CONVERSION FACTORS

The following factors may be used to convert the U.S. customary units published in this report to the International System of Units (SI).

Multiply	By	To obtain
	Length	
inch (in.)	25.4	millimeter (mm)
foot (ft)	0.3048	meter (m)
mile (mi)	1.609	kilometer (km)
	Area	
square mile (mi^2)	2.590	square kilometer (km^2)
	Velocity	
inch per hour (in./hr)	25.4	millimeter per hour (mm/hr)
foot per day (ft/d)	0.3048	meter per day (m/d)
	Mass	
pound (lb)	0.4536	kilogram (kg)
	Volume per area	
gallons per acre	0.009353	cubic meters per square hectometer (m^3/hm^2)
	Temperature	
degree Fahrenheit (°F)	5/9 (°F-32)	degree Celsius (°C)

Sea level: In this report, "sea level" refers to the National Geodetic Vertical Datum of 1929 (NGVD of 1929)--a geodetic datum derived from a general adjustment of the first-order level nets of both the United States and Canada, formerly called "Sea Level Datum of 1929."

THE HYDROGEOLOGIC FRAMEWORK AND A RECONNAISSANCE OF GROUND-WATER QUALITY IN THE PIEDMONT PROVINCE OF NORTH CAROLINA, WITH A DESIGN FOR FUTURE STUDY

by Douglas A. Harned

ABSTRACT

The U.S. Geological Survey is investigating the relation of ground-water quality and land use in the regolith and fractured rock ground-water system of the North Carolina Piedmont. The initial phase of this study provides a description of the ground-water flow system and a review of available ground-water data and formulates hypotheses that guide the design of a water-quality monitoring network for study of selected areas.

In the Piedmont, the solid igneous and metamorphic bedrock grades upward into unweathered fractured rock that is covered by a transition zone of highly-fractured, partially weathered rock, clay-rich saprolite, and the soil. The fractured bedrock, transition zone, saprolite, and soil make up a complex flow system.

A review of available ground-water quality data shows a lack of information about organic compounds and trace metals and changes in ground-water quality with depth. Land use, soils, and geology significantly influence ground-water quality.

The hypotheses that need to be tested in the next study phase are: (1) that ground-water contamination can be related to land use, and (2) that the transition zone between bedrock and regolith serves as a primary transmitter of contaminants.

Monitoring of basins containing industrial, urban, residential, and agricultural land uses in future studies will help define the relation of ground-water quality to land use. Water quality at different depths in the flow system and in streams during base flow needs to be identified.

INTRODUCTION

The Piedmont province of the eastern United States is one of the country's more developed and populated areas, with an ever-growing need for high-quality water supplies. Yet little is known about the ground-water system and the quality of its waters, because most major water supplies in the Piedmont have been developed from surface-water sources. Well yields in the igneous and metamorphic fractured rock system of the Piedmont are generally low compared to wells in many sedimentary rock terranes, so that use of ground water as a supply in the Piedmont generally has been restricted to individually owned domestic wells or small municipal and industrial supplies. However, in North Carolina more than half of the population in the Piedmont depends on ground water from private wells as the source for their water for domestic use (Heath and Giese, 1980).

Approximately 44 percent of streamflow in the Piedmont is ground-water discharge (Harned and Daniel, 1987). Nearly all of the baseflow in Piedmont streams is ground-water discharge. Therefore, quality of the ground water directly affects the quality of surface water.

Because most favorable surface-water sites have been developed and because concerns about environmental impacts of reservoir construction, inter-basin transfer of water, and declining surface-water quality have multiplied, interest in the use of ground water for larger supplies has been rekindled. Recent studies by Richardson (1982), Cressler and others (1983), Daniel and Sharpless (1983), and Daniel (1985) have focused on the potential of ground-water supply in the Piedmont. Other studies have stressed issues of ground-water quality management (LeGrand, 1984; Mew, 1985). However, there has been no regional study designed to assess ground-water quality in the Piedmont.

Very little is known about the nature and extent of ground-water contamination in the Piedmont province of North Carolina. Therefore, to define contamination, an understanding of the background water quality is essential. Currently, background ground-water quality data consist of analyses of major ions, with a few analyses of heavy metals and even fewer of organic compounds.

The Toxic Waste--Ground-Water Contamination Program of the U.S. Geological Survey is conducting a series of ground-water appraisals throughout the United States (Helsel and Ragone, 1984). As part of this program, the ground-water quality of areas of widely differing geohydrology, climate, and land uses is being examined with the objective of developing a national assessment. The principal hypothesis of the program is that levels of ground-water contamination can be related to land-use. The two-phased study in North Carolina, which focuses on segments of the North Carolina Piedmont, is geared to allow transfer of information to the rest of the Piedmont province by statistically associating ground-water quality with land use, geology, and soil characteristics.

Purpose and Scope

The purpose of this report is to describe the hydrogeologic framework, present an inventory and preliminary analysis of available ground-water quality data and potential sources of ground-water contamination, and propose a design for the second phase of the study. Geohydrologic information on the region is presented, including a conceptual model of the flow system and hypotheses about contaminant movement through the system. An evaluation of available ground-water quality data is presented and a program of sampling, designed to associate land use with ground-water quality is proposed.

Method of Study

The available ground-water data that were reviewed included data collected from shallow wells between 1978 and 1980 in a program of the North Carolina Department of Natural Resources and Community Development (NRCD). The data collection effort of the NRCD study centered in the western Piedmont. The data include: (1) physical and chemical characteristics of the ground water, such as temperature, conductance, pH, concentrations of major ionic constituents, metals concentrations, and selected analyses of nutrient concentrations; (2) lithologic logs; and (3) well characteristics, such as well depth and water level at time of sampling. In addition, because stream water is virtually all ground-water discharge at baseflow, data from studies that examined water-quality characteristics of streams at baseflow have been considered. A study by Eddins and Crawford (1984) includes low-flow sample analyses of major ionic constituents, nutrients, and metals for Mecklenburg County.

Additional data were collected specifically for the first phase of this study during January and February 1985. Samples collected in Mecklenburg and Guilford Counties were scanned for presence of organic compounds and a suite of 43 elements, including many trace metals. This information was collected to help select possible sites for detailed analysis in future study.

Historical data, collected during Geological Survey cooperative studies spanning from 1946-76, was included in the data set generated from this study. However, historical data were not used in the data analysis for this report.

The evaluation of data in this report is limited to summary presentation of certain constituents using frequency histograms, simple non-parametric analysis of variance, and Duncan multiple-range testing. A more detailed analysis of the data set is reserved for future study, which would also include additional collection of water samples from a network specifically designed to define ground-water quality.

A review of the hydrogeology of the Piedmont includes a summary of earlier work by LeGrand (1967), Heath (1984), and Daniel (1987). Temperature profile logs for several wells located in Guilford County were run to test one of the flow hypotheses of the study.

Acknowledgments

M. Groves and R. Crouch conducted the NRCD study during 1978-80 that collected much of the data that was compiled for this report. Richard Peace, of the NRCD Mooresville Regional office at the time of this study, provided access to this data.

The Climate, Topography, Geology, and Well Logs sections were written by Alexander Cardinell and Ronald Coble.

DESCRIPTION OF STUDY AREA

The Piedmont of North Carolina (fig. 1) is part of the Piedmont province as described by Fenneman (1938) that extends from New Jersey to Alabama and lies between the Blue Ridge and Coastal Plain provinces. The Piedmont province of North Carolina, shown in figure 1, is approximately 20,000 square miles or about 23 percent of the total Piedmont region of the eastern United States. The Piedmont widens to the south, reaching its maximum width of nearly 200 miles in North Carolina. The province occupies approximately 41 percent of the State.

Climate

The North Carolina Piedmont lies within a humid, subtropical climate region. The temperature is moderate, seldom dropping to zero degrees Fahrenheit in the winter and occasionally rising above 100 degrees in the summer. Mean annual temperatures range from 58 to 61 degrees Fahrenheit, with January the coldest and July the hottest month (Eder and others, 1983). The growing season, which is defined as that period without killing frosts, lasts from mid-April to the end of October, an average of about 200 days.

The average annual precipitation in the Piedmont of North Carolina ranges from 43 to 60 inches. Generally, the greatest monthly precipitation occurs during the summer months, and the least precipitation occurs in October or November. Although rainfall is heaviest in the summer, evaporation and transpiration losses are greatest then also; consequently, there is little ground-water recharge during this season.

Topography

The Piedmont is an ancient erosional surface developed, for the most part, on crystalline igneous and metamorphic rock. The Piedmont province is bordered on the east by the Fall Line, which is the western boundary of the Coastal Plain province, and on the west by the Blue Ridge front (fig. 1). The Fall Line represents the boundary where the soft, sedimentary rocks of the Coastal Plain give way to the harder crystalline rocks of the Piedmont. The Blue Ridge front is a prominent topographic feature generally thought to have resulted from displacement associated with faulting.

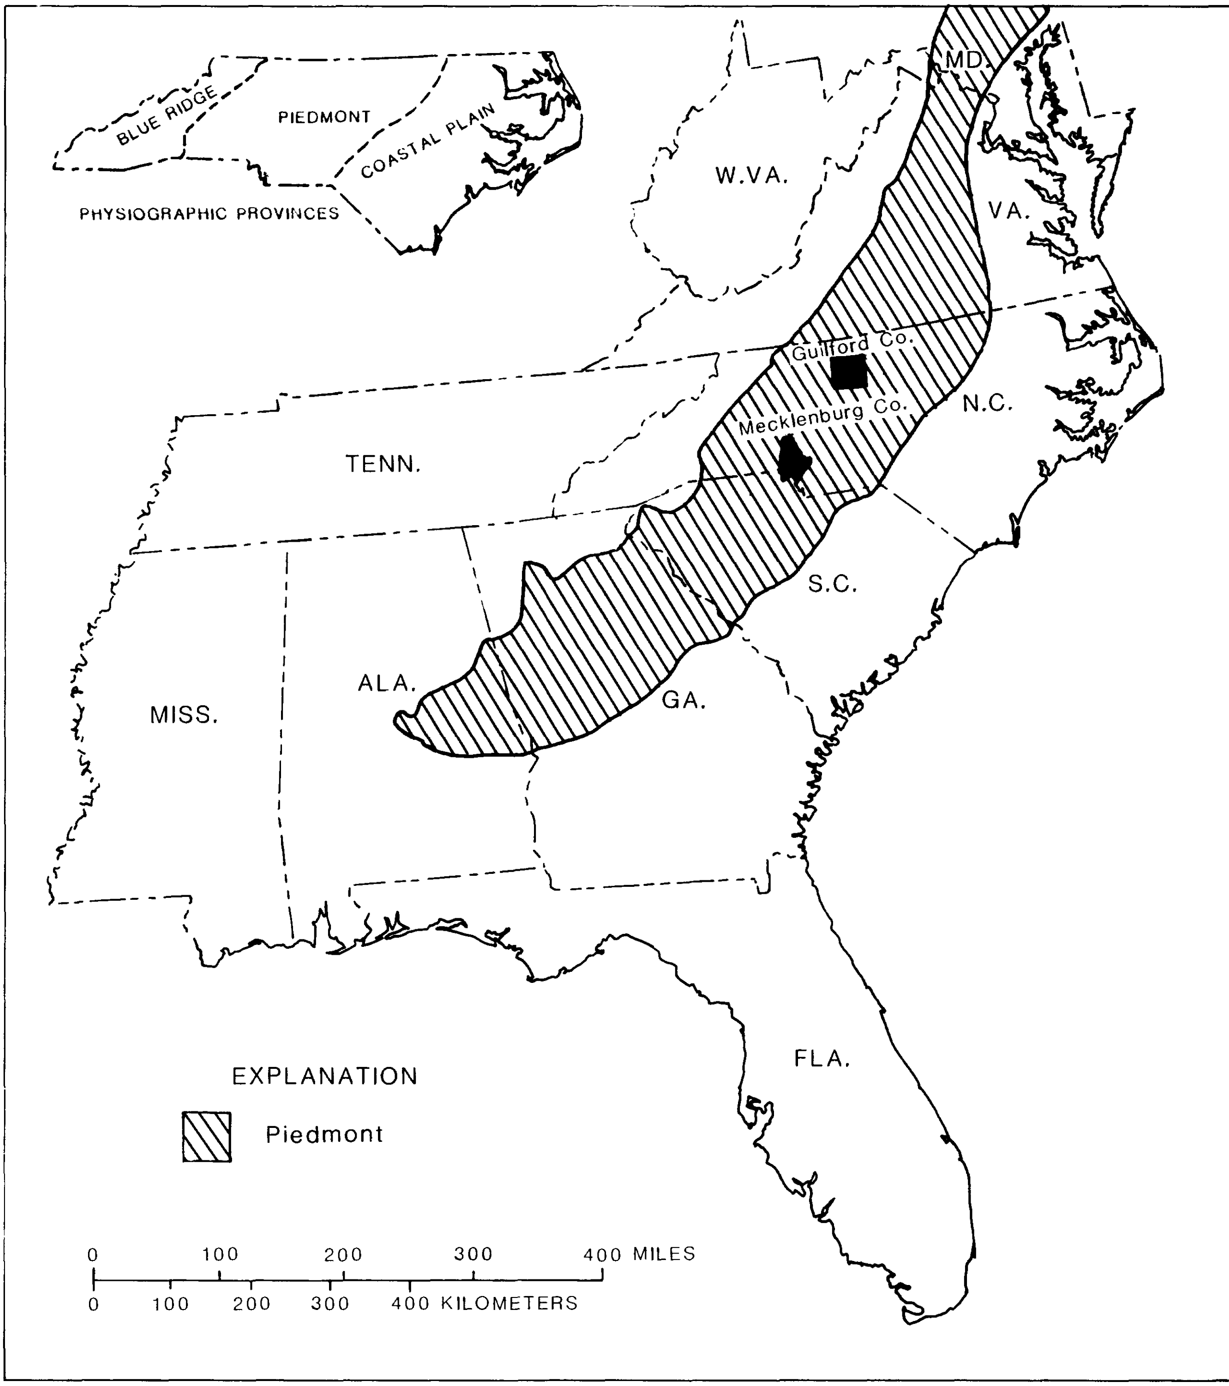

Figure 1.--The Piedmont province of the eastern United States and the physiographic provinces of North Carolina.

The Piedmont consists of low, rounded hills and long, rolling northeast-trending ridges with up to a few hundred feet of local relief. Land elevation gradually rises from about 150 feet above sea level along the Piedmont's eastern boundary to 1,900 feet along the western boundary at the foot of the Blue Ridge front.

The rolling topography is the result of streams acting on rocks of unequal resistance. Isolated hills with summit heights standing above the upland surface are remnants of extremely erosion-resistant rock. In contrast to the topography of the crystalline-rock terrane of most of the Piedmont, erosion has produced low lands in the soft sedimentary rocks of the Triassic basins.

The typical Piedmont topographic surface described by Fenneman (1938) is practically all hillside or valley side. The region has a well integrated drainage system and, in nearly all aspects, qualifies as having reached topographic maturity as defined by Thornbury (1954). LeGrand (1958 and 1984) notes that in the network of closely spaced perennial streams the upland divide is everywhere less than a mile and commonly less than half a mile from a valley.

Geology

The geology of the North Carolina Piedmont province is very complex; the bedrock consists of folded and fractured metamorphosed sedimentary and igneous basement rocks. Intruded into these metamorphic rocks are lesser bodies of unmetamorphosed igneous rocks. Typical bedrock lithologies include granite, gneiss, schist, quartzite, slate, and phyllite. Downfaulted into the basement complex are several basins (Triassic basins), which are grabens where sedimentary rock occurs.

The regional geology of the Piedmont basement is only generally understood. The crystalline igneous and metamorphic sequences may have undergone two or three regional metamorphic events and as many as four major deformation events from the Precambrian through the Paleozoic. The complex nature and variable degrees of metamorphism found in the Piedmont make precise dating of these events impossible at present. More detailed discussions of recent hypotheses for these events can be found elsewhere

(Ragland and others, 1983; Farrar, 1985; Russell and others, 1985; Wehr and Grover, 1985). Various periods of plate tectonic activity, along with the associated formation of rift margins, are believed to be responsible for these events. The Piedmont can be divided into northeast trending parallel geologic belts. Traversing from the southeast, the major geologic belts are the Carolina slate belt, the Raleigh belt, the Charlotte belt, the Kings Mountain belt, and the Inner Piedmont belt (Daniel, 1987).

The rock-type classification scheme based on lithologic and geohydrologic properties developed by Daniel (1987) for the Piedmont and Blue Ridge provinces of North Carolina has been used in this study. The near-surface earth materials of the Piedmont consist of a three-stage system which, from top to bottom, contains (1) a regolith zone, (2) a transition zone, and (3) underlying fractured crystalline bedrock (fig. 2).

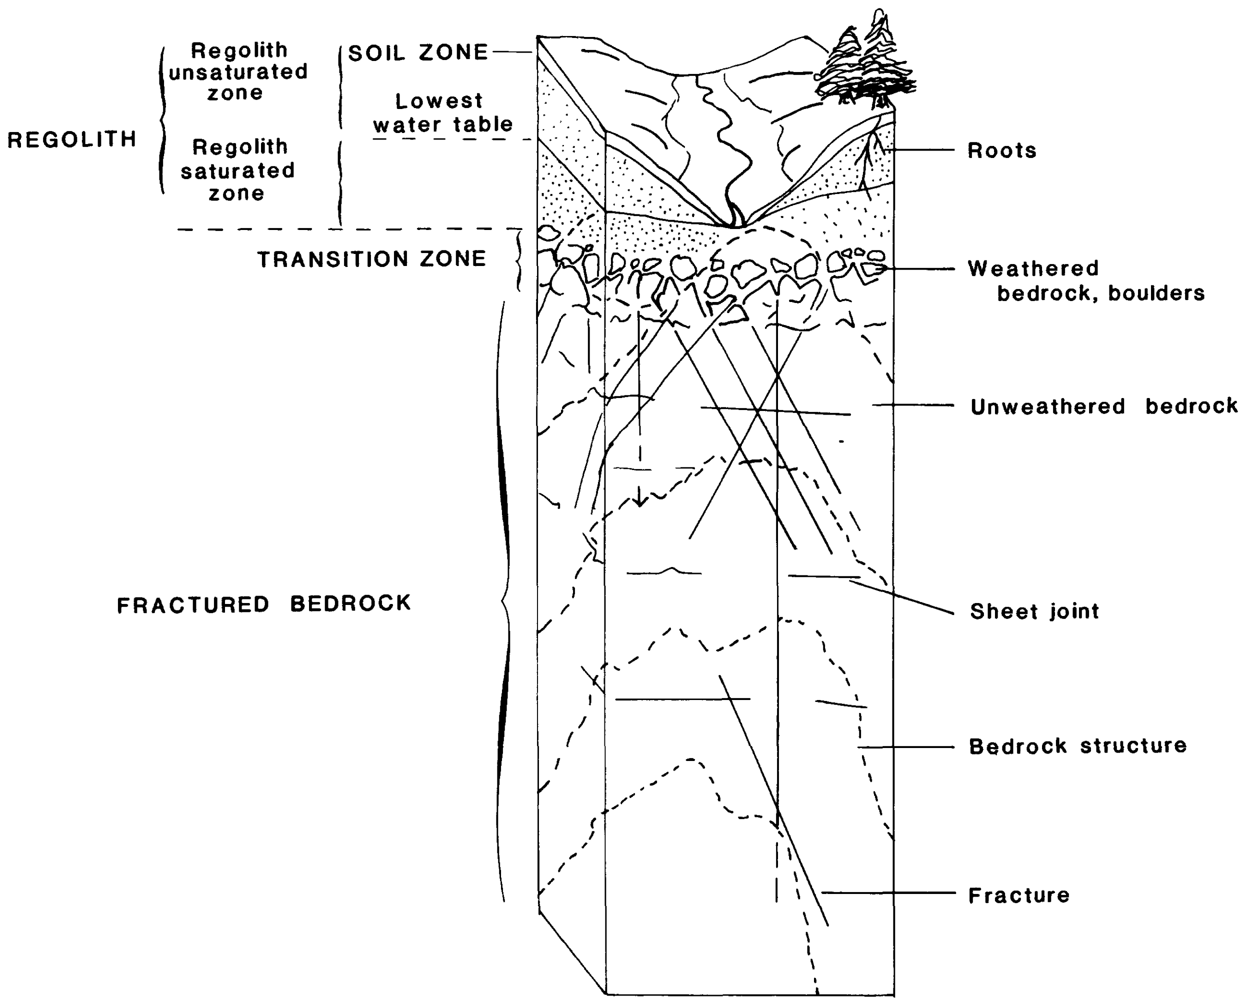

Figure 2.--Conceptual structure of the Piedmont ground-water system (modified from Heath, 1984).

Collectively, the uppermost layer is the regolith, which is composed of saprolite, alluvium, and soil (Daniel and Sharpless, 1983). The regolith zone consists of an unconsolidated or semiconsolidated mixture of clay and fragmental material ranging in grain size from silt to boulders.

Saprolite is the clay-rich, residual material derived from in-place weathering of bedrock. Saprolite deposits represent leached deposits and, being granular material with principal openings between grabens, differ significantly in texture and chemical composition from the parent rock which is unweathered, crystalline rock having principal openings along fractures. Since saprolite is the product of in-place weathering of the parent bedrock, some of the textural features of that bedrock are retained within the saprolite. Evidence of relic quartz veins, dikes, and shear zones are commonly seen in outcrops. Alluvial deposits are unconsolidated sediments deposited by streams and rivers. Soil is referred to as the natural medium for the growth of plants. Saprolite is the dominant deposit in this unconsolidated zone, with soil deposits generally restricted to the uppermost layer, and alluvium deposits restricted to locations of current and former stream channels and river beds.

The transition zone is where unconsolidated material grades into bedrock and consists of saprolite and partially weathered bedrock. Here, particle size ranges from silts and clays to large boulders of unweathered bedrock. The thickness of this zone depends a great deal on the texture and composition of the parent rock. The best defined transitional zones are usually associated with highly foliated metamorphic parent rock, while those of massive igneous rocks are often poorly defined or nonexistent (C.C. Daniel, III, U.S. Geological Survey, oral commun., 1985). In the Piedmont, 90 percent of the records for cased bedrock wells show combined thicknesses of 97 feet or less for the regolith and transition zones (Daniel, 1987).

The uppermost part of the Piedmont crystalline bedrock contains numerous closely spaced fractures which can be related to the local and regional tectonic history of the area. As a general rule, very few fractures occur in the Piedmont bedrock at depths greater than 400 feet (LeGrand, 1967).

Soils

Most Piedmont soils have formed largely from saprolite derived from the underlying parent rocks. Some soils have developed on stream-valley alluvium. Soils are a product of their local and regional environment. Geology, geomorphology, and climate, in addition to topography, moisture, and vegetation, influence the characteristics of soil cover. Combinations of factors give rise to a number of diverse soils that fit into locally and regionally recurring patterns.

Daniels and others (1984) classified four major soil systems within the Piedmont based on the major kinds of bedrock:

1. The felsic crystalline terrains composed largely of granite, gneiss, mica gneiss, and schist;
2. The Carolina slate belt of bedded argillites, felsic volcanics, and mafic volcanics;
3. The Triassic basins with mudstones, sandstones, shales, and conglomerates; and
4. The mixed mafic and felsic rocks; a complex area of granites, diorites, gabbros, and other rocks.

In the felsic crystalline area, most deeper soil horizons are clayey, but some soils originating from the coarser grained rocks, such as granite, have clay-loam or loamy-sand deeper horizons. Soils derived from Carolina slates have high silt contents, overlie relatively thin saprolite layers in comparison with the felsic crystalline area, and have low permeability in the deeper horizons. Triassic basin soils have more swelling clays in their deeper horizons than other soils. The mafic soils (from mafic dikes) are plastic and usually a reddish color.

In this study, physical parameters of soils, including permeability and available water capacity provided by the U.S. Soil Conservation Service (1978), were used to construct the detailed data base necessary to compare ground-water quality characteristics with soil type. These parameters have been included in the data set but were not used in the data analysis.

Land Use

Land Use Data Analysis maps (LUDA maps; Anderson and others, 1976) provide data on a regional scale for land use in the Piedmont. These maps were generated in the early 1970's using remote-sensing satellite data.

Estimates of the relative amount of area covered by the different land-use types were determined from LUDA maps. Land-use types lying along the 78-, 80-, and 82-degree meridians, and along the 35- and 36-degree parallels were determined from the North Carolina LUDA maps. First, the distances along each latitude or longitude line for each land-use type were measured and totaled. Then, the total for each land use was divided by the total for all the lines sampled to give a percent of the total area covered by each land use. The result of these calculations are shown in table 1. This analysis indicates that about 65 percent of the North Carolina Piedmont land area is forest, about 25 percent is crop land, and about 6 percent is urban and residential.

Table 1.--*Approximate percentages of major land uses of the Piedmont of North Carolina*
[LUDA, Land Use Data Analysis]

Land-use data from Anderson and others, 1976.

HYDROGEOLOGIC FRAMEWORK AND CONCEPTUAL MODEL OF THE FLOW SYSTEM

Heath's (1984) concept of the ground-water system for the Piedmont and Blue Ridge provinces has been adopted as the conceptual model for this study with slight modifications to emphasize the transition zone between the regolith zone and the bedrock.

The fundamental structure of the ground-water system is shown in figure 2. The components of the system are:

1. The unsaturated zone in the regolith, which generally contains the organic layers of the surface soil;
2. The saturated zone in the regolith;
3. The transition zone between the regolith and bedrock; and
4. The fractured crystalline bedrock system.

Regolith Unsaturated Zone

The unsaturated zone extends from the land surface down to the water table, which is the top of the saturated zone. The pore spaces of the regolith in the unsaturated zone contain both air and water. The unsaturated zone usually ranges from 5 to 50 feet in thickness. Daniel (1987) found a mean depth to the water table of 31.3 feet in an examination of 2,326 Piedmont wells. Water moves down from the land surface through the soil zone by intergranular flow through the larger pore spaces and passages left by burrows or decayed roots. Roots from surface vegetation can grow to 30 feet below land surface but more commonly spread laterally near the surface. At the base of the soil zone, which is generally 3 to 8 feet thick, the average grain size abruptly decreases with a corresponding decrease in pore size as the water enters the saprolite (C.C. Daniel, III, U.S. Geological Survey, written commun., 1985). At this point water movement may also be diverted somewhat by relic structures of foliation or folds in the saprolite, which are remnants from the parent rock.

The total porosity of soil is commonly around 55 percent, and its specific yield is about 40 percent (Heath, 1983). Saprolite has a total porosity of 35 to 50 percent near land surface (fig. 3), which decreases at depth, and a specific yield of 20 percent (Daniel and Sharpless, 1983).

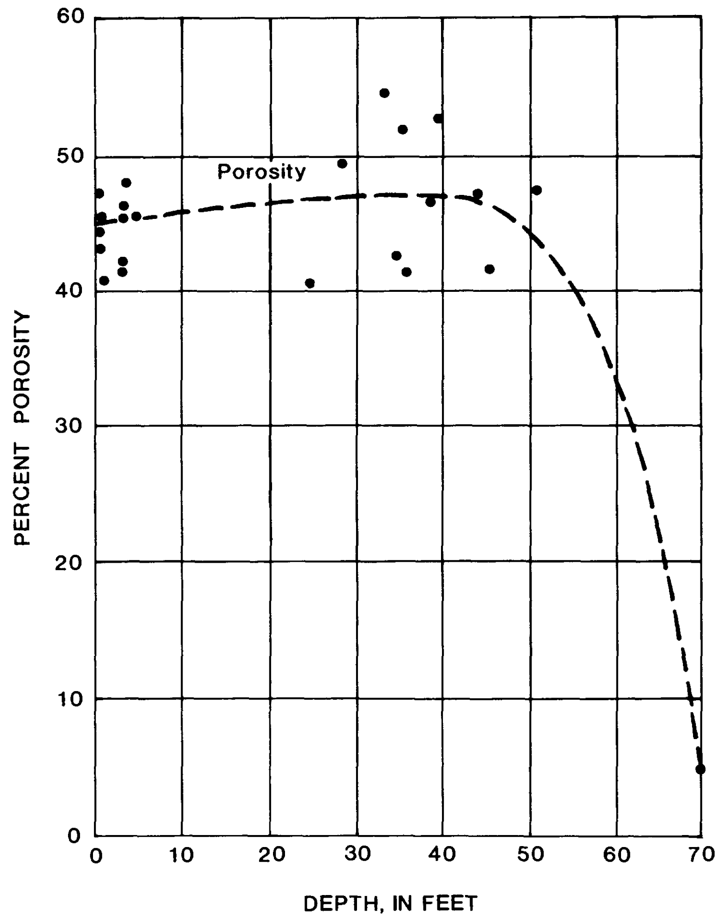

Figure 3.--Relation of porosity of saprolite with depth (after Stewart, 1962).

Topsoil in Piedmont soils to a depth of 7 to 10 inches was reported to have a mean hydraulic conductivity of 5.7 inches per hour (11.4 feet per day), and the subsoil, 7 to 20 inches below land surface, has a mean hydraulic conductivity 1.8 inches per hour (3.6 feet per day) (Lutz, 1969). These values are in line with the hydraulic conductivity values for saprolite reported by Heath (1980) that range from 0.5 to 10 inches per hour (1 to 20 feet per day). However, the hydraulic conductivity of saprolite is not the same in all directions. This anistropy may take the form of preferential permeability along the direction of relic structures within the saprolite.

Regolith Saturated Zone

The regolith saturated zone is that interval below the water table and above the transition zone. Daniel has calculated the median saturated thickness of the regolith and transition zone from records of 1,749 water-supply wells in the Piedmont of North Carolina to be 13 feet (Daniel, 1987). The median saturated thickness was shown to be a function of topography: beneath draws and valleys, it was 28 feet thick; below slopes and flats, it was 15 feet; and beneath hills and ridges, it was 9 feet.

The saturated regolith provides the bulk of the water storage within the Piedmont ground-water system (Heath, 1980). This concept is illustrated in figure 4. In the Piedmont ground-water system, the regolith has a specific yield of around 20 percent (Daniel and Sharpless, 1983), whereas the porosity of the bedrock ranges from 0.01 to 2 percent (Heath, 1984). The depth-porosity relation described by Stewart (1962) is shown in figure 3. The amount of ground water in storage as a function of the saturated thickness of the regolith has been calculated by Daniel (C.C. Daniel, III, U.S. Geological Survey, written commun., 1985) and is presented as figure 5.

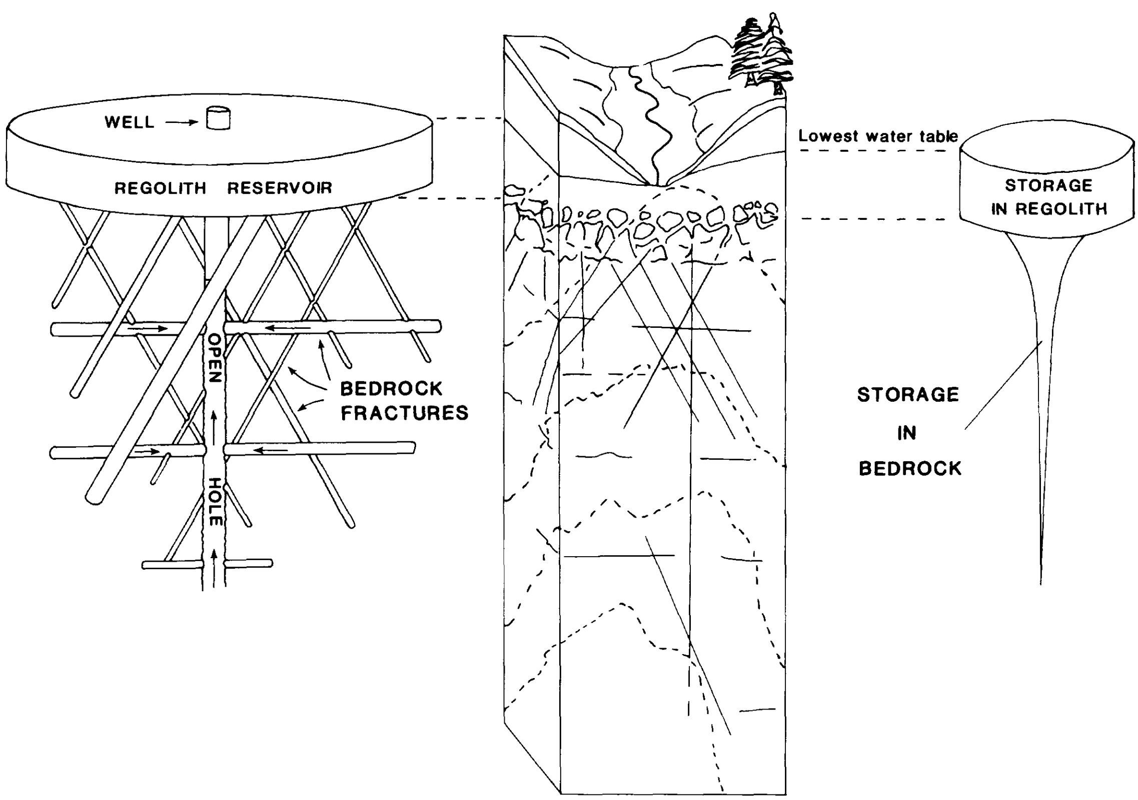

Figure 4.--Water storage within, and the reservoir-pipeline conceptual model of the Piedmont ground-water system (modified from Heath, 1984).

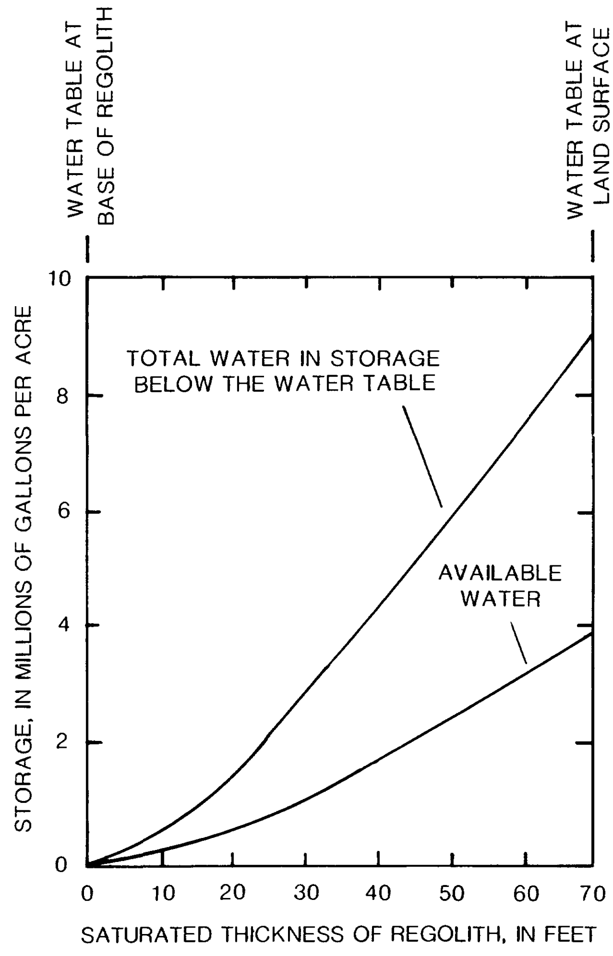

Figure 5.--Relation of ground-water storage and saturated thickness (after C.C. Daniel, III, U.S. Geological Survey, written commun., 1986).

As illustrated in figure 4, the regolith serves as a reservoir supplying water to interconnected fractures within the bedrock. In general, wells in the Piedmont are cased through the regolith, with open hole through enough of the bedrock to intercept enough fractures to furnish acceptable yields. The bedrock fractures serve as pipelines between the well and the regolith reservoir.

The depth to water table is largely a function of topography. Based on data from 2,326 water-supply wells, the median water level in wells located in draws and valleys is 20 feet, in slopes and flats 25 feet, and in hills and ridges 32 feet (Daniel, 1987). Depth to water table at any one place varies with ground-water recharge and continual discharge. An example of the response of water level due to variation in rainfall is shown in figure 6. In this example, ground-water recharge (in excess of discharge) resulting from heavy rains in late winter, when evapotranspiration is low, is reflected by a peak in the water-table hydrograph appearing a few days after heavy rainfall in late March. The time after a storm that the peak appears in the water level is directly related to the vertical hydraulic conductivity of the material in the unsaturated zone and the depth to water table. The hydrograph also shows that little recharge took place during the growing season (April through September) even though the area received significant rainfall during these months. The declining water level indicates continuing ground-water discharge that is not equaled or exceeded by recharge until fall, when evapotranspiration is low. Similar seasonal

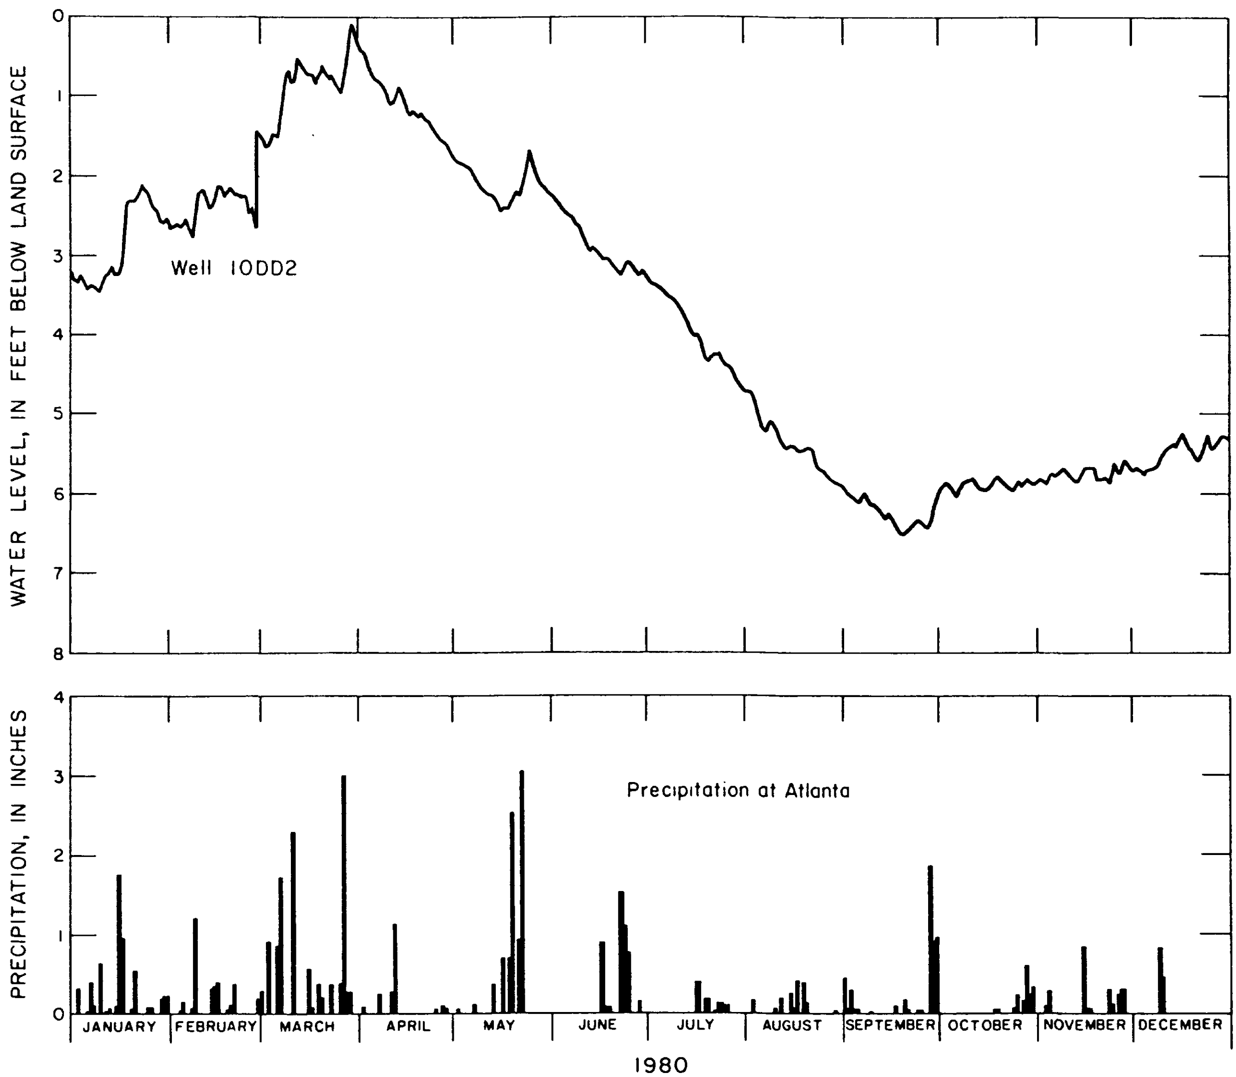

Figure 6.--Response of water-level change to rainfall (from Cressler and others, 1983).

fluctuations of the water table are also shown in the hydrograph for a well located in Iredell County, North Carolina (fig. 7).

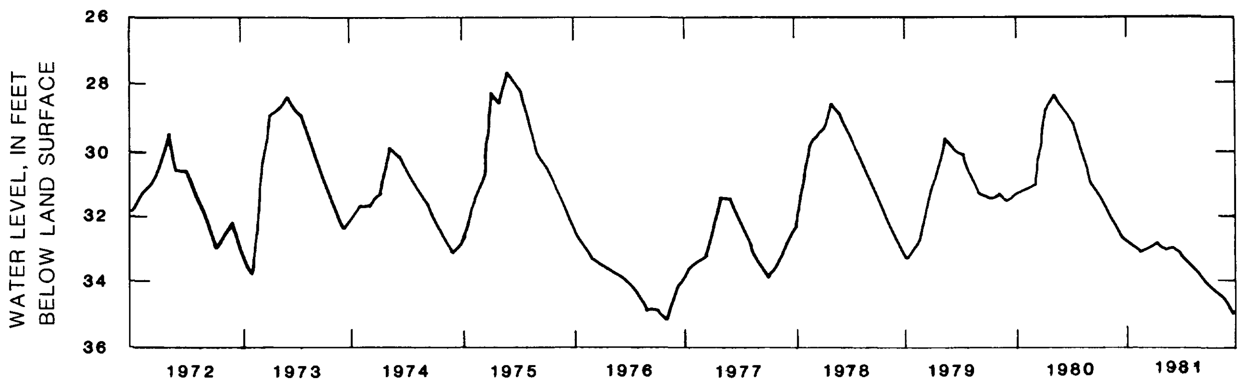

Figure 7.--Seasonal fluctuations in water-table depth in a well in Iredell County, North Carolina (from LeGrand, 1984).

Transition Zone

At the base of the regolith there is generally a transition zone of weathered rock, boulders, and saprolite. Careful augering of three wells showed this transition zone to be approximately 15 feet thick at the Guilford County, North Carolina, test site shown in figure 8 (C.C. Daniel, III, U.S. Geological Survey, written commun., 1985). This zone has been found in Georgia, Maryland, and North Carolina and reported by Stewart (1962), Nutter and Otton (1969), and Daniel (C.C. Daniel, III, U.S. Geological Survey, written commun., 1985), respectively. They describe this zone as being more permeable than the upper regolith and slightly more permeable than the soil zone. This observation is substantiated by reports from well drillers of so-called "first water" (C.C. Daniel, III, U.S. Geological Survey, written commun., 1985) in drillers' logs (Nutter and Otton, 1969).

The high permeability of the transition zone is probably due to incomplete weathering in the upper regolith. Chemical alteration of the bedrock has progressed to a stage of minute fracturing of the crystalline rock, yet it has not progressed so far that the rock minerals have been altered to clays, which would clog the tiny fractures (C.C. Daniel, III,

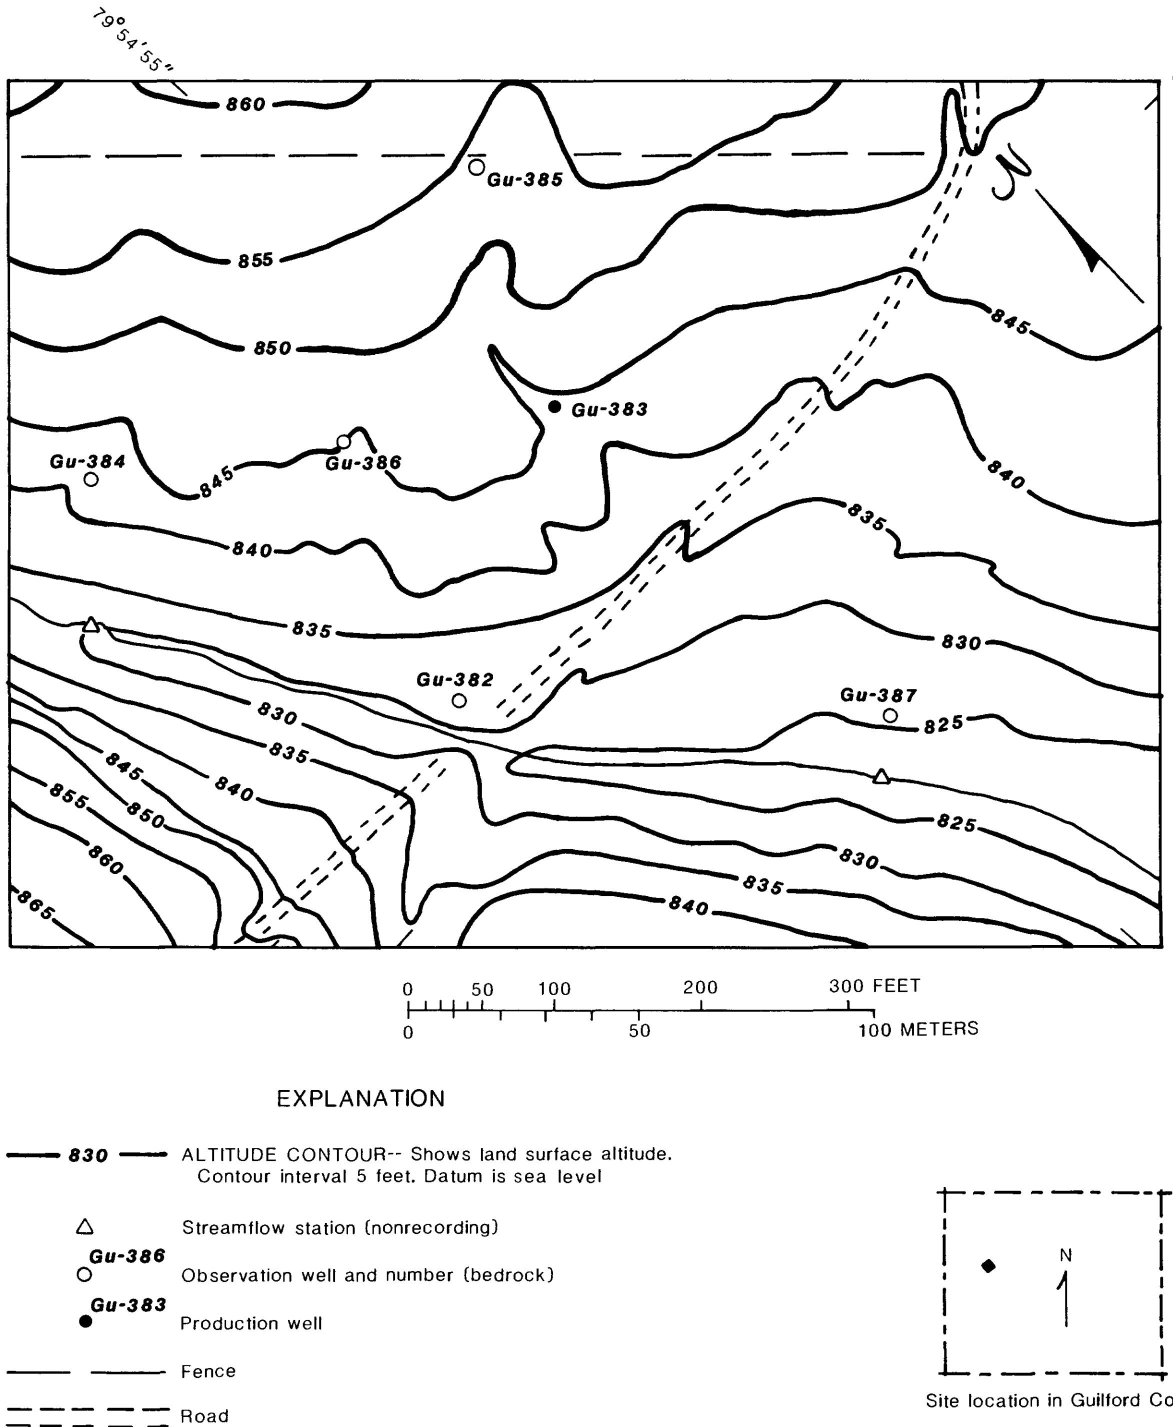

Figure 8.--Locations of data-collection sites and topography at the Greensboro-High Point Regional Airport test site (from Daniel and Sharpless, 1983).

U.S. Geological Survey, written commun., 1985). An idealized weathering profile by Nutter and Otton shown in figure 9 illustrates the effect of degree of weathering on permeability.

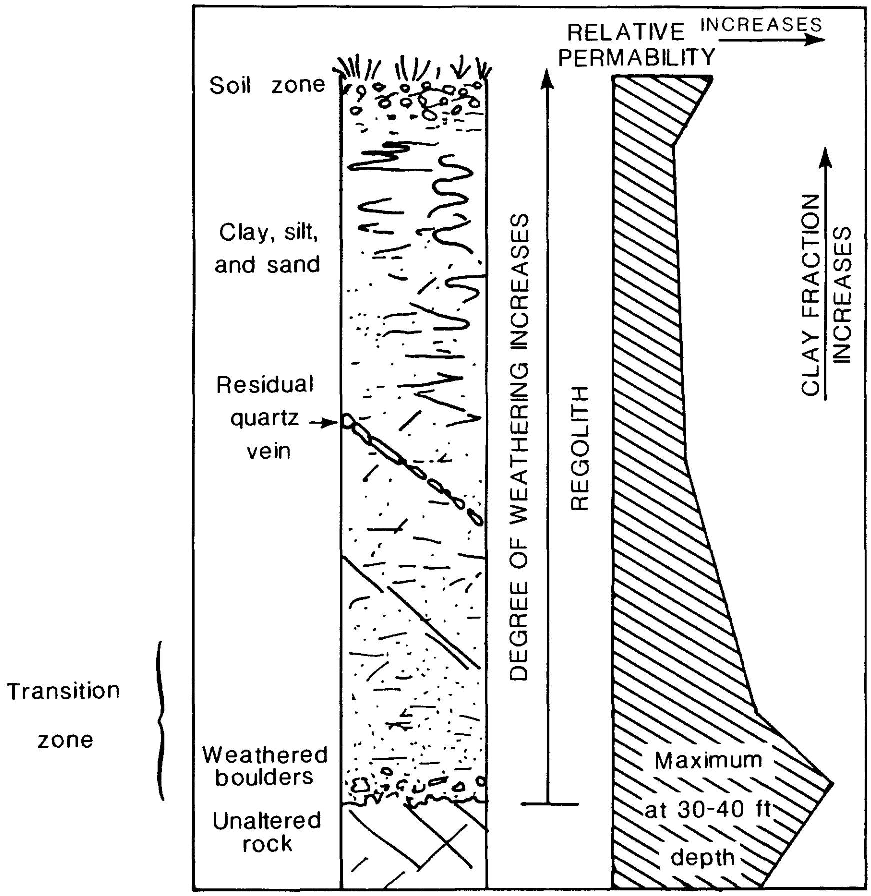

Figure 9.--An idealized weathering profile through the regolith showing relative permeability (after Nutter and Otton, 1969).

The presence of a high-permeability zone on top of the bedrock may create a zone of concentrated flow within the ground-water system. Daniel (C.C. Daniel, III, U.S. Geological Survey, written commun., 1985) cites the case where well drillers find water in the transition zone, yet end up with a dry hole after setting casing through the regolith and transition zone into the unweathered bedrock. In this case, the ground water occurs primarily in the transition zone, where there is poor connection between the regolith reservoir, the bedrock fracture pipeline system, and the well. Daniel comments that the transition zone may serve as an interval where relatively rapid movement of contaminated ground water can take place.

Fractured Bedrock

Ground-water flow within the crystalline bedrock occurs within fracture systems. LeGrand (1967) discussed what he considered to be the six common types of fracture patterns (fig. 10) that influence yields to wells. These fractures are reported to be more common near the surface and beneath valleys, draws, and surface depressions (Heath, 1980), and are considered to be zones of weakness that allowed the initial development of valleys and draws at these locations. Fracture openings are wider near the bedrock surface and decrease in size and number with depth due to increasing lithostatic pressure.

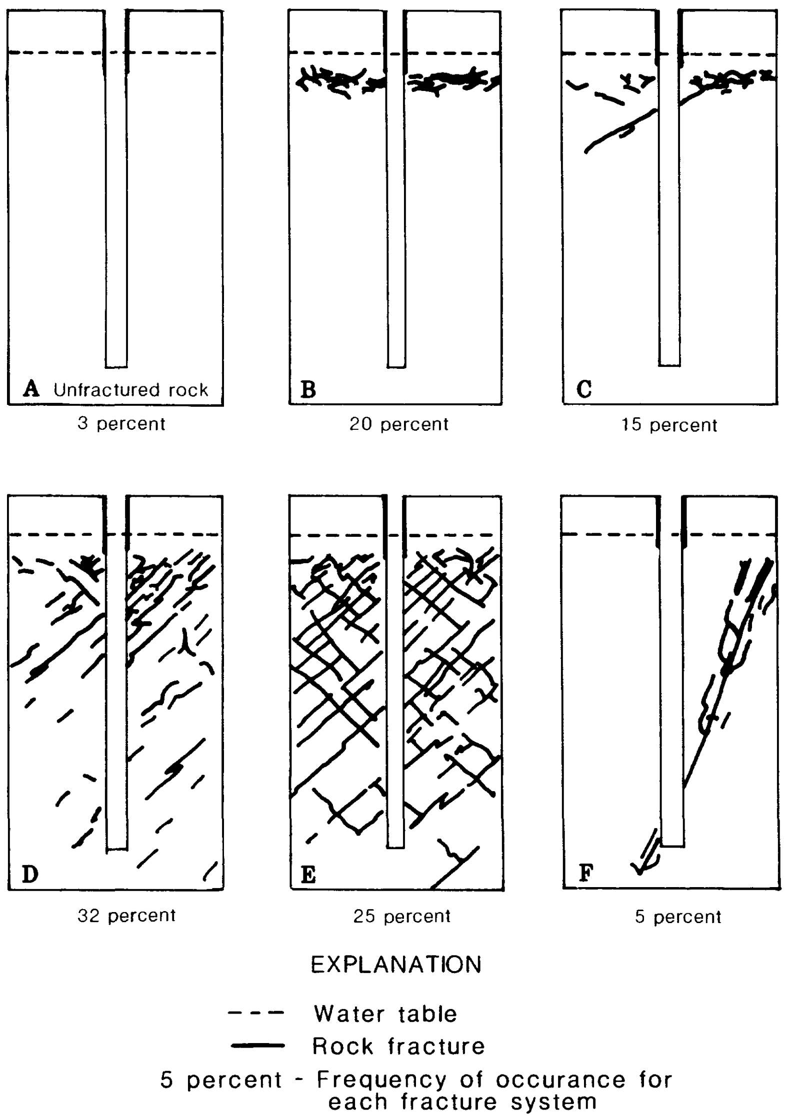

Figure 10.--Six common types of fracture systems in the Piedmont (from LeGrand, 1967).

Heath indicates that few fractures below 300 to 400 feet from land surface contain substantial amounts of water, and that those which do bear water at depth are probably associated with faults. However, Cressler and others (1983) found that for the Atlanta, Georgia, area, nearly horizontal stress-relief fractures at depths of 400 feet or more were often associated with high-yielding wells. When surface material is removed by erosion, nearly horizontal stress-relief fractures develop and widen in response to the reduction in compressional stress. Daniel also reports high-yielding wells at depths over 500 feet in the North Carolina Piedmont (Daniel, 1987). Fractures are planar features oriented along zones of lithologic and structural weakness. Water can move along the fractures with relative ease to discharge points such as wells or to natural discharge areas in stream valleys. Non-horizontal fractures may account for dramatically asymmetrical patterns of water-level decline that may be seen around a pumped well or the more rapid movement of water and contaminants in one direction than in another, creating aniostrophy in the bedrock aquifer. The hydrologic conductivity of the fractured bedrock is generally 0.001 to 3 feet per day (Heath, 1984). The primary porosity of the bedrock ranges from about 0.01 to 2 percent (Heath, 1984).

In general, the mineral assemblages determine the degree to which water will dissolve aquifer material. For example, quartz is resistant to chemical weathering and will dissolve much more slowly than less resistant ferromagnesium minerals such as biotite and hornblende and numerous iron minerals such as pyrite and magnetite. Generally, the mafic igneous rocks such as diorite-gabbro contain more ferromagnesium minerals and are more susceptible to chemical solution than the minerals of felsic rocks such as granite. Weathering of the ferromagnesium minerals produce solution openings and channels in the mafic rock units.

Ground water from a typical granite, composed largely of sodium and potassium feldspars, should have relatively high concentrations of sodium bicarbonate. Calcium and magnesium bicarbonate concentrations can be high in ground water moving through mafic rocks, such as gabbro, which is composed largely of calcium feldspars and ferromagnesium minerals. Ground water from certain metavolcanic and mica-schist units contain high concentrations of iron (Hem, 1970). However, these simple relationships are complicated if there is mixing of waters from adjacent rock types of different compositions or if the host rock is intermediate in composition.

Because the natural chemical quality of ground water is affected by the minerals in the regolith and bedrock, which form the hydrogeologic framework for the Piedmont ground-water system, the natural water quality should be considered when attempting to determine water-quality differences resulting from different land uses. The significance of the effects of geology and soils on the ground-water quality are described in the data-analysis section of the report.

Flow Hypotheses

Several aspects of the ground-water flow system in the Piedmont are particularly significant geochemically. In describing ground-water recharge and discharge and the functions of a ground-water system, Heath (1983, p. 14) states:

> Hydraulically, this system serves two functions: it stores water to the extent of its porosity, and it transmits water from recharge areas to discharge areas. Thus, a ground-water system serves as both a reservoir and a conduit.
>
> Water enters ground-water systems in recharge areas and moves through them, as dictated by hydraulic gradients and hydraulic conductivities, to discharge areas.
>
> In the humid part of the country, recharge occurs in all interstream areas--that is, in all areas except along streams and their adjoining flood plains. The streams and flood plains are, under most conditions, discharge areas.

These general conditions are assumed to apply in the Piedmont of North Carolina.

The generalized flow system in the Piedmont as represented in figure 11 occurs within a closely-spaced network of streams typical of the mature topography of the Piedmont. Ground-water flow is toward these streams, and the shape of the water table mimics the topography of the land surface,

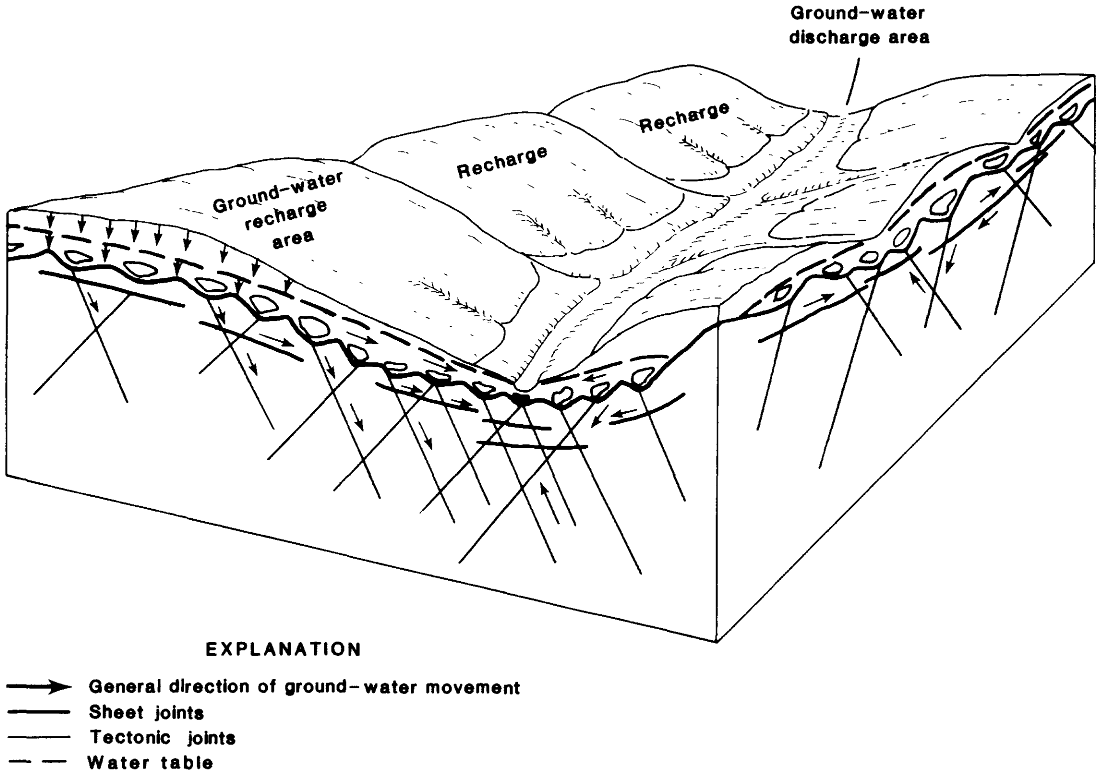

Figure 11.--Generalized ground-water flow system in the Piedmont (from Heath, 1980).

although with subdued relief. Thus, surface topography can be used to predict the natural direction of ground-water flow. The distance between the point where a drop of water or waste enters the system and the point where it discharges into the stream down slope is commonly less than a half mile (LeGrand, 1958). Most of the natural flow in the system is probably confined to the upper 30 feet of bedrock, where fractures are concentrated, and the overlying transition zone, which apparently has the highest hydraulic conductivity of any part of the hydrogeologic system (C.C. Daniel, III, U.S. Geological Survey, written commun., 1985). However, flow probably also occurs in the deeper fractured system in a manner harder to predict by local surface topography. In the deeper system, regional topography or structural features may result in flow over long distances and long ground-water residence times in the fractured rock.

The ground-water flow system in the Piedmont is directly connected to the surface-water system. The annual contribution of ground water to total streamflow for 11 streams flowing through the Piedmont is estimated to average 44 percent (Harned and Daniel, 1987). Consequently, it is a concern that ground-water contamination will eventually discharge to streams that are water-supply sources.

Because of the interconnection of the ground- and surface-water systems in the Piedmont, a drainage basin large enough to contain a perennial stream can serve as a basic unit for the description of ground-water quality (LeGrand, 1984). Each drainage basin is a flow-system cell similar to, and yet separate from, surrounding basins. Although not all of the ground-water flow for a particular area is confined within a single drainage basin, it should be possible to generalize, with a reasonable degree of confidence, about ground-water quality of larger regions from data collected in small drainage basins. This is a basic assumption used in this study.

Hypotheses about the Piedmont ground-water flow system relevant to this and future studies of the system include:

1. The transition zone between bedrock and regolith serves as a primary transmitter of contaminated ground water. The regolith serves as the principal reservoir of ground-water contamination.
2. Attenuation of ground-water contamination in the regolith is related to the degree of weathering and composition of regolith material and the hydraulic conductivity, gradient, and porosity of the material.
3. The velocity of contaminant movement can be highest within the fractured bedrock system, particularly under stressed conditions.
4. The deeper zones in basement rock generally contain the best quality water in the system due to contaminant attenuation in the regolith.
5. Geomorphological analysis can be used to identify fracture zones that help predict general subsurface-flow patterns of ground-water contamination. These methods can be verified with surface geophysical techniques.

Transition-Zone Studies

There have been some initial tests of the hypothesis that the transition zone is a principal conduit of ground-water movement and ground-water contamination. Daniel was the first investigator to focus on the transition zone and has done some initial test drilling, well construction, and well logging to define its characteristics. In particular, temperature logs run in several wells located in Cary and in Guilford County, North

Carolina, may be used to identify greater movement of water within the transition zone (Daniel and Sharpless, 1983).

Borehole geophysical log data were collected in June 1983 from five bedrock wells (Gu-382, Gu-383, Gu-385, Gu-386, Gu-387) located at a test site (fig. 8) in the Greensboro-High Point Regional Airport area by Daniel and Sharpless (1983). Well depths ranged from 200 feet to 275 feet. The borehole geophysical data from these five wells were collected in order to refine current knowledge of subsurface geology and hydrologic parameters in the test-site area. The data collected included natural gamma-ray logs, porosity logs, temperature logs, televiewer logs, and caliper logs. Temperature logs also were collected at all five well sites in March 1985.

Well-log data collected at the test site agree with the results of other well-log studies conducted in other sections of the Piedmont (Stewart, 1962). The bulk of the material in the upper 40 and 50 feet penetrated by these wells is unconsolidated regolith. Here, total porosities are as high as 60 percent and generally decrease significantly below this depth. The gamma ray logs identified most clay-rich zones in the saprolite, as well as zones of feldspars and micaceous minerals in bedrock. The temperature logs were evaluated in order to (1) obtain geothermal-gradient profiles in the bedrock wells, and (2) determine to what extent temperature profiles in an open borehole might delineate zones of ground-water entrance or movement. Nutter and Otton (1969) conducted a similar evaluation of temperature logs collected from wells located in the Maryland Piedmont detecting seasonal effects of temperature change on ground water in the first 60 feet below land surface.

The upper segments of temperature profile logs collected at well Gu-383 at the Greensboro-High Point test site in June 1983 and in March 1985 are shown in figure 12. Note the pronounced cool-water temperature bulge in June 1983 from 21 to 52 feet.

Only a slight cool-water temperature deflections were detected on temperature logs collected in March 1985 (fig. 12). Initial comparisons of recorded surface-water temperature data collected in North Carolina for the winter of 1982-83 (Gunter and others, 1984) and for the winter of 1984-85 indicate that the winter of 1982-83 may have been slightly cooler than the winter of 1984-85. The temperature profile in figure 12 may suggest that warmer water recharged the ground-water system in 1985 than in 1983 due to slightly milder winter conditions. It is interesting to note that the uppermost portions of the temperature curves (0 to 20 feet) have opposite slopes. These near-surface temperature curves may reflect the actual surface temperature conditions present when the logs were collected.

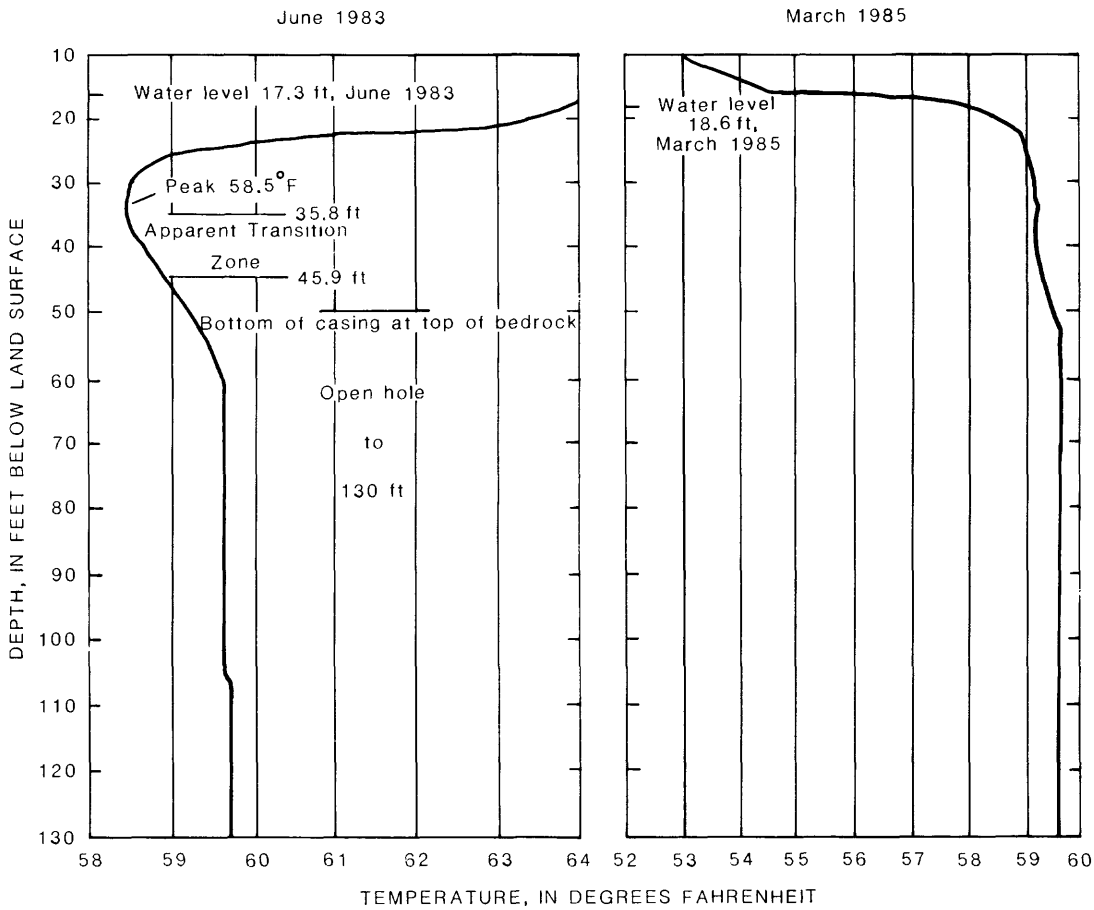

Figure 12.--Temperature logs for well Gu-383, June 1983 and March 1985, located at the Greensboro-High Point Regional Airport.

A more complete data base is needed in the Piedmont province in order to determine to what extent seasonal variations do affect ground-water temperatures and if the subsurface temperatures can provide evidence of greater flow in the transition zone than in the other zones.

POTENTIAL SOURCES OF GROUND-WATER CONTAMINATION

Assessment of potential sources of contamination is fundamental to the management of the ground-water resource. As part of this assessment process, Mew (1985) has developed a ranking system to evaluate ground-water contamination sources and has evaluated the NRCD's inventory of sources that has been compiled over the last 10 years. This inventory includes data on ownership, location, type of operation, type of waste, type of disposal facility or source, status of the source, monitoring, confirmation of ground-water contamination, data-base cross references, and regulatory history.

The waste-source inventory identified over 3,000 potential sources of ground-water contamination in North Carolina. Contamination has been verified at 240 of these sites. A subset of 592 sources from the inventory, containing only the confirmed contamination sources, the highest ranked sources, and the monitored sources was examined by Mew (1985). Two hundred and fifty-one of these sources are located in the Piedmont. Percentages of potential and confirmed sources of ground-water contamination by type for these 251 sources are shown in figure 13. Landfills, waste lagoons, and underground tanks make up most of the sources of ground-water contamination of concern.

The 1983 annual report of hazardous waste (North Carolina Department of Human Resources, Division of Health Services, 1984) states that within the State of North Carolina there were 618 facilities, each of which generated 2,200 pounds or more per month of hazardous waste. In addition, 111 facilities either treated, stored, or disposed of 2,200 pounds or more of hazardous waste. The majority of the waste generators and the waste handlers are in the Piedmont counties with Mecklenburg County (fig. 1) having the greatest number (86).

WATER-QUALITY DATA BASE

One of the principal objectives of this study has been to construct a data set containing the available data on ground-water quality in the Piedmont of North Carolina. Well locations of the combined data set are shown in figure 14.

The data set constructed during this reconnaissance study provides a strong base for current and future ground-water quality study. The construction, editing, and analysis of information contained in this data

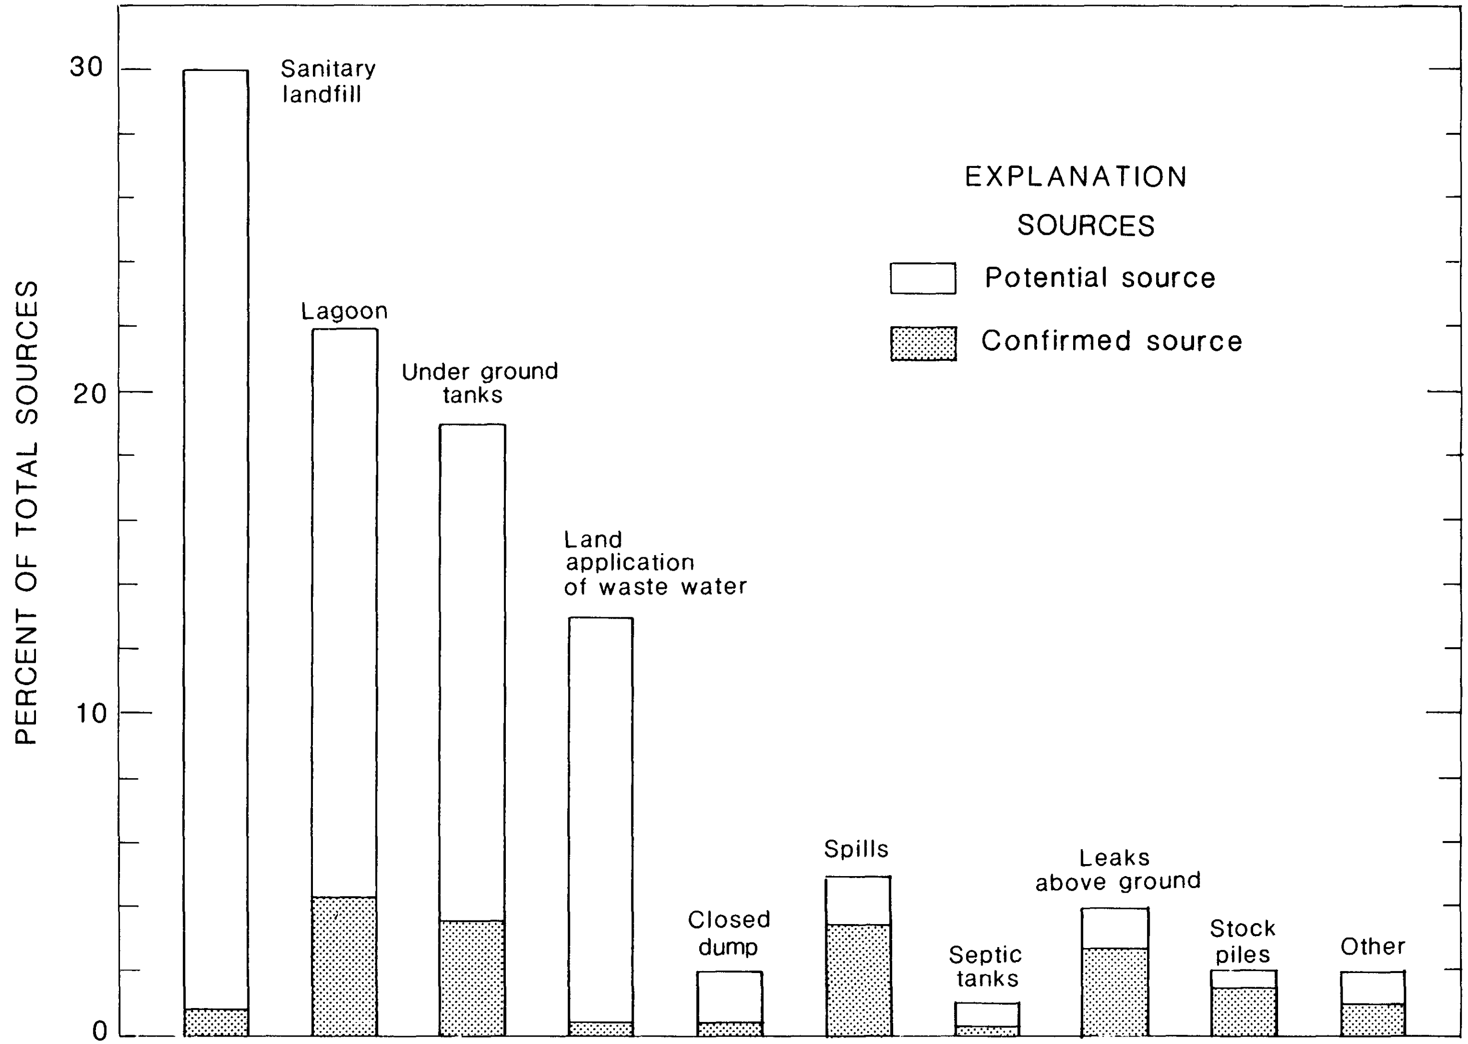

Figure 13.--Percent of ground-water contamination sources, confirmed and potential, by type, for the 251 high ranking sources in the Piedmont.

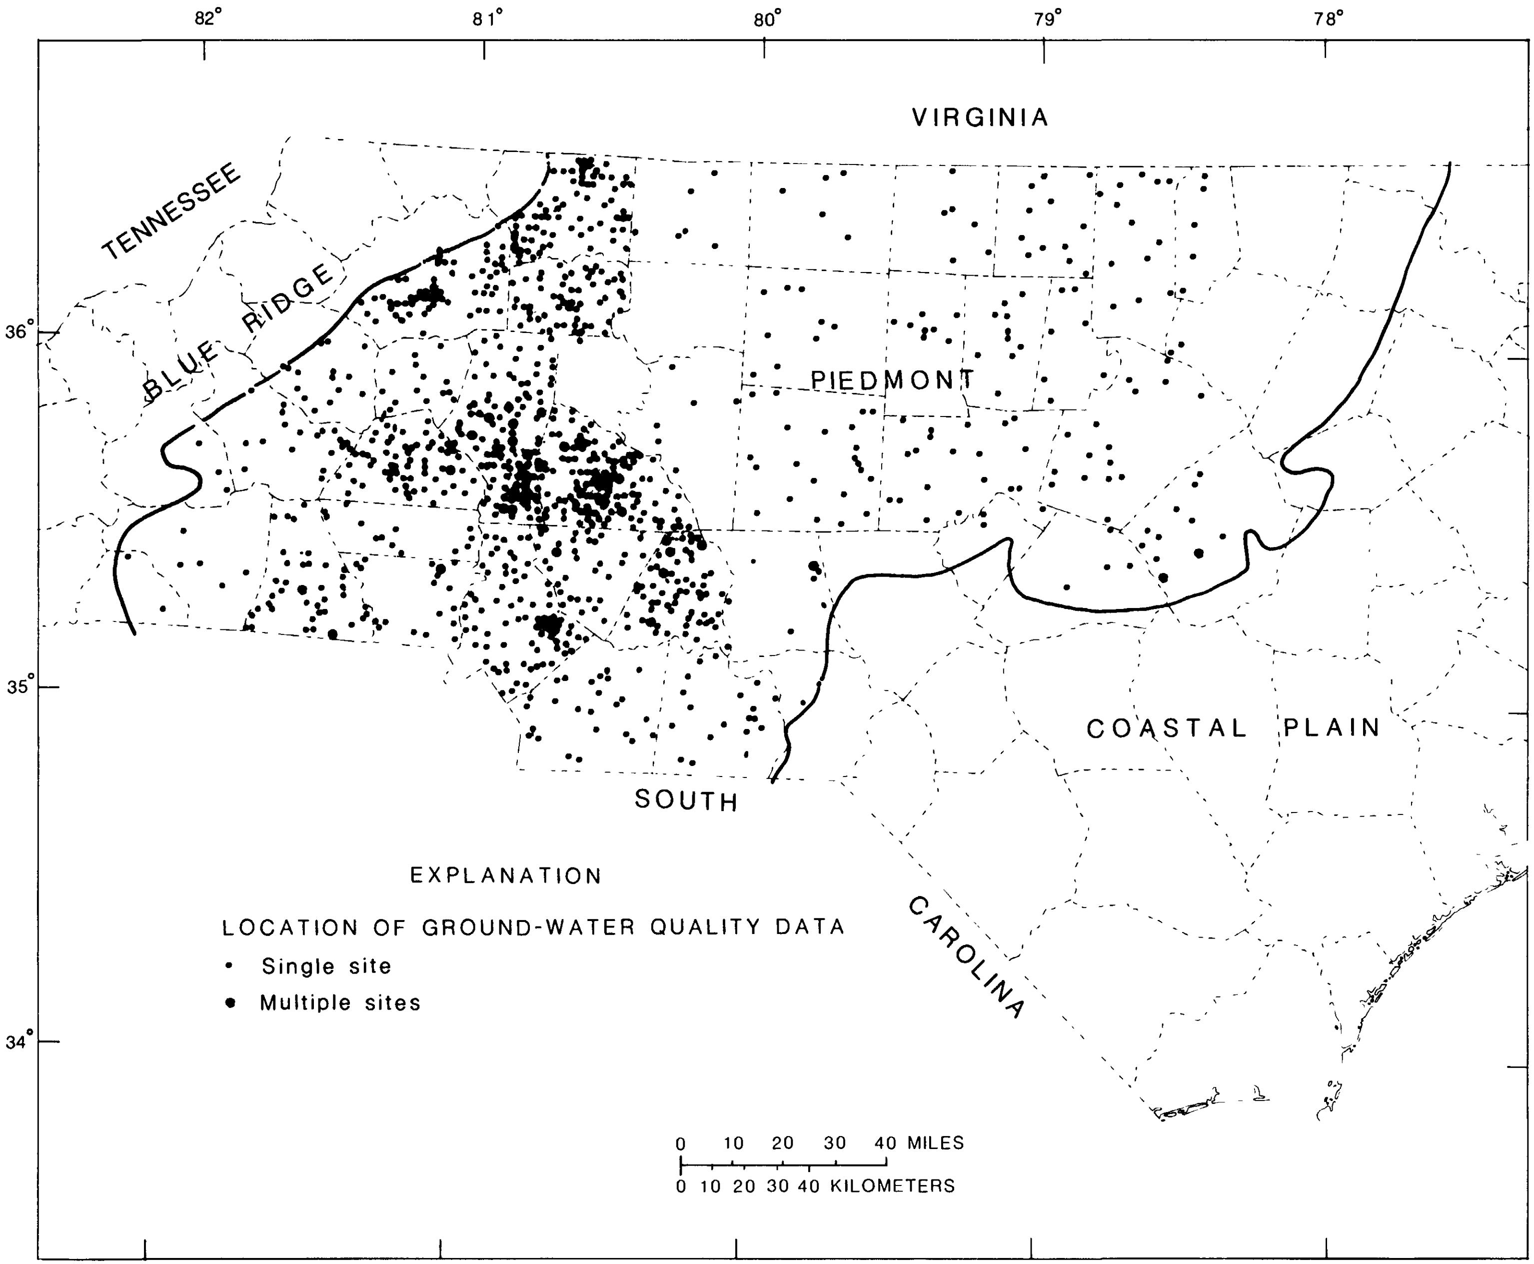

Figure 14.--Locations of available ground-water quality data in the Piedmont of North Carolina.

set is an ongoing process, and much additional work can be done to enhance its usefulness. Data on organic constituents and more trace-element data need to be collected and added to the data set.

Two principal sources of data form the bulk of the Piedmont ground-water-quality data set. The primary source is historical data, collected mainly during U.S. Geological Survey cooperative studies and published in numerous publications of the NRCD and preceding agencies. A map showing the coverage of the Piedmont province by these reports is shown in figure 15. Another important source of data has been unpublished results of ground-water analyses made for the U.S. Environmental Protection Agency (EPA) 208 Planning Study of 1978-80 (208 Study). The 208 Study, which was directed by NRCD, produced laboratory analyses of shallow ground-water quality at nearly 600 sites. The recently initiated NRCD baseline water-quality network (Perry Nelson, North Carolina Department of Natural Resources and Community Development, written commun., 1985) is an important source of information for background water quality. Data from this ongoing study will also be added to the data set.

Data from recent and ongoing U.S. Geological Survey studies are an important part of information currently available on ground water in the Piedmont. Recent U.S. Geological Survey studies provide one of the few sources of analyses of constituents such as heavy metals and organics, but even this source is limited to only a few land-use types. One U.S. Geological Survey study in particular, the city of Charlotte and Mecklenburg County urban hydrology study (Eddins and Crawford, 1984), has been instrumental to site selection. It provides detailed information on county-wide water quality of streams during low-flow periods.

The ongoing U.S. Geological Survey study of Charlotte-Mecklenburg County urban hydrology includes quarterly sampling of 24 monitoring wells in landfills around Charlotte, 10 privately-owned wells near the landfills, and streams draining landfill and residential areas.

Simmons and Heath (1979) examined baseline water quality from undeveloped basins all around North Carolina at both high and low flows. Low-flow data from this study can be used as an indicator of ground-water quality in undeveloped areas.

Figure 15.--Regional ground-water investigations in the Piedmont of North Carolina.

A study of the ground-water development potential in the Piedmont and Blue Ridge areas of North Carolina is the source of the geologic data used in correlation analysis with ground-water quality data, as well as much hydrologic framework information used in this study.

An ongoing U.S. Geological Survey study of the effects of land-management practices on sediment and chemical transport via streams in Guilford County, North Carolina, includes an examination of soil-water and ground-water quality in a tobacco-growing area.

DATA ANALYSIS

The data-analysis objective of the current study is to test the set of available ground-water quality data for relations between water quality and land use, geology, and soil characteristics. This was done using simple non-parametric analysis of variance (ANOVA) on the ranks of the data. In addition, some characterization of the data set is appropriate. However, a more complete description and analysis of the data is reserved for future study.

The data collected for the 208 Study was used for this study because the water samples were collected over a period of 3 years and analyzed at the same laboratory, and the land uses associated with the sampling sites were known. This data set is well suited for testing by ANOVA, because the effect of uncontrollable variance due to analyses at different laboratories at different periods of time is not a factor.

The 402 wells included in the 208 Study were quite shallow, with a mean depth of 27.7 feet. Daniel (1985) reports that in his survey of the North Carolina Piedmont and Blue Ridge the mean well depth for 5,221 wells is 154.0 feet, and the mean for 4,408 domestic wells is 123.6 feet. The Blue Ridge area has a similar hydrogeologic flow system to the Piedmont; therefore, wells from the Blue Ridge should not substantially differ in well characteristics from Piedmont wells. The 208 Study wells were augered in the regolith deep enough to obtain a water sample from just below the water table. The mean depth of the water table is 18.2 feet below land surface for the 208 Study. Daniel reports that the overall Piedmont and Blue Ridge mean water level in water-supply wells is 32.3 feet below land surface (n =

2,825). Water-supply wells used in Daniel's study tended to be deeper than the shallow 208 Study wells and generally had water-levels lower than those in shallow wells nearby. This indicates that in much of the area there is a downward gradient from the shallow part of the system to the deeper fractured rock system.

Water-Quality Data

An analysis of available ground-water quality data indicates that shallow ground water in the Piedmont generally is a slightly acidic (median pH, 6.5) sodium bicarbonate-type water with dissolved solids concentrations less than 100 milligrams per liter (mg/L). However, the water-quality data base contains analyses of contaminated as well as natural ground waters. Dissolved solids concentrations exceed 500 mg/L in a number of the analyses and exceed 1,000 mg/L in a few. Values of pH ranged from less than 2.0 units to as high as 10.8 units. Those samples with high dissolved-solids concentrations and extreme pH values were generally from wells in urban and industrial areas where the ground water has been contaminated.

Frequency histograms for pH, alkalinity, specific conductance, and dissolved solids concentrations in ground waters in the Piedmont are shown in figures 16-19. The histogram for pH is bell-shaped with most values falling between a pH of 5.5 and 7.5. Histograms for alkalinity, specific conductance, and dissolved solids are more log normal in shape with most values of alkalinity (as $CaCO_3$) less than 60 mg/L, most specific conductance values less than 200 microsiemens, and most dissolved solids concentrations less than 100 mg/L.

Independent Variables

Three different variables that may influence ground-water quality have been included in the data set: land use, geology, and soil type. The principal variable of interest in this study is land use. However, in defining the influences of land use on ground-water quality, it is important to account for the effects of other variables which may complicate analysis. Therefore, the variables of geology and soils have been added to the data set.

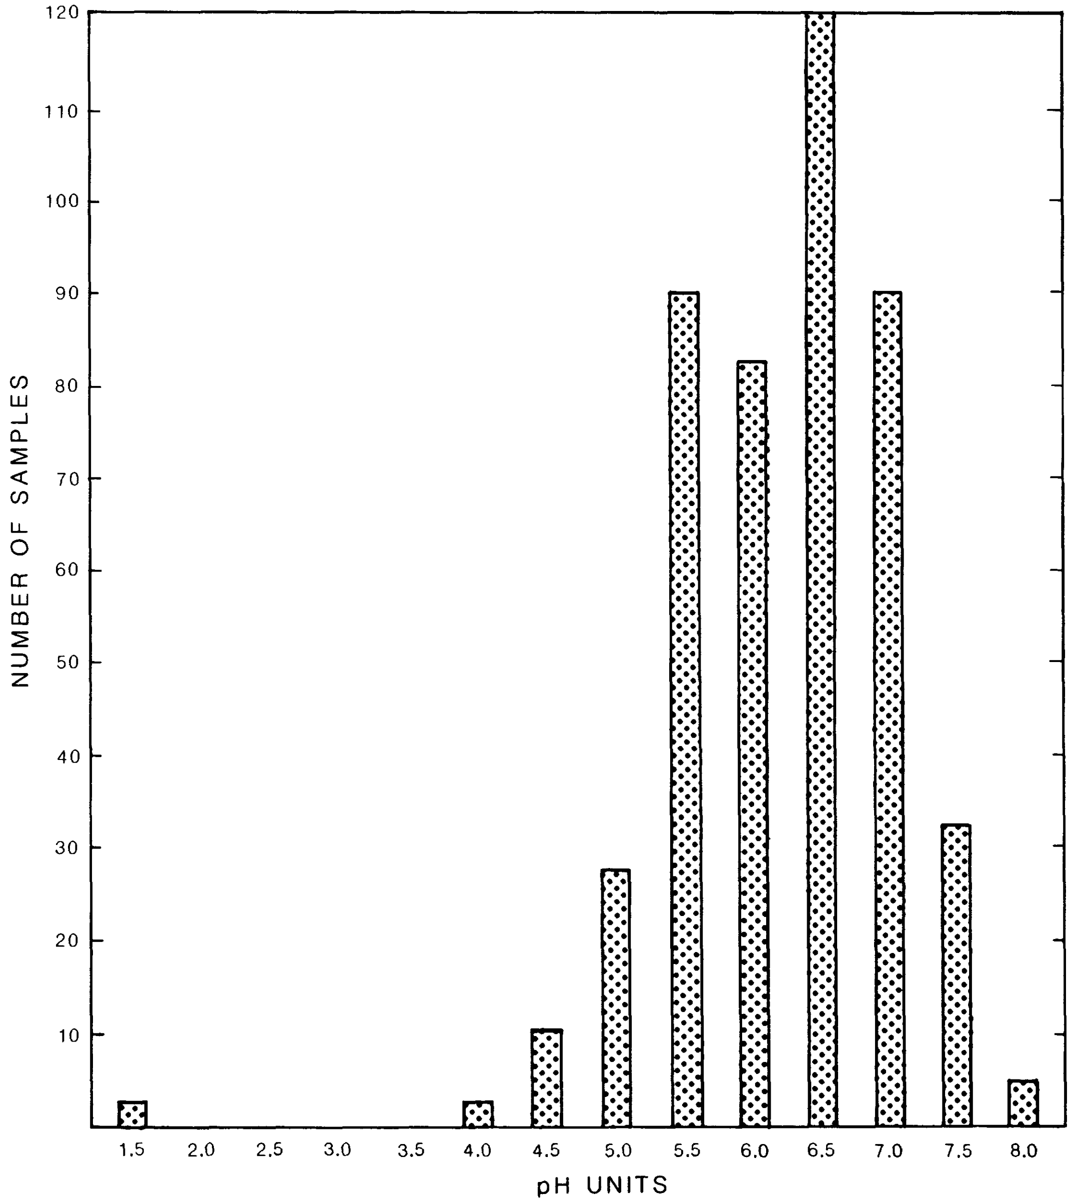

Figure 16.--A frequency histogram for pH.

Land use is represented in the data set in two forms. The Land-Use Data Analysis (LUDA) land-use type (Anderson and others, 1976) and the 208 Study land-use type have both been entered for each well location. The different categorizations of land uses produce two distinctly different ways of sorting the data set.

Bedrock geology, as compiled by Daniel (1987), was used in defining the rock type for each well. Most of the wells are located in regions of the metavolcanic and metaigneous rock types.

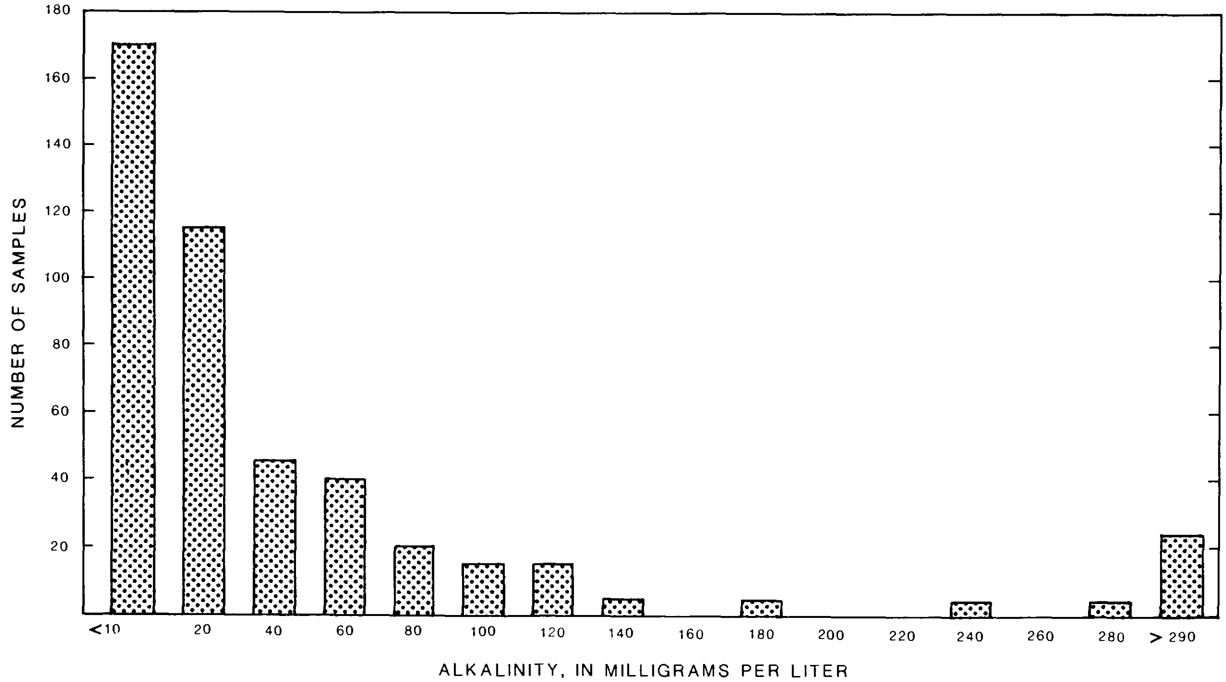

Figure 17.--A frequency histogram for alkalinity.

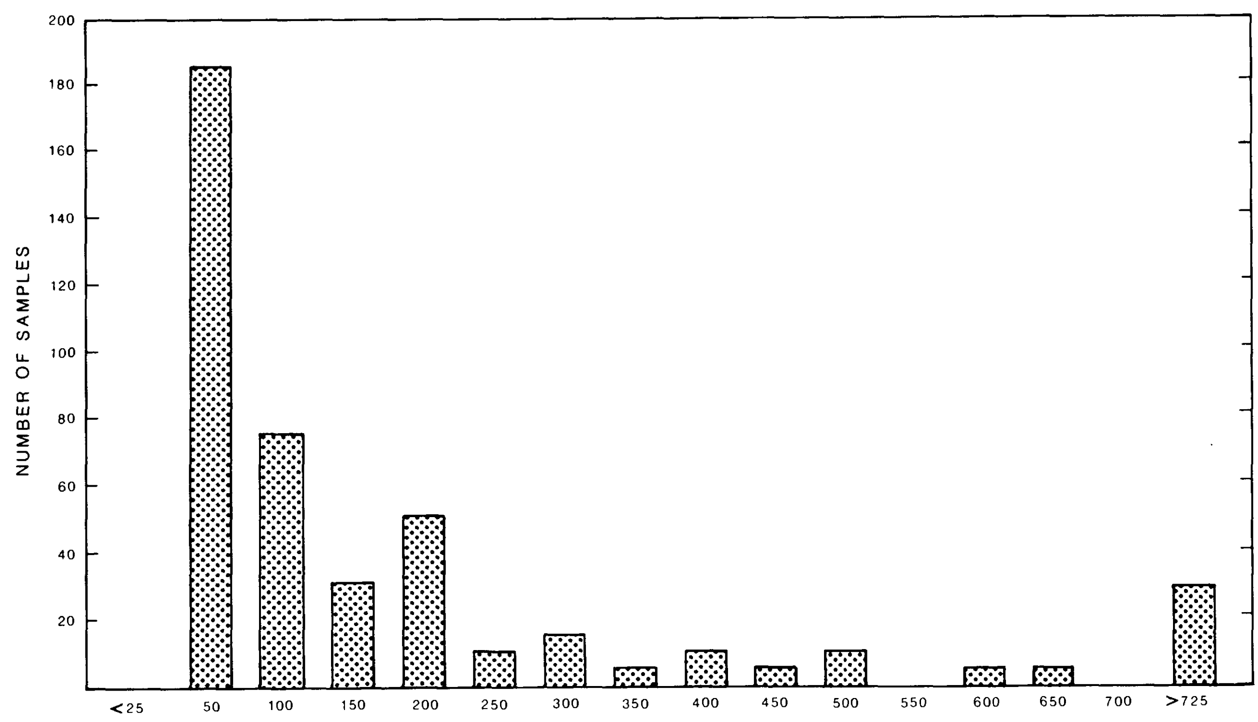

Figure 18.--A frequency histogram for specific conductance.

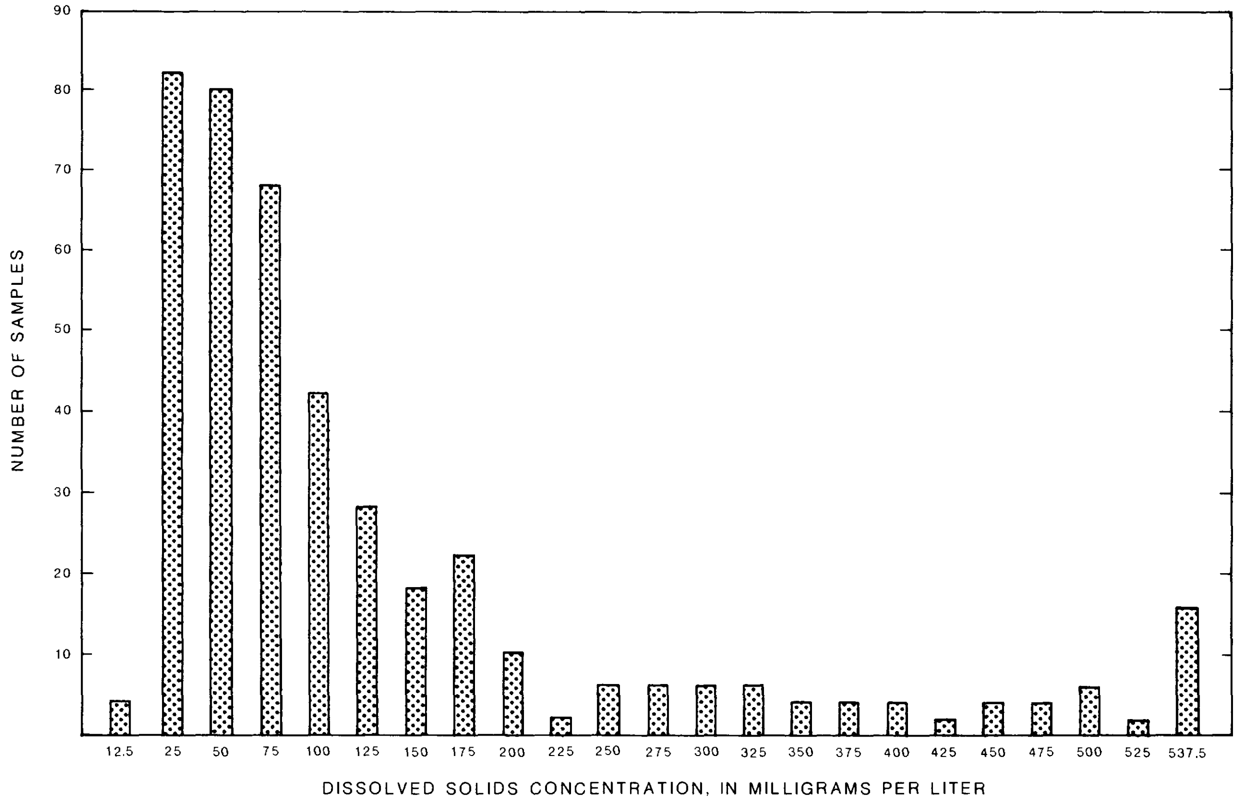

Figure 19.--A frequency histogram for dissolved-solids concentration.

Soil type at each well location was determined using the U.S. Soil Conservation Service (1978) soil classification system. The variables of soil type and rock type are not completely independent of each other since soils are usually derived from the underlying parent rock. However, in this analysis, soils and geology have been treated as separate variables simply to test if they affect ground-water quality.

Analysis of Variance

Non-parametric analysis of variance (ANOVA) on ranked data is used in this investigation to help define the relation between land use and ground-water quality. Helsel and Ragone (1984) describe the application of analysis of variance in the frame of reference of the U.S. Geological Survey ground-water quality appraisal program. Basically, one factor non-parametric ANOVA is a test for the comparison of means of the ranks of the concentrations. In other words, are the differences in the means of the concentrations of constituents in water due to chance variation alone, or are they the result of land use?

To test the null hypothesis that the means do not vary because of the effects of land use, the ratio:

$$F = \frac{\text{(Total variance) - (Within land-use region variance)}}{\text{(Within land-use region variance)}}$$

is calculated and compared to the F ratio that would be expected if the null hypothesis were true. If probability (PR) is low, then the effect investigated (land use, etc.) is significant, and the null hypothesis is rejected.

The results of analysis of variance of the water-quality constituents and the four independent variables are shown in table 2. Many of the F statistic values shown in table 2 for all the independent variables are significantly larger than the F values that might be produced by chance alone. In other words, for many of the water-quality constituents, the null hypothesis is rejected, land use, geology, and soil type do indeed influence ground-water quality for many constituents.

Simple analysis of variance has shown that there is at least one subgroup mean for land use, geology, and soils that has a variance significantly different from the variance that might be expected from chance. The next step is to find out which of the subgroup ranked means tested are significantly different from one another. One technique that can be used to show the subgroups that are significantly different from the others is the Duncan multiple-range test (Duncan, 1955).

The Duncan procedure sorts the subgroup means into groups that are statistically different from one another. When applied to the land use, geology, and soils classifications for this study, the Duncan analysis produced up to 4 out of 20 groups of different soil types, 3 out of 4 for the 208 Study land use, 3 out of the 15 LUDA classes of land use categories, and up to 4 groups of rock types that were found to be statistically different from one another out of 14 rock types. In other words, the test indicated that, in future analyses, combining of some of the land use, geology, and soils catagories may be appropriate. The results of the Duncan

Table 2.--*Summary of analysis of variance of the water-quality constituents and the four independent variables*

test suggest that the separate LUDA categories for urban areas could be grouped together. The 208 Study land-use data fared a little better, showing more separation of the subgroups than the LUDA data.

The ANOVA results shown in table 2 used 208 Study data land-use classifications of industrial, mixed urban, residential, and undeveloped. A finer division of these land-use classes into 17 categories produced similar results to the grouped classes with up to 4 Duncan groupings. The industrial land-use category was associated with the highest constituent concentrations followed generally by the mixed urban, residential and undeveloped land-use categories. Definition of the land-use catagories for the 208 Study data was based on information on the well locations. Therefore, a quantitative breakdown of the exact land uses represented by each of the classifications or categories is not possible. The industrial land use includes waste-water treatment plants, landfills, and manufacturing plants. The mixed-urban category includes a potpourri of commercial, retail, and urban land uses. The residential category includes both high and low density housing areas. The undeveloped land-use classification includes forests, fields, cropland, and farms.

A more detailed analysis of the data set is reserved for future study. As the current set of data is supplemented with organic constituents and more trace-element data, the information that can be gleaned from the data set by statistical analysis will increase.

NEED FOR ADDITIONAL STUDY

One of the principal objectives of this study has been to design a ground-water sampling program to test the relation between ground-water quality and land use. Definition of the relation of ground-water quality to land use will allow extrapolation of the data to a larger scale, giving an overall projection of ground-water quality within the Piedmont province based on land use.

The assembly of available information about the flow system and ground-water quality has led to the formulation of the following hypotheses about the system.

1. Land use.--Different land-use types are associated with different ground-water chemistry characteristics. The amount of ground-water contamination in the regolith and bedrock-fracture system is related to each land-use type. These relations can be mathematically defined to a level that allows statistical prediction and numerical modeling.

2. Contaminant-flow system.--The transition zone between bedrock and regolith serves as a primary transmitter of ground water and contaminated ground water. The regolith serves as the principal reservoir of contaminated ground water.
   a. Attenuation of ground-water contaminants in the regolith is related to the degree of weathering and composition of regolith material.
   b. The velocity of contaminant movement can be highest within the fractured-bedrock system, particularly under stressed conditions.
   c. The deeper zones in basement rock generally contain the best quality water in the system due to contaminant attenuation in the regolith and shallow fractures.
   d. Geomorphological analysis can be used to find fracture zones that help predict general subsurface-flow patterns of ground-water contamination. These methods can be verified with geophysical techniques.

3. Natural ground-water quality.--Ground-water quality is related to soil type and geology. Identification of measurable soil and geological characteristics that affect ground-water quality will allow a better characterization of the relation of land use to water quality.

Network Design

A ground-water quality monitoring network designed to test these hypotheses can provide:

1. Detailed information that can be used to refine understanding of the flow system;
2. Data that can give a regional picture of the effects of land use on water quality.

A hypothetical drainage basin (LeGrand, 1984) with multiple-contamination sources (fig. 20) illustrates the complexity of sampling to determine ground-water quality on an areal basis. The ground-water contamination from point sources such as spills and small waste lagoons is generally local and detectable only if wells are placed near the source and in the contaminant plume. Contamination from nonpoint sources, however, such as application of pesticides to farm fields, may be areal in extent but locally dilute and difficult to detect in any particular well.

Helsel and Ragone (1984) provide guidelines for experimental design within the framework of the U.S. Geological Survey national program of ground-water quality assessment. These guidelines stress the importance of:

1. <u>Representative sampling of study areas to give a characterization of overall basin ground-water quality</u>. In this respect, large localized sources such as landfills within the study area should be described separately, possibly by a separate monitoring program.

2. <u>Random sampling to reduce error in statistical testing of the data</u>. After a group of wells has been located within the study area to give representative hydrologic and geochemical coverage of the area, these wells should be randomly sampled to reduce bias in the data from any one particular well or series of wells.

3. <u>Maximization of the ability to detect effects given a limited number of samples</u>. The principal effect of interest is the influence of land use on water quality. Given a number of regions of different land uses, we wish to find:
    a. If there are significant water-quality differences between the land uses;

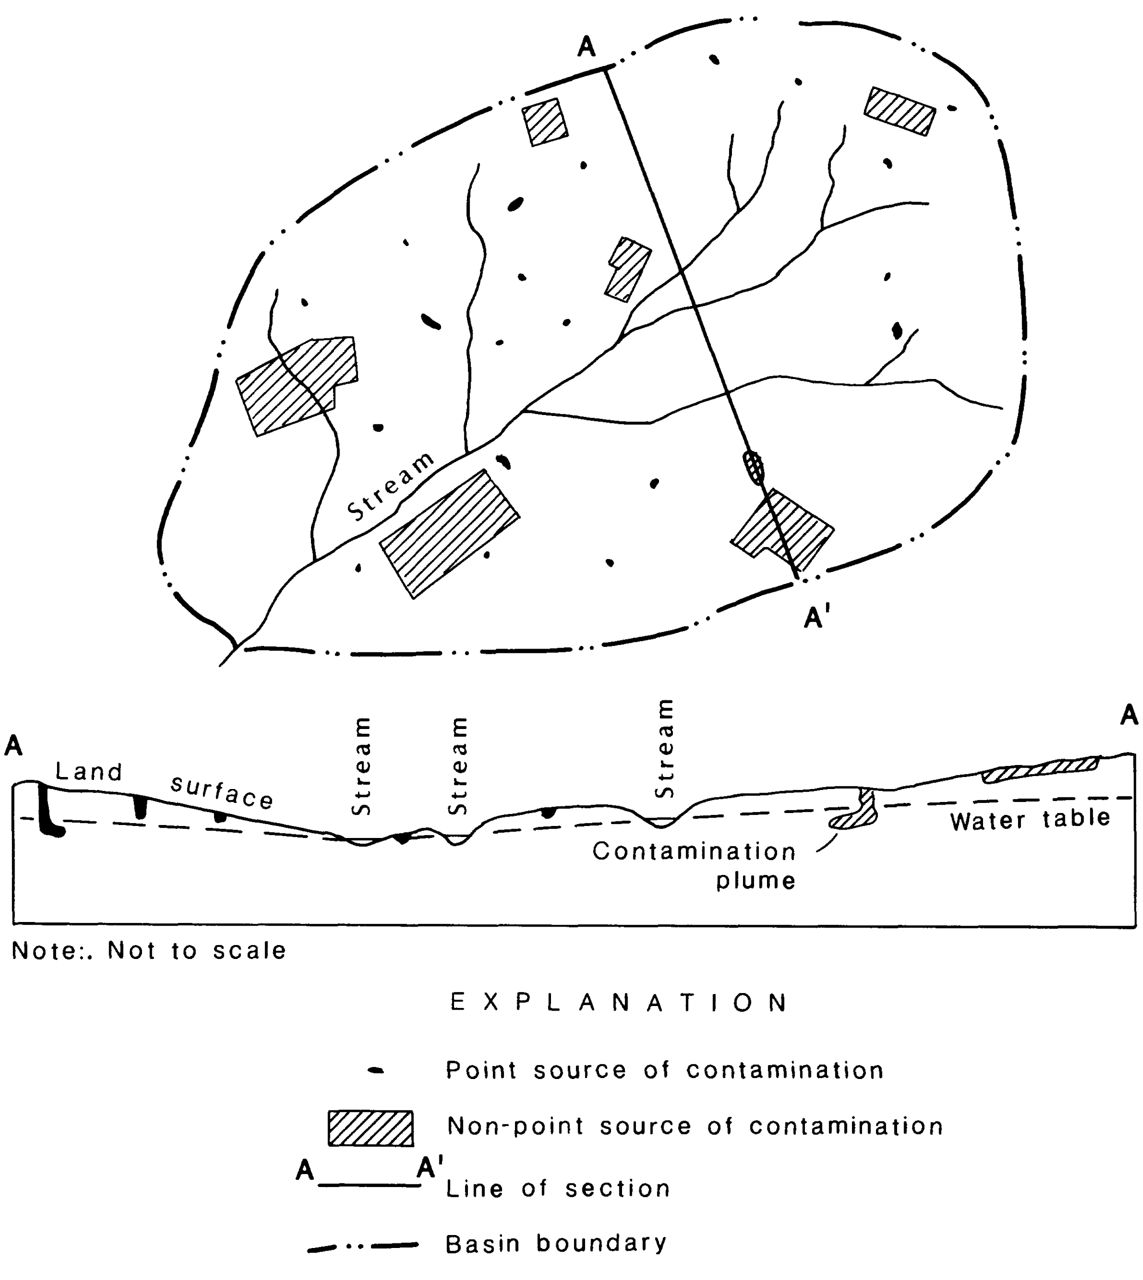

Figure 20.--A hypothetical drainage basin with multiple contamination sources (after LeGrand, 1984).

b. If there are significant areal variations in water quality in any particular land use (Significant variance between wells may obscure detection of differences between land uses. Additional sampling may improve definition of this variance); and

c. If there is significant variation over time in water quality in samples from any one well. (Significant variance between samples from a single well may obscure detection of differences between land uses. Additional sampling may improve definition of this variance.)

Once estimates for variance in concentrations between wells and variance of concentrations in the same well are known, the number of wells needed per area and the number of samples needed per well can be optimized for a given cost and number of study areas (Sokal and Rohlf, 1969; Helsel and Ragone, 1984).

Data Collection

To test the land-use and contaminant flow-system hypotheses, additional information about ground-water quality will need to be collected. In addition, special studies are needed to further refine the conceptual model of the hydrologic framework. As part of the study design, monitoring of (1) four different areas representing old industrial, new industrial, mixed urban, and residential land uses in Mecklenburg County, (2) an agricultural land-use area in Guilford County, and (3) two other sites to refine the framework are planned.

The monitoring will consist of three principal sampling programs:

1. Sampling of existing wells in and outside of the principal study areas;
2. Sampling from wells constructed specifically for the sampling program within the principal study areas; and
3. Sampling of baseflow of streams within the study areas.

There is very little information in available data bases about wells in and near the study areas. One of the first tasks of the study will be to identify the wells within the area that can be sampled. It is likely that few of these wells will be usable in the monitoring network. Domestic water-supply wells are usually cased to the fractured rock, bypassing the zones hypothesized to be most susceptible to ground-water contamination.

Usable sampling wells will be supplemented with new wells constructed specifically for this study. The goal will be to establish a network of wells which sample areas representative of particular land uses. Each well will sample a cell in the geohydrologic system. The locations of these cells will generally be in downgradient areas of the land uses under study. Wells will be installed to sample the upper part of the saturated regolith and the transition zone.

The resultant network of wells will be sampled during an initial sampling period to define spacial water-quality variability related to land use. Sampling wells open to different zones and multiple sampling in individual wells will be used to estimate within-well variability.

After the initial period of sampling, smaller groups of wells will be randomly selected from the group of wells sampling the shallow zones, the group sampling the transition zone, and the group sampling the deeper zone. Each of these three subgroups of wells will then be sampled periodically so that water-quality variation over time may be defined.

Sampling of streams during baseflow periods in basins and subbasins within the study areas will accompany sampling of wells. The sampling intervals will be nonuniform, depending on the streamflow conditions at the time of scheduled well-sampling trips.

Sampling Methods

The complexity of sampling to determine ground-water quality on a regional basis is further complicated by the difficulty of correctly measuring substances such as metals or organic substances in extremely low concentrations in the ground-water system. Wells within the network need to be designed to allow sampling of the desired zones without contamination from other zones or the casing materials. The sampling protocol will consider such factors as: sampling frequency, well diameter, sampling device used, amount of water to be removed from the well before sample collection, depth in water column that the sample is taken, bottle types and composition, sample filtering in the field, movement of sample from sampling device to the sample bottle, sample preservation, time limits required on delivery of samples to the laboratory, and quality control (Nacht, 1983).

In the initial assessment of water quality in a study area it is necessary to define which contaminants are present in the system in measurable amounts. Laboratory analyses of major inorganic constituents and nutrients combined with hydrocarbon and trace-element scans will be used to define the suite of constituents to be tested for in the following period of periodic sampling. Due to the high cost of sample analysis for organic constituents and trace metals, the assessment will begin with a relatively inexpensive scan or semi-qualitative method that indicates if contaminants are present (Helsel and Ragone, 1984). One such technique, the gas chromatograph-flame ionization detector (GC-FID) scan, is designed to detect the presence of hydrocarbons. Another technique, neutron-activation analysis (NAA), is a low-cost method that measures concentrations of a suite of elements, including many trace metals, and has very low detection limits for these elements.

During a GC-FID scan, the gas chromatograph separates organic compounds within the sample, delivering a stream of components of the sample to the flame-ionization detector (F. Cardinali, U.S. Geological Survey, oral commun., 1985). The sample stream comes out of the gas chromatograph and goes into a hydrogen flame, where the organic compounds are burned, producing ions and a current flow that is proportional to the amount of organic chemical present. This current can be detected and displayed. Standards and blanks are run to allow comparison and detection of laboratory contamination.

Careful comparative examination of the chromatographs of the series of samples, standards, and blanks may indicate that organic substances are in the sample that may warrant further investigation. The GC-FID scan can detect organic compounds, and in particular hydrocarbons, at levels of 0.5 micrograms per liter. GC-FID scans have been used in this study during the process of site selection. The technique will provide a means in the proposed monitoring studies of screening samples prior to substance-specific analysis.

In NAA, the sample is first irradiated by neutrons in a nuclear reactor (Kimberley and Bellis, 1985). The slightly radioactive sample produces gamma rays for each decaying radioisotope which can be detected. The rate of production of gamma rays for each induced radioisotope is proportional to its concentration. Spectral analysis is necessary in this analysis.

The elemental analysis produced by a complete NAA scan includes a variety of trace elements rarely tested for in traditional atomic-absorption spectrophotometry. These rare elements can individually be indicators of contamination or, in combination, can provide a signature that may be used to characterize ground water at a study location. Concentrations of 43 different elements are measured in a complete NAA scan.

Gas chromatograph-flame ionization detector and NAA scans provide a means to help define the suite of constituents to be tested for in later sampling. These scans, combined with laboratory analyses of major inorganic constituents and nutrients, will be useful in determining what constituents need to be tested for in the following period of random sampling.

Special Studies

The special-study program is designed primarily to test the principal hypothesis of the study that levels of ground-water contamination can be related to land use. However, to address the hypotheses about the contaminant-flow system, and especially the role of the transition zone in that system, a few additional special studies are proposed. These studies tie into other current U.S. Geological Survey research.

The distribution of solutes within the ground-water system is three dimensional. A vertical definition of water-quality variation within the ground-water flow system is necessary to describe solute distribution within the flow system on a local scale and to understand regional or basin-wide contaminant movement. To study the vertical variation in water quality in the regolith fractured-rock system, a nest of wells, each with a short screen interval at different depths, can be installed in areas where there is known ground-water contamination. Sampling of these well-nest sites, coupled with careful identification of the nature of the regolith and fractured-rock system at a site, will test the hypothesis that the transition zone plays a particularly important role in the contaminant-flow system.

Temperature logs can be used to detect seasonal effects on ground-water temperatures in the shallower parts of a borehole and to indicate ground-water flow (Nutter and Otton, 1969). However, a more complete data base is needed in the Piedmont province in order to determine the extent seasonal variations affect near-surface ground-water temperatures and if the subsurface temperatures provide evidence of greater flow in the transition zone than the other zones. One possible approach would be to run temperature logs monthly over a 1- to 2-year span at an established test site with a known regolith-bedrock profile. Another approach is to place thermocouples in key boreholes at the test site to record ground-water temperatures at various borehole depths for various time periods. The goal is to obtain enough temperature-profile information to test the hypothesis that differential flow within the regolith and fractured-rock system affects ground-water temperature.

SUMMARY AND CONCLUSIONS

The objective of this study is to evaluate the quality of ground water in the combined regolith and fractured-rock ground-water system in the North Carolina Piedmont and to develop and test hypotheses regarding the relationship of contamination to land use. This is a two-phase study. The first phase is the reconnaissance of available data and design of a monitoring program. The second phase is the implementation of that monitoring program and analysis of data from that program. This report documents of the progress of the first phase of the study.

The igneous and metamorphic rocks of the Piedmont are mantled by a cover of their own weathering products. The unweathered massive bedrock of about 400 feet below land surface grades upwards into fractured rock, then weathered rock with boulders of less weathered parent rock, followed by clay-rich saprolite (an unconsolidated material which contains remnant structure of the parent rock), and finally the soil horizons. In floodplains, streams rework the erodible material, sorting it into layered unconsolidated deposits. The mantle of weathered material, soil, and alluvium is generally called the regolith. In the Piedmont, the regolith is usually 30-60 feet thick. The regolith and underlying fractured rocks combine to make up a complex, multi-media flow system. The components of the system are:

1. The unsaturated zone in the regolith,
2. The saturated zone in the regolith,
3. The transition zone, and
4. The fractured-bedrock system.

The saturated thickness in the regolith provides the bulk of the water storage within the Piedmont ground-water system. The regolith serves as a reservoir supplying water to interconnected fractures within the bedrock. At the base of the regolith there is generally a zone of weathered rock, boulders, and saprolite. This transition zone has high permeability relative to other zones, and it may create a high-flow zone within the ground-water flow system.

On a regional scale, prediction of the natural direction of ground-water flow can be related to surface topography. Since most of the natural flow is probably confined to the upper 30 feet of bedrock, where there are the most fractures, and the transition zone, the distance between the point where a drop of water or waste enters the system is commonly less than a half mile from where that drop may eventually discharge to a stream (LeGrand, 1958). The perennial-stream drainage basin is essentially a complete flow-system cell, similar to and yet generally separate from surrounding basins.

Available sources of data on ground-water quality in the Piedmont of North Carolina have been identified and are being combined into a data set which also includes data on regional characteristics of the Piedmont such as land use, soils, and geology. The bulk of the data currently in the data set was collected between 1978 and 1980 in a program of the North Carolina Department of Natural Resources and Community Development (NRCD). Historical data, published in numerous publications of the North Carolina Department of Natural Resources and preceding agencies, most of which were U.S. Geological Survey cooperative studies, are also a primary source of data for this study.

Available land-use data were obtained from LUDA land-use maps, from the Mecklenburg County Planning Department, and the 208 Study. About 65 percent of the North Carolina Piedmont land area is forest, about 25 percent is cropland, and about 6 percent is urban and residential.

Several current U.S. Geological Survey studies have provided valuable information during the first phase of the investigation. One study in particular, the Charlotte and Mecklenburg County study (Eddins and Crawford, 1984), has been instrumental in the selection of possible second-phase study sites and has provided detailed information on county-wide water quality of streams during baseflow periods.

The set of ground-water quality data constructed during this reconnaissance study provides a strong base for current and future ground-water quality study. The construction, editing, and analysis of information contained in this data set is an ongoing process. The data set contains over 1,800 water-quality observations. The wells included in the 208 Study were shallow, with a mean depth of 27.7 feet. The mean depth of the water table was 18.2 feet below land surface for the 208 Study.

Temperature and pH show bell-shaped normal distributions. The other water-quality constituents show distributions that appear to be log-normal in shape.

Three different variables that may influence ground-water quality have been included in the data set. The variables of land use, geology, and soil type are all likely to affect water quality. The principal variable of interest in this study is land use. However, in defining the influences of land use on ground-water quality, it is important to account for the effects of other variables which may complicate analyses. Therefore, the variables of geology and soils have been added to the data set.

Non-parametric analysis of variance of the water-quality data indicates that land use, soil type, and geology influence ground-water quality for many constituents. The results of the Duncan multiple-range test suggest that the separate LUDA catagories for urban areas could be grouped together.

These are the hypotheses which need to be tested by further study:

1. Land use.--The amount of ground-water contamination in the regolith and bedrock-fracture system is related to land use. Each land-use type may be characterized by a particular ground-water chemistry.

2. Contaminant-flow system.--
    a. The transition zone between bedrock and regolith serves as a primary transmitter of contaminated

ground water. The regolith serves as the principal reservoir of ground-water contamination.

b. Attenuation of ground-water contaminants is related to the degree of weathering and composition of regolith material and the hydraulic conductivity, gradient, and porosity of the material.

c. Ground-water contaminants generally move in the direction of ground-water flow and at various rates depending upon water solubility.

d. The deeper zones in basement rock generally contain the best quality water in the system due to contaminant attenuation in the regolith.

e. Geomorphological analysis can be used to identify fracture zones that help predict general subsurface-flow patterns of ground-water contamination. These methods can be verified with surface geophysical techniques.

3. Natural ground-water quality.--Water quality is related to soil type and geology, and the relation can be quantified.

Future study is considered for four different land uses in Mecklenburg County, North Carolina. Drainage basins containing old industrial, new industrial, mixed urban, and residential land uses have been identified as potential study sites. Ground water from these basins will be collected from a network of wells augered to the top of the saturated zone and into the transition zone. Sampling wells open to different zones through the regolith and fractured rock system will test the hypothesis that the transition zone between the regolith and the fractured rock is a primary transmitter of contaminated ground water.

Gas chromatograph-flame ionization detector and NAA scans will be combined with selected laboratory analyses of volatile organic compounds and analyses of major inorganic constituents and nutrients in the initial period of sampling to define the suite of compounds to be tested for in the following period of random sampling. Sampling of baseflow of stream basins and subbasins within the study areas will accompany sampling of wells. The sampling intervals will be nonuniform, depending on the baseflow conditions at the time of scheduled well-sampling trips.

The Mecklenburg County studies will be coupled with other ongoing U.S. Geological Survey studies in the Piedmont. A study of ground-water quality in Guilford County, North Carolina, will provide information about agricultural land uses. A study in Mecklenburg County relating land use to surface-water quality will provide additional detailed land-use information, as well as results relevant to the proposed ground-water study.

The data collected from the Mecklenburg and Guilford County studies will be combined with the set of available ground-water quality data and used to test for correlations between land use and ground-water quality. The hypothesis that land use can be used to estimate regional ground-water quality will be tested using non-parametric analysis of variance. Comparison of results to other areas with known water-quality characteristics will allow verification of the predictive models.

A classification of natural rivers

David L. Rosgen

Wildland Hydrology, 157649 U. S. Highway 160, Pagosa Springs, CO 81147

Abstract

A classification system for natural rivers is presented in which a morphological arrangement of stream characteristics is organized into relatively homogeneous stream types. This paper describes morphologically similar stream reaches that are divided into 7 major stream type categories that differ in entrenchment, gradient, width/depth ratio, and sinuosity in various landforms. Within each major category are six additional types delineated by dominate channel materials from bedrock to silt/clay along a continuum of gradient ranges. Recent stream type data used to further define classification interrelationships were derived from 450 rivers throughout the U.S, Canada, and New Zealand. Data used in the development of this classification involved a great diversity of hydro-physiographic/geomorphic provinces from small to large rivers and in catchments from headwater streams in the mountains to the coastal plains. A stream hierarchical inventory system is presented which utilizes the stream classification system. Examples for use of this stream classification system for engineering, fish habitat enhancement, restoration and water resource management applications are presented. Specific examples of these applications include hydraulic geometry relations, sediment supply/availability, fish habitat structure evaluation, flow resistance, critical shear stress estimates, shear stress/velocity relations, streambank erodibility potential, management interpretations, sequences of morphological evolution, and river restoration principles.

1. General statement

It has long been a goal of individuals working with rivers to define and understand the processes that influence the pattern and character of river systems. The differences in river systems, as well as their similarities under diverse settings, pose a real challenge for study. One axiom associated with rivers is that what initially appears complex is even more so upon further investigation. Underlying these complexities is an assortment of interrelated variables that determines the dimension, pattern, and profile of the present-day river. The resulting physical appearance and character of the river is a product of adjustment of its boundaries to the current streamflow and sediment regime.

SSDI 0341-8162(94)E0046-3

River form and fluvial process evolved simultaneously and operate through mutual adjustments toward self-stabilization. Obviously, a classification scheme risks over-simplification of a very complex system. While this may appear presumptuous, the effort to categorize river systems by channel morphology is justified in order to achieve, to some extent, the following objectives:

1. Predict a river's behavior from its appearance;
2. Develop specific hydraulic and sediment relations for a given morphological channel type and state;
3. Provide a mechanism to extrapolate site-specific data collected on a given stream reach to those of similar character;
4. Provide a consistent and reproducible frame of reference of communication for those working with river systems in a variety of professional disciplines.

2. Stream classification review

A definition of classification was offered by Platts (1980) where "classification in the strictest sense means ordering or arranging objects into groups or sets on the basis of their similarities or relationships." The effort to classify streams is not new. Davis (1899) first divided streams into three classes based on relative stage of adjustment: youthful, mature, and old age. Additional river classification systems based on qualitative and descriptive delineations were subsequently developed by Melton (1936) and Matthes (1956).

Straight, meandering, and braided patterns were described by Leopold and Wolman (1957). Lane (1957) developed quantitative slope-discharge relationships for braided, intermediate, and meandering streams. A classification based on descriptive and interpretive characteristics was developed by Schumm (1963) where delineation was partly based on channel stability (stable, eroding, or depositing) and mode of sediment transport (mixed load, suspended load, and bedload).

A descriptive classification was also developed by Culbertson et al. (1967) that utilized depositional features, vegetation, braiding patterns, sinuosity, meander scrolls, bank heights, levee formations, and floodplain types. Thornbury (1969) developed a system based on valley types. Patterns were described as antecedent, superposed, consequent, and subsequent. The delineative criteria of these early classification systems required qualitative geomorphic interpretations creating delineative inconsistencies. Khan (1971) developed a quantitative classification for sand-bed streams based on sinuosity, slope, and channel pattern.

To cover a wider range of stream morphologies, a descriptive classification scheme was developed for and applied on Canadian Rivers by Kellerhals et al. (1972, 1976), Galay et al. (1973), and Mollard (1973). The work of these Canadian researchers provides excellent description and interpretation of fluvial features. This scheme has utility both for aerial photo delineation and for describing gradual transitions between classical river types. and to date offers the most detailed and complete list of channel and valley features. The large number of possible interpretative delineations, however, makes this scheme quite complex for general planning objectives.

An attempt to classify rivers in the great plains region using sediment transport, channel stability, and measured channel dimensions was developed by Schumm (1977). Classifying stream systems on the basis of stability is often difficult because of the qualitative criteria can vary widely among observers leading to inconsistencies in the classification. Similarly, data on ratio of bedload to total sediment load as needed in this classification, while useful, often is not readily available to those who need to classify streams.

Brice and Blodgett (1978) described four channel types of: braided, braided point-bar, wide-bend point-bar, and equi-width point-bar. A descriptive inventory of alluvial river channels is well documented by Church and Rood (1983). This data set can be very useful for many purposes including the grouping of rivers based on similar morphological characteristics. Nanson and Croke (1992) presented a classification of flood plains that involved particle size, morphology of channels, and bank materials. This classification has some of the same criteria of channel type as presented in this paper, but is restricted to flood plains. Pickup (1984) describes the relation of sediment source and relative amounts of sediment to various aspects of river type, but is not a classification of channels. Recent documentation by Selby (1985) showed a relationship between the form and gradient of alluvial channels and the type, supply and dominant textures (particle sizes) of sediments. This relationship utilizes the Schumm (1977) classification in that an increase in the ratio of bed material load to total sediment load with a corresponding increase in channel gradient leads to a decrease in stability causing channel patterns to shift from a meandering to braided channel form. In his classification, Selby (1985) treats anastomosed and braided channel patterns similarly. However, the anastomosed rivers are not similar to braided rivers in slope, adjustment processes, stability, ratio of bed material to total load or width/depth ratios as shown by (Smith and Smith, 1980).

Typically, theoretically derived schemes, often do not match observations. To be useful for extrapolation purposes, restoration designs, and prediction, classification schemes should generally represent the physical characteristics of the river. With certain limitations, most of these classification and/or inventory systems met the objectives of their design. However, the requirement for more detailed, reproducible, quantitative applications at various levels of inventory over wide hydro-physiographic provinces has led to further development of classification schemes.

2. Stream classification concepts

The morphology of the present day channel is governed by the laws of physics through observable stream channel features and related fluvial processes. Stream pattern morphology is directly influenced by eight major variables including channel width, depth, velocity, discharge, channel slope, roughness of channel materials, sediment load, and sediment size (Leopold et al., 1964). A change in any one of these variables sets up a series of channel adjustments which lead to a change in

Table 1
Hierarchy of river inventories

Level of detail	Inventory description	Information required	Objectives
I	Broad morphological characterization	Landform, lithology, soils, climate, depositional history, basin relief, valley morphology, river profile morphology, general river pattern	To describe generalized fluvial features using remote sensing and existing inventories of geology, landform evolution, valley morphology, depositional history and associated river slopes, relief and patterns utilized for generalized categories of major stream types and associated interpretations.
II	Morphological description (stream types)	Channel patterns, entrenchment ratio, width/depth ratio, sinuosity, channel material, slope	This level delineates homogeneous stream types that describe specific slopes, channel materials, dimensions and patterns from "reference reach" measurements. Provides a more detailed level of interpretation and extrapolation than Level I.
III	Stream "state" or condition	Riparian vegetation, depositional patterns, meander patterns, confinement features, fish habitat indices, flow regime, river size category, debris occurrence, channel stability index, bank erodibility	The "state" of streams further describes existing conditions that influence the response of channels to imposed change and provide specific information for prediction methodologies (such as stream bank erosion calculations, etc.). Provides for very detailed descriptions and associated prediction/interpretation.
IV	Verification	Involves direct measurements/observations of sediment transport, bank erosion rates, aggradation/degradation processes, hydraulic geometry, biological data such as fish biomass, aquatic insects, riparian vegetation evaluations, etc.	Provides reach-specific information on channel processes. Used to evaluate prediction methodologies; to provide sediment, hydraulic and biological information related to specific stream types; and to evaluate effectiveness of mitigation and impact assessments for activities by stream type.

the others, resulting in channel pattern alteration. Because stream morphology is the product of this integrative process, the variables that are measurable should be used as stream classification criteria.

The directly measurable variables that appear from both theory and experience to govern channel morphology have been included in the present classification procedure. These "delineative criteria" interact with one another to produce a stream's dominant features.

The present classification system has evolved from field observation of hundreds of rivers of various sizes in all the climatic regions of North America, experience in stream restoration, extensive teaching, and practical applications of the classification system by many hydrologists, geomorphologists, fisheries experts, and plant ecologists. Initial efforts to develop the classification procedure began in 1973, and a preliminary version was presented to the scientific community (Rosgen, 1985). The present paper includes notational changes from the earlier publication.

3. Stream classification system

The classification of rivers is an organization of data on stream features into discreet combinations. The level of classification should be commensurate with the initial planning level objective. Because these objectives vary, a hierarchy of stream classification and inventories is desirable because it allows an organization of stream inventory data into levels of resolution from very broad morphological characterizations to discreet, measured, reach-specific descriptions. Each level should include appropriate interpretations that match the inventory specificity. Further, general descriptions and characteristics of stream types should be able to be divided into even more specific levels. The more specific levels should provide indications of stream potential, stability, existing "states", etc., to respond to higher resolution data and interpretations when planning needs change. A proposed stream inventory system, including an integrated stream classification, is shown in Table 1.

Current river "state" and influences on the modern channel by vegetation, flow regime, debris, depositional features, meander patterns, valley and channel confinement, streambank erodibility, channel stability, etc., comprise additional parameters that are considered critical to evaluate by stream type at a more detailed inventory level (Level III). However, for the sake of brevity and clarity, this paper will focus on the first two levels, the broad geomorphic characterization (Level I) and the morphological description (Level II) which incorporates the general character of channel form and related interpretations. Portions of the data used for detailed assessment levels are contained in the sub-type section of the earlier classification paper (Rosgen, 1985).

