-curve sheet that is used is large enough to accommodate both parts of the plot shown in figure 263. In figure 264, the low-water discharge measurements have been replotted on rectangular-coordinate graph paper that bears a copy of the last-used discharge rating. Logarithmic rating-curve sheets have been designed with a rectangular-coordinate scale in one corner, thereby permitting both logarithmic and rectangular plotting on the same sheet.

RATING-CURVE ANALYSIS

The principles involved in simple stage-discharge relations (chap. 10) are used in analyzing the rating. After reviewing and plotting the discharge measurements, the analyst must determine whether the last-used rating is applicable for part or all of the water year. To do that, he computes percentage departures of his measured discharges from the discharges for the measurement stages, as indicated by the last-used rating table (rating no. 3 on figs. 263 and 264). The percentages are tabulated on the list of discharge measurements (fig. 262). As long as the departures are random in sign (plus and minus) and within ±5 percent, the last-used rating is kept in effect. Aside from the two ice-affected measurements, nos. 35 and 35A, all measurements above a stage of 3.00 ft closely check rating no. 3. Sometime between measurements no. 35A (January 18) and no. 36 (February 25), the ice in Clear Creek went out. When the ice went out, it apparently moved bed material which built up the lower part of the low-water control by about 0.06 ft; the build-up is evident from the change in zero-flow elevation (see "Remarks" column of fig. 262) and from the plotting of the measurements on the low-water curves of figures 263 and 264. Inspection of the gage-height chart indicates that the ice

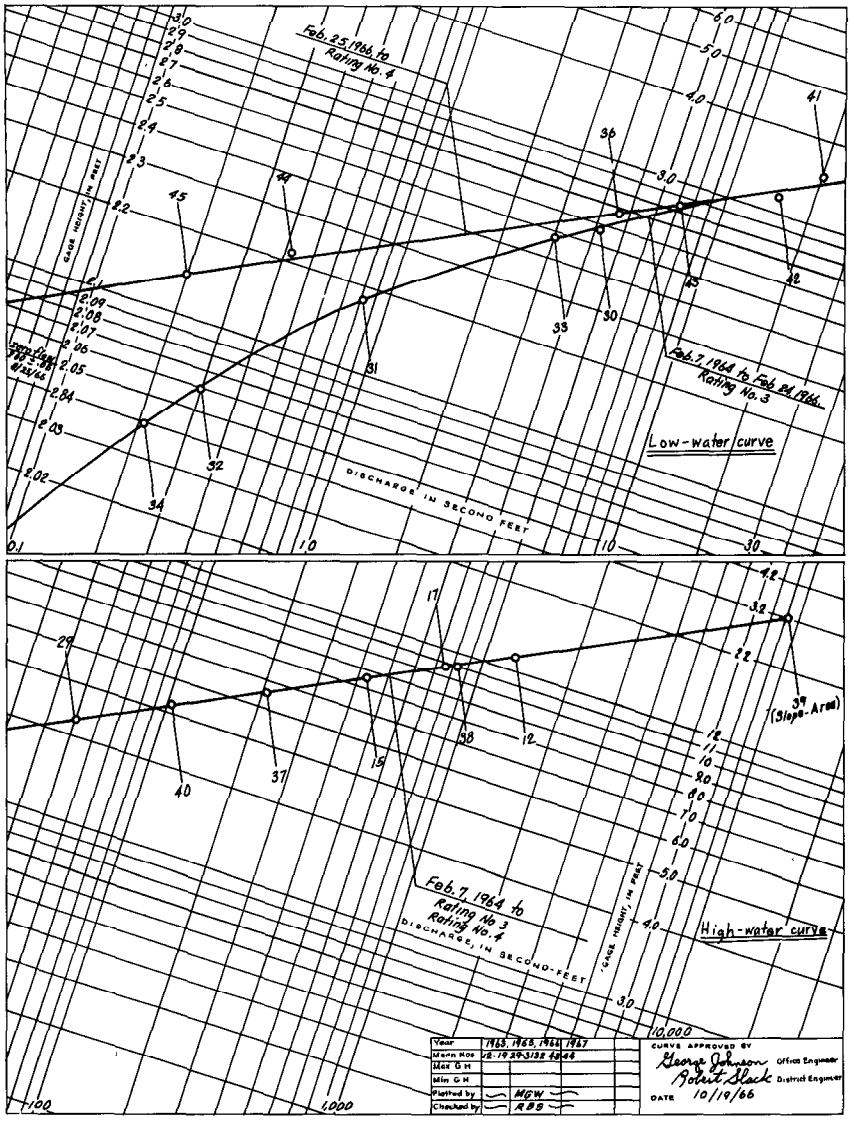

FIGURE 263.—Logarithmic plot of rating curve.

probably went out on a small rise in stage on February 24. Consequently a new rating curve (rating no. 4), based on measurements made after February 24, was developed for use starting February 25. Rating no. 4 is identical with rating no. 3 above a stage of 3.00 ft. One would expect the rating to change as a result of the major peak of May 27 (meas. no. 39), but no such change was evident from subsequent discharge measurements.

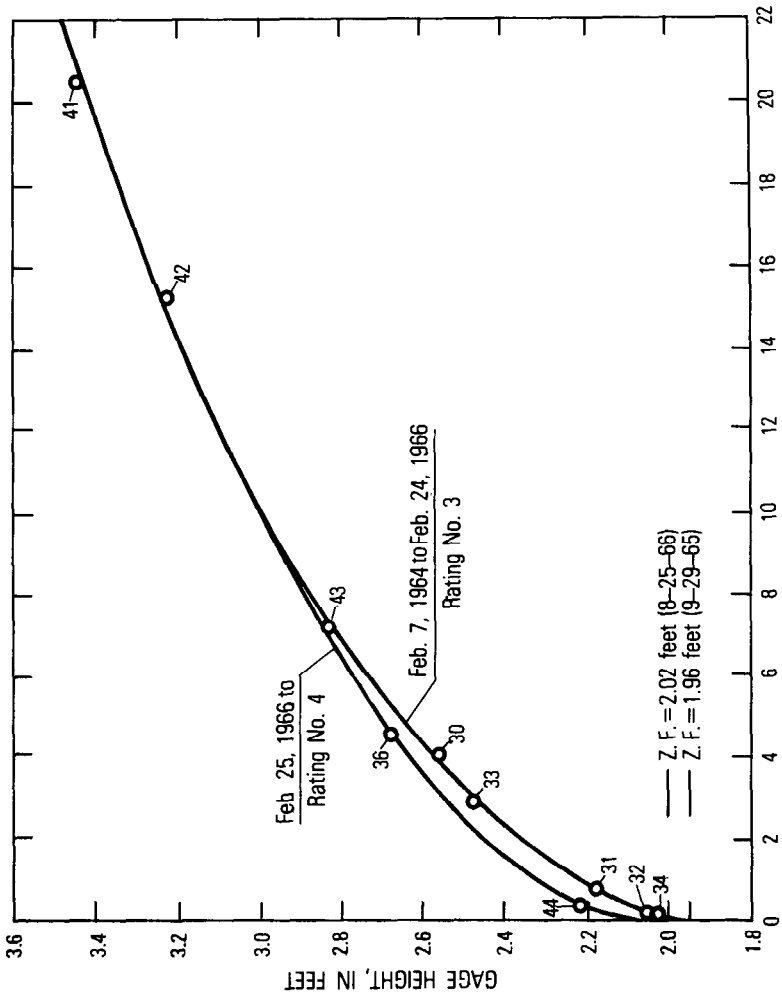

FIGURE 264.—Rectangular plot of low-water rating curve.

When discharge measurements depart from the rating curve by more than 5 percent, but the indicated change in rating is short-lived—less than a month or two—it is common practice not to establish a new rating curve, as such, for the short period. Instead, gage-height shifts (adjustments) are applied either to the rating in use prior to the period of shifting control or to a new rating, if one is later needed, that is established for use starting with the period of shifting control. (Shifts are discussed in detail in the section in chapter 10 titled, "Shifts in the Discharge Rating.") In our example for Clear Creek, aside from the period of ice effect shown by measurements nos. 35 and 35A, only one period of shifting control is in evidence. When the hydrographer visited the station on October 9, he found a heavy tree limb lodged on part of the control. He made his discharge measurement (no. 32) and then removed the limb. That is the proper sequence; had he removed the tree limb before the measurement, his results would be misleading unless he waited long enough for the surcharge storage to drain from the pool so that the stage and discharge became stabilized at the lower stage. That may take an hour or more, but if the measurement is made first, the drop in stage after removing the obstruction can be read later from the stage graph or punched tape. To get back to measurement no. 32, the stage dropped 0.02 ft after removal of the tree limb, and the measured discharge checked the rating curve at the lower gage height. The limb is believed to have lodged on the control on the recession following the minor rise of September 30. Consequently a shift of −0.02 ft is applied to all stages from October 1 to 1300h October 9 when the limb was removed. During that period 0.02 ft is subtracted from all recorded gage heights before obtaining the corresponding discharge from the rating table.

The period of rating shift that occurs as a result of ice effect is not classed as a period of shifting control because discharges are usually not computed by applying shifts to the gage-height record during an ice-affected period. The method of computing discharge for periods of ice effect is discussed in detail in chapter 10.

The basic rating curves to be used during the water year have now been defined and the next step is to transfer the ordinates of the rating curve to a rating table. That is done to refine the rating curve and to provide a more convenient way of obtaining the discharge corresponding to any given stage. The mechanics of preparing the rating table are described in the next section on "Rating Tables." At this point, we will assume that the rating table for rating no. 4 has been prepared, and the next task is to complete the forms that have been used up to now.

The first items to be considered are the two columns headed "Rat-

ing . . . ." in figure 262. A heavy line is drawn across the columns between the last measurement (no. 35A) for which rating no. 3 was used and the first measurement (no. 36) for which rating no. 4 was used, and above the latter measurement is inserted the heading "Rating 4." For measurement no. 32, the shift of −0.02 is inserted, as shown by the change in stage when the tree limb was removed from the control. Percentage differences are recomputed for measurements nos. 36–44, using discharges from rating table no. 4 as a base. The originally computed percentage differences for those measurements made at a stage greater than 3.00 ft will remain unchanged because the rating above the stage is unchanged. Shifts are computed and entered for the ice-affected measurements (nos. 35 and 35A), but no percentage differences are computed for ice-affected measurements because as mentioned earlier, shifting-control adjustments, as such, are not applied during the ice-affected periods. The shifts computed for ice-affected discharge measurements, therefore, are not an absolute requirement; they are shown solely for the purpose of giving the rating analyst a quick view of the magnitude of the backwater effect caused by ice. As an example of how shifts are computed, we consider measurement no. 35. The measured discharge of 2.15 ft^3/s corresponds to a gage height of 2.37 ft in rating table no. 3. The observed stage was 3.12 ft. The shift adjustment is −0.75 ft because that is the adjustment that must be applied to the observed stage (2.37 − 3.12) to obtain the stage corresponding to a discharge of 2.15 ft^3/s in rating table no. 3.

On figures 263 and 264 a closing date is added to rating curve no. 3. Rating curve no. 4 is replotted from the refined table for that rating—departures from the original plot of the rating should be very minor—and the new curve is tagged with its identifying number and the date on which it became effective.

To return to generalities about plotting discharge measurements and rating curves, the number of measurements and curves that have accumulated on a rating-curve sheet may in time be sufficient to clutter the sheet to the extent that the data are confusing. In that event a new rating curve should be drawn on a fresh sheet. Old high-water and extreme low-water measurements that are needed as supporting data for the new rating curve are transferred to the new curve sheet.

In the Clear Creek example that has been discussed, there was no need to extrapolate the rating curve. A slope-area determination of discharge had been made at the peak stage to define the high-water end of the curve, and current-meter discharge measurements defined the low-water end of the curve. Had extrapolation been required for either end of the curve, it would have been done by use of the methods

discussed in the section in chapter 10 titled, "Extrapolation of Rating Curves."

RATING TABLES

The rating table is a tabular expression of the information that is graphically presented by the rating curve. A part of rating table no. 4 for the Clear Creek example is given in figures 265 and 266.

In preparing the rating table from the rating curve, it is important to transfer to the table the identifying number of the rating and its starting date or period of application. Then starting with the low-water curve, the discharge is read and tabulated at intervals of 0.1 ft of stage on the standard rating-table form (fig. 265). On reaching the stage where the rating curve is no longer strongly curvilinear, the discharge may be tabulated at intervals of 0.5 ft of stage, and when the curve becomes more linear, the discharge is tabulated at intervals of 1.0 ft or more. For those parts of the rating that are truly linear on a logarithmic plot, the discharge may be computed from the equation of the rating (chap. 10). The blank spaces in the discharge column of the rating curve are then filled with values that are interpolated between the discharges that were entered in the table.

Differences in discharge for each 0.1 foot of gage height are then computed and entered in the appropriate column of the rating table (fig. 265). The differences should increase uniformly with stage, but this will seldom result from the discharges first entered from the rating curve. It will be necessary to adjust the differences so that they do vary uniformly, which in turn will necessitate a recomputation of the discharge figures, starting with the lowest value whose difference has been adjusted. The adjustment of the rating table must be done judiciously so that the recomputed discharges do not depart significantly from the original rating curve values, particularly in the vicinity of the plotted discharge measurements. Because the rating curve usually has changes in slope, the variation of the difference values can seldom be perfectly uniform. The aim of the smoothing process is to eliminate abrupt changes in the progression of differences, because those abrupt changes would indicate sharp bends in the rating curve. The differences should never decrease with increasing stage unless there is an actual reversal in the shape of the rating curve. Such reversals can only occur where some impeding effect on the discharge (increased backwater) comes into play; for example, where an arch bridge is the high-water control, the increase in waterway area with stage slows and finally ceases at the stages where the archway becomes submerged.

If difficulty is encountered in smoothing the progression of difference values while still adhering to the rating curve, it is helpful to compute second differences, that is, the differences between the dif-

FIGURE 266.—Expanded rating table.

ferences per tenth of a foot of stage. The second differences are then adjusted so that they form a uniform progression; second differences usually change quite slowly. After adjusting the second differences, the first differences are recomputed and finally the discharges are recomputed. As an aid in smoothing the second differences, it is often helpful to plot second differences against stage and then fit a smooth curve to the plotted points. It is highly desirable that a smooth rating table be obtained, but too great an effort to attain the ultimate in smoothness is unwarranted.

To obtain discharges from the rating table for gage heights that are expressed in hundredths of a foot, the discharges are computed by linear interpolation between the values shown for tenths of a foot of stage. Where sharp curvature occurs at the low-water end of the rating curve, such interpolation may be too crude. In that case the discharge for each hundredth of a foot of stage is picked from a large-scale plot of the low-water rating curve, and the discharge values are transferred to an expanded rating table (fig. 266).

Each rating table should be complete within itself for the entire range of stage through which it will be used so that it will not be necessary to refer to some other table that may be identical in part. For example, rating no.4 for Clear Creek is identical with the preceding rating no. 3 at stages above 3.0 feet. Nevertheless, rating no. 4 is completed in figure 265 for all stages above 3.0 ft so that there will be no shuffling back and forth between rating table sheets when applying discharges to recorded stages. By having each rating table complete in itself, the probability of error is reduced. If, as in the case of rating no. 4, the rating is identical with some former rating for some particular range of stage, that fact should be noted at the bottom of the rating table. The blank spaces below the rating table should also be filled to indicate the data on which the rating is based, the range of discharge that has actually been measured by current meter, and the basis of rating-curve extrapolation. As mentioned earlier, the completed rating table is used as the basis for computing the percentage differences for discharge measurements in figure 262, and it is also used to replot the rating curves in final form in figures 263 and 264. As a general rule, no more than three significant figures are used for discharge in the rating table.

STATION RATING—THREE-PARAMETER DISCHARGE RELATION

When a station rating involves three parameters—stage, discharge, and a third parameter such as fall or velocity index—the instructions given in the preceding sections will require some amending. The list of discharge measurements (fig. 262) will require an additional column for the third parameter. The additional column can

be provided by reducing the width of the "Remarks" column or by using the column normally reserved for outside gage height.

The general principles concerning the plotting of the discharge measurements and rating curves remain unchanged, but additional curves are required as shown, for example, in figures 190–195. The curves may be plotted on rectangular-coordinate graph paper, as shown in figures 190–195, but logarithmic graph paper may be preferable because then the principles of rating analysis are more easily followed. It may also be advantageous to use more than one sheet of graph paper for the curves to avoid clutter and attendant confusion in working with the graphs.

Because a 3-parameter discharge relation requires more than one relation curve—for example; a rating-fall curve, a fall-ratio curve, and a Q_r rating curve—more than one rating or relation table is required. The general principles discussed on the preceding pages for transferring curve ordinates to a table are applicable for any table.

COMPUTATION OF DISCHARGE RECORDS FOR A NONRECORDING GAGING STATION

The computation of discharge records for a nonrecording gaging station is identical with that for a recording station equipped with a graphic recorder, except for the early steps in computing the gage-height record. Consequently only those early steps will be discussed in this section of the manual. The remaining steps in the computation of the discharge record are discussed on those pages of this chapter that deal with stations equipped with graphic stage recorders.

COMPUTATION OF GAGE-HEIGHT RECORD

The first step in computing the record for a nonrecording gage is to compare the readings on the weekly gage cards mailed in by the observer with those he has entered in his quarterly book of gage height observations. (See introductory pages of the section in chapter 4 titled, "Nonrecording Stream-Gaging Stations.") The observer's readings should also be compared with readings made by the hydrographer on his regular visits. After reconciling any differences, the next step is to apply datum corrections, if any, to the observed gage heights. Both the corrections applied and the corrected gage-height values are entered in the book of gage observations (fig. 8). The corrected gage-heights are plotted at the appropriate time ordinates on fragments of unused recorder chart that are excess when a new roll of recorder paper is installed in a graphic stage-recorder. It is not necessary to plot gage heights for the long periods of gradually receding flows that follow stream rises. For the days during such periods, the

daily mean gage heights are computed as the mean of the two observed readings for each day.

A stage hydrograph is sketched through the plotted gage heights, using the graphic stage record from a nearby recording gaging station as a guide to the probable shape of the stage hydrograph. Observed high-water marks, for each of which the gage-height has been determined, and crest-stage gage readings are used where available, to give the peak stage of major rises. (Crest-stage gages are discussed in the last section of chapter 4.) The result is a stage hydrograph which, from the standpoint of discharge-computation methodology, is equivalent to the stage record from a graphic recorder after the recorder chart has had time and gage-height corrections applied to it.

Consequently, the remaining steps in computing the discharge record are, in effect, continued on the pages that follow the discussion of time and gage-height corrections for graphic-recorder charts. As mentioned above, from that point on the computation procedures are identical for nonrecording and graphic stage-recorder stations.

COMPUTATION OF DISCHARGE RECORDS FOR A RECORDING STATION EQUIPPED WITH A GRAPHIC RECORDER

COMPUTATION OF GAGE-HEIGHT RECORD

At a station visit when the recorded segment of the gage-height chart is removed and a fresh segment of chart is started, the hydrographer makes note of all information that will be needed in computing daily gage heights. His notations are made both on the end of the recorded chart and on the beginning of the fresh segment of chart. Those notations include name of the station, date, readings on all gages and the time of those readings, the instrument stage ratio, and notes explaining any unusual appearance of the pen trace. In addition to making a pen "tick" at the point where the pen rests at the time of chart removal and again at the time the fresh segment of chart is started, the hydrographer also rotates the float wheel to indicate the pen-reversal points on the chart. If the float wheel of the recorder is equipped with a tape, the step method of checking pen reversal is used. (See fig. 267.) The step method is used in making gage-height corrections to the pen trace and is explained in the section on "Determination of Gage-Height Corrections."

DETERMINATION OF TIME CORRECTIONS

Before determining the time corrections to be applied to the gage-height record, the chart should be dated. Each day is numbered on

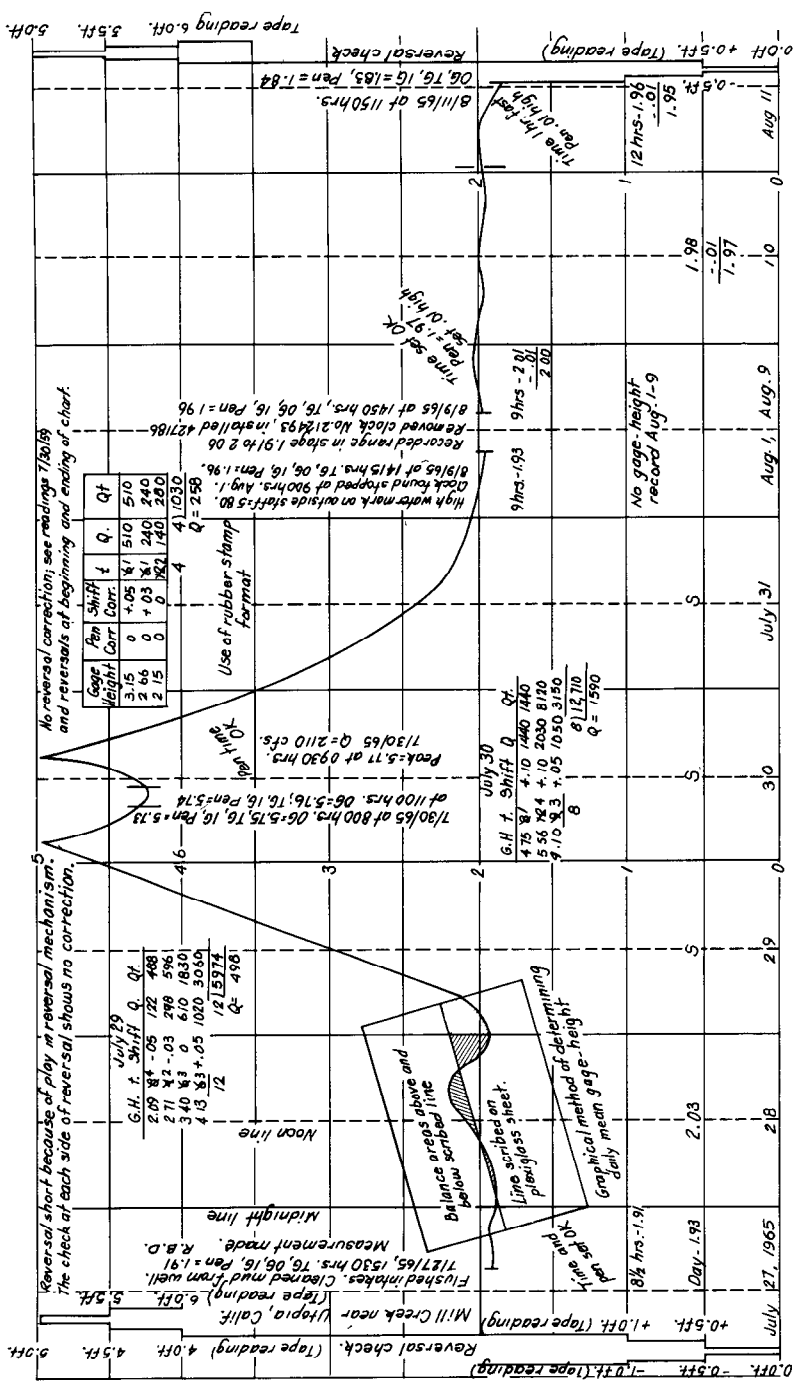

FIGURE 267.—Computation of daily mean gage height on graphic-recorder chart.

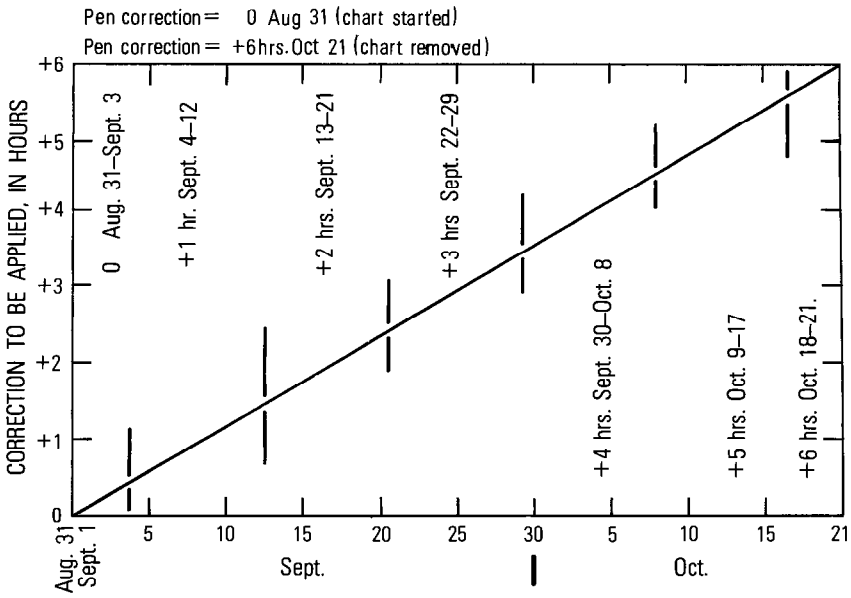

FIGURE 268.—Example of graphical interpolation to determine time corrections.

the lower base line at the noon line. The month is shown about every fifth day, and the year is shown about once a month.

The first step in computing time corrections for a segment of chart is to list the time corrections needed at each of the two or more days when the chart was field inspected. If the time correction at the end of the chart is large, the record should be inspected for evidence of large abrupt timing error—for example, clocks have been known to stop and then restart some hours later. If no abrupt timing errors are found, the time corrections are prorated by straight-line interpolation in which corrections are determined to the nearest hour. Figure 268 is an example of such an interpolation. The graph in figure 268, which is self-explanatory, would normally be drawn on the recorder chart near the beginning of the chart segment being studied. If the total time correction for the chart segment is small, the interpolated distribution of time corrections may be computed arithmetically without the use of a graph.

The computed time corrections are applied by changing the positions of the midnight lines for the affected days. Heavy vertical lines are drawn to indicate the new midnight lines, using care to ensure that the time adjustments are applied in the correct direction. It is advisable to make all interpretive notes, figures, and time corrections in colored pencil on the gage-height chart to differentiate them from the original notes.

DETERMINATION OF GAGE-HEIGHT CORRECTIONS

Gage-height corrections to the recorder trace are next determined. They are based on differences in readings of the recorder pen and the base gage, usually the inside staff, at station inspections. These corrections are also prorated with time unless there is evidence of abrupt instrumental error, such as would occur as a result of float-wheel slippage, or unless a systematic error with stage is shown to exist when the reversal points are checked by the step method at station inspections. An error in setting the pen at the start of a segment of strip chart will be carried throughout the length of that segment, but the original error may be increased or decreased by the above-mentioned errors. Gage-height corrections should be noted on the chart in such a manner that they can be easily applied to the gage-height values that are determined later.

Reversal errors, that is, errors that occur when the pen reverses direction at or near the upper or lower base lines, and systematic errors that vary with stage are usually caused by expansion or contraction of the chart, but they may also be caused by skewed travel of the chart. Reversal errors may also result from wear or maladjustment of the reversal mechanism of the stage recorder.

The step method of checking reversal points when changing the chart in the field provides a means of determining the gage-height corrections that vary with stage. The method requires that the recorder float wheel be equipped with a tape. The procedure used by the hydrographer is as follows:

1. Before removing the chart, raise the float tape to a value that is exactly 1 foot less than the foot mark at which the pen reverses; pull the chart forward a short distance to put an identifying "step" on the chart at that stage (fig. 267). Enter the tape reading on the chart.
2. Raise the float tape an additional half-foot and repeat the procedure.
3. Raise the float tape to the reversal point and repeat the procedure.
4. Repeat the above procedure, first with the tape reading 0.5 ft more than the foot mark at which the pen reverses, and again with the tape reading 1.00 ft more than the reversal foot mark.
5. Continue to raise the float tape and repeat steps 1 to 4 for the other base line reversal.
6. After the recorded segment of chart has been removed and the fresh segment of chart has been engaged, the pen is set to the correct gage height and steps 1 to 5 are repeated.

An example of the step method of checking reversal points is shown in figure 267. The step method in figure 267 actually indicates the need for a correction of +0.01 foot at a recorded stage of 4.99 ft and a

correction of −0.01 foot at a recorded stage of 5.01 ft. In other words a true stage of 5.00 ft is recorded as 4.99 ft on one side of the reversal and 5.01 ft on the other side. However, the gage inspections at 5.73 ft and 5.74 ft indicate that no corrections are needed and none were applied.

As a final step, datum corrections (see section on "Datum Corrections"), if required, are noted for each affected day. The recorder chart is now ready for the determination of daily gage heights.

DETERMINATION OF DAILY MEAN GAGE HEIGHT

Daily mean gage heights are usually determined graphically by the use of a thin rectangular piece of clear plastic whose dimensions are approximately 2 by 4 inches; a centerline is scribed on the plastic parallel to the long edge. The plastic is placed over a 24-hour segment of the recorder chart with the scribed line approximately over the pen trace. The plastic is then maneuvered into a position where the areas bounded by the midnight lines and lying above the scribed line but below the pen trace are equal in size to the areas lying below the scribed line but above the pen trace. When the areas above and below the scribed line are so balanced, the gage height of the point at which the scribed line intersects the noon line is the uncorrected mean gage height for the day. An example of the graphical method of determining daily mean gage height is shown for July 28 in figure 267.

A gage-height correction and (or) a datum correction, if applicable, will have been entered on the chart at about the noon line and about 1½ inches above the base line. The uncorrected daily mean gage height determined by the graphical method is then entered above the correction(s), the required addition or subtraction is performed to obtain the corrected daily mean gage height, and the corrected value is written below the correction as shown for August 10 in figure 267.

SUBDIVISION OF DAILY GAGE HEIGHTS

When there is large variation in stage during the day, it is necessary to: subdivide the day into smaller increments of time, determine the mean gage height for each time increment, apply the corresponding discharge from the rating table to each incremental mean gage height, and compute a time-weighted mean discharge for the day. That procedure is necessary because the stage-discharge relation is curvilinear; consequently the discharge corresponding to the mean gage height for a segment of stage of large range will differ significantly from the true discharge, which is the discharge integrated over that range of stage. The allowable range of stage, for which the use of a mean gage height introduces no significant error in

discharge, depends on the curvature of the stage-discharge relation; the more nearly linear the rating is, the larger the allowable range in stage.

The rule generally followed in the U.S.A. is to subdivide the gage-height graph for the day if the discharge corresponding to the daily mean gage height differs by 4 percent or more from the average of the two discharges corresponding to the maximum and minimum gage heights in the day. For any normal rating table, the average of the two discharges will be the larger figure. A simple method of computing a table of allowable range of stage for a rating is outlined below, using the rating table in figures 265 and 266 as an example.

First, a gage height G is selected near the lower end of the rating. Because the allowable difference in discharge is 4 percent, the average of the two extreme discharges in the allowable range of stage is $1.04\ Q_G$ where Q_G is the discharge from the rating table corresponding to gage height G. That means that $2.08\ Q_G$ equals the sum of the two extreme discharges in the allowable range of stage. (A definition sketch is given in fig. 269.) The analyst using the rating table moves small equal distances in stage up and down from gage height G until he obtains a pair of stages whose discharges total $2.08\ Q_G$. The range,

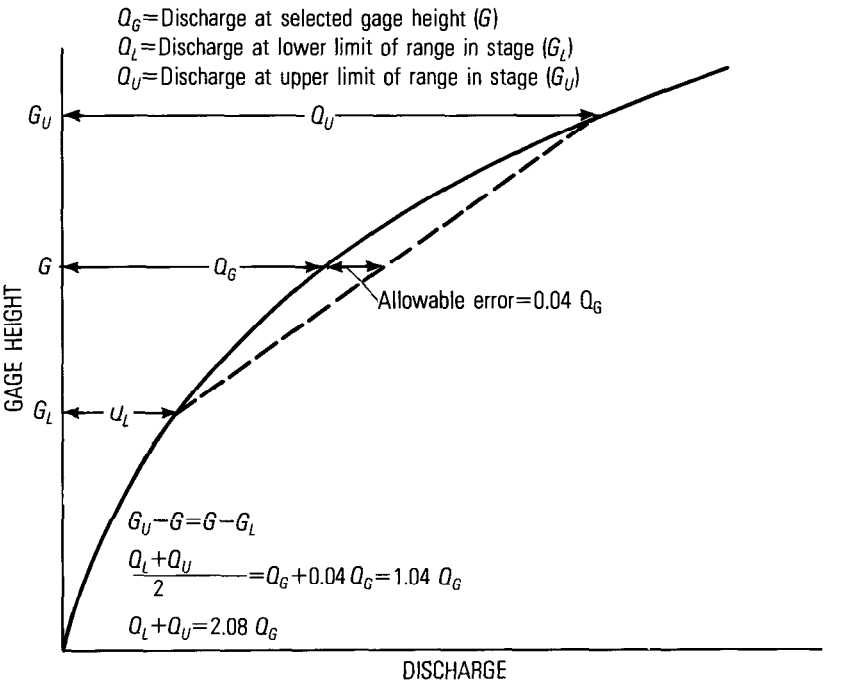

FIGURE 269.—Definition sketch illustrating computation of stage limits for application of discharge.

Mean gage height (ft)	Q (ft^3/s)	Q x 2.08 (ft^3/s)	Allowable limits of stage (ft) / Corresponding discharge (ft^3/s)	Allowable range of stage (ft)

FIGURE 270.—Results of computation of allowable limits of stage for Rating No. 4, Clear Creek near Utopia, Calif.

in feet, between the pair of stages is the allowable range in stage for a mean gage height of G. The procedure just described is then used to obtain the allowable range in stage for other values of gage height. The results of such computations for the rating table in figures 265 and 266 are shown in figure 270. The information given by the table in figure 270 is reorganized to provide the table of allowable rise shown in figure 271, which is more convenient for use in subdividing days. For days that are subdivided it is not necessary to compute the daily mean gage height.

The table of allowable ranges for subdivision may require some revision for periods when shifting-control adjustments are used.

Gage height (ft)	Allowable rise (ft)	Gage height (ft)	Allowable rise (ft)
2.15	0.10	4.2	1.2
2 32	.16	5.2	1.6
2.65	.3	6.4	2.2
3.1	.6	7.6	2.8
3.6	.8		

FIGURE 271.—Table of allowable rise for use with Rating No. 4, Clear Creek near Utopia, Calif.

However, revision will usually be necessary only in the unusual situation where the shifts to be applied are so extreme that they radically change the shape of the stage-discharge relation.

Either of two methods are used for computing discharge for subdivided days, and the procedure for subdividing the day varies with the method used. The first method is the increment-mean method. In that method the mean gage height is determined for each increment of the day by using the graphical process of balancing areas that was described earlier. Shifts, if appropriate, are applied to the mean gage heights, corresponding values of incremental mean discharge are obtained from the rating table, and a time-weighted daily mean discharge is computed. The time-weighting is done by first multiplying each incremental mean discharge by the number of hours in the increment, then adding the products, and finally dividing the sum of the products by 24 (number of hours in the day). The arithmetic is simplified if the increments of the day are all multiples of either 2, 3, 4, 6, 8, or 12 hours, because then the numerical values of the hours used can be reduced by factoring. For example, if the day had been subdivided into three increments of 6, 6, and 12 hours, those time periods could be expressed as multiples of 6. For weighting purposes, the hour values would be factored to give 1, 1, and 2, and the sum of the products would be divided by 4 rather than 24. (See subdivision for July 31 in fig. 267.)

The procedure for subdividing a day by the increment-mean method is as follows. The analyst starts at the lowest point of the pen trace and moves upward as far as the table of allowable rises will permit. That upper value of stage then becomes the starting point for the next increment of the day, whose upper limit is also determined from the table of allowable rises. The process is continued until the entire day has been subdivided. The ends of the time increments are adjusted to coincide with the nearest hour lines, but the adjustment should, if anything, decrease the range in stage for an increment from that indicated by the table of allowable rises. If feasible, the time increments are further adjusted to permit the factoring discussed in the preceding paragraph.

The second method of computing discharge for subdivided days is the point-intercept method. In that method, gage heights are noted along with the clock hour of occurrence, at the beginning of the day, the end of the day, and at all "breaks" in slope of the stage hydrograph during the 24 hours. It is important, however, not to permit the difference in stage between consecutive recorded gage heights to exceed values given by the table of allowable rises. If the stage difference for a time increment does exceed the allowable rise, one or more additional intermediate points on the hydrograph must be selected

for use. The end result is a tabulation such as that shown in the example in figure 272 where the gage heights are tabulated at the nonuniform hours associated with breaks in slope of the stage hydrograph.

Computation of the daily mean discharge by the point-intercept method is similar to that for the increment-mean method except for the manner of determining the number of hours (col. 4 of fig. 272) associated with each tabulated gage height. Each of the gage heights is assumed to represent the mean gage height for a time interval that extends from (a) the clock time midway to the preceding tabulated gage height to (b) the clock time midway to the following tabulated gage height. The discharges in column 5 of figure 272 correspond to the tabulated gage heights in column 2 after those gage heights have been adjusted for the shifts, if any, shown in column 3. The time-weighting of the discharge is then done by first multiplying each discharge (col. 5) by the correspnding number of incremental hours (col. 4). The individual products, which are not shown in figure 272, are then added, and finally the sum of the products is divided by 24 (number of hours in the day).

The advantage of the point-intercept method over the increment-mean method of computing daily mean discharge for subdivided days lies in the fact that the point-intercept method provides the data for reproducing the stage or discharge hydrograph for storm runoff. Con-

sequently, the point-intercept method is always used in flood reports. Because daily mean discharges computed by the two methods will seldom agree exactly, it is best to use the point-intercept method, at least for major runoff events. Then if the major runoff event is made the subject of a later flood report, daily mean discharge in the flood report and in the routine annual streamflow report will agree. For complex flood events, such as that shown in figure 272, the point-intercept method will usually give somewhat more accurate daily mean discharges than will the increment-mean method, but only because more gage heights per day are usually used in the point-intercept method for such events. Subdivision is really a crude form of mathematical integration of the hydrograph. Mathematical integration gives the only truly accurate value of mean discharge, and the more points that are used in the subdivision, the more closely the subdivision will resemble integration. The difference in results between mathematical integration and subdivision rapidly dwindles to insignificance when sufficient points are used in the subdivision. Mechanical integrators, now largely superseded by digital recording and computation, are available to compute daily mean discharge for stations having large and frequent stage fluctuations, such as those that occur downstream from hydroelectric power plants.

COMPUTATION OF DAILY DISCHARGE

PREPARATION OF FORM FOR COMPUTING AND TABULATING DISCHARGE

The first step in the computation of daily discharge for a nonrecording station or a recording station equipped with a graphic recorder is to prepare a form, such as USGS form 9–192a which is shown in figure 273, to receive the computed values. The form in figure 273 provides columns for daily mean gage height and discharge for the 12 months in the water year, as well as spaces for monthly and annual summaries which will be discussed in the section on "Completion of the Discharge Form." The analyst fills in the blanks at the top of the form that supply general information such as name of station, drainage area, type of recorder, water-year date, numbers of the rating tables used, and so on. It is important that the form be prepared carefully because the data are copied from this form on to offset sheets used for publication of the data. In addition, prints of the form are often furnished to water users as preliminary data in advance of the published data.

Daily mean gage heights from the original water-stage recorder chart are copied in the columns headed "Gage height." In addition, the maximum and minimum gage heights that occurred during the year are listed in the spaces provided at the left margin. For those days that are subdivided for the computation of daily discharge, no

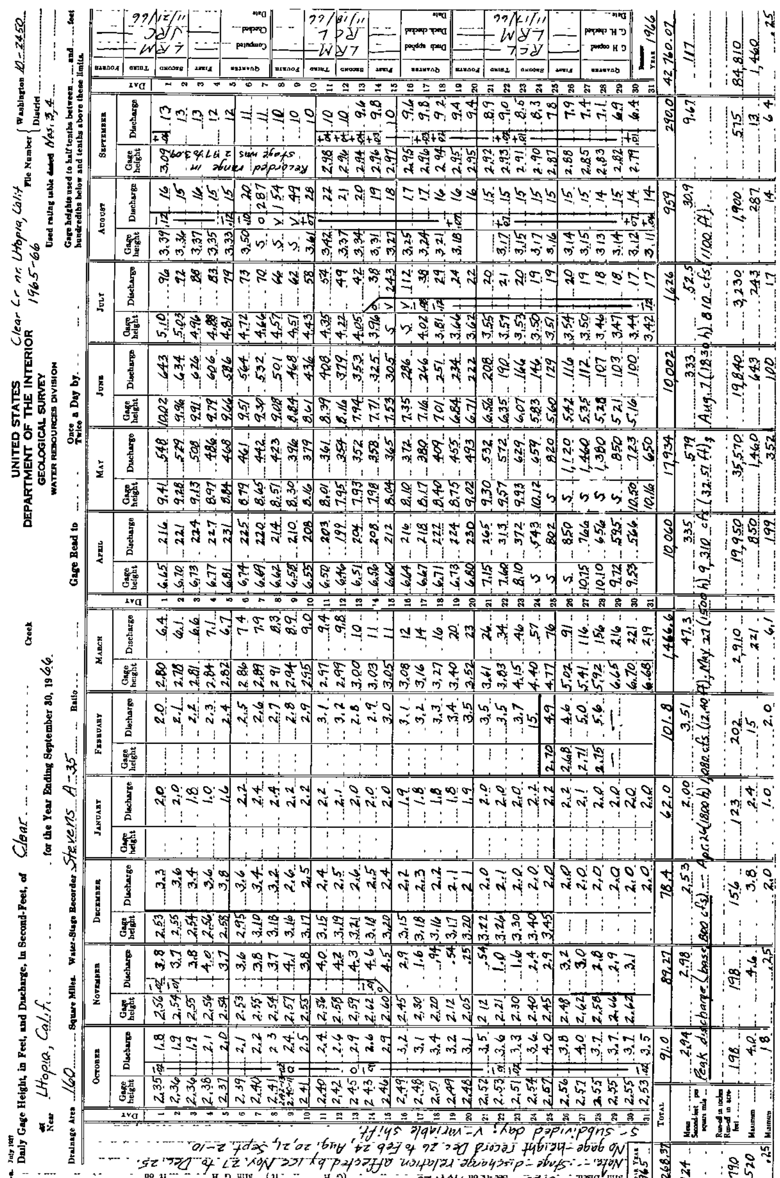

FIGURE 273.—Computation of daily discharge.

figures of daily mean gage height will be computed; for those days an uppercase letter "*S*" is entered in the gage-height columns. That symbol, as well as any others that are used, is explained by a footnote in the left margin; for example "*S*—subdivided day." For days of recorder malfunction, if the daily mean gage height is computed from a graph based on the observer's gage readings, the symbol "*g*" is added to the left of the gage-height value.

In a last step before applying discharges from the rating table to the gage heights, values of shifts to be applied are entered in columns constructed on the left side of the wide columns headed "Discharge" in figure 273. Little has been said about shifts in this chapter of the manual because they have been discussed in detail in the section in chapter 10 titled, "Shifts in the Discharge Rating." Shifts, it will be recalled, may vary with stage. If, during a subdivided day, shifts of varying magnitude are to be used because of the varying stage during the day, the symbol "v" is used in place of a numerical value in the shift column. The application of discharges to gage heights for subdivided days has been discussed in the section on "Subdivision of Daily Gage Heights." The reader is warned at this point that the shifts shown in figure 273 have no relation to the rating-curve analysis discussed in the section on "Rating-Curve Analysis." That analysis for Clear Creek indicated only a short period of shifting control in early October. Shifts have been scattered throughout figure 273 for the purpose of illustrating various conditions in applying discharge.

DETERMINATION OF DISCHARGE FROM THE GAGE-HEIGHT RECORD

Discharges are determined by applying the appropriate rating tables to the gage heights tabulated in figure 273. The rating analysis indicated a change in the rating after February 24, rating no. 3 being used up to and including that date and rating no. 4 thereafter. Consequently, before applying discharges a heavy horizontal line is drawn in the discharge column of figure 273 between February 24 and February 25 to warn the analyst of the change in rating on February 25. The daily mean discharges, in cubic feet per second, are entered in the discharge columns of figure 273. Daily discharges are shown to the nearest hundredth from 0.01 to 0.99 ft^3/s, to the nearest tenth from 1.0 to 9.99 ft^3/s, to the nearest unit from 10 to 999 ft^3/s, and to three significant figures above 1,000 ft^3/s. Where shifts are indicated, the amount of the shift is added algebraically to the tabulated gage height, and the discharge corresponding to the shift-adjusted gage height is determined from the appropriate rating table. It is important that there be no discontinuity between the discharge on the last day of the preceding water year and the first day of the

current water year. That can easily occur if a new rating table is placed in effect on the first day of the current water year, or if shift adjustments to the gage height are used on either or both the first and last days of the two water years. Consequently the discharge for the last day of the preceding water year should be examined to ensure consistency.

To facilitate the determination of discharges from the rating table, it is advisable to expand the rating table to show the discharge for each one-hundredth of a foot of stage, as in figure 266, to cover the frequently occurring stages. For example, if the rating table were expanded to a stage of 7.0 ft, it would cover most of the gage heights tabulated in figure 273, thereby reducing the probability of error in mentally interpolating discharge values between the tenths of a foot of stage given in the standard rating table (fig. 265).

At this point all boxes for daily mean discharge in figure 273 will have been filled, except those opposite gage-height boxes that are blank for lack of record because of instrument malfunction, or those opposite gage-height boxes that carry the symbol "S" for subdivided day. The discharges for subdivided days are next computed. The method of computation was explained in the section on "Subdivision of Daily Gage Heights." The daily mean discharges are computed on the gage-height chart, as shown in figure 267, where the increment-mean method of computation was used. The computed discharges are then transferred to the discharge columns in figure 273.

ESTIMATION OF DAILY DISCHARGE FOR PERIODS OF INDETERMINATE STAGE-DISCHARGE RELATION

After the mean discharge has been computed for each day of the water year for which there is a gage-height record, a hydrograph of daily mean discharge is prepared on a form that has a logarithmic discharge scale. Discharge measurements are also plotted on the hydrograph sheet. The hydrograph is used for comparison with similar hydrographs of daily discharge for nearby stations as a test for consistency of the computed record. Obviously such comparison is only valid for streams whose daily flow is essentially natural, that is, not controlled significantly by the works of man. Hydrographic comparison usually brings to light any serious errors in the basic data computations and interpretations; it also provides a means of estimating discharge for days of no gage-height record and for days of indeterminate stage-discharge relation. A period of indeterminate stage-discharge relation does not refer to one in which the gage-height record is faulty; if the recorded gage-heights do not reflect the true stage of the stream, the period affected is considered to be one of no gage-height record. A period of indeterminate stage-discharge relation is one for

which a satisfactory gage-height record is available, but one for which no stage-discharge relation can be determined. The most common situation of that kind occurs during an ice-affected period, and it may also occur during the passage of sand waves in an alluvial channel. Sometimes ephemeral backwater effect occurs when a channel is choked by debris for a few days, but in that situation the stage-discharge relation is not really indeterminate but is merely undefined because of the limited opportunity to define it by discharge measurements.

A period of indeterminate or undefined stage-discharge relation is indicated on the discharge tabulation form (fig. 273) by a heavy vertical line drawn between the gage-height and discharge columns. Such a line appears in November and December in figure 273 to indicate that the ice-affected discharges during those months bear no relation to the recorded stages. Where preliminary discharge values from the rating table have been entered for such days in figure 273 and are then shown by hydrographic comparison to be in error, they are replaced in figure 273 by the revised discharge figures.

Periods of ice effect.—The method of estimating discharge during periods of ice effect was discussed in detail in chapter 10 and will not be repeated here. Measurements nos. 35 and 35A (fig. 262) clearly indicated, by the magnitude of the backwater effect (shift values), that ice affected the stage-discharge relation.

Other periods of indeterminate stage-discharge relation.—For periods of indeterminate stage-discharge relation other than ice effect, discharges are estimated as though they occurred during periods of no gage-height record. Methods of treating periods of no gage-height record are described on the pages that follow; hydrographic comparison is one of those methods.

ESTIMATION OF DAILY DISCHARGE FOR PERIODS OF NO GAGE-HEIGHT RECORD

The analyst is often required to estimate discharge for periods of no gage-height record resulting from recorder malfunction, or a frozen well, or a plugged intake. Such periods are shown in figure 273 for periods December 26 to February 24, August 20–21, and September 2–10. The task of the analyst is greatly facilitated if the fieldman who finds the gage-height record incomplete makes an effort to collect as much supplementary information as possible. An attempt should be made to get the range in stage during the period of no gage-height record because that information indicates the limits of discharge within which any estimates made may vary. If the clock has stopped but the pen continues to function, the vertical line recorded on the chart will give the range in stage. Because of the possibility of the pen

reversing during the period of no record, when the pen was scribing a vertical line, there may be some doubt as to the maximum gage-height reached during that period. If the tape gage is equipped with either a magnet or wire clip for indicating peak stage (see the section in chapter 10 titled, "Operation of a Recording Stream-Gaging Station"), the peak indicated by either of those devices should be noted. High-water marks should be sought both in the well and outside the gage structure. If the intakes have been plugged or the well frozen and a high stage had occurred during the period of no record, again an outside high-water mark should be sought. Local residents should be interviewed in an attempt to determine the time the peak occurred.

The previously mentioned annual hydrograph of daily mean discharge, with gaps left for periods of no gage-height record, along with the annual hydrograph of daily discharge for nearby stations, are prerequisites for estimating the discharges sought. Each of the station hydrographs should be plotted on a separate graph sheet, but the logarithmic discharge scales and time scales on the individual sheets should be identical. It is particularly helpful if one or more of the stations used is on the same stream as the station being studied. The hydrographs for uncontrolled streams in the same vicinity will usually have similar patterns of discharge.

In the discussion that follows, the procedure for estimating discharge for periods of no gage-height record is described under the following subheadings:

1. No gage-height record during a low- or medium-flow recession on an uncontrolled stream.
2. No gage-height record during periods of fluctuating discharge on an uncontrolled stream.
3. No gage-height record for a station on a hydroelectric powerplant canal.
4. No gage-height record for a station immediately downstream from a reservoir.
5. No gage-height record for a station on a controlled stream where the station is far downstream from the known controlled release.

CASE A. NO GAGE-HEIGHT RECORD DURING A LOW- OR MEDIUM-FLOW RECESSION ON AN UNCONTROLLED STREAM

If the vertical trace left by the inoperative recorder indicates no stages higher than that when the clock stopped nor any stages lower than that when the stoppage was discovered, there may well have

been an unbroken recession from the time the clock first stopped. The hydrographs plotted for other nearby stations, particularly those on the stream being studied, should then be examined. If there is no evidence of anything but an unbroken recession, the discharge should be estimated by semilogarithmic interpolation. That is, the gap in the logarithmically plotted hydrograph for the station being studied should be filled by either a straight line or a smooth flat curve, depending on which best merges with the graph on either side of the dates of no gage-height record. The daily discharges that are estimated on the hydrograph are then transferred to the discharge-tabulation form with appropriate notation. (See record for September 2–10 in fig. 273.) If the period of no gage-height record involves only a few days, it is permissible to interpolate gage heights graphically on the recorder chart and then obtain the corresponding discharges from the rating table. That was actually done for August 20, 21 in figure 273.

CASE B. NO GAGE-HEIGHT RECORD DURING PERIODS OF FLUCTUATING DISCHARGE ON AN UNCONTROLLED STREAM

If a short period of recorder stoppage occurred near the peak of a stream rise, such as might occur if the float could not operate freely, knowing the peak stage of a stream makes it possible to sketch in the missing portion of gage-height record on the recorder chart. An even better estimate can be made on the recorder chart if the time of the peak is also known.

If long periods of no gage-height record are involved, the best method of making discharge estimates is by hydrographic comparison. A "light table" is used for the purpose in the manner described in the section in chapter 10 titled, "Hydrographic- and Climatic-Comparison Method." The logarithmic hydrograph of daily discharge for the study station is superposed on the logarithmic hydrograph for the reference station, and the date lines for the two sheets are matched. If the two stations are comparable, the two hydrographs should show similar runoff patterns. The study hydrograph is moved vertically until the hydrographs on either side of the period of no gage-height record match closely, making sure that the date lines match perfectly. An exception, to the perfect matching of date lines occurs, for example, where the two stations are on the same stream, but so distant from each other that the travel time between stations is approximately 24 hours. It would then be necessary to lag the hydrographs by a day. After matching the hydrographs, the missing portion of the study hydrograph is sketched by tracing the underlying reference hydrograph.

The hydrographic comparison also provides a simple means of comparing the runoff yield per square mile (unit yield) for the two stream basins. To make that comparison a short horizontal line, showing drainage-area size is marked on the logarithmic ordinate of each hydrograph. If, when the two hydrographs are matched vertically, the drainage-area lines also match, the two basins have equal unit yield. If the drainage area lines do not match, the basin whose drainage-area line is the lower of the two has the greater unit yield.

More often than not, it will be found that when the low-water part of the study hydrograph is matched with the low-water part of the reference hyrograph, the high-water parts of the two hydrographs do not match, and vice versa. When that occurs, the low-water parts of the two hydrographs are matched for sketching the low-water estimates, and the high-water parts of the two hydrographs are matched for sketching the high-water estimates of discharge. The discharge estimates for the medium-flow part of the study hydrograph is sketched while gradually sliding that hydrograph up or down, as required. Any discharge measurements made at the study station during the period of no gage-height record are especially valuable in positioning the two hydrographs, and unless it is known that the discharge measurement was made at a time of rapidly changing stage and is not representative of daily mean discharge, the sketched discharge on the study hydrograph should pass through the discharge measurement. If the range of stage for the period of no gage-height record is known, no estimated daily mean discharge should be smaller than the discharge corresponding to the minimum gage height for the period; no estimated daily mean discharge should equal or be greater than the discharge corresponding to the maximum gage height for the period, because the maximum daily discharge is seldom as great as the maximum momentary peak discharge. In figure 273 the daily mean discharges for the period of no gage-height record, December 26 to February 24, were estimated by hydrographic comparison with discharges for a nearby station.

It is desirable that hydrographic comparisons be made with more than a single reference station. The different comparisons will give estimates of daily discharge that differ from each other to some degree. In averaging the estimates, the greatest weight should be given to the results obtained from: reference hydrographs that show the closest fit with the study hydrograph; reference hydrographs on the same stream as the study station; and reference hydrographs for stations whose drainage areas approximate that of the study station.

If the period of no gage-height record involves a snowmelt period and the maximum stage is known, the maximum daily mean discharge can often be estimated fairly closely. Discharge has a diurnal

fluctuation during snowmelt periods, and the ratio of maximum daily mean to maximum momentary discharge will vary with such factors as air temperature and date. However, examination of discharge records for the study station and for a snowmelt reference station may show how concurrent ratios vary at the two stations, and thereby give a strong clue to the ratio to be used to estimate maximum daily mean discharge during the period of no gage-height record.

On occasion, the station that has a period of no gage-height record may be located immediately upstream from a reservoir for the purpose of measuring inflow to the reservoir. If reliable records are available showing daily change in reservoir contents and daily spill and release from the reservoir, it is then a simple matter to compute the daily discharge (Q) at the gaging station from the formula:

Q = Daily spill + daily release ± daily change in reservoir contents.

There may be times when record for a flood period is lacking and there is no nearby gaging station with which to compare runoff records. Under those circumstances, daily discharges for the flood period may be estimated from a model study of rainfall-runoff relations. It is beyond the scope of this manual to detail the development of such hydrologic models. A simpler task is to estimate the total volume of storm runoff from precipitation records. For general storms in the past at the study station, tabulate the total storm precipitation, its duration in days, and the total volume of storm runoff in inches or millimeters. Compute the value (infiltration index) that must be subtracted from each daily increment of precipitation during a storm to give the total volume of runoff from that storm. The infiltration index will vary with storms, but it can often be related to antecedent precipitation and month of the year. Apply the appropriate infiltration index to the storm precipitation during the period of no gage-height record to obtain the total volume of storm runoff during that period. This simple method provides only an approximate result; it should be used sparingly for general storms, and not at all for thunderstorms, which usually occur over limited areas.

CASE C. NO GAGE-HEIGHT RECORD FOR A STATION ON A HYDROELECTRIC-POWERPLANT CANAL

For a period of no gage-height record for a station on a powerplant canal, it is generally possible to use the powerplant record of daily kilowatt output to estimate reliably the daily mean discharges. That is done by means of a relation of daily discharge to daily power output that is developed for periods preceding and following the period of no gage-height record.

CASE D. NO GAGE-HEIGHT RECORD FOR A STATION IMMEDIATELY DOWNSTREAM FROM A RESERVOIR

Ratings are often available, or may be computed, for a reservoir spillway, gates, valves, and turbines (see the section in chapter 14 titled, "Pressure Conduits"). Ratings of those types will enable the engineer to estimate the discharge for a period of no gage-height record at a station immediately downstream from a reservoir.

Another method may be used if the reservoir itself is equipped with a stage gage so that a reliable record of daily change in reservoir contents is available. Daily changes in reservoir contents may be added algebraically to the daily mean discharge at the study station downstream from the reservoir to provide daily mean values of reservoir inflow during periods of record at the study station. An annual hydrograph of daily mean reservoir inflow is prepared and is compared with the hydrograph for a nearby natural-flow station. Using the technique described for Case B, the daily mean values of reservoir inflow are estimated for the period of no gage-height record at the study station. The known daily changes of reservoir contents are then subtracted algebraically from those estimated daily values of reservoir inflow to give the required daily discharge at the study station.

CASE E. NO GAGE-HEIGHT RECORD FOR A STATION ON A CONTROLLED STREAM WHERE THE STATION IS FAR DOWNSTREAM FROM THE KNOWN CONTROLLED RELEASE

Case E is a situation somewhat similar to Case D, except that the study station is so far downstream from the reservoir that tributary inflow between the reservoir and the study station cannot be ignored. Outflow from the reservoir cannot be compared directly with the discharge at the study station because the reservoir outflow is completely controlled and the discharge at the study station is partially controlled. The method of attacking the problem is to estimate daily tributary inflow during the period of no gage-height record at the study station, and then to add the estimated daily tributary inflow to the known upstream reservoir releases to obtain the required daily discharges at the study station. What is needed, therefore, is a means of estimating tributary inflow.

Daily releases from the reservoir are subtracted from the daily mean discharge at the study station to provide daily mean values of tributary inflow during periods of record at the study station. An annual hydrograph of daily mean tributary inflow is prepared and is compared with the hydrograph for a nearby natural-flow station. Using the technique described for Case B, the daily mean values of tributary inflow are estimated for the period of no gage-height record

at the study station. As mentioned above, those estimated values of tributary inflow, when added to the concurrent reservoir releases, give the required discharges at the study station.

The above computational procedure may also be used for study reaches of channel that have diversions as well as tributary inflow, provided that the diverted discharges are measured. In that situation, the diversions must be subtracted from the reservoir releases. In other words, for reservoir release or outflow in the above description, we substitute reservoir outflow minus diverted flow.

COMPLETION OF THE DISCHARGE FORM

After all daily mean discharges have been entered on the discharge form (fig. 273), little is required to complete the form. Discharges from the appropriate rating table are entered in the left margin for the maximum and minimum stages of the water year that were previously recorded there. The summary discharge values at the bottom of figure 273 for each month, the water year, and the calendar year, are next computed. The mechanics of computing those total and average values are self-evident. The remaining entry in figure 273—peak discharges above a stated base—requires some explanation.

For stations whose high flows are not significantly regulated, peak discharges are shown for all peaks whose discharge equals or exceeds a chosen peak discharge, regardless of the number of peaks that occur in any given water year. A properly chosen base discharge is one that is exceeded, on the average, three times a year. The following suggestions are offered for selecting the base discharge:

1. For stations having records of more than 5 years, list the annual flood peaks, compute their recurrence intervals (R) in years by the formula, $R = (N + 1)/M$, and select as a base the discharge (rounded upward to two significant figures) whose value of R is 1.15 years. (In the formula, N is the number of years of record; M is the order number of the peak discharge after the peaks have been ranked in order of magnitude starting with 1 for the greatest peak.)
2. For stations having records of 5 years or less, select a base discharge, guided by judgment and by comparison with nearby stations having records of longer duration. The selected base can be modified as more data become available. It is, therefore, better to select a base discharge originally that is on the low side; if the base is later raised, it is a simple matter to drop originally selected peak discharges that do not exceed the new base value. If it is desirable later to lower the base discharge, it becomes necessary to search the earlier re-

corder charts for peak discharges that are smaller than the original base discharge but greater than the new base.

If two peak discharges that exceed the base discharge occur within 48 hours of each other, it is likely that the two peaks are not independent; only the larger of the two, or the earlier of the two if they are both equal, should be listed. If two adjacent peak discharges, both larger than the base, are separated by more than 48 hours, the lower of the two peaks is shown only if it is at least 1.33 times as large as the discharge of the trough between the adjacent peaks. For periods of diurnal peak discharges caused by snowmelt, only the highest peak that occurred during each distinct period of melting is shown regardless of the fact that other peaks may meet the criterion stated in the preceding sentence.

RECORD OF PROGRESS OF DISCHARGE COMPUTATIONS

Completion of the discharge form (fig. 273) marks the end of the actual computation of discharge for the water year. It is necessary, of course, that all computations be checked before the discharge figures are considered final. Furthermore, it is customary for the checker to initial and date any graphs or computation forms that he checks.

In the interest of efficiency it is advantageous to have a progress check list (fig. 274) attached to the folder in which the station computation forms are kept. The items on the check list are shown in the order in which they should be completed for maximum efficiency. Each item on the list has two boxes on the left margin. A checkmark is placed in the box at the extreme left when the item is completed; a checkmark is placed in the other box when the item has been checked. The supervisor of the discharge computations need only glance at the set of boxes to inform himself of the progress of the computations at a station.

STATION-ANALYSIS DOCUMENT

A complete analysis of data collected, procedures used in processing the data, and the logic upon which the computations were based must be recorded for each year of record to provide a basis for review and to serve as a reference in the event that questions arise about the records at some future date. Such a report is called the "Station Analysis." A record of any changes in: records collected, equipment, location, or other physical features should be included. The document should be written clearly and concisely and should contain sufficient information so that those who are totally unfamiliar with the station will be able to follow the reasoning used in computing the records. A

PROGRESS CHECK LIST
COMPUTATION OF GRAPHIC RECORDER RECORD

Station_____ Water Year_____

Index Number_____

Check work done. Complete in order. Initial when finished.

☐ Review chart for continuity, errors, peaks, faulty record.
☐ Check level notes. Apply datum corrections to chart and measurements.
☐ Check measurements, field notes, level notes for peak data. Enter on chart.
☐ Check mean gage heights of measurements. Compare with chart.
☐ List measurements and observations of no flow chronologically on 9-207 (fig. 262).
☐ Plot measurements on rating curve. Develop new curve and table, if necessary.
☐ Copy gage heights on 9-192 (fig. 273).
☐ Compute shifts, percentage differences on 9-207 (fig. 262).
☐ Enter shift corrections on 9-192 (fig. 273). "S" days on chart.
☐ Write station analysis.

Computed_____ Checked_____

.....

☐ Apply discharge to 9-192 (fig. 273) and "S" days.

Computed_____ Checked_____

.....

☐ Plot hydrograph. Enter measurements. Show drainage area size and discharge from rating tables.

.....

☐ Estimate discharge for ice, missing, doubtful or backwater periods.
☐ Revise and complete daily discharges on 9-192 (fig. 273).
☐ Review and complete station analysis.

Computed_____ Checked_____

.....

☐ Make monthly and yearly computations on 9-192 (fig. 273).
☐ Enter notes, maximum, minimum and peaks on 9-192 (fig. 273).
☐ Revise manuscript from previous year.

Final Review_____

FIGURE 274.—Form showing progress of computation of graphic-recorder record.

station analysis should be prepared for each station, including those for which records are furnished by other agencies.

The introductory paragraphs of the station analysis describe the equipment installed and the hydrologic characteristics of the drainage basin above the station. The remaining sections of the analysis outline the quality of the base data collected and the methods used to convert those data into the final discharge figures. The discussions are organized under the headings that follow.

(Station name and number)
STATION ANALYSIS
(WATER YEAR)

Equipment.—
Hydrologic conditions.—
Gage-height record.—
Datum corrections.—
Rating.—
Discharge.—
Special computations.—
Remarks.—
Recommendations.—

The following detailed discussion of each of the above items describes the type of information to be presented. As mentioned in the introductory pages of this chapter, documentation of that information is made as the various steps in the analysis and computation of the discharge record are completed.

STATION ANALYSIS

Equipment.—Provide a short statement that describes the equipment at the site. Designate the type of gage (float sensor or bubble-gage sensor); type of recorder; measurement facilities; artificial control, if any. Report any changes in equipment that may affect the accuracy of the record. Review the station description, revise it if necessary and include the statement, "Equipment conforms to station description dated. . . ."

Hydrologic conditions.—A brief description of the hydrologic characteristics of the basin should be carried forward in the station analysis from year to year. Review this paragraph and briefly describe any changes that might affect the runoff regime. These changes may result from fire (give date and percentage of basin area affected), or urban development (describe type and extent of development and give approximate dates), or from logging or road building operations. Usually several years elapse before the effects of these hydrologic changes become stabilized. Therefore, even if no changes occur in the current year, this paragraph should carry a statement referring to changes in the recent past such as: "No changes since the fire of August 21, 1961, which burned 6,000 acres of woodland;" or "No increase in urban development since September 1962."

Gage-height record.—Tabulate periods of faulty or no gage-height record and reasons for those problems. Discuss briefly any large instrument errors that affect the accuracy of the gage-height record. If portions of the gage-height record have been synthesized or adjusted on the basis of observers' readings and other data, this should be explained. Do *not* discuss in this paragraph how discharge was computed during periods of no gage-height record. That should be explained in the "Special Computations" paragraph.

Datum corrections.—Confusion frequently exists as to what should be included in this paragraph. Datum errors result from settlement of the base or reference gage to which the recording instrument is set or from movement of the bubble-gage orifice. Care should be taken, particularly with manometer and digital recorder combinations to differentiate between datum corrections and shift corrections. If datum corrections are necessary, the reasons should be explained and corrections listed in tabular form such as:

Period	*Correction applied*
Oct. 1–Jan. 15	+0.04
Jan. 16–Apr. 15	+0.05
Apr. 16–Aug. 3	+0.06
Aug. 4–Sept. 30	0

If applicable use a simple statement such as "None applied, last levels run on (date) ."

Rating.—Start this section with a description of the channel and the control, and provide sufficient detail to give anyone unfamiliar with the site a fairly good picture of the dominant features. Items discussed should include the size of the channel, composition of the bed (sand, gravel, boulders, or bedrock), location of the gage relative to the control, and the approximate elevation of any overflow areas.

Example: "The controlling reach of channel is sharply incised in the flood plain. Bed material is predominantly sand and gravel. The low-water control is generally a gravel riffle which moves up and down the channel in response to flood flows. At bankfull stage (about 21 feet), the channel is about 150 feet wide. At higher stages, it spreads out rapidly to a width of about 300 feet at a stage of 25 feet."

The remainder of the rating paragraph should be a chronological narrative of what occurred, hydraulically, during the year. Begin with a statement as to the number of measurements made and how they plot in relation to the rating curve in use at the end of the previous year. If new ratings are required, explain how this conclusion was reached and what caused the shift from one rating to the

other. State exact time and date when rating changes were made. If ratings are modified during periods of significant flow by use of the shifting-control method, document these rating changes with shift tables or shift curves. These are rating changes too, and require the same explanations that a new table does. Because the reviewer does not always have access to the basic data, it is most important that the distribution of shifts be explained in detail, particularly if any unusual methods were used.

The statement "Shifts were distributed on basis of stage and (or) time" does not constitute a detailed explanation. The reviewer needs sufficient detail so that he can at least determine if a shift must be applied to the maximum and secondary peak stages and know its magnitude. For example, discharge measurements were obtained before and after a peak of 12.55 ft; the measurement preceding the peak shows a shift of −0.26 ft at gage height 2.56 ft, and the one following the peak shows a shift of + 0.06 ft at gage height 9.63 ft. One might reason that the rise scoured out the channel gradually, and the shift was zero at the peak. In the analysis, one might state "It was assumed that the shift of −0.26 ft indicated by measurement No. xx was gradually reduced during rise, and there was no shift at the peak; therefore, the shift between measurements No. xx and xxx was distributed on basis of stage." Or, one might have basis for this statement: "On the basis of shifts indicated by measurements No. xx and xxx and succeeding measurements, shift distribution was made on the assumption that the shift varied during the rise from −0.26 ft at gage height 2.50 ft to +0.06 ft at the peak and remained at +0.06 ft through the date of measurement No. xxx." Those two statements would indicate to the reviewer the shift needed for the peak stage and would give him a better idea of the distribution of shifts that was made. If a shift distribution were made on the basis of time, the statement "Shifts were distributed on the basis of time" is sufficient. However, if a peak discharge occurred during that shifting-control period, a statement should be added giving the shift used for the peak.

Discuss also the adequacy of the high-water rating. Is it defined to within 50 percent of the maximum discharge for the current year on the basis of measurements made during the year? (The 50 percent criterion is discussed early in the section in chapter 10 titled, "High-Flow Extrapolation.") If the extension has been made on the basis of older measurements or on the basis of a slope-area determination (chap. 9), give the date of those measurements or of the slope-area determination and state whether or not significant channel changes might have occurred within the intervening period.

Discharge.—This paragraph is a summary explaining how the stage

records and rating data were combined to produce the discharge record. The information can best be presented in tabular form; an example for a station equipped with a graphic stage-recorder follows. (The table would be more complex for a station equipped with a digital stage-recorder; see page 599.)

Period	*Rating table used*	*Periods of shifting control*
Oct. 1 to Feb. 24	No. 3	Oct. 1–9, Oct. 14 to Nov. 14
Feb. 25 to Sept. 30	No. 4	July 15 to Sept. 1, Sept. 11–30

Special computations.—Describe the methods used for determining discharges during the periods of no gage-height record, ice effect, backwater, or other special conditions. Explain any unusual method for determining shifts. If daily discharges were estimated on the basis of hydrographic comparison with records for nearby stations, state the name of the stations used and how closely the station records compared. If weather records were used in the analysis, give the name or names of the weather stations used.

Remarks.—A statement should be made concerning the general accuracy of the daily records along with special accuracy statements regarding periods of ice effect, no gage-height record, high water, low water, backwater, shifting control, or other unusual conditions. A statement should be made here indicating that a hydrographic comparison was made. Identify station or stations used for comparison and state how well the hydrographs compared. Although the statement concerning hydrographic comparison duplicates some of the material given above under the heading "Special computations," the duplication is warranted because it will expedite the preparation of the "Remarks" paragraph of the manuscript station description. (See figs. 286*H* and 289.) It is helpful if all statements to be included in that manuscript paragraph can be drawn from material in the "Remarks" section of the station-analysis document. The "Remarks" section of the station-analysis document should also include any additional comments pertinent to the analysis of the record.

Recommendations.—A sample recommendation might read, "Flood schedule for next year should place high priority on high water measurements at this site. No measurements greater than 8,000 ft^3/s have been made since 1967. There have been several major peaks since that date."

COMPUTATION OF DISCHARGE RECORDS WHEN A THREE-PARAMETER DISCHARGE RELATION IS USED

The section of this chapter titled, "Station Analysis," ended with a brief discussion of the preparation of the station rating when three parameters are involved—stage, discharge, and a third parameter such as fall or velocity index.

The first step that follows completion of the station rating is the computation of the gage-height record for the base-gage recorder, and for the auxiliary-gage recorder if fall is the third parameter. The daily mean gage heights are determined by the procedures explained for the graphic recorder in the section titled, "Computation of Gage–Height Record." Where subdivision of the day is required, the same time increments are used for both recorder charts. The daily mean fall, or mean fall for a time increment in a subdivided day, is computed by subtracting the downstream stage from the upstream stage. If a velocity index is the third parameter, as for example, where a deflection meter is used, the velocity-index record is used to determine daily mean values of the index or mean values for the time increments used in subdivided days. Gage-heights and velocity-index values are entered on a form similar to, but larger than, the form shown in figure 273. The expansion of the form is to accommodate an additional column each month for recording daily values of the third parameter; the additional column lies between the gage-height and discharge columns that are shown in figure 273.

The mechanics of computing discharge from stage and concurrent values of the third parameter were discussed in chapters 11 and 12. In chapter 11 slope (fall) is the third parameter; in chapter 12 a velocity index is the third parameter. Computed values of daily discharge are entered on the form bearing the daily values of stage and the third parameter. The daily discharges for periods of no record or of indeterminate discharge rating, such as ice-affected periods, are computed precisely as explained in a preceding section titled, "Computation of Daily Discharge;" hydrographic comparison is the principal method used. After all boxes for daily mean discharge on the discharge form are filled, the form is completed as shown in figure 273 and explained in the section on "Completion of the Discharge Form."

Throughout the computation procedure, a record of progress is kept, similar to that shown in figure 274 but modified to accommodate the additional steps needed to compute discharge when a 3-parameter discharge relation is used. A station-analysis document is prepared, similar to that described in the section immediately preceding this discussion of 3-parameter relations; the various items that are in-

cluded are documented as corresponding steps in the analysis and computation of the discharge record are completed.

COMPUTATION OF DISCHARGE RECORDS FOR A RECORDING STATION EQUIPPED WITH A DIGITAL RECORDER

GENERAL

The fact that a gaging station is equipped with a digital stage-recorder does not affect the preparation of the station analysis (see the section on "Station Analysis"). Datum corrections are determined, discharge measurements are listed and reviewed, and graphical ratings are prepared and then converted to rating tables. The computations that follow the station analysis are similar to those described for a station equipped with a graphic stage-recorder, but instead of being performed manually they are performed by an electronic computer; the principal output forms are machine adaptations of the manual computation forms. The field offices generally send their input data to a central computer center where the computations are performed. The processing between field office and computer center may be accomplished by a combination of two or more of the following: mail, 16-channel paper-tape reader-transmitter, telephone line, and computer terminal.

The sequence and operation of an automated computing system is described in general terms in the last section of this chapter. It is not practicable to include a more detailed description of each step in the sequence because although the system of automated computation is well established, the particulars of each step are somewhat in a state of flux in response to continual improvement in storage and access procedures. Space limitations in this manual are also a factor in the treatment given to the subject. Additional pertinent information for the interested reader can be found in the following references that are listed at the end of this chapter: Carter and others, 1963; Edwards and others, 1974; WMO Technical Note No. 115, 1971 (contains a noteworthy bibliography).

The automated computation of discharge records from digital stage records is now (1980) more common in the U.S.A. than the manual computation of discharge records from graphic stage records. It may therefore seem incongruous to devote more space in this manual to manual computation than to automated computation. The two types of computation, however, are essentially similar, and a description of the manual method provides a far superior vehicle for explaining the computational technique.

INPUT TO COMPUTER

The input to the computer for a routine gaging station consists of: (1) the digital record of stage, accompanied by a list of corrections, if needed, for instrumental error in recording time and (or) gage height (any necessary datum corrections are included with the gage-height corrections); and (2) the discharge ratings accompanied by a list of any necessary shift adjustments. (See USGS form 9–1536 in fig. 275.) Stations for which the stage-fall-discharge type of rating is applicable require that the digital-tape records of stage for both the primary and auxiliary gages be furnished to the computer. Also required are the stage-discharge relation and such supplementary information as the stage-fall relation and the relation of fall ratio to discharge ratio. For stations at which velocity index is a third parameter—for example, a station equipped with a deflection meter—input requirements include the digital stage record, the digital record of deflection units, the stage-area relation, and the relation of deflection units to mean velocity, along with any necessary shift adjustments to those two relations.

OUTPUT FROM COMPUTER

The principal output from the computer consists of two forms—the primary computation sheet and the print-out of daily discharge. The primary computation sheet presents the initial or preliminary discharge computations. Normally, the computation sheet is edited, discharges are corrected or revised where necessary, and the corrections are fed back to the computer before the print-out of daily discharge is produced. Computer-produced hydrographs of daily mean discharge may be obtained for both preliminary and final discharge values. The discharge hydrograph of daily mean discharge based on preliminary values of discharge is very helpful for correcting the preliminary values; the method used is that of hydrographic comparison with final records for a nearby station, as explained in the section titled, "Computation of Daily Discharge." (Hydrographic comparison of discharge records is discussed in the two subsections that deal with the estimation of daily discharge.)

The primary computation sheet for a routine gaging station includes a listing for each day of: the maximum, minimum, hourly, and mean gage heights; mean discharge; the gage height equivalent to the mean discharge; the shift adjustment; and the datum correction. Figure 276 is an example of a primary computation sheet for a routine gaging station. The primary computation sheet for a slope station, shown in figure 277, differs somewhat. Listed for each day are: the maximum, minimum, and mean gage heights, mean fall, and mean and hourly discharge. For a deflection-meter station, the primary computation sheet (fig. 278) lists for each day maximum,

minimum, and mean gage heights; maximum, minimum, hourly, and mean discharges; maximum and minimum velocities; volume and direction of flow (for a tidal stream whose flow reverses direction); and shift adjustments to the area and velocity relations.

The printout of daily discharge is virtually the same for all types of gaging stations. In addition to daily mean discharges, the printout includes monthly and yearly summaries in the same format that is used for publication (fig. 279). Besides being published, the figures on the printout are stored on a magnetic tape or disk. If, for some reason, it is found necessary to revise the computed records at some later date, corrections are made on the stored tape or disk.

SEQUENCE OF OPERATION OF AN AUTOMATED COMPUTING SYSTEM

The sequence of operation of the automated computing system used by the Geological Survey is as follows:

1. River stage is punched on 16-channel tape by the digital recorder in the gage house. When a segment of the tape is started by the hydrographer, he leaves a fresh inspection form (USGS form 9–176D in fig. 280) in the instrument shelter. On that form he fills out the box headed "Started by".
2. Tape is removed by field personnel at intervals of 30 to 60 days. Upon removal, the tape is checked for continuity and quality of record, and appropriate notes concerning identity of the station and quality of the record are made on the tape. The boxes headed "Removed by" and "Battery voltage" on inspection form 9–176D (fig. 280) are also filled out by the hydrographer, and the form accompanies the segment of 16-channel tape to the field office. If the hydrographer merely inspects the recorder without removing the punched segment of tape, he fills out the box headed "Insp'd by" on the inspection form and leaves the inspection form in the instrument shelter.
3. The tape, rating table, datum correction, and table of shifts are forwarded from the field office to the Automatic Data Processing Unit. Ratings may be submitted in one of three alternate forms. Discharge may be tabulated for each 0.01 foot of gage height for the part where curvilinear expansion between tenths of feet is necessary; it may be tabulated for each 0.1 foot; or, preferably, it may be defined by a series of coordinate values at the ends of straight-line segments on a logarithmic plot of the rating curve. The entry of ratings directly from the logarithmic plot eliminates the preparation of a rating table in the usual form. Shift adjustments are prorated with time to give a shift for each day between the days for which values of shift are submitted. A new rating may be put in use at any

time during a day, and any shift applicable to the old rating on the same day will be dropped when the new rating takes effect.

The refinement considered in ratings for the initial run through the computer depends upon the complexity of the rating problem and the completeness of the data available. Sometimes final ratings can be prepared at the outset, at other times the output from the first run will be needed to complete the analysis. In the latter situation, only base ratings and approximate shift corrections are supplied.

Data from the 16-channel tape are translated by the central processing unit onto magnetic tape. The information on ratings is manually punched on cards. The magnetic tape and punch cards comprise the input to the digital computer. The rating table is stored on magnetic disk or tape at the computer center after the initial run.

4. The computer converts each instantaneous reading of river stage into a discharge value. Both daily mean discharge and daily mean gage height are computed as an average of instantaneous values. An equivalent daily mean gage height (the gage height corresponding to the daily mean discharge) is computed for each day so that recomputation, if necessary, can be made at a later date without reference to the individual items of the original base data. Daily mean values of gage height, discharge, and equivalent gage height are stored on a magnetic tape or disk. The printed output from the first computer pass consists of two items; a primary computation sheet, which is standard, and a daily discharge sheet, which is optional.

   The primary computation sheet (fig. 276) gives for each day the maximum, minimum, and mean gage heights, equivalent mean gage height, the datum and shift corrections applied, and the daily mean discharge. In addition, hourly gage heights and the time when maximums occurred are printed out.

   The printout of daily discharges (fig. 279), which is suitable for outside distribution, lists daily mean discharges for the period from the beginning of the water year to the end of the record being computed.

5. The field offices use the primary computation sheet in quality checks of the original and computed data, in further analysis of the stage-discharge relation, and in selecting instantaneous peak discharges to be published. Daily discharges from this sheet can be plotted for comparison with adjacent streams, and the usual studies can be made for periods of ice effect, no gage-height record, or backwater from various sources. Estimates can be made for all anomalous periods, and ratings can be revised, if

necessary, so that daily discharge can be recomputed from the effective mean gage heights on the second pass through the computer. The information necessary for revision or recomputation is forwarded to the Automatic Data Processing Unit.

6. The final tabulation is the same as figure 279 except that it is complete for the year and is produced on the second pass (update) through the computer. Where rating changes have been made as a result of the quality control analysis or where individual discharge figures have been estimated, the recomputation will involve substituting the estimated figures on the magnetic storage record, recomputing other discharge figures from revised ratings and the equivalent daily mean gage height, and printing out of the final discharge figures. (A printout from the subprogram for updating the primary computation sheet is shown in figure 281.) The printout from the final computer update is for the complete year. The format of the output is suitable for direct offset reproduction. The data on this form are also stored on magnetic tape for permanent storage.
7. A tabulation of daily mean gage heights may also be printed out during the second computer pass for stations designated by the field offices. That tabulation is prepared only for those stations for which there is a specific need.
8. The documentation file in the field offices consists of the original measurement notes, the 16-channel tapes, a station analysis, a list of discharge measurements, a rating curve, the primary computation sheet, a table of daily mean discharges from the final computer run, and possibly a rating table.

A record of progress of the discharge computations is kept in the field office on a check list such as that shown in figure 282. That form or perhaps a more detailed one, such as figure 283, is especially necessary because of the complication caused by records being shuttled back and forth between the field office and the computer center.

It is also necessary that a station-analysis document be prepared in the field office, as described for the graphic recorder in the section titled, "Station-Analysis Document." In that description it was mentioned that the "Discharge" paragraph showing the ratings used during the water year would be more complex for a digital-recorder station than for a graphic-recorder station. For a digital-recorder station, it is necessary to explain the origin of figures shown on the primary computation sheet as well as those on the final print-out. Documentation received on updating computer runs should therefore be referred to in the "Discharge" paragraph. A sample table of ratings used for a digital-recorder station having a somewhat complicated rating problem follows:

CHAPTER 16—PRESENTATION AND PUBLICATION OF STREAM-GAGING DATA

GENERAL

After the computations of the discharge records for a water year are completed, the records are reviewed by designated engineering personnel and are prepared for publication. The publication process in the U.S.A. usually involves photo-offset printing, and copy must therefore be put in final form for photographing. From the photographic copy, a plate is made for use in the offset printing process.

FORMAT

The published annual report consists of an introductory text, stream-gaging and reservoir station records, tabulations of discharge at partial-record stations and at miscellaneous sites, and an index. The publication format used by the Geological Survey is illustrated in the example pages in figures 284–303 at the end of this chapter. The items that are included in the annual publication are listed in figure 284, which is an example of the table of contents of the report.

In general, most of the figures are self-explanatory, but some require additional explanation. The 9 pages of figure 286 include the 12 items in the table of contents (fig. 284) that start with "Introduction" and end with "Selected references." The 12 items are shown as part of a single figure because they constitute the introductory text that is printed on continuing pages; that is, each item is not started on a fresh page. The map in figure 287 is optional; if the map scale required to show the State or region on a single page is so small that the stations plot in a confusing clutter, the map may be omitted in the annual discharge report. However, any summary reports that cover a period of years of record for the stations should include a map of suitable scale that is folded and placed in a pocket attached to the back cover of the report. The graph in figure 288 is associated with the section titled "Hydrologic Conditions," near the end of the introductory text.

Figures 289–294 show samples of streamflow and reservoir tabulations for the water year that would appear in the main body of the annual report. Figure 289 is a sample page for a routine gaging station. Figure 290 is a sample page for a gaging station whose flow is regulated by a reservoir. Because the flow is controlled, no tabulation is made of supplementary peak discharges (those greater than a given base discharge). In the monthly and annual summaries at the bottom of figure 290, additional figures are given for the mean discharge adjusted for change in reservoir contents. Figure 291 is a sample page

for a reservoir showing daily contents along with a monthly tabulation of change in contents. Daily contents are published only for major reservoirs. More commonly only the month end contents and the monthly change in contents are published, as in figure 292. Where the river basin contains several large reservoirs for which only month end contents and monthly change in contents are to be published, a table, such as that shown in figure 293*A* is published for the entire group. A table of that kind would usually be the last table for the river basin. Figure 293*B* is a continuation sheet for a group of such reservoirs. If all the reservoirs in the basin were relatively small, the data for the group of reservoirs would be abridged to take the form shown in figure 294.

In figure 295, tables *A* and *B* illustrate the way in which the records would be published if the gaging station were originally established a short time before October 1, the starting date of the water year. Table *A* is for a station that was established on Sept. 10. The data for the last 20 days in September would be published with the data for the complete year that followed. The short table shown as Table *A* would precede the daily table for the complete year. Table *B* is for a station that was established on August 1. The short table for August and September would precede the daily table for the complete year. Table *C* in figure 295 is a sample of the daily table for a station on an ephemeral stream that has few days of flow during the water year.

Figure 296 shows a sample "Revisions" paragraph for a gaging station whose past records require extensive revision. The revisions paragraph is always the last paragraph of the station description, as in figure 292. (The symbols used in the revisions paragraph in figure 292 are explained in figure 286*F*.)

If a highly developed river basin has a system of storage and diversion facilities that is too complex to be adequately described in the "Remarks" paragraph of the individual gaging stations, a schematic diagram is provided showing the locations of the reservoirs and canals with respect to the gaging stations. Such a diagram is found in figure 297; the diagram usually precedes the first discharge record for the basin.

Figures 298 and 299 show sample discharge records for partial-record stations. Figure 298 lists low-flow discharge measurements at sites where one or more such measurements are systematically made each year. Figure 299 lists peak discharges for the year, and occasionally one or more smaller peak discharges at sites equipped with a crest-stage gage (see last section in chapter 4). The discharges corresponding to observed peak stages are obtained from a rating table based on indirect determinations of discharge, such as slope-area determinations (chap. 9). Figure 300 shows the results of discharge

measurements made at miscellaneous sites for special studies of various types. Miscellaneous sites are sites other than those where complete records or partial records are obtained each water year.

Figures 301 and 302 show the results of discharge measurements made at miscellaneous sites for two types of studies that are common enough to be identified by a general title. Figure 301 gives the results of a seepage investigation where base flow is measured at intervals in a reach of stream channel; the contribution of intervening tributary flow and the depletion of flow in intervening diversion canals are also measured. The purpose of the study is to investigate water gains and losses resulting from seepage through the streambed and banks. Figure 302 shows the results of low-flow discharge measurements made at miscellaneous sites during a drought period for the purpose of appraising the regional availability of surface flow during periods of critically low runoff.

The last section of the annual discharge report is an alphabetical index; figure 303 is a sample of the first page of such an index. Entries are made in the index for each station or measurement site for which figures of discharge or reservoir storage are given. For each station equipped with a continuous-recording gage, the entry is made under both the stream name and the place name. In addition, entries in the index are made for each section of the introductory text, for each of the terms listed under "Definitions of terms and abbreviations," for each illustration, and for each station plotted on the graph of hydrologic conditions (fig. 288).

In the past, basic groundwater and water-quality data were published under separate covers. At present (1980) the reports incorporate, in a single volume, those data with the surface-water discharge information that was described on the preceding pages. A discussion of ground-water and water-quality data is, however, beyond the scope of this manual.

WATER RESOURCES DATA FOR INDIANA. 19XX

PART 1. SURFACE-WATER RECORDS

INTRODUCTION

Surface-water records for the 19XX water year for Indiana, including records of streamflow or reservoir storage at gaging stations, partial-record stations, and miscellaneous sites, are given in this report and their locations shown in figures ___, ___. Records for a few pertinent gaging stations in bordering States also are included. The records were collected and computed by the Water Resources Division of the U.S. Geological Survey under the direction of M. D. Hale, district chief. These data represent that portion of the National Water Data System collected by the U.S. Geological Survey and cooperating State and Federal agencies in Indiana.