4.1. Geomorphic characterization (level I)

The purpose of delineation at this level is to provide a broad characterization that integrates the landform and fluvial features of valley morphology with channel relief,

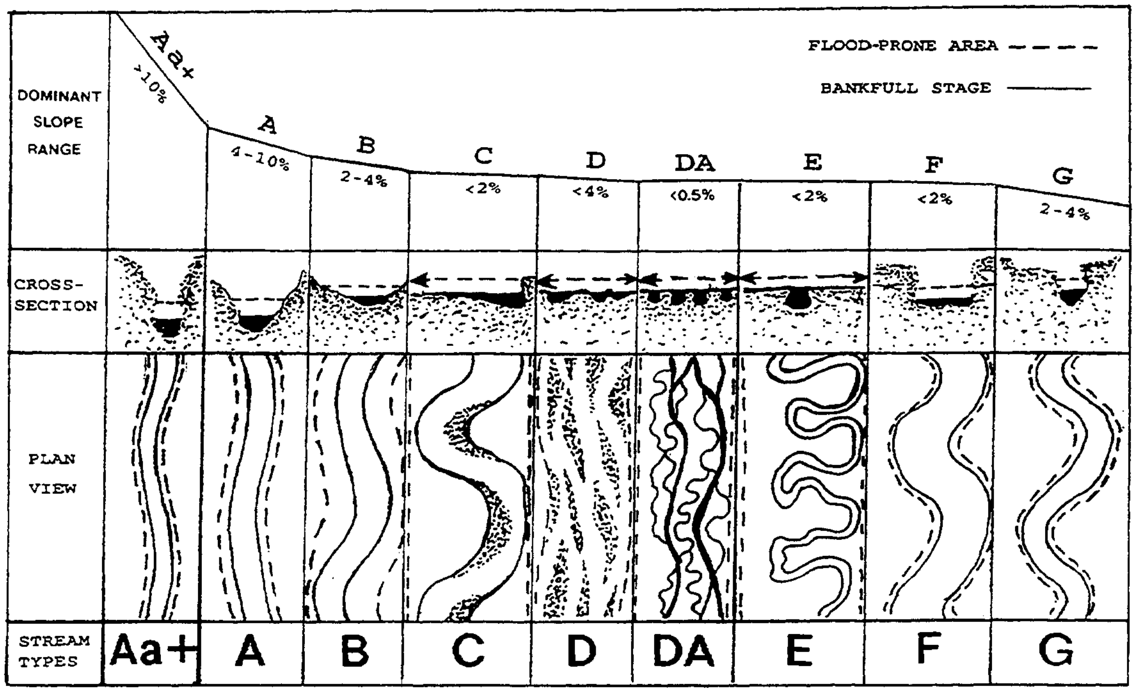

Fig. 1. Longitudinal, cross-sectional and plan views of major stream types.

pattern, shape, and dimension. Level I combines the influences of climate, depositional history, and life zones (desert shrub, alpine, etc.) on channel morphology.

The presence, description, and dimensions of floodplains, terraces, fans, deltas and outwash plains are a few examples of valley features identified. Depositional and erosional history overlay channel patterns at this level. Generalized categories of "stream types" initially can be delineated using broad descriptions of longitudinal profiles, valley and channel cross-sections, and plan-view patterns (see Fig. 1 and Table 2).

Longitudinal profiles

The longitudinal profile, which can be inferred from topographic maps, serves as the basis for breaking the stream reaches into slope categories that reflect profile morphology. For example, the stream types of Aa+ (Fig. 1) are very steep, (greater than 10%), with frequently spaced, vertical drop/scour-pool bed features. They tend to be high debris transport streams, waterfalls, etc. Type A streams are steep (4–10% slope), with steep, cascading, step/pool bed features. Type B streams are riffle-dominated types with "rapids" and infrequently spaced scour-pools at bends or areas of constriction. The C, DA, E and F stream types are gentle-gradient riffle/pool types. Type G streams are "gullies" that typically are step/pool channels. Finally, the D type streams are braided channels of convergence/divergence process that lead to localized, frequently spaced scour/depositional bed forms.

Bed features are consistently found to be related to channel slope. Grant et al. (1990) described bed features of pools, riffles, rapids, cascades, and steps as a function

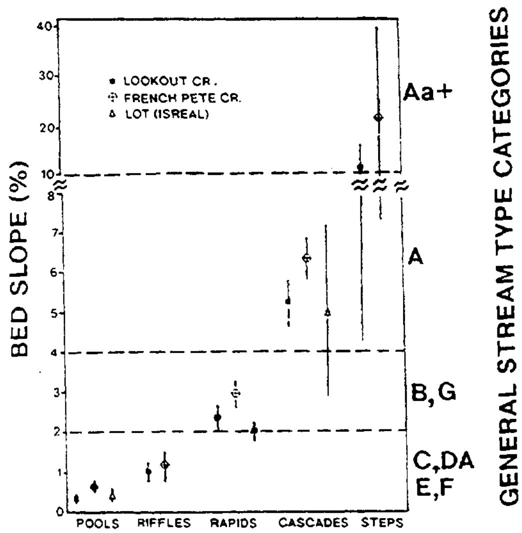

Fig. 2. Relationship of bed slope to bed forms for various stream types (from Grant et al., 1990).

of bed-slope gradient. Using their bed form descriptions, the above described stream types were plotted against the corresponding slope ranges reported by Grant et al. (1990). "Groupings", (Fig. 2), were apparent for riffle/pool stream types (C, E, and F) at less than 2%, rapids at 2–4% in "B" and "G", cascades in slopes 4–10% in type A streams, and steps for slopes 4–40% in types A and Aa+ streams. Because gradient and bed-feature relationships are integral to the delineation of stream type categories, "stream types" are more than just "arbitrary units". Bed morphology can be predicted from stream type by using bed-slope indices.

Cross-section morphology

The shape of the cross-section that would indicate a narrow and deep stream as opposed to a wide and shallow one can be inferred at this broad level. The manner in which the channel is incised in its valley can also be deduced at this level as well as information concerning floodplains, terraces, colluvial slopes, structural control features, confinement (lateral containment), entrenchment (vertical containment), and valley vs. channel dimension. For example, the type A streams are narrow, deep, confined, and, entrenched. The width of the channel and valley are similar. This contrasts with type C streams, where the channel is wider and shallower with a well-developed floodplain and a very broad valley. Type E streams have a narrow and deep channel (low width/depth ratio) but have a very wide and well developed floodplain. Type F streams have wide and shallow channels, but are an entrenched meandering channel type with little to no developed floodplain. Type G channels have low width/depth ratio channels similar to type E streams except they are well entrenched (no floodplain), are steeper, and less sinuous than type E streams (see Fig. 1).

Plan view morphology

The pattern of the river is classed as relatively straight (A stream types), low sinuosity (B stream types), meandering (C stream types), and tortuously meandering

Table 2
Summary of delineative criteria for broad-level classification

Stream type	General description	Entrenchment ratio	W/D ratio	Sinuosity	Slope	Landform/soils/features
Aa+	Very steep, deeply entrenched, debris transport streams.	< 1.4	< 12	1.0 to 1.1	> 0.10	Very high relief. Erosional, bedrock or depositional features; debris flow potential. Deeply entrenched streams. Vertical steps with/deep scour pools; waterfalls.
A	Steep, entrenched, cascading, step/pool streams. High energy/debris transport associated with depositional soils. Very stable if bedrock or boulder dominated channel.	< 1.4	< 12	1.0 to 1.2	0.04 to 0.10	High relief. Erosional or depositional and bedrock forms. Entrenched and confined streams with cascading reaches. Frequently spaced, deep pools in associated step-pool bed morphology.
B	Moderately entrenched, moderate gradient, riffle dominated channel, with infrequently spaced pools. Very stable plan and profile. Stable banks.	1.4 to 2.2	> 12	> 1.2	0.02 to 0.039	Moderate relief, colluvial deposition and/or residual soils. Moderate entrenchment and W/D ratio. Narrow, gently sloping valleys. Rapids predominate with occasional pools.
C	Low gradient, meandering, point-bar, riffle/pool, alluvial channels with broad, well defined floodplains	> 2.2	> 12	> 1.4	< 0.02	Broad valleys with terraces, in association with floodplains, alluvial soils. Slightly entrenched with well-defined meandering channel. Riffle-pool bed morphology.

D	Braided channel with longitudinal and transverse bars. Very wide channel with eroding banks.	n/a	> 40	n/a	< 0.04	Broad valleys with alluvial and colluvial fans. Glacial debris and depositional features. Active lateral adjustment, with abundance of sediment supply.
DA	Anastomosing (multiple channels) narrow and deep with expansive well vegetated floodplain and associated wetlands. Very gentle relief with highly variable sinuosities. Stable streambanks.	> 4.0	< 40	variable	< 0.005	Broad, low-gradient valleys with fine alluvium and/or lacustrine soils. Anastomosed (multiple channel) geologic control creating fine deposition with well-vegetated bars that are laterally stable with broad wetland floodplains.
E	Low gradient, meandering riffle/pool stream with low width/depth ratio and little deposition. Very efficient and stable. High meander width ratio.	> 2.2	< 12	> 1.5	< 0.02	Broad valley/meadows. Alluvial materials with floodplain. Highly sinuous with stable, well vegetated banks. Riffle-pool morphology with very low width/depth ratio.
F	Entrenched meandering riffle/pool channel on low gradients with high width/depth ratio.	< 1.4	> 12	> 1.4	< 0.02	Entrenched in highly weathered material. Gentle gradients, with a high *W/D* ratio. Meandering, laterally unstable with high bank-erosion rates. Riffle-pool morphology.
G	Entrenched "gulley" step/pool and low width/depth ratio on moderate gradients.	< 1.4	< 12	> 1.2	0.02 to 0.039	Gulley, step-pool morphology with moderate slopes and low *W/D* ratio. Narrow valleys, or deeply incised in alluvial or colluvial materials; i.e., fans or deltas. Unstable, with grade control problems and high bank erosion rates.

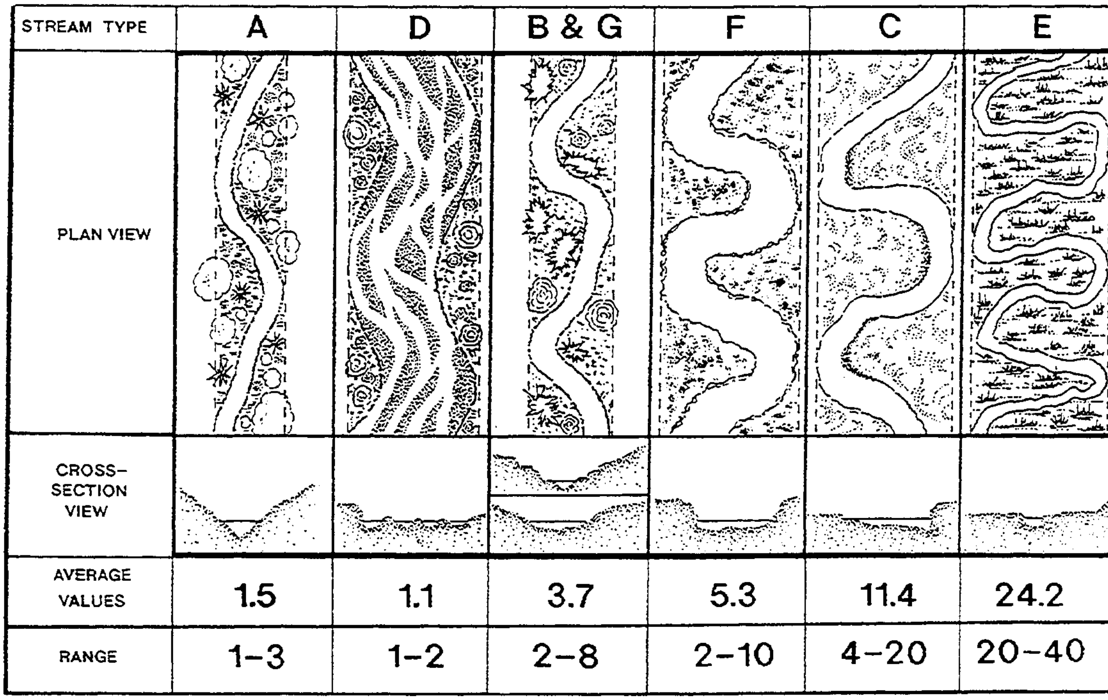

Fig. 3. Meander width ratio (belt width/bankfull width) by stream type categories.

(E stream types). Complex stream patterns are found in the multiple channel, braided (D) and anastomosed (DA) stream types. Sinuosity can be calculated from aerial photographs and often, like slope, serves as a good initial delineation of major stream types. These river patterns have integrated many processes in deriving their present form and thus, provide interpretations of their associated morphology.

Even at this broad level of delineation, consistency of dimension and associated pattern can be observed by broad stream types. Meander width ratio (belt width/ bankfull surface width) was calculated by general categories of stream types for a wide variety of rivers. Measured mean values and ranges by stream type are shown in Fig. 3. Early work by Inglis (1942) and Lane (1957) discussed meander width ratio but the values were so divergent among rivers that the ratio appeared to have little value. When stratified by general stream types, however, the variability appears to be explained by the similarities of the morphological character of the various stream types. This has value not only for classification and broad-level delineations, but also for describing the most probable state of channel pattern in stream restoration work.

Discussion

Interpretations of mode of adjustment — either vertical, lateral, or both — and energy distribution can often be inferred in these broad types. Many variables that are not discrete delineative variables integrate at this level to produce an observable morphology. A good example of this is the influence of a deep sod-root mass on type E streams that produces a low width/depth ratio, low meander length, low radius of curvature, and a high meander width ratio. Vegetation is not singled out for mapping at this level, but is implicit in the resulting morphology. If this vegetation is changed, the width/depth ratio and other features will result in adjustments to the

	A	B	C	D	DA	E	F	G
ENTRH.	<1.4	1.4–2.2	>2.2	N/A	>2.2	>2.2	<1.4	<1.4
SIN.	<1.2	>1.2	>1.4	<1.1	1.1-1.6	>1.5	>1.4	>1.2
W/D	<12	>12	>12	>40	<40	<12	>12	<12
SLOPE	.04–.099	.02–.039	<.02	<.02	<.005	<.02	<.02	.02–.039

Fig. 4. Illustrative guide showing cross-sectional configuration, composition and delineative criteria of major stream types.

type C stream morphology. Detailed vegetative information, however, is obtained at the channel state level (Level III, Table 1).

Delineating broad stream types provides an initial sorting within large basins and allows a general level of interpretation. This leads to organization and prioritization for the next more detailed level of stream classification.

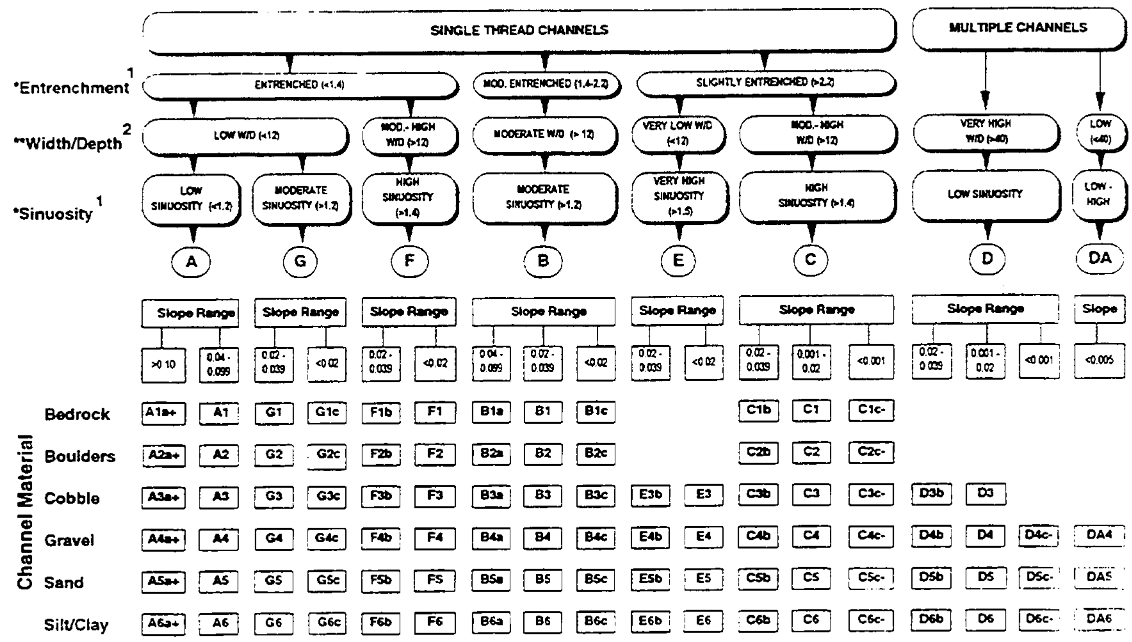
4.2. The morphological description (level II)

General description

This classification scheme is delineated initially into the major, broad, stream categories of A–G as shown in Fig. 1 and Table 2. The stream types are then broken into discreet slope ranges and dominant channel-material particle sizes. The stream types are given numbers related to the median particle size diameter of channel materials such that 1 is bedrock, 2 is boulder, 3 is cobble, 4 is gravel, 5 is sand, and 6 is silt/clay. This initially produces 42 major stream types as shown in (Fig. 4).

A range of values for each criterion is given in the key to classification for 42 major stream types (Fig. 5). The range of values chosen to represent each delineative criterion is based on data from a large assortment of streams throughout the United States, Canada and New Zealand. A recent data set of 450 rivers was statistically used to refine and test previous ranges of delineative criteria as described in the author's earlier publication (Rosgen, 1985).

Histograms were drawn of the distribution of values of each delineative criterion for each channel type. From the histograms of 5 criteria for 42 major stream types, the mean and "frequent range" of values were recorded. The most frequently observed values seemed to group into a recognizable "river form" or morphology. When values



[1] Values can vary by ± 0.2 units as a function of the continuum of physical variables within stream reaches.
[2] Values can vary by ± 2.0 units as a function of the continuum of physical variables within stream reaches.

Fig. 5. Key to classification of natural rivers.

were outside of the range of the "most frequently observed" condition, a distinctly different morphology was identified. As a result, the delineation of unique stream types representing a range of values amongst several variables were established. These variables and their ranges make up the current morphological description of stream types as shown in Figs. 4 and 5.

The classification can be applied to ephemeral as well as perennial channels with little modification. Bankfull stage can be identified in most perennial channels through observable field indicators. Although, these bankfull stage indicators, are often more elusive in ephemeral channels.

The morphological variables can and do change even in short distances along a river channel, due to such influences of change as geology and tributaries. Therefore, the morphological description level incorporates field measurements from selected reaches, so that the stream channel types used here apply only to individual reaches of channel. Data from individual reaches are not averaged over entire basins to describe stream systems. A category may apply to a reach only a few tens of meters or may be applicable to a reach of several kilometers.

Data is obtained from field measurements of representative or "reference reaches." The resultant stream type as delineated can then be extrapolated to other reaches where detailed data is not readily available. In similar valley and lithological types, stream types can often be delineated using these reference reaches through the use of aerial photos, topographic maps, etc.

Continuum concept

When the variables which make up the range of values within a stream type change, there is more often than not, a change in stream type. The ranges in slope, width/depth ratio, entrenchment ratio and sinuosity shown in Fig. 4 span the most frequently observed values. Exceptions occur infrequently, where values of one variable may be outside of the range for a given stream type.

This level recognizes and describes a continuum of river morphology within and between stream types. The continuum is applied where values outside the normal range are encountered but do not warrant a unique stream type. Often the general appearance of the stream and the associated dimensions and patterns of the stream do not change with a minor value change in one of the delineative criteria. For example, slope values as shown in Fig. 5, using the continuum concept, are not "lumped", but rather are sorted by sub-categories of: a+ (steeper than 0.10), a (0.04–0.10), b (0.02–0.039), c (less than 0.02) and c- (less than 0.001).

The application of this concept allows an initial classification of a C4 stream type (a gravel bed, sinuous, high width/depth ratio channel with a well-developed floodplain. If the slope of this stream was less than 0.001, then the stream type would be a C4c−.

Rivers do not always change instantaneously, under a geomorphic exceedance or "threshold". Rather, they undergo a series of channel adjustments over time to accommodate change in the "driving" variables. Their dimensions, profile and pattern reflects on these adjustment processes which are presently responsible for the form of the river. The rate and direction of channel adjustment is a function of the nature and magnitude of the change and the stream type involved. Some streams change very rapidly, while others are very slow in their response.

Delineative criteria

At this level of inventory each reach is characterized by field measurements and validation of the classification. The delineation criteria and ranges for various stream types are shown in Fig. 5. This classification key also represents the sequential process for classification. The classification process starts at the top of the chart (single or multiple thread channels), and proceeds downward through channel materials and slope ranges.

Entrenchment

An important element of the delineation is the interrelationship of the river to its valley and/or landform features. This interrelationship determines whether the river is deeply incised or entrenched in the valley floor or in the deposit feature. Entrenchment is defined as the vertical containment of river and the degree to which it is incised in the valley floor (Kellerhals et al., 1972). This makes an important distinction of whether the flat adjacent to the channel is a frequent floodplain, a terrace (abandoned floodplain) or is outside of a flood-prone area. A quantitative expression of this feature, "entrenchment ratio" was developed by the author so that various mappers could obtain consistent values. The entrenchment ratio is the ratio of the width of the flood-prone area to the bankfull surface width of the channel. The flood-prone area is defined as the width measured at an elevation which is determined at twice the maximum bankfull depth. Field observation shows this elevation to be a frequent

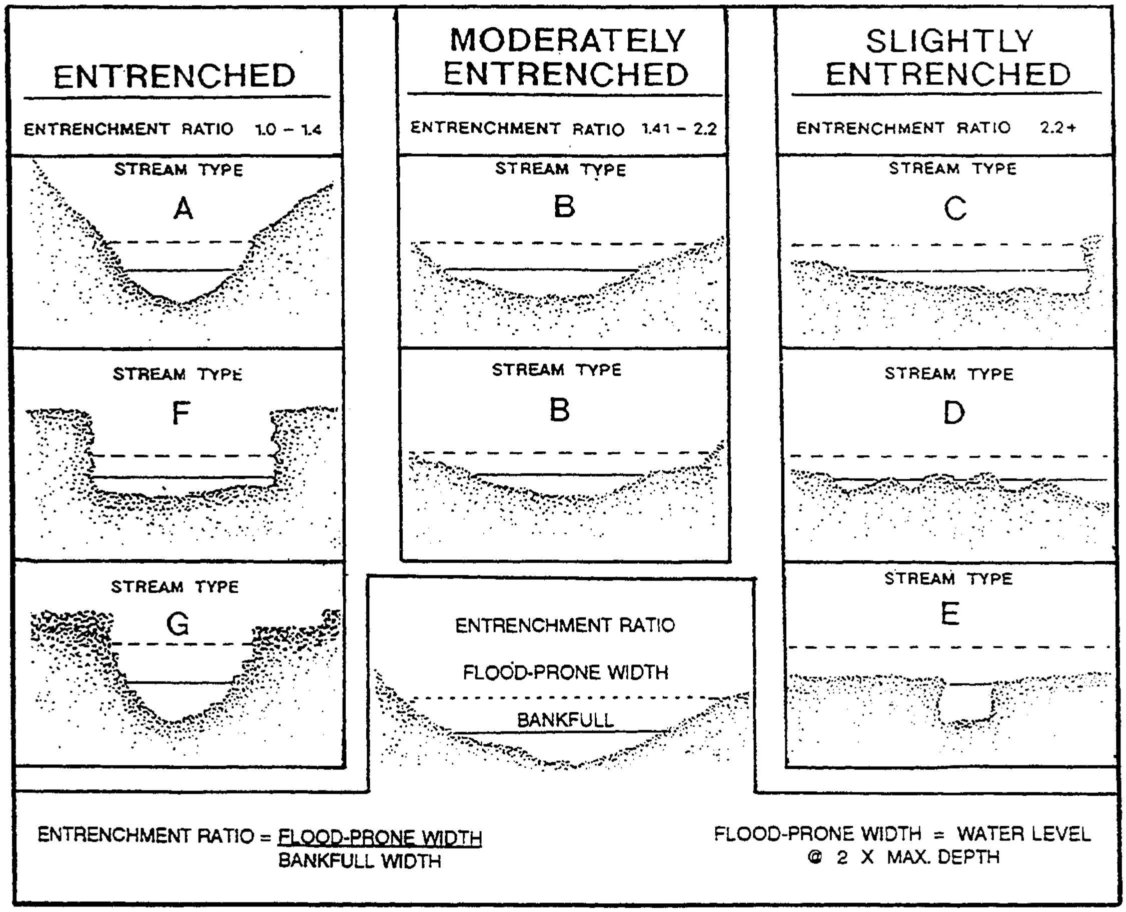


Fig. 6. Examples and calculations of channel entrenchment.

flood (50 year return period) or less, rather than a rare flood elevation. The categories are illustrated in Figs. 4, 5 and 6.

Entrenchment ratios of 1–1.4 represent entrenched streams, 1.41–2.2 represent moderately entrenched streams and ratios greater than 2.2 are slightly entrenched (well-developed floodplain). These categories were empirically derived based on hundreds of streams. As with other criteria, the measured entrenchment ratio value may lie somewhat outside of the classification range. When this occurs, the author applies the continuum concept which allows for a category description where the entrenchment is either greater or less than the most frequently observed value for a given morphology. The continuum allows for a change of \pm 0.2 units where the corresponding delineative criteria still match the range of variables consistent for that type. In this case, all of the other attributes must be considered before assigning a stream type.

Width/depth ratio

The width/depth ratio describes the dimension and shape factor as the ratio of bankfull channel width to bankfull mean depth. Bankfull discharge is defined as the momentary maximum peak flow; one which occurs several days in a year and is often related to the 1.5 year recurrence interval discharge. Specific discussions on the delineation and significance of bankfull discharge are found in Leopold et al. (1964), Dunne and Leopold (1978), and Andrews (1980). Hydraulic geometry and sediment transport relations rely heavily on the frequency and magnitude of bankfull discharge.

Osborn and Stypula (1987) utilized width/depth ratio to characterize stream channels for hydraulic relations using channel boundary shear as a function of channel shape.

For this classification, values of low width/depth ratio are those less than 12. Values greater than 12 are moderate or high. Average values and ranges are shown in the stream type summaries. As in the continuum concept, applied to entrenchment ratio, there is an occasion where width/depth ratio values can vary by ±2 units without showing a different morphology. This does not occur very frequently, but the continuum allows for some flexibility to fit the stream type into a "dominant" morphology.

Sinuosity

Sinuosity is the ratio of stream length to valley length. It can also be described as the ratio of valley slope to channel slope. Mapping sinuosity from aerial photos is often possible, and interpretations can often be made of slope, channel materials, and entrenchment once sinuosity is determined. Values of sinuosity appear to be modified by bedrock control, roads, channel confinement, specific vegetative types, etc. Generally speaking, as gradient and particle size decreases, there is a corresponding increase in sinuosity. The continuum as mentioned earlier also applies and adjustments of + or −0.2 can be applied to this delineative criteria. Meander geometry characteristics are directly related to sinuosity following minimum expenditure of energy concepts. Initial studies by Langbein and Leopold (1966) suggested that a sine generated curve describes symmetrical meander paths. From this observation they predicted the radius of curvature of meander bends from meander wavelength and channel sinuosity. In comparing observed versus predicted values of radius of curvature for 79 streams, Williams (1986) found this relation to be highly correlated when applied to an expanded data set. This demonstrates the interrelationship of sinuosity to meander geometry. Based on such relations and the relative ease of determination, sinuosity was selected as one of the delineative criteria for stream classification.

Channel materials

The bed and bank materials of the river is not only critical for sediment transport and hydraulic influences but also modifies the form, plan and profile of the river. Interpretations of biological function and stability also require this information. Often a good working knowledge of the soils associated with various landforms can predict the channel materials at the broad delineation level. Reliable estimates of the soil characteristics for glacial till, glacial outwash, alluvial fans, river terraces, lacustrine and eolian deposits, and residual soils can be derived from mapped lithology.

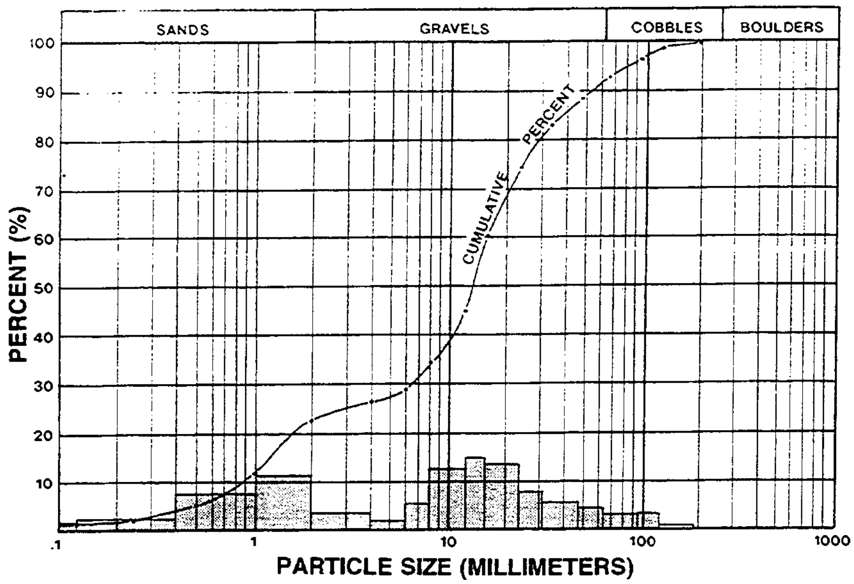

Fig. 7. Channel material sizes showing cumulative and percent distributions.

Field determination of channel materials for this classification system utilizes the "pebble count" method developed by Wolman (1954), with a few modifications to account for bank material and for sand and smaller sizes. This is a determination the frequency distribution of particle sizes that make up the channel. The pebble count data is plotted as cumulative percent and percent of total distribution (Fig. 7). The dominant particle size is identified in the cumulative percent curve as the median size of channel materials or size that 50% of the population is of the same size or finer (D_{50}). The percent distribution shown in Fig. 7 is often used to detect bimodal distributions that may be hidden in cumulative plots. This data is used in biological evaluation, sediment supply assessment, and other interpretative applications.

Slope

Water surface slope is of major importance to the morphological character of the channel and its sediment, hydraulic, and biological function. It is determined by measuring the difference in water surface elevation per unit stream length. Typically, slope is often measured through at least 20 channel widths or two meander wavelengths. As observed with the other delineative variables, slope values less or greater than the most frequently observed ranges can occur. These can occur without a significant change in the other delineative criteria for that stream type. The most frequently observed slope categories and applications of the continuum concept for slope is shown in Fig. 5.

In broad-level delineations, slopes can often be estimated by measuring sinuosity from aerial photos and measuring valley slope from topographic maps (valley slope/sinuosity = channel slope). The basin and associated landform relief can also be used to estimate stream slope ranges, as for example terraces and slopes of alluvial fans.

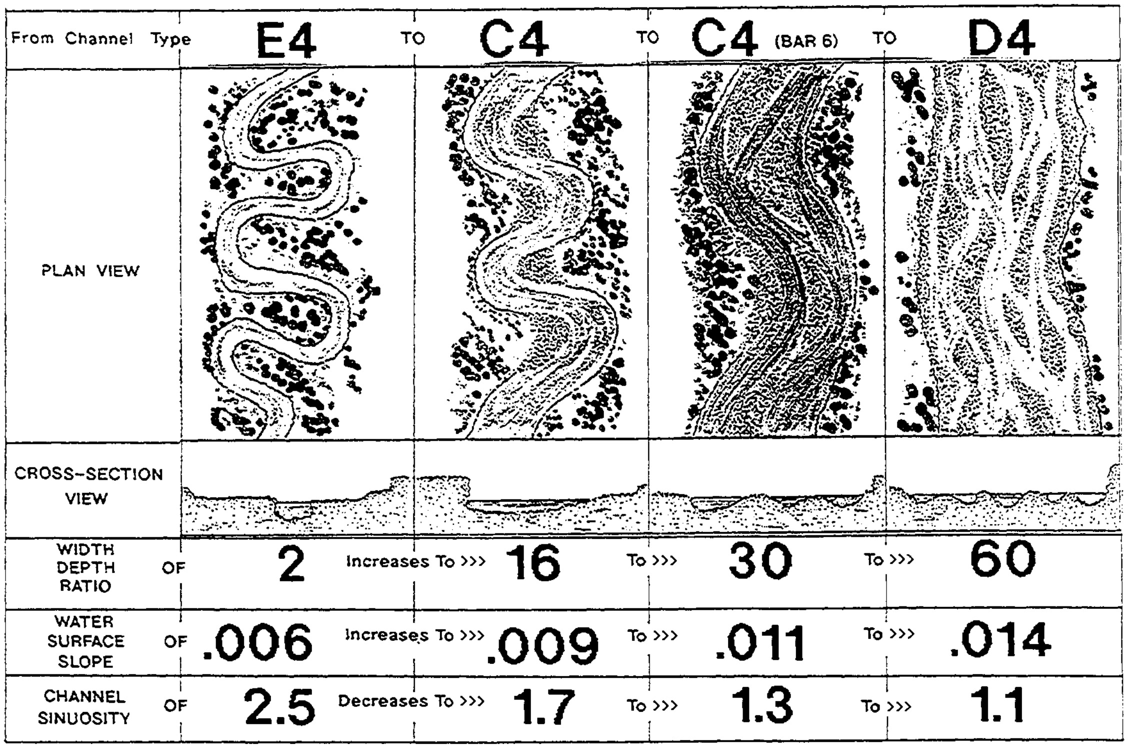

Fig. 8. Progressive stages of channel adjustment due to imposed stream bank instability.

5. Application

Past observations of adjustments of stream systems often provide insight into sensitivity and consequence of change. Stream system changes can be due to flow, sediment, or many of the interrelated variables that have produced the modern channel. If changes produces disequilibrium, similar streams types receiving similar impacts may be expected to respond the same. If the observer knows the stream type of the disturbed reach, and has cross-section, bank erosion, sediment data, riparian vegetation and fisheries data, this information can be used predictively to evaluate the risk and sensitivity to disturbance.

5.1. Evolution of stream types

In reviewing historical aerial photos, observations can be made of progressive stages in channel adjustment. These adjustments occur partially as a result of change in stream-flow magnitude and/or timing, sediment supply and/or size, direct disturbance, and vegetation changes. These observed changes in channel morphology over time can be communicated in terms of stream type changes. For example, due to streambank instability, and a resultant increase in bank erosion rate, the stream increased it's width/depth ratio; decreased sinuosity; increased slope; established a bimodal particle size distribution; increased bar deposition; accelerated bank erosion; and decreased the meander width ratio. These changes can be described more simply

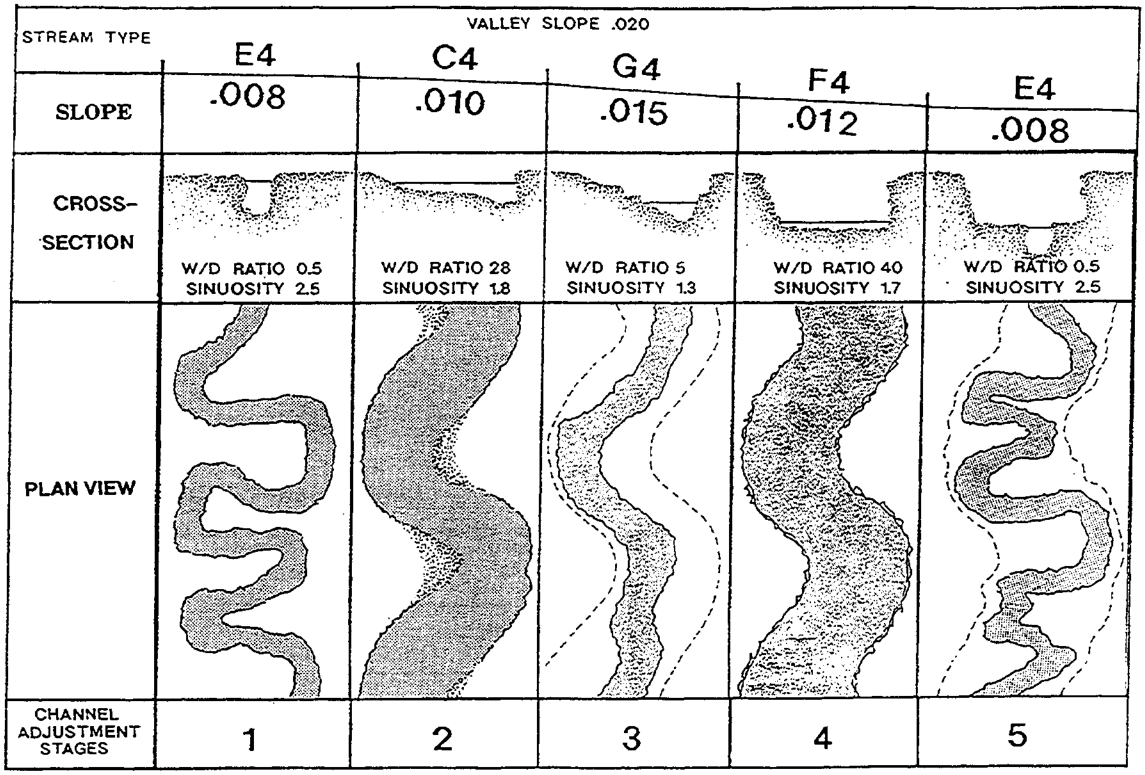

Fig. 9. Evolutionary stages of channel adjustment.

as a series of progressive changes of channel adjustment in stream type from an E4 to C4 to C4 (bar-braided) to D4 (Fig. 8).

Another example of channel adjustment where morphological patterns are changed sufficient to indicate a shift in stream type is shown in Fig. 9. In this scenario, a change in streambank stability led to an increase in width/depth ratio and slope, and a decrease in sinuosity and meander width ratio. As the slope steepened along with a high width/depth ratio, chute cutoffs occurred across large point bars creating a gulley. The stream abandoned its floodplain, decreased the width/depth ratio, steepened the slope and decreased sinuosity. This resulted in a change in base level as all of the tributaries draining into this stream were over-steepened. Sediment from both channel degradation and bank erosion was increased. As the banks continued to erode, the width/depth ratio and sinuosity both increased with a corresponding decrease in slope. The channel was still deeply entrenched, but eventually started to develop a floodplain at a new elevation. This stream eventually evolved under a changed sediment and flow regime into a sinuous, low gradient, low width/depth ratio channel with a well developed floodplain which matched the original morphology, except now exists at a lower elevation in the valley. This case is shown more simply in Fig. 9 as a shift from an E4 stream type to C4 to G4 to F4 and back to an E4 type.

These changes have been well documented throughout western North America due to various reasons including climate change and adverse watershed impacts. The knowledge provided by observing these historical adjustments and the understanding of the tendency of rivers to regain their own stability can assist those restoring disturbed river systems. Often the works of man try to "restore" streams back to a state that does not match the dimension, pattern and slope of the natural, stable form. As stream types change, there are a large number of interpretations associated with these "morphological shifts". Stream types can imply much more than what is initially described in it's alphanumeric title.

5.2. Fish habitat

When physical structures are installed in channels to improve the fish habitat, the adjustment processes that occur sometimes create more damage than habitat. For example, Trail Creek in southeast Colorado, a C4 stream type, had a gabion check dam installed at 80% of the bankfull stage to create a plunge pool for fish. The results were; decreased upstream gradient; width/depth ratio increase; decreased mean bed particle diameter; and decreased competence of the stream to move its own sediment. The longitudinal profile of the river changed creating headward aggradation. With a decrease in slope, there was a corresponding increase in sinuosity that resulted in accelerated lateral channel migration and increased bank erosion. Subsequently, the stream abandoned the original channel and created a "headcut gulley" with a gradient that was twice the valley slope. This converted the C4 stream type to a G4 type in a period of approximately two years. The "new" stream type has abandoned its floodplain, is rejuvenating tributaries headward and creating excess sediment from stream degradation and bank erosion. This disequilibrium caused by the check dam is long-term and has deteriorated the habitat that the structure was initially designed to improve. Unfortunately, structures like this continue to be installed by well-meaning individuals without a clear understanding of channel adjustment processes.

To prevent similar problems and to assist biologists in the selection and evaluation of commonly used in-channel structures, guidelines by stream type were developed (Rosgen and Fittante, 1986). In the development of these guidelines hundreds of fish habitat improvement structures were evaluated for effectiveness and channel response. A stream classification was made for each reach containing a structure. From this data, the authors rated various structures from "excellent" to "poor" for an extensive range of stream types. These guidelines provide "warning flags" of potential adverse adjustments to the river so that technical assistance may be obtained. In this manner, structures may be better designed to not only meet their objectives, but help maintain the stability and function of the river. Fisheries habitat surveys presently integrate this stream classification system (USDA, 1989). The objective for this integration is to determine the potential of the stream reach, current state, and a variety of hydraulic and sediment relations that can be utilized for habitat and biological interpretations.

5.3. Flow resistance

Application of the Manning's equation and the selection of a roughness coefficient N value to predict mean velocity is a common methodology used by engineers and

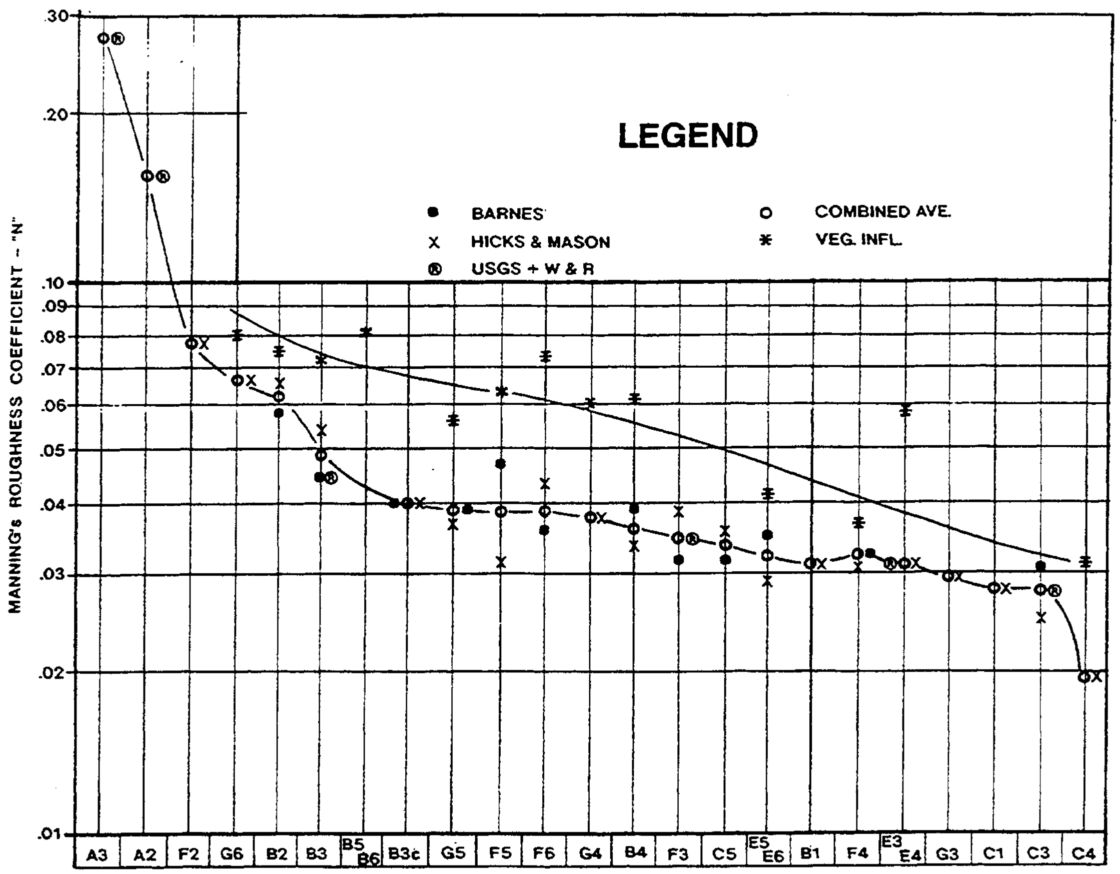

Fig. 10. Bankfull stage roughness coefficients ("N" values) by stream type for 140 streams from the United States and New Zealand.

hydrologists. The lack of consistent criteria for selection of the correct N values, however, creates great variability in the subsequent estimate of flow velocity. Barnes (1967), and Hicks and Mason (1991) produced photographs and a variety of stream data which was primarily a visual comparison approach for the selection of roughness coefficients. However, using these books for a visual estimate of roughness, actually involves looking at various stream types. The author classified each of the 128 streams described in both publications, noted the occurrence of vegetation influence, and plotted the bankfull stage N values by stream type (Fig. 10). The remarkable similarity of N values by stream type for two data bases from two countries revealed another application for estimating a bankfull stage roughness coefficient using stream classification. This may help in developing more consistent roughness estimates and provide an approach for improving stream discharge estimates by using the manning's equation. Roughness values increase as stage decreases, thus, the N values shown in Fig. 10 are for bankfull conditions only. The Hicks and Mason (1991) work is exemplary in terms of evaluating and displaying variations in N with changes in stream discharge. These variations can potentially be developed as a rate of change index for changes in stage by stream type. The influence of vegetation is shown to cause a marked adjustment in values by stream type. As would be expected, this relationship suggests the vegetation influence on roughness is diminished as channel gradient and bed material particle size increase. Stream types essentially integrate those variables affecting roughness, such as; gradient, shape and form resistance, particle size, and relative depth of bankfull discharge to the diameter of the larger particles in the channel. Rather than looking at discrete predictors, stream types integrate the many variables that influence resistance. Another recommended application to roughness estimation is to develop specific relations of roughness and associated velocity as recently developed for "mountain streams" by Jarrett (1984, 1990). In this method, equations were stratified for steeper slopes and cobble/boulder channel materials, using hydraulic radius and slope in the equations. Jarrett's results were valuable in that they produced values much different from most published equations. This work could be even more effective if the stream data were further stratified into stream types and size of stream. In this manner, much like the Manning's N values, equations could be developed using the integrating effects of stream types and thereby advance the state of the art of applications.

5.4. Hydraulic geometry relations

The original work of Leopold and Maddock (1953) made a significant contribution to the applied science in the development of hydraulic geometry relations. The variables of; depth, velocity, and cross-sectional area were quantitatively related to discharge as simple power functions for a given river cross-section. Their findings prompted numerous research efforts over the years. To refine average values of exponents, and to demonstrate the potential for applications of hydraulic geometry relations by stream types, this author assembled stream dimensions, slopes, and hydraulic data for six different stream types having the same discharge and channel materials. The objective was to demonstrate how the shape (width/depth ratio), profile (gradient), plan view (sinuosity), and meander geometry affect the hydraulic geometry relations. For example channel width increases faster than mean depth, with increasing discharge in high width/depth ratio channels. The opposite is true in low width/depth ratio channels. Streamflow values from baseflow of approximately 4 cfs up to bankfull values of 40 cfs were compared for each cross-section, and the corresponding widths, depths, velocities, and cross-sectional area for each stream type were computed. The A3, B3, C3, D3, E3 and F3 stream types selected for comparisons all had a cobble dominated bed-material size. The resultant hydraulic geometry relations for the selected array of stream types at the described flow ranges are shown in Fig. 11. Except for the E3 stream type for the plot of width/discharge, the slope of the plotted relations did not significantly change nearly as much as the intercept values.

6. Shear stress/velocity relations

Using the same data from the six stream types described previously, a "lumped" data base for all stream types from low to high flow was made for the corresponding shear stress ($\tau = \gamma RS$) (Shields, 1936) vs. mean velocity, where; $\tau =$ shear stress,

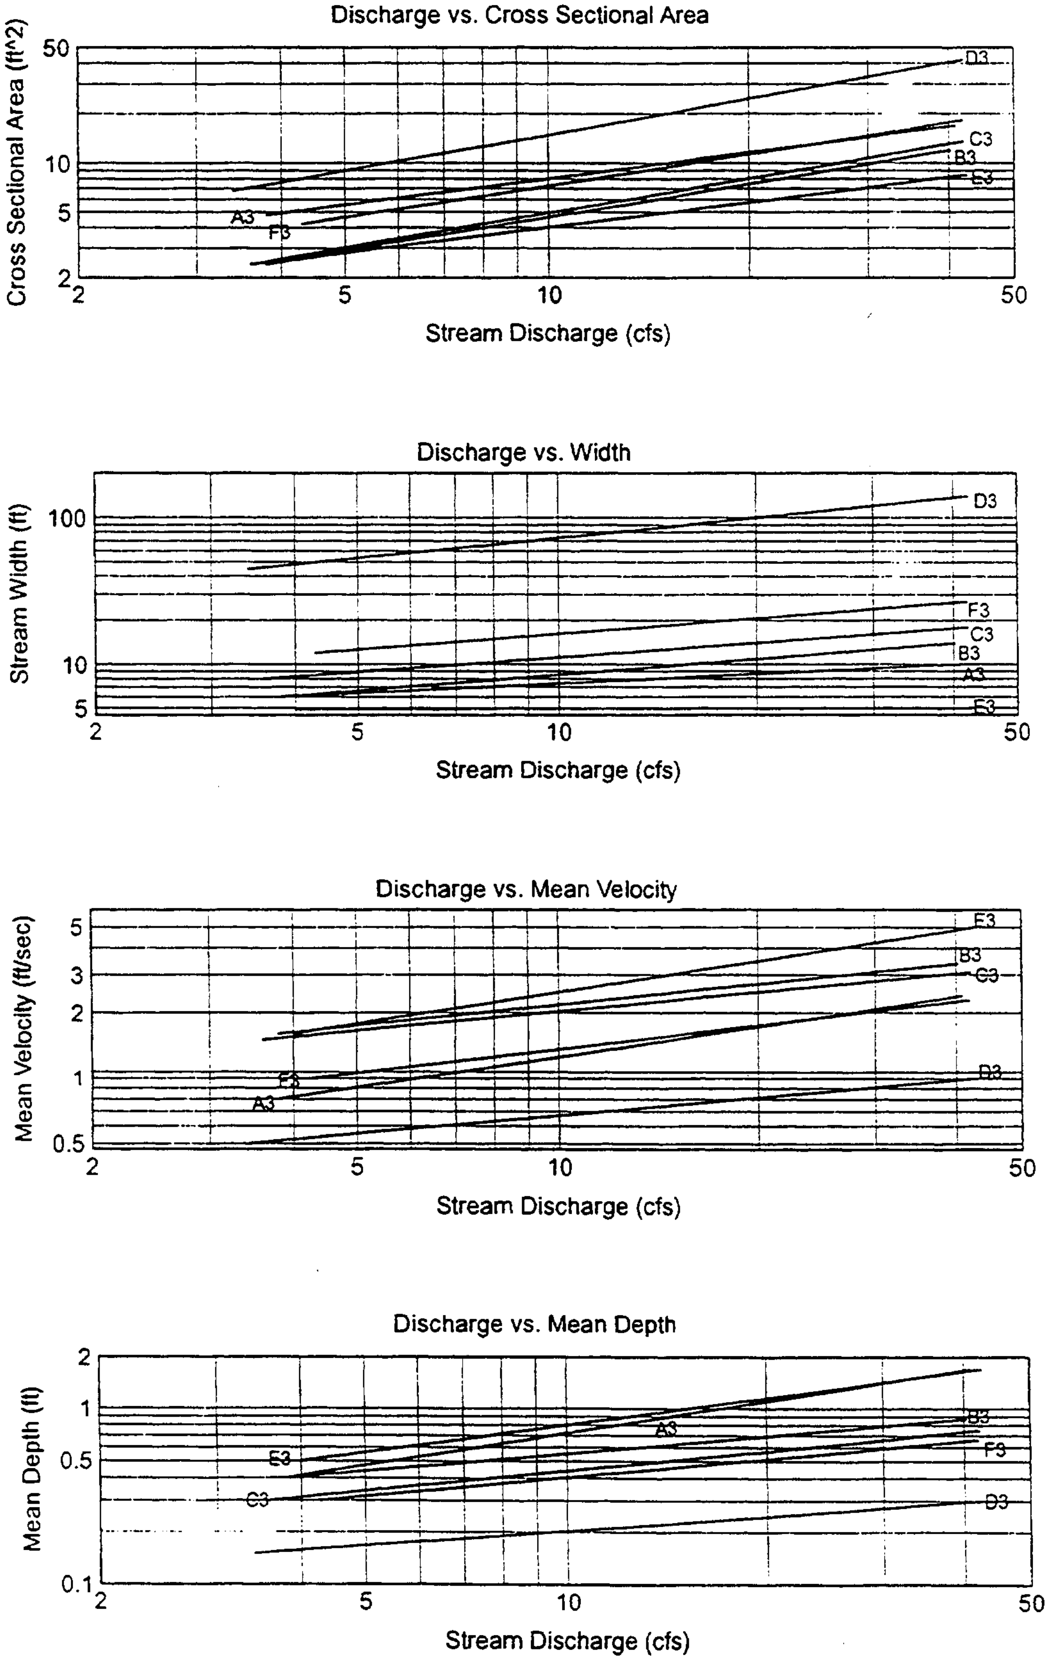

Fig. 11. Hydraulic geometry relations for selected stream types of uniform size.

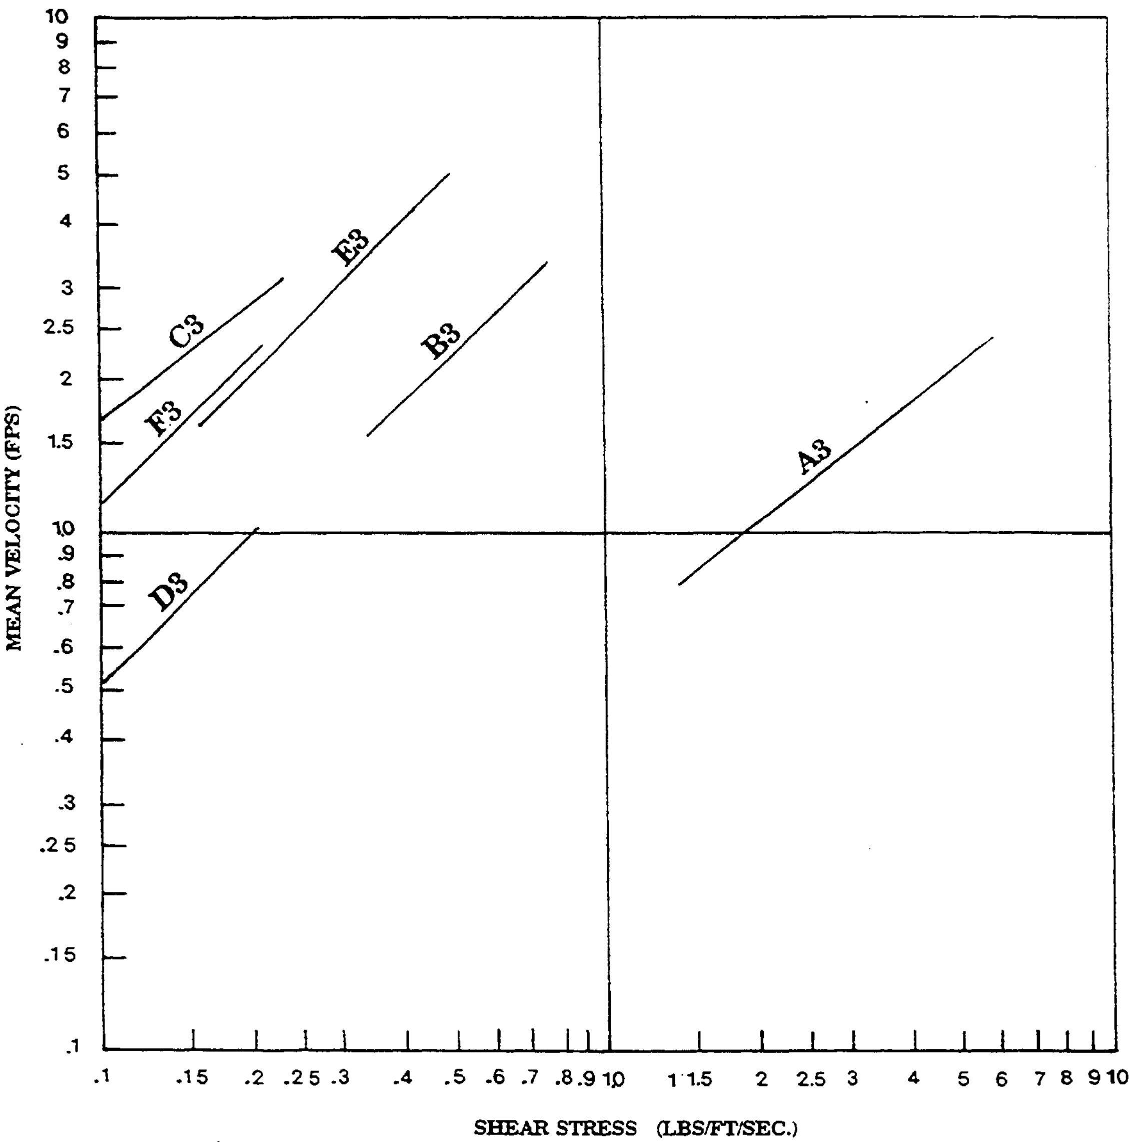

Fig. 12. Relationship of mean velocity vs. shear stress for six stream types from base flow (3–4 cfs) to bankfull discharge (40–41 cfs).

γ = density of water, R = hydraulic radius, and S = channel slope. As expected, a meaningful relation was not found. However, plotting shear stress and velocity stratification by stream type provided a trend that did shows promise (Fig. 12). While more data are needed to establish mathematical and statistical relationships, the comparisons arranged by stream type may have potential for future applications.

6.1. Critical shear stress estimates

Previous investigations of the magnitude of shear stress required to entrain various particle diameters from the stream-bed material have produced a wide range of values. A number of investigators have assumed the critical dimensionless shear

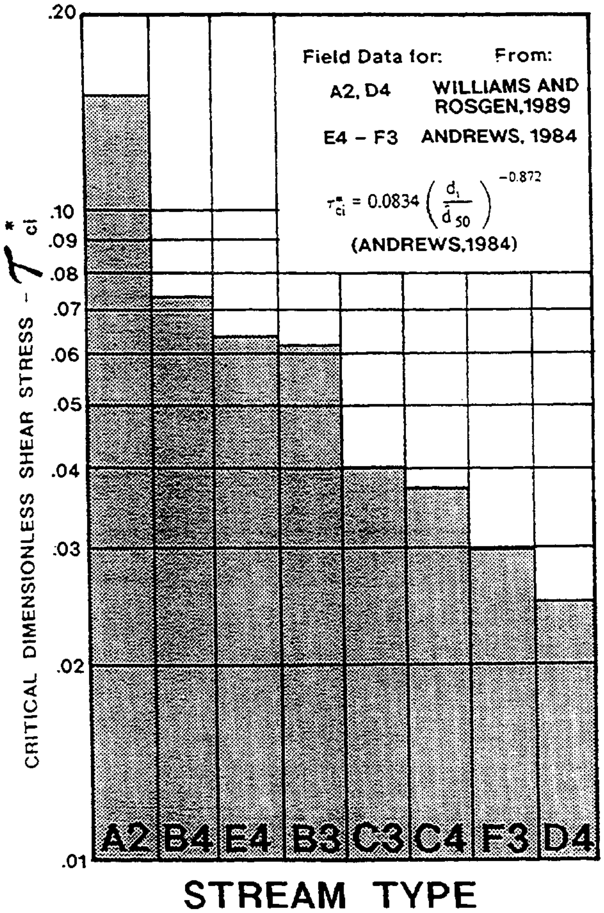

Fig. 13. Relationship of field verification of critical dimensionless shear stress values for various stream types.

stress values of 0.06 for computations of bedload transport using Shield's (1936) criteria (Baker, 1974; Baker and Ritter, 1975; Church, 1978; Bradley and Mears, 1980; Simons and Senturk, 1977; Simons and Li, 1982). In addition, critical dimensionless shear stress values computed from data compiled by Fahnestock (1963), Ritter (1967), and Church (1978) for the entrainment of gravels and cobbles from a natural river-bed, as reported by Andrews (1983) showed a range of approximately 0.02 to 0.25. The mean of the computed values was 0.06, which is the value suggested by Shields (1936).

Andrews (1983) described a relationship where to the ratio of surface (pavement) bed particles to sub-surface (sub-pavement) particles that yielded an estimate of critical dimensionless shear stress values (τ_{ci}*) from 0.02 to 0.28. Additional work using the same equation was applied to several Colorado gravel-bed streams with similar results (Andrews, 1984).

It is sometimes difficult for many engineers to obtain pavement and sub-pavement data along with the required channel hydraulics information to refine critical dimensionless shear stress estimates using the Andrews (1983, 1984) equation. The use of stream types to help bridge this gap of estimating the critical dimensionless shear stress value (τc) has potential where these study streams have been analyzed and classified. The study streams by Andrews (1984) were classified, data compiled and the values of τ_c* (critical dimensionless shear stress) were plotted (Fig. 13). A2 and D4 stream types were obtained from field measurements of bedload sediment and bed-material size distribution for those types (Williams and Rosgen, 1989). Stream types and their morphologic/hydraulic characteristics do not substitute for detailed on-site investigations as described by Andrews (1983, 1984); however, calculations of τ_{ci}* are often made without the benefit of site-specific investigation. Based on the great variability in the estimate of τ_{ci}*, sediment transport prediction errors can be from one to several orders of magnitude. A closer approximation of τ_{ci}* for stream reaches that cannot be investigated in detail, is possible using the extrapolation approach shown in Fig. 13.

A similar analysis has been made but not included here using unit stream power rather than critical shear stress. This analysis again demonstrated that stratification by stream type improved sediment transport/stream power relations as an integrative function of the supply/energy distribution/resistance factors for specific stream types.

6.2. Sediment relations

Stream types have been used to characterize sediment rating curves that reflect sediment supply in relation to stream discharge. For example, a sediment rating curve regression relation for an A2 stream type would have a characteristic low slope and intercept. The sediment rating curve for the C4 stream type, however, has a higher intercept and steeper slope. The author has used this procedure for both suspended and bedload rating curves. These relationships were initially plotted as a function of channel stability ratings as developed by Pfankuch (1975). Applications for cumulative effects analysis for non-point sediment sources utilized this approach (USEPA, 1980). Subsequent comparisons of data with stream type delineations indicated similar relations.

The ratio of bedload to total sediment load can also be stratified by stream type where measured data is available. Ranges of less than 5% bedload to total sediment load for C3 stream types have been reported, but values greater than 75% bedload to total load for G4 stream types have also been measured (Williams and Rosgen, 1989). The "high ratio" bedload streams are the A3, A4, A5, D3, D4, D5, F4, F5, G3, G4, and G5 stream types.

6.3. Management interpretations

The ability to predict a river's behavior from its appearance and to extrapolate information from similar stream types helps in applying the interpretive information in Table 3. These interpretations evaluate various stream types in terms of; sensitivity to disturbance, recovery potential, sediment supply, vegetation controlling influence, and streambank erosion potential. Application of these interpretations can be used for; potential impact assessment, risk analysis, and management direction by stream type. For example, livestock grazing effects were related to stream stability and

Table 3

[c] Includes suspended and bedload from channel derived sources and/or from stream adjacent slopes.
[d] Vegetation that influences width/depth ratio-stability.

sensitivity using stream types (Meyers and Swanson, 1992). They summarized their study results on streams in northern Nevada that "... range managers should consider the stream type when setting local standards, writing management objectives, or determining riparian grazing management strategies."

This interpretive information by stream type can also apply to establishment of watershed and streamside management guidelines dealing with; silvicultural standards, surface disturbance activities, surface disturbance activities, gravel and surface mining activities, riparian management guidelines, debris management, floodplain management, cumulative effects analysis, flow regulation from reservoirs/diversions, etc. An example of the implementation of these guidelines by stream type are shown in the Land and Resource Management Plan (USDA, 1984).

Applications for riparian areas (USDA, 1992), have utilized the stream classification system into their recently developed "Integrated Riparian Evaluation Guide" — Intermountain Region. The classification system was used to help stratify and classify riparian areas based on natural characteristics and existing conditions. It is also used to evaluate the potential risks and sensitivities of riparian areas.

6.4. Restoration

The morphologic variables that interact to form the dimensions, profile and patterns of modern rivers are often the same variables that have been adversely impacted by development and land use activities. To restore the "disturbed" river, the natural stable tendencies must be understood to predict the most probable form. Those who undertake to restore the "disturbed" river must have knowledge of fluvial process, morphology, channel and meander geometry, and the natural tendencies of adjustment toward stability in order to predict the most effective design for long-term stability and function. If one works against these tendencies, restoration is generally not successful. Restoration applications using stream classification and the previously discussed principles are documented in the "Blanco River" case study (National Research Council, 1992).

7. Summary

Rivers are complex natural systems. A necessary and critical task towards the understanding of these complex systems is to continue the river systems research. In the interim, water resource managers must often make decisions and timely predictions without the luxury of a complex and thorough data base. Therefore, a goal for researchers and managers is to properly integrate what has been learned about rivers into a management decision process that can effectively utilize such knowledge. There is often more data collected and available on rivers than is ever applied. Part of the problem is the large number of "pieces" that this data comprises and the difficulty of putting these pieces into meaningful form.

The objective of this stream classification system presented here is to assist in bringing together these "pieces" and the many disciplines working with rivers under a common format — a central theme for comparison, a basis for extrapolation, prediction, and communication. The stream classification system can assist in organizing the observations of river data and of molding the many pieces together into a logical, useable, and reproducible system.

With the recent emphasis on "natural" river restoration or "naturalization" throughout Europe and North America, understanding the potential versus the existing stream type is always a challenge. The dimension of rivers related to the flow, and the patterns, which in turn are related to the dimensions, have to be further stratified by discrete stream types. In this way, the arrangement of the variables that make up the plan, profile and section views of stable stream types that are integrated within their valley's can be emulated. This also involves re-creation of the corresponding appropriate bed morphology associated with individual stream types with the observed sequence of step/pool and/or riffle pool bed features as a function of the bankfull width. The use of meander width ratios by stream type helps to establish the minimum, average and ranges of lateral containment of rivers. This often helps the design engineer/hydrologist determine appropriate widths that need to be accommodated when natural, stable rivers are re-constructed within their valleys. River and floodplain elevations, which need to be constructed, can be often determined by the used of the entrenchment ratio, which depicts the vertical containment of rivers in the landform. Using these integrative, morphological relations by stream type, can avoid the problematic "works" done on streams which create changes in the dimensions, pattern and profile of rivers which are not compatible with the tendencies of the natural stable form.

A classification system is particularly needed to stratify river reaches into groups that may be logically compared. Such stratification reduces scatter that might appear to come from random variation, whereas the scatter often results from attempting to compare items generically different. For example, data developed from empirical relations associated with process oriented research in natural channels such as tractive force relations, resistance and sediment transport equations, etc., can be stratified by stream type. This can help reduce the scatter when applied to stream types different than those from which the relations were developed.

Utilizing quantitative channel morphological indices for a classification procedure insures for consistency in defining stream types among observers for a great diversity of potential applications. The classification presented here may be the first approximation of a system that undoubtedly will be refined over the years with continued experience and knowledge. This stream classification system hopefully can be a vehicle to provide better communication among those studying river systems and promote a better understanding of river processes, helping put principles into practice.

Acknowledgements

I would like to thank the many individuals who have contributed in data collection, analysis, thought, and spirit towards this classification. The individuals are too numerous to mention, but in particular I would like to mention my river companions, Dr. Luna Leopold, Hilton "Lee" Silvey, Dale Pfankuch, Owen Williams, Alice Johns, Jim Nankervis and Steve Belz. Their contributions to consultation, analysis, and review are much appreciated. The majority of the illustrations were drawn by H. Lee Silvey. Appreciation of the fine work of word processing is acknowledged to Kay McElwain.

Abstract

A set of maps depicting approved boundaries of, and numerical codes for, river-basin units of the United States has been developed by the U.S. Geological Survey. These "Hydrologic Unit Maps" are four-color maps that present information on drainage, culture, hydrography, and hydrologic boundaries and codes of (1) the 21 major water-resources regions and the 222 subregions designated by the U.S. Water Resources Council, (2) the 352 accounting units of the U.S. Geological Survey's National Water Data Network, and (3) the 2,149 cataloging units of the U.S. Geological Survey's "Catalog of Information on Water Data." The maps are plotted on the Geological Survey State base-map series at a scale of 1:500,000 and, except for Alaska, depict hydrologic unit boundaries for all drainage basins greater than 700 square miles (1,813 square kilometers). A complete list of all the hydrologic units, along with their drainage areas, their names, and the names of the States or outlying areas in which they reside, is contained in the report.

These maps and associated codes provide a standardized base for use by water-resources organizations in locating, storing, retrieving, and exchanging hydrologic data, in indexing and inventorying hydrologic data and information, in cataloging water-data acquisition activities, and in a variety of other applications. Because the maps have undergone extensive review by all principal Federal, regional, and State water-resource agencies, they are widely accepted for use in planning and describing water-use and related land-use activities, and in geographically organizing hydrologic data. Examples of these uses are given in the report. The hydrologic unit codes shown on the maps have been approved as a Federal Information Processing Standard for use by the Federal establishment.

INTRODUCTION

This report describes the U.S. Geological Survey's standard map series called "Hydrologic Unit Maps" and presents the codes, names, and boundaries of hydrologic units in the United States and the Caribbean outlying areas. The four-color maps depict a hydrologic system that divides the United States into 21 major regions. These *regions* are currently (1984) further subdivided into 222 *subregions*, 352 *accounting units*, and, finally, into 2,149 *cataloging units*. These four levels of subdivisions, used for the collection and organization of hydrologic data, are referred to as "hydrologic units." The identifying numeric codes associated with these units are "hydrologic unit codes." Each hydrologic unit has been assigned a name; in most cases, the name corresponds to the principal hydrologic feature within the unit. The Hydrologic Unit Maps show drainage, hydrography, culture, and political and hydrologic unit boundaries and codes, thus providing a standard geographic and hydrologic framework for detailed water-resource and related land-resource planning. Also included on the maps are the Federal Information Processing Standards State and county codes (U.S. National Bureau of Standards, 1983).

In recognition that such maps were needed by almost everyone working in water resources in the United States, this set of maps covers the entire United States and the Caribbean outlying areas. The maps, published in a series beginning in 1974 at a scale of 1:500,000 (1 inch equals nearly 8 miles), present twice the detail of previous river-basin maps using the Geological Survey State Map series as a base. They delineate all river basins having a drainage area of at least 700 square miles except for river basins in the State of Alaska. In special instances, river basins of less than 700 square miles have been delineated.

These maps and associated codes provide a standardized base for use by water-resources organizations in locating, storing, retrieving, and exchanging hydrologic data, in indexing and inventorying hydrologic data and information, in cataloging water-data acquisition activities, and in a variety of other applications.

The Hydrologic Unit Map series was initiated in the fall of 1972 by the U.S. Geological Survey's Office of Water Data Coordination, in cooperation with the U.S. Water Resources Council and supported by the U.S. Geological Survey's Resources and Land Information program (Seaber and others, 1975). The need for nationwide standardization by obtaining acceptance of and agreement on the maps by a broad spectrum of water-resource interests was acknowledged from the beginning. Thus, the maps were thoroughly reviewed throughout the country. This paper describes the methods and criteria used to produce the Hydrologic Unit Maps so that the map delineations, coding, and naming system can be understood and used to full advantage. Maintenance, updating, and use of the maps can be accomplished effectively only within a framework of the background, history, and development of the maps.

HISTORY AND DEVELOPMENT

Hydrologic maps available before 1972 were unsatisfactory for many purposes because of inadequate bases or scales as well as lack of agreement about hydrologic subdivisions among Federal, State, and local agencies. Federal and State agencies, Congress and its committees, the "Federal Register," treaties, compacts, adjudications, Presidential Executive orders, river-basin commissions, and others used many incompatible criteria for names, codes, hydrographic boundaries, and river basins (Kammerer, 1969). After many years of use of unsatisfactory and inadequate hydrologic maps, discussions among representatives of Federal and State agencies, initiated in 1972, led to nearly unanimous agreement on the need for a national project to develop uniform and widely acceptable hydrologic boundaries and to present them on nationally consistent base maps. A need for standardization of hydrologic units was evident throughout the country.

Although this project dates from 1972, the national effort to depict hydrologic units really began more than 60 years earlier:

> For the purpose of uniformity in presentation of reports, a general plan has been agreed upon by the U.S. Reclamation Service, the U.S. Weather Bureau, and the U.S. Geological Survey, according to which the area of the United States has been divided into 12 parts whose boundaries coincide with certain natural drainage areas (U.S. Geological Survey, 1910, p. 10).

Several other attempts to produce a set of uniform maps for the Nation were made between 1910 and 1972, although the Geological Survey's 12-part subdivision was generally accepted for publication of water data.

The U.S. Army Corps of Engineers and the U.S. Department of Agriculture have made comprehensive river-basin studies nationwide. The boundaries of these studies are usually as outlined in the 1959–1960 reports of the Senate Select Committee on National Water Resources known as "The Kerr Report" (U.S. Senate, 1959–1960). General river-basin planning policies were established in 1962 by Senate Document 97 prepared under the direction of the President's ad hoc Water Resources Council. These reports led to Public Law 89–80, the Water Resources Planning Act (U.S. Congress, 1965). This act, together with U.S. Bureau of the Budget (1964) Circular A–67 and other events in the mid-1960's and early 1970's provided the impetus for producing the Hydrologic Unit Map series.

The Water Resources Planning Act established the U.S. Water Resources Council and directed it to "maintain a continuing study and prepare an assessment***of the adequacy of supplies of water necessary to meet the water requirements in each water-resource region in the United States***" as well as to "maintain a continuing study of the relation of regional or river-basin plans and programs to the requirements of larger regions of the Nation."

U.S. Bureau of the Budget Circular A–67 prescribed guidelines for coordinating water-data acquisition activities of the more than 30 Federal agencies that collect or use water data and assigned lead-agency responsibility to the Department of the Interior, which in turn delegated these coordinating responsibilities to the Geological Survey.

It was immediately evident that both the Water Resources Council and the U.S. Geological Survey should perform their assigned functions on the basis of precise and systematic definitions of hydrologic areas of appropriate sizes.

The Water Resources Council's program for carrying out its duties was the National Assessment of Water and Related Land Resources. The first national assessment was issued in 1968 (U.S. Water Resources Council, 1968). Early in the program, the council found a need for standard geographic and hydrographic bases to maintain continuity in its assessments. One of the initial tasks in preparing for the second assessment was the delineation of geographic areas suitable for analysis. The regions and subregions were originated primarily by the council to meet this need (U.S. Water Resources Council, 1970).

To discharge its responsibilities as outlined in Circular A–67, the U.S. Geological Survey established the Office of Water Data Coordination to (1) maintain a catalog of information on water data, (2) undertake a continuing review of water-data requirements, (3) prepare a Federal plan for efficient utilization of water-data activities, and (4) design and operate a national water data network. Accounting units and cataloging units were originated by the Geological Survey as part of these responsibilities. The cataloging units used for the Hydrologic Unit Maps supplant an earlier set used by the Geological Survey in its "Catalog of Information on Water Data" (1966–1972).

The current Hydrologic Unit Map boundaries were adapted, in part, from several publications: "Catalog of Information on Water Data" (U.S. Geological Survey, Office of Water Data Coordination, 1973); "Water-Resources Regions and Subregions for the National Assessment of Water and Related Land Resources" (U.S. Water Resources Council, 1970); "Atlas of River Basins of the United States" (U.S. Department of Agriculture, 1963, 1970); "River Basin Maps Showing Hydrologic Stations" (Federal Interagency Committee on Water Resources, 1961); and State planning maps.

The political subdivision code was taken from "Counties and County Equivalents of the States of the United States" presented in Federal Information Processing Standards Publication 6–2, issued by the U.S. National Bureau of Standards (1973). The addition of the Federal Information Processing Standards code to the maps allows data to be cataloged politically as well as hydrologically.

DESCRIPTION OF THE HYDROLOGIC UNITS

Hydrologic Unit Codes

Basically, the United States was divided and subdivided into successively smaller hydrologic units, which were classified into four levels, as shown in figure 1. The hydrologic units are arranged within each other, from the smallest (cataloging units) to the largest (regions). Each hydrologic unit is identified by a unique numeric hydrologic unit code consisting of two to eight digits based on the four levels of classification in the hydrologic unit system.

The first level of classification divides the Nation into 21 major geographic areas, or regions (fig. 2). These geographic areas (hydrologic areas based on surface topography) contain either the drainage area of a major river, such as the Missouri region, or the combined drainage areas of a series of rivers, such as the Texas-Gulf region, which includes a number of rivers draining into the Gulf of Mexico. Eighteen of the regions occupy the land area of the conterminous United States. Alaska is region 19, the Hawaiian Islands constitute region 20, and Puerto Rico and other outlying Caribbean areas are region 21. The Pacific Trust Territories are a potential region 22.

The second level of classification divides the 21 regions into 222 subregions. A subregion includes the area drained by a river system, a reach of a river and its tributaries in that reach, a closed basin(s), or a group of streams forming a coastal drainage area.

The third level of classification subdivides many of the subregions into accounting units. These 352 hydrologic accounting units nest within, or are equivalent to, the subregions. The accounting units are used by the Geological Survey for designing and managing the National Water Data Network. The areal extent of the accounting units is shown on plate 1.

The fourth level of classification is the cataloging unit, the smallest element in the hierarchy of hydrologic units. A cataloging unit is a geographic area representing part or all of a surface drainage basin, a combination of drainage basins, or a distinct hydrologic feature. These units subdivide the subregions and accounting units into smaller areas (approximately 2,150 in the Nation) that are used by the U.S. Geological Survey for cataloging and indexing water-data acquisition activities in the "Catalog of Information on Water Data."

Within this hierarchy, units have been defined so that almost all cataloging units are larger than 700 square

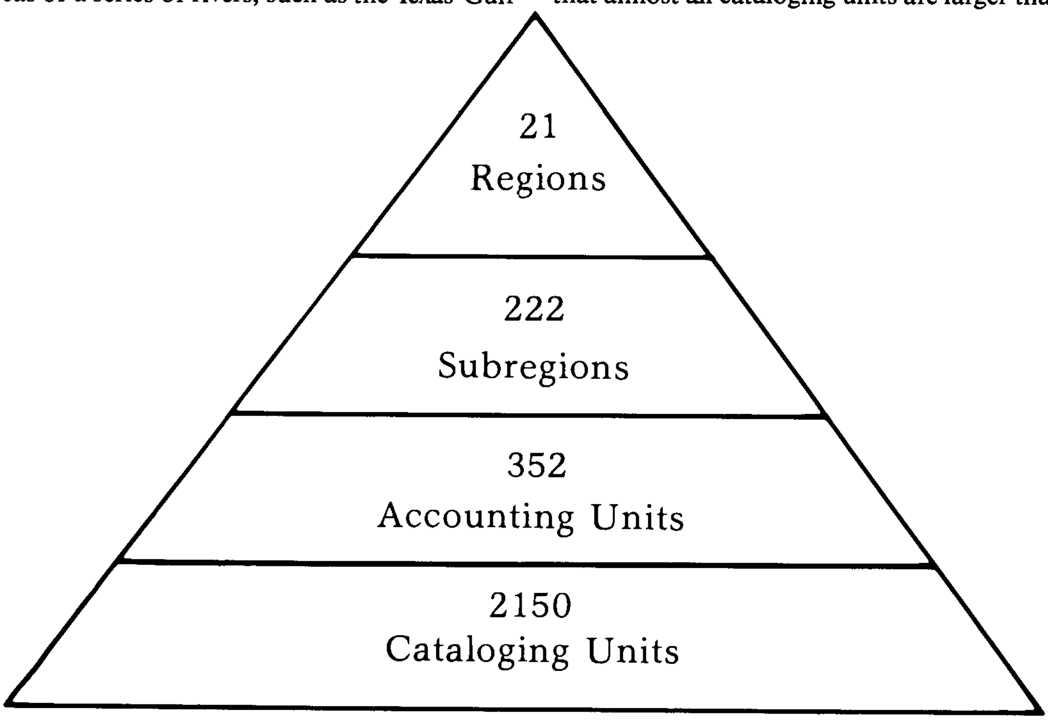

Figure 1. Hierarchy of hydrologic units shown on Hydrologic Unit Maps.

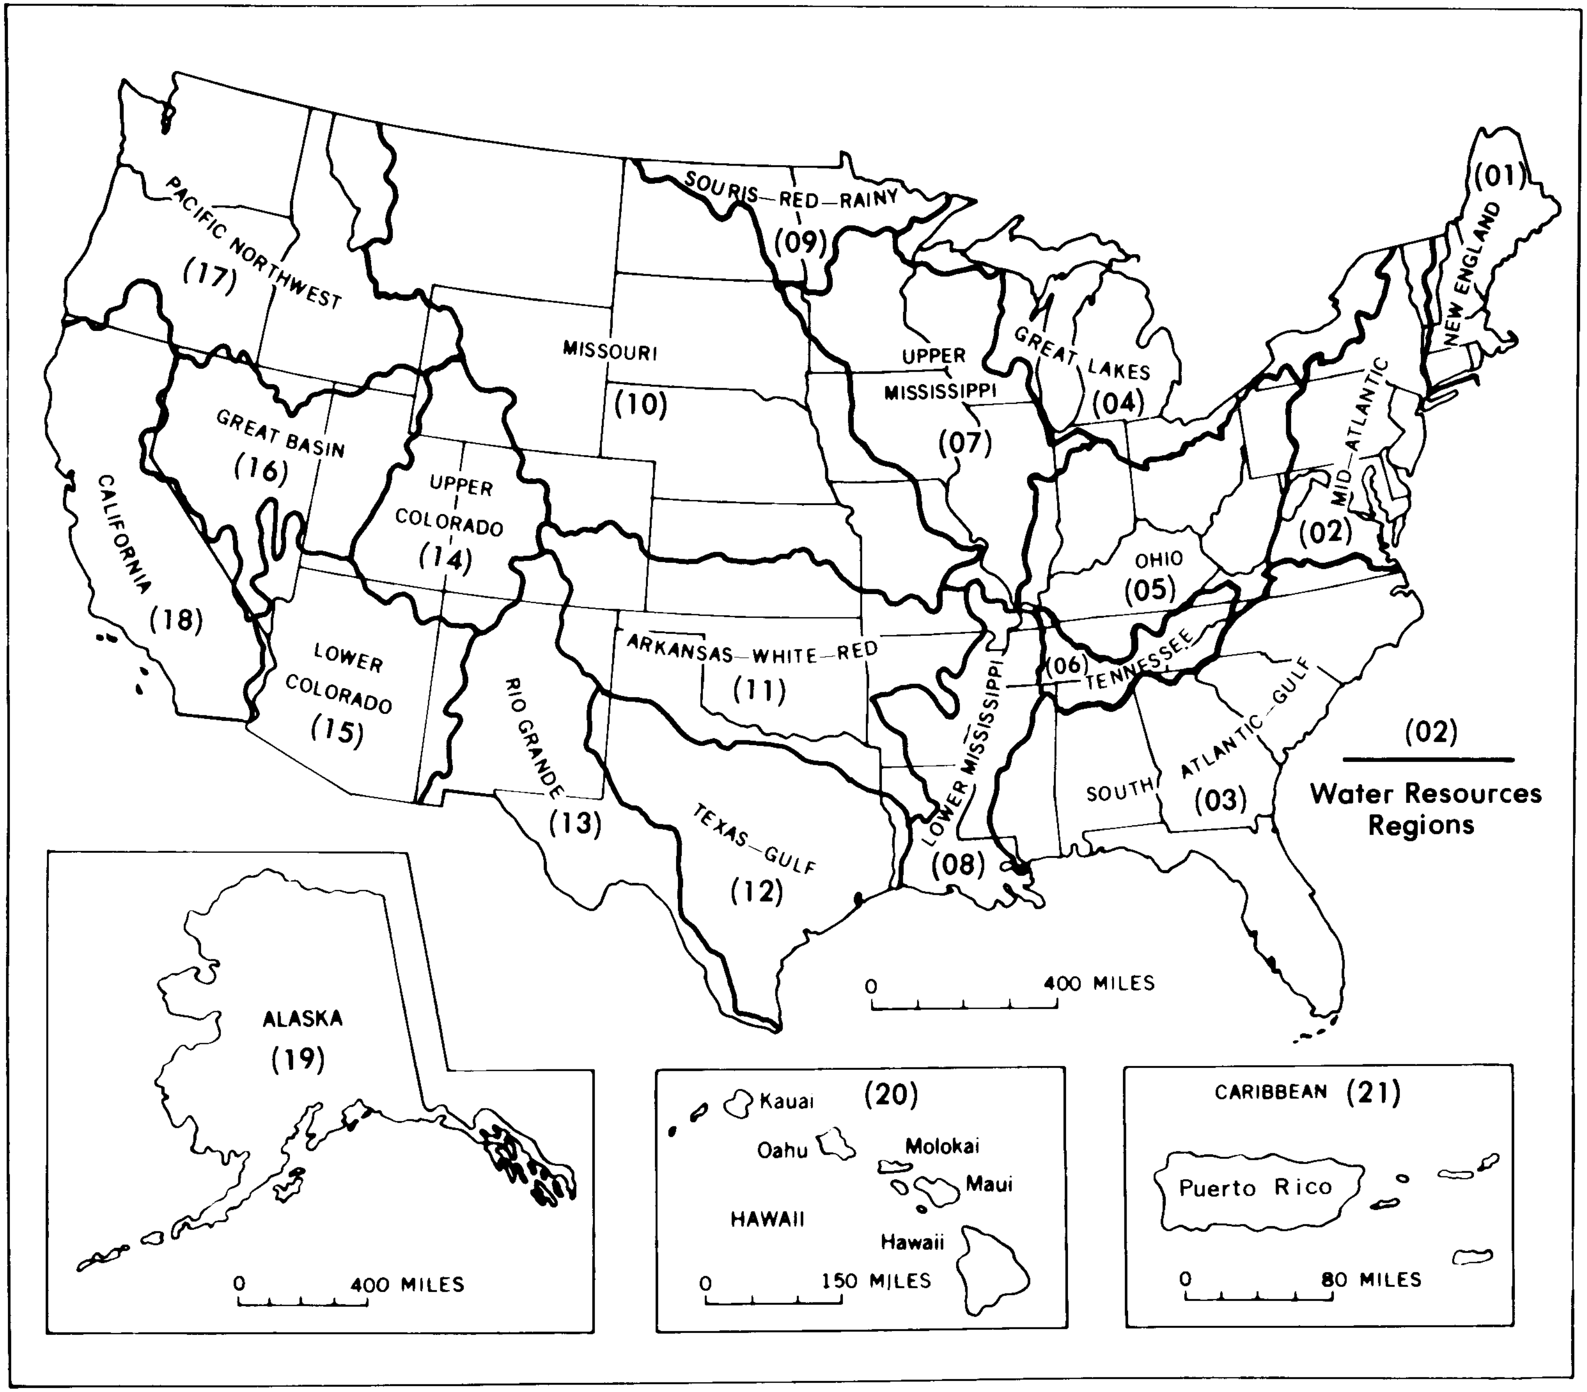

Figure 2. Water-resources regions of the United States.

miles (1,813 square kilometers) in area. In special circumstances, units smaller than 700 square miles are identified on some of the maps.

The boundaries or areal extent of the hydrologic units may be revised at the request of local users, and with the approval of the Geological Survey. Changes are more likely to be made to the cataloging unit boundaries than to boundaries of the regions, subregions, and accounting units.

An eight-digit code uniquely identifies each of the four levels of classification within four two-digit fields. The first two digits identify the water-resources region; the first four digits identify the subregions; the first six digits identify the accounting unit; and the addition of two more digits for the cataloging unit completes the eight-digit code. An example is given below using hydrologic unit code 01080204:

01—the region
0108—the subregion
010802—the accounting unit
01080204—the cataloging unit

A 00 in the two-digit accounting unit field indicates that the accounting unit and the subregion are the same. Likewise, if the cataloging unit code is 00, it is the same as the accounting unit.

Hydrologic Unit Names

In addition to hydrologic unit codes, each hydrologic unit has been assigned a name corresponding to the principal hydrologic feature(s) within the unit. In the absence of such features, the assigned name may reflect a cultural or political feature within the unit. All regions and subregions are uniquely named; however, the accounting units are uniquely named only within each region, and the cataloging units are uniquely named only within each accounting unit. Duplication of some names at the cataloging unit level is unavoidable because a large number of streams found throughout the Nation share the same names.

A complete list of all hydrologic unit codes, their names, the names of the States or outlying areas in which they reside, and their drainage areas is given in table 1 (at back of report).

DESCRIPTION OF THE HYDROLOGIC UNIT MAPS

The Hydrologic Unit Map Series consists of 47 maps on 53 sheets. The maps present 49 States at a scale of 1:500,000, or about 8 miles to the inch (1 centimeter to 5 kilometers). This scale permits most States to be shown on a single map of convenient size. Texas is shown on four sheets, and Montana, Michigan, and California are shown on two sheets each. Three groups of States—Massachusetts, Rhode Island, and Connecticut; Maryland, Delaware, and the District of Columbia; and Vermont and New Hampshire—are combined on a single sheet for each group. Alaska, because of its large size and less accurately defined drainage, is shown at a scale of 1:2,500,000, or about 40 miles to the inch (1 centimeter to 25 kilometers). Puerto Rico is shown on the Caribbean region map at a scale of 1:240,000, or about 4 miles to the inch (1 centimeter to 2.4 kilometers). The other outlying Caribbean areas are shown on this map at scales ranging from 1:250,000 to 1:1,000,000.

In preparing the maps, the best available Geological Survey State base materials were obtained and then modified where necessary to allow matching of hydrologic and political boundaries from sheet to sheet. The resulting set of maps thus provides good uniformity and accuracy on a nationwide basis. The State base is appropriate because water-resources planning and management are largely conducted at the State level. However, the maps are also usable at regional or national levels by such entities as river-basin commissions, water-management districts, and Federal agencies. Because of their uniform scale, the maps can be cut and spliced to form a mosaic of any region or area desired.

Figure 3, a section of the Hydrologic Unit Map for Wisconsin, shows the components depicted by the series. Hydrographic features (streams, lakes, and bays, and their names) are shown in blue; cultural features (political boundaries, geographic coordinates, and names of places) are in black; hydrologic unit boundaries and the eight-digit hydrologic unit codes are in red; and the county codes are in green.

Figure 4 shows the map explanation on a typical Hydrologic Unit Map. It includes the major source references from which the boundaries were adopted, and it illustrates the makeup of the eight-digit hydrologic unit code. A table shows the hydrologic units for the States broken down according to their regions, subregions, accounting units, and cataloging units. The political subdivision code is illustrated with a simple three-digit county code and a two-digit State code.

The Hydrologic Unit Maps have been adopted as "official issue" by the Federal Government. The associated codes and names for identifying hydrologic units in the United States and the Caribbean outlying areas have been adopted as a Geological Survey Data Standard (U.S. Geological Survey, 1982). This is a part of the Geological Survey program for standardizing data elements and representations used in automated earth-science systems.

The proposed codes and names were published in the December 28, 1982, "Federal Register." After a public comment period, the Secretary of Commerce approved the codes and names as a Federal Information Processing Standard on October 25, 1983.

MAP OF HYDROLOGIC UNITS

This new series of U.S. Geological Survey State base maps provide a uniform, nationally consistent set of hydrologic units accurately delineated to show drainage basins down to approximately 700 square miles in area.

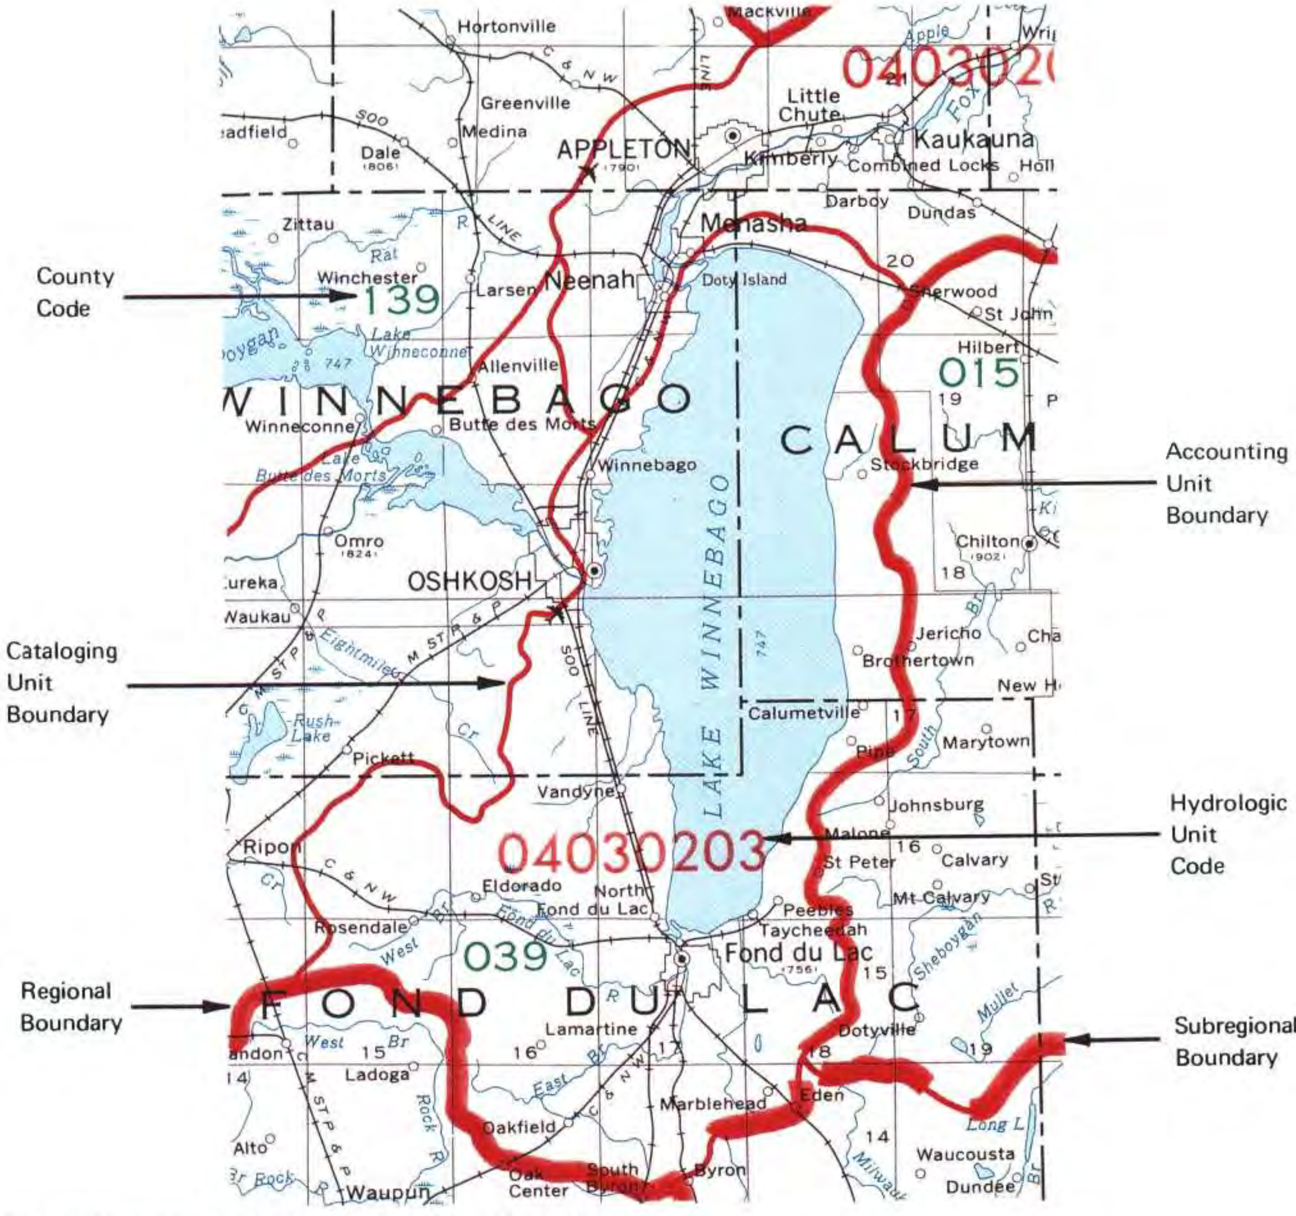

Figure 3. Section of a Hydrologic Unit Map (Wisconsin).

COMPILATION GUIDELINES

The following guidelines were used for preparing and reviewing the Hydrologic Unit Maps. The preparation of draft maps and the initial review process occurred simultaneously because one of the major criteria for producing the maps was local acceptance of the hydrologic units.

EXPLANATION

This map and accompanying table show Hydrologic Units that are basically hydrographic in nature. The Cataloging Units shown will supplant the Cataloging Units previously used by the U.S. Geological Survey in its Catalog of Information on Water Data (1966–72). The previous U.S. Geological Survey Catalog-Indexing System was by map number and letter, such as 49M. The boundaries as shown have been adapted from "The Catalog of Information on Water Data" (1972), "Water Resources Regions and Subregions for the National Assessment of Water and Related Land Resources" by the U.S. Water Resources Council (1970), "River Basins of the United States" by the U.S. Soil Conservation Service (1963, 1970), "River Basin Maps Showing Hydrologic Stations" by the Inter-Agency Committee on Water Resources, Subcommittee on Hydrology (1961), and State planning maps.

The Political Subdivision Code has been adopted from "Counties and County Equivalents of the States of the United States" presented in Federal Information Processing Standards Publication 6-2, issued by the National Bureau of Standards (1973) in which each county or county equivalent is identified by a 2-character State code and a 3-character county code.

The Regions, Subregions and Accounting Units are aggregates of the Cataloging Units. The Regions and Subregions are currently (1974) used by the U.S. Water Resources Council for comprehensive planning, including the National Assessment, and as a standard geographical framework for more detailed water and related land-resources planning. The Accounting Units are those currently (1974) in use by the U.S. Geological Survey for managing the National Water Data Network.

Figure 4. Explanation shown on a typical Hydrologic Unit Map.

Basic Criteria

Two basic criteria were used in preparing the maps:

1. All boundaries are hydrologic (hydrographic) in nature within the United States. By legal definition, however, the region and subregion boundaries end or coincide with the U.S. international boundary; thus, this criterion is violated for region and subregion boundaries along the international boundaries with Mexico and

Canada. However, because the boundaries of the cataloging units and accounting units are hydrologic in nature, they can be extended into Mexico and Canada. Essentially, the topography of stream drainage basins was the sole preferred determinant for hydrologic unit boundaries in the United States.

2. All smaller units nest within the next larger unit. All boundaries of units lying in contiguous States match precisely.

Technical Criteria

Most technical criteria used in delineating boundaries were derived from published sources:

1. Principal references. Appendix C of "Notes on Hydrologic Activities," Bulletin 4, by the Federal Interagency Committee on Water Resources, Subcommittee on Hydrology (1951), and "River Mileage Measurement," Bulletin 14, by the U.S. Water Resources Council, Hydrology Subcommittee (1967), were the principal references used in development of the technical criteria and additional specifications.

2. Selection of major areas. Figure 5 depicts types of subregions and accounting units and shows their relationship to cataloging units. In general, the subregional delineations defined by the U.S. Water Resources Council (1970) were used as the principal geographic units with the following exceptions:

a. At a major lake or reservoir, the boundary was placed at the outlet of the impoundment rather than at its head, because the headwaters can vary considerably over a period of time whereas the outlet of the impoundment is usually a fixed point.

b. The location of boundaries at gaging stations, major cities, State lines, tidal or backwater effects, or other so-called strategic hydrologic, political, or cultural points was deemphasized.

c. The boundaries of the Standard Metropolitan Statistical Areas were not used as criteria for defining hydrologic unit boundaries.

d. Relocations of boundaries or subdivisions of principal units defined in the 1970 Water Resources Council publication were made on the recommendations of the designated regional sponsors of the Water Resources Council and State agencies.

3. Size of basins. No maximum-size criterion was specified. However, every unique river basin having a drainage area of more than 700 square miles is delineated, except in Alaska. A "unique river" is defined herein as one that has been given a definitive name by the Board on Geographic Names and is shown and named on Geological Survey base maps. The 700-square-mile criterion was adapted from the Soil Conservation Service's "Atlas of River Basins of the United States" (U.S. Department of Agriculture, 1970).

4. Bays and estuaries. No firm guidelines were developed. However, the U.S. Department of Commerce's publication entitled "Measurement of Geographic Area" (Proudfoot, 1940) was followed where possible and practical.

5. Small coastal islands. No firm guidelines were developed, but individual islands usually were not divided. Again, the criteria in Proudfoot's 1940 publication were used where possible and practical.

6. Closed basins. Closed basins and large noncontributing areas were delineated as separate units if of sufficient size, for example, approximately 700 square miles.

7. Ground-water areas. These areas were assumed to be the same as areas contributing to surface-water flow and thus were not specifically given separate consideration in the development of the maps. The cataloging units are thus more hydrographic than true hydrologic entities.

8. Swamps and depressions. These were designated as separate areas if of sufficient size, for example, approximately 700 square miles.

9. Interbasin flow. Interbasin flow was not considered if it occurs only during flood conditions.

10. Man-induced changes or diversions in natural drainage. Where flow is diverted continually, boundaries were delineated correspondingly. Where flow is diverted partially or intermittently, the boundaries were not adjusted. Levees were considered permanent structures.

11. Drainage corrections. Drainage corrections to the base maps were made using the best and latest available reference maps, which are the U.S. Geological Survey's standard topographic maps published in 7.5- and 15-minute quadrangles. Unpublished maps approved for publication by the Geological Survey were occasionally used for reference.

Additional Specifications

Coastal Boundaries

Because of the varying and complex State and Federal laws governing the placement of coastal boundaries, closure of the hydrologic units is not shown on the Hydrologic Unit Maps along the coastline of the United States. However, the hydrologic units had to be closed for

Figure 5. Types of subregions and accounting units showing their relationship to the cataloging units.

the purpose of digitizing for computing areal totals. Additional problems arose in the delineation of certain shorelines and coastal areas because the areas of the hydrologic units and corresponding areal totals (county, State, and so forth) should conform as closely as possible to the areal statistics published by the U.S. Bureau of the Census. The resolution of this complex problem is described in U.S. Geological Survey Professional Paper 964 by Anderson and others (1976) and in U.S. Geological Survey Open-File Report 77-555 by George L. Loelkes (1977). Essentially, the U.S. Geological Survey accepted the guidelines for coastal areas developed in "Measurement of Geographic Area" by Malcolm J. Proudfoot (1940). The procedure is explained more fully in Loelkes (1977, p. 18-21).

Code Identification

The region numbers were those assigned by the U.S. Water Resources Council (1970). Subregion numbers, originally assigned in the same publication, were changed, if necessary, to reflect a nationally consistent downstream numbering of units. The accounting unit and cataloging unit numbers and boundaries were developed simultaneously with the maps by the two senior authors. Hydrologic unit numbers for the accounting and cataloging units were assigned in downstream order within each subregion. Where no downstream order was feasible, units were numbered north to south.

The political subdivision code was adopted from Federal Information Processing Standards Publication 6-2, issued by the U.S. National Bureau of Standards (1973). Each county or county equivalent is identified by a two-character State code and a three-character county code. The State code is shown in the map explanation and the three-character county code for each county is shown on the maps.

Digitized Units

The hydrologic unit boundaries were digitized using the scale-stable scribe coat originals of the Hydrologic Unit Maps. The scale of the 1:500,000 base maps was reduced in the digitization to 1:1,000,000. Alaska, Hawaii, and the Caribbean received special treatment. Owing to digitizer-size restrictions and base-map divisions, large States were digitized in several parts and then combined to form full State data bases. A computer program was developed to use with the full State data bases to identify the hydrologic unit code associated with the point location (latitude and longitude) of a data site. Subsequently, the State boundaries were deleted and the individual State data bases were combined to form the national data base. Information on these partial and full data bases can be found in U.S. Geological Survey Circular 817, sequence no's. 145, 173, and 191 (U.S. Geological Survey, 1979).

Drainage Areas

One of the purposes of digitizing the hydrologic unit boundaries on the Hydrologic Unit Maps was to provide a national compilation of drainage areas, which is shown in table 1. The areas originated as routine output from the digitizer are expressed in square inches of digitizer table. All areas were recomputed to square miles. Areas in all regions except Alaska are reported to three significant figures. Areas in Alaska are reported to two significant figures except for the subregions and accounting units, which are rounded to three significant figures.

The areas presented in table 1 have some inherent inaccuracies and should be used with some caution. The inaccuracies include the following: errors in locating the drainage boundaries on original topographic maps; errors in transferring the drainage boundaries to the scale-stable base materials; errors in digitizing the boundaries; errors introduced when partial States or full States were combined into the national data base; errors in rounding the final numbers; and, in the case of Alaska, errors due to the variation in map projections.

Through random comparisons with published drainage area values, it is estimated that the areas listed in table 1 are within 5 percent of the true values as determined by planimetering the same areas on the best available Geological Survey 7.5-minute topographic maps. The areas of the subregions and accounting units are generally subject to a smaller percentage of error than the cataloging units. The areas are presented herein to allow relative comparisons of drainage basin sizes, but not to establish them as official values. The areas listed for hydrologic units along the coasts or the Great Lakes may include both "inland water" and "water other than inland water" as described in Proudfoot (1940) and the U.S. Bureau of the Census (1970).

REVIEW AND APPROVAL

The need for nationwide acceptance of and agreement on the Hydrologic Unit Maps by a broad spectrum of water-resource interests was acknowledged from the beginning of the program. Thus, the hydrologic unit boundaries, codes, and names were reviewed extensively by all principal Federal, regional, and State water-resources agencies across the country during a formal review process established for the map series.

The formal review process consisted of a field review by the four regional and 46 district offices of the U.S. Geological Survey's Water Resources Division, in conjunction with their principal regional, State, and local cooperators, followed by review and approval by the National Planning and Assessment Committee of the Water Resources Council. Approval by the National Planning and Assessment Committee constituted approval by the

Council of Representatives of the Water Resources Council, which had delegated this authority to the committee. The maps received final Water Resources Council approval between 1974 and 1977.

CONFLICTS REGARDING BOUNDARIES

The overriding consideration in resolving any conflicts in boundary locations was to recognize boundaries and subdivisions most widely used and accepted by responsible State, regional, and Federal agencies, as long as the two basic criteria were met.

The Geological Survey's Water Resources Division districts were the prime source and authority for correcting hydrologic boundaries. State, regional, and Federal agencies were relied on for preferred ranking of units as well as delineation of unit boundaries and numbering of units. Boundary locations and ranking of units were essentially determined using professional judgment based on principles of hydrology and cartography.

Some boundary conflicts were resolved by the Water Resources Council after identification and documentation by the Geological Survey. Decisions at this level were limited to those for which agreement could not be reached locally or regionally, or those that were entrenched by law or Executive order. The hydrologic units affected by proposed boundary or numbering changes were documented for the Water Resources Council on a single set of State maps, which showed only those boundaries recommended by the Geological Survey after extensive field review.

All proposed changes in boundaries and numbering during the review process were documented and are on file with the Geological Survey's Office of Water Data Coordination in Reston, Va. This documentation describes the basis for the change, identifies the originator of the proposed change, and explains why each change was accepted or rejected. Minor undisputed changes in hydrologic boundaries made on the basis of hydrography or topography were not formally documented but are on file with the Geological Survey. Changes in previous boundary lines were not considered conflicts if all interested parties concurred with the changes, and if the changes were made in accordance with the criteria and specifications listed previously.

MAINTENANCE AND UPDATING

There is currently no plan to revise the Hydrologic Unit Maps except to correct major errors. Boundary, code, or name revisions can be accepted only from a responsible water-resources agency, whereas any user may notify the Geological Survey of errors on the maps. All changes in the hydrologic units, as cited in table 1 and in U.S. Geological Survey Circular 878–A (U.S. Geological Survey, 1982), are subject to approval by the Geological Survey.

Recommendations for changes and questions concerning the list of entities and codes shown in table 1 should be addressed to the Office of Water Data Coordination, which then will process all necessary amendments:

USES

The Hydrologic Unit Maps have been used and applied by many other agencies and are being increasingly adopted by them for official uses. They have lasting value in planning activities relating to land and associated water resources, and in organizing and disseminating data, on both a geographic and hydrologic basis. The maps are suitable for use in conjunction with computer graphics and for automatic plotting of station locations and other areal data.

For data collection, storage, and manipulation, a standard coding system is necessary for efficient use and dissemination. The Geological Survey uses the coding system to document all its water-data collection activities and efforts. The boundaries of the hydrologic units have been digitized for more efficient use with data processing and automatic plotting machines.

Other Federal agencies using the hydrologic units for codifying and displaying the data that were collected locally and nationwide include the Forest Service, U.S. Army Corps of Engineers, Soil Conservation Service, Fish and Wildlife Service, National Park Service, Council on Environmental Quality, and National Weather Service, as well as regional, State, and local agencies.

National Water Data Network

The entire activity involving water-data collection, handling, storage, and dissemination in the United States can be thought of as a national water-data system. This system embraces all Federal and non-Federal water-data activities that contribute to meeting the general need for water information to support planning and operating water-related programs. All organized activities concerned with collecting water data on and beneath the Earth's surface for this national system can be considered as the National Water Data Network. The Hydrologic Unit Maps show boundaries of discrete elements of this surface-water network.

Cataloging and Coordinating Data

The Hydrologic Unit Maps are used for geographically locating the data sites indexed in the National Water Data Exchange Program and the "Catalog of Information on Water Data" and, therefore, constitute an important part of this data service.

Cataloging and coordinating play major roles in establishing design objectives for the National Water Data Network and provide the necessary basic information for planning, refining, and updating the network.

The "Catalog of Information on Water Data" was established by the Geological Survey in 1966 from information on some 60,000 activities supplied by more than 200 Federal, State, and local agencies and universities in the United States and by the Water Survey of Canada. The catalog is a file of information about water-data activities; it is not a compilation of the collected water data.

In response to the increasing needs of the water-data user community, the Geological Survey established the National Water Data Exchange in 1976 to enhance the exchange of water data between collector and user. The Master Water Data Index, a computerized file developed and maintained by the National Water Data Exchange, identifies sites for which water data are available, the location of these sites, the organizations collecting the data, the types of data available, and the frequency of measurement of each major type of data. The number of activities identified in the Master Water Data Index has grown to about 400,000, representing more than 400 organizations. For example, the Geological Survey, through the National Water Data Exchange, has incorporated the hydrologic unit codes into its computer system to enable all its members to have rapid access to data holdings that consist of more than a billion water-resource measurements.

Other Uses of Hydrologic Unit Maps

The Hydrologic Unit Maps have been used by both Government agencies and private firms. The following is a partial listing of uses and users.

The Soil Conservation Service has adopted the Hydrologic Unit Maps as a base for collecting data in its natural-resource inventories and surveys. The Soil Conservation Service data are coded so that they can be stored and retrieved on the basis of hydrologic units. The addition of a hyphen and a three-digit Soil Conservation Service watershed code to the eight-digit code (for example, 05120107–014) makes the Hydrologic Unit Map coding system applicable to areas delineated as part of the implementation of Public Law 83–566. As time and resources permit, the State conservationists of the Soil Conservation Service are putting the three-digit watershed coding system into effect as a supplement to the national hydrologic unit code.

The Geological Survey's National Mapping Division uses the hydrologic unit boundaries and coding system in its land-use and land-cover mapping program. Under this program, the conterminous States will be covered on the 1:250,000 scale map series over the next several years. All boundaries are again checked on the latest available accurate topographic maps, in order to ensure accuracy at this enlarged scale. The specifications for the land-use and land-cover and associated maps are given in Loelkes (1977). A further description of these maps is given in Anderson and others (1976). These Geological Survey land-use maps show (1) land use and cover, (2) Federal land ownership, (3) political units, (4) hydrologic units, (5) census county subdivisions, and (6) State land ownership.

The U.S. Fish and Wildlife Service is using the Hydrologic Unit Maps as bases on which to overprint its Stream Evaluation Map Series. The latter maps, provided to assist Federal and State agencies and water users in assessing the impact of proposed water-development projects on existing fishery resources, are a cooperative effort by the U.S. Department of the Interior, the U.S. Environmental Protection Agency, and the State Fish and Wildlife Departments of Colorado, Idaho, Montana, Nebraska, Nevada, North Dakota, Oklahoma, South Dakota, Texas, Utah, and Wyoming. The Fish and Wildlife Service, in conjunction with the Forest Service, has published another set of nationwide maps entitled "Ecoregion, Land-Surface Form and Hydrologic Unit Maps of the United States" (Bailey and Cushwa, 1982).

The Environmental Protection Agency is using the coding system in its storage and retrieval system, as well as in its River-Reach File. The River-Reach File is a computerized catalog of streams of the United States for organizing water-resources statistics and related information. In addition, it contains the digitized traces of streams, lakes, coastlines, and basin boundaries and provides a framework for simulated routing of streamflow and pollutants through the Nation's river systems. Computerized hard-copy displays and interactive graphics displays are available from the Environmental Protection Agency.

The Forest Service is using the maps to manage the resource data available for national forests. It is also using the maps as a base for the ongoing Inventory of Federal Reserved Water Rights. The National Park Service and the Bureau of Land Management are also using the maps for their portion of the Inventory of Federal Reserved Water Rights.

The U.S. Department of Energy has contracted with the Hanford Engineering Development Laboratory for the development of a Water Use Information System to help plan energy strategy. The system, which came on line in 1979, contains data on electrical generating plants and surface-water resources; additional capabilities will be added later. The system uses the Hydrologic Unit Maps as its base and provides data for each cataloging unit in the United States. These data can, of course, be aggregated into larger units and are also tabulated for each county and State. The water-resources element of the information system will contain four groups of data: area description, surface water, ground water, and oceans and bays.

The National Weather Service is using the maps for coding its meteorological data sites, and the U.S. Bureau of Commerce has used the maps as a base for its irrigation census. The Geological Survey is using the maps for its nationwide water-use program.

Many States use hydrologic subdivisions so small that it was not deemed advisable for nationwide consistency, or possible because of scale, to adopt their smallest recommended units on the Hydrologic Unit Maps. The plates used for the preparation of the maps are available to States and regional agencies, through the Geological Survey, for use in overprinting their own hydrologic, planning, or water-management units. Agencies in Florida and Minnesota have already printed their own maps with smaller units added to the base map.

Their sales record indicates that the Hydrologic Unit Maps have widespread use for planning water-related activities, as well as in organizing and disseminating data on a hydrologic, geographic, and political basis. The maps have been accepted by many Federal, State, and regional agencies, and the codes have been a published in the "Federal Register" and were approved as a Federal Standard in 1983. Their suitability for computer plotting of station locations and other areal data, and the ability to combine them into any size desired, has increased their value.

SUMMARY

The Hydrologic Unit Maps depict basic hydrologic and political areal planning units of the United States, thus providing a standard, uniform geographical framework for water-resource and related land-resource planning. Their use has standardized, nationwide, not only the boundaries of planning activities, but also the organization and dissemination of data. Most of the differences among Federal, regional, State, and local water-resource agencies as to location, size, and extent of hydrologic unit boundaries have been resolved as a result of intensive and extensive review. The maps will generally require only minor changes for future editions, mainly for correction of errors or for further subdivision of the *cataloging units.*

REGION 01 NEW ENGLAND REGION — THE DRAINAGE WITHIN THE UNITED STATES THAT ULTIMATELY DISCHARGES INTO: (A) THE BAY OF FUNDY; (B) THE ATLANTIC OCEAN WITHIN AND BETWEEN THE STATES OF MAINE AND CONNECTICUT; (C) LONG ISLAND SOUND NORTH OF THE NEW YORK-CONNECTICUT STATE LINE; AND (D) THE RIVIERE ST. FRANCOIS, A TRIBUTARY OF THE ST. LAWRENCE RIVER. INCLUDES ALL OF MAINE, NEW HAMPSHIRE AND RHODE ISLAND AND PARTS OF CONNECTICUT, MASSACHUSETTS, NEW YORK, AND VERMONT.

SUBREGION 0101 — ST. JOHN: THE ST. JOHN RIVER BASIN WITHIN THE UNITED STATES. MAINE.
AREA = 7330 SQ.MI.

ACCOUNTING UNIT 010100 — ST. JOHN. MAINE.
AREA = 7330 SQ.MI.

CATALOGING UNITS
01010001 — UPPER ST. JOHN. MAINE. AREA = 2120 SQ.MI.
01010002 — ALLAGASH. MAINE. AREA = 1250 SQ.MI.
01010003 — FISH. MAINE. AREA = 908 SQ.MI.
01010004 — AROOSTOOK. MAINE. AREA = 2420 SQ.MI.
01010005 — MEDUXNEKEAG. MAINE. AREA = 634 SQ.MI.

SUBREGION 0102 — PENOBSCOT: THE PENOBSCOT RIVER BASIN. MAINE.
AREA = 8610 SQ.MI.

ACCOUNTING UNIT 010200 — PENOBSCOT. MAINE.
AREA = 8610 SQ.MI.

CATALOGING UNITS
01020001 — WEST BRANCH PENOBSCOT. MAINE. AREA = 2150 SQ.MI.
01020002 — EAST BRANCH PENOBSCOT. MAINE. AREA = 1130 SQ.MI.
01020003 — MATTAWAMKEAG. MAINE. AREA = 1510 SQ.MI.
01020004 — PISCATAQUIS. MAINE. AREA = 1460 SQ.MI.
01020005 — LOWER PENOBSCOT. MAINE. AREA = 2360 SQ.MI.

SUBREGION 0103 — KENNEBEC: THE KENNEBEC RIVER BASIN, INCLUDING PART OF MERRYMEETING BAY. MAINE.
AREA = 5900 SQ.MI.

ACCOUNTING UNIT 010300 — KENNEBEC. MAINE.
AREA = 5900 SQ.MI.

CATALOGING UNITS
01030001 — UPPER KENNEBEC. MAINE. AREA = 1570 SQ.MI.
01030002 — DEAD. MAINE. AREA = 878 SQ.MI.
01030003 — LOWER KENNEBEC. MAINE. AREA = 3450 SQ.MI.

SUBREGION 0104 — ANDROSCOGGIN: THE ANDROSCOGGIN RIVER BASIN, INCLUDING PART OF MERRYMEETING BAY. MAINE, NEW HAMPSHIRE.
AREA = 3530 SQ.MI.

ACCOUNTING UNIT 010400 — ANDROSCOGGIN. MAINE, NEW HAMPSHIRE.
AREA = 3530 SQ.MI.

CATALOGING UNITS
01040001 — UPPER ANDROSCOGGIN. MAINE, NEW HAMPSHIRE. AREA = 1470 SQ.MI.
01040002 — LOWER ANDROSCOGGIN. MAINE, NEW HAMPSHIRE. AREA = 2060 SQ.MI.

SUBREGION 0105 — MAINE COASTAL: THE COASTAL DRAINAGE AND ASSOCIATED WATERS FROM THE MAINE-NEW BRUNSWICK INTERNATIONAL BOUNDARY TO CAPE SMALL, MAINE, INCLUDING THE ST. CROIX RIVER BASIN WITHIN THE UNITED STATES. MAINE.
AREA = 7130 SQ.MI.

ACCOUNTING UNIT 010500 — MAINE COASTAL. MAINE.
AREA = 7130 SQ.MI.

CATALOGING UNITS
01050001 — ST. CROIX. MAINE. AREA = 999 SQ.MI.
01050002 — MAINE COASTAL. MAINE. AREA = 4880 SQ.MI.
01050003 — ST. GEORGE-SHEEPSCOT. MAINE. AREA = 1250 SQ.MI.

SUBREGION 0106 — SACO: THE COASTAL DRAINAGE AND ASSOCIATED WATERS FROM CAPE SMALL, MAINE TO THE MERRIMACK RIVER BASIN BOUNDARY. MAINE, NEW HAMPSHIRE, MASSACHUSETTS.
AREA = 4330 SQ.MI.

ACCOUNTING UNIT 010600 — SACO. MAINE, NEW HAMPSHIRE, MASSACHUSETTS.
AREA = 4330 SQ.MI.

CATALOGING UNITS
01060001 — PRESUMPSCOT. MAINE. AREA = 1240 SQ.MI.
01060002 — SACO. MAINE, NEW HAMPSHIRE. AREA = 1690 SQ.MI.
01060003 — PISCATAQUA-SALMON FALLS. MAINE, NEW HAMPSHIRE, MASSACHUSETTS. AREA = 1400 SQ.MI.

SUBREGION 0107 — MERRIMACK: THE MERRIMACK RIVER BASIN. MASSACHUSETTS, NEW HAMPSHIRE.
AREA = 4980 SQ.MI.

ACCOUNTING UNIT 010700 — MERRIMACK. MASSACHUSETTS, NEW HAMPSHIRE.
AREA = 4980 SQ.MI.

CATALOGING UNITS
01070001 — PEMIGEWASSET. NEW HAMPSHIRE. AREA = 1000 SQ.MI.
01070002 — MERRIMACK. MASSACHUSETTS, NEW HAMPSHIRE. AREA = 2300 SQ.MI.
01070003 — CONTOOCOOK. NEW HAMPSHIRE. AREA = 757 SQ.MI.
01070004 — NASHUA. MASSACHUSETTS, NEW HAMPSHIRE. AREA = 525 SQ.MI.
01070005 — CONCORD. MASSACHUSETTS. AREA = 401 SQ.MI.

SUBREGION 0108 — CONNECTICUT: THE CONNECTICUT RIVER BASIN. CONNECTICUT, MASSACHUSETTS, NEW HAMPSHIRE, VERMONT.
AREA = 11100 SQ.MI.

ACCOUNTING UNIT 010801 — UPPER CONNECTICUT: THE CONNECTICUT RIVER BASIN ABOVE VERNON DAM. NEW HAMSPHIRE, VERMONT.
AREA = 6120 SQ.MI.

CATALOGING UNITS —
01080101 — UPPER CONNECTICUT. NEW HAMPSHIRE VERMONT. AREA = 1990 SQ.MI.
01080102 — PASSUMPSIC. VERMONT.. AREA = 496 SQ.MI.
01080103 — WAITS. VERMONT. AREA = 441 SQ.MI.
01080104 — UPPER CONNECTICUT-MASCOMA. NEW HAMPSHIRE, VERMONT. AREA = 1460 SQ.MI.
01080105 — WHITE. VERMONT. AREA = 703 SQ.MI.
01080106 — BLACK-OTTAUQUECHEE. VERMONT. AREA = 418 SQ.MI.
01080107 — WEST. VERMONT. AREA = 612 SQ.MI.

ACCOUNTING UNIT 010802 — LOWER CONNECTICUT: THE CONNECTICUT RIVER BASIN BELOW VERNON DAM. CONNECTICUT, MASSACHUSETTS, NEW HAMPSHIRE, VERMONT.
AREA = 4960 SQ.MI.

CATALOGING UNITS
01080201 — MIDDLE CONNECTICUT. MASSACHUSETTS, NEW HAMPSHIRE, VERMONT. AREA = 999 SQ.MI.
01080202 — MILLER. MASSACHUSETTS, NEW HAMSPHIRE. AREA = 391 SQ.MI.
01080203 — DEERFIELD. MASSACHUSETTS, VERMONT. AREA = 658 SQ.MI.
01080204 — CHICOPEE. MASSACHUSETTS. AREA = 725 SQ.MI.
01080205 — LOWER CONNECTICUT. CONNECTICUT, MASSACHUSETTS. AREA = 1090 SQ.MI.
01080206 — WESTFIELD. CONNECTICUT, MASSACHUSETTS. AREA = 505 SQ.MI.
01080207 — FARMINGTON. CONNECTICUT, MASSACHUSETTS. AREA = 590 SQ.MI.

SUBREGION 0109 — MASSACHUSETTS-RHODE ISLAND COASTAL: THE COASTAL DRAINAGE AND ASSOCIATED WATERS FROM THE MERRIMACK RIVER BASIN BOUNDART TO AND INCLUDING THE PAWCATUCK RIVER BASIN. CONNECTICUT, MASSACHUSETTS, RHODE ISLAND.
AREA = 5510 SQ.MI.

REGION 01: NEW ENGLAND — Continued

ACCOUNTING UNIT 010900 — MASSACHUSETTS-RHODE ISLAND COASTAL. CONNECTICUT, MASSACHUSETTS, RHODE ISLAND.
AREA = 5510 SQ.MI.

CATALOGING UNITS 01090001 — CHARLES. MASSACHUSETTS.
AREA = 1130 SQ.MI.
01090002 — CAPE COD. MASSACHUSETTS, RHODE ISLAND.
AREA = 2220 SQ.MI.
01090003 — BLACKSTONE. MASSACHUSETTS, RHODE ISLAND.
AREA = 451 SQ.MI.
01090004 — NARRAGANSETT. MASSACHUSETTS, RHODE ISLAND.
AREA = 1330 SQ.MI.
01090005 — PAWCATUCK-WOOD. CONNECTICUT, RHODE ISLAND.
AREA = 383 SQ.MI.

SUBREGION 0110 — CONNECTICUT COASTAL: THE COASTAL DRAINAGE INTO LONG ISLAND SOUND FROM THE PAWCATUCK RIVER BASIN BOUNDARY TO AND INCLUDING THE BYRAM RIVER BASIN, EXCLUDING THE CONNECTICUT RIVER BASIN, AND INCLUDING LONG ISLAND SOUND NORTH OF THE NEW YORK-CONNECTICUT STATE LINE. CONNECTICUT, MASSACHUSETTS, NEW YORK, RHODE ISLAND.
AREA = 5080 SQ.MI.

ACCOUNTING UNIT 011000 — CONNECTICUT COASTAL. CONNECTICUT, MASSACHUSETTS, NEW YORK, RHODE ISLAND.
AREA = 5080 SQ.MI.

CATALOGING UNITS 01100001 — QUINEBAUG. CONNECTICUT, MASSACHUSETTS, RHODE ISLAND.
AREA = 729 SQ.MI.
01100002 — SHETUCKET. CONNECTICUT, MASSACHUSETTS.
AREA = 517 SQ.MI.
01100003 — THAMES. CONNECTICUT.
AREA = 381 SQ.MI.
01100004 — QUINNIPIAC. CONNECTICUT.
AREA = 516 SQ.MI.
01100005 — HOUSATONIC. CONNECTICUT, MASSACHUSETTS, NEW YORK.
AREA = 1930 SQ.MI.
01100006 — SAUGATUCK. CONNECTICUT, NEW YORK.
AREA = 436 SQ.MI.
01100007 — LONG ISLAND SOUND. CONNECTICUT.
AREA = 568 SQ.MI.

SUBREGION 0111 — ST. FRANCOIS: THE RIVIERE ST. FRANCOIS BASIN WITHIN THE UNITED STATES. VERMONT.
AREA = 590 SQ.MI.

ACCOUNTING UNIT 011100 — ST. FRANCOIS. VERMONT.
AREA = 590 SQ.MI.

CATALOGING UNIT 01110000 — ST. FRANCOIS. VERMONT.
AREA = 590 SQ.MI.

REGION 02 MID ATLANTIC REGION — THE DRAINAGE WITHIN THE UNITED STATES THAT ULTIMATELY DISCHARGES INTO: (A) THE ATLANTIC OCEAN WITHIN AND BETWEEN THE STATES OF NEW YORK AND VIRGINIA; (B) LONG ISLAND SOUND SOUTH OF THE NEW YORK-CONNECTICUT STATE LINE; AND (C) THE RIVIERE RICHELIEU, A TRIBUTARY OF THE ST. LAWRENCE RIVER. INCLUDES ALL OF DELAWARE AND NEW JERSEY AND THE DISTRICT OF COLUMBIA, AND PARTS OF CONNECTICUT, MARYLAND, MASSACHUSETTS, NEW YORK, PENNSYLVANIA, VERMONT, VIRGINIA, AND WEST VIRGINIA.

SUBREGION 0201 — RICHELIEU: THE RIVIERE RICHELIEU BASIN, INCLUDING LAKE CHAMPLAIN DRAINAGE, WITHIN THE UNITED STATES. NEW YORK, VERMONT.
AREA = 7720 SQ.MI.

ACCOUNTING UNIT 020100 — RICHELIEU. NEW YORK, VERMONT.
AREA = 7720 SQ.MI.

CATALOGING UNITS 02010001 — LAKE GEORGE. NEW YORK, VERMONT.
AREA = 1390 SQ.MI.
02010002 — OTTER. VERMONT.
AREA = 1090 SQ.MI.
02010003 — WINOOSKI. VERMONT.
AREA = 1220 SQ.MI.
02010004 — AUSABLE. NEW YORK.
AREA = 1070 SQ.MI.
02010005 — LAMOILLE. VERMONT.
AREA = 1130 SQ.MI.
02010006 — GREAT CHAZY-SARANAC. NEW YORK.
AREA = 1110 SQ.MI.
02010007 — MISSISQUOI. VERMONT.
AREA = 707 SQ.MI.

SUBREGION 0202 — UPPER HUDSON: THE HUDSON RIVER BASIN TO AND INCLUDING THE POPOLOPEN BROOK BASIN JUST UPSTREAM FROM BEAR MOUNTAIN BRIDGE. NEW JERSEY, NEW YORK, MASSACHUSETTS, VERMONT.
AREA = 12500 SQ.MI.

ACCOUNTING UNIT 020200 — UPPER HUDSON. NEW JERSEY, NEW YORK, MASSACHUSETTS, VERMONT.
AREA = 12500 SQ.MI.

CATALOGING UNITS 02020001 — UPPER HUDSON. NEW YORK.
AREA = 1630 SQ.MI.
02020002 — SACANDAGA. NEW YORK.
AREA = 1050 SQ.MI.
02020003 — HUDSON-HOOSIC. NEW YORK, MASSACHUSETTS, VERMONT.
AREA = 1880 SQ.MI.
02020004 — MOHAWK. NEW YORK.
AREA = 2550 SQ.MI.
02020005 — SCHOHARIE. NEW YORK.
AREA = 927 SQ.MI.
02020006 — MIDDLE HUDSON. MASSACHUSETTS, NEW YORK.
AREA = 2390 SQ.MI.
02020007 — RONDOUT. NEW JERSEY, NEW YORK.
AREA = 1190 SQ.MI.
02020008 — HUDSON-WAPPINGER. NEW YORK.
AREA = 928 SQ.MI.

SUBREGION 0203 — LOWER HUDSON-LONG ISLAND: THE COASTAL DRAINAGE AND ASSOCIATED WATERS FROM THE BYRAM RIVER BASIN BOUNDARY, TO THE MANASQUAN RIVER BASIN BOUNDARY, INCLUDING THE HUDSON RIVER BASIN DOWNSTREAM FROM THE POPOLOPEN BROOK BASIN BOUNDARY, LONG ISLAND AND BLOCK ISLAND SOUNDS SOUTH OF THE NEW YORK-CONNECTICUT STATE LINE, AND LONG ISLAND. CONNECTICUT, NEW JERSEY, NEW YORK.
AREA = 6360 SQ.MI.

ACCOUNTING UNIT 020301 — LOWER HUDSON: THE COASTAL DRAINAGE AND ASSOCIATED WATERS FROM THE BYRAM RIVER BASIN BOUNDARY, TO THE MANASQUAN RIVER BASIN BOUNDARY, INCLUDING THE HUDSON RIVER BASIN DOWNSTREAM FROM THE POPOLOPEN BROOK BASIN BOUNDARY, AND LONG ISLAND SOUND IN WESTCHESTER AND BRONX COUNTIES, NEW YORK, BUT EXCLUDING LONG ISLAND AND BLOCK ISLAND SOUNDS SOUTH OF THE NEW YORK-CONNECTICUT STATE LINE AND LONG ISLAND. CONNECTICUT, NEW JERSEY, NEW YORK.
AREA = 3790 SQ.MI.

CATALOGING UNITS 02030101 — LOWER HUDSON. CONNECTICUT, NEW JERSEY, NEW YORK.
AREA = 720 SQ.MI.
02030102 — BRONX. NEW YORK.
AREA = 190 SQ.MI.
02030103 — HACKENSACK-PASSAIC. NEW JERSEY, NEW YORK.
AREA = 1120 SQ.MI.
02030104 — SANDY HOOK-STATEN ISLAND. NEW JERSEY, NEW YORK.
AREA = 679 SQ.MI.
02030105 — RARITAN. NEW JERSEY.
AREA = 1080 SQ.MI.

ACCOUNTING UNIT 020302 — LONG ISLAND: LONG ISLAND AND LONG ISLAND AND BLOCK ISLAND SOUNDS SOUTH OF THE NEW YORK-CONNECTICUT STATE LINE, BUT EXCLUDING LONG ISLAND SOUND IN WESTCHESTER AND BRONX COUNTIES, NEW YORK. NEW YORK.
AREA = 2580 SQ.MI.

CATALOGING UNITS 02030201 — NORTHERN LONG ISLAND. NEW YORK.
AREA = 915 SQ.MI.
02030202 — SOUTHERN LONG ISLAND. NEW YORK.
AREA = 1660 SQ.MI.

SUBREGION 0204 — DELAWARE: THE COASTAL DRAINAGE AND ASSOCIATED WATERS FROM AND INCLUDING THE MANASQUAN RIVER BASIN TO AND INCLUDING THE DELAWARE RIVER BASIN WHICH INCLUDES DELAWARE BAY. DELAWARE, MARYLAND, NEW JERSEY, NEW YORK, PENNSYLVANIA.
AREA = 15500 SQ.MI.

ACCOUNTING UNIT 020401 — UPPER DELAWARE: THE DELAWARE RIVER BASIN UPSTREAM FROM THE FALL LINE (HIGHEST TIDAL EFFECT OF THE DELAWARE RIVER) AT TRENTON, NEW JERSEY. NEW JERSEY, NEW YORK, PENNSYLVANIA.
AREA = 6800 SQ.MI.

CATALOGING UNITS 02040101 — UPPER DELAWARE. NEW YORK, PENNSYLVANIA.
AREA = 1180 SQ.MI.
02040102 — EAST BRANCH DELAWARE. NEW YORK.
AREA = 828 SQ.MI.
02040103 — LACKAWAXEN. PENNSYLVANIA.
AREA = 587 SQ.MI.
02040104 — MIDDLE DELAWARE-MONGAUP-BRODHEAD. NEW JERSEY, NEW YORK, PENNSYLVANIA.

05130201 — LOWER CUMBERLAND-OLD HICKORY LAKE. TENNESSEE. AREA = 975 SQ.MI.
05130202 — LOWER CUMBERLAND-SYCAMORE. TENNESSEE. AREA = 642 SQ.MI.
05130203 — STONES. TENNESSEE. AREA = 921 SQ.MI.
05130204 — HARPETH. TENNESSEE. AREA = 861 SQ.MI.
05130205 — LOWER CUMBERLAND. KENTUCKY, TENNESSEE. AREA = 2300 SQ.MI.
05130206 — RED. KENTUCKY, TENNESSEE. AREA = 1450 SQ.MI.

SUBREGION 0514 — LOWER OHIO: THE OHIO RIVER BASIN BELOW THE CONFLUENCE WITH THE KENTUCKY RIVER BASIN, TO THE CONFLUENCE WITH THE MISSISSIPPI RIVER, EXCLUDING THE CUMBERLAND, GREEN, TENNESSEE, AND WABASH RIVER BASINS. ILLINOIS, INDIANA, KENTUCKY.
AREA = 12500 SQ.MI.

ACCOUNTING UNIT 051401 — LOWER OHIO-SALT. THE OHIO RIVER BASIN BELOW THE CONFLUENCE WITH THE KENTUCKY RIVER BASIN, TO RIVER MILE 703.((FORMERLY LOCK AND DAM 45) ON THE OHIO RIVER. INDIANA, KENTUCKY.
AREA = 6000 SQ.MI.

CATALOGING UNITS
05140101 — SILVER-LITTLE KENTUCKY. INDIANA, KENTUCKY. AREA = 1240 SQ.MI.
05140102 — SALT. KENTUCKY. AREA = 1450 SQ.MI.
05140103 — ROLLING FORK. KENTUCKY. AREA = 1430 SQ.MI.
05140104 — BLUE-SINKING. KENTUCKY, INDIANA. AREA = 1880 SQ.MI.

ACCOUNTING UNIT 051402 — LOWER OHIO: THE OHIO RIVER BASIN FROM RIVER MILE 703.0 (FORMERLY LOCK AND DAM 45) ON THE OHIO RIVER TO THE CONFLUENCE WITH THE MISSISSIPPI RIVER, EXCLUDING THE CUMBERLAND, GREEN, TENNESSEE, AND WABASH RIVER BASINS. ILLINOIS, INDIANA, KENTUCKY.
AREA = 6480 SQ.MI.

CATALOGING UNITS
05140201 — LOWER OHIO-LITTLE PIGEON. INDIANA, AREA = 1370 SQ.MI.
05140202 — HIGHLAND-PIGEON. INDIANA, KENTUCKY. AREA = 1000 SQ.MI.
05140203 — LOWER OHIO-BAY. ILLINOIS, KENTUCKY. AREA = 1090 SQ.MI.
05140204 — SALINE. ILLINOIS. AREA = 1160 SQ.MI.
05140205 — TRADEWATER. KENTUCKY. AREA = 936 SQ.MI.
05140206 — LOWER OHIO. ILLINOIS, KENTUCKY. AREA = 928 SQ.MI.

REGION 06 TENNESSEE REGION — THE DRAINAGE OF THE TENNESSEE RIVER BASIN. INCLUDES PARTS OF ALABAMA, GEORGIA, KENTUCKY, MISSISSIPPI, NORTH CAROLINA, TENNESSEE, AND VIRGINIA.

SUBREGION 0601 — UPPER TENNESSEE: THE TENNESSEE RIVER BASIN ABOVE WATTS BAR DAM. GEORGIA, NORTH CAROLINA, TENNESSEE, VIRGINIA.
AREA = 17200 SQ.MI.

ACCOUNTING UNIT 060101 — FRENCH BROAD-HOLSTON: THE TENNESSEE RIVER BASIN ABOVE THE CONFLUENCE OF AND INCLUDING THE FRENCH BROAD AND HOLSTON RIVER BASINS. NORTH CAROLINA, TENNESSEE, VIRGINIA.
AREA = 8820 SQ.MI.

CATALOGING UNITS
06010101 — NORTH FORK HOLSTON. TENNESSEE, VIRGINIA.
AREA = 708 SQ.MI.
06010102 — SOUTH FORK HOLSTON. TENNESSEE, VIRGINIA.
AREA = 1170 SQ.MI.
06010103 — WATAUGA. NORTH CAROLINA, TENNESSEE.
AREA = 870 SQ.MI.
06010104 — HOLSTON. TENNESSEE.
AREA = 990 SQ.MI.
06010105 — UPPER FRENCH BROAD. NORTH CAROLINA, TENNESSEE.
AREA = 1870 SQ.MI.
06010106 — PIGEON. NORTH CAROLINA, TENNESSEE.
AREA = 679 SQ.MI.
06010107 — LOWER FRENCH BROAD. TENNESSEE.
AREA = 792 SQ.MI.
06010108 — NOLICHUCKY. NORTH CAROLINA, TENNESSEE.
AREA = 1740 SQ.MI.

ACCOUNTING UNIT 060102 — UPPER TENNESSEE: THE TENNESSEE RIVER BASIN ABOVE WATTS BAR DAM, EXCLUDING THE FRENCH BROAD AND HOLSTON RIVER BASINS. GEORGIA, NORTH CAROLINA, TENNESSEE, VIRGINIA.
AREA = 8360 SQ.MI.

CATALOGING UNITS
06010201 — WATTS BAR LAKE. TENNESSEE.
AREA = 1340 SQ.MI.
06010202 — UPPER LITTLE TENNESSEE. GEORGIA, NORTH CAROLINA.
AREA = 839 SQ.MI.
06010203 — TUCKASEGEE. NORTH CAROLINA.
AREA = 731 SQ.MI.
06010204 — LOWER LITTLE TENNESSEE. NORTH CAROLINA, TENNESSEE.
AREA = 1050 SQ.MI.
06010205 — UPPER CLINCH. TENNESSEE, VIRGINIA.
AREA = 1970 SQ.MI.
06010206 — POWELL. TENNESSEE, VIRGINIA.
AREA = 939 SQ.MI.
06010207 — LOWER CLINCH. TENNESSEE.
AREA = 620 SQ.MI.
06010208 — EMORY. TENNESSEE.
AREA = 866 SQ.MI.

SUBREGION 0602 — MIDDLE TENNESSEE-HIWASSEE: THE TENNESSEE RIVER BASIN BELOW WATTS BAR DAM TO AND INCLUDING THE SEQUATCHIE RIVER BASIN. ALABAMA, GEORGIA, NORTH CAROLINA, TENNESSEE.
AREA = 5160 SQ.MI.

ACCOUNTING UNIT 060200 — MIDDLE TENNESSEE-HIWASSEE. ALABAMA, GEORGIA, NORTH CAROLINA, TENNESSEE.
AREA = 5160 SQ.MI.

CATALOGING UNITS
06020001 — MIDDLE TENNESSEE-CHICKAMAUGA. ALABAMA, GEORGIA, TENNESSEE.
AREA = 1870 SQ.MI.
06020002 — HIWASSEE. GEORGIA, NORTH CAROLINA, TENNESSEE.
AREA = 2060 SQ.MI.
06020003 — OCOEE. GEORGIA, NORTH CAROLINA, TENNESSEE.
AREA = 648 SQ.MI.
06020004 — SEQUATCHIE. TENNESSEE.
AREA = 586 SQ.MI.

SUBREGION 0603 — MIDDLE TENNESSEE-ELK: THE TENNESSEE RIVER BASIN BELOW THE CONFLUENCE WITH THE SEQUATCHIE RIVER BASIN TO PICKWICK DAM. ALABAMA, GEORGIA, MISSISSIPPI, TENNESSEE.
AREA = 10300 SQ.MI.

ACCOUNTING UNIT 060300 — MIDDLE TENNESSEE-ELK. ALABAMA, GEORGIA, MISSISSIPPI, TENNESSEE.
AREA = 10300 SQ.MI.

CATALOGING UNITS
06030001 — GUNTERSVILLE LAKE. ALABAMA, GEORGIA, TENNESSEE.
AREA = 1990 SQ.MI.
06030002 — WHEELER LAKE. ALABAMA, TENNESSEE.
AREA = 2890 SQ.MI.
06030003 — UPPER ELK. ALABAMA, TENNESSEE.
AREA = 1270 SQ.MI.

06030004 — LOWER ELK. ALABAMA, TENNESSEE.
AREA = 950 SQ.MI.
06030005 — PICKWICK LAKE. ALABAMA, MISSISSIPPI, TENNESSEE.
AREA = 2270 SQ.MI.
06030006 — BEAR. ALABAMA, MISSISSIPPI.
AREA = 930 SQ.MI.

SUBREGION 0604 — LOWER TENNESSEE: THE TENNESSEE RIVER BASIN BELOW PICKWICK DAM. KENTUCKY, MISSISSIPPI, TENNESSEE.
AREA = 8010 SQ.MI.

ACCOUNTING UNIT 060400 — LOWER TENNESSEE: KENTUCKY, MISSISSIPPI, TENNESSEE.
AREA = 8010 SQ.MI.

CATALOGING UNITS
06040001 — LOWER TENNESSEE-BEECH. MISSISSIPPI, TENNESSEE.
AREA = 2080 SQ.MI.
06040002 — UPPER DUCK. TENNESSEE.
AREA = 1160 SQ.MI.
06040003 — LOWER DUCK. TENNESSEE.
AREA = 1540 SQ.MI.
06040004 — BUFFALO. TENNESSEE.
AREA = 731 SQ.MI.
06040005 — KENTUCKY LAKE. KENTUCKY, TENNESSEE.
AREA = 1810 SQ.MI.
06040006 — LOWER TENNESSEE. KENTUCKY, TENNESSEE.
AREA = 689 SQ.MI.

REGION 07 UPPER MISSISSIPPI REGION — THE DRAINAGE OF THE MISSISSIPPI RIVER BASIN ABOVE THE CONFLUENCE WITH THE OHIO RIVER, EXCLUDING THE MISSOURI RIVER BASIN. INCLUDES PARTS OF ILLINOIS, INDIANA, IOWA, MICHIGAN, MINNESOTA, MISSOURI, SOUTH DAKOTA, AND WISCONSIN.

SUBREGION 0701 — MISSISSIPPI HEADWATERS: THE MISSISSIPPI RIVER BASIN ABOVE THE CONFLUENCE WITH THE ST. CROIX RIVER BASIN, EXCLUDING THE MINNESOTA RIVER BASIN. MINNESOTA.
AREA = 20200 SQ.MI.

ACCOUNTING UNIT 070101 — MISSISSIPPI HEADWATERS: THE MISSISSIPPI RIVER BASIN ABOVE BLANCHARD DAM. MINNESOTA.
AREA = 11700 SQ.MI.

CATALOGING UNITS 07010101 — MISSISSIPPI HEADWATERS. MINNESOTA.
AREA = 2010 SQ.MI.
AREA = 1390 SQ.MI.
07010103 — PRAIRIE-WILLOW. MINNESOTA.
AREA = 2060 SQ.MI.
07010104 — ELK-NOKASIPPI. MINNESOTA.
AREA = 1680 SQ.MI.
07010105 — PINE. MINNESOTA.
AREA = 774 SQ.MI.
07010106 — CROW WING. MINNESOTA.
AREA = 1970 SQ.MI.
07010107 — REDEYE. MINNESOTA.
AREA = 893 SQ.MI.
07010108 — LONG PRAIRIE. MINNESOTA.
AREA = 904 SQ.MI.

ACCOUNTING UNIT 070102 — UPPER MISSISSIPPI-CROW-RUM: THE MISSISSIPPI RIVER BASIN BELOW BLANCHARD DAM AND ABOVE THE CONFLUENCE WITH THE ST. CROIX RIVER BASIN, EXCLUDING THE MINNESOTA RIVER BASIN. MINNESOTA.
AREA = 8520 SQ.MI.

CATALOGING UNITS 07010201 — PLATTE-SPUNK. MINNESOTA.
AREA = 1020 SQ.MI.
07010202 — SAUK. MINNESOTA.
AREA = 1020 SQ.MI.

CATALOGING UNITS 07140201 — UPPER KASKASKIA. ILLINOIS.
AREA = 1540 SQ.MI.
07140202 — MIDDLE KASKASKIA. ILLINOIS.
AREA = 1680 SQ.MI.
07140203 — SHOAL. ILLINOIS.
AREA = 879 SQ.MI.
07140204 — LOWER KASKASKIA. ILLINOIS.
AREA = 1600 SQ.MI.

REGION 08 LOWER MISSISSIPPI REGION — THE DRAINAGE OF: (A) THE MISSISSIPPI RIVER BELOW ITS CONFLUENCE WITH THE OHIO RIVER, EXCLUDING THE ARKANSAS, RED, AND WHITE RIVER BASINS ABOVE THE POINTS OF HIGHEST BACKWATER EFFECT OF THE MISSISSIPPI RIVER IN THOSE BASINS; AND (B) COASTAL STREAMS THAT ULTIMATELY DISCHARGE INTO THE GULF OF MEXICO FROM THE PEARL RIVER BASIN BOUNDARY TO THE SABINE RIVER AND SABINE LAKE DRAINAGE BOUNDARY. INCLUDES PARTS OF ARKANSAS, KENTUCKY LOUISIANA, MISSISSIPPI, MISSOURI, AND TENNESSEE.

SUBREGION 0801 — LOWER MISSISSIPPI-HATCHIE: THE MISSISSIPPI RIVER BASIN FROM THE CONFLUENCE OF THE OHIO RIVER TO AND INCLUDING THE HORN LAKE CREEK BASIN, BUT EXCLUDING THE DRAINAGE WEST OF THE WEST-BANK LEVEE ALONG THE MISSISSIPPI RIVER. ARKANSAS, KENTUCKY, MISSISSIPPI, MISSOURI, AND TENNESSEE.
AREA = 11000 SQ.MI.

ACCOUNTING UNIT 080101 — LOWER MISSISSIPPI-MEMPHIS: THE MISSISSIPPI ALLUVIAL LANDS LYING IN THE FLOOD PLAIN OF THE PRESENT CHANNEL OF THE MISSISSIPPI RIVER BETWEEN THE WEST-BANK LEVEE AND THE DRAINAGE BOUNDARIES OF THE MAJOR TRIBUTARIES ALONG THE EAST BANK, FROM THE CONFLUENCE OF THE OHIO RIVER TO HORN LAKE CREEK. ARKANSAS, KENTUCKY, MISSISSIPPI, MISSOURI, AND TENNESSEE.
AREA = 1110 SQ.MI.

CATALOGING UNIT 08010100 — LOWER MISSISSIPPI-MEMPHIS. ARKANSAS, KENTUCKY, MISSISSIPPI, MISSOURI, AND TENNESSEE.
AREA = 1110 SQ.MI.

ACCOUNTING UNIT 080102 — HATCHIE-OBION: THE DRAINAGE BASINS EAST OF THE MISSISSIPPI RIVER FROM THE OHIO RIVER BASIN TO AND INCLUDING THE HORN LAKE CREEK BASIN, BUT EXCLUDING THE ALLUVIAL LANDS LYING IN THE FLOOD PLAIN OF THE PRESENT CHANNEL OF THE MISSISSIPPI RIVER EAST OF THE WEST-BANK LEVEE. KENTUCKY, MISSISSIPPI, AND TENNESSEE.
AREA = 9910 SQ.MI.

CATALOGING UNITS 08010201 — BAYOU DE CHIEN-MAYFIELD. KENTUCKY, TENNESSEE.
AREA = 957 SQ.MI.
08010202 — OBION. KENTUCKY, TENNESSEE.
AREA = 1310 SQ.MI.
08010203 — SOUTH FORK OBION. TENNESSEE.
AREA = 1150 SQ.MI.
08010204 — NORTH FORK FORKED DEER. TENNESSEE.
AREA = 952 SQ.MI.
08010205 — SOUTH FORK FORKED DEER. TENNESSEE.
AREA = 1050 SQ.MI.
08010206 — FORKED DEER. TENNESSEE.
AREA = 70 SQ.MI.
08010207 — UPPER HATCHIE. MISSISSIPPI, TENNESSEE.
AREA = 1130 SQ.MI.
08010208 — LOWER HATCHIE. MISSISSIPPI, TENNESSEE.
AREA = 1460 SQ.MI.
08010209 — LOOSAHATCHIE. TENNESSEE.
AREA = 736 SQ.MI.
08010210 — WOLF. MISSISSIPPI, TENNESSEE.
AREA = 813 SQ.MI.
08010211 — HORN LAKE-NONCONNAH. MISSISSIPPI, TENNESSEE.
AREA = 281 SQ.MI.

SUBREGION 0802 — LOWER MISSISSIPPI - ST. FRANCIS: THE MISSISSIPPI RIVER BASIN FROM THE HORN LAKE CREEK BASIN ON THE EAST BANK TO AND INCLUDING THE ARKANSAS AND WHITE RIVER BASINS BELOW THE POINTS OF HIGHEST BACKWATER EFFECT OF THE MISSISSIPPI RIVER; EXCLUDING ALL DRAINAGE EAST OF THE EAST-BANK LEVEE BELOW THE HORN LAKE CREEK BASIN. ARKANSAS, MISSISSIPPI, AND MISSOURI.
AREA = 16700 SQ.MI.

ACCOUNTING UNIT 080201 — LOWER MISSISSIPPI-HELENA: THE MISSISSIPPI ALLUVIAL LANDS LYING IN THE FLOOD PLAIN OF THE PRESENT CHANNEL OF THE MISSISSIPPI RIVER BETWEEN THE EAST-BANK LEVEE AND THE LEVEES OR THE DRAINAGE BOUNDARIES OF THE MAJOR TRIBUTARIES ALONG THE WEST BANK, FROM HORN LAKE CREEK TO THE ARKANSAS RIVER. ARKANSAS, MISSISSIPPI.
AREA = 566 SQ.MI.

CATALOGING UNIT 08020100 — LOWER MISSISSIPPI-HELENA. ARKANSAS, MISSISSIPPI.
AREA = 566 SQ.MI.

ACCOUNTING UNIT 080202 — ST. FRANCIS: THE ST. FRANCIS RIVER BASIN AND ALL MAN-MADE DIVERSIONS INTO THE BASIN. ARKANSAS, MISSOURI.
AREA = 9040 SQ.MI.

CATALOGING UNITS 08020201 — NEW MADRID-ST. JOHNS. MISSOURI.
AREA = 703 SQ.MI.
08020202 — UPPER ST. FRANCIS. MISSOURI.
AREA = 1280 SQ.MI.
08020203 — LOWER ST. FRANCIS. ARKANSAS, MISSOURI.
AREA = 3480 SQ.MI.
08020204 — LITTLE RIVER DITCHES. ARKANSAS.
AREA = 2620 SQ.MI.
08020205 — L'ANGUILLE. ARKANSAS.
AREA = 961 SQ.MI.

ACCOUNTING UNIT 080203 — LOWER WHITE: THE WHITE RIVER BASIN BELOW THE LITTLE RED RIVER BASIN. ARKANSAS, MISSOURI.
AREA = 5410 SQ.MI.

CATALOGING UNITS 08020301 — LOWER WHITE-BAYOU DES ARC. ARKANSAS.
AREA = 1110 SQ.MI.
08020302 — CACHE. ARKANSAS, MISSOURI.
AREA = 2000 SQ.MI.
08020303 — LOWER WHITE. ARKANSAS.
AREA = 1360 SQ.MI.
08020304 — BIG. ARKANSAS.
AREA = 943 SQ.MI.

ACCOUNTING UNIT 080204 — LOWER ARKANSAS: THE ARKANSAS RIVER BASIN BELOW THE PLUM BAYOU BASIN. ARKANSAS.
AREA = 1690 SQ.MI.

CATALOGING UNITS 08020401 — LOWER ARKANSAS. ARKANSAS.
AREA = 700 SQ.MI.
08020402 — BAYOU METO. ARKANSAS.
AREA = 993 SQ.MI.

SUBREGION 0803 — LOWER MISSISSIPPI - YAZOO: THE MISSISSIPPI RIVER BASIN FROM THE ARKANSAS RIVER BASIN TO AND INCLUDING THE YAZOO RIVER BASIN; EXCLUDING ALL DRAINAGE WEST OF THE WEST-BANK LEVEE BELOW THE ARKANSAS RIVER BASIN. ARKANSAS, LOUISIANA, MISSISSIPPI, AND TENNESSEE.
AREA = 14100 SQ.MI.

ACCOUNTING UNIT 080301 — LOWER MISSISSIPPI-GREENVILLE: THE MISSISSIPPI ALLUVIAL LANDS LYING IN THE FLOOD PLAIN OF THE PRESENT CHANNEL OF THE MISSISSIPPI RIVER BETWEEN THE EAST-BANK AND THE WEST-BANK LEVEES, FROM THE ARKANSAS RIVER TO THE YAZOO RIVER. ARKANSAS, MISSISSIPPI.
AREA = 629 SQ.MI.

CATALOGING UNIT 08030100 — LOWER MISSISSIPPI-GREENVILLE. ARKANSAS, LOUISIANA, MISSISSIPPI.
AREA = 629 SQ.MI.

ACCOUNTING UNIT 080302 — YAZOO: THE YAZOO RIVER BASIN. LOUISIANA, MISSISSIPPI, TENNESSEE.
AREA = 13500 SQ.MI.

CATALOGING UNITS 08030201 — LITTLE TALLAHATCHIE. MISSISSIPPI.
AREA = 1640 SQ.MI.
08030202 — TALLAHATCHIE. MISSISSIPPI.
AREA = 1010 SQ.MI.
08030203 — YOCONA. MISSISSIPPI.
AREA = 752 SQ.MI.
08030204 — COLDWATER. MISSISSIPPI, TENNESSEE.
AREA = 1920 SQ.MI.
08030205 — YALOBUSHA. MISSISSIPPI.
AREA = 2310 SQ.MI.
08030206 — UPPER YAZOO. MISSISSIPPI.
AREA = 1560 SQ.MI.
08030207 — BIG SUNFLOWER. MISSISSIPPI.
AREA = 3120 SQ.MI.
08030208 — LOWER YAZOO. LOUISIANA, MISSISSIPPI.
AREA = 222 SQ.MI.
08030209 — DEER-STEELE. LOUISIANA, MISSISSIPPI.
AREA = 938 SQ.MI.

SUBREGION 0804 — LOWER RED - OUACHITA: THE RED RIVER BASIN BELOW THE BAYOU RIGOLETTE BASIN, EXCLUDING THE BOEUF AND TENSAS RIVER BASINS. ARKANSAS, LOUISIANA.
AREA = 20500 SQ.MI.

ACCOUNTING UNIT 080401 — UPPER OUACHITA: THE OUACHITA RIVER BASIN ABOVE THE TWO BAYOU BASIN. ARKANSAS.
AREA = 5380 SQ.MI.

CATALOGING UNITS 08040101 — OUACHITA HEADWATERS. ARKANSAS.
AREA = 1550 SQ.MI.
08040102 — UPPER OUACHITA. ARKANSAS.
AREA = 1750 SQ.MI.

REGION 08: LOWER MISSISSIPPI — Continued

08040103 — LITTLE MISSOURI. ARKANSAS.
AREA = 2080 SQ.MI.

ACCOUNTING UNIT 080402 — LOWER OUACHITA: THE OUACHITA RIVER BASIN BELOW AND INCLUDING THE TWO BAYOU BASIN. ARKANSAS, LOUISIANA.
AREA = 10700 SQ.MI.

CATALOGING UNITS 08040201 — LOWER OUACHITA-SMACKOVER. ARKANSAS.
AREA = 1810 SQ.MI.
08040202 — LOWER OUACHITA-BAYOU DE LOUTRE. ARKANSAS, LOUISIANA.
AREA = 1300 SQ.MI.
08040203 — UPPER SALINE. ARKANSAS.
AREA = 1710 SQ.MI.
08040204 — LOWER SALINE. ARKANSAS.
AREA = 1510 SQ.MI.
08040205 — BAYOU BARTHOLOMEW. ARKANSAS, LOUISIANA.
AREA = 1680 SQ.MI.
08040206 — BAYOU D'ARBONNE. ARKANSAS, LOUISIANA.
AREA = 1930 SQ.MI.
08040207 — LOWER OUACHITA. LOUISIANA.
AREA = 759 SQ.MI.

ACCOUNTING UNIT 080403 — LOWER RED: THE RED RIVER BASIN BELOW THE BAYOU RIGOLETTE BASIN, EXCLUDING THE BOEUF, OUACHITA, AND TENSAS RIVER BASINS. LOUISIANA.
AREA = 4400 SQ.MI.

CATALOGING UNITS 08040301 — LOWER RED. LOUISIANA.
AREA = 898 SQ.MI.
08040302 — CASTOR. LOUISIANA.
AREA = 966 SQ.MI.
08040303 — DUGDEMONA. LOUISIANA.
AREA = 927 SQ.MI.
08040304 — LITTLE. LOUISIANA.
AREA = 987 SQ.MI.
08040305 — BLACK. LOUISIANA.
AREA = 84 SQ.MI.
08040306 — BAYOU COCODRIE. LOUISIANA.
AREA = 542 SQ.MI.

SUBREGION 0805 — BOEUF-TENSAS: THE BOEUF AND TENSAS RIVER BASINS. ARKANSAS, LOUISIANA.
AREA = 5300 SQ.MI.

ACCOUNTING UNIT 080500 — BOEUF-TENSAS. ARKANSAS, LOUISIANA.
AREA = 5300 SQ.MI.

CATALOGING UNITS 08050001 — BOEUF. ARKANSAS, LOUISIANA.
AREA = 2890 SQ.MI.
08050002 — BAYOU MACON. ARKANSAS, LOUISIANA.
AREA = 1060 SQ.MI.
08050003 — TENSAS. LOUISIANA.
AREA = 1350 SQ.MI.

SUBREGION 0806 — LOWER MISSISSIPPI - BIG BLACK: THE MISSISSIPPI RIVER BASIN FROM THE YAZOO RIVER BASIN TO THE LOWER OLD RIVER DRAINAGE BOUNDARY, BUT EXCLUDING ALL THE DRAINAGE WEST OF THE WEST-BANK LEVEE ALONG THE MISSISSIPPI RIVER. LOUISIANA, MISSISSIPPI.
AREA = 7100 SQ.MI.

ACCOUNTING UNIT 080601 — LOWER MISSISSIPPI-NATCHEZ: THE MISSISSIPPI ALLUVIAL LANDS LYING IN THE FLOOD PLAIN OF THE PRESENT CHANNEL OF THE MISSISSIPPI RIVER BETWEEN THE WEST-BANK LEVEE AND THE DRAINAGE BOUNDARIES OF THE MAJOR TRIBUTARIES ALONG THE EAST BANK, FROM THE THE YAZOO RIVER TO THE LOWER OLD RIVER. LOUISIANA, MISSISSIPPI.
AREA = 548 SQ.MI.

CATALOGING UNIT 08060100 — LOWER MISSISSIPPI-NATCHEZ. LOUISIANA, MISSISSIPPI.
AREA = 548 SQ.MI.

ACCOUNTING UNIT 080602 — BIG BLACK - HOMOCHITTO: THE DRAINAGE BASINS EAST OF THE MISSISSIPPI RIVER FROM THE YAZOO RIVER BASIN TO AND INCLUDING THE BUFFALO RIVER BASIN, BUT EXCLUDING THE ALLUVIAL LANDS LYING IN THE FLOOD PLAIN OF THE PRESENT CHANNEL OF THE MISSISSIPPI RIVER EAST OF WEST-BANK LEVEE. LOUISIANA, MISSISSIPPI.
AREA = 6550 SQ.MI.

CATALOGING UNITS 08060201 — UPPER BIG BLACK. MISSISSIPPI.
AREA = 1470 SQ.MI.
08060202 — LOWER BIG BLACK. LOUISIANA, MISSISSIPPI.
AREA = 1900 SQ.MI.
08060203 — BAYOU PIERRE. LOUISIANA, MISSISSIPPI.
AREA = 1070 SQ.MI.

08060204 — COLES CREEK. LOUISIANA, MISSISSIPPI.
AREA = 551 SQ.MI.
08060205 — HOMOCHITTO. MISSISSIPPI.
AREA = 1220 SQ.MI.
08060206 — BUFFALO. MISSISSIPPI.
AREA = 343 SQ.MI.

SUBREGION 0807 — LOWER MISSISSIPPI-LAKE MAUREPAS: THE MISSISSIPPI RIVER BASIN FROM THE LOWER OLD RIVER DRAINAGE BOUNDARY TO THE BONNET CARRE FLOODWAY, AND INCLUDING THE LOWER GRAND RIVER BASIN WEST OF THE WEST-BANK LEVEE. LOUISIANA, MISSISSIPPI.
AREA = 5870 SQ.MI.

ACCOUNTING UNIT 080701 — LOWER MISSISSIPPI-BATON ROUGE: THE MISSISSIPPI ALLUVIAL LANDS LYING IN THE FLOOD PLAIN OF THE PRESENT CHANNEL OF THE MISSISSIPPI RIVER BETWEEN THE WEST-BANK LEVEE AND THE EAST-BANK LEVEE OR THE DRAINAGE BOUNDARIES OF THE MAJOR TRIBUTARIES ALONG THE EAST BANK, FROM THE LOWER OLD RIVER TO THE BONNET CARRE FLOODWAY. LOUISIANA.
AREA = 270 SQ.MI.

CATALOGING UNIT 08070100 — LOWER MISSISSIPPI-BATON ROUGE. LOUISIANA.
AREA = 270 SQ.MI.

ACCOUNTING UNIT 080702 — LAKE MAUREPAS: THE DRAINAGE BASINS EAST OF THE MISSISSIPPI RIVER FROM THE BUFFALO RIVER BASIN TO THE BONNET CARRE FLOODWAY, BUT EXCLUDING THE MISSISSIPPI ALLUVIAL LANDS EAST OF THE WEST-BANK LEVEE; AND INCLUDING DRAINAGE FROM THE NORTH INTO LAKE PONTCHARTRAIN, EAST TO AND INCLUDING THE TANGIPAHOA RIVER BASIN. LOUISIANA, MISSISSIPPI.
AREA = 4810 SQ.MI.

CATALOGING UNITS 08070201 — BAYOU SARA-THOMPSON. LOUISIANA, MISSISSIPPI.
AREA = 698 SQ.MI.
08070202 — AMITE. LOUISIANA, MISSISSIPPI.
AREA = 1890 SQ.MI.
08070203 — TICKFAW. LOUISIANA, MISSISSIPPI.
AREA = 729 SQ.MI.
08070204 — LAKE MAUREPAS. LOUISIANA.
AREA = 719 SQ.MI.
08070205 — TANGIPAHOA. LOUISIANA, MISSISSIPPI.
AREA = 771 SQ.MI.

ACCOUNTING UNIT 080703 — LOWER GRAND: THE LOWER GRAND RIVER BASIN. LOUISIANA.
AREA = 792 SQ.MI.

CATALOGING UNIT 08070300 — LOWER GRAND. LOUISIANA.
AREA = 792 SQ.MI.

SUBREGION 0808 — LOUISIANA COASTAL: THE LOUISIANA COASTAL DRAINAGE, INCLUDING ISLANDS AND ASSOCIATED WATERS, SOUTH OF THE RED RIVER BASIN BOUNDARY AND WEST OF THE EAST-BANK LEVEE OF THE ATCHAFALAYA BASIN FLOODWAY, TO THE SABINE RIVER AND SABINE LAKE DRAINAGE BOUNDARY. LOUISIANA.
AREA = 14000 SQ.MI.

ACCOUNTING UNIT 080801 — ATCHAFALAYA - VERMILION: THE LOUISIANA COASTAL DRAINAGE, INCLUDING ISLANDS AND ASSOCIATED WATERS, SOUTH OF THE RED RIVER BASIN BOUNDARY AND WEST OF THE EAST-BANK LEVEE OF THE ATCHAFALAYA BASIN FLOODWAY, TO AND INCLUDING THE DRAINAGE INTO VERMILION BAY. LOUISIANA.
AREA = 5900 SQ.MI.

CATALOGING UNITS 08080101 — ATCHAFALAYA. LOUISIANA.
AREA = 1930 SQ.MI.
08080102 — BAYOU TECHE. LOUISIANA.
AREA = 2210 SQ.MI.
08080103 — VERMILION. LOUISIANA.
AREA = 1760 SQ.MI.

ACCOUNTING UNIT 080802 — CALCASIEU - MERMENTAU: THE LOUISIANA COASTAL DRAINAGE AND ASSOCIATED WATERS, FROM THE VERMILION BAY DRAINAGE BOUNDARY TO THE SABINE RIVER AND SABINE LAKE DRAINAGE BOUNDARY. LOUISIANA.
AREA = 8120 SQ.MI.

CATALOGING UNITS 08080201 — MERMENTAU HEADWATERS. LOUISIANA.
AREA = 1400 SQ.MI.
08080202 — MERMENTAU. LOUISIANA.
AREA = 2390 SQ.MI.
08080203 — UPPER CALCASIEU. LOUISIANA.
AREA = 1550 SQ.MI.
08080204 — WHISKY CHITTO. LOUISIANA.
AREA = 884 SQ.MI.

REGION 08: LOWER MISSISSIPPI — Continued

08080205 — WEST FORK CALCASIEU. LOUISIANA.
AREA = 818 SQ.MI.
08080206 — LOWER CALCASIEU. LOUISIANA.
AREA = 1080 SQ.MI.

SUBREGION 0809 — LOWER MISSISSIPPI: THE MISSISSIPPI RIVER BELOW THE BONNET CARRE FLOODWAY, AND THE COASTAL DRAINAGE, INCLUDING ISLANDS AND ASSOCIATED WATERS, FROM THE PEARL RIVER BASIN BOUNDARY AND THE MISSISSIPPI-LOUISIANA STATE LINE TO THE EAST-BANK LEVEE OF THE ATCHAFALAYA BASIN FLOODWAY, EXCLUDING THE DRAINAGE FROM THE NORTH INTO LAKE PONTCHARTRAIN, EAST TO THE TCHEFUNCTA RIVER DRAINAGE BOUNDARY; AND EXCLUDING THE LOWER GRAND RIVER BASIN. LOUISIANA.
AREA = 9460 SQ.MI.

ACCOUNTING UNIT 080901 — LOWER MISSISSIPPI-NEW ORLEANS: THE MISSISSIPPI RIVER BELOW THE BONNET CARRE FLOODWAY, INCLUDING THE MISSISSIPPI DELTA. LOUISIANA.
AREA = 587 SQ.MI.

CATALOGING UNIT 08090100 — LOWER MISSISSIPPI-NEW ORLEANS. LOUISIANA.
AREA = 587 SQ.MI.

ACCOUNTING UNIT 080902 — LAKE PONTCHARTRAIN: LAKE PONTCHARTRAIN AND THE COASTAL DRAINAGE, INCLUDING ISLANDS AND ASSOCIATED WATERS, FROM THE PEARL RIVER BASIN BOUNDARY AND THE MISSISSIPPI-LOUISIANA STATE LINE TO THE EAST-BANK LEVEE OF THE MISSISSIPPI RIVER, EXCLUDING THE DRAINAGE FROM THE NORTH INTO LAKE PONTCHARTRAIN, EAST TO THE TCHEFUNCTA RIVER DRAINAGE BOUNDARY. LOUISIANA.
AREA = 3520 SQ.MI.

CATALOGING UNITS 08090201 — LIBERTY BAYOU-TCHEFUNCTA. LOUISIANA.
AREA = 708 SQ.MI.
08090202 — LAKE PONTCHARTRAIN. LOUISIANA.
AREA = 648 SQ.MI.
08090203 — EASTERN LOUISIANA COASTAL. LOUISIANA.
AREA = 2160 SQ.MI.

ACCOUNTING UNIT 080903 — CENTRAL LOUISIANA COASTAL: THE COASTAL DRAINAGE, INCLUDING ISLANDS AND ASSOCIATED WATERS, FROM THE WEST-BANK LEVEE OF THE MISSISSIPPI RIVER TO THE EAST-BANK LEVEE OF THE ATCHAFALAYA BASIN FLOODWAY; EXCLUDING THE LOWER GRAND RIVER BASIN. LOUISIANA.
AREA = 5350 SQ.MI.

CATALOGING UNITS 08090301 — EAST CENTRAL LOUISIANA COASTAL. LOUISIANA.
AREA = 2460 SQ.MI.
08090302 — WEST CENTRAL LOUISIANA COASTAL. LOUISIANA.
AREA = 2890 SQ.MI.

REGION 09 SOURIS-RED-RAINY REGION -- THE DRAINAGE WITHIN THE UNITED STATES OF THE LAKE OF THE WOODS AND THE RAINY, RED, AND SOURIS RIVER BASINS THAT ULTIMATELY DISCHARGES INTO LAKE WINNIPEG AND HUDSON BAY. INCLUDES PARTS OF MINNESOTA, NORTH DAKOTA, AND SOUTH DAKOTA.

SUBREGION 0901 — SOURIS: THE SOURIS RIVER BASIN WITHIN THE UNITED STATES. NORTH DAKOTA.
AREA = 9150 SQ.MI.

ACCOUNTING UNIT 090100 — SOURIS. NORTH DAKOTA.
AREA = 9150 SQ.MI.

CATALOGING UNITS
09010001 — UPPER SOURIS. NORTH DAKOTA. AREA = 2340 SQ.MI.
09010002 — DES LACS. NORTH DAKOTA. AREA = 1030 SQ.MI.
09010003 — LOWER SOURIS. NORTH DAKOTA. AREA = 2260 SQ.MI.
09010004 — WILLOW. NORTH DAKOTA. AREA = 1850 SQ.MI.
09010005 — DEEP. NORTH DAKOTA. AREA = 1670 SQ.MI.

SUBREGION 0902 — RED: THE RED RIVER BASIN WITHIN THE UNITED STATES INCLUDING THE DEVILS LAKE CLOSED BASIN. MINNESOTA, NORTH DAKOTA, SOUTH DAKOTA.
AREA = 39800 SQ.MI.

ACCOUNTING UNIT 090201 — UPPER RED: THE RED RIVER BASIN ABOVE THE CONFLUENCE OF AND INCLUDING THE GOOSE AND MARSH RIVER BASINS, EXCLUDING THE SHEYENNE RIVER BASIN AND THE DEVILS LAKE CLOSED BASIN. MINNESOTA, NORTH DAKOTA, SOUTH DAKOTA.
AREA = 12200 SQ.MI.

CATALOGING UNITS
09020101 — BOIS DE SIOUX. MINNESOTA, NORTH DAKOTA, SOUTH DAKOTA. AREA = 1140 SQ.MI.
09020102 — MUSTINKA. MINNESOTA. AREA = 825 SQ.MI.
09020103 — OTTER TAIL. MINNESOTA. AREA = 1980 SQ.MI.
09020104 — UPPER RED. MINNESOTA, NORTH DAKOTA. AREA = 594 SQ.MI.
09020105 — WESTERN WILD RICE. NORTH DAKOTA, SOUTH DAKOTA. AREA = 2380 SQ.MI.
09020106 — BUFFALO. MINNESOTA. AREA = 1150 SQ.MI.
09020107 — ELM-MARSH. MINNESOTA, NORTH DAKOTA. AREA = 1150 SQ.MI.
09020108 — EASTERN WILD RICE. MINNESOTA. AREA = 1670 SQ.MI.
09020109 — GOOSE. NORTH DAKOTA. AREA = 1280 SQ.MI.

ACCOUNTING UNIT 090202 — DEVILS LAKE-SHEYENNE: THE SHEYENNE RIVER BASIN AND THE DEVILS LAKE CLOSED BASIN DRAINAGE. NORTH DAKOTA.
AREA = 11000 SQ.MI.

CATALOGING UNITS
09020201 — DEVILS LAKE. NORTH DAKOTA. AREA = 3700 SQ.MI.
09020202 — UPPER SHEYENNE. NORTH DAKOTA. AREA = 1940 SQ.MI.
09020203 — MIDDLE SHEYENNE. NORTH DAKOTA. AREA = 2070 SQ.MI.
09020204 — LOWER SHEYENNE. NORTH DAKOTA. AREA = 1640 SQ.MI.
09020205 — MAPLE. NORTH DAKOTA. AREA = 1620 SQ.MI.

ACCOUNTING UNIT 090203 — LOWER RED: THE RED RIVER BASIN WITHIN THE UNITED STATES BELOW THE CONFLUENCE OF THE GOOSE AND MARSH RIVER BASINS. MINNESOTA, NORTH DAKOTA.
AREA = 16600 SQ.MI.

CATALOGING UNITS
09020301 — SANDHILL-WILSON. MINNESOTA, NORTH DAKOTA. AREA = 1130 SQ.MI.
09020302 — RED LAKES. MINNESOTA. AREA = 2040 SQ.MI.
09020303 — RED LAKE. MINNESOTA. AREA = 1450 SQ.MI.

09030008 — LOWER RAINY. MINNESOTA. AREA = 292 SQ.MI.
09030009 — LAKE OF THE WOODS. MINNESOTA. AREA = 1220 SQ.MI.

REGION 10 MISSOURI REGION — THE DRAINAGE WITHIN THE UNITED STATES OF: (A) THE MISSOURI RIVER BASIN, (B) THE SASKATCHEWAN RIVER BASIN, AND (C) SEVERAL SMALL CLOSED BASINS. INCLUDES ALL OF NEBRASKA AND PARTS OF COLORADO, IOWA, KANSAS, MINNESOTA, MISSOURI, MONTANA, NORTH DAKOTA, SOUTH DAKOTA, AND WYOMING.

SUBREGION 1001 — SASKATCHEWAN: THE SASKATCHEWAN RIVER BASIN WITHIN THE UNITED STATES. MONTANA.
AREA = 697 SQ.MI.

ACCOUNTING UNIT 100100 — SASKATCHEWAN. MONTANA.
AREA = 697 SQ.MI.

CATALOGING UNITS 10010001 — BELLY. MONTANA.
AREA = 192 SQ.MI.
10010002 — ST. MARY. MONTANA.
AREA = 505 SQ.MI.

SUBREGION 1002 — MISSOURI HEADWATERS: THE HEADWATERS OF THE MISSOURI RIVER BASIN ABOVE THE CONFLUENCE OF AND INCLUDING THE GALLATIN, JEFFERSON, AND MADISON RIVER BASINS. MONTANA, WYOMING.
AREA = 14100 SQ.MI.

ACCOUNTING UNIT 100200 — MISSOURI HEADWATERS. MONTANA, WYOMING.
AREA = 14100 SQ.MI.

CATALOGING UNITS 10020001 — RED ROCK. MONTANA.
AREA = 2330 SQ.MI.
10020002 — BEAVERHEAD. MONTANA.
AREA = 1460 SQ.MI.
10020003 — RUBY. MONTANA.
AREA = 988 SQ.MI.
10020004 — BIG HOLE. MONTANA.
AREA = 2790 SQ.MI.
10020005 — JEFFERSON. MONTANA.
AREA = 1340 SQ.MI.
10020006 — BOULDER. MONTANA.
AREA = 754 SQ.MI.
10020007 — MADISON. MONTANA, WYOMING.
AREA = 2570 SQ.MI.
10020008 — GALLATIN. MONTANA, WYOMING.
AREA = 1820 SQ.MI.

SUBREGION 1003 — MISSOURI-MARIAS: THE MISSOURI RIVER BASIN BELOW THE CONFLUENCE OF THE GALLATIN, JEFFERSON, AND MADISON RIVER BASINS TO AND INCLUDING THE MARIAS RIVER BASIN. MONTANA.
AREA = 20100 SQ.MI.

ACCOUNTING UNIT 100301 — UPPER MISSOURI: THE MISSOURI RIVER BASIN BELOW THE CONFLUENCE OF THE GALLATIN, JEFFERSON, AND MADISON RIVER BASINS TO, BUT EXCLUDING THE MARIAS RIVER BASIN. MONTANA.
AREA = 10900 SQ.MI.

CATALOGING UNITS 10030101 — UPPER MISSOURI. MONTANA.
AREA = 3370 SQ.MI.
10030102 — UPPER MISSOURI-DEARBORN. MONTANA.
AREA = 2680 SQ.MI.

10190006 — BIG THOMPSON. COLORADO.
AREA = 819 SQ.MI.
10190007 — CACHE LA POUDRE. COLORADO, WYOMING.
AREA = 1910 SQ.MI.
10190008 — LONE TREE-OWL. COLORADO, WYOMING.
AREA = 573 SQ.MI.
10190009 — CROW. COLORADO, WYOMING.
AREA = 1410 SQ.MI.
10190010 — KIOWA. COLORADO.
AREA = 720 SQ.MI.
10190011 — BIJOU. COLORADO.
AREA = 1360 SQ.MI.
10190012 — MIDDLE SOUTH PLATTE-STERLING. COLORADO, NEBRASKA.
AREA = 2900 SQ.MI.

REGION 10: MISSOURI — Continued

10190013 — BEAVER. COLORADO.
AREA = 1080 SQ.MI.
10190014 — PAWNEE. COLORADO.
AREA = 728 SQ.MI.
10190015 — UPPER LODGEPOLE. COLORADO, NEBRASKA, WYOMING.
AREA = 1130 SQ.MI.
10190016 — LOWER LODGEPOLE. COLORADO, NEBRASKA, WYOMING.
AREA = 1350 SQ.MI.
10190017 — SIDNEY DRAW. COLORADO, NEBRASKA, WYOMING.
AREA = 744 SQ.MI.
10190018 — LOWER SOUTH PLATTE. COLORADO, NEBRASKA.
AREA = 1380 SQ.MI.

SUBREGION 1020 — PLATTE: THE PLATTE RIVER BASIN BELOW THE CONFLUENCE OF THE NORTH AND SOUTH PLATTE RIVER BASINS, EXCLUDING THE ELKHORN AND LOUP RIVER BASINS. NEBRASKA.
AREA = 8160 SQ.MI.

ACCOUNTING UNIT 102001 — MIDDLE PLATTE: THE PLATTE RIVER BASIN BELOW THE CONFLUENCE OF THE NORTH AND SOUTH PLATTE RIVER BASINS TO THE CONFLUENCE WITH THE LOUP RIVER BASIN. NEBRASKA.
AREA = 5130 SQ.MI.

CATALOGING UNITS 10200101 — MIDDLE PLATTE-BUFFALO. NEBRASKA.
AREA = 3270 SQ.MI.
10200102 — WOOD. NEBRASKA.
AREA = 736 SQ.MI.
10200103 — MIDDLE PLATTE-PRAIRIE. NEBRASKA.
AREA = 1120 SQ.MI.

ACCOUNTING UNIT 102002 — LOWER PLATTE: THE PLATTE RIVER BASIN BELOW THE CONFLUENCE WITH THE LOUP RIVER BASIN, EXCLUDING THE ELKHORN RIVER BASIN. NEBRASKA.
AREA = 3030 SQ.MI.

CATALOGING UNITS 10200201 — LOWER PLATTE-SHELL. NEBRASKA.
AREA = 879 SQ.MI.
10200202 — LOWER PLATTE. NEBRASKA.
AREA = 531 SQ.MI.
10200203 — SALT. NEBRASKA.
AREA = 1620 SQ.MI.

SUBREGION 1021 — LOUP: THE LOUP RIVER BASIN. NEBRASKA.
AREA = 15000 SQ.MI.

ACCOUNTING UNIT 102100 — LOUP. NEBRASKA.
AREA = 15000 SQ.MI.

CATALOGING UNITS 10210001 — UPPER MIDDLE LOUP. NEBRASKA.
AREA = 1800 SQ.MI.
10210002 — DISMAL. NEBRASKA.
AREA = 2050 SQ.MI.
10210003 — LOWER MIDDLE LOUP. NEBRASKA.
AREA = 1490 SQ.MI.
10210004 — SOUTH LOUP. NEBRASKA.
AREA = 1700 SQ.MI.
10210005 — MUD. NEBRASKA.
AREA = 1000 SQ.MI.
10210006 — UPPER NORTH LOUP. NEBRASKA.
AREA = 2250 SQ.MI.
10210007 — LOWER NORTH LOUP. NEBRASKA.
AREA = 955 SQ.MI.
10210008 — CALAMUS. NEBRASKA.
AREA = 1080 SQ.MI.
10210009 — LOUP. NEBRASKA.
AREA = 1430 SQ.MI.
10210010 — CEDAR. NEBRASKA.
AREA = 1240 SQ.MI.

SUBREGION 1022 — ELKHORN: THE ELKHORN RIVER BASIN. NEBRASKA.
AREA = 6950 SQ.MI.

ACCOUNTING UNIT 102200 — ELKHORN. NEBRASKA.
AREA = 6950 SQ.MI.

CATALOGING UNITS 10220001 — UPPER ELKHORN. NEBRASKA.
AREA = 2880 SQ.MI.
10220002 — NORTH FORK ELKHORN. NEBRASKA.
AREA = 843 SQ.MI.

11050002 — LOWER CIMARRON-SKELETON. OKLAHOMA.
AREA = 3180 SQ.MI.
11050003 — LOWER CIMARRON. OKLAHOMA.
AREA = 1380 SQ.MI.

SUBREGION 1106 — ARKANSAS - KEYSTONE: THE ARKANSAS RIVER BASIN BELOW THE WALNUT RIVER BASIN TO KEYSTONE DAM, EXCLUDING THE CIMARRON RIVER BASIN. KANSAS, OKLAHOMA.
AREA = 9750 SQ.MI.

ACCOUNTING UNIT 110600 — ARKANSAS - KEYSTONE. KANSAS, OKLAHOMA.
AREA = 9750 SQ.MI.

CATALOGING UNITS 11060001 — KAW LAKE. KANSAS, OKLAHOMA.
AREA = 926 SQ.MI.
11060002 — UPPER SALT FORK ARKANSAS. KANSAS, OKLAHOMA.
AREA = 1080 SQ.MI.
11060003 — MEDICINE LODGE. KANSAS, OKLAHOMA.
AREA = 1280 SQ.MI.
11060004 — LOWER SALT FORK ARKANSAS. KANSAS, OKLAHOMA.
AREA = 2340 SQ.MI.
11060005 — CHIKASKIA. KANSAS, OKLAHOMA.
AREA = 2000 SQ.MI.
11060006 — BLACK BEAR-RED ROCK. OKLAHOMA.
AREA = 2120 SQ.MI.

SUBREGION 1107 — NEOSHO - VERDIGRIS. THE NEOSHO AND VERDIGRIS RIVER BASINS. ARKANSAS, KANSAS, MISSOURI, OKLAHOMA.
AREA = 20500 SQ.MI.

ACCOUNTING UNIT 110701 — VERDIGRIS: THE VERDIGRIS RIVER BASIN. KANSAS, OKLAHOMA.
AREA = 8100 SQ.MI.

CATALOGING UNITS 11070101 — UPPER VERDIGRIS. KANSAS.
AREA = 1160 SQ.MI.
11070102 — FALL. KANSAS.
AREA = 868 SQ.MI.
11070103 — MIDDLE VERDIGRIS. KANSAS, OKLAHOMA.
AREA = 1500 SQ.MI.
11070104 — ELK. KANSAS.
AREA = 673 SQ.MI.
11070105 — LOWER VERDIGRIS. OKLAHOMA.
AREA = 692 SQ.MI.
11070106 — CANEY. KANSAS, OKLAHOMA.
AREA = 2080 SQ.MI.
11070107 — BIRD. OKLAHOMA.
AREA = 1130 SQ.MI.

ACCOUNTING UNIT 110702 — NEOSHO: THE NEOSHO RIVER BASIN. ARKANSAS, KANSAS, MISSOURI, OKLAHOMA.
AREA = 12400 SQ.MI.

CATALOGING UNITS 11070201 — NEOSHO HEADWATERS. KANSAS.
AREA = 1110 SQ.MI.
11070202 — UPPER COTTONWOOD. KANSAS.
AREA = 927 SQ.MI.
11070203 — LOWER COTTONWOOD. KANSAS.
AREA = 968 SQ.MI.
11070204 — UPPER NEOSHO. KANSAS.
AREA = 1360 SQ.MI.
11070205 — MIDDLE NEOSHO. KANSAS, OKLAHOMA.
AREA = 1420 SQ.MI.
11070206 — LAKE O' THE CHEROKEES. ARKANSAS, KANSAS, MISSOURI, OKLAHOMA.
AREA = 911 SQ.MI.
11070207 — SPRING. KANSAS, MISSOURI, OKLAHOMA.
AREA = 2500 SQ.MI.
11070208 — ELK. ARKANSAS, MISSOURI, OKLAHOMA.
AREA = 1010 SQ.MI.
11070209 — LOWER NEOSHO. ARKANSAS, OKLAHOMA.
AREA = 2170 SQ.MI.

SUBREGION 1108 — UPPER CANADIAN: THE CANADIAN RIVER BASIN ABOVE ITS INTERSECT WITH THE NEW MEXICO-TEXAS STATE LINE. COLORADO, NEW MEXICO.
AREA = 12500 SQ.MI.

ACCOUNTING UNIT 110800 — UPPER CANADIAN. COLORADO, NEW MEXICO.
AREA = 12500 SQ.MI.

CATALOGING UNITS 11080001 — CANADIAN HEADWATERS. COLORADO, NEW MEXICO.
AREA = 1730 SQ.MI.
11080002 — CIMARRON. NEW MEXICO.
AREA = 1040 SQ.MI.
11080003 — UPPER CANADIAN. NEW MEXICO.
AREA = 2020 SQ.MI.
11080004 — MORA. NEW MEXICO.
AREA = 1470 SQ.MI.
11080005 — CONCHAS. NEW MEXICO.
AREA = 1030 SQ.MI.
11080006 — UPPER CANADIAN-UTE RESERVOIR. NEW MEXICO, TEXAS.
AREA = 2390 SQ.MI.
11080007 — UTE. NEW MEXICO.
AREA = 2070 SQ.MI.
11080008 — REVUELTO. NEW MEXICO.
AREA = 780 SQ.MI.

SUBREGION 1109 — LOWER CANADIAN: THE CANADIAN RIVER BASIN BELOW ITS INTERSECT WITH THE NEW MEXICO-TEXAS STATE LINE TO THE CONFLUENCE WITH THE ARKANSAS RIVER, INCLUDING THAT PORTION INUNDATED BY EUFAULA LAKE AND ROBERT S. KERR RESERVOIR, BUT EXCLUDING THE NORTH CANADIAN RIVER BASIN. NEW MEXICO, OKLAHOMA, TEXAS.
AREA = 16800 SQ.MI.

ACCOUNTING UNIT 110901 — MIDDLE CANADIAN: THE CANADIAN RIVER BASIN BELOW ITS INTERSECT WITH THE NEW MEXICO-TEXAS STATE LINE TO ITS INTERSECT WITH THE OKLAHOMA-TEXAS STATE LINE. NEW MEXICO, OKLAHOMA, TEXAS.
AREA = 10100 SQ.MI.

CATALOGING UNITS 11090101 — MIDDLE CANADIAN-TRUJILLO. NEW MEXICO, TEXAS.
AREA = 1700 SQ.MI.
11090102 — PUNTA DE AGUA. NEW MEXICO, TEXAS.
AREA = 1560 SQ.MI.
11090103 — RITA BLANCA. NEW MEXICO, OKLAHOMA, TEXAS.
AREA = 1130 SQ.MI.
11090104 — CARRIZO. NEW MEXICO, TEXAS.
AREA = 864 SQ.MI.
11090105 — LAKE MEREDITH. TEXAS.
AREA = 2060 SQ.MI.
11090106 — MIDDLE CANADIAN-SPRING. TEXAS.
AREA = 2780 SQ.MI.

ACCOUNTING UNIT 110902 — LOWER CANADIAN: THE CANADIAN RIVER BASIN BELOW ITS INTERSECT WITH THE OKLAHOMA-TEXAS STATE LINE TO THE CONFLUENCE WITH THE ARKANSAS RIVER, INCLUDING THAT PORTION INUNDATED BY EUFAULA LAKE AND ROBERT S. KERR RESERVOIR, BUT EXCLUDING THE NORTH CANADIAN RIVER BASIN. OKLAHOMA, TEXAS.
AREA = 6750 SQ.MI.

CATALOGING UNITS 11090201 — LOWER CANADIAN-DEER. OKLAHOMA, TEXAS.
AREA = 2010 SQ.MI.
11090202 — LOWER CANADIAN-WALNUT. OKLAHOMA.
AREA = 1800 SQ.MI.
11090203 — LITTLE. OKLAHOMA.
AREA = 976 SQ.MI.
11090204 — LOWER CANADIAN. OKLAHOMA.
AREA = 1960 SQ.MI.

SUBREGION 1110 — NORTH CANADIAN: THE NORTH CANADIAN RIVER BASIN, INCLUDING THAT PORTION INUNDATED BY EUFAULA LAKE. KANSAS, NEW MEXICO, OKLAHOMA, TEXAS.
AREA = 17500 SQ.MI.

ACCOUNTING UNIT 111001 — UPPER BEAVER. THE BEAVER RIVER BASIN TO AND INCLUDING THE HOME CREEK BASIN. KANSAS, NEW MEXICO, OKLAHOMA, TEXAS.
AREA = 7800 SQ.MI.

CATALOGING UNITS 11100101 — UPPER BEAVER. NEW MEXICO, OKLAHOMA, TEXAS.
AREA = 2710 SQ.MI.
11100102 — MIDDLE BEAVER. KANSAS, OKLAHOMA.
AREA = 1280 SQ.MI.
11100103 — COLDWATER. OKLAHOMA, TEXAS.
AREA = 1780 SQ.MI.
11100104 — PALO DURO. OKLAHOMA, TEXAS.
AREA = 2300 SQ.MI.

ACCOUNTING UNIT 111002 — LOWER BEAVER: THE BEAVER RIVER BASIN BELOW THE HOME CREEK BASIN TO AND INCLUDING THE WOLF CREEK BASIN. OKLAHOMA, TEXAS.
AREA = 3590 SQ.MI.

CATALOGING UNITS 11100201 — LOWER BEAVER. OKLAHOMA, TEXAS.
AREA = 1740 SQ.MI.
11100202 — UPPER WOLF. TEXAS.
AREA = 779 SQ.MI.
11100203 — LOWER WOLF. OKLAHOMA, TEXAS.
AREA = 1070 SQ.MI.

ACCOUNTING UNIT 111003 — LOWER NORTH CANADIAN: THE NORTH CANADIAN RIVER BASIN, INCLUDING THAT PORTION INUNDATED BY EUFAULA LAKE, BUT EXCLUDING THE BEAVER RIVER BASIN ABOVE ITS CONFLUENCE WITH THE WOLF CREEK BASIN. OKLAHOMA.
AREA = 6160 SQ.MI.

CATALOGING UNITS 11100301 — MIDDLE NORTH CANADIAN. OKLAHOMA.
AREA = 1770 SQ.MI.
11100302 — LOWER NORTH CANADIAN. OKLAHOMA.
AREA = 1830 SQ.MI.
11100303 — DEEP FORK. OKLAHOMA.
AREA = 2560 SQ.MI.

SUBREGION 1111 — LOWER ARKANSAS: THE ARKANSAS RIVER BASIN BELOW KEYSTONE DAM TO THE POINT OF HIGHEST BACKWATER EFFECT OF THE MISSISSIPPI RIVER BELOW LOCK AND DAM 4 ON THE ARKANSAS RIVER, BUT EXCLUDING THE CANADIAN, NEOSHO, AND VERDIGRIS RIVER BASINS. ARKANSAS, OKLAHOMA.
AREA = 15600 SQ.MI.

ACCOUNTING UNIT 111101 — ROBERT S. KERR RESERVOIR: THE ARKANSAS RIVER BASIN BELOW KEYSTONE DAM TO LOCK AND DAM 13, BUT EXCLUDING THE CANADIAN, NEOSHO, AND VERDIGRIS RIVER BASINS. ARKANSAS. OKLAHOMA.
AREA = 7340 SQ.MI.

REGION 11: ARKANSAS-WHITE-RED — Continued

CATALOGING UNITS 11110101 — POLECAT-SNAKE. OKLAHOMA.
AREA = 1310 SQ.MI.
11110102 — DIRTY-GREENLEAF. OKLAHOMA.
AREA = 769 SQ.MI.
11110103 — ILLINOIS. ARKANSAS, OKLAHOMA.
AREA = 1620 SQ.MI.
11110104 — ROBERT S. KERR RESERVOIR. ARKANSAS, OKLAHOMA.
AREA = 1780 SQ.MI.
11110105 — POTEAU. ARKANSAS, OKLAHOMA.
AREA = 1860 SQ.MI.

ACCOUNTING UNIT 111102 — LOWER ARKANSAS-FOURCHE LA FAVE: THE ARKANSAS RIVER BASIN BELOW LOCK AND DAM 13 TO THE POINT OF HIGHEST BACKWATER EFFECT OF THE MISSISSIPPI RIVER BELOW LOCK AND DAM 4 ON THE ARKANSAS RIVER. ARKANSAS.
AREA = 8300 SQ.MI.

CATALOGING UNITS 11110201 — FROG-MULBERRY. ARKANSAS.
AREA = 1270 SQ.MI.
11110202 — DARDANELLE RESERVOIR. ARKANSAS.
AREA = 1860 SQ.MI.
11110203 — LAKE CONWAY-POINT REMOVE. ARKANSAS.
AREA = 1140 SQ.MI.
11110204 — PETIT JEAN. ARKANSAS.
AREA = 1070 SQ.MI.
11110205 — CADRON. ARKANSAS.
AREA = 751 SQ.MI.
11110206 — FOURCHE LA FAVE. ARKANSAS.
AREA = 1100 SQ.MI.
11110207 — LOWER ARKANSAS-MAUMELLE. ARKANSAS.
AREA = 1100 SQ.MI.

SUBREGION 1112 — RED HEADWATERS: THE NORTH FORK RED RIVER, PRAIRIE DOG TOWN FORK RED RIVER, AND THE SALT FORK RED RIVER BASINS. NEW MEXICO, OKLAHOMA, TEXAS.
AREA = 14600 SQ.MI.

ACCOUNTING UNIT 111201 — PRAIRIE DOG TOWN FORK RED: THE PRAIRIE DOG TOWN FORK RED RIVER BASIN. NEW MEXICO, OKLAHOMA, TEXAS.
AREA = 7630 SQ.MI.

CATALOGING UNITS 11120101 — TIERRA BLANCA. NEW MEXICO, TEXAS.
AREA = 1910 SQ.MI.
11120102 — PALO DURO. NEW MEXICO, TEXAS.
AREA = 966 SQ.MI.
11120103 — UPPER PRAIRIE DOG TOWN FORK RED. TEXAS.
AREA = 2120 SQ.MI.
11120104 — TULE. TEXAS.
AREA = 1100 SQ.MI.
11120105 — LOWER PRAIRIE DOG TOWN FORK RED. OKLAHOMA, TEXAS.
AREA = 1530 SQ.MI.

ACCOUNTING UNIT 111202 — SALT FORK RED: THE SALT FORK RED RIVER BASIN. OKLAHOMA, TEXAS.
AREA = 2000 SQ.MI.

CATALOGING UNITS 11120201 — UPPER SALT FORK RED. TEXAS.
AREA = 740 SQ.MI.
11120202 — LOWER SALT FORK RED. OKLAHOMA, TEXAS.
AREA = 1260 SQ.MI.

ACCOUNTING UNIT 111203 — NORTH FORK RED: THE NORTH FORK RED RIVER BASIN. OKLAHOMA, TEXAS.
AREA = 5000 SQ.MI.

CATALOGING UNITS 11120301 — UPPER NORTH FORK RED. TEXAS.
AREA = 1160 SQ.MI.
11120302 — MIDDLE NORTH FORK RED. OKLAHOMA, TEXAS.
AREA = 1630 SQ.MI.
11120303 — LOWER NORTH FORK RED. OKLAHOMA.
AREA = 1330 SQ.MI.
11120304 — ELM FORK RED. OKLAHOMA, TEXAS.
AREA = 878 SQ.MI.

SUBREGION 1113 — RED - WASHITA: THE RED RIVER BASIN ABOVE DENISON DAM, EXCLUDING THE NORTH FORK RED RIVER, PRAIRIE DOG TOWN FORK RED RIVER, AND THE SALT FORK RED RIVER BASINS. OKLAHOMA, TEXAS.
AREA = 24600 SQ.MI.

ACCOUNTING UNIT 111301 — RED-PEASE: THE RED RIVER BASIN FROM THE PRAIRIE DOG TOWN FORK RED RIVER BASIN TO THE CACHE CREEK BASIN, EXCLUDING THE NORTH FORK RED RIVER AND THE SALT FORK RED RIVER BASINS. OKLAHOMA, TEXAS.
AREA = 5730 SQ.MI.

CATALOGING UNITS 11130101 — GROESBECK-SANDY. OKLAHOMA, TEXAS.
AREA = 1300 SQ.MI.
11130102 — BLUE-CHINA. OKLAHOMA, TEXAS.
AREA = 794 SQ.MI.
11130103 — NORTH PEASE. TEXAS.
AREA = 1460 SQ.MI.
11130104 — MIDDLE PEASE. TEXAS.
AREA = 1420 SQ.MI.
11130105 — PEASE. TEXAS.
AREA = 760 SQ.MI.

ACCOUNTING UNIT 111302 — RED-LAKE TEXOMA: THE RED RIVER BASIN FROM AND INCLUDING THE CACHE CREEK BASIN TO DENISON DAM, INCLUDING THAT PORTION INUNDATED BY LAKE TEXOMA, BUT EXCLUDING THE WASHITA RIVER BASIN. OKLAHOMA, TEXAS.
AREA = 11000 SQ.MI.

CATALOGING UNITS 11130201 — FARMERS-MUD. OKLAHOMA, TEXAS.
AREA = 2340 SQ.MI.
11130202 — CACHE. OKLAHOMA.
AREA = 785 SQ.MI.
11130203 — WEST CACHE. OKLAHOMA.
AREA = 1120 SQ.MI.
11130204 — NORTH WICHITA. TEXAS.
AREA = 1090 SQ.MI.
11130205 — SOUTH WICHITA. TEXAS.
AREA = 702 SQ.MI.
11130206 — WICHITA. TEXAS.
AREA = 1010 SQ.MI.
11130207 — SOUTHERN BEAVER. TEXAS.
AREA = 679 SQ.MI.
11130208 — NORTHERN BEAVER. OKLAHOMA.
AREA = 847 SQ.MI.
11130209 — LITTLE WICHITA. TEXAS.
AREA = 1470 SQ.MI.
11130210 — LAKE TEXOMA. OKLAHOMA, TEXAS.
AREA = 982 SQ.MI.

ACCOUNTING UNIT 111303 — WASHITA. THE WASHITA RIVER BASIN, INCLUDING THAT PORTION INUNDATED BY LAKE TEXOMA. OKLAHOMA.
AREA = 7870 SQ.MI.

CATALOGING UNITS 11130301 — WASHITA HEADWATERS. OKLAHOMA, TEXAS.
AREA = 1460 SQ.MI.
11130302 — UPPER WASHITA. OKLAHOMA.
AREA = 3190 SQ.MI.
11130303 — MIDDLE WASHITA. OKLAHOMA.
AREA = 2490 SQ.MI.
11130304 — LOWER WASHITA. OKLAHOMA.
AREA = 727 SQ.MI.

SUBREGION 1114 — RED-SULPHUR: THE RED RIVER BASIN BELOW DENISON DAM TO AND INCLUDING THE BAYOU RIGOLETTE BASIN AT THE POINT OF HIGHEST BACKWATER EFFECT OF THE MISSISSIPPI RIVER. ARKANSAS, LOUISIANA, OKLAHOMA, TEXAS.
AREA = 27600 SQ.MI.

ACCOUNTING UNIT 111401 — RED-LITTLE: THE RED RIVER BASIN BELOW DENISON DAM TO AND INCLUDING THE LITTLE RIVER BASIN. ARKANSAS, OKLAHOMA, TEXAS.
AREA = 12500 SQ.MI.

CATALOGING UNITS 11140101 — BOIS D'ARC-ISLAND. OKLAHOMA, TEXAS.
AREA = 2010 SQ.MI.
11140102 — BLUE. OKLAHOMA.
AREA = 643 SQ.MI.
11140103 — MUDDY BOGGY. OKLAHOMA.
AREA = 1420 SQ.MI.
11140104 — CLEAR BOGGY. OKLAHOMA.
AREA = 1000 SQ.MI.
11140105 — KIAMICHI. ARKANSAS, OKLAHOMA.
AREA = 1820 SQ.MI.
11140106 — PECAN-WATERHOLE. ARKANSAS, OKLAHOMA, TEXAS.
AREA = 1460 SQ.MI.
11140107 — UPPER LITTLE. OKLAHOMA.
AREA = 1400 SQ.MI.
11140108 — MOUNTAIN FORK. ARKANSAS, OKLAHOMA.
AREA = 821 SQ.MI.
11140109 — LOWER LITTLE. ARKANSAS, OKLAHOMA.
AREA = 1950 SQ.MI.

ACCOUNTING UNIT 111402 — RED-SALINE: THE RED RIVER BASIN BELOW THE LITTLE RIVER BASIN TO AND INCLUDING THE BAYOU RIGOLETTE BASIN AT THE POINT OF HIGHEST BACKWATER EFFECT OF THE MISSISSIPPI RIVER, EXCLUDING THE BIG CYPRESS AND SULPHUR RIVER BASINS. ARKANSAS, LOUISIANA.
AREA = 7740 SQ.MI.

CATALOGING UNITS 11140201 — MCKINNEY-POSTEN BAYOUS. ARKANSAS, LOUISIANA, TEXAS.
AREA = 906 SQ.MI.
11140202 — MIDDLE RED-COUSHATTA. LOUISIANA.
AREA = 276 SQ.MI.
11140203 — LOGGY BAYOU. ARKANSAS, LOUISIANA.
AREA = 1470 SQ.MI.
11140204 — RED CHUTE. LOUISIANA.
AREA = 381 SQ.MI.
11140205 — BODCAU BAYOU. ARKANSAS, LOUISIANA.
AREA = 766 SQ.MI.
11140206 — BAYOU PIERRE. LOUISIANA.
AREA = 1110 SQ.MI.
11140207 — LOWER RED-LAKE IATT. LOUISIANA.
AREA = 1450 SQ.MI.
11140208 — SALINE BAYOU. LOUISIANA.
AREA = 477 SQ.MI.
11140209 — BLACK LAKE BAYOU. LOUISIANA.
AREA = 908 SQ.MI.

ACCOUNTING UNIT 111403 — BIG CYPRESS - SULPHUR. THE CROSS BAYOU AND SULPHUR RIVER BASINS, INCLUDING THE BIG CYPRESS CREEK BASIN. ARKANSAS, LOUISIANA.
AREA = 7310 SQ.MI.

CATALOGING UNITS 11140301 — SULPHUR HEADWATERS. TEXAS.
AREA = 1160 SQ.MI.
11140302 — LOWER SULPHUR. ARKANSAS, TEXAS.
AREA = 1810 SQ.MI.
11140303 — WHITE OAK BAYOU. TEXAS.
AREA = 783 SQ.MI.
11140304 — CROSS BAYOU. ARKANSAS, LOUISIANA, TEXAS.
AREA = 756 SQ.MI.
11140305 — LAKE O'THE PINES. TEXAS.
AREA = 901 SQ.MI.
11140306 — CADDO LAKE. LOUISIANA, TEXAS.
AREA = 1180 SQ.MI.
11140307 — LITTLE CYPRESS. TEXAS.
AREA = 720 SQ.MI.

REGION 12 TEXAS-GULF REGION — THE DRAINAGE THAT DISCHARGES INTO THE GULF OF MEXICO FROM AND INCLUDING SABINE PASS TO THE RIO GRANDE BASIN BOUNDARY. INCLUDES PARTS OF LOUISIANA, NEW MEXICO, AND TEXAS.

SUBREGION 1201 — SABINE: THE SABINE RIVER BASIN ABOVE SABINE LAKE. LOUISIANA, TEXAS.
AREA = 9860 SQ.MI.

ACCOUNTING UNIT 120100 — SABINE. LOUISIANA, TEXAS.
AREA = 9860 SQ.MI.

CATALOGING UNITS 12010001 — UPPER SABINE. TEXAS.
AREA = 1380 SQ.MI.
12010002 — MIDDLE SABINE. LOUISIANA, TEXAS.
AREA = 2760 SQ.MI.
12010003 — LAKE FORK. TEXAS.
AREA = 689 SQ.MI.
12010004 — TOLEDO BEND RESERVOIR. LOUISIANA, TEXAS.
AREA = 2390 SQ.MI.
12010005 — LOWER SABINE. LOUISIANA, TEXAS.
AREA = 2640 SQ.MI.

SUBREGION 1202 — NECHES: THE NECHES RIVER BASIN ABOVE SABINE LAKE. TEXAS.
AREA = 10000 SQ.MI.

ACCOUNTING UNIT 120200 — NECHES. TEXAS.
AREA = 10000 SQ.MI.

CATALOGING UNITS 12020001 — UPPER NECHES. TEXAS.
AREA = 1940 SQ.MI.
12020002 — MIDDLE NECHES. TEXAS.
AREA = 1630 SQ.MI.
12020003 — LOWER NECHES. TEXAS.
AREA = 1130 SQ.MI.
12020004 — UPPER ANGELINA. TEXAS.
AREA = 1610 SQ.MI.
12020005 — LOWER ANGELINA. TEXAS.
AREA = 1940 SQ.MI.
12020006 — VILLAGE. TEXAS.
AREA = 1100 SQ.MI.
12020007 — PINE ISLAND BAYOU. TEXAS.
AREA = 670 SQ.MI.

SUBREGION 1203 — TRINITY: THE TRINITY RIVER BASIN ABOVE TRINITY BAY. TEXAS.
AREA = 18000 SQ.MI.

ACCOUNTING UNIT 120301 — UPPER TRINITY: THE TRINITY RIVER BASIN ABOVE AND INCLUDING THE RICHLAND CREEK BASIN. TEXAS.
AREA = 11800 SQ.MI.

CATALOGING UNITS 12030101 — UPPER WEST FORK TRINITY. TEXAS.
AREA = 1970 SQ.MI.
12030102 — LOWER WEST FORK TRINITY. TEXAS.
AREA = 1510 SQ.MI.
12030103 — ELM FORK TRINITY. TEXAS.
AREA = 1840 SQ.MI.
12030104 — DENTON. TEXAS.
AREA = 727 SQ.MI.
12030105 — UPPER TRINITY. TEXAS.
AREA = 1370 SQ.MI.
12030106 — EAST FORK TRINITY. TEXAS.
AREA = 1300 SQ.MI.
12030107 — CEDAR. TEXAS.
AREA = 1070 SQ.MI.
12030108 — RICHLAND. TEXAS.
AREA = 917 SQ.MI.
12030109 — CHAMBERS. TEXAS.
AREA = 1070 SQ.MI.

ACCOUNTING UNIT 120302 — LOWER TRINITY: THE TRINITY RIVER BASIN BELOW THE RICHLAND CREEK BASIN TO BUT EXCLUDING TRINITY BAY. TEXAS.
AREA = 6210 SQ.MI.

CATALOGING UNITS 12030201 — LOWER TRINITY-TEHUACANA. TEXAS.
AREA = 2140 SQ.MI.
12030202 — LOWER TRINITY-KICKAPOO. TEXAS.
AREA = 3250 SQ.MI.
12030203 — LOWER TRINITY. TEXAS.
AREA = 815 SQ.MI.

SUBREGION 1204 — GALVESTON BAY-SAN JACINTO: THE COASTAL DRAINAGE AND ASSOCIATED WATERS FROM AND INCLUDING SABINE PASS TO THE BRAZOS RIVER BASIN BOUNDARY, BUT EXCLUDING THE NECHES AND SABINE RIVER BASINS ABOVE SABINE LAKE AND THE TRINITY RIVER BASIN ABOVE TRINITY BAY. LOUISIANA, TEXAS.
AREA = 7980 SQ.MI.

ACCOUNTING UNIT 120401 — SAN JACINTO: THE SAN JACINTO RIVER BASIN ABOVE GALVESTON BAY. TEXAS.
AREA = 3980 SQ.MI.

CATALOGING UNITS 12040101 — WEST FORK SAN JACINTO. TEXAS.
AREA = 1080 SQ.MI.
12040102 — SPRING. TEXAS.
AREA = 760 SQ.MI.
12040103 — EAST FORK SAN JACINTO. TEXAS.
AREA = 1010 SQ.MI.
12040104 — BUFFALO-SAN JACINTO. TEXAS.
AREA = 1130 SQ.MI.

ACCOUNTING UNIT 120402 — GALVESTON BAY-SABINE LAKE: THE COASTAL DRAINAGE AND ASSOCIATED WATERS FROM AND INCLUDING SABINE PASS TO THE BRAZOS RIVER BASIN BOUNDARY, BUT EXCLUDING THE NECHES AND SABINE RIVER BASINS ABOVE THE SABINE LAKE, THE TRINITY RIVER BASIN ABOVE TRINITY BAY, AND THE SAN JACINTO RIVER ABOVE GALVESTON BAY. LOUISIANA, TEXAS.
AREA = 4000 SQ.MI.

CATALOGING UNITS 12040201 — SABINE LAKE. LOUISIANA, TEXAS.
AREA = 1040 SQ.MI.
12040202 — EAST GALVESTON BAY. TEXAS.
AREA = 795 SQ.MI.
12040203 — NORTH GALVESTON BAY. TEXAS.
AREA = 395 SQ.MI.
12040204 — WEST GALVESTON BAY. TEXAS.
AREA = 1130 SQ.MI.
12040205 — AUSTIN-OYSTER. TEXAS.
AREA = 637 SQ.MI.

SUBREGION 1205 — BRAZOS HEADWATERS: THE BRAZOS RIVER BASIN ABOVE THE CONFLUENCE OF AND INCLUDING THE DOUBLE MOUNTAIN FORK BRAZOS RIVER AND THE SALT FORK BRAZOS RIVER BASINS. NEW MEXICO, TEXAS.
AREA = 14600 SQ.MI.

ACCOUNTING UNIT 120500 — BRAZOS HEADWATERS. NEW MEXICO, TEXAS.
AREA = 14600 SQ.MI.

CATALOGING UNITS 12050001 — YELLOW HOUSE DRAW. NEW MEXICO, TEXAS.
AREA = 3780 SQ.MI.
12050002 — BLACKWATER DRAW. NEW MEXICO, TEXAS.
AREA = 1560 SQ.MI.
12050003 — NORTH FORK DOUBLE MOUNTAIN FORK BRAZOS. TEXAS.
AREA = 1050 SQ.MI.
12050004 — DOUBLE MOUTAIN FORK BRAZOS. TEXAS.
AREA = 2740 SQ.MI.
12050005 — RUNNING WATER DRAW. NEW MEXICO, TEXAS.
AREA = 1620 SQ.MI.
12050006 — WHITE. TEXAS.
AREA = 1690 SQ.MI.
12050007 — SALT FORK BRAZOS. TEXAS.
AREA = 2150 SQ.MI.

SUBREGION 1206 — MIDDLE BRAZOS: THE BRAZOS RIVER BASIN BELOW THE CONFLUENCE OF THE DOUBLE MOUNTAIN FORK BRAZOS RIVER AND THE SALT FORK BRAZOS RIVER BASINS TO AND INCLUDING THE CASTLEMAN CREEK BASIN. TEXAS.
AREA = 15500 SQ.MI.

ACCOUNTING UNIT 120601 — MIDDLE BRAZOS-CLEAR FORK: THE BRAZOS RIVER BASIN BELOW THE CONFLUENCE OF THE DOUBLE MOUNTAIN FORK BRAZOS RIVER AND THE SALT FORK BRAZOS RIVER BASINS TO AND INCLUDING THE CLEAR FORK BRAZOS RIVER BASIN. TEXAS.
AREA = 8220 SQ.MI.

CATALOGING UNITS 12060101 — MIDDLE BRAZOS-MILLERS. TEXAS.
AREA = 2490 SQ.MI.
12060102 — UPPER CLEAR FORK BRAZOS. TEXAS.
AREA = 2730 SQ.MI.
12060103 — PAINT. TEXAS.
AREA = 1080 SQ.MI.
12060104 — LOWER CLEAR FORK BRAZOS. TEXAS.
AREA = 620 SQ.MI.
12060105 — HUBBARD. TEXAS.
AREA = 1300 SQ.MI.

ACCOUNTING UNIT 120602 — MIDDLE BRAZOS-BOSQUE: THE BRAZOS RIVER BASIN BELOW THE CLEAR FORK BRAZOS RIVER BASIN TO AND INCLUDING THE CASTLEMAN CREEK BASIN. TEXAS.
AREA = 7320 SQ.MI.

CATALOGING UNITS 12060201 — MIDDLE BRAZOS-PALO PINTO. TEXAS.
AREA = 3160 SQ.MI.
12060202 — MIDDLE BRAZOS-LAKE WHITNEY. TEXAS.
AREA = 2500 SQ.MI.
12060203 — BOSQUE. TEXAS.
AREA = 418 SQ.MI.
12060204 — NORTH BOSQUE. TEXAS.
AREA = 1240 SQ.MI.

SUBREGION 1207 — LOWER BRAZOS: THE BRAZOS RIVER BASIN BELOW THE CASTLEMAN CREEK BASIN. TEXAS.
AREA = 15600 SQ.MI.

ACCOUNTING UNIT 120701 — LOWER BRAZOS: THE BRAZOS RIVER BASIN BELOW THE CASTLEMAN CREEK BASIN, EXCLUDING THE LITTLE RIVER BASIN. TEXAS.
AREA = 7960 SQ.MI.

AREA = 154 SQ.MI.

ACCOUNTING UNIT 180703 — LAGUNA-SAN DIEGO COASTAL: THE DRAINAGE WITHIN THE UNITED STATES THAT DISCHARGES INTO THE PACIFIC OCEAN FROM AND INCLUDING THE MORO CANYON DRAINAGE BASIN NEAR LAGUNA BEACH TO THE CALIFORNIA-BAJA CALIFORNIA INTERNATIONAL BOUNDARY. CALIFORNIA.
AREA = 3860 SQ.MI.

CATALOGING UNITS 18070301 — ALISO-SAN ONOFRE. CALIFORNIA.
AREA = 498 SQ.MI.
18070302 — SANTA MARGARITA. CALIFORNIA.
AREA = 731 SQ.MI.
18070303 — SAN LUIS REY-ESCONDIDO. CALIFORNIA.
AREA = 766 SQ.MI.
18070304 — SAN DIEGO. CALIFORNIA.
AREA = 1390 SQ.MI.
18070305 — COTTONWOOD-TIJUANA. CALIFORNIA.
AREA = 477 SQ.MI.

SUBREGION 1808 — NORTH LAHONTAN: THE DRAINAGE EAST OF THE SIERRA NEVADA AND NORTH OF THE TRUCKEE RIVER BASIN WHICH INCLUDES THE LAHONTON CLOSED BASINS THAT DISCHARGE INTO CALIFORNIA. CALIFORNIA, NEVADA.
AREA = 4480 SQ.MI.

ACCOUNTING UNIT 180800 — NORTH LAHONTAN. CALIFORNIA, NEVADA.
AREA = 4480 SQ.MI.

CATALOGING UNITS 18080001 — SURPRISE VALLEY. CALIFORNIA, NEVADA.
AREA = 878 SQ.MI.
18080002 — MADELINE PLAINS. CALIFORNIA, NEVADA.
AREA = 835 SQ.MI.
18080003 — HONEY-EAGLE LAKES. CALIFORNIA, NEVADA.
AREA = 2770 SQ.MI.

SUBREGION 1809 — NORTHERN MOJAVE-MONO LAKE: THE CLOSED DESERT BASINS THAT DISCHARGE INTO SOUTH CENTRAL CALIFORNIA, INCLUDING MONO LAKE, OWENS LAKE, DEATH VALLEY, AND THE UPPER MOJAVE DESERT. CALIFORNIA, NEVADA.
AREA = 28000 SQ.MI.

ACCOUNTING UNIT 180901 — MONO-OWENS LAKES. THE MONO LAKE AND OWENS LAKE CLOSED BASINS. CALIFORNIA, NEVADA.
AREA = 4310 SQ.MI.

CATALOGING UNITS 18090101 — MONO LAKE. CALIFORNIA, NEVADA.
AREA = 1070 SQ.MI.
18090102 — CROWLEY LAKE. CALIFORNIA, NEVADA.
AREA = 1900 SQ.MI.
18090103 — OWENS LAKE. CALIFORNIA.
AREA = 1340 SQ.MI.

ACCOUNTING UNIT 180902 — NORTHERN MOJAVE: THE CLOSED DESERT BASINS THAT DISCHARGE INTO SOUTH CENTRAL CALIFORNIA, INCLUDING DEATH VALLEY AND THE UPPER MOJAVE DESERT, EXCLUDING MONO LAKE AND OWENS LAKE. CALIFORNIA, NEVADA.
AREA = 23600 SQ.MI.

CATALOGING UNITS 18090201 — EUREKA-SALINE VALLEYS. CALIFORNIA, NEVADA.
AREA = 1640 SQ.MI.
18090202 — UPPER AMARGOSA. CALIFORNIA, NEVADA.
AREA = 3340 SQ.MI.
18090203 — DEATH VALLEY-LOWER AMARGOSA. CALIFORNIA, NEVADA.
AREA = 5330 SQ.MI.
18090204 — PANAMINT VALLEY. CALIFORNIA.
AREA = 1600 SQ.MI.
18090205 — INDIAN WELLS-SEARLES VALLEYS. CALIFORNIA.
AREA = 2020 SQ.MI.
18090206 — ANTELOPE-FREMONT VALLEYS. CALIFORNIA.
AREA = 3310 SQ.MI.
18090207 — COYOTE-CUDDEBACK LAKES. CALIFORNIA.
AREA = 1820 SQ.MI.
18090208 — MOJAVE. CALIFORNIA.
AREA = 4580 SQ.MI.

SUBREGION 1810 — SOUTHERN MOJAVE-SALTON SEA: THE CLOSED DESERT BASINS IN SOUTHEASTERN CALIFORNIA, INCLUDING THE LOWER MOJAVE DESERT AND THE SALTON SEA. CALIFORNIA.
AREA = 16000 SQ.MI.

ACCOUNTING UNIT 181001 — SOUTHERN MOJAVE: THE LOWER MOJAVE DESERT. CALIFORNIA.
AREA = 8700 SQ.MI.

CATALOGING UNIT 18100100 — SOUTHERN MOJAVE. CALIFORNIA.
AREA = 8700 SQ.MI.

ACCOUNTING UNIT 181002 — SALTON SEA: THE SALTON SEA CLOSED BASIN. CALIFORNIA.
AREA = 7250 SQ.MI.

CATALOGING UNIT 18100200 — SALTON SEA. CALIFORNIA.
AREA = 7250 SQ.MI.

REGION 19 ALASKA REGION — THE DRAINAGE WITHIN THE STATE OF ALASKA. INCLUDES ALL OF ALASKA.

SUBREGION 1901 — ARCTIC SLOPE: THE NORTH SLOPE DRAINAGE WITHIN THE UNITED STATES THAT DISCHARGES INTO THE ARCTIC OCEAN, INCLUDING THE BAYS, ISLANDS, AND ASSOCIATED WATERS, FROM THE ALASKA-YUKON INTERNATIONAL BOUNDARY TO CAPE LISBURNE. ALASKA.
AREA = 81000 SQ.MI.

ACCOUNTING UNIT 190100 — ARCTIC SLOPE. ALASKA.
AREA = 81000 SQ.MI.

CATALOGING UNITS 19010001 — EAST ARCTIC SLOPE. ALASKA.
AREA = 24000 SQ.MI.
19010002 — COLVILLE. ALASKA.
AREA = 23000 SQ.MI.
19010003 — WEST ARCTIC SLOPE. ALASKA.
AREA = 34000 SQ.MI.

SUBREGION 1902 — NORTHWEST ALASKA: THE COASTAL DRAINAGE FROM CAPE LISBURNE TO THE YUKON RIVER BASIN BOUNDARY, INCLUDING THE BAYS, SOUNDS, ISLANDS, AND ASSOCIATED WATERS; AND ST. LAWRENCE ISLAND. ALASKA.
AREA = 75000 SQ.MI.

ACCOUNTING UNIT 190200 — NORTHWEST ALASKA. ALASKA.
AREA = 75000 SQ.MI.

CATALOGING UNITS 19020001 — KOTZEBUE SOUND. ALASKA.
AREA = 49000 SQ.MI.
19020002 — NORTON SOUND-ST. LAWRENCE ISLAND. ALASKA.
AREA = 26000 SQ.MI.

SUBREGION 1903 — YUKON: THE YUKON RIVER BASIN WITHIN THE UNITED STATES, INCLUDING ITS DELTA. ALASKA.
AREA = 204000 SQ.MI.

ACCOUNTING UNIT 190300 — YUKON. ALASKA.
AREA = 204000 SQ.MI.

CATALOGING UNITS 19030001 — FORTYMILE-WHITE. ALASKA.
AREA = 9700 SQ.MI.
19030002 — UPPER YUKON. ALASKA.
AREA = 60000 SQ.MI.
19030003 — MIDDLE YUKON. ALASKA.
AREA = 21000 SQ.MI.
19030004 — TANANA. ALASKA.
AREA = 44000 SQ.MI.
19030005 — KOYUKUK. ALASKA.
AREA = 32000 SQ.MI.
19030006 — LOWER YUKON. ALASKA.
AREA = 37000 SQ.MI.

SUBREGION 1904 — SOUTHWEST ALASKA: THE COASTAL DRAINAGE FROM THE YUKON RIVER BASIN BOUNDARY TO KUPREANOF POINT ON THE ALASKA PENINSULA, INCLUDING THE BAYS, ISLANDS, AND ASSOCIATED WATERS; AND THE ISLANDS OF ST. MATTHEW, NUNIVAK AND PRIBILOF, AND ALL OF THE ALEUTIAN ISLANDS. ALASKA.
AREA = 124000 SQ.MI.

ACCOUNTING UNIT 190400 — SOUTHWEST ALASKA. ALASKA.
AREA = 124000 SQ.MI.

CATALOGING UNITS 19040001 — KUSKOKWIM BAY-NUNIVAK ISLAND-ST. MATTHEW ISLAND. ALASKA.
AREA = 61000 SQ.MI.
19040002 — BRISTOL BAY. ALASKA.
AREA = 43000 SQ.MI.
19040003 — ALEUTIAN-PRIBILOF ISLANDS. ALASKA.
AREA = 20000 SQ.MI.

SUBREGION 1905 — SOUTH CENTRAL ALASKA: THE COASTAL DRAINAGE WITHIN THE UNITED STATES FROM KUPREANOF POINT ON THE ALASKA PENINSULA TO THE ALASKA-YUKON INTERNATIONAL BOUNDARY AND SOUTHWARD TO POINT RIOU, INCLUDING THE BAYS, ISLANDS, SOUNDS, AND ASSOCIATED WATERS. ALASKA.
AREA = 99000 SQ.MI.

ACCOUNTING UNIT 190500 — SOUTH CENTRAL ALASKA. ALASKA.
AREA = 99000 SQ.MI.

CATALOGING UNITS 19050001 — KODIAK-SHELIKOF. ALASKA.
AREA = 12000 SQ.MI.
19050002 — COOK INLET. ALASKA.
AREA = 47000 SQ.MI.
19050003 — GULF OF ALASKA. ALASKA.
AREA = 40000 SQ.MI.

SUBREGION 1906 — SOUTHEAST ALASKA: THE COASTAL DRAINAGE WITHIN THE UNITED STATES FROM POINT RIOU TO THE ALAKSA-BRITISH COLUMBIA INTERNATIONAL BOUNDARY, INCLUDING THE BAYS, ISLANDS, SOUNDS, AND ASSOCIATED WATERS. ALASKA.
AREA = 49000 SQ.MI.

ACCOUNTING UNIT 190600 — SOUTHEAST ALASKA. ALASKA.
AREA = 49000 SQ.MI.

CATALOGING UNIT 19060000 — SOUTHEAST ALASKA. ALASKA.
AREA = 49000 SQ.MI.

REGION 20 HAWAII REGION — THE DRAINAGE WITHIN THE STATE OF HAWAII. INCLUDES ALL OF HAWAII.

SUBREGION 2001 — HAWAII: THE DRAINAGE ON THE ISLAND OF HAWAII; AND ASSOCIATED WATERS. HAWAII.
AREA = 4030 SQ.MI.

ACCOUNTING UNIT 200100 — HAWAII. HAWAII.
AREA = 4030 SQ.MI.

CATALOGING UNIT 20010000 — HAWAII. HAWAII.
AREA = 4030 SQ.MI.

SUBREGION 2002 — MAUI: THE DRAINAGE ON THE ISLAND OF MAUI; AND ASSOCIATED WATERS. HAWAII.
AREA = 730 SQ.MI.

ACCOUNTING UNIT 200200 — MAUI. HAWAII.
AREA = 730 SQ.MI.

CATALOGING UNIT 20020000 — MAUI. HAWAII.
AREA = 730 SQ.MI.

SUBREGION 2003 — KAHOOLAWE: THE DRAINAGE ON THE ISLAND OF KAHOOLAWE; AND ASSOCIATED WATERS. HAWAII.
AREA = 45 SQ.MI.

ACCOUNTING UNIT 200300 — KAHOOLAWE. HAWAII.
AREA = 45 SQ.MI.

CATALOGING UNIT 20030000 — KAHOOLAWE. HAWAII.
AREA = 45 SQ.MI.

SUBREGION 2004 — LANAI: THE DRAINAGE ON THE ISLAND OF LANAI; AND ASSOCIATED WATERS. HAWAII.
AREA = 140 SQ.MI.

ACCOUNTING UNIT 200400 — LANAI. HAWAII.
AREA = 140 SQ.MI.

CATALOGING UNIT 20040000 — LANAI. HAWAII.
AREA = 140 SQ.MI.

SUBREGION 2005 — MOLOKAI: THE DRAINAGE ON THE ISLAND OF MOLOKAI; AND ASSOCIATED WATERS. HAWAII.
AREA = 260 SQ.MI.

ACCOUNTING UNIT 200500 — MOLOKAI. HAWAII.
AREA = 260 SQ.MI.

CATALOGING UNIT 20050000 — MOLOKAI. HAWAII.
AREA = 260 SQ.MI.

SUBREGION 2006 — OAHU: THE DRAINAGE ON THE ISLAND OF OAHU; AND ASSOCIATED WATERS. HAWAII.
AREA = 630 SQ.MI.

ACCOUNTING UNIT 200600 — OAHU. HAWAII.
AREA = 630 SQ.MI.

CATALOGING UNIT 20060000 — OAHU. HAWAII.
AREA = 630 SQ.MI.

SUBREGION 2007 — KAUAI: THE DRAINAGE ON THE ISLAND OF KAUAI; AND ASSOCIATED WATERS. HAWAII.
AREA = 560 SQ.MI.

ACCOUNTING UNIT 200700 — KAUAI. HAWAII.
AREA = 560 SQ.MI.

CATALOGING UNIT 20070000 — KAUAI. HAWAII.
AREA = 560 SQ.MI.

SUBREGION 2008 — NIIHAU: THE DRAINAGE ON THE ISLANDS OF NIIHAU AND KAULA; AND ASSOCIATED WATERS. HAWAII.
AREA = 72 SQ.MI.

ACCOUNTING UNIT 200800 — NIIHAU. HAWAII.
AREA = 72 SQ.MI.

CATALOGING UNIT 20080000 — NIIHAU. HAWAII.
AREA = 72 SQ.MI.

SUBREGION 2009 — NORTHWESTERN HAWAIIAN ISLANDS: THE DRAINAGE ON KURE, LAYSAN, LISIANSKI, NECKER, AND NIHOA ISLANDS; GARDNER PINNACLES; MARO, AND PEARL AND HERMES REEFS; FRENCH FRIGATE SHOALS; AND OTHER ISLETS, REEFS, AND ASSOCIATED WATERS NORTHWEST OF NIIPAU ISLAND. HAWAII.
AREA = < 10 SQ.MI.

ACCOUNTING UNIT 200900 — NORTHWESTERN HAWAIIAN ISLANDS. HAWAII.
AREA = < 10 SQ.MI.

CATALOGING UNIT 20090000 — NORTHWESTERN HAWAIIAN ISLANDS. HAWAII.
AREA = < 10 SQ.MI.

REGION 21 CARIBBEAN REGION — THE DRAINAGE WITHIN: (A) THE COMMONWEALTH OF PUERTO RICO; (B) THE VIRGIN ISLANDS OF THE UNITED STATES; AND (C) OTHER UNITED STATES CARIBBEAN OUTLYING AREAS. INCLUDES LAND AREAS OVER WHICH THE UNITED STATES HAS SOME DEGREE OF INTEREST, JURISDICTION, OR SOVEREIGNTY.

SUBREGION 2101 — PUERTO RICO: THE DRAINAGE AND ASSOCIATED WATERS WITHIN THE COMMONWEALTH OF PUERTO RICO.
PUERTO RICO.
AREA = 3480 SQ.MI.

ACCOUNTING UNIT 210100 — PUERTO RICO. COMMONWEALTH OF PUERTO RICO.
AREA = 3480 SQ.MI.

CATALOGING UNITS 21010001 — INTERIOR PUERTO RICO.
PUERTO RICO.
AREA = 404 SQ.MI.
21010002 — CIBUCO-GUAJATACA. PUERTO RICO.
AREA = 566 SQ.MI.
21010003 — CULEBRINAS-GUANAJIBO. PUERTO RICO.
AREA = 504 SQ.MI.
21010004 — SOUTHERN PUERTO RICO.
PUERTO RICO.
AREA = 851 SQ.MI.
21010005 — EASTERN PUERTO RICO. PUERTO RICO.
AREA = 1067 SQ.MI.
21010006 — PUERTO RICAN ISLANDS. PUERTO RICO.
AREA = 92 SQ.MI.

SUBREGION 2102 — VIRGIN ISLANDS: THE DRAINAGE AND ASSOCIATED WATERS WITHIN THE VIRGIN ISLANDS OF THE UNITED STATES.
U.S. VIRGIN ISLANDS.
AREA = 133 SQ.MI.

ACCOUNTING UNIT 210200 — VIRGIN ISLANDS. U.S. VIRGIN ISLANDS.
AREA = 133 SQ.MI.

CATALOGING UNITS 21020001 — ST. JOHN-ST. THOMAS.
U.S. VIRGIN ISLANDS.
AREA = 51 SQ.MI.
21020002 — ST. CROIX. U.S. VIRGIN ISLANDS.
AREA = 82 SQ.MI.

SUBREGION 2103 — CARIBBEAN OUTLYING AREAS: THE DRAINAGE AND ASSOCIATED WATERS WITHIN THE CANAL ZONE, NAVASSA ISLAND, AND RANCADOR AND SERRANA BANKS.
AREA = 650 SQ.MI.

ACCOUNTING UNIT 210300 — CARIBBEAN OUTLYING AREAS.
AREA = 650 SQ.MI.

CATALOGING UNITS 21030001 — CANAL ZONE. PANAMA CANAL ZONE.
AREA = 647 SQ.MI.
21030002 — NAVASSA. NAVASSA ISLAND.
AREA = 2 SQ.MI.
21030003 — RONCADOR-SERRANA. RONCADOR AND SERRANA BANKS.
AREA = < 1 SQ.MI.

HYPSOMETRIC (AREA-ALTITUDE) ANALYSIS OF EROSIONAL TOPOGRAPHY

By Arthur N. Strahler

Abstract

The percentage hypsometric curve (area-altitude curve) relates horizontal cross-sectional area of a drainage basin to relative elevation above basin mouth. By use of dimensionless parameters, curves can be described and compared irrespective of true scale. Curves show distinctive differences both in sinuosity of form and in proportionate area below the curve, here termed the hypsometric integral. A simple three-variable function provides a satisfactory series of model curves to which most natural hypsometric curves can be fitted. The hypsometric curve can be equated to a mean ground-slope curve if length of contour belt is taken into account.

Stages of youth, maturity, and old age in regions of homogeneous rock give a distinctive series of hypsometric forms, but mature and old stages give identical curves unless monadnock masses are present. It is therefore proposed that this terminology be replaced by one consisting of an inequilibrium stage, an equilibrium stage, and a monadnock phase.

Detailed morphometric analysis of basins in five sample areas in the equilibrium stage show distinctive, though small, differences in hypsometric integrals and curve forms. In general, drainage basin height, slope steepness, stream channel gradient, and drainage density show a good negative correlation with mean integrals. Lithologic and structural differences between areas or recent minor uplifts may account for certain curve differences. Regions of strong horizontal structural benching give a modified series of hypsometric curves.

Practical applications of hypsometric analysis are foreseen in hydrology, soil erosion and sedimentation studies, and military science.

Introduction

Topography produced by stream-channel erosion and associated processes of weathering, mass movement, and sheet runoff is extremely complex, both in the geometry of the forms themselves and in the interrelations of the processes which produce the forms. Although the fluvial-erosional landforms constitute the largest proportion of the earth's land surfaces and therefore deserve intensive study, only in recent years have investigations moved from the rather limited phase of simple visual observation and generalized verbal descriptions to the more productive but vastly more refractory phase of quantitative description and dynamic analysis.

Dynamic-quantitative studies require, first, a thorough morphological analysis in order that the form elements of a landscape may be separated, quantitatively described, and compared from region to region. Drainage network characteristics and channel gradients, slope profile forms, declivities and lengths, drainage densities, and hypsometric properties are among the general classes of morphological information for which standardized measures must be set up so that the essential differences and similarities between regions can be understood. Second, the topographic forms must be related quantitatively to the rates and intensities of the denudational processes. These relationships may take the form of empirical equations derived by methods of mathematical statistics from the observational data, or deduced mathematical models whose validity is sustained by observed values.

The material in the present paper is merely one very small part of the morphological analysis. It concerns the investigation of hypsometric properties of small drainage basins—that is, area-altitude relationships and the manner in which mass is distributed within a drainage basin.

Some parts of this paper represent work supported by the Penrose Bequest, Project Grant 525-48; but the greater part of the investigation was supported by the Office of Naval Research under Contract N6 ONR 271, Task Order 30, Project No. NR 089-042.

The writer is greatly indebted to Dr. W. W. Rubey, Chairman of the National Research Council, and Dr. Luna B. Leopold, Water Resources Division of the U. S. Geological Survey, for critically reading the manuscript and making many suggestions for its clarification. Mr. James L. Lubkin of the Columbia School of Engineering developed the model hypsometric function; Professor Robert Bechhofer and his staff of the Statistical Consulting Service of Columbia University advised the author on testing procedures.

Principles of Hypsometric Analysis

Hypsometric Curve in Absolute Units

Hypsometric analysis is the study of the distribution of ground surface area, or horizontal cross-sectional area, of a landmass with respect to elevation. The simplest form of hypsometric curve (hypsographic curve) is that in absolute units of measure. On the ordinate is plotted elevation in feet or meters; on the abscissa the area in square miles or kilometers lying above a contour of given elevation. The areas used are therefore those of horizontal slices of the topography at any given level. This method produces a cumulative curve, any point on which expresses the total area (reduced to horizontal projection) lying above that plane.

The absolute hypsometric curve has been used in regional geomorphic studies to show the presence of extensive summit flatness or terracing, where the surfaces lies approximately horizontal. Where these surfaces have a pronounced regional slope, they may not appear on the curve. Because a good topographic map, from which the hypsometric curve was prepared, will usually show these features, the justification for an elaborate hypsometric process for interpreting geomorphic history is doubtful.

For analysis of the form quality of erosional topography, use of absolute units is unsatisfactory because areas of different size and relief cannot be compared, and the slope of the curve depends on the arbitrary selection of scales. To overcome these difficulties, it is desirable to use dimensionless parameters independent of absolute scale of topographic features.

Percentage Hypsometric Curve

Hypsometric analysis, in general use for calculation of hydrologic information (Langbein *et al.*, 1947), takes a complete drainage basin above a selected point on a main stream as the area of study. The present study of form qualities of erosional topography likewise uses natural drainage basins, whether single or composite, on the assumption that the form of each drainage basin results from the interaction of slope-wasting and channel-deepening processes within the limits of the drainage divide, and hence that each basin should be treated as a unit.

Most drainage basins in homogeneous materials are pear-shaped in outline, with lateral divides converging to a clearly defined constriction, or mouth (Horton, 1941, p. 303). For hypsometric study, a geometric unit of reference consists of a solid bounded on the sides by the vertical projection of the basin perimeter and on the top and base by parallel planes passing through the summit and mouth respectively (Fig. 1). Although both of these reference planes may be expected to change as the basin is denuded, they are real points which can always be determined.

The percentage hypsometric method used in this investigation relates the area enclosed between a given contour and the upper (headward) segment of the basin perimeter to the height of that contour above the basal plane. The method has been used by Langbein (1947) for hydrologic investigations. Two ratios are involved (Fig. 1): (1) ratio of area between the contour and the upper perimeter (Area a) to total drainage basin area (Area A), represented by the abscissa on the coordinate system. (2) Ratio of height of contour above base (h) to total height of basin (H), represented by values of the ordinate.

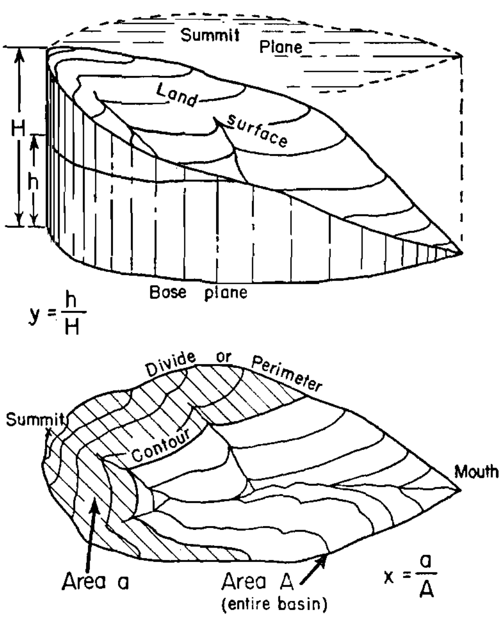

FIGURE 1.—FIGURE OF REFERENCE IN PERCENTAGE HYPSOMETRIC ANALYSIS
Showing derivation of the dimensionless parameters used in Figure 2.

The resulting hypsometric curve (Fig. 2) permits the comparison of forms of basins of different sizes and elevations. It expresses simply the manner in which the volume lying beneath the ground surface is distributed from base to top. The curve must always originate in the upper left-hand corner of the square ($x = 0$, $y = 1$) and reach the lower right-hand corner ($x = 1$, $y = 0$). It may, however, take any one of a variety of paths between these points, depending upon the distribution of the landmass from base to top.

Method of Obtaining Hypsometric Data

Actual measurement and calculation of hypsometric data have been done by the writer in the following steps: First, the drainage basin is selected and outlined. Selection of the basin is influenced by the purpose of the investigation, which may call for a study of the first-order drainage basins or of composite basins whose trunk streams have an order of 3, 4, or higher.[1] Having made this decision, the operator draws in the drainage divide on the map. The divide is carried down to the stream at its point of junction with a stream of the same or higher order.

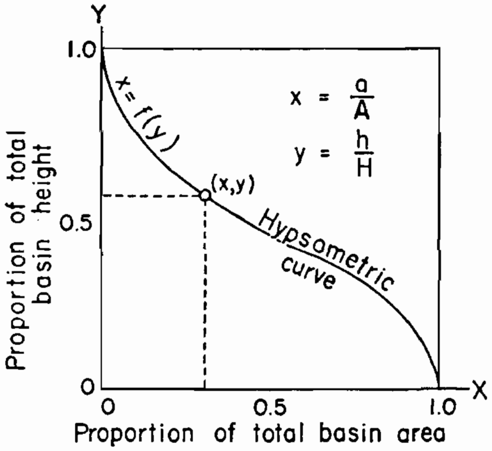

FIGURE 2.—THE PERCENTAGE HYPSOMETRIC CURVE

With a polar planimeter, the operator measures first the area of the entire basin, then the areas enclosed between each contour and the upper perimeter. Ratios are computed and will range from 1.0 to 0.0. Where relief is strong and contours closely crowded, every second or fifth contour is used, except near the summit where all available contours are used. Obviously the value of hypsometric analysis depends on use of sufficiently accurate and large-scale maps for the drainage basins involved. Where texture is fine and unit basins very small, special field maps on a large scale must first be surveyed.

Height ratios are obtained by first determining the total range between basin mouth and summit point. The height of each measured contour above the mouth elevation is then determined and ratios to total basin height computed. These will range from 0.0 to 1.0 in inverse series to the area ratios.

The ratios are plotted on any convenient cross-section paper and the curve drawn smoothly with the aid of a draftsman's curve. For purposes of comparison with model curves illustrated in Plate 1, cross-section paper of 10 divisions per ½ inch should be used, allotting a square 5 inches wide to the hypsometric graph.

Integration of the Hypsometric Function

In order to calculate the volume of earth material contained between the ground surface and the bottom and sides of the figure of reference (Fig. 1), the landmass may be thought of as consisting of horizontal slabs (Fig. 3). The total volume, V, consists of the sum of all slabs. The volume of one slab, ΔV, is obtained by multiplying the area of the slab, a, by its thickness, Δh. Following the mathematical principle of integration, the entire volume may be stated by the expression

$$\text{I} \qquad V = \int_{\text{base el}}^{\text{summit el}} a\,dh.$$

If we now divide both sides of this equation by H and A, which are constant terms,

$$\frac{V}{HA} = \frac{1}{HA}\int_{\text{base el}}^{\text{summit el}} a\,dh$$

or

$$\frac{V}{HA} = \int_{\text{base el}}^{\text{summit el}} \frac{a}{A}\,d\left(\frac{h}{H}\right)$$

This expresses the ratio of volume lying beneath the surface, V, to the entire volume of the reference figure, HA. Because $\frac{a}{A} = x$, and $\frac{h}{H} = y$, by our definition, then

$$\text{II} \qquad \frac{V}{HA} = \int_0^{1.0} x\,dy.$$

[1] Stream orders have been defined by Horton (1945, p. 281–283), but the writer has followed a somewhat different system of determining orders: The smallest, or "finger-tip", channels constitute the first-order segments. For the most part these carry wet-weather streams and are normally dry. A second-order segment is formed by the junction of any two first-order streams; a third-order segment is formed by the joining of any two second-order streams, etc. This method avoids the necessity of subjective decisions, inherent in Horton's method, and assures that there will be only one stream bearing the highest order number.

Thus, if the hypsometric function, $x = f(y)$, is integrated between the limits of $x = 0$ and $x = 1.0$, a measure of landmass volume remaining with respect to volume of the entire reference solid is obtained. This integral is here designated the hypsometric integral and is equivalent to the ratio of area under the hypsometric curve to the area of the entire square. It is expressed in percentage units and can be obtained from any percentage hypsometric curve by measuring the area under the curve with a planimeter. Whether the integration is of the function $y = f(x)$ or $x = f(y)$ is of no consequence. The latter function was used in this explanation because the unit slabs of volume are thought of as being horizontal, rather than vertical.

As discussed elsewhere in this paper, both the form of the hypsometric curve and the value of the integral are important elements in topographic form and show marked variations in regions differing in stage of development and geologic structure.

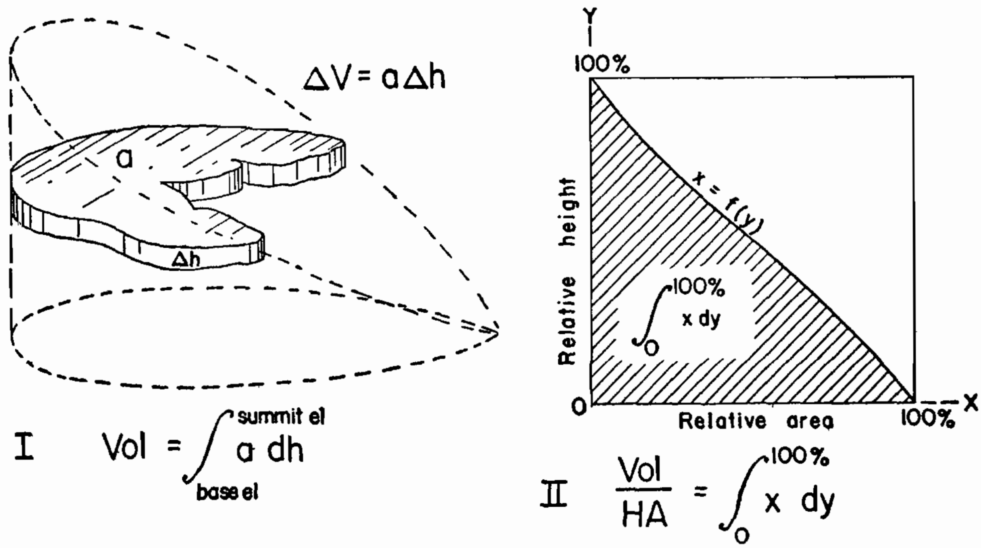

FIGURE 3.—INTEGRATION OF THE HYPSOMETRIC FUNCTION
And meaning of hypsometric integral.

A Model Hypsometric Function

It is desirable to find a relatively simple, yet flexible function which may be fitted to any natural hypsometric curve. This is necessary so that certain mathematical operations can be performed to obtain information useful in hydrologic and other applications.

Inspection of a large number of hypsometric curves has shown that the majority are s-shaped. An up-concavity is commonly present in the upper part; a convexity in the lower part. Sinuosity varies greatly so that the slopes of the curves at their inflection points have a wide range. It is therefore necessary to use an equation having two parameters, one to vary the hypsometric integral, the other to control the sinuosity.

A function[2] which meets these requirements fairly well is

$$\text{III} \qquad y = \left[\frac{d-x}{x} \cdot \frac{a}{d-a}\right]^z$$

where a and d are constants, d always greater than a, and the exponent z, positive or zero (Fig. 4). All curves pass through A and B. The slope of the curve at its inflection point depends on the ratio $\frac{a}{d}$, hereinafter designated r. The general location of the curve depends upon the exponent z.

[2] The writer is indebted to Mr. James Leigh Lubkin of the School of Engineering of Columbia University for developing this equation. It was adapted from a somewhat similar equation used by Hunter Rouse (1937, p. 536) to describe the distribution of suspended load in a stream.

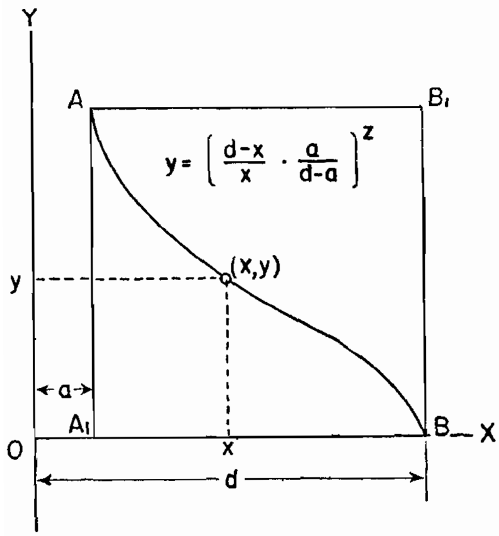

FIGURE 4.—MODEL HYPSOMETRIC FUNCTION

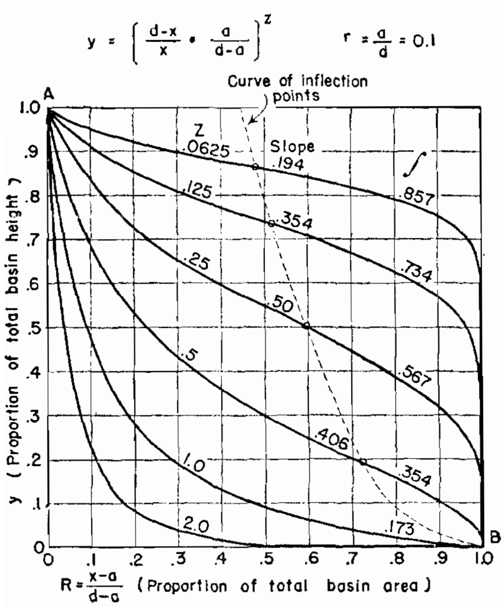

FIGURE 5.—FAMILY OF CURVES FOR THE VALUE, $r = 0.1$

For selected values of z. Given alse are the integrals and the slope of each curve at its inflection point. (Other curve families are given in Plate 1.)

In order to have a percentage scale on the abscissa, conforming with the percentage hypsometric function as previously defined, a modification of equation III is introduced. It is desired that the scale of values on the abscissa as shown in Figure 4 should range from 0 at $x = a$ to 1.0 at $x = d$. This percentage, R is therefore expressed as

$$R = \frac{x - a}{d - a}.$$

In subsequent illustrations of the model hypsometric equation (Figs. 5, 6; Pl. 1) the abscissa appears scaled in terms of R.

To plot a family of model curves having one particular degree of sinuosity, a value of r is selected; curves within each family are then obtained by using different values of the exponent, z.[3]

As an illustration of a family of curves, that particular family in which $r = 0.1$ is given in Figure 5. Curves for several values of z, ranging from 0.0625 to 2.0, are shown. Plate 1 gives five families of curves and can be used for fitting of natural curves by inspection. Curves represented by this model function have the following characteristics (1) The curves are s-shaped where $z < 1$, but are of simple concave-up form where $z > 1$. (2) Where $z < 1$, curves entering at A have a slope, whereas they are tangent to the vertical through the point B.

Decreasing the value of r increases the degree of sinuosity of the curve, thereby reducing the slope of the curve in the region of inflection. This effect may be seen by studying individual curves for the families $r =$ 0.01, 0.05, 0.1, 0.25, and 0.5 (Fig. 6). For comparison, five curves were selected whose integral is approximately the same.

It is not practical to obtain the hypsometric integrals of theoretical curves by mathematical procedures, hence these were obtained by the writer by planimeter measurement for all curves plotted. On each model curve (Pl. 1), the integral is given. The values are only approximate, being subject to errors in measure-

[3] For plotting, the following form of equation III can be used:

$$\text{IV} \quad y = \left[\frac{r}{1 - r}\right]^z \left[\frac{1}{(1 - r)\,R + r} - 1\right]^z$$

where r and R are as defined above. For a given curve, r and z are constants; hence, by substituting a series of values of R ranging from 0 to 1.0, the corresponding values of y may be obtained.

ment as well as errors in plotting the curves from which they were measured.

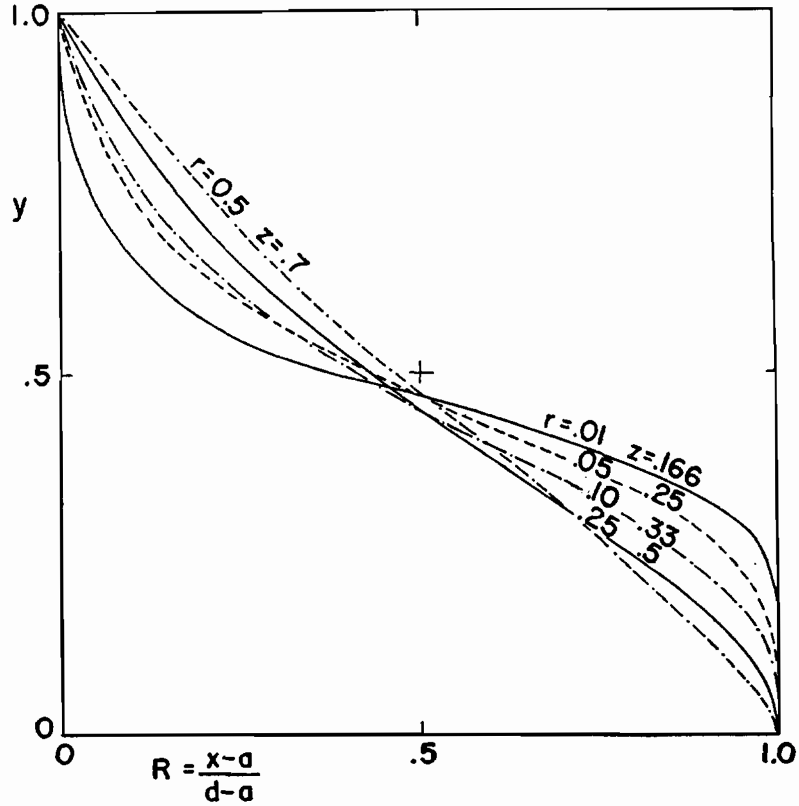

FIGURE 6.—COMPARISON OF SEVERAL CURVE FAMILIES

Showing the effect of varying the value of r in the model hypsometric function. Integrals of these curves are approximately the same.

Because one method of fitting model curves to natural hypsometric curves involves the matching of integrals, it is desirable to have a means of obtaining from a given integral the exponent, z, of a particular model curve which possesses that integral. A graphic solution is shown in Figure 7. Given an integral, measured by planimeter from a natural hypsometric curve, and having selected by inspection the curve family whose value of r gives the closest fit as to shape, one can read the desired value of z.

Inflection Points and Slopes

The point of inflection on any of the model hypsometric curves where z is less than 1.0 may be obtained by the usual method of setting the second derivative of the function equal to 0. For plotting, it is convenient to find the inflection point in terms of R in Equation IV, as the following equation:

$$\text{V} \qquad R_i = \frac{1 + z - 2r}{2\,(1 - r)}$$

where R_i is the value of R at which the curve inflects. Inflection points and the curves on which they lie are shown on the graphs for the several values of r (Fig. 5; Pl. 1).

Inflection points have morphological significance on hypsometric curves because they mark the level at which the rate of decrease of mass upwards changes from an increasingly rapid rate of decrease to a diminishing rate of decrease. Further investigation may prove this feature to be related to dynamic factors, such as the relative importance of sheet runoff

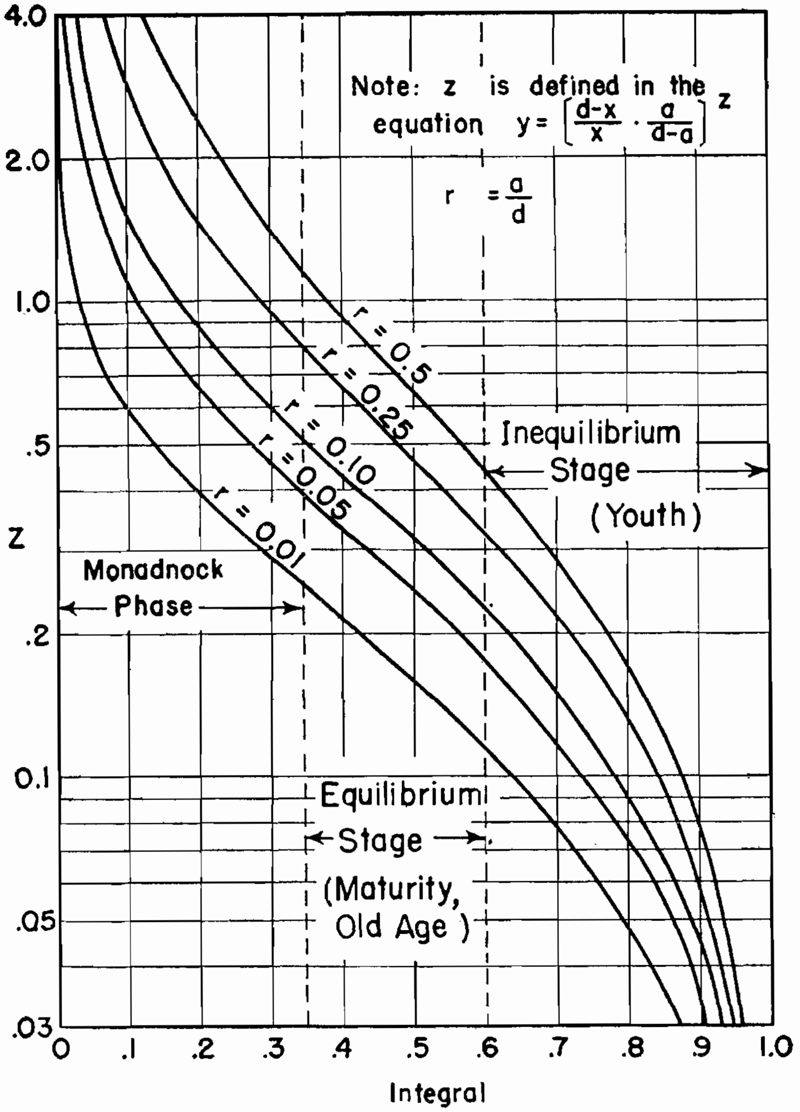

FIGURE 7.—GRAPHIC SOLUTION OF INTEGRALS AND EXPONENTS
For curve families produced by five selected values of r. (See Plate 1 for further data.)

and creep at higher levels compared to channel erosion at lower levels.

While the position of the inflection point on a natural hypsometric curve is greatly affected by chance irregularities of form not significant in the gross aspect of the drainage basin, the slope of the curve in the general region of the inflection can be expected to be a reliable form element. Comparisons of the curve families show that slope at the inflection point is steep where r has high values and diminishes as r decreases. For the curve family $r = 0.5$, the slopes approach 80 per cent near the center of the diagram, while for the family $r = 0.01$ they are reduced to about 30 per cent.

Hypsometric slope at the inflection point is thus a form characteristic which can be rapidly determined and used as one means of fitting natural to model curves. When the slope of the natural curve in the vicinity of its inflection point has been measured, the curve can be matched to the family having a similar slope.

Then, by matching integrals, the particular value of z can be determined.

Precise values of slope at inflection points can be determined from Equation IV by taking the first derivative of the function and substituting for R the various values of these inflection points already obtained. In view of the labor of calculation involved and the fact that exact values are not required for any uses of hypsometric analysis thus far made, the slopes listed opposite each integral on the graphs were determined by direct angular measurement from the graphs. These are, of course, subject to errors in the use of the protractor on a curve drawn through a number of plotted points.

Relation of Hypsometric Curve to Ground Slope

Characteristics of the hypsometric curve are closely related to ground-slope characteristics of a drainage basin. This is evident from the fact that steepening of slopes in the mid-section of a basin will be accompanied by a more rapid rate of change of elevation with respect to change of horizontal cross-sectional area of the basin. One might, at first thought, suppose that steep parts of the hypsometric curve would coincide with belts of relatively steep slopes, gently sloping parts of the curve with gentle ground slopes. Unfortunately the relationship is not so simple. Figure 8 shows a small drainage basin; Figure 9 is the corresponding hypsometric curve. The curve has a gentle slope in the upper part, corresponding with a broad divide area on the map. The steep intermediate part of the hypsometric curve corresponds with steep valley wall slopes in the mid-section of the basin. But the very lowest part of the curve is steepest of all in the region corresponding to the mouth area of the basin, whereas the contours of the map show that the ground slopes are less here than in the mid-section of the basin. The additional factor is, of course, the length of the belt between successive pairs of contours. ("Length" refers to distance along the contour.) Only if each contour belt is the same length can steepness of ground slope vary directly as steepness of hypsometric curve. In Figure 10, all contours have the same length, and the slope profile is identical with the hypsometric curve. Obviously a drainage basin cannot fulfill this condition while narrowing to a mouth through which all drainage is discharged by a narrow channel; a shortening of the length of contours to a minimum approaching zero is required as the drainage basin is followed to its mouth. At the upper end of the drainage basin, the contours can maintain nearly equal length up to the divide (which may be horizontal), but normally the contour length diminishes here, too, to approach zero on the highest peak. Thus the characteristic steepening of hypsometric curves both at the lower and upper ends in mature topography is explained by the diminishing contour lengths.

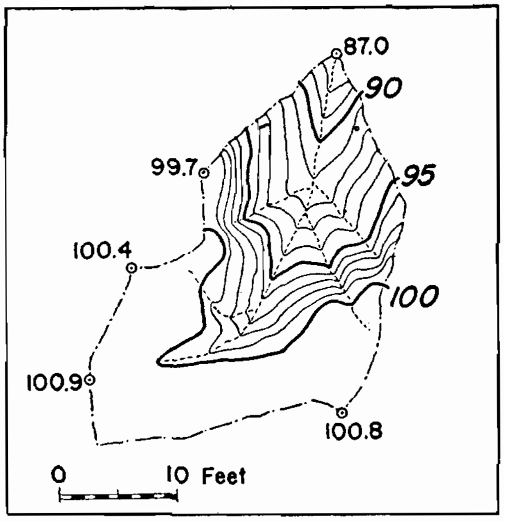

FIGURE 8—SMALL DRAINAGE BASIN IN BADLANDS, PERTH AMBOY, NEW JERSEY

From a special large-scale topographical survey.

To relate hypsometric curve to ground slope it is necessary to take contour length into account. First, the length of each contour line is measured. For each belt of ground between two successive contours the lengths of the upper and lower contours are added and the sum divided into two, giving a rough mean length for the contour belt (Fig. 11). Next the area of the contour belt is measured by planimeter. Dividing area of the contour belt by mean length gives a rough mean width (horizontal distance) for the belt. Now, by dividing the contour interval by the mean width we can

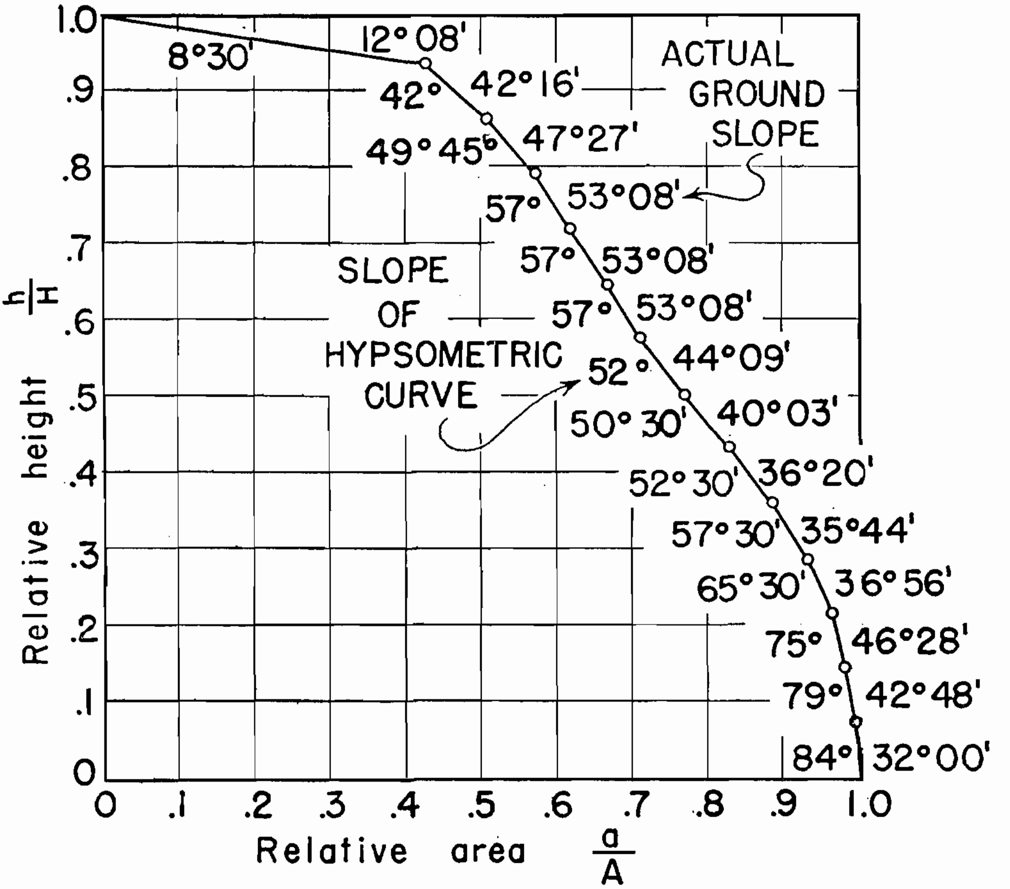

FIGURE 9.—HYPSOMETRIC CURVE OF BASIN SHOWN IN FIGURE 8
Showing relation between slope of segments of hypsometric curve and actual mean ground slopes of corresponding segments.

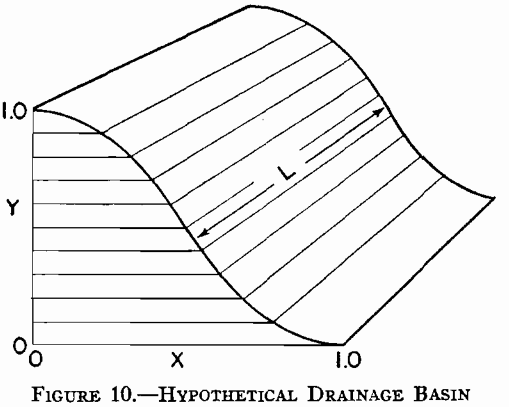

FIGURE 10.—HYPOTHETICAL DRAINAGE BASIN

determine the mean slope of the ground within this particular contour belt, for, $\tan \alpha = \frac{h}{w}$,

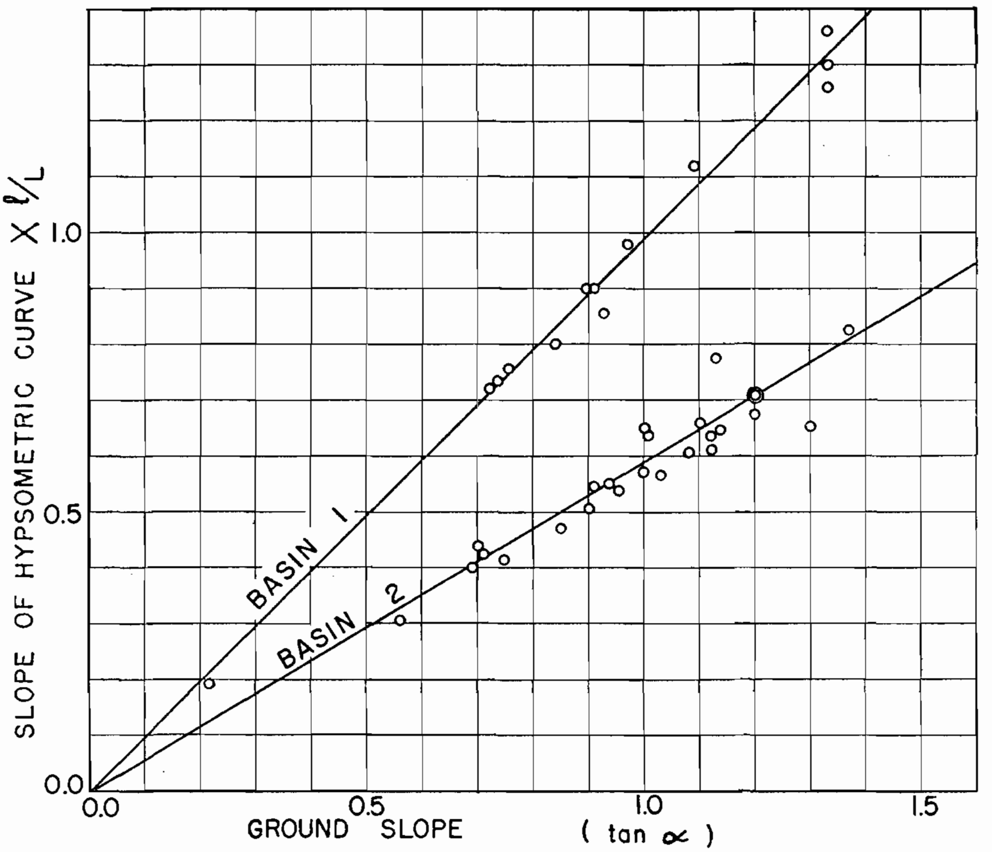

FIGURE 12.—CORRELATION OF MEAN GROUND SLOPES AND ADJUSTED SLOPES OF HYPSOMETRIC CURVE SEGMENTS
Basin 1 same as that in Figures 8 and 9.

where
α is angle of ground slope,
h is contour interval
w is mean width of the belt measured in horizontal projection.

Values of mean slope angle for the basin shown in Figure 8 are written directly on the hypsometric curve (Fig. 9) opposite the particular segments to which they relate. The calculated mean slope figures compared with the slope of the hypsometric curve shows rough correspondence only in the upper part. If, however, we correlate the mean ground slope figures with the contour map of the basin, the slope angles vary as the spacing of the contours, being highest in the midsection, where slopes up to 53° are found.

Relationship of hypsometric curve to mean ground slopes may be summarized by the following equation, which takes into account relative length of each contour belt.

VI $$\frac{l}{L}\tan\theta = \kappa\tan\alpha$$

where θ = slope of hypsometric curve
α = mean ground slope
l = contour length at given relative height
L = length of longest contour in basin
κ = a constant

To test the usefulness of this equation, the values of ground slope have been plotted against corresponding values of hypsometric curve slope for each contour interval of the drainage basin (Fig. 12, Basin 1). Also plotted on Figure 12 are corresponding data for a second drainage

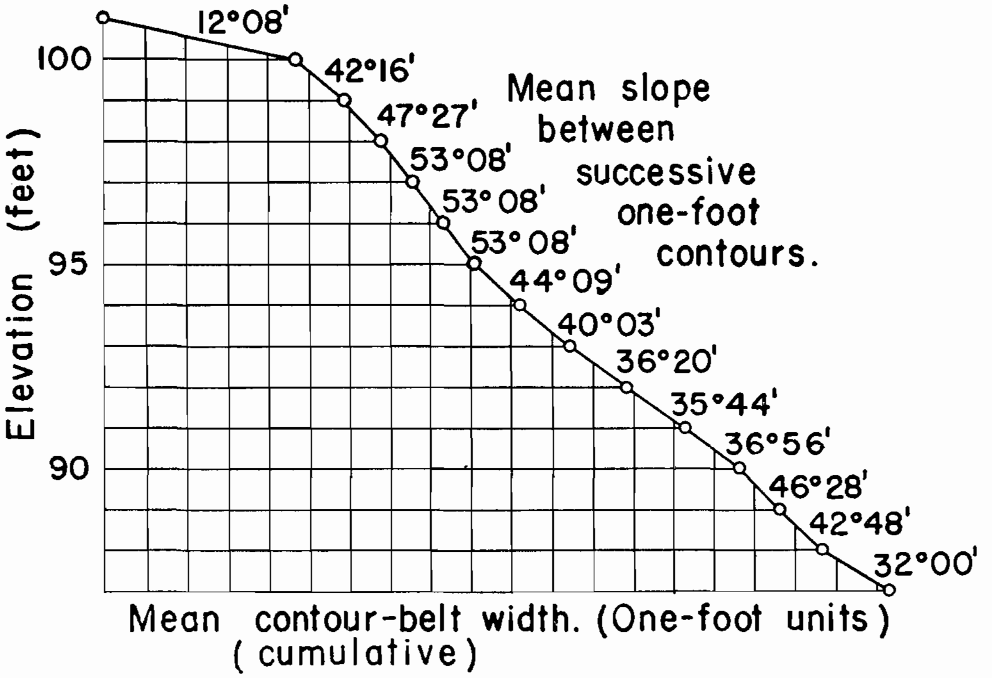

FIGURE 13.—TRUE MEAN-SLOPE CURVE OF BASIN SHOWN IN FIGURE 8

basin which is in the equilibrium (mature) stage of development and has a narrow divide ridge crest. Note that the two curves, which were fitted by inspection, pass through the origin but have markedly different slopes, which may be attributed to the difference in stage of development of the two basins. The tangent function is extremely sensitive to small errors of horizontal measurement, and, because the range of error in measurement from the map is relatively large, the values are subject to considerable variation. Hence these correlation diagrams should be thought of as only demonstrating the general validity of Equation VI.