Through September 30, 1960, the records of discharge and stage of streams and canals and contents and stage of lakes or reservoirs were published in an annual series of U.S. Geological Survey water-supply papers entitled "Surface Water Supply of the United States."

Beginning with the 1961 water year, surface-water records have been released by the Geological Survey in annual reports on a State-boundary basis. Distribution of these reports is limited; they are designed primarily for rapid release of data shortly after the end of the water year to meet local needs. The discharge and reservoir storage records for 1961-65 also will be published in a Geological Survey water-supply paper series entitled "Surface Water Supply of the United States 1961-65."

COOPERATION

The U.S. Geological Survey and organizations of the State of Indiana have had cooperative agreements for the systematic collection of surface-water records since 1930. Organizations that supplied data are acknowledged in station descriptions. Organizations that assisted in collecting data through cooperative agreement with the Survey are:

State Department of Natural Resources, J. E. Mitchell, director, through Bureau of Water and Mineral Resources, W. J. Andrews, deputy director.

State Highway Commission, R. F. Whitehead, chairman, M. L. Hayes, executive director, and F. L. Ashbaucher, chief engineer.

State Board of Health, A. C. Offutt, commissioner, and B. A. Pool, director and chief engineer.

Assistance in the form of funds or services was given by the Corps of Engineers, U.S. Army, in collecting records for 67 gaging stations published in this report.

FIGURE 286A.—Introductory text.

WATER RESOURCES DATA FOR INDIANA, 19XX

The following organizations aided in collecting records:

The city of Indianapolis, through its Board of Public Works and Sanitation and its Flood Control Board; cities of Anderson, Bloomington, Muncie, North Vernon, Richmond, and Jasper; Indianapolis Water Co.; Indianapolis Power and Light Co.; Public Service Co. of Indiana; * * *.

DEFINITION OF TERMS

Definition of terms related to streamflow and other hydrologic data, as used in this report, are defined as follows:

Acre-foot (AC-FT, acre-ft) is the quantity of water required to cover 1 acre to a depth of 1 foot and is equivalent to 43,560 cubic feet or 325,851 gallons.

Cfs-day is the volume of water represented by a flow of 1 cubic foot per second for 24 hours. It is equivalent to 86,400 cubic feet, 1.9835 acre-feet, or 646,317 gallons, and represents a runoff of 0.0372 inch from 1 square mile.

Contents is the volume of water in a reservoir or lake. Unless otherwise indicated, volume is computed on the basis of a level pool and does not include bank storage.

Control designates a feature downstream from the gage that determines the stage-discharge relation at the gage. This feature may be a natural constriction of the channel, an artificial structure, or a uniform cross section over a long reach of the channel.

Cubic feet per second per square mile (CFSM) is the average number of cubic feet of water flowing per second from each square mile of area drained, assuming that the runoff is distributed uniformly in time and area.

Cubic foot per second (cfs) is the rate of discharge representing a volume of 1 cubic foot passing a given point during 1 second, and is equivalent to 7.48 gallons per second or 448.8 gallons per minute.

Discharge is the volume of water (or more broadly, total fluids), that passes a given point within a given period of time.

Drainage area of a stream at a specified location is that area, measured in a horizontal plane, enclosed by a topographic divide from which direct surface runoff from precipitation normally drains by gravity into the stream above the specified point. Figures of drainage area given herein include all closed basins, or noncontributing areas, within the area unless otherwise noted.

Gage height (G.H.) is the water-surface elevation referred to some arbitrary gage datum. Gage height is often used interchangeably with the more general term "stage," although gage height is more appropriate when used with a reading on a gage.

Gaging station is a particular site on a stream, canal, lake, or reservoir where systematic observations of gage height or discharge are obtained. When used in connection with a discharge record, the term is applied only to those gaging stations where a continuous record of discharge is obtained.

FIGURE 286*B*.—Introductory text—Continued.

WATER RESOURCES DATA FOR INDIANA, 19XX

Partial-record station is a particular site where limited streamflow data are collected systematically over a period of years for use in hydrologic analyses.

Runoff in inches (IN.) shows the depth to which the drainage area would be covered if all the runoff for a given time period were uniformly distributed on it.

Stage-discharge relation is the relation between gage height and the amount of water flowing in a channel, expressed as volume per unit of time.

WRD is used as an abbreviation for "Water-Resources Data" in the summary REVISIONS paragraph to refer to previously published State annual basic-data reports.

WSP is used as an abbreviation for "Water-Supply Paper" in references to previously published reports.

SPECIAL NETWORKS AND PROGRAMS

Hydrologic bench-mark station is one that provides hydrologic data for a basin in which the hydrologic regimen will likely be governed solely by natural conditions. Data collected at a bench-mark station may be used to separate effects of natural from man-made changes in other basins which have been developed and in which the physiography, climate, and geology are similar to those in the undeveloped bench-mark basin.

International Hydrological Decade (IHD) River Stations provide a general index of runoff and materials in the water balance (discharge of water, and dissolved and transported solids) of the world. In the United States, IHD Stations provide indices of runoff and of the general distribution of water in the principal river basins of the conterminous United States and Alaska.

DOWNSTREAM ORDER AND STATION NUMBERS

Records are listed in a downstream direction along the main stream, and stations on tributaries are listed between stations on the main stream in the order in which those tributaries enter the main stream. Stations on tributaries entering above all mainstream stations are listed before the first mainstream station. Stations on tributaries to tributaries are listed in a similar manner. In the list of gaging stations in the front of this report the rank of tributaries is indicated by indention, each indention representing one rank.

As an added means of identification, each gaging station and partial-record station has been assigned a station number. These are in the same downstream order used in this report. In assigning station numbers, no distinction is made between partial-record stations and continuous-record gaging stations; therefore, the station number for a partial-record station indicates downstream order position in a list made up of both types of stations. Gaps are left in the numbers to allow for new stations that may be established; hence the numbers are not consecutive. The complete 8-digit number for each station, such as 03-3355.00, includes the part number "03" and a 6-digit station number. In this report, the nonessential zeros are not shown. For example, the complete number 03-3355.00 would appear as 3-3355, just to the left of the station name. In this report,

FIGURE 286C.—Introductory text—Continued.

the records are listed in downstream order by parts. All records for a drainage basin encompassing more than one State could be arranged in downstream order by assembling pages from the various State reports by station number to include all records in the basin.

EXPLANATION OF SURFACE-WATER DATA

Collection and Computation of Data

The base data collected at gaging stations consists of records of stage and measurements of discharge of streams or canals, and stage, surface area, and contents of lakes or reservoirs. In addition, observations of factors affecting the stage-discharge relation or the stage-capacity relation, weather records, and other information are used to supplement base data in determining the daily flow or volume of water in storage. Records of stage are obtained from a water-stage recorder that gives a continuous graph of the fluctuations (for digital recorders, a tape punched at 15-, 30-, or 60-minute intervals) or from direct readings on a nonrecording gage. Measurements of discharge are made with a current meter, using the general methods adopted by the Geological Survey on the basis of experience in stream gaging since 1888. These methods are described in standard textbooks on the measurement of stream discharge. (See also SELECTED REFERENCES.) Surface areas of lakes or reservoirs are determined from instrument surveys using standard methods. The configuration of the reservoir bottom is determined by sounding at many points.

For a stream-gaging station rating tables giving the discharge for any stage are prepared from stage-discharge relation curves defined by discharge measurements. If extensions to the rating curves are necessary to define the extremes of discharge, they are made on the basis of indirect measurements of peak discharge (such as slope-area or contracted-opening measurements, computation of flow over dams or weirs), velocity-area studies, and logarithmic plotting. The application of the daily mean gage heights to the rating table gives the daily mean discharge, from which the monthly and the yearly mean discharge are computed. If the stage-discharge relation is subject to change because of frequent or continual change in the physical features that form the control, the daily mean discharge is determined by the shifting-control method, in which correction factors based on individual discharge measurements and notes by engineers and observers are used in applying the gage heights to the rating tables. If the stage-discharge relation for a station is temporarily changed by the presence of aquatic growth or debris on the control, the daily mean discharge is computed by what is basically the shifting-control method.

At some stream-gaging stations the stage-discharge relation is affected by backwater from reservoirs, tributary streams, or other sources. This necessitates the use of the slope method in which the slope or fall in a reach of the stream is a factor in determining discharge. Information required for determining the slope or fall is obtained by means of an auxiliary gage set at some distance from the base gage. At some stations the stage-discharge relation is affected by changing stage; at these stations the rate of change in stage is used as a factor in determining discharge.

At some stream-gaging stations the stage-discharge relation is affected by ice in the winter, and it becomes impossible to compute the discharge in the usual manner. Discharge for periods of ice effect is computed on the basis of the gage-height record and

FIGURE 286*D*.—Introductory text—Continued.

WATER RESOURCES DATA FOR INDIANA, 19XX

occasional winter discharge measurements, consideration being given to the available information on temperature and precipitation, notes by gage observers and hydrologists, and comparable records of discharge for other stations in the same or nearby basins.

For a lake or reservoir station, capacity tables giving the contents for any stage are prepared from stage-area relation curves defined by surveys. Discharge over spillways is computed from a stage-discharge relation curve defined by discharge measurements. The application of the stage to the capacity table gives the contents, from which the daily, monthly, or yearly change in contents is computed.

If the stage-capacity curve is subject to changes because of deposition of sediment in the reservoir, periodic resurveys of the reservoir are necessary to define new stage-capacity curves. During the period between reservoir surveys the computed contents may be increasingly in error due to the gradual accumulation of sediment.

For some gaging stations there are periods when no gage-height record is obtained or the recorded gage height is so faulty that it cannot be used to compute daily discharge or contents. This happens when the recorder stops or otherwise fails to operate properly, intakes are plugged, the float is frozen in the well, or for various other reasons. For such periods the daily discharges are estimated on the basis of recorded range in stage, adjoining good record, discharge measurements, weather records, and comparison with other station records from the same or nearby basins. Likewise daily contents may be estimated on the basis of operator's log, adjoining good record, inflow-outflow studies, and other information.

The data in this report generally comprise a description of the station and tabulations of basic data. For gaging stations on streams or canals a table showing the daily discharge and monthly and yearly discharge is given. For gaging stations on lakes and reservoirs a monthly summary table of stage and contents or a table showing the daily contents is given. Tables of daily mean gage heights are included for some streamflow stations and for some reservoir stations. Records are published for the water year, which begins on October 1 and ends on September 30. A calendar for the 19XX water year is shown on the reverse side of the front cover to facilitate finding the day of the week for any date.

The description of the gaging station gives the location, drainage area, period of record, type and history of gages, average discharge, extremes of discharge or contents, and general remarks. The location of the gaging station and the drainage area are obtained from the most accurate maps available. River mileage, given under "LOCATION" for some stations, is that determined and used by the Corps of Engineers or other agencies. Periods for which there are published records for the present station or for stations generally equivalent to the present one are given under "PERIOD OF RECORD." The type of gage currently in use, the datum of the present gage above mean sea level, and a condensed history of the types, locations, and datums of previous gages used during the period of record are given under "GAGE." In references to datum of gage, the phrase "mean sea level" denotes "Sea Level Datum of 1929" as used by the Topographic Division of the Geological Survey, unless otherwise qualified. The average discharge for the number of years indicated is given under "AVERAGE DISCHARGE"; it is not given for stations having fewer than 5 complete years of record or for stations where changes in water development during the period of record cause the figure to have little significance. In addition, the median of yearly mean discharges is given for stream-gaging stations having 10 or more complete years of record if the median differs from the average by more than 10 percent. The maximum discharge (or contents) and the maximum gage height, the minimum discharge if there is little or no regulation (or the minimum contents), and the

FIGURE 286*E*.—Introductory text—Continued.

WATER RESOURCES DATA FOR INDIANA, 19XX

minimum gage height if it is significant are given under "EXTREMES." The minimum daily discharge is given if there is extensive regulation (also the minimum discharge and gage height if they are abnormally low). In the first paragraph headed "Current year:" the data given are for the complete current water year unless otherwise specified. In the second paragraph under "EXTREMES" headed "Period of record:" the data given are for the period of record given in the PERIOD OF RECORD paragraph. Reliable information concerning major floods that occurred outside the period of record is given in the third or last paragraph under "EXTREMES." Unless otherwise qualified, the maximum discharge (or contents) corresponds to the crest stage obtained by use of a water-stage recorder (graphic or digital), a crest-stage gage, or a nonrecording gage read at the time of the crest. If the maximum gage height did not occur at the same time as the maximum discharge or contents, it is given separately. Information pertaining to the accuracy of the discharge records, to conditions that affect the natural flow at the gaging station, and availability of Water Quality records, is given under "REMARKS"; for reservoir stations information on the dam forming the reservoir, the capacity, outlet works and spillway, and purpose and use of the reservoir, is also given under "REMARKS."

Previously published records of some stations have been found to be in error on the basis of data or information later obtained. Revisions of such records are usually published along with the current records in one of the annual or compilation reports. In order to make it easier to find such revised records, a paragraph headed "REVISIONS (WATER YEARS)" has been added to the description of all stations for which revised records have been published. Listed therein are all the reports in which revisions have been published, each followed by the water years for which figures are revised in that report. In listing the water years only one number is given; for instance, 1933 stands for the water year October 1, 1932, to September 30, 1933. If no daily, monthly, or annual figures of discharge were revised, that fact is brought out by notations after the year dates as follows: "(M)" means that only the instantaneous maximum discharge was revised; "(m)" that only the instantaneous minimum was revised; and "(P)" that only peak discharges were revised. If the drainage area has been revised, the report in which the revised figure was first published is given. It should be noted that for all stations for which cubic feet per second per square mile and runoff in inches are published, a revision of the drainage area necessitates corresponding revision of all figures based on the drainage area. Revised figures of cubic feet per second per square mile and runoff in inches resulting from a revision of the drainage area only are usually not published in the annual series of reports.

Skeleton rating tables are published for stream-gaging stations where they serve a useful purpose and the dates of applicability can be easily identified.

Skeleton capacity tables are published for all reservoirs for which records of contents are published on a daily basis.

The daily tables for stream-gaging stations give the discharge corresponding to the daily mean gage height unless there are large or rapid changes in the discharge during a day. For days having large or rapid changes, discharge for the day is computed by averaging the mean discharge for several parts of a day. For digital recorders, the daily mean discharge is always the average of the discharges at each punched reading. For stations equipped with nonrecording gages, the daily discharge corresponds to once-daily readings of the gage or to the mean of twice-daily readings; but for periods of rapidly changing stage the discharge is determined from a gage-height graph based on gage readings.

FIGURE 286*F*.—Introductory text—Continued.

WATER RESOURCES DATA FOR INDIANA, 19XX

The daily tables for reservoir stations give the contents corresponding to the water-surface elevation at a given time, usually at 2400 each day. For some reservoirs the elevation at a given time is given in the daily table.

The monthly summary is given below the daily table. For stream-gaging stations the line headed "TOTAL" gives the sum of the daily figures; it is the total cubic feet per second per day for the month. The line headed "MEAN" gives the average flow in cubic feet per second during the month. The lines headed "MAX" and "MIN" give the maximum and minimum daily discharges, respectively, for the month. Discharge for the month also may be expressed in cubic feet per second per square mile (line headed "CFSM"), or in inches (line headed "IN.") or in acre-feet (line headed "AC-FT"). Figures of cubic feet per second per square mile and runoff in inches are omitted if there is extensive regulation or diversion, if the drainage area includes large noncontributing areas, or if the average rainfall on the drainage basin is usually less than 20 inches.

For reservoir stations the monthly summary gives the elevation (or gage height) at the end of the month and the change in contents during the month. If elevation or gage height is given in the daily table, the monthly summary gives the contents at the end of the month, rather than the elevation or gage height. For some reservoirs a tabulation of monthly evaporation from the water surface also is included.

In the yearly summary below the monthly summary, the figures of maximum are the maximum daily discharges for the calendar and water years; likewise, the minimums in this summary are the minimum daily discharges.

For reservoir stations the yearly summary gives the change in contents for the calendar year and for the water year. For some reservoirs the yearly evaporation also is included.

Peak discharges and their times of occurrence and corresponding gage heights for many stations are listed below the yearly summary. All independent peaks above the selected base are given. The base discharge, which is given in parentheses, is selected so that an average of about three peaks a year can be presented. Peak discharges are not published for any canals, ditches, drains, or for any stream for which the peaks are subject to substantial control by man. Time of day is expressed in 24-hour local standard time; for example, 12:30 a. m. is 0030 and 1:30 p. m. is 1330.

In a general footnote, introduced by the word "NOTE" certain periods are indicated for which the discharge is computed or estimated by special methods because of no gage-height record, backwater from various sources, or other unusual conditions. Periods of no gage-height record are indicated if the period is continuous for a month or more or includes the maximum discharge for the year. Periods of backwater from an unusual source, of indefinite stage-discharge relation, or of any other unusual condition at the gage are indicated only if they are a month or more in length and the accuracy of the records is affected. Days on which the stage-discharge relation is affected by ice are not indicated. The methods used in computing discharge for various unusual conditions have been explained in preceding paragraphs. Footnotes to reservoir tables may be used to explain the use of new capacity tables or for other special conditions.

FIGURE 286*G*.—Introductory text—Continued.

WATER RESOURCES DATA FOR INDIANA, 19XX

Accuracy of Data

The accuracy of discharge data depends primarily on (1) the stability of the stage-discharge relation or, if the control is unstable, the frequency of discharge measurements, and (2) the accuracy of observations of stage, measurements of discharge, and interpretation of records.

The station description under "REMARKS" states the degree of accuracy of the records. "Excellent" means that about 95 percent of the daily discharges is within 5 percent; "good" within 10 percent; and "fair" within 15 percent. "Poor" means that daily discharges have less than "fair" accuracy.

Figures of daily mean discharge in this report are shown to the nearest hundredth of a cubic foot per second for discharges of less than 1 cfs; to tenths between 1.0 and 10 cfs; to whole numbers between 10 and 1,000 cfs; and to 3 significant figures above 1,000 cfs. The number of significant figures used is based solely on the magnitude of the figure. The same rounding rules apply to discharge figures listed for partial-record stations and miscellaneous sites.

Discharge at many stations, as indicated by the monthly mean, may not reflect natural runoff due to the effects of diversion, consumptive use, regulation, evaporation, or other factors. For such stations, discharge in cubic feet per second per square mile and runoff in inches are not published unless satisfactory adjustments can be made for such effects. Evaporation from a reservoir is not included in the adjustments for changes in reservoir contents, unless it is so stated. Even at those stations where adjustments are made, large errors in computed runoff may occur if adjustments or unadjusted losses (consumptive use, evaporation, seepage, etc.) are large in comparison with the observed discharge.

Publications

Each volume of the 1960 series of U.S. Geological Survey water-supply papers entitled "Surface Water Supply of the United States" contains a listing of the numbers of all water-supply papers in which records of surface-water data were published for the area covered by the individual volumes. Each volume also contains a list of water-supply papers that give detailed information on major floods for the area. A new series of water-supply papers containing surface-water records for the 5-year period October 1, 1960, to September 30, 1965, also will include lists of annual and special reports published as water-supply papers.

Records through September 1950 for the area covered by this report have been compiled and published in Water-Supply Papers 1305(3A), 1307(4), and 1308(5); records for October 1950 to September 1960 have been compiled and published in Water-Supply Papers 1725(3A), 1727(4), and 1728(5). These reports contain summaries of monthly and annual discharge and monthend storage for all previously published records, as well as some records not contained in the annual series of water-supply papers. All records were reexamined and revised where warranted. Estimates of discharge were made to fill short gaps whenever practical. The yearly summary table for each gaging station lists the numbers of the water-supply papers in which daily records were published for that station.

Special reports on major floods or droughts or of other hydrologic studies for the area have been issued in publications other than water-supply papers. Information relative to these reports may be obtained from the district office.

FIGURE 286*H*.—Introductory text—Continued.

WATER RESOURCES DATA FOR INDIANA, 19XX

Other Data Available

Data collected at partial-record stations and at miscellaneous sites are given in three tables at the end of the surface-water records in this report. The first is a table of discharge measurements at low-flow partial-record stations, the second is a table of annual maximum stage and discharge at crest-stage stations, and the third is a table of discharge measurements at miscellaneous sites.

More detailed information than that published for most of the gaging stations, such as discharge measurements, gage-height records, and rating tables, is on file in the district office. Many gaging-station records in (State) through (1966) have been analyzed to give several statistical summaries: (1) the number of days in each year that the daily discharge was between selected limits (duration tables); (2) the lowest mean discharge for selected numbers of consecutive days in each year; and (3) the highest mean discharge for selected numbers of consecutive days in each year.

At or near some gaging stations, water-quality records also are collected. Data are obtained on the chemical quality of the stream water, on water temperature, on suspended-sediment concentration, and on the particle-size distribution of suspended sediment and bed material. These data are given in Part 2 of this report. Under the "REMARKS" paragraph of the gaging-station description, reference is made to water-quality records collected on a regular basis.

HYDROLOGIC CONDITIONS

Precipitation was scattered throughout the year by area and time. Heavy rains the first half of December caused minor flooding in the Wabash and Maumee River basins. Lack of late summer showers left the central and southern parts 3 to 9 inches below average rainfall.

Deficient streamflow in October was relieved in the south by mid-November and in the north by the end of the month. Excessive to near excessive streamflow existed in the first part of December with near record streamflow in the upper Wabash River and Maumee River basins. Near normal streamflow existed from January to May with generally bankfull stages in March and May. Deficient * * *. *(to be completed)*

SKUNK RIVER BASIN

5-4710. South Skunk River below Squaw Creek, near Ames, Iowa

LOCATION.--Lat 42°00'31", long 93°35'38", in NE¼NW¼ sec.13, T.83 N., R.24 W., Story County, on right bank 15 ft downstream from county highway bridge, 0.2 mile downstream from Squaw Creek, 0.3 mile upstream from bridge on U.S. Highway 30, 2 miles southeast of Ames, and at mile 222.6.

DRAINAGE AREA.--556 sq mi.

PERIOD OF RECORD.--October 1952 to current year. Prior to October 1966, published as Skunk River below Squaw Creek, near Ames.

GAGE.--Water-stage recorder and concrete control. Datum of gage is 867.10 ft above mean sea level.

AVERAGE DISCHARGE.--16 years, 226 cfs (5.52 inches per year, 163,600 acre-ft per year).

EXTREMES.--Current year: Maximum discharge, 7,310 cfs June 25 (gage height, 12.07 ft); no flow for many days.
Period of record: Maximum discharge, 9,260 cfs Mar. 30, 1960 (gage height, 13.20 ft); no flow for many days during 1953-57, 1964-65, 1967-68.
Flood of May 19, 1944, reached a stage of 13 ft, from floodmarks (discharge, 10,000 cfs).

REMARKS.--Records good except those for winter periods and period of no gage-height record, which are poor.

MOBILE RIVER BASIN

2-3940. Etowah River at Allatoona Dam, above Cartersville, Ga.

LOCATION.--Lat 34°09'48", long 84°44'30", Bartow County, on right bank 0.8 mile downstream from Allatoona Dam, 2.0 miles upstream from Nashville, Chattahoogo and St. Louis Railway bridge, and 3.0 miles east of Cartersville.

DRAINAGE AREA.--1,110 sq mi, approximately.

PERIOD OF RECORD.--September 1938 to current year. Prior to October 1949, published as Etowah River above Cartersville.

GAGE.--Water-stage recorder. Datum of gage is 686.92 ft above sea level (levels by Corps of Engineers). Prior to Dec. 19, 1938, nonrecording gage at same site and datum.

AVERAGE DISCHARGE.--30 years, 1,800 cfs (22.02 inches per year), adjusted for storage since 1950.

EXTREMES.--Current year: Maximum discharge, 9,340 cfs Jan. 18 (gage height, 7.65 ft); minimum daily, 213 cfs Jan. 27, 28, Feb. 3, 4. Period of record: Maximum discharge, 40,400 cfs Jan. 8, 1946 (gage height, 20.8 ft), from rating curve extended above 26,000 cfs; minimum daily, 152 cfs Oct. 15, 1966.

REMARKS.--Flow regulated by Allatoona Reservoir since December 1949 (See sta 2-3935.)

COOPERATION.--Gage-height record, 19 discharge measurements, and computations of daily discharge furnished by Corps of Engineers; records reviewed by Geological Survey.

ARKANSAS RIVER BASIN

7-2590. Blue Mountain Reservoir near Waveland, Ark.

LOCATION.--Lat 35°06'06", long 93°39'02", in NE¼ sec.15, T 5 N., R 25 W., Yell County, at control tower for outlet works of dam on Petit Jean Creek, 1.3 miles southwest of Waveland

DRAINAGE AREA.--488 sq mi.

PERIOD OF RECORD.--March 1947 to current year.

GAGE --Water-stage recorder Datum of gage is at mean sea level (levels by Corps of Engineers)

EXTREMES --Current year. Maximum contents, 130,940 acre-ft May 23 (elevation, 405 37 ft); minimum, 2,150 acre-ft Oct 2, 3 (elevation, 370.68 ft).
Period of record: Maximum contents, 298,560 acre-ft May 26, 19XX (elevation, 422.54 ft), including 40,560 acre-ft of uncontrolled storage above spillway crest; minimum since initial filling to conservation pool level, 2,150 acre-ft Oct. 2, 3, 19XX (elevation, 370.68 ft).

REMARKS.--Reservoir is formed by earthfill dam, storage began Mar 13, 1947. Total capacity, 258,000 acre-ft at elevation 419.0 ft (crest of uncontrolled spillway), including 25,000 acre-ft at elevation 384.0 ft (conservation pool level), and 1,940 acre-ft of dead storage at elevation 370.00 ft (invert of gate sills of outlet tunnel). Under normal operating conditions reservoir water surface will be maintained at approximately conservation pool level for purposes of conservation and recreation, storage above this level is used for flood control. Figures given herein represent total contents.

COOPERATION.--Records furnished by Corps of Engineers.

MISSISSIPPI RIVER MAIN STEM

5-2010. Winnibigoshish Lake near Deer River, Minn.

LOCATION.--Lat 47°25'42", long 94°03'00", in XX¼ sec.25, T 146 N., R.27 W., Itasca County, at dam on Mississippi River, 1 mile northwest of Little Winnibigoshish Lake and 14 miles northwest of town of Deer River.

DRAINAGE AREA --1,442 sq mi

PERIOD OF RECORD.--April 1884 to current year (monthend contents only). Prior to October 1941 monthend contents published in WSP 1308. Published as Winnibigoshish Reservoir near Deer River October 1941 to September 1956.

GAGE --Water-stage recorder. Datum of gage is 1,289.47 ft above mean sea level. Prior to July 8, 1949, nonrecording gage at same site and datum

EXTREMES.--Current year: Maximum contents, 561,880 acre-ft July 29 (gage height, 9.95 ft); minimum, 466,570 acre-ft Apr. 1 (gage height, 8.50 ft).
Period of record: Maximum contents observed, 996,500 acre-ft July 30, 1905 (gage height, 14.45 ft), minimum observed, 33,680 acre-ft below zero of capacity table Oct. 20, 1931 (gage height, -0.69 ft).

REMARKS --Reservoir is formed by concrete and timber dam controlling Winnibigoshish Lake and several other natural lakes; dam completed and storage began in 1884. Capacity, 967,930 acre-ft between gage height 0.00 and 14.2 ft (maximum operating level), of which 653,580 acre-ft is usable storage above 6.00 ft (minimum allowable level). Figures given herein represent contents above gage height 0.00 ft. Water is used to benefit navigation on Mississippi River below Minneapolis.

COOPERATION.--Records furnished by Corps of Engineers in cfs-days and converted to acre-feet by Geological Survey.

REVISIONS (WATER YEARS).--WSP 1308: 1905(M).

YAKIMA RIVER BASIN

Reservoirs in Yakima River basin

12-4740. KEECHELUS LAKE.--Lat 47°19'XX", long 121°20'XX", Kittitas County, at dam on Yakima River at outlet of Keechelus Lake, 3.X miles northwest of Martin and 10 miles northwest of Easton. Drainage area, 55.8 sq mi. Period of record, January 1906 to current year. Nonrecording gage read twice daily. Datum of gage is at mean sea level (Bureau of Reclamation bench mark). Extremes for current year: Maximum contents observed, 159,930 acre-ft June 17 (elevation, 2,517.84 ft); minimum observed, 33,560 acre-ft Sept. 30 (elevation, 2,450.97 ft). Extremes for period of record: Maximum contents observed, 160,570 acre-ft May 16, 1925 (elevation, 2,518.09 ft); minimum observed, 448 acre-ft Sept. 6, 12, 13, 1906 (original crib dam); minimum elevation observed, 2,428.30 ft Sept. 20, 1926.

Reservoir is formed on natural lake by earth- and gravel-fill dam completed in 1917; storage above crib dam began Jan. 12, 1906; above present dam Aug. 19, 1914. Initial filling of present reservoir June 15, 1920. Usable capacity, 157,800 acre-ft between elevation 2,425 00 (invert of gate sill) and 2,517.00 ft (spillway crest). Dead storage below elevation 2,425.00 ft, XXX acre-ft. Spillway raised 2 ft Sept. 12, 1952. Figures given herein represent usable contents. Water is used for irrigation.

12-4755. KACHESS LAKE.-- * * *. (Format similar to the above)

12-4785. CLE ELUM LAKE.-- * * *. (Format similar to the above)

12-4875. BUMPING LAKE.--Lat 46°52'XX", long 121°18'XX", in SW¼ sec.23, T.16 N., R.12 E. (unsurveyed), Yakima County, at dam on Bumping River at outlet of Bumping Lake, 12 miles upstream from American River and 19 miles west of Nile. Drainage area, 68.6 sq mi. Period of record, June to July 1906, April 1909 to current year. Nonrecording gage read twice daily. Datum of gage is at mean sea level (Bureau of Reclamation bench mark). Extremes for current year: Maximum contents observed, 36,160 acre-ft June 16 (elevation, 3,427.85 ft); minimum observed, 4,980 acre-ft Sept. 30 (elevation, 3,396.67 ft). Extremes for period of record: Maximum contents observed, 39,840 acre-ft June 21, 22, 1925 (elevation, 3,430.55 ft); minimum obeerved, 1,130 acre-ft Feb. 5-9, 1949 (elevation, 3,390.80 ft).

Reservoir is formed on natural lake by earthfill dam completed in 1910; storage begun Nov 3, 1910. Usable capacity, 33,700 acre-ft between elevation 3,389.00 (invert of gate sill) and 3,426.00 ft (spillway crest). No dead storage Figures given herein represent usable contents Water is used for irrigation.

ANDROSCOGGIN RIVER BASIN

Reservoirs in Androscoggin River basin

1-0505. RANGELEY LAKE on Rangeley Stream, at Oquossoc, Maine, used for power and log driving, has usable capacity of 1,339,200,000 cu ft in top 4 ft of lake (top of flashboards). Gage-height record furnished by Union Water Power Co.

1-0510. MOOSELOOKMEGUNTIC LAKE at Upper Dam, in Richardson Township, Maine, used for power and log driving, has usable capacity of 8,370,000,000 cu ft between gage heights 8.3 and 20.5 ft. Gage-height record furnished by Union Water Power Co.

1-0515. UPPER AND LOWER RICHARDSON LAKES on Rapid River, at Middle Dam, Maine, used for power and log driving, has usable capacity of 5,691,500,000 cu ft between gage heights 3.0 and 20.5 ft. Gage-height record furnished by Union Water Power Co.

1-0520. AZISCOHOS LAKE on Magalloway River, in Lincoln Township, 3 miles east of village of Wilsons Mills, Maine, completed in 1911 for power, has usable capacity of 9,593,000,000 cu ft between elevations 1,490.0 and 1,535.0 ft. Elevation record furnished by Union Water Power Co.

1-0530. UMBAGOG LAKE on Androscoggin River, at Errol Dam, 0.8 mile northeast of Errol, N.H., used for power and log driving, has usable capacity of 3,080,160,000 cu ft between gage heights 5.5 and 15.0 ft. Gage-height record furnished by Union Water Power C

1-0560. GULF ISLAND POND on Androscoggin River, 3 miles upstream from Lewiston, Maine, completed in 1928 for power, has capacity of 1,100,000,000 cu ft in top 10 ft of pond below elevation 262 ft. Elevation record furnished by Central Maine Power Co.

1-0565. LAKE AUBURN on outlet stream to Androscoggin River, at East Auburn, Maine, used for storing water supply of Auburn and Lewiston, has usable capacity of 580,000,000 cu ft between elevations 254.7 and 260.7 ft. .Elevation record furnished by Auburn Water District.

1-0575. PENNESSEEWASSEE LAKE on short outlet stream to Little Androscoggin River, at Norway, Maine, used for recreation, has usable capacity of 192,000,000 cu ft between gage heights 95.0 and 100.0 ft. Gage-height record furnished by Town of Norway.

1-0580. THOMPSON LAKE on short outlet stream to Little Androscoggin River, at Oxford, Maine, used for power and process water, has usable capacity of 950,000,000 cu ft between gage heights 95.0 and 100.0 ft. Gage-height record furnished by Robinson Manufacturing Co.

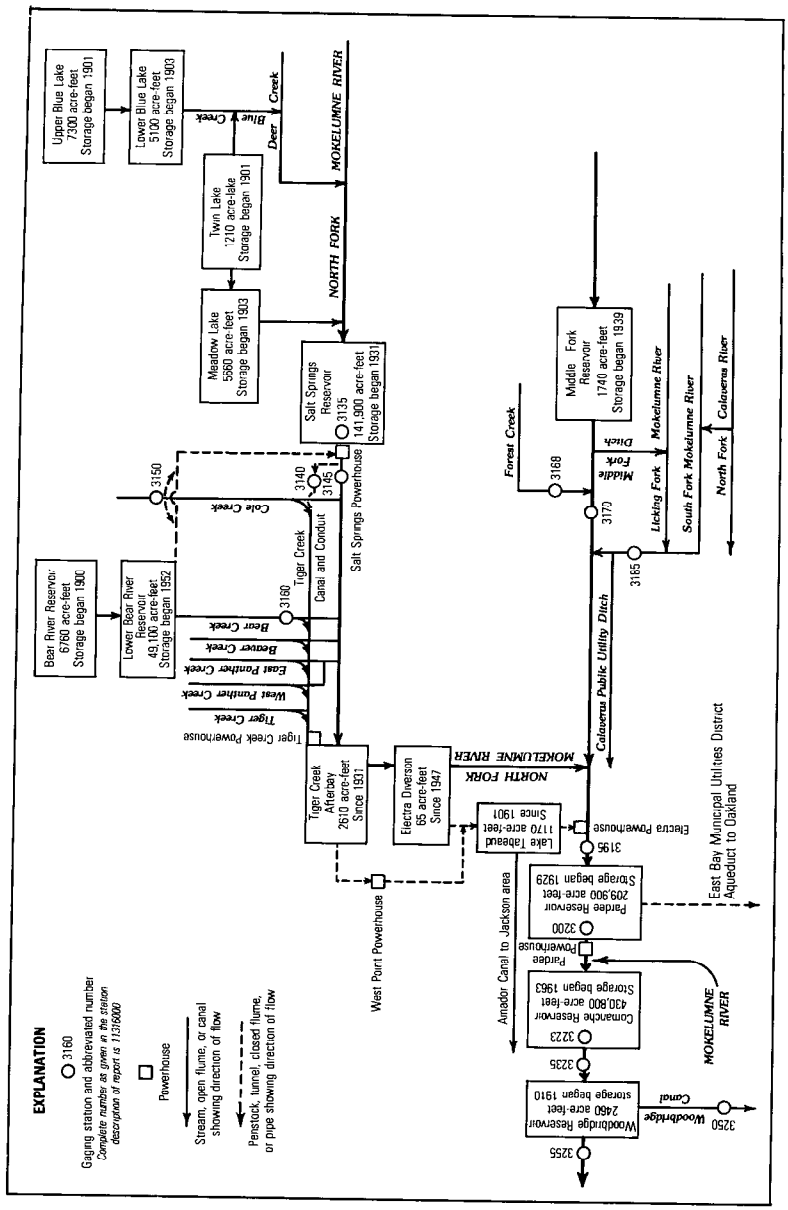

FIGURE 297.—Schematic diagram showing reservoirs, canals, and gaging stations.

DISCHARGE AT PARTIAL-RECORD STATIONS AND MISCELLANEOUS SITES

As the number of streams on which streamflow information is likely to be desired far exceeds the number of stream-gaging stations *feasible to operate at one time, the Geological Survey collects limited streamflow data at sites other than stream-gaging* stations. When limited streamflow data are collected on a systematic basis over a period of years for use in hydrologic analyses, the site at which the data are collected is called a partial-record station. Data collected at these partial-record stations are usable in low-flow or floodflow analyses, depending on the type of data collected. In addition, discharge measurements are made at other sites not included in the partial-record program. These measurements are generally made in times of drought or flood to give better areal coverage to those events. Those measurements and others collected for some special reason are called measurements at miscellaneous sites.

Records collected at partial-record stations are presented in two tables. The first is a table of discharge measurements at low-flow partial-record stations, and the second is a table of annual maximum stage and discharge at crest-stage stations. Discharge measurements made at miscellaneous sites for both low flow and high flow are given in a third table.

Low-flow partial-record stations

Measurements of streamflow in the area covered by this report made at low-flow partial-record stations are given in the following table. *Most of these measurements were made during periods of base flow when streamflow is primarily from ground-water* storage. These measurements, when correlated with the simultaneous discharge of a nearby stream where continuous records are available, will give a picture of the low-flow potentiality of a stream. The column headed "Period of record" shows the water years in which measurements were made at the same, or practically the same, site.

Discharge measurements made at low-flow partial-record stations during water year 1968

FIGURE 298.—Low-flow partial records.

DISCHARGE AT PARTIAL-RECORD STATIONS AND MISCELLANEOUS SITES

The following table contains annual maximum discharge for crest-stage stations. A crest-stage is a device which will register the peak stage occurring between inspections of the gage. A stage-discharge relation for each gage is developed from discharge measurements made by indirect measurements of peak flow or by current meter. The date of the maximum discharge is not always certain but is usually determined by comparison with nearby continuous-record stations, weather records, or local inquiry. Only the maximum discharge for each water year is given. Information on some lower floods may have been obtained, and discharge measurements may have been made for purposes of establishing the stage-discharge relation, but these are not published herein. The years given in the period of record represent water years for which the annual maximum has been determined.

Annual maximum discharge at crest-stage partial-record stations during water year 1968

Station No.	Station name	Location	Drainage area (sq mi)	Period of record	Annual maximum

RIO GRANDE BASIN

Pecos River seepage investigations—Acme to Artesia, N Mex.

Two series of discharge measurements were made during the 19XX water year, on Jan. 20 and Mar. 31, on the Pecos River and tributaries and diversions in New Mexico, to study channel gains and losses. The reach is 81 6 miles in length and extends from the gaging station Pecos River near Acme (8-3860) to the gaging station Pecos River near Artesia (8-3965). The measurements were made during periods of constant base flow of the streams, for 10 days before the investigations no measurable precipitation had fallen Tributary flow was considered a contribution and not a gain; diversion was considered a deduction and not a loss Indicated gains or losses may be substantially in error as affected by small inaccuracies in open-channel measurements Records of chemical analyses and water temperatures obtained at the time of this investigation are published in Part 2 of this report. Previous seepage investigations of this reach were made at least once each water year 1953-60, 1962-66

STREAMS TRIBUTARY TO LAKE ST. CLAIR

North Branch Clinton River basin low-flow investigations

Two series of base-flow discharge measurements were made in the North Branch Clinton River basin as part of a comprehensive program now being carried on in cooperation with the Macomb County Board of Supervisors and the Macomb County Road Commission to investigate the surface water resources of the county The first series was made on June 9, as soon as conditions were suitable for high base flow The second series was made on Aug. 18, under conditions of low base flow. The data collected in these series of measurements, along with that already collected and to be collected in the future, will provide the basis for determining the base-flow yields of various parts of the basin.

Weather records at Mount Clemens near the southern part of the area and at Romeo near the west-central part show that no precipitation occurred for five days prior to June 9 and four days prior to Aug. 18. Therefore, the measurements are considered to represent base flow

The measurements on each stream are listed in order proceeding downstream, and each tributary is inserted in the order in which it enters the main stream. Drainage areas shown were determined from recent U.S Geological Survey topographic maps of a scale of 1:24,000 and contour interval of 5 to 10 ft Previous series of measurements were made in water years 1959-64

Preface

This series of manuals on techniques and methods (TM) describes approved scientific and data-collection procedures and standard methods for planning and executing studies and laboratory analyses. The material is grouped under major subject headings called "books" and further subdivided into sections and chapters. Section A of book 3 is on surface-water techniques.

The unit of publication, the chapter, is limited to a narrow field of subject matter. These publications are subject to revision because of experience in use or because of advancement in knowledge, techniques, or equipment, and this format permits flexibility in revision and publication as the need arises. Chapter A8 of book 3 (TM 3–A8) deals with discharge measurements at gaging stations. The original version of this chapter was published in 1969 as U.S. Geological Survey (USGS) Techniques for Water-Resources Investigations, chapter A8 of book 3. New and improved equipment, as well as some procedural changes, have resulted in this revised second edition of "Discharge measurements at gaging stations."

This edition supersedes USGS Techniques of Water-Resources Investigations 3A–8, 1969, "Discharge measurements at gaging stations," by T.J. Buchanan and W.P. Somers, available at *http://pubs.usgs.gov/twri/twri3a8/*, and supplements USGS Water-Supply Paper 2175, volume 1, 1982, "Measurement and computation of streamflow: Measurement of stage and discharge," by S.E. Rantz and others, available at *http://pubs.usgs.gov/wsp/wsp2175/html/WSP2175_vol1.html*.

This revised second edition of "Discharge measurements at gaging stations" is published online at *http://pubs.usgs.gov/tm/tm3-a8/* and is for sale by the U.S. Geological Survey, Science Information Delivery, Box 25286, Federal Center, Denver, CO 80225.

Definitions of Symbols

a_i	cross-section area for the *i*th segment of the *n* segments into which the cross section is divided
arctan	arctangent
b	width of the throat section (in units of distance)
b_i	distance from initial point to location i
$b_{(i-1)}$	distance from initial point to preceding location
$b_{(i+1)}$	distance from initial point to next location
d_i	depth of water at location *i*
C	coefficient of discharge

c	speed of sound (in distance per unit time)
$\cos \alpha$	cosine of the angle alpha
°C	temperature in degrees Celsius
$CORR_{wl}$	correction (in units of distance) to subtract from the wet-line depth to obtain the vertical depth
D_{wl}	wet-line depth (in units of distance)
D_v	vertical depth (in units of distance)
Δs	average change in stage in the reach *L* during the measurement (in units of distance)
Δt	elapsed time during measurement
$\Delta \alpha$	computed phase difference
°F	temperature in degrees Farenheit
H	weighted mean gage height (in units of distance)
h	static head, head, elevation, or gage height (in units of distance)
IQR	interquartile range
L	length of reach between measuring section and control (in units of distance)
m	difference (in feet) between the air-line correction for the sounding position and that for the 0.8 position
n	difference (in feet) between the wet-line correction for the sounding position and that for the 0.8 position, if the depths are greater than 40 feet and the change in vertical angle is more than 5 percent
P	vertical angle (in degrees)
α	ratio of the circumference to the diameter of a circle; approximately equal to 3.14159
Q	discharge (in volume per unit time)
$Q1$	25 percent of samples are less than this value
$Q3$	75 percent of samples are less than this value
q_i	discharge through partial section i, (in volume per unit time)
R	number of rotor revolutions per second
T	total time for the measurement
t_1	duration of time intervals between breaks in the slop of the gage height graph
tan	tangent
α	time lag between pulses
V	velocity (in distance per unit time)
Vx	velocity (in distance per unit time) in the x direction (perpendicular to the tag line)
Vy	velocity (in distance per unit time) in the y direction (parallel to the tag line)
V	volume of water in container
v_i	mean velocity (in units of distance per unit time) of the flow normal to the ith segment, or vertical
W	average width of stream between measuring section and control (in units of distance)
W_1	weight of empty container (in units of mass)
W_2	weight of container with water (in units of mass)
w	unit weight of water (in units of mass per volume)
x	x-direction (perpendicular to the tag line) or x-component of velocity

Discharge Measurements at Gaging Stations

By D. Phil Turnipseed and Vernon B. Sauer

Abstract

The techniques and standards for making discharge measurements at streamflow gaging stations are described in this publication. The vertical axis rotating-element current meter, principally the Price current meter, has been traditionally used for most measurements of discharge; however, advancements in acoustic technology have led to important developments in the use of acoustic Doppler current profilers, acoustic Doppler velocimeters, and other emerging technologies for the measurement of discharge. These new instruments, based on acoustic Doppler theory, have the advantage of no moving parts, and in the case of the acoustic Doppler current profiler, quickly and easily provide three-dimensional stream-velocity profile data through much of the vertical water column. For much of the discussion of acoustic Doppler current profiler moving-boat methodology, the reader is referred to U.S. Geological Survey Techniques and Methods 3–A22 (Mueller and Wagner, 2009).

Personal digital assistants (PDAs), electronic field notebooks, and other personal computers provide fast and efficient data-collection methods that are more error-free than traditional hand methods. The use of portable weirs and flumes, floats, volumetric tanks, indirect methods, and tracers in measuring discharge are briefly described.

Purpose and Scope

The U.S. Geological Survey (USGS) makes tens of thousands of streamflow measurements each year across the United States and its territories. Measured discharges range from a trickle in a small ditch or stream [less than 0.01 cubic foot per second (ft^3/s)], to a flood on the Mississippi River (greater than 1,800,000 ft^3/s). Several methods are used by the USGS to make streamflow measurements. Principally, the USGS uses mechanical current meters and hydroacoustic meters [for example, acoustic Doppler current profilers (ADCPs) and acoustic Doppler velocimeters (ADVs)]. The purpose of this report is to describe the equipment and procedures used by the USGS and others for making discharge measurements, and to describe new developments in equipment and procedures. Other traditional methods of measuring streamflow include portable weirs and flumes, and volumetric, float, indirect, and tracer measurements. Relatively new developments include the use of a moving boat with the ADCP (Mueller and Wagner, 2009), the wading rod mounted ADV, electromagnetic current meters, electronic field notebooks, personal digital assistants (PDAs), and various procedural changes.

The original version of USGS Techniques of Water-Resources Investigations book 3, chapter A8 (TWRI 3–A8), by Buchanan and Somers (1969), was used as an extensive resource in the preparation of this publication because much of the equipment and techniques described by Buchanan and Somers are still applicable to current streamgaging methods. The USGS publications "Measurement and Computation of Streamflow, volumes 1 and 2," by Rantz and others (1982); "Discharge measurements using a broad-band acoustic Doppler current profiler," by Simpson (2002); "Quality-assurance plan for discharge measurements using acoustic Doppler current profiler," by Oberg and others (2005); and "Measuring discharge with acoustic Doppler current profilers from a moving boat," by Mueller and Wagner (2009), were also used extensively in the preparation of this publication. Numerous parts of this chapter were taken verbatim from Buchanan and Somers (1969), Rantz (1982), Simpson (2002), Oberg and others (2005), and Mueller and Wagner (2009), and even though some of these parts are not specifically denoted, credit is hereby given to these authors.

Definition of Streamflow

Streamflow, or discharge, is defined as the volumetric rate of flow of water (volume per unit time) in an open channel, including any sediment or other solids that may be dissolved or mixed with it that adhere to the Newtonian physics of open-channel hydraulics of water. The definition of streamflow in this chapter does not include non-Newtonian flow events such as debris flows and lahars (an avalanche of volcanic mud and water down the slopes of a volcano). Streamflow in the USGS is usually expressed in English dimensions of cubic feet per second (ft^3/s). Other common units are million gallons per day (Mgal/d) and acre-feet per day (ac-ft/d). Streamflow cannot be measured directly but must be computed from variables that can be measured directly, such as stream width, stream depth, and streamflow velocity. Even though streamflow is computed from measurements of other variables, the term "streamflow measurement" or "discharge measurement" is generally applied to the final result of the calculations.

Discharge Measurements at Gaging Stations

Procedures for making most types of current-meter [mechanical meters, electromagnetic meters, ADV meters, acoustic digital current meters (ADCs), and so forth)], moving-boat ADCP, and ADCP midsection measurements are described in the following sections. For much of the discussion of moving-boat ADCP, the reader is referenced to Mueller and Wagoner (2009). The chapter includes discussions on the selection of a measuring section, laying out the stationing for subsection verticals, width measurements, depth measurements, velocity measurements, direction of flow measurements, and recording of field notes. Additional details that pertain to instrumentation and specific types of measurements, such as wading, cableway, bridge, boat, and ice, are described in subsequent sections. Special procedures such as networks of current meters, measurement of deep, swift streams, and measurements during rapidly changing stage are also described.

Velocity-Area Method

The most practical method of measuring the discharge of a stream is the velocity-area method. Discharge is computed as the product of the area and velocity. The measurement is made by subdividing a stream cross section into segments (sometimes referred to as partial areas, sections, subareas, verticals, stations, profiles, panels, or ensembles), and by measuring the depth and velocity in a vertical within each segment. The total discharge is the summation of the products of the partial areas of the stream cross section and their respective average velocities. This computation is classically expressed by the equation

$$Q = \sum_{i=1}^{n} a_i v_i, \tag{1}$$

where Q total discharge, in cubic feet per second,
a_i cross-section area, in square feet, for the ith segment of the n segments into which the cross section is divided, and
v_i the corresponding mean velocity, in feet per second of the flow normal to the ith segment, or vertical.

Midsection Method

The current-meter midsection method of making a current-meter discharge measurement is used by the USGS and others. The method assumes that the mean velocity in each vertical represents the mean velocity in a partial rectangular area (segment). The mean velocity in each vertical is determined by measuring the velocity at one or more selected points in that vertical, as described in a later section of this chapter. The cross-section area for a segment extends laterally from half the distance from the preceding vertical to half the distance to the next vertical, and vertically, from the water surface to the sounded depth as shown in figure 1.

The cross section in figure 1 is defined by depths at locations 1, 2, 3, 4, . . . , n. At each location, the velocities are sampled by current meter to obtain the mean of the vertical distribution of velocity. The partial discharge is now computed for any partial section (segment) at location i as

$$q_i = v_i \left[\frac{\left(b_i - b_{(i-1)}\right)}{2} + \frac{\left(b_{(i+1)} - b_i\right)}{2} \right] d_i, \text{ or} \tag{2}$$

$$= v_i \left[\frac{b_{(i+1)} - b_{(i-1)}}{2} \right] d_i, \tag{3}$$

where q_i discharge through partial section i,
v_i mean velocity at location i,
b_i distance from initial point to location i,
$b_{(i-1)}$ distance from initial point to preceding location,
$b_{(i+1)}$ distance from initial point to next location, and
d_i depth of water at location i.

Thus, for example, the discharge through partial section 4 (heavily outlined in figure 1) is

$$q_4 = v_4 \left[\frac{b_5 - b_3}{2} \right] d_4. \tag{4}$$

The procedure is similar when i is at an end section. The "preceding location" at the beginning of the cross section is considered coincident with location 1; the "next location" at the end of the cross section is considered coincident with location n. Thus,

$$q_1 = v_1 \left[\frac{b_2 - b_1}{2} \right] d_1, \text{ and} \tag{5}$$

$$q_n = v_n \left[\frac{b_n - b_{(n-1)}}{2} \right] d_n. \tag{6}$$

For the example shown in figure 1, q_1 is zero because the depth at observation point 1 is zero. However, when the cross-section boundary is a vertical line at the edge of the water as at location n, the depth is not zero and velocity at the end section may or may not be zero. Equations 5 and 6 are used whenever there is water only on one side of an observation point, such as at the edge of the stream, piers, abutments, and islands. It usually is necessary to estimate the velocity at an end section because it normally is impossible to measure the velocity accurately with the current meter close to a boundary. There also is the possibility of damage to the equipment if the flow is turbulent. The estimated velocity is usually made as a percentage of the adjacent section.

The summation of the discharges for all the partial sections is the total discharge of the stream. An example of the measurement notes is shown in figure 2*A*. In the hydraulic properties reported, the summation of discharges from an ADV discharge

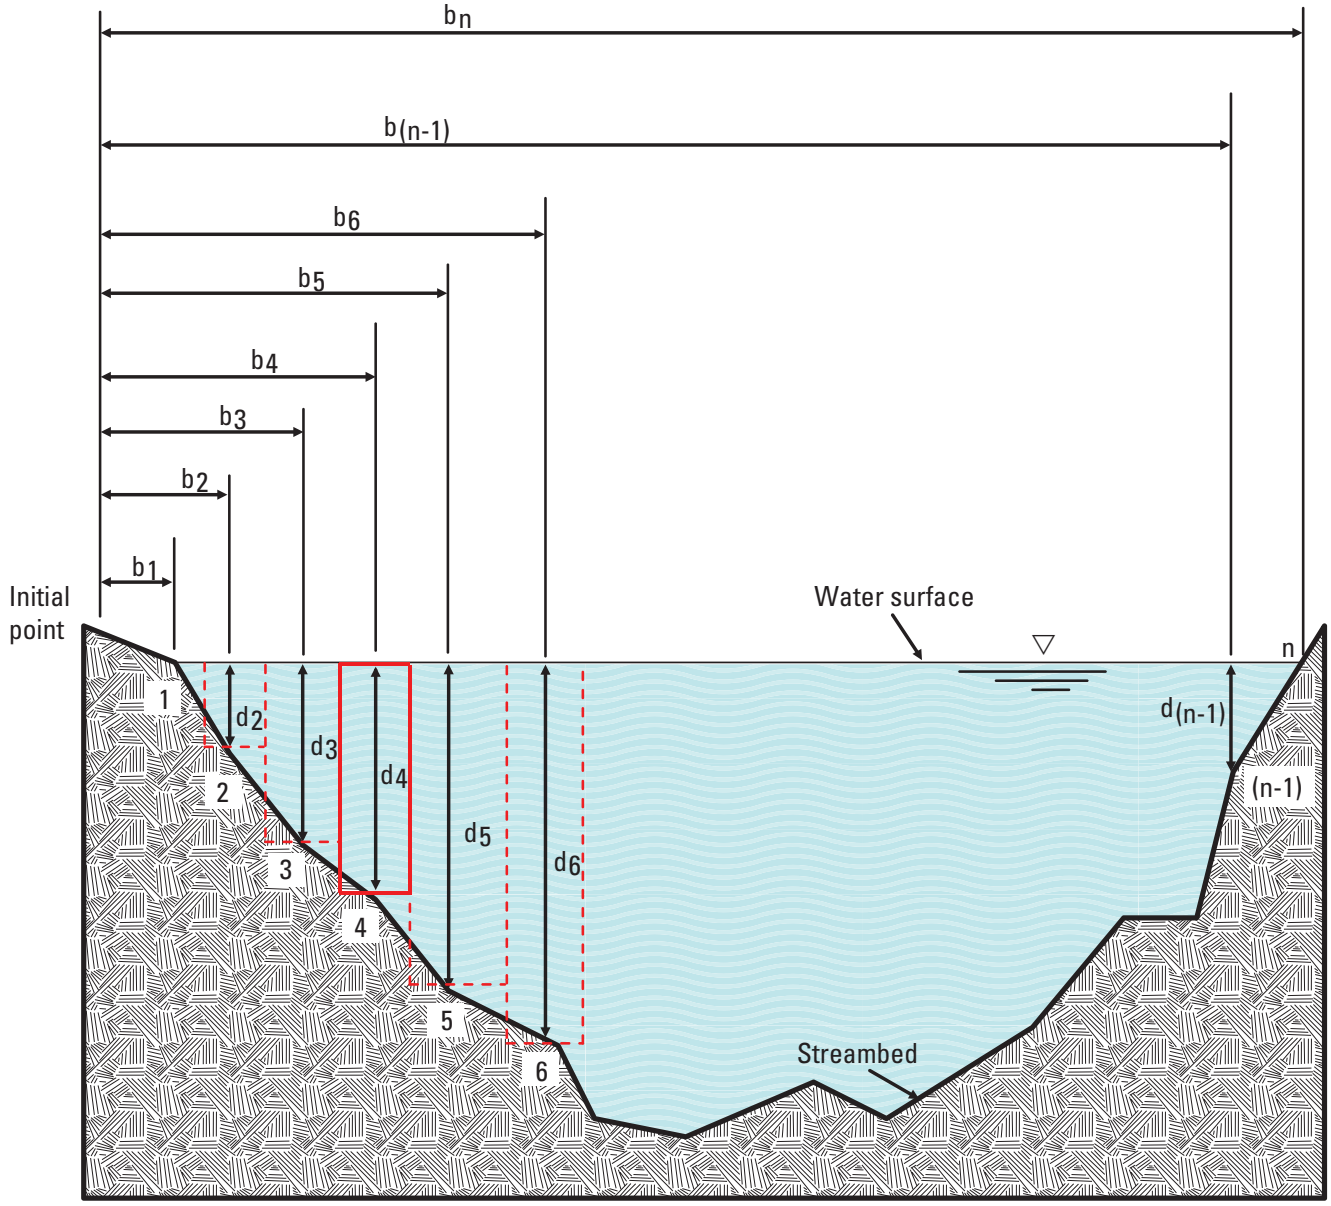

Figure 1. Definition sketch of the current-meter *midsection* method of computing cross-section area for discharge measurements.

measurement (fig. 2*B*) is similar to that of a current meter; however, it is designed to report the properties inherent to the ADV software and signal processing necessary to compute discharge using acoustic Doppler technology. A program written by staff in the USGS Maine Water Science Center entitled Surface Water Measurements and Inspections (SWAMI) has become common in use in the USGS with a PDA, and may be used to record discharge measurements, inspections, differential level surveys, and other field measurements (fig. 2*C*).

Included here for convenience is a typical, well-documented ADCP discharge measurement (fig. 2*D*). This measurement serves as an example of how an ADCP measurement note should be kept in the field. Further discussion of ADCP measurements can be found in subsequent sections of this chapter.

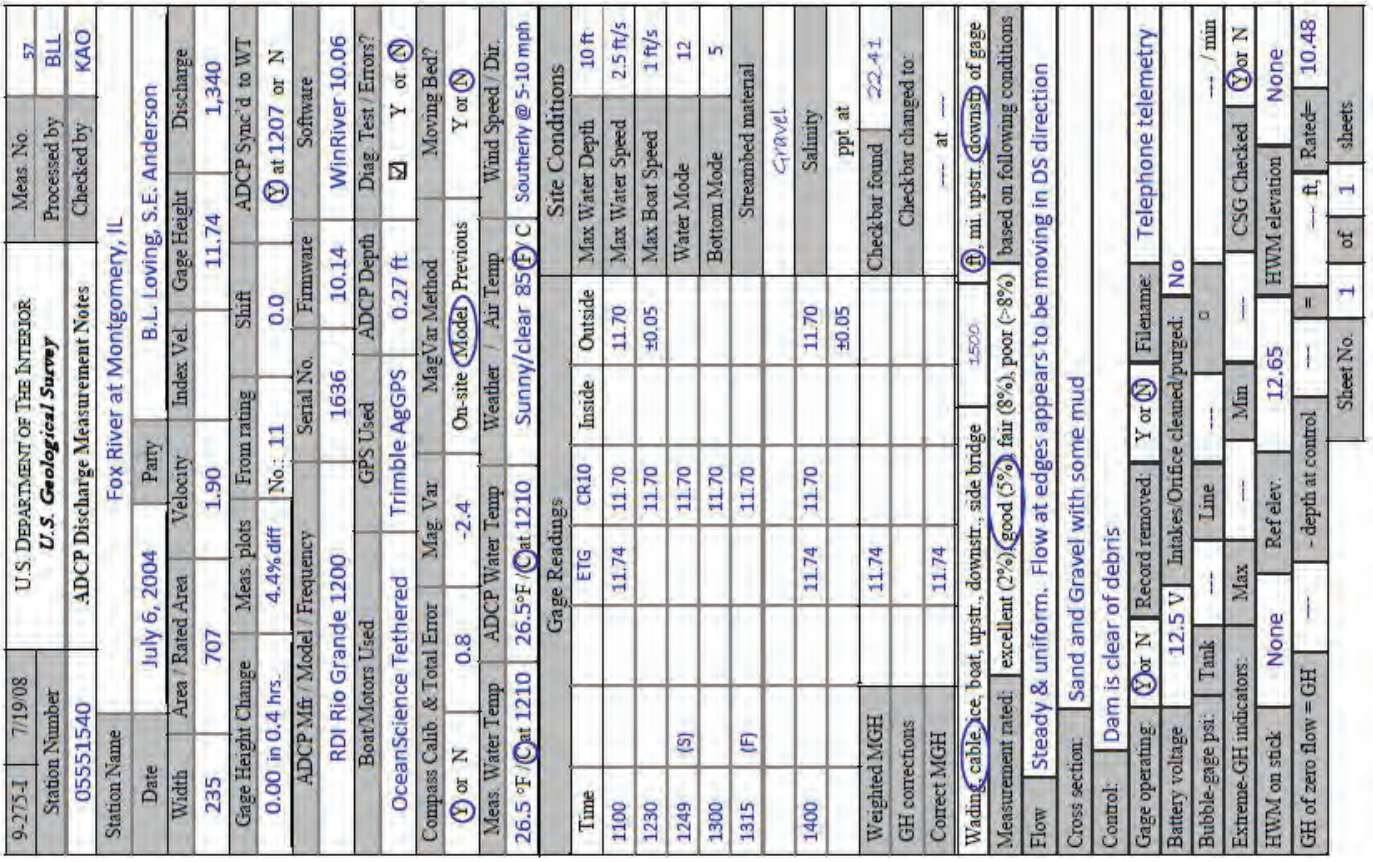
Notes	All times are in CST. Measurement was made using a temporary rope-and-pulley cableway. Edge distances were measured with laser rangefinder by marking the start and ending positions on the rope and measuring the distance from edge of water to the center of the tethered boat.						



D

The mean-section method used by the USGS prior to 1950 differs from the midsection method in computation procedure. Partial discharges are computed for partial sections between successive verticals. The velocities and depths at successive verticals are each averaged, and each partial section extends laterally from one vertical to the next. Discharge is the product of the average of two mean velocities, the average of two depths, and the distance between verticals. A study by Young (1950) concluded that the midsection method is simpler to compute and is a slightly more accurate procedure than the mean-section method.

Site Selection

The first and most critical step in making a midsection current-meter or ADV measurement, or an ADCP measurement is to select a measurement cross section of desirable qualities. If the stream cannot be waded, nor high-water measurements made from a bridge, moving or tethered boat, or cableway, the hydrographer may have little or no choice in selecting a measurement cross section. If the stream can be waded or the measurement can be made from a boat, the hydrographer should look for a cross section with the following characteristics:

- There is a reasonably straight channel with streamlines parallel to each other; a stable streambed free of large rocks, weeds, and obstructions that would create eddies, slack water, and turbulence; and desirable measurement sections that are roughly parabolic, trapezoidal, or rectangular. These conditions are obviously not always possible, but remember that most current meters are rated in a still water tank by towing them through the tank at a known speed. With that in mind, these are conditions a hydrographer should seek in the field: a smooth, mirror-like water surface with steady, uniform, nonvarying flow conditions in the stream reach where the discharge measurement will be taken.
- The velocities are, for the most part, greater than 0.5 ft/s, and depths that are greater than about 0.5 ft. These conditions are not always possible to find in the field.
- The measurement section is relatively close to the gaging station control to avoid the effect of tributary and (or) intervening drainage area inflows between the measurement section and the control, and to avoid the effect of channel storage between the measurement section and the control during periods of changing stage.

It is usually not possible to satisfy all of these conditions. Select the best possible reach using these criteria and then select a cross section. For a further discussion regarding site selection when using a mechanical or other point-velocity current meter refer to Rantz and others (1982).

For convenience, special site-selection considerations for an ADCP discharge measurement are presented as follows, and further discussion of ADCP methods and instruments is presented in subsequent sections of this chapter:

- The minimum depth near the left and right edges of water at the measurement site should allow for the measurement of velocity in two or more depth cells while being close enough to minimize the estimated edge discharges.
- Make sure velocities are, for the most part, greater than 0.5 ft/s, and depths are greater than the minimum depth required by the ADCP. Although measurements can be made in low velocities, keep boat speeds extremely slow (if possible, less than or equal to the average water velocity), which requires special techniques for boat control (Simpson, 2002).
- Avoid measurement sections having local magnetic fields, especially if a moving bed is present and a Global Positioning System with differential corrections (DGPS) or the Loop Method (Mueller and Wagoner, 2006) is used. For example, during measuring, avoid overhead truss bridges, low steel-beam spans, power lines, and other sources of magnetic fields. Just as with ADCP mounts and boats, the presence of ferrous metals will result in ADCP compass errors.
- If possible, avoid asymmetric channel geometries (for example, deep on one side and shallow on the other; Simpson, 2002) and avoid cross sections with abrupt changes in channel-bottom slope. The streambed cross section should be as uniform as possible and free from debris and vegetation or plant growth.
- When using DGPS with an ADCP, avoid cross-section locations where multipath interference, such as riparian vegetation (low-hanging trees and large bushes on river or stream banks), buildings at or near the river banks, bridges, and other flow-control structures, could impede or block signals from GPS satellites.

It is usually not possible to attain all of these conditions, but site selection cannot be understated as a critical part of a discharge measurement. Select the best possible reach using these criteria and then select a cross section. For more discussion regarding site selection when using an ADCP, refer to Mueller and Wagner (2009).

Layout and Stationing of Partial Sections and Verticals in a Midsection Current-Meter Discharge Measurement

After the cross section has been selected, determine the width of the stream. For a mechanical current-meter or other point-velocity measurement, string a tag line or measuring tape for measurements made by wading, from a boat, from ice cover, or from an unmarked bridge. Except for bridges, string the line

at right angles to the direction of flow to avoid horizontal angles in the cross section. For cableway or bridge measurements, use the graduations painted on the cable or bridge rail. Next, determine the spacing of the verticals, generally using about 25 to 30 partial sections. With a smooth cross section and even velocity distribution, fewer partial sections may be used. Space the partial sections so that no partial section has more than 10 percent of the total discharge in it. The ideal measurement is one in which no partial section has more than 5 percent of the total discharge in it; this can be challenging when only 25 partial sections are used. For example, the discharge measurement shown in figure 2*A* had 6.5 percent of the total discharge in the partial section with the greatest discharge. Equal widths of partial sections across the entire cross section are not recommended unless the discharge is evenly distributed. Lessen the width of the partial sections as depths and velocities become greater. Usually an approximate or expected total discharge can be obtained from the stage-discharge curve. Space the verticals so the discharge in each partial section is about 5 percent of the expected total discharge from the rating curve. When using an electronic field notebook [such as the JBS Instruments Aquacalc Pro Discharge Measurement Computer (Aquacalc), a PDA with the Hydrological Services Current Meter Counter signal processor (CMCsp), or the SonTek FlowTracker], the expected total discharge can be entered prior to starting the discharge measurement. During the measurement, a warning message will be displayed if a partial discharge exceeds 10 percent of the expected total discharge. When using an ADV or other acoustic point-velocity instrument, make sure the instrument is appropriately aligned and plumbed to the tag line because slight variations in the alignment of the instrument can result in large errors in the measurement of point velocity. See further discussion of the use of acoustic point-velocity instruments in this chapter.

For a standard mechanical current-meter discharge measurement, the usual procedure, after selecting and laying out the section, is to measure and record at each vertical (1) the distance from the initial point, (2) the depth, (3) the meter position, (4) the number of revolutions, (5) the time interval, and (6) the horizontal angle of flow. The starting point can be either bank. The edge of water, which may have a depth of zero, is considered to be the first vertical. The hydrographer should move to each of the verticals in succession and repeat the procedure until the measurement is completed at the opposite bank.

Measurement of Width

The first measurement made in a discharge measurement is usually the determination of horizontal stationing (width) in the cross section being measured. Width needs to be measured using the proper equipment and procedures that apply to the type of measurement being made (that is, wading, bridge, cableway, boat, or ice). Details of measuring width using a variety of equipment, and under different flow conditions, are described in subsequent sections of this chapter.

The horizontal distance to any vertical in a cross section is measured from an initial point on the bank. Cableways and bridges used regularly for making discharge measurements are commonly marked at 2-, 5-, 10-, and (or) 20-ft intervals by paint marks. Distance between markings is interpolated, or measured with a rule or pocket tape. Steel or Kevlar tag lines and metallic tapes are used for measurements made by wading, from boats, or from unmarked bridges. For wide streams of about 2,500 ft or more, where conventional measuring methods cannot be used, surveying methods and Global Positioning Systems (GPS) can be used.

Tapes and Tag Lines

Tag lines used for wading measurements are usually made of either galvanized steel aircraft cord with solder beads at measured intervals, or Kevlar, which is marked with black ink and waxed to resist abrasion. A Kevlar tag line consists of a Kevlar core with a nylon jacket.

The standard arrangement of solder beads on steel tag lines is shown in table 1. The standard markings for Kevlar tag lines is one mark every 2 ft, two marks every 10 ft, and three marks every 100 ft. The standard lengths of tag lines are 300, 400, and 500 ft, but other sizes are available.

Four types of tag-line reels typically used for the steel tag lines are the Lee-Au, Pakron, Columbus type A, and the USGS Stainless Steel Tag line as shown in figure 3. The reel used for the Kevlar tag line is shown in figure 4.

Larger reels, used for boat measurements, are designed to hold up to 3,000 ft of ⅛-inch (in.) diameter steel tag line. These reels and boat measurement methods have largely been replaced by the ADCP technology. Two different types of reels still available are as follows:

- A heavy-duty, horizontal-axis reel without a brake, and with a capacity of 5,000 ft of ⅛-in. beaded tag line or 3,000 ft of $^{3}/_{16}$-in. Kevlar boat tag line, as shown in figure 5.
- A vertical-axis reel without a brake (fig. 6), and with a capacity of 1,500 ft of ⅛-in diameter steel tag line (800 ft tag lines are standard) or up to 900 ft of 3/16-in. Kevlar boat tag-line cable.

Table 1. Standard markings for steel tag lines.

Distance from initial point (zero mark), in feet	Distance between marks, in feet	Number of solder beads, or tags
0 to 50	2	1 (single bead)
50 to 100	5	1
150 to 500	10	1
0 to 50	10	2 (double bead)
50 to 450	100	2
0 to 500	100	3 (triple bead)

Surveying Methods of Width Measurement, Surveying Level, and Electronic Total Station

For wide streams where it is not practical to string a tag line for discharge measurements from a boat, surveying methods can be used to measure stream width and stationing for measurement points. Surveying methods require the use of a surveying level, as shown in figure 7, or electronic total station instrumentation, as shown in figure 8. The procedure to determine width with a transit is used less frequently, but is described in the section of this chapter on boat measurements.

With the advent of electronic total station surveying instruments and digital surveying levels, a direct reading of the distance can be made from the digital surveying level or from the total station instrument setup point to the boat. One example of a commercially available total station instrument is shown in figure 8. Most of these instruments require a reflector target at the point where a measurement is desired (in this case the boat); however, total station instruments are also available that provide accurate measurements of distance without a reflector target. Accurate distance measurements can be made with total station instruments over distances of 1 mi or more, provided the boat can be seen and not obstructed by intervening objects.

Figure 7. Surveying level and tripod.

Figure 8. Total station surveying equipment: A, instrument and tripod and B, instrument reflector targets and surveying tape.

Global Positioning System With Differential Corrections

Measurement points can be stationed for wide streams, such as flood plains that may be several miles wide, or large tidal estuaries, with a global positioning system with differential corrections (DGPS) instrument, such as that shown in figure 9, which is a real-time kinematic (RTK) GPS base station with radio transmitter. RTK-GPS and other DGPS instruments utilize satellite telemetry from an array of satellites, and use radio triangulation to compute positions for any point on the Earth. In order to obtain the accuracy necessary for a discharge measurement, the raw GPS positions must have differential corrections applied on the basis of simultaneous readings at a base station. Most DGPS units contain built-in differential correction receivers that make automatic and instantaneous corrections. Other GPS units may use a separate receiver that attaches to the GPS unit with a cable. In either case, base station data are received by radio signal from nearby ground base stations or via communications satellites from a network of ground stations, such as the Wide Area Augmentation System (WAAS).

A surveying grade DGPS unit with capability of storing and recalling data is preferred. These units may or may not have built-in or attached differential correction receivers. If instantaneous differential corrections are not made, then use correction data obtained after the fact from a separate GPS base station to postprocess coordinate data. Various agencies collect and provide the base station data via the Internet. Coordinate data for the measurement points are downloaded from the GPS unit to a computer for postprocessing. Software is available to make the differential corrections, to compute corrected coordinates of the measurement points, and to automatically compute distances between and to plot a map of the measurement points.

Figure 9. Global positioning system with real-time kinematic (RTK–GPS) base station and radio transmitter.

Accuracy of GPS coordinates will vary depending on the type of GPS unit used and whether or not differential corrections are made. Coordinates without differential corrections can be in error by as much as ±300 ft because of various errors in the system. Obviously, this is not acceptable for discharge measurements. However, if care is taken in making observations, and then making differential corrections, errors can be reduced to as little as ±3 ft, and even less in ideal conditions. This method is acceptable for wide flood plains and inaccessible estuaries with open skies and minimal reflective surfaces, which can result in multipath errors.

Measurement of Depth

The second measurement normally made at a vertical is the stream depth. Depth should be measured using the proper equipment and procedures that apply to the type of measurement being made (that is, wading, bridge, cableway, boat, or ice). Details of measuring depth using various equipment and under different flow conditions are described in the following sections of this chapter. The water depth of a stream at a selected vertical can be measured in several ways, depending on the type of measurement being made, the total depth of the stream, and the velocity of the stream. Stream depth is usually measured by use of a wading rod, sounding lines and weights, acoustic Doppler sensor, or another sonic sounder, as described in the following sections of this chapter.

Use of Wading Rod

Use a wading rod for measuring stream depth when depth is shallow enough, or when measuring from a low footbridge or other supportive structure over the stream. Likewise, use the wading rod for measuring from ice cover for shallow depths. Wading rods can even be used from a boat if depths are not too great. The top-setting wading rod can be used for depths up to 4 ft, but greater depths can be measured with 6-, 8-, and 10-ft top-setting wading rods. The round wading rod, which is assembled with 1-ft sections, can be made up into any length, but generally is not used for depths greater than about 10 ft. Velocity of flow is also a consideration because high velocity may not allow for keeping a long wading rod in place.

Wading rods have a small foot on the bottom to allow the rod to be placed firmly on the streambed, and yet not sink into the streambed under most conditions. In sand-bottom streams, or in soft muck, it is sometimes difficult to keep the wading rod from sinking into the streambed as the weight of the rod and meter and the eroding power of the flowing water cause the foot of the wading rod to sink. The hydrographer must use care in these conditions to be sure the measured water depth, as well as the depth of the current-meter placements, are accurately based on the surface of the streambed. In some cases, the wading rod may need to be supported in some manner other than resting on the streambed.

When using a wading rod in streams with moderate-to-high velocity, there will be a velocity-head build-up of water on the wading rod. The stream depth should be based on where the surface of the stream intersects the wading rod, and not on the top of the velocity-head build-up. Wading rods are graduated in tenths-of-a-foot, and stream depths are generally measured or estimated and recorded to the nearest 0.01 ft.

Use of Sounding Lines and Weights

Water depth is measured with sounding lines and weights when the depth is too great to use a wading rod, and when measuring conditions require measuring from a bridge, cableway, or boat. This section will describe the measurement of depth when using sounding reels and handlines. It also discusses the procedures used to correct observed depths when high velocity causes the weight and meter to drift downstream.

Use of Sounding Reels

When using one of the sounding reels described in a subsequent section of this chapter, a counter or dial is used to determine the length of cable that has been dispensed. Depths are measured to the nearest 0.1 ft when using a sounding line and weight.

The size of the sounding weight used in current-meter measurements depends on the maximum depth and velocity in a cross section. A rule of thumb is that the size of the weight in pounds should be greater than the maximum product of velocity and depth in the cross section. If insufficient weight is used, the sounding line will be dragged at an angle downstream. If debris or ice is flowing or if the stream is shallow and swift, a heavier weight can be used than the rule designates. The rule is not rigid but it does provide a starting point for deciding on the size of the weight that is needed. If available, notes can be examined of previous measurements at a site to help determine the size of the weight needed at various stages.

Some sounding reels are equipped with a computing depth indicator, or spiral. To use the computing spiral, the dial pointer must be set at zero when the center of the current-meter rotor is at the water surface. After the sounding weight and meter are lowered until the weight touches the streambed, and the indicated depth should be read. The distance that the meter is mounted above the bottom of the weight should be added. For example, if a 30 C .5 (that is, a 30-pound Columbus weight is being used and the center of the meter cups is 0.5 ft above the bottom of the weight) suspension is used and the dial pointer reads 18.5 ft when the sounding weight touches the streambed, the depth would be 19.0 ft (18.5 + 0.5). To move the meter to the 0.8-depth position, merely raise the weight and the meter until the pointer is at the 19-ft mark on the graduated spiral, which will correspond to 15.2 ft on the main dial (0.8 × 19.0). To set the meter at the 0.2-depth position, raise the weight and meter until the pointer is at 3.8 ft on the main dial (0.2 × 19.0).

Tags can be placed on the sounding line a known distance above the center of the meter cups as an aid in determining depth. The tags, which are usually streamers of

different-colored binding tape, are fastened to the sounding line by solder beads or by small cable clips. Tags are used for determining depth in two ways; the following is the preferred procedure:

1. Set the tag at the water surface and then set the depth indicator to read the distance of that tag above the center of the meter cups.
2. Continue as if the meter cups themselves have been set at the water surface.
3. When the weight touches the streambed, read the depth indicator and add the distance that the meter is above the bottom of the weight to obtain the total depth.
4. Use the spiral indicator, as described above, for setting the 0.8-depth meter position. If debris or ice is flowing, this method keeps the meter below the water surface and helps to prevent damage to the meter.

This is an alternate method that is sometimes used with handlines and sounding reels: With the sounding weight on the streambed, raise the weight until the first tag below the water surface appears at the surface. If using a reel, determine the distance the weight was raised by subtracting before and after readings of the depth indicator; if using a handline, use a tape or measuring stick. The total stream depth is the sum of (a) the distance the weight was raised to bring the tag to the water surface, (b) the distance the tag is above the center of the meter cups, and (c) the distance from the bottom of the weight to the center of the cups.

Use of a Handline

Although rarely used in the USGS, handlines still provide a viable means of measuring discharge from bridges. When using a handline, unwind enough cable from the handline reel to keep the reel out of water when the sounding weight is on the streambed at the deepest part of the cross section. If the bridge is high enough above the water surface, raise and lower the weight and meter by the rubber-covered cable rather than by the bare cable.

The usual procedure for determining depths is to set the meter cups at the water surface and then lower the sounding weight to the streambed while measuring the amount of line needed to reach the streambed. Measure along the rubber-covered service cord with a steel or metallic tape or a graduated rod to determine the distance the weight is lowered. This measured distance, plus the distance from the bottom of the sounding weight to the meter cups, is the depth of water. When the meter is set for the velocity observation, stand on the rubber-covered cable or tie it to the handrail to hold the meter in place. This arrangement frees the hands to record the data.

Another method of determining depth when using a handline includes the use of tags set at a known distance above the meter. Lower the sounding weight to the streambed, and then raise the weight until one of the tags is at the water surface. Measure along the rubber-covered service cord with a steel or metallic tape or a graduated rod to determine the distance the weight is raised. The total depth of water is then the summation of (1) the distance the particular tag is above the meter cups, (2) the measured distance the meter and weight was raised, and (3) the distance from the bottom of the weight to the meter cups.

Depth Corrections for Downstream Drift of Current Meter and Weight

Where it is possible to sound but the weight and meter drift downstream, the depths measured by the usual methods are too great. Figure 10 graphically illustrates this condition. The correction for this error has two parts, the air correction and the wet-line correction. The air correction is shown in figure 10 as the distance *cd*. The wet-line correction in figure 10 is shown as the difference between the wet-line depth *de* and the vertical depth *dg*.

As shown in figure 10, the air correction depends on the vertical angle *P* and the distance *ab*. The correction is computed as follows:

$$\cos P = \frac{ab}{ad} = \frac{ab}{ac+cd} = \frac{ab}{ab+cd} \Rightarrow$$
$$ab + cb = \frac{ab}{\cos P} \Rightarrow \quad , \qquad (7)$$
$$cd = \frac{ab}{\cos P} - ab = ab\left[\frac{1}{\cos P} - 1\right]$$

where $ab = ac$

The air correction for even-numbered angles between 4 degrees and 36 degrees and vertical lengths between 10 and 100 ft is shown in table 2. The correction is applied to the nearest tenth of a foot; hundredths are given to aid in interpolation.

Use of an air correction table may be nearly eliminated by using tags at selected intervals on the sounding line and using the tags to refer to the water surface. This practice is almost equivalent to moving the reel to a position just above the water surface.

The correction for excess length of line below the water surface is obtained by using an elementary principle of mechanics. If a known horizontal force is applied to a weight suspended on a cord, the cord takes a position of rest at some angle with the vertical. The tangent of the vertical angle of the cord is equal to the horizontal force divided by the vertical force owing to the weight. If several additional horizontal and vertical forces are applied to the cord, the tangent of the angle in the cord above any point is equal to a summation of the horizontal forces below that point, divided by the summation of the vertical forces below the point.

The distribution of total horizontal drag on the sounding line is in accordance with the variation of velocity with depth. The excess in length of the curved line over the vertical depth is the sum of the products of each tenth of depth and the function $[(1/\cos P) - 1]$ of the corresponding angles. The function is derived for each tenth of depth by means of the tangent relation of the forces acting below any point.

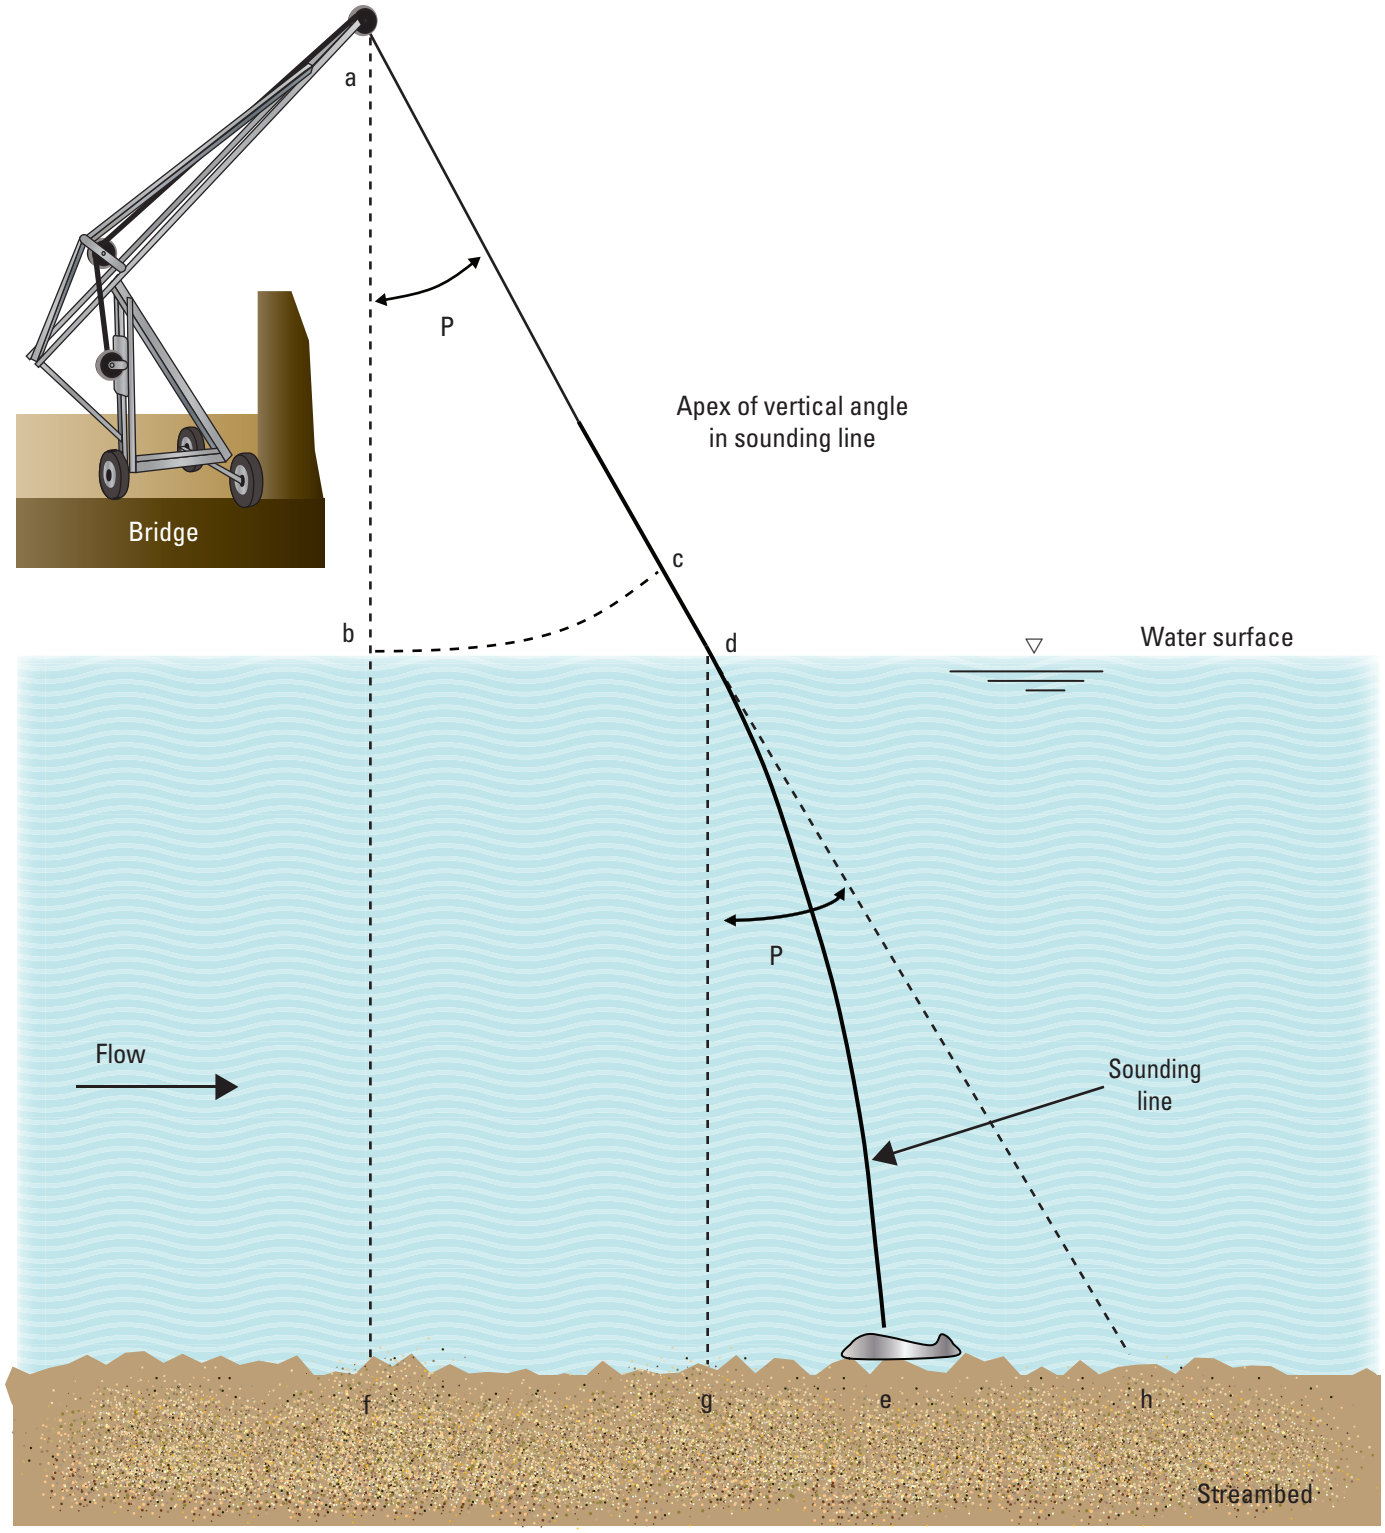

Figure 10. Position of sounding weight and line in deep, swift water.

The wet-line correction for even-numbered angles between 4 degrees and 36 degrees and wet-line depths between 10 and 100 ft is shown in table 3. The correction is applied to the nearest tenth of a foot. The wet-line correction cannot be determined until the air correction has been deducted from the observed depth.

The following assumptions were used in deriving the wet-line correction table:

1. The weight will go to the bottom despite the force of the current.
2. The sounding is made when the weight is at the bottom but entirely supported by the line.
3. Drag on the streamlined weight in the sounding position is neglected.
4. The air-line/wet-line table is generic and can be used for any size sounding weight or line, provided they are designed to offer little resistance to the current.

Wet-line corrections can also be computed with the equation below. This polynomial equation was derived by Kenneth L. Wahl (U.S. Geological Survey [ret.], Regional Surface Water Specialist, written commun., 2000) from the data in table 3, and reproduces the table values to within a few hundredths of a foot. It can be used in a field computer to quickly and easily compute wet-line corrections. With additional programming, depths and depth settings can also be computed.

$$CORR_{wl} = D_{wl} - D_v = \left(0.0004081 - 0.0001471 \times P + 0.00005731 \times P^2\right) \times D_{wl}, \quad (8)$$

where $CORR_{wl}$ the correction, in feet, to subtract from the wet-line depth to obtain the vertical depth,
D_{wl} the wet-line depth, in feet,
D_v the vertical depth, in feet, and
P the vertical angle, in degrees.

If the direction of flow is not perpendicular to the measuring section, the observed angle in the measuring line as indicated by a protractor will be less than the true angle of the line. The air correction and wet-line correction will then be too small. To correct for this, measure the horizontal angle between the direction of flow and a perpendicular to the measuring section with a protractor, or determine the horizontal angle coefficient as described in a subsequent section of this publication. The geometry of this condition is illustrated in figure 11.

If the horizontal angle of the direction of flow is called H, the observed vertical angle P, and the true vertical angle X, the relation between the angles is expressed by the equation

$$\tan X = \frac{\tan P}{\cos H}. \quad (9)$$

Table 4 gives the amounts in tenths of degrees. Add these to observed vertical angles to obtain the true vertical angles for a range of horizontal angles between 8 degrees and 28 degrees.

The conditions that cause error in sounding the depth also cause error in the placement of the meter at selected depths. The correction tables are not strictly applicable to the problem of placing the meter because of the increased pressure placed on the sounding weight by higher velocities when it is raised from the streambed. A meter placed in deep, swift water by the ordinary methods for observations at selected percentages of the depth will be too high in the water. The use of tables 2 and 3 will tend to eliminate this error in placement of the meter, and although not strictly applicable, their use for this purpose has become general.

For the 0.2-depth position, the curvature of the wet line is assumed to be negligible and the length of sounding line from the apex of the vertical angle to the weight is considered to be a straight line. The method used to place the meter at the 0.2-depth position is as follows:

1. Compute the 0.2 value of the vertical depth.
2. Lower the meter to this depth into the water and read the vertical angle.
3. Obtain the air correction from table 2. The vertical length used to obtain the air correction is the sum of (a) 0.2 of the vertical depth, (b) the distance from the water surface to the apex of the angle, and (c) the distance from the bottom of the weight to the meter.
4. Let out an additional amount of line equal to the air correction.

Table 2. Air correction table (in feet), giving differences between vertical length and slant length of sounding line above water surface for selected vertical angles.

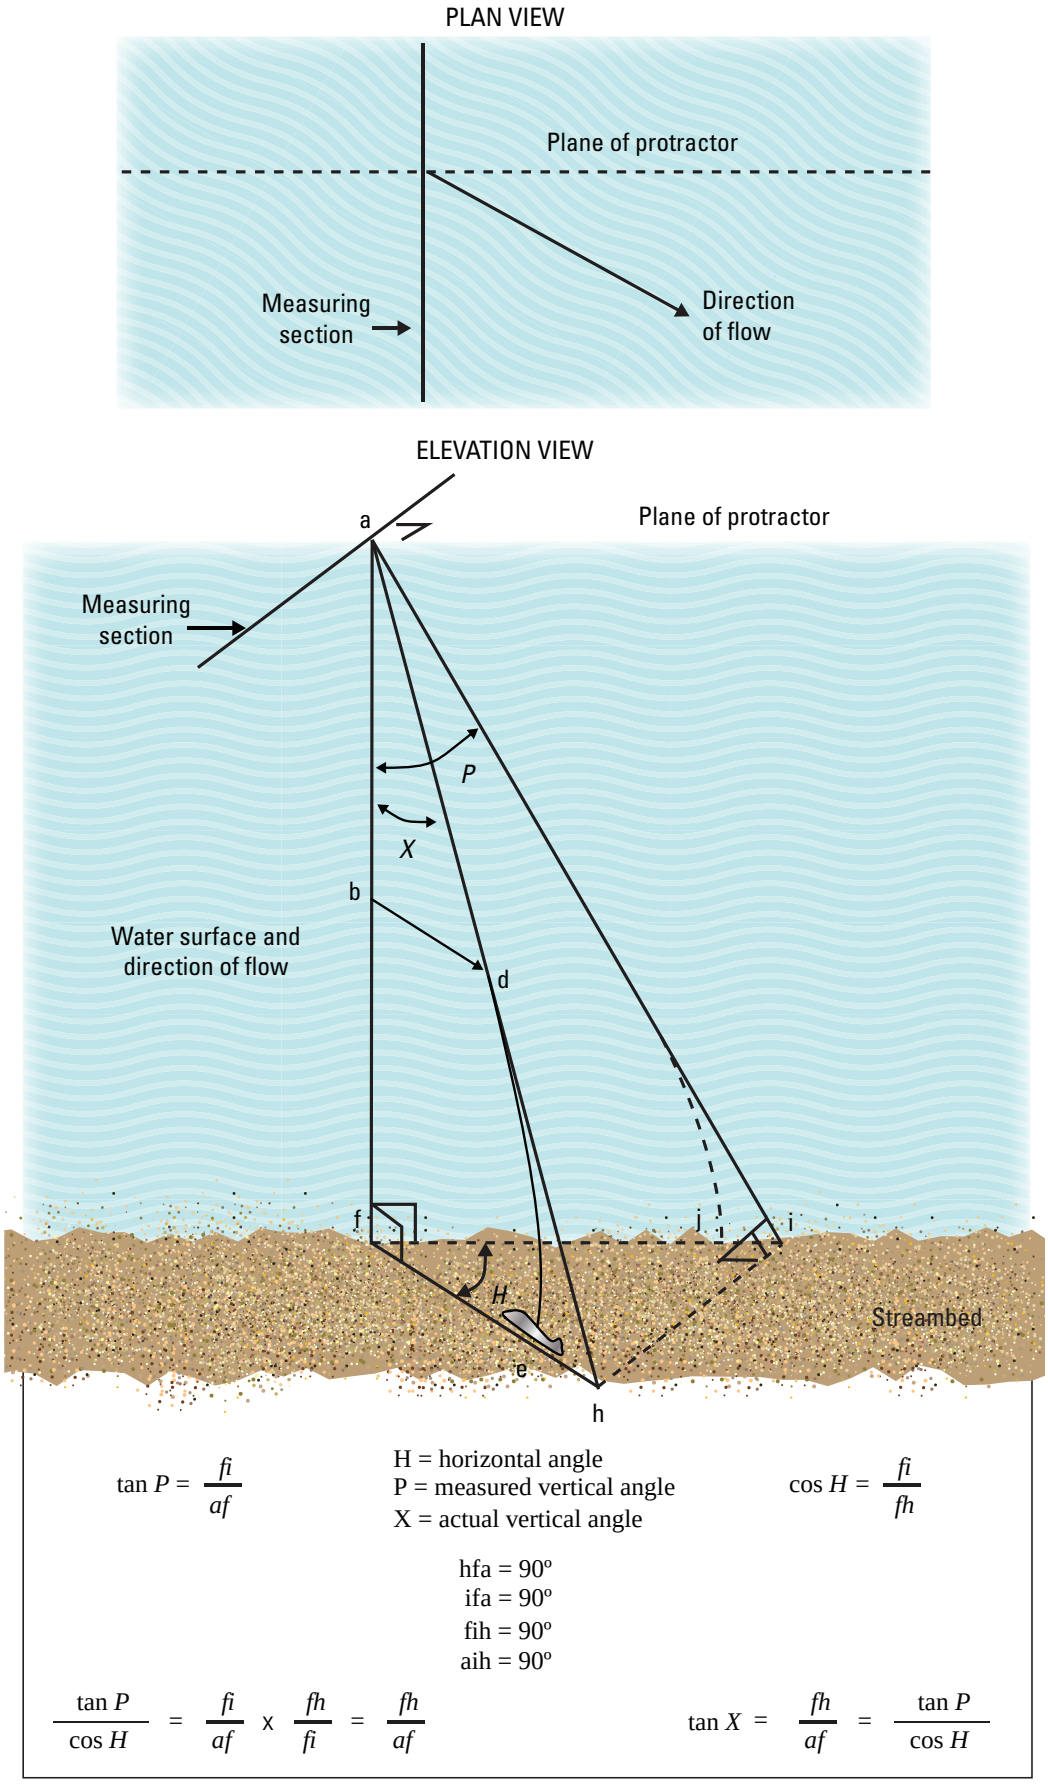

Figure 11. Sketch of geometric relationship of actual to measured vertical angle when flow direction is not normal to the measuring section.

5. If the angle increases appreciably when the additional line is let out, let out more line until the total additional line, the angle, and the vertical distance are in agreement with values presented in the air-correction table.

To place the meter at the 0.8-depth position, a correction to the amount of line reeled in must be made for the difference, if any, between the air correction for the sounding position and that for the 0.8-depth position. This difference is designated as *m* in table 5. If the angle increases for the 0.8-depth position, the meter must be lowered; if it decreases, the meter must be raised.

For the 0.8-depth position of the meter, the wet-line correction may require consideration if the depths are more than 40 ft and if the change in vertical angle is more than 5 percent. If the vertical angle remains the same or decreases, the wet-line correction (table 3) for the 0.8-depth position is less than the wet-line correction for the sounding position by some difference, designated as *n* in table 5. If the vertical angle increases, the difference in correction *n* diminishes until the increase in angle is about 10 percent; for greater increases in angle, the difference between corrections increases also. Table 5 summarizes the effect on air and wet-line corrections caused by raising the meter from the sounding position to the 0.8-depth position.

For slight changes in the vertical angle, because of the differences *m* and *n* in the air and wet-line corrections, the adjustments to the wet-line length of the 0.8-depth position are small and usually can be ignored. Table 5 indicates that the meter may be placed a little too deep if the adjustments are not made. Because of this possibility, the wet-line depth instead of the vertical depth is sometimes used as the basis for computing the 0.8-depth position with no adjustments for the differences *m* and *n*.

Use of Sonic Sounder

The sonic sounder has been used primarily for measuring depth when making a moving boat measurement and in ADCP discharge measurements, and is generally not utilized for measurements where sounding weights are used. However, it can be used in swift, debris-laden streams, where it is difficult or dangerous to lower the sounding weight and meter into the water. The sonic sounder will record the depth when the weight is just below the water surface. For moving boat measurements, the sonic sounder records a continuous trace of the streambed on a digital or analog chart. Details of the setup and use can be found in Smoot and Novak (1969). Relevant information on the use of acoustic sounders in a riverine environment is discussed in detail in Mueller and Landers (1999) and by the International Organization for Standardization (2003). For use of a sonic sounder in ADCP measurements, consult Mueller and Wagner (2009).

Table 4. Degrees to be added to observed vertical angle, *P*, to obtain true vertical angle when flow direction is not normal to measurement section.

Observed vertical angle, *P*, in degrees	Horizontal angle, *H*, in degrees					
	8 cos = 0.99	12 cos = 0.98	16 cos = 0.96	20 cos = 0.94	24 cos = 0.91	28 cos = 0.88
8	0.1	0.2	0.3	0.5	0.8	1.0
12	0.1	0.3	0.5	0.8	1.1	1.5
16	0.1	0.4	0.6	1.0	1.4	2.0

36	0.2	0.6	1.1	1.7	2.5	3.4

Table 5. Summary table for setting the meter at 0.8-depth position in deep, swift streams.

Change in vertical angle	Air correction		Wet-line correction	
	Direction of change	Correction to meter position	Direction of change	Correction to meter position
None	None	None	Decrease	Raise meter the distance *n*
Decrease	Decrease	Raise meter the distance *m*	Decrease	Raise meter the distance *n*
Increase	Increase	Lower meter the distance *m*	Decrease, then increase	[1]

[1]Raise meter the distance *n* unless the increase in angle is greater than about 10 percent, then it is necessary to lower the meter the distance *n*.

Measurement of Velocity

With point-velocity meters, after the width and depth at a vertical are measured and recorded, determine the method of velocity measurement. Normally the two-point method or the 0.6-depth method is used. Details of velocity measurement methods using various equipment and under different flow conditions are described in subsequent sections of this chapter.

Compute the setting of the meter for the particular method that will be used at that depth. For the top-setting wading rod, or the spiral-computing dial, some meter settings are self-computing. Record the meter position as 0.8, 0.6, 0.2, or another setting. After the meter is placed at the proper depth, let it adjust to the current before starting the velocity observation. With an ADV, make sure the instrument is located perpendicular to the tag line and the wading rod is plumbed (that is, vertical to the channel bed) before beginning measurement. The time required for adjustment to the undisturbed stream velocity is usually only a few seconds if the velocities are greater than 1 ft/s; however, for lower velocities, particularly if the current meter is suspended by a cable, a longer period of adjustment is needed. After the meter has become adjusted to the current, count the number of revolutions made by the rotor for a period of 40 to 70 seconds; for an ADV, this time period is typically programmed into the instrument's discharge measurement software.

If using a stopwatch to time the revolutions of a mechanical current meter, start the stopwatch simultaneously with the first signal or click, counting "zero," not "one." End the count on a convenient number given in the mechanical current meter rating table column heading. Stop the stopwatch on that count and read the time to the nearest second. Record the number of revolutions and the time interval. If the velocity is to be observed at more than one point in the vertical, determine the meter setting for the additional observation, set the meter to that depth, time the revolutions, and record the data.

When using a current meter digitizer (CMD), a personal digital assistant (PDA), or an electronic notebook such as the Aquacalc or an ADV, observe the same basic procedure for setting the meter, and for providing time for the meter to stabilize. With these instruments, however, the counting and timing of the rotor revolutions or the acoustic pulse measurement are performed automatically. The number of revolutions, time, and velocity displayed by the CMD must be transferred manually to paper field notes, whereas, these data are electronically recorded by the Aquacalc, a PDA, or an ADV. When using any of these automatic meter counting devices and a mechanical current meter, make sure that multiple counts are not occurring during measurement of slow velocity. This can sometimes be determined by visually observing the rotation of the rotor while simultaneously listening to the audible clicks or beeps from the counting device. With the ADV, instead of audible clicks, acoustic Doppler theory is applied. The ADV can sense and measure velocities much smaller than those rated and measured by mechanical meters and are not prone to the multiple count errors of the mechanical current meter.

Current meters, in general, measure stream velocity at a point. One notable exception is the ADCP. This method will be discussed in a subsequent section of this chapter; a thorough discussion of a moving boat discharge measurement using an ADCP is documented in Mueller and Wagner (2009).

The method of making discharge measurements at a cross section by using a current meter that measures point velocities requires determination of the mean velocity in each of the selected verticals. The mean velocity in a vertical is obtained from velocity observations at several points in that vertical. The mean velocity can be approximated by making a few velocity observations and using a known relation between those velocities and the mean in the vertical. The various methods of measuring velocity are: vertical-velocity curve, two-point, 0.6-depth, 0.2-depth, three-point, and surface and subsurface.

Vertical-Velocity Curve Method

In the vertical-velocity curve method, a series of velocity observations at points well distributed between the water surface and the streambed are made at each of the verticals. If there is considerable curvature in the lower part of the vertical-velocity curve, then it is advisable to space the observations more closely together in that part of the depth. Normally, the observations are taken at 0.1-depth increments between 0.1 and 0.9 of the depth. Observations are always taken at 0.2, 0.6, and 0.8 of the depth so that the results obtained by the vertical-velocity curve method may be compared with the commonly used methods of velocity observation. Observations are made at least 0.5 ft from the water surface and from the streambed with the Price AA meter, at least 0.3 ft from these boundaries with the Price pygmy meter, or at least 0.2 ft from these boundaries with the FlowTracker ADV.

The vertical-velocity curve for each vertical is based on observed velocities plotted against depth, as shown in figure 12. In order that vertical-velocity curves at different verticals may be readily compared, it is customary to plot depths as proportional parts of the total depth. The mean velocity in the vertical is obtained by measuring the area between the curve and the ordinate axis with a planimeter, or by other means, and dividing the area by the length of the ordinate axis.

The vertical-velocity curve method is valuable in determining coefficients for application to the results obtained by other methods, but is not generally adapted to routine discharge measurements because of the extra time required to collect field data and to compute the mean velocity. A typical vertical-velocity curve for the cross section should be measured and evaluated at all new measurement sites, and perhaps at new measurement sections if the new section is significantly different in hydraulic characteristics than the section normally used at a regular measurement site.

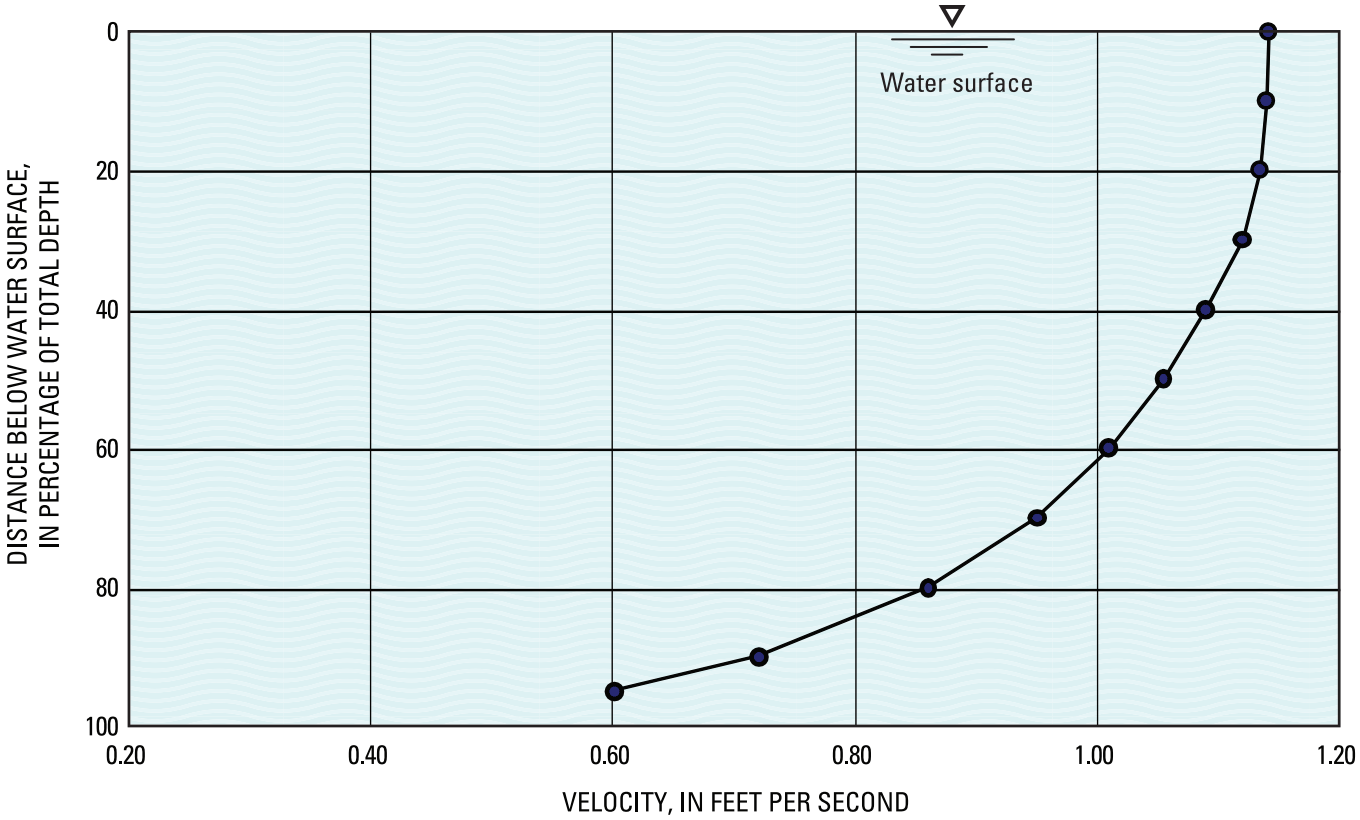

Figure 12. Typical vertical-velocity curve.

Two-Point Method

This is the preferred method for making midsection discharge measurements with point velocity meters. In the two-point method of measuring velocities, observations are made in each vertical at 0.2 and 0.8 of the depth below the surface. The average of these two observations is used as the mean velocity in the vertical. This method is based on many studies of actual observation and on mathematical theory. Experience has shown that this method gives more consistent and accurate results than any of the other methods, except for the vertical-velocity curve method. Use the two-point method for depths of 2.5 ft or greater, unless using a pygmy current meter or an ADV, in which case, this method is used in depths of 1.5 ft or greater.

With an ADV, the actual instrument has much less drag or resistance to the flow as compared to a mechanical current meter. To prevent boundary interference, avoid placing the ADV sample volume [typically 10 centimeters (about 4 in.) from the center transmitting transducer] within 2 in. from any solid boundary. This boundary condition with the ADV allows for measurement of velocity closer to the water surface and channel bed than a Price AA or to the pygmy (fig. 13). With the Price AA current meter, the two-point method is not used at depths less than 2.5 ft because the current meter would be too close to the water surface and to the streambed to give dependable results.

Six-Tenths-Depth Method

In the 0.6-depth method, an observation of velocity made at 0.6 of the depth below the water surface in the vertical is used as the mean velocity in the vertical. Actual observation and mathematical theory have shown that the 0.6-depth method gives reliable results and is used by the USGS under the following conditions:

Price AA Current Meter

1. Whenever the depth is between 0.3 ft and 2.5 ft.
2. When large amounts of slush ice or debris make it impossible to observe the velocity accurately at the 0.2 depth. (This condition prevents the use of the two-point method.)
3. When the meter is placed a distance above the sounding weight, which makes it impossible to place the meter at the 0.8 depth. (This condition prevents the use of the two-point method.)
4. When the stage in a stream is changing rapidly and you must make a quick measurement.

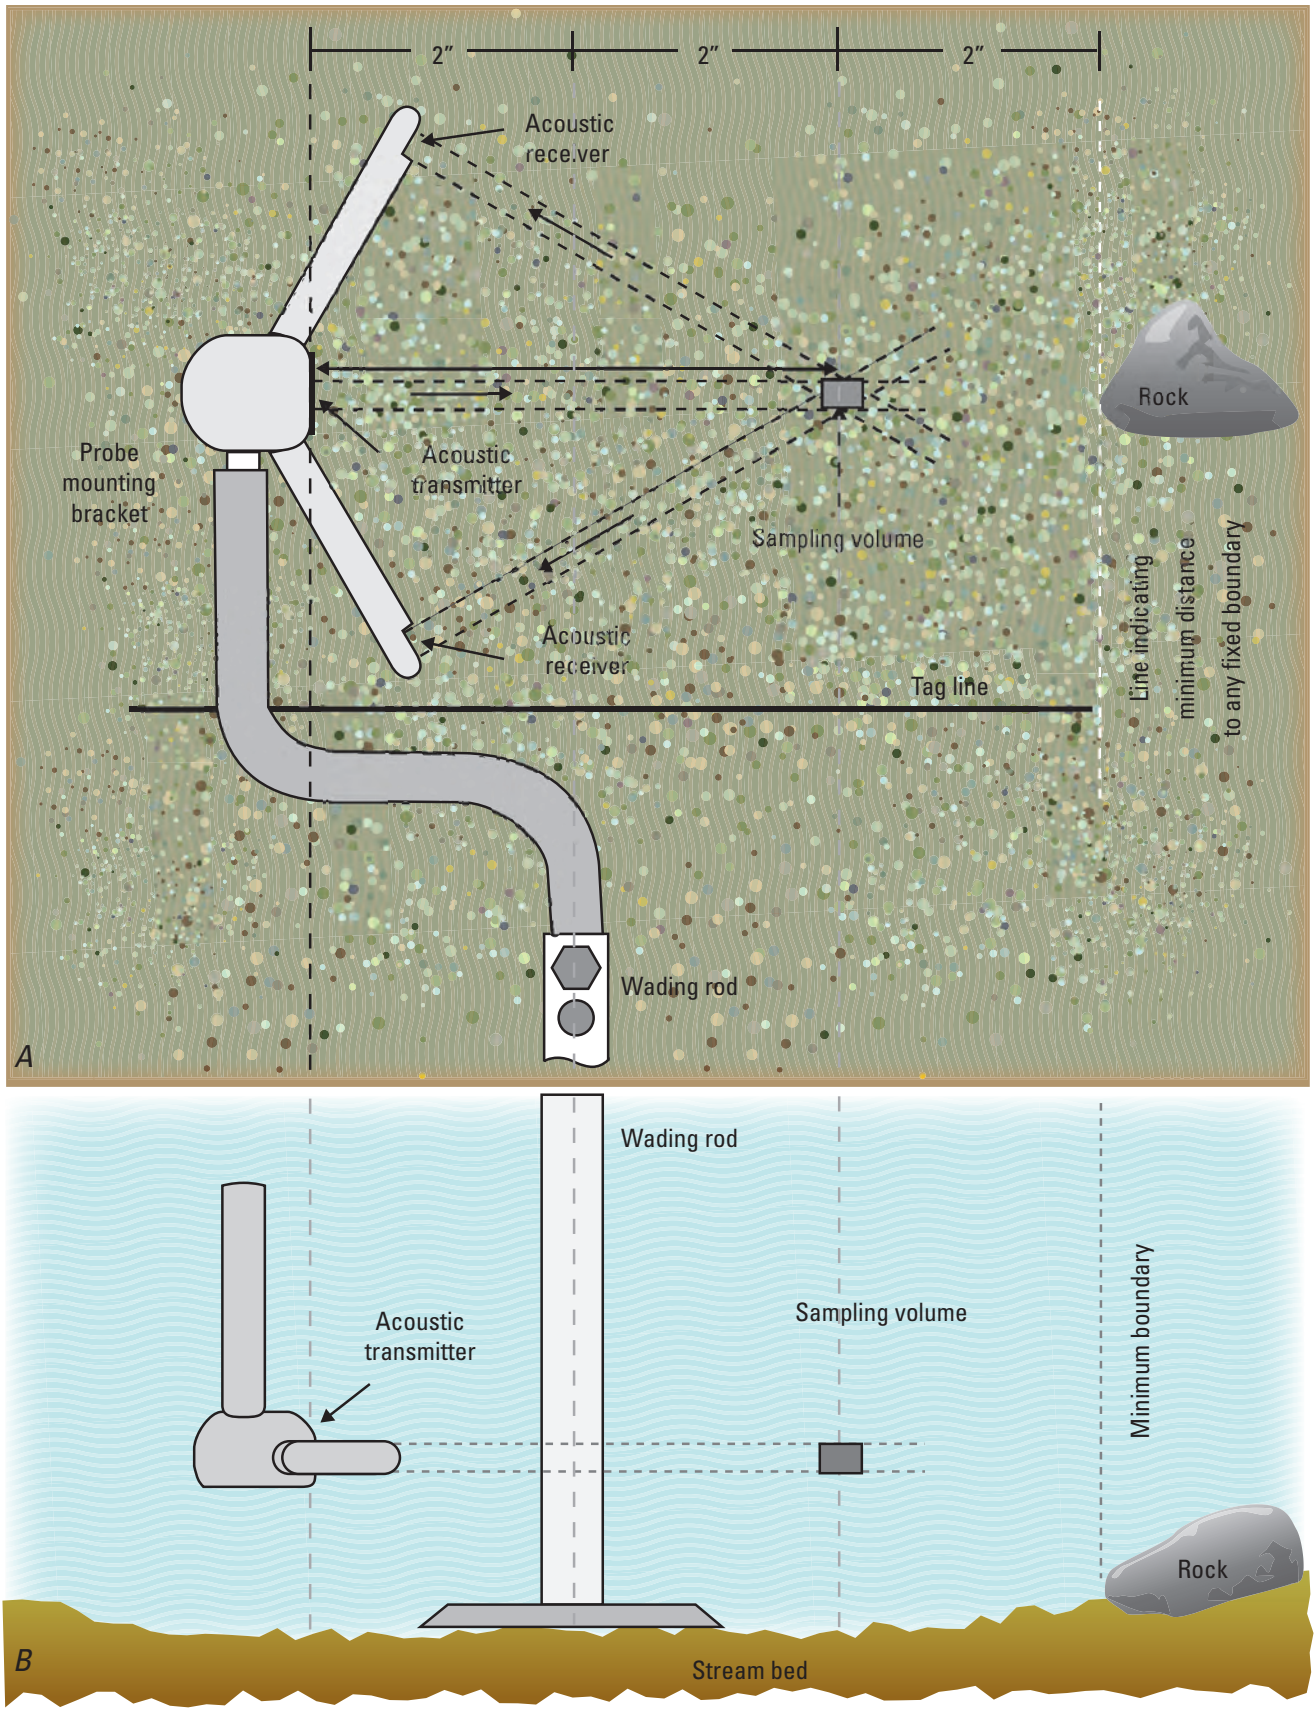

Figure 13. Schematic showing A, plan vie and B, cross section of the FlowTracker sampling volume and the proximity to a fixed boundary in the stream. (Note: Probe mounting bracket not shown.)

Pygmy Current Meter

1. Whenever the depth is between 0.3 ft and 1.5 ft.
2. When large amounts of slush ice or debris make it impossible to observe the velocity accurately at the 0.2 depth. (This condition prevents the use of the two-point method.)
3. When the stage in a stream is changing rapidly and a measurement must be made quickly.

Acoustic Doppler Velocimeter

1. Whenever the depth is between 0.25 ft and 1.5 ft.
2. When large amounts of slush ice or debris make it impossible to observe the velocity accurately at the 0.2 depth. (This condition prevents the use of the two-point method.)
3. When the stage in a stream is changing rapidly and a measurement must be made quickly.

Two-Tenths-Depth Method

The 0.2-depth method consists of observing the velocity at 0.2 of the depth below the surface and applying a coefficient to this observed velocity to obtain the mean in the vertical. It is used mainly during times of high water when the velocities are great, making it impossible to obtain soundings or to place the meter at the 0.8 or the 0.6 depth.

Use a standard cross section or a general knowledge of the cross section at a site to compute the 0.2 depth when it is impossible to obtain depth soundings. A sizeable error in an assumed 0.2 depth is not critical because the slope of the vertical-velocity curve at this point is usually nearly vertical. The 0.2 depth is also used in conjunction with the sonic sounder for flood measurements. The two-point method and the 0.6-depth method are preferred over the 0.2-depth method because of their greater accuracy.

The discharge measurement is normally computed by using the 0.2-depth velocity observations without coefficients as though each were a mean in the vertical. The approximate discharge thus obtained divided by the area of the measuring section gives the weighted mean value of the 0.2-depth velocity. Studies of many measurements made by the two-point method show that for a given measuring section, the relation between the mean 0.2-depth velocity and the true mean velocity either remains constant or varies uniformly with stage. In either circumstance, this relation may be determined for a particular 0.2-depth measurement by recomputing measurements made at the site by the two-point method using only the 0.2-depth velocity observation as the mean in the vertical. The plotting of the true mean velocity versus the mean 0.2-depth velocity for each measurement will give a velocity-relation curve for use in adjusting the mean velocity for measurements made by the 0.2-depth method.

If not enough measurements by the two-point method are available at a site to establish a velocity-relation curve, vertical-velocity curves are needed to establish a relation between the mean velocity and the 0.2-depth velocity. The usual coefficient to adjust the 0.2-depth velocity to the mean velocity is about 0.88.

Three-Point Method

The three-point method consists of observing the velocity at 0.2, 0.6, and 0.8 of the depth, thereby combining the two-point and 0.6-depth methods. The preferred method of computing the mean velocity is to average the 0.2- and 0.8-depth observations and then average this result with the 0.6-depth observation. However, when more weight to the 0.2- and 0.8-depth observations is desired, the arithmetic mean of the three observations may be used.

The three-point method is used when the velocities in the vertical are abnormally distributed [for example, the 0.2 (top) velocity is more than twice the 0.8 (bottom) velocity, or the 0.8 (bottom) velocity is greater than the 0.2 (top) velocity]. It is also used when the 0.8-depth observation is made where the velocity is seriously affected by friction or by turbulence produced by the streambed or an obstruction in the stream. If using a Price AA, the depths must be greater than 2.5 ft to use this method. If using a Price pygmy or ADV, the depths must be greater than 1.5 ft to use this method.

Surface and Subsurface Methods

Surface and subsurface methods consist of observing the velocity at the water surface or some distance below the water surface. Surface measurements may be made with the optical current meter, or by observing and timing surface floats. Subsurface measurements are made with a current meter at a distance of at least 2 ft below the surface to avoid the effect of surface disturbances. Surface and subsurface measurements are used primarily for deep swift streams where it is impossible or dangerous to obtain depth and velocity soundings at the regular 0.2, 0.6, and 0.8 depths.

Coefficients are necessary to convert the surface or subsurface velocities to the mean velocity in the vertical. Vertical-velocity curves obtained at the particular site are the best method to compute these coefficients. However, the coefficients are generally difficult to determine reliably because they may vary with stage, depth, and position in the measuring cross section. Experience has shown that the coefficients generally range from about 0.84 to about 0.90, depending on the shape of the vertical-velocity curve. The higher values are usually associated with smooth streambeds and normally shaped vertical-velocity curves, whereas the lower values are associated with irregular streambeds and irregular vertical-velocity curves.

Direction of Flow Measurements

Consider the direction of flow because the component of velocity normal to the measurement section is that which must be determined by both mechanical and acoustic Doppler point-velocity current meters. Generally, for the mechanical meter, the relation for velocity components not normal to the measuring section can be visualized in figure 14, and should be corrected using the cosine of alpha.

Flow direction is also critical with respect to an ADV, since the ADV assumes a horizontal and perpendicular plane to the flow. The hydrographer must pay close attention to the flow angle reported by the FlowTracker. Always hold the wading rod (with FlowTracker attached) perpendicular to the tag line so that the pulse generated by the transmitter is parallel to the tag line. Ideally, the tag line should be set up in the cross section to be measured so that flow is perpendicular to the tag line. Flow angle, as calculated by the FlowTracker, is defined as the direction of flow relative to the x-direction of flow, so that:

$$FlowAngle = \arctan(Vy / Vx), \quad (10)$$

where Vy is the velocity in the y direction (parallel to the tag line), and

Vx is the velocity in the x direction (perpendicular to the tag line) used to calculate discharge.

The flow angle calculated by the FlowTracker can result from two sources: (1) the flow is not perpendicular to the tag line, and (2) the flow is perpendicular to the tag line but the wading rod is not held correctly relative to the tag line, as described above. Regarding source (1), some small angles and variation in the flow angle at a site is not unusual. However, if large fluctuations of flow angles are reported, make measurements at another section with more uniform flow. Regarding source (2), holding the FlowTracker so that it is skewed at any angle relative to the tag line will result in a measurement of velocity that is biased low. Small angles do not result in significant biases, but because of these biases, users should be careful to minimize this error. If the FlowTracker is held so that it is skewed at an angle of approximately 8 degrees from the tag line, the measured velocity may be in error by as much as 1 percent (assuming that flow is perpendicular to the tag line). Large variations in flow angles may be indicative of poor or inconsistent alignment of the wading rod or poor site selection for the measurement.

In a wading measurement, if the meter used is a horizontal-axis meter with a component propeller, such as the Ott meter, the propeller should be pointed upstream at right angles to the cross section, but only if alpha is less than 45 degrees. Such a meter will register the desired component of velocity normal to the cross section when alpha is less than 45 degrees. The same procedure should be used if an electromagnetic component meter is used. These meters also measure the component of velocity normal to the measuring section. Generally, for either type of meter, if alpha is greater than 45 degrees, the component meter should be pointed directly into the current,

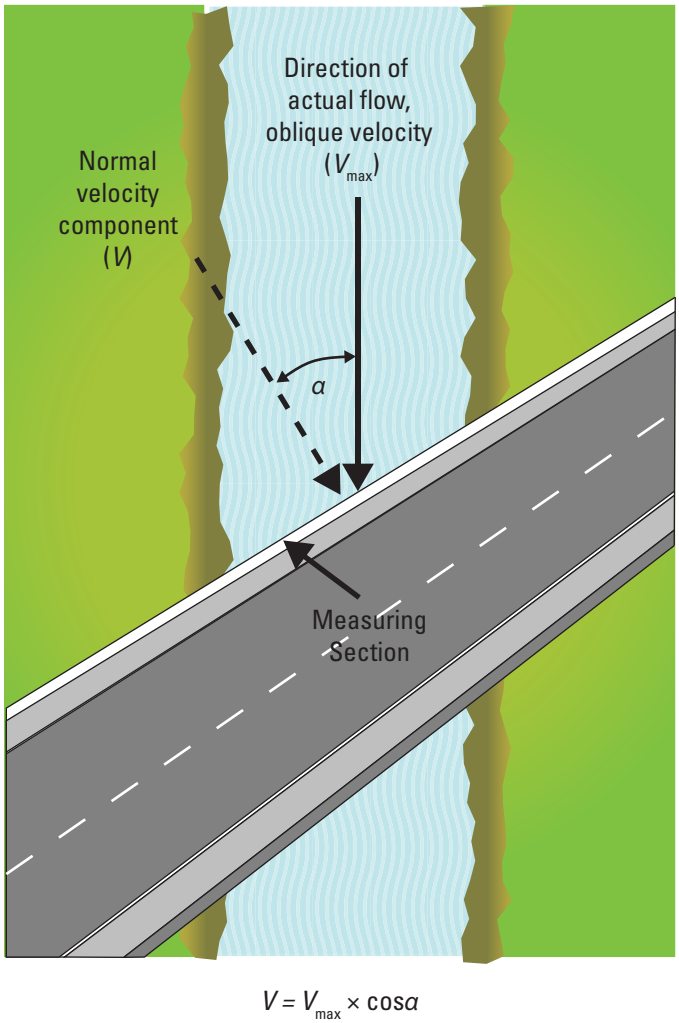

Figure 14. Velocity components when flow is not normal to measuring section.

and the horizontal angle correction should be applied as described in the following paragraphs.

Other meters on a wading-rod suspension, such as the vertical-axis Price current meter, should be pointed into the current. Any meter on a cable suspension will automatically point into the current because of the effect of the meter vanes. When the meter is pointed into an oblique current, the measured velocity must be multiplied by the cosine of the angle (alpha) between the current and a perpendicular to the measurement section in order to obtain the desired normal component of the velocity.

Either of two methods may be used to obtain the cosine of the angle alpha. In the first method, use the field note sheet that has a point of origin (o) printed on the left margin and cosine values on the right margin (see figure 2A). Measure the cosine of the angle of the current by holding the note sheet in a horizontal position with the point of origin on the tag line, bridge rail, cable rail, or any other feature parallel to the cross section, as shown in figure 15. With the long side of the note sheet parallel to the direction of flow, the tag line or bridge rail

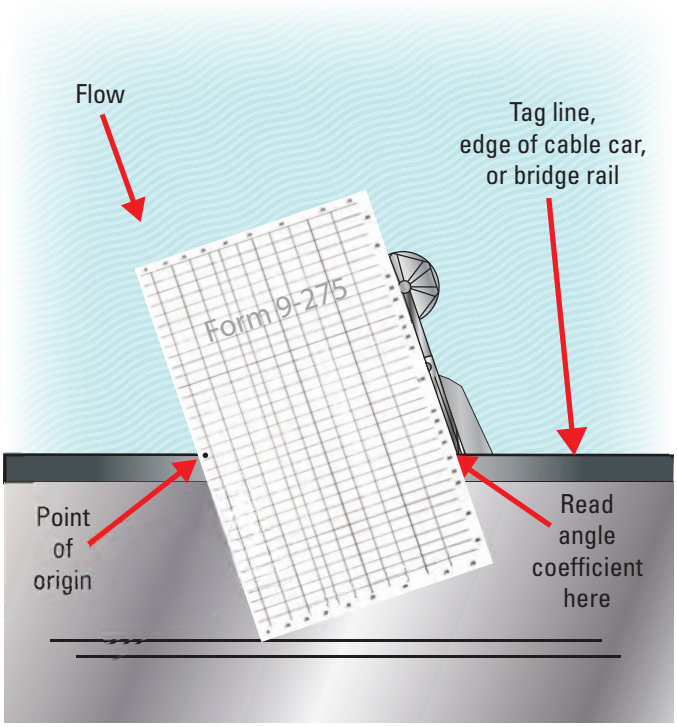

Figure 15. Measurement of horizontal angle with measurement note sheet.

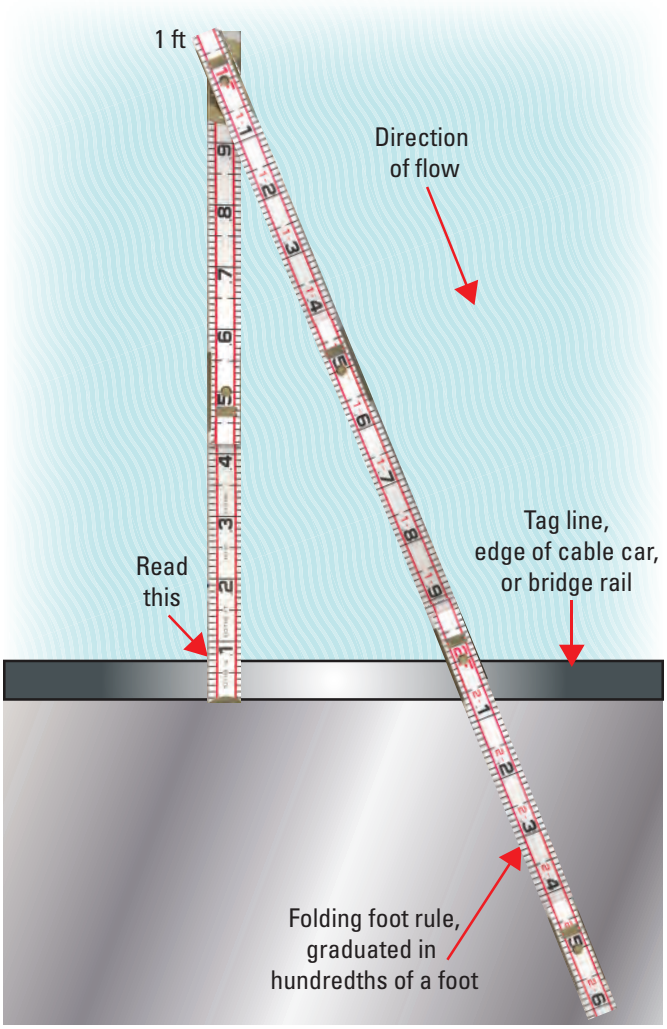

Figure 16. Measurement of horizontal angle with a folding rule.

will intersect the value of cosine alpha on the top, bottom, or right edge of the note sheet. The direction of the current will be apparent from the direction of movement of floating particles. If the water is clear of floating material, the edge of the note sheet is aligned parallel to the direction of movement. If no such material is available, the rather inelegant, but time-honored method of spitting into the stream can be used to discern the direction of flow. The position of the current meter may also be used if it can be seen below the water surface. Multiply the measured velocity by the cosine of the angle to determine the velocity component normal to the measurement section.

The second method of obtaining the cosine of the angle alpha involves the use of a folding rule that folds at 0.5-ft or 1-ft intervals. The rule must be graduated in hundredths of a foot and jointed every 0.5 ft or 1 ft. Extend the first 2 ft of the rule and place the 2.00-ft marker on the tag line or bridge rail, as shown in figure 16, with the rule aligned with the direction of flow. Fold the rule at the 1-ft mark so that the first foot of the rule is normal to the tag line or bridge rail. Make a reading where the 1-ft section intersects the tag line or bridge rail. That reading, subtracted from 1.00, is the cosine of the angle alpha. For example, if the reading on the rule is 0.07 ft (fig. 16), the cosine of alpha equals 0.93.

The direction of flow, as observed on the surface of the stream, may not always be a reliable indication of the direction of flow at some distance below the surface. For instance, when measuring a stream influenced by tidal fluctuations, it is possible to have flow moving downstream near the surface of the stream, and flow moving upstream near the bottom of the stream. Therefore, whenever it is suspected that the direction of flow is variable at different depths, other means than those already mentioned must be used to determine the direction of flow. One such method is to use a rigid rod or pole, with a vane attached to the bottom, and an indicator parallel to the vane attached to the top. Another method is to use a sounding weight with a compass and remote readout, as described in the equipment section of this chapter. If the variation of the direction of flow in the vertical is not great, then an average value of the cosine of the angle may be used for computing the component mean velocity for the vertical. However, if the variation is considerable, then you may need to subdivide the vertical and make separate computations for each subdivision. This may require additional measurements of velocity in the vertical.

If available, an ADCP from a moving boat can be used to quickly discern multidirectional flow in the vertical and across the selected cross-section. In a tidal affected reach, an ADCP is the preferred method of measuring discharge because of its use in the measurement of three dimensional velocity through most of the water column.

Current-Meter Measurements by Wading

Current-meter measurements by wading are preferred, if conditions permit. Wading measurements offer the advantage over measurements from bridges and cableways because the hydrographer can usually chose the best of several available cross sections for the measurement. Figure 17 shows a wading measurement being made with a top-setting rod.

Use the type AA, pygmy, or ADV meter for wading measurements. Table 6 lists the type of meter and velocity method to use for wading measurements at various depths.

If a type AA meter is being used in a cross section where most of the depths are greater than 1.5 ft, do not change to the pygmy meter for a few depths less than 1.5 ft or vice versa. The Price AA meter is not recommended for depths of 1.0 ft or less because the registration of the meter is affected by its proximity to the water surface and to the streambed. However, it can be used at depths as shallow as 0.5 ft to avoid changing meters if only a few verticals of this depth are required. The type AA meter or the pygmy meter should not be used in velocities less than 0.2 ft/s unless it is absolutely necessary.

Figure 17. Wading measurement using a top-setting rod.

Table 6. Current meter and velocity-measurement method for various depths.

Depth, in feet	Current meter	Velocity method
2.5 and greater	Price Type AA	0.2 and 0.8
1.5 - 2.5	Price Type AA	0.6
0.3 - 1.5	Price Pygmy	0.6
1.5 and greater	Price Pygmy	0.2 and 0.8
0.3 - 1.5	ADV	0.6
1.5 and greater	ADV	0.2 and 0.8

It is no longer recommended to use coefficients given by Pierce (1941) for the performance of current meters in water of shallow depth and low velocities.

When natural conditions for measuring are in the range considered undependable, modify the measuring cross section, if practical, to provide acceptable conditions. Often it is possible in small streams to build dikes to cut off dead water and shallow flows in a cross section, or to improve the cross section by removing the rocks and debris within the section and from the reach of stream immediately upstream from it. After modifying a cross section, allow the flow to stabilize before starting the discharge measurement.

Stand in a position that least affects the velocity of the water passing the current meter by facing the bank, with the water flowing against the side of the leg. Holding the wading rod at the tag line, stand from 1 to 3 in. downstream from the tag line and 18 in. or more from the wading rod. Avoid standing in the water if feet and legs would occupy a considerable percentage of the cross section of a narrow stream. In small streams where the width permits, stand on a plank or other support above the water rather than in the water. Velocity bias caused by effects of the hydrographer's position can be significant. Observance of these conditions is important while using mechanical meters, ADVs, and any wading measurement where an obstacle could interfere with the natural flow conditions of the stream.

When using a Price meter, keep the wading rod in a vertical position and the meter parallel to the direction of flow while observing the velocity. If the flow is not at right angles to the tag line, measure the angle coefficient carefully. When using an ADV or other instrument that can measure the x component velocity, the instrument should be aligned more precisely with the tag line. See the discussion of FlowTracker use and flow angles in the "Measurement of Velocity" section of this chapter.

During measurements of streams with shifting beds, the scoured depressions left by the hydrographer's feet can affect soundings or velocities. Generally, place the meter ahead of and upstream from the hydrographer's body and feet. Record an accurate description of streambed and water-surface configuration each time a discharge measurement is made in a sand-channel stream.

For discharge measurements of flow too small to measure with a current meter, use a volumetric method, Parshall flume, or weir plate. Those methods are described in subsequent sections of this chapter.

Current-Meter Measurements From Cableways

The Price type-AA current meter is generally used in conjunction with sounding weights and a sounding reel when measuring discharge from a cableway, although in recent years, using an ADCP mounted to a tethered craft has become much more widespread. Stationing (for width measurements) is usually determined from marks painted on the cableway. The velocity is measured by setting the meter at the proper position in the vertical, as indicated in table 7. Table 7 is designed so that no velocity observations will be made with the meter closer than 0.5 ft to the water surface. In the zone from the water surface to a depth of 0.5 ft, the current meter is known to give erratic results.

One problem found while measuring velocities from a cableway is that the movement of the cable car from one station to the next causes the car to oscillate for a short time after coming to a stop. Wait until this oscillation has decreased to a negligible amount before counting the revolutions.

By using a method of tagging the sounding cable at convenient intervals with streamers of different-colored binding tapes, each colored streamer being a known distance above the current-meter rotor (known as using tags), the meter can be kept under water at all times to prevent it from freezing in cold air. Tags are also used in measurements of deep, swift streams. See the section of this chapter on "Measurement of depth."

If large amounts of debris are flowing in the stream, raise the meter up to the cable car several times during the measurement to be certain the pivot and rotor of the meter are free of debris. However, keep the meter in the water during the measurement if the air temperature is considerably below freezing.

During floods, there is always a danger of catching a submerged or floating object, such as a tree or log, which can endanger the sounding equipment, meter, and most importantly, the hydrographer. Always be sure that the sounding cable has been installed on the sounding reel, according to the breaking loads specified in table 8. This assures that the sounding cable will break when it reaches its end, thereby preventing a potentially serious accident where the cable car and hydrographer could be spilled into the stream. Also, for added safety, always carry a pair of lineman's side-cutter pliers while making measurements from a cableway. If the sounding cable becomes hopelessly hung and does not break, as it should, cut the sounding line to ensure safety. Sometimes the cable car can be pulled to the edge of the water and the debris can be released.

When measurements are made from cableways where the stream is deep and swift, measure the angle that the meter suspension cable makes with the vertical due to the drag. The vertical angle, measured by protractor, is needed to correct the soundings to obtain the actual vertical depth, as described in the section on "Depth corrections for downstream drift of current meter and weight."

Table 7. Velocity-measurement method for various suspensions and depths.

Suspension	Minimum depth, in feet	
	0.6 method	0.2 and 0.8 method
15 C .5[1], 30 C .5	1.2	2.5
50 C .55	1.4	2.8
50 C .9	2.2	4.5
75 C 1.0, 100 C 1.0, 150 C 1.0	2.5	5.0
200 C 1.5, 300 C 1.5	3.8[2]	7.5

[1]15 pound Columbus-type weight, 0.5 above channel bed.

[2]Use 0.2 method for depths 2.5 to 3.7 feet with appropriate coefficient (for example, 0.87 or 0.88).

Table 8. Breaking loads for Ellsworth stranded cable.

Sounding cable	Diameter, in inches	Total number of strands	Rated total breaking load, in pounds	Recommended breaking load, in pounds	Number of strands to cut	Number of strands to remain
Ellsworth 0.084	0.084	36	500	250	15	21
Ellsworth 0.100	0.100	30	1,000	500	15	15
Ellsworth 0.125	0.125	30	1,500	500	20	10

Current-Meter Measurements From Bridges

When a stream cannot be waded, a bridge may be used to obtain current-meter measurements. Many measuring sections under bridges are satisfactory for current-meter measurements, but cableway sections are usually better because they provide an unobstructed reach of the channel. In addition, cableways usually have no bridges constricting the free flow of the stream in the measuring reach.

No set rule can be given for choosing between the upstream or downstream side of the bridge while making a discharge measurement. The advantages of using the upstream side of the bridge are the following:

- Hydraulic characteristics at the upstream side of bridge openings usually are more favorable. Flow is usually smoother and there is less turbulence than at the downstream side of the bridge.
- Approaching drift can be seen and be more easily avoided.
- The streambed at the upstream side of the bridge is not likely to scour as much as at the downstream side.

The advantages of using the downstream side of the bridge are:

- Vertical angles are more easily measured because the sounding line will move away from the bridge.
- The flow lines of the stream may be straightened out by passing through a bridge opening with piers.

Using the upstream side or the downstream side of a bridge for a current-meter or ADCP measurement should be decided based on circumstances for each bridge. Consider the factors mentioned above and the physical conditions at the bridge, such as location of the walkway, traffic hazards, and accumulation of trash on piles and piers.

For an ADCP measurement with a tethered craft, unless a special rigid support for deployment or bank-operated cableway has been developed for the upstream side of the bridge, the downstream side of the bridge is usually where the ADCP is most conveniently deployed. Bridge piers can cause excessive turbulence during high streamflow, especially if debris accumulates on the piers and(or) the piers are skewed to the flow. The effect of bridge-pier-induced turbulence may be reduced when deploying an ADCP from the downstream side of the bridge by lengthening the tether to increase the distance between the bridge and the tethered boat. Close attention should be paid to the cross section to ensure that no large eddies that could cause flow to be nonhomogeneous are present. Possible alternatives to measuring off the downstream side of the bridges include using a bank-operated cableway, a rigid extension that allows the hydrographer to deploy from the upstream side of the bridge, or having personnel on each bank hold a rope or cord attached to the platform to pull the tethered boat back and forth across the river.

For a mechanical current meter measurement, use either a handline, or a sounding reel supported by a bridge board or a portable crane, to suspend the current meter and sounding weight from bridges. Depth measurements should be made as described in the section entitled “Measurement of depth.” Measure the velocity by setting the meter at the position in the vertical as indicated in table 7. Keep equipment several feet from piers and abutments if velocities are high. Estimate the depth and velocity next to the pier or abutment on the basis of the observations at the nearest vertical.

If there are piers in the cross section, it is usually necessary to use more than 25 to 30 partial sections to get results as reliable as those from a similar section without piers. Piers will often cause horizontal angles that must be carefully measured. Piers also cause rapid changes in the horizontal-velocity distribution in the section.

Whether or not to exclude the area of a bridge pier from the area of the measurement cross section depends primarily on the relative locations of the measurement section and the end of the pier. If measurements are made from the upstream side of the bridge, it is the relative location of the upstream end (nose) of the pier that is relevant; for measurements made from the downstream side, it is the location of the downstream end (tail) of the pier that is relevant. If any part of the pier extends into the measurement cross section, the area of the pier is excluded. Bridges quite commonly have cantilevered walkways from which discharge measurements are made. In these cases, the measurement cross section lies beyond the end of the pier (upstream from the pier nose or downstream from the pier tail, depending on which side of the bridge is used). In that situation, it is the position and direction of the streamlines that determines whether or not the pier area is to be excluded. If the stationing of the sides of the pier when projected to the measurement cross section was not already done, the hydrographer does it at this point. If there is negligible or no downstream flow in that width interval (pier subsection), then the pier is excluded. That is, if only stagnation and (or) eddying exists upstream from the pier nose or downstream from the pier tail, whichever is relevant, the area of the pier is excluded. If there is substantial downstream flow in the pier subsection, the area of the pier is included in the area of the measurement cross section. In that circumstance, the horizontal angles of the streamlines in and near the pier subsection will usually be quite large.

Footbridges are sometimes used for measuring canals, tailraces, and small streams. Rod suspension can be used from many footbridges. The procedure for determining depth in low velocities is the same as for wading measurements. For higher velocities, obtain the depth by the difference in readings at an index point on the bridge when the base plate of the rod is at the water surface and on the streambed. Measuring the depth in this manner will eliminate errors caused by the water piling up on the upstream face of the rod. ADCP tethered boats, handlines, bridge cranes, and bridge boards are also used from footbridges.

The handline can be disconnected from the headphone wire and passed around a truss member with the sounding

weight on the bottom. This eliminates the need for raising the weight and meter to the bridge each time a move is made from one vertical to another; it is the principal advantage of a handline.

Safety is a primary consideration when measuring discharge from bridges. High-speed traffic can present a major safety hazard; in fact, it is no longer permissible to make discharge measurements from some Interstate route bridges without special permission. Observe all safety precautions, such as the use of traffic cones, traffic signs, and flag persons, that are prescribed in the USGS Water Science Center's flood plan and safety plan.

Observe the same safety precautions regarding the snagging of debris, such as floating or submerged trees or logs, as described above for cableways.

Current-Meter Measurements From Ice Cover

Discharge measurements under ice cover, as shown in figure 18, are made under the most severe conditions, but are extremely important because a large part of the discharge record during a winter period may depend on one measurement. In recent years ADCPs and ADVs have increasingly been used to make measurements from ice cover.

Select the possible locations of the cross section to be used for measurement from ice cover during the open-water season when channel conditions can be evaluated. Commonly, the most desirable measurement section will be just upstream from a riffle because slush ice that collects under the ice cover is usually thickest at the upstream end of the pools created by riffles.

The equipment used for cutting or drilling the holes in the ice is described in a previous section of this chapter.

Never underestimate the danger of working on ice-covered streams. When crossing, test the strength of the ice with solid blows using a sharp ice chisel. Ice thickness may be irregular, especially late in the season when a thick snow cover may act as an insulator. Water just above freezing can slowly melt the underside of the ice, creating thin spots. Ice that is bridged above the water may be thick but still be weak.

Cut the first three holes in the selected cross section at the quarter points to detect the presence of slush ice or poor distribution of the flow in the measuring section. If poor conditions are found, investigate other sections to find one that is free of slush ice and that has good distribution of flow. After finding a suitable cross section, make at least 20 holes in the ice for a current-meter measurement. Space the holes so that no partial section contains more than 10 percent of the total discharge. On narrow streams, it may be simpler to remove all of the ice in the cross section.

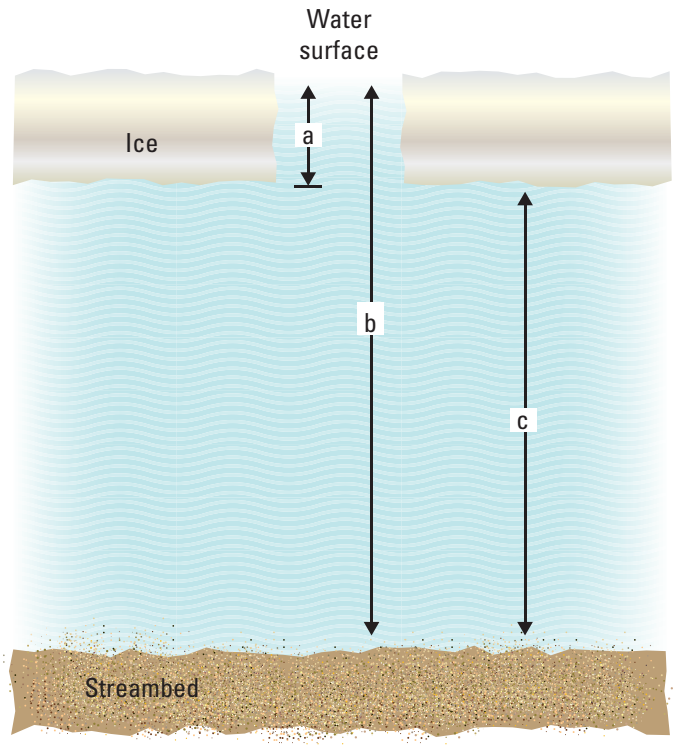
The effective depth of the water, as shown in figure 19, is the total depth of water minus the distance from the water surface to the bottom of the ice. The vertical pulsation of water

Figure 18. *A*, Ice drill being used to cut holes and *B*, ice rod being used to support current meter for a discharge measurement.

in the holes in the ice sometimes causes difficulty in determining the depths. The total depth of water is usually measured with an ice rod or with a sounding weight and reel, depending on the depth.

Measure the distance from the water surface to the bottom of the ice with an ice-measuring stick. Do not use the ice-measuring stick if there is slush under the solid ice at a hole. In order to find the depth at which the slush ice ends, suspend the current meter below the slush ice with the meter rotor turning freely. Raise the meter slowly until the rotor stops. This point is used as the depth of the interface between water and slush. After the effective depth of the water has been determined, compute the proper position of the meter in the vertical as shown in figure 19.

Use the Price winter Water Survey of Canada (WSCan) current meter yoke, with a polymer rotor, under ice cover when slush ice is present because the cups are solid and cannot become filled with slush ice; this is what happens with the cups of the regular Price meter. For situations where slush ice is not present, use the Price winter WSCan current meter yoke



a = Water surface to bottom of ice
b = Total depth of water
c = Effective depth (c=b-a)

0.2-depth setting = a + 0.2c
0.8-depth setting = b - 0.2c
0.6-depth setting = b - 0.4c

Figure 19. Method of computing meter settings for measurements under ice cover.

with regular Price metal cups. The old-style vane ice meter is no longer recommended, primarily because of its poor performance in slow velocities.

The velocity distribution under ice cover, when the water is in contact with the underside of the ice, is similar to that in a pipe, with a lower velocity nearer the underside of the ice. This is illustrated in figure 20. Use the 0.2- and 0.8-depth method for effective depths of 2.5 ft or greater, and the 0.6-depth method for effective depths of less than 2.5 ft. Define two vertical-velocity curves while making ice measurements to determine whether any coefficients are necessary to convert the velocity (obtained by the 0.2- and 0.8-depth method or the 0.6-depth method) to the mean velocity. Normally, the average of the velocities obtained by the 0.2- and 0.8-depth method gives the mean velocity, but a coefficient of about 0.92 usually is applicable to the velocity obtained by the 0.6-depth method.

When measuring the velocity, keep the meter as far upstream as possible to avoid any effect that the vertical pulsation of water in the hole might have on the meter. Eliminate as much as possible the exposure of the meter to the cold air during the measurement. The meter must be free of ice when the velocity is being measured.

If there is partial ice cover at a cross section, use the procedure described above where there is ice cover, and use open-water methods elsewhere.

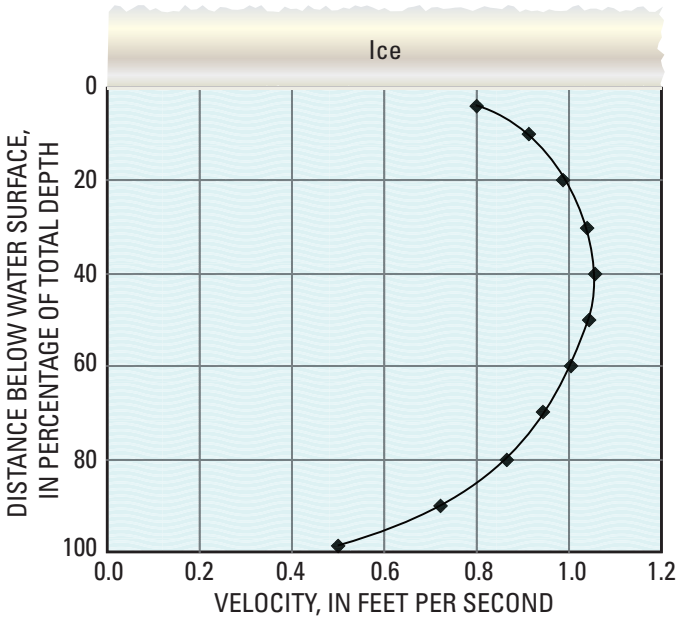


Figure 20. Typical vertical-velocity curve under ice cover.

Figure 21. Part of note sheet for discharge measurement under ice cover.

A sample sheet of discharge-measurement notes under ice cover is shown in figure 21. In this measurement, the vertical-velocity curves indicate that the 0.2- and 0.8-depth method gives the mean velocity and that the 0.6-depth method requires a coefficient of 0.92.

Current-meter measurements under ice cover are frequently made with a special winter-style sounding rod, ADV or ADCP, as described in this chapter. When depths are too deep for rod suspension, use an equipment assembly mounted on runners, such as shown in figure 22. For winter conditions, the 30-pound C-type weights should be used with a special, collapsible hanger assembly (shown in figure 22) that can be passed through an 8-in. hole in the ice. A handline can also be used for making ice measurements.

Where it is impractical to use a powered ice drill, use ice chisels to cut the holes. Ice chisels are usually 4- or 4.5-ft long and weigh about 12 pounds. Use the ice chisel when first crossing an ice-covered stream to determine whether the ice is strong enough to support the hydrographer. If a solid blow of the chisel blade does not penetrate the ice, it is safe to walk on, providing the ice is in contact with the water.

Some hydrographers supplement the ice chisel with a Swedish ice auger. The cutting blade of this auger is a spade-like tool of hardened steel that can cut a hole 6 to 8 in. in diameter by turning a brace-like arrangement on top of the shaft.

After the hole is made in the ice, water will be forced up, owing to the water being under pressure from the weight of the ice. In order to determine the effective depth of the stream, use ice-measuring sticks to measure the distance from the water surface to the bottom of the ice. Measuring this distance is done using a bar about 4 ft long, made of strap steel or wood, graduated in feet and tenths of a foot and having an L-shaped projection at the lower end. Hold the horizontal part of the L on the underside of the ice and read the depth to that point at the water surface on the graduated part of the stick. The horizontal part of the L is at least 4 in. long so that it may extend beyond any irregularities on the underside of the ice.

Figure 22. Collapsible hanger assembly for used with 30- and 50-pound C-type weights, for measurements under ice (*A*, in measurement position and *B*, collapsed).

Current-Meter Measurements From Stationary Boats

Discharge measurements are made from boats where no cableways or suitable bridges are available and where the stream is too deep to wade, although ADCP discharge measurements from a moving boat, now a USGS standard operating procedure, have largely replaced this method. Personal safety is the limiting factor in the use of boats on streams having high velocity of flow.

For boat measurements whether using a mechanical meter or an ADCP, select a cross section that has attributes similar to those described in the previous section "Site selection," except for those listed in items concerning depth and velocity. There is no need to consider depth in a boat measurement because if the stream is too shallow to float a boat, the stream can usually be waded. Velocity, however, is an important concern. If velocities are too slow, mechanical current meter registration may be affected by an oscillatory movement of the boat, in which the boat (even though fastened to a tag line) moves upstream and downstream as a result of wind action. Vertical movement of the boat as a result of wave action may also affect a vertical-axis current meter. If velocities are too fast, it becomes difficult to string a tag line across the stream.

If it is feasible to use a tag line in making a boat measurement, string it at the measuring section by unreeling the line as the boat moves across the stream. After a tag line without a brake has been stretched across the stream, take up the slack by means of a block and tackle attached to the reel and to an anchored support on the bank. If there is traffic on the river, one person must be stationed on the bank to lower and raise the tag line to allow the river traffic to pass. Place streamers on the tag line so that it is visible to boat pilots. If there is a continual flow of traffic on the river, or if the width of the river is too great to stretch a tag line, other means will be needed to position the boat. Night measurements by boat are not recommended because of the safety concerns.

When no tag line is used, the boat can be kept in the cross section by lining it up with flags positioned on each end of the cross section, as illustrated in figure 23. Flags on one bank would suffice but it is better to have them on both banks. Determine the position of the boat in the cross section by using a transit or total station on the shore and a stadia rod held in the boat. Another method of determining the position of the boat is by setting a transit or total station on one bank a convenient, known distance from and at right angles to the cross-section line. The position of the boat is determined by measuring the angle α to the boat, measuring the distance CE, and computing the distance MC as shown in figure 24. A third method of determining the position of the boat is done with a sextant read from the boat. Position a flag on the cross-section line and another at a known distance perpendicular to the line. The boat position can be computed by measuring the angle β with the sextant, as shown in figure 24. Boat position can also be determined by using a global positioning system with differential corrections (DGPS). This method is especially useful on wide streams and in flood plains where other methods of determining boat position are not applicable. Unless anchoring is more convenient, the motor must hold the boat stationary while readings are being taken.

Do not take boat measurements at velocities less than 1 ft/s when the boat is subject to wave action. The up-and-down movement of the boat (and the meter) seriously affects the velocity observations. If the maximum depth in the cross section is less than 10 ft and the velocity is low, the hydrographer can use a rod for measuring the depth and for supporting the current meter. For greater depths and velocities, use a cable suspension with a reel and sounding weight. The procedure for measuring from a stationary boat using the boat boom and crosspiece is the same as that for measuring from a bridge or a cableway, as described in previous sections of this chapter.

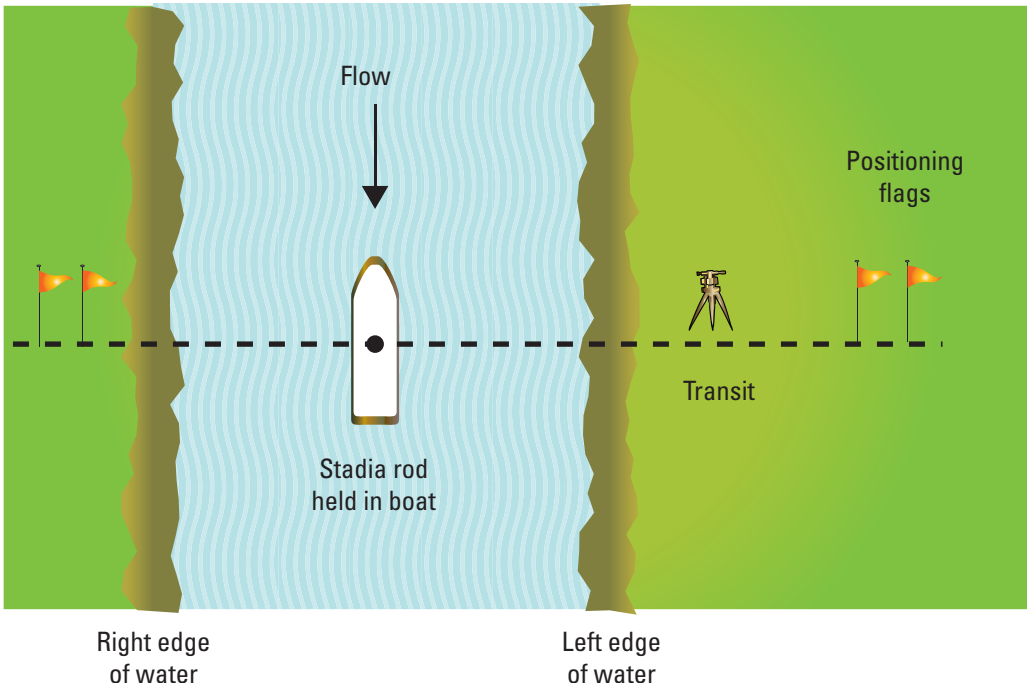

Figure 23. Determining the position in a cross section using the stadia method.

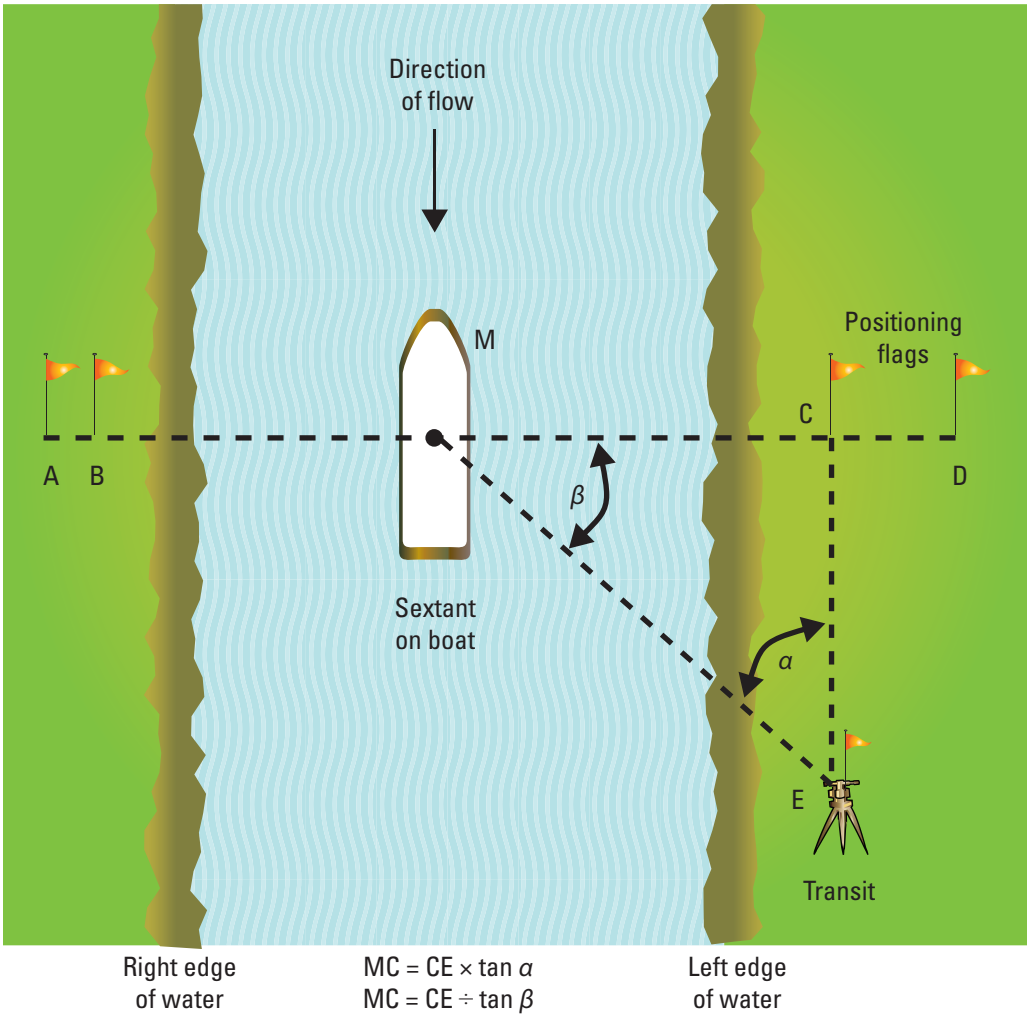

Figure 24. Determining the position in a cross section using the angular method.

Moving-Boat Measurements of Discharge

On large streams and estuaries, the midsection methods of measuring discharge are frequently impractical and involve costly and tedious procedures. There may be no facilities at remote sites. Where facilities do exist, they may be inundated or inaccessible during floods. At some sites, unsteady flow conditions require that measurements be made as rapidly as possible. Measurements on tide-affected rivers must not only be made frequently, but continually, throughout a tidal cycle. The moving-boat technique is a method of quickly measuring a large stream. It requires no fixed facilities, and it lends itself to the use of alternate sites if conditions make this applicable. Brief descriptions of three moving-boat methods are given in the following sections. It must be stated here that these methods have been almost entirely replaced by the use of ADCP discharge measurements. Details of ADCP setup and use can be found in Mueller and Wagner (2009) and subsequent section of this chapter discussing the moving boat method using an ADCP.

Manual Method, Using a Mechanical Current Meter

Smoot and Novak (1968) describe the manual moving-boat technique in detail. It is similar to the mechanical current-meter measurement in that the velocity-area approach is used to determine the discharge. The total discharge is the summation of the products of the partial areas of the stream cross section and their respective average velocities. During the traverse of a stream by boat, a sonic sounder records the geometry of the cross section, and a continuously operating current meter senses the combined stream and boat velocities.

The current meter used for a moving-boat measurement is a component propeller type, such as the Ott current meter, with a custom body made for mounting on the leading edge of a vane. The current meter and vane assembly are attached to a vertical rod and bearing assembly that allows them to rotate freely. An angle indicator is located at the top of the rod, which indicates the crab angle.

It usually takes three people to make a moving-boat measurement: one to operate the boat, one to make crab-angle observations, and one to take notes. The note keeper is responsible for recording the crab-angle observations and the current-meter pulses. Depths are recorded automatically on the sonic-sounder chart. Special computations and conversions, which are somewhat tedious, are required to determine stationing and normal mean velocities for each vertical. Discharge can then be computed similar to a standard velocity-area discharge measurement. Experience has shown that measurements obtained by the moving-boat technique compare within 5 percent of measurements obtained by conventional means.

Automatic Computerized Method, Using a Mechanical Current Meter

The automatic computerized moving-boat method is the same basic procedure as the manual moving-boat method described above, except that all readings of depth, velocity, crab angles, and boat position are automatically fed into an onboard computer. A substantial difference is that the automated moving-boat method requires only two crew members—a boat operator and an instrument operator. The manual method requires three crew members.

The automated method requires an electronic compass that provides automatic input of the crab angle. The current meter and depth sounder likewise provide automatic input of pulse rates and depth, respectively. The computer is programmed to make the conversions and computations that would normally be made manually, thereby speeding up the computation process and virtually eliminating arithmetic errors. A computed measurement is available immediately after completion of the data collection.

Moving-Boat Method, Using an ADCP

ADCPs can be used to measure unsteady, bidirectional, and other flows with nonlogarithmic velocity distributions—problems hydrologists have faced for decades. ADCPs are called profilers because they provide measurements of velocity throughout the water column. The ADCP divides the water column into depth cells (also referred to by some software and references as “bins”) and reports a velocity for each depth cell; however, an ADCP cannot measure velocities near the water surface or near the bed. The length of the unmeasured zone at the water surface is a function of the draft of the instrument deployment, the effect of the transducer mechanics, and the flow disturbance around the instrument. The length of the unmeasured zone near the streambed is due to side-lobe interference, which is a function of the mechanics of transducers and the slant angle of the beams. The ADCP must be deployed below the water surface; therefore, it cannot measure the water velocity above the transducers.

Although ADCPs have no moving parts and typically require no calibration, the instruments and associated software and firmware are complex. Using quality-assurance procedures defined by Oberg and others (2005) and Mueller and Wagner (2009) will help identify potential instrument problems.

ADCPs can be mounted on either side of manned boats, off the bow, or in a well through the hull. A tethered boat can be defined as a small boat (usually less than 6.5 ft long) attached to a rope, or tether, that can be deployed from a bridge, a fixed cableway, a moving boat, or a temporary or permanent bank-operated cableway. The tethered boat should be equipped with an ADCP mount that meets all of the specifications for manned boats. Unmanned, remote-control ADCP boats are also used and allow the deployment of ADCPs where deployment with a manned boat or tethered boat may not be feasible or ideal. Similar to (but smaller than) a manned boat,

a remote-control boat has self-contained motors and a remote-control system for maneuvering the boat across the river.

The procedures for predeployment preparation, field data collection, and processing of collected data are discussed in detail by Mueller and Wagner (2009). A detailed description of how an ADCP measures velocity and computes discharge and additional details on selected topics are presented in the appendices (Mueller and Wagner, 2009).

Networks of Current Meters

In the past, occasional special measurements made by USGS hydrographers have required simultaneous velocities at several points in a cross section, distributed either laterally or vertically. For example, it may be necessary to measure a vertical-velocity profile quickly in unsteady flows and to check it frequently in order to determine the changes in shape of the vertical profile, as well as the rates of these changes. In another example, for the measurement of tide-affected streams, it is desirable to measure the total discharge continuously during at least a full tidal cycle (approximately 13 hours). The need for so many simultaneous velocity determinations (one at each vertical in the cross section) for so long a period could be an expensive and laborious process using conventional techniques of discharge measurement.

A grouping of 21 current meters and special instrumentation has been devised in the past by the USGS to facilitate measurements of the types just described. The 21 meters are connected together so that the spacing between any two adjacent meters can vary up to 200 ft. In using this method, each meter should be uniformly calibrated and have sufficient handline cable to be suspended vertically from a bridge as much as 200 ft. Revolutions of the rotors are recorded by electronic counters that are grouped compactly in one box at the center of the bank of meters. The operator, by flipping one switch, starts all 21 counters simultaneously, and after an interval of several minutes, stops all counters. The indicated number of revolutions for the elapsed time interval is converted to a velocity for each meter. The distance between meters is known, and a record of stage is maintained to evaluate depth. Prior information at the site is obtained to convert point velocities in the verticals to mean velocities in those verticals. All of the information necessary to compute discharge in the cross section is available, and is tabulated for easy conversion to discharge. If possible a concurrent ADCP discharge measurement should be completed in close proximity and time to this measurement to corroborate the results.

Discharge Measurement of Deep, Swift Streams With a Mechanical Current Meter

Discharge measurements of deep, swift streams with a mechanical current meter usually present no serious problems when adequate sounding weights are used and when floating drift or ice is not excessive. Normal procedures must sometimes be altered, however, when measuring these streams. The four most common circumstances are the following:

1. It is possible to sound, but the weight and meter drift downstream.
2. It is not possible to sound, but a standard cross section is available.
3. It is not possible to sound, and a standard cross section is not available.
4. It is not possible to put the weight and meter in the water.

Procedures are described below for use during measurements made under each of these conditions. Use procedures for items 2, 3, and 4 where there is a stable cross section. The procedure for unstable channels must be determined by conditions at each location.

Possible To Sound, but Weight and Meter Drift Downstream

For some streams, it may be possible to sound the streambed, but because of the force of high velocities, the weight and meter are carried downstream. This may be a condition for only a few verticals near the center of the stream, or it may affect many of the verticals. Make corrections to the observed depths and meter settings to account for the downstream drift. These corrections are commonly referred to as “vertical angle corrections.” The procedure for computing vertical angle corrections is described in a previous section of this chapter entitled “Depth corrections for downstream drift of current meter and weight.” The corrections can be computed manually, or they may be computed automatically through the use of an electronic notebook or a PDA.

Not Possible To Sound, but Standard Cross Section Available

When it is not possible to sound the streambed, use a standard cross section from previous measurements at the bridge or cableway for determining depth. Such a cross section is useful only if all discharge measurements use the same permanent initial point for the stationing of verticals across the width of the stream. There should also be an outside reference gage or reference point on the bank or bridge to which the water-surface elevation at the measurement cross section

may be referred. If these conditions are met, use the following procedure to make a discharge measurement:

1. Determine the depths from the standard cross section, based on the water-surface elevation.
2. Measure the velocity at 0.2 of the depth at each vertical.
3. Compute the measurement in the normal manner using the measured 0.2-depth velocities as though they were the mean velocities in the vertical. Apply horizontal-angle corrections, if necessary. Use depths as determined in step 1 above.
4. Determine the coefficient to adjust the 0.2-depth velocity to the mean velocity on the basis of previous measurements at the site by the two-point method. See a previous section of this chapter entitled "Two-tenths-depth method."
5. Apply the coefficient from step 4 to the computed discharge from step 3.

Not Possible To Sound, and Standard Cross Section Not Available

When it is not possible to sound the streambed and a standard cross section is not available, use the following procedure:

1. Reference the water-surface elevation before and after the measurement to an elevation reference point on a bridge, on a driven stake, or on a tree at the water's edge. It is assumed here that no outside reference gage is available at the measurement cross section.
2. Estimate the depth and observe the velocity at 0.2 of the estimated depth. The meter should be at least 2.0 ft below the water surface. In the notes, record the actual depth the meter was placed below the water surface. If an estimate of the depth is impossible, place the meter 2.0 ft below the water surface and observe the velocity at that point.
3. Make a complete measurement, including some vertical-velocity curves, at a lower stage when you can sound the streambed.
4. Use the complete measurement and difference in stage between the two measurements to determine the cross section of the first measurement. To determine whether the streambed has shifted, compare the cross section with one taken for a previous measurement at that site.
5. Use vertical-velocity curves, or the relation between mean velocity and 0.2-depth velocity, to adjust the velocities observed in step 2 to mean velocity. Apply horizontal-angle corrections as necessary.
6. Compute the measurement in the normal manner using the depths from step 4 and the velocities from step 5.

Not Possible To Put the Weight and Meter in Water

If it is impossible to put the sounding weight and mechanical current meter in the water because of high velocities and (or) floating drift, use the following procedure:

1. Obtain depths at the measurement verticals from a standard cross section, if one is available. If a standard cross section is not available, determine depths by the method explained above in the section "Not possible to sound, and standard cross section not available."
2. Measure velocities and compute discharge using an ADCP.
3. Measure surface velocities by timing floating drift, or by using an optical or other approved noncontact flowmeter.
4. Compute the measurement in the normal manner, using the surface velocities as though they were the mean velocities in the vertical, and using the depths from step 1.
5. Apply the appropriate velocity coefficient to the discharge computed in step 3. Use a coefficient of 0.86 for a natural channel and 0.90 for an artificial channel.

The optical current-meter and ADCP measurement procedures are described in previous sections of this chapter and by Mueller and Wagner (2009). The optical current meter is portable, battery operated, and requires no great skill for quick and accurate readings of the surface rate of flow. The meter is not immersed, so it does not disturb the flow, and it is in no danger of damage from floating debris or ice. In many cases, the ADCP has become the most efficient alternative to the mechanical current meter where velocities are too great; however, the ADCP also has limitations. See the previous sections of this chapter for information on velocity, depth, turbidity, and other site-condition limitations of the ADCP.

Keep in mind that just after the crest, the amount of floating drift or ice is usually greatly reduced, and it may be possible to obtain velocity observations with a current meter. These observations can help define the velocity coefficient mentioned in step 5 above.

Recording Field Notes

Field notes for a discharge measurement may be recorded on standard paper note sheets (for example, USGS Forms 9-275-F, 9-275-I, and other special field forms). With the ADCP discharge measurement, the software attached to each instrument contains digital forms for the recording of some of the field data. The USGS has developed a paper form for recording field data observed during an ADCP discharge measurement (fig. 2*D*). With a current-meter discharge measurement, field forms can be recorded using an electronic notebook, such as the Aquacalc or a Personal Digital Assistant (PDA). With an ADV measurement, there are special field forms to accommodate its specifications and details. These methods are described in more detail in subsequent paragraphs in this section. The SWAMI program with a PDA (commonly used by the USGS) can be used to record discharge measurements, inspections, differential level surveys, and other field measurements. SWAMI has an interface with the National Water Information System (NWIS), so measurements are easily uploaded to NWIS (fig. 2*C*).

Standard Paper Note Keeping for a Mechanical Current-Meter Discharge Measurement

Paper note sheets, as shown in figure 2*A*, are the traditional way to record the field observations for a mechanical current meter, ADV, or ADCP discharge measurement. Generally, for each discharge measurement, the hydrographer should record the following information, at a minimum, on the front sheet of the measurement notes (the information may vary, depending on the meter and method being used):

- Measurement number, who computed, and who checked the measurement;
- Downstream station identification number and station name (station name includes stream name and location, to correctly identify an established gaging station). For a miscellaneous measurement, record the stream name and exact location of site;
- Date of measurement and members of measurement party (initials and last name);
- Measured channel width, area, average velocity (computed as a ratio of the measured discharge/measured area), average gage height, and discharge;
- Vertical velocity method(s) of measurement, number of sections, and change in gage height during the discharge measurement;
- Measurement method coefficient, horizontal-angle coefficient, type of meter suspension (for example, rod, 100#C, and so forth) and whether tags were checked;
- Type of meter (for example, AA or pygmy), the current meter's serial number; and the elevation of the meter above the channel bottom;
- Meter rating used (for example, Standard Rating No. 2) and the most recent spin test results;
- Measurement percentage (after computed) from the existing stage-discharge rating, and the indicated shift in feet from that rating;
- GAGE READINGS: Do not erase inside this block on the front sheet. If an error is made, cross through the error and write the correct reading.
  - Start time measurement using 24-hour clock time, and record the time zone (that is, EST, CST, EDT, and so forth).
  - Record inside and outside gage, and also readings from recording devices (for example, data logger, graphic, and so forth).
  - Compute weighted mean gage height either by averaging readings, or if sufficient change in gage height occurred, by using methods for weighting gage height discussed in this chapter.
  - Compute gage-height correction caused by difference in true gage height (reference gage) and recorder or other gage that is reading incorrectly.
  - Record the correct mean gage height.
- Samples collected: Indicate type of water-quality measurements and samples [that is, water-quality, sediment, and (or) biological], and indicate if the measurements are documented on separate sheets (that is, water quality, aux./base gage, other);
- Indicate whether the rain gage (if applicable) was serviced/calibrated;
- Briefly describe the weather (for example, sunny, cloudy, rainy, cold, or other);
- Record the air temperature in degrees Celsius and the time of the reading;
- Record the water temperature in degrees Celsius and the time of the reading;
- Record the check bar reading (if a wire weight is present), time of the reading, and any adjustments in elevation made to the check bar.
- Indicate the type of measurement (wading, cable, ice boat, and so forth) and location of measurement relative to the gage (upstream, downstream, and so forth).
- Rate the measurement based on the hydrologic/hydraulic conditions in which the measurement was made [that is, excellent (2 percent), good (5 percent), fair (8 percent), or poor (more than 8 percent)].
- Flow: Document the hydraulic condition of the flow (steady, unsteady, where the flow was within the cross section, and so forth).
- Cross section: Geomorphologically describe the cross section (that is, sand, clay, cobble, and so forth), shape, presence of vegetation, and any other roughness affecting flow.