A profile of the true mean ground slope (Fig. 13) is a cumulative plot of mean-slope angles for each contour belt. This curve differs from the hypsometric curve of the same basin (Fig. 9) in that the mean-slope curve is plotted with absolute values, the scale of feet being the same on both ordinate and abscissa. By use of this curve, ground slope distribution with respect to height can be depicted for direct visual analysis, inasmuch as the slope of the curve is the actual mean ground slope.

GEOMORPHIC APPLICATIONS OF HYPSOMETRIC ANALYSIS

The Geomorphic Cycle

The hypsometric curve exhibits its widest range of forms in the sequence of drainage basins commencing with early youth (inequilibrium stage), progressing through full maturity (equilibrium stage), and attaining temporarily the monadnock phase of old age.

A drainage basin in youth is shown in Figure 14. It is from the Maryland coastal plain where a large proportion of upland surface has not yet been transformed into valley-wall slopes. The hypsometric curve has a very high integral, 79.5%, indicating that about four-fifths of the landmass of the reference solid remains. Despite the bold convexity of the curve through its central and lower parts, the upper end has the concavity typical of nearly all normal drainage basins, and shows that some relief does exist in the broad divide areas.

Figure 15 represents a small drainage basin in fully mature topography of the Verdugo

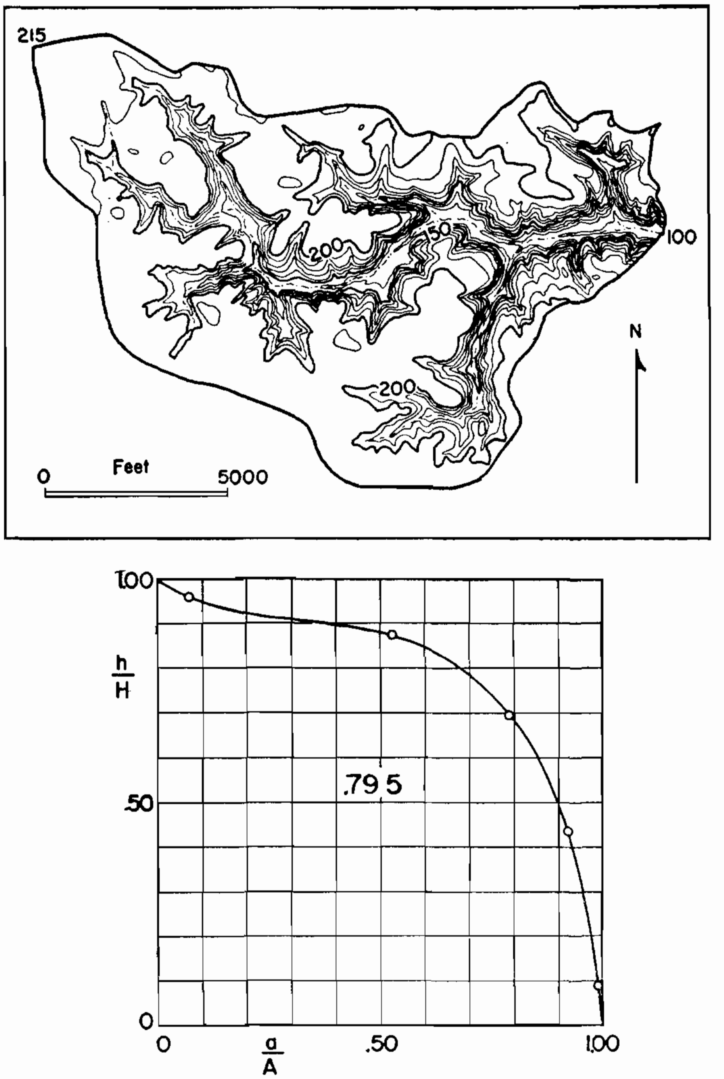

FIGURE 14.—INEQUILIBRIUM (YOUTHFUL) STAGE

Hills, southern California. Here divides are narrow and no vestiges remain of an original surface. The hypsometric curve passes approximately across the center of the diagram, with a hypsometric integral of 43%, and is smoothly s-shaped. This particular curve is typical of third- or fourth-order basins in relatively homogeneous rocks.

In late mature and old stages of topography, despite the attainment of low relief, the hypsometric curve shows no significant variations from the mature form, and a low integral results only where monadnocks remain. For example, a drainage basin in northern Alabama where low relief has developed on weak shales and limestones, but with prominent monadnock masses of sandstone which are outliers of a retreating escarpment, has a strongly concave hypsometric curve; the integral, 17.6%, is unusually low (Fig. 16). After monad-

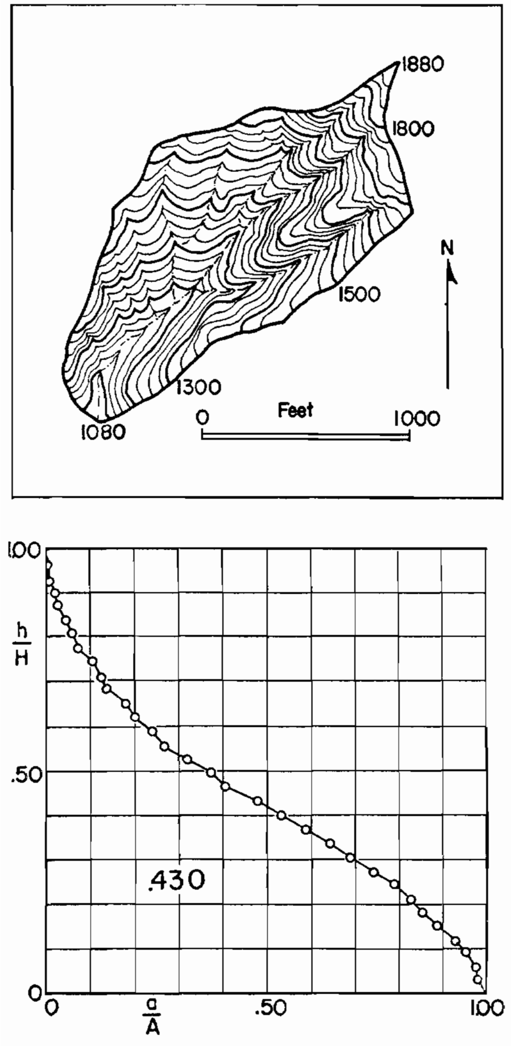

FIGURE 15.—EQUILIBRIUM (MATURE) STAGE

nock masses are removed, the hypsometric curve may be expected to revert to a middle position with integrals in the general range of 40% to 60%.

From the standpoint of hypsometric analysis, the development of the drainage basin in a normal fluvial cycle seems to consist of two major stages only; (1) an inequilibrium stage of early development, in which slope transformations are taking place rapidly as the drainage system is expanded and ramified. (2) An equilibrium stage in which a stable hypsometric curve is developed and maintained in a steady state as relief slowly diminishes. The monadnock phase with abnormally low hypsometric integral, when it does occur, can be regarded as transitory, because removal of the monadnock will result in restoration of the curve to the equilibrium form.

Figure 7 shows relations of hypsometric integral, curve form, and stage of development. Values of z are plotted against hypsometric integrals for each of five families of curves represented by five values of r. From inspection of many natural hypsometric curves and the corresponding maps, the writer estimates that transition from the inequilibrium (youthful) stage to the equilibrium (mature) stage corresponds roughly to a hypsometric integral of 60%, but that where monadnocks become conspicuous features the integrals drop below 35%. These two percentages have, therefore, been used as tentative boundaries of the stages in Figure 7.

The hypsometric curve of the equilibrium stage is an expression of the attainment of a steady state in the processes of erosion and transportation within the fluvial system and its contributing slopes (Strahler, 1950). In this state, a system of channel slopes and valley-wall slopes has been developed which is most efficiently adapted to the reduction of the landmass with available erosional forces, balanced against the resistive forces of cohesion maintained by the bedrock, soil, and plant cover. The basins are no longer expanding in area; they are in contact with similar basins on all sides. The general similarity among hypsometric curves of regions in the equilibrium stage, despite great differences in relief, drainage density, climate, vegetation, soils, and lithology, seems to show that the distribution of mass with respect to height normally follows the s-shaped model hypsometric curve with its upper concavity and lower convexity.

Characteristics of the Equilibrium Stage

Five areas were selected which showed a great range of relief, and for which excellent large-scale topographic maps and air photographs were available. Within each area, six basins of the third or fourth order were outlined and the hypsometric curves plotted for each. A mean curve for each area was obtained

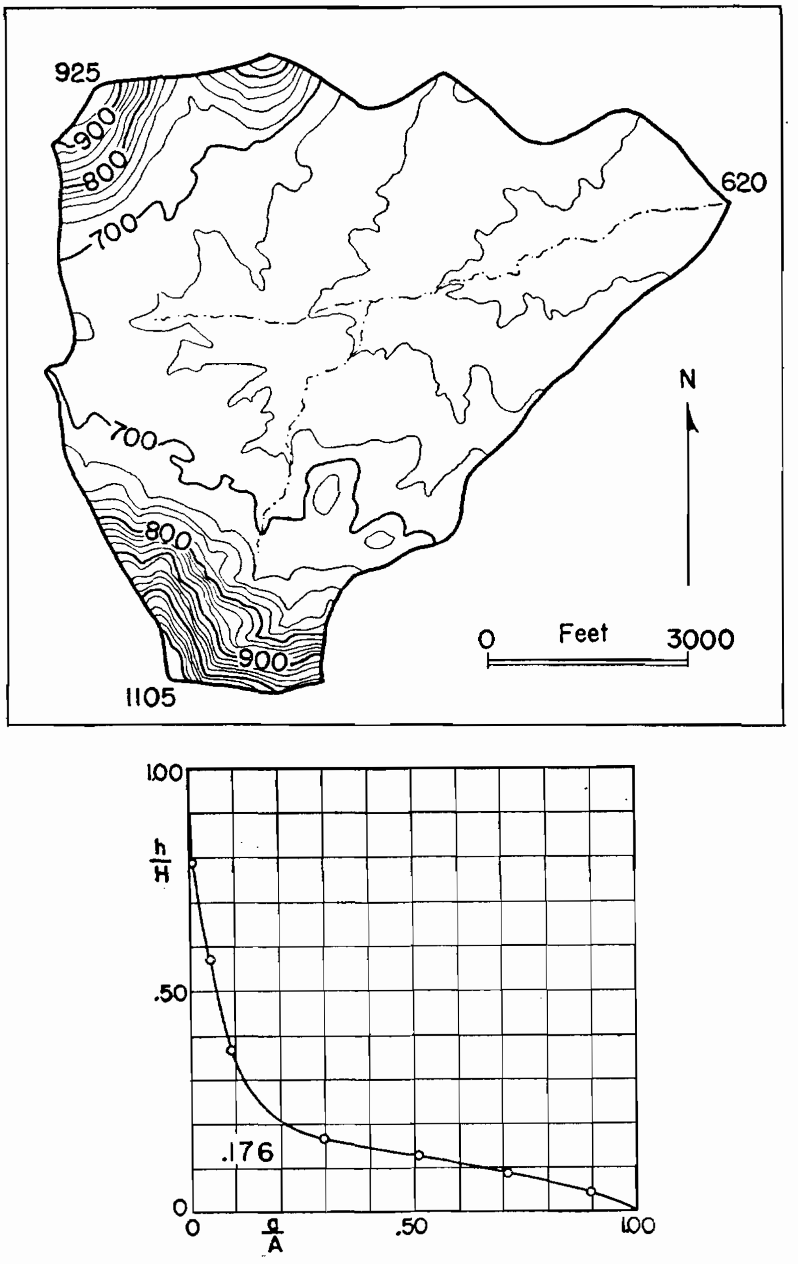

FIGURE 16.—MONADNOCK PHASE

by plotting the arithmetic means of the ordinates of the six individual basin curves at every ten per cent division on the abscissa (Fig. 17). Figure 18 shows one drainage basin from each of the five areas; that basin was selected whose hypsometric curve most closely follows the mean curve shown in Figure 17. In this way the reader can visualize the appearance of a drainage basin embodying the characteristics of the mean hypsometric curve. Table 1 gives additional data relating to composition of the drainage systems.

The five areas selected are all areas of dendritic drainage, largely free from significant structural control. Long-continued fluvial erosion has removed all traces of flat interstream uplands and it is assumed that the basins are stable in form and that the total regimen of erosion and transportation processes is in a steady state. In relief, lithology and rock structure, vegetation, and climate, however, the five areas differ widely. Extremely low relief on weak Pliocene deposits of the Citronelle formation in western Louisiana is represented by the second area; low relief on Precambrian Wissahickon schists of the Piedmont Province in Virginia by the first area: moderate relief developed on cherts and cherty limestones of the Ozark Plateau province is exemplified by the third area. Extremely rugged terrain of strong relief and steep slopes on deeply weathered metasediments of the lower coastal ranges of the Los Angeles region is seen in the fourth area; great relief with moderately steep slopes on deeply weathered Precambrian Wissahickon schists of the southern flank of the Great Smoky Mountains in the fifth area.

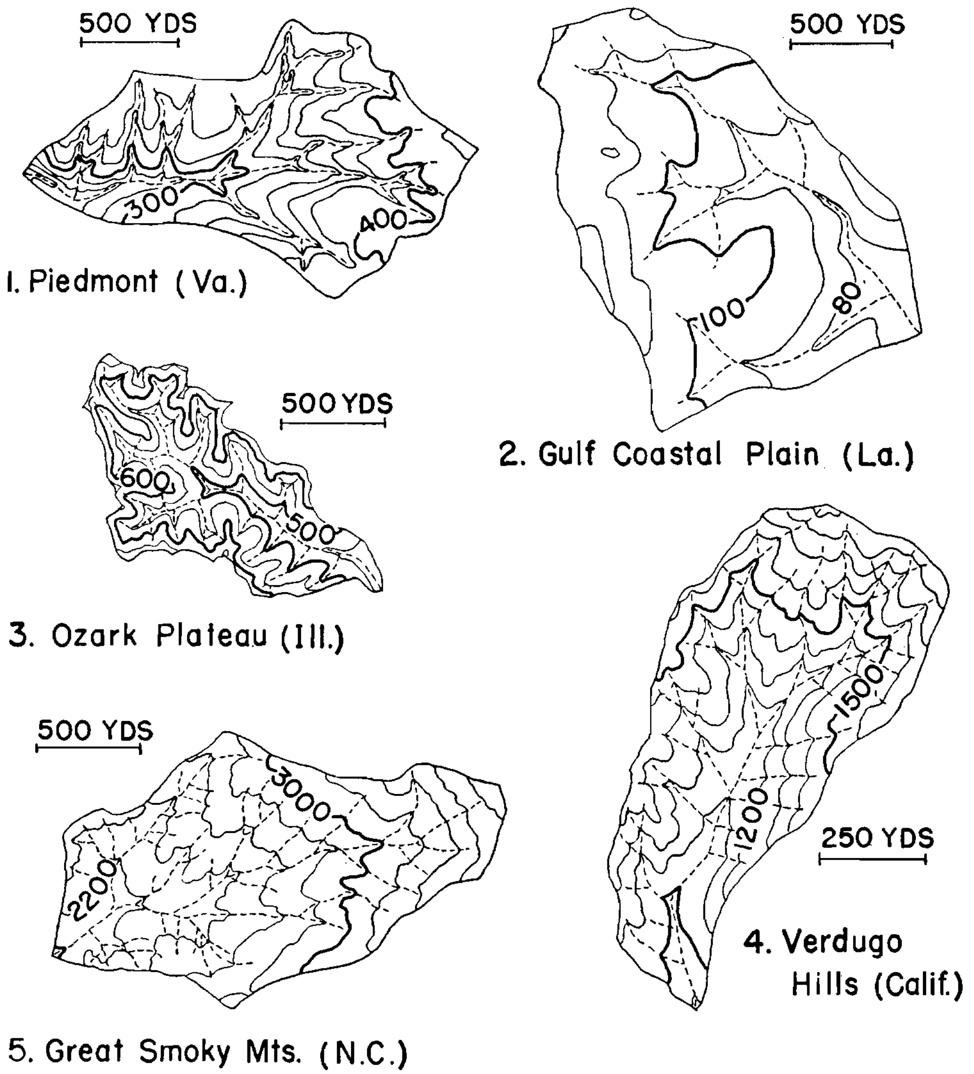

FIGURE 18.—REPRESENTATIVE BASINS FROM FIVE SAMPLE AREAS

[Showing the one drainage basin whose hypsometric curve most closely fits the sample mean curve of Figure 17. Localities as described in Figure 17.

(1) analysis of the hypsometric curves, similarities and differences, and their degree of resemblance to the model hypsometric function; (2) a comparison of hypsometric data with other categories of data, such as drainage network and slope characteristics. It was hoped that significant differences in the hypsometric curves could be correlated with significant differences in other drainage basin characteristics, and that this might provide clues to causative factors determining the hypsometric properties of mature topography.

The mean curves shown in Figure 17 have appreciable differences both in hypsometric integral and in form. The mean curves were fitted to the theoretical function by inspection, and the apparent best fits are described on the curves and in Table 1 by values of r and z. All five curves were best described by the families having r values 0.1 or 0.25 and we may infer that mature topography in relatively homogeneous materials tends to fall within this general range. Fit was very good for curves 1 and 5, but was good only in the inflection

zone and at one end in the other three. All natural hypsometric curves suffer from some degree of misfitness at the lower end owing to the development of a valley-bottom flat which prevents the curve from approaching the value of 1.0 on the abscissa as closely as on the model curves.

All five mean curves show a similar slope in the inflection zone. This ranges from 0.52 to 0.65 (27½° to 33°), and may prove to be a common characteristic of the mature or equilibrium form, along with the tendency to resemble the family of curves having values of r of 0.1 to 0.25. Note also that the location of the inflection point of the curve is generally higher for the areas of low relief (Nos. 1–3) than in the areas of great relief (Nos. 4 and 5). Within any one of the families of model curves, the inflection point likewise moves down as the integral diminishes, but in the five mean curves shown here the inflection points all tend to be located higher than in the model curves to which they were fitted.

Because each of the mean curves represents a sample of only six basins, and the differences, while conspicuous on the graph, are not great, it might well prove that the differences between integrals are not statistically significant, but might result from expectable variations inherent in small samples despite the fact that no real differences exist from one area to the other as regards the hypsometric characteristics. We must assume first that the sampling was randomized. In actual fact, basins were selected which appeared most representative of the general facies of the area as a whole. None was discarded or added after data analysis was begun. At the time of selection the writer was not aware of possible differences in hypsometric or other form characteristics which might later appear, nor did he have in mind any particular trend which he expected the analysis to reveal. The selection, therefore while not mechanically randomized, is thought to be free of conscious prejudice.

Table 2 gives the sample mean, estimated standard deviation of the population (s), and standard error of the mean ($s_{\bar{x}}$) for each sample, consisting of the hypsometric integrals of the six individual basin curves. The table also shows the percentage probabilities of any two samples being drawn from a population with the same mean. The significance test is based upon the t distribution, which is used for small samples. In this instance all tests involved samples of 6 and the table of t is entered under the heading of 10 degrees of freedom. The probability stated is that representing the area for Five Sample Areas

*Showing means, estimated standard deviation of the population, s, and standard error of the mean, $s_{\bar{x}}$, as estimated from the sample. Probability figures refer to results of t tests of significance of difference in sample means of each pair indicated by bracket. Although integrals are here ranked in descending order, as in Figure 17, the probability figures have no relationship to ranking significance. Probability figure tells only the percentage of times that sample means drawn repeatedly from the same pair of areas will differ by this amount or more through chance variations in sampling alone, assuming that no real difference in the two population means actually exists.

under both tails of the t distribution curve, and hence tells the probability of obtaining differences of sample means as great as, or greater than, the observed differences, with the possibility of either mean being the larger.

Note that, in Table 2, no significant difference is found between means of any two samples whose mean integrals differ by only 5 or 6% or less, but is present when the means differ by 8% or more. While we cannot easily determine the significance of the ranking, or the probability of rearrangements being likely to occur in the ranking if similar samples of six basins were repeatedly drawn, we can perhaps safely infer that any two consecutive members of the series might readily reverse their order if another set of samples was taken, but that it is most unlikely that one of the last two members of the series could switch places with the first two.

Relation of Hypsometric Forms to Drainage Forms

It is not immediately apparent just why any two integrals of the mean hypsometric curves should differ significantly, or why they should fall into the general sequence which they take. In an effort to obtain clues to this problem, measurement was made of the stream number and length characteristics, drainage density, slopes, relief, and stream gradients. These data are tabulated in Table 1. A number of observations relating to correlation, or lack of correlation, among the various form factors of the topography are as follows:

In general, drainage basin height, slope steepness, stream channel gradients and drainage density show a good but negative correlation with the integral of the hypsometric curve. We may say that mature basins of low relief, gentle slopes, gentle stream gradients, and low drainage density tend to have relatively high integrals; that areas of strong relief, steep slopes, steep stream gradients, and high drainage density tend to give relatively low integrals in the average drainage basin of the third or fourth order. Table 1 bears this out well if over-all trend of the series is considered, but the values of areas 1 and 2 are in reverse order, as are the values of areas 4 and 5. As already stated, however, differences of integral in these two pairs of samples are not significant (see Table 2) and they might easily exchange positions on the list if another sample were taken. What is significant is that Nos. 1 and 2 show very much lower values of drainage density, basin height, slope steepness, and stream gradient than do Nos. 4 and 5, while No. 3 occupies an intermediate position in all cases.

No correlation seems to exist between hypsometric integrals and either bifurcation ratios or length ratios (Figs. 19, 20). Horton (1945, p. 290) states that bifurcation ratios range from about 2 for flat or rolling country up to 3 or 4 for mountainous regions. The writer's data, based on large-scale maps checked in the field or by stereoscopic study of air photographs, show not only considerably higher ratios, but a complete lack of correlation of ratio with relief. Horton's data were taken from comparatively crude, small-scale maps and he must have omitted a large proportion of the stream channels of first and second order which actually exist.

A positive correlation is evident between the average length of the stream segments of any given order in each area and the corresponding mean hypsometric integrals. Figure 20, in which mean stream lengths are plotted against order numbers, shows progressive decline in stream length from left to right, in the same order as that in which the integrals diminish. Although reversals occur in the trends of the first and second order lengths, the values for areas 1 and 2 are always higher than those of areas 3, 4 and 5.

Because length of stream segments tends to become less as drainage density increases, it is only to be expected that the first two areas, whose texture is coarse, would have longer stream segments than the last three areas, whose texture is much finer. Now, since the mean integrals decrease as drainage density increases, the effect is to give a positive correlation between mean stream segment lengths and mean hypsometric integrals.

Geologic Factors Affecting Equilibrium Forms

Turning from a purely quantitative analysis of the various categories of morphometric data to a qualitative approach, there are several topographic and geologic factors apparent to the investigator to which he can attribute certain of the differences in hypsometric curve forms.

The extreme members of the series (curves 1 and 5, Fig. 17) are developed on essentially similar types of rock, mapped as the Wissahickon schist. A t test of significance of difference of sample mean integrals (Table 2) shows a probability less than .001, leading us to discard the hypothesis that both samples have

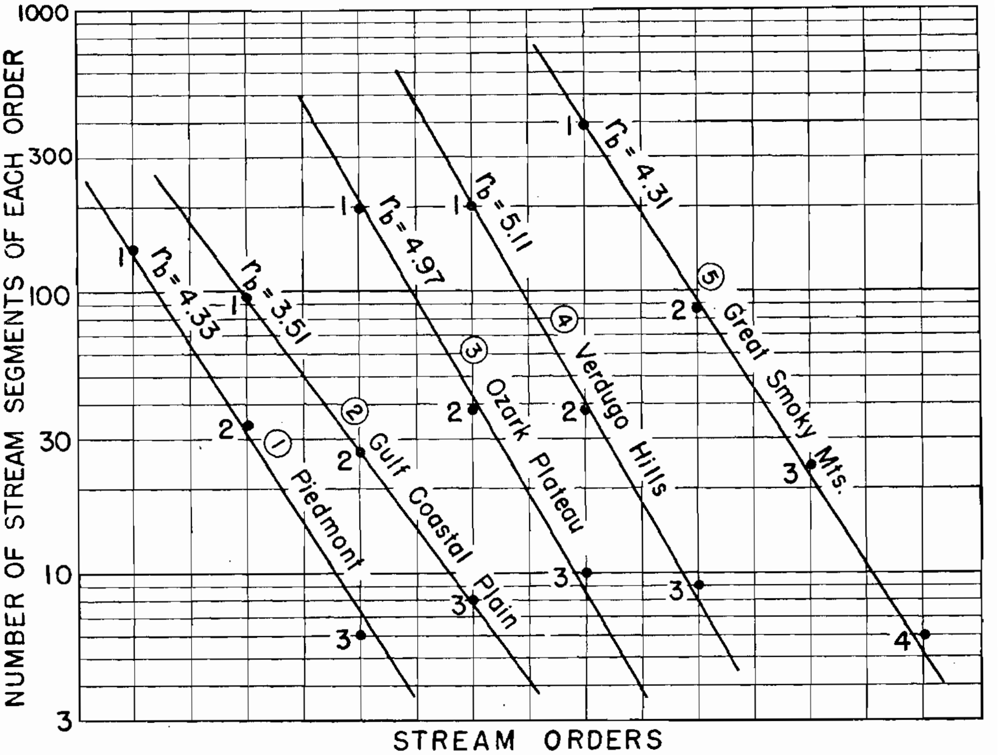

FIGURE 19.—STREAM NUMBERS AND BIFURCATION RATIOS FOR FIVE SAMPLE AREAS

Fitted curve has slope of bifurcation ratio, r_b, whose mean value is given for each area. Number beside each dot is order number.

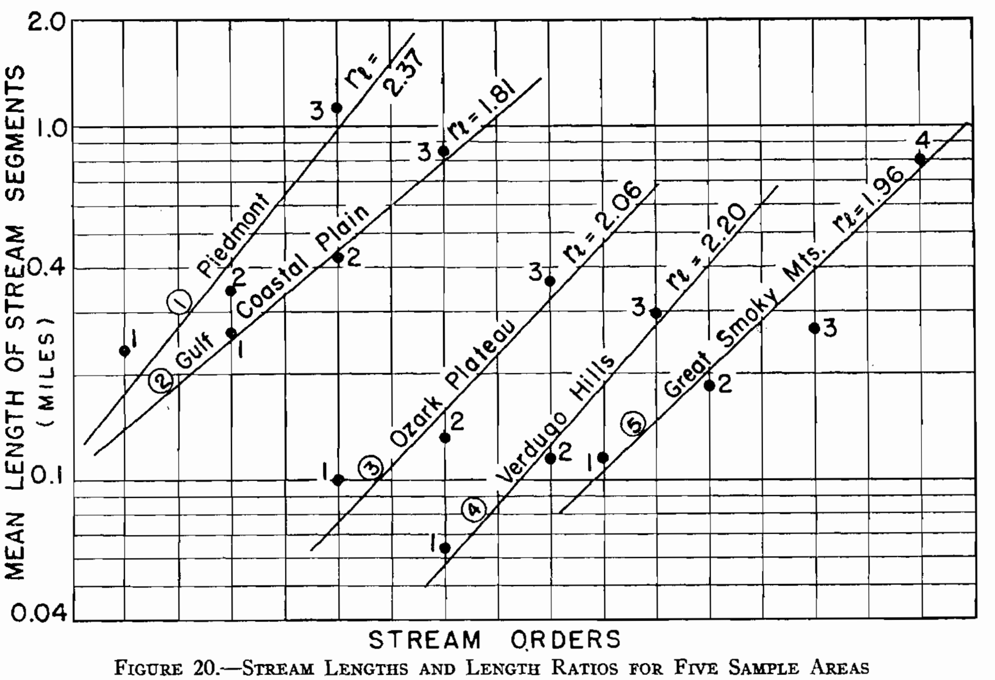

FIGURE 20.—STREAM LENGTHS AND LENGTH RATIOS FOR FIVE SAMPLE AREAS

Fitted curve has slope of length ratio, r_l, averaged for each area. Number beside each dot is order number.

the same popalation mean. The hypothesis that similarity of rock gives similarity of integral is not sustained. Some other cause (or causes) has produced a significant difference in the mean hypsometric integrals.

Cause of the hypsometric curve differences may lie in the geomorphic histories of the two areas. The Piedmont locality is thought to have been reduced to a peneplain, then dissected into a rolling topography of low relief in the present cycle. If so, the high integral (almost 0.60) may be an expression of submaturity, with extensive divide areas as yet not entirely transformed into the equilibrium slopes of the mature stage. But neither field examination nor map-air photograph study shows a distinctive unconsumed upland element, such as one is accustomed to seeing, for example, on the Maryland coastal plain (Fig. 14) or in the older drift plains of the middle west where maturity is being approached. Instead, the divides are broadly rounded and nothing suggests a composite topography involving two distinct cycles. The high integral of this hypsometric curve may, however, mean that, following the attainment of an equilibrium system, an acceleration of stream corrasion associated with increasing relief set in, perhaps induced by regional upwarping and an over-all steepening of gradient of east-flowing master streams. Do we have here a manifestation of the Penckian principle of waxing development (*aufsteigende Entwicklung*)?

The basins in the south flank of the Great Smoky Mountains produce a mean hypsometric curve with an unusually low integral, about 0.40 (Fig. 17). The inflection point is located low on the curve, and the upper two-thirds of the curve takes a broadly concave form. The topographic maps show a noticeable steepening of slopes above the level of 2800–3000 feet occurring at about 40%–50% of the basin height. The steepening of slopes with higher elevation is not sharply defined, as instructural benching found in a region of horizontal strata, but may be caused by differences in rate of rock weathering at low and high altitudes. For example, if rate of alteration of the feldspars and ferromagnesian minerals were appreciably faster in the warmer temperatures of the valleys, an opening out of the valley bottoms might perhaps be expected.

Among localities 2, 3, and 4, hypsometric differences are not strong. The curves of the Ozark Plateau basins and those of the Verdugo Hills basins are remarkably similar, with no significant difference statistically (Table 2), despite the fact that the Ozark Plateau is a region of flat-lying Paleozoic chert and cherty limestone with an over-all uniformity of summit levels, whereas the Verdugo Hills are part of a rugged, up-faulted mountain block consisting of metamorphosed sediments and intrusive bodies. The Ozark curve departs from the theoretical function at the upper end, where an excessive concavity is developed. This may be an expression of the sapping of weaker formations from beneath more resistant beds near the summit, a condition which might be expected in horizontal sedimentary strata.

The hypsometric curve of the Louisiana Gulf Coastal Plain locality has a relatively high integral, 0.54, but is otherwise quite conventional in appearance. Such small relief and faint slopes prevail here that very little of value can be discerned from the topographic map or air photographs. The area is located within the belt assigned to the Montgomery Terrace of Sangamon age by Fisk (1939, p. 193) at elevations from 120 to 140 feet. The surface is underlain by the sandy Citronelle formation. The high integral might perhaps be explained by a submature condition, in which insufficient time has elapsed for attainment of full maturity. As in the Piedmont locality, however, nothing in the topography suggests remnants of an initial surface not as yet completely consumed. The high integral may perhaps be a reflection of slightly accelerated stream erosion rates as a result of recently accelerated southward tilting of the region associated with epeirogenic uplifts (Fisk, 1939, p. 199) and might perhaps be a manifestation of waxing development (*aufsteigende Entwicklung*). At the present elementary stage of our investigations of the quantitative characteristics of erosional topography, we lack criteria for distinguishing among hypsometric curve forms modified by epeirogenic crustal movements, those modified by rejuvenations induced by falling sea level, and those representing stages in attainment of equilibrium under stable crustal and sea level conditions.

Influence of Horizontal Structure

It is obvious that drainage basins developed in horizontally layered rocks, whether sedimentary strata or lavas, will have strongly modified hypsometric curves if there are marked differences in rock resistance on a scale which is large in proportion to the height of the basin. In the region of cherts and cherty limestones of the Ozark Plateau Province, described above as one of the mature areas in apparently homogeneous materials, structural benching did not seem to produce any conspicuous influence in the hypsometric form. Let us turn, then, to a contrasting example, where structural control is predominant: the regions of cliffs, buttes, and mesas of the southern Mesa Verde, located in northwestern New Mexico, within the Rattlesnake and Chimney Rock quadrangles.

Figure 21 compares three hypsometric curves. The first is of a drainage basin about 4 square miles in extent consisting of a deeply-incised canyon surrounded by a stripped structural surface of low relief. The canyon is cut into the Mesa Verde sandstones and represents a deep re-entrant into the ragged escarpment rising above a broad lowland of weak Mancos shales. As we might expect, the hypsometric curve has a high integral, 68%, and resembles the curve of a youthful region in the inequilibrium stage of development, except for a considerable degree of relief in the upper part of the basin, above the flattened part of the curve which represents the break from canyon walls to stripped surface. In the normal curve of the young basin (Fig. 14), relief on the interstream areas is much less, as we would expect of an initial surface of deposition.

The second curve in Figure 21 shows an abnormally low integral, 33%. This basin is almost entirely in Mancos shale, which extends out from the base of the escarpment but includes a small remnant of the Mesa Verde sandstone, Chimney Rock, rising strikingly from the shale plain. This basin represents a stage in retreat of a cliff line in which the resistant bed is all but completely removed. It is in virtually the same phase as the monadnock phase of the normal cycle (Fig. 16).

The third curve, intermediate between the first and second, represents a basin entirely underlain by the Mancos shale, well out beyond the limits of the escarpment. Here no vestiges remain of the overlying resistant formation and the basin is in a virtually homogeneous

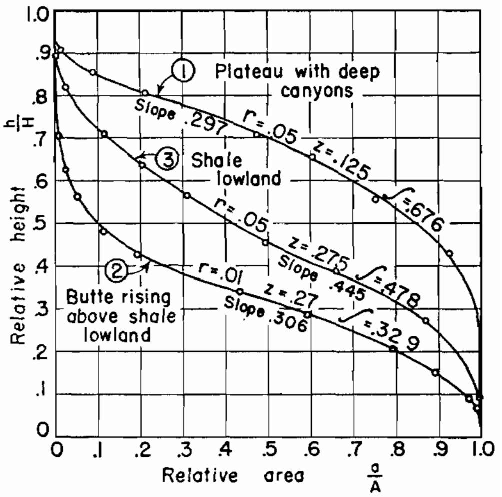

FIGURE 21.—HYPSOMETRIC CURVES OF THREE BASINS IN MESA VERDE REGION, NORTHWESTERN NEW MEXICO

From Chimney Rock Quadrangle, New Mexico, U. S. Geological Survey, 1:62,500.

weak material. Here, as is normal in the equilibrium stage, the integral is close to 50% and the curve has a smooth, s-shaped form which is well described by the model hypsometric function with the values $r = 0.05$, $z = .275$.

To summarize the effect of massive, resistant horizontal strata of an erosional escarpment upon the hypsometric function: a high integral characterizes the early phases of development in the zone of canyon dissection close to the cliffs; the integral drops to low values as the proportion of basin of low relief on weak rock increases and the remnants of resistant rock diminish; and finally, when the basin is entirely in weak rock, the curve reverts to the normal form of the equilibrium stage.

A good example of the modified hypsometric curve resulting from the presence of a massive, resistant formation above a weaker rock is found in the dissected plateau near Soissons, France, north and south of the Aisne River. There the Tertiary chalk forms an extensive interstream upland surface at 170–200 meters elevation. The Aisne and its immediate tributaries have cut into weak sands and clays be-

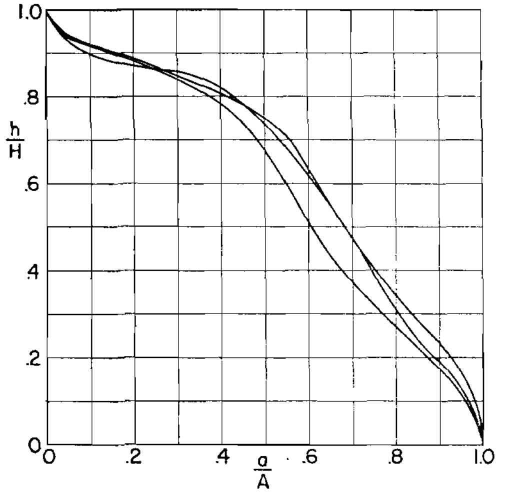

FIGURE 22.—HYPSOMETRIC CURVES OF THREE BASINS NEAR SOISSONS, FRANCE

Showing influence of a resistant chalk formation upon curve form. From Soissons Quadrangle, France, 1:50,000.

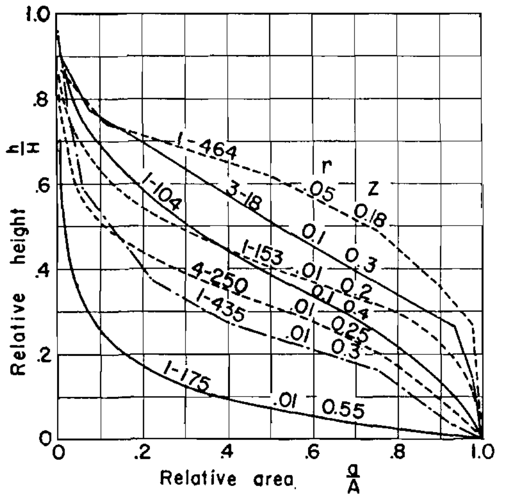

FIGURE 23.—HYPSOMETRIC CURVES OF LARGE DRAINAGE BASINS

From Langbein (1947). Values of r and z, added by writer, were fitted by inspection.

neath the chalk, giving the drainage basins steep inner slopes but very gentle slopes on the extensive divides. Curves of three third-order basins ranging from 14–26 square kilometers in area differ slightly in integral, but are remarkably alike in form (Fig. 22). Note that the resistant chalk produces a high integral and a pronounced convexity in the upper third of the curve. This curve has a double inflection and does not fit the model hypsometric function.

PRACTICAL APPLICATIONS OF HYPSOMETRIC ANALYSIS

The hypsometric analysis of drainage basins has several applications, both hydrologic and topographic. Langbein (1947) applied the percentage hypsometric curve to a number of New England drainage basins (Fig. 23) of a much larger order of size than those analyzed here, but the curves have basically similar forms and can be described by the model hypsometric function. On Figure 23 the values of r and z are given for the best fit. Fit ranges from fair to excellent, and the results are satisfactory considering that most of these basins lie in a glaciated area combined with complex structure.

Referring to practical value of hypsometric data in hydrology, Langbein states (1947, p. 141):

> "For example, snow surveys generally show an increase in depth of cover and water equivalent with increase in altitude; the area-altitude relation provides a means for estimating the mean depth of snow or its water equivalent over a drainage basin. Barrows (1933) describes a significant variation in annual precipitation and runoff in the Connecticut River Basin with respect to altitude. The obvious variation in temperature with change in altitude is further indication of the utility of the area-altitude distribution curve."

Another application might be found in the calculation of sediment load derived from a small drainage basin in relation to slope. Because the hypsometric function combines the value of slope and surface area at any elevation of the basin, it might help obtain more precise calculations of expected source of maximum sediment derived from surface runoff in a typical basin of a given order of magnitude.

Dr. Luna B. Leopold (personal communication) has applied the hypsometric method to analysis of the relationship of vegetative cover to the areal distribution of surface exposed to erosion in the Rio Puerco watershed, New Mexico. Because of distinctive vertical zoning of grassland, woodland, and forest, the relative surface areas underlain by each vegetative type can be described by the hypsometric function, which can thus be used as a basis for calculation. Furthermore, because rainfall increases with elevation, the hypsometric function can be used to calculate the total area subject to a given amount of rainfall.

A military application of the hypsometric method is foreseen in the use of the hypsometric integral as a term descriptive of the character of the terrain in quantitative terms. A high integral, such as that in Figure 14 would indicate extensive interstream areas of low relief, suitable to the rapid movement of mechanized forces, but with the valleys forming small narrow pockets suitable for defense and not readily observed from outside. A medium integral would indicate that the land surface was almost entirely in slope, which might be steep in a given region, and lacking in extensive belts of easy trafficability, either in the valley floors or along the divides. A very low integral would mean the development of extensive interconnected valley floors adapted to rapid movement, but with isolated hill summits which would offer defense positions with wide visibility. Obviously these terrain characteristics can be seen at a glance from any contour topographic map, and hypsometric analysis would be of value only in quantitative calculations using empirical formulas in which each aspect of the terrain is given a numerical statement.

Planning of soil erosion control measures and land utilization may profit from topographic analysis in which such terrain elements as hypsometric qualities, slope steepness, and drainage density are quantitatively stated.

Introduction

The Unified Stream Methodology (USM) is a collaborative effort between the U.S. Army Corps of Engineers, Norfolk District (COE) and the Virginia Department of Environmental Quality (DEQ). The purpose of this Manual is to describe a method to rapidly assess what the stream compensation requirements would be for permitted stream impacts and the amount of "credits" obtainable through implementation of various stream compensation practices. The Manual describes a process to: 1) assign a **Reach Condition Index (RCI)** to the stream to be impacted; 2) assess the type or severity of impact; 3) determine the compensation requirement; and, 4) determine what types of and the amount of the various compensation practices that will satisfy the compensation requirement. This manual may be used for projects requiring stream compensation under the COE regulatory program and the DEQ's Virginia Water Protection Permit Program (VWPP). This Manual and USM forms can be found on the COE and DEQ webpages US Army Corps of Engineers - Norfolk District and Virginia DEQ - Wetlands.

This method is not intended to take the place of project specific review and discussion, which may result in adjustments to the compensation requirements or credits obtained through application of this process. This method can be applied to stream compensation projects performed on-site, off-site, for a stream mitigation bank, or for an in-lieu fee fund project, thereby, ensuring a standard application for evaluating and crediting all stream compensation projects. This Manual is to be used in wadeable intermittent or perennial streams statewide. The following circumstances require special consideration:

Concrete, Gabion-lined or Riprap Channels

Jurisdictional streams that are entirely contained within concrete, gabion-lined, or riprap channels and do not have normal stream features (sedimentation, vegetation) will be reviewed on a case-by-case basis. Compensation for impacts to these stream channels will generally not be required. However, impacts to these streams will still need to be included in the impact area for permitting purposes. The following photos provide examples of these channel types.

Concrete-lined Channel

Riprap-lined Channel

If these streams have established a naturalized stream cross-section, with normal stream features (sedimentation, vegetation), the agencies may require compensation and the USM would then be required.

Relocated Stream Channels

Streams that will be relocated using the principles of natural channel design may be considered self-mitigating in most cases, eliminating the need to apply the USM. The relocated stream must be designed and constructed to mimic the functions and values of the impacted stream, at a minimum. All relocated streams must be stable. However, if the relocated stream results in a reduced stream length or function, compensation may be required for the difference between pre- and post-construction stream length/function.

Jurisdictional Ephemeral Streams

"Ephemeral Streams" are defined as streams that have flowing water only during and for a short duration after, precipitation events in a typical year. Ephemeral streambeds are located above the groundwater table year-round. Groundwater is not a source of water for the stream. Rainfall runoff is the primary water source for these streams. Jurisdictional ephemeral streams have the presence of an ordinary high watermark.

Ephemeral streams will be reviewed on a case-by-case basis. In the event that compensation is required for impacts to ephemeral streams, the **RCI** is determined by evaluating <u>only</u> the Riparian Buffer Parameter (Section 1.2 and Form 1). The **Condition Index (CI)** calculated from this evaluation is then divided by two (2) to obtain the **RCI**. Proceed to Section 2.0 of this Manual

Organization of USM

This Manual is divided into six sections, summarized below. The sections represent the basic types of analyses that are performed, including assessing existing conditions, characterizing proposed impacts, determining compensation requirements, evaluating precompensation conditions, determining compensation credit, and evaluating total compensation credit.

Section 1 - Stream Impact Site Assessment describes a method to rapidly assess and assign a Reach Condition Index (**RCI**) to a stream reach proposed for impact.

Section 2 - Stream Impact Factor Assessment presents a procedure for characterizing proposed impacts to a stream.

Section 3 - Determining Stream Compensation Requirements explains the method for calculating the compensation required for stream impacts. The factors used in this calculation are the stream assessment **RCI** (Section 1), the type of **Impact Factor (IF)** (Section 2), and the linear feet of impact.

Section 4 – Precompensation Evaluation provides information in evaluating the precompensation stream reach and outlines the components of the conceptual compensation plan.

Section 5 - Determining Compensation Credit explains the various methods by which stream impacts may be compensated and the process for determining credit provided by stream compensation proposals.

Section 6 – Evaluating Total Compensation Credit explains the method for calculating the linear feet of credit obtained after review of stream compensation plans. The factors used in this calculation are the activities credit (Section 5), linear footage of the compensation stream, and any applicable adjustment factors (Section 5).

USM Process

This process can be divided into six steps, outlined below:

Step 1 – Stream Impact Site Assessments

- Determine Length of Assessment Reach
- Perform Assessment and determine applicable Condition Index (**CI**)
  - Channel Condition = 1 – 3
  - Riparian Buffer = 0.5 – 1.5
  - In-Stream Habitat = 0.5 – 1.5
  - Channel Alteration = 0.5 – 1.5
- Calculate Reach Condition Index (**RCI**) using Equation 2
  - **RCI** = (Sum of all **CIs**) ÷ 5

Step 2 – Stream Impact Factor Assessment

- Obtain Impact Factor (**IF**) from Table 1
  - Severe = 1.0
  - Significant = 0.75
  - Moderate = 0.5
  - Negligible = 0

Step 3 – Determine Stream Compensation Requirement

- Calculate Compensation Requirement (**CR**) using Equation 3
  - **CR** = Length of Impact ($\mathbf{L_I}$) × Reach Condition Index (**RCI**) × Impact Factor (**IF**)

Step 4 – Precompensation Evaluation

- Assess Existing Conditions
- Develop Conceptual Plan

Step 5 – Determine Compensation Credit

- Determine Compensation Credit (**CC**) for Applicable Compensation Activities
  - Restoration = 1 credit per foot
  - Enhancement = 0.09 – 0.3 credits per foot per bank
  - Riparian Areas = 0 – 0.4 credits per foot
- Apply Applicable Adjustment Factors ($\mathbf{A_F}$)
  - Rare, Threatened, and Endangered Species or Communities = 0.1 – 0.3
  - Livestock Exclusion = 0.1 – 0.3
  - Watershed Preservation = 0.1 – 0.3

Step 6 – Evaluate Compensation Credit

- Calculate Total Compensation Credit (**Total CC**) using Equation 4
  - **Total CC** = Sum [Restoration Credit + Enhancement Credit + Riparian Buffer Credit + Adjustment Factor ($\mathbf{A_F}$) Credit]
- **Total CC** must be = **Total CR**

1.0 Stream Impact Site Assessment

Impacts are proposed in various qualities of streams. Therefore, it is important to assess the quality of the stream reach being impacted and use that as a factor in determining the **Compensation Requirements (CR)**. There are numerous methodologies that arrive at a numerical index to use as an indicator of stream quality. This assessment is not intended to be a substitute for more detailed stream studies that may be undertaken to determine stream quality, water chemistry, or biological conditions.

Stream impact projects may need to be divided into multiple **Stream Assessment Reaches (SAR)**. The length of the **SAR** is determined by significant changes in one or more of the following four parameters: 1) Channel Condition, 2) Riparian Buffer, 3) In-Stream Habitat, and 4) Channel Alteration. The **Stream Assessment Form (Form 1),** included in Appendix A, is used to record this information for each reach.

1.1 Channel Condition Parameter

Under most circumstances, channels respond to disturbances or changes in flow regime in a sequential, predictable manner. The way a stream responds to changes by degrading to a lower elevation and eventually re-stabilizing at that lower elevation (Figure 1) is the basic premise behind the stream channel evolutionary process. The differing stages of this process can be directly correlated with the current state of stream stability. The purpose of evaluating **Channel Condition** is to determine the current condition of the channel cross-section, as it relates to this evolutionary process, and to make a correlation to the current state of stream stability. These evolutionary processes apply to the majority of stream systems and assessment reaches due to the fact that the majority of stream systems are degrading, aggrading, healing, or stable.
A channel's condition can be determined by visually assessing certain geomorphological indicators. These indicators include channel incision, access to original or recently created floodplains, channel widening, channel depositional features, rooting depth compared to streambed elevation, streambank vegetative protection, and streambank erosion. Each of the categories describes a particular combination of the state of these geomorphological indicators which generally correspond to a stream channel stability condition at some stage in the evolution process.

1.1.1 Channel Condition Categories

Channel Condition is an assessment of the cross-section of the stream, along the stream reach. The channel condition of each **SAR** is assessed using the following five categories. A **Condition Index (CI)** is given for each category; however, there may be rare cases where the stream lies between the descriptions. In these cases, a **CI** between those provided may be used. The Evaluator needs to identify the prevailing channel condition or problem (erosion, deposition, disconnection to the floodplain) and record the associated score in the **CI** box for the channel condition parameter**.**

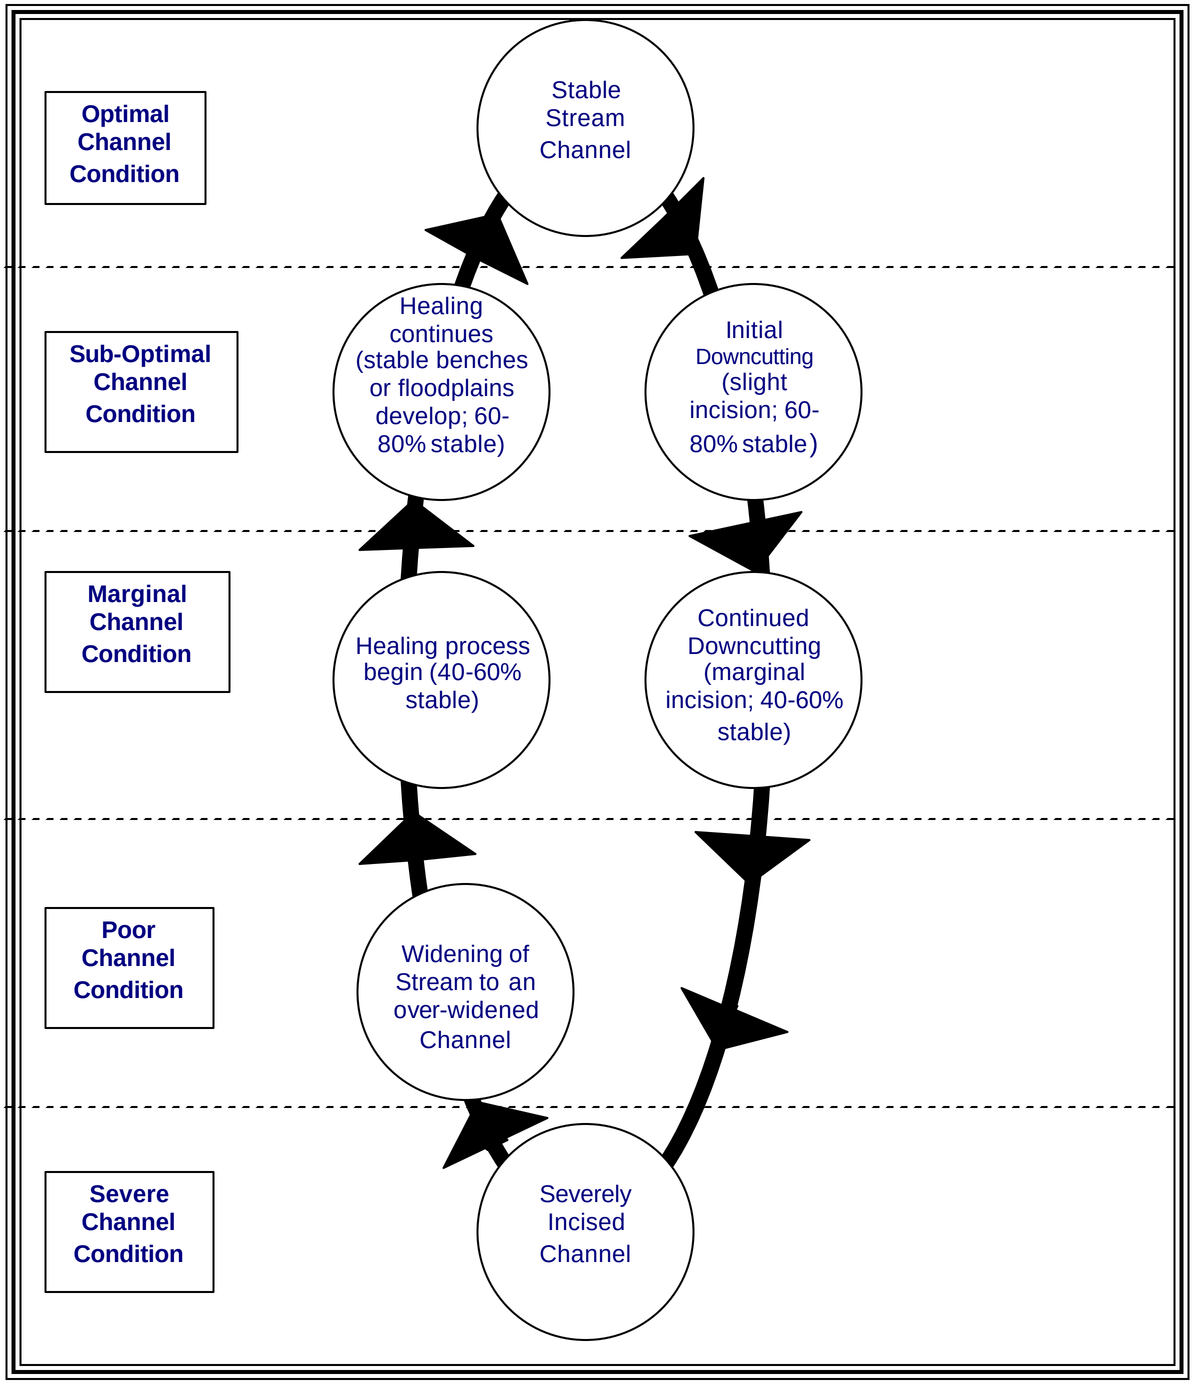

Figure 1: The relationship between the channel evolution and USM Channel Condition

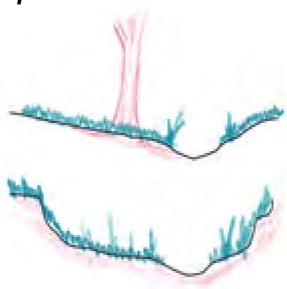
Optimal



These channels show very little incision and little or no evidence of active erosion or unprotected banks. 80-100% of both banks are stable. Vegetative surface protection may be prominent on 80-100% of the banks or natural rock stability present along the majority of the banks.

AND/OR

Stable point bars and bankfull benches are present (when appropriate for the stream type). These channels are stable and have access to their original floodplain or fully developed wide bankfull benches. Mid-channel bars, and transverse bars should be few. If transient sediment deposition is present, it covers less than 10% of the stream bottom.

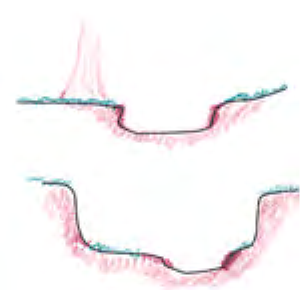
Suboptimal

These channels are slightly incised and contain few areas of active erosion or unprotected banks. The majority of both banks are stable (60-80%). Vegetative surface protection may be prominent along 60-80% of the banks or natural rock stability present along the majority of both banks.

AND/OR

Depositional features (point bars, mid-channel bars, transverse bars, and bankfull benches) are likely present (when appropriate for the stream type) and most are contributing to stability. The bankfull and low flow channels (when appropriate for the stream type) are well defined. This stream likely has access to bankfull benches, or newly developed floodplains along portions of the reach. If transient sediment is present, it affects or buries 10-40% of the stream bottom.

Marginal



These channels are often incised, but to a lesser degree than the ***Severe*** and ***Poor*** channel conditions. The banks are more stable than the stream cross sections in the ***Severe*** or ***Poor*** condition due to lower bank slopes. Erosional scars may be present on 40-60% of both banks. Vegetative surface protection may be present on 40-60% of the banks. The streambanks may consist of some vertical or undercut banks. While portions of the bankfull channel may still widen, other portions have begun to narrow in an attempt to obtain stable dimensions.

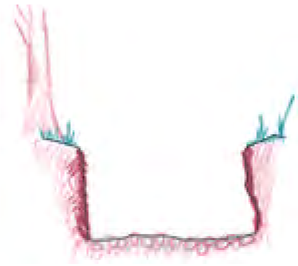
AND/OR

Between 40-60% of the natural stream bed or bottom (pools and riffles) is covered by substantial sediment deposition. Sediment depositional features may be temporary and transient in nature, and may contribute to channel instability. However, depositional features (point bars, mid-channel bars, transverse bars, and bank full benches), that contribute to stability, may be forming or present in the appropriate stream types.

AND/OR

Channels that have experienced historic incision but may be relatively stable (banks and channel) at their existing elevation. These channels may have a V-shape and no connection to their floodplain. Vegetative surface protection is present on greater than 40% of the banks but evidence of instability can be observed in unvegetated areas. Marginal V-shaped channels have depositional features (point bars, mid-channel bars, transverse bars, and bank full benches), which contribute to stability.

Poor



These channels are overwidened and are incised. These channels are vertically and/or laterally unstable. They are more likely to widen rather than incise further. The majority of both banks are near vertical with shallow to moderate root depths. Erosional scars may be present on 60-80% of the banks. Vegetative surface protection may be present on 20-40% of both banks, and is insufficient to prevent significant erosion from continuing.

AND/OR

Between 60-80% of the natural stream bed or bottom (pools and riffles) is covered by substantial sediment deposition. Sediment depositional features are temporary and transient in nature, and are likely contributing to channel instability.

AND/OR

Channels that have experienced historic incision but may be relatively stable (banks and channel) at their existing elevation. These channels may have a V-shape and no connection to their floodplain. Vegetative surface protection is present on greater than 40% of the banks but evidence of instability can be observed in unvegetated areas. Depositional features (point bars, mid-channel bars, transverse bars, and bank full benches), which contribute to stability are absent.

Severe

These channels are deeply incised (or excavated) with vertical and/or lateral instability and will likely continue to incise and widen. Incision is severe enough that flow is contained within the banks during heavy rainfall events (i.e. the stream does not have access to its floodplain). The streambed elevation may be below the average rooting depth within the banks and the majority of both banks may be vertical or undercut. Vegetative surface protection may be present on less than 20% of the banks and is not preventing erosion from continuing. Obvious bank sloughing may be present. Erosional scars or raw banks may be present on 80-100% of the banks.

AND/OR

These channels are aggrading and have an excessive sediment supply that is filling the channel with alluvium, impeding its flow. Greater than 80% of the natural stream bed or bottom (pools and riffles) is covered by substantial sediment deposition that is likely contributing to channel instability. Multiple thread channels and/or subterranean flow may be present in certain aggrading channels. Note: Stable multiple thread channels naturally occur in some low-gradient streams and should not be given a *Severe* Parameter Condition.

1.1.2 Channel Condition Photographs

(see USM Photo File)

1.2 Riparian Buffer Parameter

This Parameter is not intended to be a detailed vegetative cover survey, but instead, is a qualitative evaluation of the cover types that make up the riparian buffer. The **CI** for this parameter is determined by evaluating what cover type occupies what percent of the total riparian buffer area for each side of the stream channel within the **SAR**. The total riparian buffer assessment area (on each side of the stream channel) is calculated by multiplying the length of the **SAR** by 100 feet. The left bank (LB) and right bank (RB) are determined by facing downstream. The Riparian Buffer measurement is taken along the ground and is not an aerial distance from the stream bank.

The ideal riparian buffer would be homogenous with a mature hardwood forest occupying 100% of the assessment area. If the buffer is heterogeneous (example: 33% forested, 33% cropland, and 34% pavement), it is possible that the buffer could contain multiple condition categories. In that case, each condition category present within the buffer is scored and weighted by the percent it occupies within the buffer. An estimate of the percent area that each cover type occupies may be made from visual estimates made on-the-ground or by measuring each different area to obtain its dimensions. Multiple intrusions of roads, parks, houses, etc., into the 100-foot zone may require more detailed measurements to determine percentages. The observed cover types should be categorized and scored accordingly, based upon the parameter category descriptions.

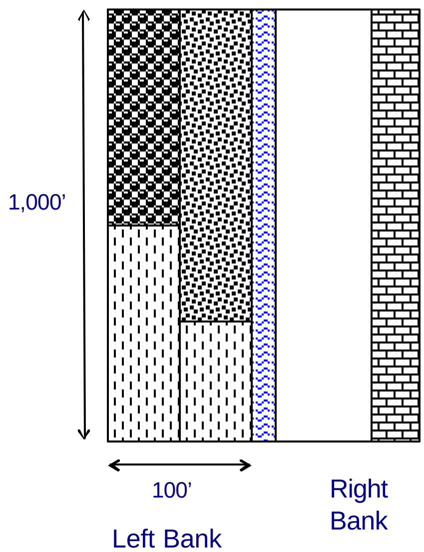
EQUATION 1: The equation is as follows:

Left Bank **CI** =SUM (%Area*Score)*0.01

Right Bank **CI** =SUM(%Area*Score)*0.01

Riparian **CI** = (Left Bank **CI** + Right Bank **CI**) / 2

The following example (Example 1) provides further details on how to assess this parameter.



Forested Buffer with 30% Canopy Cover and herbaceous understory (**Low Suboptimal** - Score of 1.1)

Forested Buffer with 30% Canopy Cover and herbaceous and shrub understory (**High Suboptimal** - Score of 1.2)

Forested Buffer with > 60% Canopy Cover (**Optimal** - Score of 1.5)

Maintained Grasses (**High Poor** - Score of 0.6)

Impervious Area (**Low Poor** - Score of 0.5)

Stream

For this example, the Evaluator considers each area within the 100’ buffer. On both sides of the stream an area of 100,000 square feet (sf) (100’ wide X 1,000’ long) is assessed using USM.

An area 60 feet wide and 1,000 feet long (60,000 sf) is located on the Right Bank and is assessed as Low Suboptimal. 60,000 sf is 60% of 100,000 sf. Therefore, 60 is entered into Right Bank Percent Area row of the Assessment Form and the Low Suboptimal Score (1.1) is entered below the 60 in the Score row. [60% X 1.1 X 0.01 = 0.66]

An area 40’ wide and 1,000’ long (40,000 sf) is located on the Right Bank and is assessed as Low Poor. 40,000 sf is 40% of 100,000 sf. Therefore, 40 is entered into Right Bank Percent Area row of the Assessment Form and the Low Poor Score (0.5) is entered below the 40 in the Score row. [40% X 0.5 X 0.01 = 0.20]

An area 50’ wide and 500’ long (25,000 sf) is located on the Left Bank and is assessed as Optimal. 25,000 is 25% of 100,000 sf. Therefore, 25 is entered into Left Bank Percent Area row of the Assessment Form and the Optimal Score (1.5) is entered below the 25 in the Score row. [25% X 1.5 X 0.01= 0.375]

An area of 50’ wide and 500’ long (25,000 sf) is located on the Left Bank and is assessed as High Poor. Another area 50’ wide and 250’ long (12,500 sf) is also located on the Left Bank and is assessed as High Poor. These two areas equal 37,500 sf and comprise 37.5% of 100,000 sf. Therefore, 37.5 is entered into Left Bank Percent Area row of the Assessment Form and the High Poor Score (0.6) is entered below the 37.5 in the Score row. [37.5% X 0.6 X 0.01 = 0.225]

An area 50’ wide and 750’ long (37,500 sf) is located on the Left Bank and is assessed as High Suboptimal. 37,500 sf is 37.5% of 100,000 sf. Therefore, 37.5 is entered into Left Bank Percent Area row of the Assessment Form and the High Suboptimal Score (1.2) is entered below the 37.5 in the Score row. [37.5% X 1.2 X 0.01 = 0.45]

The CI for each bank is the sum of all the Percent Area X Score products. The Right Bank CI is 0.86. The Left Bank CI is 1.05. These two bank CIs are then averaged, resulting in the Parameter CI of 0.955 or 0.96.

RB % Area	60%	40%		RB CI	
Score	1.1	0.5		0.86	
					Buffer CI
LB % Area	25%	37.5%	37.5	LB CI	0.96
Score	1.5	0.6	1.2	1.05	

Example 1: Riparian Buffer Assessment Example

1.2.1 Riparian Buffer Categories

The **SAR** is assessed for the condition of the **Riparian Buffer** using the following four Categories. The dominance of invasive species will lowers the CI by one category.

Optimal

Tree stratum (dbh > 3 inches) present, with > 60% tree canopy cover. Wetlands located within the riparian areas are scored as optimal.

Suboptimal

High Suboptimal: Riparian areas with tree stratum (dbh > 3 inches) present, with 30% to 60% tree canopy cover and containing both herbaceous and shrub layers or a non-maintained understory.

Low Suboptimal: Riparian areas with tree stratum (dbh > 3 inches) present, with 30% to 60% tree canopy cover and a maintained understory. Recent cutover (dense vegetation).

Marginal

High Marginal: Non-maintained, dense herbaceous vegetation with either a shrub layer or a tree layer (dbh > 3 inches) present, with <30% tree canopy cover.

Low Marginal: Non-maintained, dense herbaceous vegetation, riparian areas lacking shrub and tree stratum, areas of hay production, and ponds or open water areas. If trees are present, tree stratum (dbh >3 inches) present, with <30% tree canopy cover with maintained understory.

Poor

High Poor: Lawns, mowed, and maintained areas, nurseries; no-till cropland; actively grazed pasture, sparsely vegetated non-maintained area, recently seeded and stabilized, or other comparable condition.

Low Poor: Impervious surfaces, mine spoil lands, denuded surfaces, row crops, active feed lots, trails, or other comparable conditions.

1.2.2 Riparian Buffer Parameter Photographs

(see USM Photo File)

1.3 In-stream Habitat Parameter

The **In-Stream Habitat** assessment considers the habitat suitability for effective colonization or use by fish, amphibians, and/or macroinvertebrates. This parameter does not consider the abundance or types of organisms present, nor does it consider the water chemistry and/or quality of the stream. Other factors beyond those measured in this methodology (i.e. watershed conditions) also affect the presence and diversity of aquatic organisms. Therefore, evaluation of this parameter seeks to assess the suitability of physical elements within the stream reach to support aquatic organisms.

This Parameter includes the relative quantity and variety of natural structures in the stream, such as cobble (riffles), large rocks, fallen trees, logs and branches, persistent leaf packs, and undercut banks; available as refugia, feeding, or sites for spawning and nursery functions of aquatic macrofauna. A wide variety and/or abundance of instream habitat features provide macroinvertebrates and fish with a large number of niches, thus increasing species diversity. As variety and abundance of cover decreases, habitat structure becomes monotonous, diversity decreases, and the potential for recovery following disturbance decreases. Riffles and runs are critical for maintaining a variety and abundance of benthic organisms and serve as spawning and feeding refugia for certain fish. The extent and quality of the riffle is an important factor in the support of a healthy biological condition. Riffles and runs offer habitat diversity through a variety of particle sizes. Snags and submerged logs are also productive habitat structures for macroinvertebrate colonization and fish refugia.

This parameter does not establish a percent slope for distinguishing between high and low gradient streams. Therefore, the Evaluator has to know whether a high or low gradient stream is being assessed. Generally speaking, low gradient streams occur in the Coastal Plain, wetland / marsh conditions, or wet meadows, and do not contain riffles. High gradient streams generally have alternating riffles and pools, with gravel or cobble present in the riffles. Typically, most streams west of the Fall Line are high gradient making the majority of streams in Virginia high gradient, with the exception of streams in the Coastal Plain and low gradient streams flowing through wetlands or wet meadows throughout the state. Headwater stream channels have intermittent hydrologic regimes and may not have the diversity of habitat features found in higher order stream channels. Hyporheic flow may comprise all of the flow in intermittent streams during dry times of the year. A high gradient stream should not be scored lower because there is not submerged aquatic vegetation. Likewise, a low gradient stream should not be scored lower because it does not contain riffles.

High Gradient Streams

Physical elements of high gradient stream systems that enhance a stream's ability to support aquatic organisms and are indicative of habitat diversity include the following:

1. A varied mixture of substrate sizes (i.e., sand, gravel, cobbles, and boulders).
2. Low amount of highly mobile substrate material – While most streambed substrate mobilizes under a particular discharge, substrate that remains immobile during the more consistent and frequent discharges provides stable habitat that fish and macroinvertebrates can utilize throughout differing stages of their lifecycles.
3. Low Embeddedness of substrate material – Embeddedness is the extent to which rocks (gravel, cobble, and boulders) and snags are covered by silt, sand, or mud on the stream bottom. As rocks and snags become embedded, there is less area available for colonization for macroinvertebrates and less fish habitat. Generally, the less embedded each particle is, the more surface area available to macroinvertebrates and fish. Additionally, less embeddedness indicates less large-scale sediment movement and deposition. (Observations of embeddedness are taken in the upstream and central portions of riffles and cobble substrate areas.)
4. A varied combination of water velocities and depths (riffles and pools) - More combinations of velocity and depth patterns provide increased habitat diversity.
5. The presence of woody and leafy debris (fallen trees, logs, branches, leaf packs, etc.), root mats, large rocks, and undercut banks (below bankfull).
6. The provision of shade protection by overhanging vegetation.
7. The Hyporheic zone is wet within 12" of ground surface.

Low Gradient Streams

Physical elements of low gradient stream systems that enhance a stream's ability to support aquatic organisms and are indicative of habitat diversity include the following:

1. A varied mixture of substrate materials (i.e., sand and gravel) in pools – Varied substrate materials support a higher diversity of organisms than mud or bedrock.
2. Submerged aquatic vegetation in pools – Will also support a higher diversity of organisms.
3. The presence of woody and leafy debris (fallen trees, logs, branches, leaf packs, etc.), root mats, and undercut banks (below bankfull).
4. The provision of shade protection by overhanging vegetation.

5. The Hyporheic zone is wet within 12” of ground surface.

A diverse and abundant assemblage of these features promotes the potential for colonization by diverse and abundant epifaunal and fish communities.

1.3.1 In-Stream Habitat Categories

The **SAR** is assessed for the condition of **In-Stream Habitat** using the following four Categories. The Evaluator selects the category most representative of the **SAR**. These categories are abbreviated on Form 1.

Optimal
Physical Elements that enhance a stream’s ability to support aquatic organisms are present in greater than 50% of the reach. Substrate is favorable for colonization by a diverse and abundant epifaunal community, and there are many suitable areas for epifaunal colonization and/or fish cover.

Suboptimal
Physical Elements that enhance a stream’s ability to support aquatic organisms are present in 30-50% of the reach. Conditions are mostly desirable, and are generally suitable for full colonization by a moderately diverse and abundant epifaunal community.

Marginal
Physical Elements that enhance a stream’s ability to support aquatic organisms are present in 10-30% of the reach. Conditions are generally suitable for partial colonization by epifaunal and/or fish communities.

Poor
Physical Elements that enhance a stream’s ability to support aquatic organisms are present in less than 10% of the reach. Conditions are generally unsuitable for colonization by epifaunal and/or fish communities.

1.3.2 In-stream Habitat Parameter Photographs

(see USM Photo File)

1.4 Channel Alteration Parameter

This Parameter considers direct impacts to the stream channel from anthropogenic sources. The **SAR** may or may not have been altered throughout its entire length.

Examples of channel alterations evaluated in this Parameter that may disrupt the natural conditions of the stream include, but are not limited to the following:

1. Straightening of channel or other channelization
2. Stream crossings (bridges and bottomless culverts)
3. Riprap along streambank or in streambed
4. Concrete, gabions, or concrete blocks along streambank
5. Manmade embankments on streambanks, including spoil piles
6. Constrictions to stream channel or immediate flood prone area
7. Livestock impacted channels (i.e., hoof tread, livestock in stream)

It is important to note that this Parameter evaluates the physical alteration, separate from the impact the alteration is having on the assessment reach. Any impact to the assessment reach resulting from the alteration (i.e. scouring, head cuts, vertical banks, etc.) is accounted for in the **Channel Condition** Parameter. Any revegetation or natural re-stabilization of the channel is also accounted for in the **Channel Condition** Parameter. For example, consider two assessment reaches, each with similar bridges: the first reach shows no adverse effects to the stream channel or banks; the second shows significant scouring. The alteration is the bridge, not the effects of the bridge; therefore it is the length of bridge relative to the length of the assessment reach that is evaluated. The shorter the assessment reach, the higher percentage of alteration.

The presence of a structure does not necessarily result in a reduced score. For instance, a bridge that completely spans the floodplain would not be considered an alteration. Also, the Evaluator is cautioned not to make assumptions about past alterations. Incision can be mistaken for channelization.

1.4.1 Channel Alteration Categories

The **SAR** is assessed for the extent of channel alterations using the following four Categories. The Evaluator selects the category most representative of the assessment reach. This is recorded in Section 4 of Form 1.

Negligible
Channelization, dredging, alteration, or hardening absent. Stream has unaltered pattern or has normalized.

Minor
High Minor: Less than 20% of the stream reach is disrupted by any of the channel alterations listed above. Alteration or channelization present, usually adjacent to structures, (such as bridge abutments or culverts); evidence of past alteration, (i.e., channelization) may be present, but stream pattern and stability have recovered; recent alteration is not present.

Low Minor: Between 20-40% of the stream reach is disrupted by any of the channel alterations listed above. Alteration or channelization present, usually adjacent to structures, (such as bridge abutments or culverts); evidence of past alteration, (i.e., channelization) may be present, but stream pattern and stability have recovered; recent alteration is not present.

Moderate
High Moderate: Between 40 - 60% of reach is disrupted by any of the channel alterations listed above. If the stream has been channelized, normal stable stream meander pattern has not recovered.

Low Moderate: Between 60 - 80% of reach is disrupted by any of the channel alterations listed in the parameter guidelines. If the stream has been channelized, normal stable stream meander pattern has not recovered.

Severe
Greater than 80% of reach is disrupted by any of the channel alterations listed above. Greater than 80% of banks shored with gabion, riprap, or cement. Channels entirely lined with riprap.

1.4.2 Channel Alteration Parameter Photographs

(see USM Photo File)

1.5 Reach Condition Index (RCI)

The **Reach Condition Index (RCI)** is a numerical value placed on the stream assessment reach using the **Condition Indices (CIs)** determined for each Parameter during the stream assessment. The **RCI** values range from 0.5-1.5 and result from a weighted average of the **CIs**. The average is weighted to reflect the fact that **Channel Condition** is valued twice that of other individual Parameters because a stream's physical stability heavily influences its condition. The following equation is used to determine the **RCI**:

Equation 2 RCI = (Sum of all CIs) ÷ 5

If multiple reaches are assessed the Evaluator may use the **Stream Assessment Summary Form (Form 2)** to record multiple **RCIs** and later determine the **Compensation Requirement (CR)**.

2.0 STREAM IMPACT FACTOR ASSESSMENT

Permitted impacts result in varying levels of impairment to streams. Different types of impacts can therefore be classified based on the degree to which they are expected to impair the stream. Table 1 depicts a wide array of impacts categorized into four Impact Classifications (Severe, Significant, Moderate, Negligible). Each Impact Classification has a corresponding **Impact Factor (IF)**. As depicted in Table 1, the more severe the impact, the higher the **IF**. Therefore, an activity considered to have a *Severe* impact has the highest **IF** of 1.0, representing an activity that is presumed to have a complete or near-complete loss of all beneficial stream functions. Conversely, an activity considered to have Negligible impacts has an **IF** of 0. These activities will not require stream compensation; however they are included in Table 1 to show that if impacts can be minimized to the point that the impact activity falls into the *Negligible* classification, then stream compensation is not required.

The **IF** obtained from Table 1 is used on the Stream Impact Assessment Form (Form1) and the Stream Assessment Summary Form (Form 2) included in Appendix A to calculate the **Total Compensation Requirement (Total CR)** for the project. By using the Impact Classifications and incorporating **IF's** into the equation, the impacts resulting in greater impairment require more compensation than impacts resulting in lesser impairment. Additionally, this serves as an incentive to decrease the degree of impact and ultimately the **CR**.

If an impact is not listed, then best professional judgment must be used in determining the most applicable Impact Classification. If multiple impacts occur within the **SAR**, the highest applicable **IF** is used for that reach.

Table 1: Impact Factor Table

Impact Activity **	*Impact Factor*
Severe Elimination or filling of stream channel Impoundments (flooding of stream channel) Hardening of stream bed (i.e., concrete, gabions, concrete blocks, riprap, countersunk & non-countersunk culverts) [1,2] Channel Alteration: (i.e., modifications to profile or habitat features; straightening or adverse sinuosity modifications; modifications to cross-section or width/depth ratio through widening or narrowing bankfull channel, deepening bankfull channel, channel constriction)	1.0
Significant Hardening of stream banks (i.e., concrete, gabions, concrete blocks, riprap, bottomless culverts and other similar structures)	0.75
Moderate Bridges with piers in the stream channel. Regulator's discretion is used to determine if piers result in stream channel impacts.	0.5
Negligible Bridges or other similar structures associated with roadways or trails causing no permanent impacts to stream channels, including no riprap lining, no piers, no widening, or no constriction of stream channels.	0

** Other activities not listed above that "alter the physical, chemical, or biological properties of stream channels" shall be considered on a case-by-case basis.

[1] The addition of floodplain culverts may reduce the Impact Factor from Severe to Significant.

[2] The requirement to countersink culverts does not apply to extensions or maintenance of existing culverts that are not countersunk, to floodplain culverts being placed above ordinary high water, to culverts being placed on bedrock, or to culverts required to be placed on slopes 5% or greater.

Notes:

1. For bridges resulting in no permanent impacts, floodplain culverts are encouraged and may be assessed as a minimization measure or compensation for other impacts on the same stream in the vicinity of the bridge at the agency personnel's discretion.

2.1 Impact Factor Photographs

(see USM Photo File)

3.0 Determining Stream Compensation Requirements

The stream **Compensation Requirement (CR)** for a project is determined after the following three steps have been performed:

1) Determine the length of impact **(L_I)**;

2) Complete Form 1 to obtain the **RCI**;

3) Classify the type of impact and determine the appropriate **IF** (Table 1).

The total Length of Impact **(L_I)** equals the original length of stream being impacted, not the length of stream remaining after the impacts. For example, if 500 feet of stream is straightened resulting in 400' of stream, then 500' is the impact length.

The **CR** is calculated using the following equation:

EQUATION 3:

$$\text{Compensation Requirement (CR)} = L_I \times RCI \times IF$$

Where,

CR = compensation credits required

L_I = length of impact (in linear feet)

RCI = Reach Condition Index (Form 1)

IF = Impact Factor (Table 1)

To determine the **CR**, the length of impact **(L_I)** is multiplied by the **RCI** obtained from Form 1 and by the appropriate **IF** obtained from Table 1. Form 1 is used to generate the **CR** for each reach evaluated. If more than one reach will be impacted, the individual **$L_{I's}$** and their corresponding **CR's** may be summed on Form 2.

4.0 Precompensation Evaluation and Stream Conceptual Mitigation Plan

In order to develop a conceptual stream mitigation plan, it is necessary to first research the stream's watershed and its history to determine the cause and extent of its deficiencies. The following questions should be answered to help identify and document the specific deficiencies to be addressed within a stream reach.

1. What is the stream name?
2. What is the reach length to be evaluated? Provide a USGS topographic map with the location of the stream reach clearly identified.
3. What is the stream order?

4. What is the approximate drainage area?
5. Describe the existing watershed and the estimated proposed land use for that watershed (ie: percent residential, percent forested, percent commercial, percent cleared/logged, percent industrial, percent agricultural, other)?
6. Describe the existing riparian buffer (ie: mature forested, herbaceous and shrub layers present in understory, utility easements present, understory maintained, lawns, impervious surfaces, active row crops, etc.)? Provide the estimated percentage of the total riparian area comprised of each cover type.
7. What is the estimated bankfull width?
8. What is the estimated bank height?
9. Is the channel high gradient or low gradient?
10. Does the channel appear to have natural sinuosity or does it appear that the channel pattern has been altered?
11. Does the channel appear to be aggrading, degrading, or stable?
12. Describe the sediment supply (ie: extreme, very high, high, etc.)
13. Are the streambanks eroding? Over what percentage of the reach?
14. Are headcuts present within the reach?
15. Provide a general narrative overview of the existing stream deficiencies and the proposed necessary restoration or enhancement measures to be taken to address those deficiencies.
16. What are the goals and objectives of the mitigation, and how will the mitigation plan meet those goals and objectives?
17. The Stream Impact Assessment Form can be used to further document the existing condition of the mitigation site.

4.1 Conceptual Compensatory Mitigation Plan

In Section 5.0 the **Compensation Credit (CC)** for conceptual stream compensation plans is determined. The Evaluator needs to be familiar with the Compensation Activities and Adjustment Factors described in Sections 5.1 – 5.4 and submit the necessary information needed to determine **CC**. Sections 5.1 – 5.4 describe the process for crediting the Compensation Activities and Adjustment Factors and state the necessary information needed to complete the Compensation Crediting Form (Form 3). Note: Additional information may be required per COE & DEQ regulations/permits.

- Section 5.1: Restoration
  - The length (in linear feet) of stream channel to be restored

- Section 5.2: Enhancement
  - The length (in linear feet) of stream channel expected to benefit from and be influenced by instream structures
  - The length (in linear feet) of each streambank expected to benefit from and be influenced by habitat structures
  - The length (in linear feet) of each streambank that will have bankfull bench creation
  - The length (in linear feet) of each streambank that will have the banks laid back
  - The length (in linear feet) of each streambank that will have bioremediation techniques used
  - The length (in linear feet) of each streambank that will have streambank plantings

- Section 5.3: Riparian Buffer
  - The percent of the inner and outer 100’ buffers of each streambank that will be re-established
  - The percent of the inner and outer 100’ buffers of each streambank that will be planted heavily
  - The percent of the inner and outer 100’ buffers of each streambank that will have light or supplemental planting

- The percent of the inner and outer 100' buffers of each streambank that will be preserved only

- Section 5.4: Adjustment Factors
  - Rare, Threatened, and Endangered Species or Communities
    - The name of the species being protected
    - The indicator status of the species
    - The amount the proposed activity will aid or protect that species
    - Whether an activity will protect habitat or known locations of a species
    - The connection to other wildlife corridors
    - The number of species to be benefited

  - Livestock Exclusion
    - The length of time livestock have had access to the stream

      The number of livestock excluded
    - The expected water quality improvements provided by the project

  - Watershed Preservation
    - The nature of the restriction
    - The level of preservation or protection provided
    - The benefit to the stream system

5.0 Determining Compensation Crediting

The Total **Compensation Requirement (CR)** computed in Section 3.0 and on Form 2 represents the total stream compensation credits required for the project.

This section describes the methods and alternatives for fulfilling the **CR** for both onsite and offsite compensation, and explains the crediting process. Using this process, ensures that crediting on-site and off-site compensation projects, evaluating and approving stream compensation banks through the Mitigation Bank Review Team, and in-lieu fee fund projects are all credited in the same manner. This process does not include a method for crediting out-of-kind compensation activities such as removing effluent/straight pipes, correcting acid mine drainage, or removing fish blockages. These activities may serve to fulfill the **CR** in certain situations, but will be credited on a case-by-case basis.

The process categorizes compensation methods and utilizes a Compensation Crediting Form (Form 3), included in Appendix B, to determine the **CC** for various levels of stream and riparian buffer preservation, enhancement, and restoration activities. The **CC** is refined by applying the appropriate **Adjustment Factors (A_F)** to the credits obtained through the various activities.

The following is a step-wise summary of the procedure for calculating the **CC's** obtained from a stream compensation plan:

- Enter the project number, project name, locality, Cowardin classification, HUC, date, stream compensation length, name of evaluators, stream name, and reach ID number.

- If restoration is proposed, then enter the length of stream channel to be restored in the appropriate box on Form 3. The length is multiplied by the credit and restoration credit is calculated.

- If Enhancement with Instream Structures is proposed, determine the affected length. Enter this length in the appropriate box on form 3. The length is multiplied by the credit for Instream Structures.

- If other Enhancement activities are proposed, determine which techniques will be employed, and enter the corresponding length and credit, for each bank, in the appropriate boxes on Form 3. The length of each proposed activity is multiplied by the credit for each activity. The sum of credits provided by each of the activities and the credit provided by Instream Structures result in a total enhancement credit and is entered in the appropriate box of Form 3.

- Determine the riparian buffer area and enter the percent area for the inner 100 and its corresponding credit for each bank in the appropriate box on Form 3. The percent area is multiplied by the credit. The sum of these products for each bank results in the credit for that bank. The right bank and left bank credits are then averaged to obtain an average per-foot credit for the work being done on the reach. This average credit is then multiplied by the total length of the stream reach to obtain the total riparian credit for that particular reach. This calculation is repeated for the outer 100' (100'-200').

- Determine which adjustment factors apply to the project and enter the corresponding length and credit in the appropriate box on Form 3. The length is multiplied by the credit and the amount of the additional credit is calculated. The sum of additional credits provided by each is entered in the appropriate box of Form 3.

- The total credits generated under each activity are added together and result in the total credit.

Methods employed to improve or protect streams include a wide range of activities aimed at preserving, enhancing, stabilizing, or restoring various stream functions. Some of these methods require greater efforts and provide greater benefits than others. When these methods are proposed as stream compensation, the amount of effort required and the resulting benefits from such activities must be taken into account when determining the amount of **CC** granted. Therefore, the amount of **CC** is based on the activity, the expected level of improvement to stream function and quality, and the amount of effort required and methods employed.

This section demonstrates how to credit design components included in the compensation plan. Compensation Crediting is determined by using the USM Compensation Crediting Form (Form 3). The complexity of the project will dictate the number of forms required to be completed. The needed improvements should be based on an assessment of the existing stream deficiencies.

This USM method does not determine whether or not a compensation proposal/plan is appropriate. Agency personnel will rely on the information provided in the Precompensation Evaluation, the conceptual compensation plan, knowledge of the site, natural stream channel design techniques, and best professional judgment to make that determination. Form 3 is utilized simply to calculate the credit provided by each activity on a given reach and any adjustment factors. It should be noted that no credit will be given for unnecessary techniques and/or structures.

The following provides details on compensation practices and guidelines for using the USM Compensation Crediting Form (Form 3).

5.1 Restoration (1 CC per foot)

Restoration is the process of converting an unstable, altered, or degraded stream corridor, including flood-prone areas, to a natural stable condition considering recent and future watershed conditions. This process should be based on a reference condition/reach for the stream valley type and includes restoring the appropriate geomorphic dimension (cross-section), pattern (sinuosity), and profile (channel slope). This process supports reestablishing the streams biological and chemical integrity, including transport of the water and sediment produced by its watershed in order to achieve dynamic equilibrium.

An analysis of the existing geomorphological parameters of the compensation stream is compared to those in a stable reference stream. Natural stream channel design methods and calculations are then applied to result in a stable stream dimension, pattern, and profile that maintains itself within the natural variability of the design parameters. Restoration activities utilizing the natural stream channel design approach typically address the following:

1. Deficiencies in sinuosity, radius of curvature, belt width, meander length
2. Deficiencies in spacing, lengths, and depths for riffles, runs, pools, & glides
3. Restore appropriate critical shear stress
4. Deficiencies in slopes for channel, riffles, runs, pools, & glides
5. Deficiencies in width-depth ratio and cross-sectional area

Situations that readily lend themselves to inclusion in the Restoration Category include Priority 1, 2, or 3 relocations and restorations as described in *A Geomorphological Approach to Restoration of Incised Rivers*, Rosgen 1997[1]. The following provides additional information on these Priorities:

Priority 1 Restoration[1]
Priority 1 Restoration is defined as stream channel restoration that involves the re-establishment of a channel on the original floodplain, using a relic channel or constructing a new channel. The new channel is designed and constructed with the proper dimension, pattern, and profile characteristics for a stable stream. The existing, incised channel is either backfilled or made into discontinuous oxbow lakes level with the new floodplain elevation. (Rosgen, 1997)

Priority 2 Restoration[1]
Priority 2 Restoration is defined as stream channel restoration that involves re-establishment of a new floodplain at the existing level or higher but not at the original level. The new channel is designed and constructed with the proper dimension, pattern, and profile characteristics for a stable stream. (Rosgen, 1997)

Priority 3 Restoration[1]
Priority 3 Restoration is defined as stream channel restoration to a channel without an active floodplain but with a flood prone area (Rosgen, 1997). However, the channel restoration must involve establishing proper dimension, pattern, and profile. Some sites may present difficulties in reestablishing a sinuous pattern when they are laterally contained or have limitations in available belt width. This is often caused by utilities, infrastructure, and other floodplain encroachments. Such physical constraints often favor the creation of a step/pool bed morphology with less sinuosity (associated with Priority 3) over a riffle/pool bed morphology with greater sinuosity (associated with Priorities 1 & 2). It is necessary to consider the available belt width and the slope of the proposed stream when designing the appropriate stream type that is suitable for that

[1] Rosgen, David. 1997. *A Geomorphological Approach to Restoration of Incised Rivers*. Proceedings of the Conference on Management of Landscapes Disturbed by Channel Incision. 11pp.

situation. Information should be provided showing that the appropriate dimension, pattern, and profile are being restored for the proposed stream type in that particular situation.

The compensation plan narrative needs to describe, and the plan design sheets need to clearly demarcate, the stream channel length (in linear feet) and stream reaches to be restored, as defined above. The restoration length should be recorded in the appropriate box on Form 3 then it is multiplied by 1.0 resulting in the restoration credit.

Restoration Restrictions:

1. **No enhancement activities can be coupled with restoration on the same linear foot of stream channel.**

2. **The difference between projects that are credited as Restoration and projects that are credited as Enhancement, is whether or not changes are necessary to address the current channel's dimension, pattern, and profile, as described for each of the Priorities, to produce a stable channel. All three geomorphic variables are required to be addressed, with noted pattern limitations for Priority 3, in order to receive Restoration credit. Enhancement credit is given in all other situations when only two geomorphic variables are addressed to produce a stable channel.**

5.1.1 Restoration Photographs

(see USM Photo File)

5.2 Enhancement

Enhancement Activities include physical alterations to the channel that do not constitute Restoration but that directly augment channel stability, water quality, and stream ecology in accordance with a reference condition, where appropriate. These activities may include in-stream and/or streambank activities, but in total fall short of restoring one or more of the geomorphic variables: dimension, pattern and profile. There are 6 activities included in this category: 1) Instream Structures (cross vanes, j hooks, etc.), 2) Habitat Structures (fish boards, root wads, etc), 3) Bankfull Bench Creation, 4) Laying Back Banks, 5) Bioremediation Techniques, and 6) Stream Bank Planting.

These compensation activities <u>directly</u> improve the stability of, or enhance the streambanks, streambed, and in-stream habitat by physically manipulating them.

Instream Structures (0.3 credit per foot of effect)
This activity includes structures that are specifically designed and result in grade control and/or bank stabilization. Accepted structures include, but are not limited to, cross-vanes, j-hook vanes, native material revetments, W rock weirs, rock vortex weirs, log-vanes, constructed riffles, and step-pools. These structures may be created out of appropriate sized rock or logs, boulders or cobbles based on the size of the stream and the flow regime. Structures not listed will be considered on case-by-case basis. Normally, a pool is constructed in combination with these structures, however, if one is not constructed this does not alter the credit provided.

The compensation plan needs to state, and clearly demarcate, the length (in linear feet) of stream channel and reaches of stream channel expected to benefit from and be influenced by the structures. Record this length in the appropriate box on Form 3. This length is multiplied by 0.3 and the credit is calculated.

Habitat Structures (0.1 credit per foot per bank)
This activity includes structures designed specifically for habitat creation. Although, Instream Structures typically provide habitat, they are constructed for channel stability and will not receive credit for Habitat Structures. Habitat Structures do not typically contribute to channel stability. Accepted structures include, but are not limited to, submerged shelters, fish boards or bank cover, floating log structures, root wads, and half-log cover. Riffle and pool complexes and over hanging vegetation do not qualify for credit in this activity.

The compensation plan should state, and the plan sheets should clearly demarcate, the length (in linear feet) of stream channel where habitat structures are proposed. This length is recorded in the appropriate bank row on Form 3. This length is multiplied by 0.10 and the credit for that structure is calculated.

Bankfull Bench Creation (0.15 credit per foot per bank)
This activity involves the creation of a bankfull bench along one or both of the stream banks. This activity may result in less than the proper entrenchment ratio but does result in a stable channel. The compensation plan should state, and the plan sheets should clearly demarcate, the length (in linear feet) of stream channel where bankfull benches are proposed. This length is recorded in the appropriate bank row on Form 3. This length is multiplied by 0.15 and the credit for that length of bench is calculated.

Lay Back Bank (0.1 credit per foot per bank)
This activity involves the manual manipulation of the bank slope but does not create a bankfull bench or floodplain. The compensation plan should state, and the plan sheets should clearly demarcate, the length (in linear feet) of stream channel where laying back the banks is proposed. This length is recorded in the appropriate bank row on Form 3. This length is multiplied by 0.1 and the credit for that length of bank is calculated.

Bioremediation Techniques (0.1 credit per foot per bank)
This activity primarily relates to the use of coir logs or similar materials for bank stabilization. Techniques and materials in this category include, but are not limited to, live fascines, branch packing, brush mattresses, coir logs, and natural fiber rolls. More than one of these materials or techniques may be warranted over the same stream length. In this case, no additional credit will be applied for that length. In other words, the compensation plan should include all bioremediation techniques required over a particular length. Techniques and materials other than those listed will be considered on a case-by-case basis for approval by the agencies.

The compensation plan should state, and the plan sheets should clearly demarcate, the length (in linear feet) of stream channel where bioremediation techniques are proposed. This length is recorded in the appropriate bank row on Form 3. This length is multiplied by 0.1 and the credit for that length of bank is calculated.

Streambank Planting (0.09 credit per foot per bank)
This activity includes the installation of plants other than seed along the immediate stream bank area. This is primarily done for streambank stabilization. This activity includes live stakes, dormant post/stakes, branch layering, and the installation of plants. The length of the bank over which this activity occurs is entered into the Form 3. If it occurs on both banks, it is entered in both rows.

The compensation plan should state, and the plan sheets should clearly demarcate, the length (in linear feet) of stream channel where streambank plantings are proposed. This length is recorded in the appropriate bank row on Form 3. This length is multiplied by 0.09 and the credit for that length of bank is calculated.

EQUATION 4:

Structure Credit = Length affected*Credit

Left Bank Credit =SUM (Length*Credit)

Right Bank Credit = SUM (Length*Credit)

Enhancement Credit = Structure Credit + Left Bank Credit + Right Bank Credit

Enhancement Restrictions:

1. **Activities cannot be credited as both Restoration and Enhancement activities.**
2. **A structure cannot be credited as both an Instream Structure and a Habitat Structure.**
3. **Mechanical bank work cannot be credited as both Bankfull Bench and Laying Back the Banks.**
4. **Bioremediation Techniques do not include Erosion Control matting.**

5.2.1 Enhancement Photographs

(see USM Photo File)

5.3 Riparian Areas

This compensation activity includes improvements to riparian zones and includes their preservation in perpetuity. This activity includes: Buffer Re-Establishment, Heavy Buffer Planting, Light Buffer Planting, and Preservation Only.

The credit is determined by calculating the area within the first 100' buffer in which a given riparian activity is proposed. For each bank, the Percent Area for each activity is multiplied by the credit given to that area. No area can be counted twice. The sum of these products for each bank results in the credit for that bank. The right bank and left bank credits are then averaged to obtain an average per-foot credit for the work being done on the reach. This average credit is then multiplied by the total length of the stream reach to obtain the total riparian credit for that particular reach. See Example 2 below, for further explanation.

The same process is used to determine the percent area within the outer 100' buffer using the outer 100 feet credit values. Credit is reduced since this buffer area has less influence on stream stability, water quality, and instream habitat.

Buffer Re-Establishment (0.4 inner 100 feet/0.2 outer 100 feet)
Credit for this activity is given when invasive plant species are eradicated and the buffer area is returned to native species, monitored to ensure invasive species eradication and the success of the native species. Invasive species are those listed as highly or moderately invasive on the Department of Conservation and Recreation *Invasive Alien Plant Species of Virginia* List.

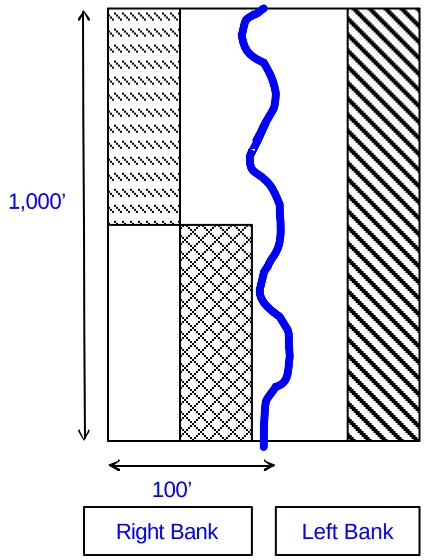
Heavy Buffer Planting (0.38 inner 100 feet/0.19 outer 100 feet)
Credit for this activity is given when the buffer area requires extensive planting (example: 400 stems per acre or more) and may include balled and burlapped specimens and/or containerized specimens.

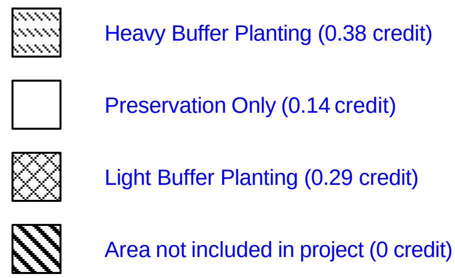
Light Buffer Planting (0.29 inner 100 feet/0.15 outer 100 feet)
Credit for this activity is given when the buffer area requires only light or supplemental planting. This activity would involve planting at less than ideal densities (example: less than 400 stems per acre), either because vegetation is already present, a seed source is present, or the project does not otherwise warrant it.

Preservation Only (No Work Proposed)
Credit for this activity is given when no work to a riparian buffer area is proposed but that area will be placed under perpetual protection through the implementation of appropriate legal mechanisms. Credit is given based on the quality of the stream preserved. Additional credit is given for the preservation of High Quality streams (streams with an **RCI** from 1.25 to 1.5). Low Quality streams are those with an RCI from 1.0 to 1.24. Preservation is rarely allowed for streams that score below an **RCI** of 1.0. When preservation of the buffer is conducted on streams where stream restoration/enhancement activities are proposed, the credit for High Quality streams is applied since the compensation proposal will result in an improvement. For the inner 100 feet, High Quality streams receive 0.14 credit per percent area and Low Quality streams receive 0.07 credit per percent area. For the outer 100 feet, all streams receive 0.07 credit per percent area.

Riparian Areas Restrictions:

1. **Buffer proposals for less than 25 feet in width or greater than 200 feet in width, on either side of the stream, must be approved by the Agencies on a case-by-case basis.**
2. **When trees are removed in order to perform restoration or enhancement activities, the areas to be replanted cannot be credited toward heavy or light buffer planting. These areas will be credited as Preservation Only.**
3. **No area of buffer can be credited under more than one Riparian Buffer category.**
4. **Credit is reduced by 0.03 for each of the three vegetative layers excluded from any particular riparian area. For example, if a riparian buffer is preserved but maintained as shrub and herbaceous vegetation without trees, the preservation credit of 0.14 is reduced by 0.03 for the missing tree layer.**





For this example, a proposed project consists of the preservation of 50’ buffer on one side of the stream and 100’ buffer on the other. Within the 100’ buffer, the outer 50’ (over 500’ of stream length) will be restored with Heavy Buffer Planting and inner 50’ will be restored with Light Buffer Planting (over 500’ of stream length).

For this example, the Evaluator considers the area of each activity within the 100’ buffer. On both sides of the stream an area of 100,000 square feet (sf) is available for consideration (100’ wide X 1,000’ long).

An area of 25,000 sf on the Right Bank is being restored with Heavy Buffer Planting (50’ wide X 500’ long). 25,000 sf is 25% of 100,000 sf. Therefore, 25 is entered into Right Bank Percent Area row of the CC form and 0.38 is entered into the credit row below the corresponding Percent Area (25%). [25 X 0.38 X 0.01 = 0.095]

An area of 25,000 sf on the Right Bank is being restored with Light Buffer Planting (50’ wide X 500’ long). 25,000 sf is 25% of 100,000 sf. Therefore, 25 is entered into Right Bank Percent Area row of the CC form and 0.29 is entered into the credit row below the corresponding Percent Area (25%). [25 X 0.29 X 0.01 = 0.0725

An area of 50,000 sf on the Right Bank is only being preserved (50’ wide X 500’ long X .14). 50,000 sf is 50% of 100,000 sf. Therefore, 50 is entered into Right Bank Percent Area row of the CC form and 0.14 is entered into the credit row below the corresponding Percent Area (50%). [50 X 0.14 X 0.01 = 0.07]

An area of 50,000 sf on the Left Bank is only being preserved (50’ wide X 500’ long). 50,000 sf is 50% of 100,000 sf. Therefore, 50 is entered into Left Bank Percent Area row of the CC form and 0.14 is entered into the credit row below the corresponding Percent Area (50%).
[50X 0.14 X 0.01 = 0.07]

An area of 50,000 sf on the Left Bank (50’ wide X 500’ long) is not part of the proposed project (0 credit earned). 50,000 sf is 50% of 100,000 sf. Therefore, 50 is entered into Percent Area row of the CC form and 0 is entered into the credit row below the corresponding Percent Area (50%).
[500 X 0.0 X 0.01 = 0.00]

This project alone (not considering any restoration, enhancement, or adjustment factors) provides 153.75 credits of Compensation Credit.

RB % Area	25	25	50	RB Credit		Reach Length
Credit	0.38	0.29	0.14	0.24		1,000
					CREDIT	Buffer Credit
LB % Area	50	50		LB Credit	0.16	160
Credit	0.14	0.0		0.07

5.3.1 Riparian Areas Photographs

(see USM Photo File)

5.4 Adjustment Factors

Adjustment Factors **(A_F)** are used to account for exceptional or site specific circumstances associated with the compensation site. These circumstances may provide ecological benefits that exceed the minimal requirements of the method presented in this Manual. The Adjustment Factors are applied only when ecological and/or water quality benefits are achieved.

Each **A_F** activity is credited within a prescribed range. The range is to account for variation in activities and conditions that warrant **A_F** credit. Examples are given for each of the ranges. The agency representative shall make this determination on a case-by-case basis and use best professional judgment.

Rare, Threatened, and Endangered Species or Communities
Increased **Compensation Credit (CC)** is warranted for sites that show a significant improvement in restoring, enhancing, or preserving communities or individuals of rare or threatened and endangered species (T&E). It is necessary to consider the influences of activities upstream of the compensation site before applying this **A_F**. If upstream activities would prevent significant improvement from occurring, this **A_F** may not be warranted. The agency representative should coordinate with State and Federal agencies such as Virginia Department of Conservation and Recreation (DCR), Virginia Department of Game and Inland Fisheries (DGIF), or U.S. Fish and Wildlife Service (FWS) prior to applying this **A_F.**

The range of credit provided by this activity is 0.1 – 0.3. The following factors are considered in determining the credit: 1) the indicator status of the species, 2) the amount the proposed activity will aid or protect that species, 3) whether an activity will protect habitat or known locations of a species, 4) the connection to other wildlife corridors, and 5) the number of species protected. **This A_F does not apply to projects where compensation of T&E species is required as a result of consultation with state and federal resource agencies.**

Livestock Exclusion
Increased compensation credit is warranted for sites that exclude livestock because it has significant water quality and streambank stability benefits. Livestock exclusion is a process of placing fencing around a stream and adjacent riparian buffer so that livestock access is limited. Livestock must be excluded for a site to be accepted as compensation. Infrequent livestock crossings or watering holes may be permitted, if necessary.

Sites where livestock have been recently placed for the purposes of obtaining additional credit will not be considered for this **A_F**. This Af does not apply to sites where livestock are excluded due to land development.

The range of credit provided by this activity is 0.1 – 0.3. The following factors are considered when determining the credit: 1) the number of livestock excluded, and 2) the water quality and streambank stability improvements.

Watershed Preservation
Increased **CC** may be warranted if the compensation site incorporates additional legal mechanisms that prohibit any increase in runoff rates in the watershed above pre-development rates, and the site is designed to accommodate the existing rates. These legal mechanisms may be in the form of preserving the entire watershed as is, or instituting future runoff restrictions within the watershed. This factor does not apply to sites designed to accommodate future increases in runoff rates that do not incorporate these additional legal mechanisms. This factor

also does not apply if such restrictions are already in place or when they are otherwise required by another agency or entity.

The range of credit provided by this activity is 0.1 – 0.3. The following factors are considered when determining the credit: 1) the nature of the restriction, 2) the level of preservation or protection provided, and 3) the benefit to the stream system.

6.0 Evaluating Compensation Credit

The sum of all of the credits provided by all of the Compensation Activities and Adjustment Factors within the reach equals the Total Compensation Credit (Total **CC**) provided by the reach. This is calculated using the following equation:

EQUATION 5

Total CC=SUM (Restoration Credit + Enhancement Credit + Riparian Buffer Credit + Adjustment Factor Credit)

If more than one form is completed, then the results from each form are recorded on the Compensation Summary Form (Form 4), included in Appendix B, which is used to summarize each individual stretch of stream and to calculate **Compensation Credits (CC)**.

Appendix C

Definitions

Channel Dimension- The cross-sectional profile of a channel.

Channel Pattern - The sinuosity or meander geometry of a channel.

Channel Profile – The longitudinal slope of a channel.

Embeddness - is measurement of the degree to which larger particles are covered with finer particles.

Enhancement - physical alterations to the channel that do not constitute Restoration but that directly augment channel stability, water quality, and stream ecology in accordance with a reference condition where appropriate.

Ephemeral Streams - streams that have flowing water only during and for a short duration after, precipitation events in a typical year. Ephemeral streambeds are located above the groundwater table year-round. Groundwater is not a source of water for the stream. Runoff from rainfall is the primary source of water for these streams.

High Gradient Streams – is defined by EPA as streams with moderate-high gradient landscapes; substrates primarily composed of coarse sediments [gravel (2mm) or larger] or frequent coarse particulate aggregations; riffle/run prevalent.

Intermittent Streams - streams that have flowing water during certain times of the year, when groundwater provides water for stream flow. During dry periods, intermittent streams may not have flowing water. Runoff from rainfall is a supplemental source of water for stream flow.

Low Gradient Streams - is defined by EPA as streams with low-moderate gradient landscapes; substrates of fine sediment particles or infrequent aggregations of coarse sediment particles [gravel (2mm) or larger]; glide/pool prevalent.

Macroinvertebrates - are small stream dwelling animals that do not have vertebrae and are visible with the naked eye.

Natural Channel Design - proper dimension, pattern, and profile for a given stream type. (See definitions for channel dimension, channel pattern, and channel profile).

Priority 1 Restoration - is defined as stream channel restoration that involves the re-establishment of a channel on the original floodplain, using either a relic channel or construction of a new channel. The new channel is designed and constructed with the proper dimension, pattern, and profile characteristics for a stable stream. The existing, incised channel is either backfilled or made into discontinuous oxbow lakes level with the new floodplain elevation.

Priority 2 Restoration - is defined as stream channel restoration that involves re-establishment of a new floodplain at the existing level or higher but not at the original level. The new channel is designed and constructed with the proper dimension, pattern, and profile characteristics for a stable stream.

Priority 3 Restoration - is defined as stream channel restoration to a channel without an active floodplain but with a floodprone area. However, the restoration of the channel must involve establishing proper dimension, pattern, and profile. Some sites may present difficulties in reestablishing a sinuous pattern when they are laterally contained or have limitations in available belt width. This is often caused by utilities, infrastructure, and other floodplain encroachments. Such physical constraints often favor the creation of a step/pool bed morphology with less sinuosity (associated with Priority 3) over a riffle/pool bed morphology with greater sinuosity (associated with Priorities 1 & 2). It is necessary to consider the available belt width and the slope of the proposed stream when designing the appropriate stream type that is suitable for that situation. Information should be provided showing that the appropriate dimension, pattern, and profile are being restored for the proposed stream type in that particular situation.

Stream Preservation - The protection of ecologically important aquatic resources in perpetuity through the implementation of appropriate legal and physical mechanisms. Preservation will include protection of riparian areas adjacent to stream channels or other aquatic resources as necessary to ensure protection and/or enhancement of the aquatic ecosystem.

Stream Relocation - Movement of a stream from one location to another, usually by filling the old channel and redirecting the stream to a separate location.

Stream Restoration - Converting an unstable, altered, or degraded stream corridor, including adjacent riparian zone (buffers) and flood-prone areas, to its natural stable condition considering recent and future watershed conditions. This process should be based on a reference condition/reach for the valley type and includes restoring the appropriate geomorphic dimension (cross-section), pattern (sinuosity), and profile (channel slopes), as well as reestablishing the biological and chemical integrity, including transport of the water and sediment produced by the stream's watershed in order to achieve dynamic equilibrium.

Acknowledgements

RUSLE2 was developed cooperatively by the USDA-Agricultural Research Service (ARS), the USDA-Natural Resources Conservation Service (NRCS), and the Biosystems Engineering and Environmental Science Department of the University of Tennessee. Each project participant maintains a RUSLE2 Internet site directed toward their specific interests. Consult these sites for a list of the employees of these organizations who contributed to the development of RUSLE2. Contributors from several other organizations also participated in the development of RUSLE2.

The USDA-ARS was responsible for providing the erosion science on which RUSLE2 is based including the mathematical equations used in RUSLE2, core data values used to calibrate RUSLE2, scientific documentation, and a user's reference guide for RUSLE2.

The USDA-NRCS was the principal client for RUSLE2. The NRCS provided information to ensure that RUSLE2 could be easily used in their local field (district) offices. The NRCS also developed an extensive RUSLE2 operational (working) database, primarily for cropland. The NRCS has developed RUSLE2 templates and user guides specifically for their purposes.

The University of Tennessee participated in the development of the mathematical equations used in RUSLE2, developed the computer science used in RUSLE2, and developed the RUSLE2 computer program. They also developed user guides and other RUSLE2 information for their clients.

The interests and needs of a wide variety of other users were considered during RUSLE2's development. RUSLE2 was developed to be land-use independent to give RUSLE2 the widest applicability range possible and to accommodate the needs of these users.

This RUSLE2 Science Documentation was reviewed by USDA-Natural Resources Conservation Service technical specialists from several disciplines; Kenneth G. Renard (retired), USDA-Agricultural Research Service, Tucson, Arizona; and Seth Dabney, USDA-Agricultural Research Service, Oxford, Mississippi.

Preface

The Revised Universal Soil Loss Equation, Version 2 (RUSLE2) is used to guide conservation and erosion control planning at the local field office level. RUSLE2 estimates average annual rill and interrill erosion based on site-specific conditions. In a typical application, the planner identifies several potential erosion control alternatives for the site and estimates erosion for each alternative. The planner then chooses the alternative that provides adequate erosion control and best meets other requirements.

RUSLE2 is computer-based technology that involves a computer program, mathematical equations, and a large database. The RUSLE2 user describes a specific site by making selections from the database. RUSLE2 uses this information in its mathematical equations to compute erosion estimates for alternative erosion control practices for the site.

RUSLE2 can be used to estimate rill and interrill erosion where mineral soil is exposed to the erosive forces of impacting raindrops and water drops falling from vegetation and surface runoff produced by Hortonian overland flow. RUSLE2 is land use independent and can be applied wherever these conditions exist. RUSLE2 can be used on cropland, pastureland, rangeland, constructions site, reclaimed mine land, landfills, mine tailings, mechanically disturbed and burned forestlands, military training sites, and similar lands.

This document describes the RUSLE2 science, which is primarily embodied in the mathematical equations used in RUSLE2. The RUSLE2 User's Reference Guide, a companion document, describes how RUSLE2 works, how to interpret values computed by RUSLE2, how to select and enter values into the RUSLE2 database, and how to judge the adequacy of RUSLE2. Additional information is available on the RUSLE2 Internet site maintained by the USDA-Agricultural Research Service: http://www.ars.usda.gov/Research/docs.htm?docid=6010. Additional information is also available on RUSLE2 Internet sites maintained by the USDA-Natural Resources Conservation Service and the University of Tennessee.

Each chapter in this document stands alone with its own list of symbols given at the end of the chapter. Symbols are defined on their occurrence. Refer to the list of symbols at the end of each chapter because symbol usage differs between chapters.

RUSLE2 uses mathematical equations from several disciplines. In most cases, the symbols that are common in a given discipline are used in this document, which results in the same symbol being used for multiple variables, even within the same chapter. Using the typical symbol for a given variable was considered to be more useful than having a unique symbol for each variable.

Also, topics overlap between chapters. The topics within and between chapters are organized according to the mathematical structure of RUSLE2 rather than along a user oriented structure, which is followed in the RUSLE2 User Reference Guide. Consequently, the mathematical representation of key variables such as residue may be discussed in several places in this document. Cross references to other sections where this variable is discussed are included for the major variables.

Disclaimer

The purpose of RUSLE2 is to guide and assist erosion-control planning. Erosion-control planners should consider information generated by RUSLE2 to be only one set of information used to make an erosion-control decision. RUSLE2 has been verified and validated, and every reasonable effort has been made to ensure that RUSLE2 works as described in RUSLE2 documentation available from the USDA-Agricultural Research Service. However, RUSLE2 users should be aware that errors may exist in RUSLE2 and exercise due caution in using RUSLE2.

Similarly, this RUSLE2 Science Documentation has been reviewed by erosion scientists and RUSLE2 users. These reviewers' comments have been faithfully considered in the revision of this document.

Every reasonable effort has been made to ensure that this document is accurate. The USDA-Agricultural Research Service alone is responsible for this document's accuracy and how faithfully the RUSLE2 computer program represents the information in this document.

Glossary of Terms

Term	Description
10 yr EI	Storm EI with a 10-year return period
10 yr-24 hr EI	Storm EI for the 10 yr-24 hr precipitation amount
10 yr-24 hr precipitation	24 hour precipitation amount having a 10 year return period
Antecedent soil moisture subfactor	See cover-management subfactors
Average annual, monthly, period, and daily erosion	RUSLE2 computes average daily erosion for each day of the year, which represents the average erosion that would be observed if erosion was measured on that day for a sufficiently long period. Average period, monthly, and annual erosion are sums of the average daily values
Average erosion	Average erosion is the sediment load at a given location on the overland flow path divided by the distance from the origin of overland flow path to the location
b value	Coefficient in equation for effect of ground cover on erosion, values vary daily with rill-interrill erosion ratio and residue type
Buffer strips	Dense vegetation strips uniformly spaced along overland flow path; can cause much deposition
Burial ratio	Portion of existing surface (flat) cover mass that is buried by a soil disturbing operation (dry mass basis-not area covered basis)
Calibration	Procedure of fitting an equation to data to determine numerical values for equation’s coefficients
Canopy cover	Cover above soil surface; does not contact runoff; usually vegetation
Canopy shape	Standard shapes used to assist selection of fall height values
Canopy subfactor	See cover-management subfactors
Climate description	Input values for variables used to represent climate, stored under a location name in the climate component of RUSLE2 database

Concentrated flow area	Area on landscape where channel flow occurs; ends overland flow path
Conservation planning soil loss	A conservation planning erosion value that gives partial credit to deposition as soil saved, credit is function of location on overland flow path where deposition occurs
Contouring	Support erosion control practice involving ridges-furrows that reduces erosion by redirecting runoff around hillslope
Contouring failure	Contouring effectiveness is lost where runoff shear stress exceeds a critical value
Contouring description	Row grade used to describe contouring; stored in contouring component of RUSLE2 database; ridge height in *operation* description used in cover-*management* description also key input
Core database	RUSLE2 database that includes values for base conditions used to validate RUSLE2; input values for a new condition must be consistent with values in core database for similar conditions
Cover-*management* description	Values for variables that describe cover-management, includes dates, *operation* descriptions, *vegetation* descriptions, vegetation production levels (yields), external *residue* descriptions and amount applied, cover-*management* descriptions named and saved in the management component of RUSLE2 database
Cover-management subfactors	Cover-management subfactor values used to compute detachment (sediment production) by multiplying subfactor values; subfactor values vary through time as cover-management conditions vary temporally
Canopy	Represents how canopy affects erosion; function of canopy cover and fall height, canopy varies through time
Ground cover	Represents how ground cover affects erosion; function of portion of soil surface covered
Surface roughness	Represents how soil surface roughness affects erosion; function of roughness index
Soil biomass	Represents how live and dead roots in upper 10 inches and buried residue in upper 3 inches and less affect erosion
Soil consolidation	Represents how a mechanical disturbance affects erosion;, erosion decreases over time after last disturbance as the soil consolidates (soil consolidation as used in RUSLE2 represents soil particles rebonding during soil wetting and drying; rebonding process is not

	to occur by mechanical compaction)
Ridging	Represents how ridges increase detachment (sediment production)
Ponding	Represents how a water layer on soil surface reduces erosion
Antecedent soil moisture	Represents how previous vegetation affects erosion by reducing soil moisture; used only in Req zone
Critical slope length	Location where contouring fails on a uniform overland flow path
Cultural practice	Erosion control practice such as no-till cropping where cover-management variables are used to reduce erosion
Curve number	An index used in NRCS curve number method to compute runoff; RUSLE2 computes curve number values as a function of hydrologic soil group and cover-management conditions
Database	RUSLE2 database stores both input and output information in named descriptions
Dead biomass	Represents live above ground and root biomass converted to dead biomass by *kill vegetation* process in an *operation* description; dead biomass decomposes
Dead root biomass	A *kill vegetation* process in an *operation* description converts live root biomass to dead root biomass; dead roots decompose at the same rate as surface and buried residue
Decomposition	Loss of dead biomass as a function of material properties, precipitation, and temperature; decomposition rate for all plant parts and buried and surface biomass is equal; decomposition rate for standing residue is significantly decreased because of no soil contact
Deposition	Process that transfers sediment from sediment load transported by runoff to soil surface; net deposition causes sediment load to decrease with distance along overland flow path; depends on sediment characteristics and degree that sediment load exceeds sediment transport capacity; enriches sediment load in fines; computed as a function of sediment particle class fall velocity, runoff rate, and difference between sediment load and transport capacity
Deposition portion	Portion of overland flow path where net deposition occurs
Detachment	Separates soil particles from soil mass by raindrops, waterdrops falling from vegetation, and surface runoff; net detachment causes

	sediment load to increase along overland flow path; detachment is non-selective with respect to sediment characteristics; computed as function of erosivity, soil erodibility, distance along overland flow path, steepness of overland flow path, cover-management condition, and contouring
Disaggregation	Mathematical procedure used to convert monthly precipitation and temperature values to daily values assuming that daily values vary linearly; daily precipitation values sum to equal monthly values, average daily monthly temperature values equals average monthly temperature value
Diversion/terrace/ sediment basin	A set of support practices that intercept overland flow to end overland flow path length.
Diversions	Intercepts overland flow and directs it around hillslope in channelized flow, grade is sufficiently steep that deposition does not occur but not so steep that erosion occurs
EI_{30}	Storm (rainfall) erosivity; product of storm energy and maximum 30 minute intensity; storm energy closely related to rain storm amount and partly to rainfall intensity
Enrichment	Deposition is selective, removing the coarse and dense particles and leaving the sediment load with increased portion of fine and less dense particles
Enrichment ratio	Ratio of specific surface area of sediment after deposition to specific surface area of soil subject to erosion
Eroding portion	Portion of overland flow path where net detachment (erosion) occurs
Erosivity	Index of average annual rainfall erosivity at a location; closely related to rainfall amount and intensity; monthly erosivity is average sum of individual storm values in month, annual erosivity is average sum of values in year; storm rainfall amount must be ½ inch or more to be included in sum
Erosivity density	Ratio of monthly erosivity to monthly precipitation amount
External residue	Material, usually biomass, added to soil surface or placed in the soil; affects erosion as surface residue and buried residue produced by vegetation
Fabric (silt) fence	Fabric about 18 inches wide placed against upright posts on the contour; porous barrier that ponds runoff and causes deposition;

	widely used on construction sites
Fall height (effective)	Effective fall height is the effective height from which waterdrops fall from canopy; depends on canopy shape, canopy density gradient from bottom to top of canopy, and top and bottom canopy heights
Filter strip	A single strip of dense vegetation at the end of an overland flow path; can induce high amounts of deposition
Final roughness	Soil surface roughness after roughness has decayed to unit-plot conditions; primarily represents roughness provided by soil resistant clods
Flattening ratio	Describe how much standing residue that an operation flattens; ratio of standing residue before operation to standing residue after operation; values depend on operation and residue dry mass basis.
Flow interceptors	Topographic features (ridge or channel) on an overflow path that collects overland flow and directs the runoff around hillslope; ends overland flow path; diversions, terraces, and sediment basins are flow interceptors
Gradient terraces	Terraces on a uniform grade (steepness)
Ground cover	Represents the portion of the soil surface covered by material in direct contact with soil; includes plant litter, crop residue, rocks, algae, mulch, and other material that reduces both raindrop impact and surface flow erosivity
Ground cover subfactor	See cover-management subfactors
Growth chart	The collection of values that describe the temporal vegetation variables of live root biomass in upper 4 inches, canopy cover, effective fall height, and live ground cover; values are in a *vegetation* description in the vegetation component of the RUSLE2 database
Hortonian overland flow	Overland flow generated by rainfall intensity being greater than infiltration rate; although flow may be concentrated in micro-channels (rills), runoff is uniformly distributed around hillslope
Hydraulic (roughness) resistance	Degree that ground cover, surface roughness, and vegetation retardance slow runoff; daily values vary as cover-management conditions change
Hydraulic element	RUSLE2 hydraulic elements are a channel and a small

	impoundment
Hydraulic element flow path description	Describes the flow path through a sequence of hydraulic elements; named and saved in hydraulic element flow path component of RUSLE2 database
Hydraulic element system description	Describes a set of hydraulic element paths that are uniformly spaced along the overland flow path described without the hydraulic element system being present, named and saved in the hydraulic element system component of the RUSLE2 database
Hydrologic soil group	Index of runoff potential for a soil profile at a given geographic location, at a particular position on the landscape, and the presence or absence of subsurface drainage
Impoundment	A flow interceptor; impounds runoff; results in sediment deposition; represents impoundments typical of impoundment terraces on cropland and sediment basins on construction sites
Impoundment parallel terrace	Parallel terraces; impoundments occur where terraces cross concentrated flow areas; impoundments drains through risers into underground pipe
Incorporated biomass	Biomass incorporated (buried) in the soil by a *soil disturbing* operation; also biomass added to the soil by decomposition of surface biomass; amount added by decomposition of surface material is function of soil consolidation subfactor
Inherent organic matter	Soil organic matter content in unit-plot condition
Inherent soil erodibility	Soil erodibility determined by inherent soil properties, measured under unit-plot conditions (see soil erodibility)
Initial conditions	Cover-management conditions at the beginning of a no-rotation cover-*management* description
Initial input roughness	Roughness index value assigned to *soil disturbing* operation for the base condition of a silt loam soil having a high biomass on and in the soil; actual initial roughness value used in computations is a function of soil texture, soil biomass, existing roughness at time of soil disturbance, and tillage intensity
Injected biomass	Biomass placed in the soil using an *add other residue/cover* process in a *soil disturbing operation* description; biomass placed in lower half of disturbance depth (see operation processes)
Interrill erosion	Erosion caused by water drop impact; not function of distance along overland flow path unless soil, steepness, and cover-

	management conditions vary, interrill areas are the spaces between rills; very thin flow occurs on interrill areas
Irrigation	Water artificially added to the soil to enhance seed germination and vegetation production
Land use independent	RUSLE2 applies to all situations where Hortonian overland flow occurs and where raindrop impact and surface runoff cause rill and interrill erosion of exposed mineral soil; the same RUSLE2 equations are used to compute erosion regardless of land use
Live above ground biomass	Live above ground biomass provided by vegetation (dry matter basis); converted to standing residue (dead biomass) by a *kill vegetation* process in an *operation* description.
Live ground (surface) cover	Parts of live above ground biomass that touches the soil surface to reduce erosion.
Live root biomass	RUSLE2 distributes input values for live root biomass in upper four inches over a constant rooting depth of 10 inches for all vegetation types and plant growth stages; a *kill vegetation* process in an *operation* description converts live root biomass to dead root biomass. Primarily refers to fine roots that are annually produced, RUSLE2 uses live and dead root biomass in the upper 10 inches to compute a value for the soil biomass subfactor
Local deposition	Deposition that occurs very near, within a few inches, the point of detachment in surface roughness depressions and in furrows between ridges; given full credit for soil saved
Long term roughness	Roughness that naturally develops over time; specified as input in cover-*management* description; depends on vegetation characteristics (e.g., bunch versus sod forming grasses, root pattern near soil surface) and local erosion and deposition, especially by wind erosion; RUSLE2 computes roughness over time; fully developed by *time to soil consolidation*
Long term vegetation	Permanent vegetation like that on pasture, range, reclaimed mined land, and landfills; vegetation description can include temporal values starting on seeding date through maturity, any arbitrary date, or only for the annual cycle of vegetation at maturity
Management alignment offset	Used to sequence cover-management descriptions along an overland flow path to create alternating strips
Mass-cover relationship	Equation used to compute portion of soil surface covered by a

	particular residue mass (dry basis)
Mass-yield relationship	Equation used to compute standing biomass (dry basis) as a function of vegetation production (yield) level
Maximum 30 minute intensity	Average rainfall intensity over the continuous 30 minutes that contains the greatest amount in a rain storm
Non-erodible cover	Cover such as plastic, standing water, snow, and other material that completely eliminates erosion; material can be porous and disappear over time
Non-uniform overland flow path	Soil, steepness, and/or cover-management vary along an overland flow path; path is divided into segments where input selections are made for each segment
NRCS curve number method	Mathematical procedure used in RUSLE2 to compute runoff; a daily runoff value is computed using the 10 yr-24 hr precipitation amount and temporally curve number values that vary as cover-management varies
NWWR	Northwest Wheat and Range Region, a region in the Northwestern US covering eastern Washington and Oregon, northern Idaho (see Req zone)
Operation	An operation changes soil, vegetation, or residue; typically used to represent common farm and construction activities such as plowing, blading, vehicular or animal traffic, and mowing; also used to represent burning and natural processes such as killing frost and germination of volunteer vegetation.
Operation disturbance depth	Surface residue buried by a *soil disturbing* operation is a function of operation disturbance depth
Operation description	Information used to describe an operation, named and stored in the operations component of the RUSLE2 database
Operation processes	An operation is described by a sequence of processes; used to describe how an operation changes cover-managements conditions that affect erosion
No effect	Has no effect on computations; commonly used to reference dates in a cover-management description and to cause RUSLE2 to display information for a particular set of dates
Begin growth	Tells RUSLE2 when to begin using data from a particular *vegetation* description

Kill vegetation	Converts live above ground biomass to standing residue and to convert live root biomass to dead root biomass
Flatten standing residue	Converts a portion of the standing residue to surface residue
Disturb (soil) surface	Mechanically disturbs soil; required to bury surface residue; resurfaces buried residue; required to create roughness and ridges; required to place material (external residue) directly into the soil
Add other cover	Adds material (external residue) to the soil surface and/or places it in the soil
Remove live above ground biomass	Removes a portion of the live above ground biomass; leaves a portion of the affected biomass as surface (flat) residue and standing residue
Remove residue/cover	Removes a portion of standing and surface (flat) residue
Add nonerodible cover	Adds nonerodible cover such as plastic, water depth, snow, or other material that allows no erosion for portion of soil surface covered, cover disappears over time; cover can be porous; cover has no residual effect; not used to represent erosion control blankets and similar material
Remove nonerodible cover	Removes portion of nonerodible cover
Operation speed	Surface residue buried by a soil disturbing operation is a function of operation speed
Overland flow path	Path taken by overland flow on a smooth soil surface from its point of origin to the concentrated flow area that ends the overland flow path; runoff is perpendicular to hillslope contours
Overland flow path (profile) description	Includes values for steepness, names for *soil* and cover-*management* descriptions for segments along an overland flow path; a uniform overland flow path (profile) is where steepness, soil, or cover-management does not vary with distance along overland flow path; a convex profile is where steepness increases with distance; a concave profile is where steepness decreases with distance; a complex profile is a combination of convex, concave, and/or uniform sub-profiles or where soil and/or cover-management vary along the overland flow path

Overland flow path length	Distance along the overland flow path from the origin of overland flow to the concentrated flow area (channel) that intercepts runoff to terminate overland flow;, does not end where deposition begins (see USLE slope length and steepness)
Overland flow path segments	Overland flow path is divided into segments to represent spatial variability along an overland flow path; conditions are considered uniform within each segment
Overland flow path steepness	Steepness along the overland flow path, not hillslope steepness (see USLE slope steepness)
Permeability index	Index for the runoff potential of the soil under the unit-plot condition; used in RUSLE2's soil erodibility nomographs, similar to inverse of hydrologic soil group
Plan description	Collection of RUSLE2 *profile* descriptions used to computed weighted averages for a complex area based on the portion of the area that each profile represents; named and saved in plan component of RUSLE2 database
Ponding subfactor	See cover-management subfactors
Porous barriers	Runoff flows through a porous barrier; does not affect overland flow path; typically slows runoff to cause deposition; examples are stiff grass hedges, fabric (silt) fences, gravel dams, and straw bales
Precipitation amount	Includes all forms of precipitation; RUSLE2 disaggregates input monthly values into daily values to compute decomposition and temporal soil erodibility
Production (yield) level	A measure of annual vegetation live above ground biomass production; user defines yield measure and preferred units on any moisture content basis; input value used to adjust values in a vegetation description at a base yield; maximum canopy cover in base vegetation description must be less than 100 percent
Profile description	Information used to describe profile (overland flow path); includes names for location, topography, soil, cover-management, and support practices used to make a particular RUSLE2 computation, named and stored in profile component of RUSLE2 database
Profile shape	See overland flow path description
Rainfall (storm) energy	Computed as sum of products of unit rainfall energy and rainfall amount in storm intervals where rainfall intensity is assumed uniform; storm energy is closely related to rain storm amount

Rainfall intensity	Rainfall rate express as depth (volume of rainfall/per unit area) per unit time
Remote deposition	Deposition that occurs a significant distance (tens of feet) from the point where the sediment was detached; examples include deposition by dense vegetation strips, terraces, impoundments, and toe of concave overland flow paths; only partial credit given to remote deposition as soil saved; credit depends on location of deposition along overland flow path; very little credit given for deposition near end of overland flow path
Req	Equivalent erosivity for the winter months in the Req zone; used to partially represent Req effect
Req effect	Refers to Req equivalent erosivity; erosion per unit rainfall erosivity in the winter period in the Req zone is much greater than in summer period; winter effect is much greater than in other regions because of a greatly increased soil erodibility; effect partially results from an elevated soil water content, increased runoff, and soil thawing
Req zone	Region where erosion is elevated in the winter months because of the Req effect; region primarily in eastern WA and OR, portions of ID, CA, UT, CO, and limited area in other western US states
Residue	Has multiple meanings in RUSLE2; generally refers to dead biomass, such as crop residue, created when vegetation is killed; plant litter from senescence; and applied mulch material (external residue) such as straw, wood fiber, rock, and erosion control blankets used on construction sites; material is generally assumed to be biomass that decomposes; also used to represent applied material like rock that does not decompose
Residue description	Values used to describe residue, named and stored in the residue component of the RUSLE2 database
Residue type	Refers to fragility and geometric residue characteristics; affects residue amount buried and resurfaced by an operation; affects degree that residue conforms to surface roughness; affects erosion control on steep slopes like those on construction sites
Resurfacing ratio	Portion (dry mass basin) of the buried residue in the soil disturbance depth that a soil disturbing operation brings to the soil surface; function of residue and operation properties
Retardance	Degree that vegetation (live above ground biomass) and standing residue slows runoff; varies with canopy cover; function of

	production (yield) level; part of *vegetation* description
Ridge height	Height of ridges created by a *soil disturbing* operation; major variable along with row grade that determines contouring effectiveness; decays as a function of precipitation amount and interrill erosion
Ridge subfactor	See cover-management subfactors
Rill erosion	Caused by overland flow runoff; increases with distance along the overland flow path
Rill to interrill erosion ratio	Function of slope steepness, rill to interrill soil erodibility, and how cover-management conditions affect rill erosion different from interrill erosion
Rock cover	Rock cover entered in the *soil* description; represents naturally occurring rock on soil surface; operations do not affect this rock cover; rock cover created by an operation that *adds other cover* (rock residue) is treated as external residue; soil disturbing operations bury and resurface rock added as external residue
Root biomass	See dead and live root biomass
Root sloughing	Annual decrease in root biomass, RUSLE2 adds the decrease in live root biomass to dead residue biomass pool
Rotation	Refers to whether a list of operation descriptions in a cover-*management* description are repeated in a cycle; length of cycle is rotation duration; list of operation descriptions are repeated in RUSLE2 until computed average annual erosion value stabilizes; eliminates need to specify initial conditions; *operation* descriptions in a no-rotation cover-*management* descriptions are sequentially processed in a single pass, first *operation* descriptions in cover-*management* description establish initial conditions
Rotation duration	Time (length of cycle) before the list of *operation* descriptions in a rotation type cover-*management* description repeats; time period over which RUSLE2 makes its computation in a no-rotation cover-*management* description
Rotational strip cropping	A rotation type cover-management description that involves periods of dense vegetation that are sequenced along the overland flow path to create strips of alternating dense vegetation that cause deposition
Row grade	Grade along furrows separated by ridges; usually expressed as

	relative row grade, which is the ratio of grade along the furrows to steepness of the overland flow path
Runoff	RUSLE2 computes runoff using NRCS curve number method and the 10 yr-24 hour precipitation amount; used to compute contouring effect, contouring failure (critical slope length), and deposition by porous barriers, flow interceptors, and concave overland flow path profiles
Sediment basin	Small impoundment typical of those used on cropland and construction sites; discharge is usually through a perforated riser that completely drains basin in about 24 hours
Sediment characteristics	Deposition is computed as a function of sediment characteristics, which are particle class diameter and density and the distribution of sediment among particle classes
Sediment particle classes	RUSLE2 uses sediment particle classes of primary clay, silt, and sand and small and large aggregate classes, diameter of aggregate classes and the distribution of sediment among particle classes at point of detachment is function of soil texture; RUSLE2 computes how deposition changes the distribution of sediment particle classes
Sediment load	Mass of sediment transported by runoff per unit hillslope width
Sediment transport capacity	Runoff's capacity for transporting sediment; depends on runoff rate, overland flow path steepness, and hydraulic roughness; deposition occurs when sediment load is greater than runoff's transport capacity
Sediment yield	Sediment load at the end of the flow path represented in a RUSLE2 computation; flow path ends at overland flow path unless hydraulic elements (channel or impoundment) are present; sediment yield for site only if RUSLE2 flow path ends at site boundary
Segments	The overland flow path divided into segments based on topography, soil, and cover-management to represent spatial variation
Senescence	Decrease in vegetation canopy cover; senescence adds biomass to surface (flat) residue unless RUSLE2 is instructed that a decrease in canopy cover, such as leaves drooping, does not add to surface residue
Shear stress	Total runoff shear stress is divided into two parts of that acting on the soil (grain resistance) and that acting on surface residue, surface

	roughness, live vegetation, and standing residue (form resistance); shear stress acting on the soil is used to compute sediment transport capacity; total shear stress is used to compute contouring failure; also function of runoff rate and steepness of overland flow path
Short term roughness	Roughness created by a soil disturbing operation, decays over time as a function of precipitation amount and interrill erosion
Slope length exponent	Exponent in equation used to compute rill-interrill erosion as a function of distance along overland flow path, function of rill to interrill erosion ratio.
Soil biomass subfactor	See cover-management subfactors
Soil consolidation effect	Represents how wetting/drying and other processes cause soil erodibility to decrease over time following a mechanical soil disturbance; increase in soil bulk density (mechanical compaction) not the major cause of reduced soil erodibility; affects runoff, accumulation of biomass in upper 2 inch soil layer, and soil biomass effectiveness
Soil consolidation subfactor	See cover-management subfactors
Soil description	Describes inherent soil properties that affect erosion, runoff, and sediment characteristics at point of detachment on unit plot conditions, named and saved in the soil component of the RUSLE2 database
Soil disturbance width	Portion of the soil surface disturbed; weighted effects of disturbance computed as a function of erosion on disturbed and undisturbed area to determine an effective time since last disturbance, effective surface roughness, and effective ground cover
Soil disturbing operation	*Operation* description that contains *disturb soil* process
Soil erodibility	RUSLE2 considers two soil erodibility effects, one based on inherent soil properties and one based on cover-management; inherent soil erodibility effect represented by K factor value empirically determined from erosion on unit plot; part related to cover-management is represented in cover-management subfactors
Soil erodibility nomograph	Mathematical procedure used to compute a K factor value, i.e., inherent soil erodibility
Soil loss	Proper definition is the sediment yield from a uniform overland

	flow path divided by the overland flow path length; loosely used as the net removal of sediment from an overland flow path segment
Soil loss from eroding portion	Net removal of sediment from the eroding portion of the overland flow path
Soil loss tolerance (T)	Erosion control criteria, objective is that "soil loss" be less than soil loss tolerance T value, special considerations must be given to non-uniform overland flow paths to avoid significantly flawed conservation and erosion control plans
Soil mechanical disturbance	Mechanical soil disturbance resets soil consolidation effects; *disturb soil* process must be included in an *operation* description to create surface roughness and ridges and to place biomass into the soil
Soil saved	Portion of deposited sediment that is credited as soil saved; computed erosion is reduced by soil saved to determine a conservation planning soil loss value; credit depends on location of deposition along overland flow path
Soil structure	Refers to the arrangement of soil particles in soil mass; used to compute soil erodibility (K) factor values
Soil texture	Refers to the distribution of primary particles of sand, silt, and clay in soil mass subject to erosion
Standing residue	Created when live vegetation is *killed*, decomposes at a reduced rate; falls over at a rate proportional to decomposition of surface residue
Strip/barrier *description*	Support practice, describes porous barriers, named and stored in the strip/barrier component of RUSLE2 database
Subfactor method	See cover-management subfactors
Subsurface drainage description	Support practice that lowers water table to reduce soil water content, runoff, and reduces erosion; RUSLE2 uses difference between hydrologic soil groups for drained and undrained conditions to compute erosion as affected by subsurface drainage, named and save in subsurface drainage component of RUSLE2 database
Support practices	Erosion control practice used in addition to cultural erosion control practice, hence a support practice; includes contouring, filter and buffer strips, rotational strip cropping, silt (fabric) fences, stiff grass hedges, diversions/terraces, gravel dams, and sediment basins

Surface (flat) residue	Material in direct contact with the soil surface; main source is plant litter, crop residue, and applied mulch (external residue).
Surface roughness	Random soil surface roughness; combination of soil peaks and depressions that pond runoff; created by a *soil disturbing* operation, decays as a function of precipitation amount and interrill erosion
Surface roughness index	A measure of soil surface roughness; standard deviation of surface elevations measured on a 1 inch grid about mean elevation; effect of ridges and land steepness removed from measurements
Surface roughness subfactor	See cover-management subfactors
Temperature	Input as average monthly temperature; disaggregated into daily values, used to compute biomass decomposition and temporal soil erodibility
Template	Determines the computer screen configuration of RUSLE2 and inputs and outputs; determines the complexity of field situations that can be described with RUSLE2
Terraces	Flow interceptors (channels) on a sufficiently flat grade to cause significant deposition
Three layer profile schematic	Some RUSLE2 templates include an overland flow path schematic having individual layers to represent cover-management, soil, and topography; used to graphically divide the overland flow path into segments to represent complex conditions
Tillage intensity	Degree that existing soil surface roughness affects roughness left by a soil disturbing operation
Tillage type	Identifies where a soil disturbing operation initially places buried residue in soil, also refers to how operation redistributes buried residue and dead roots
Time to soil consolidation	Time required for 95 percent of the soil consolidation effect to be regained following a soil disturbing operation
Topography	Refers to steepness along the overland flow path and the length of the overland flow path
Uniform slope	Refers to an overland flow path where soil, steepness, and cover-management along the overland flow path do not vary along flow path

Unit rainfall energy	Energy content of rainfall per unit of rainfall; function of rainfall intensity
Unit plot	Base condition used to determine soil erodibility; reference for effects of overland flow path steepness and length; cover-management, and support practices; continuous tilled fallow (no vegetation; tilled up and downhill, maintained in seedbed conditions; topographic, cover-management, support practice factor values equal 1 for unit-plot condition
USLE slope length and steepness	USLE slope length is distance to a concentrated flow (e.g., terrace or natural waterway) or to the location where deposition occurs; USLE soil loss is sediment yield from this length divided by length (mass/area); USLE steepness is steepness of the slope length, uniform steepness often assumed
Validation	Process of ensuring that RUSLE2 serves its intended purpose as a guide to conservation and erosion control planning.
Vegetation description	Information used by RUSLE2 to represent the effect of vegetation on erosion; includes temporal values in growth chart, flow retardance, and biomass-yield information; named and stored in the vegetation component of the RUSLE2 database
Verification	Process of ensuring RUSLE2 correctly solves the mathematical procedures in RUSLE2
Worksheet description	A form in RUSLE2 program; used to compare conservation and erosion control practices for a given site; used to compare erosion computer for profile descriptions; named and saved in the worksheet component of the RUSLE2 database

Rusle 2 Science Documentation

1. ABOUT RUSLE2

1.1. Introduction

The Revised Universal Soil Loss Equation, Version 2 (RUSLE2) is a computer program that estimates rill and interrill erosion by solving a set of mathematical equations (Toy et al., 2002). RUSLE2 makes estimates based on site specific conditions, which allows erosion control practices to be tailored to each specific site. The RUSLE2 user describes the site by making selections from the RUSLE2 database. RUSLE2 uses this information to compute its erosion estimates. The purpose of RUSLE2 is to serve as a guide to conservation and erosion control planning. RUSLE2 is land use independent and applies to all conditions where rill and interrill erosion occurs when mineral soil is exposed to the erosive forces of impacting raindrops and water drops falling from vegetation and runoff produced by Hortonian overland flow. RUSLE2 computes erosion and deposition along a single overland flow path. RUSLE2 also computes deposition in channels and small impoundments that end overland flow paths.