- Document if the gage is operating and whether the record was removed during this visit;
- Note the battery voltage and the cleaning of the orifice or intakes;
- If appropriate, indicate pressure readings of the nonsubmersible pressure transducer (that is tank, line, bubble-rate (bubbles/minute);
- Indicate if appropriate, readings of extreme indicators of high flow.
- Document the condition of the crest stage gage (CSG) and record the high water mark (HWM) if a reading is available on the CSG and the reference elevation.
- Record any other HWM obtained at the gage, if appropriate.
- Control conditions: Describe what and where the control of flow is for the gage pool (that is, gravel riffle about 80 ft downstream of the gage, and so forth).
- REMARKS: Use this space to document any unusual conditions in the gage reach that might affect the measurement, record, or other pertinent information regarding the accuracy of the discharge measurement and conditions that might affect the stage-discharge relation and document any observer reading or results of discussions with an observer.
- Measure the gage height of zero flow as many times a year as possible; record to the nearest 0.1 ft. Do this by recording the gage height at the gage at the time the gage height at zero flow is measured. Subtract the gage height from the depth of flow at the point the gage height at zero flow is measured and rate this measurement as good, fair, or poor.
- Fill in all items on the front sheet or mark with a dash after the measurement is completed and computed.

Mechanical Current-Meter Inside Notes

In the inside notes of a mechanical current-meter discharge measurement, identify the measurement starting point by either left edge of water or right edge of water (LEW or REW, respectively), when facing downstream, and record the time you started the measurement. If a significant change in stage is expected during the measurement, periodically record the time for intermediate verticals during the course of the measurement. If possible, synchronize this time with the recording interval of the digital recorder or data logger. Intermediate times are important because if there is any appreciable change in stage during the measurement, these recorded times are used to determine intermediate gage heights, which are then used to compute a weighted mean gage height for the measurement, as described in a subsequent section of this chapter. When the measurement is completed, record the time and the bank of the stream (LEW or REW) where the section ends.

Begin the measurement by recording the distance from the initial point to the edge of the water. Measure and record the depth, and velocity (if any), at the edge of water. Compute the width using the midsection method described in a previous section of this chapter. Proceed across the measurement section by measuring and recording the distance of each vertical from the initial point; the depth at the vertical; the observation depths as 0.6, 0.2, 0.8, and so forth; the revolutions and time for each velocity observation; and the horizontal angle coefficient if different than 1.00.

Complete all computations required for the inside notes to determine the total width, area, and discharge. Transfer these values to the front sheet and complete other items on the measurement front sheet. The measurement computations should be made, and the note sheets completed, before the hydrographer leaves the gaging station.

Erasures of original field data are not allowed. This includes items such as gage readings, distances, depths, meter revolutions, times, horizontal-angle coefficients, and other field measurements that cannot be repeated. If a variable is remeasured, and it is necessary to change the originally recorded value of that variable, cross it out and record the new measurement above or adjacent to the original. The original measurement should remain legible, even though it is crossed out. On the other hand, it is permissible to erase computed values, such as velocities, areas, widths, and discharges.

Standard Paper Note Keeping for an ADV Discharge Measurement

Paper note sheets, as shown in figure 2*B*, are the traditional method to record the field observations for an ADV discharge measurement. If using paper note keeping with an ADV for each measurement, the hydrographer should record the information, at a minimum, as if it were a mechanical velocity-meter discharge measurement, with a few variations. Indicate the filename of the infield diagnostic test performed on the ADV during the discharge measurement. Fill in all items on the front sheet or mark with a dash after the measurement is completed and computed.

ADV Inside Notes

An electronic summation of an ADV discharge measurement is produced by the ADV software. This information contains much of the information on the front sheet of the standard discharge measurement form, plus depths, widths, velocities, angles, area, and discharge. Typically ADV software does all the computations for an ADV discharge measurement. Print this output and attach it to the discharge measurement form for archival. Recent programming with personal digital assistants (PDAs) has further facilitated the collection, processing, and entry of discharge measurements into digital databases. See the sections entitled Electronic counters" and "Other electronic counters, electronic field notebooks, and personal digital assistants" for further discussion of the use of PDAs for field measurements.

Mean Gage Height of Discharge Measurements

The mean gage height of a discharge measurement represents the mean height of the stream during the period the measurement was made and is referenced to the datum of the gaging station. Just as an accurate determination of the discharge is important, so is an accurate determination of the mean gage height because it is one of the coordinates used in plotting the discharge measurement to establish the stage-discharge relation. The computation of the mean gage height presents no problem when the change in stage is small (0.1 ft or less). At gage-height changes of less than 0.1 ft, the mean gage height for the discharge measurement can be obtained by averaging the gage heights at the beginning and end of the measurement, without significant error. Measurements, however, must sometimes be made during floods or regulation when the stage significantly changes more than 0.1 ft.

To compute an accurate mean gage height for a discharge measurement, read the gage at the beginning and end of the discharge measurement, and several times during the measurement if there are significant changes. If the station is equipped with an electronic data logger or DCP that automatically records at intervals of 15 minutes or less, you can take the intermediate gage-height readings from those instruments after the measurement is completed. The hydrographer should accurately synchronize watch time and recorder time, and should record watch time for selected verticals at intervals during the discharge measurement. If the recording interval is greater than 15 minutes (that is, 30 minutes or 1 hour), intermediate gage- height readings should be obtained by reading the gage once or twice during the discharge measurement.

If the change in stage during the measurement is greater than about 0.1 ft (Rantz, 1982, suggests a change of 0.15 ft), the mean gage height should be computed by weighting the gage-height readings. In the past, the mean gage height was computed by weighting the gage readings with partial discharges from the discharge measurement. Later studies show, however, that this method tends to overestimate the mean gage height. Time weighting has also been used to compute a weighted mean gage height, but this method tends to underestimate the mean gage height. Therefore, it is recommended that both methods of weighting be used for discharge measurements having stage changes of 0.10 or more, and that an average of the two results be used for the mean gage height.

Plot the gage-height readings so that intermediate readings can be interpolated where necessary. Pay particular attention to breaks in the slope of the gage-height graph. Figure 25 illustrates a plot of gage heights for a discharge measurement. Gage heights for this measurement were determined from the stage recorder at 15-minute intervals.

In the discharge-weighting procedure, the partial discharges measured between recorded watch times are used with the mean gage height for that same time period. The equation used to compute the weighted mean gage height is:

$$H = \frac{q_1h_1 + q_2h_2 + q_3h_3 + \ldots + q_nh_n}{Q}, \quad (11)$$

where H weighted mean gage height, in feet,
Q total discharge measured, in cubic feet per second = $q_1 + q_2 + q_3 + \ldots + q_n$,
$q_1, q_2, q_3 \ldots q_n$ amount of discharge measured during time interval 1, 2, 3...n, in cubic feet per second,
$h_1, h_2, h_3 \ldots h_n$ average gage height during time interval 1, 2, 3...n, in feet.

Figure 25 shows the computation of a discharge-weighted mean gage height. The graph at the bottom is a reproduction of the gage-height graph during the discharge measurement. To help explain the method, the discharges are taken from the current-meter measurement shown in figure 2*A*. The upper computation of the mean gage height in figure 25 shows the computation using the given formula. The lower computation was calculated using a shortcut method to eliminate the multiplication of large numbers. In this method, after the average gage height for each time interval has been computed, a base gage height, which is usually equal to the lowest average gage height, is chosen. Then, the difference between the base gage height and the average gage heights is used to weight the discharges. When the mean difference has been computed, the base gage height is added to it.

In the time-weighting procedure, the arithmetic mean gage height for time intervals between breaks in the slope of the gage-height graph is used with the duration of those time periods. The equation used to compute mean gage height is

$$H = \frac{t_1h_1 + t_2h_2 + t_3h_3 + \ldots + t_nh_n}{T}, \quad (12)$$

where H weighted mean gage height, in feet,
T total time for the measurement, in minutes ($t_1 + t_2 + t_3 + \ldots + t_n$),
$t_1, t_2, t_3, \ldots, t_n$ duration of time intervals between breaks in the slope of the gage height graph, in minutes, and
$h_1, h_2, h_3, \ldots, h_n$ average gage height, in feet, during time interval 1, 2, 3, ..., n.

Using the data from figure 25, the computation of the time-weighted mean gage height is as follows:

Average gage height (*h*) in ft	Time interval (*t*) in minutes	*h* x *t*
1.92	15	28.80
1.70	15	25.50
1.67	15	25.05
1.88	15	28.20
Totals	60	107.55

The mean gage height is computed as $H = 107.55/60 = 1.79$ ft.

In this example, there is little difference between the discharge-weighted mean gage height (1.77 ft) and the time-weighted mean gage height (1.79 ft). The average of the

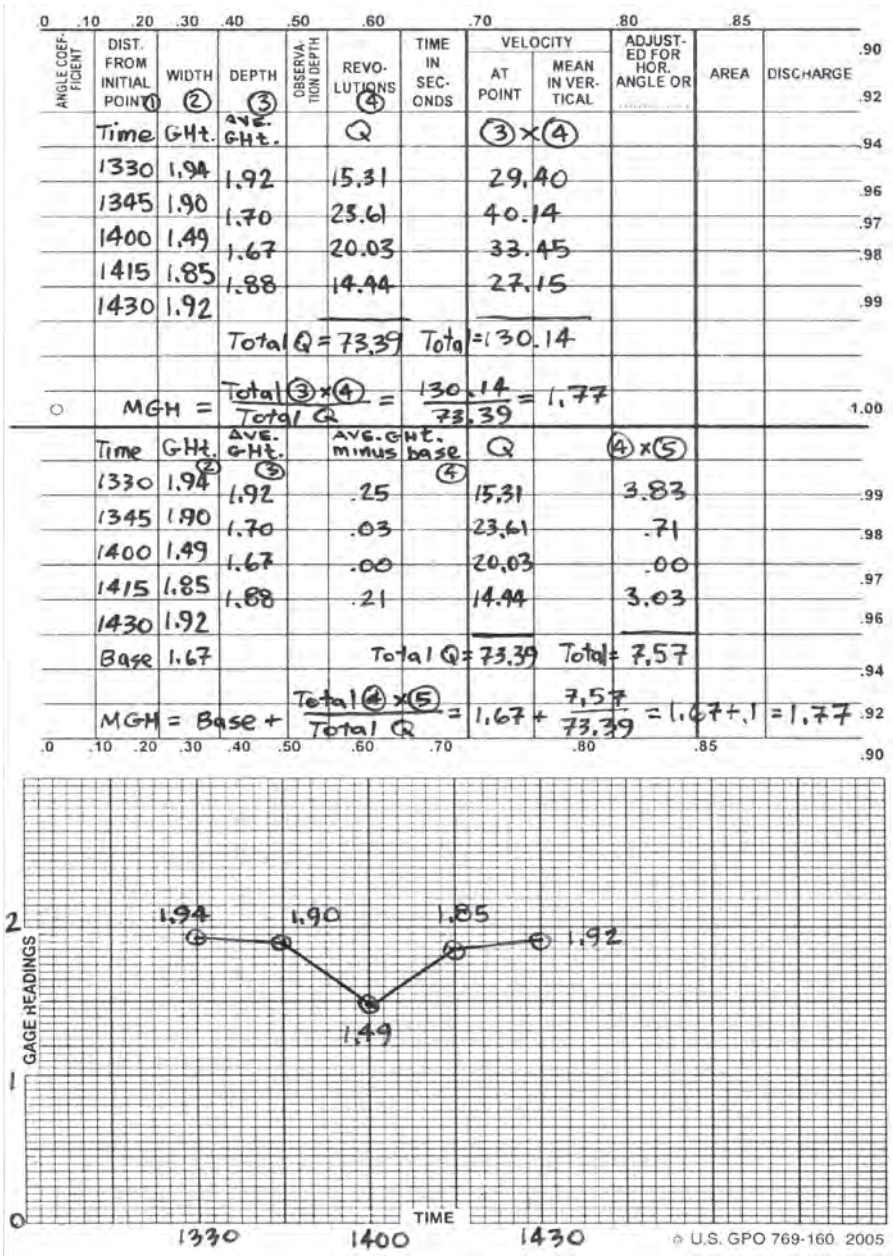

Figure 25. Graph of readings used to compute a weighted mean gage height.

two values, 1.78 ft, is the preferred mean gage height for the discharge measurement.

When extremely rapid changes in stage occur during a measurement, the weighted mean gage height is not truly applicable to the discharge measured. To reduce the range in stage during the measurement, try to reduce the time required for making the discharge measurement; however, keep in mind that shortcuts in the measurement procedure usually reduce the accuracy of the measured discharge. Therefore, measurement procedures during rapidly changing stage must be optimized to produce a minimal combined error in measured discharge and computed mean gage height. The following section of this chapter describes procedures for making discharge measurements during periods of rapidly changing stage.

Discharge Measurements During Rapidly Changing Stage

Discharge measurements during periods of rapidly changing stage are more difficult to obtain, and accuracy is often not as good as for measurements made when the stage is fairly constant. The computation of total discharge and the corresponding stage are both subject to more uncertainty when the stage significantly changes during the period of the measurement. Two procedures are suggested for shortening the time required for a discharge measurement. The first procedure is applicable more for large streams where the stage changes are usually not as great as for small streams. The second procedure is designed more for the flash-flood conditions experienced with small streams, where peaks can be of momentary duration, and where the rising and falling stage is rapid. Keep in mind that the moving-boat ADCP discharge measurement can be used during these conditions. For a more detailed discussion of procedures for using an ADCP moving-boat during rapidly changing stage, see Mueller and Wagoner (2009).

Measurements of Large Streams With Rapidly Changing Stage

During periods of rapidly changing stage in a large stream, make measurements as quickly as possible to keep the change in stage to a minimum. This will minimize discharge errors caused by the shifting of flow patterns and other variables as the stage changes, and will provide a more accurate stage computation for the measurement. To reduce the time required for making a discharge measurement, make fewer than the usual number of observations and shorten the time to make them. This is sometimes referred to as a shortcut method. Following is a list of some of the things that can be done to reduce the time:

1. Use the 0.6-depth method rather than the 0.2 and 0.8 method. If the 0.6 method cannot be used because the flow is too swift, or if debris makes it too hazardous, then use the 0.2-depth method or the subsurface method. If an optical meter is available, use surface-velocity measurements.
2. Reduce the velocity observation time to about 20 to 30 seconds. This is referred to as half-counts.
3. Only measure about 15 to 18 sections. For some conditions, even use less than 15 sections may be used.
4. Observe and record the watch time at about every third vertical. If possible, observe and record the stage once or twice during the measurement.

By incorporating the above practices, a measurement can usually be made in 15 to 20 minutes. The surface or subsurface method for observing velocities is used, then some vertical-velocity curves will be needed later to establish coefficients to convert observed velocity to mean velocity. Compute a weighted mean gage height for the discharge measurement, as described in a previous section of this chapter.

Use the determination of error in discharge measurements, as described by Sauer and Meyer (1992), to illustrate the difference in errors between the standard measurement procedure and the shortcut procedure. The results shown in table 9 are based on a firm and smooth streambed. The additional uncertainty caused by using the shortcut method is generally less than the error that can be expected from the shifting of flow patterns and other variables that may occur during periods of rapidly changing stage.

Measurements of Small Streams With Rapidly Changing Stage

A series of "instantaneous" discharge measurements can be made during flash flood conditions on small streams by rating individual subsections, or verticals. This method requires repeated observations of gage height, depth, and velocity at selected verticals during the rise and fall of the flood wave. Two procedures are described below, with the primary difference being the method of determining depth at each vertical. In the first procedure, the streambed elevation referenced to gage datum is predetermined for each selected vertical. Depth is then determined as the difference between the gage height and the streambed elevation. In the second procedure, depth is measured at the selected verticals by sounding each time velocity is observed. The first procedure is faster; however, it may not be suitable if the streambed is unstable.

The method of computing the discharge measurements is also slightly different for the two procedures. For both procedures, a rating of gage height versus mean velocity is required

Table 9. Comparison of discharge measurement error for standard and shortcut methods.

[No., number; s, seconds; ft/s, feet per second; ft, feet]

Measurement	Meter type	No. of verticals	Points in vertical	Suspension	Observation time, s	Mean velocity, ft/s	Mean depth, ft	Uncertainty percent	Measurement rated
Standard	AA	30	2	cable	50	2.50	10.0	2.3	Excellent/good.
Shortcut	AA	15	1	cable	25	2.50	10.0	5.1	Good/fair.

for each subsection, or vertical. For the second procedure, a rating of gage height versus depth is required for each vertical. The two procedures are described below.

Procedure 1—Depth Is Computed From Predetermined Streambed Elevations at Each Vertical

1. Select about 10 verticals, or subsections. For very small streams, you may use fewer verticals. Mark the selected verticals in some way so that repeated observations can be made at the same vertical each time.
2. Determine the streambed elevation referenced to gage datum for each selected vertical prior to making the series of discharge measurements. After the flood recedes, determine the streambed elevations at each vertical again to see if changes occurred during the flood. If the streambed is not stable, it will be necessary to interpolate the changes based on time and the best judgment of the hydrographer. Depth is determined at each vertical as the difference between this elevation and the gage height.
3. Take velocity observations at each vertical using the 0.6-depth method. Full counts of 40 seconds or more are recommended, but half-counts may be used if the stream is rising or falling extremely fast. If the 0.6 method cannot be used, then take velocity observations at the 0.2 depth or the subsurface depth. If an optical or other approve noncontact flowmeter is available, use it to take surface-velocity readings. For surface- and subsurface-velocity readings, it will be necessary to determine the coefficient required for converting the readings to a mean velocity. Meter positions should be based on the depth, as computed in item 2 above.
4. Make observations of other factors that would affect the computation of discharge, such as horizontal-angle coefficients.
5. Repeat the velocity and other observations at each of the selected verticals several times over the duration of the flood wave.
6. Record the watch time of each vertical measurement, and make corresponding gage- height observations frequently during the period of the flood wave.
7. Develop a rating of gage height versus mean velocity for each of the selected verticals. If surface- or subsurface-velocity observations were made, apply adjustments so that the rating represents mean velocity in the vertical. In some cases, it may be necessary to develop more than one rating for each vertical. For instance, a rating for the rising side of the flood wave, and a separate rating for the falling side of the flood wave, may be necessary.
8. Select a gage height for which a discharge measurement is to be computed. Use a standard discharge measurement note sheet for computing the discharge measurement. Enter the stationing for the edge of water and for each of the selected verticals. Enter the depths at each vertical, computed on the basis of the selected gage height minus the streambed elevation. Enter the mean velocity at each vertical on the basis of the gage height versus mean velocity ratings. Enter other adjustments, such as horizontal-angle coefficients, as observed during the observation of velocities. Compute the discharge measurement similar to a regular discharge measurement.
9. Repeat the process described in item 8 above for other selected gage heights. If the ratings of gage height versus mean velocity change, such as for rising and falling stage, then compute separate discharge measurements for the rising and falling limbs of the flood wave.

Procedure 2—Depth Is Measured by Sounding at Each Vertical

1. Select about 10 verticals, or subsections, as described in the first procedure above. For very small streams, fewer verticals may be used. Mark the selected verticals in some way so that repeated observations can be made at the same vertical each time.
2. Determine the depth for each selected vertical by sounding the streambed each time you measure a vertical. Use this method when it is possible to easily make soundings, and when there is a likelihood of streambed elevation changes caused by scour or fill during the course of the measurement.
3. Take velocity observations at each vertical using the 0.6-depth method. Full counts of 40 seconds or more are recommended, but half-counts may be used if the stream is rising or falling extremely fast. It is not likely that you will need to make surface or subsurface observations because depth soundings are possible with this procedure. Meter positions should be based on the sounded depth.
4. Make observations of other factors that would affect the computation of discharge, such as horizontal-angle coefficients.
5. Repeat the observations of depth, velocity, and other variables at each of the selected verticals several times over the duration of the flood wave.
6. Record the watch time of each vertical measurement, and make frequent, corresponding gage-height observations during the period of the flood wave.
7. Develop a rating of gage height versus mean velocity for each of the selected verticals. As described in the first procedure, it may be necessary to develop more than one rating, such as for the rising and falling sides of the flood wave.
8. Develop a rating of gage height versus depth for each of the selected verticals. If streambed changes occur during the measurements, it will be necessary to take these into account by making appropriate corrections.

9. Select a gage height for which a discharge measurement is to be computed. Using a standard discharge-measurement note sheet, enter the stationing for the edge of water and for each of the selected verticals. Enter the depths at each vertical, based on the selected gage height and the ratings of gage height versus depth. Enter the mean velocity at each vertical on the basis of the gage height versus mean velocity ratings. Enter other adjustments, such as horizontal-angle coefficients, as observed during the observation of depths and velocities. Compute the discharge measurement similar to a regular discharge measurement.
10. Repeat the process described in item 9 above for other selected gage heights. If the depth and (or) mean velocity ratings change, such as for rising and falling stage, or for streambed scour or fill, then compute separate discharge measurements for conditions before and after the changes.

Correction of Discharge for Storage During Measurement

Most discharge measurements are made at or near the gaging station and the gage control. However, at some gages, it may be necessary to make discharge measurements at a substantial distance away from the gage and (or) control. For instance, during a flood, the only place to measure may be at a bridge located some distance from the gage. Or for some sites, the low-water section control may be located at a substantial distance downstream from the gage. If a discharge measurement is made at a substantial distance from the gage control during a change in stage, the discharge passing the control during the measurement will not be the same as the discharge at the measurement section. In these situations, an adjustment must be applied to the measured discharge to account for the change in channel storage that occurs between the measurement section and the control during the period of the measurement. The adjustment for channel storage is computed by multiplying the channel surface area by the average rate of change in stage in the reach between the measurement section and the control. The equation is

$$Q_G = Q_m \pm WL\frac{\Delta h}{\Delta t}, \quad (13)$$

where Q_G discharge going over the control, in cubic feet per second,
Q_m measured discharge, in cubic feet per second,
W average width of stream between measuring section and control, in feet,
L length of reach between measuring section and control, in feet,
Δh average change in stage in the reach L during the measurement, in feet, and
Δt elapsed time during measurement, in seconds.

Determine the change in stage at each end of the reach (that is, at the control and at the measuring section) and use an average of these two values. Generally, the gage height at the gage is used at one end of the reach, and a reference point (RP) or a temporary gage is set at the other end of the reach. The water-surface elevation at each end of the reach is determined before and after the measurement to compute Δh. If the measurement is made upstream from the control, the adjustment will be plus for falling stages and minus for rising stages; if it is made downstream from the control, it will be minus for falling stages and plus for rising stages.

An example computation for a flood measurement that was made 0.6 mile upstream from the gage (and control) during a period of changing stage is shown below:

- Measurement made 0.6 mile upstream, L = 3,170 feet. Average width between measuring section and control, W = 150 ft.
- Gage height at beginning of measurement, at the gage (and control) = 5.84 ft.
  Gage height at end of measurement, at the gage (and control) = 6.74 ft.
  Change in stage at gage (and control), 6.74 – 5.84 = +0.90 ft.
- Gage height at beginning of measurement, at measuring section, = 12.72 ft.
  Gage height at end of measurement, at measuring section = 13.74 ft.
  Change in stage at measuring section, 13.74 – 12.72 = +1.02 ft.

Readings taken at measuring section from a reference point before and after measurement.

- Average change in stage in the reach, Dh = (0.90+1.02)/2 = 0.96 ft.
  Elapsed time during measurement, Dt = l.25 hours = 4,500 seconds.
  Measured discharge, Q_m = 8,494 ft^3/s.

$$Q_G = 8,494 - \left(150 \times 3,170 \times \frac{0.96}{4,500}\right) = 8,494 - 101 = 8,393\ \frac{ft^3}{s}, \quad (14)$$

This discharge should then be rounded to 8,390 ft^3/s, which represents the discharge at the gage, or control.

The adjustment of the measured discharge for storage between the gage (or control) and measuring site, as described above, is a separate and distinct problem from that of making adjustments owing to variable water-surface slopes caused by changing discharge. Those adjustments are related to stage-discharge rating analysis, and are described by Kennedy (1984), and by Rantz (1982). The storage adjustment they described should be made immediately following the completion of the discharge measurement, and the resulting adjusted discharge is later used for rating analysis.

Instruments and Equipment

Point-velocity current-meter and profiler measurements are usually classified in terms of the method used to cross the stream during the measurement (that is, wading, bridge, cableway, or ice), the method used to compute the discharge, such as midsection, ADCP, flume, or volumetric, and the method used to compute the velocity (if applicable to the discharge method), such as Price AA meter, ADCP, or ADV. Instruments and equipment used in making current-meter measurements will vary, depending upon which of these measurement types are being used. Current meters, timers, and electronic and other counting equipment are generally common to all types of current-meter and profiler measurements. This section describes equipment currently used by USGS field offices.

Current Meters

A point-velocity current meter, in the context of this report, is a precision instrument calibrated to measure the velocity of flowing water in a single point or fixed volume. Several types of current meters are available for use, including rotating-element mechanical meters, electromagnetic meters, acoustic Doppler velocimeters (ADVs or FlowTrackers), acoustic digital current meters (ADCs), and optical meters.

The principle of operation for a mechanical meter is based on the proportionality between the velocity of the water and the resulting angular velocity of the meter rotor. By placing a mechanical current meter at a point in a stream and counting the number of revolutions of the rotor during a measured interval of time, the velocity of water at that point can be determined from the meter rating.

An electromagnetic current meter is based on the principle that a conductor (water) moving through a magnetic field will produce an electrical current. By measuring this current and the resultant distortion in the magnetic field, the instrument can be calibrated to determine point velocities of flowing water.

The acoustic meter or profiler (for example, ADV or ADCP) uses the Doppler principle to determine velocities of flowing water. Acoustic meters and profilers have been developed to measure point velocities in the vertical profile of an open-channel flow, as well as multicell vertical-velocity profiles. The ADCP has been adapted for use with the moving-boat method of measuring discharge, as described by Mueller and Wagner (2009). The ADV has been developed and adapted to mount on the standard USGS wading rod to measure point velocities in a manner similar to the method for measuring velocity with a vertical-axis rotating-element mechanical meter. ADVs will be described in a later section of this chapter.

The following sections describe the various types of current meters and profilers in more detail, give advantages and disadvantages of each, and provide guidance on care and maintenance.

Current Meters—Mechanical and Vertical Axis

Historically, the most commonly used meter by the USGS to measure open-channel velocities in rivers and streams has been the vertical-axis, mechanical current meter. The original prototype for this kind of current meter was designed and built in 1882 by W.G. Price, while he was working with the Mississippi River Commission. The Price current meter has evolved through a number of different models and refinements since 1882, but the basic theory and concepts remain the same. The Price AA meter is the most commonly used mechanical current meter for discharge measurements made by the USGS; however there are other variations of this meter, such as the Price AA slow velocity, the Price pygmy, and the Price AA winter meter. The following sections describe the various Price meters in more detail, and table 10 summarizes the various configurations and recommendations for the Price current meter, Price AA low velocity, the Price pygmy, the Price AA winter yoke with polymer and metal cups, and the SonTek FlowTracker ADV.

Price AA Meter

Historically, most current-meter measurements made by the USGS have been made with the vertical-axis Price AA and the Price pygmy current meters, as shown in figures 26 and 27. The basic components of the Price AA meter include the shaft and rotor (bucket wheel) assembly, the contact chamber, the yoke, and the tailpiece. The rotor, or bucket wheel, is 5 in. in diameter and 2 in. high with six cone-shaped cups mounted on a stainless-steel shaft. A vertical pivot supports the vertical shaft of the rotor, hence the name vertical-axis current meter. The contact chamber houses the upper part of the shaft and provides a method of counting the number of revolutions the rotor makes. A reduction gear (commonly referred to as the penta gear) on the lower part of the shaft allows counting every fifth revolution of the rotor when it is activated. The penta gear is used in discharge measurements with very high velocities. Contact chambers that can be used on the Price AA meter are described in a later section of this chapter. The yoke is the framework that holds the other components of the meter. A tailpiece is used for balance and keeps the meter pointing into the current.

When placed in flowing water, the rotors of the Price current meters turn at a speed proportional to the speed of the water. For practical purposes, these current meters are considered nondirectional because they register the maximum velocity of the water, even though they may be placed at an angle to the direction of flow. Advantages of the vertical-axis current meter are:

1. They operate in lower velocities than do horizontal-axis meters.
2. Bearings are well protected from silt-laden water.
3. The rotor is easily repairable in the field without adversely affecting the rating.
4. USGS standard ratings apply to the Price AA and Price pygmy meters.
5. A single rotor serves for the entire range of velocities.

Table 10. Price current meter and SonTek ADV configurations, usages, and recommended ranges of depth (without boundary interference) and velocity.

Meter	Contact chamber	Counting method	Rating	Velocity range, feet per second[1]	Depth range, feet	Remarks
Price AA	Standard, cat'swhisker and penta gear	Headphones, CMD[2], or EFN[3]	Standard	0.2 to 12	1.25 or greater	The Price AA meter can be used as a low-velocity meter if equipped with an optic contact chamber.
			Individual	0.1 to 12		
	Magnetic	CMD[2] or EFN[3]	Standard	0.2 to 12		
			Individual	0.1 to 12		
	Optic		Standard or individual	0.1 to 12		
Price AA, low velocity	Cat's-whisker with double contact lobe on shaft. No penta gear.	Headphones, CMD[2], or EFN[3]	Individual	0.1 to 12	1.25 or greater	This is the traditional Price AA low velocity meter. An individual rating is recommended; however, a standard rating can be used if less accuracy is acceptable.
Price pygmy	Cat's whisker	Headphones, CMD[2], or EFN[3]	Standard or individual	0.2 to 4.0	0.3 to 1.5	--
Price, winter WSC[4] yoke, polymer cups	Cat's whisker	Headphones, CMD[2], or EFN[3]	Individual, with suspension device	0.1 to 12	1.25 or greater	This meter is recommended for conditions where slush ice is present.
	Magnetic or Optic	CMD[2] or EFN[3]				
Price, winter WSC[4] yoke, metal cups	Cat's whisker	Headphones, CMD[2], or EFN[3]	Individual, with suspension device	0.1 to 12	1.25 or greater	This meter is recommended for conditions where slush ice is not present.
	Magnetic or Optic	CMD[2] or EFN[3]				
SonTek FlowTracker ADV	N/A	N/A	Individual	0.003 to 13[5]	0.25 or greater	The FlowTracker has been documented by the USGS to provide velocities comparable to mechanical vertical axis current meters.

[1]Low- and high-velocity limits shown in the table are based on a small-to-moderate extrapolation of the lower and upper meter calibration limits. It is not recommended that the meters be used for velocities less than the lower limit. The velocity rating for the Price meter may allow additional extrapolation in the upper range to about 20 feet per second. The upper range of the Price pygmy meter rating may be extrapolated to about 5 feet per second. Standard errors within the meter calibration limits are less than ±5% in all cases. Standard errors in the extrapolated range of velocities are unknown, but are probably within ± 5%.

[5]Manufacturer's specification.

Price AA Meter (Slow Velocity)

In addition to the Price AA meter described above, there is a Price AA meter modified slightly for use in measuring low velocities. To reduce friction, the penta gear has been removed from this meter, and the shaft has two eccentrics making two contacts with the cat's whisker per revolution. The low-velocity meter normally is rated from 0.2 to 2.5 ft/s and is recommended when the mean velocity at a cross section is less than 1 ft/s.

Price Pygmy Meter

A miniature version of the Price AA meter is the Price pygmy meter, as shown in figures 26 and 27, which is used for measuring velocities in shallow depths. The Price pygmy meter is scaled two-fifths the size of the standard meter and has neither a tailpiece nor a penta gear. The contact chamber is an integral part of the yoke of the meter. The Price pygmy meter makes one contact for each revolution and is used only for rod suspension.

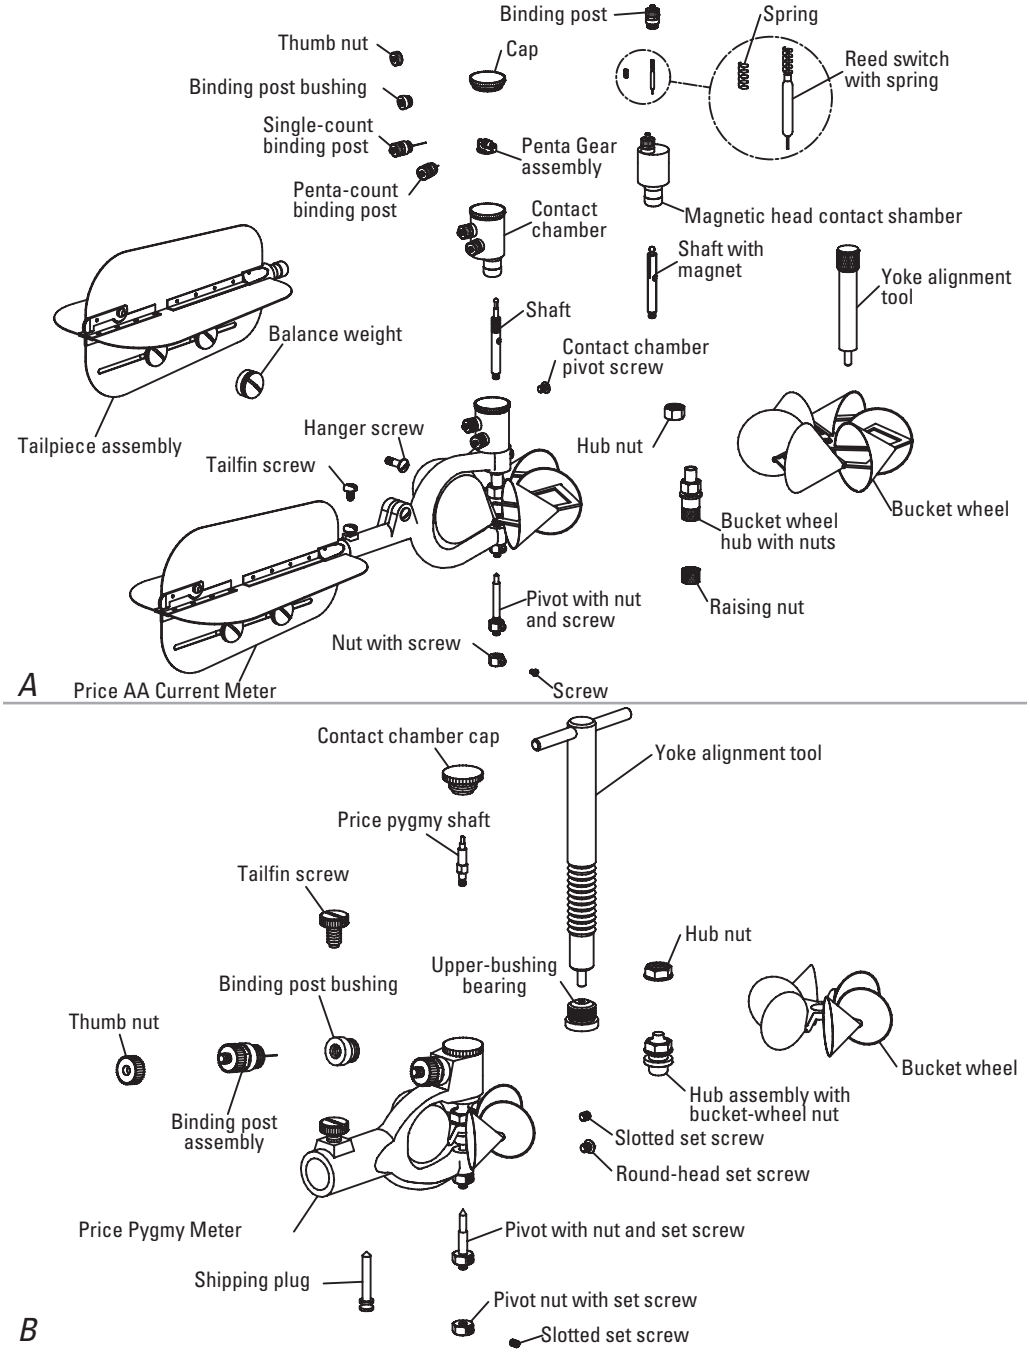

Figure 26. Assembly drawing of the *A*, Price AA current meter and *B*, Price pygmy current meter.

Figure 27. *A*, Price AA and *B*, Price pygmy current meters.

Price AA Winter Meter

In streams where slush ice is present, use a modified Price AA meter, as shown in figure 28. This meter is built with a WSCan winter-style yoke, and uses a polymer rotor (bucket wheel) in place of the standard metal-cup rotor. The WSCan winter-style yoke meters require an individual rating due to increased tolerances in manufacturing. The solid polymer rotor has the advantage that it does not fill with slush ice during a measurement, and the slush ice does not easily adhere to it. If slush ice is not present, alternative methods can be used, including replacing the polymer rotors with metal cups or using a pygmy meter. Regular Price AA meters with metal-cup rotors are also acceptable for slush-free conditions, if there are no problems with cutting the required larger holes through the ice. In recent years, the USGS has increasingly used ADCPs and ADVs as alternatives to the Price AA for making discharge measurements in streams where ice is present.

Figure 28. Price AA meter with winter-style yoke and polymer rotor.

Current Meters—Mechanical and Horizontal Axis

A number of mechanical current meters are available that have a propeller-, or vane-, type of rotor mounted on a horizontal shaft. These meters are used extensively in Europe and some Asian countries, but very little in the United States, and are generally not recommended by the USGS because they are not as durable as the Price current meter. Horizontal-axis current meters include the Ott (Germany), Neyrpic (France), Haskell (U.S.), Hoff (U.S.), Braystoke (United Kingdom), and Valeport. Various models of each of these are also available. As a group, horizontal-axis current meters have the following advantages:

1. The rotor, or propeller, disturbs flow less than vertical-axis rotors because of axial symmetry with flow direction.
2. The rotor is less likely to be entangled by debris than vertical-axis rotors.
3. Bearing friction is less than for vertical-axis rotors because bending moments on the rotor are eliminated.
4. In oblique currents, some of these meters (for example, the Ott meter) measure the velocity normal to the measuring section when the meter is held normal to the measuring section.
5. Rotors with propellers of different pitches are available for some of the meters, allowing measurement of a considerable range of velocity.

See figures 29, 30, and 31, respectively, for examples of the Ott, Hoff, and Valeport current meters.

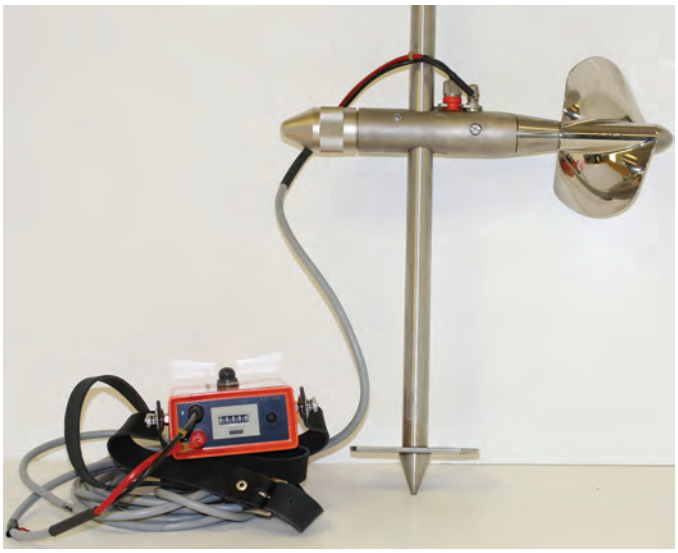

Figure 29. Ott current meter.

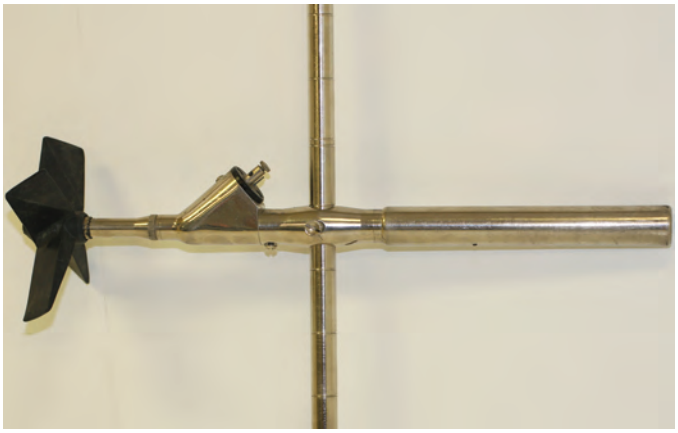

Figure 30. Hoff current meter.

Figure 31. Valeport current meter.

Current-Meter Contact Heads (Vertical Axis)

The Price current meter is normally fitted with a contact chamber that has a cat's-whisker type of circuitry used for counting the number of revolutions of the rotor. Two other types of contact chambers—the magnetic switch type and the optical type—can be fitted to the Price AA meter.

Cat's Whisker

When placed in flowing water, the rotor of the current meter turns at a speed proportional to the speed of the water. The number of revolutions of the rotor is obtained by counting electrical impulses generated in the contact chamber. An eccentric contact on the upper end of the rotor shaft wipes a slender alloy wire (cat's whisker) attached to the binding post, which closes an electrical circuit. This electrical impulse produces an audible click in a headphone or registers a unit on a counting device. Contact points in the chamber are designed to complete the electrical circuit at selected frequencies of revolution, such as twice per revolution, once per revolution, or once per five revolutions (by use of the penta gear). The penta gear, wire, and binding post provide a contact each time the rotor makes five revolutions. Figure 32 shows the contact chamber and shaft for the cat's-whisker-type chamber, with a single-count binding post.

Two types of cat's-whisker wires have been used: one is the simple bronze wire, and the other is the old type of wire with a small solder bead on the end of it. Adjust the cat's whisker for the penta gear so that it always touches the penta eccentric, even when the penta counter is not in use. Otherwise, the meter rating may be affected.

Magnetic Switch

A contact chamber housing a magnetic-type switch, as shown in figure 32, is available to replace the cat's-whisker-contact chamber. The magnetic switch is composed of glass that is enclosed in a hydrogen atmosphere and hermetically sealed. The switch assembly is rigidly fixed in the top of the meter head just above the tip of the shaft. The switch is operated by a small permanent magnet rigidly fastened to the shaft. Two types of magnets used: (1) a bar magnet and (2) a circular magnet. If the contact chamber uses the bar magnet, it should be identified with an "A" stamped on the top surface of the chamber to indicate it has been modified. Older, unmodified contact chambers with the bar magnet were found to under-register for velocities greater than about 2 ft/s. The chambers that utilize the circular magnets fit the standard rating throughout its range.

The magnetic switch quickly closes when the magnet is aligned with it, and then promptly opens when the magnet moves away. The magnet is properly balanced on the shaft. Any type of AA meter can have a magnetic switch added by replacing the shaft and the contact chamber. The magnetic switch is placed in the contact chamber through the tapped hole for the binding post. The rating of the meter is not altered by the change.

An automatic counter, as described in a later section of this chapter, is used with the magnetic-switch contact chamber. Do not use a headphone with the magnetic head because arcing can weld the contacts.

Figure 32. *A*, Price AA magnetic head current meter contact chamber; *B*, single count binding post; and *C*, shaft with magnet for magnetic heads.

Optical Head

A contact head utilizing fiber-optics technology is available for reading the pulse rate of the Price AA current meter. A special rotor containing two fiber-optic bundles is attached to the upper end of the bucket-wheel shaft. The rotation of these fiber-optic bundles gates infrared light from a photo diode to a photo transistor, creating a pulse rate that is proportional to the rotor's revolutions. The pulses are counted, stored, and then compared with a quartz crystal oscillator. This information is processed to display stream velocity on a liquid crystal readout. The display has three averaging periods selected by a rotary switch. The averaging periods range from a minimum of about 5 seconds to a maximum of about 90 seconds. The unit is powered by a 9-volt battery.

Output of pulses from the optical sensing unit can be counted by the current-meter digitizer and the electronic field notebooks described in subsequent sections of this chapter. A standard rating table based on tow-tank calibration tests at the USGS Hydrologic Instrumentation Facility (HIF) is used to convert pulse rate to stream velocity.

A special tail-fin assembly is required for the optical meter so it will balance properly when submerged. The vertical section of this tail fin is marked with the letters OAA, and the horizontal section is marked PAA.

Vertical-Axis Current-Meter Timers and Counters

The determination of velocity using a mechanical current meter requires that the number of revolutions of the rotor be counted during a specified time interval, usually 40 to 70 seconds. Several methods are available for timing and counting the revolutions, as described in the following paragraphs.

Stopwatch and Headset

For current meters having a cat's-whisker-type contact chamber, an electrical circuit is closed each time the contact wire touches the single or penta eccentric of the current meter. A battery and headphone, as shown in figure 33, are parts of the electrical circuit, and an audible click can be heard in the headphone at each electrical closure. Some hydrographers have adapted compact, comfortable hearing-aid-type phones to replace headphones. Beepers that can be heard without the headset are also sometimes used. Do not use a headset, or similar device, with the magnetic contact chamber because arcing can weld the contacts.

Measure the time interval to the nearest second with a stopwatch. Figure 33 shows the standard analog stopwatch; however, a digital wrist watch can also be used.

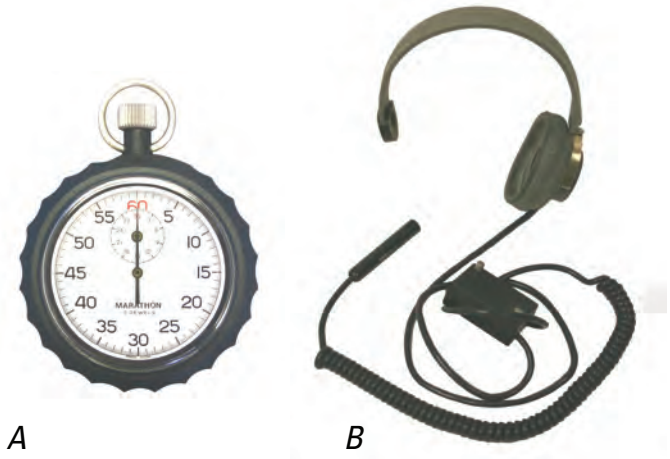

Figure 33. *A*, Analog stopwatch and *B*, current-meter headset.

Electronic Counters

Current-Meter Digitizer (CMD)

A current-meter digitizer (CMD), or automatic electronic counter, as shown in figure 34, was developed for use with the cat's-whisker-, optic-, and magnetic-contact chambers. It can be used with any of the mechanical, vertical-axis current meters, but be careful to avoid false counts when using it for low velocities when the cat's-whisker-contact chamber is used. The CMD automatically counts and displays the number of revolutions of the current-meter rotor and the elapsed time. A buzzer produces an audible signal at each contact closure, and the total counts and elapsed time are shown in the display at the completion of the velocity measurement. A coded chip can be installed in the CMD that will compute and display the velocity from the standard rating table for the particular meter being used. The CMD is powered with five rechargeable batteries, and has an adapter that can be used to attach it to the top of a wading rod.

Figure 34. Current-meter digitizer.

Other Electronic Counters, Electronic Field Notebooks, and Personal Digital Assistants

Electronic counters and timers for mechanical current meters are also available in some commercially available devices. Electronic field notebooks (EFNs), such as the JBS Instruments Aquacalc Pro Discharge Measurement Computer, are designed for electronic recording of discharge-measurement data. These will be described in more detail in a later section of this chapter. Both the Aquacalc and the Hydrological Services Current Meter Counter signal processor (CMCsp) contain built-in digitizers that count and time the current-meter rotor revolutions. Built-in ratings convert the revolutions and elapsed time to velocity. Just as with the CMD described above, the EFNs should be used with caution to avoid false counts when measuring low velocities with meters equipped with a cat's-whisker-contact chamber.

The USGS is increasing development and use of personal digital assistants (PDAs) for primary data collection and processing of discharge measurements and surface-water field data. Software programs such as the Surface WAter Measurement and Inspection application (SWAMI) continue to streamline field activities by reducing the need for paper forms in the field through the development of electronic field forms written for the PDA. SWAMI, as described in previous sections of this chapter, is used in many USGS Water Science Centers, and other PDA applications and programs are continually being developed.

Care of the Vertical-Axis Mechanical Current Meter

There are a number of documents describing the care and maintenance of the vertical-axis current meters. Among these, the most important originated from the USGS and are by Smoot and Novak (1968) and by Rantz (1982), and Office of Surface Water Technical Memorandum No. 89.07 (1989) and Office of Surface Water Technical Memorandum No. 99.06 (1999). These instructions represent a long history of experience based on field use of the meters, as well as from individuals in the Office of Surface Water Hydraulic Laboratory who have repaired and adjusted current meters to calibrate them within close tolerances. A brief description of the recommended procedure for checking the condition of a current meter, and for its care and cleaning during daily field use, is presented in the next few paragraphs. For complete details, consult the above-mentioned documents.

Recommended Procedure Before, During, and After Each Discharge Measurement

1. Before each discharge measurement, make a visual examination of the meter cups or vanes, pivot, bearing, and shaft for damage, wear, or faulty alignment. Inspect the bearing surface for water. This will usually appear as a milky emulsification of oil and water on the lower bearing and pivot, and in the contact chamber. If water is found, dry the meter parts and re-oil because the presence of water will affect the performance of the meter. The lower bearing is probably the most susceptible to the entrance of water.
2. Spin the rotor to make certain it operates freely, and allow it to slowly return to a resting position. If the rotor does not turn smoothly, or if it stops abruptly, then it is a sign of some problem and it should be corrected before using the meter. Check the balance and alignment of the meter on the hanger or wading rod. Be sure that the conductor wire does not interfere with meter balance and rotor spin.
3. During measurements, check the meter periodically when it is out of the water to be sure that the rotor spins freely, and that there is no debris or other substance obstructing it.
4. After a measurement is completed, make another visual inspection as described above to ensure that nothing was damaged or caused the meter to malfunction during the measurement. If there is a problem, you may have to make another discharge measurement.
5. Timed spin tests (described later in this chapter) are not required for each discharge measurement. The visual inspection described above is preferred over timed spin tests made in the field.

Recommended Procedure After a Day of Use in the Field

1. Examine the pivot and bearing surfaces for wear and damage, especially the pivot point. The pivot should feel sharp, not rounded or dull. It should not have a burr detectable visually or with the fingernail. A magnifying glass is helpful in making this examination. If the pivot is dull or burred, replace it with a new one.
2. Clean and lightly oil the pivot, bearing, and upper shaft with current-meter oil. Do not use regular machine oil, such as “3-in-1,” because it tends to become gummy when exposed to water.
3. Check and carefully adjust cat’s-whisker contacts, if necessary. Cat’s whiskers should be made of simple bronze wire, not beaded wire.
4. After replacing the contact-chamber cap, spin the meter to see if it is operating correctly, as previously described. A timed spin test is not required.

Recommended Procedure After Each Field Trip

After each field trip, completely disassemble, inspect, and clean current meters. Make any necessary repairs. Detailed instructions for the disassembly, inspection, and adjustment of Price AA (both standard and magnetic head) and pygmy current meters are contained in the attachments to Office of Surface Water Technical Memorandum No. 99.06 (1999). A timed spin test may also be performed after each field trip, and after meter repairs.

Inactive Current Meters

Disassemble, inspect, and clean current meters as described above, prior to storing them. If the period of storage is less than 1 year, the meter may be used without further maintenance if an inspection and a spin test indicate it is operating properly. If the meter has been in storage longer than 1 year, or an indeterminate period, complete inspection, cleaning, and adjustment before using the meter.

Spin Tests

A timed spin test, made in the field before and after each discharge measurement, is no longer a requirement as it was in the past. The visual tests as described above are adequate for checking the meter in the field. Note “OK” or “free” in the spaces on the front sheet of the discharge measurement for spin test information to indicate that the visual check of the meter was acceptable.

Perform the full-timed spin test under controlled conditions between field trips, when the meter is suspect, and before and after repairs. Place the meter on a stable, level surface to perform the spin test. There should be no wind currents or drafts that can affect the rotor spin. Sharply spin the rotor while starting a stopwatch. Stop the stopwatch when the rotor comes to a complete stop. The minimum, acceptable spin times are as follows:

All types of Price pygmy meters	0:45 seconds
All types of Price AA meters	2:00 minutes

These are considered to be absolute minimum spin times. Meters in good condition will perform substantially better.

Recordkeeping

Maintain a current-meter log to record the results of the timed spin tests for each current meter. In addition, the log should contain information that identifies the meter and rotor, a history of repairs to the meter, as well as the name of the person who checked the meter, and dates of occurrences. Figure 35 shows a recommended format for the current meter log. The current-meter log should become a permanent record and archived with other water-resources data.

Rating of Mechanical Current Meters

In order to determine the velocity of the water from the revolutions of the rotor of a mechanical current meter, a relation must be established between the angular velocity of the rotor and the velocity of the water turning it. This relation is referred to as the current-meter rating, and is expressed in an equation or in tabular format.

The current-meter rating facility is operated by the USGS, and is located at the Hydraulics Laboratory of the HIF at Stennis Space Center, Miss. The rating facility consists of a sheltered, reinforced concrete basin 400 ft long, 6 ft wide, and 6 ft deep, commonly called the tow tank. An electrically driven car rides on rails alongside and extending the length of the water-filled basin, and carries the current meter at a constant rate through the still water. Although the rate of travel can be accurately adjusted by means of a hydraulic regulating gear, the average velocity of the moving car is determined for each run by making an independent measurement of the distance it travels during the time that the revolutions of the rotor are electrically counted. A scale graduated in feet and tenths of a foot is used for this purpose. Eight pairs of runs are usually made for each current meter. A pair of runs consists of two traverses of the basin, one in each direction, at approximately the same speed. Practical considerations usually limit the ratings to velocities ranging from 0.1 ft/s to about 15 ft/s, although the rating car can be operated at lower speeds. Unless a special request is made for a more extensive rating, the lowest velocity used in the rating is about 0.2 ft/s, and the highest is about 8.0 ft/s.

Because there is rigid control in the manufacture of the Price meter, virtually identical meters are produced and, for practical purposes, their rating equations are identical. Therefore, there is no need to calibrate the meters individually, which is a major advantage and time saver. Instead, a standard rating is established by calibrating a group of meters that have been constructed according to USGS specifications. This standard rating is essentially an average rating for the calibration group, and it is then supplied with all meters manufactured according to USGS specifications. Identicalness of meters is ensured by supplying the dies and fixtures for the construction of Price current meters to the manufacturer who makes the successful bid. Another advantage of the standard rating is that field repairs can be made to a meter without requiring that it be recalibrated. On the other hand, there are somewhat larger errors associated with the standard ratings, as opposed to the individual meter ratings. For additional details see Office of Surface Water Technical Memoranda Nos. 91.01 (1991) and 99.05 (1999).

Standard current-meter ratings are not mandatory for use with the Price meters. For some applications, it may be appropriate to use individually rated meters to avoid the additional uncertainty of the standard ratings. All winter-style meters must be individually rated with the suspension device that will be used with it.

Standard current-meter ratings, as of 1999, have been defined for the Price AA with the cat's-whisker- and magnetic-contact chambers, and the Price pygmy with the cat's-whisker-contact chamber. The standard rating for the Price AA with the fiber-optic-contact chamber was defined in 1991. These ratings are as follows:

- Price AA with cat's-whisker- and magnetic-contact chambers (Standard rating No. 2)

$$V = 2.2048R + 0.0178 \quad (15)$$

- Price pygmy with cat's-whisker-contact chamber (Standard rating No. 2)

$$V = 0.9604R + 0.0312 \quad (16)$$

- Price AA with fiber-optic-contact chamber

$$V = 2.194R + 0.014 \ (R<0.856) \quad (17)$$

$$V = 2.162R + 0.041 \ (R>0.856) \quad (18)$$

where V velocity, in feet per second (ft/s), and
R the number of rotor revolutions per second.

For convenience in field use, the data from the current-meter ratings are reproduced in tables, samples of which are shown in figures 36 and 37. In figure 36, the velocities corresponding to a range of 3 to 200 revolutions of the rotor within a period of 40 to 70 seconds are listed in the tables.

In figure 37, the velocities corresponding to a range of 3 to 350 revolutions of the rotor within a period of 40 to 70 seconds are listed in the tables. This range in revolution and time has been found to cover general field requirements. To provide the necessary information for extending a table for the few instances where extensions are required, the equation of the rating table is shown in the heading.

Meters that have been rated by means of rod suspension, and then by means of cable suspension using Columbus-type weights and hangers, have not shown significant differences in their ratings. Therefore, no suspension coefficients are needed if weights and hangers are properly used.

The preceding discussion relates primarily to the Price current meters. Other types of meters, such as the horizontal-axis meters and the electromagnetic meters, can also be calibrated in the tow tank in a similar manner as the Price meters. The HIF designed and constructed a special tow tank for testing and calibrating the acoustic Doppler point-velocity FlowTracker velocimeter. In the near future, there are HIF plans to build and operate a tow tank designed to test and calibrate ADCPs.

Figure 37. Example of a standard current-meter rating table No. 2 for Price AA current meters with cat's-whisker and magnetic contact chambers.

Electromagnetic Current Meters

Electromagnetic current meters, with no moving parts, are commercially available for measuring point velocities. These meters are based on the principle that a conductor (in this case, water) moving through a magnetic field will produce an electric current. The velocity of the moving water can be related to the electric current produced, and the distortion created in the magnetic field. The electromagnetic meters can be accurately calibrated in a tow tank, similar to the calibration of mechanical meters; however, tests have shown that the electromagnetic meters are less accurate than the Price AA meters, especially at low velocities (less than about 0.5 ft/s). The Price AA meters also have less variance than the electromagnetic meters at all velocities. Advantages of the electromagnetic current meter are as follows: no moving parts; direct readout of velocity; and, in oblique flow, the velocity measured is normal to the measuring section when the meter is held normal to it.

Marsh-McBirney 2000

An electromagnetic current meter successfully used by the USGS for making discharge measurements is the Model 2000, produced by Marsh-McBirney. This meter, as shown in figure 38, is designed to mount on a standard round or top-setting wading rod. The meter is not designed for cable suspension.

A display meter, also shown in figure 38, shows a direct readout of the velocity. No conversion equation or table is necessary. The meter must be kept clean for accurate readings, and it is recommended that the rating be occasionally spot checked to verify that it is still accurate. This can be done in two ways. First, submerge the meter in a bucket of still water to verify the zero point of the rating. Second, place the meter in close proximity to a Price AA meter, in flowing water, to verify that it gives the same velocity reading. If there are differences, rate the electromagnetic meter again in the tow tank.

Figure 38. Marsh-McBirney Model 2000 electromagnetic flowmeter and display meter.

Ott Electromagnetic Current Meter

An Ott electromagnetic current meter is available; however, it has not been used extensively in the United States. The Ott meter, shown in figure 39, works in a manner similar to the Marsh-McBirney meter.

Figure 39. Ott electromagnetic current meter.

Acoustic Current Meters

Acoustic Doppler current meters, with no moving parts, are commercially available for measuring point velocities. These meters are based on the Doppler principle. The velocity of the moving water is measured using the transmitted and received signals from sound pulses reflecting off particles in the moving water column. These acoustic meters can be accurately calibrated in a tow tank, similar to the calibration of mechanical meters. Advantages of an acoustic Doppler current meter are as follows: no moving parts; direct readout of velocity; and ability to sense very low velocities less than the rated velocities in standard mechanical current meters.

Acoustic Doppler Velocimeter (ADV)

The SonTek/YSI FlowTracker handheld ADV ("FlowTracker" and "ADV" are used interchangeably in this chapter) is designed as an alternative to the Price AA and pygmy meters for wading discharge measurements. The FlowTracker operates at an acoustic frequency of 10 MHz and measures the phase change caused by the Doppler shift in acoustic frequency that occurs when a transmitted acoustic signal reflects off particles in the flow. The magnitude of the phase change is proportional to the flow velocity. The phase difference can be positive or negative, allowing ADVs to measure positive and negative velocities. The FlowTracker measures the velocity at a rate of approximately 10 MHz, averages the data, and records 1-second velocity-vector data.

The maximum velocity the FlowTracker can measure is reduced when measuring flow that is not perpendicular to the transmitting transducer. The receiving transducers can measure a velocity range of only ±1.15 m/s (3.77 ft/s). A velocity component placed directly toward or away from the receiving transducers larger than 1.15 m/s (3.77 ft/s) will result in erroneous velocities. Because of the geometric arrangement of the transmitting and receiving transducers, a velocity of 4.5 m/s flowing perpendicular to the transmitting transducer face will result in the maximum velocity towards a receiving transducer of 1.15 m/s (3.77 ft/s).

The FlowTracker probe is mounted to a standard top-setting wading rod with a special offset-mounting bracket (fig. 40). This bracket is designed to locate the FlowTracker probe at the front of the wading rod, with the sampling volume

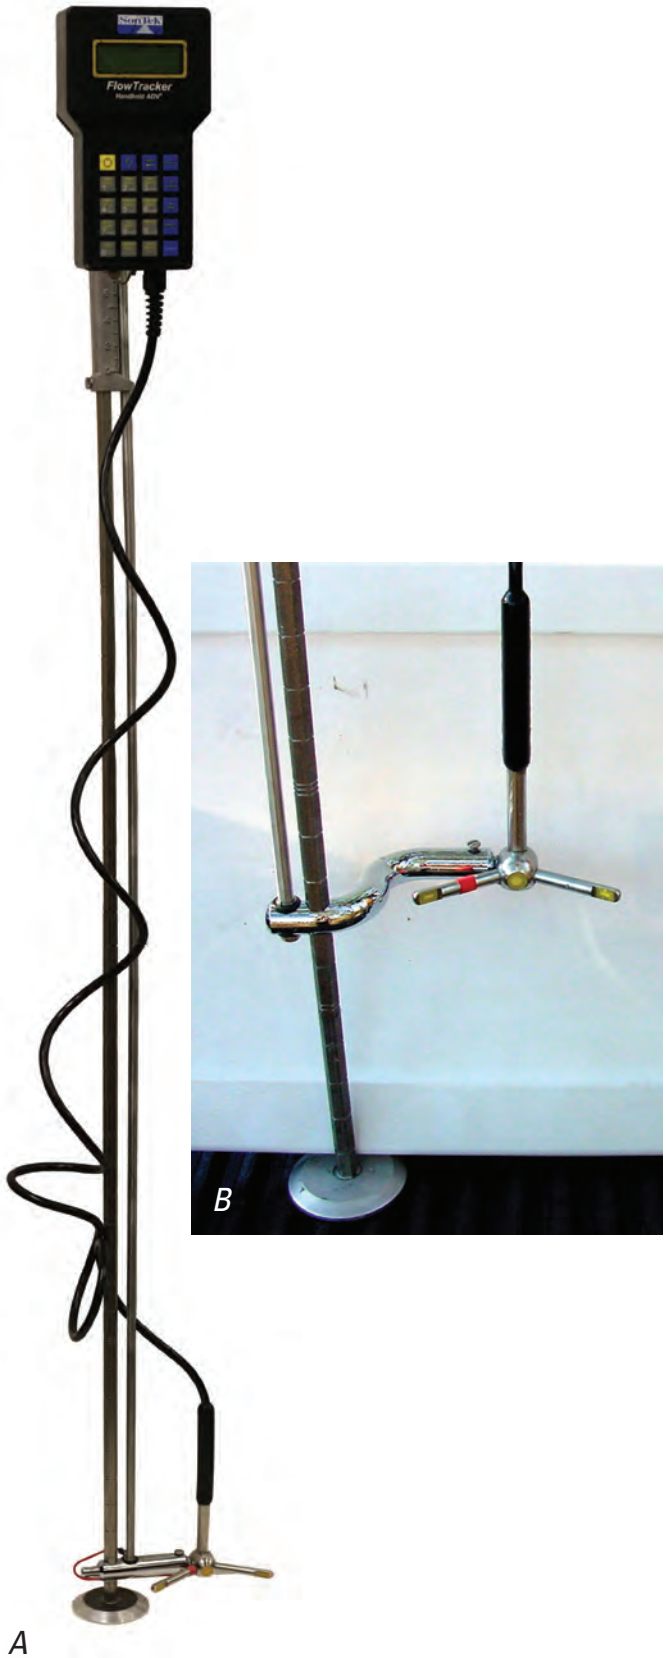

Figure 40. *A*, SonTek/YSI FlowTracker acoustic Doppler velocimeter (ADV) mounted on a standard top-setting wading rod and *B*, closer view of transmitting and receiving transducers and offset-mounting bracket.

about 2 in. (5 cm) to the right of the wading rod. Although the probe is inserted into the flow, the sampling volume is about 4 in. (10 cm) away from all physical parts of the probe, to minimize flow disturbance in the sampling volume.

FlowTrackers have several unique data-processing requirements because of their method of operation and some of the inherent limitations of the acoustic Doppler measurement technique. Unlike mechanical meters that use the momentum of the water to turn a propeller and directly measure the velocity of the water, the FlowTracker does not measure the velocity of the water. The FlowTracker measures the velocity of particles (sediment, small organisms, and bubbles) suspended in the flow, assuming that these particles travel at the same velocity as the water. Therefore, the quality of the measurement is dependent on the presence of particles within the sampling volume that reflect a transmitted signal. The FlowTracker records the signal-to-noise ratio (SNR), standard error of velocity (based on 1-second data), angle of the measured flow (relative to the x-axis of the FlowTracker probe), number of filtered velocity spikes, and a boundary quality-control flag. These velocity and quality-assurance data may be used to evaluate the measurement conditions. Few similar quality-assurance data are available for Price current-meter measurements.

Although a FlowTracker can measure within about 1.2 in. (3 cm) of a boundary, the velocity measurement might be affected by acoustic interference when the sampling volume is close to boundaries or underwater objects, even when the sampling volume is not directly on or past the boundary. At the start of each velocity measurement, if the probe detects nearby acoustic boundaries that could cause interference with the velocity measurement, a boundary adjustment is automatically made. The boundary adjustment attempts to overcome the possible interference by reducing the lag times of the acoustic signals transmitted by the FlowTracker, causing a reduction of the velocity range that can be measured. Any changes are noted in the boundary quality-control flag. Because the sampling volume is located about 4 in. (10 cm) from the transmitting transducer it can be difficult to ascertain the precise location of the sampling volume. If the sampling volume is on or past a boundary, the velocity data will be erroneous. Be careful to avoid boundaries while making measurements in depths less than 3.54 in. (9 cm), especially in channels with irregular bottoms.

Spikes in velocity data occur with any acoustic Doppler velocity sensor such as the FlowTracker. Spikes may have a variety of causes (for example, large particles in the flow, air bubbles, or acoustic anomalies). Velocity data from each FlowTracker measurement are evaluated to look for spikes. The FlowTracker spike filter is a variation on a method called "Tukey's Outlier." In this method, a histogram of each velocity component is calculated. The FlowTracker determines the lower quartile (*Q1*; 25 percent of samples are less than this value), the upper quartile (*Q3*; 75 percent of samples are less than this value), and the interquartile range ($IQR = Q3-Q1$). If the *IQR* is less than 0.015 m/s (0.049 ft/s), *IQR* is set to

0.015 m/s (0.049 ft/s). Any value less than (*Q1–2*IQR*) or greater than (*Q3+2*IQR*) is considered a spike and is not used for mean-velocity calculations.

The FlowTracker measures magnitude and direction of velocity. The operator must keep the wading rod perpendicular to the tag line so that the pulse generated by the transmitter is parallel to the tag line, regardless of flow direction. To compute discharge, the FlowTracker uses the component of velocity perpendicular to the transmitting transducer and reports the flow angle from the FlowTracker's x-axis as a quality-control value. A flow angle measured by the FlowTracker may be the result of flow that is not perpendicular to the tag line, or a wading rod that is not being held perpendicular to the tag line (operator error). Flow angles of less than 20 degrees with small variations between verticals are not unusual. Large fluctuations of flow angles between verticals, however, may indicate a poorly measured cross section. If there is angular flow, and the wading rod is oriented with the flow, the velocity used and resulting discharge would be biased high. If the flow is truly perpendicular to the cross section, but the wading rod is erroneously held at an angle, the velocity and resulting discharge would be biased low. To avoid possible errors in the measured velocities, it is important that the operator always carefully and accurately aligns the wading rod.

Signal-to-Noise Ratio (SNR)

Adequate signal-to-noise ratio is needed to obtain an accurate measurement of the flow velocity. SNR is a measure of the strength of the reflected acoustic signal relative to the ambient noise level of the instrument. SNR is a function of the concentration and size distribution of the particles that reflect the acoustic signal. SNR is recorded for each beam with each 1-second sample. The manufacturer states that optimal SNR is 10 decibels (dB) or above (SonTek/YSI, 2002). USGS policy is that FlowTrackers should not be used for measuring discharge if the SNR for any single beam is less than 4 dB.

Speed of Sound

The accuracy of hydroacoustics instruments like the FlowTracker is dependent on an accurate speed of sound. The speed of sound is primarily a function of the temperature and salinity of the water. The FlowTracker has a built-in temperature sensor. To verify that the temperature sensor is working correctly, take an independent water-temperature measurement prior to each discharge measurement. If the FlowTracker has been stored in an environment with a different ambient temperature from the water, the probe may need to be placed in the water for a period of time, allowing it to equilibrate with the water temperature. A 5°F error in temperature will result in approximately a 1-percent bias in the measured velocity. The speed of sound is also sensitive to salinity. A 5-part-per-thousand error in salinity would result in an approximate velocity bias of 1 percent, when used in saline environments like estuaries; therefore, the operator needs to measure the salinity and input the value into the FlowTracker.

Maintenance and Care

Although the built-in QCTest is reliable for detecting issues, a BeamCheck stores more system performance data and still may be needed to evaluate the unit in more detail when there is a potential issue.

QCTests and BeamChecks

- Perform a QCTest and store it with each measurement. When a QCTest is completed as part of a measurement, it will print out on the measurement summary.
- Complete a QCTest in flowing water with the sample volume away from any boundaries.
- Perform a BeamCheck if you notice any anomalies in the QCTest. Any failures in a QCTest require a BeamCheck.
- Perform a BeamCheck after any possible physical damage (drop, and so forth), firmware upgrade, or repair.

As stated previously, the FlowTracker is an acoustic Doppler velocimeter (ADV) that has been adapted to fit on a typical USGS streamgaging wading rod, developed by the USGS in cooperation with the SonTek/YSI Inc., and is widely used by the USGS. The FlowTracker has undergone extensive testing to evaluate differences between the FlowTracker performance and vertical-axis current meters (that is, Price AA, pygmy, and so forth).

The USGS Office of Surface Water, through the HIF, has put into place a process that will check and recalibrate each FlowTracker approximately every 3 years to ensure the quality assurance/quality control of this instrument in the measurement of the Nation's surface-water resources. For additional details, see Office of Surface Water Memorandum 2010.02 (2010).

Acoustic Digital Current Meter (ADC)

Another development that is a potential alternative to the Price AA and pygmy meters for wading discharge measurements is the Ott acoustic digital current meter (ADC) (fig. 41). The Ott ADC operates with two transducers at an acoustic frequency of 6 MHz, and measures the phase change caused by the Doppler shift in acoustic frequency that occurs when a transmitted acoustic signal reflects off particles in the flow. The phase measurement is restricted to ±180 degrees and uses a pulse scheme with two different time delays to resolve the phase ambiguity.

The velocity (V) is computed using the following formula:

$$V = \frac{c \times \Delta\Phi}{4 \times \Pi \times \tau}, \quad (19)$$

where V velocity (in distance per unit time),
c speed of sound in water (in distance per unit time),
$\Delta\Phi$ computed phase difference, and
τ time lag between pulses.

The Ott ADC uses a pulse-coherent technique. Transmitted pulses have a known lag time (τ). Backscatter echoes are amplified in the sensor head and then sent to the handheld display where they are digitized. A stable quartz oscillator controls the measurement sequence.

The Ott ADC has several unique data-processing requirements because of its method of operation and some of the inherent limitations of the acoustic Doppler measurement technique. Unlike mechanical meters that use the momentum of the water to turn a propeller and directly measure the velocity of the water, the Ott ADC, as with other acoustic Doppler current meters in use in the USGS and elsewhere, does not measure the velocity of the water. The Ott ADC measures the velocity of particles (sediment, small organisms, and bubbles) suspended in the flow, assuming that these particles travel at the same velocity as the

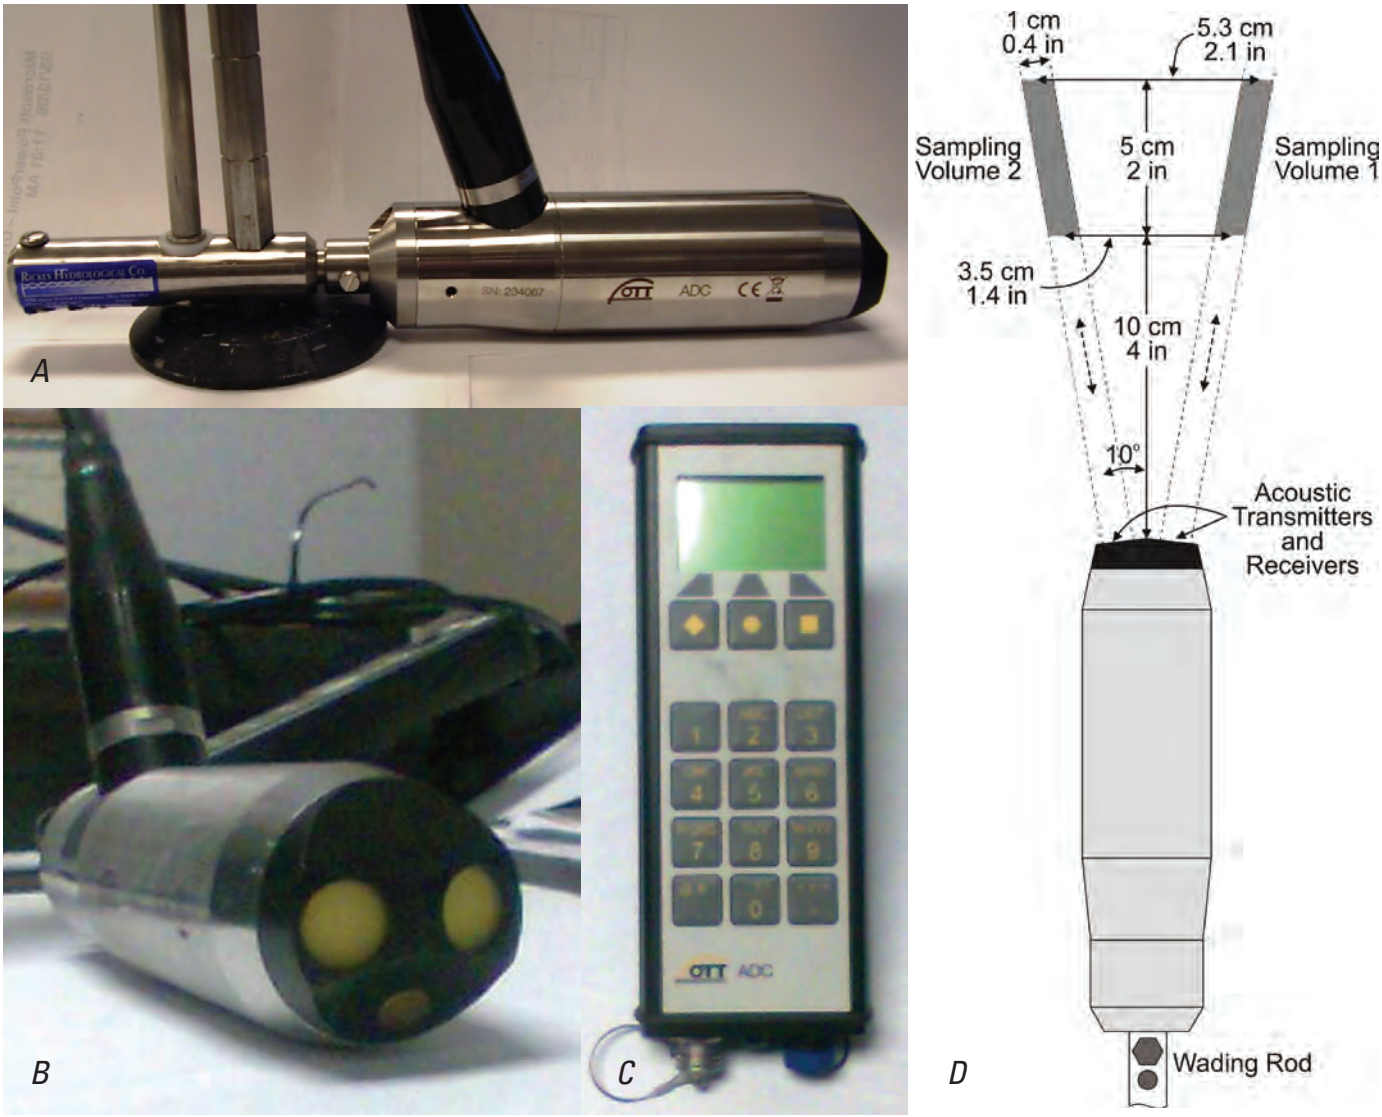

Figure 41. *A*, Ott acoustic digital current meter (ADC) mounted on a standard top-setting wading rod; *B*, closer view of transmitting and receiving transducers; *C*, ADC datalogger; and *D*, schematic of the sampling volume and transducers.

water. Therefore, the quality of the measurement is dependent on the presence of particles within the sampling volume that reflect a transmitted signal. In addition, the Ott ADC measures depth by using an absolute piezoresistive pressure cell with a range of 0 to about 16.4 ft (0–5 m). The pressure cell is located inside the probe and protected by the wading rod adapter, which is securely fastened with two screws. The hydrographer can estimate a depth without reading the top-setting rod.

Preliminary testing of the Ott ADC at the HIF indicates this technology has a lot of potential for use as an alternative to mechanical current meters.

Acoustic Doppler Current Profiler (ADCP)

The ADCP measures velocity magnitude and direction using the Doppler shift of acoustic energy reflected by material suspended in the water column, providing essentially a complete vertical profile of velocity.

Broadband, narrowband, and other pulse-to-pulse coherent ADCPs transmit pairs of acoustic pulses along a narrow beam from each of multiple transducers. As the pulses travel through the water column, they strike suspended sediment and organic particles (referred to as "scatterers") that reflect some of the acoustic energy back to the ADCP. The ADCP receives and records the reflected pulses. The reflected pulses are separated by time differences (range gating) into successive volumes called "depth cells." The frequency shift (known as the Doppler effect) is proportional to the velocity of the scatterers relative to the ADCP. The ADCP computes a velocity component along each beam, because the beams are positioned at a known angle from the vertical (usually 20 or 30 degrees) and in known horizontal orientations so that trigonometric relations can be used to compute three-dimensional water-velocity vectors for each depth cell. Therefore, the ADCP produces vertical profiles of velocity composed of water speeds and directions at regularly spaced intervals, vertical profiles of velocity, discharge profiles, and a wealth of information for a discharge measurement (fig. 42).

The Broadband ADCPs (such as the Teledyne RD Instruments Rio Grande ADCPs) use phase-coded pulses, such that many independent measurements of velocity can be made by a single Broadband pulse of the same length as a narrow-band pulse. These independent measurements are averaged to produce a velocity with a lower uncertainty than would be possible with a single measurement. Narrow-band systems (such as the SonTek/YSI RiverSurveyor S5 and M9) typically compensate for this characteristic by pinging faster (sending more pulses per second, up to 20 Hz) and reporting a velocity based on the average of many pulses with a typical velocity output of 1 Hz.

Currently, the most common main external components of an ADCP are a transducer assembly and a pressure case. Commonly, the transducer assembly consists of three to nine transducers that operate at a fixed, ultrasonic frequency, typically 300 to 3,000 kilohertz (kHz). The transducers are horizontally spaced around the transducer assembly; all transducers have the same fixed angle from the vertical, referred to as a "beam angle," that is typically between 20 and 30 degrees. The transducer assembly may have a convex or concave configuration or, in the case of the phased array, an essentially flat surface. The pressure case is attached to the transducer assembly. Examples of several different ADCPs used in the USGS are shown in figure 43.

When an ADCP is deployed from a moving boat, it is connected by cable to a power source and by cable or radio modem to a portable microcomputer. The computer is used to program the instrument, monitor its operation, and collect and store the data. For a detailed description of how an ADCP measures velocity and computes discharge, and detailed instruction in the use of ADCP technology with reference to moving boats, see Mueller and Wagner (2009).

Midsection Method With an ADCP

When an ADCP is deployed to perform a midsection method discharge measurement, most best practices used for mechanical-meter discharge measurements still apply. These practices, including site selection, are well documented in Rantz and others (1982). The midsection method with an ADCP is similar to the midsection method used for mechanical-meter discharge measurements and involves measuring the channel area and water velocities of a stream at a cross section; however, instead of point measurements of velocity, with this method, the average velocity is obtained by profiling the velocity in the water column at each section. The channel is divided into a number of vertical subsections. Most natural channels must be divided into 20 or 30 subsections to adequately characterize their irregular geometry. The depth and average velocity are measured at each subsection and are applied to a subarea whose width extends halfway to the preceding and following observation points. The area of each subsection is determined by directly measuring width and depth. The average water velocity in each subsection is estimated using the measured velocity at elected locations in the vertical. The total discharge within the stream is the sum of the individual subsection discharges.

Additional details and in-depth discussion of ADCP technology, methodology, and quality assurance and quality control can be found in USGS publications by Simpson and Oltmann (1993), in Lipscomb (1995), Morlock (1996), Oberg and others (2005), and Mueller and Wagner (2009). The ADCP method is a relatively new and evolving technology, and as a result, there are ongoing changes to the hardware, software, and firmware.

Optical Current Meters

An optical current meter, as shown in figure 44, is a stroboscopic device designed to measure surface velocities in open channels without immersing equipment in the stream. The optical current meter is used principally in measurements of surface velocity during floods when it is impossible to use streamgaging equipment that requires placement in the water, because of extremely high velocities and high-debris content in the stream. Use of this technology and other technologies, such as radar, deserves further investigation in the measurement of discharge using surface velocities.

Figure 44. Hydrographer using an optical current meter to measure surface velocity.

Sounding Equipment

Sounding (determination of depth) is commonly done mechanically; the equipment used depends upon the type of measurement being made. Measure depth and position in the vertical with a rigid rod or by a sounding weight suspended from a cable. The cable is controlled either by a reel or by a handline. A sonic sounder is also available, but it is usually used in conjunction with a reel and a sounding weight. The various equipment that can be used for sounding is described in the following paragraphs. In addition, ADCPs can sound depths using sophisticated algorithms that may have global positioning features and capabilities. Mueller and Wagner (2009) discuss ADCP sounding in more detail.

Top-Setting Wading Rods

The two types of wading rods commonly used are the top-setting rod and the round rod. The top-setting rod is preferred because of the convenience in setting the meter at the proper depth and because the hydrographer can keep his hands dry.

The top-setting wading rod, as shown in figure 45, has a ½-in. hexagonal main rod for measuring depth and a ⅜-in. diameter round rod for setting the position of the current meter.

The rod is placed in the stream so the base plate rests on the streambed, and the depth of water is read on the graduated main rod. When the setting rod is adjusted to read the depth of water, the meter is positioned automatically for the 0.6-depth method, as shown in figure 46. The 0.6-depth setting is the setting measured down from the water surface. This setting is the same as the 0.4-depth position when measured up from the streambed. When the depth of water is divided by 2, and this value is set on the setting rod, the meter will be at the 0.8-depth position from the water surface. When the depth of water is multiplied by 2, and this value is set, the meter will be at the 0.2-depth position from the water surface.

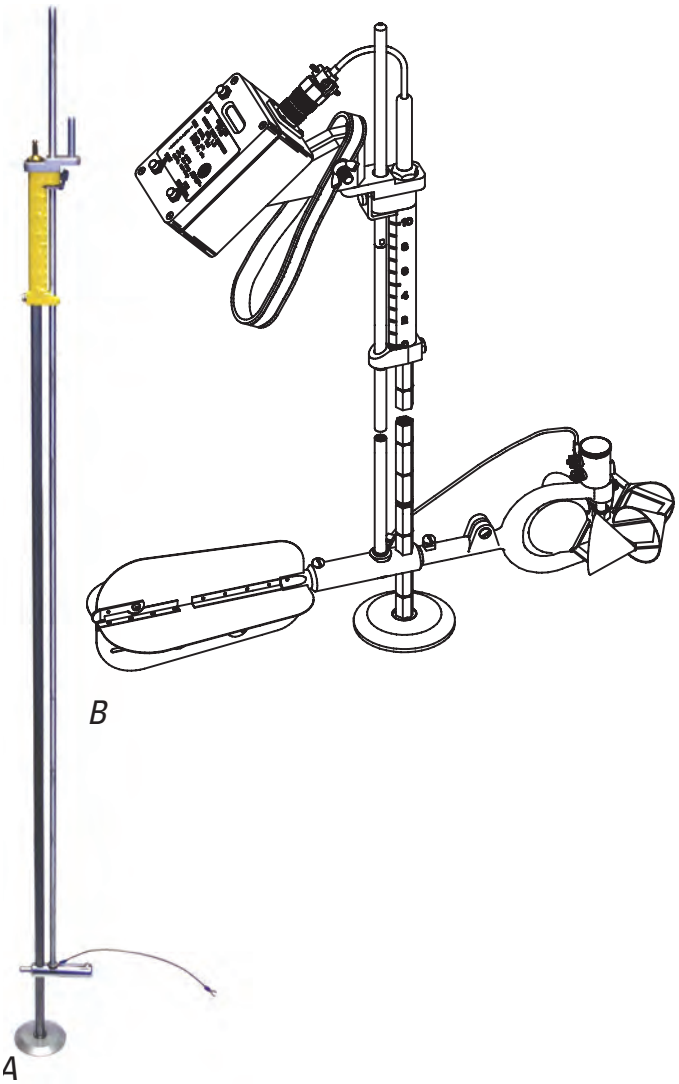

Figure 45. *A*, Top-setting wading rod and *B*, schematic of a top-setting wading rod with Price AA current meter and current-meter digitizer (CMD) attached.

Figure 46. Closeup view of setting scale on handle of top-setting wading rod.

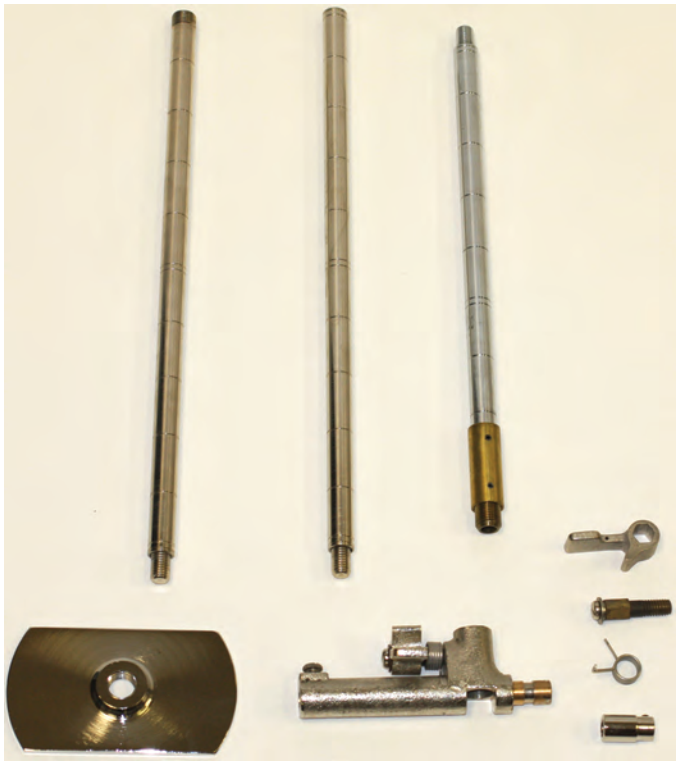

Figure 47. Parts for the round wading rod.

Round Wading Rods

The round wading rod, as shown in figure 47, consists of a base plate, lower section, sliding support, three or four intermediate sections, and a rod end (not essential). The parts are assembled as shown in figure 48. The meter is mounted on the sliding support and is set at the desired position on the rod by sliding the support. The round rod can be assembled into various lengths using the 1-ft sections, and it is easy to store and transport when disassembled.

Figure 48. Round wading rod with Price AA current meter attached.

Winter-Style Suspension Wading Rods

Measurements made under ice cover should use the WSCan winter sounding rods, either in the ½- or 1-in.-diameter versions. These rods are available in sections so that the desired length can be assembled. A special foot fits the lower section, and the rods will accommodate the winter-style current-meter yoke, as shown in figure 49.

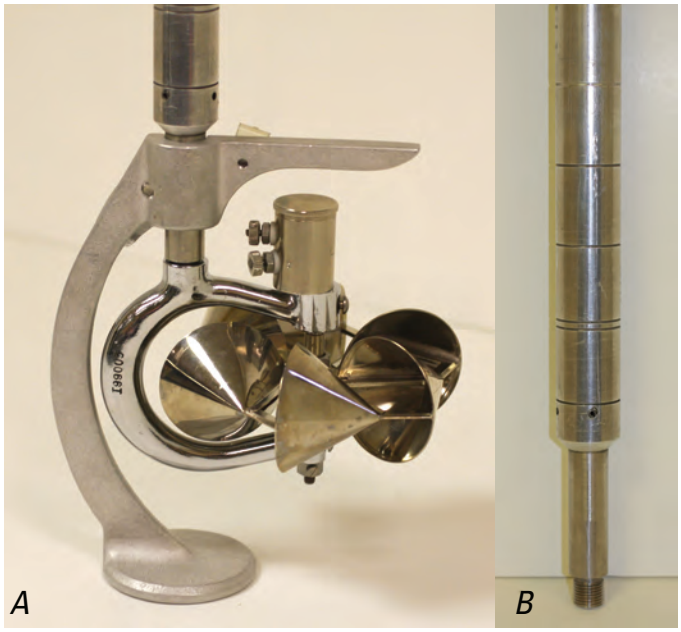

Figure 49. Water Survey Canada winter-style round 1-inch suspension rod and meter: *A*, with Price AA meter in a winter-style yoke attached and *B*, closer view of round 1-inch diameter suspension rod.

Figure 50. Columbus C-type sounding weights (15 through 300 pounds).

Sounding Weights

If a stream is too deep or too swift to wade, the current meter is suspended in the water from a boat, bridge, or cableway. A sounding weight is suspended below the current meter to keep it stationary in the water. The weight also prevents damage to the meter when the assembly is lowered to the streambed.

The sounding weights currently used are the Columbus weights, commonly called the C type, and are shown in figure 50. The weights are streamlined to offer minimum resistance to flowing water. The weights are available in 15-, 30-, 50-, 75-, 100-, 150-, 200-, and 300-pound sizes. Each weight has a vertical slot and a drilled horizontal hole to accommodate a weight hanger and securing pin.

Hanger Bars

The weight hanger is attached to the end of the sounding line by a connector. The current meter is attached to the hanger bar beneath the connector, and the sounding weight is attached to the lower end of the hanger bar.

There are three types of weight hanger bars, as shown in figure 51:

1. The Columbus or C type, ⅛ × ¾ × 12 in. (for weights up to 150 pounds);
2. Heavy weight, ⅛ × ¾ × 18 in. (for 200- and 300-pound weights);
3. Heavy weight, ⅛ × 1 ½ ×18 in. (for 200- and 300-pound sounding weights that have the slots properly extended to accommodate a l½-in. wide hanger bar).

Figure 51. Sounding weight hanger bars and hanger pins.

The Columbus hanger bar contains three holes in order to properly position the meter. The hanger screw of the current-meter yoke is placed through the bottom hole to support the meter when a 30-pound sounding weight is used. The center of the meter cups is then 0.5 ft above the bottom of the weight. This arrangement is designated as 30 C .5, which means that a 30-pound Columbus weight is being used and the center of the meter cups is 0.5 ft above the bottom of the weight. The hanger screw goes through the middle hole when 15- or 50-pound weights are used. The designations for these arrangements are 15 C .5 and 50 C .55. The hanger screw goes through the upper hole when 50-, 75-, 100-, and 150-pound weights are used. The designations for these arrangements are 50 C .9, 75 C 1.0, 100 C 1.0, and 150 C 1.0. Each of the two heavy-weight hangers has only one hole for the hanger screw of the meter. The designations for these arrangements are 200 C 1.5 and 300 C 1.5.

Weight-hanger pins of various lengths, as shown in figure 51, are available for attaching the sounding weight to the hanger bar. The stainless steel pins are threaded on one end to screw into the hanger bar and slotted on the other.

Sounding Reels

Several different types of sounding reels are available for use with the Columbus C-type weights. In general, a sounding reel has a drum for winding the sounding cable, a crank-and-ratchet assembly for raising and lowering the weight or holding it in any desired position, and a depth indicator. Table 11 contains detailed information on each of the five most commonly used reels.

The A-pack reel, as shown in figure 52, is light, compact, and ideal for use at cableway sites a considerable distance from the highway. It can also be used on cranes, bridge boards, and boat booms.

Figure 52. A-pack reel.

Table 11. Sounding reel data.

Reel	Sounding cable	Cable diameter, in inches	Drum circumference, in feet	Cable capacity, in feet	Maximum weight, in pounds	Depth indicator	Brake	Type of operation
A-pack	Ellsworth	0.084	1	45	50	Counter	No	Hand.
Canfield	Single conductor[1]	.0625	1	45	50	Counter	No	Hand.
A-55	Ellsworth	.084 .10	1	95 80	50 100	Self computing	No	Hand.
B-56	Ellsworth	.10 .125	1.5	144 115	150 200	Self computing	Yes	Hand or power.
E-53	Ellsworth	.10 .125	2	206 165	150 300	Self computing	Yes	Power.

[1]Some Canfield reels have been converted to double-conductor cable but most of them are still used as single-conductor reels.

The Canfield reel, as shown in figure 53, is also compact with uses similar to that of the A-pack reel. The Canfield reel is not available from the HIF, and must be obtained from Leupold and Stevens Instruments, Inc.

The A–55 reel is for general purpose use with the lighter sounding weights, as shown in figure 54.

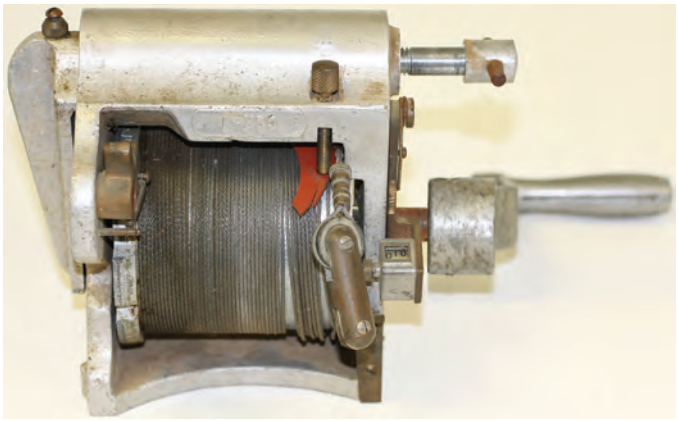

Figure 53. Canfield reel.

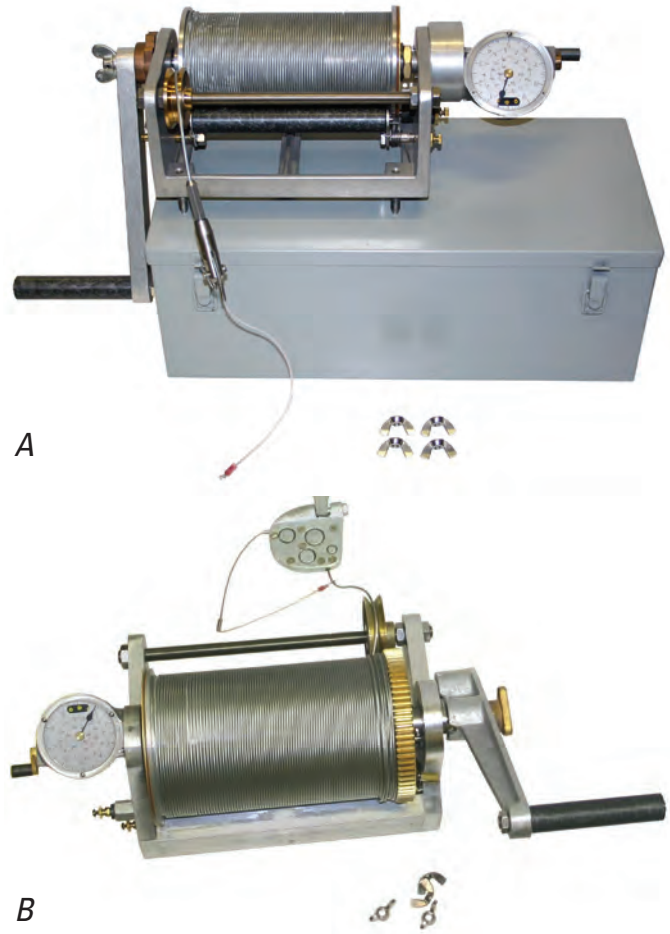

Figure 54. *A*, A–55 reel and *B*, B–56 reel.

The B–56 reel (a major modification of the B–50 reel) can handle all but the heaviest sounding weights and has the advantage that it can be used with a hand crank or power equipment, as shown in figure 54.

The E–53 reel is the largest reel commonly used for current-meter measurements. This reel will handle the heaviest sounding weights and is designed exclusively for use with power equipment. It has a hand crank for emergency use, as shown in figure 55.

Figure 55. E–53 reel.

Sounding Cable

Ellsworth reverse-lay two-conductor stranded cable is normally used on all sounding reels, except the single-conductor Canfield reel, which uses galvanized steel aircraft cord. Ellsworth cables are normally available in 0.084-, 0.100-, and 0.125-in. diameters. It is important to use the appropriate size cable-laying sheave on the reels.

For safety purposes, when measuring floods, it is important to connect the sounding cable to the sounding reel in such a way that the cable will break in the event that heavy debris is caught and cannot be released. The cable will usually unwind (pay out) from the sounding reel until it reaches its end, at which point there is danger to the equipment and the hydrographer unless the cable is cut or breaks. Precut some of the cable strands when installing the cable on the reel so that the remaining strands will break when the load reaches a specified limit. Table 8 provides information about cable strength and number of strands to cut to provide the necessary safety margin. Complete instructions for making the cable installation are given in a HIF technical information sheet dated April 1999.

Connectors

A connector is used to join the end of the sounding cable to the sounding-weight hanger. The three types of connectors generally used are types B, C1, and pressed sleeve, as shown in figure 56. The type B connector is used with A–55, B–56, and E–53 reels. The C1 connector is used with the A-pack and Canfield reels, although the pressed-sleeve connector can be used on these reels. The pressed-sleeve connector is also used on handlines.

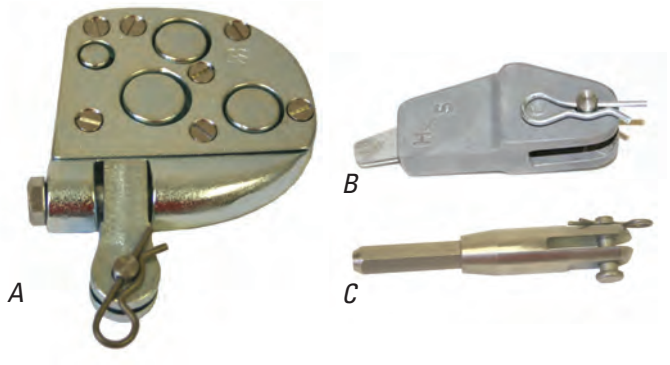

Figure 56. Connectors for attaching sounding cable to sounding-weight hanger; *A*, Type B; *B*, Type C1; and *C*, pressed sleeve.

Depth Indicators

A computing depth indicator, as shown in figure 57, is used on the A–55, B–56, and E–53 reels. The stainless-steel indicator is less than 3 in. in diameter and has nylon bushings that do not require oil. The main dial is graduated in feet and tenths of a foot from 0 to 10 ft. The depth is indicated by a pointer. Tens of feet are read on a numbered inner dial through an aperture near the top of the main dial.

The main dial has a graduated spiral to indicate directly the 0.8-depth position for depths up to 30 ft.

The A-pack and Canfield reels, shown in figures 52 and 53, are equipped with counters for indicating depths.

Figure 57. Computing depth indicator.

Handlines

A handline, shown in figure 58, is a device used for making discharge measurements from bridges using a 15- or 30-pound sounding weight. The advantages of using the handline are that it is easy to set up, it eliminates the use of a sounding reel and supporting equipment, and it reduces the difficulty in making measurements from bridges, which have interfering members, such as trusses. The disadvantages of using the handline are that there is a greater possibility of making errors in determining depth because of slippage of the handline, measuring scale, or tape, and it requires great physical exertion, especially in deep streams. Handlines can be used from cable cars, but this is not recommended because of the disadvantages mentioned above.

Ellsworth cable is recommended for handlines because of its flexibility and durability. Two-conductor electrical service cord is used between the headset connector and the handline reel.

The pressed-sleeve connector or the C1 connector is used on handlines because they are lighter in weight than the type B connector, yet strong enough for the sounding weights used with handlines.

Figure 58. Handline.

Power Unit

Power units, as shown in figure 59, are available for the B–56 and E–53 reels to raise and lower the sounding weight and meter. The power unit can be used with 6-, 12-, 18-, or 24-volt batteries.

Figure 59. Power units for sounding reels; *A*, J & H Single Speed Power Drive and *B*, USGS Variable Speed Reel Drive System.

Sonic Sounder

A commercial, compact, portable sonic sounder has been adapted to measure stream depth. The sounder is powered by either a 6- or 12-volt storage battery and will operate continuously for 10 hours on a single battery charge. Three recording speeds are available—36, 90, and 180 in. per hour. Four operating ranges—0 to 60 ft, 60 to 120 ft, 120 to 180 ft, and 180 to 240 ft—allow intervals of 60 ft of depth. The sounder is portable, weighing only 46 pounds. The depth recorded is from the water surface to the streambed. The transducer has a narrow beam angle of 6 degrees, which minimizes errors on inclined streambeds and allows the hydrographer to work close to piers or other obstructions.

Measurements can be made with this equipment without lowering the meter and weight to the streambed. As soon as the weight is in the water, the depth will be recorded. The meter can then be set at the 0.2 depth, or just below the water surface where a velocity reading is obtained. Then a coefficient is applied to convert measured velocity to the mean in the vertical.

Temperature change affects the sound propagation velocity, but this error is limited to about plus or minus 2 percent in freshwater. This error can be eliminated completely by adjusting the sounder to read correctly at a particular average depth determined by other means.

Cableway Equipment

The USGS cableway provides a track for the operation of a manned cable car from which the hydrographer makes a current-meter measurement. Most cableways have a clear span of 1,000 ft or less, although a few structures have been built with clear spans approaching 2,000 ft. The design and construction of cableways are described in detail by Wagner (1995).

Cable cars provide a movable platform from which the hydrographer, sounding reel, and other necessary equipment are supported. The newer versions of these cable cars are fabricated from aluminum, and have a standard follower brake and integral-reel mounts, which will accept all standard sounding reels, including battery-powered reels. Cable cars can also be equipped with the Sandpoint type cable-car brake, which allows the cable car to be slowed or stopped. Both sitdown and standup types of manually propelled cable cars are used in streamgaging, as shown in figures 60 and 61, and have space for two people to work. Some older cable cars still in use are fabricated partially from wood, may or may not have permanent reel mounts, and may have space for only one person.

Manned cable cars are moved from one point to another on the cableway by means of cable-car pullers, as shown in figure 62. The standard car puller is an aluminum-cast handle with a snub attached. The snub, usually four-ply belting, is placed between one of the car sheaves and the cable to prevent movement of the car along the cable. A second type of puller, also shown in figure 62, is used when a car is equipped with a follower brake. A third type, the Colorado River cable-car

Figure 60. Sit-down cable car.

Figure 61. Stand-up cable car.

Figure 62. Cable-car pullers: *A*, with belt and *B*, with follower brake.

puller, is the same in principle as the puller used on cars equipped with a follower brake.

Power-operated cable cars, such as the battery-powered car shown in figure 63, are available for extremely long spans or other special situations where extensive streamgaging and monitoring is required. The power assist on these cable cars is also utilized to operate a type E sounding reel.

Unmanned, remotely operated cable carriages, such as the Hydrological Services Hornet, are used for discharge measurements as well as for sediment sampling. The cable carriage and sounding equipment can be remotely operated from the stream bank, as shown in figure 64. They are used in areas where it is impossible to wade, where no bridges are available, and where it is not practical to build or maintain a manned cableway.

Unmanned cableways are used more in Europe than in the United States, but are becoming more common in the United States. These bank-operated cableways have obvious benefits in safety and convenience (fig. 65). Both permanent and portable bank-operated cableways are becoming more useful in the measurement of discharge, especially for more narrow streams, generally 300 ft or less in top-bank width.

Bridge Equipment

Streamflow measurements are frequently made from a bridge. The meter and sounding weight can be supported by a handline, a bridge board, or by a sounding reel mounted on a crane. An ADCP mounted on a tethered craft can also be deployed from a bridge. Tethered ADCP craft are rapidly becoming the prevalent means of measuring discharge from a bridge.

Handlines and Bridge Boards

A handline, as described in a previous section of this chapter, is the simplest form of bridge-measuring equipment. Used extensively in the 20th century, it does not require any separate reels or handling equipment; however, it can only be used with light sounding weights, such as the 15- and 30-pound size. It also requires that depth be measured with tags, and a tape or measuring stick.

A bridge board is a portable platform made from wood or metal upon which a small reel can be mounted. Bridge boards may be used with an A-pack, A–55, or B–56 sounding reel and weights up to 75 pounds. A bridge board is usually about 6 to 8 ft long, with a sheave at one end over which the meter cable passes, and a reel seat near the other end. The board is placed on the bridge rail so that the force exerted by the sounding weight suspended from the reel cable is counterbalanced by the weight of the sounding reel. The bridge board may be hinged near the middle to allow one end to be placed on the sidewalk or roadway. Figure 66 shows a bridge board in use.

Figure 66. Measuring from a bridge with a bridge board.

Portable Cranes

Two types of hand-operated portable cranes are the type A for weights up to 100 pounds, and the type E for weights greater than 100 pounds. The type A crane mounts on a three-wheel or four-wheel base or truck, and the type E crane mounts on a four-wheel base or truck. Cranes can be easily moved by hand along the sidewalk or floor of the bridge. Figure 67 shows a type A crane mounted on a three-wheel base, and figure 68 shows a type E crane mounted on a four-wheel base.

Any of the reels described in table 11 may be used on either of the portable cranes; however, the power-driven reels (B–56 and E–53) are used only with the Type E crane. Various combinations of cranes, bases (trucks), and reels are possible.

Figure 67. Type A crane mounted on a three-wheel base.

Figure 68. Type E crane mounted on a four-wheel base.

All cranes are designed so that the crane can be tilted forward over the bridge rail far enough for the meter and weight to clear most rails and be lowered to the water. Where bridge members obstruct passage of the crane along the bridge, the weight and meter can be raised and the crane can be tilted back to pass by the obstruction.

Use cast-iron counterweights weighing 60 pounds with four-wheel-base cranes. The number of such weights needed depends upon the size of sounding weight being supported, the depth and velocity of the stream, and the amount of debris being carried by the stream.

Use a protractor on the outer end of cranes to measure the angle the sounding line makes with the vertical when the weight and meter are dragged downstream by high-velocity water. The protractor is a graduated circle clamped to an aluminum plate. A plastic tube, partly filled with colored antifreeze (ethylene glycol), is the protractor index. This tube is fitted in a groove between the graduated circle and the aluminum plate. A stainless-steel rod is attached to the lower end of the plate to ride against the downstream side of the sounding cable. The protractor will measure vertical angles from -25 degrees to +90 degrees. Figure 69 is a close-up view of a protractor mounted at the outer end of the boom.

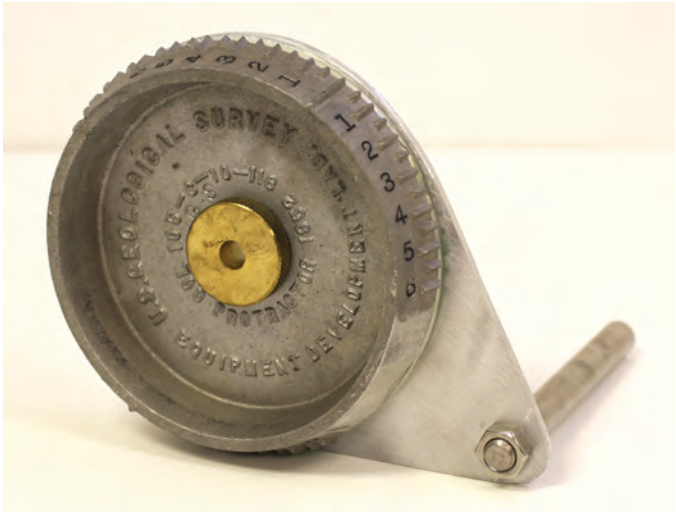

Figure 69. Protractor used for measuring vertical angles.

Power-Driven Cranes

Many special arrangements for measuring from bridges have been devised to suit a particular purpose. Vehicle-mounted cranes are often used for measuring from bridges over larger rivers, as shown in figure 70. Monorail streamgaging cars have also been developed for large rivers. The car is suspended from the substructure of bridges by means of I-beams.

Tethered Craft

The USGS, in cooperation with manufacturers, continues to test and refine tethered-platform designs for measuring streamflow. Platform specifications have been developed for

Figure 70. Vehicle-mounted, power-driven crane.

radio-modem telemetry of acoustic Doppler current profiler (ADCP) data, potential platform-hull sources have been investigated, and many hull configurations have been tested and evaluated.

Platforms, which included a variety of hull configurations, were tested for drag and stability at the USGS Hydraulic Laboratory tow tank and at a field site below a reservoir. The testing indicated that trimaran designs provided the best all-around performance under a range of conditions. The trimaran designs house the ADCP in the center hull. Waterproof radio modems that operate at 900 MHz are used to communicate wirelessly with instruments at high-baud rates.

A tethered-platform design with a trimaran hull, and 900-MHz radio modems, are commercially available from several vendors. Continued field use has resulted in USGS procedures for making tethered-platform discharge measurements, including methods for tethered-boat deployment, moving-bed tests, and measurement of edge distances. Figure 71 shows a tethered craft ADCP in wide usage in the USGS (Mueller and Wagner, 2009; Rehmel and others, 2003).

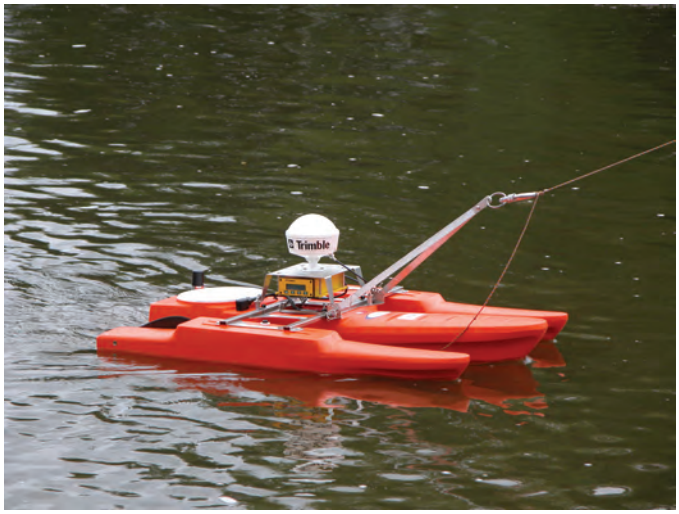

Figure 71. Measuring with a tethered ADCP, DGPS, and trimaran.

Boat Equipment

There are five basic types of boat measurements: the manual stationary boat, the manual moving boat, the automatic moving boat, the ADCP moving boat, and the remote-controlled ADCP moving boat. Equipment requirements for each of these boat measurement types are described in the following paragraphs.

Manual Stationary Boat

The manual stationary boat method uses a boat as a platform for the hydrographer and the sounding equipment. The boat is attached to a tag line or cable to stabilize it at each vertical where soundings are made. The heavy-duty tag lines required for boat measurements are described in a previous section of this chapter.

Special equipment assemblies, as shown in figure 72, are necessary to suspend the meter from the boat if the depths do not allow using rod suspension. A crosspiece spanning the boat is clamped to its sides, and a boom attached to the center of the crosspiece extends out over the bow. The crosspiece is equipped with a guide sheave and clamp arrangement at each end to attach the boat to the tag line, and makes it possible to slide the boat along the tag line from one station to the next. A small rope can be attached to these clamps so that in an emergency a tug on the rope will release the boat from the tag line. The crosspiece also has a clamp that prevents lateral movement of the boat along the tag line during readings. The boom consists of two structural aluminum channels, one telescoped within the other to permit adjustments in length. The boom is equipped with a reel plate on one end and a sheave over which the meter cable passes. The sheave end of the boom is designed so that by adding a cable clip to the sounding cable a short distance above the connector, the sheave end of the boom can be retracted when the meter is raised out of the water. The raised meter is easy to clean and is in a convenient position when not being operated.

Figure 72. Manual stationary-boat equipment assembly.

All sounding reels fit the boat boom, except the A-pack and the Canfield, which can be made to fit by drilling additional holes in the reel plate on the boom.

In addition to the equipment already mentioned, the following items are needed for making boat measurements:

1. A stable boat big enough to support the hydrographers and equipment;
2. A motor that can easily move the boat against the maximum current in the stream;
3. A pair of oars for standby use;
4. A personal floatation device (PFD) for each hydrographer; and
5. A bailing device.

Manual Moving Boat

Equipment requirements for the manual moving boat method of making a discharge measurement are described in detail by Smoot and Novak (1969); they are not described in this chapter. In summary, the manual moving-boat method requires a sonic sounder, a vane with indicator, a special current meter, and an easily maneuverable small boat. The manual moving-boat method is seldom used since the advent of the ADCP moving-boat method, which is described below.

Automatic Moving Boat

The automatic moving-boat method is similar to the manual moving-boat method, except that all readings of depth, velocity, angles, and distance are recorded automatically by onboard computer equipment. Equipment requirements are more complex in order to enable the automatic sensing and recording.

Like the manual moving-boat method, the automatic moving-boat method is seldom used since the advent of the ADCP moving-boat method.

ADCP Moving Boat

Currently, the ADCP moving-boat method is the most common moving-boat method in the USGS. All readings of depth, velocity, angles, and distance are recorded to a laptop or PDA and the discharge measurement is computed using ADCP software and input from the hydrographer.

As shown in figure 73, described in other sections of this chapter, and in depth by Mueller and Wagoner (2009), ADCP moving-boat measurement techniques have almost entirely superseded the automatic moving method.

Remote-Controlled ADCP Moving Boat

There are commercially available unmanned, remote-controlled craft with ADCPs used by the USGS and others for the measurement of discharge where a manned boat or tethered boat may not be feasible. Similar to but smaller than the ADCP moving-boat, these remote-controlled craft typically come with self-contained motors and a remote-controlled system for driving the boat across a stream or river. See Mueller and Wagner (2009) for an in depth discussion of remote-controlled ADCP moving boat discharge measurements.

Figure 73. ADCP equipment mounted and operated on *A*, a moving boat and *B*, a tethered platform.

Electronic Field Notebooks and Personal Digital Assistants (PDAs)

Recent developments in electronics have produced commercially available electronic field notebooks (EFNs) and personal digital assistants (PDAs), designed specifically for the purpose of recording field notes while making a discharge measurement (fig. 74) . The PDAs are also designed for other field procedures, including discharge-measurement data collection and processing, station inspection, differential-level survey notes, and water-quality data collection and equipment calibration. The USGS commonly uses the Surface Water Measurements and Inspections (SWAMI) program with a PDA. The program can be used to record discharge measurements, inspections, differential-level surveys, and other field measurements. This software provides an efficient means of collecting field data (fig. 2*C*) and has been specifically designed to interface with the USGS NWIS.

The recording process is semiautomatic. Basic information and data still must be entered manually for measurements of stream depth, stationing, horizontal angle of flow, equipment, and other basic data.

EFNs automatically count meter revolutions and elapsed times, and make the conversion to stream velocity. They also assist the hydrographer with certain tasks, such as locating each subsection so that no more than 10 percent of the total flow will be included in each subsection. The notebook makes all of the measurement calculations to obtain the final discharge, and to summarize all pertinent items of the measurement.

The EFNs and PDAs can store many discharge-measurement reports. The EFN and (or) PDA reports for a discharge measurement are similar to the paper note sheets used for manual note keeping. A header, similar to the paper "front sheet," contains site information, equipment information, and a summary of measurement data. The report also contains

Figure 74. Personal digital assistants (PDAs) and electronic field notebooks (EFNs), clockwise from the top: *A*, the Trimble Juno SB PDA with GPS, Bluetooth, and Parani Serial Adapter; *B*, the Trimble Nomad 800 GL PDA with GPS and Bluetooth; *C*, the Trimble Recon PDA without GPS; *D*, the JBS Instruments Aquacalc Pro Discharge Measurement Computer; and *E*, the Hydrological Services Current Meter Counter Signal Processor with Bluetooth (CMCsp).

complete measurement data, similar to the paper "inside notes," for all of the individual subsections. In addition, the report contains various warning flags and quality-control information. Complete reports for each discharge measurement can be downloaded to a computer for viewing, printing, and other analysis.

One EFN widely used within the USGS is the Aquacalc Pro Discharge Measurement Computer (Aquacalc) by JBS Instruments. The Current Meter Counter Signal Processor (CMCsp) by Hydrological Services is used in concert with a PDA to measure discharge with a mechanical current meter, as shown in figure 74. The Aquacalc and the CMCsp will work with the cat's-whisker-, magnetic-, and optic-contact chambers on the Price current meters. As with all EFNs, care should be taken to avoid false counting of meter revolutions when measuring low velocities with mechanical meters that have a cat's-whisker-contact chamber.

PDAs are manufactured by many computer companies in the United States and abroad. Several are considered reliable and have been successfully field tested. At this writing, the PDA can interface with most of the ADCPs and electronic data loggers used by the USGS.

Miscellaneous Equipment and Personal Items

Other personal equipment and items will be needed while making discharge measurements, or when working in and around rivers, creeks, and streams. Waders or boots should be worn while making wading measurements. Waders should be loose fitting, even when allowing for heavy winter clothing.

Ice chains, as shown in figure 75, should be strapped onto the soles of boots or waders for use on steep or icy stream banks, and on rocky or smooth and slippery streambeds.

A properly fitted personal-floatation device (PFD) must be worn when working near, in, or over water. This includes while wading streams, and working on a cableway, bridge, or water retention or control structure, on ice, or in a boat.

Figure 75. *A*, Ice chains for boots and waders and *B*, Sure Grip Ice Treads for boots and waders.

Accuracy of Current-Meter Discharge Measurements

The accuracy of a discharge measurement is dependent on many factors, including the equipment used, the location and characteristics of the measuring section, the number and spacing of verticals, the rate of change in stage, the measurement of depth and velocity, presence of ice and (or) debris in the measuring section, wind, experience of the hydrographer, carefulness (or carelessness) of the hydrographer, and various conditions that can occur during the process of making the measurement. The evaluation of the accuracy of a measurement has long been a qualitative assessment that takes some or all of these factors into account. A quantitative measure of the accuracy for some discharge measurements can also be made. The following two sections of this chapter describe these methods.

Qualitative Evaluation

Every discharge measurement should be evaluated for accuracy using the qualitative method. Historically, this has been the preferred method, and the hydrographer should make this evaluation immediately after making the measurement. The evaluation should be based on the hydrographer's opinion of the accuracy of the measurement—not on how well, or how poorly, the measurement plots on the stage-discharge relation. It is difficult to provide written guidelines for making a qualitative evaluation of accuracy. A good qualitative evaluation depends mostly on the experience and training of the hydrographer. Several of the factors that should be considered by the hydrographer are as follows:

Measuring section.—Consider factors such as the uniformity of depths, the smoothness of the streambed, the streambed material (that is, smooth sand; small, firm gravel; large rocks; soft muck; and so forth), the ability to accurately measure the depth, the approach conditions, presence of bridge piers, and other conditions that would affect measurement accuracy.

Velocity conditions.—Consider smoothness of velocity, uniformity of velocity, very slow velocity, very high velocity, turbulence, obstructions that may affect the vertical velocity distribution, use of one-point or two-point method, length of counting (40 or more seconds versus half-counts), and other factors that affect accuracy of velocity measurements.

Equipment.—Consider the type of current meter used (Price AA, Price pygmy, acoustic, or electromagnetic), the type of depth-sounding equipment, and the condition of the equipment.

Spacing of observation verticals.—Use about 25 to 30 verticals for a discharge measurement, spaced so that no more than 5 percent of the total discharge is contained in each subsection. Although this is frequently difficult to attain, except in unusual cases, no more than 10 percent of the total discharge should be in a subsection. Otherwise, the accuracy will be negatively affected.

Rapidly changing stage.—Although discussed in previous sections of this chapter, this condition should also be considered when assessing the accuracy of the measurement. Using the shortcut methods previously described will result in less accurate measurements of discharge.

Ice measurements.—Making discharge measurements under ice cover is usually more difficult, and sometimes less accurate, than making open-water discharge measurements. Presence of slush ice, layered ice, and anchor ice will have adverse affects on accurate measurement of depth and velocity. Velocity distribution will be affected if the water surface is in contact with the ice. Freezing of water in the meter cups and pivot chamber may affect performance of the equipment.

Wind.—Wind can affect the accuracy of a discharge measurement by obscuring the angle of the current, or by creating waves that make it difficult to sense the water surface prior to making depth soundings. Wind can also affect the vertical-velocity distribution, particularly near the surface, and can cause vertical and (or) horizontal movement of the current meter while making a boat measurement, introducing possible error in velocity measurements.

The qualitative method of assessing the accuracy of a discharge measurement requires that the hydrographer consider all of the above items and their cumulative effect on the measurement accuracy. The front page of the discharge measurement note sheet (see figure 2) has space for describing (1) the cross section, (2) the flow, (3) the weather, and (4) any other flow conditions that relate to the accuracy. These descriptions, along with the type of equipment, number of verticals, velocity measurement method, and other measurement conditions, should provide the basis for rating the measurement as excellent (2 percent), good (5 percent), fair (8 percent), or poor (more than 8 percent).

For instance, a measurement might be rated as excellent (2 percent) if (1) the cross section is smooth, firm, and uniform; (2) the velocity is smooth and evenly distributed; (3) the equipment is in good condition; (4) the two-point velocity measurement method was used; and (5) weather conditions are good (no wind or ice). On the other hand, if several of these factors make it difficult to accurately measure depth and (or) velocity, the measurement might be rated fair (8 percent), or even poor (more than 8 percent).

As stated previously, it is not possible to provide absolute guidelines for making the qualitative evaluation of accuracy. As a general rule, the accuracy of most discharge measurements will be about 5 percent, or qualitatively a "good" measurement. This is sometimes used as the base-line accuracy, with accuracy upgraded to "excellent" when measuring conditions are substantially better than average, and accuracy downgraded to "fair" or "poor" when conditions are substantially worse than average. The qualitative-accuracy evaluation is based on the hydrographer's judgment. For more detailed qualitative-evaluation information on discharge measurements using ADCPs, see Oberg and others (2005) and Mueller and Wagner (2009).

Quantitative Evaluation

A quantitative-accuracy evaluation can be made for some current-meter discharge measurements by using the procedure described by Sauer and Meyer (1992), Herschy (1994), and the International Organization for Standardization (1997). These procedures compute the uncertainty, or standard error, using a root-mean-square error analysis of individual component errors. The component errors include errors in the measurement of width, depth, and velocity, and in computation procedures. These procedures can be used to compute the standard error for most discharge measurements made with the vertical-axis, cup-type current meter. These procedures do not apply to measurements made with other types of current meters, or other methods of making discharge measurements. Likewise, they do not apply to discharge measurements where wind, ice, boundary effects, flow obstructions, improper equipment, incorrect measuring procedures, and hydrographer carelessness are factors in the measurement.

The details of the Sauer and Meyer (1992) method are described in USGS Open-File Report 92–144, and therefore are not included in this chapter. A computer program is available to compute the standard error for individual discharge measurements, and it is recommended that this quantitative evaluation be made for each discharge measurement for which it applies. Computations using this method show that the standard error of individual discharge measurements can range from about 2 percent for ideal conditions, to about 20 percent for very poor measuring conditions. Standard errors range from about 3 percent to 6 percent for measurements having generally normal measuring conditions. The standard errors computed by this method are in close agreement with qualitative evaluations.

ADCP Discharge-Measurement Accuracy

There are many sources of error in an ADCP discharge measurement. A complete measurement is composed of the ADCP-measured channel subsection, extrapolated top subsection, extrapolated bottom subsection, and edge-estimated subsections.

The largest and most substantial subsection is the ADCP-measured channel subsection. Most errors can be greatly reduced if factors, such as moving bed, water temperature, salinity, cross-section choice, instrument configuration, and boat speed, are carefully considered and accounted for, as described in previous sections of this chapter. Software is usually provided by the manufacturer that can be used to compute the ADCP instrument error for the measured subsection.

Errors for the extrapolated top, bottom, and edge subsections will vary, depending upon the extrapolation methods and relative proportion of the total discharge represented in these subsections. Again, these errors can be kept to a minimum through proper choice of cross section and careful measurement of variables, such as ADCP transducer depth and distances from each shore to the nearest ADCP section.

Studies by Morlock (1996) and Oberg and Mueller (2007) concluded that ADCP discharge measurements can be used successfully for streamflow data collection under a variety of field conditions. In Morlock (1996), 31 ADCP discharge measurements were compared to discharge ratings defined by conventional methods for the period over which the ADCP measurements were made. These comparisons showed that 25 ADCP measurements were within 5 percent of the conventional measurements. Six of the ADCP measurements differed by more than 5 percent, the maximum departure being 7.6 percent.

The study by Morlock (1996) stated that ADCP discharge measurement error was indicated by the standard deviations of the ADCP discharge measurements. The standard deviations ranged from about 1 to 7 percent of the measurement discharges. The estimated error of each ADCP discharge measurement also was computed from formulas derived by the manufacturer of ADCPs. The computations of estimated measurement error assume that ADCP instrument- and unmeasured-subsection extrapolation errors are the main source of measurement error. The standard deviations for most ADCP discharge measurements were higher than the estimated measurement errors, indicating that significant components of measurement error were not related to the instruments; errors of this nature include temporal variations of flow. It was concluded that measurement precision can be positively affected by selection of a measurement location with minimal flow variations, and negatively affected by instrument- and boat-operation factors.

Uncertainties in Discharge Measurements

All discharge measurements, no matter how carefully made, are subject to uncertainty. The measurement uncertainty can be thought of as a quantitative measure of the dispersion of the measured discharge about the true discharge. This uncertainty arises because each measurement is subject to errors of unknown magnitude. The total uncertainty in a discharge measurement may arise from several sources, including:

- uncertainty in the measurement of the cross-sectional area, which in turn arises from the following:
  - uncertainty in measurements of width; and
  - uncertainty in measurements of depth;
- uncertainty in the measurement of the water-velocity profile, which in turn arises from the following:
  - instrument uncertainty;
  - pulsation and turbulence in open-channel flow;
  - deviation from our assumptions about the vertical-velocity distribution; and
  - uncertainty due to oblique angles in the flow velocity;
- uncertainty due to deviation from assumptions used in the computation procedures; and
- other random or systematic errors.

These component uncertainties can be combined to estimate the total uncertainty of a single discharge measurement. Where feasible, values for these component uncertainties should be estimated independently for each site.

The uncertainty is often expressed as a standard deviation. If we assume that measurement errors are normally distributed, then this uncertainty can be used to construct confidence intervals for the measured discharge value. For example, the true discharge can be expected to be within one standard deviation of the measured value at the 68-percent confidence level. At the 95-percent confidence level, the true discharge can be expected to be within two standard deviations of a single measured value.

Quality Assurance and Quality Control

It should be the goal of each hydrographer to make discharge measurements of the highest quality and with as little error as possible. As explained in other sections of this chapter there are many actions that must be performed before, during, and after the actual measuring process. In the many implicit decisions that must be made during the course of a discharge measurement, the hydrographer, through training and experience, must develop a keen sense of what is correct and incorrect through hydrologic/engineering judgment, and strive to continually take the correct course of action in making a discharge measurement. This is commonly known as quality assurance and quality control, sometimes referred to as QA/QC. Some of the QA/QC functions are implicit; that is, they are generally understood, performed automatically, and are not specifically defined in the measurement notes and sometimes must be accomplished through hydrologic/engineering judgement. Careful regard for safety, good hydrologic/engineering judgment, and observance of proper procedure are implicit functions that cannot be overstressed in making a precise and accurate discharge measurement. On the other hand, some actions are explicit, such as performing regular spin tests of current meters, or making check measurements when the first measurement may be suspect. Following are some of the QA/QC actions that should be observed for making high-quality discharge measurements. These are not all inclusive, and each hydrographer should always include and document any other actions that relate to the quality of the measurement. Additional QA/QC requirements are given in the QA/QC plan for each USGS Water Science Center.

- *Care of current meters, current profilers, and sounding equipment.*—Previous sections of this chapter describe the proper care of current meters, current profilers, and sounding equipment. Current meters are especially susceptible to damage and misalignment while in use, as well as in transit, if they are not properly protected. The hydrographer should follow all established guidelines to ensure that the streamgaging equipment, especially the current meter and (or) profiler, are in good working condition. While making a discharge measurement, the current meter should be periodically observed and checked to be sure it is operating smoothly and has not become fouled by debris, ice, or other obstructions.
- *Spin tests of current meters.*—One of the requirements for maintaining and checking current meters is a periodic, timed spin test under controlled conditions. The procedure for making a timed spin test is described in a previous section of this chapter. In addition, before, during, and after a discharge measurement, check that the rotor is turning smoothly and does not come to an abrupt stop.
- *Carefulness, good judgment, and proper procedure.*—It is the hydrographer's responsibility to apply proper procedures with care and good judgment while making streamflow measurements. These implicit functions of QA/QC should be observed at all times.
- *Computing and plotting the measurement on site.*—Compute a discharge measurement as soon as possible after it is completed. Do this at the site before leaving. If the measurement does not plot within 5 percent (or other specified percentage) of the rating curve in use, or if it is not in line with the previous trend of measurements, try to find an explanation. For instance, there may be an obvious change of the control that would explain the deviation. All such explanations should be documented in the measurement notes. If a satisfactory explanation cannot be found, then make a check measurement.
- *Making check measurements.*—If possible, while making a check measurement, select a different cross section from the original section and use a different current meter. Make the check measurement as close in time and gage height to the original measurement as possible.
- *Checking discharge measurements.*—In general, hand-computed discharge measurements are not checked for mathematical errors. Nevertheless, check measurements that do not plot within an acceptable percentage of the rating curve, or within the previous trend of measurements. Likewise, check measurements that define a significant extrapolation of the low end or high end of a rating curve. Discharge measurements recorded in an electronic notebook, such as the Aquacalc, are automatically computed and do not require checking.
- *Documentation of QA/QC.*—Document in the measurement notes, if possible, all measures taken to ensure that discharge measurements are accurate and of high quality. Some QA/QC measures require specific documentation independent of the measurement notes. For example, current-meter spin tests have specific forms that document the spin-test results and all repairs to the meter.

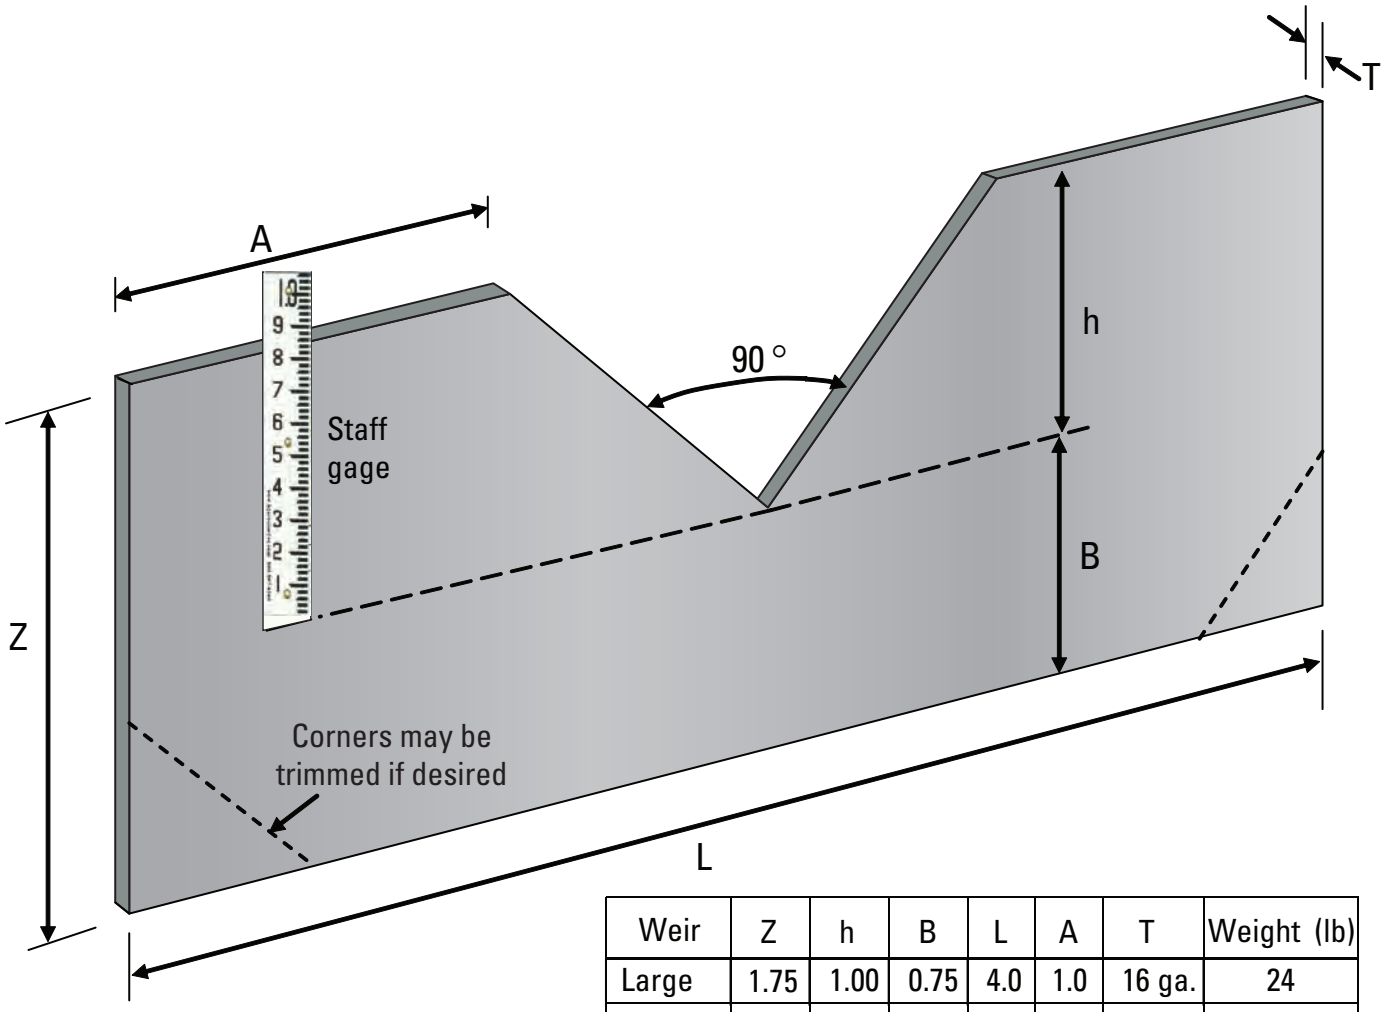
Safety Requirements

Practicing personal and overall safety is of utmost importance when working near, in, and above water. It is not the purpose of this chapter to describe all of the safety requirements; however, each hydrographer should be familiar with, and should observe, those requirements. Other documents provide the details of specific safety requirements for making wading measurements, and for working on ice, bridges, cableways, and boats. For instance, each USGS Water Science Center flood plan addresses such things as one-person versus multiple-person field parties, use of an approved PFD, and traffic control while making discharge measurements from bridges, cableway safety, and boat safety. USGS WRD Memorandum No. 99.32 (1999) provides safety guidance as it is related to discharge measurements, sampling, and other related streamgaging activities. Each Water Science Center has a safety officer and a safety plan; both should be consulted for specific safety issues.

Portable Weir-Plate Measurements

Current-meter measurements made in shallow depths and low velocities are usually inaccurate, if not impossible, to obtain. Under these conditions, a portable weir plate is a useful device for measuring the discharge.

A 90-degree V-notch weir is suitable because of its favorable accuracy at low flows. A weir made of 10- to 16-gage galvanized sheet iron will produce a free-flowing nappe, having the effect of a sharp-crested weir, and will give satisfactory performance. The thickness of the plate should vary with the size of the weir. Refer to figure 76 for recommended proportions. Decreasing the plate thickness on larger weirs will help maintain portability. The notch is cut, without sharpening, leaving a flat, even edge. Framing, in the form of small-angle irons, is required for medium and large sizes. Canvas attached on the downstream or upstream side prevents leakage under or around the weir. Eyebolts, properly placed, will secure rods driven in earth channels to stabilize the plate.



Weir	Z	h	B	L	A	T	Weight (lb)
Large	1.75	1.00	0.75	4.0	1.0	16 ga.	24
Medium	1.25	0.80	0.45	3.0	0.7	14 ga.	17
Small	0.75	0.47	0.28	2.0	0.53	10 ga.	8

Figure 76. Portable weir plate.

Attach a staff gage to the upstream face of the weir plate, with the zero point at the same elevation as the bottom of the weir notch. The staff should be far enough from the notch to be outside of the zone of drawdown, which is a distance greater than twice the head on the notch. The staff gage is used to obtain head on the weir.

The general equation for flow over a sharp-edged triangular weir with a 90-degree notch is

$$Q = Ch^{\frac{5}{2}}, \tag{20}$$

where Q discharge, in ft³/sec,
h static head, in ft, and
C the coefficient of discharge.

The weir should be rated by determining the flow volumetrically for various values of head, or by having it rated in the HIF laboratory. In the absence of a rating, a value of C of 2.47 may be used.

Flows from 0.02 to 2.0 ft³/s are measured with the large weir of figure 76. Discharges can be measured within 3-percent accuracy if the weir is not submerged. A weir is not submerged when there is free circulation of air on all sides of the nappe.

To place the plate in a sand or silt channel, only a carpenter's level and a shovel are needed. Push the weir into the streambed, and drive the rods through the eyebolts on each end to stabilize the weir. Use the level to make the top of the plate horizontal and the plate plumb. Another way to level the plate is by fastening a staff gage or level bubble to each end of the weir, where the staff gages are set at the same elevation. The plate is leveled by making the staff-gage readings identical or by using the level bubbles. Pack soil and streambed material around the ends and bottom of the weir to prevent leakage. Place canvas immediately downstream from the weir to prevent the falling jet from undercutting the streambed. Let the flow stabilize before making a measurement. Read the gage height at half-minute intervals for a period of about 3 minutes, and use a mean value in the above equation to compute the discharge. Ordinarily, one person can measure with a weir of this type. Remove the weir after you have completed the measurement.

Portable Parshall-Flume Measurements

A portable Parshall measuring flume is useful for measuring discharge when the depths are shallow and the velocities are low. The standard Parshall flume has a converging section, a throat, and a diverging section. The floor of the converging (or upstream) section is level both longitudinally and transversely when in place. The floor of the throat section slopes downward and the floor of the diverging or downstream section slopes upward. The standard Parshall flume can be used to measure discharge under free-flow conditions, as well as submerged conditions.

The flume used by the USGS is a modified version of the standard Parshall flume. The modification consists primarily of the removal of the downstream section, which reduces the weight of the flume and makes it easier to install. Because it has no downstream section, however, it can only be used to measure free-flow conditions (that is, where the submergence ratio is 0.6 or less). This can usually be accomplished by building up the streambed by a couple of inches under the level, converging floor of the flume when the flume is installed.

Free flow occurs when the ratio of the lower head to the upper head is less than 0.6. The discharge under this condition depends only on the length of crest (width of throat section) and depth of water at the upper gage. A flume that is properly constructed has an accuracy of 2 to 3 percent under free-flow conditions.

Install the flume by placing it in the channel; fill in with available channel bed or bank material around it to prevent any water from bypassing it. Use a carpenter's level to set the floor of the converging section level. Some flumes are equipped with levels attached to the braces on the flume. After the flume is in place, the streamflow is allowed to stabilize before reading the gage. After the flow stabilizes, take gage readings at about half-minute intervals for about 3 minutes. Use an average of the gage readings with the flume rating to determine the discharge. Remove the flume after the measurement is complete.

A modified 3-in. Parshall flume is shown in figure 77. This modified version is virtually the same as the standard Parshall flume except that it does not have a diverging section. The gage height, or upstream head on the throat, is read in the small stilling well that is hydraulically connected to the flow by a ⅜-in. hole.

The basic rating equation for a flume is

$$Q = Cbh^{\frac{3}{2}}, \tag{21}$$

where Q discharge, in cubic feet per second (ft³/s),
C a dimensionless coefficient of discharge that can vary with head and other factors,
b width of the throat section, in feet, and
h head, or gage height, in the converging section, in feet.

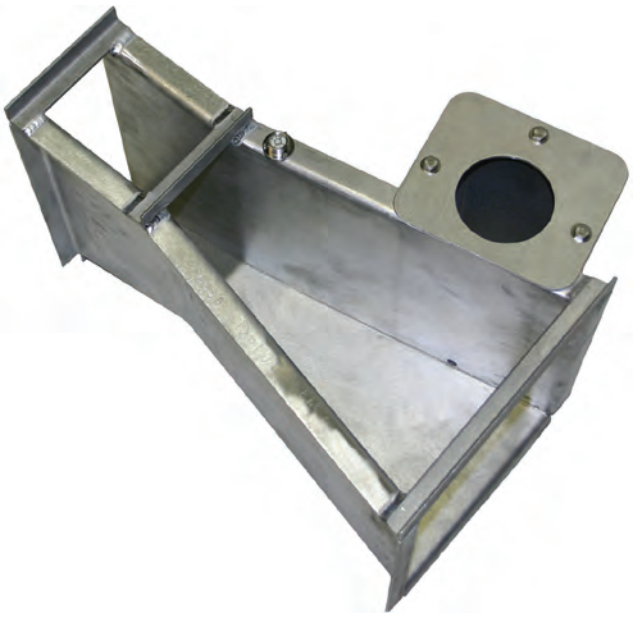


Figure 77. Modified 3-inch Parshall flume.

The rating for the 3-in. modified Parshall flume described in this section is given in table 12, and was taken from Buchanan and Somers (1969). An identical table is published by Kilpatrick and Schneider (1983), and also by Rantz (1982). The original source of this rating is unknown, but was probably based on laboratory tests. The rating in table 12 plots as a straight line on logarithmic plotting paper, and the equation for this rating was computed by regression analysis as follows:

$$Q = 1.1392h^{1.5797}. \quad (22)$$

This equation is close to one that can be derived for the 3-in. modified Parshall flume, based on the procedures given by Kilpatrick and Schneider (1983). The above equation will reproduce values of discharge precisely as shown in table 12, except for a few instances where the computed discharge deviates by 0.001 to 0.005 ft^3/s. This equation should not be used for values of gage height less than 0.01 ft or greater than 0.59 ft.

Table 12. Rating table for 3-inch modified Parshall flume.

[ft, feet; ft^3/s, cubic foot per second]

Gage height (ft)	Discharge (ft^3/s)	Gage height (ft)	Discharge (ft^3/s)	Gage height (ft)	Discharge (ft^3/s)

Volumetric Measurements

The most accurate way of measuring small discharges is the volumetric method. This method is performed by observing the time it takes to fill a container of known capacity, or the time required to partly fill a calibrated container to a known volume. The basic equipment needed for this method is a calibrated container and a stopwatch.

Two methods can be used to calibrate the container. The first method is to add known volumes of water by increments and note the depth of water in the container. The second method is to first weigh the empty container and then add varying amounts of water to it, each time weighing the container with water, and noting the depth of water in the container. The following equation can then be used to compute the volume of water corresponding to the depth that was read:

$$V = \frac{W_2 - W_1}{w}, \tag{23}$$

where V volume of water in container, in cubic feet,
W_2 weight of container with water, in pounds,
W_1 weight of empty container, in pounds,
w unit weight of water, 62.4 lb/ft^3.

Volumetric measurements of discharge are made with two types of conditions:

- When the flow is or can be concentrated so that all of it may be diverted into a calibrated container.
- When the depth of water flowing over broad-crested weirs and dams is small and volumetric-increment samples can be obtained.

Under the first condition, measurements are made at V-notch weirs at artificial controls where all the flow is in a notch or catenary, and at places where a small earth dam can be built and all the water diverted through a pipe of small diameter. Sometimes it is necessary to place a trough against the artificial control to carry the water from the control to the calibrated container. If a small dam is built, the stage behind the dam must be allowed to stabilize before the measurement is begun. The measurement is made three or four times to ensure error-free and consistent results.

Volumetric measurements are made under the second condition by catching a segment of the streamflow with a container having a known width of opening. Samples are taken at a number of locations across the dam or weir similar to procedures used for current-meter measurements. The flow rate of each sample is increased by the ratio of the subsection width to the sampled width to obtain a discharge rate for each subsection. The total discharge of the stream is the summation of the discharge rates of each subsection.

Float Measurements

Floats have limited use in streamgaging, but they can be used where the velocity is too low to obtain reliable measurements with the current meter, or where flood measurements are needed and the measuring structure has been destroyed or it is impossible to use a meter. Both surface floats and rod floats can be used. Surface floats may be almost anything that floats, such as wooden disks, partly filled bottles, oranges, or pumpkins. Floating debris or ice cakes may serve as natural floats. Rod floats are usually made of wood and weighted on one end so they will float upright in the stream. Rod floats are sometimes made in sections so their length can be adjusted to fit the stream depth; however, they should not touch the streambed.

Two cross sections are selected along a reach of straight channel for a float measurement. The cross sections should be far enough apart so that the time the float takes to pass from one cross section to the other can be measured accurately. A travel time of at least 20 seconds is recommended, but a shorter time can be used on small streams with high velocities, where it is impossible to select an adequate length of straight channel. The edge of water for both cross sections should be referenced to stakes (or other marker) on each bank. Those points will be used at a later date, when conditions permit, to survey cross sections of the measurement reach, and to obtain the distance between cross sections. The surveyed cross sections will be used to determine the average cross section for the reach.

Float measurements may sometimes be made through a reach extending from the upstream to the downstream side of a bridge. This kind of reach may be useful where velocity is very slow and velocity observations by current meter are not reliable.

The procedure for a float measurement is to distribute a number of floats uniformly over the stream width, noting the position of each with respect to the bank. They should be placed far enough upstream from the first cross section so they attain the velocity of the stream before they reach the first cross section. Use a stopwatch to time their travel between the two cross sections. As each float passes the second cross section, note its distance.

The velocity of the float is equal to the distance between the cross sections divided by the time of travel. The mean velocity of flow in the vertical is equal to the float velocity multiplied by a coefficient that is based on the shape of the vertical-velocity profile and relative depth of immersion of the float. A coefficient of about 0.85 to 0.88 is commonly used to convert surface velocity to mean velocity. The coefficient for rod floats varies from 0.85 to 1.00, depending upon the shape of the cross section, the length of the rod, and the velocity distribution.

The procedure for computing discharge is similar to that for a mechanical current-meter measurement. The discharge in each partial section is computed by multiplying the average area of the partial section by the mean velocity in the vertical for that partial section. The total discharge is equal to the sum of the discharges for all the partial sections.

Discharge measurements made with floats under favorable conditions may be accurate to within ±10 percent. Wind may adversely affect the accuracy of the computed discharge by its effect on the velocity of the floats, especially if velocity is very slow. If a poor reach is selected and not enough float runs are made, the results can be as much as 25 percent in error.

Indirect Discharge Measurements

During floods, it is frequently impossible or impractical to measure peak discharges when they occur. Roads may be impassable; structures from which current-meter measurements might have been made may be nonexistent, not suitably located, or destroyed; knowledge of the flood rise may not be available enough in advance to allow reaching the site near the time of the peak; the peak may be so sharp that a satisfactory current-meter measurement could not be made, even with a hydrographer present at the time; the flow of debris or ice can prevent use of a current meter; or personnel limitations might make it impossible to obtain direct measurements of high-stage discharge at numerous locations during a short flood period. Consequently, many peak discharges must be determined after the passage of the flood by indirect methods, such as slope-area, contracted-opening, flow-over-dam, or flow-through-culvert, rather than by direct current-meter measurement. Detailed descriptions of the procedures used in collecting field data and in computing the discharge are given by Benson and Dalrymple (1967), Dalrymple and Benson (1967), Bodhaine (1968), Matthai (1967), and Hulsing (1967), which are in book 3, chapters Al–A5, of the USGS Techniques and Methods series. Various computer programs are available for computing the discharge for indirect measurements.

Tracer Discharge Measurements

Measurement of discharge by this method depends on determination of the degree of dilution of an added tracer solution by the flowing water. A solution of a stable tracer, such as a fluorescent dye or a radioactive chemical, is injected into the stream at either a constant rate or all at once. The solution becomes diluted by the discharge of the stream. Measurement of the rate of injection, the concentration of the tracer in the injected solution, and the concentration of the tracer at a cross section downstream from the injection point permits the computation of stream discharge. The accuracy of the method critically depends upon complete mixing of the injected solution through the stream cross section before the sampling station is reached and upon no adsorption of the tracer on stream-bottom materials. The method is recommended only for those sites where conventional methods cannot be employed owing to shallow depths, extremely high velocities, or excessive turbulence. A detailed description of the procedures and equipment used in measuring discharge by a dye-dilution method is given by Kilpatrick and Cobb (1985).

Red mangrove in Titusville, Florida

Key Message 1

Urban Infrastructure and Health Risks

Many southeastern cities are particularly vulnerable to climate change compared to cities in other regions, with expected impacts to infrastructure and human health. The vibrancy and viability of these metropolitan areas, including the people and critical regional resources located in them, are increasingly at risk due to heat, flooding, and vector-borne disease brought about by a changing climate. Many of these urban areas are rapidly growing and offer opportunities to adopt effective adaptation efforts to prevent future negative impacts of climate change.

Key Message 2

Increasing Flood Risks in Coastal and Low-Lying Regions

The Southeast's coastal plain and inland low-lying regions support a rapidly growing population, a tourism economy, critical industries, and important cultural resources that are highly vulnerable to climate change impacts. The combined effects of changing extreme rainfall events and sea level rise are already increasing flood frequencies, which impacts property values and infrastructure viability, particularly in coastal cities. Without significant adaptation measures, these regions are projected to experience daily high tide flooding by the end of the century.

Key Message 3

Natural Ecosystems Will Be Transformed

The Southeast's diverse natural systems, which provide many benefits to society, will be transformed by climate change. Changing winter temperature extremes, wildfire patterns, sea levels, hurricanes, floods, droughts, and warming ocean temperatures are expected to redistribute species and greatly modify ecosystems. As a result, the ecological resources that people depend on for livelihood, protection, and well-being are increasingly at risk, and future generations can expect to experience and interact with natural systems that are much different than those that we see today.

Key Message 4

Economic and Health Risks for Rural Communities

Rural communities are integral to the Southeast's cultural heritage and to the strong agricultural and forest products industries across the region. More frequent extreme heat episodes and changing seasonal climates are projected to increase exposure-linked health impacts and economic vulnerabilities in the agricultural, timber, and manufacturing sectors. By the end of the century, over one-half billion labor hours could be lost from extreme heat-related impacts. Such changes would negatively impact the region's labor-intensive agricultural industry and compound existing social stresses in rural areas related to limited local community capabilities and associated with rural demography, occupations, earnings, literacy, and poverty incidence. Reduction of existing stresses can increase resilience.

Executive Summary

The Southeast includes vast expanses of coastal and inland low-lying areas, the southern portion of the Appalachian Mountains, numerous high-growth metropolitan areas, and large rural expanses. These beaches and bayous, fields and forests, and cities and small towns are all at risk from a changing climate. While some climate change impacts, such as sea level rise and extreme downpours, are being acutely felt now, others, like increasing exposure to dangerous high temperatures, humidity, and new local diseases, are expected to become more significant in the coming decades. While all regional residents and communities are potentially at risk for some impacts, some communities or populations are at greater risk due to their locations, services available to them, and economic situations.

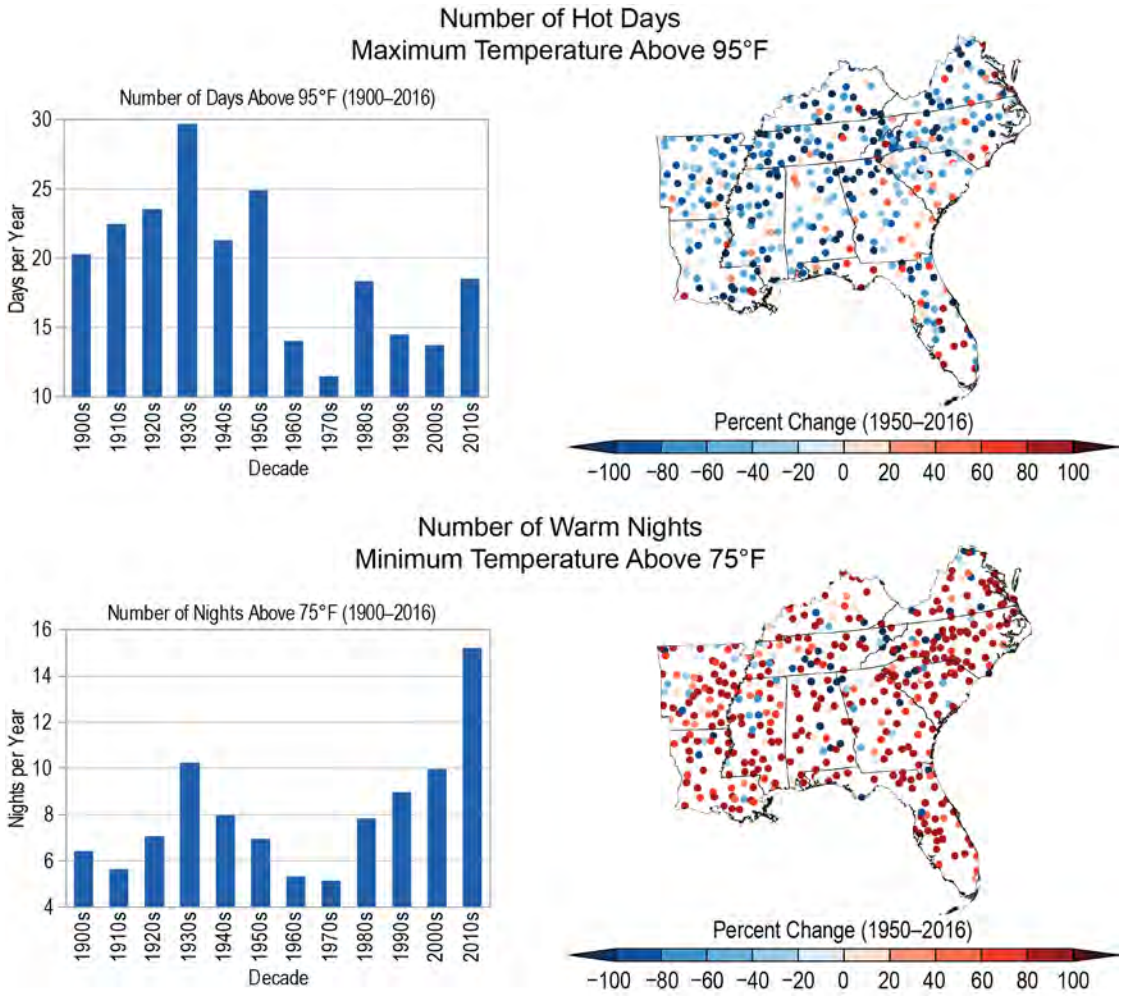
Observed warming since the mid-20th century has been uneven in the Southeast region, with average daily minimum temperatures increasing three times faster than average daily maximum temperatures. The number of extreme rainfall events is increasing. Climate model simulations of future conditions project increases in both temperature and extreme precipitation.

Trends towards a more urbanized and denser Southeast are expected to continue, creating new climate vulnerabilities. Cities across the Southeast are experiencing more and longer summer heat waves. Vector-borne diseases pose a greater risk in cities than in rural areas because of higher population densities and other human factors, and the major urban centers in the Southeast are already impacted by poor air quality during warmer months. Increasing precipitation and extreme weather events will likely impact roads, freight rail, and passenger rail, which will likely have cascading effects across the region. Infrastructure related to drinking water and wastewater treatment also has the potential to be compromised by climate-related events. Increases in extreme rainfall events and high tide coastal floods due to future climate change will impact the quality of life of permanent residents as well as tourists visiting the low-lying and coastal regions of the Southeast. Sea level rise is contributing to increased coastal flooding in the Southeast, and high tide flooding already poses daily risks to businesses, neighborhoods, infrastructure, transportation, and ecosystems in the region.[1,2] There have been numerous instances of intense rainfall events that have had devastating impacts on inland communities in recent years.

The ecological resources that people depend on for livelihoods, protection, and well-being are increasingly at risk from the impacts of climate change. Sea level rise will result in the rapid conversion of coastal, terrestrial, and freshwater ecosystems to tidal saline habitats. Reductions in the frequency and intensity of cold winter temperature extremes are already allowing tropical and subtropical species to move northward and replace more temperate species. Warmer winter temperatures are also expected to facilitate the northward movement of problematic invasive species, which could transform natural systems north of their current distribution. In the future, rising temperatures and increases in the duration and intensity of drought are expected to increase wildfire occurrence and also reduce the effectiveness of prescribed fire practices.[3,4,5,6]

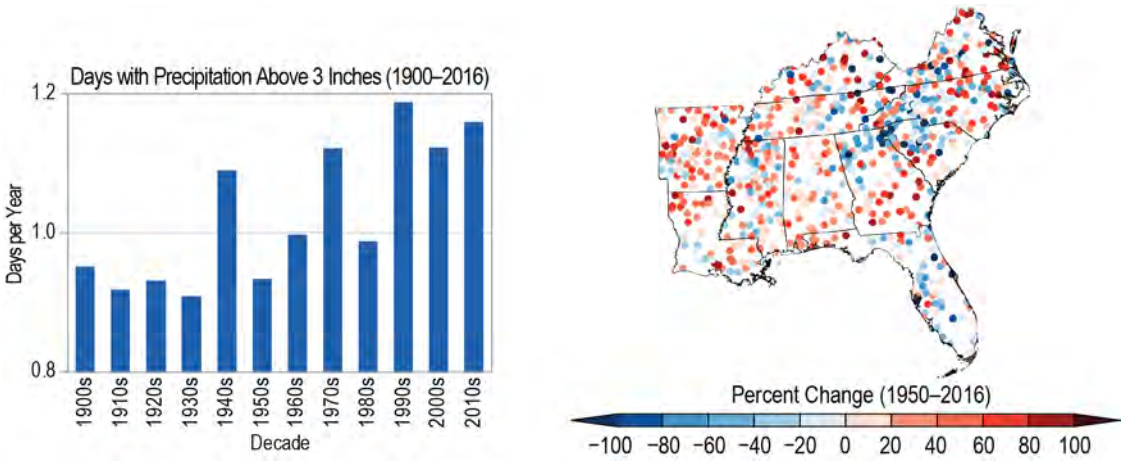
Many in rural communities are maintaining connections to traditional livelihoods and relying on natural resources that are inherently vulnerable to climate changes. Climate trends and possible climate futures show patterns that are already impacting—and are projected to further impact—rural sectors, from agriculture and forestry to human health and labor productivity. Future temperature increases are projected to pose challenges to human health. Increases in temperatures, water stress, freeze-free days, drought, and wildfire risks, together with changing conditions for invasive species and the movement of diseases, create a number of potential risks for existing agricultural systems.[7] Rural communities tend to be more vulnerable to these changes due to factors such as demography, occupations, earnings, literacy, and poverty incidence.[8,9,10] In fact, a recent economic study using a higher scenario (RCP8.5)[11] suggests that the southern and midwestern populations are likely to suffer the largest losses from future climate changes in the United States. Climate change tends to compound existing vulnerabilities and exacerbate existing inequities. Already poor regions, including those found in the Southeast, are expected to continue incurring greater losses than elsewhere in the United States.

Historical Changes in Hot Days and Warm Nights



Sixty-one percent of major Southeast cities are exhibiting some aspects of worsening heat waves, which is a higher percentage than any other region of the country.[12] Hot days and warm nights together impact human comfort and health and result in the need for increased cooling efforts. Agriculture is also impacted by a lack of nighttime cooling. Variability and change in (top) the annual number of hot days and (bottom) warm nights are shown. The bar charts show averages over the region by decade for 1900–2016, while the maps show the trends for 1950–2016 for individual weather stations. Average summer temperatures during the most recent 10 years have been the warmest on record, with very large increases in nighttime temperatures and more modest increases in daytime temperatures, as indicated by contrasting changes in hot days and warm nights. (top left) The annual number of hot days (maximum temperature above 95°F) has been lower since 1960 than the average during the first half of the 20th century; (top right) trends in hot days since 1950 are generally downward except along the south Atlantic coast and in Florida due to high numbers during the 1950s but have been slightly upward since 1960, following a gradual increase in average daytime maximum temperatures during that time. (bottom left) Conversely, the number of warm nights (minimum temperature above 75°F) has doubled on average compared to the first half of the 20th century and (bottom right) locally has increased at most stations. *From Figure 19.1 (Sources: NOAA NCEI and CICS-NC)*.

Historical Change in Heavy Precipitation



The figure shows variability and change in (left) the annual number of days with precipitation greater than 3 inches (1900–2016) averaged over the Southeast by decade and (right) individual station trends (1950–2016). The number of days with heavy precipitation has increased at most stations, particularly since the 1980s. *From Figure 19.3 (Sources: NOAA NCEI and CICS-NC)*

Background

Throughout the southeastern United States, the impacts of sea level rise, increasing temperatures, extreme heat events, heavy precipitation, and decreased water availability continue to have numerous consequences for human health, the built environment, and the natural world. This assessment builds on the above concerns described in the Third National Climate Assessment (NCA3) and includes impacts to urban and rural landscapes as well as natural systems. The impacts from these changes are becoming visible as 1) flooding increases stress on infrastructure, ecosystems, and populations; 2) warming temperatures affect human health and bring about temporal and geographic shifts in the natural environment and landscapes; and 3) wildfires and growing wildfire risk create challenges for natural resource managers and impacted communities.

The Southeast includes vast expanses of coastal and inland low-lying areas, the southern (and highest) portion of the Appalachian Mountains, numerous high-growth metropolitan areas, and large rural expanses. Embedded in these land- and seascapes is a rich cultural history developed over generations by the many communities that call this region home. However, these beaches and bayous, fields and forests, and cities and small towns are all at risk from a changing climate. These risks vary in type and magnitude from place to place, and while some climate change impacts, such as sea level rise and extreme downpours, are being acutely felt now, others, like increasing exposure to dangerously high temperatures—often accompanied by high humidity—and new local diseases, are expected to become more significant in the coming decades. While all regional residents and communities are potentially at risk for some impacts, some communities or populations are at greater risk due to their locations, services available, and economic situations. In fact, a recent economic study using a higher scenario (RCP8.5)[11] suggests that the southern and midwestern populations are likely to suffer the largest losses from projected climate changes in the United States. According to the article, "[b]ecause losses are largest in regions that are already poorer on average, climate change tends to increase preexisting inequality in the United States."[11] Understanding the demographic and socioeconomic composition of racial and ethnic groups in the region is important, because these characteristics are associated with health risk factors, disease prevalence, and access to care, which in turn may influence the degree of impact from climate-related threats.

Historical Climate and Possible Future Climates

The Southeast region experienced high annual average temperatures in the 1920s and 1930s, followed by cooler temperatures until the 1970s. Since then, annual average temperatures have warmed to levels above the 1930s; the decade of the 2010s through 2017 has been warmer than any previous decade (App 5: FAQs, Figure A5.14), both for average daily maximum and average daily minimum temperature. Seasonal warming has varied. The decade of the 2010s through 2017 is the warmest in all seasons for average daily minimum temperature and in winter and spring for average daily maximum temperature. However, for average daily maximum temperature, the summers of the 1930s and 1950s and the falls of the 1930s were warmer on average. The southeastern United States is one of the few regions in the world that has experienced little overall warming of daily maximum temperatures since 1900. The reasons for this have been the subject of much research, and hypothesized causes include both human and natural influences.[13,14,15,16,17] However, since the early 1960s, the Southeast has been warming at a similar rate as the rest of the United States (Ch.

2: Climate, Figure 2.4). During the 2010s, the number of nights with minimum temperatures greater than 75°F was nearly double the long-term average for 1901–1960 (Figure 19.1), while the length of the freeze-free season was nearly 1.5 weeks greater than any other period in the historical record (Figure 19.2). These increases were widespread across the region and can have important effects on both humans and the natural environment.[18] By contrast, the number of days above 95°F has been lower since 1960 compared to the pre-1960 period, with the highest numbers occurring in the 1930s and 1950s, both periods of severe drought (Figure 19.1). The differing trends in hot days and warm nights reflect the seasonal differences in average daily maximum and average daily minimum temperature trends.

Historical Changes in Hot Days and Warm Nights

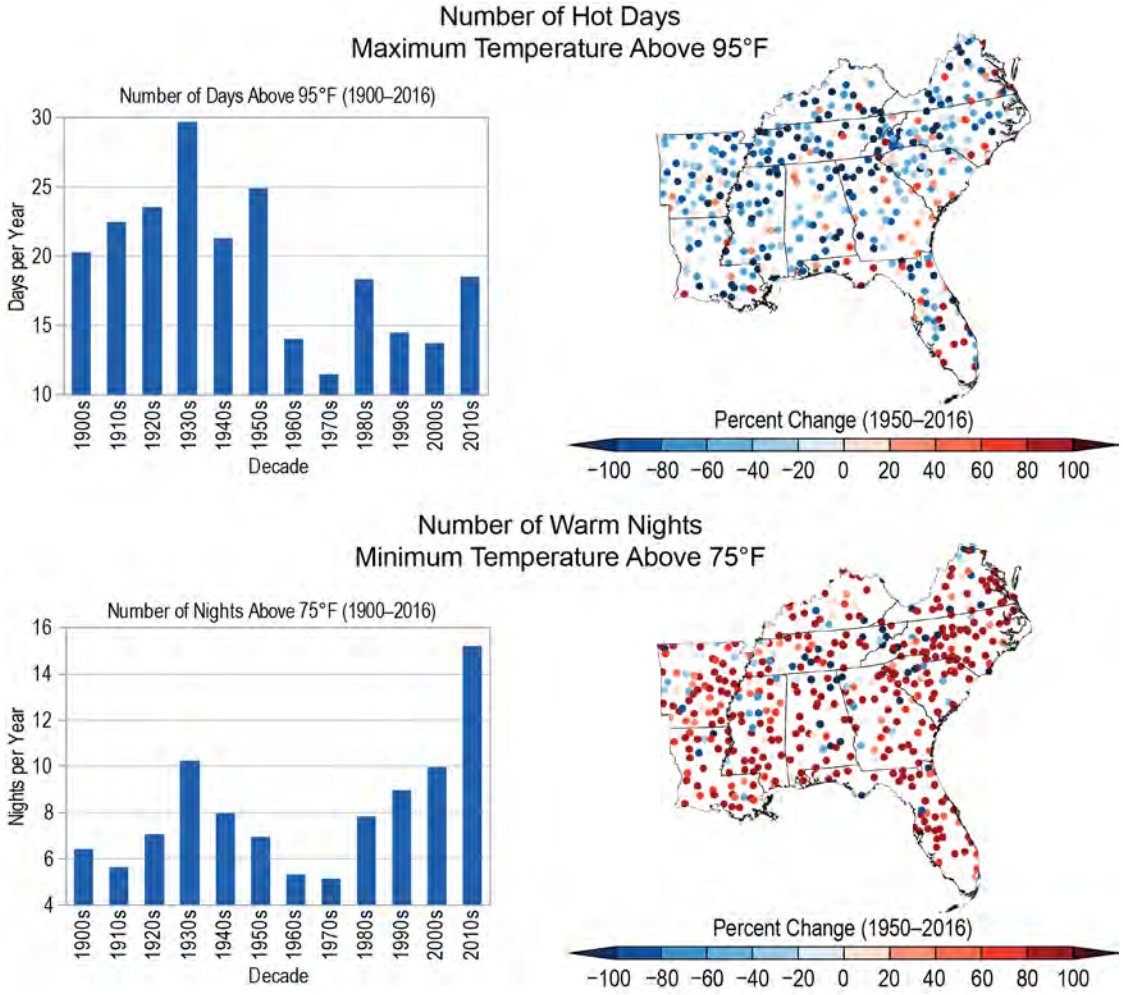


Figure 19.1: Sixty-one percent of major Southeast cities are exhibiting some aspects of worsening heat waves, which is a higher percentage than any other region of the country.[12] Hot days and warm nights together impact human comfort and health and result in the need for increased cooling efforts. Agriculture is also impacted by a lack of nighttime cooling. Variability and change in (top) the annual number of hot days and (bottom) warm nights are shown. The bar charts show averages over the region by decade for 1900–2016, while the maps show the trends for 1950–2016 for individual weather stations. Average summer temperatures during the most recent 10 years have been the warmest on record, with very large increases in nighttime temperatures and more modest increases in daytime temperatures, as indicated by contrasting changes in hot days and warm nights. (top left) The annual number of hot days (maximum temperature above 95°F) has been lower since 1960 than the average during the first half of the 20th century; (top right) trends in hot days since 1950 are generally downward except along the south Atlantic coast and in Florida due to high numbers during the 1950s but have been slightly upward since 1960, following a gradual increase in average daytime maximum temperatures during that time. (bottom left) Conversely, the number of warm nights (minimum temperature above 75°F) has doubled on average compared to the first half of the 20th century and (bottom right) locally has increased at most stations. Sources: NOAA NCEI and CICS-NC.

Historical Change in Freeze-Free Season Length

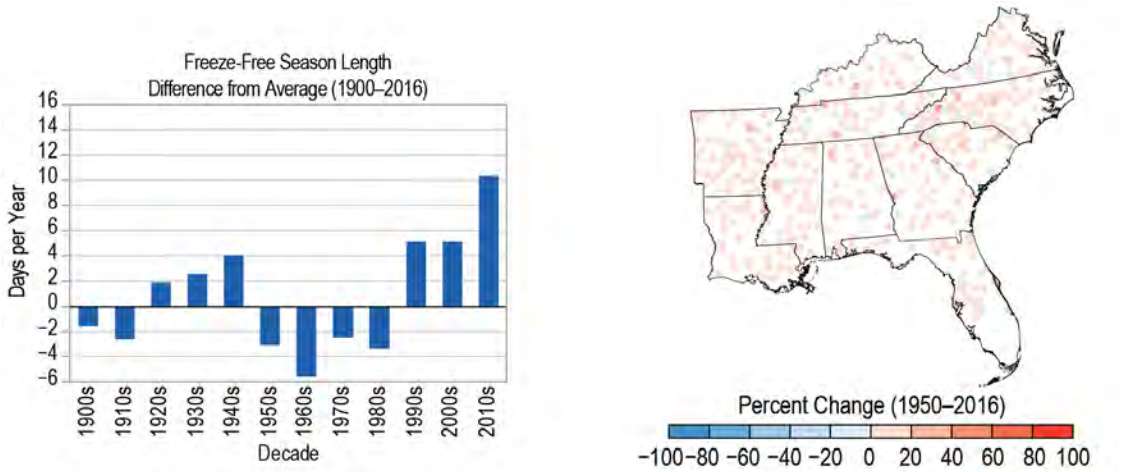

Figure 19.2: The figure shows the variability and change in the length of the freeze-free season. (left) The bar chart shows differences in the length of the freeze-free season by decade (1900–2016) as compared to the long-term average for the Southeast. (right) The map shows trends over 1950–2016 for individual weather stations. The length of the freeze-free season has increased at most stations, particularly since the 1980s. Sources: NOAA NCEI and CICS-NC.

Historical Change in Heavy Precipitation

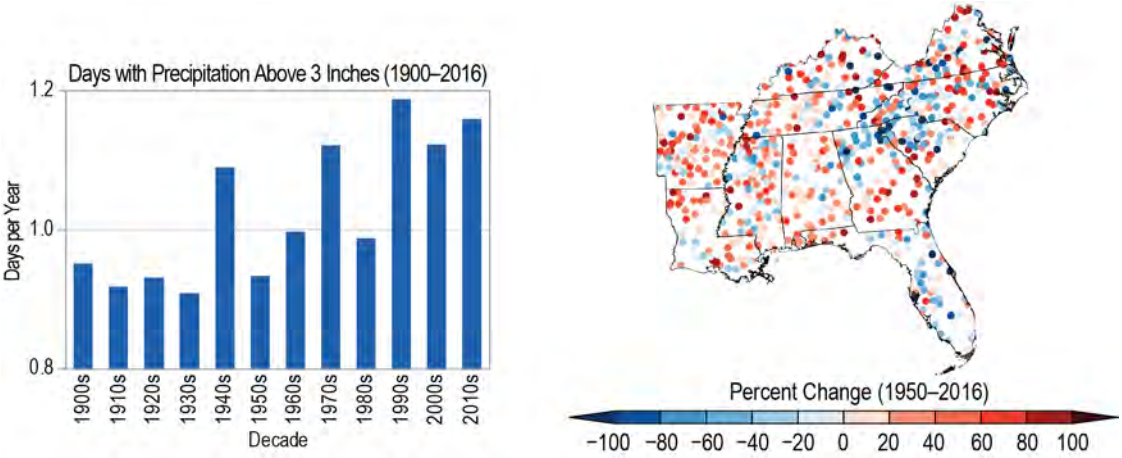

Figure 19.3: The figure shows variability and change in (left) the annual number of days with precipitation greater than 3 inches (1900–2016) averaged over the Southeast by decade and (right) individual station trends (1950–2016). The numbers of days with heavy precipitation has increased at most stations, particularly since the 1980s. Sources: NOAA NCEI and CICS-NC.

The number of extreme rainfall events is increasing. For example, the number of days with 3 or more inches of precipitation has been historically high over the past 25 years, with the 1990s, 2000s, and 2010s ranking as the decades with the 1st, 3rd, and 2nd highest number of events, respectively (Figure 19.3). More than 70% of precipitation recording locations show upward trends since 1950, although there are downward trends at many stations along and southeast of the Appalachian Mountains and in Florida (Figure 19.3).

Climate model simulations of future conditions project increases in temperature and extreme precipitation for both lower and higher scenarios (RCP4.5 and RCP8.5; see Figure 19.5).[13,19] After the middle of the 21st century, however, the projected increases are lower for the lower scenario (RCP4.5). Much larger changes are simulated by the late 21st century under the higher scenario (RCP8.5), which most closely tracks with our current consumption of fossil fuels. Under the higher scenario, nighttime

minimum temperatures above 75°F and daytime maximum temperatures above 95°F become the summer norm and nights above 80°F and days above 100°F, now relatively rare occurrences, become commonplace. Cooling degree days (a measure of the need for air conditioning [cooling] based on daily average temperatures rising above a standard temperature—often 65°F) nearly double, while heating degree days (a measure of the need for heating) decrease by over a third (Figure 19.22). The freeze-free season lengthens by more than a month, and the frequency of freezing temperatures decreases substantially.[20,21]

Key Message 1

Urban Infrastructure and Health Risks

Many southeastern cities are particularly vulnerable to climate change compared to cities in other regions, with expected impacts to infrastructure and human health. The vibrancy and viability of these metropolitan areas, including the people and critical regional resources located in them, are increasingly at risk due to heat, flooding, and vector-borne disease brought about by a changing climate. Many of these urban areas are rapidly growing and offer opportunities to adopt effective adaptation efforts to prevent future negative impacts of climate change.