RUSLE2 has three major components. One component is the science component that includes the mathematical equations that RUSLE2 uses to compute erosion and deposition. Inputs to the equations are user selected to represent the four major factors that affect erosion at a specific site. Those factors are climate (determined by location), inherent soil properties including soil erodibility, topography, and land use.

The second major RUSLE2 component is the RUSLE2 database. The RUSLE2 user makes selections from the database to describe site-specific conditions. The database contains information that describes climate (weather) at various locations, soils, cover-management systems, vegetations, residues, operations, porous strips and barriers, flow interceptors including diversions and terrace channels and small impoundments, subsurface drainage systems, irrigation systems, overland flow paths, worksheets, and plan views (collections of overland flow paths). A single overland flow path is the basic RUSLE2 computational unit. Erosion can be compared in a worksheet for multiple erosion control alternatives for a single overland flow path or multiple overland flow paths. A plan view is used to compute erosion on overland flow areas in spatially complex landscapes.

The third major RUSLE2 component is the computer program. The program includes a powerful computational engine that organizes and solves the mathematical equations, database maintenance tools, and an interface (computer screen) that accepts user inputs and displays computed values.

The USDA-Agricultural Research Service had overall lead responsibility for developing RUSLE2 and lead responsibility for developing the science (i.e., mathematical equations used in RUSLE2). The University of Tennessee had lead responsibility for developing the RUSLE2 computer program including its interface and computational engine. The USDA-Natural Resources Conservation Service had lead responsibility for developing user requirements as the principal RUSLE2 client and the RUSLE2 database for cropland. Other organizations developed database information, user guides, and instructional material for RUSLE2. For example, the University of Denver developed database information and other materials for application of RUSLE2 to construction sites, reclaimed mined land, landfills, and other highly disturbed lands.

This document describes the RUSLE2 science, which is primarily embodied in the mathematical equations used in RUSLE2 to compute erosion and deposition estimates.

1.2. Major requirements

The RUSLE2 erosion prediction technology was designed to meet several requirements, many of which affected RUSLE2's science and the equations. These requirements included:

1) Purpose of RUSLE2 is to serve as a guide to conservation and soil erosion control planning at the local field office level.

2) Be easy to use.

3) Be robust so that computed erosion values are not overly sensitive to small changes in variables where input values involve considerable uncertainty. Helps ensure good estimates when extrapolated beyond range of data used to derive RUSLE2.

4) Input values are physically meaningful to typical RUSLE2 users and directly measurable where possible.

5) Not require resources beyond those available at the field office level, especially for the USDA-Natural Resources Conservation Service that is the primary RUSLE2 user.

6) Produce useful information for conservation and erosion control planning that is consistent with the resources (i.e., expertise, time, effort, and other costs) required to implement and use RUSLE2.

7) Lead to desired conservation and erosion control planning decisions as expected based on available erosion research data, accepted erosion science, field experience, and professional judgment.

8) Apply to Hortonian overland flow where rill and interrill erosion is caused by mineral soil being exposed to the erosive forces of surface runoff and impacting waterdrops from rainfall and rainwater falling from vegetation.

9) Be land-use independent by using relationships based on the fundamental variables that affect erosion.

10) Produce accurate erosion estimates comparable to measured research values and estimated by the Universal Soil Loss Equation (USLE).

11) Be an evolution of the USLE and RUSLE1.

12) Be thoroughly and carefully reviewed and evaluated to ensure that RUSLE2 performs acceptably.

13) Recommendations on how to best apply RUSLE2 would be a part of the RUSLE2 development and documentation.

1.3. Major guiding principles used to develop RUSLE2 science

The following principles guided the development of the RUSLE2 science according to the requirements listed in **Section 1.2**.

1) The USLE is accepted in term of its conceptual basis, equation structure, empirical derivation, and computed values by both the scientific and user communities.

2) The USLE is valid (i.e., serves its intended purpose) for conservation and soil erosion control planning.

3) RUSLE2 development will start from the USLE structure and extend that structure and empirical derivation.

4) RUSLE2 will represent main effects that can be considered in the conservation and erosion control planning. These main effects are those established by empirical data and fundamental erosion science.

5) Erosion data available for empirically deriving RUSLE2 equations are very limited. The data set is small in relation to the many variables and their many complex interactions that affect erosion. The dataset is not a statistically robust data set because of non-uniform coverage of important variables. The data contain much unexplained variability that can not be resolved.

6) Equations will be chosen to best represent established main effects rather than using regression procedures to fit equations to data to provide the best overall statistical fit. Equations will be chosen based on main effects conclusively established by empirical data, fundamental erosion science, practical experience, professional judgment, and overall good judgment (common sense).

7) First establish mathematical relationships empirically using experimental data and then use process-based equations based on fundamental erosion science to extend the RUSLE2 beyond the available research data.

8) Start from a mean, typical, or accepted value consistent with the USLE unit-plot concept and use normalized variables to compute values that deviate about the

value for a base condition to capture main effects. Equations and limits will be selected to produce a robust erosion prediction technology.

9) Minimize use of geographic zones and variable classes to avoid step changes (discontinuities) between zones and classes.

10) Achieve land-use independence by having a single set of equations that vary as a continuous function of the major variables that affect erosion across all land uses.

11) Make judgments in the context of reasonableness and appropriateness for conservation and erosion planning and implementation. Do the results make good overall sense? If one had perfect knowledge, what would be the planning decision? RUSLE2 is a tool for conservation and erosion control planning, not a scientific product designed to produce new scientific knowledge and understanding.

2. BASIC MATHEMATICAL STRUCTURE

RUSLE2 computes values for the three fundamental erosion processes of detachment (sediment production), transport, and deposition.[1] The empirical equation form of the USLE is used to compute detachment while process-based equations are used to compute sediment transport and deposition. These equations, which are written for a point in time and a location on an overland flow path, are integrated in both time and distance to produce average annual and spatial estimates for segments along the overland flow path and for the entire overland flow path.

2.1. Detachment (Sediment Production) Equation

The USLE in its original form is:

$$A = RKLSCP \qquad [2.1]$$

where: A = average annual erosion rate (mass/area·year) for the slope length λ, R = erosivity factor (erosivity unit/area·year), K = soil erodibility factor (mass/ erosivity unit), L = slope length factor (dimensionless), S = slope steepness factor (dimensionless), C = cover-management factor (dimensionless), and P = support practice factor (dimensionless).[2] The USLE, equation 2.1, has two parts, the part that computes unit-plot erosion and the part that adjusts unit plot-erosion to represent actual field conditions. The part that computes unit-plot erosion is:

---

[1] Refer to the RUSLE2 User's Reference Guide for detailed explanations of RUSLE2 terms. Also, see **Glossary of Terms** section in this document.

[2] See List of symbols at end of this chapter.

$$A_u = RK \qquad [2.2]$$

where: A_u = average annual erosion (mass/area·year) for the unit plot (mass/area·year).[3] The terms LSCP are normalized with respect to the unit plot and, therefore, have a value of 1 for unit plot conditions.[4] In effect, the USLE computes erosion for unit plot conditions with the product RK and then uses the terms LSCP to adjust the unit plot erosion to account for differences between unit plot conditions and actual field conditions.

Equation 2.2 is a temporal integration of the basic USLE equation that computes unit-plot erosion for individual storms as:

$$a_{us} = (EI_{30})K \qquad [2.3]$$

where: a_{us} = the unit-plot erosion (mass/area) from the storm that has the rainfall erosivity EI_{30} (force·length/area)(length/time), E = rain storm energy (force·length/area), and I_{30} = average intensity (length/time) over the continuous 30 minutes with the most rainfall in the storm. The linear relationship between unit plot erosion and storm erosivity EI_{30} means that the erosivity factor R can be computed for a locations as:

$$R = \sum_{j=1}^{M_r} \sum_{m=1}^{M_{s(j)}} (EI_{30})_m \Big/ M_r \qquad [2.4]$$

where: EI_{30} = storm erosivity for storm events greater than 0.5 inches (12 mm), $M_{s(j)}$ = the number of storms in the *jth* year, M_r = number of years in the record being used to compute erosivity.[5]

The linear relationship between erosion on the unit plot and erosivity mathematically means that average daily erosion can be computed as:[6]

$$a_u = rK \qquad [2.5]$$

---

[3] The unit plot is 72.6 ft (22.1 m) long on a 9 percent slope, maintained in continuous fallow, tilled up and down hill to a seedbed condition periodically to control weeds and break crusts that form on the soil surface.

[4] The terms A_u, R, and K have dimensions and units. The terms LSCP are ratios of erosion from a given field condition to erosion for the unit-plot condition, and these terms are, therefore, dimensionless and have no units.

[5] See RUSLE2 User's Reference Guide for a detailed description of the computation of RUSLE2 erosivity values.

[6] Daily erosion computed by RUSLE2 is a long-term average erosion for that day.

where: a_u = daily erosion from the unit plot on the *ith* day and r = the average daily erosivity on the *ith* day. Average daily erosivity values are determined by the disaggregation of average monthly erosivity input values into daily values (see **Section 3.1**).

Although the terms LSCP vary with time as field conditions change, the cover-management factor C is the only one of these USLE terms that is mathematically integrated with time. An average annual representative value is selected for the other terms. The mathematical equation used in the USLE to compute erosion for a crop stage period is:

$$a_k = KLS\,\mathrm{P}r_k\, c_k \qquad [2.6]$$

where: a, r, and c = the erosion, erosivity, and cover-management (soil loss ratio) factors, respectively, for the *kth* crop stage.[7] The erosivity for the *kth* crop stage is given by:

$$r_k = f_k R \qquad [2.7]$$

where: f_k = the portion of the average annual erosivity that occurs during the *kth* crop stage.[8] Therefore, the average annual cover management C factor in the USLE is computed as:

$$C = \left(\sum_{k=1}^{M_k} f_k c_k \right) \Big/ N_c \qquad [2.8]$$

where: M_k = the number of crop stages over the period of N_c years involved in the computation, such as years in a crop rotation or years after disturbance of a construction site, used to compute erosion.

The mathematics of the USLE equation structure, therefore, allows RUSLE2 to compute an average daily erosion as:

$$a = rklScp_p p_c p_d \qquad [2.9]$$

---

[7] A crop stage period is a time interval over which a constant soil loss ratio can be assumed. The soil loss ratio is the ratio of erosion with a given cover-management condition to the unit plot erosion for the same period, with all other conditions being the same between the two cover-management conditions.

[8] Erosivity varies during the year. The empirical curve that describes this temporal distribution is referred to as the EI distribution.

where: r = daily erosivity (erosivity unit/area·day), k = daily soil erodibility factor (mass/erosivity unit), l = daily slope length factor dimensionless, c= daily cover-management (soil loss ratio) factor (dimensionless), p_p = daily ponding subfactor (dimensionless), p_c = daily contouring subfactor (dimensionless), and p_d = daily subsurface drainage subfactor (dimensionless).[9] The average daily erosion computed by equation 2.9 is the average erosion (mass/area) for the slope length λ. All terms in equation 2.9 use average daily values except for the slope steepness factor that is assumed to be constant in RUSLE2 for all conditions except for variations in slope steepness.[10]

2.1.1. Equation for rill and interrill detachment combined

Equation 2.9 is converted to an equation that computes rill and interrill erosion combined at a point so that RUSLE2 can be applied to non-uniform overland flow paths where soil, steepness, and cover-management vary along the overland flow path. This equation is (Foster and Wischmeier, 1974):

$$D = (m+1)rk(x/\lambda_u)^m Scp_p p_c p_d \qquad [2.10]$$

where: D = average daily net detachment by both rill and interrill erosion (mass/area) at a point at the distance x from the origin of the overland flow path, λ_u = the unit plot length (72.6 ft, 22.1 m), and m = daily slope length exponent. The value for each term, except erosivity r, is the value for the term at the location x on the overland flow path.

2.1.2. Equation for interrill erosion

Interrill erosion is assumed to occur even when RUSLE2 computes deposition (see **Sections 2.3.1, 2.3.6, and 2.3.8**). The RUSLE2 equation for interrill erosion is:

$$D_i = 0.5rkS_i cp_r p_c p_d \qquad [2.11]$$

where: D_i = daily interrill erosion (mass/area·day), and S_i = the slope steepness factor for interrill erosion. Equation 2.11 for interrill erosion is similar to equation 2.10 for rill and interrill erosion combined except that equation 2.11 has no distance (x) term, has a slope steepness factor specifically for interrill erosion, and has a 0.5 factor. The reason for not having a distance term is that detachment on interrill areas is caused by impacting

---

[9] RUSLE2 describes the effect of other support practices besides contouring on erosion. Those effects are described using process-based equations that compute deposition rather than a P factor value as in the USLE.

[10] Lower case symbols are used in equation 2.9 to distinguish between the daily factor values used in RUSLE2 and the average annual factor values used in the USLE. An upper case symbol is used for the slope steepness factor because a constant value is used in RUSLE2 that is equivalent to the USLE slope steepness factor value.

raindrops and waterdrops falling from vegetation. Detachment on interrill areas is assumed to be uniform along the overland flow path provided soil, steepness, or cover-management does not change along the overland flow path (Foster and Meyer, 1975; Foster et al., 1977a; Toy et al., 2002).

The slope steepness factor for interrill erosion differs from the slope steepness for rill erosion because the detachment forces produced by impacting waterdrops differ from the detachment forces produced by flow in rill areas. The interrill erosion slope steepness factor in equation 2.11 was empirically derived from experimental data (Lattanzi et al., 1974; Foster, 1982; McGregor et al., 1990). The slope steepness factor in the equation 2.10 represents the effect of slope steepness on rill and interrill erosion combined. The 0.5 factor in equation 2.11 results from the assumption that interrill erosion and rill erosion are equal for unit plot conditions (Foster and Meyer, 1975; Foster et al., 1977b; McCool et al., 1989).

2.1.3. Ratio of rill to interrill erosion

The slope length exponent m in equation 2.10 is a function of the ratio of rill to interrill erosion. RUSLE2 computes the slope length exponent m as (Foster et al., 1977b; McCool et al., 1989):

$$m = \beta/(1+\beta) \qquad [2.12]$$

where: β = ratio of rill to interrill erosion. The typical slope length exponent in the USLE is 0.5, which is the value computed by equation 2.12 when rill and interrill erosion are equal. The slope length exponent m computed by equation 2.12 varies about 0.5 as the ratio of rill erosion to interrill erosion varies about 1. The base condition for rill erosion equaling interrill erosion is for unit plot conditions.

The ratio of rill to interrill erosion is computed from:[11]

---

[11] Equations 2.11 and 2.13 illustrate an important design principle in RUSLE2. The terms that represent interrill erosion in equation 2.13 differ from those in equation 2.11 used to compute absolute interrill erosion, which seems inconsistent. The design philosophy in RUSLE2 is that RUSLE2 starts from accepted empirical values, which is 0.5 for the slope length exponent for unit plot conditions. Empirical values are used to the extent that they can be determined from experimental data, especially to represent main effects. The best possible empirical value is determined from the experimental data, and then the accepted empirical value is adjusted using process-based equations. The adjustment is up or down about the accepted empirical value, which is almost always a ratio in RUSLE2 because the LSCP variables are non-dimensional ratios. This approach of adjusting up or down about an accepted empirical ratio value rather than computing absolute values gives RUSLE2 increased robustness and avoids RUSLE2 giving seriously erroneous values when it is extrapolated. The ratio of rill to interrill ratio can be computed more accurately than can an absolute value for interrill erosion. The advantage of equation 2.11 is that it computes values that are close to erosion values computed by the USLE, which is a more conservative and robust approach than computing an absolute value of interrill erosion using variables from equation 2.13.

$$\beta = \left(\frac{K_r}{K_i}\right)\left(\frac{c_{pr}}{c_{pi}}\right)\left(\frac{\exp(-b_r f_g)}{\exp(-0.025 f_g)}\right)\left(\frac{s/0.0896}{3s^{0.8}+0.56}\right) \qquad [2.13]$$

The ratio K_r/K_i = the inherent rill to interrill soil erodibility ratio (see **Section 4.3**), which is computed as a function of soil texture to reflect that some soils are inherently more susceptible to rill erosion than to interrill erosion than are other soils. The term c_{pr}/c_{pi} = the rill to interrill erosion ratio for prior land use soil erodibility (see **Section 6.2.2**), which reflects how soil consolidation and soil biomass affect rill erosion differently from how it affects interrill erosion. The ratio $\exp(-b_r f_g)/\exp(-0.025 f_g)$ reflects how ground cover affects rill erosion more than it affects interrill erosion, where b_r and 0.025 = coefficients (percent^{-1}) that express the relative effectiveness of ground cover for reducing rill erosion and interrill erosion, respectively (see **Section 6.2**), and f_g = ground cover expressed as a percent (see **Section 6.2.2**).

The term $(s/0.0896)/(3s^{0.8}+0.56)$ [where s = steepness of overland flow path (sine of slope angle)] reflects how steepness affects rill erosion differently than it does interrill erosion (Foster, 1982). This term assumes that rill erosion varies linearly with steepness.

The assumption in equation 2.12 that rill erosion varies with a slope length exponent of 1 (McCool et al., 1989) is consistent with the maximum slope length exponent of 1 observed in the experimental plot data used to derive the USLE [AH537 (Wischmeier and Smith, 1978)]. The maximum exponent of 1 is also consistent with the variation of erosion with discharge on steep slopes (Meyer et al., 1972) but is less than a value of 0.75 reported in other field research (Govers, 1991; McCool et al., 1989) where rill erosion is the dominant erosion process.

The slope length exponent base value is 0.5. Equation 2.12 increases or decreases this value as rill erosion increases or decreases relative to interrill erosion. The terms in equation 2.13 represent the main variables that affect rill erosion relative to interrill erosion.

Given that rill erosion varies with a slope length exponent of 1, the rill erosion term in equation 2.13 should have included a slope length term. The reason that a slope length term is not in equation 2.13 is because of mathematical limitations in devolving the USLE equation structure into rill and interrill erosion terms. If a slope length term had been included in equation 2.13, RUSLE2 could not have met the requirement that erosion computed for the entire overland flow path length be independent of how many overland flow path segments are used in the computations when other conditions are uniform along the overland flow path (see **Section 5.Appendix 1**).

2.2. Spatial and Temporal Integration

RUSLE2 requires both a spatial and temporal integration. The spatial integration is made by solving the governing equations along the overland flow path each day. Temporal integration is made by summing daily values to obtain totals for the computation duration.[12] The average annual erosion is the sum of the daily values divided by the number of years (duration) in the computation.

If RUSLE2 were applied to only spatially uniform overland flow paths, equation 2.9 could be analytically solved for each day and the values summed to compute total erosion for a **rotation duration**. However, the solution is complex when soil, steepness, and cover-management vary along the overland flow path (i.e., spatially non-uniform overland flow paths), especially when deposition occurs.[13] RUSLE2 performs a spatial integration each day to compute daily spatially-distributed erosion, deposition, and sediment load values along the overland flow path. The spatial integration process in RUSLE2 is referred to as **sediment routing**, a common term used in hydraulic analyses.

2.3. Sediment Routing (Spatial Integration)

2.3.1. Continuity equation

The RUSLE2 governing equation that is spatially integrated is the steady state continuity (conservation of mass equation) given by (Foster, 1982):

$$dg / dx = D_i + D_{rorp} \qquad [2.14]$$

where: g = sediment load (mass/unit overland flow width·time), x = distance along the overland flow path from its origin, and D_{rorp} = either rill erosion rate (D_r) (mass/area· time) or deposition (D_p) (mass/area· time) by runoff in rill areas.

Equation 2.14 is solved numerically because it can not be analytically solved except for the special case of a uniform overland flow path where neither soil, steepness, nor cover-management vary along the overland flow path. RUSLE2 applies in the general case where any or all of these variables change along the overland flow path. The numerical solution requires that the overland flow path be divided into segments as illustrated in Figure 2.1 where the soil, steepness, and cover-management conditions are uniform over each segment. The numerical form of equation 2.14 for this computation is:

$$g_i = D_i\left(x_{(i)} - x_{(i-1)}\right) + \int_{x_{(i-1)}}^{x_{(I)}} D_{rorp}\, dx + g_{(i-1)} \qquad [2.15]$$

---

[12] Computation duration is the rotation duration (cycle length) for a **rotation** type cover-management description. The computation duration is the length of time specified for the duration of a no-rotation type cover-management description.

[13] RUSLE2 is much more powerful than the USLE because the USLE can not be applied to spatially non-uniform conditions that cause deposition (Foster and Wischmeier, 1974).

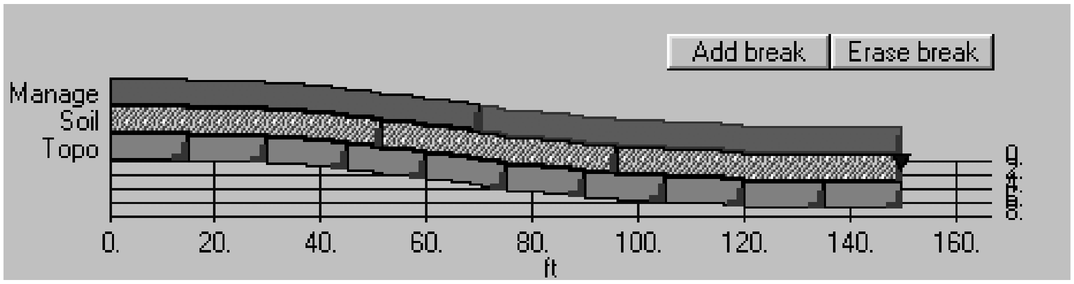

Figure 2.1. Schematic of the three layers that represent an overland flow path (a RUSLE2 hillslope(overland flow path) profile).

The lower and upper ends of the segment are delineated by $x_{(i)}$ and $x_{(i-1)}$, respectively, and the segment length is the difference $x_{(i)} - x_{(i-1)}$. Equation 2.12 is applied sequentially along the overland flow path starting at x = 0, which is the origin of the overland flow path. The incoming sediment load $g_{(i-1)}$ to the first segment at x = 0 is zero because no runoff enters at the origin of the overland flow path. The sediment load, g_{i-1}, entering the *ith* segment is known from the computation for the upslope *(i-1)th* segment. The sediment load g_i is the sediment load leaving the *ith* segment.

Rill and interrill erosion combined are computed with equation 2.10 rather computing interrill erosion and rill erosion separately as implied in equation 2.15. Equation 2.10 is solved analytically over the segment by assuming that soil, steepness, and cover-management are uniform over the segment. If deposition occurs, interrill erosion D_i is computed with equation 2.11 and the integral for deposition D_p is solved numerically (see **Section 2.3.6**).

The RUSLE2 assumption of uniformity within a segment causes step changes in input variables and certain computed variables where segments adjoin. Each soil, steepness, and cover-management variable is constant over a segment, but these variables make step changes at the common point between two segments. For example, the steepness values for two segments are not averaged to obtain a single steepness value at the intersection of two segments. Consequently, computed detachment and deposition values are discontinuous (i.e., step change) across segment intersections where soil, steepness, or cover-management changes between segments. However, runoff rate and sediment load are continuous at adjoining segment points. These step changes require sufficiently short segments to represent variables that vary continuously along the overland flow path. An example is a concave overland flow path (profile) where steepness continuously decreases from its upper end to lower end. A preliminary sensitivity analysis can be conducted to determine appropriate segment lengths for developing an erosion control plan for a specific site.

RUSLE2 could have been constructed to accommodate both step and continuous changes with distance. However, the benefits of representing both continuous and step changes were judged insufficient to merit the increased complexity in the equations, inputs, and programming for most RUSLE2 applications in erosion control planning. Step changes seem to occur more frequently than continuous changes in variables along an overland flow path in most field situations. RUSLE2 represents these step changes, such as those associated with buffer strips and intersection of land slopes on construction sites.

2.3.2. Transport capacity-detachment limiting concept

RUSLE2 uses the transport capacity-detachment limiting concept to compute rill detachment or deposition (Foster et al., 1981a). The assumption is that rill erosion occurs where runoff transport capacity exceeds sediment load. Rill erosion is assumed not to be affected by the degree that sediment load fills runoff's sediment transport capacity, except where rill erosion would overfill transport capacity if rill erosion were to occur at its capacity rate. In this situation, rill erosion occurs at the rate that just fills transport capacity.[14]

A very important RUSLE2 assumption is that detachment and deposition by flow in rill areas at a location on an overland flow path can not occur simultaneously. Another important assumption is that both rill and interrill erosion are non-selective (Foster et al., 1985b). When rill and interrill detachment occur, the detached sediment contains all of the sediment classes having a distribution and size based solely on soil texture (see **Section 4.7**). That is, neither rill nor interrill detachment processes can "reach into the soil" and selectively remove sediment from particular sediment classes and not remove sediment from other particle classes. The basis of this assumption is that most soils are cohesive. Detachment is a process that separates soil particles from the soil mass by breaking cohesive bonds within the soil. This separation process produces sediment in all sediment classes because not all bonds in the soil are uniformly broken, much like striking a piece of concrete with a hammer produces a mixture of particles.[15]

Another important RUSLE2 assumption is that interrill erosion and deposition in rill areas occur simultaneously. When flow causes rill erosion, small incised channels are eroded. When deposition by runoff in rill areas occurs, the deposition is spread across the slope so that deposition covers the entire local area unless ridges are present (Toy et al., 2002). Therefore, a case can be made that no interrill erosion occurs on depositional areas, especially where deposition rates are high and flow is deep to protect the underlying soil surface from raindrop impact. However, even in these cases, deposition and water depths are quite spatially non-uniform, resulting in local areas that are not

---

[14] The concept of the interaction between rill erosion, sediment load, and transport capacity is valid, especially in ideal conditions and has advantages for RUSLE2 (Foster and Meyer, 1975; Foster, 1982). However, rill erosion in most field conditions is highly variable along rills where very intense local erosion occurs (e.g., at headcuts) and intervening areas of very low rill erosion. Because the hydraulic equations used in RUSLE2 do not represent this high degree of spatial non-uniformity, RUSLE2 can not adequately capture this important interaction.

[15] Soils can contain gravel that runoff does not transport. Conceptually, those particles are not assumed in RUSLE2 to be a part of the cohesive soil mass. The reason that gravel particles are not transported is that the runoff does not have sufficient transport capacity to move these particles. The effect of gravel and rock fragments on erosion is taken into account in RUSLE2 (see **Section 4.6**).

protected by deposited sediment or deep water. Also, many soil disturbing operations, such as tillage, leave surface roughness and ridges where soil protrudes above the flow and is directly exposed to interrill erosion. The RUSLE2 assumption is that interrill erosion and deposition by rill flow occurs simultaneously has the important benefit of allowing RUSLE2 to compute local deposition in soil surface roughness, furrows between ridges, and similar local roughness features.[16]

2.3.3. Basic deposition equation

RUSLE2 computes deposition when sediment load exceeds transport capacity using (Foster et al., 1981a; Foster, 1982):

$$D_p = (\alpha_d V_f / q)(T_c - g) \qquad [2.16]$$

where: D_p = deposition rate (mass/area·time), α_d = a deposition coefficient determined by calibration, V_f = fall velocity of the sediment in still water (length/time), q = overland flow (runoff) rate (volume/overland flow width·time) where flow depth is assumed to be uniform across the slope, T_c = transport capacity (mass/overland flow width·time). Equation 2.16 is solved for each sediment class (see **Section 4.7**). The distribution of the total transport capacity among the sediment classes is assumed to equal the distribution of the total sediment load among the classes. Equation 2.16 gives RUSLE2 its capability for computing deposition's selectivity where coarse, dense sediment is deposited more readily than fine, less dense sediment. The orders of magnitude variation in sediment fall velocity among the sediment classes is the major factor in computing selective deposition.

2.3.4. Sediment transport capacity equation

The RUSLE2 equation for sediment transport capacity of runoff in the rill areas is (Foster and Meyer, 1972; Foster and Meyer, 1975; Nearing et al., 1989, Finkner et al., 1989):

$$T_c = K_T \zeta q s \qquad [2.17]$$

where: the coefficient K_T coefficient for sediment transportability (mass/volume) and the ζ = coefficient for effect of hydraulic resistance on sediment transport capacity (dimensionless).

---

[16] Equation 2.11, which computes interrill erosion, actually computes sediment load delivered to rill flow rather than detachment on interrill areas. An improved approach is to use separate equations to compute detachment, deposition, and sediment transport on interrill areas, but that approach was judged to be too complex for RUSLE2. The RUSLE2 limitation regarding interrill erosion is that RUSLE2 does not compute sufficient enrichment of fines in the sediment although interrill erosion is appropriately computed. However, this limitation can be overcome by using the procedure described by Foster (1982) that can be used to compute distribution of sediment by sediment class delivered from interrill areas as a function of soil surface roughness.

A RUSLE2 assumption is that all sediment regardless of its composition is equally transportable, and therefore, a single value for sediment transportability is used in RUSLE2 (see **Section 4.7**). This assumption is questionable because the transportability of coarse sediment is much less than for fine sediment. Sediment transport capacity equations are available that could be used to vary sediment transportability as a function of sediment characteristics, but these equations were judged not to be sufficiently robust for RUSLE2 (Foster and Meyer, 1972; Alonso et al., 1981). For example, slight changes in fine sediment properties significantly affect overland flow's sediment transport capacity computed with sediment transport equations. Slight spatial variations in overland flow hydraulics that can not be described in RUSLE2 also dramatically affect overland flow's sediment transport capacity. Using a complex sediment transport equation is not warranted when RUSLE2 does not capture important details in describing flow hydraulics. Furthermore, the effect of sediment transportability is partially captured by RUSLE2's soil erodibility factor (see **Section 4.1**).[17]

A value for the transportability coefficient K_T was obtained by fitting RUSLE2 to experimental data where deposition occurred on a concave profile overland flow path (Foster et al., 1980c). Sediment transport capacity equals sediment load at the location where deposition begins. Values for K_T were adjusted until computed sediment transport capacity matched the measured sediment load at the location where deposition began in the field study. The K_T value was validated by computing deposition along on the same overland flow path used to determine the K_T value the point where deposition started. The K_T value was also validated by computing deposition for other laboratory and field experimental data (Foster et al., 1980; Neibling and Foster, 1982; Lu et al., 1988). Deposition was computed with RUSLE2 for a wide range of field conditions and those values were inspected for reasonableness and consistency with field observations (see the **RUSLE2 User's Reference Guide**).

The RUSLE2 calibrated value for K_T is 250,000 (lbs_m/ft^3). This value is based on the following set of units. T_c: $lbs_m/(sec \cdot ft\ width)$, ζ: dimensionless, q: $ft^3/(sec \cdot ft\ width)$, s: dimensionless.

The coefficient ζ represents the effect of hydraulic resistance on runoff's sediment transport capacity. This coefficient, which is the ratio of transport capacity with a hydraulic rough surface to transport capacity for a hydraulic smooth surface, varies from essentially 0 for a very hydraulic rough surface to 1 for a hydraulically smooth surface. Hydraulic resistance (roughness) is provided by soil surface roughness, ground cover (material in direct contact with the soil surface), and vegetation retardance. Flow over a soil surface applies a total shear stress. Part of the shear stress is applied to form

---

[17] RUSLE2 is a hybrid empirical/process-based model. Many of the variables and equations used in RUSLE2 are not nice and crisp where elemental properties and processes are described. For example, the RUSLE2 soil erodibility factor represents both detachability and transportability. RUSLE2 has been validated to ensure that it acceptably computes erosion over the vast majority of situations where RUSLE2 is applied. See the RUSLE2 User's Reference Guide for a discussion of RUSLE2's validation.

roughness (soil surface roughness, ground cover, and vegetation retardance) and the other part is applied to grain roughness (the individual soil particles and aggregates at the soil-flow interface). The shear stress exerted on grain roughness is assumed to be responsible for sediment transport (Foster et al., 1981a; Foster, 1982). The grain roughness shear stress decreases as form roughness increases, and consequently values for ζ decrease as form roughness increase (see **Section 3.4.1**). RUSLE2 computes a change in ζ, and thus sediment transport capacity, as cover-management conditions change.

2.3.5. Runoff

RUSLE2 uses flow rate values for runoff to compute sediment transport capacity (see **Section 2.3.4**), contouring effectiveness (see **Section 7.1**), and contouring failure (see **Section 3.4.3**). Discharge rate at a location along an overland flow path is computed with:

$$q = q_{(i-1)} + \sigma\left(x - x_{(i-1)}\right) \quad [2.18]$$

where: q = discharge rate at the location x between the segment ends x_{i-1} and x_i, q_{i-1} = discharge rate at x_{i-1}, and σ = excess rainfall rate (rainfall rate minus infiltration rate) on the *ith* segment. Excess rainfall rate is computed using the NRCS runoff curve number method that computes runoff depth (see **Section 3.3.1.1**). The RUSLE2 assumption is that excess rainfall rate equals runoff depth divided by one hour. The difference between the two is accounted for in calibration coefficients including the K_T value for sediment transport capacity in equation 2.17. The RUSLE2 principle is to capture runoff's main effects sufficiently well for erosion control planning. RUSLE2 computes excess rainfall rate as a function of hydrologic soil group, surface roughness, ground cover, soil biomass, and soil consolidation to represent cover-management's effect on runoff.

In most cases, runoff rate q increases within each segment, where the rate of increase depends on infiltration within the segment. RUSLE2 computes a decreasing runoff rate within a segment if infiltration rate in the segment is sufficiently high (see **Sections 2.3.8.3.3 and 3.3.1.1**).

2.3.6. Numerical solution of deposition equation

The deposition equation (equation 2.16) combined with the continuity equation (equation 2.14) must be integrated to compute deposition over a segment of an overland flow path. RUSLE2 solves these equations numerically because an analytical solution was not found. Equations 2.15 and 2.16 along with an equation for transport capacity were written in discrete form for each sediment class as:

$$\frac{D_{pk(1)} + D_{pk(2)}}{2} = \frac{\alpha_d V_{fk}}{[(q_{(1)} + q_{(2)})/2]}\left(\frac{T_{ck(1)} + T_{ck(2)}}{2} - \frac{g_{k(1)} + g_{k(2)}}{2}\right) \quad [2.19]$$

$$g_{k(2)} = g_{k(1)} + D_{ik}\Delta x + \left(\frac{D_{pk(1)} + D_{pk(2)}}{2}\right)\Delta x \quad [2.20]$$

and

$$T_{ck} = (g_k / g)T_c \quad [2.21]$$

where: D_{ik} = interrill erosion for the *kth* sediment class, D_{pk} = deposition rate of the *kth* sediment class, α_d = a deposition coefficient, V_{fk} = fall velocity for the *kth* sediment class, T_{ck} = transport capacity for the *kth* sediment class, T_c = the total sediment transport capacity for all sediment classes, g_k = sediment load for the *kth* sediment class, g = total sediment load, and Δx = the length of the distance step used in the numerical integration. The subscript (1) refers to the upstream end of the distance step and the subscript (2) refers to the downstream end of the distance step.

These equations are combined and solved for the deposition rate D_2, which is the only unknown, at the lower end of the distance step. The solution is by trial and error because a value for sediment transport capacity for a sediment class is not known until a value for the total sediment load is computed. The total sediment load can not be computed until sediment load is computed for each sediment class. The trial-and-error solution starts with the sediment load distribution computed in the previous distance step. This distribution is updated with each trial-and-error iteration until the total sediment load becomes stable.

An alternative approach and perhaps simpler approach is to numerically solve equations 2.15 as:

$$g_{k(2)} = D_{ik}\Delta x + \left(\frac{D_{pk(1)} + D_{pk(2)}}{2}\right)\Delta x + g_{k(1)} \quad [2.22]$$

Substitution for D_2 using equation 2.14 in equation 2.22 gives:

$$g_{k(2)} = D_{ik}\Delta x + \left(\frac{D_{pk(1)} + (\alpha_d V_{fk} / q_2)(T_{ck(2)} - g_{k(2)})}{2}\right)\Delta x + g_{k(1)} \quad [2.23]$$

Equation 2.23 is solved for the sediment load $g_{k(2)}$, the only unknown in equation 2.23, at the end of the distance step. A trial-and-error solution is also required for this procedure as well because transport capacity for a single sediment class computed with equation 2.21 depends on the total sediment load.

Regardless of the numerical procedure, the boundary condition must the determined for each segment (see **Section 2.3.8.2)**. This boundary condition is the deposition rate of each sediment class determined at the upper end of the *ith* segment to start the step by step solution of the equations. The deposition rate at the lower end of the *(i-1)th* segment can not be used as the boundary condition for the upper end of the *ith* segment because deposition values are not continuous at common points of segments. Deposition rates change stepwise at these points even though discharge rate and sediment load are continuous at these points. Steepness makes a step change at common segment points.

The deposition rate at the upstream end of the *ith* segment is computed from:

$$D_{puk(i)} = \left(\alpha_d V_{fk} / q_{(i-1)}\right)\left(T_{cuk(i)} - g_{k(i-1)}\right) \qquad [2.24]$$

where: equation 2.24 is solved for each sediment class using sediment transport capacity computed for each class using equation 2.21. The sediment load $g_{k(i-1)}$ is the sediment load at the end of the upslope *(i-1)th* segment, which is the same as the sediment load at the upper end of the *ith* segment because sediment load is continuous along the overland flow path.

A value of 3 was determined by calibration for the deposition coefficient. Values for α_d were adjusted until the computed sediment distribution matched observed distributions for situations where deposition occurred (Foster et al., 1980c). This calibration coefficient is partly needed to adjust for runoff depth rather than excess rainfall rate being used to compute runoff rate.

The numerical procedure used to compute deposition must be carefully chosen so that computed values are not affected by arbitrary division of a segment. Segments by definition are uniform in soil, steepness, and cover-management. Dividing a portion of the overland flow path where conditions do not change into segments as illustrated in Figure 2.2 should not affect the detachment and erosion computations. Also, the computations for a segment must not be affected by downslope conditions, including overland flow path length beyond the segment.

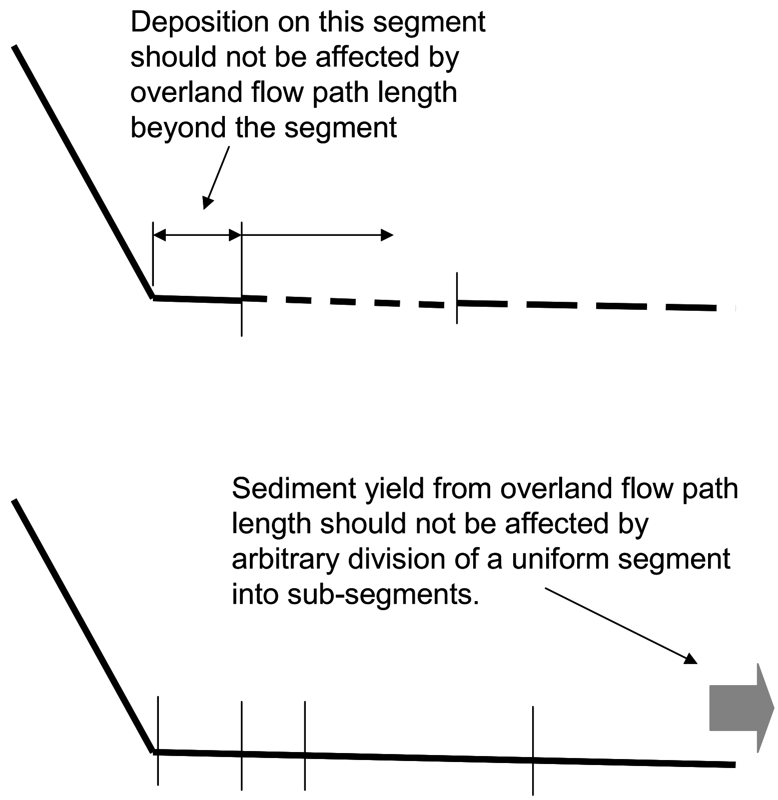

Figure 2.2. Situations where overland flow path lengths and segment divisions should have no effect on computed deposition.

The RUSLE2 procedure avoids these problems by dividing the entire overland flow path into a particular number of segments. The number of sub-segments used in RUSLE2 for an overland flow path length is 200. The sub-segments are only used in the segments having deposition. Thus, the density of sub-segments within a particular segment is the same for all segments. The number of sub-segments within a segment x_{i-1} to x_i is:

$$n_i = [(x_i - x_{i-1})/\lambda_o]n_o \qquad [2.25]$$

where: n_i = an integer number of sub-segments within the *ith* segment, λ_o = the overland flow path length, and n_o = 200, the number of sub-segments for the entire overland flow path length. The length of the sub-segment Δx used in the numerical solution of the deposition equations is:

$$\Delta x = \left(x_{(i)} - x_{(i-1)}\right)/n_i \qquad [2.26]$$

These equations ensure that the end sub-segments within a particular segment begin and end on the segment ends.

A sensitivity analysis was conducted to determine how the sediment delivery ratio (sediment yield/sediment production) for an overland flow path like the ones in Figure

2.2 varied as a function of n_o, the number of sub-segment for the entire overland flow path length. The variation in sediment delivery ratio was about 5 percent as the number of sub-segments for the overland flow path length varied from 100 to 10,000. The value of 200 was chosen, which gives acceptable accuracy while minimizing computer run time.

2.3.7. Concept of a representative storm

Runoff is a key RUSLE2 variable used to compute erosion reduction by support practices including contouring, porous barriers, and flow interceptors and deposition on concave overland flow paths. The intent for using RUSLE2 as a guide to erosion control planning is that RUSLE2 compute the relative erosion control effectiveness of support practices by location. For example, support practices like contouring are less effective in the southern US than in the northern US because of differences in storm severity (Foster et al., 1997). RUSLE2 is calibrated to compute the effectiveness of support practices at the base Columbia, Missouri location. RUSLE2 compute the deviation in support practice effectiveness by the degree that climatic conditions at a specific location vary from those at the base Columbia, Missouri location. This approach gives RUSLE2 increased robustness.

RUSLE2 uses the 10 year (return period-frequency), 24 hour (storm duration) P_{10y24h} precipitation amount to capture the climatic variation by location to compute erosion control by support practices.[18] This precipitation variable is used as an index of storm severity. A more erosive storm than an average annual storm is used as a storm severity index because support practice effectiveness, especially for contouring, depends on storm severity (Foster et al., 1997). For example, contouring can greatly reduce erosion for small storms but fail completely for large storms.

The effect of support practices and concave overland flow path profile shape on erosion and deposition depends much more on runoff than the combination of raindrop impact and runoff. RUSLE2 uses a representative storm in process-based equations to compute runoff that in turn is used to compute deposition. The daily erosion and deposition values computed with this representative storm are scaled to match the daily detachment values computed with equation 2.10 (**see Section 2.3.9**). The same representative storm is used in the process-based equations for each day, but the computed daily runoff values vary as cover-management conditions change daily. The representative storm is used as an index for storm severity at a location. The intent is not to compute actual runoff on each day but to compute runoff values that show the how relative effectiveness of support practices and concave overland flow path profiles changes daily for the index storm. The index storm captures main-effect differences between locations. RUSLE2 computes comparable P-factor type effects for each day rather than using a single temporally constant P factor value like the USLE and RUSLE1.

---

[18] The 10 year-24 hour precipitation procedure used in RUSLE2 is a replacement for the 10 year EI procedure used in RUSLE1.

RUSLE2 also computes an erosivity value for the P_{10y24h} index storm in addition to runoff. The storm erosivity r_{10y24h} for the 10 year-24 precipitation amount P_{10y24h} is computed from:

$$r_{10y24h} = 2\gamma_m P_{10y24h} \quad [2.27]$$

where: γ_m = the maximum monthly erosivity density at the location. Monthly erosivity density is the ratio of average monthly erosivity to average monthly precipitation amount (see **Section 3.2.1.4.1**).

2.3.8. Solving the sediment routing equations segment by segment

The sediment routing equations are solved using the value for the 10 year-24 hour precipitation amount P_{10y24h} used as an index storm. Although the same storm is used each day, computed sediment load changes daily as cover-management conditions temporally change. Daily sediment load values computed using the representative index storm are scaled to compute daily sediment load values appropriate for the daily erosivity values (see **Section 2.3.9**).

2.3.8.1. Inconsistency between slope effect in detachment and sediment transport capacity equations

Inconsistencies occur between the empirical detachment equation (equation 2.10) and the process-based sediment transport capacity equation (equation 2.17) because of differences in the steepness terms in the equations. The steepness effect in equation 2.10 for detachment is a two piece linear equation (see **Section 5.6**), whereas the steepness effect in equation 2.17 for sediment transport capacity is a single linear term. Equations 2.10 and 2.17 are calibrated to be close at the unit-plot nine percent steepness. However, the steepness effect in equation 2.10 can exceed the steepness effect in equation 2.17 at both flat and steep slopes depending on values for the other terms in the equations. Although equation 2.10 is generally assumed to represent detachment limiting conditions in RUSLE2, this empirical equation reflects a mixture of both detachment and transport capacity limiting at low steepness. The assumption used to deal with this and other similar inconsistencies that occur between the empirical USLE formulation and the process-based equations is that RUSLE2 gives the empirical USLE erosion estimate for uniform overland flow paths.[19]

The inconsistencies between these two steepness effects could not be reconciled for non-uniform overland flow paths at low steepness, but RUSLE2 was very carefully evaluated to ensure that the inconsistencies have little effect in conservation planning.

---

[19] These inconsistencies could be eliminated by developing RUSLE2 so that it uses all process-based equations rather than combining the empirical USLE equation with process-based equations. However, the RUSLE2 hybrid approach combines the best of the empirical USLE approach with the best of the process-based approach (see **Section 1.2 and 1.3**).

2.3.8.2. Boundary values

Boundary values must be determined for each segment to solve the sediment routing equations. The equations are solved sequentially starting with the first segment at the origin of the overland flow path and then moving downslope segment by segment. The computed values for runoff and sediment load at the end of the last segment become boundary values for the next segment. The major boundary values for the first segment at x = 0 is that no inflow of either runoff or sediment occurs (i.e., $q_0 = 0$ and $g_0 = 0$).

2.3.8.3. Special boundary conditions cases

Five special cases were used to organize the sediment routing computations and to set boundary values.

2.3.8.3.1. Case 1: First segment

The first segment is a special case because of the no-inflow boundary condition and because the sediment load leaving this segment must equal the sediment load computed by the USLE (i.e., equation 2.10), (assuming the RUSLE2 factor values are used in the USLE). The first segment directly matches the USLE uniform slope assumptions.

Many RUSLE2 conservation and erosion control planning applications involve a uniform overland flow path. In these situations, RUSLE2 uses a single uniform overland flow path segment and only the equations for the Case 1: First Segment special case in its sediment routing computations.

An important logic check for the first segment is to determine if local deposition is computed within the segment. RUSLE2 computes no deposition if the rate of increase in sediment transport capacity with distance dT_c/dx is greater than the interrill erosion rate D_i within the first segment. The rate of increase in transport capacity in the first segment is computed as:

$$dT_c / dx = K_T \zeta \sigma s \qquad [2.28]$$

Excess rainfall rate σ is computed using the 10 year-24 hour representative storm P_{10y24h} and the interrill erosion rate D_i is computed with equation 2.11 using the representative (index) storm erosivity r_{10y24h} (see **Section 3.2.4**).

2.3.8.3.1.1. $dT_c/dx > D_i$ - No local deposition

RUSLE2 computes no local deposition in the first segment when the rate of increase in sediment transport capacity with distance dT_c/dx is greater than the interrill erosion rate D_i. No local deposition occurs because runoff's sediment transport capacity is sufficient to transport the sediment load produced by interrill erosion. The interrill erosion rate $D_{i10y24h}$ in the first segment is computed using the erosivity r_{10y24y} value computed with equation 2.27 for the P_{10y24h} representative storm. In that case, the sediment load leaving the segment is given by equation 2.15 after rill and interrill erosion are combined into a single term as:[20]

$$g = r_{10y24h} kScp_p p_c p_d x_{(1)}^{m_i+1} / \lambda_u^{m_i} \quad [2.29]$$

where: g = the total sediment load for all sediment classes and $x_{(1)}$ = distance to downstream of the first segment.[21] The sediment load g_k of each sediment class at the end of the first segment is given by:

$$g_k = \psi_k g \quad [2.30]$$

where: ψ_k = sediment mass in the *kth* sediment class (fraction). This special case is detachment limiting. Therefore, the distribution of sediment classes in the sediment load at the end of segment 1 for Case 1 where $dT_c/dx > D_i$ equals the distribution of the sediment classes at the point of detachment (see **Section 4.7.5**). The enrichment ratio is one (1) for this case because no deposition is computed (see **Section 4.7.6**).

2.3.8.3.1.2. $dT_c/dx < D_i$ - Local deposition occurs

When the interrill erosion rate D_i within the first segment exceeds the rate of increase in transport capacity with distance dT_c/dx, local deposition is computed. Even though local deposition is computed, equation 2.29 is used to compute sediment load at the end of the first segment to ensure that RUSLE2 gives the USLE result for the first segment. However, local deposition enriches the sediment in fines. RUSLE2 computes quasi-deposition and -sediment load values to estimate the distribution of the sediment classes for the sediment leaving the first segment. The sole purpose of this computation is to obtain the sediment distribution; this computation does not affect the value computed for sediment load at the end of the first segment, which is computed with equation 2.29.

Equations 2.14, 2.16, 2.17, and 2.18 were solved in closed form to compute the quasi-deposition and -sediment load values in segment 1 (Renard and Foster, 1983). The equation used to compute deposition is:

---

[20] The units for sediment load depend on the units used for erosivity r, soil erodibility k, distance x, and length λ_u. For example, in the US customary units system for the USLE, the typical units for sediment load g would be $(tons_m/acre \cdot day) \cdot ft$. These set of units are multiplied by $(2000\ lbs_m/ton)/(43560\ ft^2/acre)$ to obtain a consistent set of units of lbs for mass and ft for length. In RUSLE2, erosion values are computed for each day using a daily erosivity value (see **Sections 2.1 and 3.1**), which is the reason for the day unit in sediment load. The sediment amount values have mass units. In the US customary USLE units, lbs-mass and lbs-force are equal. In the SI system, kg is the recommended unit for sediment mass, although the output would likely be displayed in metric tonnes. See AH703 (Renard et al., 1997) for additional discussion of USLE/RUSLE units.

[21] Equation 2.29 is the USLE equation form when the slope length λ is substituted for x_i and the equation is divided by slope length λ to compute average erosion for the slope length.

$$D_{qk} = [(a_d V_{fk} / \sigma)/(1 + a_d V_{fk} / \sigma)][(dT_c / dx - D_i)\psi_k] \qquad [2.31]$$

$$g_{qk} = \psi_k T_c - qD_{qk} /(a_d V_{fk}) \qquad [2.32]$$

$$q = \sigma x_{(1)} \qquad [2.33]$$

$$T_c = K_T \zeta q s \qquad [2.34]$$

where: D_{qk} and g_{qk} are the quasi-deposition and -sediment load variables used specifically to compute the distribution of the sediment load among the sediment classes for the first segment when local deposition occurs and $x_{(1)}$ = the distance to the end of the first segment. The subscript k refers to sediment class. Equations 2.31-2.34 are solved for each sediment class. The fraction of the sediment load in each sediment class for the sediment load at the end of the first segment is computed as:

$$\omega_k = g_{qk} / \sum_{k=1}^{5} g_{pk} \qquad [2.35]$$

where: ω_k = the portion of the total sediment load leaving the first segment that is composed of sediment in the *kth* sediment class and 5 is the number of sediment classes used in RUSLE2. The sediment load in each sediment class at the end of the first segment is computed as:

$$g_k = \omega_k g \qquad [2.36]$$

The enrichment ratio for the sediment at the end of the first segment is greater than 1 based on the portion of the interrill erosion that RUSLE2 computes as deposited in the first segment. Enrichment ratio is based on specific surface area of the sediment (see **Section 4.7.6**).

2.3.8.3.2. Case 2: Detachment over entire segment

Two boundary conditions must be met for detachment to be computed over an entire segment. The incoming sediment load at the upper end of the segment must be less than transport capacity at the upper end of the segment. The mathematical condition for this check is that $g_{i-1} < T_{cu(i)}$ where $T_{cu(i)}$ = transport capacity at the upstream end of the *ith* segment. This transport capacity is computed using the runoff discharge rate q_{i-1}, the slope steepness s_i, and sediment transport capacity coefficient ζ_i for the ith segment. Therefore, transport capacity at the upstream end of the *ith* segment $T_{cu(i)}$ does not equal the transport capacity $T_{cl(i-1)}$ at the downstream end of the *(i-1)th* segment if steepness and/or cover-management changes between the segments.

The second condition is that the potential sediment load at the end of the segment computed as the sum of the incoming sediment load plus the sediment produced by interrill erosion within the segment is less than the transport capacity at the lower end of the segment. This potential sediment load is computed as:

$$g_{p(i)} = g_{(i-1)} + D_{i(i)}\left(x_{(i)} - x_{(i-1)}\right) \quad [2.37]$$

where: g_p = potential sediment load. The boundary condition is that this potential sediment load be less than transport capacity at the downstream end of the segment, i.e., $g_{p(i)} < T_{cl(i)}$.

2.3.8.3.2.1. Sediment load when rill erosion occurs at capacity rate

A subsequent check must also be made to determine if rill erosion can occur at its capacity over the segment. A second potential sediment load is computed as:

$$g_{p(i)} = g_{(i-1)} + r_{10y24h}k_{(i)}S_{(i)}c_{(i)}p_{p(i)}p_{c(i)}p_{d(i)}\left(x_{(i)}^{m_i+1} - x_{(i-1)}^{m_i+1}\right)/\lambda_u^{m_i} \quad [2.38]$$

where rill erosion is assumed to occur at its capacity rate. If this potential sediment load is less than sediment transport capacity at the lower end of the segment, rill erosion is assumed to occur at its capacity rate and the sediment load leaving the segment is given by equation 2.38.

The distribution of the sediment load among the sediment classes is computed by:

$$g_{k(i)} = g_{k(i-1)} + \psi_k\left(g_{(i)} - g_{(i-1)}\right) \quad [2.39]$$

which results from detachment being non-selective.[22] That is, the distribution of the sediment added within the sediment load, $g_{(i)} - g_{(i-1)}$, is assumed to be the same as sediment at the point of detachment.

2.3.8.3.2.2. Sediment load when rill erosion at less than capacity rate

If potential load computed by equation 2.39 exceeds the transport capacity at the downstream end of the segment, rill erosion is limited to the rate that will just fill transport capacity, which means that sediment load at the end of the segment is given by:

$$g_{(i)} = T_{Cl(i)} \quad [2.40]$$

Even though rill erosion is not computed at its capacity rate, some rill erosion is computed, and, therefore, no local deposition is computed. The distribution of the sediment load at the end of the segment is given by equation 2.39.

[22] Sediment characteristics at the point of detachment change as soil texture changes by segment. RUSLE2 starts at the first segment with the five sediment classes for that segment based on soil texture. RUSLE2 adds sediment classes to represent soil texture changes in the segments along the overland flow path.

2.3.8.3.3. Case 3: Detachment on upper portion of segment, deposition on lower portion of segment

An example where detachment occurs on the upper portion of a segment and deposition occurs on the lower portion of the segment is illustrated in Figure 2.3. Infiltration rate on the *ith* (second) segment is greater than the rainfall rate, which causes the runoff rate to decrease within the segment. Sediment load increases within the segment while sediment transport capacity decreases within the *ith* segment. Deposition begins at the point where sediment load equals transport capacity.

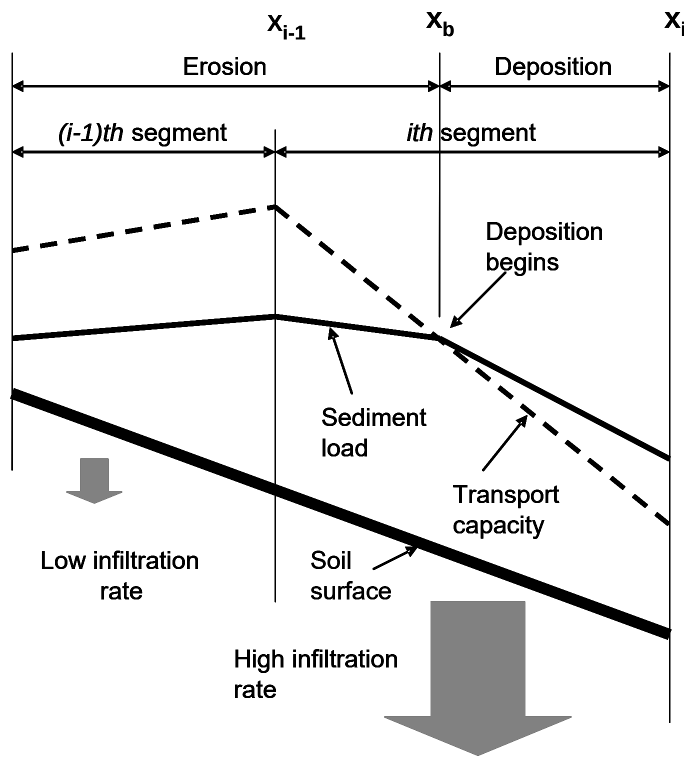

Figure 2.3. Illustration where detachment ends and deposition begins within the ith segment

Two conditions must be met for this case. The first condition is that the incoming sediment load is less than sediment transport capacity at the upstream end of the segment, i.e., $g_{(i-1)} < T_{cu(i)}$. The second condition is that the potential sediment load at the lower end of the segment computed with equation 2.37 is greater than the transport capacity at the downstream end of the segment.

When this condition is met, deposition begins at the location where the sediment load equals transport capacity. The sediment load where deposition begins is given by:

$$g_b = g_{(i-1)} + D_{i(i)}\left(x_b - x_{(i-1)}\right) \qquad [2.41]$$

where: g_b = sediment load at the location x_b = where deposition begins. The sediment transport capacity T_{cb} where deposition begins is given:

$$T_{cb} = K_T \zeta_{(i)} s_{(i)} \left[q_{(i-1)} + \sigma_i \left(x_b - x_{(i-1)} \right) \right] \qquad [2.42]$$

where: σ = the excess rainfall rate (rainfall rate minus infiltration rate).[23] Equations 2.41 and 2.42 are combined and solved to determine a value for the location x_b where deposition begins.

The sediment load by sediment class at the location where deposition begins is given by:

$$g_{bk} = g_{k(i-1)} + \psi_k \left(g_b - g_{(i-1)} \right) \qquad [2.43]$$

Deposition is computed on the portion of the segment from x_b to x_i using equations 2.19-2.21. The main boundary values are that deposition rate is zero and sediment load equals sediment transport capacity at $x = x_b$. These equations compute values for total sediment load and sediment load for each sediment class at the lower end of the segment.

2.3.8.3.4. Case 4: Deposition over entire segment

Figure 2.4 illustrates deposition occurring over an entire segment. In this case, the width of the vegetation strip is so narrow that sediment transport capacity does not increase within the strip to where it exceeds sediment load. The first boundary condition for this case is that the incoming sediment load is greater than sediment transport capacity at the upper end of the segment. The second condition is that the interrill erosion rate D_i within the segment is greater than the increase in sediment transport capacity with distance dT_c/dx within the segment. This boundary condition is the same as the incoming sediment load plus sediment production by interrill erosion within the segment being greater than sediment transport capacity at the lower end of the segment.

Equation 2.24 is used to compute the deposition rate at the upper end of the segment, which is a boundary value along with the incoming discharge rate $q_{(i-1)}$ and sediment load $g_{(i-1)}$ from the immediate upslope segment. These boundary values are used in equations 2.19-2.21 to compute deposition within the segment and values for total sediment load and sediment load by sediment class at the lower end of the segment.

---

[23] Excess rainfall rate is negative for situations where RUSLE2 computes a decreasing runoff rate within a segment (see **Section 3.3.1.1**).

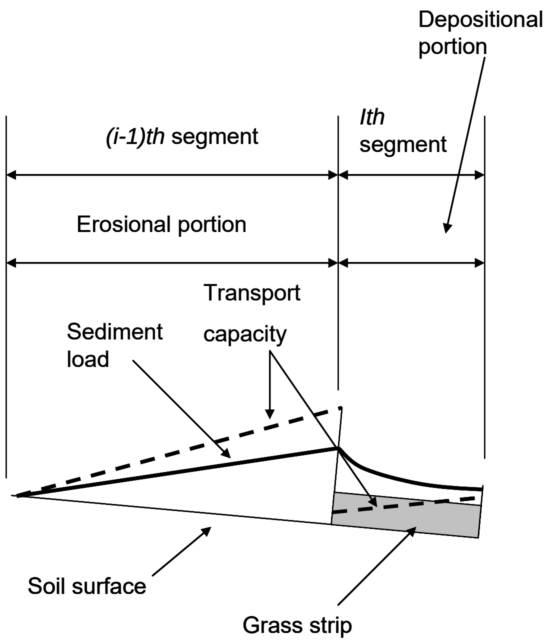

Figure 2.4. Narrow grass where deposition occurs over entire segment

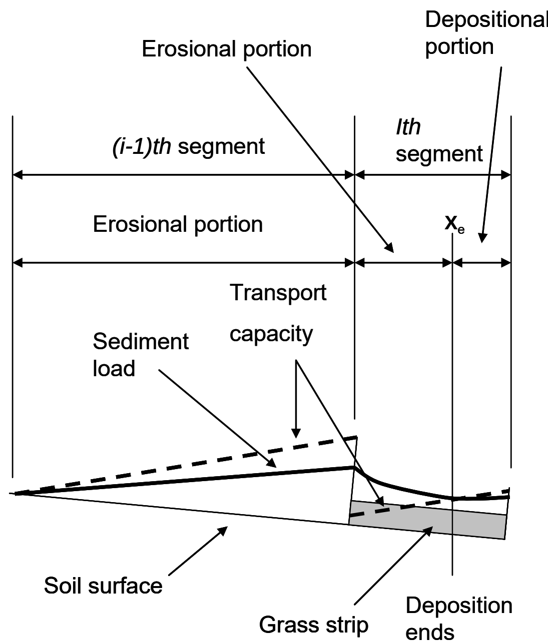

Figure 2.5. Grass strip sufficiently wide that deposition ends within segment and erosion occurs on lower portion of segment

2.3.8.3.5. Case 5: Deposition over upper part of segment, detachment over lower part of segment

Figure 2.5 illustrates deposition ending within a segment. Another example of deposition ending within a segment is illustrated in Figure 2.2 provided the segment is sufficiently long. As discussed in **Section 5.3**, RUSLE2 assumes that segments are discontinuous, even when used to represent a smooth, continuous concave overland flow path profile. The result is that RUSLE2 computes deposition on the upper portion of the segment and detachment on the lower portion of the segment if the segment is sufficiently long. This result is opposite from that for a smooth, continuously decreasing slope steepness where detachment occurs on the upper portion of the segment and deposition occurs on the lower portion of the segment where deposition begins. The error from not properly computing the location of the deposition is minimized by choosing short segment lengths to represent smooth, continuous overland flow path profiles.

The first boundary condition is that incoming sediment load is greater than the transport capacity at the upper end of the segment. The second boundary condition is that the incoming sediment load plus the sediment produced by interrill erosion within the segment is less than the transport capacity at the lower end of the segment. This boundary condition is the same as the boundary condition that the rate of increase in transport capacity with distance dT_c/dx is greater than the interrill erosion rate D_i within the segment. These boundary conditions are required but are not sufficient to determine that deposition ends within the segment if the segment length is short. The location x_e where deposition ends within the segments is determined by solving equations 2.19-2.21 and 2.24. Deposition ends at the location where computed deposition rate becomes zero. These equations compute the total sediment load g_e and the sediment load of each sediment class $g_{e(k)}$ at the location that deposition ends.

Detachment occurs on the lower portion of the segment. The potential sediment load at the end of the segment is computed from:

$$g_{p(i)} = g_e + r_{10y24h} k_{(i)} S_{(i)} c_{(i)} p_{p(i)} p_{c(i)} p_{d(i)} \left(x_i^{m_i+1} - x_e^{m_i+1} \right) / \lambda_u^{m_i} \quad [2.44]$$

This potential sediment load is checked against sediment transport capacity at the lower end of the segment. If the sediment transport capacity at the lower end of the segment exceeds this sediment load, then the sediment load leaving the segment is the potential sediment load computed by equation 2.44, i.e, $g_{(i)} = g_{p(i)}$. However, if the potential sediment load computed with equation 2.44 exceeds the transport capacity at the end of the segment, then rill erosion is limited to the rate that will just fill sediment transport capacity. In that case, the sediment load at the end of the segment equals sediment transport capacity at the lower end of the segment, i.e., $g_{(i)} = T_{cl(i)}$.

The sediment load for each sediment class at the end of the segment is given by:

$$g_{k(i)} = g_{ek} + \psi_k \left(g_{(i)} - g_e \right) \quad [2.45]$$

2.3.9. Scaling values computed with representative storm to create daily values

The daily sediment load values computed using the sediment routing equations and the representative storm P_{10y24h} must be scaled to compute daily sediment load values appropriate for the daily erosivity values. This scaling factor is computed as the ratio of sediment load computed at the end of each segment with the sediment routing equations and the sediment load at the lower end of each segment that would be produced if detachment occurs at detachment capacity for the representative storm. That sediment load g_{detcap} is computed as:

$$g_{\det cap(i)} = r_{10y24h} k_{(i)} S_{(i)} c_{(i)} p_{p(i)} p_{c(i)} p_{d(i)} \left(x_{(i)}^{m_i+1} - x_{(i-1)}^{m_i+1} \right) / \lambda_u^{m_i} \quad [2.46]$$

The scaling factor δ_i for each *ith* segment is computed as:

$$\delta_{(i)} = g_{(i)} / g_{\det cap(i)} \quad [2.47]$$

A sediment load based on detachment capacity comparable to $g_{detcap(i)}$ is computed using daily values for erosivity and the other factors as:

$$g_{daily \det cap(i)} = r k_{(i)} S_{(i)} c_{(i)} p_{p(i)} p_{c(i)} p_{d(i)} \left(x_{(i)}^{m_i+1} - x_{(i-1)}^{m_i+1} \right) / \lambda_u^{m_i} \quad [2.48]$$

where: $g_{dailydetcap(i)}$ = daily sediment load at end of *ith* segment that would be produced if full detachment occurred in each segment, r = the daily erosivity value determined from the disaggregation of the monthly erosivity values (see **Section 3.1**), and all of the other values in equation 2.48 are the same daily values used in the sediment routing equations.

The daily sediment load value is computed as the product of this daily detachment sediment load and the sediment load scaling factor as:

$$g_{daily(i)} = \delta_{(i)} g_{daily\,det\,cap(i)} \qquad [2.49]$$

where: $g_{daily(i)}$ = average daily sediment load at the end of the *ith* segment. The average daily net erosion rate $D_{daily(i)}$for the *ith* segment is computed as:

$$D_{daily(i)} = \left(g_{daily(i)} - g_{daily(i-1)}\right) / \left(x_{(i)} - x_{(i-1)}\right) \qquad [2.50]$$

2.3.10. Computing average annual erosion values for conservation and erosion control planning[24]

RUSLE2 computes average annual values for four variables used in conservation and erosion control planning. These variables are: (1) average annual erosion rate for the entire overland flow path (sediment yield from the overland flow path), (2) average annual detachment rate for the entire overland flow path, (3) average annual erosion rate for the eroding portion of the overland flow path, and (4) an average annual conservation planning soil loss for the overland flow path that gives partial credit to deposition as soil saved.

2.3.10.1. Average annual erosion rate for entire overland flow path (sediment yield)

The average annual erosion rate for the entire overland flow path is the ratio of the average annual sediment amount leaving the overland flow path divided by the overland flow path length. The sediment load at the end of the last segment on the overland flow path is also known as sediment yield or sediment delivery from the overland flow path.

The average annual sediment load at the end of the overland flow path is given by:

$$G_{\lambda} = \left(\sum_{j=1}^{J_d} g_{daily\lambda(j)} \right) \Big/ M_d \qquad [2.51]$$

where: G_{λ} = the average annual sediment load (i.e., sediment yield, sediment delivery) at the end of the overland flow path, $gdaily\lambda_{(j)}$ = the daily sediment load at the end of the overland flow path on the *jth* day, M_d = the number of years in the computation period

---

[24] See the RUSLE2 User's Reference Guide for detailed information on these variables and how they are used in conservation and erosion control planning.

(duration entered in cover-management description, see **Section 2.2**), and J_d = the total number of days in the computation period (i.e., $J_d = 365 \cdot M_d$). The subscript n refers to each day in the computation period and the subscript I is the index value of the last segment used to describe the overland flow path.

The average annual erosion rate (sediment yield, sediment delivery) for the overland flow path is given by:

$$A_{sedyld} = G_{\lambda} / \lambda_o \qquad [2.52]$$

where: A_{sedyld} = the average annual erosion rate for the overland flow path length, λ_o.

2.3.10.2. Average annual detachment rate (sediment production) for entire overland flow path

The average annual detachment rate for the entire overland flow path represents a measure of total sediment production on the overland flow path. This variable is a measure of local erosion and sediment that has been moved away from its local point of origin. RUSLE2 computes detachment on each segment in its sediment routing computations and a sediment load value based on detachment. That sediment load is given by:

$$g_{\det(i)} = g_{\det(i-1)} + D_{i(i)}\left(x_{(i)} - x_{(i-1)}\right) + \Delta g_{r(i)} \qquad [2.53]$$

where: g_{det} = the sediment load produced by detachment at the lower end of the *ith* segment and ΔG_r = the sediment amount produced by rill erosion within the segment. Interrill erosion D_i is assumed to occur over an entire segment regardless of whether deposition occurs. If deposition does not occur, rill detachment occurs. Rill detachment in each segment is computed as described for each of the special cases in **Section 2.3.8.3**.

The average annual sediment load produced by detachment at the end of the overland flow path is given by:

$$G_{\det\lambda} = \left(\sum_{j=1}^{J} g_{\det\lambda(j)}\right) \Big/ M_d \qquad [2.54]$$

where: $G_{det\lambda}$ = the average annual sediment load at the end of the overland flow path. The average annual detachment rate for the entire overland flow path is given by:

$$A_{\det} = G_{\det\lambda} / \lambda_o \qquad [2.55]$$

where: A_{det} = the average annual detachment rate for the entire overland flow path.

2.3.10.3. Average annual erosion rate for eroding portions of the overland flow path

The average annual sediment load is computed for each segment as:

$$G_{(i)} = \left(\sum_{j=1}^{J_d} g_{daily(i,j)} \right) \Big/ M_d \qquad [2.56]$$

The average annual erosion rate for each segment is given by:

$$D_{aseg(i)} = \left(G_{(i)} - G_{(i-1)}\right)/(x_{(i)} - x_{(i-1)})/\left(x_{(i)} - x_{(i-1)}\right) \qquad [2.57]$$

where: $D_{aseg(i)}$ = the average annual erosion rate for the *ith* segment. Positive values for $D_{aseg(i)}$ values indicate net erosion and negative values indicate deposition. The eroding portions of the overland flow path are the segments where $D_{aseg(i)}$ is positive. The value for average annual erosion rate for the eroding portions of the overland flow path is computed as:

$$A_{erod} = \left[\left(G_{(l1)} - G_{(u1)}\right) + \left(G_{(l2)} - G_{(u2)}\right) + \left(G_{(l3)} - G_{(u3)}\right) + \ldots\right] / \qquad [2.58]$$

$$\left[\left(x_{(l1)} - x_{(u1)}\right) + \left(x_{(l2)} - x_{(u2)}\right) + \left(x_{(l3)} - x_{(u3)}\right) + \ldots\right]$$

where: A_{erod} = average annual erosion rate for the eroding portions of the overland flow path, the subscript l refers to the downstream end of an eroding portion of the overland flow path, the subscript u refers to the upstream end of an eroding portion of the overland flow path, and the subscript 1, 2, 3, and ... refers to individual eroding portions of an overland flow path.

2.3.10.4. Conservation planning soil loss

The conservation planning soil loss variable gives partial credit for remote deposition as soil saved. The credit that is given to remote deposition along an overland flow path as soil saved is computed as (Foster et al., 1997):[25]

$$b_{d(i)} = 1 - \left(x_{du(i)} / \lambda_o\right)^{1.5} \qquad [2.59]$$

where: $b_{d(i)}$ = the fraction of the deposition in the *ith* segment that is credited as soil saved (i.e., deposition benefit) and $x_{du(i)}$ = the location of the upper edge of deposition in the

[25] Remote deposition is the deposition of sediment some distance from the location on the overland flow path that the sediment is detached. Examples of remote deposition are deposition upslope of dense vegetation strips, on the toe of concave overland flow path profiles, and in terrace channels. Local deposition is deposition very near the point of detachment such as deposition in the depressions created by random roughness and in the furrows between ridges on a low grade. Local deposition is given full credit as soil saved, which is implicit in the empirical equation structure for computing detachment. Local deposition associated with random roughness is explicitly computed only for the first segment in an overland flow path description. Deposition computed for segments other than the first segment for overland flow paths involving multiple segments is considered to be remote deposition and is given partial credit as soil saved according to equation 2.59.

segment in which the deposition occurs. A significantly reduced benefit is computed when the deposition occurs close to the overland flow path end, which is the location x = λ. The credited deposition in a segment is computed as:[26]

$$\Delta g_{pb(i)} = \Delta gp_{a(i)} b_{d(i)} \quad [2.60]$$

where: $\Delta g_{pb(i)}$ = daily deposited sediment credited as soil saved (mass/width) and $\Delta g_{pa(i)}$ = the daily computed total deposition for the segment before any credit is taken (mass/width). The daily conservation planning sediment load along the overland flow path is computed as:

$$g_{cp(i)} = g_{cp(i-1)} + \Delta g_{pb(i)} + \Delta g_{i(i)} + \Delta g_{r(i)} \quad [2.61]$$

where: g_{cp} = daily conservation planning sediment load along the overland flow path, $\Delta g_{i(i)}$ = total interrill detachment within the segment (mass/width) and $\Delta g_{r(i)}$ = total rill detachment within the segment (mass/width). Interrill erosion D_i is assumed to occur over an entire segment regardless of whether deposition occurs. If deposition does not occur, rill detachment occurs. Rill detachment in each segment is computed as described for each of the special cases in **Section 2.3.8.3**.

The average annual conservation planning sediment load at the end of the overland flow path or at the end of terrace channels for the computation period is given by:

$$G_{cp\lambda} = \left(\sum_{j=1}^{J_d} g_{cp\lambda(j)} \right) \Big/ M_d \quad [2.62]$$

where: $G_{cp\lambda}$ = the average annual sediment load for conservation planning.

The conservation planning soil loss is given by:

$$A_{cp} = G_{cp\lambda} / \lambda_o \quad [2.63]$$

where: A_{cp} = the average annual conservation planning soil loss.

Deposition occurs in terrace channels that are on a sufficiently low grade. The credit for soil saved computed for this deposition is computed with (Foster and Highfill, 1983; Foster et al., 1997):

$$a_{cpt} = a_{ty} \exp[-0.011(\lambda_t - 100)] \quad \lambda_t > 100 \quad [2.64]$$

---

[26] These computations are made using the scaled values that match the daily erosivity values.

$$a_{cpt} = 0.45 a_{ty} \quad \lambda_t \le 100 \qquad [2.65]$$

where: a_{cpt} = the daily conservation planning sediment yield [average erosion for area (mass/area)] when deposition occurs in terrace channels, a_{yt} = daily sediment yield [average erosion for area (mass/area)] from terrace channels, and λ_t = terrace spacing (feet). The average annual conservation planning soil loss for conservation planning is:

$$A_{cp} = \left(\sum_{j=1}^{J_d} a_{cp(j)} \right) \Big/ M_d \qquad [2.66]$$

2.3.10.5. Comments on conservation and erosion control planning variables

The values for all four of these conservation and erosion control planning variables are equal for a uniform overland flow path. If a dense vegetation strip is located at the end of the overland flow path, the value for average erosion rate for the entire overland flow path (sediment yield) will be much lower than the other values because of deposition caused by the grass strip and its backwater. The highest value of the four will be the average erosion rate for the eroding portion of the overland flow path. In this example, this part of the overland flow path is from its origin to the location where deposition begins at the upper edge of the backwater created by the vegetation strip. The value for the average detachment rate for the entire overland flow path will be less than the average erosion rate for the eroding portion of the overland flow path because of the greatly reduced detachment in the backwater and in the vegetation strip itself. The conservation planning soil loss will be less than the detachment value but greater than the sediment yield value because of the partial credit taken for deposition as soil saved. In this example, the conservation planning soil loss value will be closer to the detachment value than to the sediment yield value. Not much credit (benefit) is given to the deposition because it occurs near the end of the overland flow path (see the RUSLE2 User's Reference Guide).

2.4. List of symbols

a = daily erosion (mass/area·day)

a_{cpt} = daily conservation planning soil loss for terraces (mass/area·day)

a_{yt} = daily average sediment yield expressed for terrace interval expressed as average erosion for area (mass/area·day)

a_k = erosion in *kth* crop stage (mass/area)

a_u = unit plot daily erosion (mass/area·day)

a_{us} = unit plot erosion for a single storm (mass/area)

A = average annual erosion (mass/area·year)

A_{cp} = average annual conservation planning soil loss (mass/area·year)

A_{det} = average annual detachment rate for the entire overland flow path (mass/time·year)

A_{erod} = average annual erosion for the eroding portions of the overland flow path (mass/area·year)

A_{sedyld} = average annual erosion rate for the overland flow path length (mass/area·year)

A_u = unit plot average annual erosion (mass/area·year)

b_d = deposition in a segment credited as soil saved (i.e., deposition benefit) (fraction)

b_r = **b** value, coefficient for ground surface) cover effectiveness for rill erosion ($percent^{-1}$)

c = daily cover-management factor (soil loss ratio) (dimensionless)

c_k = cover-management factor (soil loss ratio) for *kth* crop stage (dimensionless)

c_{pr}/c_{pi} = rill to interrill prior land use soil erodibility ratio

C = average annual cover-management factor (dimensionless)

D = daily detachment by rill and interrill erosion combined (mass/area·day)

D_{aseg} = average annual erosion for a segment (mass/area·day)

D_i = daily detachment by interrill erosion (mass/area·day)

D_i = interrill erosion rate (mass/area·time)

$D_{daily =}$ average daily net erosion for a segment (mass/area·day]

D_p = deposition rate in rill areas (mass/area· time)

D_{pk} = deposition rate for the *kth* sediment class (mass/area·time)

D_{puk} = deposition rate at the upstream end of a segment for the *kth* sediment class (mass/area·day)

D_{qk} = quasi-deposition rate in first segment for *kth* sediment (mass/area· time)

D_r = rill erosion rate(mass/unit area· time)

D_{rorp} = either rill erosion (D_r) or deposition (D_p) in rill areas (mass/area·time)

$\exp(-b_r f_g)/\exp(-0.025 f_g)$ = rill erosion surface cover effect to interrill erosion surface cover effect ratio

E = rain storm energy (force·length/area)

EI_{30} = rain storm erosivity (force·length/area)·(length/time)

f_g = ground (surface) cover (percent)

f_k = portion of average annual erosivity that occurs during *kth* crop stage (fraction)

g = sediment load (mass/unit overland flow width· time)

g_b = sediment load at the location where deposition begins within segment (mass/width· time)

g_{bk} = sediment load for the *kth* sediment class at the location where deposition begins within segment (mass/width· time)

g_{cp} = daily conservation planning sediment load (mass/width·day)

$g_{cp\lambda}$ = daily conservation planning sediment load at end of overland flow path (mass/width·day)

g_{daily} = daily sediment load (mass/width· day)

$g_{daily\lambda}$ = daily sediment load at end of overland flow path (mass/width· day)

$g_{dailydetcap}$ = daily sediment load that would be produced if detachment occurred at detachment capacity (mass/width· day)

g_{det} = daily sediment load produced by detachment (mass/width· day)

g_{detcap} = daily sediment load that would result from detachment at capacity rate (mass/width· day)

g_{ek} = sediment load where deposition ends for *kth* sediment class (mass/width· time)

g_k = sediment load for *kth* sediment class (mass/width· time)

g_0 = 0, sediment load at x = 0 (mass/width· time)

g_p = potential sediment load at end of segment (mass/width· time)

g_{qk} = quasi-sediment load for *kth* sediment class rate for first segment (mass/width·time)

$G_{cp\lambda}$ = average annual conservation planning sediment load at end of overland flow path (mass/width·year)

$G_{det\lambda}$= average annual sediment load produced by detachment at end of overland flow path (mass/width·year)

G_λ = average annual sediment load (i.e., sediment yield, sediment delivery) at end of overland flow path (mass/width·year)

I_{30} = average intensity over the continuous 30 minutes with most rainfall in storm (distance/time)

J_d = number of days in computation period (J_d =365M_d)

k = daily soil erodibility factor (mass/erosivity unit)

K = average annual soil erodibility factor (mass/erosivity unit)

K_r/K_i = inherent rill to interrill soil erodibility ratio

K_T = sediment transportability coefficient (mass/volume)

l = daily slope length factor (dimensionless)

L = average annual slope length factor (dimensionless)

m = daily slope length exponent (dimensionless)

M_c = number of year in computation for cover-management computation

M_d = number of years in the computation period

M_k = number of crop stages in computation period

M_r = number of years in the record being used to compute erosivity

$M_{s(j)}$ = the number of storms in the *jth* year

n_i = number of sub-segments within the *ith* segment (integer)

n_o = 200, number of sub-segments for the entire overland flow path length, used to solve numerical deposition equation

p_c = daily contouring subfactor dimensionless)

p_d = daily subsurface drainage subfactor (dimensionless)

p_p = daily ponding subfactor (dimensionless)

P = average annual support practice factor (dimensionless)

P_{10y24h} = 10 year(return period)-24 hour (storm duration) precipitation amount (length)

q = overland flow (runoff) rate (volume/width·time)

q_0 = 0, discharge rate at x = 0 (mass/width·time)

r = daily erosivity (erosivity unit/area·day)

r_k = erosivity during *kth* crop stage (erosivity unit/area)

r_{10y24h} = storm erosivity associated with 10 year-24 hour precipitation amount P_{10y24h} (erosivity unit)

R = average annual erosivity factor (erosivity unit/area·year)

$(s/0.0896)/(3s^{0.8}+0.56)$ = steepness effect for rill erosion to interrill erosion ratio

s = overland flow path steepness (sine of slope angle)

S = average annual slope steepness factor (dimensionless)

S_i = slope steepness factor for interrill erosion

T_c = sediment transport capacity in rill areas (mass/overland flow width·time)

T_{ck} = transport capacity for *kth* sediment class (mass/width·time)

T_{clk} = sediment transport capacity at the downstream (lower) end of segment (mass/width·time)

T_{cuk} = sediment transport capacity at the upstream (upper) end segment (mass/width·time)

T_{cb} = sediment load where deposition begins (mass/width·time)

V_f = sediment fall velocity (length/time)

V_{fk} = sediment fall velocity for *kth* sediment class (length/time)

x = distance from origin of overland flow path (length)

x_b = location where deposition begins (length)

x_e = location where deposition ends (length)

x_{ud} = location of upper edge of deposition in a segment in which deposition occurs (length)

α_d = deposition coefficient (dimensionless)

β = daily ratio of rill to interrill erosion for unit plot length

δ = scaling factor used to compute daily sediment load

Δg_i = daily sediment load produced by interrill erosion in a segment (mass/width·day)

Δg_{pa} = daily sediment load deposited in a segment before any credit is taken for deposition benefit (mass/width·day)

Δg_{pb} = daily sediment load deposited in a segment credited as soil saved (mass/width·day)

Δg_r = daily sediment load produced by rill erosion in a segment (mass/width·day)

Δx = length of the distance step used in the numerical integration to compute deposition (length)

γ_m = the maximum monthly erosivity density at the location (erosivity unit/length)

ζ = coefficient for effect of hydraulic resistance on sediment transport capacity

K = the number of crop stages

λ = slope length (length)

λ_o = overland flow path length (length)

λ_u = unit plot length (length)

σ = excess rainfall length rate (rainfall rate - infiltration rate) (length/time)

ψ_k = sediment mass in *kth* sediment class (fraction)

indices

i = segment along overland flow path

j = year

k = crop stage

k = sediment class

m = storm

1 and 2 = subscript 1 for upstream (upper) end of distance step and subscript 2 for downstream (lower) end of distance step in numerical integration of deposition equation

3. CLIMATE (WEATHER), RUNOFF, AND HYDRAULICS

The major weather variables used by RUSLE2 are monthly erosivity, precipitation, and temperature and the 10 year (return period)-24 hour (storm duration) precipitation amount. Erosivity values are an index of erosive rainfall at a location for causing rill and interrill erosion. Erosivity is a major variable in the equations used to compute detachment (e.g., see Section **2.1**). Precipitation and temperature influence the loss of biomass on and in the soil and how that loss varies among locations (e.g., see **Section 10.4.1**). Precipitation and temperature also affect the temporal distribution of soil erodibility and how that distribution varies by location (see **Section 4.5**). The 10 year-24 hour precipitation amount is a representative (index) storm that is used to compute the effect of ponding on erosivity, deposition on concave overland flow path profiles, deposition by dense vegetation strips, deposition in terrace channels, and the effectiveness of contouring (e.g., see **Section 7.1**). These computations are made using runoff and flow hydraulics based equations.

3.1. Disaggregation of monthly values into daily values

RUSLE2 uses daily values for erosivity, precipitation, and temperature to compute daily erosion (see **Section 2.1**). The RUSLE2 disaggregation procedure converts (disaggregates) the input monthly erosivity, precipitation, and temperature into daily values.

3.1.1. Basic disaggregation procedure

The same basic disaggregation procedure is used for monthly temperature, precipitation, and erosivity. The procedure assumes that daily values vary linearly within each month according to a two-piece linear equation. A requirement is that the average of the daily values in a month equals the input monthly value.

The daily value at the beginning of a month is assumed to equal the mean of the monthly values for the current and immediately preceding month and the daily value at the end of the month equals the mean of the monthly values for the current and next month as illustrated in Figure 3.1. That is:

$$Y_b = (M_{(j)} + M_{(j-1)})/2 \qquad [3.1]$$

and

$$Y_e = (M_{(j+1)} + M_{(j)})/2 \qquad [3.2]$$

where: M = the average monthly value of the variable being disaggregated, Y_b = the daily value at the beginning of the *jth* month, Y_e = the daily value at the end of the month, and the index j refers to the month.

Figure 3.1 illustrates an example of increasing monthly values. The same equations apply to both increasing and decreasing values. A second set of equations apply for local maximums and local minimums illustrated in Figure 3.2.

3.1.1.1. Increasing or decreasing monthly values

The third major value is the time t_c where the two linear lines in Figure 3.1 equal the average monthly value M_j. The value for t_c is determined so that the total area under the two linear lines equals the average monthly value M_j. The area under the two lines is given by:

$$M_{(j)} = t_c (Y_b + M_{(j)})/2 + (1 - t_c)(M_{(j)} + Y_e)/2 \qquad [3.3]$$

A value for t_c is determined by rearranging equation 3.3 as:

$$t_c = [M_{(j)} - (Y_e + M_{(j)})/2]/[(Y_b + M_{(j)})/2 - (Y_e + M_{(j)})/2] \qquad [3.4]$$

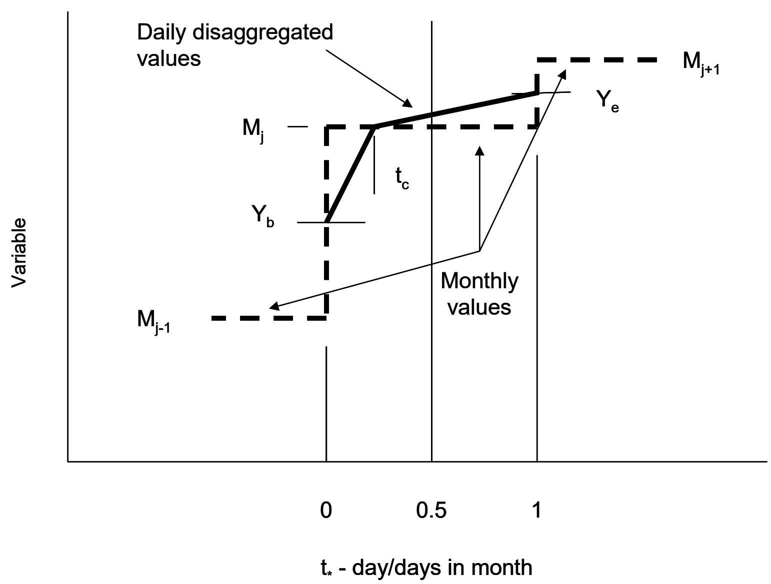

Figure 3.1. Illustration of two linear equations used to disaggregate monthly values into daily values for increasing or decreasing monthly values.

The equation used to compute daily values for times less than t_c is given by:

$$y_d = (d / D_{(j)})[(M_{(j)} - Y_b)/t_c] + Y_b \qquad [3.5]$$

where: y_d = the daily value on day d of the month and D_j = the number of days in the month. The equation to compute daily values for times greater than t_c is given by:

$$y_d = (1 - d / D_{(j)})[(M_{(j)} - Y_e)/(1 - t_c)] + Y_e \qquad [3.6]$$

3.1.1.2. Local maxima and minima

Figure 3.2 illustrates a local maximum. The equations apply both to local maximums and minimums.

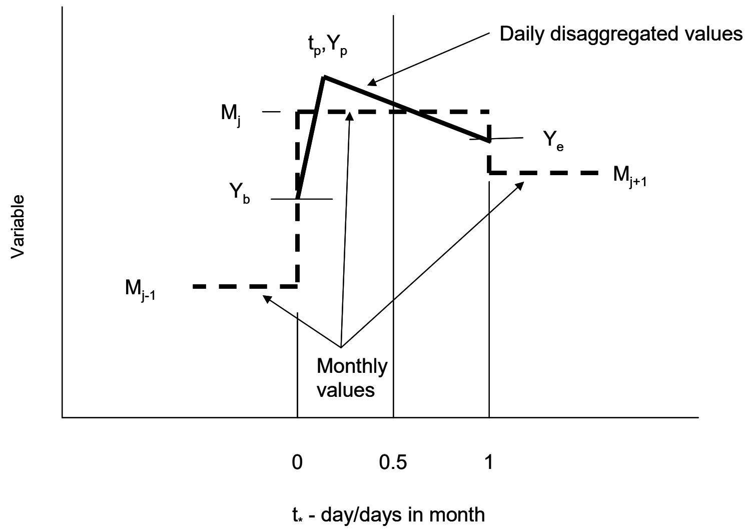

Figure 3.2. Illustration of two linear equations used to disaggregate monthly values for a local maxima or minima.

The daily value at the beginning and end of the month are computed using equations 3.1 and 3.2. The total area under the two lines must equal the average monthly value as:

$$M_{(j)} = (Y_b + Y_p)t_p / 2 + (Y_p + Y_e)(1 - t_p)/2 \qquad [3.7]$$

where: Y_p = the maximum value during the month that occurs at time t_p. Equation 3.7 is rearranged so that a value for the maximum value Y_p can be computed from:

$$Y_p = 2M_{(j)} + t_p(Y_e - Y_b) - Y_e \qquad [3.8]$$

The equation for the time of the peak t_p is given by:

$$t_p = 1 - (M_{(j)} - Y_b)/(2M_{(j)} - Y_b - Y_e) \qquad [3.9]$$

The equation for daily values for times less than the time of the peak is given by:

$$y_d = (d / D_{(j)})(Y_p - Y_b)/t_p + Y_b \qquad [3.10]$$

and the equation for times after the time to peak is given by:

$$y_d = [(Y_p - Y_e)/(1 - t_p)](1 - d / D_{(j)}) + Y_e \qquad [3.11]$$

3.1.2. Disaggregation procedure for temperature and erodibility

The disaggregation procedure is applied directly as described in **Section 3.1.1** for temperature. Figure 3.3 illustrates disaggregation of monthly temperature values into daily values for Columbia, Missouri. Notice that the date of the minimum daily temperature occurs in the third week of January as expected.

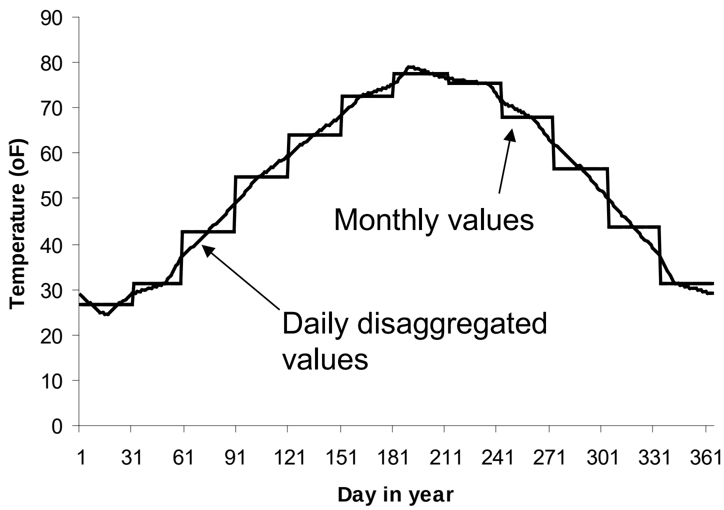

Figure 3.3. Daily temperature values obtained by disaggregating monthly temperature values at Columbia, Missouri.

3.1.3. Disaggregation procedure for precipitation and erosivity

When the disaggregation procedure is applied to monthly precipitation and erosivity, the average monthly value is divided by number of days in the month to obtain a mean daily value for the month. The disaggregation procedure is applied to the mean daily value in each month. Daily precipitation and erosivity values must be checked for negative values in very low rainfall areas like Yuma, Arizona. Daily precipitation and erosivity values are set to zero when negative values are computed. Setting these values to zero results in the sum of the disaggregated daily values being slightly greater than the monthly values in the months when the negative values occur. This adjustment has an insignificant effect on computed erosion values. Figure 3.4 shows daily disaggregated precipitation values for Columbia, Missouri.

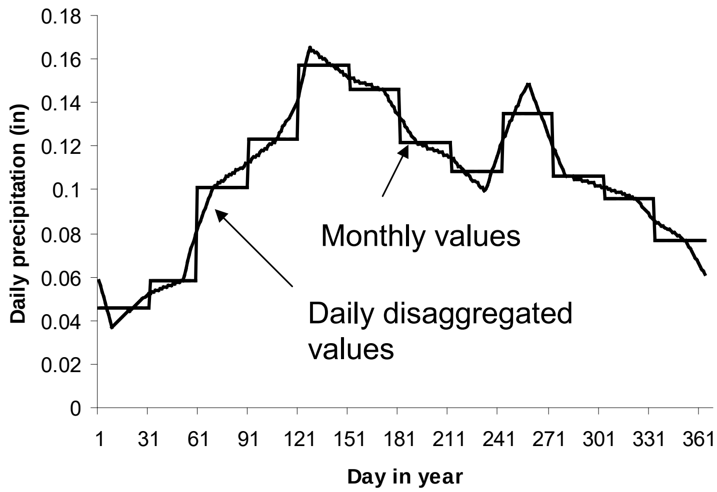

Figure 3.4. Daily precipitation values obtained from disaggregating monthly precipitation values at Columbia, Missouri.

3.2. Climate (weather) variables

The four basic RUSLE2 weather variables are monthly erosivity, precipitation, and temperature and the 10 year-24 hour precipitation amount. Selection of values for these variables is described in the RUSLE2 User's Reference Guide. This section describes underlying concepts, principles, and equations for processing weather data to develop input values consistent with RUSLE2 procedures and RUSLE2's purpose as a guide to conservation and erosion control planning.

3.2.1. Erosivity

RUSLE2 disaggregates average monthly erosivity values to obtain daily erosivity values used to compute daily erosion (see **Section 3.1**). Monthly erosivity values can be input directly into RUSLE2 in three ways, the recommended procedure for the Continental US is to input average monthly values for erosivity density.[27] Erosivity density, which is the ratio of monthly erosivity to monthly precipitation, is multiplied by monthly precipitation to obtain monthly erosivity values. The first step in developing average monthly erosivity density values is to compute erosivity values for individual storms using measured weather data.

---

[27] RUSLE2 can uses monthly erosivity values (1) computed by multiplying monthly erosivity density and precipitation values (see **Section 3.2.1.4.1**), (2) input directly, or (3) determined from input values for annual erosivity and the biweekly temporal distribution of erosivity.

3.2.1.1. Storm erosivity

Erosivity, the product of a storm's energy and its maximum 30 minute intensity, for an individual storm is computed as (Wischmeier and Smith,1978):

$$r_s = EI_{30} \qquad [3.12]$$

where: r_s = storm erosivity, E = storm energy, and I_{30} = maximum 30-minute intensity. Maximum 30 minute intensity is the average intensity over the continuous 30 minutes in the storm with the most rainfall. Storm energy is computed using (Renard et al., 1997):

$$E = \sum_{k-1}^{m} e_k \Delta V_k \qquad [3.13]$$

where: e = unit energy (energy content per unit area per unit rainfall depth) in the *kth* period, and ΔV = the amount (depth) of rainfall in the *kth* period, k = index for periods during the rainstorm where rainfall intensity is considered uniform, and m = the number of periods in the rainstorm. Unit energy is computed from (Brown and Foster, 1987; McGergor et al., 1995; Renard et al., 1997):

$$e_k = 0.29[1 - 0.72\exp(-0.082 i_k)] \qquad [3.14]$$

where: e_k = the unit energy [MJ/(mm·ha)] for the *kth* period and i_k = rainfall intensity (mm/h) for the *kth* period.[28]

Data for storms less than 0.5 inch (12 mm), non-rainfall precipitation events, and extreme storm erosivity events with a return period greater than 50 years are excluded in the RUSLE2computation of storm erosivity.

3.2.1.2. Determining average annual erosivity values from measured precipitation data

Data from 15-minute precipitation gages that provide rainfall intensity values are required to compute storm erosivity values using equations 3.12-3.14. Modern data from 1960 through 1989 (1960-1999 in several cases) were analyzed to determine rainstorm erosivity and precipitation values at approximately 3700 15-minute precipitation gage locations across the Continental US (Hollinger et al., 2002). Erosivity values computed for the qualifying storms (i.e., rain events where amount was 0.5 inch or greater) were summed over the record length and divided by the years of record to determine an average annual erosivity value for each 15-minute precipitation station.

---

[28] See Foster et al. (1981) and AH703 (Renard et al., 1997) for a discussion of RUSLE2 units and how to convert between customary US units and SI units.

The plan was to develop an average annual erosivity contour map based on values computed from measured data at as many 15-minute precipitation gage locations as possible. Initial maps had many “bull’s eyes” and irregular spatial trends rather than smooth trends required for RUSLE2 application as a guide for conservation planning. Data analysis showed that short and differing record lengths among locations greatly contributed to undesired spatial variability. The analysis also showed that the record length should be at least 18 years for directly computing average annual erosivity from measured 15-minute precipitation gage data. Even then the spatial variability among precipitation gage locations was sometimes too great.

3.2.1.3. Need for consistency in conservation and erosion control planning

Consistency in computed erosion estimates (hence, consistency in erosivity values) between locations within geographic regions and between regions is just as important as the absolute erosion estimates computed with RUSLE2. Land users impacted by erosion prediction perceive inconsistency and variability in erosion estimates for no apparent reason to be unfair, especially when the results negatively affect them. The probability distribution (return periods) of storms in a measured precipitation record used to compute erosivity values should be the consistent among locations. To illustrate, the average annual erosivity values at Wink, Texas and Pecos, Texas, towns in West Texas, computed from measured 15-minute precipitation data differed by a factor of two for no obvious reason. Inspection of the data showed that a 600-year return period storm caused the much larger average annual erosivity at one location.

The benefits or costs incurred by land users impacted by RUSLE2 should not be determined by the “luck of the draw” based on where they happen to be located. Furthermore, extreme events, such as a 100-, 200-, and 600-year storms, in the last 30 years are a very poor indicator of events likely to occur in the next 30 years. An average annual record that excludes extreme events is the best predictor of the immediate future for conservation planning where the objective is to protect the on-site soil resource from excessive degradation by erosion. However, other erosion prediction applications such as protecting highly sensitive water bodies and designing sediment storage in reservoirs may well require a different consideration of extreme events and a different set of input erosivity values than those developed for RUSLE2. Most erosion control practices are not designed or expected to withstand extreme events because in most cases failure does not cause catastrophic damages and the practices can be reinstalled without great costs.

Therefore, all storms with a return greater than 50 years were deleted from the measured data used in the RUSLE2 analysis to develop erosivity values.

3.2.1.4. Erosivity density approach to developing erosivity values

3.2.1.4.1. Erosivity density analysis

The RUSLE2 erosivity density approach for determining monthly erosivity values was developed in consideration of RUSLE2’s consistency requirements for conservation planning and to maximize the information that could be extracted from the measured 15-minute precipitation data. RUSLE2 multiplies input values for average monthly erosivity density by input values for average monthly precipitation to compute monthly erosivity values as:

$$R_{m(j)} = \alpha_{(j)} P_{md(j)} \quad [3.15]$$

where: R_m = average monthly erosivity, α = average monthly erosivity density, and P_{md} = average monthly precipitation determined from daily precipitation gage data, all for the *jth* month. Erosivity density refers to the erosivity content per unit precipitation. Erosivity density for a month is computed from measured 15-minute precipitation data as:

$$\alpha = \frac{\sum_{i=1}^{n} E_{(i)} I_{30(i)}}{\sum P_{15}} \quad [3.16]$$

where: all values were determined from 15-minute precipitation gage data including precipitation amount P_{15} from all storms and storm energy E is computed using equations 3.13 and 3.14, i = the index for storm in a month and n = total number of storms greater than 12 mm but smaller than a 50-yr event in a given month. Unit energy e_k for each *kth* period is computed from the average intensity for each 15-minute period in the storm (i.e., $i_k = \Delta V_k/15$ minutes and V_k = the rainfall amount in the *kth* 15-minute period). The I_{30} values used in equation 3.16 using 15-minute precipitation data were multiplied by a 1.04 factor to account for the fact that maximum intensity values from the 15-minute precipitation data are slightly lower than those computed with breakpoint rainfall (Hollinger et al., 2002). Breakpoint rainfall data are data divided into non-uniform periods where constant rainfall intensity can be assumed for each period. Breakpoint data are preferred rather than 15-minute precipitation data for computing storm erosivity.[29]

Approximations can be made in Equation 3.16 to aid the interpretation of erosivity density. Unit energy e does not vary greatly with intensity such that storm energy can be approximated with $\hat{e}P_{15}$ where $\hat{e}$ = effective unit energy for a month (Foster et al., 1982d). By assuming a representative $\bar{I}_{30}$ for the month, erosivity density is approximated by:

---

[29] The storm data including computed storm erosivity values were provided by the Illinois State Water Survey. The analysis of erosivity data was a joint effort between the Illinois State Water Survey, the USDA-ARS and NRCS, and the University of Tennessee.

$$\alpha \approx \frac{\bar{I}_{30}\hat{e}\sum_{i=1}^{n} P_{15(i)}}{\sum_{i=1}^{n} P_{15(i)}} \qquad [3.17]$$

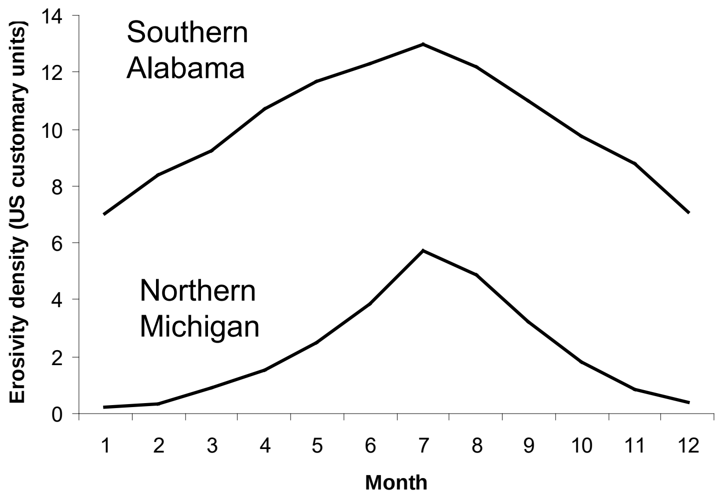

Figure 3.5. Erosivity density values for two locations.

where: $\bar{I}_{30}$ = the representative maximum 30-minute intensity for the month. Equation 3.17 in turn reduces to:

$$\alpha \approx \hat{e}\bar{I}_{30} \qquad [3.18]$$

Equation 3.18 shows that erosivity density varies directly with 30-minute rainfall intensity.

Erosivity density varies by location as illustrated in Figure 3.5 that shows that erosivity is higher in Southern Alabama than in Northern Michigan. In both locations, erosivity density is higher in the summer months than in the winter months, which according to equation 3.18, is caused by rainfall intensity varying with season. Rainfall intensity is greater in the summer than in the winter, resulting in erosivity being greater in the summer than in the winter for a given amount of rainfall. Also, most of the precipitation in Northern Michigan in the winter is snow and, therefore, is not included in the rainfall erosivity index.[30]

---

[30] The storm precipitation and erosivity values used in this analysis were provided by the Illinois State Water Survey and the USA-Natural Resources Conservation Service Water and Climate Center. These

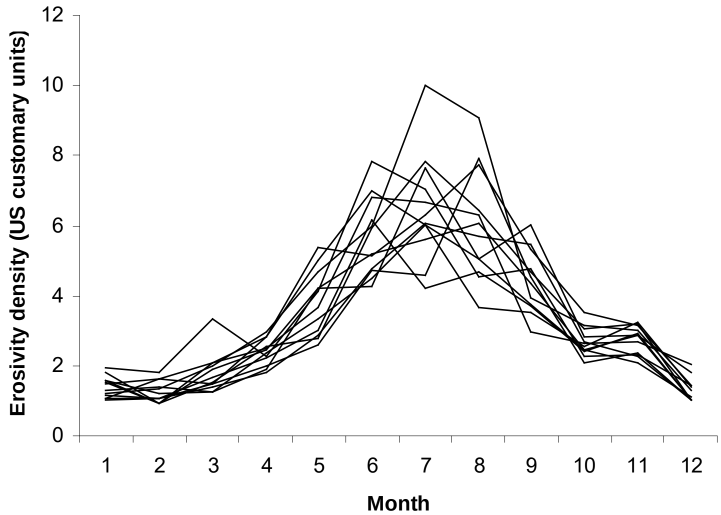

Figure 3.6. Spatial and temporal variability in erosivity density for locations in Southwestern Indiana.

Spatial and temporal variation in the erosivity density values computed from the 15-minute precipitation data was a major problem. Erosivity density values computed directly from the 15-minute precipitation data, as illustrated in Figure 3.6 for 15-minute gage locations in the southwest quadrant of Indiana, do not provide the smooth temporal and spatial trends required for RUSLE2 as a conservation and erosion control planning tool. Spatially averaging the erosivity density values by quadrant in Indiana smoothed the erosivity density values, both temporally and spatially, across Indiana as illustrated in Figure 3.7.

Geographic information systems (GIS) techniques, including kriging, were used to spatially average the erosivity density values computed from 15-minute precipitation data measured at the various gage locations. The procedure is similar to a spatial, moving average fitting technique and produced results similar to that illustrated in Figure 3.7.[31] Before kriging was applied, the monthly erosivity density values computed from the measured data in a relatively small region, such as a quadrant of Indiana, were inspected and analyzed for outliers. Monthly erosivity density values that departed from the mean in this local region by more than two times the standard deviation were considered outliers. Rather than excluding the entire dataset for a location (i.e., deleting the location from the entire data set), the outlier data point was adjusted to be consistent with other

---

values are computed from measured weather data collected by the National Weather Service. See (Hollinger et al., 2002) for additional information.

[31] The GIS and kriging analysis was conducted by the Department of Biosystems Engineering and Environmental Science, University of Tennessee, Knoxville.

monthly erosivity density values at the location. Adjusting individual monthly data points kept the number of locations in the dataset as large as possible. In most cases, the same outliers at a location identified by the statistical test could also be identified by inspection. Outliers were monthly erosivity density value outside the smooth trend obtained by averaging the data points in the local region as was done in Figure 3.7. This process of identifying and adjusting outliers typically involved two or three iterations.

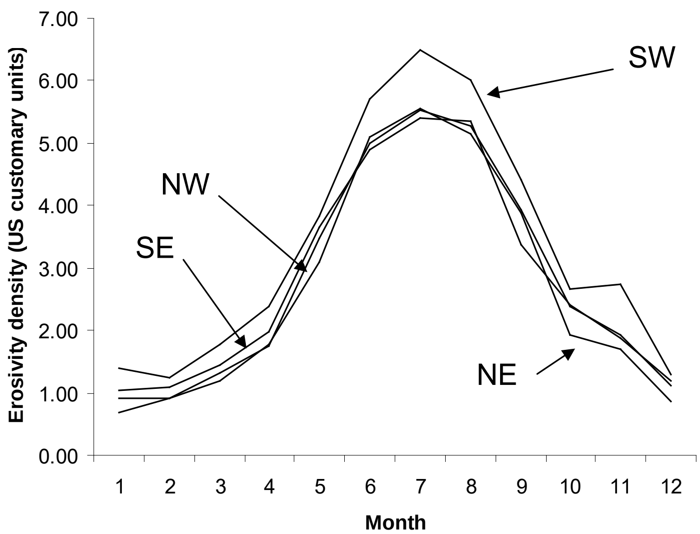

Figure 3.7. Erosivity density values spatially averaged for the four quadrants in Indiana.

A compromise was made in the number of nearest neighbors used in the kriging analysis. Using the 10 nearest neighbors worked well in the eastern US, but it did not work well along the eastern side of the Cascade Mountains in Washington and Oregon where erosivity density values decrease very rapidly with distance in this area. This rapid decrease necessitated using five rather than 10 nearest neighbors. This problem was also related to a very low density of 15-minute precipitation stations in the region. Using the five nearest neighbors also worked better than 10 nearest neighbors along coastlines and borders between Canada and Mexico where no precipitation data were available.

This procedure produced erosivity density values that varied smoothly over the Continental US, including mountainous regions. The hypothesis that erosivity density was not affected by mountainous terrain was tested in two ways. The first test involved fitting a linear equation to erosivity density values as a function of elevation at the 15-minute precipitation gage locations in a local region. The region had to relatively small, such as a quadrant of Utah, to avoid cross and spurious correlations. For example, the linear equation could not be fitted to erosivity density values for the entire state of Montana. When erosivity density values for all of Montana were included in the analysis, erosivity density values appeared to be a function of elevation, but that correlation was spurious. Elevation decreases from west to east across Montana while erosivity density increases across Montana. The increase in erosivity density across

Montana was not caused by elevation but by a west to east broad geographic increase in erosivity density.

Measured precipitation data from the 15-minute precipitation gages were available to compute erosivity density values for elevations up to about 10,000 ft. Statistical analysis for eleven local regions in mountainous areas throughout the western US and two local regions in the eastern US were conducted to determine if the hypothesis that erosivity density varied with elevation could be rejected. The analysis involved fitting a linear equation to the erosivity density values as a function of elevation. The data for three regions are shown in Figure 3.8-3.10. The result of the analysis was that the hypothesis that erosivity density values are independent of elevation could not be rejected. This test was not especially robust because of data variability. Elevation clearly affects erosivity density in the winter months because an increasing fraction of the precipitation occurs as snow at higher elevations. However, the assumption of no effect of elevation on erosivity density values in the summer months is considered acceptable.

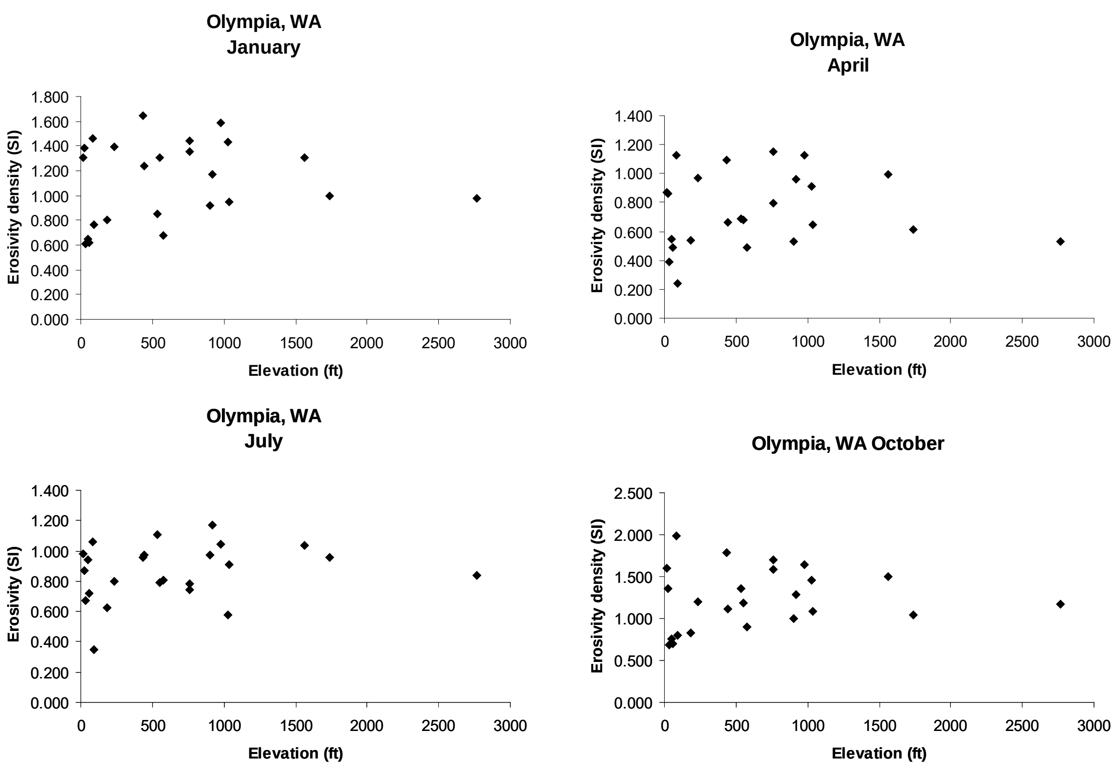

Figure 3.8. Variation of erosivity density with elevation in the Olympia, Washington region.

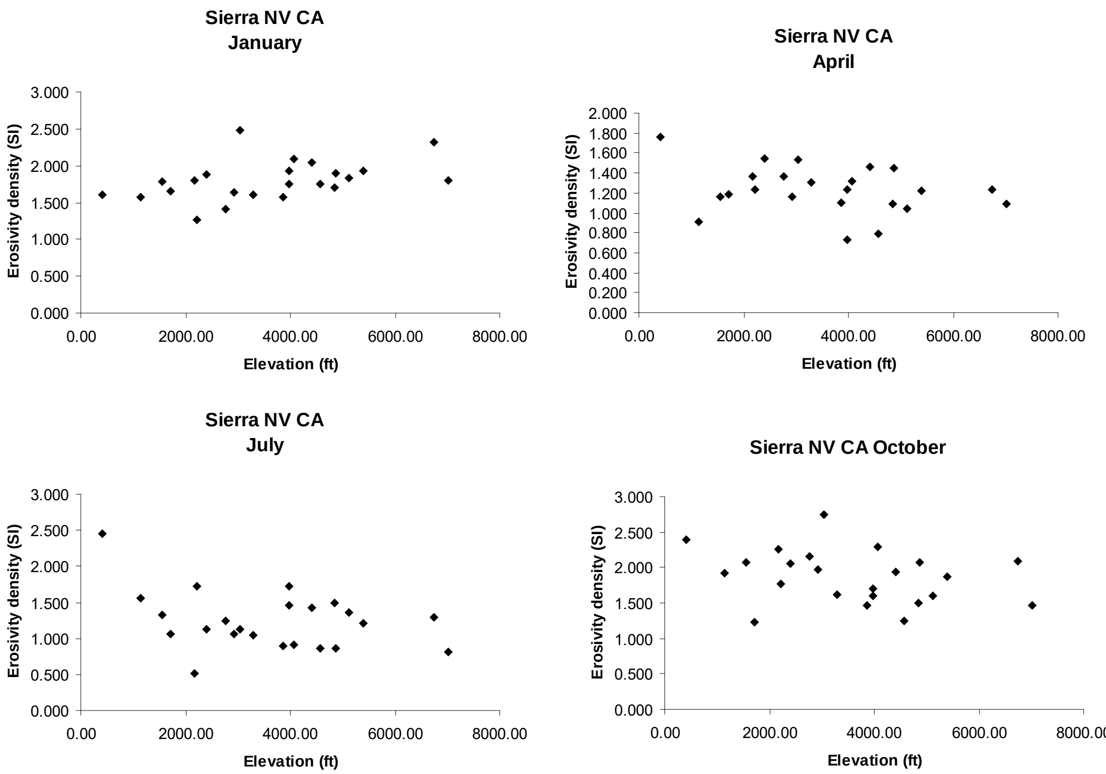

Figure 3.9. Variation of erosivity density with elevation in Sierra NV-CA region.

Another test of the hypothesis that erosivity density values are independent of elevation was to inspect a map, shown in Figure 3.11, of average 30 minute intensity for all storms in the data set (Hollinger et al., 2002). Even though these data were extensively smoothed as a part of the contouring process, the map shows no effect of mountainous terrain in the Western US on maximum 30-minute intensity. Equation 3.18 shows that erosivity density is approximately proportional to maximum 30-minute rainfall intensity. Therefore, if 30-minute intensity is independent of elevation in mountainous regions, as indicated in Figure 3.11, then erosivity density is independent of elevation. This result means that the effect of mountainous terrain on erosivity can be fully captured in how terrain affects monthly precipitation. While these tests are not especially robust, the erosivity density approach is a major improvement over previously available erosivity values in AH703 (Renard et al., 1997) for the Western US.

3.2.1.4.2. Advantages of erosivity density approach

The erosivity density approach has major advantages. It produces consistent, smoothly varying erosivity density values across the US as desired for conservation and erosion control planning. The erosivity density approach uses data from daily precipitation gage stations, which are far more numerous than the 15-minute precipitation stations, to fill in erosivity values between the 15-minute precipitation gage locations where erosivity was computed from measured precipitation data. The erosivity maps for the Eastern US in AH282 (Wischmeier and Smith, 1965) and AH537 (Wischmeier and Smith, 1978) were based on approximately 2000 data points (see AH282). However, storm erosivity was computed from detailed intensity precipitation data comparable to the 15-mintue precipitation data at only 181 locations. An equation involving 2 year-6 hour precipitation amount and other variables was fitted to average annual erosivity values computed from the measured detailed precipitation data at the 181 locations (AH282, AH537). This equation was then used to estimate average annual erosivity values at the approximately 2000 locations used to draw the AH282 and AH537 erosivity maps for the Eastern US. The erosivity density approach using monthly precipitation measured by daily precipitation gages to compute erosivity at any particular location serves this function in RUSLE2.

The USLE and RUSLE1 use EI distribution zones in the US to describe the spatial variations in the temporal distribution of erosivity during the year. The temporal distribution of erosivity is assumed to be constant within a zone. Differences in temporal erosivity distributions between zones resulted in major differences in erosion estimates across certain zone boundaries. For example, Little Rock, Arkansas is very close to a EI zone boundary. The USLE and RUSLE1 compute a 25 percent change in erosion across the EI zone boundary at this location for a conventionally tilled corn cropping system. The impact of this step change is that a client should not be expected to change management practices unless estimated erosion changes by at least 25 percent. RUSLE2's estimated erosion values vary smoothly across the US because RUSLE2 does not use such zones. See RUSLE2 User's Reference Guide for a discussion on how aggregating input weather data by counties affects estimated erosion across county boundaries.

Precipitation data measured by daily precipitation gages are much more stable and reliable and have much less missing data than precipitation data measured with the 15-mintue precipitation gages. That is, the quality of the 15-minute precipitation data is less than the quality of the daily precipitation data. The erosivity density approach computes a ratio in contrast to the standard approach that computes an absolute sum. The data requirements for computing a ratio of monthly erosivity to monthly precipitation amount are less demanding than for computing an absolute erosivity sum. An absolute sum is greatly affected by missing data, unless the missing data are so small that the missing values have little effect on the sum. In contrast, missing data have no effect on the ratio if the missing data are not biased. Although the missing 15-minute precipitation data were surely biased, problems caused by missing data and errors in reconstructing missing data are much less in the ratio erosivity density approach than in the absolute standard approach.

The erosivity density approach also reconciles differences in precipitation amounts measured by the daily and 15-minute precipitation gages. The Illinois State Water Survey provided precipitation data for 14 locations in West Texas and Eastern New Mexico where daily and 15-minutes precipitation gages were located sufficiently close so that annual precipitation measured by the two gages types could be compared. Overall, the annual precipitation measured by the 15-minute gages was 85 percent of that measured by the daily gages. The annual precipitation measured by the 15-minute gages was less than that measured by the daily gages for all 14 locations. The ratio of the precipitation amounts for the two gage types ranged from 0.76 to 0.94. This disparity between gage types affects erosivity density values much less than it does absolute erosivity values. The erosivity density approach computes monthly erosivity values, determined from 15-minute precipitation gage data that are consistent with the monthly precipitation values, determined from daily precipitation gage data, used in RUSLE2.

A shorter record length and a record with more missing data can be used to compute erosivity density values than can be used to directly compute erosivity values with the standard method. Record length, including both number of years and number of storms, is especially critical in the Western US where spatial density of 15-minute precipitation gages is low, spatial and temporal variability is great, and records are often short with missing data. Twenty years was the minimum data record length considered to be acceptable for computing erosivity values for the Eastern US. That record length was actually too short using the standard procedure, but it was a compromise to include as many stations as possible. A data record length of 15 years was judged to be satisfactory for computing erosivity density values in the Eastern US. This conclusion was based on analysis of precipitation data collected by the USDA-Agricultural Research Service in Northern Mississippi in a research environment where data quality was very carefully maintained (McGregor et al. 1995). As Table 3.1 shows, a record length of 10 years was acceptable for these data using the erosivity density approach. Most important, the analysis showed that a shorter length of record could be used in the erosivity density approach than in the standard approach.

Table 3.1. Percent error in estimating monthly R from measured preciptiation data. Ratio refers to erosivity density approach. Abs refers to standard approach that computes absolute values.

18	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

The length of record in years and number of storms in the record are more important in the Western US than in the Eastern US. Figure 3.12 shows the effect of record length for a precipitation gage located in Beaver County, Utah. The example in Figure 3.12 is not very robust, but it represents typical conditions for the 15-minute precipitation data in the Western US where the data record was short, the data was highly variable and contained relatively few storms, and number of the 15-minute gage locations was sparse. The erosivity density approach much more effectively uses the limited data in the Western US than does the standard procedure.

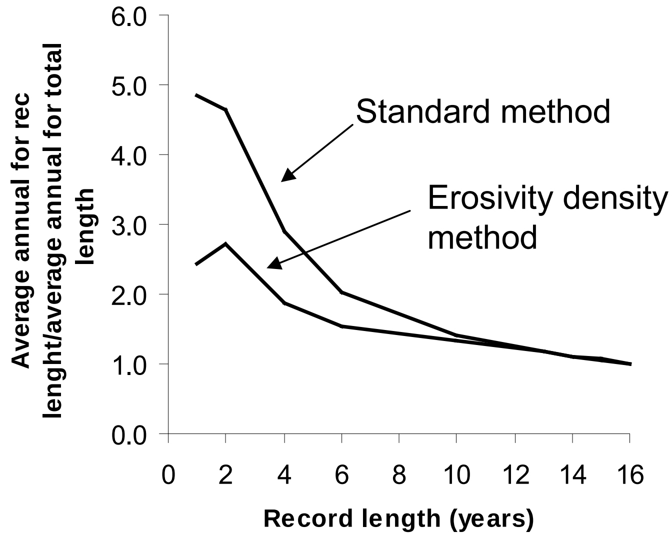

Figure 3.12. Effect of record length on variation of average annual values for erosivity and erosivity density for Beaver County, Utah.

Data for a gage location were not automatically discarded because of a short record length in the Western US in order to include as many stations as possible. The overall curve of monthly erosivity density by month computed by averaging erosivity density values in a local region was examined (e.g., see Figures 3.6 and 3.7), and the data for the location were left in the analysis if the trend at the location matched the local regional trend. When the trends in a dataset at a location did not match the overall trend, the record length at the location was almost always short.

3.2.1.4.3. Comments on erosivity density approach

Precipitation amount is a very poor indicator of erosivity (Wischmeier, 1958; Foster et al., 1982). Measures of both rainfall intensity and amount are required in erosivity measures and indices. Monthly erosivity values computed using the erosivity density method have the immediate appearance of being solely a function of monthly precipitation amount. The erosivity density value for each month depends strongly on intensity as shown by equation 3.18. The erosivity density method also seems to conflict with the empirical result that storm erosivity is a nonlinear function of storm amount (Richardson et al., 1983). The empirical erosivity density values account for this nonlinearity. Nonlinear mathematical relationships can be linearized by dividing the solution space into sufficiently small intervals so that linear equations can be assumed within each interval. The erosivity density approach is a linearized procedure that captures the effect of both intensity and nonlinearity between storm erosivity and storm amount.

Care must be taken in developing and applying the erosivity approach in other situations, especially when it is used where only very limited precipitation data are available. The erosivity density method can be quite useful in these situations, but sufficient data must be available and analysis must be conducted to determine the variation of erosivity density values over the region where the method is being applied. Assuming constant erosivity density values over too large of a region can produce very erroneous results.

3.2.1.4.4. Alternative procedures for estimating erosivity involving precipitation amount

Lack of adequate precipitation data to derive RUSLE2 erosivity values is a major limitation in applying RUSLE2 in many countries. Erosivity values are estimated from storm, monthly, and annual precipitation amounts. Rainfall intensity is a critical element in erosivity indices and any estimation procedure must account for how intensity varies over space and time in relation to precipitation amount. The effect of intensity on erosivity varies by location and by month as Figure 3.5 and equation 3.18 indicate.

A procedure to estimate storm or daily erosivity from storm or daily precipitation, respectively, uses the equation (Richardson et al., 1983):

$$r_s = a_p P_s^b \qquad [3.19]$$

where: r_s = storm or daily erosivity, P_s = storm or daily precipitation amount, and a and b are coefficients that vary by location and month. Values for a_p and b are determined by empirically fitting equation 3.19 to observed data. The procedure requires sufficient data and analysis to determine values for a_p and b over space and by month or season. The Illinois State Water Survey (ISWS) attempted to apply this procedure to US data but concluded they had insufficient data to properly compute a and b values (Hollinger et al., 2002). Another problem was that they used a logarithmic transformation and linear regression in fitting equation 3.19 to the data rather than a nonlinear fitting procedure. The logarithmic transformation-linear regression procedure returns the mean of the logarithms of the observed values rather than the mean of the absolute observed values. Erosivity values that would be used in RUSLE2 produced by the ISWS procedure had a systematic error by being too low by about 10 percent. Use of equation 3.19 can work if the proper precautions are followed and sufficient data are available to determine values for a_p and b in equation 3.19 over space and time by month or season.

Another procedure is to compute storm erosivity using a design storm that has a particular intensity distribution (Cooley, 1980; Brown and Foster, 1987). The requirement for this procedure is that design storm intensity distributions vary over space and time. A few design storms are available that vary intensity distributions over space in the US, but no design storms seem to be available that vary intensity distributions by month or season.

A modified Fournier index is widely used to estimate erosivity where precipitation data are very limited. A value for the modified Fournier index is computed from (Renard and Freimund, 1994):

$$F = \frac{\sum_{j=1}^{12} P_{m(j)}^2}{\sum_{j=1}^{12} P_{m(j)}} \qquad [3.20]$$

where: F = the modified Fournier index, P_m = average monthly precipitation, and j = index for each month. The usual procedure is to fit a linear equation involving average annual erosivity as a function of the modified Fournier index (Fournier, 1960). Values of the modified Fournier index were computed at the US locations listed in Table 3.2. Average annual erosivity values at these locations are plotted as a function of the modified Fournier index in Figure 3.13.

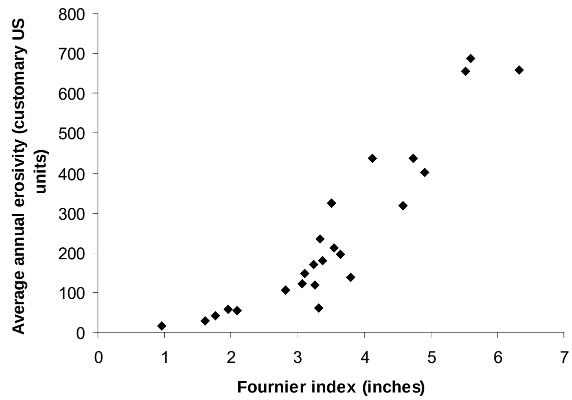

Figure 3.13. Relation of average erosivity to modified Fournier index for several US locations.

These results show that the relation between average annual erosivity and the modified Fournier index is nonlinear rather than linear. Renard and Freimund (1994) also found that the relationship of average annual erosivity to the modified Fournier index was nonlinear where erosivity varied with the index raised to the 1.85 power for US data that are comparable to data represented in Figure 3.13. That equation is given by:

$$R = a_F F^{1.85} \qquad [3.21]$$

where: R = average annual erosivity. When this equation form is fitted to the data represented by Table 3.2, the exponent is 2.24. The difference in these exponent values is caused by differences in datasets and fitting procedures.