Rapid Population Shifts and Climate Impacts on Urban Areas

While the Southeast is historically known for having a rural nature, a drastic shift toward a more urbanized region is underway. The Southeast contains many of the fastest-growing urban areas in the country, including a dozen of the top 20 fastest-growing metropolitan areas (by percentage) in 2016.[22] Metropolitan Atlanta has been swiftly growing, adding 69,200 residents in just one year.[23] At the same time, many rural counties in the South are losing population.[24] These trends towards a more urbanized and dense Southeast are expected to continue, creating new climate vulnerabilities but also opportunities to adapt as capacity and resources increase in cities (Ch. 17: Complex Systems). In particular, coastal cities in the Southeast face multiple climate risks, and many planning efforts are underway in these cities. Adaptation, mitigation, and planning efforts are emphasizing "co-benefits" (positive benefits related to the reduction of greenhouse gases or implementation of adaptation efforts) to help boost the economy while protecting people and infrastructure.

Increasing Heat

Cities across the Southeast are experiencing more and longer summer heat waves. Nationally, there are only five large cities that have increasing trends exceeding the national average for all aspects of heat waves (timing, frequency, intensity, and duration), and three of these cities are in the Southeast region—Birmingham, New Orleans, and Raleigh. Sixty-one percent of major Southeast cities are exhibiting some aspects of worsening heat waves, which is a higher percentage than any other region of the country.[12] The urban heat island effect (cities that are warmer than surrounding rural areas, especially at night) adds to the impact of heat waves in cities (Ch. 5: Land Changes, KM 1). Southeastern cities including Memphis and Raleigh have a particularly high future heat risk.[25]

The number of days with high minimum temperatures (nighttime temperatures that stay above 75°F) has been increasing across the Southeast (Figure 19.1), and this trend is projected to intensify, with some areas experiencing more than 100 additional warm nights per year by the end of the century (Figures 19.4 and 19.5). Exposure to high nighttime minimum temperatures reduces the ability of some people to recover from high daytime temperatures, resulting in heat-related illness and death.[26] This effect is particularly pronounced in cities, many of which have urban heat islands that already cause elevated nighttime temperatures.[27] Cities are taking steps to prevent negative health impacts from heat. For example, the Louisville, Kentucky, metro government conducted an urban heat management study and installed 145,000 square feet of cool roofs as part of their goal to lessen the risk of climate change impacts.[28]

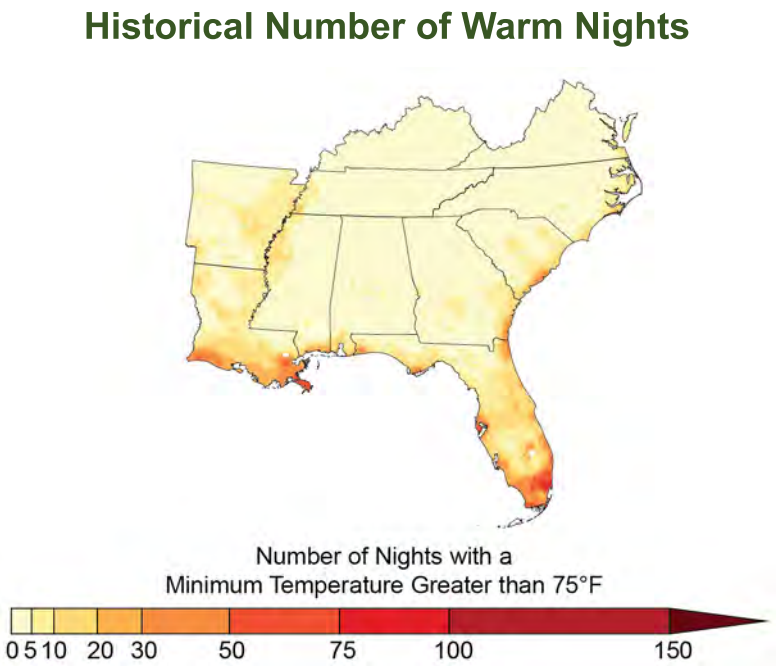

Figure 19.4: The map shows the historical number of warm nights (days with minimum temperatures above 75°F) per year in the Southeast, based on model simulations averaged over the period 1976–2005. Sources: NOAA NCEI and CICS-NC.

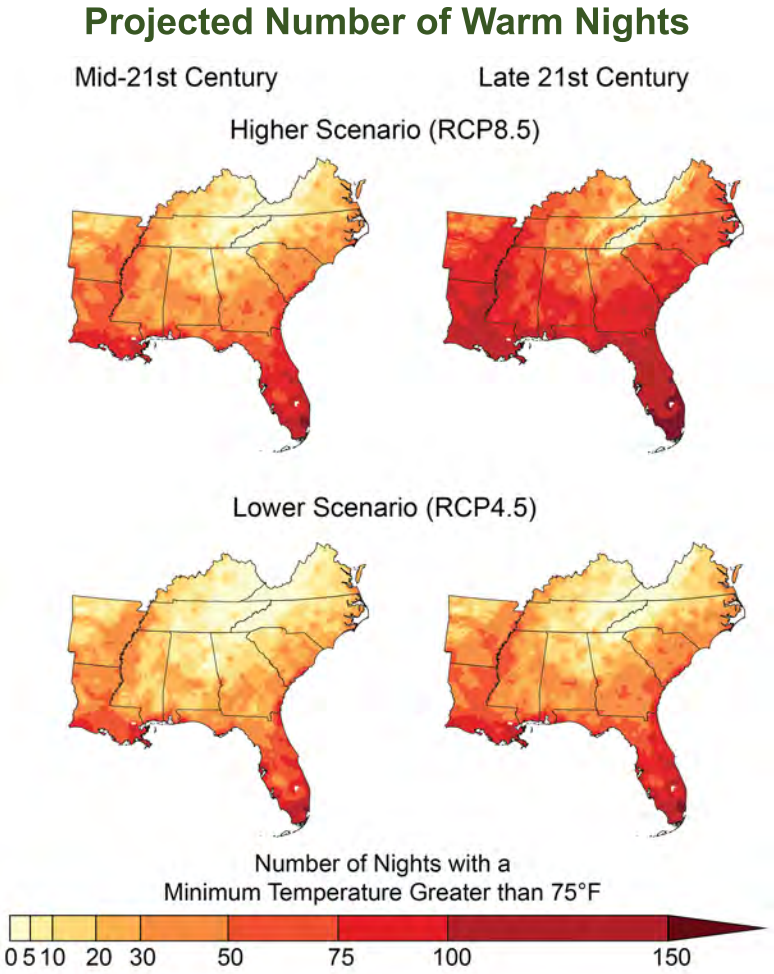

Figure 19.5: The maps show the projected number of warm nights (days with minimum temperatures above 75°F) per year in the Southeast for the mid-21st century (left; 2036–2065) and the late 21st century (right; 2070–2099) under a higher scenario (RCP8.5; top row) and a lower scenario (RCP4.5; bottom row). These warm nights currently occur only a few times per year across most of the region (Figure 19.4) but are expected to become common events across much of the Southeast under a higher scenario. Increases in the number of warm nights adversely affect agriculture and reduce the ability of some people to recover from high daytime temperatures. With more heat waves expected, there will likely be a higher risk for more heat-related illness and deaths. Sources: NOAA NCEI and CICS-NC.

Vector-Borne Disease

The transmission of vector-borne diseases, which are spread by the bite of an animal such as a mosquito or tick, is complex and depends on a number of factors, including weather and climate, vegetation, animal host populations, and human activities (Ch. 14: Human Health, KM 1). Climate change is likely to modify the seasonality, distribution, and prevalence of vector-borne diseases in the Southeast.[29] Vector-borne diseases pose a greater risk in cities than in rural areas because of higher population densities and other human factors (for example, pools of standing water in man-made structures, such as tires or buckets, are breeding grounds for some species of mosquitoes). Climatic conditions are currently suitable for adult mosquitoes of the species *Aedes aegypti*, which can spread dengue, chikungunya, and Zika viruses, across most of the Southeast from July through September (Figure 19.6), and cities in South Florida already have suitable conditions for year-round mosquito activity. The Southeast is the region of the country with the most favorable conditions for this mosquito and thus faces the greatest threat from diseases the mosquito carries.[30] Climate change is expected to make conditions more suitable for transmission of certain vector-borne diseases, including year-round transmission in southern

Florida. Summer increases in dengue cases are expected across every state in the Southeast. Despite warming, low winter temperatures may prevent permanent year-round establishment of the virus across the region.[31] Strategies such as management of urban wetlands have resulted in lower dengue fever risk in Puerto Rico.[32] Similar adaptation strategies have the potential to limit vector-borne disease in southeastern cities, particularly those cities with characteristics similar to Caribbean cities that have already implemented vector control strategies (Ch. 20: U.S. Caribbean).[33,34] The Southeast is also the region with the greatest projected increase in cases of West Nile neuroinvasive disease under both a lower and higher scenario (RCP4.5 and RCP8.5).[35,36]

Air Quality and Human Health

Poor air quality directly impacts human health, resulting in respiratory disease and other ailments. In the Southeast, poor air quality can result from emissions (mostly from vehicles and power plants), wildfires, and allergens such as pollen. The major urban centers in the Southeast are already impacted by poor air quality during warmer months. The Southeast has more days with stagnant air masses than other regions of the country (40% of summer days) and higher levels of fine (small) particulate matter ($PM_{2.5}$), which cause heart and lung disease.[37] There is mixed evidence on the future health impacts of these pollutants. Ozone concentrations would be expected to increase under higher temperatures; however, a variety of factors complicate projections (Ch. 13: Air Quality, KM 1). There are many possible future wind and cloud cover conditions for the Southeast as well as the potential for continued shifts in land-use patterns, demographics and population geography, and vehicle and power plant emissions standards. Increases in precipitation and shifts in wind trajectories may reduce future health impacts of ground level ozone in the Southeast,[35] but warmer and drier autumns are expected to result in a lengthening of the period of ozone exposure.[38] Warmer August temperatures in the Southeast from 1988 to 2011 were associated with increased human sensitivity to ground-level ozone.[39]

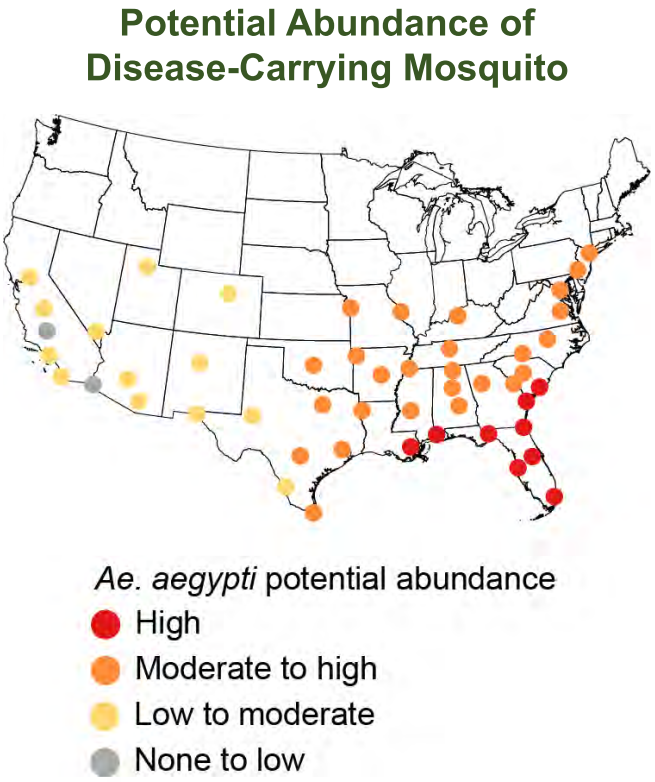

Figure 19.6: The map shows current suitability for the *Aedes aegypti* mosquito in July in 50 different cities. *Aedes aegypti* mosquitoes can spread several important diseases, including dengue fever, chikungunya, and Zika fever. The Southeast is the region of the country with the greatest potential mosquito activity. Warming temperatures have the potential to expand mosquito habitat and disease risk. Source: adapted from Monaghan et al. 2016.[30]

The fast growth rate of urban areas in the Southeast contributes to aeroallergens, which are known to cause and exacerbate respiratory diseases such as asthma. Urban areas have higher concentrations of CO_2, which causes allergenic plants, such as ragweed, to grow faster and produce more pollen than in rural areas.[40] Continued rising temperatures and atmospheric CO_2 levels are projected to further contribute to aeroallergens in cities (Ch. 13: Air Quality, KM 3).

Infrastructure

Infrastructure, particularly roads, bridges, coastal properties, and urban drainage, is vulnerable to climate change and climate-related events (see Key Message 2) (see also Ch. 3: Water, KM 2; Ch. 11: Urban, KM 2; Ch. 12: Transportation, KM 1).[41] By 2050, the Southeast is the region expected to have the most vulnerable bridges.[35] An extreme weather vulnerability assessment conducted by the Tennessee Department of Transportation found that the urban areas of Memphis and Nashville had the most at-risk transportation infrastructure in the state.[42] Increasing precipitation and extreme weather events will likely impact roads, freight rail, and passenger rail, especially in Memphis, which will likely have cascading effects across the region.[43] Transit infrastructure, such as the rail lines of the Metropolitan Atlanta Rapid Transit Authority (MARTA), are also at risk. As a result, MARTA has begun to identify vulnerable assets and prioritize improvements to develop a more resilient system.[44]

Many cities across the Southeast are planning for the impacts sea level rise is likely to have on their infrastructure (see Case Study "Charleston, South Carolina, Begins Planning and Reinvesting" and Key Message 2). Flood events in Charleston, South Carolina, have been increasing, and by 2045 the city is projected to face nearly 180 tidal floods (flooding in coastal areas at high tide) per year, as compared to 11 floods per year in 2014.[45] These floods affect tourism, transportation, and the economy as a whole. The city has responded by making physical modifications, developing a more robust disaster response plan, and improving planning and monitoring prior to flood events.

Infrastructure related to drinking water treatment and wastewater treatment may be compromised by climate-related events (Ch. 3: Water, KM 2). Water utilities across the Southeast are preparing for these impacts. Tampa Bay Water, the largest wholesale water utility in the Southeast, is coordinating with groups including the Florida Water and Climate Alliance to study the impact of climate change on its ability to provide clean water in the future.[46,47] Spartanburg Water, in South Carolina, is reinforcing the ability of the utility to "cope with, and recover from disruption, trends and variability in order to maintain services."[48] Similarly, the Seminole Tribe of Florida, which provides drinking and wastewater services, assessed flooding and sea level rise threats to their water infrastructure and developed potential adaptation measures.[49] The development of "green" water infrastructure (using natural hydrologic features to manage water and provide environmental and community benefits), such as the strategies promoted in the City of Atlanta Climate Action Plan, is one way to adapt to future water management needs. Implementation of these strategies has already resulted in a reduction in water consumption in the city of Atlanta, relieving strain on the water utility and increasing resilience.[50]

There are still gaps in knowledge regarding the potential effects of climate change on cities across the Southeast. Cross-disciplinary groups such as the Georgia Climate Project (http://www.georgiaclimateproject.org) are developing research roadmaps that can help to prioritize research and action with relevance to policymakers, practitioners, and scientists.

Key Message 2

Increasing Flood Risks in Coastal and Low-Lying Regions

The Southeast's coastal plain and inland low-lying regions support a rapidly growing population, a tourism economy, critical industries, and important cultural resources that are highly vulnerable to climate change impacts. The combined effects of changing extreme rainfall events and sea level rise are already increasing flood frequencies, which impacts property values and infrastructure viability, particularly in coastal cities. Without significant adaptation measures, these regions are projected to experience daily high tide flooding by the end of the century.

Sea Level Rise Is Contributing to Increased Coastal Flooding in the Southeast

Average global sea level (or global mean sea level; GMSL) has risen about 8–9 inches since 1880, with about 3 inches of that rise occurring since 1990.[51,52] This recent increase in the rate of rise is projected to accelerate in the future due to continuing temperature increases and additional melting of land ice.[51] This recent global rate increase, combined with the local effects of vertical land motion (sinking) and oceanographic effects such as changing ocean currents, has caused some areas in the Southeast to experience even higher local rates of sea level rise than the global average.[53,54,55,56,57,58,59] Analyses at National Oceanic and Atmospheric Administration (NOAA) tide gauges show as much as 1 to 3 feet of local relative sea level rise in the past 100 years in low-lying areas of the Southeast.[54,59] This recent rise in local relative sea level has caused normal high tides to reach critical levels that result in flooding in many coastal areas in the region.

Monthly and seasonal fluctuations in high tide levels are caused by a combination of astronomical factors (sun and moon gravitational attraction) and non-astronomical factors such as geomorphology (landscape of the area), as well as meteorological (weather) conditions. The highest tides of the year are generally the perigean, or spring, tides, which occur when the moon is full or new and is closest to the Earth. These perigean tides, also known as "king tides," occur twice a year and in many cities are causing what has been called "nuisance" or "recurrent" flooding (referred to herein as high tide flooding). These floods can cause problems ranging from inconvenient to life changing. While the challenges brought on by rising perigean tides are diverse, important examples include increasingly frequent road closures, excessive water in storm water management systems, and deterioration of infrastructure such as roads and rail from saltwater. NOAA's National Weather Service (NWS) issues coastal flood advisories and warnings when water levels at tide gauges are expected to exceed flood thresholds. These thresholds correspond to discrete water levels relative to NOAA tide gauges.

Recent analyses of historical water levels at many NOAA tide gauges has shown an increase in the number of times that these warning thresholds were exceeded compared to the past. Annual occurrences of high tide coastal flooding have increased 5- to 10-fold since the 1960s in several low-lying coastal cities in the Southeast (Figure 19.7).[51,60] In 2015, several Southeast coastal cities experienced all-time records of coastal flooding occurrences, including Wilmington, NC (90 days), Charleston, SC (38 days), Mayport, FL (19 days), Miami, FL (18 days), Key West, FL (14 days), and Fernandina Beach, FL (7 days). These flooding occurrences increased more than 50% in 2015 compared to 2014.[58] In 2016, three all-time records were either tied (14 days at Key West,

FL) or broken (50 days at Charleston, SC, and 38 days at Savannah, GA). The Miami area nearly matched the 2015 record of 18 days.[61] This increase in high tide flooding frequency is directly tied to sea level rise. For example, in Norfolk, Virginia, local relative sea level rise has led to a fourfold increase in the probability of exceeding NWS thresholds compared to the 1960s (Figure 19.8). High tide flooding is now posing daily risks to businesses, neighborhoods, infrastructure, transportation, and ecosystems in the Southeast.[1,2]

Global sea level is very likely to rise by 0.3–0.6 feet by 2030, 0.5–1.2 feet by 2050, and 1.0–4.3 feet by 2100 under a range of scenarios from very low (RCP2.6) to high (RCP8.5),[51,52,62] which would result in increases in both the depth and frequency of coastal flooding (Figure 19.7).[51] Under higher emissions scenarios (RCP8.5), global sea level rise exceeding 8 feet (and even higher in the Southeast) by 2100 cannot be ruled out.[51] By 2050, many Southeast cities are projected to experience more than 30 days of high tide flooding regardless of scenario.[63] In addition, more extreme coastal flood events are also projected to increase in frequency and duration.[60] For example, water levels that currently have a 1% chance of occurring each year (known as a 100-year event) will be more frequent with sea level rise. This increase in flood frequency suggests the need to consider revising flood study techniques and standards that are currently used to design and build coastal infrastructure.

Higher sea levels will cause the storm surges from tropical storms to travel farther inland than in the past, impacting more coastal properties. The combined impacts of sea level rise and storm surge in the Southeast have the potential to cost up to $60 billion each year in 2050 and up to $99 billion in 2090 under a higher scenario (RCP8.5).[35] Even under a lower scenario (RCP4.5), projected damages are $56 and $79 billion in 2050 and 2090, respectively (in 2015 dollars, undiscounted).[35] Florida alone is estimated to have a 1-in-20 chance of having more than $346 billion (in 2011 dollars) in property value (8.7%) below average sea level by 2100 under a higher scenario (RCP8.5).[64] An assessment by the Florida Department of Health determined that 590,000 people in South Florida face “extreme” or “high” risk from sea level rise, with 125,000 people living in these areas identified as socially vulnerable and 55,000 classified as medically vulnerable.[65] In addition to causing direct injury, storm surge and related flooding can impact transportation infrastructure by blocking or flooding roads and affecting access to healthcare facilities (Ch. 12: Transportation, KM 1). Marine transportation can be impacted as well. Large ports in the Southeast, such as Charleston, Savannah, and Jacksonville, and the rails and roads that link to them, are particularly vulnerable to both coastal flooding and sea level rise (Ch. 12: Transportation, KM 1; Ch. 8: Coastal, KM 1). The Port of Jacksonville provides raw material for industries, food, clothes, and essential goods to Puerto Rico, thus impacting the U.S. Caribbean region, as well (Ch. 20: U.S. Caribbean, KM 3). It is estimated that with a meter (about 3.3 feet) of sea level rise, the Southeast would lose over 13,000 recorded historic and prehistoric archaeological sites and more than 1,000 locations currently eligible for inclusion on the National Register of Historic Places.[66] This includes many historic buildings and forts in cities like Charleston, Savannah, and St. Augustine.

Annual Number of High Tide Flooding Days

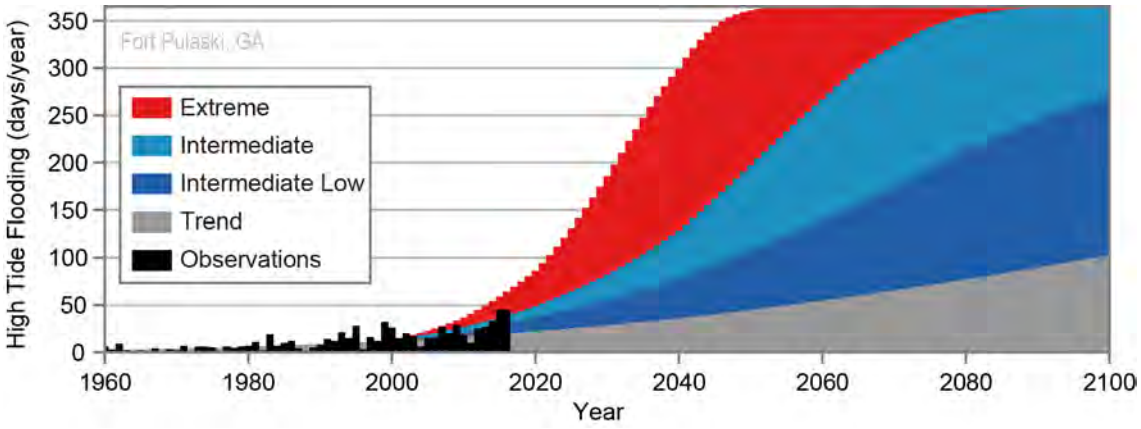

Figure 19.7: The figure shows the annual number of days experiencing high tide floods based on observations for 1960–2016 for Fort Pulaski, near Savannah, Georgia (black), and projected increases in the number of annual flood events based on four future scenarios: a continuation of the current relative sea level trend (gray) and the Intermediate-Low (dark blue), Intermediate (light blue), and Extreme (red) sea level rise scenarios. See Sweet et al. (2017)[51] and Appendix 3: Data & Scenarios for additional information on projection and trend data. Source: adapted from Sweet and Park 2014.[63]

Range of Daily Highest Water Levels in Norfolk, Virginia

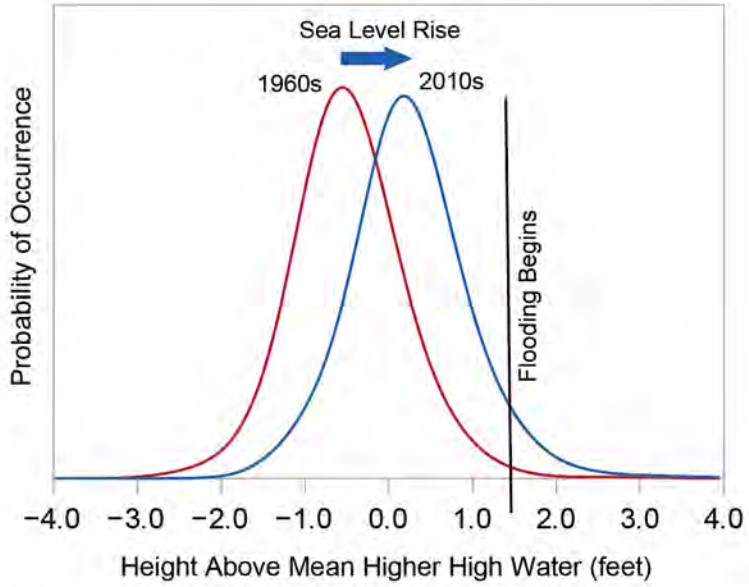

Figure 19.8: The curves in this figure show a range of daily Mean Higher High Water (MHHW) levels in Norfolk, Virginia (Sewells Point), for the 1960s and 2010s. Local sea level rise has shifted the curve closer to the point where high tide flooding begins (based on warning thresholds established by the National Weather Service). This shows why many more high tide flood events occur now than they did in the past (increase of 6 flood days per year). Source: adapted from Sweet et al. 2017.[52] *This figure was revised in June 2019. See Errata for details: https://nca2018.globalchange.gov/downloads*

Case Study: Charleston, South Carolina, Begins Planning and Reinvesting for Sea Level Rise

The main crosstown traffic artery in Charleston, South Carolina (U.S. 17 Septima Clark Parkway–crosstown), has historically been susceptible to flooding events (Figure 19.9). Charleston experienced all-time record high tide flood occurrences in 2015 (38 days) and 2016 (50 days).[52,58] By 2045, Charleston is projected to experience up to 180 high tide flood events a year.[1] The City of Charleston estimated that each flood event that affects the crosstown costs $12.4 million (in 2009 dollars). Over the past 50 years, the resultant gross damage and lost wages have totaled more than $1.53 billion (dollar year not specified). As a result, Charleston has developed a Sea Level Rise Strategy that plans for 50 years out based on moderate sea level rise scenarios (Figure 19.10) and that reinvests in infrastructure, develops a response plan, and increases readiness.[45] As of 2016, the City of Charleston has spent or set aside $235 million (in 2015 dollars) to complete ongoing drainage improvement projects (Figure 19.9) to prevent current and future flooding.

Figure 19.9: (left) U.S. Highway 17 (Septima Clark Parkway—crosstown) in Charleston, South Carolina, during a flood event. Floodwaters can get deep enough to stall vehicles. (right) Market Street drainage tunnel being constructed in Charleston, South Carolina, as part of a drainage improvement project to prevent current and future flooding. This tunnel crosses a portion of downtown Charleston 140 feet underground and is designed to rapidly convey storm water to the nearby Ashley River. Photo credit: City of Charleston 2015.[45]

Projected Sea Level Rise for Charleston, South Carolina

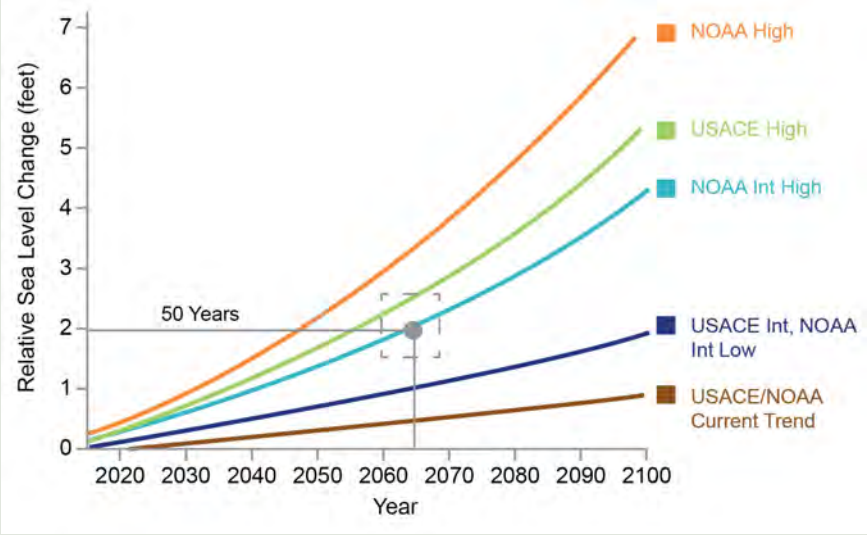

Figure 19.10: The City of Charleston Sea Level Rise Strategy calls for a 50-year outlook, based on existing federal sea level change projections in 2015 (colored curves), and calls for using a range of 1.5–2.5 feet of sea level rise (dashed box). A 1.5-foot increase will be used for short-term, less vulnerable investments, such as a parking lot. A 2.5-foot increase will be used for critical, longer-term investments, such as emergency routes and public buildings. This 1-foot range was chosen to approximate the average of these projections in 2065. Source: City of Charleston 2015.[45]

Many of the older historical coastal cities in the Southeast were built just above the current Mean Higher High Water (MHHW) level (the average height of the higher of the two daily high tides at a given location), with a gravity-driven drainage system designed to drain rainwater into the tidal estuaries. As sea levels have risen locally in the last one hundred years, the storm water systems in these areas are no longer able to perform as designed. When these cities experience high tide coastal flooding due to perigean tides, the tidewater enters the storm water system, which prevents rainwater from entering storm drains and causes increased impacts from flooding. In the future, the gravity-driven nature of many of these systems may cease to function as designed, causing rainwater to flood streets and neighborhoods until the tide lowers and water can drain normally. Cities such as Charleston and Miami have already begun to improve storm water infrastructure and explore natural and nature-based infrastructure design to reduce future flood risk.

Much of the Southeast region's coast is bordered by large expanses of salt marsh and barrier islands. Long causeways with intermittent bridges to connect the mainland to these popular tourism destinations were built decades ago at only a few feet above MHHW. Sea level rise has put these transportation connection points at risk. High tide coastal flooding has started to inundate these low-lying roads, restricting access during certain times of the day and causing public safety concerns. The U.S. East Coast, for example, already has 7,508 miles of roadways, including over 400 miles of interstate roadways, currently threatened by high tide coastal flooding (Ch. 12: Transportation, KM 1 and Figure 12.2).

Sea level rise is already causing an increase in high tide flood events in the Southeast region and is adding to the impact of more extreme coastal flooding events. In the future, this flooding is projected to become more serious, disruptive, and costly as its frequency, depth, and inland extent grow with time (Ch. 12: Transportation, KM 1).[52,63,67,68]

Case Study: A Lesson Learned for Community Resettlement: Isle de Jean Charles Band of Biloxi-Chitimacha-Choctaw Tribe

Coastal communities in the Southeast are already experiencing impacts from higher temperatures, sea level rise, increased flooding, and extreme weather events.[69,70,71,72] Several communities in the United States are already discussing the complexities of relocation; most are tribal and Indigenous communities.[73] Some have chosen to stay in their homelands, while others have few options but to relocate (Ch. 15: Tribes, KM 3).

Isle de Jean Charles is a narrow island in the bayous of South Terrebonne Parish, Louisiana, and home to the Isle de Jean Charles Band of Biloxi-Chitimacha-Choctaw, a tribal community already living the day-to-day impacts of land loss, sea level rise, and coastal flooding. The island has lost 98% of its landmass since 1955 and has only approximately 320 acres (approximately 1/2 square mile) remaining. The population living on the Island has fallen from 400 to 85 people. The decline is due in large part to land loss and flooding driven by climate change, extreme weather, and unsustainable development practices, which stem from oil and gas production, extraction, and water-management practices.[74] This process has resulted in family separation, spreading them across southern Louisiana.[75] In addition, the Tribe continues to lose parts of its livelihood and culture, including sacred places, cultural sites and practices, healing plants, traditional foods, and lifeways.[76]

Case Study: A Lesson Learned for Community Resettlement: Isle de Jean Charles Band of Biloxi-Chitimacha-Choctaw Tribe, *continued*

The Third National Climate Assessment[77] discussed the initial plans for resettlement of the Isle de Jean Charles community. Recently, after nearly 20 years of tribal persistence and two previous efforts, the U.S. Department of Housing and Urban Development (HUD) through the National Disaster Resilience Competition,[78] along with technical assistance from The Rockefeller Foundation, awarded the State of Louisiana $48 million (in 2016 dollars) to implement the Tribe's resettlement plan: a community-driven, culturally appropriate, sustainable development-based plan. It was developed in partnership with the Lowlander Center, a local nongovernmental organization with a long-standing relationship with the Tribe and other scientists, researchers, and planners. The award provides the Tribe with a historic opportunity to reunite a community.[79] While the application to relocate was initiated by the Tribe, the relocation funds now are for all residents of Isle de Jean Charles, according to the Louisiana State Office of Community Development.[75]

Figure 19.11: Chantel Comardelle, Isle de Jean Charles Tribe's Executive Secretary, leads a discussion at a community meeting for the Tribe's resettlement planning process in Pointe-aux-Chenes, Louisiana, on January 18, 2016. The meeting was supported by the Lowlander Center. Photo credit: The Lowlander Center Team.

The resettlement plan is expected to be implemented by 2022 with the inclusion of many facilities in the new location to revitalize the tribal community, including a tribal center and a healthcare facility. The Tribe's experience highlights how success can be achieved when at-risk communities are engaged in the resettlement planning process from the beginning to ensure long-term successful relocation and maintain community integrity.[80] It also highlights an opportunity for institutions to evolve in more flexible ways to accommodate the growing number of communities that may need to relocate.

Extreme Rainfall Events Are Contributing to Increased Inland and Coastal Flooding

Extreme rainfall events have increased in frequency and intensity in the Southeast, and there is *high confidence* they will continue to increase in the future (Figure 19.3).[19] The region, as a whole, has experienced increases in the number of days with more than 3 inches of precipitation (Figure 19.3) and a 16% increase in observed 5-year maximum daily precipitation (the amount falling in an event expected to occur only once every 5 years).[19] Both the frequency and severity of extreme precipitation events are projected to continue increasing in the region under both lower and higher scenarios (RCP4.5 and RCP8.5). By the end of the century under a higher scenario (RCP8.5), projections indicate approximately double the number of heavy rainfall events (2-day precipitation events with a 5-year return period) and a 21% increase in the amount of rain falling on the heaviest precipitation days (days with a 20-year return period).[19,81] These projected increases would directly affect the vulnerability of the Southeast's coastal and low-lying areas. Natural resources (see Key Message 3),

industry, the local economy, and the population of the region are at increasing risk to these extreme events.

Across the Southeast since 2014, there have been numerous examples of intense rainfall events—many approaching levels that would be expected to occur only once every 500 years[82,83]—that have made state or national news due to the devastating impact they had on inland communities. Of these events, four major inland flood events have occurred in just three years (2014–2016) in the Southeast, causing billions of dollars in damages and loss of life (see Table 19.1 and Case Study "Coastal and Inland Impacts of Extreme Rainfall").[84]

A closer look at the August 2016 event in Louisiana provides an example of how vulnerable inland communities in the Southeast region are to these extreme rainfall events. Between August 11–15 2016, nearly half of southern Louisiana received at least 12–14 inches of rainfall. While urban areas such as Baton Rouge and Lafayette were hit the hardest, receiving upwards of 30 inches in a few days, coastal locations were also inundated with up to 20 inches of rain. Rainfall totals across the region exceeded amounts that would be expected to occur once every 1,000 years (or a less than 0.1% annual probability of occurrence), causing the Amite and Comite Rivers to surge past their banks and resulting in some 50,000 homes across the region filling with more than 18 inches of water.[85] Nearly 10 times the number of homes received major flooding (18 inches or more) during this event compared to a historic 1983 flood in Baton Rouge, and the damage resulted in more than 2 million cubic yards of curbside debris from cleaning up homes (enough to fill over 600 Olympic-sized pools).[86] A preceding event in northern Louisiana on March 8–12, 2016, caused $2.4 billion in damages (in 2017 dollars; $2.3 billion in 2015 dollars) and five casualties,[84] illustrating that inland low-lying areas in the Southeast region are also vulnerable to flooding impacts. Events of such magnitudes are projected to become more likely in the future due to a changing climate,[19,87] putting more people in peril from future floods. Existing flood map boundaries do not account for future flood risk due to the increasing frequency of more intense precipitation events, as well as new development that would reduce the floodplain's ability to manage storm water. As building and rebuilding in flood-prone areas continue, the risks of the kinds of major losses seen in these events will continue to grow.

The growing number of extreme rainfall events is stressing the deteriorating infrastructure in the Southeast. Many transportation and storm water systems have not been designed to withstand these events. The combined effects of rising numbers of high tide flooding and extreme rainfall events, along with deteriorating storm water infrastructure, are increasing the frequency and magnitude of coastal and lowland flood events.[45,88,89,90]

Billion-Dollar Flood Events in the Southeast, 2014–2016

Event	Date	Damages	Casualties
Southeast tornadoes and flooding (FL, AL, AR)	April 27–28, 2014	$1.8 Billion	33
South Carolina record flooding	October 1–5, 2015	$2.1 Billion	25
Hurricane Matthew	October 7–9, 2016	$10.1 Billion	49
Louisiana flooding (Baton Rouge)	August 11–15, 2016	$10.1 Billion	13

Table 19.1: Values are Consumer Price Index adjusted and are in 2017 dollars. Source: NOAA NCEI 2017.[84]

The recent increases in flood risk have led many cities and counties to take adaptive actions to reduce these effects. Four counties in Southeast Florida formed a climate compact in 2010 to address climate change impacts, including sea level rise and high tide flooding.[91] Recently updated in 2017, their climate action plan was one of the first intergovernmental collaborations to address climate change, adaptation, and mitigation in the country. Since then, cities like Charleston, South Carolina, have started to invest in flood management activities (see Case Study "Charleston, South Carolina, Begins Planning and Reinvesting"). Other examples include Miami Beach, Florida, which has a multiyear, $500-million program to raise public roads and seawalls and improve storm water drainage.[92] Norfolk, Virginia, has begun comprehensive planning to fix its high tide flooding issues.[93] Biloxi, Mississippi, has put in place several adaptation strategies to lessen the future impacts, including enacting a new building code that requires elevating structures an additional one foot above the base flood elevation.[94] Tybee Island, Georgia, has developed a sea level rise adaptation plan with recommendations to flood-proof a 5.5-mile stretch of their sole access causeway, replace two vulnerable bridges, and retrofit their existing storm water infrastructure to improve drainage.[95] In response to the 2016 flooding, eight parishes in the Acadiana region of Louisiana came together to collaborate at a watershed level, pooling their federal hazard mitigation grant funding to support projects across the Teche-Vermilion watershed. This is the only watershed-level hazard mitigation collaboration of this kind happening in the state and has the support of the Federal Emergency Management Agency (FEMA), the Governor's Office of Homeland Security and Emergency Preparedness, and the Louisiana Office of Community Development.[96]

Many communities in the Southeast also participate in FEMA's Community Rating System (CRS) program, which provides reduced flood insurance premiums to communities that go above and beyond the minimum National Flood Insurance Program regulation standards.[97] Many communities require a safety factor, also known as freeboard, expressed as feet above the base flood elevation, for construction in special flood hazard areas. Several Southeast communities—such as Hillsborough and Pinellas Counties, Florida; Biloxi, Mississippi; Chatham County, Georgia; and Myrtle Beach, South Carolina—have earned low CRS classes (5 on a scale of 1–10, with 1 being the best or most insurance premium discount) by implementing freeboard and other regulations that exceed the minimum standards.[97]

Case Study: Coastal and Inland Impacts of Extreme Rainfall

In October 2015, an extreme rainfall event impacted both inland and coastal South Carolina, leading to the largest flood-related disaster in the state since Hurricane Hugo struck in 1989. The October 2015 event is among a series of devastating precipitation events that have occurred across the Southeast in recent years. From October 1–5, 2015, deep tropical moisture combined with a slow-moving (stalled) upper-level low pressure system to pump moisture into South Carolina's coastal and interior regions. Much of the affected region received between 10 and 26 inches of rain over the 4-day event, breaking many all-time precipitation records (Figure 19.12). Mount Pleasant, located on South Carolina's coast, received 26.88 inches of rain, which is an extremely rare event. The rainfall sparked inland flooding that led to three dam breaches and the destruction of countless roads and homes (see Figure 19.13 showing flash flooding impacts to inland roads). Roughly 52,000 residents applied for disaster relief, and 160,000 homes sustained some type of damage. At the coast, a combination of high tide and heavy rain caused significant flooding in downtown Charleston. A high tide of 2.38 feet above Mean Higher High Water (MHHW) occurred in the afternoon of October 3. This was the seventh highest tide ever recorded in Charleston Harbor and the highest since Hurricane Hugo in 1989. Under future climate scenarios, the combination of extreme precipitation and higher tides due to local sea level rise will likely cause more frequent events of this intensity and magnitude.[98]

Case Study: Coastal and Inland Impacts of Extreme Rainfall, *continued*

October 2015 Extreme Rainfall Event

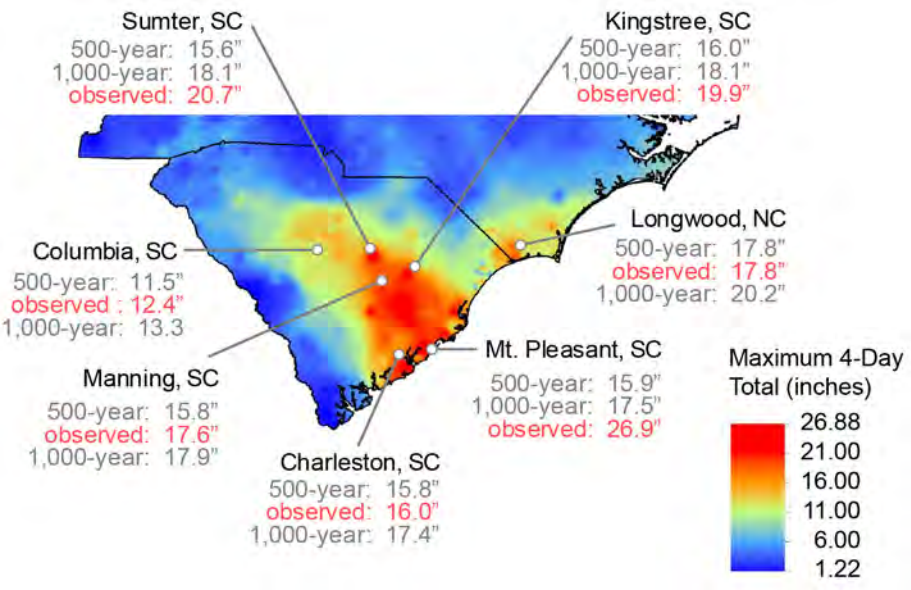

Figure 19.12: The map shows rainfall totals from the October 2015 South Carolina flood event. Red colors in the map indicate areas that received excessive rainfall totals that broke all-time records. Some of these totals exceeded the 500-year and 1,000-year return period amounts (rainfall amounts that would be expected to have only a 0.2% or 0.1% chance of occurring in a given year). Extreme precipitation events will likely increase in frequency in the Southeast. Source: CISA 2015.[98]

Increases in extreme rainfall events and high tide coastal floods due to future climate change could impact the quality of life of permanent residents as well as tourists visiting the low-lying and coastal regions of the Southeast. Recent social science studies have indicated that people may migrate from many coastal communities that are vulnerable to the impacts of sea level rise, high tide flooding, saltwater intrusion, and storm surge.[71] Even though many communities are starting to develop adaptation strategies to address current flooding issues, many adaptation strategies are not being designed for longer time horizons and more extreme worst-case climate scenarios.[1,67]

The 2017 Hurricane Season

For the United States, 2017 was a historic year for weather and climate disasters, with widespread impacts and lingering costs. While 2017 tied the previous record year of 2011 for the total number of billion-dollar weather and climate disasters—16—the year broke the all-time previous record high costs by reaching $306.2 billion in damages (in 2017 dollars; $297 billion in 2015 dollars). The previous record year was 2005 with a total of $214.8 billion (in 2017 dollars; $208.4 billion in 2015 dollars), which included the impacts of Hurricanes Dennis, Katrina, Rita, and Wilma.[99]

In 2017, Hurricane Irma was one of three major hurricanes to make landfall in the United States and territories, with the most significant impacts occurring in the Southeast region. Irma was a Category 4 storm with 130 mph wind speeds when it made landfall at Cudjoe Key, Florida (20 miles north of Key West). Storm surge inundations at Cudjoe and the surrounding Keys were between 5 and 8 feet.[100] Prior to landfall in Florida, Irma caused significant damage in the U.S. Virgin Islands and parts of Puerto Rico as a Category 5 hurricane with 185 mph wind speeds (see Ch. 20: U.S. Caribbean, Box 20.1 and KM 5).[84]

Irma's intensity was impressive by any measure. According to the National Weather Service, Hurricane Irma was only the fifth hurricane with winds of 185 mph or higher in the whole of the Atlantic Basin since reliable record keeping began, and it was the strongest observed hurricane in the open Atlantic Ocean.[101] For three days, the storm maintained maximum sustained winds of 185 miles per hour, the longest observed duration in the satellite era.[101,102] Not only was Irma extremely strong, it was also very large with tropical storm force winds reaching as far away as 400 miles from the hurricane's center and driving hurricane force winds up to 80 miles away.[101] Two factors supported Irma's strength: the very warm waters it passed over, which exceeded 86°F,[102] and the light winds Irma encountered in the upper atmosphere (Figure 19.14).[101] High-intensity hurricanes such as Irma are expected to become more common in the future due to climate change.[103] Rapid intensification of storms is also more likely as the climate warms,[104] even though there is also some historical evidence that the same conditions that lead to this intensification also act to weaken hurricane intensity near the U.S. coast, but it is unclear whether this relationship will continue as the climate warms further (see Kossin et al. 2017,[103] Box 9.1).

The storm tracked up the west coast of Florida, impacting both coasts of the Florida peninsula with 3–5 feet of inundation from Cape Canaveral north to the Florida–Georgia border and even further, impacting coastal areas of Georgia and South Carolina with high tides and storm surge that reached 3–5 feet. Inland areas were also impacted by winds and heavy rains with river gauges and high-water marks showing upwards of 2–6 feet above ground level.[100] The winds eventually fell below tropical storm strength near Columbus, Georgia. Even though the wind speed fell below tropical storm strength, many communities along the coasts of Florida, Georgia,

North and South Carolina, and Virginia experienced severe wind and storm surge damage with some near-historic levels of coastal flooding. A state of emergency was declared in four states from Florida north to Virginia and in Puerto Rico and the U.S. Virgin Islands, and, for the first time ever, Atlanta was placed under a tropical storm warning.[105,106,107,108] In Florida, a record 6.8 million people were ordered to evacuate, as were 540,000 coastal residents in Georgia and untold numbers in other coastal locations.[102,109,110] Nearly 192,000 evacuees were housed in approximately 700 emergency shelters in Florida alone.[109] According to NOAA's National Centers for Environmental Information (NCEI),[84] Irma significantly damaged 65% of the buildings in the Keys and destroyed 25% of them.

Warm Waters Contribute to the Formation of Hurricane Irma

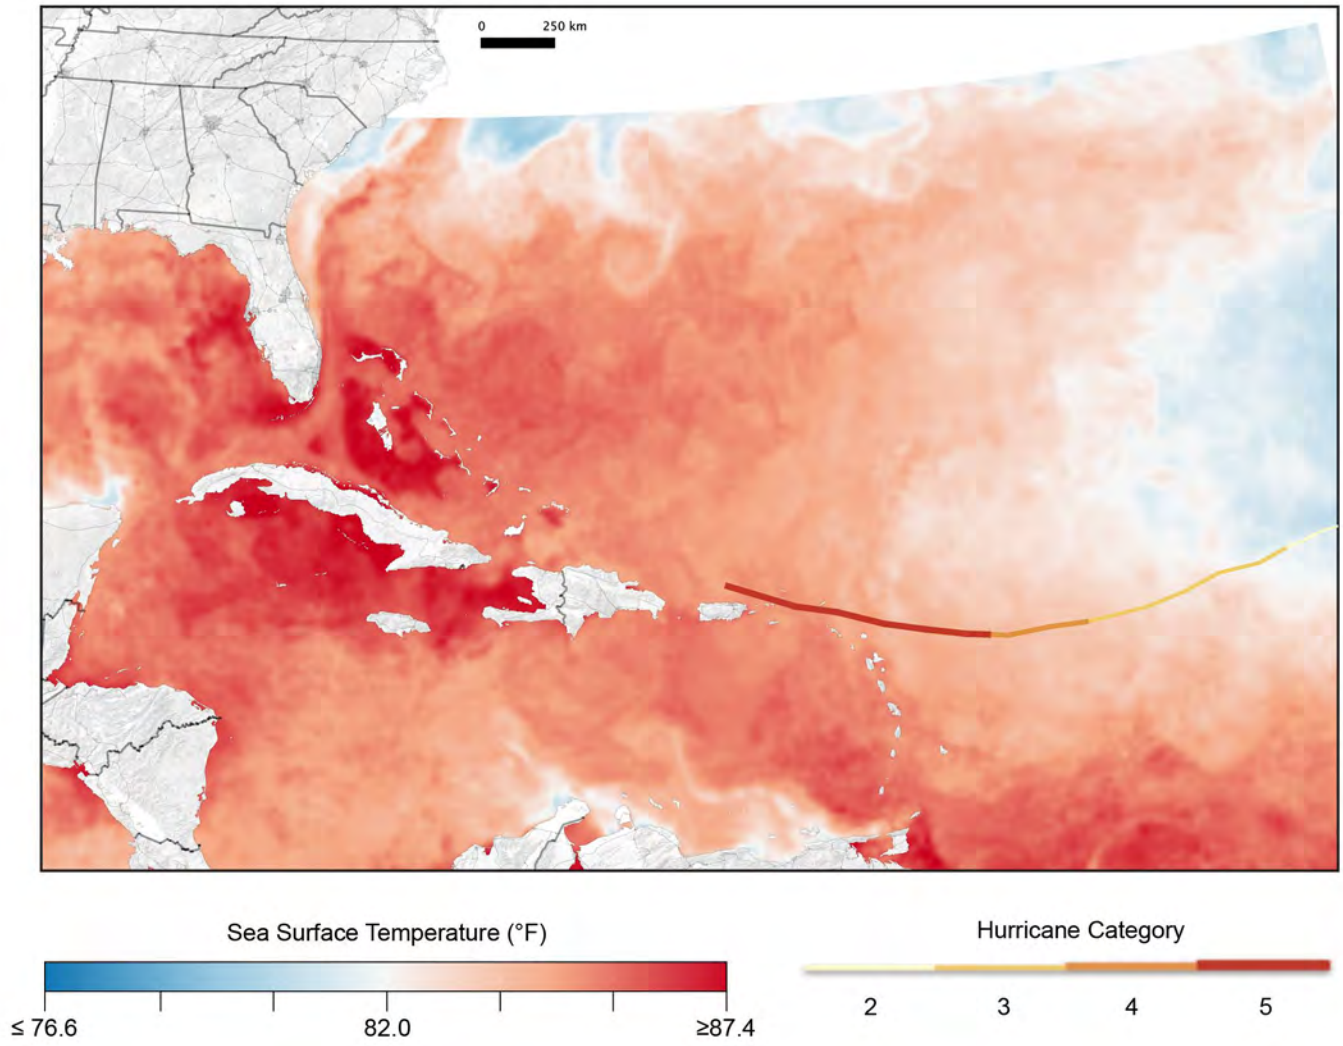

Figure 19.14: Two factors supported Hurricane Irma's strength as it reached the Southeast region: the very warm waters it passed over, depicted in this figure, and the light winds Irma encountered in the upper atmosphere.[101] High-intensity hurricanes such as Irma are expected to become more common in the future due to climate change.[103] Source: NASA 2017.[102]

High rainfall totals were experienced in many impacted areas, with Fort Pierce, Florida, receiving the highest rainfall of more than 21.5 inches[100] and the Florida Keys receiving 12 inches of rain.[84,102] Flooding occurred on most rivers in northern Florida and in many rivers in both Georgia and South Carolina to the point that rescues were required. In Jacksonville, Florida, heavy rains were the major issue causing rivers to reach major or record flood stage and flooded some city streets up to 5 feet deep in water. The heavy rainfall was noted even in Alabama, at 5 inches, and near 6 inches in the mountains of western North Carolina.[100] Twenty-five tornadoes were confirmed from Hurricane Irma, and many of them occurred along the east coast of central and northern Florida.[100] Even as Irma headed north, continuing to lose force, there were still 6.7 million people without electricity.[109]

According to NCEI,[84] the U.S. direct cost from Hurricane Irma is approximately $50 billion (in 2017 dollars), and the non-U.S. territory Caribbean Islands could add another $10–$15 billion to that total. Of the $50 billion, approximately $30–$35 billion accounts for wind and flood damage to a combination of residential and commercial properties, automobiles, and boats—with 80%–90% of this cost felt in Florida. The remainder of the costs include $5 billion for infrastructure repairs and $1.5–$2.0 billion for damage to the agricultural sector, also mainly in Florida. The remaining costs would address losses in the U.S. Virgin Islands and Puerto Rico.[84] The losses could have been worse except for the fact that Florida has implemented one of the strictest building codes in the country after the destruction caused by Hurricane Andrew in 1992.[111] Recent estimates using insured loss data show that implementing the Florida Building Code resulted in a 72% reduction of windstorm losses, and for every $1 in added cost to implement the building code, there is a savings of $6 in reduced losses, with the return or payback period being roughly 8 years (in 2010 dollars).[111]

Indirect impacts and costs are difficult to calculate and would add to the totals. In Central and South Florida, such things would include the closing of schools, colleges, and universities; the closing of tourist attractions and the cancellation of thousands of flights into and out of region; and the closing or restricting of the use of seaports including Canaveral, Key West, Miami, and Jacksonville, among others.[109,112] The Select Committee on Hurricane Response and Preparedness: Final Report[109] estimates that there were 84 U.S. deaths attributable to Hurricane Irma and other untold damage and human suffering. While the hurricane directly damaged portions of the Southeast, the impacts could be felt around the country in the form of business interruptions (such as tourism), transportation and infrastructure damages (such as ports, roadways, and airports), increases in fuel costs, and $2.5 billion (in 2018 dollars) in total estimated crop losses,[109] which had the potential to impact the cost of food and other products for all Americans.

Key Message 3

Natural Ecosystems Will Be Transformed

The Southeast's diverse natural systems, which provide many benefits to society, will be transformed by climate change. Changing winter temperature extremes, wildfire patterns, sea levels, hurricanes, floods, droughts, and warming ocean temperatures are expected to redistribute species and greatly modify ecosystems. As a result, the ecological resources that people depend on for livelihood, protection, and well-being are increasingly at risk, and future generations can expect to experience and interact with natural systems that are much different than those that we see today.

Ecosystems in the Southeast span the transition zone between tropical and temperate climates. The region's more temperate ecosystems include hardwood forests, spruce-fir forests, pine-dominated forests, and salt marshes. The region's more tropical ecosystems include mangrove forests, coral reefs, pine savannas, and the tropical freshwater wetlands of the Everglades. Ecological diversity in the Southeast is high,[113,114,115,116,117] and southeastern ecosystems and landscapes provide many benefits to society. In addition to providing habitat for fish and wildlife species, ecosystems in the Southeast provide recreational opportunities, improve water quality, provide seafood, reduce erosion, provide timber, support food webs, minimize flooding impacts, and support high rates of carbon sequestration (or storage).[118,119,120] These ecological resources that people depend on for livelihoods, protection, and well-being are increasingly at risk from the impacts of climate change.

Climate greatly influences the structure and functioning of all natural systems (Ch. 7: Ecosystems). An analysis of ecological changes that have occurred in the past can help provide some context for anticipating and preparing for future ecological changes. In response to past climatic changes, many ecosystems in the Southeast were much different than those present today. For example, since the end of the last glacial maximum (about 19,000 years ago—the most recent period of maximum ice extent),[121] forests in the region have been transformed by warming temperatures, sea level rise, and glacial retreat.[122,123] Spruce species that were once present in the region's forests have moved northward and have been replaced by oaks and other less cold-tolerant tree species that have expanded from the south.[124] And along the coast, freeze-sensitive mangrove forests and other tropical coastal species have been expanding northward and upslope since the last glacial maximum.[125,126,127,128,129]

In the coming decades and centuries, climate change will continue to transform many ecosystems throughout the Southeast,[6,130,131,132,133,134,135] which would affect many of the societal benefits these ecosystems provide. As a result, future generations can expect to experience, interact with, and potentially benefit from natural systems that are much different than those that we see today (Ch. 7: Ecosystems).[136,137]

Warming Winter Temperature Extremes

Changes in winter air temperature patterns are one aspect of climate change that will play an especially important role in the Southeast. By the late 21st century under the higher scenario (RCP8.5), the freeze-free season is expected to lengthen by more than a month. Winter air temperature extremes (for example, freezing and chilling events) constrain the northern limit of many tropical and subtropical species.[138,139,140,141,142,143,144] Certain ecosystems in the region are located near thresholds where small changes in winter air temperature regimes can trigger comparatively large and abrupt landscape-scale ecological changes (in other words, ecological regime shifts).[135,145] Reductions in the frequency and intensity of cold winter air temperature extremes can allow tropical and subtropical species to move northward and replace more temperate species. Where climatic thresholds are crossed, certain ecosystem and landscapes will be transformed by changing winter air temperatures.

Plant hardiness zone maps help convey the importance of winter air temperature extremes for species and natural systems in the Southeast. To help gardeners and farmers, the U.S. Department of Agriculture has produced plant hardiness zone maps that can be used to determine which species are most likely to survive and thrive in a given location. The plant hardiness zones are reflective of the frequency and intensity of winter air temperature

extremes in a specific region. Already, in response to climate change, plant hardiness zones in certain areas are moving northward and are expected to continue their northward and upslope progression.[139,142,146,147] Continued reductions in the frequency and intensity of winter air temperature extremes are expected to change which species are able to survive and thrive in a given location (Figure 19.15). For example, citrus species are sensitive to freezing and chilling temperatures.[148] However, in the future, climate change is expected to enable the survival of citrus in areas that are north of the current tolerance zone.[142]

The effects of changing winters reach far beyond just agricultural and garden plants. Along the coast, for example, warmer winter temperatures are expected to allow mangrove forests to move northward and replace salt marshes (Figures 19.16 and 19.17).[135,149,150,151,152] Coastal wetlands, like mangrove forests and salt marshes, are abundant in the Southeast.[153,154] The societal benefits provided by coastal wetlands are numerous.[119] Hence, where coastal wetlands are abundant (for example, the Mississippi River Delta), their cumulative value can be worth billions of dollars each year and trillions of dollars over a 100-year period.[155] Coastal wetlands provide seafood, improve water quality, provide recreational opportunities, reduce erosion, support food webs, minimize flooding impacts, and support high rates of carbon sequestration.[118] Foundation species are species that create habitat and support entire ecological communities.[156,157] In coastal wetlands and many other ecosystems, foundation plant species play an especially important role. Hence, the loss and/or replacement of foundation plant species, like salt marsh grasses, will have ecological and societal consequences in certain areas.[135,145,157,158,159,160,161,162,163,164]

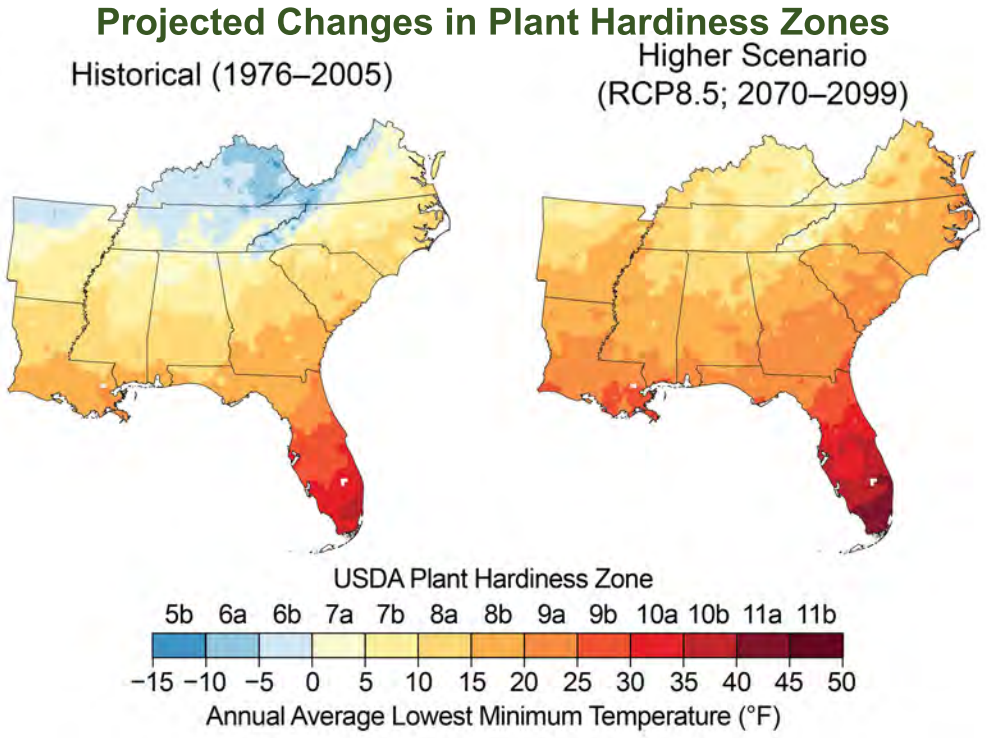

Figure 19.15: Increasing winter temperatures are expected to result in a northward shift of the zones conducive to growing various types of plants, known as plant hardiness zones. These maps show the mean projected changes in the plant hardiness zones, as defined by the U.S. Department of Agriculture (USDA), by the late 21st century (2070–2099) under a higher scenario (RCP8.5). The USDA plant hardiness zones are based on the average lowest minimum temperature for the year, divided into increments of 5°F. Based on these projected changes, freeze-sensitive plants, like oranges, papayas, and mangoes, would be able to survive in new areas.[142] Note that large changes are projected across the region, but especially in Kentucky, Tennessee, and northern Arkansas. Sources: NOAA NCEI and CICS-NC.

While salt marsh and mangrove wetlands both contain valuable foundation species, some of the habitat and societal benefits provided by existing salt marsh habitats will be affected by the northward expansion of mangrove forests.[145,158,160,161,164,165]

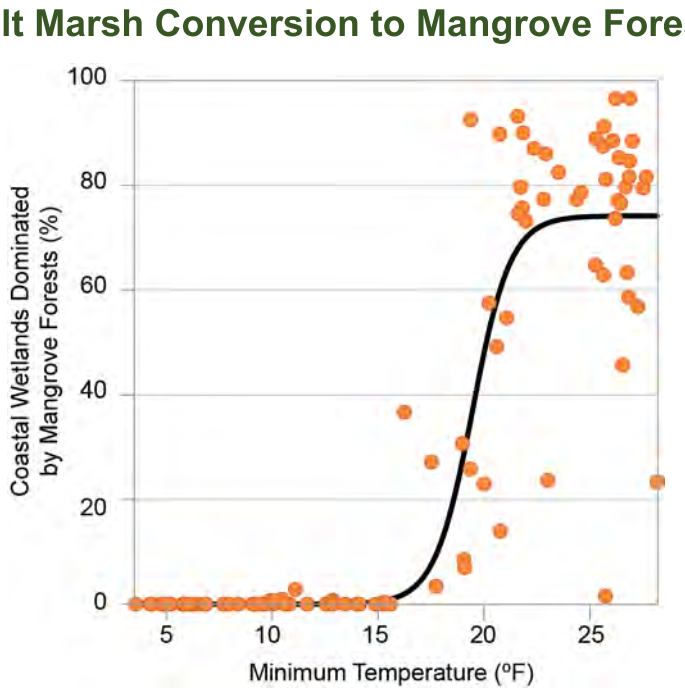

Figure 19.16: Where tropical and temperate ecosystems meet, warmer winter temperatures can lead to large ecological changes such as mangrove forest replacement of salt marshes along the Gulf and Atlantic Coasts. Mangrove forests are sensitive to freezing temperatures and are expected to expand northward at the expense of salt marshes. The figure shows the relationship between temperature and the percentage area dominated by mangrove forests. Mangrove expansion would entail a grassland-to-forest conversion, which would affect fish and wildlife habitat and many societal benefits. Source: adapted from Osland et al. 2013.[135] ©2012 Blackwell Publishing Ltd.

Transitioning Coastal Ecosystems

Figure 19.17: In Louisiana and parts of northern Florida, future coastal wetlands are expected to look and function more like the mangrove-dominated systems currently present in South Florida and the Caribbean. Like salt marshes (left), mangrove forests (right) provide coastal protection against wind and waves (Ch. 20: U.S. Caribbean, KM 2). Photo credit: Michael Osland.

In addition to plants, warmer winter air temperatures will also affect the movement and interactions between many different kinds of organisms. For example, certain insect species, including mosquitoes and tree-damaging beetles, are expected to move northward in response to climate change, which could affect human health and timber supplies.[30,144,166,167,168,169,170,171,172] And some bird species, including certain ducks, are not expected to migrate as far south in response to milder winters,[173] which could affect birding and hunting recreational opportunities. Many recreational fishery populations in tropical coastal areas are freeze-sensitive[138,174,175,176,177,178] and are, therefore, expected to move northward in response to warmer water and air temperatures. Although the appearance of tropical recreational fish, like snook for example, may be favorable for some anglers, the movement of tropical marine species is expected to greatly modify existing food webs and ecosystems (Ch. 7: Ecosystems, Figure 7.4).[179] Some problematic invasive species are expected to be favored by changing winters. For example, in South Florida, the Burmese python and the Brazilian pepper tree are two freeze-sensitive, nonnative species that have, respectively, decimated mammal populations and transformed native plant communities within Everglades National Park.[180,181,182,183,184,185,186,187,188] In the future, warmer winter temperatures are expected to facilitate the northward movement of these problematic invasive species, which would transform natural systems north of their current distribution.

Warm Winters Favor Invasive Species

Figure 19.18: Burmese pythons are apex predators (not preyed upon by other animals) that are sensitive to cold temperatures and are expected to be favored by warming winters. This photo is from Everglades National Park, where unintentionally introduced pythons have expanded and reduced native mammal populations. Photo credit: U.S. Geological Survey.

Changing Patterns of Fire

In the Southeast region, changing fire regimes (defined by factors including frequency, intensity, size, pattern, season, and severity) are expected to have a large impact on natural systems. Fire has historically played an important role in the region, and ecological diversity in many southeastern natural systems is dependent upon fire.[115,116,134,189] Although the total area burned by wildfire is greatest in the western United States, the Southeast has the largest area burned by prescribed fire (see Case Study "Prescribed Fire") and the highest number of wildfires.[134,190] In the future, rising temperatures and increases in the duration and intensity of drought are expected to increase wildfire occurrence and also reduce the effectiveness of prescribed fire.[3,4,5,6] Moreover, rapid urban expansion near managed forests has the potential to reduce opportunities to use prescribed fire, which could lead to native species declines, increased wildfire occurrence, and economic and health impacts.[134,191]

A recent example of the importance of fire lies in the forests of the southern Appalachians. Over the last century, invasive insects, logging, and pathogens have transformed forests in the region.[192] Warmer temperatures and insects have led to the loss of cold-adapted boreal communities, and flammable, fire-adapted tree species have been replaced by less flammable, fire-sensitive species—a process known as mesophication.[193,194] However, intense fires, like those observed in 2016, can halt the mesophication process. High temperatures, increases in accumulated plant material on the forest floor, and a four-month seasonal drought in the fall of 2016 collectively produced the worst wildfires the region has seen in a century. Intra-annual droughts, like the one in 2016, are expected to become more frequent in the future.[6] Thus, drought and greater fire activity[134] are expected to continue to transform forest ecosystems in the region (see Ch. 6: Forests, KM 1).

Case Study: Prescribed Fire

With wildfire projected to increase in the Southeast,[6,191] prescribed fire (the purposeful ignition of low-intensity fires in a controlled setting), remains the most effective tool for reducing wildfire risk.[4,195] Department of Defense (DoD) lands represent the largest reservoirs of biodiversity and native ecosystems in the region.[117] Military activities are a frequent source of wildfires, but increases in prescribed fire acres (Figure 19.19) show a corresponding decrease in wildfire ignitions for DoD.[4] Climate resilience by DoD is further achieved through restoration of native longleaf pine forests that occupy a wide range of site types, including wetland and well-drained soils—the latter leading many to characterize this forest as being drought resistant.[196,197,198,199] In addition to proactive adaptation through prescribed fire, DoD has been a leader in climate strategies that include regional conservation planning, ecosystem management, endangered species recovery, and research funding.

Wildlife and Prescribed Fire

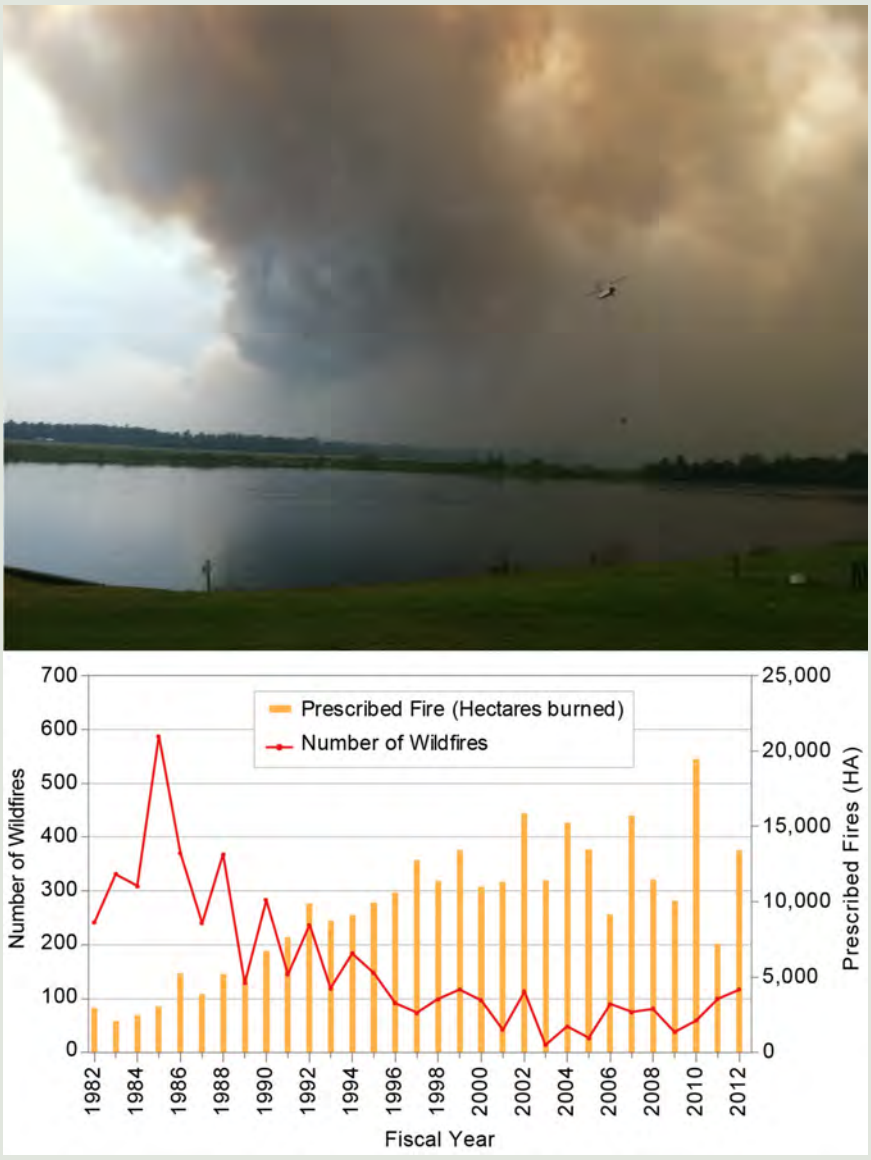

Figure 19.19: (top) A helicopter drops water on a 1,500-hectare wildfire on Hurlburt Field (Eglin Air Force Base) in Florida in June of 2012. (bottom) The increased use of prescribed fire at Ft. Benning, Georgia, led to a decrease in wildfire occurrence from 1982 to 2012. Photo credit: Kevin Hiers, Tall Timbers. Figure source: adapted from Addington et al. 2015.[4] Reprinted by permission of CSIRO Australia, ©CSIRO.

Rising Sea Levels and Hurricanes

Rising sea levels and potential changes in hurricane intensity are aspects of climate change that are expected to have a tremendous effect on coastal ecosystems in the Southeast (Ch. 8: Coastal, KM 2; Ch. 9: Oceans, KM 1). Since coastal terrestrial and freshwater ecosystems are highly sensitive to increases in inundation and salinity, sea level rise will result in the rapid conversion of these systems to tidal saline habitats. Historically, coastal ecosystems in the region have adjusted to sea level rise by vertical and horizontal movement across the landscape.[125,129,200,201] As sea levels rise in the future, some coastal ecosystems will be submerged and converted to open water, and saltwater intrusion will allow salt-tolerant coastal ecosystems to move inland at the expense of upslope and upriver ecosystems.[128,202,203,204,205,206,207,208] Where barriers are present (for example, levees and other coastal infrastructure), the potential for landward migration of natural systems will be reduced and certain coastal habitats will be lost (Ch. 20: U.S. Caribbean, KM 3).[204] With higher sea levels and increasing saltwater intrusion, the high winds, high precipitation rates, storm surges, and salts that accompany hurricanes will have large ecological impacts to terrestrial and freshwater ecosystems.[209,210]

An example of the effects of rising sea levels can be found in Louisiana, which faces some of the highest land loss rates in the world. The ecosystems of the Mississippi River Delta provide at least $12–$47 billion (in 2017 dollars) in benefits to people each year.[155] These benefits include hurricane storm protection, water supply, furs, habitat, climate stability, and waste treatment. However, between 1932 and 2016, Louisiana lost 2,006 square miles of land area (see Case Study "A Lesson Learned for Community Resettlement"),[211] due in part to high rates of relative sea level rise.[212,213,214,215] The rate of wetland loss during this period equates to Louisiana losing an area the size of one football field every 34 to 100 minutes.[211] To protect and restore the Louisiana coast, the Louisiana Coastal Protection and Restoration Authority (CPRA) has worked with local, state, and federal partners to iteratively develop a 2017 Coastal Master Plan that identifies investments that can provide direct restoration and risk reduction benefits.[216] The aim of the 50-year, $50-billion strategy is to sustain Louisiana's coastal ecosystems, safeguard coastal populations, and protect vital economic and cultural resources.[216]

Drought and Extreme Rainfall

Climate change is expected to intensify the hydrologic cycle and increase the frequency and severity of extreme events like drought and heavy rainfall. Drought and extreme heat can result in tree mortality and transform the region's forested ecosystems (Ch. 6: Forests, KM 1).[217,218,219,220,221,222,223] Drought can also affect aquatic and wetland ecosystems,[224] for example by contributing to mortality and ecological transformations in salt marshes,[225,226] mangrove forests,[227,228,229,230,231] and tidal freshwater forests.[232] In addition to drought, extreme rainfall events are also expected to become more frequent and severe in the future. The prolonged inundation and lack of oxygen that results from extreme rainfall can also result in mortality, such as the dieback of critical foundation plant species, and other large impacts to natural systems.[233] In combination, future increases in the frequency and severity of both extreme drought and extreme rainfall are expected to transform many ecosystems in the Southeast region. Natural systems in the region will have to become resistant and resilient to both too little water and too much water. The ecological transformations induced by these extreme events will affect many of the benefits that natural systems provide to society.

Warming Ocean Temperatures

Warming ocean temperatures due to climate change are expected to have a large effect on marine and coastal ecosystems (Ch. 9: Oceans, KM 3).[234,235,236] Many species are sensitive to small changes in ocean temperature; hence, the distribution and abundance of marine organisms are expected to be greatly altered by increasing ocean temperatures. For example, the distribution of tropical herbivorous fish has been expanding in response to warmer waters, which has resulted in the tropicalization of some temperate marine ecosystems and decreases in the cover of valuable macroalgal plant communities.[179] A decrease in the growth of sea turtles in the West Atlantic has been linked to higher ocean temperatures.[237] Due to climate change, warming ocean temperatures in the coming decades are expected to transform many marine and coastal ecosystems across the Southeast. However, the impacts to coral reef ecosystems in the region have been and are expected to be particularly dire. Coral reefs are biologically diverse ecosystems that provide many societal benefits, including coastal protection from waves, habitat for fish, and recreational and tourism opportunities.[238,239] However, coral reef mortality in the Florida Keys and across the globe has been very high in recent decades, due in part to warming ocean temperatures, nutrient enrichment, overfishing, and coastal development.[240,241,242,243,244] Small increases in ocean temperature can cause corals to expel the symbiotic algae upon which they depend for nourishment. When this happens, corals lose their color and die in a process known as coral bleaching (Ch. 9: Oceans, KM 1). Coral elevation and volume in the Florida Keys have been declining in recent decades,[245] and present-day temperatures in the region are already close to bleaching thresholds; hence, it is likely that many of the remaining coral reefs in the Southeast region will be lost in the coming decades.[246,247] In addition to warming temperatures, accelerated ocean acidification is also expected to contribute to coral reef mortality and decline.[248,249] When coral reefs are lost, coastal communities lose the many benefits provided by these valuable ecosystems, including lost tourism opportunities, a decline in fisheries, and a decrease in wave protection.[246,247]

Key Message 4

Economic and Health Risks for Rural Communities

Rural communities are integral to the Southeast's cultural heritage and to the strong agricultural and forest products industries across the region. More frequent extreme heat episodes and changing seasonal climates are projected to increase exposure-linked health impacts and economic vulnerabilities in the agricultural, timber, and manufacturing sectors. By the end of the century, over one-half billion labor hours could be lost from extreme heat-related impacts. Such changes would negatively impact the region's labor-intensive agricultural industry and compound existing social stresses in rural areas related to limited local community capabilities and associated with rural demography, occupations, earnings, literacy, and poverty incidence. Reduction of existing stresses can increase resilience.

In the Southeast, over 56% of land remains rural (nonmetropolitan) and home to approximately 16 million people, or about 17% percent of the region's population.[250] These rural areas are important to the social and economic well-being of the Southeast. Many in rural communities are maintaining connections to traditional livelihoods and relying on natural

resources that are inherently vulnerable to climate change. The Southeast has the second highest number of farmworkers hired per year compared to other National Climate Assessment (NCA) regions.[251] Climate trends and possible climate futures show patterns that are already impacting—and are expected to further impact—rural sectors, from agriculture and forestry to human health and labor productivity (Ch. 10: Ag & Rural, KM 3). For example, shrimping, oystering, and fishing along the coast are long-standing traditions in the coastal economy that are expected to face substantial challenges. For example, by the end of the century, annual oyster harvests in the Southeast are projected to decline between 20% (19%–22%) under a lower scenario (RCP4.5) and 46% (44%–48%) under a higher scenario (RCP8.5), leading to projected price increases of 48% (RCP4.5) to 140% (RCP8.5).[35] Projected warming ocean temperatures, sea level rise, and ocean and coastal acidification are raising concern over future harvests (Ch. 9: Oceans, KM 2).[35,252] While adaptation and resilience can moderate climate change impacts, rural areas generally face other stressors, such as poverty and limited access to healthcare, which will make coping to these climate-related challenges more difficult.

Heat-related stresses are presently a major concern in the Southeast. Future temperature increases are projected to pose challenges for human health. While recent regional temperature trends have not shown the same consistent rate of daytime maximum temperature increase as observed in other parts of the United States, climate model simulations strongly suggest that daytime maximum temperatures are likely to increase as humans continue to emit greenhouse gases into the atmosphere.[13] The resulting temperature increases are expected to add to the heat health burden in rural, as well as urban, areas.[35] Projected temperature increases also pose challenges for crop production dependent on periods of lower temperatures to reach full productivity. Drought has been a recurrent issue in the Southeast affecting agriculture, forestry, and water resources.[253] With rapid growth in population and overall demand, drought is increasingly a concern for water resource management sectors such as cities, ecosystems, and energy production.

Diverse Rural Regions

Urban and rural areas exist along a continuum from major metro areas to suburbs, small towns, and lightly populated places. These areas are linked through many processes, commuting patterns, and shared central services, such as airports and hospitals, that connect the risks. Rapid population growth with associated urbanization and suburbanization over the last several decades has resulted in a more fine-grained forest landscape with smaller and more numerous forest patches.[254] Agriculture, manufacturing, tourism, and other major economic sectors are spread across the Southeast region. Rural counties in the region generally have a diversified economy with a relatively low percentage being heavily dependent on one sector. While well known for agriculture and forestry, rural areas also support manufacturing and tourism.[250]

In 2013, approximately 34% of the U.S. manufacturing output, or about $700 billion (dollar year not reported), came from the Southeast and Texas, including rural areas.[255] While manufacturing growth has been particularly strong in the Southeast in recent years, future climate changes would pose challenges for economic competitiveness. For companies involved in food processing, there are additional secondary economic risks associated with climate impacts on crops and livestock that could alter price or availability.[64,255] Facilities that are energy- or water-intensive are more likely to face increases in the costs and

decreases in the availability of these resources, with potential impacts to their economic competitiveness.[246,255]

Energy production, and its dependence on water availability, is a key concern in the Southeast, given the region's growing population and large, diversified economy. An increasing number of high heat and dry days as the climate warms poses a risk to efficient power generation, particularly under conditions where the mode of primary generation moves towards natural gas and water-intensive nuclear power.[256]

Risks to Agriculture and Forestry

Agriculture, livestock rearing, and forestry activities are widespread and varied through the Southeast region.[7] Climate change is expected to have an overall negative impact on agricultural productivity in the United States,[35] although some crops could also become newly viable alternatives (Key Message 3, Figure 19.15). Increases in temperatures, water stress, freeze-free days, drought, and wildfire risks, together with changing conditions for invasive species and the movement of diseases, create a number of potential risks for existing agricultural systems (Ch. 10: Ag & Rural, KM 1).[7] In particular, precipitation trends for the Southeast region show an inclination towards slightly drier summers, which could reduce productivity, and wetter fall seasons, which can make it difficult to harvest the full crop. Multimodel averages of climate model simulations (CMIP3 [SRES A2] and CMIP5 [RCP8.5] higher scenarios) show that there is a greater risk of drier summers by the middle of the century in the western portion of the Southeast and in southern Florida, while wetter fall seasons are more likely in the eastern portion of the region.[257]

The conditions for raising and harvesting crops and livestock are projected to change. Higher temperatures can result in decreasing productivity of some cultivated crops, including cotton, corn, soybeans, and rice.[7] Livestock, which includes hogs and pigs, horses, ponies, mules, burros, and donkeys as well as poultry and processed poultry for consumption (for example, chicken nuggets), is a large component of the agricultural sector for these states and the Nation.[258] Livestock are all vulnerable to heat stress, and their care under projected future conditions would require new or enhanced adaptive strategies (Ch. 10: Ag & Rural, KM 3).

Recent changes in seasonal temperatures that are critical for plant development will continue to impact regionally important crops. Plants collected from the wild may become less available as the ideal conditions for their growth shift to other areas (see Case Study "Mountain Ramps"). Peaches—an important crop in the Southeast—require an adequate period of cool temperatures, called the chill period, to produce yields that are economically viable. Peaches also require warm temperatures at specific times during their development.[259] If the warm temperatures come too early, the chill periods could be too short or the peach blossoms can flower too soon and be in danger of late freeze impacts. A late freeze in March 2017 caused over a billion dollars of damages to peaches and other fruit crops.[84] To assist peach growers in adapting to such changes, researchers are working to develop peach varieties that can produce quality fruits in warmer winters and are developing winter chill models that can assist in adaptation planning efforts.[260,261]

Forests, both natural and plantation, in the Southeast are vulnerable to climate variability and change. Southeastern forests represent almost 27% of the U.S. total[262] and are the highest-valued crop in the region.[7] The vast majority of forest is held in private hands, primarily corporate. Forest cover ranges from almost 50% to 80% in these states, creating

large areas of interface between populations and forests.[262] Jobs in timber, logging, and support for agriculture and forestry totaled approximately 458,000.[263] (See Ch. 6: Forests, KM 3 for additional discussion on forest change impacts on rural landscapes.)

The Southeast is one of the most dynamic regions for forest change on the globe,[269] though much of the change owes to intensive rotations of pine production and economic forces that drive frequent conversion between forest and agricultural uses in rural areas.[270,271] Climate is expected to have an impact on the region's forests primarily through changes in moisture regimes.[272] Species migration westward across the eastern United States in response to changing precipitation patterns has already been noted.[273] Drought is likely to alter fire regimes and further interact with species distributions (see Key Message 3). The interactions of altered precipitation and natural disturbances will be important in understanding impacts to the forests not dominated by industrial forestry (Ch. 6: Forests, KM 1 and KM 3).[274]

Wildfire is a well-known risk in the Southeast region, where it occurs with greater frequency than any other U.S. region.[275] However, mitigation strategies, particularly the use of prescribed fire, can significantly reduce wildfire risk and have been widely adopted across rural communities in the Southeast.[190] A doubling of prescribed fire at the landscape scale has been found to reduce wildfire ignitions by a factor of four,[4] while it is well documented that prescribed fire reduces the potential for crown fire in treated forest stands.[276] With greater projected fire risks,[191,277] more attention on how to foster fire-adapted communities offers opportunities for risk reduction (see Case Study "Prescribed Fire" and Key Message 3).[278,279]

Case Study: Mountain Ramps

The Cherokee have been harvesting ramps, a wild onion (*Allium tricoccum*), in the southern Appalachians, their ancestral homelands, for thousands of years.[264,265] Collecting ramps for food sustenance is only one aspect of this cultural tradition. The family-bound harvesting techniques are equally as important and make up part of the deeply held tribal lifeways (Ch. 15: Tribes, KM 2). Ramps emerge in springtime and provide important nutrients after a long winter with a dearth of fresh vegetables. These plants grow in moist forest understory areas that are sensitive to temperature and soil moisture.[266]

Figure 19.20: This up-close image of a ramp (*Allium tricoccum*), harvested from the wild, shows leaves and the bulb/corm of the plant. Photo credit: Gary Kaufman, USDA Forest Service Southern Research Station.

In the southern Appalachians, ramps are threatened by two major processes: overharvesting pressures and a changing climate that could expose these plants to higher temperatures and lower soil moisture conditions during sensitive growth periods (Ch. 10: Ag & Rural, KM 1).[267,268] Although ramps are found all along the Appalachian mountain range, on Cherokee ancestral lands, they are already in their southernmost range. Climate change thus acts to increase the vulnerability of this plant to the existing stressors.

Heat, Health, and Livelihoods

Heat-related health threats are already a risk in outdoor jobs and activities. While heat illness is more often associated with urban settings, rural populations are also at risk. For example, higher rates of heat-related illness have been reported in rural North Carolina compared to urban locations.[280] However, strategies to reduce health impacts on hot days, such as staying indoors or altering times outdoors, are already contributing to reducing heat-related illness in the Southeast.[281]

Workers in the agriculture, forestry, hunting, and fishing sectors together with construction and support, waste, and remediation services work are the most highly vulnerable to heat-related deaths in the United States, representing almost 68% of heat-related deaths nationally.[282] Six of the ten states with the highest occupational heat-related deaths in these sectors are in the Southeast region, accounting for 28.6% of occupational heat-related deaths between 2000 and 2010.[282] By 2090, under a higher scenario (RCP8.5), the Southeast is projected to have the largest heat-related impacts on labor productivity in the country, resulting in average annual losses of 570 million labor hours, or $47 billion (in 2015 dollars, undiscounted), a cost representing a third of total national projected losses, although these figures do not include adaptations by workers or industries (Figure 19.21).[35]

Investing in increased cooling is one likely form of adaptation. Among U.S. regions, the Southeast is projected to experience the highest costs associated with meeting increased electricity demands in a warmer world.[35]

Compounding Stresses and Constraints to Adaptation

The people of the rural Southeast confront a number of social stresses likely to add to the challenges posed by increases in climate stresses.[283] Rural communities tend to be more vulnerable due to factors such as demography, occupations, earnings, literacy, poverty incidence, and community capacities (Ch. 10: Ag & Rural, KM 4).[8,9,10] Reducing stress associated with these factors can increase household and community resilience.[9,284]

Projected Changes in Hours Worked

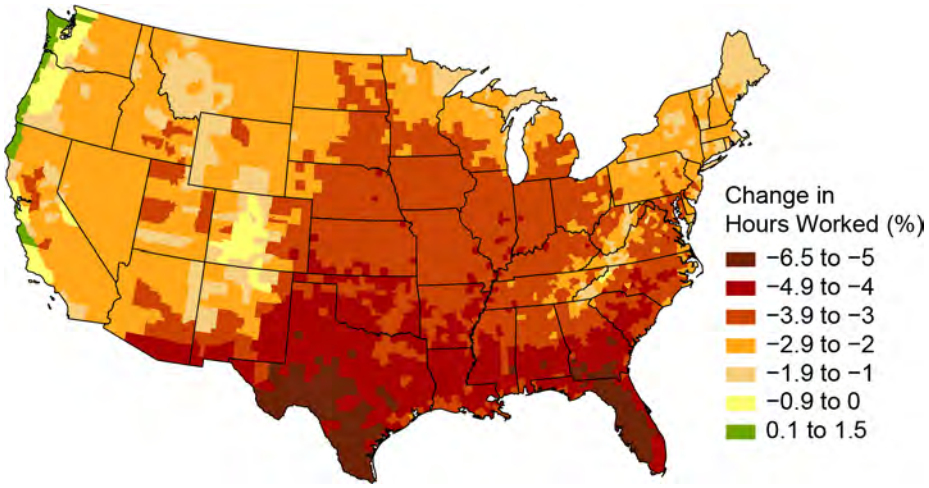

Figure 19.21: This map shows the estimated percent change in hours worked in 2090 under a higher scenario (RCP8.5). Projections indicate an annual average of 570 million labor hours lost per year in the Southeast by 2090 (with models ranging from 340 million to 820 million labor hours).[35] Estimates represent a change in hours worked as compared to a 2003–2007 average baseline for high-risk industries only. These industries are defined as agriculture, forestry, and fishing; hunting, mining, and construction; manufacturing, transportation, and utilities. Source: adapted from EPA 2017.[35]

Persistent rural poverty stands out in the Southeast (Figure 19.22). The rural counties in the region are experiencing higher levels of population loss (13% of rural counties lost population) and low educational attainment (38% of rural counties), with 35% of rural counties experiencing poverty rates of more than 20% persisting over approximately 30 years.[10] The Southeast is expected to experience the highest costs associated with meeting increased energy demands; an estimated $3.3 billion each year under a higher scenario (RCP8.5) and $1.2 billion annually under a lower scenario (RCP4.5) by the end of the century.[35] Energy poverty is a situation "where individuals or households are not able to adequately heat or provide other required energy services in their homes at affordable cost."[285] A case study from rural eastern North Carolina further explains energy poverty as a function of the energy efficiency of the home, energy provision infrastructure, physical health, low incomes, and support of social networks, which collectively influence households' choices about the amount of heating and cooling they can afford.[286] The National Weather Service (NWS) calculates degree days,[287] a way of tracking energy use. NWS starts with the assumption that when the average outside temperature is 65°F, heating or cooling is not needed in order to be comfortable. The difference between the average daily temperature and 65°F is the number of cooling or heating degrees for that day. These days can be added up over time—a month or a year—to give a combined estimate of energy needed for heating or cooling. Although heating costs are expected to decrease as the climate warms in the Southeast, the number of cooling degree days is expected to increase and the length of the cooling season expected to expand, increasing energy demand and exacerbating rural energy poverty (Figure 19.22).

The ability to cope with current and potential impacts, such as flooding, is further reduced by limited county resources. A study of hazard management plans (2004–2008) in 84 selected rural southeastern counties found these plans scored low across various criteria.[288] The rural, geographically remote locations contributed to more difficult logistics in reaching people. Interviewees also identified low-income and minority communities, substandard housing, lack of access to vehicles for evacuation, limited modes of communication, and limited local government capacity as contributing factors to difficulties in emergency planning.[288]

The healthcare system in the Southeast is already overburdened and may be further stressed by climate change. Between 2010 and 2016, more rural hospitals closed in the Southeast than any other region, with Alabama, Georgia, Mississippi, and Tennessee being among the top five states for hospital closures.[289] This strain, when combined with negative health impacts from climate change stressors (such as additional patient demand due to extreme heat and vector-borne diseases and greater flood risk from extreme precipitation events), increases the potential for disruptions of health services in the future. The Green River District Health Department recently did an assessment of ways to reduce vulnerability to negative health impacts of climate change in a mostly rural region of western Kentucky.[290] As a result, the local health department plans to enhance existing epidemiology, public health preparedness, and community health assessment services.[290]

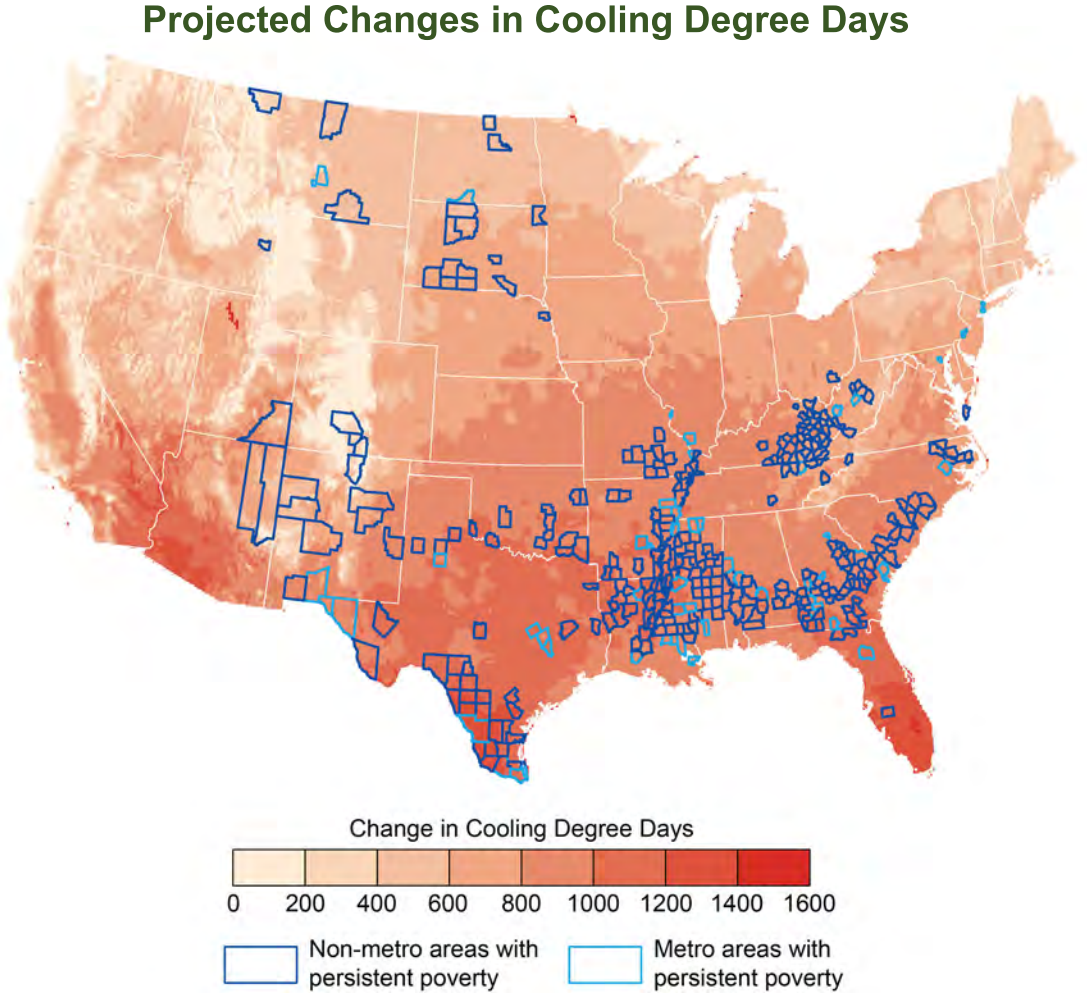

Figure 19.22: The map shows projected changes in cooling degree days by the mid-21st century (2036–2065) under the higher scenario (RCP8.5) based on model simulations. Rural counties experiencing persistent poverty are concentrated in the Southeast, where the need for additional cooling is expected to increase at higher rates than other areas of the country by mid-century. Process Description

Prior to identifying critical issues for the Southeast assessment focuses for the Fourth National Climate Assessment (NCA4), the Chapter Lead (CL) contacted numerous professional colleagues representing various geographic areas (e.g., Florida, Louisiana, and South Carolina) for expert opinions on critical climate change related issues impacting the region, with a particular emphasis on emerging issues since the Third National Climate Assessment (NCA3) effort.[77] Following those interviews, the CL concluded that the most pressing climate change issues to focus on for the NCA4 effort were extreme events, flooding (both from rainfall and sea level rise), wildfire, health issues, ecosystems, and adaptation actions. Authors with specific expertise in each of these areas were sought, and a draft outline built around these issues was developed. Further refinement of these focal areas occurred in conjunction with the public Regional Engagement Workshop, held on the campus of North Carolina State University in March 2017 and in six satellite locations across the Southeast region. The participants agreed that the identified issues were important and suggested the inclusion of several other topics, including impacts on coastal and rural areas and people, forests, and agriculture. Based on the subsequent authors' meeting and input from NCA staff, the chapter outline and Key Messages were updated to reflect a risk-based framing in the context of a new set of Key Messages. The depth of discussion for any particular topic and Key Message is dependent on the availability of supporting literature and chapter length limitations.

Key Message 1

Urban Infrastructure and Health Risks

Many southeastern cities are particularly vulnerable to climate change compared to cities in other regions, with expected impacts to infrastructure and human health (*very likely, very high confidence*). The vibrancy and viability of these metropolitan areas, including the people and critical regional resources located in them, are increasingly at risk due to heat, flooding, and vector-borne disease brought about by a changing climate (*likely, high confidence*). Many of these urban areas are rapidly growing and offer opportunities to adopt effective adaptation efforts to prevent future negative impacts of climate change (*very likely, high confidence*).

Description of evidence base

Multiple studies have projected that urban areas, including those in the Southeast, will be adversely affected by climate change in a variety of ways. This includes impacts on infrastructure[41,42,43,291,292,293] and human health.[30,31,38,294] Increases in climate-related impacts have already been observed in some Southeast metropolitan areas (e.g., Habeeb et al. 2015, Tzung-May Fu et al. 2015[12,39]).

Southeastern cities may be more vulnerable than cities in other regions of the United States due to the climate being more conducive to some vector-borne diseases, the presence of multiple large coastal cities at low elevation that are vulnerable to flooding and storms, and a rapidly growing urban and coastal population.[22,295,296]

Many city and county governments, utilities, and other government and service organizations have already begun to plan and prepare for the impacts of climate change (e.g., Gregg et al. 2017; FTA 2013; City of Fayetteville 2017; City of Charleston 2015; City of New Orleans 2015; Tampa Bay Water 2014; EPA 2015; City of Atlanta 2015, 2017; Southeast Florida Regional Climate Change Compact 2017[44,45,46,50,91,246,297,298,299]). A wide variety of adaptation options are available, offering opportunities to improve the climate resilience, quality of life, and economy of urban areas.[77,300,301,302,303,304]

Major uncertainties

Population projections are inherently uncertain over long time periods, and shifts in immigration or migration rates and shifting demographics will influence urban vulnerabilities to climate change. The precise impacts on cities are difficult to project. The scope and scale of adaptation efforts, which are already underway, will affect future vulnerability and risk. Technological developments (such as a potential shift in transportation modes) will also affect the scope and location of risk within cities. Newly emerging pathogens could increase risk of disease in the future, while successful adaptations could reduce public health risk.

Description of confidence and likelihood

There is *very high confidence* that southeastern cities will *likely* be impacted by climate change, especially in the areas of infrastructure and human health.

Key Message 2

Increasing Flood Risks in Coastal and Low-Lying Regions

The Southeast's coastal plain and inland low-lying regions support a rapidly growing population, a tourism economy, critical industries, and important cultural resources that are highly vulnerable to climate change impacts (*very likely, very high confidence*). The combined effects of changing extreme rainfall events and sea level rise are already increasing flood frequencies, which impacts property values and infrastructure viability, particularly in coastal cities. Without significant adaptation measures, these regions are projected to experience daily high tide flooding by the end of the century (*likely, high confidence*).

Description of evidence base

Multiple lines of research have shown that global sea levels have increased in the past and are projected to continue to accelerate in the future due to increased global temperature and that higher local sea level rise rates in the Mid-Atlantic and Gulf Coasts have occurred.[51,52,53,54,55,56,57,59,61,62]

Annual occurrences of high tide flooding have increased, causing several Southeast coastal cities to experience all-time records of occurrences that are posing daily risks.[1,52,58,60,61,63,67,68]

There is scientific consensus that sea level rise will continue to cause increases in high tide flooding in the Southeast as well as impact the frequency and duration of extreme water level events, causing an increase in the vulnerability of coastal populations and property.[1,60,63,67,68]

In the future, coastal flooding is projected to become more serious, disruptive, and costly as the frequency, depth, and inland extent grow with time.[1,2,35,64,65,67,68]

Many analyses have determined that extreme rainfall events have increased in the Southeast, and under higher scenarios, the frequency and intensity of these events are projected to increase.[19,21,88]

Rainfall records have shown that since NCA3, many intense rainfall events (approaching 500-year events) have occurred in the Southeast, with some causing billions of dollars in damage and many deaths.[68,82,84]

The flood events in Baton Rouge, Louisiana, in 2016 and in South Carolina in 2015 provide real examples of how vulnerable inland and coastal communities are to extreme rainfall events.[81,85,86]

The socioeconomic impacts of climate change on the Southeast is a developing research field.[65,71]

Major uncertainties

The amount of confidence associated with the historical rate of global sea level rise is impacted by the sparsity of tide gauge records and historical proxies as well as different statistical approaches for estimating sea level change. The amount of unpredictability in future projected rates of sea level rise is likely caused by a range of future climate scenarios projections and rate of ice sheet mass changes. Flooding events are highly variable in both space and time. Detection and attribution of flood events are difficult due to multiple variables that cause flooding.

Description of confidence and likelihood

There is *high confidence* that flood risks will *very likely* increase in coastal and low-lying regions of the Southeast due to rising sea level and an increase in extreme rainfall events. There is *high confidence* that Southeast coastal cities are already experiencing record numbers of high tide flooding events, and without significant adaptation measures, it is *likely* they will be impacted by daily high tide flooding.

Key Message 3

Natural Ecosystems Will Be Transformed

The Southeast's diverse natural systems, which provide many benefits to society, will be transformed by climate change (*very likely, high confidence*). Changing winter temperature extremes, wildfire patterns, sea levels, hurricanes, floods, droughts, and warming ocean temperatures are expected to redistribute species and greatly modify ecosystems (*very likely, high confidence*). As a result, the ecological resources that people depend on for livelihood, protection, and well-being are increasingly at risk, and future generations can expect to experience and interact with natural systems that are much different than those that we see today (*very likely, high confidence*).

Description of evidence base

Winter temperature extremes, fire regimes, sea levels, hurricanes, rainfall extremes, drought extremes, and warming ocean temperatures greatly influence the distribution, abundance, and performance of species and ecosystems.

Winter air temperature extremes (for example, freezing and chilling events) constrain the northern limit of many tropical and subtropical species.[30,48,127,132,135,138,139,140,141,142,143,144,145,148,149,150,152,166,167,168,169,170,172,173,174,175,176,177,178] In the future, warmer winter temperatures are expected to facilitate the northward movement of cold-sensitive species, often at the expense of cold-tolerant species.[132,135,142,145,149,150,152,166,169,173,179] Certain ecosystems are located near thresholds where small changes in winter air temperature regimes can trigger comparatively large and abrupt landscape-scale ecological changes (i.e., ecological regime shifts).[135,145,152]

Changing fire regimes are expected to have a large impact on natural systems. Fire has historically played an important role in the region, and ecological diversity in many southeastern natural systems is dependent upon fire.[115,116,134,189] In the future, rising temperatures and increases in the duration and intensity of drought are expected to increase wildfire occurrence and also reduce the effectiveness of prescribed fire.[3,4,5,6]

Hurricanes and rising sea levels are aspects of climate change that will have a tremendous effect on coastal ecosystems in the Southeast. Historically, coastal ecosystems in the region have adjusted to sea level rise via vertical and/or horizontal movement across the landscape.[125,129,200,201] As sea levels rise in the future, some coastal ecosystems will be submerged and converted to open water, and some coastal ecosystems will move inland at the expense of upslope and upriver ecosystems.[203,204] Since coastal terrestrial and freshwater ecosystems are highly sensitive to increases in inundation and/or salinity, sea level rise will result in the comparatively rapid conversion of these systems to tidal saline habitats. In addition to sea level rise, climate change is expected to increase the impacts of hurricanes; the high winds, storm surges, inundation, and salts that accompany hurricanes will have large ecological impacts to terrestrial and freshwater ecosystems.[209,210]

Climate change is expected to intensify the hydrologic cycle and increase the frequency and severity of extreme events. Extreme drought events are expected to become more frequent and severe. Drought and extreme heat can result in tree mortality and transform southeastern forested ecosystems.[217,218,219,220,221,222,223] Drought can also affect aquatic and wetland ecosystems.[224,225,226,227,228,229,232] Extreme rainfall events are also expected to become more frequent and severe in the future. The prolonged inundation and lack of oxygen that result from extreme rainfall events can also result in mortality and large impacts to natural systems.[233] In combination, future increases in both extreme drought and extreme rainfall are expected to transform many southeastern ecosystems.

Warming ocean temperatures due to climate change are expected to have a large effect on marine and coastal ecosystems.[234,235,236] Many species are sensitive to small changes in ocean temperature; hence, the distribution and abundance of marine organisms are expected to be greatly altered by increasing ocean temperatures. For example, the distribution of tropical herbivorous fish has been expanding in response to warmer waters, which has resulted in the tropicalization of some temperate marine ecosystems and decreases in the cover of valuable macroalgal plant communities.[179] A decrease in the growth of sea turtles in the West Atlantic has been linked to higher ocean temperatures.[237] The impacts to coral reef ecosystems have been and are expected to be particularly dire. Coral reef mortality in the Florida Keys and across the globe has been very high in recent decades, due in part to warming ocean temperatures, nutrient enrichment, overfishing, and coastal development.[240,241,242,243,244] Coral elevation and volume in the Florida Keys have been

declining in recent decades,[245] and present-day temperatures in the region are already close to bleaching thresholds; hence, it is likely that many of the remaining coral reefs in the Southeast will be lost in the coming decades.[246,247] In addition to warming temperatures, accelerated ocean acidification is also expected to contribute to coral reef mortality and decline.[248,249]

Major uncertainties

In the Southeast, winter temperature extremes, fire regimes, sea level fluctuations, hurricanes, extreme rainfall, and extreme drought all play critical roles and greatly influence the distribution, structure, and function of species and ecosystems. Changing climatic conditions (particularly, changes in the frequency and severity of climate extremes) are, however, difficult to replicate via experimental manipulations; hence, ecological responses to future climate regimes have not been fully quantified for all species and ecosystems. Natural ecosystems are complex and governed by many interacting biotic and abiotic processes. Although it is possible to make general predictions of climate change effects, specific future ecological transformations can be difficult to predict, especially given the number of interacting and changing biotic and abiotic factors in any specific location. Uncertainties in the range of potential future changes in multiple and concurrent facets of climate and land-use change also affect our ability to predict changes to natural systems.

Description of confidence and likelihood

There is *high confidence* that climate change (e.g., changing winter temperatures extremes, changing fire regimes, rising sea levels and hurricanes, warming ocean temperatures, and more extreme rainfall and drought) will *very likely* affect natural systems in the Southeast region. These climatic drivers play critical roles and greatly influence the distribution, structure, and functioning of ecosystems; hence, changes in these climatic drivers will transform ecosystems in the region and greatly alter the distribution and abundance of species.

Key Message 4

Economic and Health Risks for Rural Communities

Rural communities are integral to the Southeast's cultural heritage and to the strong agricultural and forest products industries across the region. More frequent extreme heat episodes and changing seasonal climates are projected to increase exposure-linked health impacts and economic vulnerabilities in the agricultural, timber, and manufacturing sectors (*very likely, high confidence*). By the end of the century, over one-half billion labor hours could be lost from extreme heat-related impacts (*likely, medium confidence*). Such changes would negatively impact the region's labor-intensive agricultural industry and compound existing social stresses in rural areas related to limited local community capabilities and associated with rural demography, occupations, earnings, literacy, and poverty incidence (*very likely, high confidence*). Reduction of existing stresses can increase resilience (*very likely, high confidence*).

Description of evidence base

Analysis of the sensitivity of some manufacturing sectors to climate changes anticipates secondary risks associated with crop and livestock productivity.[64,255]

Multiple analyses anticipate that energy- or water-intensive industries could face water stress and increased energy costs.[8,64,255,256]

A large body of evidence addresses the sensitivity of many crops grown in the Southeast to changing climate conditions including increased temperatures, decreased summer rainfall, drought, and change in the timing and duration of chill periods.[7,35] Extensive research documents livestock sensitivity to heat stress.[7]

Multiple lines of evidence indicate that forests are likely to be impacted by changing climate, particularly moisture regimes and potential changes in wildfire activity.[191,195,272,274] There is extensive research on heat-related illness and mortality among those living and working in the Southeast. While there is more evidence focused on urban areas, limited research has identified higher levels of heat-related illness in rural areas.[280,281] Research on occupational heat-related mortality identifies some of the Nation's highest levels in southeastern states.[282] Computer model simulations of heat-related reductions in labor productivity anticipate the greatest losses will occur in the Southeast. However, these models do not account for adaptations that may reduce estimated losses.[35,64] By the end of the century, mean annual electricity costs are estimated at $3.3 billion each year under RCP8.5 (model range: $2.4 to $4.2 billion; in 2015 dollars, undiscounted) and mean $1.2 billion each year under RCP4.5 (model range $0.9 to $1.9 billion; in 2015 dollars, undiscounted).[35]

Rural communities tend to be vulnerable due to factors such as demography, occupations, earnings, literacy, and poverty incidence.[8,9,10,250,283,284,305] Reducing the stress created by such factors can improve resilience.[9,284] The availability and accessibility of planning and health services to support coping with climate-related stresses are limited in the rural Southeast.[288,289]

Major uncertainties

There are limited studies documenting direct connections between climate changes and economic impacts. Models are limited in their ability to incorporate adaptation that may reduce losses. These factors restrict the potential to strongly associate declines in agricultural and forest productivity with the level of potential economic impact.

Projections of potential change in the frequency and extent of wildfires depend in part on models of future population growth and human behavior, which are limited, adding to the uncertainty associated with climate and forest modeling.

Many indicators of vulnerability are dynamic, so that adaptation and other changes can affect the patterns of vulnerability to heat and other climate stressors over time. Limited studies indicate concerns over the planning and preparedness of capacity at local levels; however, information is limited.

Projected labor hours lost vary by global climate model, time frame, and scenario, with a mean of 0.57 and a model range of 0.34–0.82 billion labor hours lost each year for RCP8.5 by 2090. The annual mean projected losses are roughly halved (0.28 billion labor hours) and with a model range from 0.19 to 0.43 billion labor hours lost under RCP4.5 by 2090.[35]

Description of confidence and likelihood

There is *high confidence* that climate change (e.g., rising temperatures, changing fire regimes, rising sea levels, and more extreme rainfall and drought) will *very likely* affect agricultural and forest products industries, potentially resulting in economic impacts. There is *high confidence* that increases in temperature are *very likely* to increase heat-related illness, deaths, and loss of labor productivity without greater adaptation efforts.

7 Precipitation Change in the United States

KEY FINDINGS

1. Annual precipitation has decreased in much of the West, Southwest, and Southeast and increased in most of the Northern and Southern Plains, Midwest, and Northeast. A national average increase of 4% in annual precipitation since 1901 is mostly a result of large increases in the fall season. (*Medium confidence*)

2. Heavy precipitation events in most parts of the United States have increased in both intensity and frequency since 1901 (*high confidence*). There are important regional differences in trends, with the largest increases occurring in the northeastern United States (*high confidence*). In particular, mesoscale convective systems (organized clusters of thunderstorms)—the main mechanism for warm season precipitation in the central part of the United States—have increased in occurrence and precipitation amounts since 1979 (*medium confidence*).

3. The frequency and intensity of heavy precipitation events are projected to continue to increase over the 21st century (*high confidence*). Mesoscale convective systems in the central United States are expected to continue to increase in number and intensity in the future (*medium confidence*). There are, however, important regional and seasonal differences in projected changes in total precipitation: the northern United States, including Alaska, is projected to receive more precipitation in the winter and spring, and parts of the southwestern United States are projected to receive less precipitation in the winter and spring (*medium confidence*).

4. Northern Hemisphere spring snow cover extent, North America maximum snow depth, snow water equivalent in the western United States, and extreme snowfall years in the southern and western United States have all declined, while extreme snowfall years in parts of the northern United States have increased (*medium confidence*). Projections indicate large declines in snowpack in the western United States and shifts to more precipitation falling as rain than snow in the cold season in many parts of the central and eastern United States (*high confidence*).

Introduction

Changes in precipitation are one of the most important potential outcomes of a warming world because precipitation is integral to the very nature of society and ecosystems. These systems have developed and adapted to the past envelope of precipitation variations. Any large changes beyond the historical envelope may have profound societal and ecological impacts.

Historical variations in precipitation, as observed from both instrumental and proxy records, establish the context around which future projected changes can be interpreted, because it is within that context that systems have evolved. Long-term station observations from core climate networks serve as a primary source to establish observed changes in both means and extremes. Proxy records, which are used to reconstruct past climate conditions, are varied and include sources such as tree ring and ice core data. Projected changes are examined using the Coupled Model Intercomparison Project Phase 5 (CMIP5) suite of model simulations. They establish the likelihood of distinct regional and seasonal patterns of change.

7.1 Historical Changes

7.1.1 Mean Changes

Annual precipitation averaged across the United States has increased approximately 4% over the 1901–2015 period, slightly less than the 5% increase reported in the Third National Climate Assessment (NCA3) over the 1901–2012 period.[1] There continue to be important regional and seasonal differences in precipitation changes (Figure 7.1). Seasonally, national increases are largest in the fall, while little change is observed for winter. Regional differences are apparent, as the Northeast, Midwest, and Great Plains have had increases while parts of the Southwest and Southeast have had decreases. The slight decrease in the change in annual precipitation across the United States since NCA3 appears to be the result of the recent lingering droughts in the western and southwestern United States.[2,3] However, the recent meteorological drought in California that began in late 2011[4,5] now appears to be largely over, due to the substantial precipitation and snowpack the state received in the winter of 2016–2017. The year 2015 was the third wettest on record, just behind 1973 and 1983 (all of which were years marked by El Niño events). Interannual variability is substantial, as evidenced by large multiyear meteorological and agricultural droughts in the 1930s and 1950s.

Changes in precipitation differ markedly across the seasons, as do regional patterns of increases and decreases. For the contiguous United States, fall exhibits the largest (10%) and most widespread increase, exceeding 15% in much of the Northern Great Plains, Southeast, and Northeast. Winter average for the United States has the smallest increase (2%), with drying over most of the western United States as well as parts of the Southeast. In particular, a reduction in streamflow in the northwestern United States has been linked to a decrease in orographic enhancement of precipitation since 1950.[6] Spring and summer have comparable increases (about 3.5%) but substantially different patterns. In spring, the northern half of the contiguous United States has become wetter, and the southern half has become drier. In summer, there is a mixture of increases and decreases across the Nation. Alaska shows little change in annual precipitation (+1.5%); however, in all seasons, central Alaska shows declines and the panhandle shows increases. Hawai'i shows a decline of more than 15% in annual precipitation.

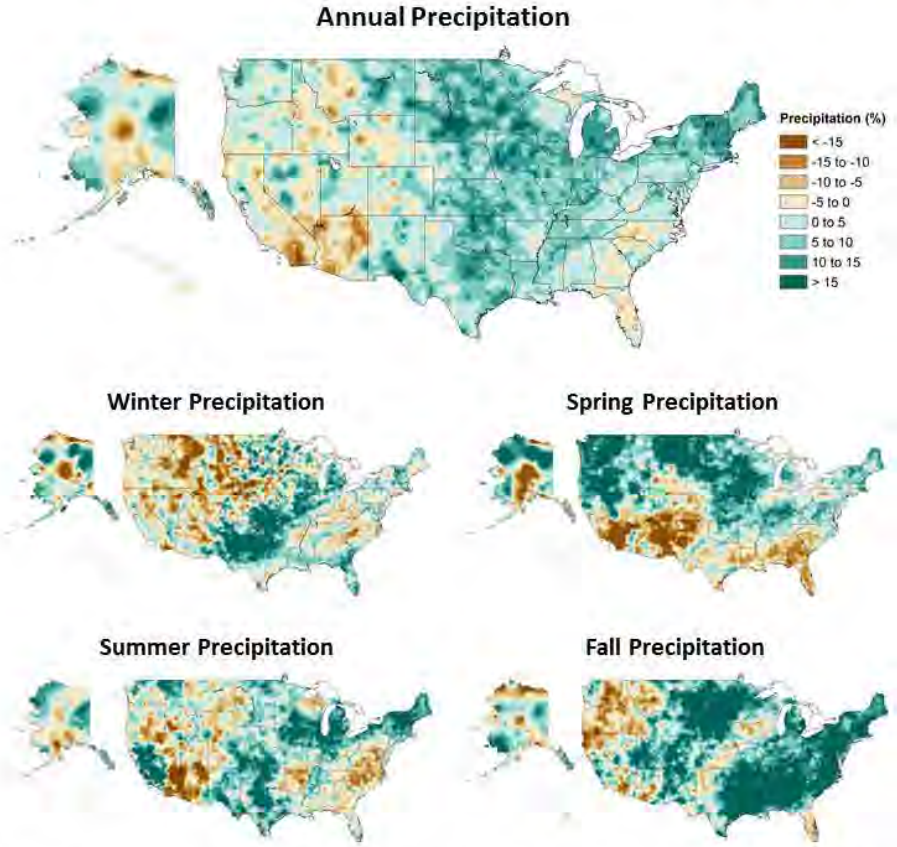

Figure 7.1: Annual and seasonal changes in precipitation over the United States. Changes are the average for present-day (1986–2015) minus the average for the first half of the last century (1901–1960 for the contiguous United States, 1925–1960 for Alaska and Hawai'i) divided by the average for the first half of the century. (Figure source: [top panel] adapted from Peterson et al. 2013,[78] © American Meteorological Society. Used with permission; [bottom four panels] NOAA NCEI, data source: nCLIMDiv].

7.1.2 Snow

Changes in snow cover extent (SCE) in the Northern Hemisphere exhibit a strong seasonal dependence.[7] There has been little change in winter SCE since the 1960s (when the first satellite records became available), while fall SCE has increased. However, the decline in spring SCE is larger than the increase in fall and is due in part to higher temperatures that shorten the time snow spends on the ground in the spring. This tendency is highlighted by the recent occurrences of both unusually high and unusually low monthly (October–June) SCE values, including the top 5 highest and top 5 lowest values in the 48 years of data. From 2010 onward, 7 of the 45 highest monthly SCE values occurred, all in the fall or winter (mostly in November and December), while 9 of the 10 lowest May and June values occurred. This reflects the trend toward earlier spring snowmelt, particularly at high latitudes.[8] An analysis of seasonal maximum snow depth for 1961–2015 over North America indicates a statistically significant downward trend of 0.11 standardized anomalies per decade and a trend toward the seasonal maximum snow depth occurring earlier—approximately one week earlier on average since the 1960s.[8] There has been a statistically significant decrease over the period of 1930–2007 in the frequency of years with a large number of snowfall days (years exceeding the 90th percentile) in the southern United States and the U.S. Pacific Northwest and an increase in the northern United States.[9] In the snow belts of the Great Lakes, lake effect snowfall has increased overall since the early 20th century for Lakes Superior, Michigan-Huron, and Erie.[10] However, individual studies for

Lakes Michigan[11] and Ontario[12] indicate that this increase has not been continuous. In both cases, upward trends were observed until the 1970s/early 1980s. Since then, however, lake effect snowfall has decreased in these regions. Lake effect snows along the Great Lakes are affected greatly by ice cover extent and lake water temperatures. As ice cover diminishes in winter, the expectation is for more lake effect snow until temperatures increase enough such that much of what now falls as snow instead falls as rain.[13, 14]

End-of-season snow water equivalent (SWE)—especially important where water supply is dominated by spring snow melt (for example, in much of the American West)—has declined since 1980 in the western United States, based on analysis of in situ observations, and is associated with springtime warming.[15] Satellite measurements of SWE based on brightness temperature also show a decrease over this period.[16] The variability of western United States SWE is largely driven by the most extreme events, with the top decile of events explaining 69% of the variability.[17] The recent drought in the western United States was highlighted by the extremely dry 2014–2015 winter that followed three previous dry winters. At Donner Summit, CA, (approximate elevation of 2,100 meters) in the Sierra Nevada Mountains, end-of-season SWE on April 1, 2015, was the lowest on record, based on survey measurements back to 1910, at only 0.51 inches (1.3 cm), or less than 2% of the long-term average. This followed the previous record low in 2014. The estimated return period of this drought is at least 500 years based on paleoclimatic reconstructions.[18]

7.1.3 Observed changes in U.S. seasonal extreme precipitation.

Extreme precipitation events occur when the air is nearly completely saturated. Hence, extreme precipitation events are generally observed to increase in intensity by about 6% to 7% for each degree Celsius of temperature increase, as dictated by the Clausius–Clapeyron relation. Figure 7.2 shows the observed change in the 20-year return value of the seasonal maximum 1-day precipitation totals over the period 1948–2015. A mix of increases and decreases is shown, with the Northwest showing very small changes in all seasons, the southern Great Plains showing a large increase in winter, and the Southeast showing a large increase in the fall.

A U.S. index of extreme precipitation from NCA3 was updated (Figure 7.3) through 2016. This is the number of 2-day precipitation events exceeding the threshold for a 5-year recurrence. The values were calculated by first arithmetically averaging the station data for all stations within each 1° by 1° latitude/longitude grid for each year and then averaging over the grid values across the contiguous United States for each year during the period of 1896–2015. The number of events has been well above average for the last three decades. The slight drop from 2006–2010 to 2011–2016 reflects a below-average number during the widespread severe meteorological drought year of 2012, while the other years in this pentad were well above average. The index value for 2015 was 80% above the 1901–1960 reference period average and the third highest value in the 120 years of record (after 1998 and 2008).

Maximum daily precipitation totals were calculated for consecutive 5-year blocks from 1901 (1901–1905, 1906–1910, 1911–1915, …, 2011–2016) for individual long-term stations. For each 5-year block, these values were aggregated to the regional scale by first arithmetically averaging the station 5-year maximum for all stations within each 2° by 2° latitude/longitude grid and then averaging across all grids within each region to

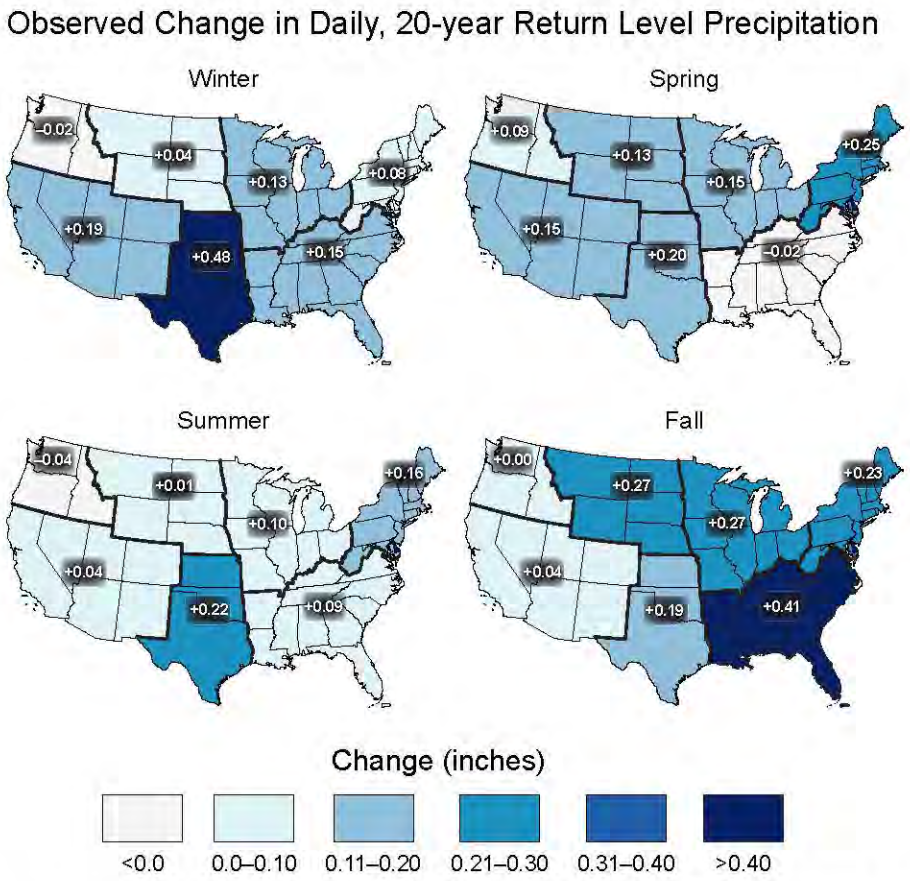

Figure 7.2: Observed changes in the 20-year return value of the seasonal daily precipitation totals for the contiguous United States over the period 1948 to 2015 using data from the Global Historical Climatology Network (GHCN) dataset. (Figure source: adapted from Kunkel et al. 2013;[61] © American Meteorological Society. Used with permission.)

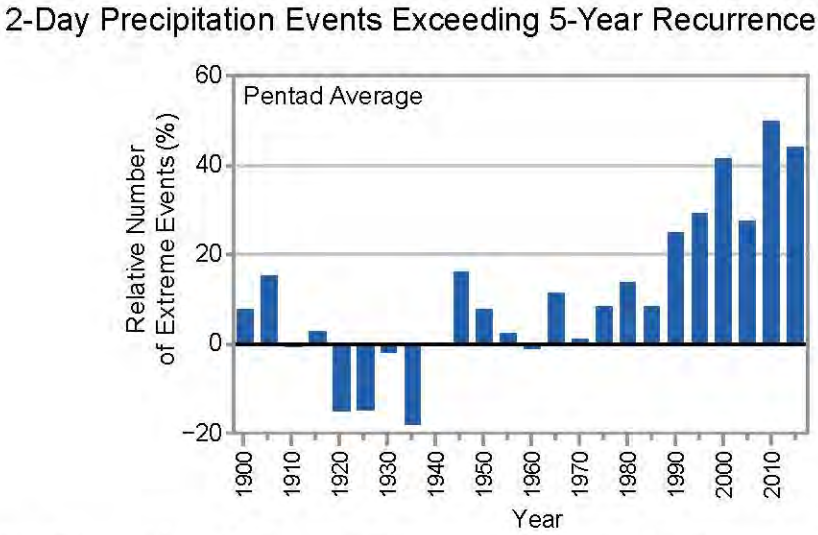

Figure 7.3: Index of the number of 2-day precipitation events exceeding the station-specific threshold for a 5-year recurrence interval in the contiguous United States, expressed as a percentage difference from the 1901–1960 mean. The annual values are averaged over 5-year periods, with the pentad label indicating the ending year of the period. Annual time series of the number of events are first calculated at individual stations. Next, the grid box time series are calculated as the average of all stations in the grid box. Finally, a national time series is calculated as the average of the grid box time series. Data source: GHCN-Daily. (Figure source: CICS-NC and NOAA NCEI).

create a regional time series. Finally, a trend was computed for the resulting regional time series. The difference between these two periods (Figure 7.4, upper left panel) indicates substantial increases over the eastern United States, particularly the northeastern United States with an increase of 27% since 1901. The increases are much smaller over the western United States, with the southwestern and northwestern United States showing little increase.

Another index of extreme precipitation from NCA3 (the total precipitation falling in the top 1% of all days with precipitation) was updated through 2016 (Figure 7.4, upper right panel). This analysis is for 1958–2016. There are increases in all regions, with the largest increases again in the northeastern United States. There are some changes in the values compared to NCA3, with small increases in some regions such as the Midwest and Southwest and small decreases in others such as the Northeast, but the overall picture of changes is the same.

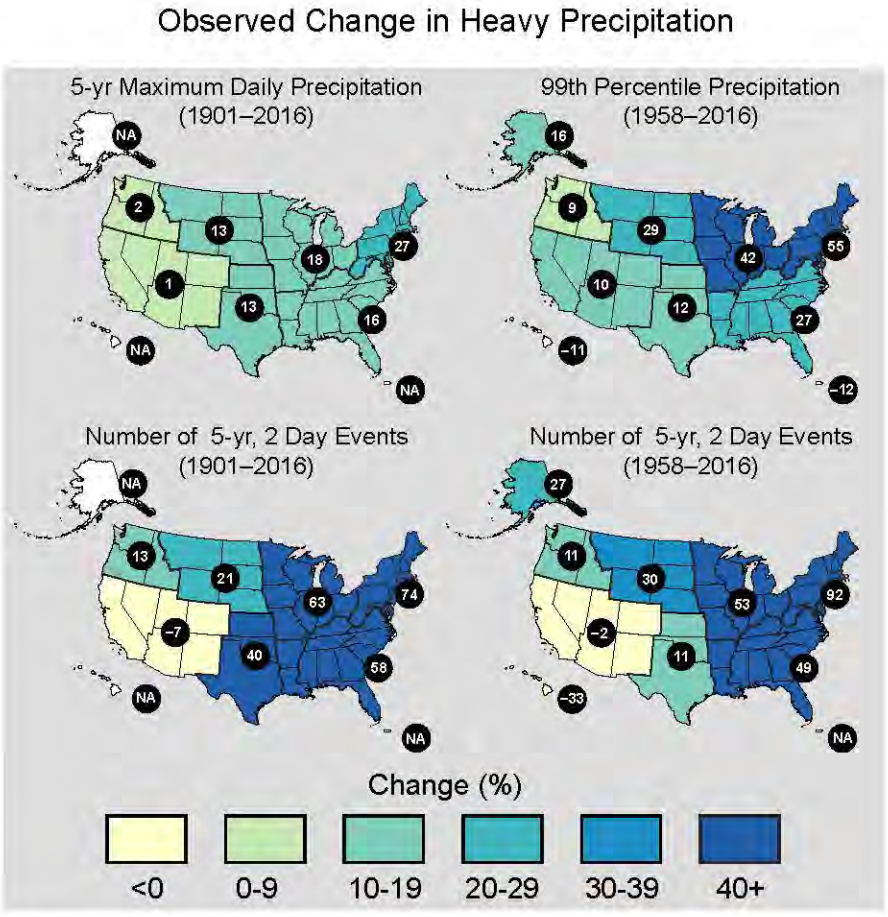

Figure 7.4: These maps show the change in several metrics of extreme precipitation by NCA4 region, including (upper left) the maximum daily precipitation in consecutive 5-year blocks, (upper right) the amount of precipitation falling in daily events that exceed the 99th percentile of all non-zero precipitation days, (lower left) the number of 2-day events with a precipitation total exceeding the largest 2-day amount that is expected to occur, on average, only once every 5 years, as calculated over 1901–2016, and (lower right) the number of 2-day events with a precipitation total exceeding the largest 2-day amount that is expected to occur, on average, only once every 5 years, as calculated over 1958–2016. The numerical value is the percent change over the entire period, either 1901–2016 or 1958–2016. The percentages are first calculated for individual stations, then averaged over 2° latitude by 2° longitude grid boxes, and finally averaged over each NCA4 region. Note that Alaska and Hawai'i are not included in the 1901–2016 maps owing to a lack of observations in the earlier part of the 20th century. (Figure source: CICS-NC and NOAA NCEI).

The national results shown in Figure 7.3 were disaggregated into regional values for two periods: 1901–2016 (Figure 7.4, lower left panel) and 1958–2016 (Figure 7.4, lower right panel) for comparison with Figure 7.4, upper right panel. As with the other metrics, there are large increases over the eastern half of the United States while the increases in the western United States are smaller and there are actually small decreases in the Southwest.

There are differences in the magnitude of changes among the four different regional metrics in Figure 7.4, but the overall picture is the same: large increases in the eastern half of the United States and smaller increases, or slight decreases, in the western United States.

7.1.4 Extratropical Cyclones and Mesoscale Convective Systems

As described in Chapter 9: Extreme Storms, there is uncertainty about future changes in winter extratropical cyclones (ETCs).[19] Thus, the potential effects on winter extreme precipitation events is also uncertain. Summertime ETC activity across North America has decreased since 1979, with a reduction of more than 35% in the number of strong summertime ETCs.[20] Most climate models simulate little change over this same historical period, but they project a decrease in summer ETC activity during the remainder of the 21st century.[20] This is potentially relevant to extreme precipitation in the northeastern quadrant of the United States because a large percentage of the extreme precipitation events in this region are caused by ETCs and their associated fronts.[21] This suggests that in the future there may be fewer opportunities in the summer for extreme precipitation, although increases in water vapor are likely to overcompensate for any decreases in ETCs by increasing the likelihood that an ETC will produce excessive rainfall amounts. A very idealized set of climate simulations[22] suggests that substantial projected warming will lead to a decrease in the number of ETCs but an increase in the intensity of the strongest ETCs. One factor potentially causing this model ETC intensification is an increase in latent heat release in these storms related to a moister atmosphere. Because of the idealized nature of these simulations, the implications of these results for the real earth–atmosphere system is uncertain. However, the increased latent heat mechanism is likely to occur given the high confidence in a future moister atmosphere. For eastern North America, CMIP5 simulations of the future indicate an increase in strong ETCs.[19] Thus, it is possible that the most extreme precipitation events associated with ETCs may increase in the future.

Mesoscale convective systems (MCSs), which contribute substantially to warm season precipitation in the tropics and subtropics,[23] account for about half of rainfall in the central United States.[24] Schumacher and Johnson[25] reported that 74% of all warm season extreme rain events over the eastern two-thirds of the United States during the period 1999–2003 were associated with an MCS. Feng et al.[26] found that large regions of the central United States experienced statistically significant upward trends in April–June MCS rainfall of 0.4–0.8 mm per day (approximately 20%–40%) per decade from 1979 to 2014. They further found upward trends in MCS frequency of occurrence, lifetime, and precipitation amount, which they attribute to an enhanced west-to-east pressure gradient (enhanced Great Plains low-level jet) and enhanced specific humidity throughout the eastern Great Plains.

7.1.5 Detection and Attribution

Trends

Detectability of trends (compared to internal variability) for a number of precipitation metrics over the continental United States has been examined; however, trends identified for the U.S. regions have not been clearly attribut-

ed to anthropogenic forcing.[27, 28] One study concluded that increasing precipitation trends in some north-central U.S. regions and the extreme annual anomalies there in 2013 were at least partly attributable to the combination of anthropogenic and natural forcing.[29]

There is *medium confidence* that anthropogenic forcing has contributed to global-scale intensification of heavy precipitation over land regions with sufficient data coverage.[30] Global changes in extreme precipitation have been attributed to anthropogenically forced climate change,[31, 32] including annual maximum 1-day and 5-day accumulated precipitation over Northern Hemisphere land regions and (relevant to this report) over the North American continent.[33] Although the United States was not separately assessed, the parts of North America with sufficient data for analysis included the continental United States and parts of southern Canada, Mexico, and Central America. Since the covered region was predominantly over the United States, these detection/attribution findings are applicable to the continental United States.

Analyses of precipitation extreme changes over the United States by region (20-year return values of seasonal daily precipitation over 1948–2015, Figure 7.2) show statistically significant increases consistent with theoretical expectations and previous analyses.[34] Further, a significant increase in the area affected by precipitation extremes over North America has also been detected.[35] There is likely an anthropogenic influence on the upward trend in heavy precipitation,[36] although models underestimate the magnitude of the trend. Extreme rainfall from U.S. landfalling tropical cyclones has been higher in recent years (1994–2008) than the long-term historical average, even accounting for temporal changes in storm frequency.[10]

Based on current evidence, it is concluded that detectable but not attributable increases in mean precipitation have occurred over parts of the central United States. Formal detection-attribution studies indicate a human contribution to extreme precipitation increases over the continental United States, but confidence is *low* based on those studies alone due to the short observational period, high natural variability, and model uncertainty.

In summary, based on available studies, it is concluded that for the continental United States there is *high confidence* in the detection of extreme precipitation increases, while there is *low confidence* in attributing the extreme precipitation changes purely to anthropogenic forcing. There is stronger evidence for a human contribution (*medium confidence*) when taking into account process-based understanding (increased water vapor in a warmer atmosphere), evidence from weather and climate models, and trends in other parts of the world.

Event Attribution

A number of recent heavy precipitation events have been examined to determine the degree to which their occurrence and severity can be attributed to human-induced climate change. Table 7.1 summarizes available attribution statements for recent extreme U.S. precipitation events. Seasonal and annual precipitation extremes occurring in the north-central and eastern U.S. regions in 2013 were examined for evidence of an anthropogenic influence on their occurrence.[29] Increasing trends in annual precipitation were detected in the northern tier of states, March–May precipitation in the upper Midwest, and June–August precipitation in the eastern United States since 1900. These trends are attributed to external forcing (anthropogenic and natural) but could not be directly attributed to anthropogenic forcing alone. However, based on this analysis, it is

Table 7.1. A list of U.S. extreme precipitation events for which attribution statements have been made. In the far right column, "+" indicates that an attributable human-induced increase in frequency and/or magnitude was found, "–" indicates that an attributable human-induced decrease in frequency and/or magnitude was found, "0" indicates no attributable human contribution was identified. As in Tables 6.1 and 8.2, several of the events were originally examined in the *Bulletin of the American Meteorological Society's* (BAMS) State of the Climate Reports and reexamined by Angélil et al.[76] In these cases, both attribution statements are listed with the original authors first. Source: M. Wehner.

concluded that the probability of these kinds of extremes has increased due to anthropogenic forcing.

The human influence on individual storms has been investigated with conflicting results. For example, in examining the attribution of the 2013 Colorado floods, one study finds that despite the expected human-induced increase in available moisture, the GEOS-5 model produces fewer extreme storms in the 1983–2012 period compared to the 1871–1900 period in Colorado during the fall season; the study attributes that behavior to changes in the large-scale circulation.[37] However, another study finds that such coarse models cannot produce the observed magnitude of precipitation due to resolution constraints.[38] Based on a highly conditional set of hindcast simulations imposing the large-scale meteorology and a substantial increase in both the probability and magnitude of the observed precipitation accumulation magnitudes in that particular meteorological situation, the study could not address the question of whether such situations have become more or less probable. Extreme precipitation event attribution is inherently limited by the rarity of the necessary meteorological conditions and the limited number of model simulations that can be performed to examine rare events. This remains an open and active area of research. However, based on these two studies, the anthropogenic contribution to the 2013 Colorado heavy rainfall-flood event is unclear.

An event attribution study of the potential influence of anthropogenic climate change on

the extreme 3-day rainfall event associated with flooding in Louisiana in August 2016[39] finds that such extreme rainfall events have become more likely since 1900. Model simulations of extreme rainfall suggest that anthropogenic forcing has increased the odds of such a 3-day extreme precipitation event by 40% or more.

7.2 Projections

Changes in precipitation in a warmer climate are governed by many factors. Although energy constraints can be used to understand global changes in precipitation, projecting regional changes is much more difficult because of uncertainty in projecting changes in the large-scale circulation that plays an important role in the formation of clouds and precipitation.[40] For the contiguous United States (CONUS), future changes in seasonal average precipitation will include a mix of increases, decreases, or little change, depending on location and season (Figure 7.5). High-latitude regions are generally projected to become wetter while the subtropical zone is projected to become drier. As the CONUS lies between these two regions, there is significant uncertainty about the sign and magnitude of future anthropogenic changes to seasonal precipitation in much of the region, particularly in the middle latitudes of the Nation. However, because the physical mechanisms controlling extreme precipitation differ from those controlling seasonal average precipitation (Section 7.1.4), in particular atmospheric water vapor will increase with increasing temperatures, confidence is *high* that precipitation extremes will increase in frequency and intensity in the future throughout the CONUS.

Global climate models used to project precipitation changes exhibit varying degrees of fidelity in capturing the observed climatology and seasonal variations of precipitation across the United States. Global or regional climate models with higher horizontal resolution generally achieve better skill than the CMIP5 models in capturing the spatial patterns and magnitude of winter precipitation in the western and southeastern United States (e.g., Mearns et al. 2012;[41] Wehner 2013;[42] Bacmeister et al. 2014;[43] Wehner et al. 2014[44]), leading to improved simulations of snowpack and runoff (e.g., Rauscher et al. 2008;[45] Rasmussen et al. 2011[46]). Simulation of present and future summer precipitation remains a significant challenge, as current convective parameterizations fail to properly represent the statistics of mesoscale convective systems.[47] As a result, high-resolution models that still require the parameterization of deep convection exhibit mixed results.[44, 48] Advances in computing technology are beginning to enable regional climate modeling at the higher resolutions (1–4 km), permitting the direct simulation of convective clouds systems (e.g., Ban et al. 2014[49]) and eliminating the need for this class of parameterization. However, projections from such models are not yet ready for inclusion in this report.

Important progress has been made by the climate modeling community in providing multimodel ensembles such as CMIP5[50] and NARCCAP[41] to characterize projection uncertainty arising from model differences and large ensemble simulations such as CESM-LE[51] to characterize uncertainty inherent in the climate system due to internal variability. These ensembles provide an important resource for examining the uncertainties in future precipitation projections.

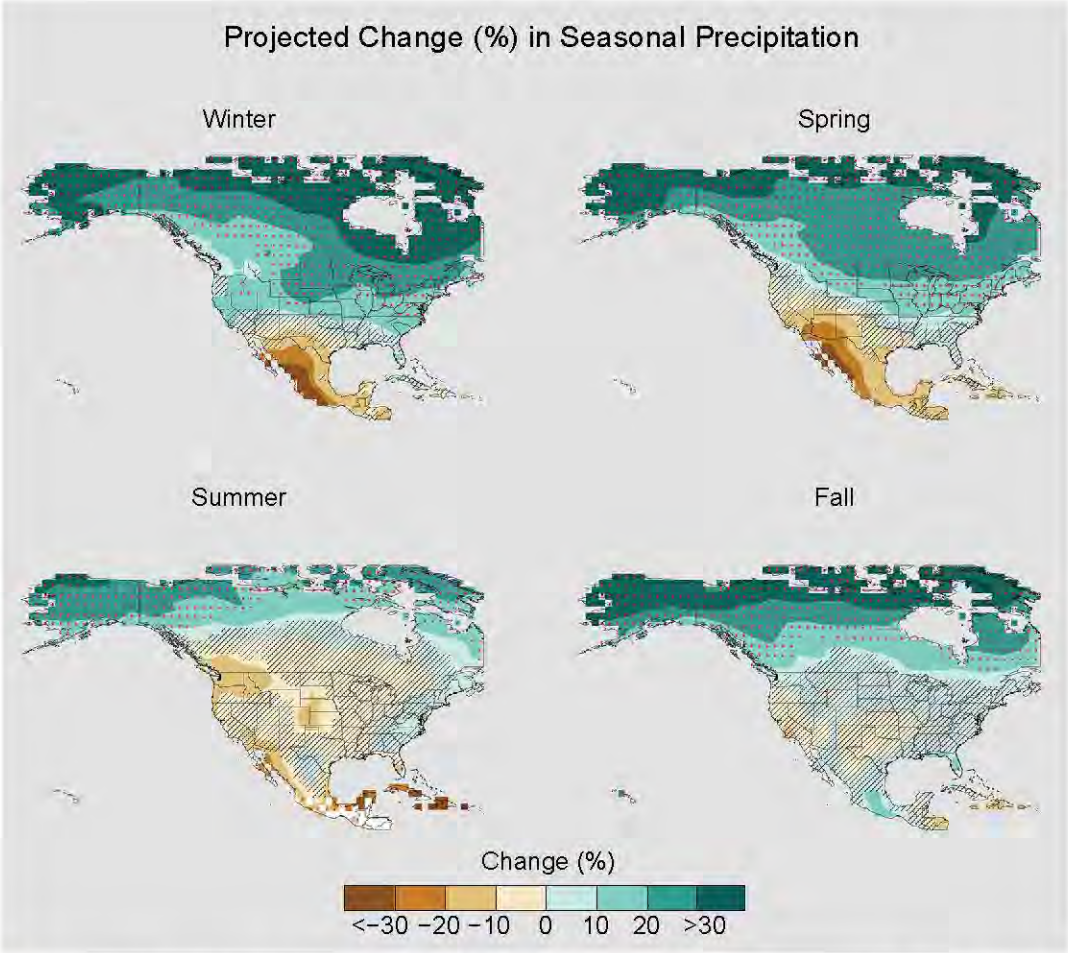

Figure 7.5: Projected change (%) in total seasonal precipitation from CMIP5 simulations for 2070–2099. The values are weighted multimodel means and expressed as the percent change relative to the 1976–2005 average. These are results for the higher scenario (RCP8.5). Stippling indicates that changes are assessed to be large compared to natural variations. Hatching indicates that changes are assessed to be small compared to natural variations. Blank regions (if any) are where projections are assessed to be inconclusive. Data source: World Climate Research Program's (WCRP's) Coupled Model Intercomparison Project. (Figure source: NOAA NCEI).

7.2.1 Future Changes in U.S. Seasonal Mean Precipitation

In the United States, projected changes in seasonal mean precipitation span the range from profound decreases to profound increases. In many regions and seasons, projected changes in precipitation are not large compared to natural variations. The general pattern of change is clear and consistent with theoretical expectations. Figure 7.5 shows the weighted CMIP5 multimodel average seasonal change at the end of the century compared to the present under the higher scenario (RCP8.5; see Ch. 4: Projections for discussion of RCPs). In this figure, changes projected with high confidence to be larger than natural variations are stippled. Regions where future changes are projected with high confidence to be smaller than natural variations are hatched. In winter and spring, the northern part of the country is projected to become wetter as the global climate warms. In the early to middle parts of this century, this will likely be manifested as increases in snowfall.[52] By the latter half of the century, as temperature continues to increase, it will be too warm to snow in many current snow-producing situations, and precipitation will mostly be rainfall. In the southwestern

United States, precipitation will decrease in the spring but the changes are only a little larger than natural variations. Many other regions of the country will not experience significant changes in average precipitation. This is also the case over most of the country in the summer and fall.

This pattern of projected precipitation change arises because of changes in locally available water vapor and weather system shifts. In the northern part of the continent, increases in water vapor, together with changes in circulation that are the result of expansion of the Hadley cell, bring more moisture to these latitudes while maintaining or increasing the frequency of precipitation-producing weather systems. This change in the Hadley circulation (see Ch. 5: Circulation and Variability for discussion of circulation changes) also causes the subtropics, the region between the northern and southern edges of the tropics and the midlatitudes (about 35° of latitude), to be drier in warmer climates as well as moving the mean storm track northward and away from the subtropics, decreasing the frequency of precipitation-producing systems. The combination of these two factors results in precipitation decreases in the southwestern United States, Mexico, and the Caribbean.[53]

Projected Changes In Snow

The Third National Climate Assessment[54] projected reductions in annual snowpack of up to 40% in the western United States based on the SRES A2 emissions scenario in the CMIP3 suite of climate model projections. Recent research using the CMIP5 suite of climate model projections forced with a higher scenario (RCP8.5) and statistically downscaled for the western United States continues to show the expected declines in various snow metrics, including snow water equivalent, the number of extreme snowfall events, and number of snowfall days.[55] A northward shift in the rain–snow transition zone in the central and eastern United States was found using statistically downscaled CMIP5 simulations forced with RCP8.5. By the end of the 21st century, large areas that are currently snow dominated in the cold season are expected to be rainfall dominated.[56]

The Variable Infiltration Capacity (VIC) model has been used to investigate the potential effects of climate change on SWE. Declines in SWE are projected in all western U.S. mountain ranges during the 21st century with the virtual disappearance of snowpack in the southernmost mountains by the end of the 21st century under both the lower (RCP4.5) and higher (RCP8.5) scenarios.[57] The projected decreases are most robust at the lower elevations of areas where snowpack accumulation is now reliable (for example, the Cascades and northern Sierra Nevada ranges). In these areas, future decreases in SWE are largely driven by increases in temperature. At higher (colder) elevations, projections are driven more by precipitation changes and are thus more uncertain.

7.2.2 Extremes

Heavy Precipitation Events

Studies project that the observed increase in heavy precipitation events will continue in the future (e.g. Janssen et al. 2014,[58] 2016[59]). Similar to observed changes, increases are expected in all regions, even those regions where total precipitation is projected to decline, such as the southwestern United States. Under the higher scenario (RCP8.5) the number of extreme events (exceeding a 5-year return period) increases by two to three times the historical average in every region (Figure 7.6) by the end of the 21st century, with the largest increases in the Northeast. Under the lower scenario (RCP4.5), increases are 50%–100%. Research shows that there is strong evidence, both from the observed record and modeling studies, that increased water vapor resulting from high-

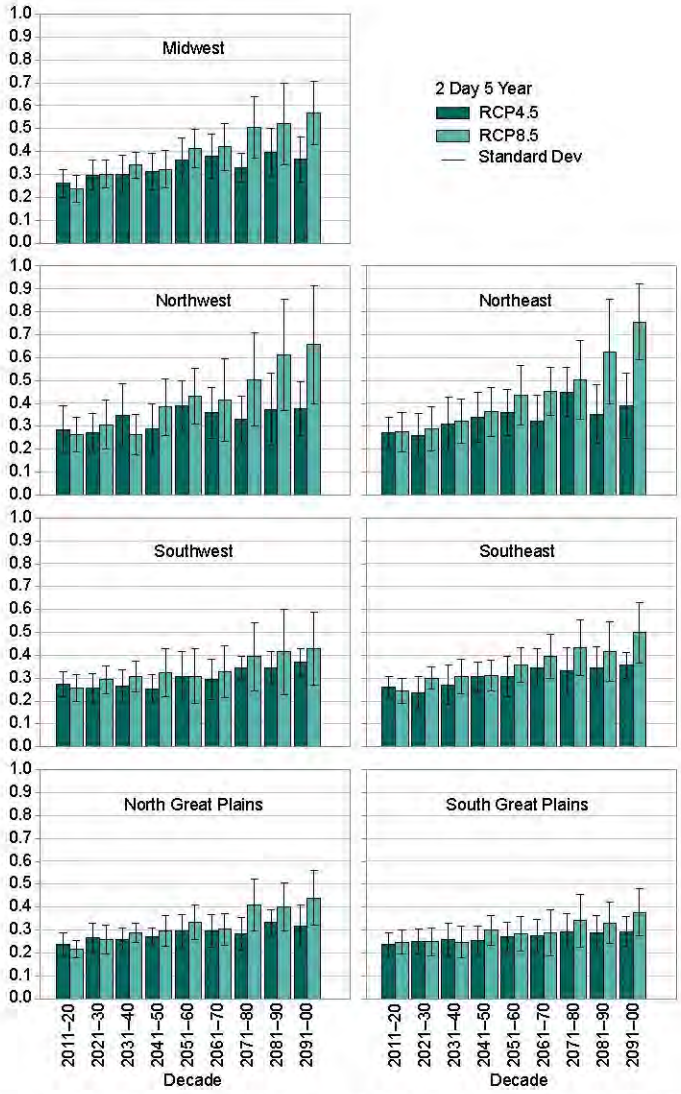

Figure 7.6: Regional extreme precipitation event frequency for a lower scenario (RCP4.5) (green; 16 CMIP5 models) and the higher scenario (RCP8.5) (blue; 14 CMIP5 models) for a 2-day duration and 5-year return. Calculated for 2006–2100 but decadal anomalies begin in 2011. Error bars are ±1 standard deviation; standard deviation is calculated from the 14 or 16 model values that represent the aggregated average over the regions, over the decades, and over the ensemble members of each model. The average frequency for the historical reference period is 0.2 by definition and the values in this graph should be interpreted with respect to a comparison with this historical average value. (Figure source: Janssen et al. 2014[58]).

er temperatures is the primary cause of the increases.[42, 60, 61] Additional effects on extreme precipitation due to changes in dynamical processes are poorly understood. However, atmospheric rivers (ARs), especially along the West Coast of the United States, are projected to increase in number and water vapor transport[62] and experience landfall at lower latitudes[63] by the end of the 21st century.

Projections of changes in the 20-year return period amount for daily precipitation (Figure 7.7) using LOcally Constructed Analogs (LOCA) downscaled data also show large percentage increases for both the middle and late 21st century. A lower scenario (RCP4.5) show increases of around 10% for mid-century and up to 14% for the late century projections. A higher scenario (RCP8.5) shows even larger increases for both mid- and late-century

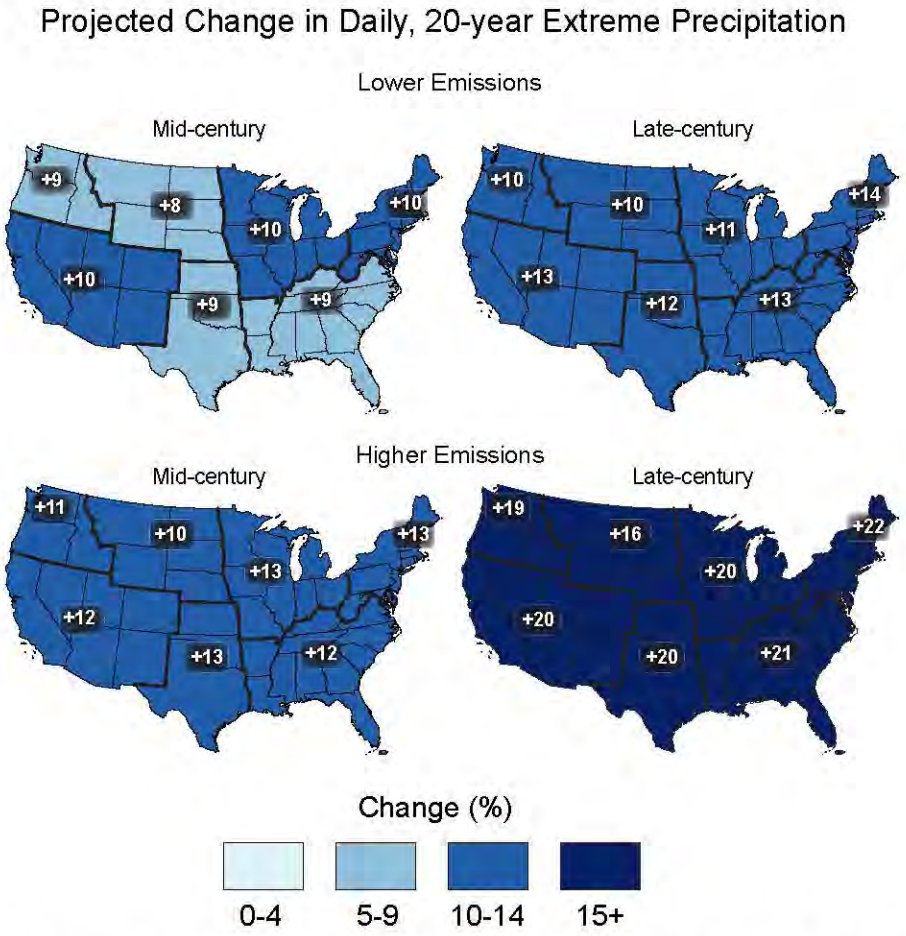

Figure 7.7: Projected change in the 20-year return period amount for daily precipitation for mid- (left maps) and late-21st century (right maps). Results are shown for a lower scenario (top maps; RCP4.5) and for a higher scenario (bottom maps, RCP8.5). These results are calculated from the LOCA downscaled data. (Figure source: CICS-NC and NOAA NCEI).

projections, with increases of around 20% by late 21st century. No region in either scenario shows a decline in heavy precipitation. The increases in extreme precipitation tend to increase with return level, such that increases for the 100-year return level are about 30% by the end of the century under a higher scenario (RCP8.5).

Projections of changes in the distribution of daily precipitation amounts (Figure 7.8) indicate an overall more extreme precipitation climate. Specifically, the projections indicate a slight increase in the numbers of dry days and the very lightest precipitation days and a large increase in the heaviest days. The number of days with precipitation amounts greater than the 95th percentile of all non-zero precipitation days increases by more than 25%. At the same time, the number of days with precipitation amounts in the 10th–80th percentile range decreases.

Most global climate models lack sufficient resolution to project changes in mesoscale convective systems (MCSs) in a changing climate.[64] However, research by Cook et al.[65] attempted to identify clues to changes in dynamical forcing that create MCSs. To do this, they examined the ability of 18 coupled ocean–atmosphere global climate models (GCMs) to simulate potential 21st century changes in warm-season flow and the associated U.S. Midwest hydrology resulting from increases in greenhouse gases. They selected a subset of six models that best captured the

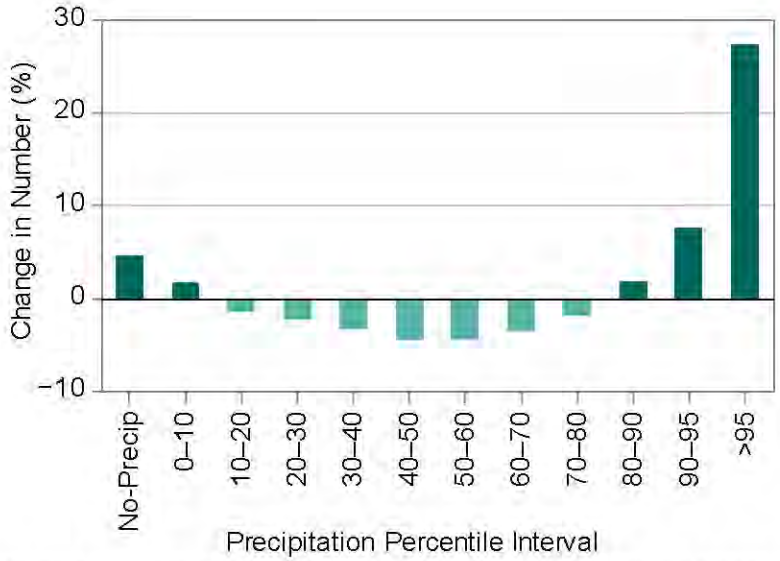

Figure 7.8: Projected change (percentage change relative to the 1976–2005 reference period average) in the number of daily zero ("No-Precip") and non-zero precipitation days (by percentile bins) for late-21st century under a higher scenario (RCP8.5). The precipitation percentile bin thresholds are based on daily non-zero precipitation amounts from the 1976–2005 reference period that have been ranked from low to high. These results are calculated from the LOCA downscaled data. (Figure source: CICS-NC and NOAA NCEI).

low-level flow and associated dynamics of the present-day climate of the central United States and then analyzed these models for changes due to enhanced greenhouse gas forcing. In each of these models, springtime precipitation increases significantly (by 20%–40%) in the upper Mississippi Valley and decreases to the south. The enhanced moisture convergence leading to modeled future climate rainfall increases in the U.S. Midwest is caused by meridional convergence at 850 hPa, connecting the rainfall changes with the Great Plains Low-Level Jet intensification.[66] This is consistent with findings from Feng et al.[26] in the observational record for the period 1979–2014 and by Pan et al.[67] by use of a regional climate model.

Changes in intense hourly precipitation events were simulated by Prein et al.[68] where they found the most intense hourly events (99.9 percentile) in the central United States increase at the expense of moderately intense (97.5 percentile) hourly events in the warm season. They also found the frequency of seasonal hourly precipitation extremes is expected to increase in all regions by up to five times in the same areas that show the highest increases in extreme precipitation rates.

Hurricane Precipitation

Regional model projections of precipitation from landfalling tropical cyclones over the United States, based on downscaling of CMIP5 model climate changes, suggest that the occurrence frequency of post-landfall tropical cyclones over the United States will change little compared to present day during the 21st century, as the reduced frequency of tropical cyclones over the Atlantic domain is mostly offset by a greater landfalling fraction. However, when downscaling from CMIP3 model climate changes, projections show a reduced occurrence frequency over U.S. land, indicating uncertainty about future outcomes. The average tropical cyclone rainfall rates within 500 km (about 311 miles) of the storm center increased by 8% to 17% in the simulations, which was at least as much as expected from the water vapor content increase factor alone.

Several studies have projected increases of precipitation rates within hurricanes over ocean regions,[69] particularly for the Atlantic basin.[70] The primary physical mechanism for this increase is the enhanced water vapor content in the warmer atmosphere, which enhances moisture convergence into the storm for a given circulation strength, although a more intense circulation can also contribute.[71] Since hurricanes are responsible for many of the most extreme precipitation events in the southeastern United States,[10, 21] such events are likely to be even heavier in the future. In a set of idealized forcing experiments, this effect was partly offset by differences in warming rates at the surface and at altitude.[72]

TRACEABLE ACCOUNTS

Key Finding 1

Annual precipitation has decreased in much of the West, Southwest, and Southeast and increased in most of the Northern and Southern Plains, Midwest, and Northeast. A national average increase of 4% in annual precipitation since 1901 is mostly a result of large increases in the fall season. (*Medium confidence*)

Description of evidence base

The key finding and supporting text summarizes extensive evidence documented in the climate science peer-reviewed literature. Evidence of long-term changes in precipitation is based on analysis of daily precipitation observations from the U.S. Cooperative Observer Network (http://www.nws.noaa.gov/om/coop/) and shown in Figure 7.1. Published work, such as the Third National Climate Assessment,[73] and Figure 7.1 show important regional and seasonal differences in U.S. precipitation change since 1901.

Major uncertainties

The main source of uncertainty is the sensitivity of observed precipitation trends to the spatial distribution of observing stations and to historical changes in station location, rain gauges, the local landscape, and observing practices. These issues are mitigated somewhat by new methods to produce spatial grids through time.[74]

Assessment of confidence based on evidence and agreement, including short description of nature of evidence and level of agreement

Based on the evidence and understanding of the issues leading to uncertainties, confidence is *medium* that average annual precipitation has increased in the United States. Furthermore, confidence is also *medium* that the important regional and seasonal differences in changes documented in the text and in Figure 7.1 are robust.

Summary sentence or paragraph that integrates the above information

Based on the patterns shown in Figure 7.1 and numerous additional studies of precipitation changes in the United States, there is *medium confidence* in the observed changes in annual and seasonal precipitation over the various regions and the United States as a whole.

Key Finding 2

Heavy precipitation events in most parts of the United States have increased in both intensity and frequency since 1901 (*high confidence*). There are important regional differences in trends, with the largest increases occurring in the northeastern United States (*high confidence*). In particular, mesoscale convective systems (organized clusters of thunderstorms)—the main mechanism for warm season precipitation in the central part of the United States—have increased in occurrence and precipitation amounts since 1979 (*medium confidence*).

Description of evidence base

The key finding and supporting text summarize extensive evidence documented in the climate science peer-reviewed literature. Numerous papers have been written documenting observed changes in heavy precipitation events in the United States, including those cited in the Third National Climate Assessment and in this assessment. Although station-based analyses (e.g., Westra et al. 2013[34]) do not show large numbers of statistically significant station-based trends, area averaging reduces the noise inherent in station-based data and produces robust increasing signals (see Figures 7.2 and 7.3). Evidence of long-term changes in precipitation is based on analysis of daily precipitation observations from the U.S. Cooperative Observer Network (http://www.nws.noaa.gov/om/coop/) and shown in Figures 7.2, 7.3, and 7.4.

Major uncertainties

The main source of uncertainty is the sensitivity of observed precipitation trends to the spatial distribution of observing stations and to historical changes in station location, rain gauges, and observing practices. These issues are mitigated somewhat by methods used to produce spatial grids through gridbox averaging.

Assessment of confidence based on evidence and agreement, including short description of nature of evidence and level of agreement

Based on the evidence and understanding of the issues leading to uncertainties, confidence is *high* that heavy precipitation events have increased in the United States. Furthermore, confidence is also *high* that the important regional and seasonal differences in changes documented in the text and in Figures 7.2, 7.3, and 7.4 are robust.

Summary sentence or paragraph that integrates the above information

Based on numerous analyses of the observed record in the United States there is *high confidence* in the observed changes in heavy precipitation events, and *medium confidence* in observed changes in mesoscale convective systems.

Key Finding 3

The frequency and intensity of heavy precipitation events are projected to continue to increase over the 21st century (*high confidence*). Mesoscale convective systems in the central United States are expected to continue to increase in number and intensity in the future (*medium confidence*). There are, however, important regional and seasonal differences in projected changes in total precipitation: the northern United States, including Alaska, is projected to receive more precipitation in the winter and spring, and parts of the southwestern United States are projected to receive less precipitation in the winter and spring (*medium confidence*).

Description of evidence base

Evidence for future changes in precipitation is based on climate model projections and our understanding of the climate system's response to increasing greenhouse gases and of regional mechanisms behind the projected changes. In particular, Figure 7.7 documents projected changes in the 20-year return period amount using the LOCA data, and Figure 7.6 shows changes in 2 day totals for the 5-year return period using the CMIP5 suite of models. Each figure shows robust changes in extreme precipitation events as they are defined in the figure. However, Figure 7.5, which shows changes in seasonal and annual precipitation, indicates where confidence in the changes is higher based on consistency between the models and that there are large areas where the projected change is uncertain.

Major uncertainties

A key issue is how well climate models simulate precipitation, which is one of the more challenging aspects of weather and climate simulation. In particular, comparisons of model projections for total precipitation (from both CMIP3 and CMIP5, see Sun et al. 2015[75]) by NCA3 region show a spread of responses in some regions (for example, the Southwest) such that they are opposite from the ensemble average response. The continental United States is positioned in the transition zone between expected drying in the subtropics and wetting in the mid- and higher-latitudes. There are some differences in the location of this transition between CMIP3 and CMIP5 models and thus there remains uncertainty in the exact location of the transition zone.

Assessment of confidence based on evidence and agreement, including short description of nature of evidence and level of agreement

Based on evidence from climate model simulations and our fundamental understanding of the relationship of water vapor to temperature, confidence is *high* that extreme precipitation will increase in all regions of the United States. However, based on the evidence and understanding of the issues leading to uncertainties, confidence is *medium* that that more total precipitation is projected for the northern U.S. and less for the Southwest.

Summary sentence or paragraph that integrates the above information

Based on numerous analyses of model simulations and our understanding of the climate system there is *high confidence* in the projected changes in precipitation extremes and *medium confidence* in projected changes in total precipitation over the United States.

Key Finding 4

Northern Hemisphere spring snow cover extent, North America maximum snow depth, snow water equivalent in the western United States, and extreme snowfall years in the southern and western United States have all declined, while extreme snowfall years in parts of the northern United States have increased (*medium confidence*). Projections indicate large declines in snowpack in the western United States and shifts to more precipitation falling as rain than snow in the cold season in many parts of the central and eastern United States (*high confidence*).

Description of evidence base

Evidence of historical changes in snow cover extent and a reduction in extreme snowfall years is consistent with our understanding of the climate system's response to increasing greenhouse gases. Furthermore, climate models continue to consistently show future declines in snowpack in the western United States. Recent model projections for the eastern United States also confirm a future shift from snowfall to rainfall during the cold season in colder portions of the central and eastern United States. Each of these changes is documented in the peer-reviewed literature and are cited in the main text of this chapter.

Major uncertainties

The main source of uncertainty is the sensitivity of observed snow changes to the spatial distribution of observing stations and to historical changes in station location, rain gauges, and observing practices, particularly for snow. Another key issue is the ability of climate models to simulate precipitation, particularly snow. Future changes in the frequency and intensity of meteorological systems causing heavy snow are less certain than temperature changes.

Assessment of confidence based on evidence and agreement, including short description of nature of evidence and level of agreement

Given the evidence base and uncertainties, confidence is *medium* that snow cover extent has declined in the United States and *medium* that extreme snowfall years have declined in recent years. Confidence is *high* that western United States snowpack will decline in the future, and confidence is *medium* that a shift from snow domination to rain domination will occur in the parts of the central and eastern United States cited in the text.

Summary sentence or paragraph that integrates the above information

Based on observational analyses of snow cover, depth, and water equivalent there is *medium confidence* in the observed changes, and based on model simulations for the future there is *high confidence* in snowpack declines in the western United States and *medium confidence* in the shift to rain from snow in the eastern United States.

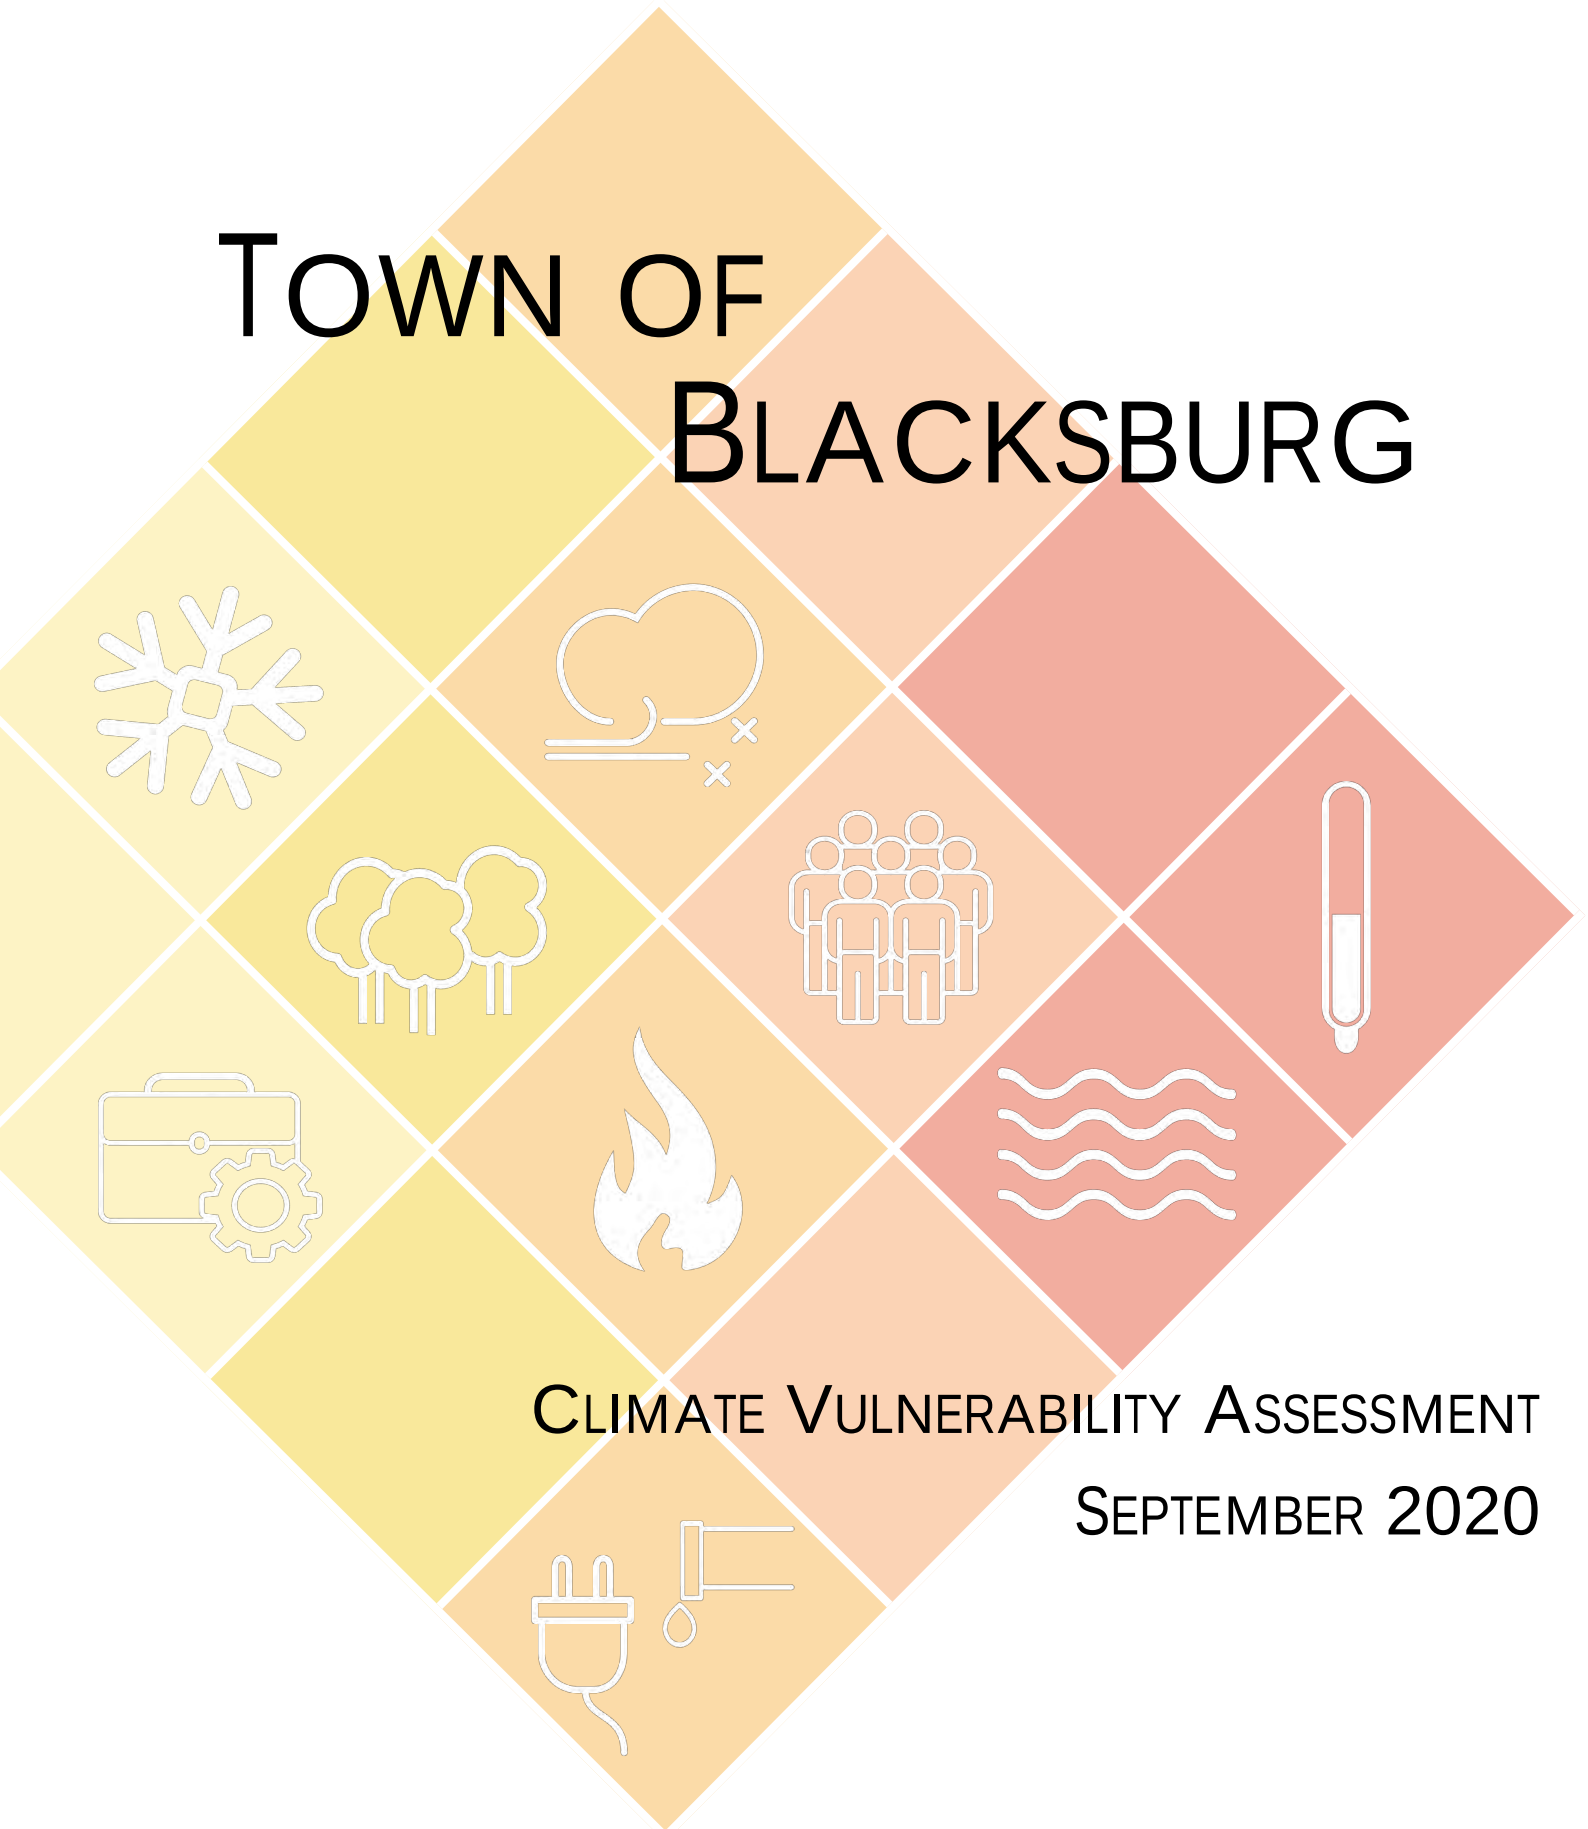
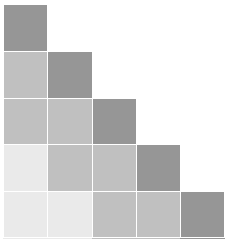
Town of Blacksburg



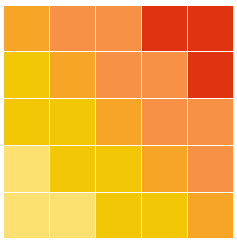
Climate Vulnerability Assessment

September 2020

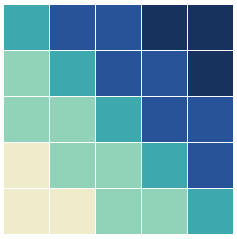
Table of Contents



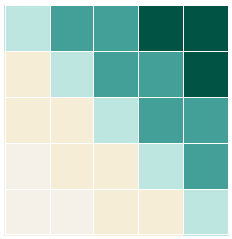
Introduction & Background



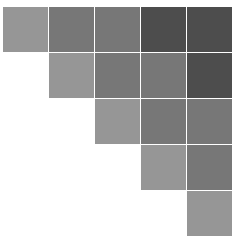
Hotter Summers



Warmer Winters



Changing Precipitation Patterns



Sources, Conclusion & Next Steps

Message from Mayor Leslie Hager-Smith

Blacksburg is proud to be counted among the hundreds of local governments across America that are taking action to address climate change, while making their communities healthier and more resilient. We have long recognized our fundamental responsibility to take stock of our share of the planet's greenhouse gas emissions and hold up our end of the bargain to ensure a stable climate for future generations. One key way we are doing that is by integrating goals from Blacksburg's 2016 Climate Action Plan into its Comprehensive Plan, which will elevate climate priorities into future land-use, infrastructure, and transportation decision.