Another concern with the modified Fournier index is whether the square of monthly precipitation in equation 3.20 is the appropriate value for the exponent. A modified Fournier index with a generalized value for the exponent would be computed as:

$$F_r = \frac{\sum_{j=1}^{12} P_{m(j)}^{z}}{\sum_{j=1}^{12} P_{m(j)}} \qquad [3.22]$$

$$R = a_r F_r \qquad [3.23]$$

where: F_r = the modified Fournier index where a value for the exponent z is determined by fitting equations 3.22 and 3.23 to observed data. In this formulation, the relationship between average annual erosivity and the generalized modified Fournier index is linear as shown in equation 3.23. The value for the exponent b most likely varies with the dataset. A value of 3.02 was obtained when equations 3.22 and 3.23 were fitted to the data represented in Table 3.2. Figure 3.14 shows a comparison between the values computed by equations 3.20 and 3.21 and equations 3.22 and 3.23. The values computed by equation 3.21 are slightly better than the values computed with equations 3.22 and 3.23. Using equations 3.20 and 3.21 or equations 3.22 and 3.23 is an improvement over fitting a linear equation to the standard modified Fournier index with the square exponent.

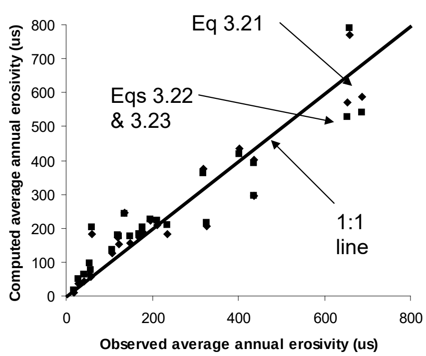

Figure 3.14 Comparison of alternate ways of using a modified Fournier index to estimate average annual erosivity.

The best approach for fitting either equations 3.20 or 3.21 or equations 3.22 and 3.23 is to divide the data into subsets by geographic region where the relationship between precipitation amount and intensity is constant over the region. A separate equation is fitted to the sub-dataset for each region. If the regions are too large, the variation in the relationship of intensity to precipitation amount over geographic space will be too large. Otherwise, the error in estimated erosivity will be very large. For example, the range in average annual erosivity in Figure 3.13 is from about 50 to 325 (US units) for a modified Fournier index value of about 3.5 inches. Obviously this great difference in erosivity for a particular value of the modified Fournier index results in very large errors in estimated erosion.

The implicit assumption in the modified Fournier procedure is that the monthly precipitation distribution coincides with the monthly intensity distribution. That is, the monthly precipitation distribution must coincide with the monthly erosivity density distribution. These distributions coincide well at Minneapolis, Minnesota but not at Oxford, Mississippi. The effect of the coincidence of the distributions on the monthly erosivity distribution is illustrated in Figure 3.15. The monthly erosivity distribution computed from the Fournier index, assuming a square power as in equation 3.20, compares reasonably well with the observed distribution at Minneapolis but compares very poorly at Oxford. Therefore, if the Fournier index is used to estimate monthly erosivity for the USLE, RUSLE1, or RUSLE2, the monthly erosivity density distribution must correspond closely to the monthly precipitation distribution.

Another procedure to estimate erosivity from monthly or annual precipitation amounts is to empirically fit equations involving these variables to observed data (Renard and Freimund, 1994). These procedures work satisfactorily only if the spatial and temporal variations in the relationship between precipitation amount and intensity are taken into account. For example, average annual erosivity ranged from 88 (US units) to 470 (US units) for an average annual precipitation of 39 inches in the data analyzed by Renard and Freimund (1994). This variation in average annual erosivity for a particular average annual precipitation is much too great to be useful in erosion prediction used for

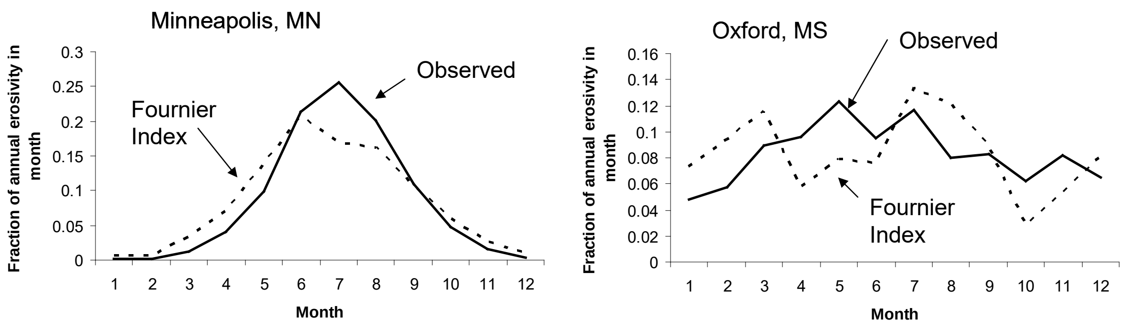

Figure 3.15. Comparison of monthly erosivity distributions computed with the modified Fournier index with observed monthly erosivity distributions.

conservation and erosion control planning. The data should be divided into subsets according to the relation of intensity to precipitation amount.

Any method used to estimate erosivity from precipitation amount MUST take into account how the relationship between precipitation and intensity varies over space and time.

3.2.2. Precipitation

RUSLE2 uses average monthly precipitation values as input values for precipitation. RUSLE2 uses the disaggregation procedure described in **Section 3.1** to disaggregate average monthly precipitation values into daily values. A consistent and sufficient record length should be used to determine average monthly precipitation values from measured data. A 22-year record length was used to develop erosivity values for the USLE (Wischmeier and Smith, 1958, 1965, 1978) because climate was thought to vary in a 22-year cycle. The modern accepted record length seems to be 30 years for hydrologic modeling. The National Weather Service has assembled 30-year data records for the locations where daily precipitation was measured. These data have been reviewed to correct erroneous and missing data. In addition, the USDA-NRCS, National Weather Service, and other agencies used the PRISM (Daly et al., 1997) computer program that extrapolates the measured data at each weather station to compute monthly precipitation values across the US on a 4 km grid. This mathematical procedure adjusts measured values for the effect of elevation, proximity to a coastline, and other variables that spatially affect precipitation. RUSLE2 users should contact their USDA-NRCS state office for precipitation data to use in RUSLE2.

The data available from the NRCS, referred to as the PRISM data, were analyzed to ensure that the probability distribution of the data is uniform for all locations. For example, extreme summer precipitation events can be highly localized. The PRISM data should be reviewed to ensure that the return periods for the precipitation input data are uniform among locations where RUSLE2 is being applied so that a land user is not unfairly affected by the happenstance of extreme precipitation occurring at their location and not at other locations (See RUSLE2 User's Reference Guide). In general, events having a return period greater than 50 years should be excluded when using RUSLE2 for conservation and erosion control planning.

3.2.3. Temperature

RUSLE2 uses average monthly values for input temperature values. RUSLE2 uses the disaggregation procedure described in **Section 3.1** to compute average daily temperature values from average monthly input values. The time period used to obtain monthly precipitation values should be the same as that used to obtain average monthly temperature values so that precipitation and temperature input values will be consistent. The most recent 30 years is an acceptable period over which to obtain average monthly temperature values. However, the data should be reviewed to ensure that the data record does not contain unusually extreme events that would have extraordinary effect on RUSLE2's computations. Extreme events in the observed temperature data do not seem be as severe as in the precipitation record.

The best source of temperature values for use in RUSLE2 is from the USDA-NRCS. Their data have been produced with the PRISM program that takes into account how elevation and other variables affect temperature. Like precipitation, the USDA-NRCS PRISM temperature values are available on a 4 km grid across the US.

3.2.4. 10 year-24 hour precipitation

RUSLE2 uses the precipitation amount for a 24-hour event that has a 10-year return period as a representative storm to compute the effect of ponding on rainfall erosivity, runoff's sediment transport capacity, and the location along an overland flow path length that contouring fails (e.g., see **Section 3.4.3**). The fundamental structure of RUSLE2 computes daily erosion for unit plot conditions (see **Section 2.1**), which in turn is multiplied by non-dimensional ratios to account for effects of topography, cover-management, and support practices. A single storm is used to compute values for these non-dimensional ratios that involve ponding and runoff. The RUSLE2 intent is to capture main effects related to runoff as they vary with location, soil, and cover-management. RUSLE2 starts with accepted USLE values and uses runoff computations to adjust the ratio values up or down as runoff departs from a base condition. An advantage of this approach is ratio values vary less temporally than erosivity, which allows a single precipitation event to be used to compute runoff. Most of the temporal variation is captured by the temporal varying erosivity. Other temporal differences are captured by computing daily runoff for the representative storm as cover-management variables change temporally. The 10 year-24 hour precipitation was chosen to make the runoff computations because most of the rill-interrill erosion at a site is caused by moderate to large rainfall events (Wischmeier and Smith, 1958, 1978).

The 10-year EI storm was used for the same purpose in RUSLE1 [Foster et al., 1997; AH703 (Renard et al., 1997)]. The procedure in RUSLE1 computed a precipitation amount for the 10 year-EI storm using an empirical equation. This equations was derived by fitting storm erosivity values as a function of storm precipitation amount (Richardson et al., 1983). The RUSLE1 procedure worked satisfactory for the eastern US but not for the Western US, especially in the Northwest Wheat and Range Region (NWRR) that includes the eastern portions of Washington and Oregon and northern portion of Idaho. Winter precipitation causes most of the erosion in the NWRR. This precipitation occurs at a very low intensity, which has low unit energy whereas most of the erosion in the Eastern US is caused by summer precipitation at high unit energy. Directly using the 10 year-24 hour precipitation values more accurately computes runoff for RUSLE2 purposes than computing runoff from a precipitation value computed from an erosivity-precipitation equation empirically derived from eastern US data as was done in RUSLE1.

An erosivity value is needed for the 10 year-24 hour precipitation amount. This erosivity value should reflect the 10 year-24 hour precipitation amount and unit energy at the location. The equation used in RUSLE2 to compute the erosivity for the 10 year-24 hour precipitation amount is:

$$EI_{10y24h} = 2\alpha_m P_{10y24h} \qquad [3.24]$$

where: EI_{10y24h} = the storm erosivity associated with the 10 year-24 hour precipitation amount, α_m = the maximum monthly erosivity density at the location, and P_{10y24h} = the 10 year-24 hour precipitation amount. The 2 coefficient in equation 3.24 was obtained by calibrating equation 3.24 to observed values for the 10-year EI from modern precipitation data in the Eastern US (Hollinger et al., 2002).

Equation 3.24 is consistent with the procedure used to compute monthly erosivity using monthly precipitation amount and monthly erosivity density (see **Section 3.2.1.4.1**). The implicit assumption is that the 10 year-24 hour precipitation event occurs in the month having the maximum erosivity density. A procedure that uses the erosivity density from the month with the maximum precipitation was evaluated. That procedure gave inconsistent results because of spatial variability in the month with the maximum precipitation. The month having the maximum precipitation varies greatly within a relatively small region, which in turn results in relatively large variations in the monthly erosivity density values used in equation 3.24.

The main role of using the 10 year-24 hour precipitation event in RUSLE2 and the 10 year EI in RUSLE1 was to compute the variation in the effectiveness of support practices, especially contouring and strip cropping, across the US. The 10-year EI map published in AH703 (Renard et al., 1997) shows numerous narrow ridges and valleys for the 10-year EI contours. Those narrow ridges and valleys were judged to represent unexplained variability in the measured data used to compute 10-year EI values rather than trends in precipitation important in support practice effectiveness. The smooth trends in the widely accepted maps of the 10 year-24 hour precipitation for the Eastern

US were judged to much more accurately represent precipitation trends important in support practice effectiveness.

3.2.5. Req

In the Northwest Wheat and Range Region (NWRR), erosion per unit erosivity is much greater during the winter months than during the summer months and much greater than for the Eastern US. A unique set of conditions in the NWRR related to highly saturated thawing soil produces a highly erodible soil condition (McCool et al. 1995). The approach used in RUSLE2 computes erosion using standard soil erodibility values (see **Section 4.1**) and adjusted erosivity, i.e., Req for the effective (equivalent) average annual erosivity. Also, a special monthly erosivity distribution is used to distribute the annual Req erosivity over each month.

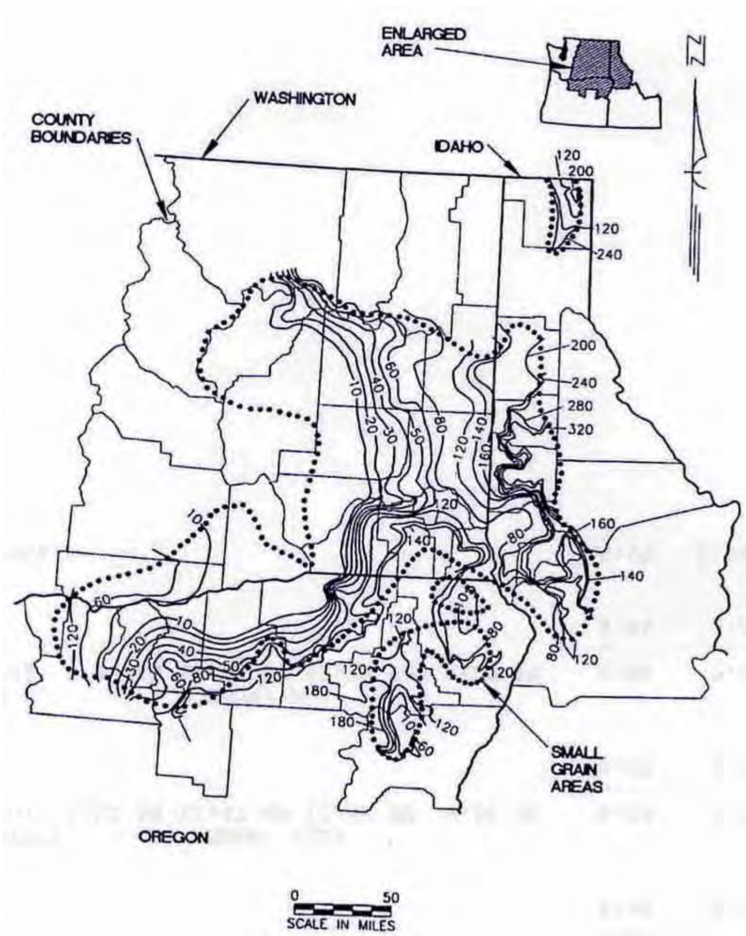

Figure 3.16. Area in Oregon, Washington, and Oregon where RUSLE2 Req procedure works best. Ignore contour lines.

The principal source of data for determining Req has been from research erosion plots operated by the USDA-ARS at Pullman, WA and Pendleton, OR. The procedure is to measure erosion on plots having the unit plot cover-management condition (see **Section 2.1** and **Footnote 3**) and to adjust measured erosion values for the effect of length and steepness to account for differences between the actual plots and unit plots. The adjusted average annual erosion value is divided by the standard soil erodibility value to produce an Req value. The distribution of measured erosion on unit-plot conditions by month is used to obtain an Req erosivity distribution.

The RUSLE2 Req procedure works well for the region shown in Figure 3.16, which is mainly northeastern Oregon, eastern Washington and northern Idaho. The Req effect occurs in other parts of the Western US, but the Req relationships for these regions have not been well determined. RUSLE2 compute Req as a function of average annual precipitation based on conditions across eastern Washington. Whether that relationship applies in other regions where the precipitation and temperature differs from that in eastern Washington is a concern. Certainly the monthly distribution for Req differs in other regions where the monthly distribution of precipitation differs from that in eastern Washington. The Req distribution for eastern Washington should not be used at other locations without making adjustments for differences in monthly precipitation and temperature distributions.

Another consideration is that winter temperatures are so low at some locations that soil freezing significantly decreases erosion, which is represented by a decreased soil erodibility value during that period. Also, snow covers the soil at high elevations to prevent winter erosion. Another factor is erosion by snowmelt in late winter and early spring, but RUSLE2 is not designed to estimate erosion by snowmelt. Erosion research at Morris, Minnesota showed that only about seven percent of the erosion occurred by snowmelt (Knisel, 1980). Thawing and recently thawed soil can be highly erodible in late winter and early spring in all locations, including the eastern US. Even though soil erodibility can be greatly increased for a short time, less than three weeks, not much erosion occur if little erosivity occurs during this period, which is the case in Minnesota. A similar effect occurs in the Mid-South region. This effect is partially captured in the temporal soil erodibility equation for the mid-south US and similar regions (see **Section 4.5**).

The Req effect is described in detail in the **RUSLE2 User's Reference Guide**. Additional information can be obtained by contacting D.K. McCool, USDA-ARS, Pullman, WA, and by reviewing his scientific publications.

3.3. Runoff

RUSLE2 uses the 10 year-24 hour index (representative) storm to compute runoff depth, which is subsequently used as an index to compute deposition, erosion control effectiveness of support practices, and effect of water depth (ponding) on erosion (see **Sections 2.3.3, 7 and 3.4.5**). This procedure captures runoff's main effects but not every detail. For example, RUSLE2 uses this approach to estimate how contouring effectiveness differs between the Northern and Southern US.

Both runoff amount and rate are important for computing erosion. RUSLE2's equations for runoff hydraulics (see **Section 3.4**) are based on runoff rate. RUSLE2 computes a daily sediment load to erosivity ratio, which RUSLE2 multiplies by daily erosivity to estimate daily erosion, deposition, and sediment load (see **Section 2.3.9**). The RUSLE2 assumption is that excess rainfall rate (depth/time) equals runoff depth divided by one hour. Rainfall depth is the major determinant of excess rainfall rate. The 10 year-24 hour precipitation amount is used each day to compute daily runoff depth as cover-management conditions temporally vary. The resulting runoff values are indices of how runoff varies by location as a function of soil and cover-management.

3.3.1. Computation of runoff

RUSLE2 uses the NRCS curve number method to compute runoff depth as a function of precipitation amount and curve number (Haan et al., 1994). Curve number values vary with cover-management, hydrologic soil group, and antecedent soil moisture. A moderate antecedent soil moisture condition is used in RUSLE2.

3.3.1.1. NRCS curve number method

The NRCS curve number equation computes runoff depth as:

$$Q = \frac{(P - 0.2S)^2}{P + 0.8S} \qquad [3.25]$$

where: Q = runoff depth, P = precipitation depth, and S = a variable computed with:

$$S = 1000 / N - 10 \qquad [3.26]$$

where: N = curve number and inches are the units for P, Q, and S.

A requirement for equation 3.25 is that precipitation depth P is greater than 0.2S. Equation 3.25 was modified so that RUSLE2 computes decreasing runoff rate with distance along the overland flow path where a segment has a much higher infiltration rate than do upslope segments. The modified equation computes the additional precipitation amount that would be needed to just produce runoff for the precipitation depth P as:

$$P_a = P - 0.2\left[\left(\frac{1000}{N}\right) - 10\right] \qquad [3.27]$$

where: P_a = the additional precipitation (inches) needed to produce runoff.

Excess rainfall rate σ (inches/hour) in equation 2.18 is set equal to Q (inches) in equation 3.25 or to P_a (inches) in equation 3.27 if P < 0.2S (see **Section 2.3.5**). The negative excess rainfall rate causes RUSLE2 to compute a decreasing discharge rate along the overland flow path.

3.3.1.2. Curve number as function of cover-management variables

RUSLE2 uses equations that are functions of cover-management variables to compute curve number N values. Curve number values vary daily as cover-management variables including ground cover, soil surface roughness, soil biomass, and soil consolidation, change daily (see **Section 6**).

Equations were derived for RUSLE2 that compute curve number values as a function of cover-management variables and hydrologic soil group. First, curve number values was assigned to each hydrologic soil group for a wide range of cover-management conditions based on standard NRCS procedures for non-Req conditions and measured runoff from USDA-ARS research plots at Pullman, Washington for Req conditions. These curve number values are comparable to those used in RUSLE1. The equations used to compute RUSLE2 curve numbers were empirically derived using equation forms chosen to represent the trend of curve number values as a function of key cover-management variables. Coefficient values for these equations were obtained by fitting the equations to the assigned curve number values.

3.3.1.2.1. Standard conditions – no Req, no non-erodibile cover, no irrigation, no adjustment made for subsurface drainage

Curve number N represents the effect of cover-management on runoff and the inherent potential of the soil for producing runoff. Hydrologic soil group is the variable used in RUSLE2 to represent the inherent runoff potential of the soil. Cover-management affects runoff in several ways. For example, improved soil management, which is represented in RUSLE2 by increased soil biomass, decreases runoff. Mechanical soil disturbance like tillage reduces runoff on soils having no biomass in comparison to the soils not disturbed for several years. Soil biomass and soil consolidation interact to affect runoff. Soil consolidation increases runoff when soil biomass is very low, typical of construction sites not recently mechanically disturbed. Conversely, soil consolidation decreases runoff when soil biomass is very high, typical of undisturbed, high production pasture. Increased soil surface roughness and ground cover decrease runoff depending on soil biomass levels. Curve numbers and how they are affected by cover-management are also a function of soil properties as represented by hydrologic soil group. For example, cover-management decreases runoff more on soils having a high infiltration potential, hydrologic soil group A, than on soils having a low infiltration potential, hydrologic soil group D.

RUSLE2 curve number equations were calibrated to curve number values commonly used by NRCS (Haan et al., 1994). Indices in these empirical equations reflect how cover-management is known to affect infiltration and runoff.

The main RUSLE2 equation used to compute curve number values is:

$$N = [N_{u100} - s_u(1 - s_c)] f_B \exp(b_D B_s) \qquad [3.28]$$

where: N = curve number used in equations 3.25, 3.26, and 3.27 to compute runoff, N_{u100} = a curve number value that represents the effect of ground cover and soil roughness on curve number on a soil recently mechanically disturbed (i.e., $s_c = 1$), s_u = the change in curve number per unit change in the soil consolidation subfactor (see **Section 6.6**), f_B = a fraction, which along with the term $\exp(b_D B_s)$, describes the main effect of soil biomass and its interaction with soil consolidation on curve number, b_D = a coefficient that is a function of the soil consolidation subfactor s_c, and B_s = soil biomass. Soil biomass B_s is the sum of buried residue averaged over the residue accounting depth (see **Section 6.2**) and the live and dead root biomass averaged over the upper 10 inch soil depth (see **Section 6.2.1**). Units for B_s are biomass on a dry basis/(land area·unit soil depth). The accounting depth for buried residue decreases from 3 inches to 1 inch as the soil consolidation subfactor s_c decreases from 1 to 0.45 (see Section **6.6**).

The curve number N_{u100} is determined by starting with a base curve number for a recently mechanically tilled soil. This curve number is decreased for increases in both ground cover and adjusted soil surface roughness r_a greater than 0.24 inch, which is the base roughness value assumed for unit plot conditions (see **Section 2.1** and **Footnote 3**). Curve number values increase when adjusted roughness is less than 0.24 inch, which represents a condition where runoff is greater than from the unit plot condition. The adjusted soil surface roughness is used in equation 6.26 to compute a soil surface roughness subfactor value (see **Section 6.3**).

The equations used to compute N_{u100}, which do not consider any effect of soil biomass or soil consolidation on curve number, are given by:

Table 3.3. Curve number and coefficient values used in standard RUSLE2 curve number equations (not Req)

Hydrologic soil group	N_{s100}	N_{uB}	N_{lB}	N_{u45}	N_{lb45}	b_B (in ac/lbs$_m$)	a_{cu}	a_{cl}	a_{ru}	a_{rl}	a_{45}
A	87.0	87.0	53.0	94.0	70.0	0.00219	-12.0	-6.5	-12.0	6.5	-0.12
B	92.0	92.0	68.0	98.0	82.0	0.00174	-12.0	-6.5	-12.0	6.5	-0.12
C	93.0	93.0	75.0	98.6	84.6	0.00200	-7.0	-5.0	-7.0	5.0	-0.07
D	94.0	94.0	79.0	98.7	88.4	0.00153	-5.0	-3.0	-5.0	4.0	-0.05

$$N_{u100} = N_{s100} + a_{cu}(f_g/100) + a_{ru}\{1 - \exp[-1.7(r_a - 0.24)]\} \quad [3.29]$$

$$N_{u100} = N_{s100} + a_{cl}(f_g/100) + a_{rl}[(0.24 - r_a)/0.24] \quad r_a \le 0.24 \text{ in} \quad [3.30]$$

where: N_{u100} = a curve number for a recently mechanically disturbed soil (i.e., s_c = 1) with no soil biomass, N_{s100} = a starting curve number value for unit plot conditions that are recently mechanically disturbed, adjusted soil surface roughness r_a = 0.24 in, and no soil biomass, a_{cu} = a coefficient for the effect of ground cover when surface roughness is greater than 0.24 inches, a_{cl} = a coefficient for the effect of ground cover when surface roughness is less than 0.24 inches, f_g = ground cover (percent), a_{ru} = a coefficient for the effect of soil surface roughness when roughness is greater than 0.24 inches, a_{rl} = a coefficient for the effect of adjusted soil surface roughness when the adjusted soil surface roughness is less than 0.24 inches, and r_a = adjusted soil surface roughness index (inches) (see **Section 6.3**). Values for starting curve number N_{s100} and the coefficients a_{cl}, a_{clu}, a_{rl}, and a_{ru}, which vary with hydrologic soil group, are given in Table 3.3.

The main effect of soil consolidation is represented in the terms involving s_u, which is the rate of change in the curve number per unit change in the soil consolidation subfactor s_c. The equation for s_u is given by:

$$s_u = (N_{u100} - N_{u45})/0.55 \quad [3.31]$$

where: N_{u45} = the curve number for a fully consolidated soil with no ground (surface) cover or soil biomass and soil surface roughness = 0.24 inches, 0.55 = the range in the soil consolidation subfactor s_c from 1 for a recently mechanically disturbed soil to 0.45 for a fully consolidated soil. Values for the curve number N_{u45}, given in Table 3.3, are for a fully consolidated soil with no ground cover and soil biomass.

The fraction f_B represents the main effect of soil biomass on curve number. A value for f_B is computed with:

$$f_B = [(N_{uB} - N_{lB})\exp(-b_B B_s) + N_{lB}] / N_{uB} \qquad [3.32]$$

where: N_{uB} = the curve number value when no biomass is present in the soil and the soil has been recently mechanically disturbed, N_{lB} = the curve number for a very high soil biomass (i.e., when $\exp(-b_B B_s)$ is near zero) and the soil has been recently mechanically disturbed, and b_B = a decay coefficient that represents how the curve number decreases exponentially as a function of soil biomass. Curve number values for N_{uB} and N_{lB} are given in Table 3.3. The effect of soil biomass on curve number is assumed to be greater in soils having a low runoff potential, i.e., hydrologic soil group A, than soils having high runoff potential, i.e., hydrologic soil group D. Values for the decay coefficient b_B, are also given in Table 3.3.

The term $\exp(b_D B_s)$ in equation 3.28 represents how the interaction between soil biomass and soil consolidation affect curve number values. A value for the coefficient b_D is computed from:

$$b_D = \ln(N_l / N_u)/1750 \qquad [3.33]$$

where: N_l and N_u = lower and upper curve numbers, respectively, that represent the difference in curve numbers for a soil with no soil biomass and one with a high soil biomass of 1750 $lbs_m/(\text{acre}\cdot\text{in})$ value. The value for N_u is computed from:

$$N_u = N_{u100} - s_u(1 - s_c) \qquad [3.34]$$

A value for the lower curve number that is comparable to the upper curve number N_u is computed as:

$$N_l = N_{u100} - s_l(1 - s_c) \qquad [3.35]$$

where: s_l is computed from:

$$s_l = (N_{l100} - N_{l45})/0.55 \qquad [3.36]$$

The curve number N_{l45} is adjusted for ground cover is computed as:

$$N_{l45} = N_{lb45}(1 + a_{45} f_g / 100) \qquad [3.37]$$

where: a_{45} = a coefficient having values given in Table 3.3. Soil surface roughness is assumed not to affect curve number for a fully consolidated soil with high soil biomass.

Values for the index curve number N_{lb45} used to calculate curve numbers for fully consolidated soil at high soil biomass with no ground cover are also given in Table 3.3.

Table 3.4. RUSLE2 (R2) curve numbers computed for Columbia, Missouri compared with curve numbers used in RUSLE1 (R1) for A, B, C, and D hydrologic soil groups

Cover-management condition		A		B		C		D	
R1 class	Description	R1	R2	R1	R2	R1	R2	R1	R2
C1	Established meadow, very dense cover with high soil biomass	30	45	58	64	71	71	78	78
C2	Mixed grass-legume hay, moderate cover, and moderate to high soil biomass	46	61	66	75	78	80	83	85
C3	Heavy cover (75-95%) or very rough with moderate biomass	54	46	69	62	79	70	84	77
C4	Moderate cover (40-65%) or rough with moderate soil biomass	55	54	72	66	81	75	85	81
C5	Light cover (10-30%), moderate roughness, and low to moderate soil biomass	56	61	75	70	83	76	87	82
C6	Essentilly no cover (5%), minimal roughness and low to moderate soil biomass	64	67	78	78	85	82	89	84
C7	Very little soil biomass and smooth	77	84	86	90	91	91	94	93
	Cut soil, no soil biomass without mulch		94		98		99		99
	Cut soil, no soil biomass with 4000 lbs/ac straw mulch		94 - 63		98 - 77		98 - 82		99 - 87
	Fill soil, graded smooth with no mulch		87 - 88		92 - 93		93 - 94		94 - 95
	Fill soil, graded smooth with 4000 lbs/ac straw mulch		81 - 85		86 - 90		89 - 92		91 - 94

Notes:

The curve numbers from RUSLE2 were taken at planting time because theRUSLE1 curve numbers are most applicable for that period.

The range in RUSLE2 curve numbers for the construction site conditions are for the 12 month period

A-hydrologic soil group (lowest runott potential) to D-hydrologic soil group (highest runoff potential)

RUSLE2 computed curve number values as shown in Table 3.4 along with the curve number values used in RUSLE1. RUSLE2 adequately captures the trends in curve numbers for land use that varies from construction sites to dense grass. RUSLE2 computes higher curve number values for the A-hydrologic soil group soils (low runoff potential) than those used in RUSLE1. However, the higher curve numbers are considered more appropriate for RUSLE2 applications. RUSLE2 also computes curve number values that are consistent with those reported for a wide range of land uses (Haan et al. 1994).

3.3.1.2.2. Req conditions, no irrigation, no adjustment made for subsurface drainage

The procedure described in Section 3.3.1.2.1 is also used to compute runoff for Req conditions, but different runoff curve number and coefficient values are used. A major effect in the Req zone is that infiltration is very low during the winter unless residue cover, soil biomass, and soil surface roughness is very high. The soil becomes highly saturated resulting in a very high portion of the precipitation becoming runoff during the winter period. High residue cover, soil biomass, and surface roughness seem to keep open macro-pores for significantly increased infiltration. The values given in Table 3.5 are used during by RUSLE2 for the winter Req period to compute runoff while the values given in Table 3.3 can be used for the summer months.

Table 3.5. Curve number and coefficient values used in RUSLE2 curve number equations for Req conditions

Hydrologic soil group	N_{s100}	N_{uB}	N_{lB}	N_{u45}	N_{lb45}	b_B (in ac/lbs$_m$)	a_{cu}	a_{cl}	a_{ru}	a_{rl}	a_{45}
A	92.0	92.0	22.0	94.0	70.0	0.00024	-12.0	-6.5	-25	2.0	-0.12
B	97.0	97.0	58.0	98.0	82.0	0.00020	-12.0	-6.5	-25	2.0	-0.12
C	98.0	98.0	73.0	98.6	84.6	0.00025	-7.0	-5.0	-15	2.0	-0.07
D	98.0	98.0	78.0	98.7	88.4	0.00020	-5.0	-3.0	-10	2.0	-0.05

3.3.1.2.3. Effect of non-erodible cover on runoff

RUSLE2 assumes no detachment for the portion of the soil surface covered by non-erodible cover. However, RUSLE2 assumes that non-erodible cover can be permeable. A RUSLE2 input value used to describe non-erodible cover is the fraction of the non-erodible cover that is fully permeable so that infiltration is controlled by the underlying soil. All of the precipitation is assumed to become runoff for the remaining portion of the non-erodible cover. The overall effective curve number for this condition is computed by RUSLE2 as:

$$N = N_b(1 - f_\mu) + f_\mu[N_b f_\rho + 100(1 - f_\rho)] \qquad [3.38]$$

where: N = overall, effective curve number used in equation 3.25 or 3.27 to compute runoff, f_μ = fraction of the soil surface covered by non-erodible cover, f_ρ = fraction of the non-erodible cover that is permeable, N_b = the curve number for the portion of the soil not covered by the non-erodible cover, and 100 = the curve number for the non-permeable portion of the non-erodible cover. A 100 curve number means that all of the precipitation becomes runoff.

3.3.1.2.4. Effect of subsurface drainage on runoff

The RUSLE2 procedure for adjusting for subsurface drainage is to select a hydrologic soil group that describes runoff potential for the undrained condition and one that describes runoff potential for the drained condition (see **Sections 7.4** and the RUSLE2 User's Reference Guide). RUSLE2 uses the hydrologic soil group assigned to the drained and undrained soil conditions to compute runoff using the values in either Table 3.3 or 3.4.

A RUSLE2 input for subsurface drainage is the portion of the area represented by the overland flow path that is subsurface drained. RUSLE2 uses this input to compute an effective curve number value for the entire overland flow path. The effective curve number is computed with:

$$N = N_d f_d + N_{ud}(1 - f_d) \quad [3.39]$$

where: N = effective curve number used in equation 3.25 or 3.27 to compute runoff, N_d = curve number for the drained condition, N_{ud} = the curve number for the undrained condition, and f_d = the fraction of the area represented by an overland flow path that is drained.

3.3.1.2.5. Effect of irrigation on runoff

RUSLE2 computes the effect of irrigation on erosion when rainfall occurs. RUSLE2 does not compute erosion caused by the applied water. RUSLE2 computes increased erosion on irrigated areas because increased soil moisture increases soil erodibility and residue decomposition and decreases soil surface roughness. However, RUSLE2 does not compute increased runoff caused by irrigation.

3.4. Hydraulics

RUSLE2 uses shear stress as the hydraulic variable to compute sediment transport capacity and locations where contouring fails. Runoff's total shear stress is applied to surface soil particles, ground cover, soil surface roughness elements, and stems of live and standing dead vegetation. Total shear stress is computed with (Chow, 1959):

$$\tau_t = \gamma y s \quad [3.40]$$

where: τ_t = total shear stress (force/unit area), γ = weight density of water (force/volume), y = flow depth (length), and s = overland flow path steepness (sine of slope angle). Flow depth is computed with the Manning equation as (Chow, 1959):

$$y = \left(\frac{q n_t}{1.49 s^{1/2}} \right)^{3/5} \quad [3.41]$$

where: q = discharge rate, n_t = total Manning's n (index for hydraulic roughness-resistance), and the 1.49 is used when US customary units [q - ft3/(sec·ft width), y – ft] are used.

3.4.1. Concept of grain and form roughness

The total shear stress can be divided into two parts (Graf, 1971), the part referred to as grain roughness shear stress that acts on surface soil particles and the part referred to as form roughness shear stress that acts on ground cover, stems of live and dead standing vegetation, and soil surface roughness elements. Grain roughness shear stress is assumed to be responsible for sediment transport while form roughness shear stress is assumed to be responsible for contouring failure (Foster, 1982; Foster et al., 1982b).

3.4.2. Grain roughness shear stress for computing sediment transport capacity

RUSLE2 uses Equation 2.17 to compute sediment transport capacity. That equation is based on the assumption that sediment transport capacity can be computed as:

$$T_c = K_T \tau_g^{3/2} \quad [3.42]$$

where: T_c = sediment transport capacity (mass/width·time), and τ_g = grain roughness shear stress(force/aea). By using the concept that flow depth can be divided into parts associated with grain and form roughness, equations 3.41 and 3.42 can be combined with a Manning's n for grain roughness to give equation 2.17 where the coefficient ζ is given by (Foster et al., 1982b):

$$\zeta = 0.0008 n_t^{-1.5} \quad [3.43]$$

where: the coefficient ζ has absorbed γ and the Manning's n_g value for grain roughness, which is assumed to be 0.01.[32] Total Manning's n_t is computed by RUSLE2 as a function of soil surface roughness, ground cover, live vegetation biomass, and standing residue biomass (see **Section 3.4.6**).

3.4.3. Form roughness shear stress for computing contouring failure

3.4.3.1. Main equations

RUSLE2 computes form roughness shear stress as a function of discharge rate as:

$$\tau_f = a_f q^{0.85714} s / n_t^{1.2857} \quad [3.44]$$

[32] This equation is based on US customary units of ft^3/sec per ft width for discharge rate (q), ft for flow depth (y), and lbs_f/ft^2 for shear stress (τ).

where: τ_f = grain roughness shear stress and a_f =a coefficient that includes γ in equation 3.40, 1.49 in equation 3.41, and other empirical coefficients. RUSLE2 assumes contouring failure where form roughness shear stress computed with equation 3.44 exceeds a critical shear stress. A value for critical shear stress for contouring failure was determined by calibrating equation 3.44 to critical slope length values given in AH537 (Wischmeier and Smith, 1978). The resulting critical shear stress for contour failure is 3619 value when US customary units are used in the equations. The value for a_f in equation 3.44 is absorbed in the critical shear stress value along with conversion factors that would be used to convert excess rainfall rate to ft/sec rather than using inches/hour. Form roughness shear stress for contouring failure is computed with:

$$\tau_f = q_i^{0.85714} s / n_t^{1.2857} \qquad [3.45]$$

where: the discharge rate q_i is computed using excess rainfall rate (σ_i) in inches/hour rather than ft/sec as $q_i = x\sigma_i$ and x = distance (feet) along overland flow path.[33]

The critical slope length values beyond which contouring failure is assumed were based on judgment of soil conservation technical specialists and were not determined by research. These values were developed at a 1956 workshop (Wischmeier and Smith, 1978) and therefore represented observations from research studies and field observations from the early 1930's to the mid 1950's The base condition used in calibrating the critical shear stress for contouring failure represents those conditions rather than modern conditions. The assumed base condition is conventionally tilled, low yield (50 bu/ac), continuous corn at Columbia, Missouri. The operations assumed for this cropping system include a moldboard plow in the spring for primary tillage, two secondary tillage operations to prepare the seedbed, row planter to seed the crop, row cultivator to control weeds, and harvest. Table 3.6 shows a comparison between the values computed with RUSLE2 and those given in AH537 (Wischmeier and Smith, 1978). The values compare well except at very flat steepness where RUSLE2 computed values are much longer than those given in AH537. The values computed by RUSLE2 are considered acceptable.

Table 3.6. Critical slope lengths

	Critical slope length (ft)	
Slope steepness (%)	AH537	RUSLE2
1.5	400	>1000
4.0	300	384
7.0	200	200
10.5	120	125
14.5	80	86
18.5	60	66
23.0	50	51

RUSLE2 sets the contouring subfactor value to 1 for those portions of the overland flow path where form roughness shear stress exceeds the critical shear stress for contouring failure (see **Section 7.1**). No adjustments are made in the cover-management subfactors used to compute detachment in equation 2.10. RUSLE2 also computes the location

[33] Mixed units are given in these equations for consistency with the equations used in the RUSLE2 computer program to facilitate a comparison of computer code with this documentation.

where runoff shear stress acting on form roughness equals the critical shear stress for contour failure. That equation is:

$$q_c = 13900 n_t^{1.5} / s^{1.1667} \qquad [3.46]$$

where: q_c = the discharge rate (where excess rainfall rate in equation 2.18 is in units of in/hr) at which contouring fails. The location of this discharge rate can be determined from equation 2.18.

RUSLE2 computes where contouring fails along overland flow paths as a function of location (i.e., as reflected by the $P_{10y\text{-}24h}$ precipitation amount), runoff, soil infiltration potential, overland flow path steepness, and cover-management conditions. For example, RUSLE2 computed critical slope length values are a function of crop yield. Increased crop yield increases critical slope length. The increased biomass improves soil properties that increase infiltration and reduce runoff, increases soil surface roughness, and increases ground cover provided by crop residue. The critical slope length increases from 103 to 151 ft for an increase in corn yield from 50 to 115 bu/ac in a grain corn-silage corn-alfalfa hay-alfalfa hay-alfalfa hay crop rotation for an overland flow path on a silt loam soil at 20 percent steepness at LaCrosse, Wisconsin. Tillage systems that leave increased surface soil roughness and surface crop residue cover also increase RUSLE2 computed critical slope length as illustrated in Table 3.7.

Table 3.7. RUSLE2 computed critical slope lengths for three tillage systems for continuous 50 bu/ac corn.

	RUSLE2 computed critical slope length (ft)		
Slope steepness (%)	Conv till	Mulch till	No-till
1.5	>1000	>1000	>1000
4.0	384	594	837
7.0	200	310	436
10.5	125	194	273
14.5	86	134	188
18.5	66	101	143
23.0	51	79	112

RUSLE2 does not compute contouring failure as a function of how soil properties affect the soil's critical shear stress for contouring failure. This capability is desirable, but sufficient empirical data are not available to develop the required critical shear stress values as a function of soil properties. Contouring failure in RUSLE2 is assumed not to be a function of ridge height or grade along the ridges-furrows. Clearly contouring failure is a function of ridge height because ridge height affects storage of runoff water and the likelihood of ridge breakover especially in low areas. However, accurately describing flow hydraulics and water storage on a specific field site is very difficult because of imperceptible variations of row grade and ridge heights along the ridges-furrows. Although RUSLE2 has these shortcomings, it was developed to guide conservation planning, and in that context, RUSLE2 is a major improvement over the USLE and RUSLE1.

3.4.3.2. Form roughness shear stress below segment having a high hydraulic roughness

RUSLE2 assumes a gradual rather than a step decrease in total hydraulic roughness where total hydraulic roughness decreases from one overland flow path segment to the next segment. Consequently, the form roughness shear stress increases gradually rather than abruptly between segments. An example is runoff exiting from dense vegetation onto a relatively smooth, bare soil surface. The dense vegetation spreads the runoff so that the flow has a laterally uniform depth as it exits the vegetation. Form roughness shear stress is assumed to be less when flow depth is laterally uniform than when concentrated in rills. A distance is required below the dense vegetation for the runoff to become concentrated in rills with increased form roughness shear stress.

This concept is implemented in RUSLE2 by assuming that the effective total hydraulic roughness decreases exponentially below a segment having a high total hydraulic roughness. The equation for the total Manning's n_t in the transitional region is:

$$n_{et} = n_{tl} + (n_{tu} - n_{tl})\exp[-0.065(x - x_u)] \qquad [3.47]$$

where: n_{et} = Manning's n_t in the transitional zone, n_{tl} = the total Manning's n_t in the lower segment, Manning's n_{tu} = the Manning n_t in the upper segment, x = distance along the overland flow path (ft), and x_u = the distance to the upper end of the lower segment (ft). Figure 3.17 shows the RUSLE2 computed decrease in Manning's n_t below a hay strip in a typical strip cropping system used in LaCrosse, Wisconsin and evaluated in research studies (Hays and Attoe, 1957; Hays et al., 1949). Also, erosion from other strip cropping systems was also studied at other locations (Borst et al., 1945; Hill et al.,. 1944; Hood and Bartholomew, 1956; Smith et al. 1945). RUSLE2 gives similar results for these systems discussed in AH703 (Renard et al., 1997; Foster et al., 1997).

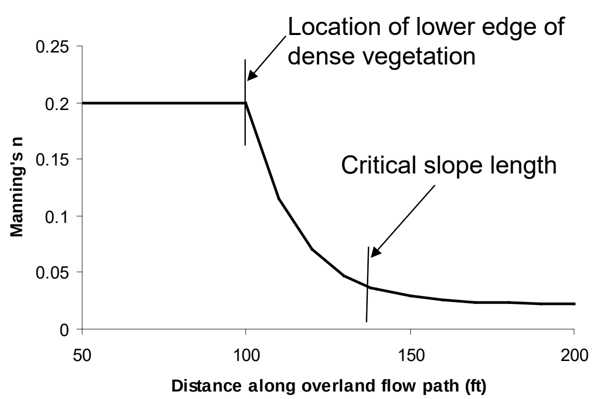

Figure 3.17. Decrease in Manning's n_t along overland flow path below a segment having a high Manning's n_t.

The reduction in form roughness shear stress by runoff spreading reduces the portion of an overland flow path where form roughness shear stress can exceed critical shear stress for contouring failure. The result is that contour strip cropping increases computed critical slope length (i.e., the location where contouring fails). The assumption that contour strip cropping increases critical slope length has long been accepted and used in conservation planning [e.g., see AH282 (Wischmeier and Smith, 1965) and AH537 (Wischmeier and Smith, 1978)]. In AH537, the critical slope length (referred as slope length limits in AH537) is doubled for contour strip cropping without regard to cover-management condition such as type, quality, and density of vegetation on each overland flow path segment. However, the AH537 contouring factor values for contour strip cropping do vary with cover-management condition.

Data from research in Wisconsin (Hays and Attoe,1957; Hays et al., 1949) were the best available in the 1950's to guide development of critical slope length concepts and values by erosion scientist and soil conservation specialists for use in the USLE (AH282, AH537). The RUSLE1 developers judged that critical slope length with strip cropping was 1.5 times the critical slope length without strip cropping [AH703 (Renard et al., 1997)]. A major RUSLE2 improvement is that RUSLE2 computes how location (i.e., $P_{10y\text{-}24h}$ precipitation), runoff, overland flow path steepness, cover-management conditions, number of strips, and relative placement of strips along an overland flow path affect critical slope length. The RUSLE2 procedure is far more comprehensive that previous USLE and RUSLE1 procedures.

The 0.065 ft^{-1} value in equation 3.47 was selected to give critical slope length values considered appropriate for the LaCrosse, Wisconsin experimental contour strip cropping (Hays et al., 1949). For example, RUSLE2 computes a critical slope length of 103 ft on a 20 percent steep overland flow path for the crop rotation used in the contour stripping studies without the crops being arranged in strips. That is, cover-management along the overland flow path is uniform at any particular time although cover-management temporally changes during the crop rotation. The crop rotation is a year of grain corn and a year of silage corn conventionally tilled with a moldboard plow, and three years of alfalfa hay fall seeded immediately after the silage corn is harvested. The assumed corn yield is 50 bu/acre, a typical yield in the 1930's and 1940's. The RUSLE2 computed critical slope length is 191 ft when the crops are arranged in a four strip contour strip cropping system.

The RUSLE2 computed critical slope length is a function of number of strips along the overland flow path. For example, the RUSLE2 computed critical slope length is 153 ft for the LaCrosse, Wisconsin crop rotation placed in two rather than four strips. Strip width is 50 ft for the four-strip system on a 200 ft overland flow path length while it is 100 ft for the two-strip system. As Figure 3.17 shows, about 38 ft is required for total effective hydraulic roughness computed with equation 3.47 to decrease to where form roughness shear stress exceeds the critical shear stress for contouring failure. Strip width should be no wider than 38 ft, according to Figure 3.17 for these conditions, to prevent form roughness shear stress from exceeding the critical shear stress for contour failure. The 100 ft strip width in the two-strip contouring strip cropping system greatly exceeds 38 ft. In contrast, the 50 ft wide strip in the four-strip contour strip cropping system is sufficiently narrow that the form roughness shear stress only exceeds critical shear stress for contouring failure over the last 9 ft of the overland flow path length.

3.4.3.3. Determining location where contouring failure occurs

RUSLE2 uses rules to determine where the form roughness shear stress exceeds critical shear stress for contouring failure within an overland flow path segment.

3.4.3.3.1. Discharge rate increases within segment

If discharge rate increases within a segment and form roughness shear stress at both the upper and lower ends of the segment is less than the critical shear stress for contouring failure, contouring failure does not occur within the segment. If form roughness shear stress exceeds the critical shear stress for contouring failure at both the upper and lower ends of the segment, contouring failure occurs over the entire segment. However, if form roughness shear stress at the upper end of the segment is less than the critical shear stress for contouring failure, and form roughness shear stress at the lower end of the segment exceeds critical shear stress for contouring failure, contouring failure occurs over the lower portion of the segment beginning at the location where form roughness shear stress equals the critical shear stress for contouring failure. This location is computed with equations 2.18 and 3.46.

3.4.3.3.2. Discharge rate decreases within segment

If discharge rate decreases within a segment and form roughness shear stress at both the upper and lower ends of the segment is less than the critical shear stress for contouring failure, contouring failure does not occur within the segment.

If form roughness shear stress at the upper end of the segment is less than the critical shear stress for contouring failure but exceeds critical shear stress for contouring failure at the lower end of the segment, contouring failure occurs over the lower portion of the segment beginning at the location where form roughness shear stress equals the critical shear stress for contouring failure. This location is computed with equations 2.18 and 3.46.

If form roughness shear exceeds the critical shear stress for contouring failure at both the upper and lower ends of the segment, the possibility exists for contouring failure on upper and lower portions of the segment without contouring failure in the middle portion of the segment. RUSLE2 determines where the form roughness shear stress is a maximum within the segment and if that shear stress is greater than the critical shear stress for contouring failure, then contouring failure occurs over the entire segment. If the minimum form roughness shear stress within the segment is less than the critical shear stress for contouring failure, then form roughness shear stress equals the critical shear stress at two locations within the segment. These locations are determined with equations 2.18 and 3.46.

If form roughness shear stress is less than the critical shear stress for contouring failure at both the upper and lower ends of the segment, the possibility exists that form roughness shear stress increases to a value greater than the critical shear stress for contouring failure within the segment and then decreases to below this critical shear stress above the lower end of the segment. Contouring failure occurs on a middle portion within the segment. This check can be made by computing the maximum form roughness shear stress within the segment, and if it exceeds the critical shear stress for contouring failure, this condition exists. The portion where contouring fails lies in the middle of the segment between the two locations where form roughness shear stress equals the critical shear stress for contouring failure, which are determined from equations 2.18 and 3.46.

3.4.3.4. Runoff rate used to compute contouring failure

To compute contouring failure, RUSLE2 computes a daily runoff rate that varies with both cover-management and the probability of an intense storm occurring when contouring is susceptible to failure. The daily precipitation amount used to compute contouring failure is assumed to vary linearly with the temporal daily erosivity distribution (see **Sections 3.1 and 3.2.1**) with the maximum daily precipitation occurring on same day that the maximum daily erosivity occurs. This daily precipitation amount is computed as:

$$P_{cf} = (f_{Rd} / f_{Rmx})P_{10y24h} \qquad [3.48]$$

where: P_{cf} = the daily precipitation amount used to compute contouring failure, f_{Rdj} = the fraction of the annual erosivity that occurs on the *jth* day, and f_{Rmx} = the fraction of the annual erosivity that occurs on the day when maximum daily erosivity occurs.[34] **The time varying precipitation computed with equation 3.48 is only used to compute contouring failure. It is not used anywhere else in RUSLE2.**

3.4.4. Backwater

Backwater occurs at locations on an overland path where total hydraulic roughness makes a step increase, such as at the upper edge of a dense vegetation strip. This backwater is especially important because most of the deposition caused by dense vegetation strips occurs in the backwater (Dabney et al., 1995; Flanagan et al., 1989; Foster et al., 1980a; Hayes et al., 1984; McGregor et al., 1999). Ignoring backwater length would cause RUSLE2 to greatly underestimate deposition when computing deposition caused by narrow, dense vegetation strips.

The Manning equation is used in RUSLE2 to compute flow depth at the upper edge of segments where Manning's n_t makes a step increases. An effective backwater length is computed from this flow depth assuming that the backwater is level. The combined equation for computing backwater length is:

$$\Delta x_b = 3.44[n_t q_u /(1.49 s_{lh}^{0.5})]^{0.6} / s_{uh} \qquad [3.49]$$

where: Δx_b = the backwater length (ft), q_u = discharge rate (ft^2/s) at the upper edge of the segment having the high total Manning's n_t, s_{lh} = the steepness of the segment having the high Manning's n (**sine** of the slope angle), and s_{uh} = steepness of the immediately upslope segment (the **tangent** of the slope angle). The 3.44 value in equation 3.49 was determined by calibration. The coefficient was adjusted until RUSLE2 computed the observed sediment yield from plots having a dense 1.5 ft wide dense stiff grass hedge below conventionally tilled cotton on a 5 percent steepness at Holly Springs, Mississippi (McGregor et al., 1999). The RUSLE2 computed backwater length was compared to

---

[34] In an early version of RUSLE2, contouring failure was computed with the single precipitation P10y,24h precipitation amount. Runoff rate varies temporally only as cover-management variables varied temporally. Although RUSLE2 was calibrated to give the correct critical slope length, the timing of contouring failure was out of phase with precipitation during the year. Use of Equation 3.48 gave the correct timing for contouring failure.

measured backwater values and locations of deposited sediment above the stiff grass hedge. Although the upper edge of deposition moves upslope as deposited sediment accumulates (Dabney et al., 1995), this dynamic effect is not considered in RUSLE2. The RUSLE2 computed backwater length is an index that captures the effects of location through the 10 year-24 hour precipitation amount, runoff, hydraulic roughness, and overland flow path steepness. The maximum computed backwater length is limited to 15 ft to prevent RUSLE2 from computing excessively long backwater lengths on relatively flat overland flow paths. Also, RUSLE2 assumes a 3 ft minimum for special cases like fabric filter fence on construction sites (see **Section 7.2**). RUSLE2 adds the computed backwater length to the lower edge of the segment having the high total Manning's n_t and decreases the length of the immediate downslope segment by the same amount except for the segment at the end of the overland-flow path.

3.4.5. Ponding

Water deeper than about 3 mm reduces raindrop impact erosivity (Mutchler, 1970; Mutchler and Murphree, 1985; Mutchler and Young. 1975). The judgment of soil conservation specialists is that water depth reduces erosion on flat overland flow paths in high erosivity locations, such as the lower Mississippi Delta [AH703 (Renard et al., 1997)]. Erosivity (R) values along the Gulf Coast Region were reduced to consider this effect in the USLE (e.g., compare erosivity values between AH282 (Wischmeier and Smith, 1965) and AH537 (Wischmeier and Smith, 1978). RUSLE1 uses a ponding subfactor that reduces effective erosivity based on flow depth if ridges are not present. Water depth (ponding) was assumed to have no effect on erosivity in RUSLE1 when high ridges are present. However, in RUSLE2, the ponding effect is assumed to reduce erosivity regardless of the presence or absence of ridges.

The 10 year-24 hour precipitation amount is used to compute a runoff amount using equation 3.25. A normalized flow depth is computed using the Manning equation as:

$$y_n = (v_r / 3.03)^{0.6} (0.01 / s)^{0.3} \qquad [3.50]$$

where: y_n = the normalized flow depth, v_r = the runoff amount (inches), computed with P10y24h precipitation amount, 3.03 = a reference runoff depth (inches) selected to represent runoff and 0.01 = a reference overland flow path steepness to represent slopes typical of cotton production in the Mississippi Delta where the water depth effect is most highly important. This ponding effect has been studied by Mutchler et al. (1982), Mutchler and McGregor (1983), Mutchler and Murphree (1985), and McCool et al. (1987). This normalized flow depth is then used to compute a ponding subfactor value using:

$$p_r = \exp[-0.49(y_n - 1)] \text{ if } p_r < 0.4, p_r = 0.4 \text{ if } p_r > 1, p_r = 1 \qquad [3.51]$$

where: p_r = the ponding subfactor for the effect of water depth on raindrop impact erosivity. The minimum value for the ponding subfactor is 0.4. The 0.49 value in equation 3.51 was chosen by calibration to represent the judgment of erosion scientists and soil conservationists regarding the ponding effect [AH537 (Wischmeier and Smith, 1978), AH703 (Renard et al., 1997)]. Example values for the average annual ponding factor are given in Table 3.8 where daily ponding values have been weighted by the temporal erosivity distribution (see **Sections 3.1** and **3.2.1**).

Table 3.8. Example values for the ponding subfactor

Location, 0.5% steepness	Value	Steepness (%), at Jackson, MS	Value
New Orleans, LA	0.58	0.001	0.45
Baton Rouge, LA	0.63	0.005	0.73
Jackson, MS	0.73	0.01	0.85
Memphis, TN	0.82	0.02	0.96
Columbia, MO	0.86	0.04	1.00

3.4.6. Manning's n_t as a function of cover-management and row grade

RUSLE2 computes total Manning's n_t values as a function of soil surface roughness, ground cover, live vegetation, and standing residue using:

$$n_t = 0.11[1 - \exp(-0.6 r_n)] + [0.075(f_g/100)/\exp(0.35 r_n)] + n_v + n_s \text{ if } n_t < 0.01, n_t = 0.01 \quad [3.52]$$

$$r_n = r_a \text{ if } r_n > 5, r_n = 5 \text{ inches} \quad [3.53]$$

where: n_t = total Manning's n_t, r_n = r_a = adjusted roughness index value (inches) used to compute roughness subfactor values (see **Section 6.3**), f_g = net ground (surface) cover (percent) (see **Section 6.2**), n_v = Manning's n contributed by live vegetation (see **Section 9.2.6**), and n_s = the Manning's n contributed by standing residue (see **Section 10.4.3**). Equation 3.52 was derived from multiple data sets where overland flow velocity was measured for a wide variety of conditions. Manning's n values derived from these measurements have been compiled and used in numerous models including CREAMS, RUSLE1, and scientific articles (Foster et al., 1980b; Foster, 1982; Foster et al., 1982a; Foster et al., 1997; Gilley and Finkner, 1991; Gilley and Kottwitz, 1994; Gilley and Kottwitz, 1995).

Equation 3.52 represents form and form roughness combined rather than representing them as two separate terms. The condition on n_t in equation 3.52 is to prevent total Manning's n_t from being less than the grain roughness Manning's n_g of 0.01.

The ground (surface) cover and soil surface roughness combination term in equation 3.52 reduces the effect of ground cover on hydraulic roughness as soil surface roughness increases. Ground cover in depressions is inundated by ponded water and deposited sediment so that ground cover has reduced effect on runoff hydraulics as soil surface roughness increases.

The condition that adjusted roughness not be greater than 5 inches is primarily because no research data were available at high roughness values to derive equation 3.52. Actually the high soil surface roughness condition has little effect on computed Manning's n_t values. For example, the first term in equation 3.52 is 0.105 for r_a = 5 inches and 0.11 for r_a = 10 or more inches.

Net ground cover is (1 – the fraction of soil surface not covered by ground cover). Net ground cover takes into account surface residue overlapping rock cover and live ground cover overlapping both surface residue and rock cover.

The maximum Manning's n value for vegetation in rows perpendicular to the overland flow path (i.e., on the contour) is computed with:

$$n_{vmxc} = 0.017154 R_v + 3.82 \times 10^{-5} R_v^5 \qquad [3.54]$$

where: n_{mvxc} = the Manning's n for live vegetation in rows on the contour at maximum canopy cover and R_v = vegetation retardance at maximum canopy cover for vegetation in rows on the contour, which is a measure of how much vegetation and porous barriers like fabric fences slow runoff. Input retardance values are chosen to represent the combined hydraulic roughness of the vegetation in rows and bare soil between the rows for vegetation at its maximum growth in the RUSLE2 vegetation description.[35] Using these input retardance values listed in Table 3.9, RUSLE2 computes a retardance value based on vegetation production (yield) level (see **Section 9.3.1**). The Manning's n_{mvc} represents the effect of stems and any vegetation component, besides live ground cover, that slows runoff. Live ground cover values in the RUSLE2 vegetation description are used to represent the effect of leaves and similar plants components touching the soil surface and slowing runoff.

Table 3.9. Retardance classes used in RUSLE2

Class	Retardance index
no retardance (wide plant spacing in strip-row)	0
low retardance (corn)	1
moderate low (soybeans, cotton)	2
moderate (dense wheat)	3
moderate high (legume hay before mowing)	4
high (legume-grass hay before mowing)	5
very high (dense sod)	6
extreme (stiff grass hedge, silt fence)	7

Table 3.10. Factor values used to multiply Manning's vegetation n on contour to obtain Manning's n value for orientation parallel to overland flow path

Row width	Factor
Vegetation on ridges	0.063
Wide row	0.125
Moderate row spacing	0.250
Narrow row spacing	0.500
Very narrow row spacing	0.750
No rows (broadcast)	1.000

The hydraulic roughness for vegetation rows oriented parallel to the overland flow path (up and down hill) differs from the hydraulic roughness for the vegetation's rows on the contour. RUSLE2 computes a value for the Manning's n_{mvud} for vegetation in rows parallel to the overland flow path by multiplying the contour vegetation Manning's n_{vmxc}

[35] Assignment of retardance values considers the geometrical arrangement of the vegetation rows. For example, retardance for small grain represents the net retardance for multiple grain rows whereas the retardance for a narrow stiff grass hedge considers only a single row of the vegetation. In the case of the stiff grass hedge, the overland flow path is divided into segments to represent the bare soil separately from the vegetation in a situation where backwater created by the dense vegetation has an important effect on deposition.

by a factor based on the user entered row width. Values for this factor are given in Table 3.10. The **No rows (broadcast)** input means that the vegetation is randomly spaced in both directions so that no row orientation exists. Manning's n is the same in all directions. The **Vegetation on ridges** represents vegetation rows so widely spaced or the vegetation being on ridges so that the vegetation stems have no effect on hydraulic roughness.

Depending on row grade (steepness along the vegetation rows), vegetation Manning's n varies between the Manning's n for vegetation rows on the contour and the Manning's n for the vegetation rows oriented up and down hill. The RUSLE2 equation used to compute vegetation Manning's n for intermediate row orientations is:

$$n_{vrg} = n_{vud} + (n_{vc} - n_{vud})[1-(s_r / s_{ud})^{1/2}] \qquad [3.55]$$

where: n_{vrg} = vegetation Manning's n for the row grade s_r, n_{vc} = vegetation Manning's n for rows on the contour (perpendicular to the overland flow path), n_{vud} = vegetation Manning's n for rows parallel to overland flow path (i.e., up and down slope), s_r = row grade (tangent of slope angle), and s_{ud} = overland flow path steepness (tangent of slope angle).

RUSLE2 assumes that vegetation Manning's n varies temporally as the vegetation's effective fall height varies (see **Section 6.1**). The equation used to compute vegetation Manning's n values through time is:

$$n_v = n_{vmx}(h_f / h_{fmx})^{0.3} \qquad [3.56]$$

where: n_{vm} = the vegetation Manning's n at maximum growth in the vegetation description, h_f = the daily effective fall height for a particular vegetation description and h_{fmx} = the maximum daily effective fall height for the vegetation description (see **Section 9**).

When live vegetation is killed in RUSLE2, it becomes standing residue that continues to provide hydraulic roughness. The hydraulic roughness caused by standing residue is assumed to vary through time as:

$$n_s = n_{sk}(B_{td} / B_{tk}) \qquad [3.57]$$

where: n_s = Manning's n for standing residue on day d, n_{sk} = Manning's n for the standing residue on the day that the live vegetation is killed, B_{td} = standing residue biomass (dry matter basis) on day d, and B_{tk} = the live vegetation biomass (dry matter basis) on the day that the vegetation is killed (see **Section 9.2.5**).

3.5. List of symbols

a_{cl} = a coefficient used to compute curve number values as a function of ground (surface) cover when surface roughness is less than 0.24 inches

a_{cu} = a coefficient used to compute curve number values as a function of ground (surface) cover when surface roughness is greater than 0.24 inches

a_f = coefficient used to compute form roughness shear stress

a_F = coefficient used to compute average annual erosivity from Fournier index

a_p = coefficient in equation that computes storm or daily erosivity from storm or daily precipitation

a_r = coefficient used to average annual erosivity from RUSLE2 modified Fournier index

a_{rl} = a coefficient used to compute curve number values as a function of soil surface roughness when soil surface roughness is less than 0.24 inches

a_{ru} = a coefficient used to compute curve number values as a function of soil surface roughness when soil surface roughness is greater than 0.24 inches

a_{45} = coefficient used to compute curve number values for fully consolidated soils as a function of ground (surface) cover

b= exponent in equation that computes storm or daily erosivity from storm or daily precipitation

b_B = a decay coefficient used how the curve number values decreases exponentially as a function of soil biomass

b_D = a decay coefficient used to compute how curve number values are affected by the interaction of the soil consolidation factor and soil biomass

B_s = soil biomass per unit depth (dry mass/area·soil depth)

B_{tk} = live above ground biomass on day that vegetation is killed (mass/area)

B_{td} = live above ground biomass on day d (mass/area)

D = number of days in the month

e = unit storm energy (energy content per unit area per unit rainfall depth) [force-distance/(area·length)]

$\hat{e}$ = effective unit storm energy directly (force-length)/(area·length)

E = storm energy (force-distance/area)

EI_{10y24h} = the storm erosivity associated with the 10 year-24 hour precipitation amount (erosivity units)

EI_{30} = storm erosivity (erosivity units)

f_B = a fraction that represents the main effect of soil biomass on curve number values

f_d = fraction of area represented by an overland flow path that is subsurface drained

f_g = net ground (surface) cover (percent)

f_{Rd} = fraction of the annual erosivity that occurs on *jth* day

f_{Rmx} = fraction of the annual erosivity that occurs on day when maximum daily erosivity occurs

f_μ = portion of the soil surface covered by non-erodible cover (fraction)

f_ρ = portion of the non-erodible cover that is permeable (fraction)

F = the modified Fournier index

F_r = the RUSLE2 modified Fournier index

h_f = daily effective fall height for a particular vegetation description (length)

h_{fmx} = maximum daily effective fall height for the vegetation description (length)

i = rainfall intensity for a period during rainstorm (length/time)

I_{30} = maximum 30-minute intensity for a rain strom (length/time)

$\bar{I}_{30}$ = representative maximum 30 minute intensity for rain storms occurring in amonth (length/time)

m = number of periods in a storm used to compute storm energy

M = monthly value of climate variable being disaggregated

n = number of rainstorms in a month

n_{et} = Manning's n_t in the transitional zone below a high hydraulic resistance segment

n_g = grain roughness Manning's n

n_k = Manning's n for standing residue on day that live vegetation is killed

n_s = Manning's n contributed by standing residue

n_{sk} = Manning's n contributed by standing residue on the day that live vegetation is killed

n_t = total Manning's n

n_{tl} = total Manning's n_t in segment downslope of high hydraulic resistance segment

n_{tu} = Manning n_t in upslope high hydraulic resistance segment

n_v = Manning's n contributed by live vegetation

n_{vc} = vegetation Manning's n for rows (strips) on the contour (perpendicular to the overland flow path)

n_{vmx} = vegetation Manning's n at maximum growth in the vegetation description

n_{vmxc} = Manning's n for live vegetation in rows (strips) on the contour at maximum canopy cover

n_{vrg} = vegetation Manning's n for row grade s_r

n_{vud} = vegetation for Manning's n for rows up and down slope (parallel to overland flow path)

N = curve number in NRCS curve number method used to compute runoff

N_b = curve number for the portion of the soil not covered by the non-erodible cover

N_d = curve number for the drained condition

N_l = lower curve numbers that represents difference in curve numbers for a soil with no soil biomass and one with a high soil biomass of 1750 lbs_m/(acre·in) value

N_{lb45} = index curve number for fully consolidated soil at high soil biomass with no ground cover

N_{lB} = the curve number for a very high soil biomass and the soil has been recently mechanically disturbed

N_{l45} = N_{lB} curve number adjusted for ground cover

N_{s100} = a starting curve number value for unit plot conditions

N_u = upper curve numbers that represents difference in curve numbers for a soil with no soil biomass and one with a high soil biomass of 1750 lbs_m/(acre·in) value

N_{uB} = curve number value when no biomass is present in the soil and the soil has been recently mechanically disturbed

N_{ud} = curve number for the undrained condition

N_{u45} = the curve number for a fully consolidated soil with no ground (surface) cover or soil biomass and soil surface roughness = 0.24 inches

N_{u100} = curve number value that represents the effect of ground cover and soil roughness on curve number on a soil recently mechanically disturbed with no soil biomass

p_r = daily ponding subfactor

P = precipitation depth (length)

P_a = additional precipitation required so that zero runoff would be computed when infiltration is greater than precipitation (length)

P_{cf} = daily precipitation amount used to compute contouring failure (length)

P_{md} = average monthly precipitation from daily precipitation gage data (length)

P_m = average monthly precipitation (length)

P_s = storm or daily precipitation amount (length)

P_{10y24h} = the 10 year-24 hour precipitation amount (length)

P_{15} = storm precipitation amount determined from 15-minute precipitation gage data (length)

q = discharge rate (volume/width·time)

q_c = discharge rate (where excess rainfall rate is in units of in/hr) at which contouring fails (volume/width·time)

q_i = discharge rate $q_i = x\sigma_i$ computed using excess rainfall rate in inches/hour rather than ft/sec

q_u = discharge rate at upper edge of segment having high hydraulic resistance (volume/width·time)

Q = runoff depth computed with NRCS curve number method (length)

r_a = adjusted soil surface roughness index (length)

r_n = adjusted soil surface roughness index used to compute Manning n for soil surface roughness (length)

r_s = storm erosivity (erosivity units)

R = average annual erosivity (erosivity units)

R_m = average monthly erosivity (erosivity units)

R_v= vegetation retardance at maximum canopy cover for vegetation in rows (strips) on contour, which is a measure of how much vegetation and porous barriers like fabric fences slow runoff

s = overland flow path steepness (sine of slope angle)

s_c = soil consolidation subfactor

s_l = change in lower curve numbers per unit change in soil consolidation subfactor

s_{lh} = steepness of segment having high hydraulic resistance (**sine** of slope angle)

s_r = row grade (**tangent** of slope anagle)

s_u = change in upper curve number per unit change in the soil consolidation

s_{ud} = steepness of overland flow path (**tangent** of soil angle)

s_{uh} = steepness of segment immediately upslope of high hydraulic resistance segment (**tangent** of slope angle)

S = a variable in NRCS curve number equation used to compute runoff

t_c = time during month that disaggregated value equals monthly value

t_p = time during month of peak or minimum of climate variable being disaggregated

T_c = sediment transport capacity (mass/width·time)

x = distance along overland flow path (length)

x_u = the distance to the upper end of segment immediately downslope of high hydraulic resistance segment (length)

y = flow depth (length)

y_d = daily value of climate variable being disaggregated

v_r = runoff amount used to compute ponding subfactor (length)

y_n = normalized flow depth used to compute ponding subfactor

Y_b = daily value of climate variable being disaggregated at beginning of month

Y_e = daily value at end of month

Y_p = maximum value of climate variable being disaggregated when peak or minimum occurs within month

z = exponent in RUSLE2 modified Fournier index

α = average monthly erosivity density (erosivity units/length)

α_m = maximum monthly erosivity density

Δx_b = backwater length upslope of a segment having a high hydualic resistance (length)

ΔV = rainfall depth during a period in a rainstorm (length)

γ = weight density of water (force/volume)

σ_i = excess rainfall rate in inches/hour (length/time)

τ_f = form roughness shear stress (force/area)

τ_g = grain roughness shear stress (force/area)

τ_t = total shear stress (force/area)

ζ = coefficient that has absorbed γ and the Manning's n_g for grain roughness

Indices

i – storm

j - month

k – period during a rainstorm

4. SOIL

4.1. Erodibility

The major RUSLE2 soil variable is the soil erodibility factor. A value for the soil erodibility factor for soils that have their soil horizons in place and have not been disturbed other than for cultivation can be selected from the USDA-NRCS soil survey database. However, soil erodibility values are not available for all soils, especially highly disturbed soils where the original soil layers have been mixed. RUSLE2 includes two sets of equations referred to as the standard soil erodibility nomograph and the RUSLE2 modified soil erodibility nomograph. These nomographs can be used to estimate soil erodibility factor values for most situations (See RUSLE2 User's Reference Guide), especially where the original soil profile has been disturbed.

The RUSLE2 soil erodibility factor is a measure of soil erodibility under unit plot conditions. These conditions empirically measure soil erodibility where cover-management effects are removed so that the measured erosion represents how inherent soil properties and local climate affect soil erodibility as defined in RUSLE2. The RUSLE2 soil erodibility factor is not an inherent soil property like soil texture. It is defined in terms of the RUSLE2 erosivity variable and, therefore, should not be used in other erosion prediction technologies that use a different erosivity factor than the RUSLE2 erosivity factor. Conversely, soil erodibility factor values from other erosion models that use an erosivity factor that differs from the RUSLE2 erosivity factor can not be used in RUSLE2.

The RUSLE2 soil erodibility factor, which is the same as the USLE and RUSLE1 soil erodibility factor (Wischmeier and Smith, 1965 and 1978; Römkens et al,, 1997), is a measure of erosion per unit erosivity EI for unit plot conditions. The RUSLE2 soil erodibility factor is a function of local climate in addition to soil properties because erosion per unit erosivity is greater where runoff is increased per unit erosivity. For example, if the same soil properties were to occur in two locations, the RUSLE2 soil erodibility factor would be increased in locations where frequent, high, intense rainfall occurs that produces increased runoff per unit precipitation. Unfortunately, the soil erodibility nomograph commonly used to estimate soil erodibility factor values, including those in RUSLE2, is not a function of climate variables. However, the RUSLE2 temproal soil erodibility equation described below takes location into account.

4.1.1. Standard soil erodibility nomograph

The standard soil erodibility nomograph (Wischmeier et al., 1971) was derived from erosion data produced by applying simulated rainfall to about 55 agricultural soils, primarily in Indiana (Wischmeier. and Mannering, 1969). Although these soils represented a range of inherent soil properties, the standard nomograph best fits medium textured soils.

The equation for the standard soil erodibility nomograph is:[36]

$$K = (k_t k_o + k_s + k_p)/100 \qquad [4.1]$$

where: K = soil erodibility factor, k_t = texture subfactor, k_o = organic matter subfactor, k_s = soil structure subfactor, and k_p =soil profile permeability subfactor.

4.1.1.1. Texture subfactor

The soil texture subfactor equation is (Wischmeier et al., 1971):

$$k_{tb} = 2.1[(P_{sl} + P_{vfs})(100 - P_{cl})]^{1.14}/10000 \qquad [4.2]$$

$$k_t = k_{tb} \qquad \text{if } P_{sl} + P_{vfs} \le 68\% \qquad [4.3]$$

where: P_{sl} = percent silt, P_{vfs} = percent very fine sand based on the total soil primary particles and not just the portion of the sand content, and P_{cl} = percent clay. Although equation 4.2 was derived using regression analysis, Wischmeier et al. (1971) used judgment to graphically draw the k_t relationship for P_{sl} + P_{vfs} percentage above 68 percent. The RUSLE2 equations fitted to the Wischmeier et al. (1971) graphical curves are:

$$k_{t68} = 2.1[68(100 - P_{cl})]^{1.14}/10000 \qquad [4.4]$$

$$k_t = k_{tb} - [0.67(k_{tb} - k_{t68})^{0.82}] \qquad \text{if } P_{sl} + P_{vfs} > 68\% \qquad [4.5]$$

where: k_{t68} = base soil texture subfactor in soil erodibility nomograph when $P_{sl} + P_{vfs} > 68\%$.

4.1.1.2. Organic matter subfactor

The equation for the soil erodibility nomograph organic matter subfactor is:

$$k_o = (12 - O_m) \qquad [4.6]$$

where: O_m = percent inherent soil organic matter. Inherent organic matter is the organic matter content of the soil in unit plot conditions. The experimental plots used to develop the soil erodibility nomograph were not in unit plot condition (Wischmeier and

---

[36] Units for K and associated variables are US customary units

Mannering, 1969). Above ground biomass was removed but the plots were not maintained in a tilled fallow condition for more than a few months. Soil organic matter had not reached inherent soil organic matter levels for unit plot conditions, which resulted in measured soil organic matter being higher than it would have been in unit plot conditions. However, measured erosion values were adjusted to remove land use residual effects from previous cover-management conditions (see **Section 6**), but organic matter content values were not adjusted to unit plot conditions.

The organic matter relationship in the soil erodibility nomograph ***can not be used*** to evaluate how biomass additions and organic farming practices affect rill and interrill erosion. Those effects are considered in RUSLE2's cover-management relationships (see **Section 6**). Furthermore, the experimental conditions used to derive the soil erodibility nomograph were very dissimilar to organic matter conditions associated with organic farming or application of manure, biological waste, or other biological soil amendments.

4.1.1.3. Soil structure subfactor

The soil erodibility nomograph soil structure subfactor refers to how the arrangements of soil primary particles in aggregates and the arrangement of aggregates in the soil affect erosion under unit plot conditions. Four structural classes are used in the nomograph. These classes are 1-very fine granular, 2-fine granular, 3-medium or coarse granular, and 4-blocky, platy, or massive. These classes are defined in the USDA-NRCS soil survey manual. The classes used to derive the soil erodibility nomograph were those in use in the mid-1960's when the experiments were conducted. The definitions for those classes should be used to assign RUSLE2 values for soil structure.

The equation for the soil erodibility nomograph soil structure subfactor is:

$$k_s = 3.25(S_s - 2) \qquad \text{if } (k_t k_o + k_s) \geq 7 \qquad [4.7]$$

$$k_t k_o + k_s = 7 \qquad \text{if } (k_t k_o + k_s) < 7 \qquad [4.8]$$

where: S_s = the soil structure class. The graphical soil structure relationship in the soil erodibility nomograph has a slight "knee" close the origin of the subfactor (Wischmeier et al., 1971), which is represented with equation 4.8.

4.1.1.4. Soil profile permeability subfactor

The soil permeability subfactor is a measure of the potential of the soil profile in unit-plot conditions for generating runoff. Six permeability classes that range from 1-rapid (very low runoff potential) to 6-very slow (very high runoff potential) are used to rate the soil profile for infiltrating precipitation and reducing runoff. The USDA-NRCS soil survey definitions for soil profile permeability used in the mid-1960's should be used to assign a soil permeability class in applying the soil erodibility nomograph. ***The assigned permeability class must not be based on a permeability measurement of the surface soil layer.*** The permeability rating should take into account the presence of restricting layers such as rock, claypan, or fragipan. Also, the rating should consider landscape position.

For example, the permeability rating for a sandy soil underlain by a restricting layer might be moderate for the soil at the top of a hillslope but be very slow if the soil is at the bottom of the hillslope. The input permeability rating should consider the presence of rock fragments. ***The permeability rating should not reflect current or past cover-management on runoff; it is a rating for the soil in unit plot condition*** (see **Sections 4.6 and 7.4** and RUSLE2 User's Reference Guide). The RUSLE2 temporal soil erodibility equation described in **Section 4.5** takes into account how the permeability rating varies as climate varies among locations.

The equation for the permeability subfactor is given by:

$$k_p = 2.5(P_r - 3) \qquad [4.9]$$

where: P_r = the soil profile permeability class.

4.1.2. RUSLE2 modified soil erodibility nomograph

Soil erodibility factor values computed with the standard soil erodibility nomograph do not show the expected range or trend for very high sand soils and very high clay soils typical of highly disturbed lands, such as reclaimed mined land and construction sites. This problem seemed most associated with the soil structure subfactor. Soil erodibility is expected to decrease as soil structure changes from very fine granular to blocky, platy, or massive because of the role of clay as a bonding agent and its effect on soil structure.

The unexpected trend in the soil structure subfactor most likely resulted from the empirical derivation of the standard soil erodibility nomograph from a relatively small database where the soils were predominantly medium texture (Wischmeier and Mannering, 1969; Wischmeier et al., 1971). Consequently, the data points were not uniformly distributed among the major variables that affect soil erodibility. Furthermore, all of the nomograph variables are correlated with each other, which can result in empirical equations derived from a small database not reflecting proper trends for how major variables affect soil erodibility. For example, soil structure is related to soil texture. The soil structure subfactor in the standard soil erodibility nomograph may well represent an interactive effect rather than a main effect in the particular dataset used to derive the standard soil erodibility nomograph.

After reviewing measured erosion data from high clay soils typical of construction sites (Römkens et al., 1975; Römkens et al., 1977; Roth et al., 1974), the judgment was made to modify the soil structure subfactor in the standard nomograph. The modification results in the RUSLE2 modified nomograph computing soil erodibility values that decrease as soil structure goes from fine granular to blocky, platy, and massive and decrease as soil structure goes from fine granular to coarse granular. Soil erodibility factor values computed with the RUSLE2 modified soil erodibility nomograph are smaller than those computed with the standard nomograph for high clay and high sand soils.

4.1.2.1. Soil structure subfactor

The soil structure subfactor equation used in the RUSLE2 modified soil erodibility nomograph is:

$$k_s = 3.25(2 - S_s) \qquad [4.10]$$

The difference between this equation and the comparable equation, equation 4.7, in the standard soil erodibility nomograph is the algebraic sign on the variables in the second term in equations 4.7 and 4.10. A nice feature of both the standard and the RUSLE2 modified nomographs is that they use equations referenced to a midpoint. The equations compute values about the midpoint well established by the experimental data. The midpoint for the soil structure subfactor is the fine granular structure. Both soil erodibility nomographs give the same soil erodibility factor values for the fine granular soil structure, but the two nomographs give different trends for departures from this midpoint soil structure.

4.1.2.2. Other subfactors in RUSLE2 modified soil erodibility nomograph

All other subfactors in the RUSLE2 modified soil erodibility nomograph are the same as those used in the standard nomograph.

4.1.3. Special soil erodibility cases

Special cases, described in the RUSLE2 User's Reference Guide, exist where neither RUSLE2 soil erodibility nomograph applies. Equations are available in AH703 (Renard et al., 1997) and elsewhere (El-Swaify and Dangler, 1976; Mutchler et al., 1976; Young and Mutchler. 1977; Roth et al., 1974) to estimate soil erodibility for some of these special conditions. However, these equations were not included in RUSLE2 even though some of them were included in RUSLE1 [AH703 (Renard et al., 1997)]. The equations were judged to give poor results or to use variables that were not properly defined or could not be easily measured for input in typical RUSLE2 applications. Soil erodibility values can be user determined outside of RUSLE2 and entered in RUSLE2.

4.2. Very fine sand

Soil texture is the single most important variable in estimating soil erodibility. In many cases, the standard soil texture such as clay loam, silt loam, or sandy loam based on the USDA classification may be known or can be estimated. However, as Wischmeier et al. (1971) found, this standard classification does not work as well as including the very fine sand fraction with the silt fraction. Unfortunately, the sand, silt, and clay content may be known for a soil, but information on the very fine sand fraction may not be available. A mechanical analysis of the soil is required to determine the very fine sand fraction. The following RUSLE2 equation was developed to estimate the very fine sand fraction from sand, silt, and clay content:

$$P_{vfs} = (0.74 - 0.62 P_{sd}/100) P_{sd} \qquad [4.11]$$

where: P_{vfs} and P_{sd} are in percent. Regression analysis was used to fit equation 4.11 to the USDA-NRCS soil survey data for Lancaster County, Nebraska.

4.3. Rill to interrill soil erodibility

RUSLE2 computes a ratio of rill to interrill erosion used to compute a slope length exponent in equation 2.10 (e.g., see **Section 2.1.3**) and a **b** value in the subfactor equation for the ground cover effect on erosion (see **Section 6.2**). The RUSLE2 equation used to compute a value for the rill to interrill soil erodibility ratio is:

$$K_r / K_i = (P_{sd}/100)[(1-\exp(-0.05P_{sd})] + 2.7(P_{sl}/100)^{2.5}[1-\exp(-0.05P_{sl})] \quad [4.12]$$

$$+0.35(P_{cl}/100)[1-\exp(-0.05P_{cl})]$$

where: K_r/K_i = the rill to interrill soil erodibility ratio and all soil texture values are in percent. Rill to interrill soil erodibility ratio values computed with equation 4.12 are shown in Table 4.1 at the central point of the textural classes.

Table 4.1. Rill to interrill soil erodibility ratio as a function of soil texture

Soil textural class	Rill to interrill soil erodibility ratio
Clay	0.36
Clay loam	0.50
Loam	0.65
Loamy sand	0.82
Sand	0.89
Sandy clay	0.61
Sandy clay loam	0.65
Sandy loam	0.7
Silt	1.91
Silt loam	1.04
Silty clay	0.53
Silty clay loam	0.73

Equation 4.12, like many RUSLE2 equations, is based on computing variations about a mid or central point that is well established by experimental data. As shown in Table 4.1, equation 4.12 gives a value of 1 for the reference silt loam soil. Equation 4.12 computes values that vary about one as soil texture deviates from silt loam. Although soil erodibility data from the Water Erosion Prediction Project (WEPP) were reviewed as the basis for deriving equation 4.12 (Elliot et al., 1989; Laflen et al., 1991a), the equation was derived based on judgment.

For example, increased clay content is assumed to reduce rill erosion much more rapidly than it reduces interrill erosion. Conversely, soils very high in silt are assumed to have increased rill erosion relative to interrill erosion. Increased rill erosion relative to interrill erosion is expected because of reduced clay content that reduces soil cohesiveness, which increases rill erosion more than interrill erosion. In addition, soils high in silt produce increased runoff, which increases rill erosion more than interrill erosion.

Soils high in sand are more susceptible to rill erosion than interrill because of low clay content and reduced cohesiveness. However, offsetting the increase in rill erosion susceptibility is decreased runoff, which would reduce rill erosion more than interrill erosion because rill erosion is directly related to runoff. Overall, the rill to interrill soil erodibility ratio is assumed to be reduced for soils high in sand but not as much as for soils high in clay.

Equation 4.12 quantifies concepts and advice that users were expected to consider in RUSLE1 for selecting LS and ground cover effect relationships [(AH703 (Renard et al., 1997)]. Equation 4.12 is considered to be a significant improvement over RUSLE1 procedures.

4.4. Geographic soil erodibility variability

Even when soil properties are identical, RUSLE2 soil erodibility factor values should vary with location because of climatic differences among locations. For example, erosion is greater per unit rainfall erosivity in locations such as the southern US, where frequent, high, and intense rainfall occurs, than in the northern Great Plains. Average annual soil erodibility factor values also vary with the temporal distribution of erosive precipitation because of the interaction between the temporal variation of erosive precipitation and the temporal variation of soil erodibility values [(AH703 (Renard et al., 1997)]. The temporal variation of erosive precipitation varies among locations

The RUSLE2 standard and modified soil erodibility nomographs do not take these factors into consideration. The data used to derive the standard soil erodibility nomographs were produced by uniform intensity simulated rainfall applied in a sequence of three events. The first simulated storm was 60 minutes of rainfall at 2.5 in/hr on dry soil conditions. The second storm was 30 minutes of rainfall at 2.5 in/hr approximately 24 hour later. The third storm was also 30 minutes long at 2.5 in/hr that occurred approximately 15 minutes after the second storm. When Wischmeier et al. (1971) developed the standard soil erodibility nomograph, they weighted measured erosion values produced by each simulated storm to compute an average annual soil erodibility factor value. This sequence of storms reflects a greater likelihood of a storm on dry conditions than on wet conditions.

This weighting procedure was assumed to apply at all locations, which is probably satisfactory for conservation planning on cropland in the eastern US. However, major questions arise about applying the soil erodibility nomograph to the western US where the precipitation patterns and rainfall amounts and intensities differ significantly from that used to derive the soil erodibility nomograph.

Although questions can be raised about the applicability of the soil erodibility nomograph for these and other reasons, the RUSLE2 assumption is that the nomographs provide soil erodibility values suitable for conservation and erosion control planning. Some of the nomograph issues are not significant with respect to conservation planning when uncertainty in the RUSLE2 soil erosion estimates are considered (See Section 17, RUSLE2 User's Reference Guide) because other factors have a much greater effect on rill-interrill erosion than does the soil erodibility factor.

The temporal soil erodibility equation described in **Section 4.5** takes into account soil erodibility factor values vary with location as temperature and precipitation var with location. Also, the effect of rainfall amount, intensity, and temporal climate patterns are considered in RUSLE2 equations for estimating rill-interrill erosion from rainfall on irrigated lands (see **Section 7.5**).

4.5. Temporal soil erodibility factor values

Along with factors for slope length, cover-management, and supporting practices, the RUSLE2 soil erodibility factor varies temporally (Mutchler and Carter, 1983). Erosion is significantly increased if peak soil erodibility occurs, for example, when cover-management conditions are most susceptible to erosion. An equation is needed to compute daily soil erodibility so that daily erosion can be computed to improve the mathematical accuracy of the RUSLE2 (see **Section 2.1**).

Soil erodibility is high for thawing soil and for the immediate period after the soil has thawed because the soil's susceptibility to detachment is increased (Van Klaveren and McCool, 1998.). Also, soil erodibility is high when soil moisture is high, which increases runoff per unit rainfall and hence erosion per unit erosivity. Erosion on the unit plot per unit erosivity is soil erodibility in RUSLE2. Runoff per unit rainfall is increased on the unit plot, and hence rill erosion is increased, when rainfall is frequent and soil evaporation is low. Soil erodibility may also be related to biological activity in the soil, which is a function of soil moisture and temperature (Vigil and Sparks, 2004).[37]

Although the reasons for soil erodibility varying temporally are partially known, adequate equations for temporal soil erodibility are lacking. The pattern for temporally varying soil erodibility seems well defined for plots at Morris, Minnesota and Holly Springs, Mississippi but not at other locations (Mutchler and Carter, 1983). A complication in making soil erodibility measurements is the coincidence of plot maintenance with highly erosive rains. The unit plots used to experimentally determine soil erodibility factor values are periodically tilled to break the soil crust and to control weeds. Erosion per unit erosivity, hence RUSLE2's soil erodibility factor, can be very high if a highly erosive rain occurs immediately after plot tillage.

The RUSLE1 temporal soil erodibility equations were reexamined and found to work poorly at most of the 11 locations where temporal soil erodibility data are available. Also, the equations performed very poorly in Minnesota and northern Iowa where computed temporal soil erodibility factor values varied too much with slight differences in weather between adjacent counties. Furthermore, the empirically derived RUSLE1 temporal soil erodibility equations are not applicable in the Western US. Consequently, a new temporal soil erodibility equation was derived for RUSLE2 using data collected at the locations listed in Table 4.2. The record length for these data is about 10 years.

---

[37] The RUSLE2 soil erodibility factor is solely related to unit plot conditions. Soil erodibility is also influenced by cover-management conditions but those effects, such as related to soil moisture and runoff, are considered in cover-management variables (see **Section 6**).

Table 4.2. Locations where unit plot conditions were used to determine monthly soil erodibility factor values

Location
Tifton, GA
Watkinsville, GA
Holly Springs, MS
Bethany, MO
Independence, IA
Beaconsfield, IA
Castana, IA
Clarinda, IA
Morris, MN
LaCrosse, WI
Presque Isle, ME

Temporal soil erodibility values grouped by geographic area are shown in Figure 4.1. A similar pattern in the temporal erodibility values by location was expected for each geographic area, especially for the four Iowa locations. The patterns are similar for the two northern Midwestern US and Northern Maine locations where almost no rill-interrill erosion occurs during the winter. The patterns are mostly similar for the two Georgia locations but differ significantly from the pattern at Holly Springs, Mississippi. The difference in patterns, especially among the Iowa locations, indicates that other variables besides weather, such as timing of plot maintenance with erosive rains, affect temporal soil erodibility.

With the exception of the southern locations, the data do not capture the increased soil erodibility in late winter and early spring during and immediately after soil thawing. The very few data available for these conditions are not usable because of very large variability. In many cases, measurements were not made during late winter and early spring because measuring equipment was difficult to operate during cold weather. Also, increased soil erodibility during the thawing and recently thawed period seems to be related to a unique set of conditions that do not occur every year.

Regardless of these limitations, a temporal soil erodibility equation seemed advisable for

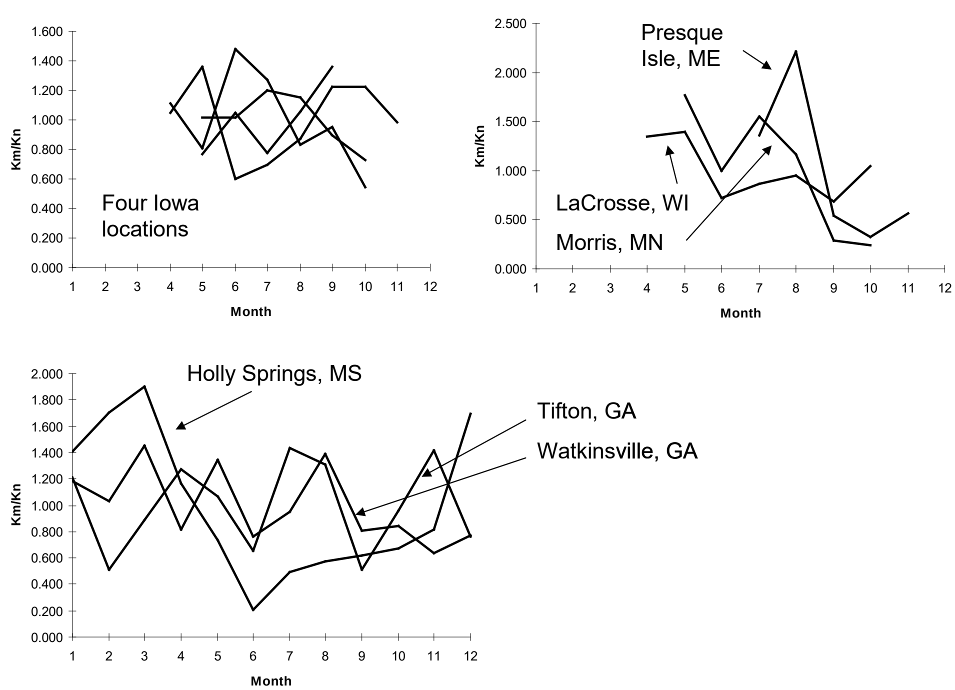

Figure 4.1. Monthly variation in soil erodibility at several locations.

RUSLE2. An equation for RUSLE2was empirically derived from these data.

4.5.1. Basic assumptions

The RUSLE2 assumption is that the soil erodibility value entered in RUSLE2, whether user entered or computed with either of the RUSLE2 soil erodibility nomographs, represents average soil erodibility for a summer period. The RUSLE2 summer period is defined for temporal soil erodibility purposes as the period when average daily temperature exceeds 40 ^{o}F. Analysis of soil erodibility data at Pullman, WA indicates that a better definition is the time between when average daily temperature reaches 45 ^{o}F early in the year to when it decreases to 35 ^{o}F late in the year.

The major assumption used to derive the RUSLE2 temporal soil erodibility equation is that monthly precipitation and temperature can be used as indices to estimate the temporal variability in soil erodibility during the RUSLE2 summer period.

4.5.2. Temporal soil erodibility for the summer period referenced to summer conditions at location

Average values for the ratio of monthly soil erodibility to average soil erodibility for the RUSLE2 summer period were computed for the data collected at the locations listed in Table 4.2. Average soil erodibility for the RUSLE2 summer period was computed as the total erosion for the period of record divided by total erosivity, excluding storms less than 0.5 inches (see **Section 3.2.1**). The period of record at all locations closely corresponded to the RUSLE2 summer definition because the plots were not operated during the winter as can be seen in Figure 4.1. However, the plots were operated throughout the year in the southern US locations and the total data for the year were used to compute an average erodibility value for the southern locations.

The resulting equation from fitting the data is:

$$K_j / K_n = 0.591 + 0.732(P_j / P_s) - 0.324(T_j / T_s) \quad [4.13]$$

where: K_j = average daily soil erodibility factor value for the *jth* day, K_n = soil erodibility value from the RUSLE2 soil erodibility nomographs or user entered into RUSLE2, T_j = average daily temperature for the *jth* day (^{o}F), T_s = the average temperature for the RUSLE2 summer period defined above, P_j = the average daily precipitation, and P_s = the average precipitation for the RUSLE2 summer period. This equation follows the expected trends of increased soil erodibility when precipitation is high and decreased soil erodibility when temperature is high. Equation 4.13 does not describe increased soil erodibility during or immediately after soil thawing.

The fit of equation 4.13 to the observed data at three locations is shown in Figure 4.2, which also represents the fit at the other locations. Equation 4.13 is a major improvement over the RUSLE1 equations as can be seen by inspection and by comparing the sum of squares of differences between observed and computed values. However, the fit of

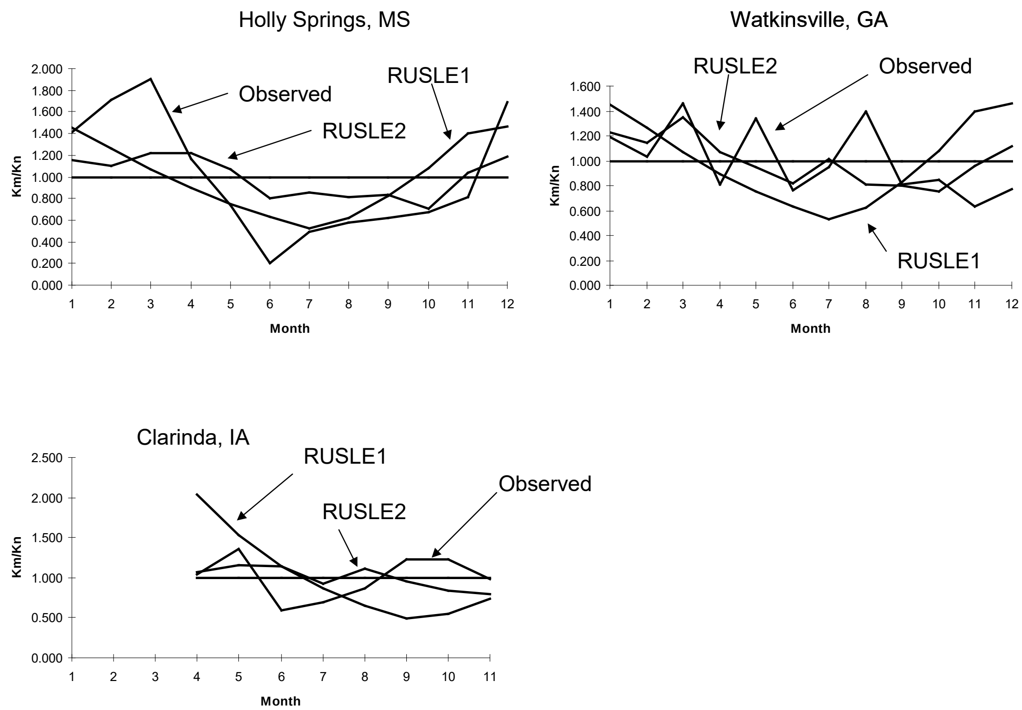

Figure 4.2. Fit of RUSLE2 temporal erodibility equation (equation 4.13), RUSLE1 equation, and constant value to observed data.

equation 4.13 is only slightly better than assuming a time invariant soil erodibility factor value for the summer period.

Computed values from equation 4.13 are shown in Figure 4.3 for Tombstone, Arizona and compared to values computed with the RUSLE1 equations and observed values. Very clearly, equation 4.13 performs much better than the RUSLE1 equations, which illustrates why a time invariant soil erodibility factor value should be assumed when applying RUSLE1 to the western US. The observed values shown in Figure 4.3 were obtained by applying rainfall each month with a rainfall simulator.[38] The observed values are not

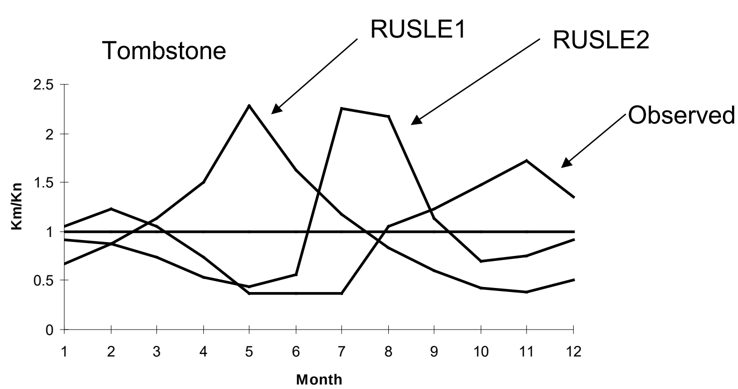

Figure 4.3. Fit of temporal erodibility equations to data from simulated rainfall on rangeland plots at Tombstone, Arizona.

JSDA-Agricultural Research
Service, Tucson, Arizona.

directly comparable to soil erodibility values produced by natural precipitation because of temporal differences between natural precipitation and the uniform precipitation of the simulated rainfall. Nevertheless, the fit of equation 4.13 to the observed Tombstone, Arizona data is comparable to the fit of equation 4.13 to soil erodibility values produced by natural rainfall in the eastern US.

Therefore, the recommendation is that the RUSLE2 temporal soil erodibility equation be used for all locations in the US except for Req periods (see **Section 3.2.5** and RUSLE2 User's Reference Guide).

4.5.3. Temporal soil erodibility for the summer period referenced to summer conditions at Columbia, Missouri

Equation 4.13 does acceptably well in capturing the relative temporal variations in soil erodibility at a location. Equation 4.13 is an improvement over using a constant soil erodibility factor at a location.

However, equation 4.13 gives exceptionally high soil erodibility values that do not seem reasonable in many western US locations. For example, equation 4.13 computes summer soil erodibility values at Tombstone, Arizona that are twice the average erodibility for summer period (i.e, the period that average daily temperature exceed 100 ^oF). The soil erodibility nomograph gives the same average erodibility for both Columbia, Missouri and Tombstone when soil properties are the same at the two locations.. However, the absolute July soil erodibility at Tombstone should not be higher than the absolute July soil erodibility at Columbia.

The root cause of the problem is that the soil erodibility nomograph is not a function of climate at a location. This deficiency does not cause major problems in the Eastern US, but it does cause great problems in the Western US.

To fix this problem, the P_s and T_s variables in equation 4.13 were changed from location values to values at Columbia, MO. The temporal soil erodibility equation referenced to Columbia, Missouri is:

$$K_j / K_n = 0.591 + 0.732(P_j / 0.123) - 0.324(T_j / 62.8) \qquad [4.14]$$

$$If\,(K_j / K_n) > 2.0 \text{ then } (K_j / K_n) = 2.0$$

$$If\,(K_j / K_n) < 0.4 \text{ then } (K_j / K_n) = 0.4$$

where: P_j = daily precipitation (inches), 0.123 (inches) = the daily average reference precipitation at Columbia, Missouri, T_j = the daily temperature (^oF), and 62.8 (^oF) = the daily average reference temperature at Columbia, Missouri. The j subscript is for the *jth* day. The reference precipitation and temperature value for Columbia, Missouri are for the time period that the average daily temperature is above 40 ^oF.

Either the standard or RUSLE2 soil erodibility nomographs can be used to determine a value for the nominal soil erodibility factor K_n, or another soil erodibility value can be used if values computed by the RUSLE2 soil erodibility nomographs are not applicable. The upper limit of 2 and the lower limit of 0.4 for the ratio K_j/K_n provides robustness by preventing extreme precipitation and temperature from excessively affecting daily soil erodibility factor values.

4.5.4. Temporal soil erodibility for the winter period

Equation 4.14 is used to compute temporal RUSLE2 soil erodibility factor values in the winter period as well as the summer period, except when average daily temperature is less than 30 ^oF. The RUSLE2 temporal soil erodibility equation for average daily temperature less than 30 ^oF is:

$$K_{(j)} / K_n = (K_{s(j)} / K_n) \exp[-0.2(30 - T_{(j)})] \qquad [4.15]$$

where: $K_{s(j)}$ = the soil erodibility factor value computed with equation 4.14 on the *jth* day, T_j = the average daily temperature on the *jth* day (^oF), and 30 = the average daily temperature below which soil erodibility is reduced because of soil freezing (^oF). The *exp* term in equation 4.15 computes a K_j/Kn value less than 0.05 when average daily temperature is less than 15 ^oF. The exponential decay term in equation 4.15 takes into account the fact that temperature in some years on a given day will not be less than freezing even though average daily temperature is below freezing. Also, the temperature used in equation 4.15 is air temperature rather than soil temperature.

Equation 4.15 does not compute increased erosion during and immediately after soil thawing.

4.5.5. Temporal soil erodibility for winter and summer periods combined

Figure 4.4 shows temporal soil erodibility factor values computed for the entire year at selected locations. Note the difference in the mean soil erodibility factor value among the locatins for the same base soil erodibility factor value.

4.5.6. Temporal soil erodibility for the Req regions

Winter erosion processes differ greatly from summer erosion processes in the Northwest Wheat and Range Region (NWRR) and other areas in the Western US (McCool et al., 1995). Soil erodibility is very high during the winter in these regions, resulting in very high erosion. This winter effect is accounted for in RUSLE2 by assuming an equivalent erosivity known as Req. Equation 4.14 can be used to estimate temporal erodibility for the summer period defined as the time between the day when average daily temperature reaches 45 ^oF early in the year and decreases to 35 ^oF late in the year. Equation 4.15 does not apply where Req effects are assumed to occur (see **Section 3.2.5** and RUSLE2 User's Reference Guide).

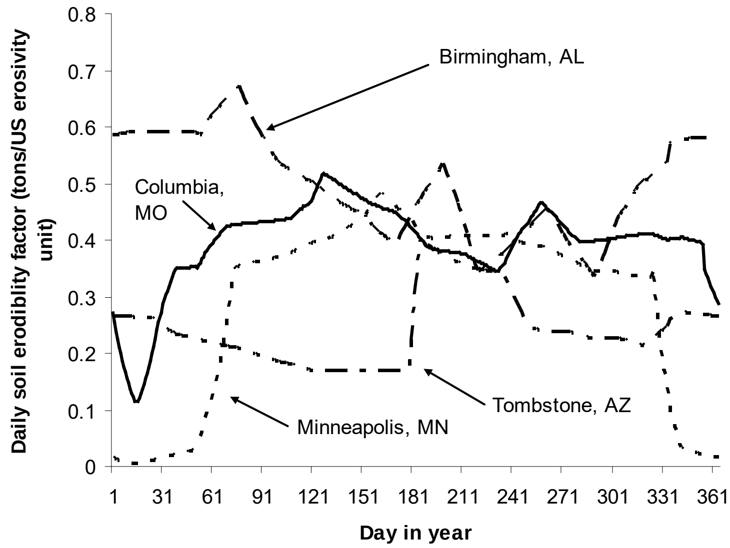

Figure 4.4. RUSLE2 computed temporal soil erodibility factor values for the same base soil erodibility factor value. The temporal soil erodibility factor equations are referenced to Columbia, Missouri.

4.6. Effect of rock on soil erodibility

Rock on and in the soil affects rill-interrill erosion. RUSLE2 treats rock on the soil surface as ground cover (see **Section 6.2**). Rock in the soil is assumed to affect runoff and this effect on erosion is represented by choosing a soil erodibility factor value based on how rock in the soil profile is assumed to affect runoff under unit plot conditions. **User entered soil erodibility values should reflect how rock in the soil profile affects erosion but not account for any effect of rock on the soil surface.**

The permeability class input should reflect how rock in the soil profile affects runoff when a RUSLE2 soil erodibility nomograph is used to compute a soil erodibility factor value. Although RUSLE2 includes the RUSLE1 soil erodibility nomograph equations used to estimate how rock in the soil profile affect soil erodibility (Römkens et al., 1997), these equations should not be used in RUSLE2, especially for construction sites and reclaimed surface mine lands. Toy and Foster (1998) describes how to adjust input values to the RUSLE2 modified soil erodibility nomograph to estimate the effect of large rock fragments in the soil on soil erodibility. 20-40=+1; 40-60=+2; 60-80=+3; >80=+4; max permeability is class=6 (very slow).

A value for soil surface cover provided by rock that is a natural part of the soil can be entered in RUSLE2's soil input. RUSLE2 assumes that this rock cover is not affected by mechanical soil disturbing operations. Rock cover can also be represented in RUSLE2 as an operation that adds surface cover, but RUSLE2 handles this rock cover differently from how it handles rock cover entered in the soil input. Rock cover represented as surface cover added by an operation is affected by soil disturbing operations and

RUSLE2 treats this rock as an organic material. Special inputs are required when rock cover is represented in this way (see **Section 10.1** and RUSLE2 User's Reference Guide).

The USDA-NRCS soil survey database includes soil erodibility factor values that have been adjusted for rock cover on the soil surface. **NRCS soil erodibility factors values adjusted for rock surface cover must not be used in RUSLE2.** The ground cover subfactor relationship used by NRCS to adjust for rock surface cover differs from the comparable RUSLE2 relationship (see **Section 6.2.1**). The surface cover relationship used by the NRCS is the USLE mulch cover subfactor [AH537 (Wischmeier and Smith, 1978)], which has an approximate 0.026 **b** value whereas the approximate RUSLE2 **b** value is 0.035. The error in estimated erosion from this difference for a 20 percent rock cover is 20 percent.

Also, RUSLE2 uses a net ground cover that takes into account surface residue and live ground cover overlapping rock surface cover. This overlap is not taken into account when NRCS soil erodibility factor values adjusted for rock surface cover are used, which can result in serious errors because the ground (mulch) cover relationships are highly non-linear (see RUSLE2 User's Reference Guide). The error in estimated erosion from neglecting the overlap for a 50 percent residue cover and a 20 percent rock cover is 30 percent even when if the proper **b** value had been used in the NRCS adjustment.

4.7. Sediment characteristics

RUSLE2 computes deposition and enrichment ratio as a function of sediment characteristics (see **Sections 2.3.3** and **4.7.6**). Diameter, specific gravity, distribution among sediment particle classes, and composition of sediment particle classes are the RUSLE2 variables used to describe sediment characteristics. RUSLE2 uses only soil texture and inherent soil organic matter content to compute values for sediment characteristics at the point of detachment although soil management affects these sediment characteristics. Sufficient information was not available to develop equations for the effect of soil management on sediment characteristics at the point of detachment.

The RUSLE2 equations used to compute sediment characteristics at the point of detachment are described by (Foster et al., 1985b). The RUSLE2 intent in representing sediment characteristics is to capture main effects rather than precisely representing all variables that affect sediment characteristics at the point of detachment. Also, more detail, such as more than the five sediment particle classes used in RUSLE2 equations is desired for computing deposition. However, the desired information is not readily available for most RUSLE2 applications as a conservation planning tool in local field offices. The RUSLE2 approach is far better than assuming that sediment characteristics at the point of detachment are the same as the characteristics of dispersed samples of the soil subject to detachment. A critically important point is that sediment is eroded as a mixture of aggregates and primarily particles. Assuming that sediment is composed entirely of primary particles produces serious errors when computing deposition. RUSLE2 computes how deposition changes sediment characteristics so that the characteristics of sediment leaving an overland flow path, terrace/diversion channels, and small impoundments can be quite different from the characteristics of the soil being eroded, especially where RUSLE2 computes a high degree of deposition.

4.7.1. Definition of sediment particle classes

Five sediment particle classes are used to represent the sediment produced by detachment for each soil along an overland flow path. The five classes are primary clay, primary silt, small aggregate, large aggregate, and primary sand. Sediment from cohesive soils is eroded as a mixture of primary particles (small mineral particles that the soil can be divided into) and aggregates (conglomerates of primary particles) (Foster et al., 1985b). Also, the sediment distribution for many cohesive soils is bimodal, having a peak in the silt-size range and a peak in the sand-size range (Meyer et al., 1980). The two aggregate sediment particle classes represent these two peaks in the sediment distribution. The three primary sediment particle classes represent primary particles in the sediment while the two aggregate classes represent aggregates in the sediment.

4.7.2. Density of sediment particle classes

Densities, expressed as specific gravity, of the sediment particle classes are given in Table 4.3. The slightly reduced density for the primary clay class relative to the primary silt and sand classes is because of the platy nature of clay particles. The difference is of no consequence in RUSLE2. The significantly reduced densities of the aggregate classes from the primary particle classes reflect how aggregates are conglomerates of primary particles with internal open spaces in them that are partially or fully filled with water. Sediment particle density is especially important for sediment sizes larger than 0.1 mm because density seems to affect deposition by overland flow as much as size (Lu et al., 1988; Neibling and Foster, 1982). A smaller density is assigned to the large aggregate class than to the small aggregate class because density decreases as aggregate size increases (Foster et al., 1985b).

Table 4.3. Densities of sediment particle classes

Particle class	Density (specific gravity)
Primary clay	2.60
Primary silt	2.65
Small aggregate	1.80
Large aggregate	1.60
Primary sand	2.65

4.7.3. Diameters of sediment particle classes

The diameters of the sediment particle classes are given in Table 4.4. The diameter of each primary particle class is fixed. However, the diameter for each aggregate sediment particle class varies with soil clay content, which reflects the role of clay as a bonding agent.

Table 4.4. Diameter of sediment particle classes.

Particle class	Diameter		Condition where equation applies
	Symbol	Size (mm)	
Primary clay	d_{cl}	0.002	
Primary silt	d_{sl}	0.010	
Small aggregate	d_{sa}	0.030	$P_{cl} < 25$
	d_{sa}	$0.2(P_{cl}/100 - 0.25) + 0.03$	$25 \le P_{cl} \le 60$
	d_{sa}	0.100	$P_{cl} > 60$
Large aggregate	d_{la}	0.300	$P_{cl} \le 15$
	d_{la}	$2P_{cl}/100$	$P_{cl} > 15$
Primary sand	d_{sd}	0.200	

The diameter of each aggregate class is a function of soil clay content for certain ranges of clay content. RUSLE2 adds aggregate sediment particle classes as necessary along the overland flow path where soil clay differs by segment to represent unique particle classes having different diameters. The same primary sediment particle classes are used for all soils along an overland flow path because the diameters used for these classes do not vary with soil.

4.7.4. Distribution of sediment mass among particle classes at point of detachment

As shown in Table 4.5, the distribution of sediment mass among the sediment particle classes at the point of detachment depends mainly on the soil's clay content. Seventy four percent of the clay in the sediment at the point of detachment is in the aggregate sediment particle classes while only 26 percent is in the primary clay sediment particle class.

Table 4.5. Distribution of sediment mass among particle classes at the poi				
Particle class	Fraction			
	Symbol		Condition	Comment
Primary clay	F_{cl}	$0.26P_{cl}/100$		
Primary silt	F_{sl}	$P_{sl}/100 - F_{sa}$		
Small aggregate	F_{sa}	$1.8P_{cl}/100$	$P_{cl} < 25$	
	F_{sa}	$0.45 - 0.6(P_{cl}/100 - 0.25)$	$25 \le P_{cl} \le 50$	If $F_{sl} < 0$, $F_{sl} = 0.0001$ and
	F_{sa}	$0.6P_{cl}/100$	$P_{cl} > 50$	$F_{sa} = P_{sl}/100 - F_{sl}$
Large aggregate	F_{la}	$1 - F_{cl} - F_{sl} - F_{sa} - F_{sd}$		If $F_{la} < 0$, each fraction is multiplied by the same fraction to give F_{la} = 0.0001
Primary sand	F_{sd}	$(P_{sd}/100)(1 - P_{cl}/100)^5$		
Note:				
If the clay content of the large aggregate class is less than $0.5P_{cl}$, the value for F_{sa} must be reduced to meet this condition.				

Soil clay content determines the fraction of the sediment mass that is in the small aggregate sediment particle class at the point of detachment. The fraction of the sediment in the primary silt class at the point of detachment is the soil's silt content less the silt fraction computed to be in the small aggregate class. The fraction of sediment mass in the small aggregate class at the point of detachment can not be larger than the silt content in the soil.

Both clay and sand content in the soil determine the fraction of the sediment mass that is in the primary sand sediment particle class at the point of detachment. The role of soil clay content in determining this fraction increases rapidly as soil clay content increases. The fraction of sediment mass in the large aggregate sediment particle class at the point of detachment is computed as 1 minus the sum of the fractions of the other four sediment particle classes. The fractions for the other four classes are adjusted when the fraction of the large aggregate sediment particle class is computed as being less than zero.

4.7.5. Composition of each sediment particle class

Detachment in RUSLE2 is assumed to be non-selective. Consequently, the sediment's primary particle composition at the point of detachment is the same as the composition of the surface soil subject to detachment.

4.7.5.1. Primary clay sediment particle class

The primary sediment particle is composed of primary clay and the organic matter associated with the clay.[39] The RUSLE2 assumption is that the ratio of organic matter to clay on a mass basis is the same for all sediment particle classes where clay is present. That ratio is given by:

$$r_{om,cl} = P_{om} / P_{cl} \qquad [4.16]$$

where: $r_{om,cl}$ = the fraction (mass) of the primary clay sediment particle class that is composed of organic matter and P_{om} = 100 times the ratio of mass of organic matter in the soil to the mass of soil mineral particles.

4.7.5.2. Primary silt sediment particle class

The primary silt sediment particle class is composed solely of silt. This particle class contains no organic matter because the class contains no clay.

4.7.5.3. Small aggregate sediment particle class

The small aggregate sediment particle class is composed of clay, silt, and organic matter. This particle class contains no sand by definition. The size of the small aggregate particle class is too small to contain any sand except very fine sand. However, the RUSLE2 assumption is that this particle class does not contain even very fine sand. The distribution of the clay and silt is assumed to equal the proportion of clay and silt in the soil subject to detachment. That is,

$$f_{cl,sa} = P_{cl} /(P_{cl} + P_{sl}) \qquad [4.17]$$

where: $f_{cl.sa}$ = the fraction (mass) of the small aggregate that is composed of clay. The fraction of the small aggregate that is composed of silt is given by:

$$f_{sl,sa} = P_{sl} /(P_{cl} + P_{sl}) \qquad [4.18]$$

where: $f_{sl,sa}$ = the fraction (mass) of the small aggregate that is composed of silt. The fraction of the small aggregate that is composed of organic matter is given by:

$$f_{om,sa} = r_{om,cl} f_{cl,sa} \qquad [4.19]$$

where: $f_{om,sa}$ = fraction (mass) of the small aggregate sediment class composed of organic matter.

---

[39] The terms clay, silt, and sand sometimes refer to particle sizes. However, as used herein, clay, silt, and sand refer to mineral particles in the clay, silt, and sand sizes. The fractions of the primary particles sum to 1. Organic matter is not considered in determining fraction of the particles classes.

4.7.5.4. Large aggregate sediment particle class

The large aggregate sediment particle class is assumed to be composed of clay, silt, sand, and organic matter. The total of each constituent among the sediment particles classes must equal the constituent's amount in the soil. The mass of a constituent, except organic matter, in the large aggregate is computed as the total minus the sum of that constituent in the other sediment particle classes That is:

$$f_{cl,la} = (P_{cl}/100 - F_{cl} - f_{cl,sa}F_{sa})/F_{la} \quad [4.20]$$

$$f_{sl,la} = (P_{si}/100 - F_{si} - f_{sl,sa}F_{sa})/F_{la} \quad [4.21]$$

$$f_{sd,la} = (P_{sd}/100 - F_{sa})/F_{la} \quad [4.22]$$

Equations 4.20-4.22 directly result from the RUSLE2 assumption that detachment is a non-selective process, which requires that the distribution of the constituents in the sediment at the point of detachment be the same as that in the soil subject to detachment. A check is made of the clay content in the large aggregate sediment particle class. Because clay and the organic matter associated with it are assumed to be bonding agents for the two aggregate classes, clay must be sufficient in the large aggregate class to give those particles stability. To meet this requirement, the RUSLE2 assumption is that the clay content in the large aggregate class must be at least half of the soil's clay content. If the clay content in the large aggregate particle class computed with equation 4.20 is less than half the soil's clay content, the fraction F_{sa} of the small aggregate sediment particle class is reduced to meet this requirement.

The fraction of the organic matter in the large aggregate sediment particle class is given by:

$$f_{om,la} = f_{cl,la}r_{om,cl} \quad [4.23]$$

4.7.5.5. Primary sand sediment particle class

The primary sand class is solely composed of sand. It contains no organic matter because it contains no clay.

4.7.6. Specific surface area

Table 4.6. Specific surface area of soil/sediment constituents.

Constituent	Specific surface area (m^2/g)
Clay	20
Silt	4
Sand	0.05
Organic matter	1000

Each constituent of clay, silt, sand, and organic matter is assigned a specific surface area so that RUSLE2 can compute an enrichment ratio based on specific area of the soil subject to detachment and the computed sediment yield from the overland flow path, terrace/diversion channel, or small impoundment, represented in a RUSLE2 computation. Specific surface area is the total surface area of the soil or sediment per unit mass. The specific surface areas used in RUSLE2 are given in Table 4.6, which were used in the CREAMS model (Foster et al.1980a, 1980b; Foster et al., 1981a). As Table 4.6 shows, most of the surface area is associated with organic matter and clay with almost no specific surface area associated with sand. Because organic matter is directly associated with the clay, the specific surface of both the soil and the sediment is directly related to clay content in each.

Specific surface area of the soil subject to detachment and the sediment leaving the RUSLE2 flow path is used to compute an enrichment ratio as:

$$E_r = S_{sed} / S_{soil} \quad [4.24]$$

where: E_r = enrichment ratio, S_{sed} = the specific surface area of the sediment and S_{soil} = the specific surface area of the soil. The enrichment ratio is a measure of the degree that RUSLE2 computes that deposition enriches the sediment in fine particles, especially clay. Deposition is a selective process that first deposits particles that are coarse and dense, which have a low specific surface area, leaving the sediment enriched in fine particles that have a high specific surface area. The enrichment ratio increases as deposition increases. A sediment delivery ratio can be computed as the ratio of sediment yield at the end of the RUSLE2 flow path divided by the total amount of sediment produced by detachment. Enrichment ratio increases as the sediment delivery ratio decreases. A low sediment delivery ratio represents a high degree of deposition. Enrichment ratio is a relative term and not an absolute term. A high enrichment ratio means that the specific area of the sediment is greater than that of the soil that produced the sediment, but the specific surface area of the sediment may still be low if the soil being eroded has a high sand content and a low inherent organic matter content.

Table 4.7. RUSLE2 computed enrichment ratios for a filter strip

Soil textural class	Enrichment ratio
Clay	1.95
Clay loam	2.23
Loam	2.65
Loamy sand	7.56
Sand	11.50
Sandy clay	2.13
Sandy clay loam	3.07
Sandy loam	3.47
Silt	0.94
Silt loam	1.58
Silty clay	1.19
Silty clay loam	1.44

The enrichment ratio computed by RUSLE2 is strongly affected by soil texture as shown in Table 4.7. Interestingly, the highest enrichment ratio is for a sand soil while the lowest enrichment ratio is for a high silt soil. Enrichment ratio values are moderate for high clay soils. These results are directly related to the sediment being a mixture of aggregates and primary particles, the role of clay as a bonding agent in determining size of the large the aggregates, and the distribution of sediment between the small aggregate and large aggregate sediment particle classes. An important point to remember when interpreting and using the RUSLE2 computed enrichment ratio values is that about 74 percent of the clay is in the small and large aggregate particle classes at the point of detachment. RUSLE2 computes that a moderate sized large aggregate class is deposited at a rate comparable to the primary sand sediment particle class. Because much of the clay is assumed to be in the large aggregate class, a significant amount of clay is deposited when the large aggregate class is deposited.

The enrichment ratio values computed by RUSLE2 are very different from those that would be computed if the sediment at the point of detachment was assumed to be composed entirely of primary particles. High sand soils have very low clay contents such that the portion of the sediment in the aggregates classes at the point of detachment is low. The aggregate classes, which contain most of the clay, have small diameters for high sand soils and are, therefore, less readily deposited. Consequently, the enrichment ratio for sediment from high sand soils is generally high as illustrated in Table 4.7. In contrast, the diameters of both the small and large aggregate classes, which contain most of the clay, are very large for the high clay soils. These aggregates classes are more readily deposited than the aggregate classes produced by high sand soils. The result is that a higher fraction of the clay in a high sand soil remains in the sediment after deposition than for a high clay soil.

Essentially no enrichment occurs with the high silt soil because of the very low clay content and a very high portion of the sediment at the point of detachment being in the primary silt class that is not readily deposited. Most of the clay is in the aggregate classes that are more readily deposited than the primary silt class where most the sediment is concentrated at the point of detachment.

Although specific surface area of clay varies significantly with clay mineralogy, RUSLE2 does not consider that effect. Also, RUSLE2 uses the inherent soil organic matter content under unit plot conditions in these computations. Soil organic matter content as influence by cover-management is a more appropriate measured than inherent soil organic matter content.

The enrichment ratio values computed by RUSLE2 represent an index. The enrichment ratio value indicates the concentration of sediment associated chemicals in the sediment relative to their concentration in the soil. Calibration should be used to empirically relate the concentration of chemicals on sediment to the RUSLE2 enrichment ratio values because the values computed by RUSLE2 are lower than expected (Knisel et al., 1980).

4.8. Time to soil consolidation

Soil consolidation refers to the soil becoming resistant to erosion over time after a mechanical soil disturbance and not to a mechanical increase in bulk density of the soil (see **Section 6.6**). RUSLE2 computes time to soil consolidation as function of annual precipitation using:

$$t_c = 20 \quad P_a < 10 \qquad [4.25]$$

$$t_c = 26.5 - 0.65 P_a + 0.5 \quad 10 \le P_a \le 30 \qquad [4.26]$$

$$t_c = 7 \quad 30 < P_a \qquad [4.27]$$

where: t_c = the time to soil consolidation (years) and P_a = annual precipitation (inches). The equation that computes values for the soil consolidation subfactor uses the ratio of time since last mechanical soil disturbance to time to soil consolidation and computes subfactor values that asymptotically approach the 0.45 final value (see **Section 6.6.2**). The time to soil consolidation is defined as the time for 95 percent of the reduction in the soil consolidation subfactor to occur. The time to soil consolidation occurs when the soil consolidation factor equals 0.4775, which is 95 percent of the decrease from 1 for the soil consolidation subfactor immediately after a mechanical soil disturbance to the final 0.45 value.

After a mechanical soil disturbance, the soil becomes resistant to detachment by the soil experiencing wetting and drying cycles in the presence of soil moisture and bonding agents including clay and organic matter (Foster et al., 1985b). Mechanical compaction of the soil is assumed to have little effect on this increase in erosion resistance in RUSLE2. The seven year time to soil consolidation is based on analysis of fallow plot data from Zanesville, Ohio (Borst et al., 1945), which are the only sufficient data available to empirically determine time to soil consolidation. This seven year period is assumed to apply to all areas where annual precipitation is greater than 30 inches. The increase of time to soil consolidation based on average annual precipitation is an approximate way to capture the idea that soil consolidation occurs more slowly in the western US than in the eastern US because of reduced rainfall amount and reduced number of rainfall events. Equations 4.25 and 4.26 are based on judgment.

5. TOPOGRAPHY

This section describes mathematical consequences of RUSLE2's equation structure rather than providing additional equations except for the steepness factor and adjusting soil loss tolerance values for position along the overland flow path.

Equations that describe how topography affects rill-interrill erosion where the overland flow streamlines are parallel are described in **Section 2**. Those equations provide RUSLE2's fundamental, underlying mathematical structure. Those equations accommodate spatial variability in soil, steepness, cover-management, and support practices along the overland flow path. Those equations compute whether detachment or deposition occurs along the overland flow path. RUSLE2 computes its erosion and sediment load values using a numerical solution of the governing RUSLE2 equations written as a function of distance along the overland flow path. The numerical solution is a spatial integration of the governing equations. Furthermore, RUSLE2 performs a temporal integration of the governing equations, where the slope length exponent m in equation 2.10, along with soil erodibility and cover-management relationships change daily.

5.1. Converging-diverging streamlines on overland flow areas

The RUSLE2 assumption is that overland flow streamlines are parallel. Consequently, RUSLE2 does not estimate how converging or diverging overland flow affects rill-interrill erosion. An analysis based on a simple process-based erosion model showed that rill-interrill erosion with converging overland flow is about 7/6 times that where the streamlines are parallel (Toy and Foster, 2000). The same analysis showed that rill-interrill erosion with diverging overland flow is about 5/6 times that where the streamlines are parallel.

5.2. Topographic equations for overland flow having parallel streamlines on uniform overland flow paths

RUSLE1 requires users to select a slope length exponent value, m in equation 2.10, based on land use classes [AH703, (Renard et al., 1997); Toy and Foster, 1998]. The RUSLE1 slope length exponent is time invariant and thus does not change as cover-management conditions change temporally. Overland flow path steepness is the only variable considered in adjusting the slope length exponent in the USLE [AH537 (Wischmeier and Smith, 1978)].

A RUSLE2 major improvement is that it computes slope length exponent values as a function of overland flow path steepness, soil, and cover-management conditions. Consequently, the RUSLE2 slope length exponent varies as cover-management conditions vary temporally. RUSLE2 automatically computes slope length exponent values from basic input data rather than the user selecting a value as required by RUSLE1.

The slope length exponent should vary with position along the overland flow path according to erosion theory (Foster and Meyer, 1975). However, equation 2.10 is based on the assumption that the slope length exponent is a not a function of position x. The slope length exponent not varying with position greatly simplifies RUSLE2 mathematics and numerical procedures (see **Section 2.3**) and gives RUSLE2 increased robustness for overland flow paths longer than 150 ft (see **Section 5-Appendix I**).

If equation 2.10 is used to compute erosion for a slope length exponent that varies with position, RUSLE2 computes erroneous erosion values for a uniform overland flow path divided into segments, even if conditions are the same for all segments. Computed erosion should be independent of the number and length of segments used to represent a uniform overland flow path.

Some of the sediment produced by interrill erosion is deposited in "rill" areas when overland flow path steepness is low and interrill erosion is sufficiently high. RUSLE2 computes no rill erosion when it computes deposition. RUSLE2 computes this local deposition[41] when interrill erosion rate is greater than the increase in transport capacity with distance along the overland flow path (i.e., $D_i > dT_c/dx$ where D_i = interrill erosion rate, T_c = runoff's sediment transport capacity, and x = distance). Interrill erosion is computed with equation 2.11, dT_c/dx is computed using equation 2.17, and deposition and net erosion is computed using equation 2.16 and its companion equations. RUSLE2-computed net erosion does not vary with distance along the overland flow path as expected (Renard and Foster, 1983; Meyer and Harmon, 1985).

Erosion values computed with equations 2.16 and 2.17 differ from values computed by the empirical USLE, which is equation 2.10. This inconsistency, which should not occur, results from RUSLE2 combining the empirical USLE equation with a process-based sediment transport capacity equation. These equations do not work well together for this condition. A choice must be made as to whether the USLE based erosion value or the process-based erosion value will be the RUSLE2-computed value.

A RUSLE2 development principle is that RUSLE2 compute erosion values agree with USLE computed values (see **Section 1**). The conflict between equation 2.16 and the USLE equation forms, therefore, is resolved by having RUSLE2 produce the same results as the USLE. However, RUSLE2 uses equation 2.16 to compute how local deposition change sediment characteristics.

This procedure works well for local deposition on a uniform overland flow path not subdivided into segments. Subdivision without changing any of the segment variable values should not affect computed erosion and sediment values. Subdivision does not

---

[41] Local deposition is where sediment is deposited almost adjacent to the point of detachment such as in soil surface roughness depressions and in furrows between ridges. Remote deposition is where sediment is deposited a significant distance from the point detachment such as at the upper edge of dense vegetation strips and on the toe of concave-shaped overland flow path profiles.

affect computed erosion values but does affect computed enrichment ratio values when RUSLE2 computes local deposition. The RUSLE2-computed enrichment ratio value is correctly computed when a uniform overland flow path is not subdivided.

RUSLE2 was constructed so that its remote deposition computations are independent of segment subdivision. An example of remote deposition is the deposition that occurs at the upper end of a 0.5 percent segment downslope from a one percent steep segment. RUSLE2 also computes local deposition on the 1 percent steep segment if interrill erosion is sufficiently great.

RUSLE2 makes these computations correctly if the upper one percent segment is not subdivided. However, if that segment is subdivided, it will compute erroneous enrichment ratio values, especially if the subdivision is near the upper end of the segment. The erosion values are affected only very slightly by subdivision of the upslope segment.

The error in the enrichment ratio values caused by subdividing the overland flow path is a RUSLE2 flaw. This flaw can not be eliminated because of differences in equation structure between the USLE and the process-based sediment transport capacity equation used in RUSLE2. The enrichment ratio error could have been prevented by developing RUSLE2 entirely from process-based equations. However, RUSLE2's power of giving the well-accepted, empirically derived USLE values would have been lost. RUSLE2 was derived, developed, and evaluated to ensure that inconsistencies, which can not be totally eliminated, are acceptable for the purpose of conservation and erosion control planning. Fortunately, most RUSLE2 conservation planning applications assume a uniform overland flow path without subdivision.

5.3. Topographic equations for overland flow having parallel streamlines on non-uniform overland flow paths

RUSLE2 uses the equations described in **Section 2** to compute erosion and sediment load on non-uniform overland flow paths. The overland flow path is divided into segments where soil, steepness, or cover-management change along the overland flow path. The governing equations are numerically solved along the overland flow path starting at the upper end of the overland flow path where overland flow originates (see **Section 2.3**).

Each soil, steepness, and cover-management variable that changes between segments is treated as a step rather than a continuous change (see **Section 2.3.1**). Assuming step changes is appropriate for most cover-management changes, whereas continuous change is appropriate for changes in soil and steepness for overland flow paths on most natural landscapes.

Steepness at the intersection of two segments could be treated as the average of the steepness of the two segments, which is appropriate for describing an overland flow path where steepness changes continuously along the overland flow path, such as a concave overland flow path profile. However, a continuous change in steepness is not appropriate for constructed slopes where steepness makes a step change. Examples include the intersection a landfill's top with a sideslope and the intersection of a hillslope cut with a flat area. RUSLE2 assumes a step change in steepness to accommodate step changes in steepness common to constructed slopes. The effect of step changes in representing gradual soil and steepness changes along an overland flow path is minimized by dividing the overland flow path into several segments (see the RUSLE2 User's Reference Guide).

A concern in applying RUSLE2 to non-uniform overland flow paths is dealing with changes in infiltration caused by soil and cover-management changes along the overland flow path. RUSLE2 considers how changes in infiltration along an overland flow path affect contouring failure, sediment transport capacity, and deposition. RUSLE2 does not consider how changes in infiltration along an overland flow path affect detachment on a downslope segment. While interrill erosion on a particular segment is only affected by infiltration rate on that segment, rill erosion on a segment is affected by both the runoff generated on that segment and by the runoff that arrives from the upslope area of the overland flow path. This effect can be partially represented by adjusting the upslope overland flow path length to reflect runoff coming into a downslope segment.

Nevertheless, a conflict exists in RUSLE2 between the way that overland flow path distance is treated for computing runoff and the way that overland flow path distance is treated for computing detachment. An example situation is runoff from an upslope pasture draining onto a cultivated field where infiltration on the pasture area is much higher than on the cultivated area. If the actual overland flow length is entered, RUSLE2 computes detachment values that are too high on the cultivated area because runoff reaching the cultivated area will be much less than is implicitly assumed in RUSLE2. If an effective overland flow path length is entered to correctly compute detachment on the cultivated area, RUSLE2 computes runoff rates that are too low on the cultivated area and incorrectly computes detachment on the pasture area. See the RUSLE2 User's Reference Guide for recommendations for selecting overland flow path lengths where infiltration varies greatly along an overland flow path.

The resolution to this problem is to have derived RUSLE2 using process-based erosion equations. Given that most RUSLE2 conservation planning applications involve uniform overland flow paths or overland flow paths where infiltration does not vary greatly along the path, RUSLE2 is considered to produce satisfactory results for most conservation planning applications.

5.4. Applying RUSLE2 to complex topography with converging and diverging overland flow

The RUSLE2 User's Reference Guide describes the proper procedure for applying RUSLE2 to complex topography. The effect of converging and diverging overland flow on RUSLE2 computed erosion is discussed in **Section 5.1**.

The USLE and RUSLE1 are used in GIS applications to compute erosion on topographically complex areas where overland flow converges and diverges. In these applications, overland flow path distance is considered equivalent to upslope drainage area (Desmet and Govers, 1996). This assumption is questionable as discussed in **Sections 5.2** and **5.Appendix I**. The slope length exponent should be a function of upslope drainage area. If the slope length exponent is used as a function of upslope drainage area, the proper numerical procedure must be used. The irregular slope procedure derived by Foster and Wischmeier (1974) assumes that the slope length exponent does not vary with position along the overland flow path. If the slope length exponent is varied with the Foster and Wischmeier irregular slope procedure, erroneous erosion values will be computed (see **Sections 5.3** and **5.Appendix I**).

RUSLE2 is much more complex than the USLE or RUSLE1 regarding the rill to interrill erosion ratio used to compute slope length exponent values. RUSLE2 may be used in GIS applications to represent complex topography where distance along an overland flow path is assumed to be comparable to upslope drainage area. Such applications should be made ***only*** **where infiltration rate varies little spatially and where convergence or divergence of overland flow is minimal.**

A much better approach than using the RUSLE2 equations is to derive separate rill erosion, interrill erosion, and deposition equations using RUSLE2 assumptions, concepts, and equations. In this approach, a discharge rate can be properly computed from upslope drainage area. The discharge rate can be used to compute rill erosion, sediment transport capacity, deposition, and contouring failure. Interrill erosion is computed independent of upslope drainage area.

A common error in using the USLE and RUSLE1 in GIS applications is that excessively long overland flow path lengths are assumed. Inadequate resolution in topographic data, results in excessively long overland flow paths and poor representation of steepness along the overland flow path (Toy and Foster, 2000). The maximum overland flow path length allowed in RUSLE2 is 1,000 ft (see RUSLE2 User's Reference Guide). In fact, overland flow is collected in concentrated flow areas within 200 ft on most farm fields (Foster, 1985).

When using GIS applications to compute erosion, deposition, and sediment yield, separate relationships should be used to compute sediment production and sediment transport capacity needed to compute deposition. Desmet and Govers (1996) illustrate this procedure.

5.5. Slope length exponent

5.5.1. Slope length exponent for standard (non-Req) conditions

The slope length exponent is the exponent m in equations 2.10 and 5.1. The RUSLE2 slope length exponent is a function of the rill to interrill erosion ratio just is it was in RUSLE1 [Foster and Meyer, 1975; McCool et al., 1989; AH703 (Renard et al., 1997)]. However, in contrast to RUSLE1 where the slope length exponent is time invariant, the RUSLE2 slope length exponent varies daily as cover-management conditions change. A value for the RUSLE2 slope length exponent for standard, non-Req conditions is computed daily using equations 2.12 and 2.13 (see **Section 5.2**).

5.5.2. Slope length exponent for Req conditions

The erosion processes that occur during the winter Req conditions (see **Section 3.2.5** and RUSLE2 User's Reference Guide) differ from those that occur with standard rill-interrill erosion. Most of the erosion during Req conditions is by surface runoff. The empirically derived RUSLE2 soil length exponent for Req conditions is m = 0.5 (McCool et al., 1989, 2002); [AH703, (Renard et al., 1997)]. The slope length exponent for Req conditions is time invariant and does not vary with the rill to interrill erosion ratio.

The slope length exponent (equations 2.12 and 2.13) for standard, non-Req rill-interrill erosion can be used for the non-Req period (summer period) at Req locations. Standard rill-interrill erosion can be assumed for the summer months at Req locations. This summer period defined for RUSLE2 as the time between the day when average daily temperature becomes greater than 45 ^oF early in the year to the day average daily temperature falls to 35 ^oF late in the year (see **Section 4.5.1**).

5.6. Steepness effect on rill-interrill erosion

5.6.1. Steepness factors for standard (non-Req) conditions

An interrill erosion steepness factor is used in equation 2.11 and 6.13 to compute interrill erosion and to compute the rill to interrill erosion ratio in several equations (e.g., equations 2.13). A steepness relation for rill erosion is needed to compute rill erosion (e.g., equation 6.13) and the rill to interrill ratio in several equations including equations 2.13. Also, a steepness factor equation is needed to compute rill-interrill erosion combined in equation 2.10.

The same equation used for interrill erosion in RUSLE1 is also used in RUSLE2 [Foster, 1982; AH703 (Renard et al., 1997)]:

$$S_i = 3s_i^{0.8} + 0.56 \qquad [5.1]$$

where: S_i = the interrill erosion steepness factor, s_i = steepness of the interrill area (sine of slope angle). Equation 5.1 is referenced to the unit-plot steepness so that the equation gives a value of 1 for nine percent steepness. The interrill steepness is the same as the overland flow path steepness in RUSLE2. However, the overland flow path steepness and the interrill steepness are not always the same as the land steepness. An example is when RUSLE2 is used to compute erosion on ridge side slopes, where the interrill and overland flow path steepness equals the steepness of the ridge side slopes (see RUSLE2 User's Reference Guide).

A simple rill erosion equation is assumed to compute the rill to interrill erosion ratio (Foster and Meyer, 1975). The steepness factor for rill erosion is:

$$S_r = s_r / 0.0896 \quad [5.2]$$

where: S_r = the rill erosion steepness factor and s_r = steepness of the rill area (sine of slope angle). This steepness factor is normalized to the nine steepness of the unit plot. The steepness of the rill area is the same as the overland flow path steepness, which can differ from the land steepness.

A third steepness factor is used to compute rill-interrill erosion in equation 2.10. The relationship of rill-interrill erosion for a wide range of studies is shown in Figure 5.1 (McCool et al., 1987). These erosion data were normalized to the erosion for 20 percent steepness rather than to the unit plot nine percent steepness.

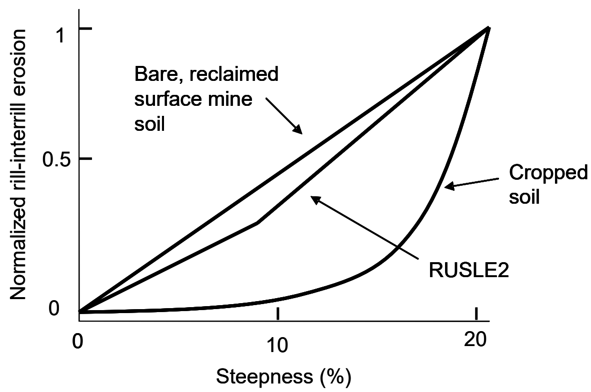

Figure 5.1. Effect of slope steepness on rill-interrill erosion.

The steepness factor for rill-interrill differed greatly among cover-management conditions. At one extreme is where erosion varied linearly for a bare reclaimed, surface mine soil. Steepness had little effect on runoff in this case. At the other extreme is erosion for a cropped soil where the relationship between erosion and steepness is very non-linear. In this case, runoff increased as steepness increased. Most of the erosion for the cropped soil at low steepness is caused by interrill erosion with little or no rill erosion. Once the overland flow path steepness exceeds a critical steepness, rill erosion begins, which results in rill-interrill erosion increasing rapidly. Runoff's shear stress must exceed a critical shear stress for rill erosion to begin, much like contouring failure. The resulting rill erosion equation would have rill erosion being proportional to the difference between shear stress applied to the soil and a critical shear stress related to soil conditions (Meyer et al., 1975b; Foster, 1982; Graf, 1971; Foster et al., 1980a).

The relation of rill-interrill erosion to overland flow path steepness should be a function of the rill to interrill erosion ratio and a critical shear stress at which rill erosion begins. However, in contrast to the temporally varying slope length effect, RUSLE2 uses an invariant slope steepness factor. Although erosion theory indicates reasons why the steepness factor should vary, the experimental plot data were not sufficient to develop a RUSLE2 steepness factor as a function of the rill to interrill erosion ratio, critical shear stress, or other variables. Consequently, RUSLE2 uses the invariant steepness relationship illustrated by the middle curve in Figure 5.1. The equation for that curve is given by [McCool et al., 1987; AH703 (Renard et al., 1997)]:

$$S = 10.8s + 0.03 \quad s_p < 9\% \quad [5.3]$$

$$S = 16.8s - 0.50 \quad s_p \geq 9\% \qquad [5.4]$$

where: S = steepness factor in equation 2.10, s = overland flow path steepness (sine of slope angle) and s_p = overland flow path steepness (100 times tangent of slope angle). Equations 5.3 and 5.4 give a value of 1 referenced to the unit plot 9 percent steepness rather than the 20 percent steepness in Figure 5.1.

5.6.2. Steepness factor for Req conditions

A special steepness factor relationship is used for Req winter conditions because erosion processes for the Req condition differ significantly from the standard rill-interrill erosion conditions. Most of the erosion is caused by surface runoff during the Req conditions. The empirically derived steepness factor for Req conditions is given by [McCool et al., 1987; McCool et al., 1997; AH703 (Renard et al., 1997)]:

$$S = 10.8s + 0.03 \quad s_p < 9\% \qquad [5.5]$$

$$S = (s / 0.0896)^{0.6} \quad s_p \geq 9\% \qquad [5.6]$$

where: 0.0896 = the sine of the angle for 9 percent unit plot steepness. Equations 5.4 and 5.6 are also referenced to the unit plot steepness.

Equations 5.3 and 5.4 can be used for the summer period at locations where the Req winter effects occur.

5.7. Topographic relationships for short overland flow paths (x ≤ 15 ft)

Equation 2.10 does not apply for short overland flow path distances because these equations compute a zero erosion rate for a zero overland flow path length. Erosion rate should equal the interrill erosion rate at the origin of overland flow (x = 0). Experimental interrill erosion studies show that overland flow path length must be about 15 feet before rill erosion begins to occur (Meyer and Harmon, 1989), a distance that is also consistent with field observations, including rainfall simulator studies of the variables that affect rill-interrill erosion (Meyer et al., 1975ab). Therefore, equation 2.10 is assumed not to apply to short overland flow path distances less than 15 ft.

5.7.1. Overland flow steepness < 9 percent

The overland flow path distance x is set to 15 ft when the actual overland flow path distance is less than 15 ft to represent the concept that interrill erosion is independent of distance. The preferred steepness factor for interrill erosion is equation 5.1, but his equation conflicts with the empirically derived rill-interrill erosion S factor given by equation 5.3 for steepness less than 9 percent. Therefore, the rill-interrill erosion steepness factor, equation 5.3, is used for all overland flow distances less than 15 ft if the overland flow path steepness is less than 9 percent. The variables used for $(x/\lambda_u)^m S$ in equation 2.10 are $(15/72.6)^m S_i$ where S_i is the rill-interrill steepness factor computed from equation 5.3, 15 = 15 ft, the overland flow path length assumed for all overland flow path lengths less than 15 ft, and 72.6 = 72.6 ft, the unit plot length.

5.7.2. Overland flow path steepness ≥ 9 percent

5.7.2.1. Overland flow path length ≤ 3 ft

The inconsistency between the interrill steepness factor, equation 5.1, and the rill-interrill steepness, equation 5.4, does not occur when overland flow path steepness exceeds 9 percent. If the overland flow path length is less than or equal to 3 ft, the rill-interrill steepness factor in equation 2.10 equals the interrill steepness factor, equation 5.1. The overland flow path distance is set to 15 ft regardless of actual overland flow path distance. The variables used for $(x/\lambda_u)^m S$ in equation 2.10 are $(15/72.6)^m S_i$ where S_i is the interrill steepness factor computed from equation 5.1, 15 = 15 ft, the overland flow path length assumed for all overland flow path lengths less than 15 ft, and 72.6 = 72.6 ft, the unit plot length.

5.7.2.2. Overland flow path 3 ft < x ≤ 15 ft

A logarithmic interpolation is used to transition between the interrill steepness factor, equation 5.1, at a 3 ft overland flow distance to the rill-interrill steepness factor, equation 5.4, at a 15 ft overland flow distance. This interpolation is computed as:

$$\alpha_3 = (3/72.6)^m S_i \qquad [5.7]$$

$$\alpha_{15} = (15/72.6)^m S \qquad [5.8]$$

where: α_3 and α_{15} = the combined distance and steepness factor for 3 ft and 15 ft overland flow path lengths, respectively, at the given steepness, 15 = 15 ft, the assumed overland flow path distance for all actual overland flow path distances less than 15 ft. The interrill steepness factor S_i, equation 5.1, is used to compute and S = the rill-interrill steepness factor, equation 5.3, is used to compute the steepness effect at a 15 ft overland flow distance. A logarithmic interpolation is made between α_3 in equation 5.7 and α_{15} in equation 5.8 as:

$$\ln(\alpha_x) = [\ln(\alpha_{15}) - \ln(\alpha_3)][(\ln(x) - \ln(15)]/[\ln(15) - \ln(3)] + \ln(\alpha_3) \qquad [5.9]$$

$$\alpha_x = \exp[\ln(\alpha_x)] \qquad [5.10]$$

where: α_x = the combined length and steepness factor at the overland flow distances between 3 and 15 ft and an overland flow path steepness greater than 9 percent. This distance and steepness factor value is used in equation 2.10 for the variables $(x/\lambda_u)^m S$.

5.8. Effect of position along overland flow path on soil loss tolerance (T) factor

The powerful conservation planning approach of comparing an estimated erosion rate to an allowable erosion rate developed in the mid 1940's (Mannering, 1981; McCormack and Young, 1981; Toy et al., 2002). Erosion control practices resulting in an estimated erosion rate that is less than the allowable erosion rate are considered to provide adequate erosion control for the site. Soil loss tolerance (T) values assigned to soil mapping units in the USDA-NRCS Soil Survey are widely used for allowable erosion rate on croplands.[42] Other values for the erosion control criteria are used when RUSLE2 is applied to other lands including construction sites and rangelands. For example, very low soil loss tolerance values are used for very fragile soils that are easily damaged by erosion. Soil loss tolerance values larger than those used for cropland are often used for construction sites for the disturbance and reclamation periods. However, cropland soil loss tolerance values are used for the after-reclamation period where maintenance of the soil for long-term vegetation production is the primary erosion control concern.

Erosion is not considered excessive if the estimated erosion rate is less than the T value. The procedure implicitly assumes a uniform overland flow path, which is common practice in most erosion prediction applications and in research used to determine soil loss tolerance (T) values. The average erosion rate for the entire overland flow path, rather than maximum erosion rate, is compared to the soil loss tolerance (T) value.

The erosion rate computed with RUSLE2 varies along even a uniform overland flow path from an interrill erosion rate at the origin of overland flow ($x = 0$) to ($m+1$) times the average erosion rate for the entire overland flow path length at the end of the path ($x = \lambda$). Therefore, erosion rate over the approximate lower one half of uniform overland flow paths exceeds T when the average erosion rate for the overland flow path equals T. That is, the conservation planning criteria does not require that maximum erosion rate along an overland flow path be less than soil loss tolerance; only that average erosion rate for a uniform overland flow path be less than soil loss tolerance [AH703 (Renard et al., 1997); Toy et al., 2002].

Comparing average erosion rate for the overland flow path to soil loss tolerance is not appropriate for overland flow paths on non-uniform shape profiles, especially convex profiles. To make these comparisons, RUSLE2 computes an adjusted soil loss tolerance value that is compared against the RUSLE2 estimated erosion rate for each segment along a non-uniform overland flow path (see the RUSLE2 User's Reference Guide). The comparison with the adjusted T value puts conservation planning on the same basis for non-uniform overland flow paths as for a uniform overland flow path. The adjusted soil

---

[42] Soil loss tolerance (T) values have a specific definition in the NRCS Soil Survey and NRCS RUSLE2 applications. However, T in general RUSLE2 applications refers to the erosion control criteria used in a specific RUSLE2 application. This value can be quite different from the assigned NRCS T value depending on the application. See the RUSLE2 User's Reference Guide.

loss tolerance values are the T factor values for the soil on *jth* segment times a factor value computed with [(AH703 (Renard et al., 1997)]:

$$F_j = (x_j^{m_i+1} - x_{j-1}^{m_i+1})/[(x_j - x_{j-1})\lambda^{m_i}] \qquad [5.11]$$

where: F_j = the factor that is used to multiply the soil loss tolerance (T) value to obtain a soil loss tolerance value adjusted based on the position of the *jth* segment along the overland flow path, x_j = distance to the lower end of the *jth* segment, m_j = slope length exponent for the *jth* segment, and λ = the entire length of the overland flow path. The ratio of computed erosion rate to the adjusted soil loss tolerance value is the same for all segments along a uniform overland flow path.

5.9. Conservation planning soil loss

RUSLE2 computes a conservation planning soil loss where deposition is given partial credit based on the location where the deposition occurs along the overland flow path. This type of deposition, which is referred to as remote deposition, occurs on concave overland flow path profiles and at the upper edge of dense vegetations strips. The use of conservation planning soil loss in conservation planning is discussed in the RUSLE2 User's Reference Guide, and the equations used to compute a value for conservation planning soil loss are given in **Section 2.3.10.4**.

Partial credit for deposition as soil saved also is taken with terraces. The deposition credit decreases as terrace spacing increases beyond 90 ft. However, the credit for deposition remains constant for terrace spacing closer than 90 ft.

High ridges spaced about 3 ft apart on a uniform, nearly flat grade act like small terraces. RUSLE2 can be applied to the ridge side slopes just like RUSLE2 is applied to the inter-terrace interval. The furrows between the ridges act like terrace channels. The deposition in the furrows should be treated as local deposition rather than remote deposition. The conservation planning soil loss that RUSLE2 computes for this case incorrectly assumes that this deposition is remote deposition. The user should ignore the conservation planning soil loss and use sediment yield as the conservation planning soil loss.

5.10. List of symbol

a = coefficient that is product of terms that do not vary with x in $D = ax^m$

a_e = product of terms that do not vary with x in $D = a_e x_e^m$ when x_e is the overland flow distance adjusted in proportion to upslope drainage area for converging runoff surface

a_p = product of terms that do not vary with x in equation $D = a_p x^m$ when runoff streamlines are parallel

a_T = product of terms that do not vary with x in sediment transport capacity equation $T_c = a_T q$

A = average combined rill-interrill erosion rate for the slope length λ (mass/area·time)

D = combined rill-interrill erosion (detachment) rate at location x along an overland flow path (mass/area·time)

D_i = interrill erosion rate (mass/area·time)

D_r = rill erosion rate (mass/area·time)

D_{rc} = capacity rill erosion rate (mass/area·time)

F = factor used to multiply soil loss tolerance (T) to obtain adjusted soil loss tolerance value based on position of segment along overland flow path

g = sediment load (mass/width·time)

g_λ = sediment load at end of overland flow path

k_c = product of terms that do not vary with x in equation $A = k_c\lambda^m$

k_r = product of terms that do not vary with x in rill erosion equation $D_r = k_r x$

m = slope length exponent

q = discharge rate (volume/width·time)

q_c = discharge rate at which runoff shear stress applied to soil equals the soil's critical shear stress

s = overland flow path steepness (sine of slope angle)

s_i = interrill area steepness (sine of slope angle)

s_p = overland flow path steepness (100 times tangent of slope angle)

s_r = rill area steepness (sine of slope angle)

S = combined rill-interrill erosion steepness factor

S_i = interrill erosion steepness factor

S_r = rill erosion steepness factor

T = soil loss tolerance (mass/area·time)

T_c = runoff's sediment transport capacity (mass/width·time)

$T_{c\lambda}$ = runoff's sediment transport capacity at end of overland flow path (mass/width·time)

W = width of runoff surface at location x (length)

x = distance along overland flow path (length)

x_e = distance along overland flow path that is proportional to upslope drainage area for converging runoff surface (length)

α_x = combined length and steepness factor at overland flow distances between 3 and 15 ft and overland flow path steepness greater than 9 percent

α_3 = combined distance and steepness factor for 3 ft overland flow path length at a particular steepness

α_{15} = combined distance and steepness factor for 15 ft overland flow path length at a particular steepness

Δ = change in a variable

β = ratio of rill erosion sediment load to interrill erosion sediment load

λ = overland flow path length

λ_u = unit plot overland flow path length (72.6 ft, 22.1 m)

ρ = term in equation $\beta = \rho x$

σ = excess rainfall rate (length/time)

Indices

j – segment

5.Appendix 1. Slope length exponent that varies with position

5.Appendix 1.1. Derivation of equations

The RUSLE2 slope length exponent m does not vary with position along the overland flow path. The topographic equations for the slope length exponent m varying with position along the overland flow path are much more complex than the equations used in RUSLE2. The additional complexities and reduced robustness did not warrant their use in RUSLE2 for routine erosion-control planning in local field offices. However, a variable slope length exponent m that varies with position along the overland flow path is very important for applying RUSLE2 to landscapes where surface runoff converges or diverges. Representation of flow convergence/divergence must be considered when RUSLE2 equations are used in GIS models applied to three dimensional landscapes.

In the 1940's when erosion prediction was first developed as an erosion-control planning tool, the following simple empirical equation became widely accepted for describing how erosion varies with overland flow path length for uniform slopes (Zingg, 1940).[43]

$$A = k_c \lambda^m \qquad \text{[V.1]}$$

where: A = average erosion rate (mass/area·time) for the slope length λ, k_c = a term that combines the other terms used to compute A that are not a function of λ, and m = the slope length exponent. Equation V.1 is a derived equation. The equation that actually represents the measured field data is:

$$g_\lambda = k_c \lambda^{m+1} \qquad \text{[V.2]}$$

where: g_λ = the sediment load (mass/width·time) at the end of the slope length λ, which was the measured sediment discharge from the plots used to measure erosion. The term A in equation V.1 was determined by dividing equation V.2 by the slope length λ. Soil loss A was the variable needed in erosion-control planning.

Equation V.2, not equation V.1, is the starting point for developing RUSLE2 (and the USLE and RUSLE1) equations that represent spatial variability along overland flow paths (Foster and Wischmeier, 1974). The equation for detachment at any point along a uniform overland flow path can be derived by differentiating equation V-2 as:

$$D = dg / dx \qquad \text{[V.3]}$$

where: D = detachment rate (mass/area·time) at the location x along an overland flow path. The derivation of a detachment equation is simple where the slope length exponent m is not a function of position x along the overland flow path. By inspection, equation

[43] Uniform means that steepness does not vary with x and the surface runoff streamlines are parallel.

V.2 is recognized to compute sediment load g (mass/width·time) at any position x along a uniform slope as well as sediment load at the end of the overland flow path. If m does not vary with position, the detachment equation is:

$$D = (m+1)k_c x^m \qquad \text{[V.4]}$$

Equation V.4 is equation 2.10 with terms except x and m combined in k_c. **Thus, equation 2.10 is based on the assumption that m does not vary with x**. Consequently, the rill to interrill erosion ratio term in equation 2.13 does not contain a distance (x or λ) term. Equation V.4 does not correctly compute detachment if m is varied by segment. If that computation is attempted, sediment load values at the end of the overland flow path for a uniform overland flow path become a function of how many segments and their lengths that are used to divide the overland flow path even if conditions do not vary between segments. **Therefore, if the slope length exponent m is to vary with position x, a new detachment equation must be derived to replace equation 2.10**.[44]

The slope length exponent m was observed to vary from about 0 to 1 for measured ersion data (McCool et al., 1989). Other than m increasing with slope steepness up to five percent steepness, possible reasons for m varying did not seem to be understood when the USLE was developed (Wischmeier and Smith, 1975; Foster and Meyer, 1975).

As early as the mid 1940's, detachment on overland flow areas was recognized to be caused by raindrop impact and surface runoff (Ellison, 1947). Detachment by flow varied much more along the overland flow path than detachment by raindrop impact. These terms are written as (Meyer and Wischmeier, 1969; Foster and Meyer, 1975):

$$D = D_r + D_i \qquad \text{[V.5]}$$

where: D_r = rill erosion (mass/area·time), D_i = interrill erosion (mass/area·time), and D = the total of rill and interrill erosion (mass/area·time) at the location x. Interrill erosion is assumed not to vary along a uniform overland flow path, while rill erosion is assumed to vary with (Foster and Meyer, 1975):

$$D_r = k_r x \qquad \text{[V.6]}$$

where: k_r = a product of terms that do not vary with x. The combined equation for rill-interrill erosion is therefore:

---

[44] RUSLE2 did not have the slope length exponent m as a function of x to avoid extrapolation too far beyond the experimental data. Only two sets of plots used to derive RUSLE2 had overland flow path lengths greater than 150 ft. Not having the slope length exponent vary with position x significantly increases RUSLE2's robustness, which is important for an erosion control planning tool.

$$D = k_r x + D_i \qquad [V.7]$$

Equation V.4 was chosen as the basic RUSLE2 detachment equation because a wide array of empirically derived and **accepted** factor values are available for that form (see **Section 1**). Equation V.7 was used to extrapolate equation V.4 to conditions beyond that represented in the USLE plot data.

The RUSLE2 approach was to start with equation V.4 and mold it to equation V.7 as much as possible. However, the difference in equation form between equations V.4 and V.7 causes conflict within RUSLE2. Rules were established to deal with those conflicts (see **Section 2.3.8.3**).

The m value for equation V.7 increases from 0 at x = 0 to 1 as either x or k_r becomes large or D_i becomes small (McCool et al., 1989). Mathematical analysis of equation V.7 shows that the slope length exponent m varies from 0 to 1 and is a function of the rill to interrill erosion ratio as (Foster and Meyer, 1975):

$$m = \beta / (\beta + 1) \qquad [V.8]$$

where: β = the ratio of rill sediment load to interrill erosion sediment load, which is equation 2.12. The equation for β from equation V.7 is:

$$\beta = \frac{(k_r x / 2)}{D_i} \qquad [V.9]$$

which is equation 2.13 with an x term in the numerator.

Equation V.9 can be simplified to:

$$\beta = \rho x \qquad [V.10]$$

where: $\rho = k_r/2D_i$. Substitution of equation V.10 into equation V.8 gives:

$$m = \rho x / (\rho x + 1) \qquad [V.11]$$

Substitution of equation V.11 into equation V.2 gives:

$$g = k_c x^{[\rho x / (\rho x + 1)] + 1} \qquad [V.12]$$

The equation form for sediment load when the slope length exponent m varies with position x differs significantly from equation V.2, which is the RUSLE2 form. An equation for D can be derived by differentiating equation V.12 with respect to x. The resulting equation is much more complicated than equation V.4 used in RUSLE2. However, equation V.12 can be solved numerically to determine values for average detachment for a segment to route sediment downslope as described in **Section 2.3**. However, equation V.12 was not used in RUSLE2 because of concerns about its robustness.

Equation V.12 is based on the assumption that equation V.6 describes rill erosion. Equation V.6 could be written as:

$$D_r = k_r q \qquad [V.13]$$

where: q = discharge rate (volume/width·time), q = σx where σ = excess rainfall rate (length/time) that is assumed to be constant along the overland flow path, and k_r = a collection of terms that do not vary with x.

A case can be made for two other rill erosion equation forms. One form is (Meyer et al., 1975):

$$D_r = k_r(q - q_c) \qquad if\,(q \le q_c) D_r = 0 \qquad [V.14]$$

where: q_c = the discharge rate where runoff shear stress applied to soil exceeds the soil's critical shear stress and rill erosion begins and k_r = the collection of terms that do no vary with x.

A case can also be made for (Foster and Meyer, 1975):

$$D_r = D_{rc}(1 - g/T_c) \qquad [V.15]$$

where: D_{rc} = detachment capacity (mass/area·time) computed with equation V.6 or V.14 and T_c = runoff's sediment transport capacity (mass/width·time). Transport capacity is computed with:

$$T_c = a_T q \qquad [V.16]$$

where: the term a_T is the product of terms that do not vary with position x. Equation V.15 reduces rill erosion as transport capacity becomes filled with sediment on long overland flow paths or where sediment production rate by rill or interrill erosion is very high.

As Figure V.1 shows, the ax^m form (equation 2.10) fits well the equation form D_i+k_rx except for short overland flow paths. This deficiency is corrected as described in Section 5.7. However, neither of these two equation forms fits V.14 or V.15, an equation form that involves a critical shear stress term for estimating rill erosion.

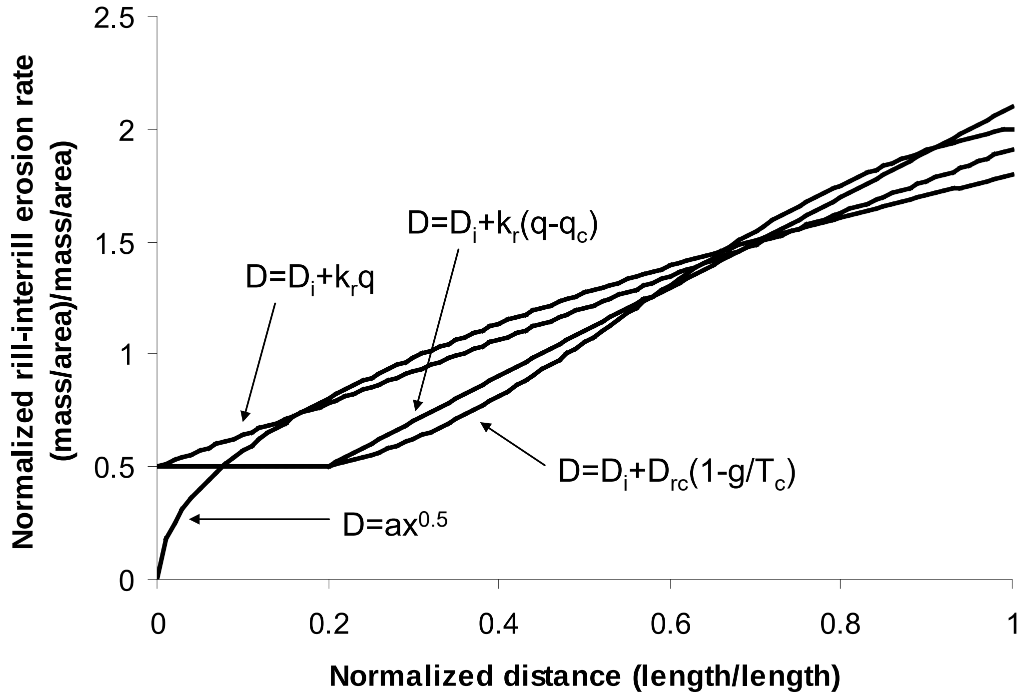

Figure V.1. Variation of detachment along an overland flow path for various rill erosion equation forms.

These advanced rill erosion equation forms greatly complicate RUSLE2 mathematics and further reduce RUSLE2's robustness of. A questionable gain in accuracy while losing robustness is not a wise choice for RUSLE2 as an erosion control planning tool. Choices were made in RUSLE2 that favor robustness for erosion control planning. RUSLE2 may not be as accurate as it could be but it is less likely to give poor results because of uncertainties when extrapolated.

5.Appendix 1.2. Implications for use of RUSLE2 in GIS models

A sediment transport capacity equation should be included with RUSLE2 detachment equations when RUSLE2 is used in a GIS model that computes that computes the spatial variability in erosion and deposition over the landscape. Equation 2.10 is used to compute sediment production (detachment) and equation 2.17 and other equations are used to compute deposition. A sediment transport capacity is required to compute deposition, and a deposition equation like equation 2.16 should be used also. The RUSLE2 sediment production equation (i.e., equation 2.10) does not and can not be used to compute deposition that occurs on the toe of many natural hillslopes.

Also, the RUSLE2 detachment equation 2.10 should be modified to compute how erosion varies with either converging or diverging surface runoff. Applying equation 2.10

without varying the slope length exponent m can result in significant error, even when the overland flow path length is varied in proportion to upslope drainage area.

5.Appendix 1.2.1. Computing detachment and sediment transport capacity

RUSLE2 computes sediment transport capacity per unit width as a function of discharge rate per unit width. An equivalent overland flow path length can be used to represent a converging or diverging landscape to compute discharge rate per unit width and sediment transport capacity per unit width. However, RUSLE2 does not compute the proper sediment production (detachment) values because equation 2.10 does not contain a runoff term. The equivalent overland flow path length that works for computing sediment transport capacity is not the equivalent length required to compute detachment. Furthermore, even though the overland flow path length is adjusted, the slope length exponent m also should be varied with position along the overland flow path to properly represent convergence/divergence in computing detachment with equation 2.10.

5.Appendix 1.2.2. Equations for RUSLE2 in a GIS model

A simple erosion model can be used to evaluate the behavior of RUSLE2 equations in a GIS model. The watershed for a single rill on a hillslope where the streamlines are parallel is a rectangle of width W and length λ. The watershed for a single rill on a converging surface is pie (wedge) shaped. The width at the upper end is 2W and 0 at the lower end. Figure V.2 shows a plot of computed erosion along the overland flow path where streamlines are parallel and where streamlines converge. Erosion was computed with the equation form D_i+k_rq using discharge rate computed by multiplying the excess rainfall rate by the upslope area divided by the watershed width at x. This equation form is assumed to give the desired values, and thus the other equation forms are compared against this one.

The x in the ax^m equation form in Figure V.2 is proportional to upslope drainage area. As Figure V.2 shows, the ax^m approximation does well where streamlines are parallel except for short overland flow paths. In contrast, the ax^m approximation does not work well where the streamlines converge.

When discharge is assumed to be a broad sheet flow across the individual rill watersheds, discharge rate rapidly increases and approach infinity as x approaches λ, the overland flow path length. A corresponding increase in rill erosion is computed. An infinite discharge rate per unit width at $x = \lambda$ computes an infinite rill erosion rate. Such high erosion rates near the end of converging surfaces are not observed in the field. Consequently, the broad sheet flow assumption should not be used without carefully constructed limits on converging surfaces. This problem does not exist on diverging surfaces.

A better approach than assuming broad sheet flow across the entire rill watershed is to assume that surface runoff is concentrated in defined rills. The overland flow path ends where the interrill path length becomes zero, which is where the rill edges meet. Discharge rate (volume; not volume per unit width) does not go to infinity, which means that rill erosion rate does not go to infinity (Toy and Foster, 2000).

The other equation form evaluated in Figure V.2 is equation V.12 where the slope length exponent varies with distance along the overland flow path. This equation was solved numerically to compute detachment along the overland flow path. In these computations, the slope length exponent m was varied with discharge rate rather actual distance to reflect the increase in rill erosion as the surface runoff converges. This approach, while improved, is less than satisfactory.

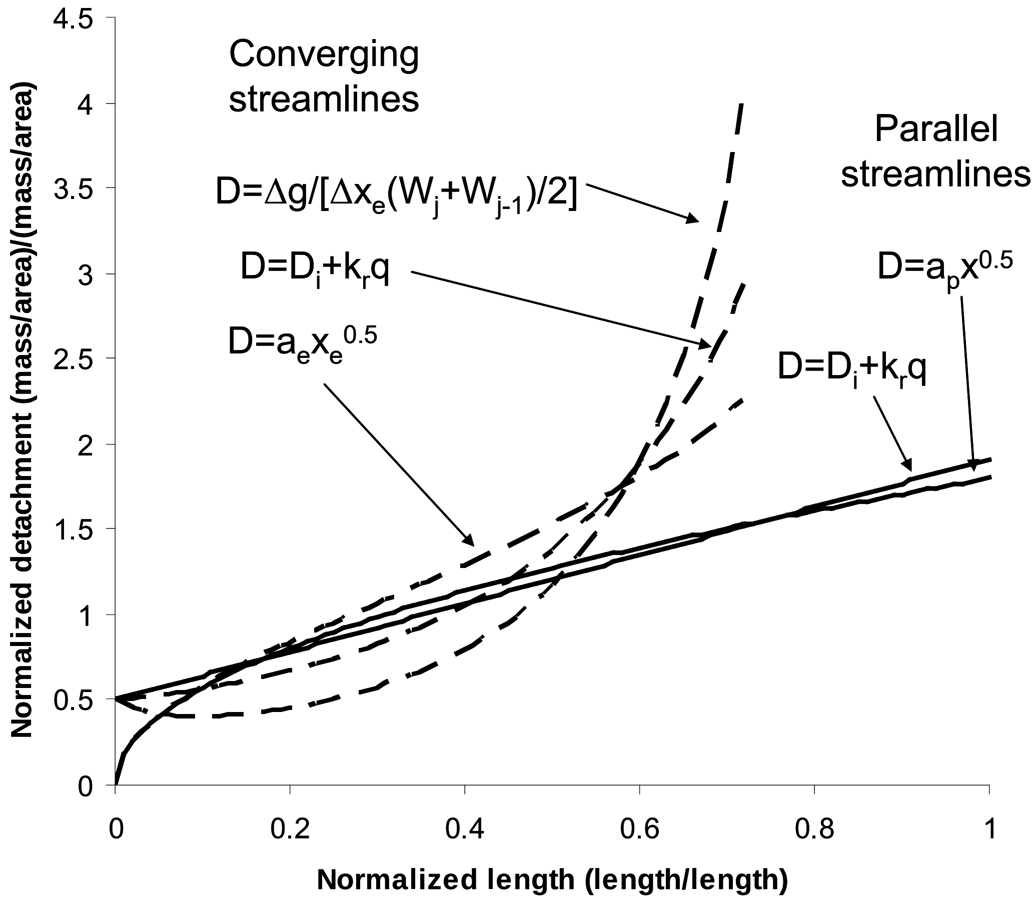

Figure V.2. Erosion along the overland flow paths for parallel and for a converging streamlines.

None of the approximations compare well to the preferred erosion equation that has separate terms for rill and interrill erosion. The best approach in applying RUSLE2 in a GIS model is to devolve the equation 2.10 into separate terms for rill and interrill erosion. Discharge rate can be computed and used directly in both the detachment and sediment transport equations without having to make the overland flow path length proportional to upslope drainage area. This approach would significantly simplify RUSLE2 and would remove the inconsistencies between equation forms.

6. COVER-MANAGEMENT

Equation 2.10 includes the term c used to compute the main effect of cover-management on detachment. The c factor is the product of subfactors as:[45]

$$c = c_c g_c s_r r_h s_b s_c s_m \quad [6.1]$$

where: c = daily cover-management factor, c_c = daily canopy subfactor, g_c = daily ground (surface) cover subfactor, daily s_r =soil surface roughness subfactor, r_h = daily ridge height subfactor, s_b = daily soil biomass subfactor, s_c = daily soil consolidation subfactor, and s_m = daily antecedent soil moisture subfactor used when RUSLE2 is applied in Req zones (see RUSLE2 User's Reference Guide). A daily cover-management c factor value is computed using daily values for each of the subfactors in equation 6.1.[46]

6.1. Canopy subfactor

Canopy is live and dead vegetative cover above the soil surface that intercepts raindrops but does not contact the surface runoff. The portion of the above ground plant biomass touching the soil surface is treated as live ground cover. The canopy subfactor equation is (Wischmeier, 1975; Yoder et al. 1997):

$$c_c = 1 - f_{ec} \exp(-0.1 h_f) \quad [6.2]$$

where: f_{ec} = daily effective canopy cover (fraction) and h_f = daily effective fall height (ft). Equation 6.2 is based on how canopy cover affects the impact energy of waterdrops falling from canopy that has intercepted rainfall. The impact energy of a waterdrop striking the soil surface is:

$$e_d = m_d V^2 / 2 \quad [6.3]$$

where: e_d = impact energy of the waterdrop, m_d = waterdrop mass, and V_d = the waterdrop impact velocity.

Canopy cover affects waterdrop impact energy in several ways. Canopy cover increases the size of waterdrops falling from the canopy. Waterdrops falling from canopy have

---

[45] The RUSLE2 subfactor procedure is an extension of the RUSLE1 procedure [AH703 (Renard et al., 1997)]. The RUSLE2 procedure has several scientific improvements and added capability, and it uses of a daily time step rather than the RUSLE1 half-month time step. The RUSLE1 and RUSLE2 subfactor procedures are patterned after ones developed and used by Wischmeier (1975); (Wischmeier, 1978); Dissmeyer and Foster (1981); Mutchler et al. (1982); and Laflen et al. (1985).

[46] This section describes the subfactor relationships. Other sections describe how RUSLE2 computes values for variables used by the subfactor equations.

about a 3 mm drop diameter compared to 1.5 mm for median drop diameter of raindrops (Wischmeier, 1975). Therefore, canopy must be sufficiently close to the ground surface for waterdrops falling from canopy to have reduced impact velocity to offset the increased mass of waterdrops falling from canopy in comparison to raindrops. Because of the increased drop size, the impact energy of water drops falling from tall canopies, (e.g., 30 ft high) exceeds the impact energy of raindrops (Chapman, 1948). Equation 6.2 is based on an assumed 3 mm diameter for waterdrops falling from canopy and empirical fall velocities of waterdrops based on effective fall height h_f (Gunn and Kinzer. 1949).

Equation 6.2 should be interpreted as empirically representing the main effects of canopy cover on detachment with a particular equation form rather than describing how a physical variable, impact energy, affects detachment. Equation 6.2 does not directly represent all of the ways that canopy affects detachment. For example, some of the intercepted rainfall becomes stem flow and reaches the soil surface without falling from the canopy. Also, some of the intercepted rainfall evaporates from the vegetation, never to reach the soil surface by drop impact or stemflow. Also, RUSLE2 does not consider how wind driven rainfall in conjunction with vegetation affects erosion.[47]

Input effective fall height values are chosen based on judgment of how canopy of a particular plant type affects erosion (see RUSLE2 User's Reference Guide). The reference fall height, illustrated in Figure 6.1, is one third of the distance from the bottom of the canopy to the top of a canopy for a cylindrical shaped canopy where the vegetative surface area is uniformly distributed along the vertical axis of the canopy.

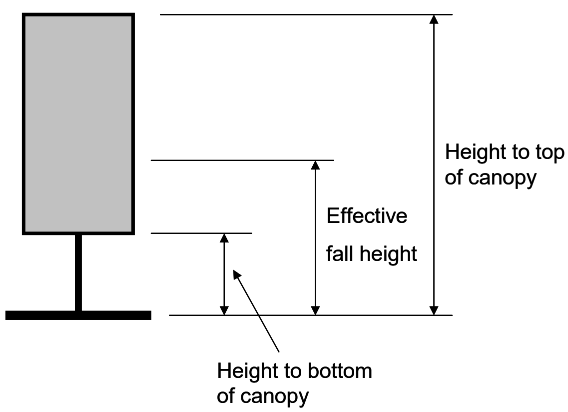

Figure 6.1. Effective fall height for a cylindrical shaped, uniform gradient canopy.

RUSLE2 also includes an equation that can be used to compute effective fall height. The equation is a function of canopy shape, vertical gradient of vegetative surface area, and heights to the bottom and top of the canopy. The effective fall height equation is:

$$h_f = h_b + a_s a_g (h_t - h_b) \qquad [6.4]$$

where: h_b = the height to the bottom of the canopy, h_t = the height to the top of the canopy, and a_s = a coefficient that is a function of canopy shape, and a_g = a coefficient

[47] An improved approach would be to divide equation 6.2 into two parts, one part related to interrill erosion and one part related to rill erosion.

Table 6.1. Values for the coefficient a_s used to estimate effective fall height as a function of canopy

Canopy shape	Value
Inverted trianagle	0.5
Rectangle	0.33
Diamond	0.29
Round	0.29
Triangle	0.25

Table 6.2. Values for coefficient a_g used to estimate fall height as a function of concentration of surface area within canopy.

Location of surface surface area concentration	Value
Top	1.33
Toward top	1.17
Uniform	1.00
Toward bottom	0.88
Bottom	0.75

related to the height within the canopy where vegetative surface area is concentrated. Values for the coefficient a_s and a_g are given in Tables 6.1 and 6.2, respectively.

Some vegetation communities involve multiple plant types that produce over and under stories. RUSLE2 uses only a single set of variables to represent the net effect of canopy on erosion. RUSLE2 does not mathematically combine sets of values for over and under stories nor does RUSLE2 separately compute how each canopy type affects erosion. RUSLE2 uses a single set of values in equation 6.2 to compute the net canopy effect for the vegetation that exists on any given day.

In addition to varying with plant community type, effective fall height varies with production (yield) level and with time as vegetation emerges, grows, matures, and experiences senescence. The RUSLE2 computes effective fall height as a function of production (yield) level and time (see **Sections 9.1** and **9.3.3.3)**.

Canopy cover directly above ground cover is assumed not to affect erosion. The equation used to compute daily effective canopy cover f_{ec} is:

$$f_{ec} = f_c(1 - f_g) \qquad [6.5]$$

where: f_c = daily canopy cover (fraction) and f_g = daily net ground cover, which takes into account the overlap of different types of ground (surface) cover (see **Section 10.2.4**). Net ground cover equals 1 – fraction of the soil surface exposed to direct waterdrop impact from either rainfall or waterdrops falling from canopy.

Furthermore, the RUSLE2 assumption is that canopy cover affects erosion the same way as does ground cover when effective fall height becomes zero. Therefore, the value for the canopy subfactor c_c can not be less than the ground cover subfactor g_c when ground cover equals the effective canopy cover value f_{ec}.

6.2. Ground cover subfactor

Ground cover is provided by material directly in contact with the soil surface. Ground cover affects both waterdrop impact, which in turn affects interrill erosion, and surface runoff, which in turn affects rill erosion. The RUSLE2 equation for the ground cover subfactor is given by (Foster and Meyer, 1975; Laflen et al., 1985; Yoder et al., 1997):

$$g_c = \exp[-bf_g(0.24/R_a)^{0.08}] \qquad [6.6]$$

where: **b** = a coefficient (percent^{-1}) that describes the relative effectiveness of the ground (surface) cover for reducing erosion, f_g = net ground cover (percent), R_a = adjusted roughness used to compute the soil surface roughness subfactor (inches) (see **Section 6.3**), and 0.24 is the assumed adjusted soil surface roughness value (inches) for unit plot conditions. Research has shown that a single variable, portion of the soil surface covered by material directly in contact with the soil surface, describes how all types of ground (surface) cover affects rill-interrill erosion. Analysis based on fundamental erosion mechanics shows that large diameter, long pieces of material, such as intact corn stalks, perpendicular to the overland flow path should affect rill-interrill erosion per unit of soil surface covered more than small diameter, flat pieces (Brenneman and Laflen, 1982). A special concern is how rock fragments on the soil surface affects rill-interrill erosion (see **Section 4.6**). However, when data from various types and rates of surface cover are combined, portion of the soil surface covered seems adequate as a single ground cover variable to use in the ground cover subfactor, equation 6.6 (Box, 1981; Dickey et al., 1983; Dickey et al., 1985; Laflen and Colvin, 1981; Meyer et al., 1972; Simanton et al., 1984; Meyer et al., 1970; Swanson et al., 1965; 1970; Mannering and Meyer, 1963; Meyer and Mannering, 1967).

Net ground cover used in equation 6.6 takes into account the overlap of ground cover materials. For example, applied materials, such as mulch and erosion control blankets, and plant residue are assumed to lie on top of rock cover entered in the RUSLE2 soil input. Live ground cover is assumed to lie on top of applied material and plant residue. Thus, net ground cover (percent) is 100 – bare ground (percent).

The soil surface roughness term in equation 6.6 computes a reduced effect of ground cover on rough soil surfaces. The RUSLE2 assumption is that ground cover in soil depressions is covered by water and deposited sediment, and therefore has no effect on erosion.

The RUSLE2 ground cover subfactor computed with equation 6.6 only partially captures the effect of ground (surface) cover material on rill-interrill erosion. A RUSLE2 ground cover subfactor value is primarily the ratio of rill-interrill erosion at a given point in time with ground (surface) cover to rill-interrill erosion from the same soil in unit plot conditions. The effect most represented by the RUSLE2 ground cover subfactor is how the physical presence of surface cover material affects the erosive forces applied to the soil by impacting raindrops and waterdrops falling from canopy and surface runoff. Other subfactors, such as soil surface roughness and soil biomass, are affected by ground (surface) cover materials (see **Sections 6.3 and 6.5**).

Many of the **b** values reported in the literature were determined by plotting erosion solely a function of ground cover. The RUSLE2 **b** values used in equation 6.6 are not the same as the literature **b** values. The RUSLE2 **b** values are smaller than the literature values because the literature **b** values include other effects not included in equation 6.6. Erosion values were computed with RUSLE1 for a range of corn yields for mulch-till and no-till cropping systems to illustrate this difference. The net **b** value for equation 6.6 without the surface roughness terms fitted to erosion values plotted as a function as cover immediately after planting was 0.058. In comparison, the **b** values used in equation 6.6

as used in RUSLE1 were 0.031 for the mulch till systems and 0.04 for the no-till systems. The conclusion of this preliminary analysis using RUSLE1, which uses a similar but simpler cover-management subfactor method, is that **b** values used in the RUSLE2 subfactor method can not be compared to widely reported literature values. Also, terms in addition to ground cover are needed in the RUSLE2 subfactor procedure to adequate how cover-management affects erosion, even for the same cover-management practice.

6.2.1. b value (ground cover effectiveness index)

6.2.1.1. Literature b values

Research shows that **b** values derived from measured erosion data range from approximately 0.025 to greater than 0.1 (Box, 1981; Colvin and Gilley. 1987; Dickey et al., 1983; Gilley et al., 1986; Laflen et al., 1980; Laflen and Colvin, 1981; Mannering and Meyer, 1963; Meyer and Mannering, 1967; Meyer et al., 1970; Meyer et al., 1972; Simanton et al., 1984). The reason for a variation in **b** is obvious in some cases. For example, Mannering and Meyer (1963) and Meyer and Mannering (1967) conducted two similar studies involving wheat straw applied to recently tilled soil. In one case, infiltration increased significantly as mulch rate increased, which in turn gave a larger **b** value than was the case where mulch rate did not affect infiltration. In some cases, large **b** values resulted when other effects of a tillage system including soil surface roughness and residue incorporation were lumped with the ground cover effect.

6.2.1.2. Rill-interrill effect on b values

Another reason for a range of **b** values is related to the erosion mechanics of rill and interrill erosion. A given amount of ground cover reduces rill erosion more than interrill erosion as illustrated in Figure 6.2 (Foster and Meyer, 1975). The term in equation 2.13 that represents the effect of ground cover on the rill to interrill erosion ratio is:

$$\frac{g_{cr}}{g_{ci}} = \left[\frac{\exp(-b_r f_g)}{\exp(-0.025 f_g)} \right] \qquad [6.7]$$

where: g_{cr} = the surface cover subfactor for rill erosion, g_{ci} = the surface cover subfactor for interrill erosion, b_r = the coefficient for how ground cover affects rill erosion and 0.025 = the value for the coefficient for how ground cover affects interrill erosion.[48] Consequently, RUSLE2 **b** values range between the **b** value (0.025) for interrill erosion and the **b** value (b_r) for rill erosion. The **b** value of 0.025 used in RUSLE2 for interrill

---

[48] Although not used in RUSLE2 an improved approach would be to assume that the **exp** expression for ground cover effect on interrill erosion should end where it becomes tangent to the linear line in Figure 6.2, where values follow the linear line to zero for a completely covered surface.

erosion was derived from the Lattanzi et al. (1974) and McGregor et al. (1988) data (Foster, 1982).

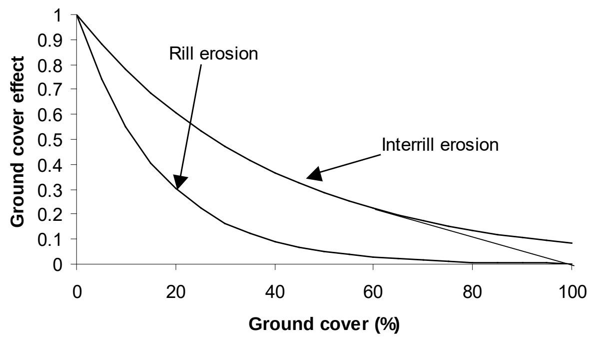

Figure 6.2. Effect of ground cover on rill and interrill erosion

The **b** value for rill erosion is the upper limit for the range of **b** values computed by RUSLE2. A 0.05 b_r value was chosen for soil conditions where ground (surface) cover does not affect infiltration, and the largest values used for b_r by RUSLE2 is 0.06 for situations where increased ground (surface) has a major effect on infiltration. RUSLE2's upper limit on **b** values is less than values reported in the literature, partly because RUSLE2 accounts for other subfactor effects that researchers included in a ground-cover type effect. Also, the reduced upper limit for **b** values was chosen so that RUSLE2 would be conservative in its computations of how much mulch, crop residue, and other ground cover materials reduce erosion for conservation planning purposes.

The coefficient b_r is assumed to increase in RUSLE2 from 0.05 to a maximum of 0.06 as ground cover increases, buried residue in the soil accounting depth increases, and the soil consolidation subfactor decreases. Mechanical soil disturbance is assumed to disrupt macro-pores and large aggregates, which increases runoff and increases erosion for a given ground cover. Conversely, biomass accumulates in a shallow, undisturbed soil surface layer with time after a mechanical soil disturbance increases infiltration, which in turn reduces runoff and rill erosion. The equation for the rill erosion ground cover effectiveness coefficient is given by:

$$b_r = 0.05 + 0.01 c_a \quad [6.8]$$

where: c_a = coefficient for the combined effect of buried residue and soil consolidation on ground (surface) cover effectiveness in relation to rill erosion. The equation for c_a is:

$$c_a = 3.52 \times 10^{-6} B_{rs}^2 (1 - s_c) \text{ if } c_a > 1 : c_a = 1 \quad [6.9]$$

where: B_{rs} = buried residue mass (dry basis) density [$lbs_m/(ac \cdot in)$] in the accounting soil depth d_{rs}. The value for the coefficient c_a varies between 0 and 1. A value of zero is computed when the soil has been recently mechanically disturbed, which sets b_r to a value of 0.05 and a value of 1 for the combination of high buried residue and low soil consolidation subfactor. If a value greater than 1 is computed for c_a, the value is set to 1.

The equation for the soil accounting depth for the effect of buried residue on erosion is given by:

$$d_{rs} = 1 + 2(s_c - 0.45)/0.55 \quad [6.10]$$

where: d_{rs} = the soil depth (inches) over which the density of buried residue mass is computed, 1 = the minimum accounting depth (inches) when the soil is fully consolidated (i.e., s_c = 0.45), 2 = the range (inches) over which the accounting depth varies as a function of the soil consolidation subfactor s_c (see **Section 6.6**), and 0.55 = the range of the soil consolidation subfactor. The maximum accounting depth is 3 inches when the soil has just been mechanically disturbed (i.e., s_c =1).

Values computed by equation 6.10 are rounded to the nearest 1 inch. RUSLE2 divides the soil depth into 1-inch intervals and accounts for soil biomass within these 1-inch intervals. RUSLE2 does not subdivide soil depth intervals further in making its buried residue density computations.

6.2.1.3. RUSLE2 b value equations

RUSLE2 uses a series of equations to compute a **b** value for equation 6.6 based on the fundamental concept that **b** values are a function of the rill to interrill erosion ratio. The starting point for developing these equations is the simple equation that computes erosion when ground cover is present as:

$$D_c = D_b \exp(-bf_g) \quad [6.11]$$

where: D_c = rill-interrill erosion when ground (surface) cover is present and D_b = rill and interrill erosion when ground cover is not present (bare soil). Therefore, a **b** value is computed by rearranging equation 6.11:

$$b = -\ln(D_c / D_b) / f_g \quad [6.12]$$

The equation for rill-interrill erosion D_c when ground cover is present is:

$$D_c = D_{ib}(3s^{0.8} + 0.56)\exp(-0.025 f_g) + D_{rb}(s/0.0896)\exp(-b_r f_g) \quad [6.13]$$

where: D_{rb} and D_{ib} = rill and interrill erosion, respectively, when ground cover in not present (bare soil). A value for rill erosion for bare soil is computed from:

$$D_{rb} = [\alpha/(\alpha + 1)] \quad [6.14]$$

where: the term α in equation 6.14 represents a rill to interrill erosion ratio for bare soil. Equation 6.14 is the same as β in equation 2.13 without the ground cover effect. The term $(3s^{0.8} + 0.56)$ adjusts for the effect of overland flow path steepness on interrill erosion and the term s/0.0896 adjusts for the effect of overland flow path steepness on rill erosion.[49] Rill and interrill erosion D_{rb} and D_{ib} are normalized so that they sum to 1 for a base, reference condition. Consequently, interrill erosion D_{ib} is computed from:

$$D_{ib} = 1 - D_{rb} \quad [6.15]$$

The term D_b in equations 6.11 and 6.12 is computed as:

$$D_b = D_{ib}(3s^{0.8} + 0.56) + D_{rb}(s / 0.0896) \quad [6.16]$$

The next step is to compute a value for the rill to interrill erosion ratio for bare soil as:

$$\alpha = (K_r / K_i) a_2 a_4 \quad [6.17]$$

where: the rill to interrill soil erodibility ratio (K_r/K_i) is computed using equation 4.12 and the coefficients a_2 and a_4 describe how soil consolidation, soil biomass, and conformance of the ground cover to the soil surface affect the rill to interrill erosion ratio for the purpose of computing a **b** value.

The coefficient a_2 is given by:

$$a_2 = a_1 + a_b \text{ if } a_2 > 8 : a_2 = 8 \quad [6.18]$$

where: the coefficient a_1 is given by:

$$a_1 = 1 - \{0.9[(1 - s_c) / 0.55][1 - \exp(-0.0022 B_{rt})]\} \quad [6.19]$$

where: B_{rt} = mass (dry basis) density (lbs_m/acre·inch) of the total of the live and dead roots in the soil accounting depth (10 inches) for roots. The a_1 coefficient represents how the rill to interrill erosion ratio changes as the soil becomes consolidated and as live and dead root biomass in the soil increases. This coefficient reflects how soil consolidation and root biomass affect rill erosion differently than it does interrill erosion.

The coefficient $a_{b,}$ which represents how soil consolidation and buried residue affects the rill to interrill erosion ratio, is given by:

$$a_b = 1.76x10^{-5} B_{rs}^2 (1 - s_c) \quad [6.20]$$

---

[49] No adjustment is made for overland flow path length because of mathematical limitations in devolving the USLE equation structure into rill and interrill terms while meeting the requirement that erosion computed for the entire overland flow path be independent of how many overland flow path segments are used in the computations when other conditions are uniform along the overland flow path.

The a_b coefficient computes the effect of buried residue on the b value increasing as soil consolidation increases, such as for no-till crop, pasture, range, and similar lands that are not mechanically disturbed and B_{rs} = buried residue mass density in the soil accounting depth for buried residue.

Research shows that straw mulch cover is less effective at reducing rill-interrill erosion on steep overland flow paths characteristic of construction sites where mulch is applied to a smooth cut or graded soil in comparison to mulch applied to steep cropland soils [Meyer and Ports, 1976; AH537 (Wischmeier and Smith, 1978), Meyer et al., 1970; 1971; 1972].

RUSLE2 computes this effect assuming that the lost of ground (surface) effectiveness is determined by how well the mulch material conforms to the soil surface and stays in place. The coefficient a_4 describes how conformance of ground cover to the soil surfaces affects the rill to interrill erosion ratio. Poor conformance of ground cover to the soil surface affects rill erosion more than it does interrill erosion. The equation for a_4 is:

$$a_4 = a_3 + (1 - a_3)[1 - \exp(-0.0055 B_{rt})] \qquad [6.21]$$

where: the equation for a_3 is given by:

$$a_3 = \exp[-\psi(\lambda / s^{1/2})^{0.6} s] \qquad [6.22]$$

where: λ = the overland flow path length and ψ = a coefficient that describes conformance of ground cover to the soil surface.

Three classes of ground (surface) cover conformance that vary with material properties are used in RUSLE2 (see RUSLE2 User's Reference Guide). The values used for the conformance coefficient ψ are 0.0 for material like gravel that very closely conforms to the soil surface, 0.15 for materials that conform to the soil surface much like typical pieces of soybean stems and wheat straw after having passed through a combine, and 0.3 for corn stalks and woody debris that do not conform well to the soil surface.

Equations 6.21 and 6.22 compute reduced effectiveness of mulch, erosion control blankets, and similar materials applied on construction sites where overland flow paths are steep and long and no roots or plant stems are present. Both live and dead roots provide plant stems that help hold ground cover in place so that runoff does not dislodge and move mulch downslope or undercut erosion control blankets (Foster et al., 1982a). The tendency for mulch failure and rill erosion under erosion control blankets increases when these materials bridge soil surface roughness elements.

6.2.2. Slope length exponent m

Equations 2.12 and 2.13 are the equations used to compute the slope length exponent **m**. Values for the prior land use residual effect term in equation 2.13 are computed with:

$$c_{pr} / c_{pi} = 0.45 + 1.55(s_c s_b)^2 \qquad [6.23]$$

Equation 6.23 is based on the assumption that soil consolidation and soil biomass have a greater relative effect on rill erosion than on interrill erosion. The term for effective ground cover in equation 2.13 is computed from:

$$f_{ge} = f_g(0.4 + 0.6\delta) \qquad [6.24]$$

where: the cover adjustment term δ is given by:

$$\delta = (b_r - 0.05)/0.01 \qquad [6.25]$$

Equations 6.24 and 6.25 reflects how ground cover has a greater effect on rill erosion than on interrill erosion when the soil has not been mechanically disturbed recently and soil biomass is high in the soil surface layer (e.g., no-till type crop, pasture, range, and similar undisturbed lands).

6.2.3. Non-uniform ground cover

The user can divide the overland flow path into segments to partially represent spatial variability of ground cover. However, RUSLE2 assumes that ground cover is spatially uniform within a segment. When a soil disturbing operation occurs that disturbs only a portion of the soil surface, RUSLE2 computes detachment on both the undisturbed and disturbed portions, and it then determines the overall detachment based on the relative areas of the undisturbed and disturbed portions. An effective ground cover that gives the overall detachment is then back calculated using equation 6.6. The effective surface residue mass associated with that ground cover is determined (see **Section 10.2**). The ratio between this effective mass and the actual mass is maintained as surface residue is lost by decomposition.

6.2.4. b and m values for Req conditions

Most of the erosion during the winter Req period in Req areas is caused by rill erosion. Constant values of 0.50 and 0.046 are used for the slope length exponent **m** and the ground cover effectiveness index **b** for these conditions. These values are based on analysis of experimental research data (McCool et al., 2002).

6.2.5. Comments on b and m equations

The equations used to describe how ground cover affects erosion are empirically based on the RUSLE2 developers' judgment of how various factors affect the ratio of rill to interrill erosion. These empirical equations replace user inputs of selecting LS tables and **b** values [AH703 (Renard et al., 1997)] or land use classes (Toy and Foster, 2000). Although the equations were not fitted to experimental research data, the equations qualitatively represent both laboratory and field research findings.

These equations for **b** and **m** values, along with other cover-management equations, give RUSLE2 its **land use independence**. RUSLE2 uses fundamental variables common to all land uses to compute how cover-management affects rill-interrill erosion.

6.3. Soil surface roughness subfactor

6.3.1. How surface roughness created by mechanical soil disturbance affects erosion

The soil surface roughness subfactor represents how random soil surface roughness created by mechanical soil disturbance affects rill-interrill erosion. Soil surface roughness includes depressions where local deposition occurs and soil peaks of large, stable soil aggregates that are resistant to detachment depending on soil biomass content. Infiltration is increased, which reduces runoff and rill erosion. Also, soil surface roughness slows surface runoff, which reduces its erosivity.

The RUSLE2 equation for the soil surface roughness subfactor is:

$$s_r = \exp[-0.66(R_a - 0.24)] \quad [6.26]$$

where: R_a = daily adjusted roughness value (inches) and 0.24 inches (6 mm) = the adjusted roughness value assigned to unit plot conditions. Equation 6.26 was derived from research measurements of roughness and erosion (Cogo et al., 1984).

The reference condition where the soil roughness subfactor s_r equals 1 is the unit plot condition during and after intense rainfall. The reference unit plot soil surface roughness of 0.24 (6 mm) is produced by a harrow or similar soil finishing tool after disking or similar tools used to prepare seedbeds. Most soil surface conditions are rougher than the unit plot conditions, which give s_r values less than 1. However, some soil surfaces are smoother than the unit plot. Equation 6.26 gives s_r values up to 1.17 for soil surface roughness smoother than 0.24 inches, the roughness value assumed for unit-plot conditions. Mechanical soil disturbing operation such as roto-tilling that finely pulverizes soil, cutting and filling with a blade, and rolling a finely pulverized soil surface produces a surface that is smoother than the unit plot soil surface.

6.3.2. Random roughness as affected by soil biomass

Biomass production (yield) level affects the soil surface roughness subfactor. The effect of biomass production level on the roughness subfactor, as seen in experimental soil loss ratio values [AH537 (Wischmeier and Smith, 1978)] is illustrated in Table 6.3. The roughness subfactor values in Table 6.3 were computed by dividing the soil loss ratio for the fallow crop stage period by the soil loss ratio for the seedbed period.[50] The only essential difference in soil conditions between these two short periods is soil surface roughness.

---

[50] Crop stages are periods where soil loss ratio values are considered constant in the USLE [AH537 (Wischmeier and Smith, 1978)]. The fallow period is for the time between when the soil is first tilled with a primary tillage tool such as a moldboard plow and when the soil is first tilled afterwards with a secondary tillage tool to prepare a seedbed. The seedbed period is the time between the first secondary tillage following primary tillage to when canopy cover of the planted crop reaches 10 percent.

Table 6.3. Effect of corn production level and soil biomass on soil surface roughness subfactor s_r				
		Soil loss ratio		
Yield (bu/acre)	Management	Fallow	Seedbed	Roughness subfactor
112	Grain	0.31	0.55	0.56
87	Grain	0.36	0.60	0.60
67	Grain	0.43	0.64	0.67
49	Grain	0.51	0.68	0.75
112	Silage	0.66	0.74	0.89
87	Silage	0.67	0.75	0.89
67	Silage	0.68	0.76	0.89
49	Silage	0.69	0.77	0.90

Experimental roughness subfactor values increased as production (yield) level decreased as shown in Table 6.3. Similarly, experimental roughness subfactor values [AH537 (Wischmeier and Smith, 1978)], as shown in Table 6.4, were significantly reduced when a corn grain crop followed an established meadow (sod), which has a very high soil biomass. Roughness subfactor values increased as hay yield decreased and increased in the second year of corn following sod. Residual soil biomass was less in the second year after the sod than in the first year immediately after the meadow. Also, roughness subfactor values were higher when corn followed small grain than when it followed sod. The small grain provided less soil biomass than did the sod.

Table 6.4 Effect of sod on soil surface roughness subfactor s_r for moldboard plow period		
Hay yield (tons/acre)	Year after sod	Roughness subfactor
4	1	0.35
2.5	1	0.38
1.5	1	0.39
4	2	0.49
2.5	2	0.50
1.5	2	0.50

Roughness subfactor values are interpreted as being a function of soil biomass level caused by different yield levels, soil biomass level determined by whether crop residue is removed such as with silage or left with grain harvest, and the difference in biomass level caused by type of preceding crop such as hay, small grain, or row crop grain. Recommendations for the USLE [AH537 (Wischmeier and Smith, 1978)] are that non-sod forming meadows such as sweet clover or lespedeza have less effect on rill-interrill erosion than does sod forming vegetation, which is explained by the difference in soil biomass production between these vegetation types.

RUSLE2 computes initial soil roughness after a mechanical soil disturbance as a function of the soil biomass in the soil disturbance depth using:

$$R_{ib} = 0.24 + (R_{it} - 0.24)\{0.8[1 - \exp(-0.0015B_{td})] + 0.2\} \qquad [6.27]$$

where: R_{ib} = the initial roughness adjusted for the soil texture and biomass effect, R_{it} (inches) = the initial roughness after the input roughness value is adjusted for soil texture and B_{td} = the total mass (dry basis) [lbs_m/(acre·inch)] of buried residue and live and dead roots averaged over the soil disturbance depth after the operation. The 0.24-inch value is the roughness value assumed for unit plot conditions. The 0.2 value reflects the portion of the roughness value that is not affected by soil biomass.

6.3.3. Adjusting roughness input values for soil texture

Input roughness entered in the RUSLE2 database for a soil disturbing operation is adjusted for soil texture before equation 6.27 is used to adjust for the soil biomass effect on roughness. The equation that adjusts input roughness values for soil texture is:

$$R_{it} = R_{in}[0.16(P_{sl}/100)^{0.25} + 1.47(P_{cl}/100)^{0.27}] \qquad [6.28]$$

where: R_{in} = the input roughness value entered for a soil disturbing operation in the RUSLE2 database, P_{sl} = percent silt in the soil, and P_{cl} = percent clay in the soil. The roughness values R_{it} adjusted for soil texture are the same as roughness input R_{in} values for the reference silt loam soil texture. Roughness values computed by equation 6.28 are greater than the roughness input values for soils high in clay and less than roughness input values for soils high in sand. Equation 6.28 was developed based on judgment and field observations of how soil surface roughness varies with soil texture when mechanically disturbed.

6.3.4. Assigning input roughness values for operations

Input values entered in the RUSLE2 database for soil surface roughness created by a mechanical soil disturbing operation are assigned according to the soil surface roughness that the operation creates for a base, reference condition. This condition is a smooth, silt loam soil (clay = 15%, silt = 65%) having a very high soil biomass (dry basis) density of greater than 1000 lbs_m/(acre·inch) in the soil disturbance depth, which includes both buried residue and dead roots. These soil biomass levels occur where crop yield exceeds 200 bu/acre corn, 70 bu/acre wheat, and 4 tons/acre hay or pasture land (see RUSLE2 User's Reference Guide).

The roughness index used in RUSLE2 for input values assigned to soil disturbing operations in the RUSLE2 database is the standard deviation soil surface elevations measured on a 1-inch grid. The elevations are relative to a plane that removes elevation differences caused by land steepness and ridges.

6.3.5. Effect of existing roughness at time of soil disturbance (tillage intensity effect)

Roughness left by a soil disturbing operation is a function of the operation itself and existing roughness at the time of the operation. The RUSLE2 assumption is that existing roughness has no effect if the roughness, adjusted for soil texture and biomass, left by a soil disturbing operation is greater than the existing soil roughness at the time of the operation. However, the RUSLE2 assumption is that the roughness left by a soil disturbing operation is a function of existing roughness if the adjusted roughness created by an operation is less than existing roughness. In this case, the resulting roughness is a function of the initial adjusted roughness, existing roughness, and tillage intensity of the soil disturbing operation. Tillage intensity is a measure of the aggressiveness of the soil disturbing operation for obliterating existing roughness. The equation for how existing roughness and tillage intensity affect soil roughness is:

$$R_{aa} = (1-\xi)(R_{ae} - R_{ib}) + R_{ib} \qquad [6.29]$$

where: R_{aa} = the adjusted roughness immediately after a soil disturbing, ξ = tillage intensity for the operation, R_{ae} = existing adjusted roughness immediately before the operation, and R_{ib} = the input roughness for the soil disturbing operation after adjustment for soil biomass and soil texture, which is computed with equation 6.27.

A tillage intensity of 1 means that the soil disturbing operation is so aggressive that existing roughness has no effect on the roughness left by the operation. Examples of these operations include moldboard plows and roto-tillers. Conversely, a tillage intensity of 0 means roughness after the soil disturbing operation is the same as existing roughness before the operation. Harrows that have a tillage intensity of 0.4 are examples of operations where existing roughness has a significant effect on roughness left after a soil disturbing operation.

6.3.6. Roughness decay

Roughness diminishes (decays) after a mechanical soil disturbance because of soil slumping (i.e., settlement and subsidence) caused by the presence of moisture, interrill erosion wearing away roughness peaks, and local deposition in roughness depressions. The RUSLE2 equation used to represent this effect is given by [AH703 (Renard et al., 1997)]:

$$f_r = \exp[-0.07(P_d + I) - 0.006 r_d c_c g_{ci})] \qquad [6.30]$$

where: f_r = the fraction of the current roughness greater than 0.24 inch that remains, P_d = the daily precipitation amount (inches), I = daily amount (inches) of water added by irrigation, r_d = the daily erosivity (US customary units), and g_{ci} = the interrill ground cover factor. The term in equation 6.30 associated with precipitation amount represents roughness loss by settlement and subsidence and the term associated with erosivity represents roughness loss by interrill erosion. The RUSLE2 assumption is that half of the roughness loss is by settlement and the other half is by interrill erosion. Roughness loss by local deposition is not explicitly represented. Roughness decay is not computed as a function of soil properties including texture and soil biomass. The adjustment made to initial roughness by equations 6.27 and 6.28 is assumed to adequately represent the effect of soil texture and soil biomass on roughness at any time.

The interrill ground cover factor is given by:

$$g_{ci} = \exp(-0.025 f_g) \qquad [6.31]$$

where: f_g = the net ground cover (percent). Daily adjusted roughness used in equation 6.26 is computed as:

$$R_a = 0.24 + f_r (R_{ap} - 0.24) \qquad [6.32]$$

where: R_{ap} = adjusted roughness on the previous day. The RUSLE2 assumption is that roughness is not decayed when the input initial roughness in the RUSLE2 database for a soil disturbing operation is less than the unit plot roughness of 0.24 inch.

6.3.7. Base roughness value

The 0.24-inch value in equations 6.27 and 6.32 represents a base roughness value for unit plot conditions. The assumption is that soil clods persist so that the unit-plot surface never becomes perfectly smooth. The unit plot final roughness value is not varied as a function of soil texture because that effect is empirically accounted for in the RUSLE2 soil erodibility factor. However, RUSLE2 allows the user to enter a “final” roughness value for an operation that is greater than 0.24 inch to represent conditions where roughness decays to a final value greater than 0.24 inch. If an input final roughness value greater than 0.24 inch is entered in the RUSLE2 database for a soil disturbing operation, RUSLE2 uses that value instead of the 0.24 value in equations 6.27 and 6.32. RUSLE2 does not allow roughness to decay to a value less than 0.24 inch, even if the input final roughness is less than 0.24 inches. The input initial and final roughness values can be used force RUSLE2 to use a particular roughness in its computations (see RUSLE2 User’s Reference Guide).

6.3.8. Long term roughness development

A natural soil roughness develops over time after the last mechanical soil disturbance. The final natural roughness is a function of soil properties, vegetation characteristics, and local erosion and deposition. RUSLE2 assumes that the time required for this long-term roughness to develop equals the time to soil consolidation (see **Section 4.8**). The RUSLE2 equation used to compute long term roughness is given by:

$$R_l = 0.24 + (R_{alf} - 0.24)/\{1 + \exp[(0.5 - t_d / t_c)/0.1]\} \qquad [6.33]$$

where: R_l = daily long term roughness, R_{alf} = the adjusted final long term roughness value, t_d = number of days since the last mechanical soil disturbance, and t_c = the time to soil consolidation (days). A value for R_{alf} is computed using equations 6.27and 6.28 using the input long-term natural roughness values entered in the RUSLE2 database. The biomass value used in equation 6.27 is based on total soil biomass including buried residue and dead and live roots in the upper 4 inches of the soil. The value input for final long-term roughness for a given cover-management description is relative to the reference condition for short term roughness associated with mechanical soil disturbance (see **Section 6.3.4** and RUSLE2 User’s Reference Guide). RUSLE2 adjusts this input value for soil texture and soil biomass just as it does roughness created by mechanical disturbance. The assumption is that vegetation must be present for long term surface roughness to develop and be effective. Equation 6.33 is illustrated in Figure 6.3 where the time to soil consolidation is 7 years.

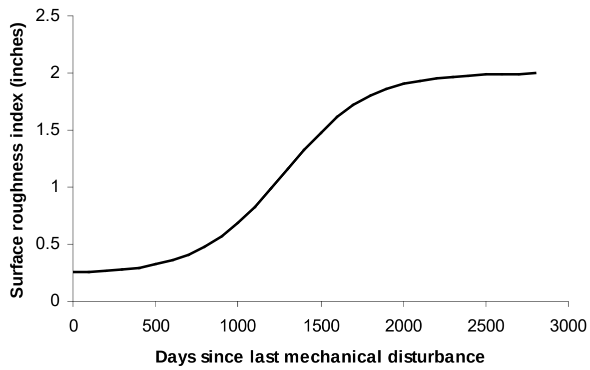

Figure 6.3. Development of long term roughness as a function of time since last mechanical soil disturbance.

RUSLE2 tracks both short term roughness resulting from mechanical soil disturbance and long term roughness development. RUSLE2 uses the maximum of the two roughness values in equation 6.26 to compute a soil surface roughness subfactor value.

6.3.9. Accounting for spatial variability in roughness

RUSLE2 can take soil surface roughness spatial variability partially into account by dividing the overland flow path into segments. However, roughness is assumed to be uniform within a segment. Some mechanical soil disturbing operations disturb the soil in strips. For these operations, RUSLE2 computes soil surface roughness subfactor values for both the undisturbed and disturbed areas and the overall soil surface roughness subfactor value based on the portion of the soil surface that the operation disturbs. RUSLE2 then back-calculates an effective roughness using equation 6.26 that gives the effective roughness subfactor value. This single effective roughness value is assigned to the segment and decayed over time using equation 6.30.

6.3.10. Comments on roughness subfactor

RUSLE2 captures the main effects of roughness on rill-interrill erosion. The intent is not to explicitly model soil roughness to produce roughness values comparable to field measured values except for input values determine from the reference condition (see **Section 6.3.4**). For example, internal RUSLE2 computed roughness values are less than those measured in the field on construction sites where soil clay content is high. The roughness effect on erosion is more than the geometric effect of soil surface roughness slowing runoff, ponding water, and depositing sediment. It also includes an infiltration effect that is less related to soil surface roughness than are the other erosion processes. The adequacy of the soil roughness relationships in RUSLE2 should be judged on the basis of how well RUSLE2 computes rill-interrill erosion as affected by soil disturbing operations that create soil surface roughness.

6.4. Ridge height subfactor

6.4.1. Effect of ridges on rill-interrill erosion

Ridges affect erosion primarily in two ways. When the ridges are oriented parallel to the overland flow path, ridges increase rill-interrill erosion because of increased interrill erosion on the ridge sideslopes. This effect is represented by the ridge height subfactor. When ridges are nearly perpendicular to the overland flow path, ridges alter the runoff flow path by partially redirecting runoff around the hillslope or by ponding runoff behind the ridges if the ridges are perfectly on the contour. This effect of ridges is considered in the contouring subfactor (see **Section 7.1**).

Increased ridge height increases ridge sideslope (interrill) steepness, which in turn increases interrill erosion steepness (Lattanzi et al., 1974). RUSLE2 uses only ridge height to compute ridge height subfactor values although both ridge height and spacing determine interrill steepness. Accurately identifying ridge spacing or number of ridges per unit overland flow path width is difficult whereas ridge height can be easily visualized and measured.

6.4.2. Reference condition for ridge height subfactor

The reference condition for the ridge height subfactor, as with all cover-management subfactors, is the unit plot condition. Unit plots are prepared to a seedbed condition (see **Section 2.1** and **Footnote 3**) using tools like spike tooth harrow that leave small ridges up and down slope. The RUSLE2 ridge subfactor must be 1 for the unit plot condition. Unit plot conditions are not static because the unit plots are periodically tilled to break soil crusts and to control weeds. A ridge subfactor value of 1 for unit plot conditions represents an average over time because of periodic ridge formation and decay.

The ridge subfactor equations are also derived for the reference condition of the ridges being parallel to the overland flow path (i.e., up and down slope).

6.4.3. Ridge height subfactor for low steepness

The RUSLE2 ridge height subfactor is constant for overland flow path steepness less than six percent as determined from experimental data and the judgment of scientists who experimentally measured the effect of ridges on rill-interrill erosion from almost flat slopes (<1%) to land steepness as great as 5 percent (Young and Mutchler, 1969; Mutchler and Murphree, 1985; McGregor et al., 1999).[51] The RUSLE2 ridge height subfactor equations derived from experimental data are:

$$r_{h6} = 0.9(1 + 0.0582H^{1.84}) \quad H \le 3 \text{ inches} \qquad [6.34]$$

$$r_{h6} = 2.136[1 - \exp(-0.484H)] - 0.336 \quad H > 3 \text{ inches} \qquad [6.35]$$

where: r_{h6} = daily ridge height subfactor when the overland flow path steepness is less than or equal to 6 percent and H = daily ridge height (inches). The significance of the 0.9 in equation 6.34 is that the minimum ridge height subfactor is 0.9 for a flat soil surface and the maximum ridge height subfactor from equation 6.35 is 1.8, which is consistent

---

[51] C.K. Mutchler and K.C. MCGregor. 1999. Effect of ridge height on erosion on low slopes. Personal communication. Scientists (retired) at the USDA-National Sedimentation Laboratory, Oxford, Mississippi.

with the values given in AH537 (Wischmeier and Smith, 1978) for applying the USLE to cotton production on high ridges [Mutchler et al., 1982; Mutchler and Murphree, 1985, AH537 (Wischmeier and Smith, 1978)]. Also, equation 6.34 gives a subfactor value of 1 for a ridge height of 1.42 inch, which represents unit plot conditions except for the difference between six percent steepness and the unit plot nine percent steepness.

6.4.4. Adjustment for effect of overland flow path steepness

Interrill steepness is affected by land steepness. Interrill steepness is much greater than land steepness on flat slopes than on steep slopes. For example, local interrill steepness with high ridges (about 8 inches high when formed) like those used in cotton production in the Mississippi Delta is about 20 percent (Meyer and Harmon, 1985; Mutchler and Murphree, 1985), which is the interrill steepness when the land is flat (about 0.5%). As land steepness increases, local interrill steepness increases but much more slowly than does land steepness. Local interrill steepness of the ridge sideslope almost equals land steepness on steep slopes. For example, the same ridges that give a 20 percent steep ridge sideslope on a 6 percent land steepness give a 54 percent interrill steepness on a land steepness of 50 percent. The ridge height subfactor, therefore, approaches 1 for steep overland flow paths.

A simple rill-interrill erosion model was used to develop equations for the ridge height subfactor for overland flow path steepness greater than six percent. That simple equation is:

$$D_t = 0.5[(s/0.0896) + (3s_i^{0.8} + 0.56)] \qquad [6.36]$$

where: the 0.5 represents the assumption that rill and interrill erosion are equal for unit plot conditions (Foster and Meyer, 1975; Foster et al., 1977a, 1977b; Foster, 1982), the term s/0.0896 represents the effect of steepness on rill erosion, and the term $(3s_i^{0.8} + 0.56)$ represents the effect of steepness on interrill erosion. Steepness s_i of the interrill area is greater than the steepness s of the rill area because ridge height increases interrill steepness (i.e., the ridge sideslope steepness).

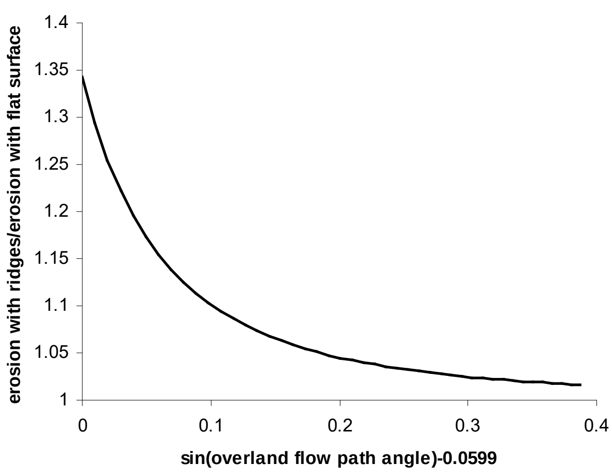

Figure 6.4. Effect of overland flow path steepness on the ratio of erosion with a 20% ridge sideslope to erosion from a flat surface.

Equation 6.36 was solved for overland flow path steepness between and 6 and 50 percent for a range of ridge side slope steepness and for a flat (i.e., non-ridged soil surface). Erosion computed for a given ridge sideslope steepness for a particular flow path steepness was divided by erosion for a flat soil surface at that same overland flow path steepness. An example of those values is shown in Figure 6.4 for a ridge sideslope of 20 percent. The RUSLE2 equations used to represent this effect are:

$$r_h = r_{h6} \quad s_p < 6\% \qquad [6.37]$$

$$r_h = 1 + (r_{h6} - 1)\exp[-a_h(s - 0.05989)] \quad s_p \geq 6\% \qquad [6.38]$$

where: s_p = overland flow path steepness (100 times tangent of slope angle) and a_h is computed from:

$$a_h = 16.02 - 0.927H \quad H \leq 10 \text{ inches} \qquad [6.39]$$

$$a_h = 6.75 \quad H > 10 \text{ inches} \qquad [6.40]$$

where: ridge height H has units of inches.

6.4.5. Effect of row grade on ridge height subfactor

The ridge height subfactor equations given above apply to the reference condition of the ridges being parallel to the overland flow path (i.e., up and down slope). As relative row grade (i.e., ratio of grade along the ridges to overland flow path steepness) decreases from 1 (up and down slope) to 0 (on contour), the ridge subfactor value should become 1. The effect of ridge height on rill-interrill erosion is represented in the contouring subfactor when the ridges are on the contour (see **Section 7.1**). However, this requirement can not be met because of RUSLE2's mathematical structure. Instead, the ridge subfactor value is 0.9 when ridges are perfectly on the contour, which is the ridge height subfactor value for a flat soil surface.

The equations that compute ridge height subfactor values as a function of ridge orientation (i.e., relative row grade) are:

$$r_h = 0.9 - (0.9 - r_{h,u\&d})g_r^2 \quad r_{h,u\&d} \leq 1 \qquad [6.41]$$

$$r_h = 0.9 + (r_{h,u\&d} - 0.9)g_r^2 \quad r_{h,u\&d} > 1 \qquad [6.42]$$

where: $r_{h,u\&d}$ = the ridge height subfactor value when ridge orientation is parallel to the overland flow path, which are computed equations 6.37 and 6.38 and g_r = relative row grade (grade along the ridges/overland flow path steepness).

6.4.6. Ridge height decay

Ridge height decays because of settlement and interrill erosion. Settlement occurs quickly after the ridges are formed when water is presence. The RUSLE2 assumption is that forty percent of the initial ridge height is lost by settlement while the remaining sixty percent is lost by interrill erosion based on analysis of experimental data (Lyles and.

Tatarko. 1987).[52] Thus, the initial ridge height left by a soil disturbing operation is divided into two parts as:

$$H = H_s + H_e \quad [6.43]$$

where: H_s = daily ridge height component associated with settlement and H_e = daily ridge height component associated with interrill erosion. The initial value for H_s is 0.4 times the ridge height left by the soil disturbing operation, while the initial value for H_e is 0.6 times the ridge height left by the soil disturbing operation. The daily settlement component ridge height is computed as:

$$H_s = H_{sp} \exp = [-0.2343(P_d + I)] \quad [6.44]$$

where: H_{sp} = the daily ridge height associated with settlement from the previous day. The daily interrill erosion ridge height is computed as:

$$H_e = H_{ep} - a_e r_d c_c g_{ci} \quad [6.45]$$

where: H_{ep} = ridge height associated with interrill erosion for the previous day and the coefficient a_e is computed as:

$$a_e = 0.033 - 0.002 H_i \quad H_i \le 10 \text{ inches} \quad [6.46]$$

$$a_e = 0.013 \quad H_i > 10 \text{ inches} \quad [6.47]$$

where: the units for a_e are inches/(US customary EI unit) and H_i = initial ridge height left by the soil disturbing operation (inches). The reason for the coefficient a_e is a function of ridge height is the RUSLE2 assumption that high ridges have a wide base so that the overall loss of ridges having a wide base occurs more slowly than does the loss of ridges with a narrow base. The minimum allowable ridge height is zero. These equations and their coefficients were derived from research data (Lyles and Tatarko, 1987) and from field observations in cotton fields in the Mississippi Delta.[53]

6.4.7. Effect of existing ridge height, soil, and cover-management on ridge height when new ridges are formed

The RUSLE2 assumption is that existing ridges have no effect on the ridges created by a soil disturbing operation. Also, the RUSLE2 assumption is that initial ridge height.

---

[52] K.C. McGregor. 1999. Field observations of ridge height decay in the Mississippi Delta. Personal communtation. Scientist (retired), USDA-National Sedimentation Laboratory, Oxford, Mississippi.

[53] McGregor, K.C. 1999. Loss of ridge heights in the spring in the Mississippi Delta. Personal communication. Scientist (retired), USDA-National Sedimentation Laboratory, Oxford, Mississippi.

Ridge height at formation is determined entirely by the soil disturbing operation. The effect of existing ridges and soil and cover-management conditions on ridge height can be taken into account in RUSLE2 by creating multiple soil disturbing operation decriptions having a range of ridge height values. The user then selects a particular operation description for RUSLE2 input that gives the desired ridge height for the given situation.

6.4.8. Comments on ridge height subfactor

The intent in RUSLE2 is to capture the main effect of ridge height on rill-interrill erosion as ridge height interacts with land steepness and to capture the main effect of variables that cause ridge height to decay. The intent is not to explicitly model ridge height. The adequacy of the RUSLE2 ridge height subfactor equations should be judged on the basis of how well RUSLE2 computes rill-interrill erosion as a function of soil disturbing operations that create ridges.

RUSLE2 not giving 1 for the ridge subfactor when ridges are perfectly on the contour is a limitation of RUSLE2's empirical mathematical structure not being consistent with process-based equations. RUSLE2 was constructed so that these problems do not significantly affect RUSLE2's utility as a conservation and erosion control planning tool.

6.5. Soil biomass subfactor

6.5.1. Soil biomass effect

The RUSLE2 soil biomass subfactor estimates how soil biomass affects rill-interrill erosion [Mannering et al., 1968; Foster et al., 1985c; McGregor et al., 1990; Brown et al., 1989; Toy et al., 2002; Van Liew and Saxton, 1983, AH537 (Wischmeier and Smith, 1978)]. Soil biomass represented by RUSLE2 includes buried residue, live roots, and dead roots.

Live roots produce exudates that reduce soil erodibility. Also, live root biomass is a measure of plant transpiration, which reduces soil moisture that in turn increases infiltration and decreases runoff. Dead roots add organic matter to the soil that increases infiltration and decrease soil erodibility. Both live and dead roots mechanically hold the soil in place, hold soil in "clumps" when the soil is mechanically disturbed, and reduce waterdrop impact and runoff erosivity if the roots are exposed.

Buried residue is biomass that has been mechanically incorporated into the soil. RUSLE2 also "incorporates" up to 25 percent of the daily decomposition of surface residue into the soil to represent the accumulation of high organic matter at the soil surface for no-till and other conditions where little or no soil disturbance occurs (Kay and VanderBygaart, 2002; Shelton and Bradley, 1987). Incorporated biomass, such as crop residue, manure, or bio-solids in sewage waste, provides organic compounds that increase infiltration and decrease soil erodibility [Browning et al., 1948; Copley et al., 1944; Hays et al., 1949; AH537 (Wischmeier and Smith, 1978)]. Also, pieces of organic material, such as incorporated crop residue, can be sufficiently large to mechanically reduce rill erosion (Brown et al., 1989).

6.5.2. Soil biomass subfactor equation

The equation for the RUSLE2 soil biomass subfactor is:

$$s_b = 0.951\exp(-0.0026B_{rt} - 0.0006B_{rs} / s_c^{0.5}) \quad s_b \le 0.9035 \qquad [6.48]$$

$$s_b = \exp[-1.9785(0.0026B_{rt} + 0.0006B_{rs} / s_c^{0.5})] \quad s_b > 0.9035 \qquad [6.49]$$

Equation.6.49 is used for very low soil biomass where the soil biomass subfactor s_b is greater than 0.9035. Equation 6.48 does not give the required value of 1 for unit plot conditions that has no soil biomass (i.e., B_{rt} and $B_{rs} = 0$). The common point of s_b = 0.9035 results from the product of 0.951 in equation 6.48 and 0.95, the upper value for which the exp(…) term in equation 6.48 is assumed to apply.

The coefficient values in equation 6.48 were obtained by fitting the equation to soil biomass subfactor values estimated from research-based soil loss ratio values. The values points for no-till and mulch (reduced) till were obtained from the literature.[54] The other values selected from AH537 (Wischmeier and Smith, 1978). These values are given in Table 6.5, and the fit of equation 6.48 to the observed values is shown in Figure 6.5. The data points (soil loss ratio values) shown in Table 6.5 were selected across the range of soil biomass represented by Table 5, AH537. Equation 6.48 fits the observed values well except for the 112 bu/acre corn following 1.5 tons/acre meadow.

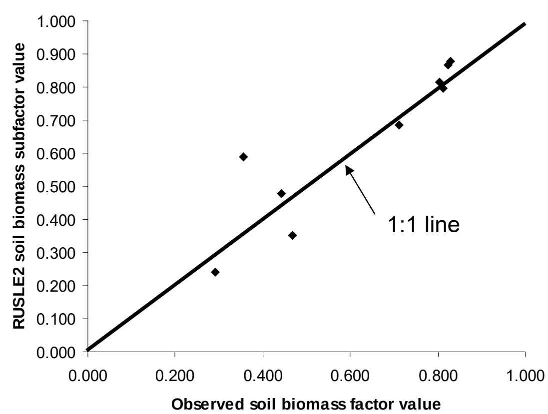

Figure 6.5. Comparison of RUSLE2 soil biomass values to observed values

Observed soil biomass subfactor values were estimated from the soil loss ratio values given in Table 6.5. Soil biomass subfactor values were computed from soil loss ratio values by rearranging equation 6.1 to solve for the soil biomass subfactor and substituting RUSLE2 estimated values for the other subfactors. Soil loss ratio values were substituted for cover-management factor c in equation 6.1.

Using soil loss ratios in Table 5, AH537 for the seedbed crop stage period for conventional, clean tillage,

[54] More than 100 articles were reviewed to evaluate the effect of no-till and mulch till cropping on rill-interrill erosion. Those articles are listed in the **Additional References Section**.

which is most like the unit plot condition, minimizes the error in estimated subfactor values used in equation 6.1 to estimate soil biomass subfactor values. The major subfactor affecting soil loss ratio values for the seedbed crop stage for conventional, clean tillage is soil biomass although some ground (surface residue) cover is present and soil surface roughness is rougher than for unit-plot conditions.

Soil loss ratio values given in Table 5, AH537 are assumed to apply to the reference silt loam soil at Columbia, Missouri. RUSLE2 was used to compute subfactor values for ground cover (surface residue) and surface roughness for all conditions listed in Table 6.5 and soil consolidation for the no-till data condition. The canopy subfactor value was 1 for all conditions and the soil consolidation subfactor was 1 except for no-till. RUSLE2 was used to compute soil biomass values using values in the RUSLE2 **core database** (see RUSLE2 User's Reference Guide).

Table 6.5. Soil biomass subfactor values used to derive RUSLE2 subfactor equation

Cover-management (yield)	Data source	Seedbed soil loss ratio	Soil biomass factor Obs	Soil biomass factor RUSLE2
conv corn 112 bu/ac	AH537	0.55	0.71	0.69
conv corn 50 bu/ac	AH537	0.68	0.80	0.82
conv corn sillage 112 bu/ac	AH537	0.74	0.81	0.79
conv corn sillage 50 bu/ac	AH537	0.77	0.83	0.88
conv corn 112 bu/ac soybeans 25 bu/ac	AH537	0.72	0.82	0.87
conv corn 112 bu/ac after meadow 4 tons/acre	AH537	0.18	0.29	0.24
conv corn 112 bu/ac after meadow 1.5 tons/acre	AH537	0.29	0.35	0.59
no till corn 112 bu/ac	literature	0.028	0.47	0.35
mulch till corn 112 bu/ac	literature	0.24	0.44	0.48

The soil consolidation term s_c in equation 6.48 gives increased credit for buried residue to represent no-till cropping and other undisturbed soil conditions. For example, a given amount of buried residue at the soil surface decreased rill-interrill erosion more with no-till than with clean tillage. Increased soil macro-pores and aggregation develop in the upper few inches of soil under no-till cropping and other undisturbed soil conditions (Kay and VanderBygaart, 2002). Frequent, routine tillage and other mechanical soil disturbance prevent these conditions from developing. Mechanical soil disturbance disrupts these favorable soil conditions for reducing rill-interrill erosion, and time is required for these soil conditions to become reestablished. The term $1/s_c^{0.5}$ in equation 6.48 and 6.49is used as an index for the development of these favorable soil properties.

Values for the accounting depths d_{rs}, described in **Section 6.2** for buried residue, and d_{rt} for roots were determined during the fitting of equation 6.48 and 6.49. The best fit was obtained with a buried residue accounting depth of three inches for conventional, clean tillage, which is represented by $s_c = 1$. The accounting depth is reduced to 1 inch as the soil consolidation subfactor value decreases from 1 for a soil recently mechanically disturbed to 0.45 for a fully consolidated soil (see equation 6.10). The accounting depth for buried residue reflects the soil depth over which buried residue has its major effect on infiltration, soil erodibility, and runoff erosivity.

The accounting depth determined for roots was 10 inches. This depth contains the bulk of roots for most vegetation, especially major agricultural crops like corn, soybeans, and wheat. The apparent depth over which roots affect erosion is greater than that for buried residue because live roots affect infiltration by extracting soil water. The 10-inch accounting depth for roots is also influenced by the common depth of 10 inches for modern moldboard plows, which invert the soil. Moldboard plow bring roots near the bottom of the plow depth to near the soil surface. Moldboard plows also move surface residue and buried residue near the soil surface to near the bottom of the plow depth, where the buried residue has little effect on rill-interrill erosion. Although the case can be made that live roots and dead roots should be treated differently in RUSLE2 because of moisture extraction, the effect of live roots and dead roots per unit mass are considered to be the same for both live and dead roots.

See **Sections 8.2** and **9.2.1** for additional comments.

6.5.3. Soil biomass subfactor equation for Req conditions

When RUSLE2 is applied to Req conditions (see **Section 3.2.5** and the RUSLE2 User's Reference Guide), soil biomass values are multiplied by 1.65 to give increased erosion reduction per unit biomass. Most of the rill-interrill erosion for Req conditions is rill erosion, and soil biomass has a greater relative effect on rill erosion than on interrill erosion (Van Liew and Saxton,1983; Brown et al., 1989; McGregor et al., 1990). The 1.65 value was determined by fitting RUSLE2 to data collected at Pullman, Washington (McCool et al., 2002).

6.5.4. Applicability of soil biomass subfactor equation for biomass additions

The data used to derive equations 6.48 and 6.49 were for cropped conditions where the biomass source was vegetation grown on-site. RUSLE2 must also represent the effect of incorporation of applied biomass from other sources including animal manure, compost, bio-solids in sewage and similar waste, and forest litter. The applicability of RUSLE2 for these conditions was evaluated by computing and comparing rill-interrill RUSLE2 erosion estimates with measured erosion in research studies. Tables 6.6 and 6.7 show estimated and observed erosion values for surface application of manure and its incorporation into the soil using primary tillage at Clarinda, Iowa and La Crosse, Wisconsin (Browning et al, 1948; Hays et al., 1949). Table 6.8 shows erosion values for various biomass types applied and incorporated in the soil for cotton grown at Statesville, North Carolina (Copley et al., 1944). RUSLE2 is judged to adequately estimate how surface applied and soil incorporated biomass affects rill-interrill erosion.

Table 6.6. Effect of manure additions on erosion at Clarinda, Iowa

			Ratio of erosion with manure to erosion without manure	
Cover	Yield (bu/ac)	Manure application (tons/acre wet basis)	Obs	RUSLE2
Corn	22	0	1.00	1.00
Corn	30	8	0.42	0.39
Corn	36	16	0.21	0.20
Fallow		0	-	-
Fallow		8	0.79	0.42
Fallow		16	0.63	0.24

Table 6.7. Effect of manure additions on erosion at La Crosse, Wisconsin

			Ratio of erosion with manure to erosion without manure	
Cover	Yield (bu/ac)	Manure application (tons/acre wet basis)	Obs	RUSLE2
Corn	30	0	1.00	1.00
Corn, manure spring applied	30	8	0.82	0.42
Corn, manure fall applied	30	8	0.80	0.42
Fallow		0	1.00	1.00
Fallow, manure spring applied		5	0.85	0.75

Several factors complicate this analysis. One factor is data variability. Incorporated animal manure decreased erosion much more at Clarinda, Iowa than at La Crosse, Wisconsin. RUSLE2 seems to seriously over estimate the effect of manure applied to fallow conditions at both Clarinda and La Crosse. A comparison of observed erosion with manure applied to corn with erosion for manure applied to fallow soil at Clarinda indicates a much greater effect of the corn biomass than is supported by data in Table 5, AH537 (Wischmeier and Smith, 1978). Another problem with the experimental data is that manure applied to the corn at La Crosse did not reduce erosion as much as expected based on the results for the fallow soil. Such unexplained variability in erosion data is common.

Another complicating factor is how well the biomass was incorporated into the soil by the 6-inch deep manual spading operation used on the research plots to replicate moldboard plowing. The RUSLE2 inputs were based on the assumption that the spading incorporated the biomass more like a chisel plow than like a moldboard plow. Assuming that the incorporation was like a moldboard plow rather than a chisel plow results in RUSLE2 estimating that the ratio of erosion with incorporated biomass to erosion without incorporated biomass increases from 0.42 to 0.48 for applying 8 tons/acre of manure at Clarinda, Iowa. Consequently, the uncertainty in how the spading operation incorporated the biomass does not seem to account for the large difference between the RUSLE2 values and the measured values for fallow conditions.

Table 6.8. Effect of biomass additions on erosion with cotton at Statesville, North Carolina

Yield (lbs/acre seed cotton)	Biomass type	Biomass application (tons/acre wet basis)	Ratio of erosion with biomass to erosion without manure	
			Obs	RUSLE2
800	-	none	1.00	1.00
1800	Animal manure	8	0.19	0.27
1800	Compost	12	0.39	0.21
1800	Compost	18	0.13	0.16
1800	Compost	60	0.03	0.04
1800	Wood litter	24	0.09	0.13
1800	Pine needles	24	0.10	0.13

Another complicating factor is that the reported application rates were on a wet basis rather than a dry basis required as input to RUSLE2. The dry biomass was assumed to be 25 percent of the wet basis application rates for all biomass types. The erosion ratios for fallow conditions at La Crosse assuming a 6 inch deep moldboard plowing are 0.65, 0.48, and 0.29 for the dry biomass inputs of 2000, 4000, and 8000 lbs/acre, respectively. Errors in estimating the dry biomass can have a significant effect on the RUSLE2 estimate erosion.

RUSLE2 assumes that the effect of all types of buried residue on rill-interrill erosion is described solely by biomass amount on a dry basis. Mechanical characteristic, such as diameter and length of individual pieces, of buried residue are assumed not to affect rill-interrill erosion in RUSLE2. This assumption is supported by the experimental and RUSLE2 results for the Statesville, North Carolina data.

The experimental results given in Tables 6.6 - 6.8 do not indicate the effect of biomass addition on rill-interrill erosion with modern farming practices. The depth of incorporation in these studies, which were conducted primarily in the late 1930's, was six inches while common modern moldboard plows incorporate material to 10 inches deep. Changing incorporation depth affects the RUSLE2 estimated ratio of erosion with incorporated biomass to erosion without biomass incorporation. Increasing incorporation depth from 10 to 6 inches increases the erosion ratio from 0.42 assuming a chisel plow type incorporation in the soil (0.48 assuming a moldboard plow incorporation) to 0.82 assuming incorporation with a modern moldboard plow for the 8 tons/acre manure spring application to corn at La Crosse, Wisconsin. The reason for the major difference is the effect of machine operation depth on the fraction of the biomass that is incorporated (see **Section 8.2.4.2**) and the biomass density in the surface 3-inch soil depth.

6.5.5. Soil biomass subfactor for pasture, range, and similar undisturbed lands

The equations for the soil biomass subfactor, equations 6.48 and 6.49, are considered to apply to all land use conditions (i.e., that is RUSLE2 is land-use independent). Range, pasture, and other undisturbed lands are highly variable in both time and space. Accurately measuring root biomass is extremely difficult, if not impossible for undisturbed lands because of temporal and spatial variability. Reliable measurements of root biomass and buried residue are not available to either directly validate equations 6.48 and 6.49 or derive alternative equations for these lands.[55] Therefore, erosion data from research plots under simulated rainfall were used to derive effective root biomass values for rangeland plant communities rather than use measured root biomass values. [56]

The common approach for applying the USLE [AH537 (Wischmeier and Smith, 1978)] and RUSLE1 [AH703 (Renard et al., 1997)] to undisturbed lands is to input values that represent average annual conditions to make a single erosion computation using subfactors similar to those in equation 6.1 to for the year rather than to compute daily erosion. This approach can also be used in RUSLE2, although a better approach is to use time varying inputs to represent temporal effects on rill-interrill erosion (see RUSLE2 User's Reference Guide). The lack of both measured soil biomass data and research that establishes how soil biomass and its characteristics affect rill-interrill erosion required derivation of effective root biomass ratio values, which is defined as the ratio of effective root biomass to average annual above ground biomass production on a dry basis. Values for this ratio vary by plant community and were determined directly from experimental soil erosion research data (See RUSLE2 User's Reference Guide; Simanton et al., 1991). This derivation empirically accounts for differences between cropland and undisturbed land conditions and overcomes the impossibility of measuring root biomass on undisturbed lands.

First, a **c** factor value was computed for each site from measured erosion data by rearranging equation 2.1 as:

$$c_p = A_p / [R_p K_n (\lambda_p / \lambda_u)^m S_p] \qquad [6.50]$$

where: c_p = the c factor value for the measured erosion data obtained from applying simulated rainfall to field plots 12 ft wide by 35 ft long, A_p = measured erosion, R_p = the erosivity for the simulated rainfall, K_n = the soil erodibility value determined by applying the standard soil erodibility nomograph (see **Sections 4.1.1** and **4.1.2**) using soil property values measured at each site, λ_p = the plot length, λ_u = unit plot length, and S_p = the slope steepness factor computed from the measured plot steepness. Next an observed soil biomass subfactor value s_c was computed for each experimental site by rearranging

[55] An extensive review of measured root biomass for rangeland plant communities was conducted during the development of RUSLE1. The variability in these values, as indicated in Table 5-4, [AH703 (Renard et al., 1997) , is far too great to use these values as either input to RUSLE2 or to develop a soil biomass subfactor, especially a temporally varying one, for these conditions.

[56] Data from the WEPP study (Simanton et al., 1991) were used in the analysis to compute effective root biomass values. Data from the USDA Range Study Team study Spaeth et al., 2003) were considered for use in the development of RUSLE2. However, the data were not used because of inconsistencies in the data, which were not resolved by the researchers who collected the data (see the RUSLE2 User's Reference Guide).

equation 6.1, substituting c_p values for c and values for the subfactors, and solving for the soil biomass subfactor s_b value.

An effective root biomass value was computed by rearranging equation 6.48 and assuming no buried residue effect (i.e., assuming $B_{rs} = 0$). RUSLE2 does not consider a buried residue effect when using a single average annual input for root biomass. This RUSLE2 application method also requires using RUSLE2 inputs that add surface residue that does not decompose (see RUSLE2 User's Reference Guide). The value for the effective root biomass was divided by the average annual dry matter above ground biomass production to compute a value for effective root biomass ratio for the site. These values were averaged where the same plant community occurred at multiple sites. RUSLE2 multiplies the input value for above ground annual production by the effective root biomass ratio to obtain a value for effective root biomass B_{rt} that is used in equation 6.48 or 6.49 to compute a value for the soil biomass subfactor. Derivation of RUSLE2 effective root biomass values was the same as that used to derive comparable values for RUSLE1 [Yoder et al., 1997; AH703 (Renard et al., 1997)], except that RUSLE2 equations and procedures were used for equations 6.1, 6.48, and 6.50.

The RUSLE2 User's Reference Guide discusses how time varying inputs can be used in RUSLE2 to represent changes in time during the establishment of permanent cover on mechnanically disturbed lands such as construction sites, reclaimed mined lands, rangelands, military training grounds, and logged and burned forest lands. This Guide also describes how time varying inputs can be used in RUSLE2 to represent long-term vegetation that has reached maturity on undisturbed land. Using time varying inputs for canopy and root biomass allows RUSLE2 to compute a litter cover produced by senescence, soil biomass produced by dead (soughed) roots, and soil biomass produced by buried residue that are a function of plant community, production level, and location (Reeder et al., 2001).

RUSLE2 was fitted directly to the measured erosion data for rangelands to determine the soil biomass effect for these lands. However, RUSLE2 erosion estimates for undisturbed lands, especially rangelands, are much more uncertain than erosion estimates for cropland. This increased uncertainty exists for all erosion prediction technologies and is not unique to RUSLE2. Reasons for this uncertainty and its magnitude are discussed in detail in the RUSLE2 User's Reference Guide.

6.5.6. Sources of soil biomass in RUSLE2

The sources of soil biomass in RUSLE2 are biomass applied to the soil surface or directly injected into the soil, above ground biomass from vegetation grown on site, and roots from vegetation grown on-site. The amount of applied biomass is a direct input to RUSLE2 (see **Section 10**). The amounts of above ground and root biomass for vegetation grown on-site are directly related to RUSLE2 inputs (see **Section 9**). Once live above ground biomass becomes dead biomass (i.e., residue) by senescence or killed by an operation such as mowing, it disappears by decomposition discussed in **Section 10.3.** Similarly, once live roots become dead roots either by the plants being killed or by root sloughing, this biomass disappears by decomposition. Operations, including soil disturbing operations, move biomass between the various biomass pools and redistribute biomass within the soil (see **Section 8**). The RUSLE2 User's Reference Guide describes the RUSLE2 biomass pools in detail and how these pools are manipulated in RUSLE2.

6.5.7. Transfer of surface residue to soil biomass by decomposition in RUSLE2

The organic matter content of the approximate 2-inch soil depth for no-till cropped soil is about twice that for conventional, clean-till cropping (Kay and VanderBygaart, 2002; Shelton and Bradley, 1987). A RUSLE2 assumption is that biomass occurs in the soil only by roots grown in the soil or a mechanical soil disturbing operation incorporating biomass. To accommodate the accumulation of high organic matter level in a shallow soil surface layer where little or no mechanical soil disturbance occurs, such as for no till croplands and undisturbed lands, RUSLE2 assumes that a portion of the daily surface residue decomposition is added to the top 2-inch soil layer. Once in this soil layer, this biomass is treated as any other buried residue that is subject to decomposition and has the same effect on rill-interrill erosion as any other buried residue.

This empirical procedure is used as a mechanism for increasing soil biomass in the upper soil layer when the soil is minimally disturbed. The equation used to compute this buried residue addition is:

$$f_b = 0.25[(1/s_c) - 1] \qquad [6.51]$$

where: f_b = the fraction of the daily biomass decomposed from surface residue that is added to the buried residue biomass in the upper 2-inch soil layer. The 0.25 value was determined during the fitting of equation 6.48 to observed data. The 0.25 variable was adjusted so that RUSLE2 computes a soil biomass in the top 2-inch soil layer for the no-till data point that is approximately twice the soil biomass for conventional, clean tillage. The structure of equation 6.51 was chosen so that the rate of change in the effect of soil consolidation is least immediately after a mechanical soil disturbance (i.e., $s_c = 1$). The rate of increase in f_b increases as the soil approaches full soil consolidation (i.e., s_c = 0.45).

The soil consolidation s_c subfactor term in equation 6.51 and the time to soil consolidation (see **Section 4.8**) determine the time required after a conversion from conventional, clean tillage to no tillage for soil biomass to come to a new equilibrium. Seven years is used for the time to soil consolidation in the eastern US, which is too short for all of the soil biomass changes to occur (Kay and VanderBygaart, 2002). However, seven years for time to soil consolidation is sufficient for RUSLE2 to represent particulate organic matter, and seven years seems sufficiently long for most major land use changes that affect rill-interrill erosion in the context of conservation planning. The time to soil consolidation is also used to compute change in soil erodibility when no biomass is present. Consequently, thus the RUSLE2 time to soil consolidation variable is a compromise for describing multiple effects.

Equation 6.51 computes no transfer of biomass from the surface residue to the buried residue when the soil has been recently mechanically disturbed, which is indicated by s_c =

1, which gives $f_b = 0$ from equation 6.51. If the soil is totally undisturbed where $c_s = 0.45$, $f_b = 0.31$, which means that for each day, approximately 30 percent of the surface residue that is lost by decomposition on that day is added to the buried residue in the upper 2-inch soil depth. In no-till corn cropping where the only soil disturbing operation is a planter that disturbs 15 percent of the soil surface, the c_s ranges from 0.54 to 0.61 during the year. The approximate annual average is 0.58, which gives a value of 0.18 from equation 6.51. That is, approximately 18 percent of the daily surface residue decomposition is added to the upper 2-inch soil depth for typical no-till corn cropping in comparison to almost 30 percent being added for a completely undisturbed soil condition (e.g., a pasture or rangeland).

6.5.8. Spatial variability in the soil biomass subfactor

Soil biomass and the soil biomass subfactor are assumed to be spatially uniform within a segment along the overland flow path, even when the soil is disturbed in strips. Non-uniformity in soil biomass along the overland flow path can be represented by dividing the overland flow path into segments.

6.5.9. Comments on soil biomass subfactor

The purpose of the soil biomass subfactor is to capture the main effect of live and dead roots and buried residue on rill-interrill erosion. The RUSLE2 soil biomass relationships are not meant to be a model of soil biomass that stands alone from how it used in RUSLE2 to estimate rill-interrill erosion for conservation and erosion control planning. The soil biomass subfactor does not capture all interactions, such as how the effect of soil biomass on erosion is affected by soil texture.

The importance of the soil biomass subfactor is often overlooked in evaluating how cover-management practices affect rill-interrill erosion. For example, large amounts of biomass added to the soil can greatly reduce rill-interrill erosion as indicated in Table 6.8. Similarly, large amounts of live and dead root biomass also greatly reduce erosion.

RUSLE2 only uses biomass amount as the variable to capture how soil biomass affects erosion. For example, RUSLE2 makes no distinction between how small and larges roots affect erosion. However, preference in selecting root biomass input values is given to fine roots instead of coarse roots (see RUSLE2 User's Reference Guide). Not much of the mass of coarse roots is entered for root biomass because coarse roots are assumed to have relatively little effect on erosion. Fine roots are assumed to have much greater effect on erosion per unit biomass than do coarse roots. Fine roots have greater surface area per unit mass than coarse roots and often are very close to the soil surface where they have a greater effect on runoff and erosion than coarse roots. Fine roots are readily sloughed and become a part of the soil organic matter pool.

Research to directly determine the effect of buried residue on rill-interrill erosion has been limited and incomplete (Van Liew and Saxton, 1983; Brown et al., 1989; McGregor et al., 1990; Box, Jr. and Bui, 1993). Research to measure soil buried residue and its characteristics as they affect rill-interrill erosion is difficult and is very incomplete.

However, research, such as that summarized in AH537 (Wischmeier and Smith, 1978), conclusively shows that root biomass reduces erosion. No studies have shown how root characteristics affect rill-interrill erosion.

Getting good results from RUSLE2 requires that instructions in the RUSLE2 User's Reference Guide for selecting input values be carefully followed. RUSLE2's soil biomass subfactor equation and other subfactor equations were calibrated using the data in the RUSLE2 **core database**. When those values and the procedures described in the RUSLE2 User's Reference Guide are followed, RUSLE2 users can expect good results from RUSLE2 for conservation and erosion control planning. If one disagrees with the soil biomass values used by RUSLE2, one can not simply change RUSLE2 input values because of RUSLE2 having been calibrated using values from the RUSLE2 **core database**. If soil biomass values are changed, the soil biomass subfactor equation must be re-derived because the RUSLE2 equation was derived using RUSLE2 computed soil biomass values.

The importance of this point can not be over emphasized.

6.6. Soil consolidation subfactor

6.6.1. Soil consolidation effect

The RUSLE2 assumption is that mechanical soil disturbance by tillage, construction activities, and other soil loosening operations significantly increases soil susceptibility to erosion. Rill-interrill erosion immediately after a mechanical soil disturbance is assumed to be about twice that when the soil has not been disturbed for an extended period. The effect is much greater for rill erosion than for interrill erosion (Foster, 1982; Foster et al., 1982c).

The term soil consolidation does not accurately connote the process by which soil becomes less susceptible to erosion over time. The reduction in soil erodibility over time represented by the soil consolidation subfactor is related to internal cohesive soil bonding increasing over time rather than to a mechanical increase in soil bulk density. Cohesive bonding increases as the soil experiences wetting and drying cycles in the presence of organic matter and chemical bonding agents in the soil (Foster et al., 1985c; Toy et al., 2002). The important role of soil moisture is the reason for the time to soil consolidation being a function of average annual precipitation between 10 and 30 inches (see **Section 4.8**).

The soil consolidation effect is based on a comparison of erosion from a soil in the unit plot condition to erosion of the same soil that has not been mechanically disturbed for some time after being left in unit-plot condition by the last mechanical soil disturbance. Soil disturbance also affects the ground cover, soil surface roughness, and soil biomass subfactors in addition to the soil consolidation subfactor. The soil consolidation subfactor represents solely the effects of soil loosening on erosion relative to time since the last mechanical soil disturbance that left unit plot conditions. The soil consolidation subfactor variable is also used to compute values for the soil biomass subfactor, rill to interrill erosion ratio, and runoff curve number. Therefore, the effect of soil loosening computed by RUSLE2 can be significantly greater than the effect represented by the soil consolidation subfactor.

6.6.2. Soil consolidation subfactor equation

The equation for the RUSLE2 soil consolidation subfactor is:

$$s_c = 0.45 + \exp\{-3.314[0.1804 + (t_d / t_c)^{1.439}]\} \qquad [6.52]$$

where: t_d = days since last mechanical soil disturbance and t_c = the time to soil consolidation The 0.45 value in equation 6.52 represents the minimum soil consolidation subfactor value that occurs for time exceeding the time to soil consolidation.[57] The soil consolidation subfactor value is 1 for $t_d = 0$, which is immediately after a mechanical soil disturbance. A plot of equation 6.52 is shown in Figure 6.6 for two times to soil consolidation.

Equation 6.52 was derived from experimental erosion data collected from natural runoff plots at Zanesville, Ohio (Borst et al., 1945). Erosion was measured for a few years from a plot periodically tilled to maintain unit plot conditions. Tillage was stopped and erosion measurements were continued for several years after tillage stopped. Measured annual erosion values were adjusted based on the annual erosivity to account for weather differences between years. Observed soil consolidation subfactor values were computed by dividing the adjusted annual erosion values after tillage stopped by adjusted average annual erosion before tillage stopped.

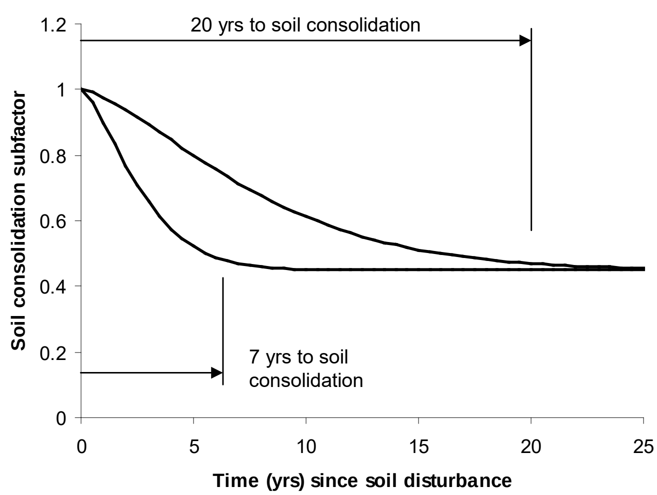

Figure 6.6. Variation of the soil consolidation subfactor as a function of time after last mechanical soil disturbance.

Experimental erosion studies on mine spoil and reconstructed shoed that compaction can increase rill-interrill erosivity by as much as 40 percent (Barfield et al.,

---

[57] Equation 6.52 approaches 0.45 asymptotically. The time to soil consolidation is defined as the time when 95 percent of the decrease in the soil consolidation subfactor has occurred (see **Section 4.8**).

1988). About half of this effect can be captured in RUSLE2 by inputting a 0 soil surface roughness value for the soil disturbing operation used to describe the compaction. The 0 input value for soil surface roughness represents a smooth soil surface that is assumed to result from the compaction. This value is increased to represent the roughness effect left by a compactor such as a sheep's foot roller that leaves some soil surface roughness.

6.6.3. Spatial variability effect on soil consolidation subfactor

RUSLE2 accommodates spatial variability along the overland flow path when the overland flow path is divided into segments. RUSLE2 also represents the effect of operations that disturb only a portion of the soil surface (e.g., strip tillage) based on the fraction of the soil surface that the operation disturbs. An effective value for the soil consolidation subfactor is computed as the weighted average of $s_c = 1$ for the portion disturbed and the s_c value for the undisturbed portion at the time of the mechanical soil disturbance. An effective time since soil disturbance is calculated by rearranging equation 6.52 and solving for the time t_d that gives the effective s_c value (see **Section 8.3.1**). The time since last soil disturbance is reset to this effective time, and time accounting for soil consolidation begins again from the effective time value.

6.6.4. Comments on soil consolidation subfactor

The RUSLE2 soil consolidation subfactor only captures the soil loosening effect on rill-interrill erosion in the broadest terms. The soil consolidation subfactor is the most poorly defined of all the RUSLE2 cover-management subfactors. Very little empirical and not much fundamental research has been conducted to determine how the soil consolidation effect varies with climate, soil texture, and other factors. The RUSLE2 soil consolidation subfactor is determined from a single set of data collected at a single location on a single soil texture. The effect is greater for rill erosion than for interrill erosion (Foster et al., 1982c). However, the soil consolidation effect on rill erosion can be quite variable. In one study, rill erosion of a silt loam soil decreased by about 75 percent over about a year's time (Dissmeyer and Foster, 1981). In another study, sediment eroded from ridges and deposited in furrows became quite resistant to erosion in just four weeks (Foster et al., 1982c).

The soil consolidation effect surely must be a function of soil texture. For example, the range in the soil consolidation subfactor for soils high in sand is assumed to be less than for silt loam soils. Also, the time to soil consolidation is assumed to be a function of soil texture. However, available research information is not sufficient to include these effects in the RUSLE2 soil consolidation subfactor.

The RUSLE2 assumption is that mechanical soil compaction (i.e., mechanical increases in soil bulk density) does not affect rill-interrill erosion. Soil compaction has two offsetting effects. One is to decrease infiltration, which increases runoff and hence rill-interrill erosion. The other effect is to decrease erosion by decreasing the detachability of soil particles by raindrop and runoff forces. The assumption of no effect of soil compaction on erosion is false for a high clay soil being mechanically compacted at optimum soil moisture. Soil compaction of a high clay soil can greatly reduce rill erosion

(Graf, 1971). Available research information was not sufficient to include a RUSLE2 relationship that computes erosion as a function of soil bulk density. An input value less tha 0.24 inches for soil surface roughness can be used to represent increase in erosion caused by compaction. Also, the soil erodibility factor value can be reduced to represent decreased erosion caused by compaction of high clay soils.

RUSLE2 does represent the effect on rill-interrill erosion of subsoiling, scarifying, and similar mechanical soil disturbances designed to break up soil to increase infiltration, which in turn decreases runoff and erosion. RUSLE2 represents this effect though the soil surface roughness subfactor (see the RUSLE2 User's Reference Guide).

The RUSLE2 soil erodibility factor does not represent the effect of soil compaction. Soil compaction is a cover-management effect. Changing a soil erodibility input value to represent soil compaction is for convenience only in RUSLE2 because no other input method is available to represent the effect of compaction. RUSLE2 soil erodibility are based on the tilled unit plot condition.

6.7. Antecedent soil moisture subfactor

The antecedent soil moisture subfactor is used only when RUSLE2 is applied to Req conditions (see **Section 3.2.5**).

6.7.1. Antecedent soil moisture effect

Rill-interrill erosion under Req conditions is highly sensitive to soil moisture [AH703 (Renard et al., 1997); Van Klaveren and McCool,1998]. High soil moisture significantly increases erosion during the winter Req period. Freezing and thawing cycles in the presence of very high soil moisture and other processes dramatically increase soil erodibility during the winter months at Req locations [see RUSLE2 User's Reference Guide, AH703 (Renard et al., 1997); Van Klaveren and McCool,1998). Highly saturated soil in the tilled surface layer plays a major role in Req processes that do not occur to nearly the same degree or regularity in non-Req locations.

6.7.2. Antecedent soil moisture subfactor equations

The RUSLE2 antecedent soil moisture subfactor equations are a refinement of those in RUSLE1 [Yoder et al., 1997; AH703 (Renard et al., 1997); McCool et al., 2002]. The year is divided into periods of soil moisture replenishment (October 1 – March 31), stable at maximum soil moisture (April 1 – April 30), depletion (May 1 – July 31), and stable at minimum soil moisture (August 1 – September 30).

6.7.2.1. Replenishment (October 1 – March 31)

The average daily soil moisture replenishment rate is computed as:

$$R_m = 0.5/182 \quad P_a \le 10 \text{ inches} \qquad [6.53]$$

$$R_m = [0.5 + 0.062(P_a - 10)]/182 \quad 10 < P_a \le 18 \text{ inches} \qquad [6.54]$$

$$R_m = 1/182 \quad P_a > 18 \text{ inches} \qquad [6.55]$$

where: R_m = an index (dimensionless) for daily moisture replenishment rate, P_a = average annual precipitation (inches), and 182 = number of days over which replenishment occurs.

$$s_m = s_{mp} + R_m \quad if\,(s_m > 1): s_m = 1 \qquad [6.56]$$

where s_m = daily antecedent soil moisture subfactor and s_{mp} = the soil moisture subfactor on the previous day.

6.7.2.2. Depletion (May 1 – July 31)

The daily soil moisture depletion rate is computed as:

$$D_m = \phi_m / 91 \qquad [6.57]$$

where: D_m = an index (dimensionless) for daily moisture depletion rate, ϕ_m = the total soil moisture depletion as a function of vegetation, and 91 is the number of days over which depletion is assumed to occur. Example values for ϕ_m are given in Table 6.9.

$$s_m = s_{mp} - D_m \quad if\,(s_m < 0): s_m = 0 \qquad [6.58]$$

6.7.2.3. Minimum and maximum periods (April 1 – April 30) and (August 1 – September 30)

The soil moisture subfactor is assumed not to change during the minimum period between the depletion and replenishment periods and the maximum period between the replenishment and depletion periods. That is:

$$s_m = s_{mp} \qquad [6.59]$$

6.7.2.4. Initial s_m value

Table 6.9. Soil moisture depletion index for vegetation grown in Req location

Vegetation	Depletion index
Winter wheat and other deep rooted crops	1.00
Spring wheat and barley	0.75
Spring peas and lentils	0.67
Shallow rooted crops	0.50
Summer fallow	0.00
Vegetation that has been killed	0.00

The initial default value for the antecedent soil moisture subfactor s_m is 1. The initial condition is not important when cover-management practice are rotations (i.e., the set of operations is repeated in cycles). RUSLE2 runs until dynamically stable conditions are reached. However, when the cover-management practice is not a rotation, the initial operations in the cover-management description are used to set the desired initial condition (see RUSLE2 User's Reference Guide). Specific values can not be entered in the RUSLE2 computer program to set initial values of RUSLE2 variables.

6.7.2.5. Applicability of RUSLE2 antecedent soil moisture subfactor equations

The RUSLE2 antecedent soil moisture subfactor equations (equations 6.53 - 6.59) strictly apply only to the portion of the Req zone from central Washington across northern Idaho and in northeastern Oregon illustrated in Figure 3.16 (also, see RUSLE2 User's Reference Guide). Although Req conditions occur in other locations, equations 6.53 – 6.59 do not apply to those locations because of differences in precipitation patterns. These equations were empirically derived from data collected at Pullman, Washington. Differences in monthly precipitation distributions between Pullman Washington and Salt Lake City, Utah are illustrated in Figure 6.7. Equation 6.53 – 6.55 do take into account differences in annual precipitation between locations but not differences in monthly precipitation and vegetation extraction patterns. Replenishment and depletion rates are expected to differ among locations as monthly precipitation distributions vary.

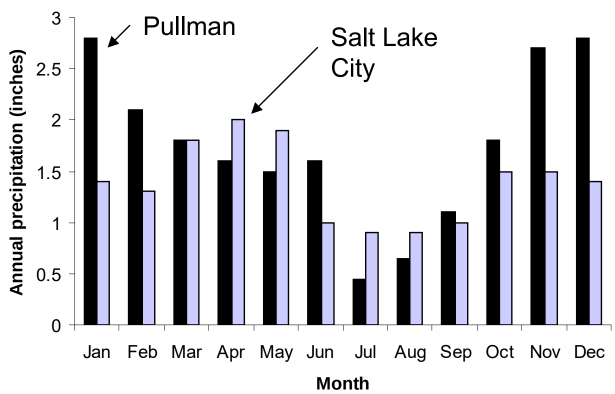

Figure 6.7. Distribution of monthly precipitation at Pullman, Washington (P_a = 20.9 inches) and Salt Lake City, Utah (P_a = 16.9 inches)

6.7.3. Comments on antecedent soil moisture subfactor

The antecedent soil moisture subfactor is a very important variable at Req locations. For example, changing the moisture depletion variable ϕ_m from 1, its standard value, to 0 for no moisture depletion, increased estimated erosion from 8.9 to 14 tons/acre per year for a typical conventional, clean-till continuous wheat crop at Pullman, Washington. Given that the antecedent soil moisture subfactor has a major effect on rill-interrill erosion emphasizes the need for improved equations for this subfactor as a function of monthly precipitation distribution.

The RUSLE2 antecedent soil moisture subfactor should be used only for Req locations. The antecedent soil moisture subfactor equations were empirically derived from data collected at Pullman, Washington where climatic conditions are very different from those in other US regions. Antecedent soil moisture affects rill-interrill erosion in all locations. Those effects are empirically described by the canopy and soil biomass subfactors and by the precipitation and temperature variables used to compute temporal soil erodibility factor values (see **Section 4.5**). Using the antecedent soil moisture subfactor in non-Req location causes serious errors in RUSLE2 estimated erosion.

6.8. Validation of cover-management factor values

RUSLE2 should represent the effect of cover-management on rill-interrill erosion better than it does for any other major factor. Rill-interrill erosion varies more as cover-management varies over its likely range than it does for the likely range of any other factor. Cover-management type erosion control practices are used more widely than any other type of erosion control practice. RUSLE2 must accurately estimate how cover-management affects erosion to avoid excessive expense of installing more erosion control than necessary. Likewise, RUSLE2 must accurately estimate how cover-management affects erosion to ensure adequate erosion control and prevention of excessive damages. The RUSLE2 User's Reference Guide extensively discusses the validity of RUSLE2 for estimating how cover-management affects rill-interrill erosion.

Tables 6.10 – 6.12 illustrate how well the RUSLE2 cover-management subfactors compute soil loss ratios in relation to summarized experimental data taken from AH537 (Wischmeier and Smith, 1978) and other sources. As these tables show, RUSLE2 estimates very well the variation in soil loss ratios as a function of crop stage periods and as a function of the major cover-management variables that affect rill-interrill erosion.

In addition, an extensive set of literature was reviewed and analyzed in validating RUSLE2 for conservation tillage especially no till (see **Section 12.23**).

Table 6.10. Soil loss ratios for conventional clean tilled continuous 112 bu/ac from AH537 and RUSLE2 computed values.

Crop stage (defined in AH537)	AH537 soil loss ratio	RUSLE2 computed soil loss ratio
Fallow	0.31	0.28
Seedbed	0.55	0.54
1 - 10% < canopy cover < 50%	0.48	0.52
2 - 50% < canopy cover < 75%	0.38	0.3
3 - 75% < canopy cover to maturity	0.23	0.18
4 after harvest (stalks spread)	0.06	0.06

Table 6.11. Soil loss ratio values for conventional clean till flat planted continuous 750 lbs/acre cotton at Holly Springs, Mississippi.

Crop stage (defined in AH537)	AH537 soil loss ratio	RUSLE2 computed soil loss ratio
Fallow	0.39	0.54
Seedbed	0.64	0.74
1- 10% canopy cover < 35%	0.59	0.74
2 - 35% < canopy cover < 60%	0.46	0.49
3 - 60% canopy cover to maturity	0.32	0.23
Defoliation to Dec 31	0.26	0.24
Jan 1 to Feb. tillage	0.32	0.32

Table 6.12. Soil loss ratio values for conventional clean till ridge (hipped) continuous planted 750 lbs/acre cotton at Holly Springs, Mississippi.

Crop stage (defined in AH537)	AH537 soil loss ratio	RUSLE2 computed soil loss ratio
1st hip, no prior tillage	0.84	0.88
Split ridges with a “do-all”	0.54	0.52
Hip after 2 prior tillages	1.08	1.01
Split ridges with a “do all”	0.62	0.58
Hip after 3 or more tillages	1.1	1.12
Split ridges with a “do all”	0.64	0.64
Seedbed	0.64	0.64
1 - 10% canopy cover < 35%	0.59	0.64
2 - 35% < canopy cover < 60%	0.46	0.45
3- 60% canopy cover to maturity	0.32	0.21
Defoliation to Dec 31	0.22	0.23
Jan 1 to Feb. tillage	0.32	0.27

6.9. List of symbols

a_b = coefficient related to buried residue and soil consolidation used to compute a_2

a_e = coefficient used to compute loss of ridge height by interrill erosion (inch/customary US erosivity unit)

a_g = coefficient related to height within the canopy where vegetative surface area is concentrated, used to compute effective fall height

a_h = coefficient used to compute ridge subfactor values

a_s = coefficient that is a function of canopy shape, used to compute effective fall height

a_1 = coefficient related to soil biomass and soil consolidation used to compute a_2

a_2 = coefficient, along with a_4, for how soil consolidation, soil biomass, and conformance of ground cover to the soil surface affect rill to interrill erosion ratio

a_3 = coefficient related overland flow path length and steepness and conformance of ground cover to soil used to compute a_4

a_4 = coefficient, along with a_2, for how soil consolidation, soil biomass, and conformance of ground cover to the soil surface affect rill to interrill erosion ratio

A_p = measured erosion from simulated rainfall applied to plots used to determine c_p factor values (mass/area)

b = coefficient for how ground (surface) cover affects rill-interrill erosion (percent^{-1})

b_r = coefficient for how ground cover affects rill erosion (percent^{-1})

B_{rs} = buried residue mass (dry basis) density in soil accounting depth for buried residue (mass/area·length)

B_{rt} = live and dead root mass (dry basis) density in soil accounting depth for roots (mass/area·length)

B_{td} = total mass (dry basis) density of buried residue and live and dead roots averaged over soil disturbance depth after the operation (lbs_m/acre·inch)

c = daily cover-management factor

c_a = coefficient for combined effect of buried residue and soil consolidation on ground cover effectiveness in relation to rill erosion

c_c = daily canopy subfactor

c_p = c factor value for measured erosion data obtained from applying simulated rainfall to field plots

c_{pr}/c_{pi} = rill to interrill prior land use soil erodibility ratio

d_{rs} = accounting soil depth for buried residue (inches)

D_b = rill-interrill erosion when ground cover is not present (bare soil) (mass/area)

D_c = rill-interrill erosion when ground cover is present (mass/area)

D_{ib} = interrill erosion when ground cover is not present (bare soil) (mass/area)

D_m = index for daily moisture depletion rate

D_{rb} = rill erosion when ground cover in not present (bare soil) (mass/area)

D_t = normalized rill-interrill erosion

e_d = waterdrop impact energy (force-distance)

f_b = fraction of the daily biomass decomposed from surface residue added to buried residue biomass in upper 2-inch soil layer

f_c = daily canopy cover (fraction)

f_{ec} = daily effective canopy cover (fraction)

f_g = ground (surface) cover (fraction or percent when used to compute g_c)

f_{ge} = effective ground cover used to compute values for slope exponent m (percent)

f_{gn} = net ground cover, portion of soil surface covered

f_r = fraction of today's soil surface roughness greater than 0.24 inch that remains after today's loss of roughness

g_c = daily ground (surface) cover subfactor

g_{ci} = interrill erosin ground (surface)cover subfactor

g_{cr} = rill erosion ground (surface)cover subfactor

g_r = relative row grade (grade along the ridges/overland flow path steepness)

h_b = height to canopy bottom (length)

h_f = daily effective fall height (feet)

h_t = height to canopy top (length)

H = daily ridge height (inches)

H_e = ridge height component associated with interrill erosion (inches)

H_{ep} = previous day ridge height component associated with interrill erosion (inches)

H_s = ridge height component associated with settlement (inches)

H_{sp} = previous day ridge height component associated with settlement (inches)

I = daily amount of water added by irrigation (inches)

K_n = soil erodibility value determined from standard soil erodibility nomograph using soil property values measured at each site (mass/erosivity unit)

K_r/K_i = rill to interrill soil erodibility ratio

m = slope length exponent

m_d = waterdrop mass

P_a = average precipitation (inches)

P_{cl} = mass portion of soil composed of clay (percent)

P_d = daily precipitation (inches)

P_{sl} = mass portion of soil composed of silt (percent)

r_d = daily erosivity (erosivity units)

r_h = daily ridge height subfactor

$r_{h,u\&d}$ = ridge height subfactor value when ridge orientation is parallel to overland flow path

r_{h6} = daily ridge height subfactor when overland flow path steepness is less than or equal to 6 percent

R_a = daily adjusted sil surface roughness roughness used to compute soil surface roughness subfactor values (inches)

R_{aa} = adjusted soil surface roughness immediately after soil disturbing operation (inches)

R_{ae} = existing adjusted soil surface roughness before a soil discturbing operation (inches)

R_{alf} = adjusted final long term soil surface roughness value after input value for long term roughness adjusted for soil texture and soil biomass (inches)

R_{ap} = adjusted soil surface roughness on previous day (inches)

R_{ib} = initial soil surface roughness after input roughness adjusted for soil texture and biomass (inches)

R_{in} = input soil surface roughness value for reference condition for soil disturbing operation (inches)

R_{it} = initial soil surface roughness after input roughness value adjusted for soil texture (inches)

R_l = daily adjusted long long term soil surface roughness (inches)

Req = equivalent erosivity related to greatly increased soil erodibility during winter months in Nrthwestern US

R_m = index for daily moisture replenishment rate

R_p = erosivity for simulated rainfall applied to plots used to determine c_p factor values (erosivity units)

s = overland flow path steepness (sine of slope angle)

s_b = daily soil biomass subfactor

s_c = daily soil consolidation subfactor

s_i = interrill area steepness (sine of slope angle)

s_m = daily antecedent soil moisture subfactor used in Req zone

s_p = overland flow path steepness (100 times tanget of slope angle)

s_r = daily soil surface roughness subfactor

S_p = slope steepness factor computed from steepness of plots used with simulated rainfall to determine c_p factor values

t_c = time to soil consolidation (days)

t_d = time since the last mechanical soil disturbance (days)

V = waterdrop impact velocity (length/time)

α = rill to interrill erosion ratio for bare soil

δ = cover adjustment term used to compute slope length exponent

ξ = tillage intensity

λ = overland flow path length (length)

λ_p = length of plots used with simulated rainfall to determine c_p factor values

λ_u = unit plot length (72.6, 22.1 m)

ϕ_m = the total soil moisture depletion as a function of vegetation

ψ = coefficient related to conformance ground (surface) cover to soil surface

7. SUPPORT PRACTICES

7.1. Contouring (ridging)

7.1.1. Description of contouring (ridging)

Contouring is an erosion control practice where ridges are placed on the contour around the hillslope perpendicular to the overland flow path. Runoff flows uniformly over the ridges along their length when the ridges are perfectly on the contour and the ridge top is level. Ponded water in the furrows between the ridges reduces detachment and causes a major portion of the sediment eroded from the ridges to be deposited in the furrows.