We also know that reducing emissions, while critically important, will not be enough. As a global community, we have been burning fossil fuels at an ever-accelerating pace since the advent of the industrial revolution. Those emissions are already in our atmosphere and we will have to contend with a certain amount of climate change that is already baked in.

Stressors like poverty, inequality, public health challenges, economic volatility, and environmental degradation will almost certainly be made worse by a changing climate. These changes have the potential to disrupt our lives and livelihoods in numerous ways, and we know we will need to adapt. For Blacksburg to do that, we need to first assess which community systems might be at risk. We also recognize that the needs of people who are likely to be hurt first and worst by climate change should be prioritized in our future plans for climate adaptation.

To become a truly climate-resilient community, Blacksburg has to do three things: continue to act boldly to reduce our greenhouse gas emissions; begin adapting to changes that cannot be avoided under a low-emissions scenario; and, pro-actively plan for how we might respond to the challenges of a high-emissions scenario. The good news is, climate mitigation and adaptation strategies can work in concert, providing benefits that align with community goals around affordable housing, resilient natural systems, expanded transportation options, and thriving civic spaces.

As I reflect on the ways in which Blacksburg has come together so many times in the past to overcome daunting challenges, I know we are equal to the task ahead of us.

Leslie Hager-Smith

Mayor of Blacksburg, VA

Centering Equity

Centering Equity in Climate Adaptation and Resiliency Planning & Implementation

Climate change does not affect everyone equally. In evaluating potential impacts a key consideration is to recognize that some people will be disproportionately worse off than others. These groups are commonly referred to as "vulnerable populations" or "marginalized groups." For the purposes of this report, they will be identified as **FRONTLINE COMMUNITIES**, because it is they who will be on the front lines of the unfolding climate emergency. Factors that increase the potential impact of climate hazards on individuals include:

- Age factors (very young and very old people are more vulnerable to heat stress)
- Complex health challenges -or- mobility, sensory or cognitive impairments
- Limited social connections or support networks
- Limited financial resources
- Working outdoors or in unconditioned spaces
- Inadequate, unstable or unaffordable housing options
- Insecure or unaffordable transportation options
- Language or cultural barriers

With the exception of age, the factors listed above are disproportionately found among people of color, indigenous peoples, immigrant communities, and in rural areas. The following excerpt from "Making Equity Real in Climate Adaptation and Community Resilience Guidebook", emphasizes the historical context and clear need to place equity at the center of climate adaptation work:

> *"Decades of underinvestment and unjust systems have left frontline communities with high levels of poverty and pollution, poorer health outcomes, a lack of quality jobs and education opportunities, outdated and weak critical infrastructure, disproportionately high costs for energy, transportation and basic necessities, and limited access to public services. Moreover, frontline communities have long been excluded from policy and funding decision-making processes that can be used to address the injustices they experience and support a transition to healthy communities. Exclusion from the decision-making table is one reason the needs of frontline communities have not been prioritized. As a result of these injustices, frontline communities have fewer resources to deal with the risks from climate change. These communities are often hit first and worst by climate impacts, which only exacerbate the environmental and socioeconomic inequities they already face."*

To make equity real in its climate adaptation and resilience work, the Town of Blacksburg commits to:

1. Embedding equity in the mission, vision and values for Blacksburg's adaptation and resilience plan.
2. Building equity and deep engagement into the planning and implementation process.
3. Ensuring equity outcomes by responding to community needs in policy-making and implementation.
4. Measuring and analyzing for equity outcomes over time with an eye toward continual improvement.

How hot is too hot and when does it become a problem?

How wet is too wet and when does it become a problem?

How do these and other changes to the climate intersect?

How should localities like Blacksburg plan and adapt?

The answers to these questions are challenging to navigate. We can explore the question through some comparative examples. Take for instance, a midsummer day in Anchorage, Alaska where a temperature above 80°F would be considered extremely hot, since the average daily highs in July are usually in the mid to high 60s. Yet this same temperature would be considered unseasonably cool for Phoenix, Arizona, where July average daily highs topping 105°F are the norm. In these two places, as in all places, both the natural systems and the built environment have emerged, were cultivated, or were constructed to accommodate a predictable range of climatic conditions.

Blacksburg falls between these two extremes, with an average high temperature in July in the low to mid 80s. Occasional hotter days are not unheard of in our region. The historic record shows that between 1950 and 2013, Blacksburg had around 4-5 days per year where the temperatures got above 90°F, with far fewer days that topped 95°F. (source: NOAA Climate Explorer, Blacksburg, VA in Montgomery County—Days with max >90°F, >95°F, Historical Observed).

Communities are built over a long time. Buildings and infrastructure are constructed to perform within a predictable range of conditions and are expected to be around for many decades, if not centuries. Similarly, natural systems, which contribute diverse and incalculable value to the surrounding community, are highly tied to a predictable set of climatic conditions for that region. Whole economies like agriculture and tourism revolve around predictability of the seasons. All of these systems become vulnerable and potentially unstable if climatic conditions change substantially.

Communities like Blacksburg will be well served by taking an honest look at the climate vulnerabilities they will be facing in the coming years and decades. Decisions we make now around infrastructure, land use, transportation investments, buildings, and public health can prepare us, not just to survive in a changing climate, but to thrive.

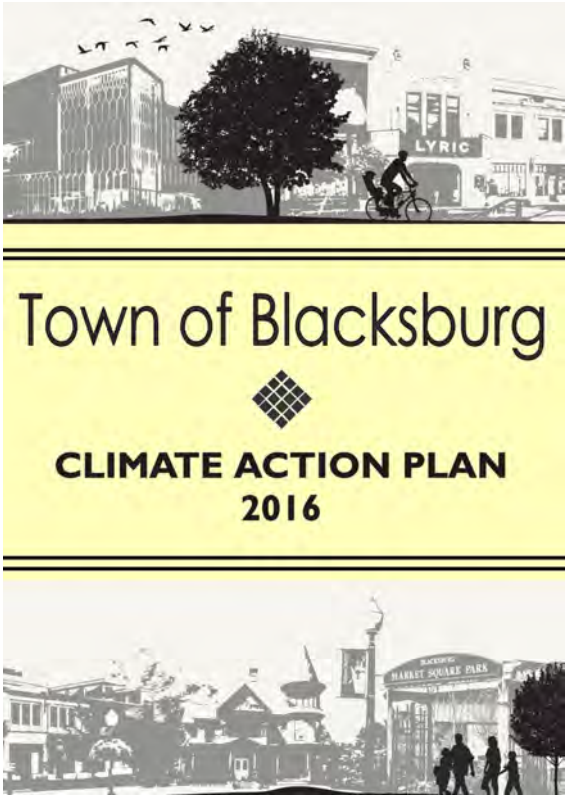
Introduction, Background & Process

Climate Action: Mitigation *and* Adaptation

Climate Change will be the defining challenge of the 21st century. Evidence continues to mount that continued inaction on greenhouse gas emissions could lead to catastrophic changes, destabilizing the very systems that support and sustain human civilizations. Billions of people will experience these changes through threats to public health, disruption of national and local economies, and food and water insecurity. Buildings and infrastructure will be increasingly impacted by the severity and frequency of weather events. For certain coastal communities, these threats will be amplified by rising sea levels.

A business-as-usual pattern of carbon emissions is likely to create 4°C of warming, and could lock in enough sea level rise to submerge land currently home to 470 to 760 million people, with unstoppable rise unfolding over centuries. By contrast, significant cuts to global carbon emissions limiting warming to 2°C could bring the number as low as 130 million people. Foreign policy experts increasingly warn that people internally displaced from sea level rise, droughts, wildfires, food insecurity, and super storms are considered a risk to domestic stability within their own countries and international security more broadly.

While a worldwide policy response to climate change is urgently required, a great deal of the action and implementation will have to take place at the local level. Back in 2007, Blacksburg was proud to join a growing list of U.S. cities that stepped forward to make a formal commitment to reduce their community's greenhouse gas emissions. In 2016, Blacksburg took a major step toward operationalizing that commitment by adopting a Climate Action Plan.



Blacksburg's Climate Action Plan (CAP) is solely focused on mitigation, and establishes a set of strategies that will enable Blacksburg to significantly reduce community-wide greenhouse gas emissions. While recognizing the seriousness of the climate crisis, the CAP does not attempt to evaluate ***how Blacksburg might be specifically vulnerable*** in a changing climate, or what we, as a community can do to prepare and adapt. Mitigation and adaptation measures are both clearly needed if we intend transition to a thriving, resilient future.

In the pages that follow, this Climate Vulnerability Assessment will demonstrate these area of heightened vulnerability for Blacksburg and will point toward a set of objectives for how Blacksburg can adapt.

Planning for the Unavoidable...and More

Climate change is already here. We can see the evidence in temperature records being broken year after year along with other accelerating indicators like sea level rise, melting glaciers, and more frequent and intense storms. Blacksburg has committed to doing its part to reduce its share of greenhouse gas emissions. At the same time, we also recognize that there is a certain amount of climate change that is unavoidable, even under a best-case scenario. Even if we are successful, not just locally, but as a global community in sharply reducing greenhouse gas emissions over the next decade, there is a certain amount of climate change that is simply "baked in" at this point. At a minimum, all communities should start planning now for how they will address the changes that are anticipated under this best case/low-emissions scenario. Despite near unanimity among climate scientists that this is a problem requiring urgent, bold, and coordinated action, it is increasingly unclear if the needed political leadership will emerge on the national and world stages to put us on a path to that lower-emission scenario. Therefore, common sense dictates that it would be wise to plan for higher-emissions scenarios as well.

Climate Metrics Considered

To evaluate the climate hazards Blacksburg may need to start planning for, thirteen key temperature and precipitation metrics were analyzed. Each of these metrics point to potential areas of vulnerability: to people, to natural systems, to the economy, and to infrastructure and basic services.

The climate metrics evaluated for this report include:

- **Cooling Degree Days** (indicator of energy required to cool buildings in warmer months)
- **Growing Degree Days** (indicator of agricultural production potential, as well as plant heat stress)
- **Modified Growing Degree Days** (indicator of heat-related plant stress for key agricultural staple crops)
- **Heating Degree Days** (indicator of energy required to heat buildings in cold months)
- **Days with Maximum Temperature > 90 degrees** (hot days—risk of heat stress)
- **Days with Maximum Temperature > 95 degrees** (very hot days—high risk of heat stress)
- **Days with Minimum Temperature < 32 degrees** (cold days)
- **Days with Maximum Temperature < 32 degrees** (very cold days)
- **Average Daily Minimum Temperature** (overnight temperatures)
- **Total Annual Precipitation** (indicator of changes to overall hydrological cycle)
- **Total Monthly Precipitation** (indicator of changes in seasonal precipitation)
- **Days with > 1" precipitation** (indicator of potential flooding events)
- **Dry Days, days with < .01" precipitation** (indicator of drought or change of precipitation frequency)

Introduction, Background & Process

Temporal, Emissions, and Geographic Scopes Evaluated

While it might seem intuitive that only local changes to the climate would be relevant, changes at the national level may prove to be just as impactful. At the local level, we can anticipate vulnerabilities for individuals, private property, natural systems, and infrastructure. At the national level, we may see complex, interdependent systems like the electric grid or networks of food production stressed, possibly to the breaking point. Extreme changes to the climate may even make some parts of the country less livable to its residents prompting populations to voluntarily displace.

With an eye toward development of an adaptation and resiliency plan, it is also useful to explore different time scales. For some adaptation strategies, a shorter time horizon is most appropriate (e.g. a public engagement campaign on mitigating heat stress for outdoor workers). For others, particularly those that involve investments in infrastructure or buildings, a focus on climate realities nearer the end of this century are more salient.

For these reasons, mid-century and end-of-century time scales, low- and high- emissions scenarios, and local and national geographic scopes were evaluated for each of the thirteen climate metrics under consideration in order to identify and prioritize the top climate hazards of concern for Blacksburg.

Temporal Scopes & Emissions Scenarios

Historical Averages:

Local Observed Historical Average (1950-2013)

Local Modeled Historical Average (1950-2006)

National Observed Historical Average (1961-1990)

Mid-Century Projections/Modeling

Local Modeled Low-Emissions Scenario (avg. 2036-2065)

Local Modeled High-Emissions Scenario (avg. 2035-2065)

National Model Low-Emission Scenario (avg. 2050s)

National Modeled High-Emissions Scenario (avg. 2050s)

End-of-Century Projections/Modeling

Modeled Low-Emissions Scenario (avg. 2065-2095)

Modeled High-Emissions Scenario (avg. 2065-2095)

National Model Low-Emission Scenario (avg. 2090s)

National Modeled High-Emissions Scenario (avg. 2090s)

Geographic Scopes

Local/Regional (Montgomery County, VA)

Low-Emissions Scenario

High-Emissions Scenario

Continental United States

High-Emissions Scenario

Identifying Top Climate Hazards

Evaluating each climate metric in this way indicates the primary climate hazards of concern for Blacksburg:

- **HOTTER SUMMERS** (Blacksburg and U.S.)
- **WARMER WINTERS** (Blacksburg and U.S.)
- **INCREASED PRECIPITATION** (Blacksburg) & **CHANGING PRECIPITATION PATTERNS** (U.S.)

Now that we have a sense of the degree of change (frequency, intensity) of each of the key climate metrics, we can turn our attention to what that might mean for Blacksburg. Specifically, what community systems might be most impacted?

Community Systems at Risk

Changes to the climate are expected to impact most aspects of our lives and livelihoods. Significant shifts in precipitation patterns and seasonal temperatures within and even beyond Blacksburg's borders have the potential to result in an array of local impacts that we can and should begin planning for today. However, in order to determine where the Town should focus its efforts, the critical community systems that may be at risk should first be identified. The table below organizes these community systems into four broad categories: people & community, natural systems, economy & employment, and infrastructure & basic services. Elements and systems that are critical to the functioning of our community and the well being of residents are listed below each heading.

Climate Hazards and Critical Community Systems: Potential Areas of Vulnerability

People & Community	Natural Systems	Economy & Employment	Infrastructure & Basic Services
A. Financial Wellbeing (HH)	G. Agriculture/Farming	L. Business Continuity	P. Emergency Services/Management
B. Food Security	H. Ecosystem Services	M. Employment Continuity	Q. Energy Access & Delivery
C. Homes & Buildings	I. Forests/Tree Cover	N. Industrial Operations	R. Internet & Communications
D. Human Health & Wellbeing	J. Hydrology/Watershed	O. Tourism	S. Law & Order
E. Population Displacement	K. Invasives/Species Shift		T. Stormwater Infrastructure
F. Public Safety			U. Transportation System
			V. Water Supply
			W. Water/Wastewater Infrastructure

Introduction, Background & Process

Prioritizing Risks

To be sure, not all community systems are created equal, nor will they be equally impacted by hotter summers, warmer winters, and changing precipitation patterns. For each of the thirteen climate metrics the following questions were used to evaluate the relative vulnerability of each community system:

What is the **POTENTIAL IMPACT** of a given climate metric on this community system? (low to high)

- Probability, frequency, and intensity of change
- Community systems that could be adversely impacted
- Types and degree of anticipated impact on each community system
- Geographic scope of impact (narrow to broad)
- Demographic scope + equity lens: likelihood of disproportionate impacts on frontline communities

How much **ADAPTIVE CAPACITY** exists to mitigate these anticipated impacts? (high to low)

- Practical or technological feasibility of adaptation measures
- Degree of local control to enact adaptation measures
- Available resources to pursue adaptation measures

Within each chapter, a **CRITICAL COMMUNITY SYSTEMS TABLE** and **RISK PRIORITIZATION MATRIX** offer a snapshot of the community systems most at risk from each climate hazard. The Critical Community Systems Table is broken up into four groupings: People & Community, Natural Systems, Economy & Employment, and Infrastructure & Basic Services.

PEOPLE AND COMMUNITY

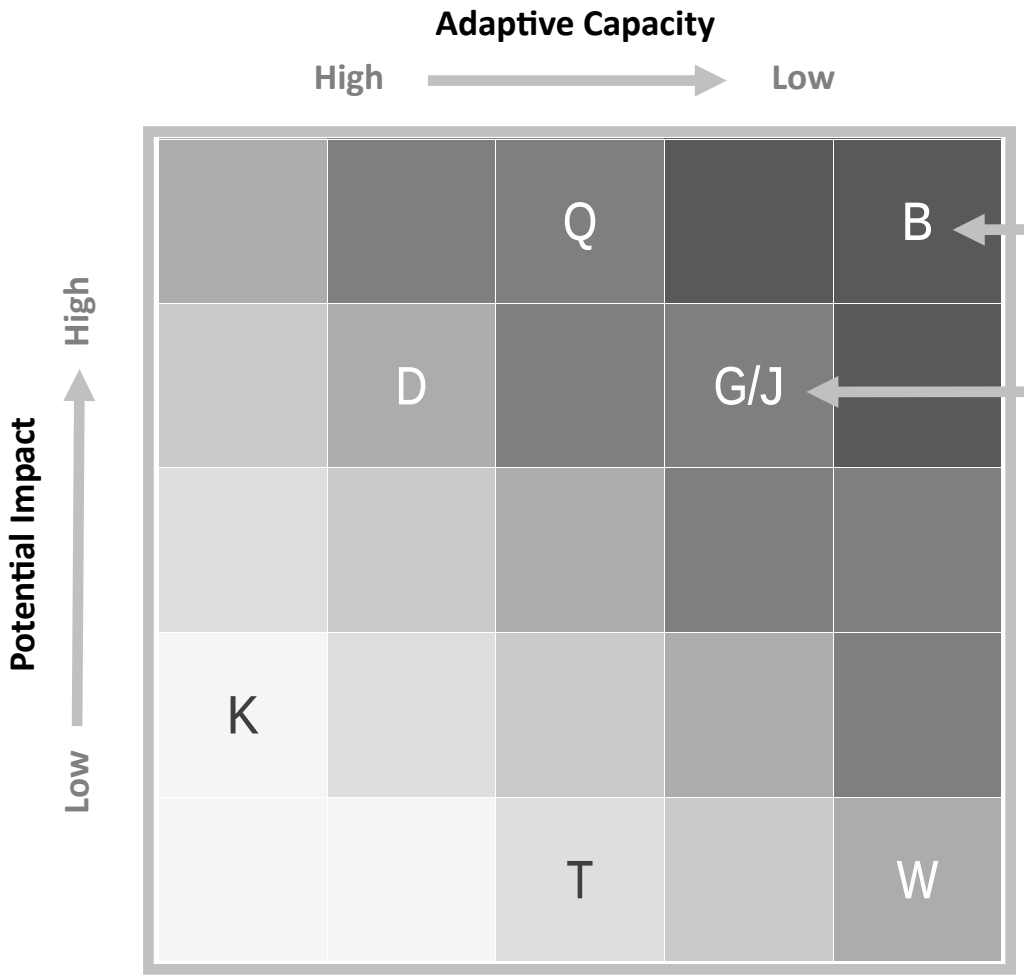
NATURAL SYSTEMS

ECONOMY AND EMPLOYMENT

INFRASTRUCTURE AND BASIC SERVICES

Note that the letters A-W in both the table and matrix correspond with one another. For both, the darker squares indicate the community systems that may be the most vulnerable in a changing climate. It is these areas of heightened potential vulnerability that will warrant special attention and focus for climate adaptation policy-making.

Critical Community Systems: Potential Areas of Vulnerability (Sample)			
People & Community	**Natural Systems**	**Economy & Employment**	**Infrastructure & Basic Services**
A. Financial Wellbeing (HH)	G. Agriculture/Farming	L. Business Continuity	P. Emergency Services/Management
B. Food Security	H. Ecosystem Services	M. Employment Continuity	Q. Energy Access & Delivery
C. Homes & Buildings	I. Forests/Tree Cover	N. Industrial Operations	R. Internet & Communications
D. Human Health & Wellbeing	J. Hydrology/Watershed	O. Tourism	S. Law & Order
E. Population Displacement	K. Invasives/Species Shift		T. Stormwater Infrastructure
F. Public Safety			U. Transportation System
			V. Water Supply
			W. Water/Wastewater Infrastructure



In the chapters that follow, you will find a paired community systems table (above) with a risk matrix (left) similar to the samples shown here.

These show the anticipated degree of risk for each community system relative to Blacksburg's primary climate hazards:

Hotter Summers
Warmer Winters
Changing Precipitation

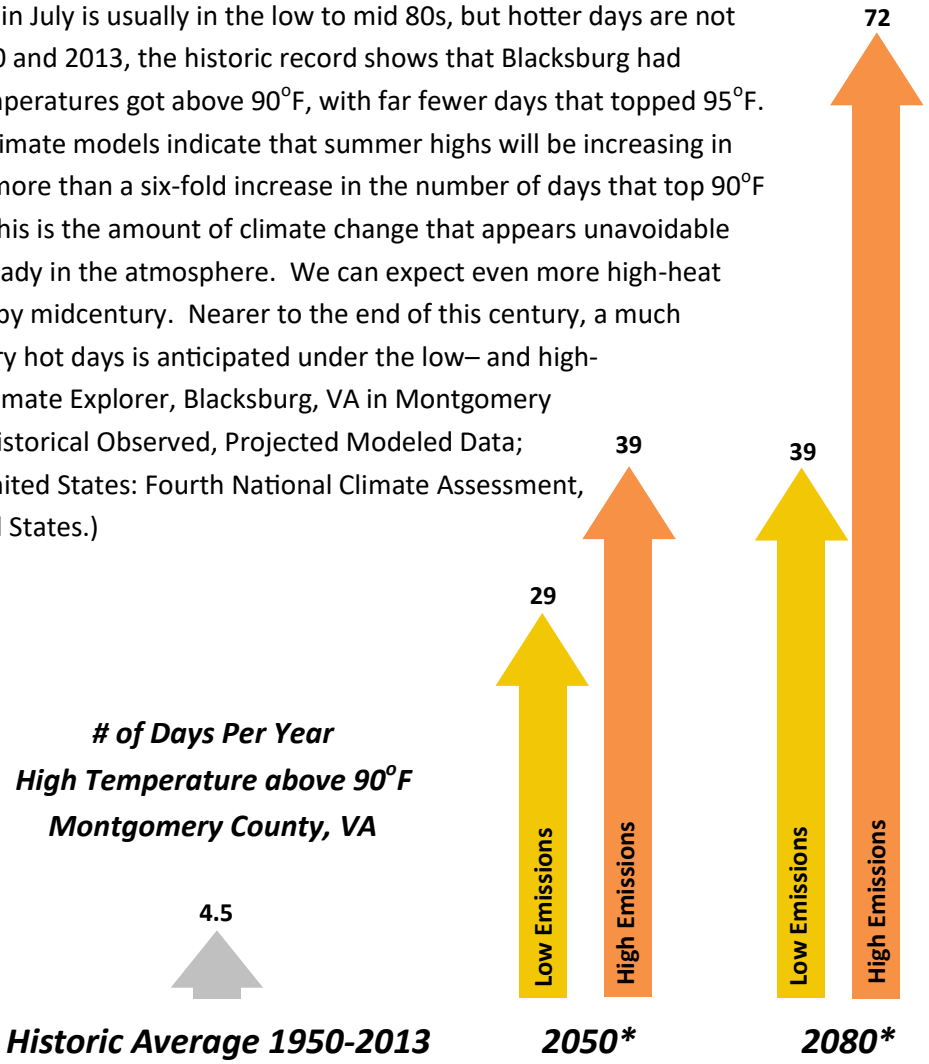
Proposed adaptation strategies will center around areas of highest anticipated risk (darker squares).

HOTTER SUMMERS

Hazard: Hotter Summers in Blacksburg

In Blacksburg, the average temperature in July is usually in the low to mid 80s, but hotter days are not unheard of in our region. Between 1950 and 2013, the historic record shows that Blacksburg had around 4-5 days per year where the temperatures got above 90°F, with far fewer days that topped 95°F. Looking ahead, the weighted mean of climate models indicate that summer highs will be increasing in our area. By 2050, we are likely to see more than a six-fold increase in the number of days that top 90°F even under a low-emissions scenario. This is the amount of climate change that appears unavoidable based on greenhouse gas emissions already in the atmosphere. We can expect even more high-heat days under a higher emissions scenario by midcentury. Nearer to the end of this century, a much sharper divergence in the number of very hot days is anticipated under the low– and high-emissions scenarios. (sources: NOAA Climate Explorer, Blacksburg, VA in Montgomery County—Days with max >90°F, >95°F, Historical Observed, Projected Modeled Data; Impacts, Risks, and Adaptation in the United States: Fourth National Climate Assessment, Volume II, Chapter 19, Southeast United States.)

Outdoor workers and people who lack air conditioning may experience extreme discomfort or heat illness on hot days, especially if humidity is high and wind is light. Hot days also stress plants, animals, and infrastructure such as electric lines, roads, and rails. Increased demand for electricity to cool homes and businesses also stresses energy infrastructure on hot days.



**30 year averages around each target year for low– and high-emissions scenarios; 2035-2065 and 2065-2095, respectively*

Climate modeling for our area also indicate other measures of heat increasing over the next century, with a range of potential impacts to people & community, natural systems, economy & employment, and infrastructure & basic services.

Frontline Communities & Hotter Summers

Frontline communities are likely to be disproportionately impacted by hotter summers. For instance, if someone is suffering from asthma that is exacerbated by an extended heat wave, and they don't have health insurance...how would they get the medical help they need? As we evaluate the range of possible adaptation strategies to hotter summers in Blacksburg, frontline communities should be at the decision-making table to guide the process of identifying and developing the policies and programs that will best align with their needs.

- Age factors (very young and very old)
- Complex health challenges
- Mobility, sensory or cognitive impairments
- Limited social connection or support networks
- Limited financial resources
- Working outdoors or in unconditioned spaces
- Inadequate, unstable or unaffordable housing
- Insecure or unaffordable transportation
- Language or cultural barriers

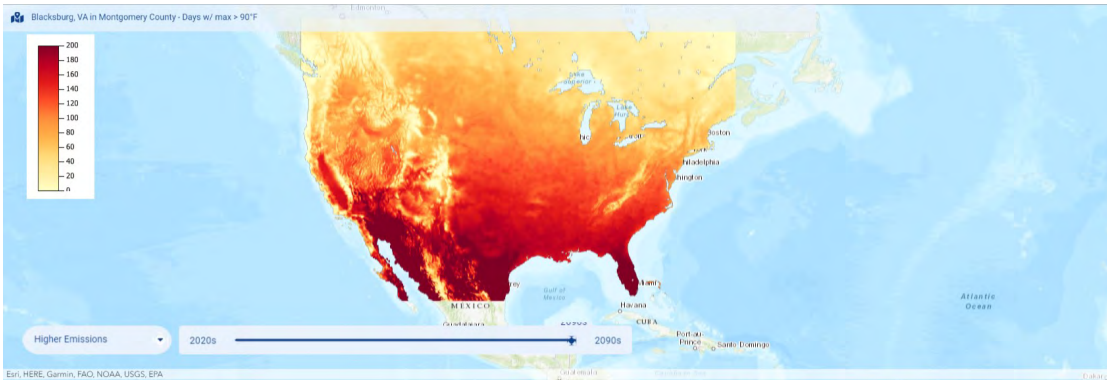
Hazard: Hotter Summers across the United States

Increasing heat beyond Blacksburg's borders also has the potential to create local impacts. The maps below compare different scenarios for # of days with a maximum temperature above 90°F. The top map shows the historical average, while the middle and bottom maps show the anticipated # of high-heat days across the continental United States by midcentury under low–emissions and end of century under a high-emissions scenarios, respectively. While an overall warming trend is indicated, note that greater relative warming that is expected for the South and Midwest. What might this mean for agricultural productivity and overall food security? Or for population migration due to water scarcity or wildfire risk? Or the range of certain disease-vector insects? In addition to the local heat-related hazards identified on the previous page, increasing summer heat at the national scale has the potential to create local impacts that should also be considered as we evaluate Blacksburg's vulnerabilities to climate change.

United States: # of Days Per Year with Maximum Temperature > 90°F

Historical Average 1961-1990

Low-Emissions Scenario 2050s



High-Emissions Scenario 2090s

Climate Metrics: Hotter Summers in Blacksburg & the U.S.

Hotter Summers: Key Climate Metrics & Findings

Of the thirteen climate metrics evaluated, these six point to an array of potential vulnerabilities for Blacksburg.

Cooling Degree Days (CDDs)

- The number of cooling degree days reflects the amount of energy typically used to cool a building when it is warm outside. At the household level, increasing cooling degree days will disproportionately impact low-income households, and people without air-conditioning or who live in older less energy-efficient homes. At the regional and national level, increasing cooling degree days points to the potential for energy infrastructure to become stressed beyond its capacity.

Modified Growing Degree Days

- Corn growers use the number of modified growing degree days to monitor the development of corn crops. As corn development occurs only when temperature is above 50°F but below 86°F, the standard calculation for growing-degree days is modified to omit conditions outside this range. In future decades, regions where temperatures regularly exceed 86°F may be less successful in growing corn and potentially other staple crops that form the backbone of our food system.

Days with Max Temp > 90 degrees and **Days w/Max Temp > 95 degrees** (hot and very hot days)

- Outdoor workers and people who lack air conditioning may experience extreme discomfort or heat illness on hot days, especially if humidity is high and wind is light. Hot days also stress plants, animals, and infrastructure such as electric lines, roads, and rails. A significant anticipated increase in hot and very hot days will lead to higher and more frequent peak demand for electric power, further stressing the electricity grid and increasing the risk of power interruptions.

Average Daily Minimum Temperature and **Days with Minimum Temperature > 80 degrees**

- A day's lowest (minimum) temperature usually occurs in the early morning, just before sunrise. Averaging the daily low temperatures for any period results in a mean minimum temperature for that period. These daily periods of low temperature give plants, animals, and people a chance to recover from daytime heat. When daily minimum temperatures aren't sufficiently cool, plant and animal responses can trigger ecosystem changes. The # of warm nights associated with rising average daily minimum temperatures, especially # of days with minimum temperature above 80 degrees can also increase the demand for energy in a 24-hour period and can stress energy infrastructure.

Prioritized Areas of Risk: Hotter Summers

Prioritized Areas of Risk

To identify areas of heightened potential vulnerability, climate metrics for hotter summers were evaluated relative to critical community systems for Blacksburg. In addition to evaluating the direction of anticipated change for these climate metrics, the following factors were explored to evaluate overall risk:

What is the **POTENTIAL IMPACT** of **HOTTER SUMMERS** on our critical community system? (low to high)

- Probability, frequency, and intensity of change
- Community systems that could be impacted
- Types and degree of anticipated impact on each community system
- Geographic scope of impact (narrow to broad)
- Demographic scope + equity lens: likelihood of disproportionate impacts on frontline communities

How much **ADAPTIVE CAPACITY** exists to mitigate these anticipated impacts? (high to low)

- Practical or technological feasibility of adaptation measures
- Degree of local control to enact adaptation measures
- Available resources to effectively pursue adaptation measures

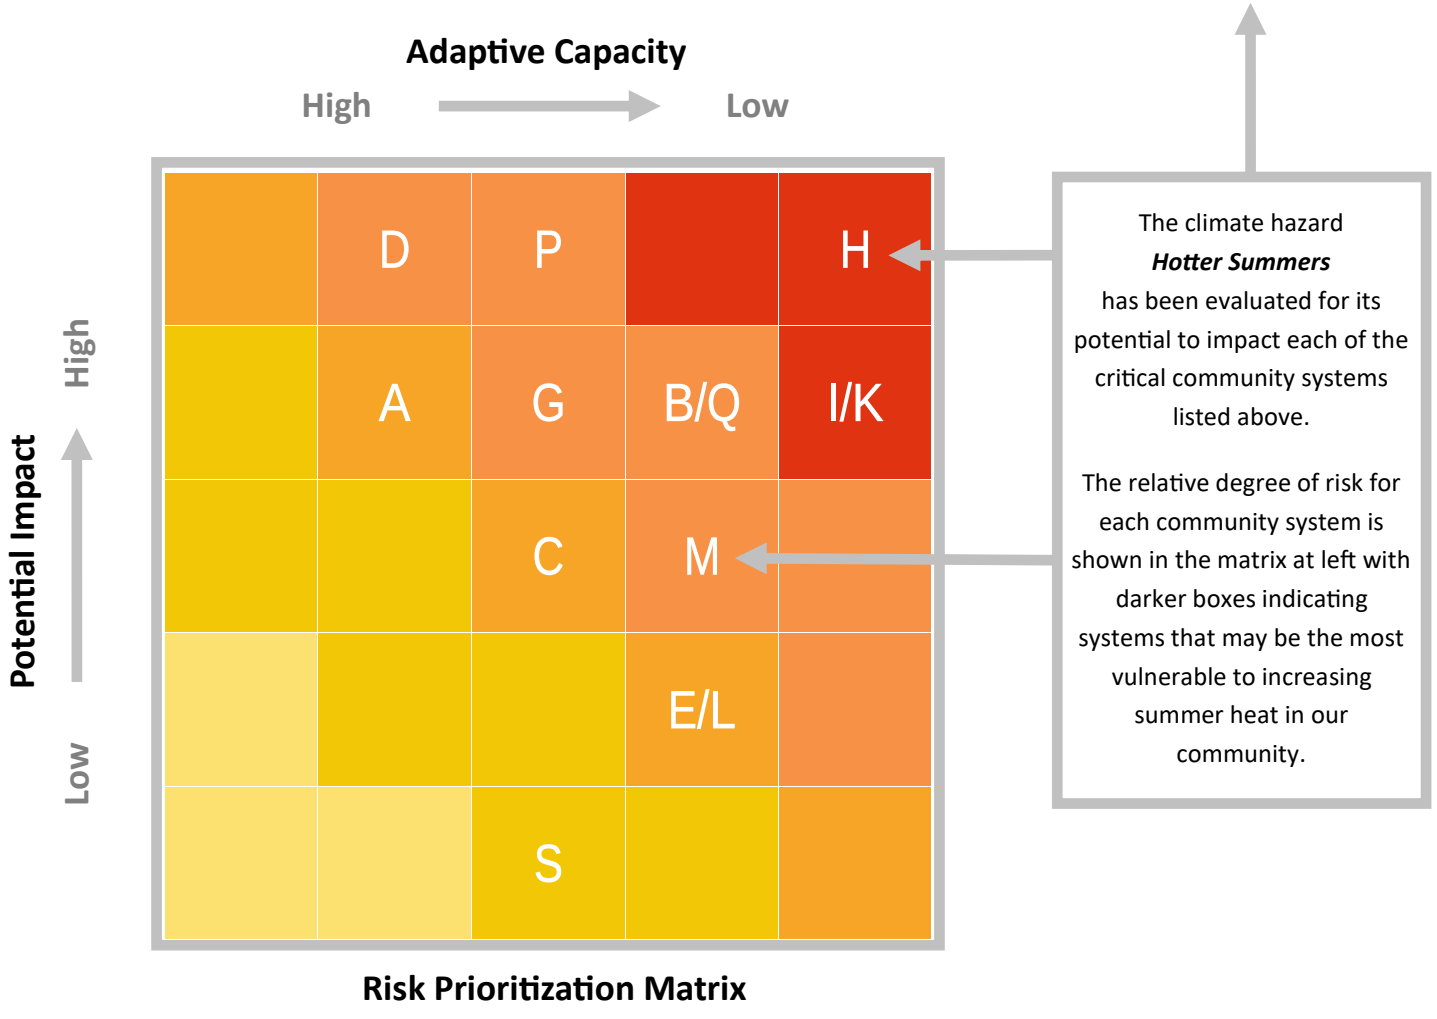
The **COMMUNITY SYSTEMS TABLE** and **RISK PRIORITIZATION MATRIX** on the following page offer a snapshot of the community systems most at risk from hotter summers. At a glance, it is apparent that hotter summers have the potential to disrupt most of our community's critical systems to some degree. Note that the letters A-W in the risk matrix correspond to the community systems listed in the community systems table above it. The darker squares indicate the systems that may be the most vulnerable to increasing heat in our community. It is these areas of heightened potential vulnerability that will warrant special attention and focus for climate adaptation policy-making.

To be sure, the task before us is daunting. For some of the community systems most at risk (ecosystem services), the scale of the challenge and our capacity to implement effective adaptation strategies seem quite limited. For others, (public health) a path forward to address heat stress and heat illness for vulnerable segments of the population may be more straightforward.

The following pages list out some recommended adaptation paths for community systems most at risk from hotter summers. Translating these recommendations into actionable policies and programs will require further collaboration with frontline communities, decision-makers and other stakeholders to ensure the resulting adaptation and resilience strategies are realistic, effective, and equitable.

Hotter Summers and Critical Community Systems: Potential Areas of Vulnerability

People & Community	Natural Systems	Economy & Employment	Infrastructure & Basic Services
A. Financial Wellbeing (HH)	G. Agriculture/Farming	L. Business Continuity	P. Emergency Services/Management
B. Food Security	H. Ecosystem Services	M. Employment Continuity	Q. Energy Access & Delivery
C. Homes & Buildings	I. Forests/Tree Cover	N. Industrial Operations	R. Internet & Communications
D. Human Health & Wellbeing	J. Hydrology/Watershed	O. Tourism	S. Law & Order
E. Population Displacement	K. Invasives/Species Shift		T. Stormwater Infrastructure
F. Public Safety			U. Transportation System
			V. Water Supply
			W. Water/Wastewater Infrastructure



Adaptation & Resilience Strategies: Hotter Summers

People and Community

Community System at Risk	Anticipated Impacts	Sources
Food Security	>> reduced ag output, rising food prices	21,22,23,25
Human Health & Wellbeing	>> heat related illness, quality of life	8,9,11,12

Natural Systems

Community System at Risk	Anticipated Impacts	Sources
Agriculture/Farming	>> reduced ag output and quality	18, 19, 20
Ecosystem Services	>> loss of biodiversity	6
Forests/Tree Cover	>> loss of heat intolerant tree species	6
Invasive Species	>> shift of invasive plants, insects	6

Economy and Employment

Community System at Risk	Anticipated Impacts	Sources
Employment Continuity	>> reduced productivity, outdoor workers	10, 13, 16

Infrastructure and Basic Services

Community System at Risk	Anticipated Impacts	Sources
Emergency Services/Mgmt	>> increase demand for EMS, urgent care	14
Energy Access & Delivery	>> critical stress on electrical grid	15

Adaptation & Resilience Strategies: Hotter Summers

Recommendations: Hotter Summers + People and Community

- Convene a climate food resiliency and security stakeholder team for the region; develop a food resiliency plan.
- Develop a community heat action plan strategy >> advocate for adoption into regional heat action plan.

Recommendations: Hotter Summers + Natural Systems

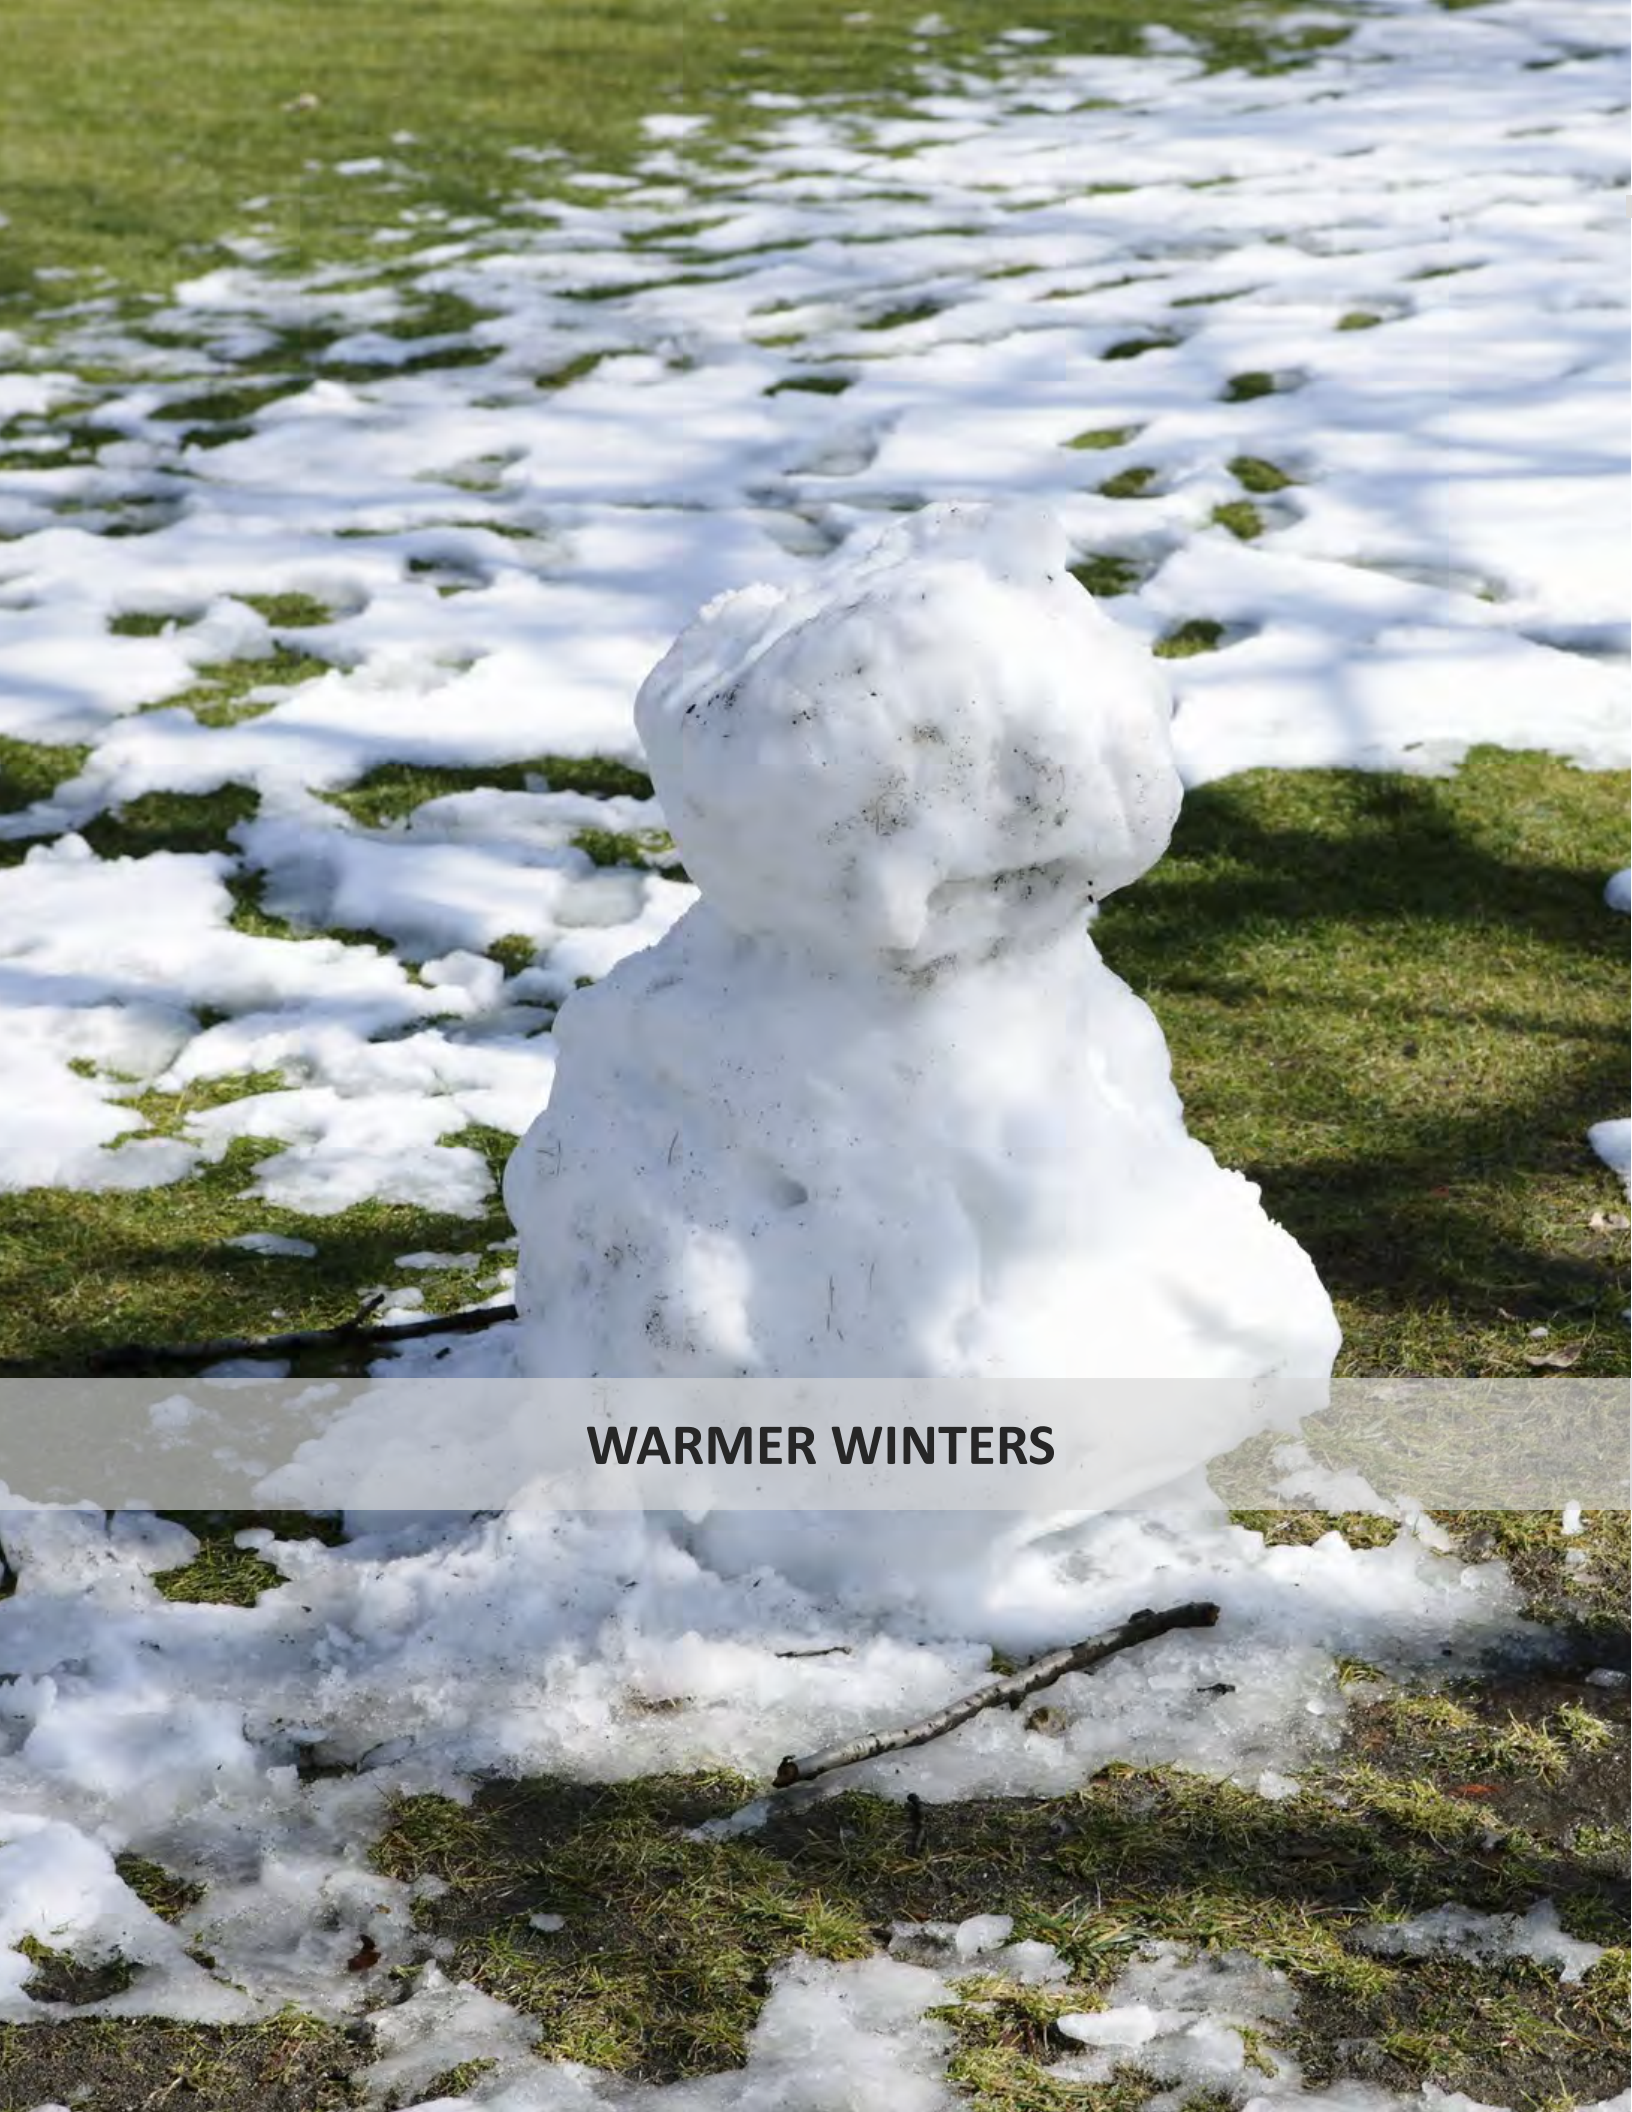
- Identify and foster agricultural climate adaptation best practices (collaboration with ag extension).
- Protect open and natural spaces to serve a reservoir for biodiversity.
- Offer incentives/establish policies to plan tree species on private and public lands that are more heat tolerant.
- Develop invasive species management plans for public lands; encourage private landowners to adopt practices.

Recommendations: Hotter Summers + Economy & Employment

- Develop a hot weather employment safety and continuity plan (integrate into regional heat action plan)

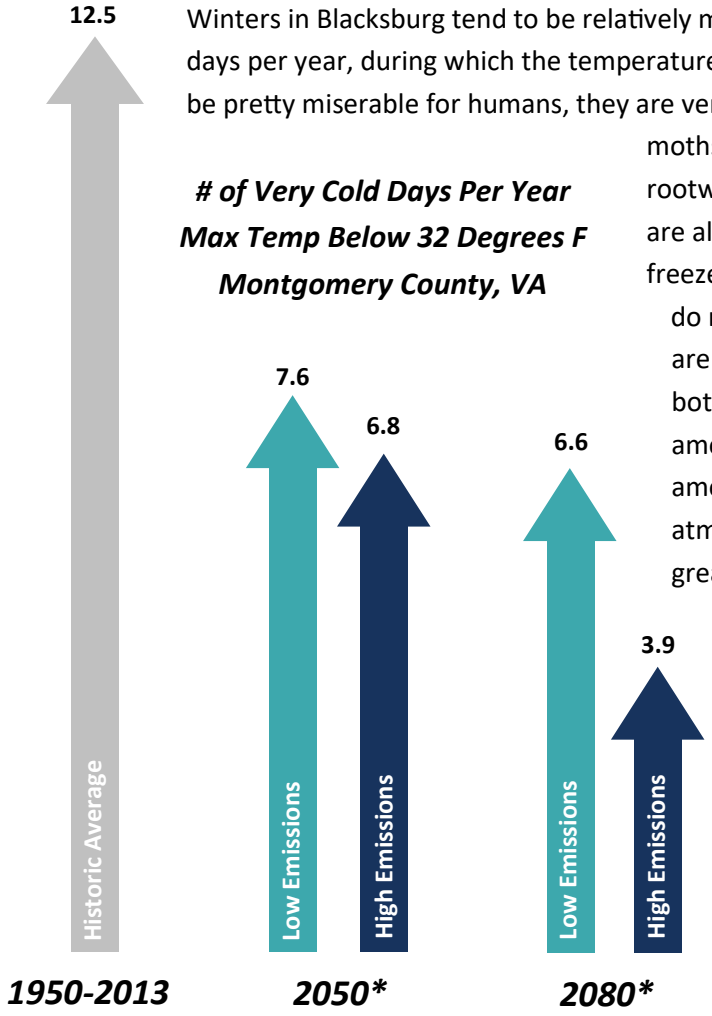
Recommendations: Infrastructure & Basic Services

- Develop a hot weather response plan for EMS and healthcare facilities (integrate into regional heat action plan)
- Provide accessible/cost-effective options for individuals to be safe in their homes and at work from heat illness



WARMER WINTERS

Hazard: Warmer Winters in Blacksburg



# of Very Cold Days Per Year
Max Temp Below 32 Degrees F
Montgomery County, VA

Winters in Blacksburg tend to be relatively mild. Traditionally, we have around a dozen deep freeze days per year, during which the temperature never gets above 32 degrees F. Although these days can be pretty miserable for humans, they are very important for the health of farms and forests. Gypsy moths, hemlock woolly adelgids, emerald ash borers, corn rootworm, southern pine beetles, and marmorated stink bugs are all susceptible to very cold temperatures. With fewer deep freeze events, populations of these pest insects may flourish and do major damage to our local forests and farms. By 2050, we are likely to see the number of very cold days cut in half under both the low-emissions and high-emissions scenarios. This amount of climate change appears unavoidable based on the amount of greenhouse gas emissions already in the atmosphere. Nearer to the end of this century, there is greater anticipated divergence between the low– and high-emissions scenarios, and the number of very cold days could fall to less than a third of the historic average. In addition to a reduction in the number of very cold days and deep freeze events, average daily temperatures in the winter months are expected to rise. This may bring about an additional agricultural challenge due to a reduction in "chill hours", periods when the temperature hovers just above freezing. Many fruit-bearing trees require a certain number of chill hours in order to produce fruit the following year.

**30 year averages around each target year for low– and high-emissions scenarios; 2035-2065 and 2065-2095, respectively*

Climate modeling for our area also indicate other measures of winter warming over the next century, with a range of potential impacts to people & community, natural systems, economy & employment, and infrastructure & basic services.

Frontline Communities & Warmer Winters

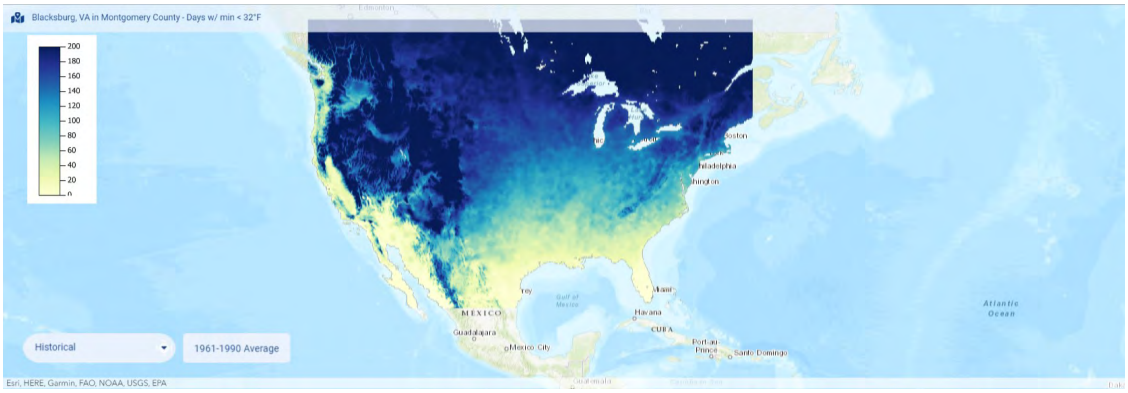
At the local geographic scale, warmer winters may not seem to pose much of a disproportionate risk to frontline communities, in fact, there is likely to be reduced energy cost burden in the winter months, a challenge for many low-income households. At a national geographic scale, however, warmer winters are anticipated to be very disruptive to ecological cycles and agricultural productivity. Warmer winters may also extend the range of disease-carrying insects farther north. As a result, vector-borne diseases and food insecurity may both rise.

- Age factors (very young and very old)
- Complex health challenges
- Mobility, sensory or cognitive impairments
- Limited social connection or support networks
- Limited financial resources
- Working outdoors or in unconditioned spaces
- Inadequate, unstable or unaffordable housing
- Insecure or unaffordable transportation
- Language or cultural barriers

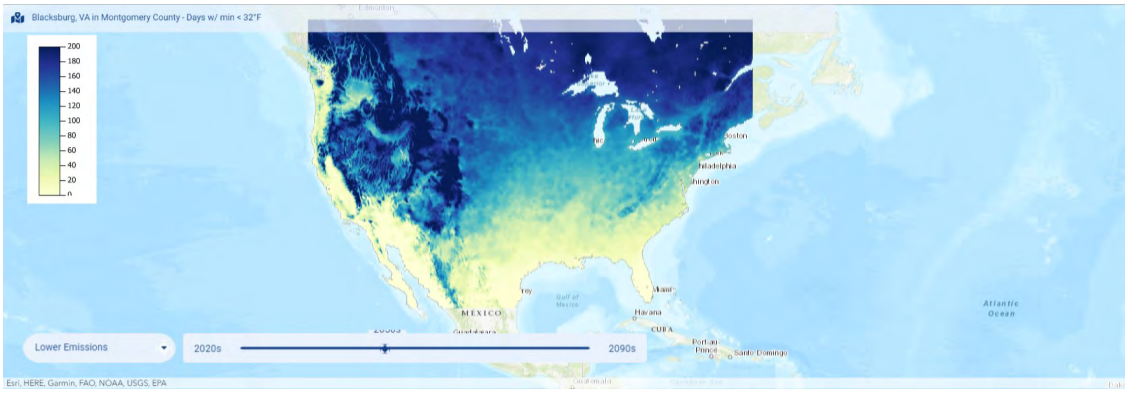
Hazard: Warmer Winters in the United States

In addition to concerns about the affect of warmer winters on farms and forests there are also public health implications to consider, namely that warmer winters across much of the U.S. are likely to expand the territory of human disease vector insects carrying tropical illnesses like malaria, yellow fever, Zika, dengue, and Chagas disease. Of these tropical diseases, dengue is probably the most concerning for Blacksburg and the surrounding region, as the northernmost bound of this virus is just to the south of us and may reach our area by 2085. For tick– and mosquito-borne diseases that are already here such as Lyme disease, Rocky Mountain Spotted Fever, and West Nile Virus, warmer winters will likely increase the number of ticks and mosquitoes that are able to survive the winter and expand the number of months per year when they are active.

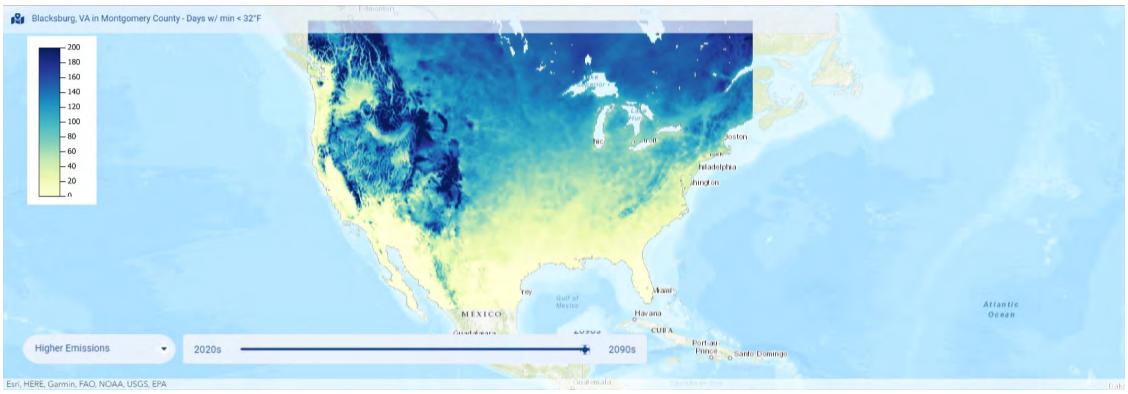
United States: # of Days Per Year with Minimum Temperature Below 32°F



Historical Average 1961-1990



Low-Emissions Scenario 2050s



High-Emissions Scenario 2090s

Climate Metrics: Warmer Winters in Blacksburg & the U.S.

Warmer Winters: Key Climate Metrics & Findings

Of the thirteen climate metrics evaluated, these three point to a mix of vulnerabilities and other outcomes for Blacksburg.

Heating Degree Days (HDDs)

- The number of heating degree days at any location reflects the amount of energy people use to heat a building when it is cool outside. Lower numbers of heating degree days indicate lower demand for energy. Heating degree days measure how much (in degrees), and for how long (in days), outside air temperature is below 65°F. Engineers and utility companies use a location's annual number of heating degree days as one input when estimating demand for energy in the cold season.

Days with Minimum Temperature < 32 degrees (cold days)

- The total number of days per year when the temperature dips below 32°F (0°C) is an indicator of how often cold days occur. A decrease in the number of days temperature drops below freezing promotes earlier spring snowmelt and runoff, with important consequences for managing water resources. Below-freezing temperatures can cause driving hazards, aircraft icing, and damage to infrastructure, yet ski resorts and other winter recreation businesses depend on sufficiently cold days to maintain snowpack. Some plants require a cumulative number of days below freezing before they can begin budding or blooming in the spring.

Days with Maximum Temperature < 32 degrees (very cold days)

- The total number of days per year when the highest temperature is less than 32°F (0°C) is an indicator of how often very cold days occur. Days when the highest temperature doesn't rise above the freezing point of water are called "icing days." The annual number of icing days tells us how much rest plants get from growing. With too few icing days, some plants do not perceive a "reset" signal to begin budding or blooming in the spring. The annual number of icing days can also help predict how populations of pest and disease-vector insects will grow or shrink in response to changing seasonal patterns.

Prioritized Areas of Risk: Warmer Winters

Prioritized Areas of Risk

To identify areas of heightened potential vulnerability, climate metrics for warmer winters were evaluated relative to critical community systems for Blacksburg. In addition to evaluating the direction of anticipated change for these climate metrics, the following factors were explored to evaluate overall risk:

What is the **POTENTIAL IMPACT** of **WARMER WINTERS** on our critical community systems? (low to high)

- Probability, frequency, and intensity of change
- Community systems that could be impacted
- Types and degree of anticipated impact on each community system
- Geographic scope of impact (narrow to broad)
- Demographic scope + equity lens: likelihood of disproportionate impacts on frontline communities

How much **ADAPTIVE CAPACITY** exists to mitigate these anticipated impacts? (high to low)

- Practical or technological feasibility of adaptation measures
- Degree of local control to enact adaptation measures
- Available resources to effectively pursue adaptation measures
- Available resources to effectively pursue adaptation measures

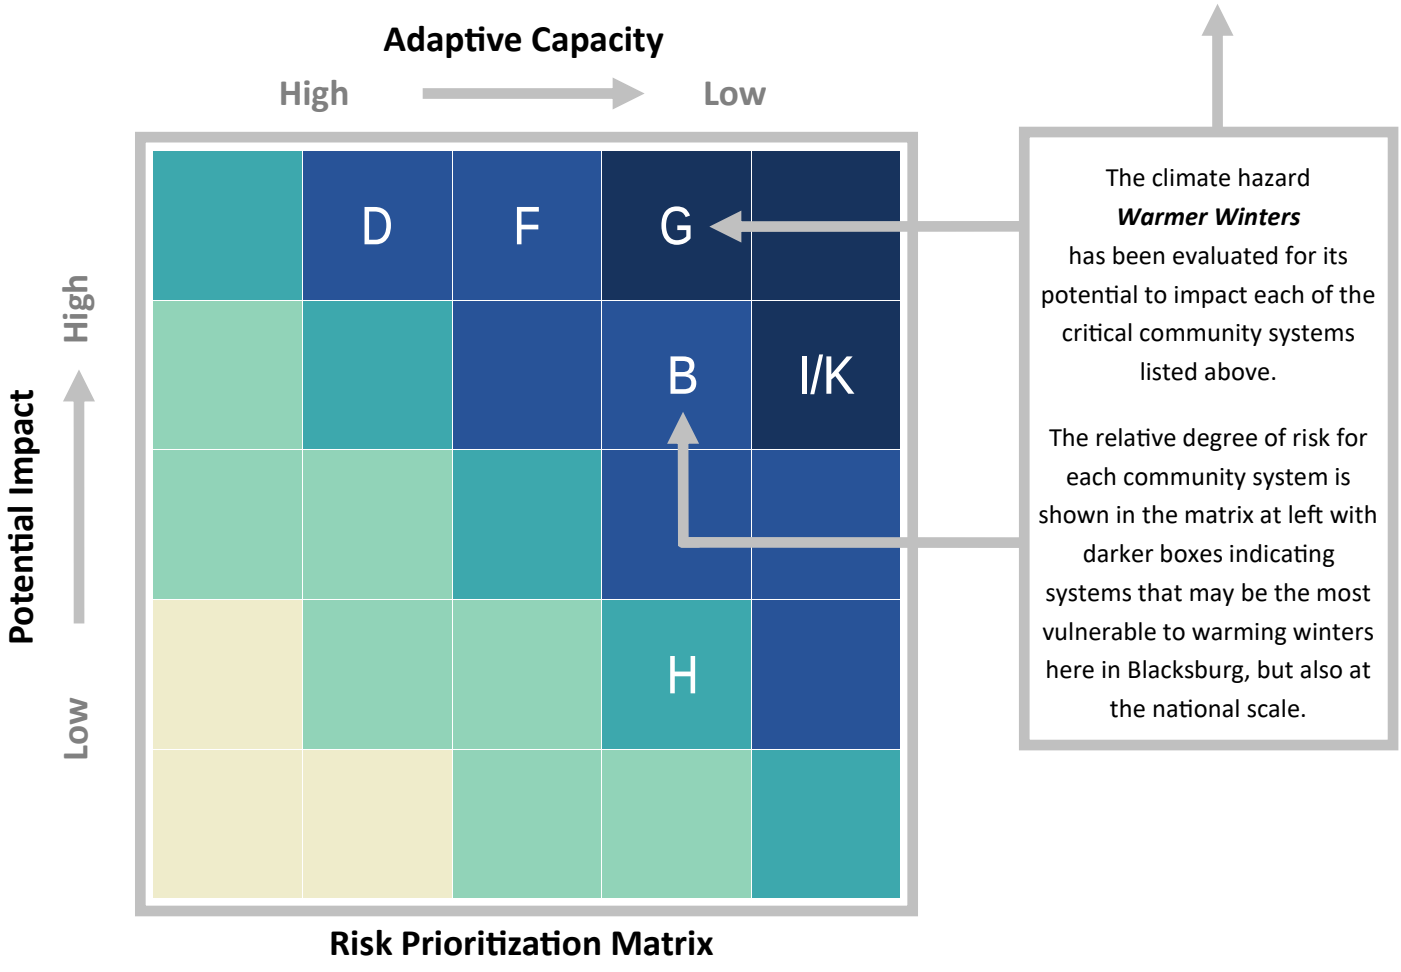
The **COMMUNITY SYSTEMS TABLE** and **RISK PRIORITIZATION MATRIX** on the following page offer a snapshot of the community systems most at risk from warmer winters. At a glance, it is apparent that warmer winters have the greatest potential to disrupt our natural systems with additional worrying impacts to food security and human health. Note that the letters A-W in the risk matrix correspond to the community systems listed in the community systems table above it. The darker squares indicate the systems that may be the most vulnerable to warmer winters in our community and beyond. It is these areas of heightened potential vulnerability that will warrant special attention and focus for climate adaptation policy-making.

As with hotter summers, warmer winters' potential to affect agricultural productivity at the national and international scale is worrying. Similarly, northward spread of disease vector insects, invasive species, and agricultural pests is likely. Local forestlands, with tree species that are accustomed to a certain climatic range may become stressed. All of these risks are very challenging to adapt to at the local level.

The following pages list out some recommended adaptation paths for community systems most at risk from warmer winters. Translating these recommendations into actionable policies and programs will require further collaboration with frontline communities, decision-makers, and other stakeholders to ensure the resulting adaptation and resilience strategies are realistic, effective, and equitable.

Prioritized Areas of Risk: Warmer Winters

Warmer Winters and Critical Community Systems: Potential Areas of Vulnerability			
People & Community	**Natural Systems**	**Economy & Employment**	**Infrastructure & Basic Services**
A. Financial Wellbeing (HH)	**G. Agriculture/Farming**	L. Business Continuity	P. Emergency Services/Management
B. Food Security	**H. Ecosystem Services**	M. Employment Continuity	Q. Energy Access & Delivery
C. Homes & Buildings	**I. Forests/Tree Cover**	N. Industrial Operations	R. Internet & Communications
D. Human Health & Wellbeing	J. Hydrology/Watershed	O. Tourism	S. Law & Order
E. Population Displacement	**K. Invasives/Species Shift**		T. Stormwater Infrastructure
F. Public Safety			U. Transportation System
			V. Water Supply
			W. Water/Wastewater Infrastructure



The climate hazard ***Warmer Winters*** has been evaluated for its potential to impact each of the critical community systems listed above.

The relative degree of risk for each community system is shown in the matrix at left with darker boxes indicating systems that may be the most vulnerable to warming winters here in Blacksburg, but also at the national scale.

Anticipated Impacts: Warmer Winters in Blacksburg

People and Community

Community System at Risk	Anticipated Impacts	Sources
Food Security	>> reduced ag output, rising food prices	28, 29
Human Health & Wellbeing	>> increased risk of disease vector insects	27, 30-41
Public Health	>> introduction of novel diseases	35, 37

Natural Systems

Community System at Risk	Anticipated Impacts	Sources
Agriculture/Farming	>> reduced ag output and quality	29,30
Forests & Tree Cover	>> loss of trees intolerant to warmer winters	27
Invasives/Species Shift	>> geographic shift of invasive plants/insects	27

Economy and Employment

Limited Adverse Impact

Infrastructure and Basic Services

Limited Adverse Impact

Adaptation & Resilience Strategies: Warmer Winters in Blacksburg

Recommendations: Warmer Winters + People and Community
• Convene a climate food resiliency and security stakeholder team for the region; develop a food resiliency plan.
• Engage the public on behaviors and best practices to reduce residents' exposure to insect borne diseases.
• Develop an action plan to mitigate insect-borne disease; special focus on outdoor workers and vulnerable groups.

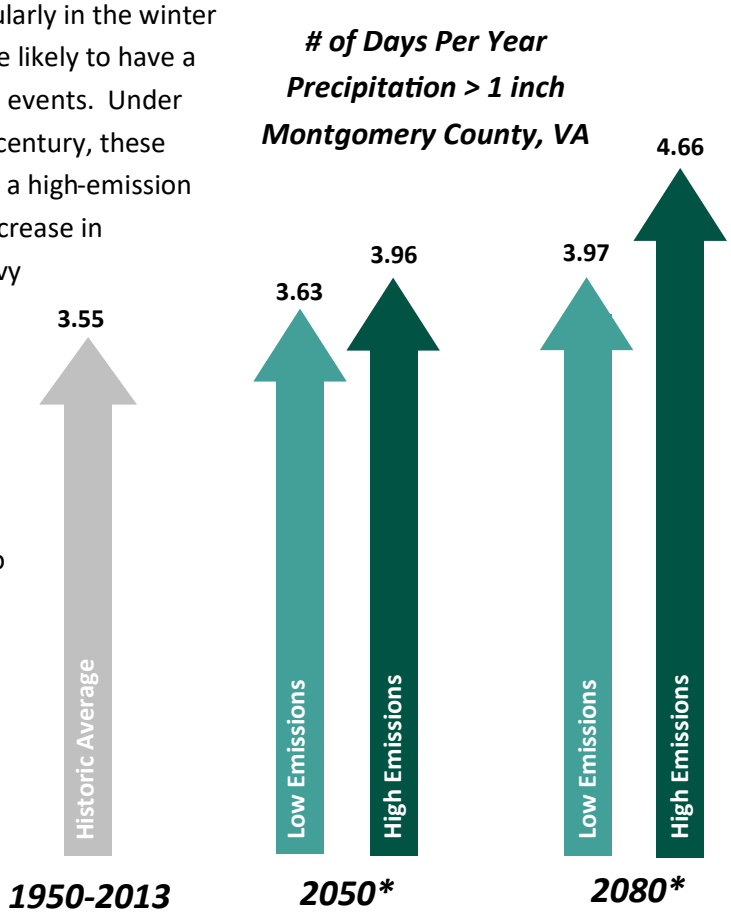
Recommendations: Warmer Winters + People and Community
• Identify and promote agricultural climate adaptation best practices
• Offer incentives/establish polices to plant tree species on private and public lands that are suited to warmer temps
• Develop invasive species management plans for public lands; encourage private landowners to adopt practices.

CHANGING PRECIPITATION PATTERNS

Hazard: Increased Precipitation in Blacksburg

Blacksburg typically gets between 38-39" of rain per year. While many parts of the country are anticipated to experience reduced precipitation and even severe drought conditions due to climate change, it appears that precipitation will be increasing in Blacksburg, particularly in the winter months. Climate modeling also indicates that we are likely to have a modest increase in the annual number of heavy rain events. Under both the low– and high-emissions scenarios by mid-century, these changes are likely to be nearly imperceptible. Under a high-emission scenario, however, we may see as much as a 31% increase in heavy rainfall events by the end of the century. Heavy rainfall events always have the potential to create flooding risks, putting people in harms way, and increasing the likelihood of costly damage to buildings and infrastructure.

While more overall precipitation is anticipated for the region, we are also (paradoxically) anticipated to have a slight increase in the number of dry days. Longer dry periods between rains, particularly heavier ones, can actually raise the risk of destructive flooding and even forest fires. Overall, there is a lot of uncertainty about how local ecosystems and the built environment could be impacted by changing precipitation patterns.



**30 year averages around each target year for low– and high-emissions scenarios; 2035-2065 and 2065-2095, respectively*

Climate modeling for our area also indicate other measures of changing precipitation patterns over the next century, with a range of potential impacts to people & community, natural systems, economy & employment, and infrastructure & basic services.

Frontline Communities & Precipitation Patterns

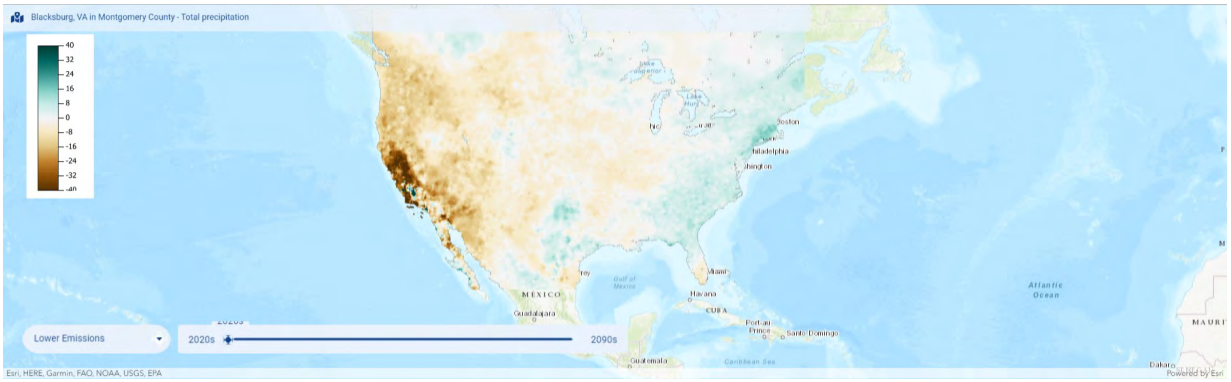
At the local geographic scale, total precipitation is anticipated to increase which may pose a disproportionate risk to frontline communities, who are statistically more likely to live in flood-prone areas. At a national geographic scale, widespread hydrological changes are anticipated. Some areas will see a substantial increase in annual precipitation while others will encounter drier conditions. Both are anticipated to be very disruptive to ecological cycles and agricultural productivity. As a result, vector-borne diseases and food insecurity may both rise.

- Age factors (very young and very old)
- Complex health challenges
- Mobility, sensory or cognitive impairments
- Limited social connection or support networks
- Limited financial resources
- Working outdoors or in unconditioned spaces
- Inadequate, unstable or unaffordable housing
- Insecure or unaffordable transportation
- Language or cultural barriers

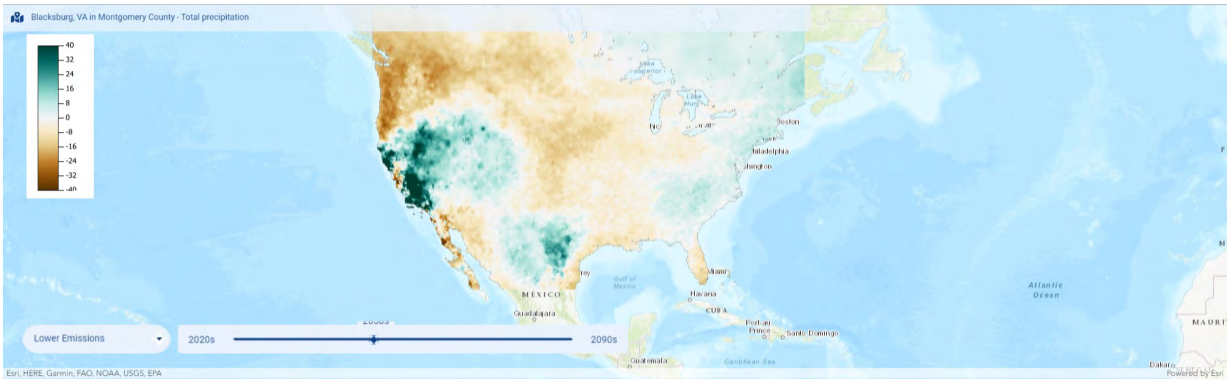
Areas of Vulnerability: Increased Precipitation in Blacksburg

At the national scale, there is great variability in what the climate models are telling us about precipitation patterns. Some areas may experience extended, severe drought while others will see a great deal more precipitation. These changes at the national scale have the potential to disrupt and destabilize food production, create widespread ecological disruption and loss of biodiversity, and could even contribute to population displacement due to repeated flooding, wildfires, and insufficient water supply.

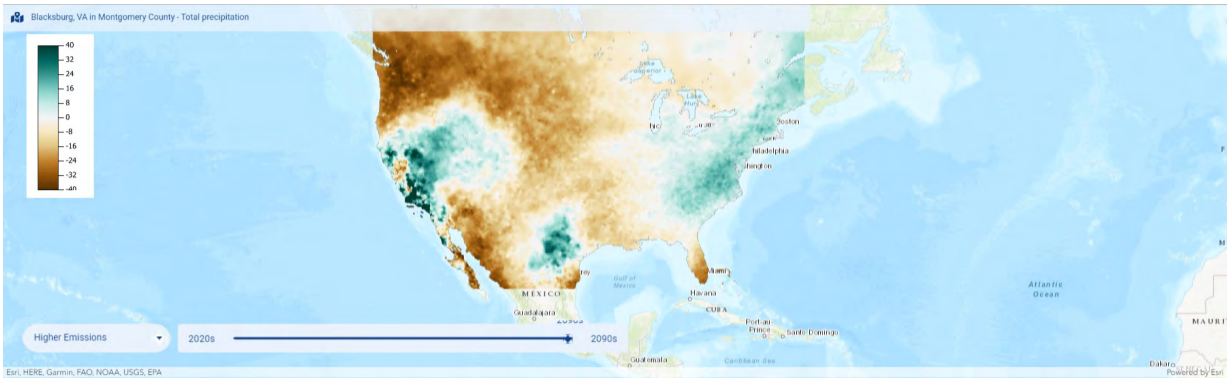
United States: Total Summer Precipitation



Low-Emissions Scenario 2020s



Low-Emissions Scenario 2050s



High-Emissions Scenario 2090s

Climate Metrics: Changing Precipitation Patterns in Blacksburg & the U.S.

Changing Precipitation Patterns Key Climate Metrics & Findings

Of the thirteen climate metrics evaluated, these three point to a mix of vulnerabilities and other outcomes for Blacksburg.

Total Annual Precipitation (indicator of changes to local and national hydrological cycle)

- At the local level, total annual precipitation is anticipated to increase around 5-6% by midcentury under both the low– and high-emission scenarios. Closer to the end of the century, there is more divergence between the low– and high-emissions scenarios, with an expected 7% and 10% average annual increase expected, respectively. At the national level, some areas are expected to receive more precipitation while others will be getting drier. All of these changes are anticipated to have wide ranging effects that could directly and indirectly impact Blacksburg.

Total Monthly Precipitation (indicator of changes in seasonal precipitation)

- In Blacksburg, the largest increase in precipitation relative to the historic average is expected for winter months by end of century under a high-emission scenario (15%), followed by spring (12%), summer (7%), and fall (3%). The unpredictability of the type of winter precipitation is a challenging factor to plan around. Snow and ice can increase road hazards and contribute to widespread disruption to the community. All types of increased precipitation have the potential to overwhelm stormwater infrastructure, particular in areas that are already at or near system capacity.

Days with > 1" precipitation (indicator of potential flooding events)

- The number of days per year when locations receive more than 1 inch of precipitation is an indicator of how often very heavy precipitation events occur. This measurement may also be used as an indicator of flood risk. Comparing the number of days with heavy precipitation at a single location over time can reveal a trend of increasing or decreasing flood risk.

Dry Days, days with <.01" precipitation

- The number of dry days per year—days when precipitation is less than 0.01 inches—gives a sense of the portion of the year when no moisture is being added to the environment. Changes in the number of dry days can indicate a tendency toward drier or wetter conditions. Paradoxically, while it appears that Blacksburg will see an increase in total precipitation, the # of dry days per year is also expected to increase slightly under a high emissions scenario, which may mean that we can expect precipitation events to become more intense. Additionally, when the ground is drier, these higher intensity precipitation events can be more damaging, with a higher risk of flash floods, erosion, mudslides, and sedimentation of local waterways.

Prioritized Areas of Risk: Changing Precipitation Patterns

Prioritized Areas of Risk

To identify areas of heightened potential vulnerability, climate metrics for warmer winters were evaluated relative to critical community systems for Blacksburg. In addition to evaluating the direction of anticipated change for these climate metrics, the following factors were explored to evaluate overall risk:

What is the **POTENTIAL IMPACT** of **CHANGING PRECIPITATION PATTERNS** on our critical community systems? (low to high)

- Probability, frequency, and intensity of change

Stormwater Infrastructure	>> stress on stormwater facilities	53

Adaptation & Resilience Strategies: Changing Precipitation Patterns

Recommendations: Changing Precipitation Patterns + People and Community
• Offer incentives for land and property owners to reduce flood risk for existing structures
• Convene a climate food resiliency and security stakeholder team for the region; develop a food resiliency plan.
• Expand land use policies and green/gray infrastructure to reduce flood risk for existing and future buildings
• Expand gray and green stormwater infrastructure in areas prone to flash flooding; public engagement on risk.

Recommendations: Changing Precipitation Patterns + People and Community
• Identify and promote agricultural climate adaptation best practices
• Develop invasive species management plans for public lands; encourage private landowners to adopt practices.

Recommendations: Changing Precipitation Patterns + People and Community
• Expand capacity of local EMS to respond to swift water and flash flood emergencies; public engagement on risk
• Expand gray and green stormwater infrastructure in areas prone to repeated or flash flooding

Next Steps

Communities like Blacksburg will be well served by taking an honest look at the climate vulnerabilities they will be facing in the coming years and decades. Decisions we make now around infrastructure, land use, transportation investments, buildings, and public health can prepare us, not just to survive in a changing climate, but to thrive.

Blacksburg's Climate Vulnerability Assessment has revealed a handful of community systems that are most at risk in a changing climate, as highlighted in the chart below:

People and Community	Natural Systems	Economy and Employment	Infrastructure and Basic Services
Financial Wellbeing	Agriculture/Farming	Business Continuity	Emergency Services
Food Systems/Security	Ecosystem Services	Employment Continuity	Energy Access/Delivery
Homes & Buildings	Forests/Tree Cover	Industrial Operations	Internet/Communications
Human Health/Wellbeing	Hydrology/Watershed	Tourism	Law & Order
Population Displacement	Invasives/Species Shift		Stormwater Infrastructure
Public Safety			Transportation System
			Water Supply
			Water Infrastructure

Going forward, the Town intends to convene expert and equity-centered policy development teams to investigate our best strategy options for adaptation and future resilience. The four policy teams will focus on the following themes: **Food Resiliency & Security**, **Human Health & Wellbeing**, **Biodiversity & Ecosystems**, and **Infrastructure and Basic Services**.

The public is invited to share their ideas and priorities and submit questions as we investigate the range of potential adaptation strategies.

Next Steps

Feedback and Engagement Process

This report was developed to identify and prioritize the climate hazards that Blacksburg will be facing in the coming decades, the community systems that may be most at risk, and to put forth a set of broad policy recommendations to be considered. Translating those recommendations into actionable policies and programs will require collaborative and creative partnerships with the whole community.

If you have questions or feedback for the Climate Vulnerability Assessment Advisory Team or the Town, you can provide comments directly at **Let's Talk Blacksburg: Climate Vulnerability**. There you will find a separate tab for each of the four policy teams: Food Resiliency & Security, Human Health & Wellbeing, Biodiversity & Ecosystems, and Infrastructure & Basic Services.

You can also send questions or comments directly to the Sustainability Office: **sustainability@blacksburg.gov**