These ideal conditions seldom occur in the field. Breakovers occur in low ridge areas and where the soil is susceptible to rill erosion. Erosion reduction with contouring is reduced when breakovers occur. However, erosion reduction occurs even with breakovers if furrow (row) grade is sufficiently flat to cause deposition in the furrows or to cause reduced rill erosion in relation to the rill-interrill erosion that occurs when the ridges are parallel to the overland flow path. Runoff travels long distances in the furrows between high ridges to concentrated flow areas where ephemeral gully erosion occurs. RUSLE2 does not explicitly estimate ephemeral gully erosion (see RUSLE2 User's Reference Guide), although ephemeral gully erosion occurred in the small watersheds used to derive the RUSLE2 contour subfactor relationships. Thus, ephemeral gully erosion is partially included in RUSLE2 erosion estimates for contoured conditions.

The effect of ridging (contouring) on rill-interrill erosion must be considered even when ridging is not used explicitly as an erosion control practice. For example, tillage direction in an agricultural field is often parallel to a field boundary, which results in ridges at an angle to the overland flow path. Rill-interrill erosion varies between the extremes of being minimal when the ridges are perfectly on the contour and maximum when the ridges are parallel to the overland flow path.

The base, reference unit plot condition is that ridges-furrows are parallel to the overland flow path. Thus, the RUSLE2 contouring subfactor represents the effect of ridge-furrow orientation with respect to the overland flow path on rill-interrill erosion.

7.1.2. Contouring (ridging) effect

Figure 7.1 is a graph of experimental data that shows how contouring affects rill-interrill erosion on plots that ranged in width from12 to 150 ft and small watersheds that were about 5 acres in area (Foster et al., 1997; see other references in **Section 7.1** and **Section 12.2.1**).

Each type of measurement area has shortcomings. A shortcoming of watersheds is that measured sediment from watersheds includes sediment produced by ephemeral gully erosion, which is not estimated by RUSLE2. A shortcoming of plots narrower than about

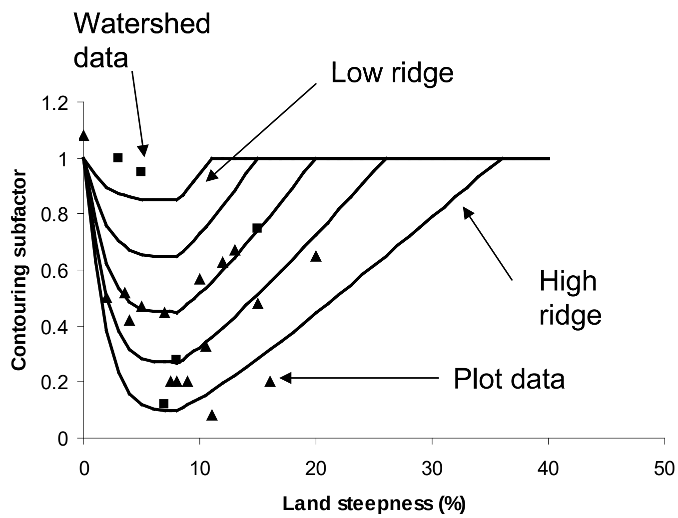

Figure 7.1. Experimental data from plots and small watershed (~ 5 acres) for effect of contouring (ridging) on rill-interrill erosion and fitted lines for effect of ridge height on contouring.

20 ft is that runoff rates are too low at the ridge breakovers. Several plot widths exceeded 20 ft with some as wide as 150 ft, which are sufficiently wide to represent field contouring. Although, neither plot nor watershed data are entirely satisfactory, data from both plots and watersheds were combined to derive RUSLE2 contouring subfactor equations.

The well accepted general contouring subfactor relationship is an upward concave curve that starts at 1 for a zero steepness, decreases to a minimum as land steepness increases to an approximate 8 percent steepness and then increases to 1 at an upper steepness beyond which contouring is assumed not to reduce erosion [AH537 (Wischmeier and Smith, 1978)]. Contouring has no effect at zero land steepness because no flow direction is defined. Contouring has no effect beyond a maximum steepness that is a function of ridge height because the land is so steep that no water can be stored by the ridges.

The range in the data illustrated in Figure 7.1 for the effect of contouring on rill-interrill erosion is assumed to be caused primarily by a ridge height variation. Experimental data show that contouring's erosion reduction increases as ridge height increases (Moldenhauer and Wischmeier, 1960). Increased ridge height increases storage of runoff, decreases interrill detachment, and increases deposition in the furrows, which is the basis for the curves in Figure 7.1 being a function of ridge height. Also, dense plant stems in narrow rows on the contour have the same effect on rill-interrill erosion as ridges on the contour (Daniel et al., 1943; Van Doren et al., 1950). Experimental data show that contouring is less effective for large intense runoff events than for small ones (Moldenhauer and Wischmeier, 1960). In some cases, erosion on watersheds was greater with contouring than with tillage up and down hill as illustrated in Figure 7.1 (Hill et al., 1944). These examples of increased erosion are associated with concentrated flow erosion where ridge-breakovers occurred. Thus, the effective of contouring on rill-interrill erosion depends on storm, soil, and cover-management characteristics that affect runoff.

A long accepted principle by soil conservationists is that contouring fails if the overland flow path length exceeds a critical length that is a function of land steepness [(AH282 (Wischmeier and Smith, 1965); AH537 (Wischmeier and Smith, 1978)]. That critical length is assumed in RUSLE2 to be a function of the shear stress applied to the soil by runoff, which in turn is a function of storm characteristics, inherent potential of the soil for generating runoff, and how cover-management affects runoff and the shear stress that runoff applies to the soil.

The RUSLE2 contouring subfactor equations are very similar to the comparable RUSLE1 equations [Foster et al, 1997, AH703 (Renard et al., 1997)] except for the RUSLE2 equations being a function of daily ridge height, runoff, and cover-management conditions.

7.1.3. Contouring (ridging) subfactor equations

The RUSLE2 contouring equations were developed to give accepted values for a base, reference condition of conventional, clean tilled 50 bu/ac corn grown on a silt loam hydrologic C soil group soil located at Columbia, Missouri.[58] This management practice was common when the contouring data were collected from the mid 1930's to the mid 1950's for much of the data represented in Figure 7.1.

The RUSLE2 equations vary contouring subfactor values about base, reference values as climate, soil, and cover-management conditions depart from the base, reference condition. The RUSLE2 equations were structured to meet required boundary conditions and were calibrated to experimental data to give similar contouring subfactor values used by the USLE and computed by RUSLE1 for base, reference conditions. In contrast to the RUSLE1 equations that used a representative ridge height and cover-management condition to represent the cover-management practice to compute an average annual contouring subfactor value (Foster et al, 1997), the RUSLE2 equations compute daily contouring subfactor values as climate, cover-management, runoff, and ridge height vary daily.

7.1.3.1. Base equations

The data shown in Figure 7.1 were collected from several locations in the eastern US. However, the data were insufficient for directly deriving explicit equations and coefficient values that consider all of the major variables related to contouring's effect on rill-interrill erosion. The data in Figure 7.1 were assumed to represent the overall effect of contouring for the base, reference condition described in **Section 7.1.3**.

The first step in deriving the RUSLE2 contouring equations was to develop a set of equations that represent the base, reference condition. Those equations, which follow similar RUSLE1 equations, are given by:

---

[58] These farming conditions differ from current farming practices. Also, these farming practices are not typical of rangelands, surface mine reclamation, construction sites, and other conditions where ridging (contouring) is used to control rill-interrill erosion. RUSLE2 includes procedures to account for these differences.

$$p_b = a_c(s_m - s_c)^4 + p_{bm} \quad s_c < s_m \qquad [7.1]$$

$$p_b = c_c(s_c - s_m)^{1.5} + p_{bm} \quad s_m \le s_c < s_{be} \qquad [7.2]$$

$$p_b = 1 \qquad s_{be} \le s_c \qquad [7.3]$$

where: p_b = base contouring subfactor value, s_c = a scaled land steepness (sine of slope angle), s_m = the land steepness (sine of slope angle) at which $p_b = p_{bm}$, the minimum base contouring value and s_{be} = the steepness (sine of slope angle) at which the contouring subfactor reaches 1. Values for the coefficients a_c and c_c are computed from:

$$a_c = (1 - p_{bm}) / s_m^4 \qquad [7.4]$$

$$c_c = (1 - p_{bm}) / (s_{be} - s_m)^{1.5} \qquad [7.5]$$

These equations satisfy the boundary conditions that $p_b = 1$ at $s_c = 0$, $p_b = p_m$ at $s_c = s_m$, $p_b = 1$ at $s_c = s_{be}$, and the slope of equations 7.1 and 7.2 is zero at $s_c = s_m$.

7.1.3.2. Ridge height adjustments

The minimum contouring subfactor value p_{bm}, which occurs at $s = s_m$, is assumed to be a function of ridge height as (Moldenhauer and Wischmeier, 1960):

$$p_{bm} = 0.05 + 0.95\exp(-0.5512 H_e) \quad if\,(H_e > 8) : H_e = 8 \text{ inches} \qquad [7.6]$$

where: H_e = daily effective total ridge height (inches), which is the sum of the daily soil ridge height H (see **Sections 6.4.6 and 8.3.5**) and the daily effective vegetation ridge height H_{vr} (see **Section 9.2.7**). The steepness s_{bm} at which the base contouring subfactor is minimum (i.e., $p_b = p_{bm}$) is also assumed to be a function of effective ridge height as:

$$s_{bm} = 4[1 - \exp(-0.7903 H_e)] + 4 \quad if\,(H_e > 8) : H_e = 8 \text{ inches} \qquad [7.7]$$

The steepness s_{be} at which the contouring subfactor p_b becomes 1 as steepness increases is assumed to be a function of effective ridge height as:

$$s_{be} = \sin\{\tan^{-1}[(9 + 53.09 H_e / 8)/100]\} \; if\,(H_e > 8) : H_e = 8 \text{ inches} \qquad [7.8]$$

where: s_{be} = the steepness (sine of slope angle) that the contouring subfactor becomes 1. Maximum effective ridge height for equations 7.6, 7.7, and 7.8 is limited to 8 inches.[59]

[59] The uncertainty of contouring's erosion control effectiveness at any specific site is greater than for all other erosion control practices. Also, data for the effect of ridge height and other factors on the erosion control effectiveness of contouring are very limited for a wide range of conditions. Contouring using high ridges can be highly effective, especially in low rainfall areas, but result in very high erosion for rarely

7.1.3.3. Runoff adjustments

The minimum contouring subfactor values p_{rm} at s_m are assumed to vary directly with the ratio of runoff with the given climate, soil, and cover-management condition to the runoff for the base, reference condition as:

$$p_{rm} = p_{bm}(d_r / 4.16) \qquad [7.9]$$

where: p_{rm} = the minimum contouring subfactor value adjusted for runoff, d_r = runoff depth (inches) for the 10 year-24 hour precipitation amount P_{10y24h} at the given location, soil, and cover-management condition on the day that a contouring factor value is computed, and 4.16 (inches) = runoff computed with the 10 year-24 hour storm for the base, reference condition (see **Section 2.3.7**).

The steepness at which the contouring subfactor becomes 1 for a given condition is assumed to be related to the shear stress that the runoff applies to the soil. It is computed from:

$$s_{re} = s_{be} / (d_r / 4.16)^{0.8571} \qquad [7.10]$$

where: s_{re} = the runoff adjusted steepness (sine of slope angle) above which the contouring subfactor equals 1.

7.1.3.4. Steepness scaling

A scaled steepness s_c is used to compute a base contouring p_b subfactor value using equation 7.1, 7.2, or 7.3. The equation for the scaled steepness at low steepness is given by:

$$s_c = s \quad s \le s_m \qquad [7.11]$$

where: s = the steepness (sine of slope angle) of the overland flow path. The scaled steepness for $s > s_m$ is given by:

$$s_c = s_{bm} + \frac{(s - s_{bm})(s_{be} - s_{bm})}{s_{re} - s_{bm}} \quad s > s_m \qquad [7.12]$$

The reason that steepness used to compute a p_b value must be scaled is that the upper steepness where the contouring subfactor becomes equal to 1 varies as conditions vary from the base, reference condition.

---

occurring intense storms. The 8 inch limit in these equations was chosen based on professional judgment and experience (see **Section 7.1.5**). See the RUSLE2 User's Reference Guide for guidance on using RUSLE2 to evaluate the erosion control effectiveness of contouring (ridging).

7.1.3.5. Contouring subfactor scaling

The contouring subfactor value must also be scaled because the contouring factor value at s_m for the given condition differs from the contouring subfactor value for the base, reference conditions. The contouring subfactor value for level furrow (row) is computed from the scaling equation as:

$$p_{c0} = 1 - \frac{(1-p_b)(1-p_{rm})}{1-p_{bm}} \quad if\,(p_{c0} > 1): p_{c0} = 1 \qquad [7.13]$$

where: p_{c0} = the contouring subfactor for a zero row grade (grade along furrows separating the ridges).

7.1.3.6. Contouring subfactor limits

Contouring subfactor values computed by equation 7.13 must be within certain limits. The upper limit is that contouring subfactor values can not be greater than 1. The other limit is a lower limit assumed to be acceptable for conservation and erosion control planning. RUSLE2 must account for the possibility of an extreme storm occurring even when annual erosivity and the P_{10y24h} precipitation amounts are low. The lower limit for contouring subfactor values is computed from:

$$p_{c0,\min} = 0.05 + 0.95\exp(-h_e) \qquad [7.14]$$

$$if\,(p_{c0} > p_{c0,\min}): p_{c0} = p_{c0,\min} \qquad [7.15]$$

where: $p_{c0,min}$ = minimum contouring subfactor value for a given ridge height.

7.1.3.7. Adjusting for row grade

The RUSLE2 assumption, which is the same as the RUSLE1 assumption, is that contouring rapidly loses its effectiveness as row grade increases (Foster et al., 1997).

$$p_c = p_{c0} + (1-p_{c0})(s_f / s_p)^{1/2} \qquad [7.16]$$

where: p_c = the daily contouring subfactor and s_f = grade along the furrows separating the ridges (row grade) (100·tangent of slope angle). The variable s_f/s_p is designated as the relative row grade and sp =land steepness (100·tangent of slope angle). Measured erosion on 150 ft wide plots on a 5 percent land steepness showed that the contouring subfactor values vary with row grade (McGregor et al., 1969). The observed contouring subfactor values were 0.10 and 0.39 for the ridges perfectly on the contour and ridges on a 0.3 percent row grade, respectively. Given the observed p_{c0} = 0.10 contouring subfactor value for ridges perfectly on the contour (i.e., row grade = 0), the computed contouring subfactor value from equation 7.16 is 0.32, which is slightly less than the 0.39 observed value.

7.1.4. Contouring failure

The RUSLE2 assumption is that contouring fails when the shear stress applied to the soil by runoff exceeds a critical shear stress. The contouring subfactor is set to 1 for those portions of the overland flow path where contouring failure is computed. The equations used in these computations are described in **Section 3.4.3**.

Once contouring failure occurs at a location on an overland flow path, the daily contouring subfactor remains at 1 until the next soil disturbing operation. The RUSLE2 assumption is that contouring failure results from runoff breaking through the ridges, and thus the contouring effect can be regained only after ridges are re-established to fill the breakthrough areas. The RUSLE2 procedure is that only a soil disturbing operation creates ridges that repair the ridge breakthroughs that represent contouring failure (see RUSLE2 User's Reference Guide).

7.1.5. Comments on contouring subfactor

RUSLE2 allows row grade to be input as absolute row grade or as relative row grade. In most applications, relative row grade should be used as the input for consistency with the concepts behind equation 7.16 for the effect of row grade on the contouring subfactor. Using relative row grade implicitly results in the quality of contouring being treated equally regardless of land steepness (see RUSLE2 User's Reference Guide).

RUSLE2 accurately represents the general trends of how major variables affect contouring's reduction on rill-interrill erosion. However, local conditions that can not be easily measured or visualized, especially before a storm event, greatly affect contouring's effectiveness. For example, slight and imperceptible variations in ridge height and furrow grade along the ridges greatly affect the number and locations of breakovers. Therefore, while RUSLE2 accurately represents the overall effect of contouring on rill-interrill erosion, the uncertainty in how contouring affects rill-interrill erosion on a specific site is greater than for any other major RUSLE2 variable (see RUSLE2 User's Reference Guide).

7.2. Porous barriers

7.2.1. Description of porous barriers

A porous barrier is a portion of the overland flow path that has a significantly higher hydraulic resistance than the overland flow path immediately upslope of the barrier. The RUSLE2 assumption is that runoff passes through porous barriers. That is, porous barriers do not end the overland flow path. Porous barriers include strips of dense vegetation used in rotational strip cropping; grass buffers, filter strips, and stiff grass hedges; a strip of dense vegetation left undisturbed along a channel on construction and logging sites; and fabric fences and gravel bag dams used on construction sites (see RUSLE2 User's Reference Guide).

7.2.2. Processes associated with porous barriers

The significantly increased hydraulic resistance of the porous barrier slows and ponds runoff in backwater at the upper edge of the barrier. Runoff's sediment transport capacity is greatly reduced in both the backwater and within the porous barrier. Deposition occurs if the sediment transport capacity is reduced to less than the sediment load coming into the backwater and barrier. Most of the deposition caused by porous barriers actually occurs in the backwater. The upper edge of deposited sediment and backwater advance upslope as deposition occurs in the backwater, which increases transport capacity within the backwater. Eventually the backwater becomes filled with sediment and most of the incoming sediment load is then transported into the barrier itself. However, RUSLE2 does not account for sediment accumulation within the backwater and change in sediment transport capacity as sediment accumulates in the backwater.

Runoff is assumed to pass through porous barriers. Infiltration rate within the barrier can be much higher than that on the overland flow path immediately upslope of the barrier, which reduces runoff downslope of the barriers. The high hydraulic resistance in a porous barrier can eliminate rill erosion and spread runoff within the barrier so that runoff exits the barrier as a thin uniform depth flow along the lower edge of the barrier. Spreading of the runoff reduces its erosivity immediately downslope of a porous barrier.

7.2.3. RUSLE2 equations used to describe porous barriers

The RUSLE2 equations used to compute deposition caused by porous barriers and the sediment load leaving porous barriers are described in **Sections 2.3 and 3.4**. This section describes key features of these equations.

RUSLE2 uses the same cover-management values to compute detachment within the backwater as it uses to compute detachment within the porous barrier. The RUSLE2 assumption is that detachment downslope of a porous barrier is not affected by the barrier except as the barrier affects contouring failure. RUSLE2 does not compute how increased infiltration on an overland flow path segment affects detachment on downslope segments because of reduced runoff. That is, RUSLE2 computes the same detachment, except for contouring failure, immediately downslope of a porous barrier regardless of the presence or absence of the barrier.

The conceptual basis for this assumption is that spreading the overland flow by the porous barrier reduces runoff erosivity. However, the very low sediment concentration in the runoff leaving the barrier increases runoff erosivity. Flow has greater erosivity when it has a very low sediment load in contrast to when the runoff's sediment transport capacity is nearly filled with sediment (Foster and Meyer, 1975; Foster, 1982). The RUSLE2 assumption is that these two effects on runoff erosivity offset each other.

The assumption that downslope detachment is unaffected by high infiltration on an upslope segment is obviously invalid where a porous barrier is sufficiently wide and has a sufficiently high infiltration rate to significantly reduce the runoff that leaves the barrier.

The RUSLE2 User's Reference Guide describes how to choose RUSLE2 inputs to partially represent conditions where high infiltration and reduced runoff affects downslope detachment.

RUSLE2 computes reduced runoff from segments, including those with porous barriers, having high infiltration rates. RUSLE2 computes reduced sediment yield from these segments if transport capacity is less than sediment load within the segment because of reduced runoff. Also, reduced runoff from high infiltration segments affects downslope sediment transport capacity and deposition computations. For example, computed deposition and sediment load on a concave shaped overland flow profile is affected by high infiltration and reduced runoff for an upslope segment.

RUSLE2 computes how reduced runoff caused by high infiltration within a porous barrier and runoff spreading by the barrier affects shear stress applied by runoff to the soil immediately downslope from the barrier. Contouring failure is assumed to occur if this shear stress exceeds a critical shear stress (see **Section 3.4.3**). RUSLE2 computes reduced erosion below a porous barrier where RUSLE2 computes no contouring failure below the barrier but computes contouring failure without the barrier.

Hydraulic resistance is a major variable that affects the amount of deposition caused by a porous barrier. A Manning's n value, RUSLE2's measure of hydraulic resistance, is computed as a function of retardance (see **Section 3.4.6**), which varies temporally as vegetation changes through time. All porous barriers are represented in RUSLE2 as strips of vegetation, even when the barriers are non-vegetative including fabric fences, gravel bags, and similar behaving barriers. Non-vegetative porous barriers slow runoff as do vegetative porous barriers.

Eight retardance classes are used to describe porous barriers based on the degree that a barrier slows runoff (see **Section 3.4.6** and RUSLE2 User's Reference Guide). The eighth retardance class is a special case used to describe barriers such as stiff grass hedges and silt fences that provide maximum retardance. The minimum backwater length that RUSLE2 uses for this retardance class is 3 ft, whereas no minimum backwater length is used for the other retardance classes (see **Section 3.4.4**). The maximum backwater length allowed by RUSLE2 is 15 ft for all retardance classes.

7.2.4. Effect of row grade

Runoff must pass through porous barriers for them to reduce sediment load. A ridge of soil at the upper side of porous barriers left by tillage or deposited sediment or debris collected on a fabric fence causes runoff to flow along the upper edge of the barrier and never enter the barrier if the grade along the upper edge of the barrier is too steep. The barrier acts as a flow interceptor (see **Section 7.3**) that ends the overland flow path.

Inputs used to describe porous barriers can be entered in two ways. One way is to select porous barriers from a list of supporting practices. When this input method is used, RUSLE2 requires that the relative row grade for the barrier be less than 10 percent. RUSLE2 assumes that trapping efficiency is independent of row grade for relative row grade less than 10 percent. The RUSLE2 assumption with this input method is that runoff does not enter the barrier but runs along the upper edge of the barrier if the relative row grade along the upper edge of the barrier exceeds 10 percent. In that case, the barriers operate as a flow interceptor barrier.

The other way to input information to describe porous barriers in RUSLE2 is to divide the overland flow path into segments and enter information for each segment, including those segments used to represent the porous barriers. When this input method is used, RUSLE2 assumes that runoff enters the porous barrier regardless of the relative row grade along the upper edge of the porous barrier (see RUSLE2 User's Reference Guide).

7.2.5. Spatial variability

When the RUSLE2 input method of selecting a support practice is used to represent porous barriers, RUSLE2 assumes that multiple barriers are spaced uniformly along the overland flow path length. Also, the conditions are assumed to be the same for each barrier. When the input method of dividing the overland flow path into segments is used, each segment can be described individually and barriers can be spaced non-uniformly. Conditions are assumed to be uniform within a segment.

7.2.6. Validation of RUSLE2 computed values

7.2.6.1. Strip cropping

RUSLE2 computed values for the effect of strip cropping and narrow stiff grass hedges on sediment yield from an overland flow path were compared with measured data reported in the literature (Foster et al., 1997, see references this section). Because strip cropping data are highly variable, many more years of data and/or experimental plots and small watersheds are required to accurately evaluate strip cropping than for any other soil conservation practice. Sediment yield from strip cropping is closely related to the storm events that occur when the erodible strips are at the end of the overland flow path. Data must be recorded over a sufficiently long duration for representative storms to occur on the erodible strips in all positions along the overland flow path. Sediment yield is much less when an extreme event occurs when an erodible strip is near the upper end of the overland flow path than at the lower end of the overland flow path. Data from such a storm would indicate that strip cropping is much more effective than it actually is. Very little of the available strip cropping data are for an adequate duration. Also, much of the strip cropping data are inconsistent. In one study, erosion with a small grain in a rotation in a strip cropping system was much less than when in the same crop rotation was not in strip cropping.

Priority was given to ensuring that RUSLE2 fits strip cropping data from Wisconsin (Hays et al., 1949; Hays and Attoe,1957) and to values given in AH282 and AH537 (Wischmeier and Smith, 1965, 1978) for a base, reference condition. Strip cropping has been used extensively and highly successfully since the 1930's in the La Crosse, Wisconsin region. The support practice factor values given in AH282 and AH537 have been well accepted in conservation planning by USDA-NRCS personnel for this region. Also, the Wisconsin data seem to be of higher quality than most of the other available data. Wischmeier and Smith (1965, 1978) and technical and scientific personnel from the USDA-Agricultural Research Service and Soil Conservation Service reviewed these same data and developed recommendations included in AH282 and 537. These values are established and accepted based on many years of field applications of the USLE.

The values in AH282 and AH537 are that strip cropping reduces sediment yield from the end of an overland flow path by 50 percent "For 4-year rotation of row crop, small grain with meadow (mixture of legume and grass hay), and 2 years of meadow. A second row crop can replace the small grain if meadow is established in it [AH537 (Wischmeier and Smith, 1978)]." The comparable RUSLE2 computed value is 0.43 for the base, reference condition of a 150 ft long, six percent steep overland flow path on a silt loam soil at Columbia, Missouri for crops and yields comparable to those represented in the data on which the AH282 and 537 values are based. The comparable measured values from research in Wisconsin are 0.42 and 0.55 (Hays et al, 1949; Hays and Attoe, 1957).

The AH282/537 values for the ratio of sediment yield with strip cropping to sediment yield without strip cropping is 0.75 "For 4-year rotation of 2 years row crop, winter grain with meadow seeding, and 1-year meadow." The RUSLE2 computed value is 0.54.

The AH282/537 values for the ratio of sediment yield with strip cropping to sediment yield without strip cropping is 1 "For alternate strips of row crop and small grain." RUSLE2 also computes a value of 1 for this condition.

7.2.6.2. Stiff grass hedges

RUSLE2 computed value of 0.25 for fraction of the incoming sediment load from a conventional, clean tilled cotton that is trapped by a stiff grass hedge at Holly Springs, MS is very close to the measured value of 0.25 (McGregor et al., 1999). RUSLE2 computes a value of 0.20 for no-till cotton upslope of the stiff grass hedge while the measured value was 0.43. The study was run for three years. The hedges were much better established and uniform in the third year of the experiment than in the first year. The fraction of the incoming sediment load that was trapped by the hedges in the third year was 0.29 and 0.33 for the conventional and no-till managements, respectively, which are close to the RUSLE2 computed values.

7.2.7. Comments on porous barriers

The RUSLE2 intent for computing how porous barriers affect erosion is for the purpose of conservation and erosion control planning where the main effects of the major variables are captured. The equations are based on well accepted hydraulic principles. The performance of porous barriers is highly dependent on how well the barriers are installed and maintained. For example, fabric fences are widely used on construction sites to control sediment leaving the site. However, very poor sediment control occurs in far too many cases because of substandard installation and/or maintenance. The actual sediment trapping of fabric in a typical field situation is much less than the sediment trapping measured in laboratory studies.

A comparable situation exists with vegetative strips that are poorly established and/or maintained. For example, non-uniform grass stands within a strip or damage caused by tillage, construction activities, or other soil disturbing operations can significantly reduce sediment trapping efficiency.

RUSLE2 does not represent the variations that result from poor installation and maintenance. RUSLE2 represents the performance of porous barriers that are installed and maintained according to specifications and inspections.

The RUSLE2 equations and input values were chosen to represent barriers that perform well in the field but less than would be measured in carefully controlled laboratory hydraulic studies.

7.3. Interceptor barriers

7.3.1. Characteristics of interceptor barriers

Interceptor barriers are topographic features that end the overland flow path. Examples of interceptor barriers represented by RUSLE2 include terraces, diversions, and small impoundments. Terraces are defined as channels on a sufficiently flat grade to cause deposition while diversions are channels are on a sufficiently steep grade that deposition does not occur in them but are not on such a steep grade that erosion occurs in them. Impoundments are water bodies where flow velocities are almost negligible. RUSLE2 represents typical impoundments comparable to those used with impoundment terraces in farm fields [e.g., parallel tile outlet (PTO) terraces] and small sediment basins used on construction sites.

Interceptor barriers reduce erosion by cutting overland flow path length and causing deposition. RUSLE2 also computes how deposition by interceptor barriers affects sediment characteristics. RUSLE2 does not compute ephemeral gully erosion that occurs in concentrated flow areas (channels) (Foster, 1985).

7.3.2. Channels (Terraces/diversions)

7.3.2.1. Deposition and sediment load equations

Deposition occurs in a channel when the incoming sediment load exceeds sediment transport capacity of flow in the channel (Foster, 1982; Foster et al., 1980a). Deposition rate is computed in RUSLE2 using (Renard and Foster, 1983):

$$D_{p(k)} = f_{(k)}\left(\frac{\phi_{(k)}}{1+\phi_{(k)}}\right)\left(\frac{dT_c}{dx} - g_o\right) \quad dT_c / dx < g_o \qquad [7.17]$$

$$D_{p(k)} = 0 \quad dT_c / dx \geq g_o \qquad [7.18]$$

$$\phi_{(k)} = 400000 V_{f(k)} / q_o \qquad [7.19]$$

where: $D_{p(k)}$ = deposition rate for the *kth* particle class [mass/(unit channel length·time)], $f_{(k)}$ = fraction, based on mass, of the total incoming sediment load g_0 (mass/unit channel length·time) from the overland flow area made up of the *kth* particle class, T_c = sediment transport capacity of the flow in the channel (mass/time), x = distance along the channel $V_{f(k)}$ = the fall velocity (ft/sec) of the *kth* sediment particle class, and q_o = the discharge rate at the end of the overland flow path (ft^3/sec per ft channel length). Equation 7.17 is derived from equation 2.16 and the assumptions of uniform channel grade, uniform sediment input from the overland flow area along the channel length, incoming sediment load for each particle class exceeds the sediment transport capacity in the channel for that particle class, and channel sediment transport capacity for each particle is proportional to the distribution (mass basis) of the incoming sediment load.

The change in sediment load with distance along the channel is computed using:

$$dT_c / dx = 450 s_{ch}^{1.16} q_0 \qquad [7.20]$$

where: T_c = transport capacity (lbs_m/sec), s_{ch} = grade (steepness) of the channel (sine of channel slope angle), and x = distance along the channel (ft). Equation 7.20 was derived from the assumptions that transport capacity is directly proportional to the 3/2 power of shear stress applied to the channel boundary by the flow and that Manning's equation is used to compute hydraulic radius for flow in the channel (Foster and Meyer, 1975; Foster, 1982; Foster et al., 1980). The channel's hydraulic roughness is assumed to be that of deposited sediment that covers soil surface roughness, surface residue, and standing vegetation. The effect of standing live or dead vegetation on deposition in channels is not considered in RUSLE2 because most of the deposition is assumed to occur when little vegetation is present, such as at seedbed time when crops are planted. The 450 coefficient value in equation 7.20 was determined by calibrating RUSLE2 to compute values similar to those given by the RUSLE1 sediment delivery ratio equation, which was empirically derived from field data [AH703(Renard, 1997); Foster et al., 1997; Foster and Ferreira, 1981; Foster and Highfill, 1983).

Equation 7.17 and its companion equations compute a uniform deposition rate along the channel. The sediment leaving the channel is computed with:

$$g_{ch(k)} = g_{o(k)} - D_{p(k)} \qquad [7.21]$$

where: $g_{ch(k)}$ = the sediment load (mass/unit channel length·time) leaving the end of the channel for the *kth* particle class. The sediment load leaving the channel expressed as the ratio of sediment load at the end of the channel to unit drainage area for the channel is computed with:

$$A_{ch(k)} = g_{ch(k)} / \lambda_o \qquad [7.22]$$

where: $A_{ch(k)}$ = the sediment load for the *kth* particle class leaving the end of the channel expressed as mass/time per unit drainage area and λ_o = the length of the overland flow path that discharges into the channel. The sediment delivery ratio for the channel for the *kth* particle class is given by:

$$\omega_{(k)} = 1 - D_{p(k)} / g_{o(k)} \qquad [7.23]$$

where: $\omega_{ch(k)}$ = sediment delivery ratio for a channel for the *kth* sediment particle class. Total sediment load is computed by summing the sediment load values for the five RUSLE2 particle classes (see **Section 4.7**).

7.3.2.2. Comments on channels

When flow interceptors are represented in RUSLE2 as a support practice, the spacing between flow interceptors is the same for all flow interceptors represented by the support practice. However, non-uniform spacing among flow interceptors can be represented by manually entering appropriate spacing values. Similarly, the grade is assumed the same for all channels when flow interceptors are represented as a support practice. However, separate grade values for each channel can be entered in RUSLE2.

RUSLE2 requires that a representative channel grade be chosen for channels on a non-uniform grade. This limitation can be of consequence for parallel terraces where grade varies along the channel. In most of these situations, channel grade is flattest at the upper channel end with grade increasing along the channel. RUSLE2's estimates for deposition for these conditions are less accurate than for uniform grade channels. A grade flatter than the average channel grade for its length is the appropriate input grade.

RUSLE2 does not represent channels where sediment inflow varies along the channel length. Not many field situations occur where this limitation is of consequence.

The RUSLE2 equations used to compute deposition in channels are based on commonly used equations for channel hydraulics. However, RUSLE2 is a conservation and erosion control planning tool, not a hydraulic design tool. Appropriate hydraulic equations should be used to design the channels represented in RUSLE2. Channels are usually designed to accommodate runoff rate from a particular design storm under particular soil and cover conditions whereas most conservation and erosion control planning is based on average annual erosion rates for the range of cover-management conditions expected over the time period being represented in the RUSLE2 computation. See the RUSLE2 User's Reference Guide for information on the types of channels represented by RUSLE2.

7.3.3. Impoundments

7.3.3.1. Sediment delivery ratio equation

The RUSLE2 assumption is that sediment transport capacity in impoundments is essentially zero. Impoundments are treated as a fixed length settling basin in RUSLE2. The RUSLE2 equation for computing sediment deliver ratio for an impoundment is:

$$\omega_{(k)} = \exp(-c_i V_{f(k)}) \quad [7.24]$$

where: $\omega_{i(k)}$ = the sediment delivery ratio for an impoundment for the *kth* sediment particle class. Sediment delivery ratio is the ratio of sediment mass leaving the sediment basin to incoming sediment mass.

A 10000 $(ft/sec)^{-1}$ value for the coefficient c_i for a base reference silt loam soil was determined by fitting equation 7.24 to experimental data for impoundments used in parallel tile outlet terraces (Laflen et al., 1972). The average trapping efficiency of those impoundments was 94 percent. Literature reporting measured trapping efficiency of sediment basins on construction sites was reviewed during the development of RUSLE1.06 (Toy and Foster, 2000; Bonta and Hamon, 1980, Fennessey and Jarret, 1997; USEPA, 1976 a, 1976b). The trapping efficiency of these basins is comparable to that for impoundment terraces when the sediment basins are well designed, constructed, and maintained and perform at maximum efficiency. Also, no deposition is assumed to occur between the point that the sediment is detached and where the sediment reaches the impoundment. If deposition occurs along the overland flow path upstream of the impoundment, trapping efficiency will be less than computed by RUSLE2 (see **Section 7.3.3.2**).

Many sediment basins on construction sites do not perform at maximum efficiency because of poor design, the basins being partly filled with sediment, and water/sediment chemistry that keeps fine sediments highly dispersed.

The RUSLE2 user can select a base sediment delivery ratio for the reference silt loam soil texture to accommodate trapping efficiency variations by specific site. The c_i coefficient values used in RUSLE2 for a range of sediment delivery ratios are given in Table 7.1.

Table 7.1. Values for the coefficient c_i used to compute sediment delivery ratio for deposition of sediment from reference silt loam soil in impoundments.

Sediment trapping ratio (%)	c_i $(ft/sec)^{-1}$
6.4	10000 (1)
10	5900
15	3500
20	2300
25	1700

Note (1): Coefficient value determined by fitting RUSLE2 equation to experimental data for impoundment terraces

7.3.3.2. Effect of incoming sediment characteristics

RUSLE2 computes trapping efficiency for impoundments solely as a function of incoming sediment characteristics. RUSLE2 does not consider basin geometry or flow withdrawn characteristics in these computations. However, RUSLE2 computes sediment delivery ratios as a function of texture of the soil that produces the sediment, upslope deposition amount, and the feature that produces the upslope deposition as shown in Table 7.2 because these variables affect sediment characteristics. As a point of reference, the RUSLE2 computed sediment characteristics leaving the uniform overland flow path represented in Table 7.2 are the same as the sediment characteristics at the point of detachment because

RUSLE2 computed no local deposition for this particular overland flow path.

Table 7.2. RUSLE2 computed sediment delivery ratio for sediment basin in various flow sequence.

	Flow path			
Soil texture	uniform overland flow path into basin	steep flow segment onto low steepness segment into basin	uniform flow path into grass strip into basin	uniform overland flow path into basin into basin
silt loam	0.064	0.469	0.317	0.678
silt	0.068	0.157	0.101	0.216
silty clay	0.119	0.612	0.581	0.825
clay	0.105	0.741	0.905	0.902
loamy sand	0.014	0.125	0.531	0.890
sand	0.009	0.127	0.333	0.900

The primary particle distribution of the soil producing the sediment does not accurately indicate the RUSLE2 computed sediment delivery ratio for impoundments. Sediment is eroded as a mixture of primary particles and aggregates (see **Section 4.7**). The size and density distributions of the sediment do not parallel the distribution of primary particles in the soil. Clay is assumed in RUSLE2 to be a bonding agent that influences aggregate sizes and densities and the mass distribution between the particle classes, especially the small and large aggregates. Consequently, sediment eroded from high clay soils has a large portion of the sediment in aggregates of increased size. Conversely, soils very high in silt produce poorly aggregated sediment that is almost entirely in small-sized primary silt particles that are not rapidly deposited. Soils high in sand produce poorly aggregated sediment that is almost entirely in sand-sized primarily particles that are readily deposited. Consequently, the sediment delivery ratio computed for sediment eroded from high clay soils is not proportionally higher than that for silt loam soils when no upslope or local deposition occurs. **Expecting RUSLE2 computed sediment delivery ratio values for an impoundment to be directly related to the primary particle distribution of either the soil or sediment is a very serious error.**

As illustrated in Table 7.2, RUSLE2 computed sediment delivery ratio values for impoundments also vary with the type of upslope feature that causes deposition. Even though the sediment delivery ratios for the overland flow path with a low steepness segment, a grass strip, and a sediment basin are comparable, the characteristics of the sediment leaving each of these flow paths and entering a sediment basin are quite different because of differences in upslope erosion and deposition processes. RUSLE2 computes a relatively high interrill erosion rate for the overland flow path that has the low steepness segment in comparison to the one with a dense grass strip at the end of the overland flow path. Interrill erosion is very low in the grass strip, which adds very little sediment to the sediment load in the grass strip in contrast to interrill erosion adding sediment to the sediment load on the low steepness segment. The sediment leaving the grass strip is finer than the sediment leaving the low steepness segment. Consequently, the RUSLE2 computed sediment delivery ratio values for impoundments are generally larger for the grass strip overland flow path than for the low steepness segment overland flow path. Sediment delivery ratios for sediment eroded from high silt soils are not affected as much as for the other soil textures because sediment eroded from the high silt soils is poorly aggregated and has a very narrow size range in a relative small size range.

Sediment delivery ratio values are high for a basin downstream of another sediment basin. That is, much less sediment trapping occurs in the second basin than in the first basin, except for the sediment eroded from the high silt soils. The upstream sediment basin removes almost all of the sediment that is easily deposited.

7.3.3.3. Design

RUSLE2 should not be used to design sediment basins unless regulations explicitly state that RUSLE2 can be used. The RUSLE2 values computed for impoundments are for the purpose of conservation and erosion control planning. The accuracy of RUSLE2's computations for sediment trapping by small impoundments is comparable to that for other erosion and sediment control practices. The specific hydraulic and sediment trapping performance of impoundments depends on many complex, interactive variables. Accepted design procedures should be used to design impoundments (e.g., see Haan et al., 1994).

7.3.3.4. Comments

RUSLE2 results for sediment trapping by impoundments must be interpreted very carefully. The flow path up to the sediment basin must be properly represented. For example, RUSLE2 seriously under-computes sediment delivery by an impoundment if a uniform steepness overland flow path is assumed when in fact the overland flow path has a segment at the lower end of the overland flow path that causes a high degree of deposition. Likewise, when RUSLE2 computed values are compared to research and field measurements, the RUSLE2 inputs must be very carefully selected to accurately represent measurement conditions. The characteristics of the sediment entering the experimental basin must match those assumed in RUSLE2. For example, as Table 7.2 shows, if upstream deposition is not considered, the sediment delivery values computed by RUSLE2 will be much less than is measured.

Another consideration is that RUSLE2 does not represent basin geometry, degree that the basin is filled, and other factors. The assumption in RUSLE2 is that the basin is well designed and maintained. Standards and specifications for design, construction, and maintenance of impoundments should be a principal tool used to ensure expected results.

7.3.4. Hydraulic flow paths

Simple channels and impoundments can be combined into simple hydraulic flow paths. RUSLE2 can represent an overland flow area discharging into a channel from a single side and the channel in turn discharging into an impoundment or a series of impoundments. Non-uniform conditions along the channel can not be represented. RUSLE2 can not represent a channel on a particular grade discharging into a channel on a different grade. That is, RUSLE2 can not represent channels in series nor can RUSLE2 represent an impoundment discharging into a channel. However, RUSLE2 can represent overland areas discharging into a channel from both sides. Also, RUSLE2 can represent an overland flow area discharging directly into an impoundment without involving a channel. (See the RUSLE2 User's Reference Guide)

7.3.5. Benefit of deposition caused by porous barriers and flow interceptors

7.3.5.1. Concepts

Deposited sediment trapped on the hillslope by porous barriers and by flow interceptors including channels/impoundments (e.g., terraces) is assumed to be a soil conservation benefit. Landscape quality is degraded less when sediment is retained by deposition on the hillslope.

Partial credit is taken for deposition on the hillslope as soil saved based on the location of the deposition along the overland flow path (see Section **2.3.10.4)**. The credit taken for deposition caused by flow interceptors is less than the credit taken for porous barriers because most flow interceptors are much more permanent and the deposition more localized than with porous barriers. Porous barriers such as grass strips are assumed to be periodically removed and reestablished in new locations. An increased portion of the hillslope benefits from deposition with these barriers than occurs with flow interceptor such as impoundment-type terraces. Full credit for deposition as soil saved is taken for rotational strip cropping (see Section **2.3.10.4**).

Partial credit is given to deposition as soil saved with flow interceptors (e.g., channels/impoundments in farm fields) because the deposition is localized although the deposited sediment is spread over a significant-sized area on either side of channels/impoundments in farm fields. The absolute size of this area is the same regardless of channel/impoundment spacing. Consequently, the fraction of the total field area over which the sediment is spread becomes less as channel/impoundment spacing increases.

Deposition near the end of the original overland flow path before porous/interceptor barriers were placed is assumed to be less valuable for maintaining landscape quality than sediment deposited near the upper end of the overland flow path. This concept is consistent with that used to compute the benefit of deposition on the overland flow area (see **Section 2.3.10.4**).

Deposition is a selective process that enriches the deposited sediment in coarse particles. Even though coarse sediment is deposited first, clay and silt primary particles are deposited because sediment is assumed to be a mixture of primary particles and aggregates so that fine primary particles are deposited along with sand particles (see **Section 4.7.5**). The assumption that deposition on overland flow areas is predominantly sand is erroneous. Thus, deposition is assumed to be beneficial because deposited sediment includes clay and silt particles even though the deposited sediment is partially enriched in sand.

7.3.5.2. Equations for benefit of deposition caused by flow interceptors

The RUSLE2 equation for the benefit of deposition by a flow interceptor is:

$$b_{s(i)} = 0.45\exp[-0.011(\delta_{s(i)} - 100)] \quad \delta_{s(i)} \geq 100 \text{ ft} \qquad [7.25]$$

$$b_{s(i)} = 0.45 \quad \delta_{s(i)} < 100\,\text{ft} \qquad [7.26]$$

where: $b_{s(i)}$ = the fraction of the deposition that is credited as soil saved for the *ith* flow interceptor and δ_s = flow interceptor spacing (ft). The credit $b_{p(i)}$ for deposition as affected by the *ith* flow interceptor location along the original overland flow path is computed with:

$$b_{p(i)} = 1 - (\lambda_{s(i)} / \lambda_o)^{1.5} \qquad [7.27]$$

where: $\lambda_{s(i)}$ = distance from the origin of overland flow for the original overland flow path to the *ith* flow interceptor and λ_o = the overland flow path length without flow interceptors. The conservation planning sediment load (see **Section 2.3.10.4**) for each channel is computed from:

$$g_{cp(i)} = g_{o(i)}[1 - (b_{s(i)} + 0.2b_{p(i)})(1 - \omega_{(i)})] \qquad [7.28]$$

where: $g_{cp(i)}$ = the conservation planning sediment load per unit channel length for the *ith* channel, the $g_{o(i)}$ = the sediment load for conservation planning from the overland flow area immediately above the *jth* channel, and ω = sediment delivery ratio. The conservation planning soil loss in term of mass per unit area for the area represented by the overland flow path without channels is:

$$A_{cp} = \left(\sum_{i=1}^{J} g_{cp(i)} \right) \Big/ \lambda_o \qquad [7.29]$$

where: A_{cp} = the conservation planning soil loss (mass/area) for the area represented by λ_o and i = the index for each flow interceptor along the original overland flow path, and J = number of flow interceptors.

7.4. Subsurface drainage

The effect of subfactor drainage on detachment is represented by the subsurface drainage subfactor p_d in equation 2.10.[60] In general, research has shown that subsurface drainage reduces rill-interrill erosion by approximately 40 percent (Bengston and Sabbage, 1988; Formanek et al., 1987; Schwab and Fouss, 1967; Schwab, 1976; Skaggs et al., 1982). The reduction is caused by reduced runoff and an increased vegetation production (yield) level. The input value for production (yield) level in vegetation descriptions should reflect production level under subsurface drained conditions. RUSLE2 does not adjust production (yield) level as a function of environmental inputs.

---

[60] The effect of subsurface drainage on runoff is discussed in **Section 3.3.1.2.4**.

The runoff effect on erosion with subsurface drainage is assumed to be same as the soil erodibility factor being a function of a soil's runoff potential. Therefore, equation 4.9, the permeability subfactor equation used to compute soil erodibility factor values, is used to compute how subsurface drainage affects detachment. The subsurface drainage subfactor is computed as:

$$p_d = K_d / K_u \quad if\,(p_d < 0.2): p_d = 0.2 \qquad [7.30]$$

where: K_d and K_u = soil erodibility factors (US customary units) for the drained and undrained conditions, respectively (see **Section 4.1**). A minimum value of 0.2 is set for the subsurface drainage subfactor. A base soil erodibility factor value without the permeability subfactor is computed as:

$$K_b = K_u - 0.025(P_{ru} - 3) \qquad [7.31]$$

where: K_b = a base soil erodibility factor value (US customary units) computed without the permeability subfactor and P_{ru} = the soil profile permeability class for the undrained condition. The soil erodibility factor with subsurface drainage is computed with:

$$K_d = K_b + 0.025(P_{rd} - 3) \qquad [7.32]$$

where: P_{rd} = the soil profile permeability class for the drained condition.

Hydrologic soil group (see **Section 3.3.1 and** RUSLE2 User's Reference Guide) used in NRCS soil survey descriptions is used as the RUSLE2 input to describe how subsurface drainage affects soil profile permeability class. The RUSLE2 relationship between hydrologic soil group and the soil profile permeability class is given in Table 7.3.

Table 7.3. Relation between hydroligc soil groups and permeabiltiy classes.

Hydrologic soil group	Permeability class
A	1
B	2.67
C	4.33
D	6

RUSLE2 computed subsurface drainage subfactor values are shown in Table 7.4. As expected, subsurface drainage reduces the subsurface drainage subfactor the greatest when subsurface drainage causes the greatest change in hydrologic soil group from D to A in contrast to a change from D to C. The erosion reduction is also related to the soil erodibility (K factor) value. The subsurface drainage subfactor reduction is greatest when soil erodibility factor values are low. This effect results from the additive equation form used to compute soil erodibility factor values (See **Section 4.1.1**). Location has only a slight effect on the RUSLE2 subsurface drainage subfactor and probably should be greater than is computed by RUSLE2. However, the values computed by RUSLE2 are considered adequate for conservation and erosion control planning. Other erosion estimation procedures can be used when increased accuracy is desired (Skaggs et al., 1982).

Table 7.4. Subsurface drainage subfactor values as affected by soil erodibility factor value (US customary units) for undrained soil condition and for a change in hydrologic soil group by hydrologic soil group.

	subsurface drainage subfactor p_d			
	K = 0.20	K = 0.20	K = 0.30	K = 0.55
Location	D to A	D to C	D to A	D to A
Ft Wayne, IN	0.38	0.83	0.58	0.77
Raleigh, NC	0.38	0.78	0.57	0.76
Jackson, MS	0.38	0.75	0.60	0.77

7.5. Irrigation

RUSLE2 computes how irrigation affects rill-interrill erosion caused by precipitation, but RUSLE2 does not compute erosion caused by water drop impact and surface runoff directly produced by the applied irrigation water. The increase soil moisture from irrigation affects rill-interrill erosion by precipitation during the irrigation period because of increased soil erodibility, increased biomass decomposition, decreased soil surface roughness and ridge height, and increased vegetation production (yield). The effect of irrigation on production (yield) level is accounted for by inputting yield values appropriate for production under irrigated conditions. RUSLE2 does not adjust production (yield) level as a function of environmental inputs.

7.5.1. Effect on soil erodibility

The effect of increased soil moisture on soil erodibility during the irrigation period is computed using equation 4.14 that computes temporal (daily) values for the soil erodibility factor. This equation is modified by adding the daily amount of water added by irrigation to the daily precitation amount as:

$$K_{(j)}/K_n = 0.591 + 0.732[(P_{(j)} + I_{(j)})/0.123] - 0.324(T_{(j)}/62.8) \qquad [7.33]$$

$$If\,(K_{(j)}/K_n) > 2.0 \quad \text{then} \quad (K_{(j)}/K_n) = 2.0$$

$$If\,(K_{(j)}/K_n) < 0.4 \quad \text{then} \quad (K_{(j)}/K_n) = 0.4$$

where: $K_{(j)}$= the soil erodibility factor on the *jth* day, K_n = the soil erodibility factor value computed with a RUSLE2 soil erodibility nomograph for the frost free period defined as the period that average daily temperature $T_{(j)}$ is above 40 ^oF, 62.8 = the average temperature during the frost free period (^oF), $P_{(j)}$ = daily precipitation (inches), $I_{(j)}$ = average daily water added by irrigation (inches), and 0.123 = average daily precipitation during the frost free period (inches).

The average daily water added by irrigation on the *jth* day is computed from:

$$I_{(j)} = V_{w(j)} - P_{(j)} \quad if\,(I_{(j)} < 0) : I_{(j)} = 0 \qquad [7.34]$$

where: $V_{w(j)}$ = consumption use (inches) by the vegetation on the *jth* day (Schwab et al., 1966). Plant consumption use values are input for the vegetation descriptions that represent irrigated conditions.

7.5.2. Effect on soil surface roughness, ridge height, and decomposition

The daily amount of water added by irrigation is added to the daily precipitation amount to compute the effect of irrigation on soil surface roughness (see **Section 6.3.6** and equation 6.30), ridge height (see **Section 6.4.6** and equation 6.43), and decomposition (see **Section 10.3.1** and equation 10.5).

7.5.3. Effect on vegetation

Individual vegetation descriptions must be created to describe vegetation under irrigated conditions. These descriptions include values for consumptive water use that are a function of the soil properties and location and location where the RSULE2 computation is being made. Figure 7.2 illustrative consumptive use values for a particular corn crop grown at Lincoln, Nebraska.

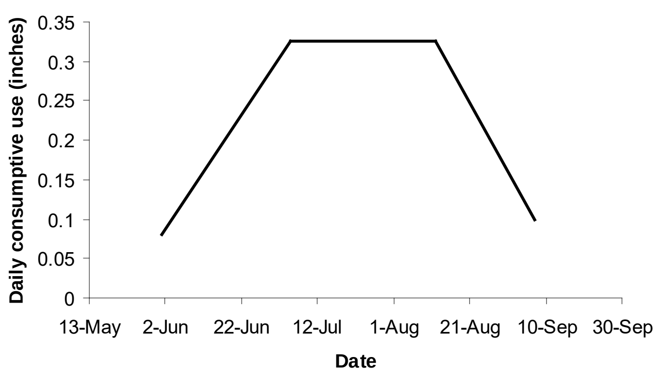

Figure 7.2. Daily consumptive water use for a 120 day corn crop grown at Lincoln, Nebraska.

The input yield for the vegetation description is the yield expected for the consumptive use water values entered because RUSLE2 does not compute how environmental conditions affect yield. RUSLE2 adjusts consumptive use values in its yield adjustment procedures directly in proportion to live above ground biomass (see **Section 9.3**).

7.6. List of symbols

a_c = coefficient used to compute values for base contouring subfactor values

$A_{ch(k)}$ = sediment load for *kth* particle class leaving end of the channel (mass/ unit drainage area·time)

A_{cp} = conservation planning soil loss for the area having channels (mass/area)

$b_{p(i)}$ = deposition credit as affected by the *ith* flow interceptor location along the original overland flow path

$b_{s(i)}$ = fraction of the deposition that is credited as soil saved for the *ith* flow interceptor

c_c = coefficient used to compute values for base contouring subfactor values

c_i = coefficient used to sediment delivery ratio in an impoundment for base reference silt loam soil

d_r = runoff depth for P_{10y24h} storm (inches)

$D_{p(k)}$ = deposition rate for *kth* sediment class (mass/unit channel length·time)

$f_{(k)}$ = mass fraction of the incoming sediment load g_0 from the overland flow area made up of *kth* sediment class

$g_{ch(k)}$ = sediment load leaving end of the channel for *kth* particle class (mass/unit channel length·time)

$g_{cp(i)}$ = conservation planning sediment load for the *jth* channel (mass/unit channel length)

g_o =total incoming sediment load from overland flow area (mass/unit channel length·time)

$g_{o(k)}$ = incoming sediment load from overland flow area (mass/unit channel length·time)

$g_{o(i)}$ = sediment load for conservation planning from overland area immediately above the *jth* channel (mass/unit channel length·time)

H = daily soil ridge height (inches)

H_e = daily effective total ridge height, which is sum of soil ridge height and effective vegetation ridge height (inches)

H_{vr} = daily effective vegetation ridge height (inches)

I_j = average water added by irrigation on *jth* day (length)

J = number of flow interceptors along an overland flow path

K_b = base soil erodibility factor value computed without the permeability subfactor (US customary units)

K_d = soil erodibility factor for drained condition (US customary units)

K_j = soil erodibility factor on the *jth* day (US customary units)

K_n = soil erodibility factor computed with a RUSLE2 soil erodibility nomograph for frost free period (US customary units)

K_u = soil erodibility factor for undrained condition (US customary units)

p_b = base contouring subfactor value

p_{bm} = minimum base contouring subfactor value

p_c = the daily contouring subfactor

p_{c0} = contouring subfactor for a zero row grade

$p_{c0,min}$ = minimum contouring subfactor value for a given ridge height

p_d = subsurface drainage subfactor

p_{rm} = minimum contouring subfactor value adjusted for runoff

P_j = daily precipitation (length)

P_{rd} = the soil profile permeability class for the drained condition

P_{ru} = the soil profile permeability class for the undrained condition

P_{10y24h} = 10 year-24 hour precipitation amount (length)

q_o = discharge rate at end of the overland flow path (volume/ unit channel length·time)

s = overland flow path steepness (sine of slope angle)

s_{be} = land steepness at which the contouring subfactor reaches 1 (sine of slope angle)

s_{bm} = land steepness at which contouring subfactor value is minimum (sine of slope angle)

s_c = scaled land steepness (sine of slope angle)

s_{ch} = grade of the channel (sine of channel angle with horizontal)

s_f = grade along the furrows separating the ridges (row grade) (100 time tangent of slope angle)

s_f/s_p = relative row grade

s_m = land steepness at which $p_b = p_{bm}$ (sine of slope angle)

s_p = land steepness (100 time tangent of slope angle)

s_{re} = runoff adjusted land steepness above which contouring subfactor equals 1 (sine of slope angle)

T_c = total sediment transport capacity for all sediment classes of the flow in the channel (mass/time)

$V_{w(j)}$ = daily consumption watercuse by vegetation (length)

$V_{f(k)}$ = fall velocity of *kth* sediment class (length/time)

x = distance along the channel (length)

$\delta_{s(i)}$ = *ith* flow interceptor spacing (feet)

λ_o = overland flow path length without flow interceptors (length)

$\lambda_{s(i)}$ = distance from origin of overland flow for the original overland flow path to the *ith* flow interceptor (length)

$\phi_{(k)}$ = a deposition coefficient for the *kth* sediment class ($length^{-1}$)

$\omega_{(k)}$ = sediment delivery ratio for *kth* sediment class

$\omega_{(i)}$ = total sediment delivery ratio for the *ith* flow interceptor

Indices

i – flow interceptor

j - day

k – sediment class

8. OPERATIONS

A RUSLE2 operation is an event that changes vegetation, residue, or soil conditions. RUSLE2 uses a set of rules and 10 processes to represent how operations affect rill and interrill erosion (see the RUSLE2 User's Reference Guide). RUSLE2 computes erosion based on user supplied descriptions of the variables that affect rill-interrill erosion. For example, RUSLE2 does not use simulation modeling to compute how environmental conditions affect vegetation. This section discusses the RUSLE2 equations used to describe how operations affect vegetation, residue, and soil variables.

8.1. Effect on vegetation

RUSLE2 uses **begin growth**, **kill vegetation**, and **remove live vegetation processes** to describe how operations affect vegetation variables.

8.1.1. Begin growth

The **begin growth** process tells RUSLE2 to stop using data in the current vegetation description and start using data from another vegetation description. The change occurs on the date of the operation that uses the **begin growth** process (See RUSLE2 User's Reference Guide).

RUSLE2 uses only a single vegetation description on any particular date. RUSLE2 does not combine data from multiple vegetation descriptions to represent a composite of vegetations having different properties. For example, a single vegetation description is used to describe a rangeland plant community that involves multiple plant types such as shrubs that provide an over-story and grasses that provide an under-story under the shrubs with open space between the individual shrub-grass clumps.

8.1.2. Kill vegetation

The **kill vegetation** process transfers the biomass (dry mass basis) of live vegetation to the dead standing residue pool and transfers live root biomass to the dead root biomass pool in the soil. Both the standing residue and dead root biomass pools disappear by daily decomposition.

8.1.3. Remove live vegetation

The purpose of the **remove live vegetation** process is to determine the amount of residue left by a field operation like a hay harvest that removes live biomass and leaves both standing and surface residue. The standing and surface residue biomass left by a remove live vegetation process is computed as:

$$\Delta B_{tr} = f_{tl}(f_{lr} B_{al}) \qquad [8.1]$$

$$\Delta B_{sr} = f_{sl}(f_{lr} B_{al}) \qquad [8.2]$$

where: ΔB_{tr} = the biomass left as standing residue that is added to the existing standing biomass pool, $f_{lr}B_{al}$ = the live biomass that is affected by the operation, f_{tl} = the fraction of the affected biomass that is left as standing residue, f_{lr} = the fraction of the above ground live biomass that is affected by the operation, B_{al} = existing live vegetation biomass, ΔB_{sr} = the biomass left as surface residue that is added to the existing surface residue biomass pool, and f_{sl} = the fraction of the affected biomass that is left as surface residue. These residue biomass values are added to the existing biomass values in the respective residue pools.

The amount of live aboveground biomass left after a remove live biomass process is computed from:

$$B_{al} = (1 - f_{lr})B_{alp} \qquad [8.3]$$

where: Bal = the mass (dry basis) of the above bround live biomass that is left after the operation and Balp = the mass (dry basis) of the above bround live biomass that exists immediately before the operation.

8.2. Effect on residue/dead roots

RUSLE2 tracks the three residue pools of standing residue, surface residue, and buried residue. Operations that include a **flatten standing residue** process transfer biomass from the standing residue pool to the surface residue pool. Operations that include a **disturb soil** process bury transfer surface residue to the buried residue pool and transfers buried residue to the surface residue pool. RUSLE2 rules are that standing residue can not be buried without first being flattened and live above ground biomass can not be flattened or buried without first being killed (i.e., transferred from the live above ground biomass pool to the standing residue pool).

8.2.1. Flatten standing residue

The **flatten standing residue** process transfers biomass from the standing residue pool to the surface residue pool using:

$$\Delta B_{tr} = f_f B_{tr} \qquad [8.4]$$

where: f_f = the fraction of the existing standing residue that is flattened (i.e., added to the surface biomass pool).[61] The standing residue biomass pool after the operation is computed as:

[61] Flattening, burial, and resurfacing ratios are based on mass, not portion of the soil surface covered (see RUSLE2 User's Reference Guide).

$$B_{tr} = B_{trp}(1 - f_f) \quad [8.5]$$

where: B_{tr} = mass (dry basis) of the standing residue immediately after the operation and B_{trp} = the mass (dry basis) that existed immediately before the operation.

8.2.2. Burial of surface residue

Burial of surface residue is the transfer of biomass from the surface residue pool to the buried residue pool. The amount of surface residue that is buried is computed by:

$$\Delta B_{sr} = f_b B_{sr} \quad [8.6]$$

where: ΔB_{sr} = the mass of the surface residue that is transferred to the buried residue pool and f_b = the fraction of the surface residue that is buried.

The surface residue mass is computed by (Wagner and Nelson, 1995):

$$B_{sr} = (B_{trp} f_f + B_{srp})(1 - f_b) + B_{brp} f_u \quad [8.7]$$

where: B_{sr} = the surface residue mass (dry basis) immediately after the operation, B_{srp} = the surface mass immediately before the operation, f_u = the fraction of the buried residue mass that is resurfaced and B_{brp} is the amount of buried biomass in the soil disturbance depth immediately before the operation. Note that the surface residue mass in equation 8.7 is the sum of the existing surface residue mass plus the mass added by flattening of standing residue and the mass of buried residue that is resurfaced.

8.2.3. Resurfacing of buried residue

The mass of buried residue that is resurfaced by the operation is computed from:

$$\Delta B_u = f_u B_{br} \quad [8.8]$$

where: ΔB_u = residue that is resurfaced from soil disturbance depth, f_u = the resurfacing ratio, and B_{br} = the mass of buried residue in the soil disturbance depth. RUSLE2 does not consider the resurfacing of dead roots.

8.2.4. Determining values for the flattening, burial, and resurfacing ratios

8.2.4.1. Base reference values

A single data point can be used to determine a value for the flattening ratio. However, equation 8.7 involves the two unknowns of burial and resurfacing ratios, which requires at least two data points to determine values for these two ratios. The proper data for determining values for these ratios is where the same operation is repeated multiple times, preferably at least four times. Only two data sets were found that meet this requirement (Brown et al., 1992; Wagner and Nelson, 1995) and even then the (Brown et al., 1992) data set did not include standing residue. Most data previously used to determine burial ratio values are not usable because they are from situations where a particular operation was used a single time.

Base reference values for the flattening ratio were determined by fitting equation 8.5 to observed data reported by (Wagner and Nelson, 1995). Values for the burial and resurfacing ratios were determined by fitting equation 8.7 to observed data reported by (Brown et al., 1992; Wagner and Nelson, 1995). Surface residue biomass values were estimated for the (Brown et al., 1992) data from measured surface residue cover values using equation 10.1 that estimates surface cover as a function of surface biomass (see **Section 10.2**).

The minimization function that was minimized to fit equations 8.5 and 8.7 to measured data to determine flattening, burial, and resurfacing ratio values is:

$$\delta = \left\{ \sum_{n=1}^{N} \left[\ln(y_{e(n)} - \ln(y_{o(n)}) \right]^2 \right\} \Big/ N \qquad [8.9]$$

where: δ = the function that is minimized, $y_{e(n)}$ = estimated value for the *nth* data point, $y_{o(n)}$ = observed value for the *nth* data point, and N = number of observations. A minimization function using logarithms rather than absolute values gives a more uniform relative error among the observations in comparison to a minimization function that uses absolute values. A minimization function using absolutes values gives flattening, burial, and resurfacing ratio values that are biased to the large surface biomass values. Equations 8.5 and 8.7 were fitted by the soil disturbing implement types represented in the observed data. The flattening, burial, and resurfacing ratio values obtained by fitting equations 8.5 and 8.7 were used to guide assign values in the RUSLE2 core database (see the RUSLE2 User's Reference Guide).

8.2.4.2. Effect of soil disturbance depth on residue burial

The input value for burial ratio is for a reference depth, which is assumed to the manufacturer recommended or normal operating depth for the implement, machine, tool, or other residue burial process.

The effect of operation depth (i.e., soil disturbance depth) on the residue burial ratio is computed using:

$$\alpha_d = [1-(1-y_d/y_m)^{2.7}]/[1-(1-y_{rc}/y_m)^{2.7}] \qquad [8.10]$$

where: α_d = an adjustment factor for depth, y_{rc} = reference soil disturbance depth, y_d = the soil disturbance depth of the operation, and y_m = the maximum soil disturbance depth for the operation. The fit of equation 8.10 to observed data is shown in Figure 8.1 (Hanna et al., 1995; Hill and Stott, 2000; Johnson, 1988).[62]

8.2.4.3. Effect of speed on surface residue burial

The effect of operation speed on residue burial ratio values is computed using:

$$\alpha_s = [0.6 + 0.4(v_s / v_m)^{1/2}]/[0.6 + 0.4(v_r / v_m)^{1/2}] \qquad [8.11]$$

where: α_s = an adjustment factor for speed, v_r = reference speed, v_s = operation speed, and v_m = maximum operation speed. The fit of equation 8.11 to observed data is shown in Figure 8.2 (Hanna et al., 1995; Hill and Stott, 2000; Johnson, 1988).

8.2.4.4. Combined effect of soil disturbance depth and speed on surface residue burial

The burial ratio for the effect of both depth and speed is computed from:

$$f_b = \alpha_d \alpha_s f_{br} \qquad [8.12]$$

where: f_{br} = the burial ratio for the given residue type for the reference soil disturbance depth y_{rc} and reference operation speed v_r.

8.2.5. Distribution of buried residue and dead roots by soil disturbing operations

Soil disturbing operations resurface buried residue but not dead roots, redistribute existing buried residue in the soil, redistribute dead roots in the soil, and bury surface residue. RUSLE2 makes these computations in three steps. The first step computes inversion of the burial material. The second step computes the redistribution of existing buried residue and dead roots and resurfacing of buried residue from the upper soil layer(s). The third step computes the mass distribution by soil layer of the material buried by the

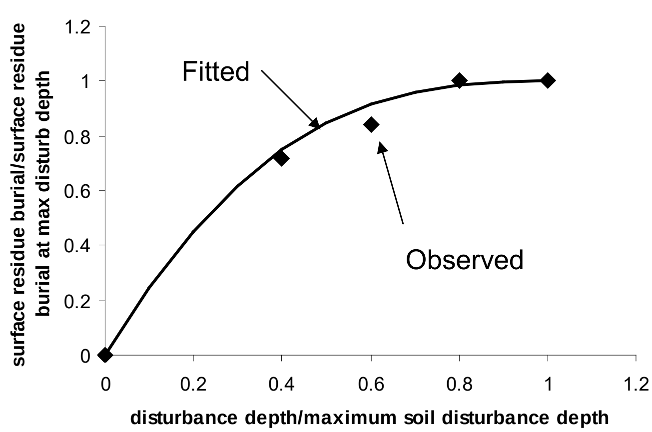

Figure 8.1. Effect of soil disturbance depth on surface residue burial.

[62] R.L. Raper, USDA-Agricultural Research Service, researched the literature and assembled the data used to derive the equations for effect of soil disturbance depth and operation speed on residue burial and equations for distribution of buried material by soil layer.

operation.

8.2.5.1. Types of soil disturbance operations

Types types of soil disturbing operations are used in RUSLE2 to describe how these operations distribute bury residue and dead roots in the soil. These types are: inversion, mixing with some inversion, and mixing. The *inversion* type represents machines like moldboard plows and soil disturbances (e.g., hand tillage with a spading fork) that primarily bury and mix material in the soil by inverting the disturbed soil layer. The *mixing with some inversion* type represents machines like field cultivators, chisel plows, tandem disks, and scarifiers and soil disturbances that bury material in the soil primarily by mixing with some inversion. The *mixing* type represents machines like rotary powered machines (e.g., rototillers); shank machines used to inject manure, fertilizers, and other materials into the soil; and soil disturbances that incorporate material by mixing with essentially no inversion. The mixing type also represents materials pressed into the soil by cattle trampling, sheep's foot compactors, and similar operations. Burial of residue by compression does not involve soil disturbance.

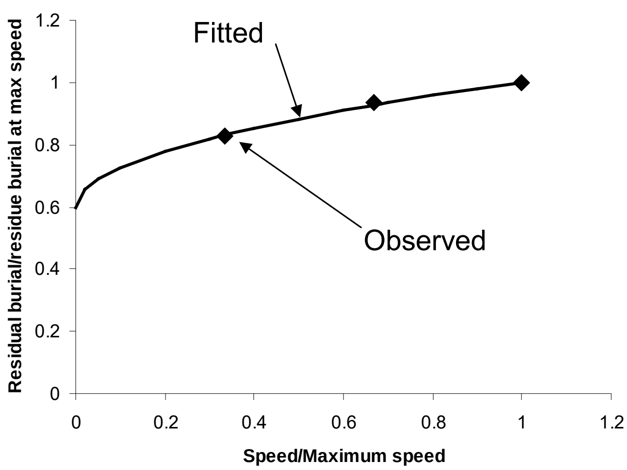

Figure 8.2. Effect of speed on surface residue burial.

8.2.5.2. Equations for redistribution of buried residue and dead roots

A sifting concept is used in RUSLE2 to compute redistribution of buried material by soil disturbing operations. RUSLE2 computes separately the redistribution of buried residue and dead roots. Conceptually, soil disturbance "sifts" each soil layer so that some of the buried material (i.e., buried residue or roots) is retained in each layer and the remainder moves downward to the next soil layer.[63]

RUSLE2 assumes that no material moves upward except by inversion-type soil disturbances. The first step is to compute inversion of the buried material for inversion type soil disturbing operations. This computation assigns the existing buried material

[63] The RUSLE2 equations used to redistribute buried residue and dead roots are based on empirical data reported in the literature cited in **Section 12.2.4.**

mass in the bottom soil layer to the top soil layer, the existing material in the top layer to the bottom layer, the existing material in the next to bottom soil layer is assigned to the soil layer next to top layer, and so forth. For example, the buried material mass in the top soil layer after inversion is set equal to the material mass in the bottom soil layer before inversion and the mass in the bottom layer after inversion is set equal to the mass in the top soil layer before inversion.

The next step for all soil disturbing operations is to "sift" the soil layers to compute the buried material that leaves each soil layer using:

$$\Delta B_{(i)} = (1 - \phi_{k(i)})(B_{p(i)} + \Delta B_{(i-1)} - R_{(i)}) \qquad [8.13]$$

where: $\Delta B_{(i)}$ = the buried material (dry mass/area) that moves from the *ith* soil layer to the *(i+1)th* layer, $\Delta B_{(i-1)}$ = the buried material (dry mass/area) that moves from the *(i-1)th* soil layer to the *)th* layer ϕ_k = the mass fraction of the buried material in the *ith* layer that is retained for the *kth* type soil disturbance operation, $B_{p(i)}$ = existing buried material (mass/area) in the *ith* soil layer, $R_{(i)}$ = the buried residue (dry mass/area) that is resurfaced for the *ith* layer. The soil disturbance depth is divided into 10 layers to make these computations where i = index for the soil layers (i = 1 for surface soil layer). The computations start with the top layer and proceed downward. The inflow to the top layer is set to zero in this step. The amount of material that enters the top layer by burial is added in the third step described below.

The fine roots tightly bound to soil particles dead roots are assumed to have the greatest effect on erosion. Therefore, the RUSLE2 assumption is that dead roots are not resurfaced.[64]

Values for R in equation 8.13 are zero when equation 8.13 is used to compute the redistribution of dead roots. The total mass of buried residue that is resurfaced is computed using equation 8.8. The value for R in the top soil layer (i.e., R_1) in equation 8.13 is set to the value computed by 8.8. If the value computed by equation 8.8 exceeds the buried residue mass in layer 1, the value for the mass removed is set equal to the buried residue in layer 1 before sifting. The remainder of the buried residue mass needed to provide the mass computed by equation 8.8 is removed from layer 2. If the buried residue mass in layer 2 is insufficient, the entire buried residue before sifting is removed from layer 2. The check moves to subsequent layers until the total resurfaced residue mass computed by equation 8.8 is satisfied.

[64] The fact that soil disturbing operations surface dead roots is recognized. However, the fraction of dead roots in the soil that is resurfaced is considered to be much smaller than the fraction of buried residue that is resurfaced.

Table 8.1. Retention coefficient Φ values for redistributing buried material among soil layers

	Type soil disturbance operation		
Layer	Inversion w/mixing	Mixing w/inversion	Mixing
1 (top)	0.40	0.32	0.50
2	0.40	0.39	0.56
3	0.40	0.47	0.61
4	0.40	0.54	0.67
5	0.40	0.62	0.72
6	0.40	0.69	0.78
7	0.40	0.77	0.83
8	0.40	0.84	0.89
9	0.50	0.92	0.94
10	1.00	1.00	1.00

Values for the retention coefficient ϕ are given in Table 8.1. The value of 1 for the *10th* layer denotes that no buried material passes through the bottom layer in the soil disturbance depth. Retention values for the mixing-type soil disturbing operations are assumed to increase linearly from the value for the top layer to 1 for the bottom layer. This increase with depth means that buried material is more likely to move downward in the upper part of the disturbed soil layer than in the lower part. The increased retention coefficient values with depth indicate greater retention because of less stirring and mixing in the bottom of the soil disturbed layer. In contrast, stirring, mixing, and retention are assumed to be nearly uniform with depth for inversion-type soil disturbing operations as shown in Table 8.1.

The retention ϕ values in Table 8.1 were determined by fitting equation 8.13 to measured data where the same operation was repeated multiple times. These data conclusively show that buried material redistributed by multiple events of mixing with some inversion and mixing types soil disturbing operations forms a bulge that moves downward in the soil rather than producing a uniform distribution (see RUSLE2 User's Reference Guide). In contrast, the distribution of buried material becomes nearly uniform with multiple events of an inversion-type soil disturbing operation. Retention values were independent of characteristics of the buried material.

The third step is to distribute surface residue by soil layer when it is buried by a soil disturbing operation. That mass is added to the buried residue mass after sifting as computed with equation 8.13 for redistribution and resurfacing of existing buried residue. The equation used to compute the distribution of surface residue when it is buried in the soil by mixing-type soil disturbing operations is:

$$M = (y / y_d)^b \quad [8.14]$$

where: M = cumulative normalized mass (cumulative mass above depth in soil/total mass buried in soil depth disturbed by operation) of buried residue with depth (i.e., M = 0 at y = 0 and M =1 at y = y_d), y = depth in soil, y_d = soil disturbance depth for a specific soil disturbing operation, and b = 0.5 for *mixing with some inversion* type soil disturbing operations and b = 0.3 for *mixing* type soil disturbing operations.

The comparable equations for inversion-type soil disturbing operations are:

$$M = 0.28\{\exp[1.83(y / y_d) - 1]\} \quad y / y_d \le 0.6 \quad [8.15]$$

$$M = 1 - 0.441\{[1 - (y / y_d)] / 0.4\}^{1.4} \quad y / y_d > 0.6 \quad [8.16]$$

Equations 8.14 - 8.16 were derived from observed data where surface material was buried by a single occurrence of an operation when no buried residue existed in the soil. The distributions of buried residue computed by equations 8.14 – 8.16 are shown in Figure 8.3.

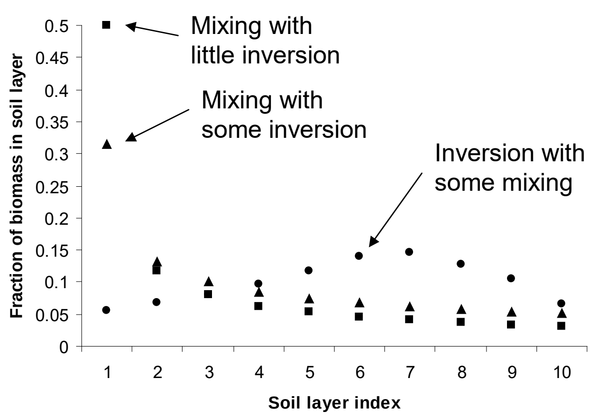

Figure 8.3. Distribution of residue by soil layer when initially buried by a soil disturbing operation.

In summary, RUSLE2 computes buried residue mass in each soil layer after an operation by (1) computing inversion of buried residue biomass if the operation is an inversion-type operation, (2) using equation 8.13 to compute redistribution of existing buried residue mass caused by stirring and mixing (i.e., sifting), and (3) using equations 8.14 – 8.16 to distribute the surface biomass among soil layers that is buried by the operation, which is added to the buried residue mass computed in step 2. The steps for computing redistribution of dead roots is to (1) add the dead roots produced by the kill live vegetation process to the existing dead roots in each soil layer if the operation includes a kill vegetation process, (2) invert the dead roots by soil layer if the operation is an inversion type operation, and (3) compute the sifting of dead roots using equations 8.13.

8.2.6. Add other cover

The **add other cover** process is used to apply material to the soil surface and/or place (inject) material into the soil.

8.2.6.1. Add cover to soil surface

The **add other cover** process has the inputs of the residue, amount (dry mass basis) added as well as the portion added to the soil surface and the portion placed (injected) in the soil. The mass of the material added to the soil surface is added to the surface residue pool.

8.2.6.2. Injection of material (residue) into the soil by a soil disturbing operation

The **add other cover** process along with a **disturb soil** process are used together to inject material into the soil. This material is assumed to be added in the lower half of the disturbed soil depth in a parabolic distribution. The equations for cumulative mass with depth for material injected into the soil are:

$$M = 6\left[\frac{(2y/y_d - 1)^2}{2} - \frac{(2y/y_d - 1)^3}{3}\right] \quad y/y_d \geq 0.5 \qquad [8.17]$$

$$M = 0 \quad y/y_d < 0.5 \ [8.18] \qquad [8.18]$$

where: m = cumulative normalized mass (cumulative mass above depth in soil/total mass), y = depth in soil, and y_d = soil disturbance depth. The mass placed in the soil is added to the buried residue pool.

8.2.7. Remove residue cover

The **remove residue cover** process is used to describe removal of standing and surface residue. Inputs for this process include the portions of the standing and surface residue masses that are removed. The masses of standing and surface residue are reduced by these portions. Another input is whether the residue removal applies to all residues involved in the RUSLE2 computation or only the last residue added to the soil surface in the computation. An example is where corn and wheat grain crops are grown in sequence. The harvest of each crop leaves residue. The straw is baled (removed) but the corn residue is left in the field. The input to remove the last residue is selected in this situation. Another example is burning where all residues is selected.

8.2.8. Add/remove non-erodible cover

8.2.8.1. Description of add/remove non-erodible cover processes

The **add non-erodible** cover process sets detachment to zero for the portion of the soil surface covered with non-erodible cover. That is:

$$c = c_{\omega}(1 - f_{\mu}) \qquad [8.19]$$

where: c = the c in equations 2.10 and 6.1 used to compute detachment, c_{ω} = the c term in equation 2.10 without the non-erodible cover effect, and f_{μ} = the portion of the soil surface covered by non-erodible cover. Equation 8.19 in effect adds a non-erodible cover subfactor to equation 6.1.

Non-erodible cover also affects runoff. The equations used to adjust cover number values used to compute runoff when non-erodible cover is present are given in **Section 3.3.1.2.3**.

The **remove non-erodible cover** process removes non-erodible cover. The input value is the portion of the existing non-erodible cover that is removed by the operation. A 100 percent input value removes all of the existing non-erodible cover. A 40 percent input value removes 40 percent of the existing non-erodible cover. For example, assume that the existing non-erodible cover is 72 percent on the day of an operation that removes 40 percent of the non-erodible cover. The remaining non-erodible cover is 43 percent [72·(100-40)/100] after the operation.

8.2.8.2. Loss of non-erodible cover over time

RUSLE2 assumes that non-erodible cover disappears over time because of photo-chemical and other processes. The equation for the loss of non-erodible cover is given by:

$$f_\mu = f_0 \exp(-\alpha_\mu \Delta t_\mu) \qquad [8.20]$$

where: f_0 = the fraction of the soil surface covered by non-erodible cover immediately after an operation affects non-erodible cover (i.e., added or removed) and Δt_μ = the days since the non-erodible cover was affected. The coefficient α_μ = a coefficient (days^{-1}) that describes the rate of loss of non-erodible cover. Equation 8.20 is not written as a function of environmental conditions. To consider the effect of environmental conditions on this cover loss, users select α_μ values that reflect both material properties and local environmental conditions. Consequently, α_μ values can differ among locations for the same material based on variation of environmental conditions between locations.

8.3. Effect on soil

The **disturb soil** process is used to describe how operations affect the soil. An operation that includes a disturb soil process is referred to as a soil disturbing operation. Soil disturbing operations loosen the soil, buries surface residue, resurfaces buried residue, redistributes buried residue and dead roots, affects soil roughness, and affects ridges. Some operations such as planting disturb only a portion of the soil surface.

8.3.1. Loosen soil

The effect of an operation loosening the soil is described by the soil consolidation subfactor. The equation for the soil consolidation subfactor is given in **Section 6.6.2**.

For those operations that do not disturb the entire soil surface area, RUSLE2 computes a net soil consolidation subfactor as:

$$s_{cn} = f_d + (1 - f_d) s_{cu} \qquad [8.21]$$

where: $s_{c,n}$ = the net soil consolidation subfactor for the overall soil surface, f_d = the fraction of the soil surface that is disturbed, $s_{c,u}$ = the soil consolidation subfactor for the portion of the soil surface not disturbed by the operation, and 1 = the consolidation subfactor value for the soil surface portion that is disturbed.

An effective soil consolidation time t_{de} since last soil disturbance is computed by solving equation 6.52 for the time that gives the value for the net soil consolidation subfactor value computed with equation 8.21. The time used in equation 6.52 to compute the soil consolidation subfactor starts from this effective soil consolidation time.

8.3.2. Burying and resurfacing residue

Soil disturbing operations bury surface residue and resurface buried residue. The RUSLE2 assumption is that surface residue can only be buried by disturbing the soil. The equations used to compute residue mass buried and resurfaced by soil disturbing operations are given in **Section 8.2**. Important variables used in these computations are the fraction of the surface residue mass that the operation buries and the faction of the buried residue mass in the soil disturbance depth that is resurfaced. **The burial and resurfacing ratios apply to the entire soil surface and not just to the portion of the soil surface that is disturbed** (see the RUSLE2 User's Reference Guide).

Some soil disturbing operations that disturb only a portion of the soil surface. The RUSLE2 procedure that determines an effective surface residue biomass for the entire surface is described in **Section 6.2.3**.

8.3.3. Redistribution of buried residue and dead roots

Soil disturbing operations redistribute existing buried residue and dead roots on the date of the operations. The equations used in these computations are given in **Section 8.2.5**.

The RUSLE2 assumption is that soil disturbance is required to place material in the soil (e.g., manure and fertilizer injection). The equations used to compute the distribution of material placed in the soil by an **add other cover** process are given in **Section 8.2.6.1**.

8.3.4. Soil surface roughness

A soil disturbing operation affects soil surface roughness. An operation can either smooth the soil surface (i.e., reduce soil surface roughness) or roughen the soil (i.e., increase soil surface roughness). Roughness decays over time because of subsidence (settlement), interrill erosion, and local deposition.

The RUSLE2 assumption is that soil surface roughness can only be created by a soil disturbing operation. Consequently, operations with a disturb soil process must be used to represent soil surface roughness creation.

8.3.4.1. Inputs for soil surface roughness in an operation description

Three inputs are used in a **disturb soil** process to describe soil surface roughness. One input is initial roughness, which is the roughness created by the operation when performed on a smooth surface under the base, reference condition of high biomass and silt loam soil (see **Section 6.3.1** and **6.3.6** and RUSLE2 User's Reference Guide). Equations given in **Sections 6.3.2, 6.3.3,** and **6.3.5** are used to adjust this initial roughness value for soil texture, biomass, and existing soil surface roughness to represent site specific conditions where RUSLE2 is being applied.

RUSLE2 computes soil surface roughness decay over time as a function of precipitation and interrill erosion using equations given in **Section 6.3.6**. RUSLE2 computes roughness decay to the final roughness value input for the particular operation. The final roughness value is usually set to 0.24 inches and not adjusted for soil texture or soil biomass. This final roughness value represents persistent, highly stable soil clods that remain even after extensive erosivity applied to the reference silt loam soil in unit plot conditions. The roughness subfactor value is 1 for unit plot conditions (see **Section 6.3.1**). Final roughness on unit plots varies by soil texture, but that effect on rill-interrill erosion is captured in the soil erodibility factor (see **Section 4.1**).

In special cases such as construction sites where a high clay soil is scarified, a final roughness value greater than 0.24 inches can be entered to represent an increased roughness effect (see the RUSLE2 User's Reference Guide). A final roughness value less than 0.24 inches is entered for operations, such as for fine seedbeds typical of vegetable production or smooth surfaces left by a blading operation on a construction site, that create roughness smoother than that for unit-plot conditions (see **Section 2.1**). When the final roughness value is less than 0.24 inches, the initial roughness input value should be the same as the final roughness input value. RUSLE2 computes no roughness decay when the final roughness input is less than 0.24 inches.

8.3.4.2. Partial soil disturbance

In contrast to the assumption made for burying and resurfacing residue, the RUSLE2 assumption is that the input roughness values only apply to the portion of the soil surface disturbed. A net soil surface roughness value is computed as:

$$s_{rn} = f_d s_{rd} + (1 - f_d) s_{ru} \qquad [8.22]$$

where: s_{rn} = the net soil surface roughness subfactor immediately after a soil disturbing operation that occurs on day t, s_{rd} = the soil surface roughness subfactor for the disturbed portion of the soil surface immediately after the operation on day t, and s_{ru} = the soil surface roughness subfactor for the undisturbed portion of the soil surface on day of the operation. The starting value in equation 6.26 for the roughness subfactor immediately after the operation that is decayed is the s_{rn} value computed with equation 8.22.

RUSLE2 assumes that an operation that disturbs only a portion of the soil surface disturbs some of the undisturbed soil. Consequently, multiple occurrences of an operation that disturbs only a portion of the soil surface ultimately disturb most of the soil surface. That is, RUSLE2 can not represent an operation that disturbs the same area with each occurrence of the operation.

8.3.4.3. Tillage intensity (effect of existing roughness)

The RUSLE2 assumption is that the roughness left by a soil disturbing operation can depend on existing roughness. The input for this effect is a **tillage intensity** value assigned to the disturb soil process (see RUSLE2 User's Reference Guide). Tillage intensity refers to the degree that a soil disturbing operation obliterates existing roughness (i.e., conversely the degree that existing roughness affects roughness left by the soil disturbing operation). A tillage intensity value of 1 means that the soil disturbing operation is so aggressive that existing roughness has no effect on roughness left by the operation. For example, the tillage intensity value of 1 is used to describe moldboard plows and rototillers. A tillage intensity of 0 means that the operation does not affect existing roughness. Harrows used as secondary tillage to create a seedbed are assigned 0.4 for tillage intensity to reflect that existing roughness has a significant effect on the roughness left by harrows. For example, the soil surface roughness after a harrow is greater when it follows a moldboard plow than when it follows a tandem disk used for secondary tillage. The tillage intensity effect is computed using:

$$R_a = (R_{ae} - R_{ao})(1-\xi) + R_{ao} \quad R_{ao} \le R_{ae} \qquad [8.23]$$

$$R_a = R_{ao} \quad R_{ao} > R_{ae} \qquad [8.24]$$

where: R_a = adjusted roughness after a soil disturbing operation, R_{ae} = existing adjusted roughness immediately before the operation, ξ = tillage intensity, and R_{ao} = the adjusted roughness left by the operation when applied to a smooth surface. Roughness values used in equations 8.23 and 8.24 have been adjusted for soil texture and biomass effects using the procedures described in **Section 6.3**.

8.3.5. Ridges

The RUSLE2 assumption is that only soil disturbing operations create ridges. Consequently, operations with a disturb soil process must be used to represent ridge creation.

The ridge input for the **disturb soil** process is initial ridge height. In contrast to soil surface roughness, the input ridge height is not adjusted for soil texture, soil biomass, existing ridges, or portion of the soil surface disturbed. For example, the ridge height left by a planter run on top of existing ridges depends on the existing ridge height. This effect is represented in RUSLE2 by having a set of planter descriptions in the RUSLE2 database for a range of ridge heights. A particular planter entry is selected from this input set based on the operations that precede the planter operation (see the RUSLE2 User's Reference Guide).

8.4. List of symbols

b = exponent in equation for distribution of buried residue left by an operation

$B_{(i)}$ = buried material in *ith* soil layer (mass/area)

B_{al} = live vegetation biomass (mass/area)

B_{br} = buried biomass in soil disturbance depth (mass/area)

B_{sr} = surface residue (mass/area)

B_{tr} = stading residue biomass (mass/area)

c = daily cover-management factor value in equation 2.10 with non-erodible cover effect

c_{ω} = daily cover-management factor in equation 2.10 without non-erodible cover effect

f_b = portion of surface residue that is buried (fraction)

f_{br} = burial ratio for given residue type for reference soil disturbance depth and speed

f_d = portion of the soil surface that is disturbed (fraction)

f_f = portion of existing standing residue biomass that is flattened a flatten standing residue process operation (fraction)

f_{lr} = portion of above ground live biomass that is affected by a **remove live vegetation** process operation (fraction)

f_n = faction of soil surfaced by non-erodible cover

f_{sl} = portion of affected biomass that is left as surface residue by a **remove live vegetation** process operation (fraction)

f_{tl} = portion of affected biomass that is left as standing residue by a **remove live vegetation** process operation (fraction)

f_u = portion of the buried residue biomass in soil disturbance depth that is resurfaced that is resurfaced (fraction)

f_0 = portion of soil surface covered by non-erodible cover immediately after an operation affects non-erodible cover (i.e., added or removed) (fraction)

f_{μ} = portion of soil surface covered by non-erodible cover (fraction)

M = cumulative buried residue normalized with depth (cumulative mass above depth in soil/total mass buried in soil disturbance depth) bured by a **soil disturb** process operation

N = number of data points

$R_{(i)}$ = buried residue niomass that is resurfaced from a soil layer (mass/area)

R_a = roughness after a soil disturbing operation (length)

R_{ae} = existing roughness immediately before the operation (length)

R_{ao} = the roughness left by the operation when applied to a smooth surface (length)

s_{cn} = net soil consolidation subfactor

s_{cu} = soil consolidation subfactor for the portion of soil surface not disturbed by operation

s_{rn} = net soil surface roughness subfactor immediately after a soil disturbing operation that occurs on day t

s_{rd} = soil surface roughness subfactor for disturbed portion of the soil surface immediately after the operation

s_{ru} = soil surface roughness subfactor for undisturbed portion of the soil surface on day t

v_m = maximum operation speed (length/time)

v_r = reference speed (length/time)

v_s = operation speed (length/time)

y = depth in soil (length)

y_d = soil disturbance depth of operation (length)

y_{en} = estimated value for the *nth* data point

y_m = the maximum soil disturbance depth for operation (length)

y_{on} = observed value for the *nth* data point

y_{rc} = reference soil disturbance depth (length)

α_d = adjustment factor for depth

α_s = adjustment factor for speed

α_μ = coefficient that describes rate of loss of non-erodible cover ($days^{-1}$)

δ = function that is minimized

$\Delta B_{(i)}$ = buried material that moves from *ith* soil layer to *(i+1)th* layer (mass/area)

$\Delta B_{(i-1)}$ = buried material that moves from (*i-1)th* soil layer to *i)th* layer (mass/area)

ΔB_{sr} = standing residue added to surface residue biomass pool by a **remove live vegetation** operation process or surface residue biomass transferred to the buried residue pool by a **soil disturb** process operation (mass/area)

ΔB_{tr} = live above ground biomass added to standing biomass pool added by a **remove live vegetation** process operation or biomass lost from standing residue bimass and added to surface bimass by a **flatten standing residue** process in an operation (mass/area)

$\Delta B_{u(i)}$ = residue biomass that is resurfaced from soil disturbance depth by a **soil disturb** process operation (mass/area)

Δt_{μ} = time since non-erodible cover was affected (days)

ξ = tillage intensity

$\phi_{k(i)}$ = portion of buried material in the *ith* layer that is retainedby a *kth* type soil disturbance operation (fraction)

Indices

i – soil layer

j – day

k - type of soil disturbance operation

n – data point

9. VEGETATION

The input variables used to describe vegetation are biomass (dry basis) at maximum canopy cover and the temporal variables of root biomass (dry basis) in the upper 4-inch (100 mm) soil depth, canopy cover, effective fall height, and live ground cover. These variables are used to compute values for the temporal variables of the live root biomass by soil layer, dead root biomass produced by root sloughing, live above ground biomass, biomass produced by senescence that falls to the soil surface, and retardance. All of these variables are used to compute values for the cover-management subfactors (see **Section 6**), curve numbers used to compute runoff (see **Section 3.3.1.2**), and hydraulic resistance (see **Section 3.4.6**). The RUSLE2 User's Reference Guide describes selection of input values for variables used to describe vegetation.

9.1. Input of temporal variables

Input values for the temporal vegetation variables are often manually constructed and entered in RUSLE2 using values in the RUSLE2 core database as a guide (see RUSLE2 User's Reference Guide). This procedure works satisfactorily for simple vegetation descriptions for annual agricultural and horticultural crops and annual descriptions for mature perennial plant communities. However, creating and entering values for vegetation descriptions for long term vegetation from seeding to maturity is cumbersome and time consuming. RUSLE2 includes a long term vegetation tool that can be used to create long term vegetation descriptions (see RUSLE2 User's Reference Guide).

Temporal variables used to describe vegetation are assumed to vary linearly between the times in the data points entered for these variables. The time between data points should be sufficiently small to accurately represent non-linear variations.

9.2. Computed temporal vegetation variables

9.2.1. Live root biomass by soil layer

RUSLE2 uses input values for live root biomass in the upper 4-inch soil depth to compute daily live root biomass values in individual soil layers.

The literature was reviewed to obtain measured data for root biomass and its distribution in the soil at plant maturity for the major agricultural crops of corn, soybeans, cotton, and wheat; several vegetable crops; and several pasture/range plant communities (see **Section 12.2.5**). The RUSLE2 equations for the distribution of live root biomass in the soil were derived from these data, especially the data by Long (1959). These equations are:

$$M_r = y[24.24y\exp(-5.50y) + 0.778] \quad y \le 0.533333 \qquad [9.1]$$

$$M_r = 0.783391 + 0.147688(y - 0.533333) \quad 0.533333 < y \le 2 \qquad [9.2]$$

$$M_r = 0 \quad 2 < y \qquad [9.3]$$

where: M_r = cumulative root biomass (dry basis) above the depth y, y = Y/15, Y = depth (inches) in soil (Y = 0 at soil surface), and 15 = a reference depth (inches) used to normalize the depth variable y. A plot of these equations by 1 inch layer is shown in Figure 9.1.

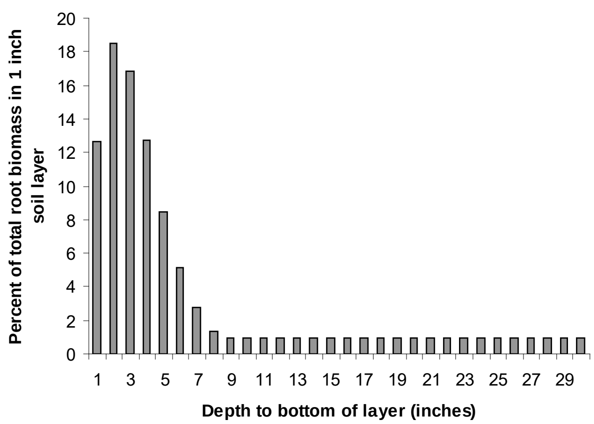

Figure 9.1. Fraction of total root biomass in 1 inch soil layers.

No data were found for measured root biomass in 1-inch soil layers. Accurately measuring roots is very difficult in soil layers as thin as 1-inch, especially near the soil surface. Preference was given to data where root biomass was measured in soil layers sufficiently thick to obtain accurate measurements, which is one of the reasons why the input value for root biomass is based on the upper 4-inch soil layer. This depth also contains the bulk of the roots that significantly affect rill-interrill erosion as discussed below.

The shape of the curve in Figure 9.1 within the upper 4-inch soil layer is based on judgment. A power equation gave the best fit to the observed data, but it was not used because a power equation form gives maximum root biomass density at the soil surface. The judgment is that root mass in the upper 1-inch layer is less than that at a slightly deeper soil depth. Soil moisture at the soil surface is reduced because of evaporation when soil surface (residue) cover is minimal, which in turn results in reduced root biomass near the soil surface. Increased surface residue reduces evaporation, which increases soil moisture at the soil surface. The form of equation 9.1, which represents reduced root biomass near the soil surface, was judged more appropriate overall for RUSLE2 than the power equation form. The shape of the curve in the upper 4-inch soil depth is of minimal consequence because RUSLE2 uses the average root biomass density in the upper 10-inch soil depth to compute runoff curve values, b values for effect of ground (surface) cover, slope length exponent, soil surface roughness, and soil biomass subfactor values (see **Sections 3.3.1.2, 6.2.1, 6.2.2, 6.3, and 6.5**).

A major result from the literature review and data analysis was that rooting depth for the roots judged to have the greatest effect on rill-interrill erosion do not vary greatly among agricultural crops and pasture/range plant communities. However, the rooting depths for most vegetable crops were about one half of that for agricultural crops. A rooting depth of 30 inches was assumed in RUSLE2 for all plant communities, including vegetable crops. Other RUSLE2 assumptions based on data analysis were that 85 percent of live root biomass was above the 15-inch depth, the live root biomass distribution by depth was the same for all plant communities, and rooting depth does not temporally vary.

The adequacy of these RUSLE2 assumptions must be judged in terms of RUSLE2's stated purpose of being an easily used guide for erosion control planning. Do RUSLE2's erosion estimates adequately represent the effect of temporal variability in root biomass for purposes of erosion control planning? Such an evaluation described in the RUSLE2 User's Reference Guide shows that RUSLE2 meets that criterion. Capturing the main effects of root biomass rather than all of the details is adequate for RUSLE2 purposes.

RUSLE2 uses average live root biomass density in the upper 10 inch soil depth to compute values for the soil biomass subfactor (see **Section 6.5.2**). The RUSLE2 live root distribution described by equations 9.1 and 9.2 compute that 61 percent of the total live root biomass is in the upper 4-inch soil depth and 80 percent is in the upper 10-inch soil depth. The constant rooting depth assumption does not result in large errors for estimating the soil biomass subfactor because the input variable is the root biomass in the upper 4-inch soil depth that contains more than half of the total root biomass.[65] Temporal live root biomass values given in the RUSLE2 Core Database (see the RUSLE2 User's Guide) were scaled from measured values at plant maturity. RUSLE2 accurately computes expected erosion estimates for times before the vegetation reaches maturity for major agricultural crops (see RUSLE2 User's Reference Guide), which strongly indicates that these assumptions are adequate for RUSLE2 purposes.

These assumptions are in accordance with the RUSLE2 objective to provide a system where the major vegetation variables affecting rill-interrill erosion can be easily described and measured and values for variables used to describe vegetation can be easily entered in RUSLE2. The objective is to sufficiently represent vegetation for RUSLE2 to estimate the effects of vegetation for conservation and erosion control planning. The adequacy of RUSLE2 for conservation and erosion control planning is the criteria for judging these RUSLE2 relationships. **The RUSLE2 User's Reference Guide guidelines must be followed to ensure accurate RUSLE2 erosion estimates.**

9.2.2. Live root biomass becoming dead root biomass

RUSLE2 uses a single vegetation description on any particular day (see **Section 8.1.1**). An operation that includes a **kill vegetation** process transfers the entire live root biomass in each soil layer to the dead root biomass in the corresponding soil layer. RUSLE2 does not allow killing a portion of the live root biomass. That effect can be accomplished by using an operation that includes a **begin growth** process that instructs RUSLE2 to begin using values for a new vegetation description. RUSLE2 assumes that the difference between the live root biomass on the last day that a vegetation description is used and the live root biomass on day zero in the new vegetation description represents dead root biomass that is added to the existing root biomass. RUSLE2 assumes that a decrease in

---

[65] A possible RUSLE2 improvement would be to temporally vary rooting depth according to plant community. Similarly, the root distribution should also be varied with plant community and plant growth stage. These improvements were judged to excessively complicate RUSLE2.

root biomass from one day to the next represents root sloughing (Reeder et al., 2001). Each daily decrease in live root biomass is added that day to the dead root biomass.

9.2.3. Live above ground biomass

RUSLE2 vegetation descriptions are divided into new growth, senescence, and regrowth periods, illustrated in Figure 9.2, to compute temporal values for live above ground biomass as a function of canopy cover.[66]

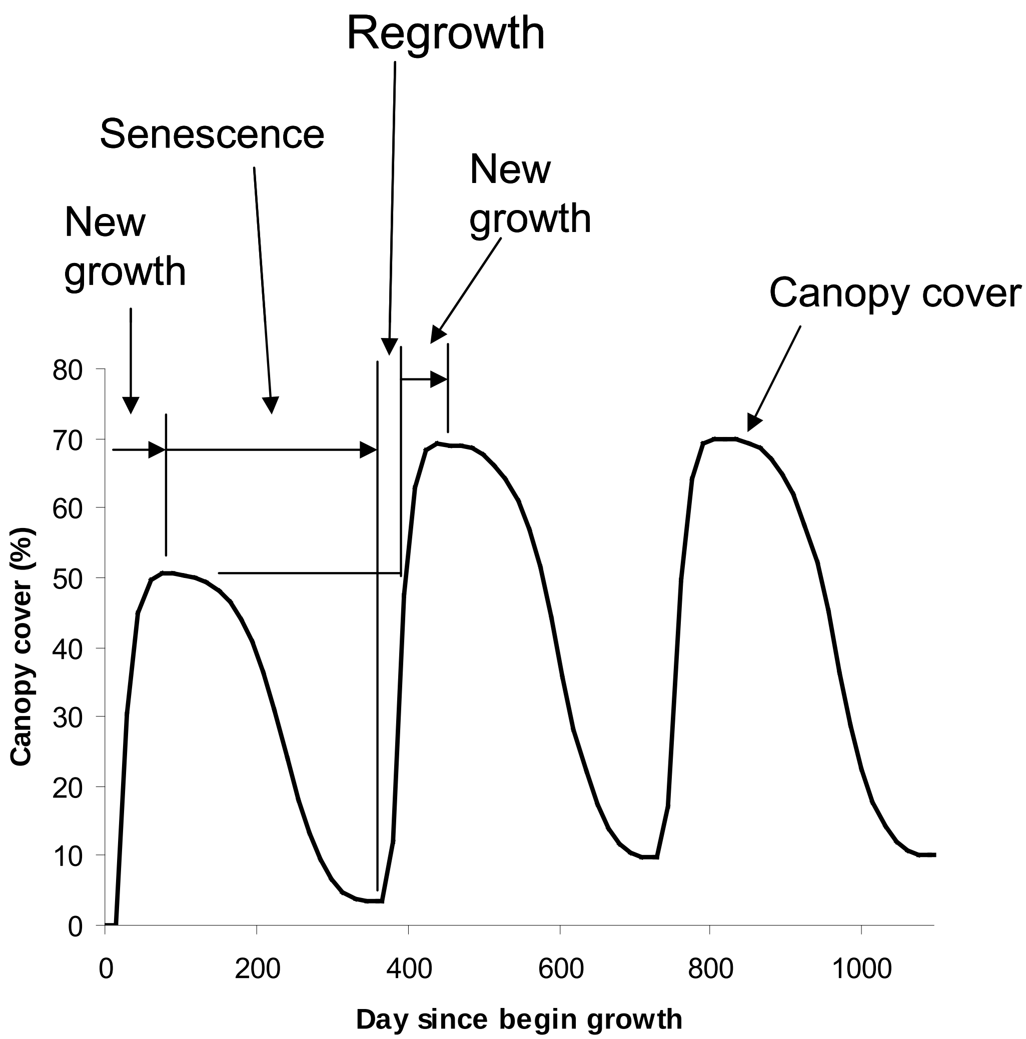

Figure 9.2. Vegetation growth periods used to compute live above ground biomass as a function of canopy cover.

9.2.3.1. New growth period

A **new growth** period is the time during which particular canopy cover values are first reached in a vegetation description. For example, the canopy cover from the seeding date to the first canopy cover maxima is a new growth period as illustrated in Figure 9.2. A second new growth period occurs in the second year over the time that canopy cover increases from the value of the first local canopy cover maxima in the first year to the local canopy cover maxima in the second year, also illustrated in Figure 9.2. A similar third new growth period, not illustrated, occurs in the third year. A composite of plant materials including leaves and stems is assumed to be produced during new growth periods.

The local canopy cover maxima that occurs in the third year for the vegetation description illustrated in Figure 9.2 is also the absolute canopy cover maxima for the vegetation description. The local canopy cover minima that occurs immediately after the absolute local canopy cover maxima is defined in RUSLE2 as the local absolute canopy cover minima for the vegetation description, even though other local canopy cover minima are less than this canopy cover. Values for the absolute canopy maxim and minima and the corresponding live above ground biomass values for these canopy values are user RUSLE2 inputs.

Live above ground biomass is computed from canopy cover during a new growth period using:

$$B_l = B_{lamx}(C/C_{amx})^{1.5} \qquad [9.4]$$

where: B_l = daily live above ground biomass during a new growth period, B_{lamx} = the live above ground biomass at absolute maximum canopy cover for a vegetation description, C = daily canopy cover, and C_{amx} = canopy cover at absolute maximum canopy cover for a vegetation description.

9.2.3.2. Senescence period

A **senescence** period is the time over which canopy cover decreases in a vegetation description from a local canopy cover maxima to a local canopy cover minima as illustrated in Figure 9.2. The equation used to compute live above ground biomass for a senescence period is:

$$B_l = B_{lmn(k)} + (B_{lmx(k)} - B_{lmn(k)})[(C - C_{mn(k)})/(C_{mx(k)} - C_{mn(k)})]^{1.5} \qquad [9.5]$$

where: $B_{lmn(k)}$ = live above ground biomass at the *kth* local canopy cover minima, $B_{lmx(k)}$ = live above ground biomass at the *kth* local canopy cover maxima, $C_{mn(k)}$ = canopy cover at the *kth* local minima, and $C_{mx(k)}$ = canopy cover at the *kth* local maxima. The index k refers to canopy cover maxima-canopy cover minima combinations where canopy cover minima occur after the corresponding canopy cover maxima.

The live above ground biomass and canopy cover at local canopy cover minima must be on the curve given by:

$$B_{lmn(k)} = B_{lamn}(C_{mn(k)} / C_{mn(1)})^{1.5} \qquad [9.6]$$

where: B_{lamn} = the absolute minimum live above ground biomass which occurs at $C_{mn(1)}$ = the first minimum canopy cover defined in **Section 9.2.3.1.** Values for live above ground biomass and canopy cover at local maxima must fall along the curve defined by equation 9.4.

The live above ground biomass-canopy cover curves for the new growth and the senescence periods are illustrated in Figure 9.3 for the first year of the vegetation description represented in Figure 9.2. The live above ground biomass for a given canopy cover during the senescence period is greater than that during the new growth period. Canopy cover loss during the senescence period is primarily by leaves falling to the soil surface. The biomass per unit canopy cover is much less for leaves than for the material, primarily stems, left standing during senescence. Each daily decrease in live above ground biomass is assumed to be biomass that falls and reaches the soil surface. This daily above ground biomass loss is added to the daily surface residue pool.

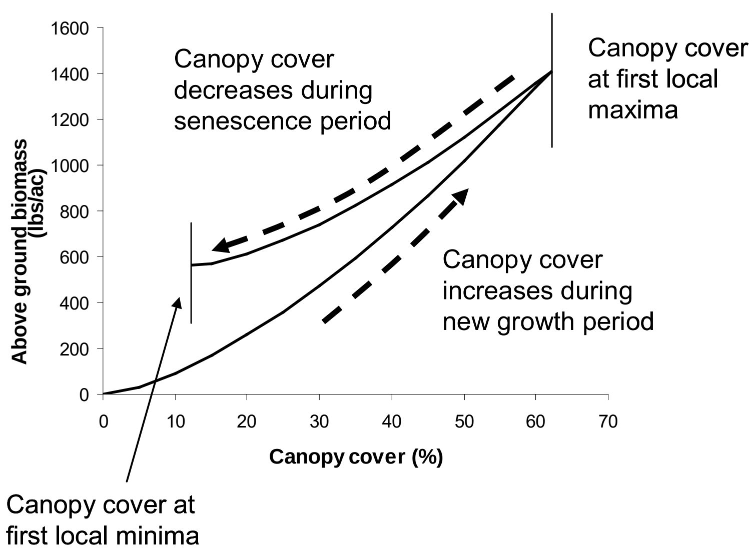

Figure 9.3. Live above ground biomass-canopy cover relationships for new growth and senescence periods during first year.

Equations 9.4 and 9.5 compute a decrease in live above ground biomass for a decrease in canopy cover. However, a decrease in live above ground biomass can occur with some plant communities with canopy cover remaining at 100 percent. An exponential equation form was evaluated to describe these plant communities. However, an exponential type equation was not used in RUSLE2 because such an equation can not be easily calibrated using the desired RUSLE2 inputs. Also, the exponential equation form did not give desired values for low canopy cover values.

Multiple vegetation descriptions are used in a RUSLE2 cover-management description to describe significant changes in live above ground biomass during periods when canopy cover changes very little. The inputs for these vegetation descriptions are selected so that

RUSLE2 computes a significant change in live above ground biomass for very little change in canopy cover such as from 99.9 percent to 99.5 percent. Such small changes in canopy cover have essentially no effect on canopy subfactor values (see **Section 6.1**). Additional vegetation descriptions are used for times during the cover-management description that canopy cover changes rapidly.

9.2.3.3. Regrowth period

The **regrowth** period starts from the canopy cover and live above ground biomass at the last local minima that was reached in the RUSLE2 computations as illustrated in Figure 9.2. Equation 9.5 is used to compute live above ground biomass values for the regrowth period as the live above ground biomass-canopy cover relationship retraces the senescence curve as illustrated in Figure 9.4. Most of the live biomass added during this period is assumed to be leaves and other material that has low biomass for the canopy cover that it provides. The regrowth period ends when canopy cover becomes equal to the canopy cover value of the last local maxima. A new growth period begins at this

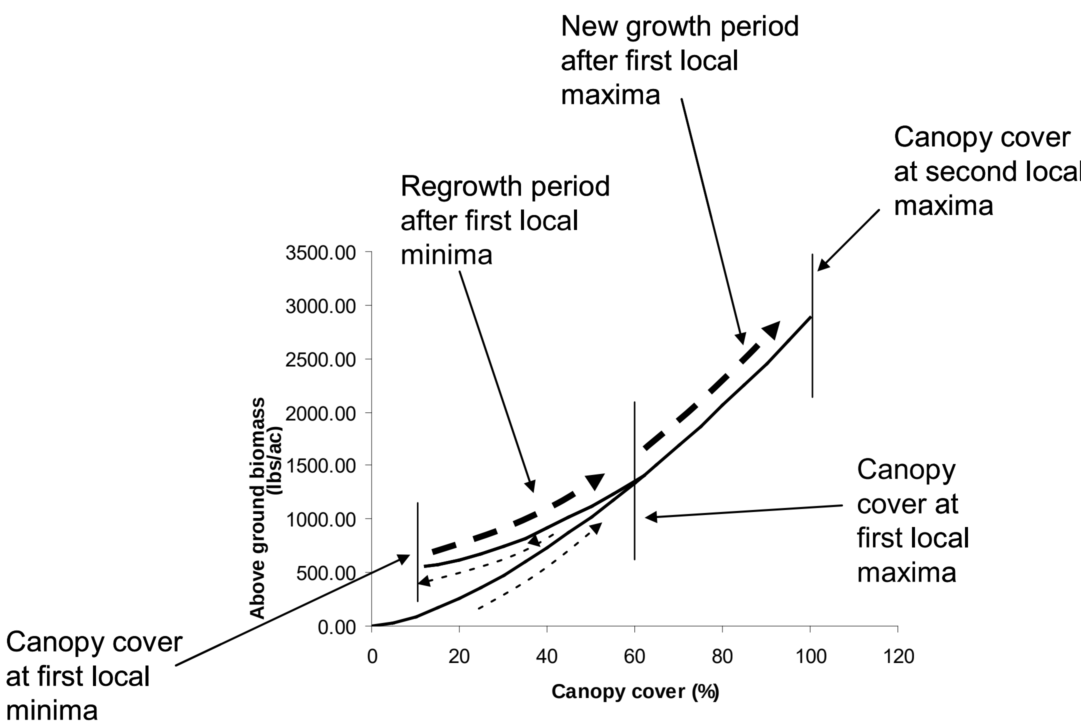

Figure 9.4. Live above ground biomass-canopy cover relationships for regrowth and new growth periods during second year.

point and continues until canopy cover becomes equal to the canopy cover of the next local maxima as illustrated in Figures 9.2 and 9.4. Equation 9.4 is used to compute values for live above ground biomass from canopy cover values during this new growth period. Once the next local maximum is reached, the next senescence period begins where equation 9.5 is used to compute live above ground biomass values.

Computations for this sequence of vegetation periods are repeated until the end of the RUSLE2 computation period.

9.2.3.4. Special cases

9.2.3.4.1. Annual plant communities that experience senescence

Most agricultural crops are annual and are described with either a single new growth period or by a single new growth period and a senescence period. Soybeans and cotton are examples of crops that experience senescence.

9.2.3.4.2. Annual plant communities that experience a decrease in canopy cover without a corresponding decrease in live above ground biomass

RUSLE2 also represents vegetation (e.g., corn and wheat) where canopy cover decreases by leaves drooping instead of falling to the soil surface. In this special case, the live above ground biomass does not decrease as canopy cover decreases. However, RUSLE2 can not represent perennial (long term) vegetation (i.e., multiple sequences of new growth-senescence-regrowth periods in the vegetation description) that has these characteristics.

9.2.4. Litter fall by other processes than senescence

9.2.4.1. Simultaneous birth and death of live above ground biomass

Litter is produced during the increase in growth period before canopy cover begins to decrease by senescence (Dubeux et al., 2005; Thomas and Asakawa, 1993). The litter produced during this period adds substantially to the surface residue produced by litter fall during senescence.

The amount of litter fall during the increase in growth period and into the first part of the senescence period is computed using:

$$L_f = c_f(B_l - B_{lmn(k)}) \quad if(B_l < B_{lmn(k)}): L_f = 0 \qquad [9.7]$$

where: L_f = day litter fall rate (mass/area·day) during the birth-death period and c_f = coefficient for birth-death litter fall (day^{-1}). A single value of 0.01 day^{-1} probably can be used almost all vegetation types (Dubeux et al. 2005; Thomas and Asakawa, 1993). However, this conclusion needs further research.

Litter fall is computed using equation 9.7 into the senescence period until the rate of litter falls computed by the difference in above ground biomass in a day exceeds the litter fall rate computed by equation 9.7.

9.2.4.2. Litter fall caused by mechanical traffic

Mechanical traffic by humans, animals, and vehicles can transfer biomass from the canopy to the soil surface that adds to surface residue. That biomass transfer is estimated by:

$$L_m = c_m(B_l - B_{lmn(k)}) \;\; if\,(B_l < B_{lmn(k)}) : L_f = 0 \qquad [9.8]$$

where: L_m = litter fall rate (mass/area·day) caused by mechanical traffic and c_m = a litter fall coefficient (day^{-1}) for the litter fall caused by mechanical traffic. The input value for c_m is based on the user's judgment.

9.2.4.3. Adjustment in above ground biomass for litter fall

RUSLE2 does not adjust live above ground biomass for litter fall. The user entered input values for canopy cover are assumed to represent the canopy that exists in the field regardless of what affects canopy cover. RUSLE2 converts those values to biomass, which like the canopy cover values are the live above ground biomass that exists regardless of how it came to be. RUSLE2's litter fall computations describe the disposition of live above ground biomass.

9.2.5. Operations that affect live vegetation

Operations that include **begin growth**, **kill vegetation**, **remove live biomass, and Process: Perennial biomass & current standing res removal** processes affect live above ground biomass. A **begin growth** process instructs RUSLE2 to begin using values from a new vegetation description. RUSLE2 assumes no relationship between live above ground biomass for the two vegetation descriptions although a relationship is assumed for live root biomass (see **Section 9.2.2**). The RUSLE2 assumption is that a decrease in live root biomass between the last day that a vegetation description is used to compute daily erosion and the live root biomass on day zero in the new vegetation description is biomass added to the existing dead root biomass pool. In contrast, no such connections are assumed for live above ground biomass. The RUSLE2 user explicitly use operations, such as **remove live biomass**, to describe the fate of live above ground biomass between vegetation descriptions when a begin growth process is executed. Within the period represented by a vegetation description, the RUSLE2 assumption is that a decrease in canopy cover represents a senescence period and the decrease in live above ground biomass during a senescence period is daily added to the surface residue biomass pool.

Consequently, RUSLE2 assumes that a new growth vegetation period begins on day zero for a new vegetation description when a begin growth process is executed. This assumption applies to transplanted crops and to vegetation that regrows after hay harvest or mowing where canopy and live above ground biomass are greater than zero on day zero in the vegetation description. Similarly, an operation that includes the **remove live biomass** process can leave live above ground biomass after the operation. RUSLE2 assumes that a new growth period begins immediately after the remove live biomass process is executed. The increase in live above ground biomass is assumed to be a composite of above ground plant components, including stems and leaves, during a new growth vegetation period in contrast to the increase in live above ground biomass being primarily leaves during the regrowth period that follows a senescence period.

A **kill vegetation** process transfers the entire live above ground biomass that exists on the day that the process is executed to the standing residue pool. The relation between standing residue biomass and canopy cover is given in **Section 9.2.3**.

9.2.6. Temporal standing live vegetation Manning's n

Standing vegetation contributes to total hydraulic resistance (see **Section 3.4**). The temporal contribution of standing live vegetation, not including live ground cover, to Manning's n is computed using:

$$n_v = n_{vmx}(h_f / h_{fmx})$$

where: n_v = daily Manning's n contributed by live standing vegetation not including live ground cover, n_{vmx} = maximum Manning's n contributed by live standing vegetation, not including live ground cover, during the period represented by the vegetation description, h_f = daily effective fall height, h_{fmx} = maximum effective fall height during the vegetation description, and i = subscript for day. Manning's n contributed by standing live vegetation is most affected by stems. Of the temporal input or computed variables used in a RUSLE2 vegetation description, Manning's n for standing live vegetation was assumed to be best related to effective fall height. The Manning's n contributed by live ground (surface) cover is consider in the relation of Manning's n to net ground (surface) cover (see **Section 3.4.6**)

Table 9.1. Coefficient a_H values used to multiply maximum effective vegetation ridge height on contour to obtain effective vegetation ridge height for effect of row spacing

Row width	Coefficient a_H
Vegetation on ridges	0.25
Wide row (≥ 30 inches)	0.50
Moderate row spacing (15 to 20 inches)	0.75
Narrow row spacing (7 to 10 inches)	1.00
Very narrow row spacing (≤5 inches)	0.50
No rows (broadcast)	0.00

Maximum Manning's n for live standing vegetation for a vegetation description is computed from the user input vegetation retardance at maximum canopy cover. Vegetation retardance is a function of vegetation stem density and orientation of vegetation strips (rows) to the overland flow path (see **Section 3.4.6**). The live vegetation Manning's n when vegetation strips (rows) are on the contour (i.e., perpendicular to the overland flow path) is computed using equation 3.54. A Manning's n value for live standing vegetation for vegetation in rows up and downhill (i.e., parallel to the overland flow path) is computed using values in Table 3.10. The live standing vegetation Manning's n for the actual orientation of vegetation rows to the overland flow path (i.e., row grade) is computed using equation 3.55.

9.2.7. Temporal effective vegetation ridge height

Densely spaced stems of vegetation rows on the contour affect rill-interrill erosion much like soil ridges (see **Section 7.1.3**). An effective live vegetation ridge height is added to the soil ridge height to obtain an effective total ridge height used to compute values for the contouring subfactor in equation 7.6. The effect of live standing vegetation rows on erosion depends on row spacing. If row spacing is zero (i.e., the vegetation is not in rows and the plant stems are randomly spaced over the entire soil surface), orientation of vegetation rows to the overland flow path and row spacing has no meaning or effect on the contouring subfactor. The erosion reduction (i.e., contouring effect) for effective live standing vegetation ridge height increases as vegetation row spacing increases to a maximum at the narrow row width of approximately 8 inches). Erosion reduction by effective vegetation ridge height decreases as row spacing widens beyond the narrow row spacing. This effect is represented by the coefficient α_h values given in Table 9.1.

The maximum effective live standing vegetation ridge height for contour vegetation strips (rows) for a vegetation description is computed using:

$$H_{vmx} = 0.5 a_H R_v \quad if\,(R_v > 7) : R_v = 7 \qquad [9.10]$$

where: H_{vmx} = maximum effective live standing vegetation ridge height (inches) for the vegetation description when vegetation strips (rows) are on the contour, a_H = the coefficient that adjusts for row spacing (inches), and R_v = the retardance class at maximum canopy cover in the vegetation description (see **Section 9.3.1**).

Daily effective live standing vegetation ridge height H_v is computed using:

$$H_v = H_{vmx}(h_f / h_{fmx})^{0.3} \qquad [9.11]$$

Like Manning's n for live standing vegetation, of the temporal vegetation variables, effective live vegetation ridge height is assumed to be most related to effective fall height.

9.3. Adjust input values for vegetation production (yield) level

Input values in RUSLE2 vegetation descriptions are functions of vegetation production (yield) level, and each RUSLE2 vegetation description applies to a particular production (yield) level. RUSLE2 computes values in a vegetation description for a new production (yield) level by adjusting values in a base vegetation description. The maximum canopy cover in the base vegetation description must be less than 100 percent for RUSLE2 to make the proper mathematical computations. RUSLE2 can use a base vegetation description that has a maximum canopy cover of 100 percent to adjust for production (yield) levels greater than the production (yield) level for the base vegetation description, but RUSLE2 can not use a base vegetation description with a 100 percent maximum canopy cover to adjust to a lower production (yield) level.

Biomass values used in RUSLE2 computations are on a dry basis, but input values for vegetation production (yield) level are on a user defined basis. The user inputs information that RUSLE2 uses to convert production (yield) level value on the user defined basis to the dry basis needed for RUSLE2's computations (see RUSLE2 User's Reference Guide).

Multiple RUSLE2 vegetation descriptions can be used to compute erosion for a particular plant community over the period represented in the RUSLE2 computation (i.e., rotation duration). For example, vegetation descriptions are used to describe a multiple year alfalfa hay production system. The first vegetation description describes the alfalfa crop from seeding to first hay harvest, the second vegetation description describes regrowth after each hay harvest in the first harvest year, the third vegetation description describes senescence and regrowth after senescence to the first hay harvest in the second harvest year, and so on. Input values such for live above ground biomass at maximum canopy apply to that particular vegetation description and not to the vegetation as a whole over the RUSLE2 computation period, such as the example alfalfa crop.

9.3.1. Live above ground biomass at maximum canopy cover

A major vegetation input is live above ground biomass at maximum canopy cover for a particular vegetation description. When multiple vegetation descriptions are used to represent a particular vegetation, the live above ground biomass entered for each vegetation description is for the maximum canopy cover in that particular vegetation description.

The RUSLE2 assumption is that live above ground biomass at maximum canopy varies linearly as a function of production (yield) level. That is:

$$B_{lamx} = a_y + b_y Y_d \qquad [9.12]$$

where: B_{lamx} = live above ground biomass (dry basis, mass/area) at maximum canopy cover for the vegetation description and Y_d = production (yield) level (dry basis, mass/area). The user provides inputs that RUSLE2 uses to convert production (yield) level in user units to biomass on a dry basis. These equations have the form:

$$Y_d = b_u Y_u \qquad [9.13]$$

where: Y_u = production level (yield) in user defined units and b_u = a conversion factor that RUSLE2 computes from user inputs. The values for the coefficients a_y and b_y in equation 9.12 are computed from user inputs for two live above ground biomass at maximum canopy cover-production (yield level) data points (see RUSLE2 User's Reference Guide).

9.3.2. Retardance at maximum canopy cover

Retardance for live vegetation at maximum canopy cover is computed from:

$$R_v = c_R + d_R Y_u \qquad [9.14]$$

where: R_v = retardance at maximum canopy cover for a vegetation description and Y_u = production (yield) level in user defined units for the vegetation description. The user enters two input data points for retardance-production (yield) level that RUSLE2 uses to determine values for the coefficients c_R and d_R in equation 9.14. RUSLE2 uses eight retardance classes that vary with the degree that vegetation grown in strips (rows) on the contour slows runoff (see Table 3.9). Equation 9.14 computes continuous values that are used in equation 3.54 to compute Manning's n values.

Vegetation descriptions are used to describe both live vegetation and porous barriers (fabric fences, gravel bag dams, and similar mechanical devices used on construction sites to trap and retain sediment on site) (see **Section 7.2** and RUSLE2 User's Reference Guide). The yield input for the vegetation description selected to describe these devices is used to represent the degree that the installed device retards runoff. The eighth retardance class is reserved for conditions that provide extremely high retardance such as stiff grass hedges, fabric (silt) fences and gravel bag dams. RUSLE2 computes backwater length caused by vegetation strips and flow retarding devices as a function of Manning's n, which are computed from the retardance class for the vegetation description (see **Section 3.4.4**). RUSLE2 assigns a minimum backwater length of 3 ft for the extremely high retardance class but uses the backwater length computed for the other retardance classes. RUSLE2 assumes a maximum backwater length of 15 ft for all vegetation/mechanical retarding strips.

9.3.3. Temporal input vegetation variables

Simple equations based on values computed by the EPIC model (Williams et al., 1989) are used in RUSLE2 to compute values for the temporal variables of root biomass, canopy cover, effective fall height, live ground cover, and consumptive water use.

9.3.3.1. Root biomass

Live root biomass values are assumed to vary linearly with live above ground biomass at maximum canopy cover. Live root biomass values for a new vegetation are computed as a function of production level (yield) using:

$$B_{rn(j)} = B_{rb(j)}(B_{lamxn} / B_{lamxb}) \qquad [9.15]$$

where: $B_{rn(j)}$ = root biomass value in the new vegetation description for the *jth* data point, $B_{rb(j)}$ = root biomass value for the *jth* data point in the base vegetation description, and B_{lamxb} = absolute maximum live above ground biomass in the base vegetation description. A value for the live above ground biomass at absolute maximum canopy B_{lamxn} in the new vegetation description is computed using equation 9.12 and the production (yield) level value for the new vegetation description.

9.3.3.2. Canopy cover

The equation used to adjust canopy cover values for production (yield) level is:

$$C_{n(j)} = C_{b(j)}(B_{lamxn} / B_{lamxb})^{0.5} \qquad [9.16]$$

where: $C_{n(j)}$ = canopy cover for *jth* data point the new vegetation description and $C_{b(j)}$ = the corresponding canopy cover value for the *jth* data point in the base vegetation description.

9.3.3.3. Effective fall height

The equation used to adjust effective fall height values for production (yield) level is:

$$h_{fn(j)} = h_{fb(j)} (B_{lamxn} / B_{lamxb})^{0.2} \qquad [9.17]$$

where: $h_{fn(j)}$ = effective fall value for the *jth* data point in the new vegetation description and $h_{fb(j)}$ = corresponding effective fall height value for the *jth* data point in the base vegetation description.

9.3.3.4. Live ground cover

The equation used to adjust live ground cover values as a function of production (yield) level is:

$$f_{\lg cn(j)} = f_{\lg cb(j)} (B_{lamxn} / B_{lamxb})^{0.5} \qquad [9.18]$$

where: $f_{lgcn(j)}$ = live ground cover value for the *jth* data point in the new vegetation description (percent) and $f_{lgcb(j)}$ = corresponding live ground cover value for the *jth* data point in the base vegetation description (percent).

9.3.3.5. Consumptive water use

Consumptive water use is used to compute how irrigation affects rill-interrill erosion by precipitation (see **Section 7.5**). Consumption water use is a function of production (yield) level. The equation used to adjust consumptive water use values as a function of production (yield) level is:

$$V_{wn(j)} = V_{wb(j)} (B_{lamxn} / B_{lamxb}) \qquad [9.19]$$

where: $V_{wn(j)}$ = consumptive water use value for the *jth* data point in the new vegetation description and $V_{wb(j)}$ = corresponding values for consumptive water use value for the *jth* data point in the base vegetation description.

9.4. List of symbols

a_y = coefficient used to compute live above ground biomass at absolute maximum canopy cover for a vegetation description

a_H = coefficient used to computed effective vegetation ridge height from vegetation retardance (inches)

b_u = coefficient used to convert user defined yield units to dry mass

b_y = coefficient used to compute live above ground biomass at absolute maximum canopy cover for a vegetation description

B_l = daily live above ground biomass (dry basis) during a new growth period (mass/area)

B_{lamn} = live above ground biomass (dry basis) at first minimum canopy cover $C_{mn(1)}$ for a vegetation description (mass/area)

B_{lamx} = absolute maximum live above ground biomass (dry basis) at absolute maximum canopy cover for a vegetation description (mass/area)

$B_{lmn(k)}$ = live above ground biomass (dry basis) at *kth* local canopy cover minina in a vegetation description (mass/area)

$B_{lmx(k)}$ = live above ground biomass (dry basis) at *kth* local canopy cover maxima in a vegetation description (mass/area)

B_{lamxb} = live above ground biomass at absolute maximum canopy cover in base vegetation description (mass/area)

B_{lamxn} = live above ground biomass at absolute maximum canopy cover in new vegetation description (mass/area)

$B_{rb(j)}$ = root biomass value for the *jth* data point in the base vegetation description (mass/area in upper 4-inch depth)

$B_{rn(j)}$ = root biomass value for the *jth* data point in the new vegetation description (mass/area in upper 4-inch depth)

$B_{t,mn}$ = live above ground biomass (dry basis) at a local canopy cover minima (mass/area)

$B_{t,mx}$ = live above ground biomass (dry basis) at a local canopy cover maxima (mass/area)

c_f = coefficient for birth-death litter fall (day^{-1})

c_m = cooefficient fr litter fall caused by mechanical traffic (day^{-1})

c_R = coefficient used to compute retardance from user input yield

C = daily canopy cover (fraction)

C_{amx} = canopy cover at absolute maximum canopy cover for a vegetation description (fraction)

$C_{mn(k)}$ = canopy cover at the *kth* local canopy minima (fraction)

$C_{mx(k)}$ = canopy cover at the *kth* local canopy maxima (fraction)

$C_{b(j)}$ = canopy cover value for *jth* data point in base vegetation description (fraction)

$C_{n(j)}$ = canopy cover for *jth* data point in new vegetation description (fraction)

d_R = coefficient used to compute retardance from user input yield

$f_{lgcb(j)}$ = live ground cover value for *jth* data point in base vegetation description (percent)

$f_{lgcn(j)}$ = live ground cover value for *jth* data point in new vegetation description (pecent)

h_f = daily effective fall height (length)

$h_{fb(j)}$ = effective fall height value for the *jth* data point in the base vegetation description (length)

$h_{fn(j)}$ = effective fall value for *jth* data point in new vegetation description (length)

h_{fmx} = maximum effective fall height for a vegetation description (length)

H_v = daily effective live standing vegetation ridge height (inches)

H_{vmx} = maximum effective live standing vegetation ridge height for a vegetation description

L_f = daily litter fall during birth-death period (mass/area·day)

L_m = daily litter fall caused by mechanical traffic (mass/area·day)

M_r = cumulative root biomass (dry basis) above the depth y (mass/area)

n_v = daily Manning’s n contributed by live standing vegetation not including live ground cover

n_{vmx} = maximum Manning’s n contributed by live standing vegetation not including live ground cover for a vegetation description

R_v = vegetation retardance class at maximum canopy cover for a vegetation description

$V_{wb(j)}$ = corresponding values for consumptive water use value for *jth* data point in base vegetation description (inches)

$V_{wn(j)}$ = consumptive water use value for *jth* data point in the new vegetation description (inches)

y = normalized depth in soil from soil surface Y/15 inches

Y = depth in soil from soil surface (inches)

Y_d = production (yield) level (dry basis) (mass/area)

Y_u = production level (yield) in user defined units

15 = reference depth in inches for determining root mass distribution in soil

Indices

j – data point

k - refers to canopy cover maxima-canopy cover minima combination where canopy cover minima occur after a canopy cover maxima

10. RESIDUE AND DEAD ROOTS

10.1. Description of residue and dead roots

Residue and dead roots are materials lost by decomposition. RUSLE2 includes standing, surface, and buried residue pools that account for material produced when live above ground biomass is converted to standing residue (**Sections 6.1, 6.2, 6.5, and 9.2.5**). RUSLE2 accounts for the movement of residue mass between these pools by harvest, tillage, ripping, and other operations that affect vegetation, residue, and soil (see **Section 8.2**). The RUSLE2 surface residue pool also includes material such as mulch, manure, and erosion control blankets applied to the soil surface (see **Section 6.2**). The RUSLE2 buried residue pool includes material such as manure and bio-solids in sewage sludge that are injected or incorporated into the soil (see **Sections 6.3 and 6.5**).

Mass in the RUSLE2 dead root residue pool results from live root biomass associated with a vegetation description being transferred to the dead root biomass pool (see **Sections 6.5.6 and 9.2.2**).

The general RUSLE2 assumption is that residue and dead roots are organic materials that decompose. RUSLE2 also describes the effects of non-organic material such as erosion control blankets and rock placed on the soil surface or incorporated into the soil. However, special inputs are used to represent non-organic material (see **Section 10.2.5**).

Crop residue and plant litter are composed of diverse components including stems, leaves, seed pods, and chaff. Similarly, dead roots vary from very fine to coarse roots. A single residue description is used to represent a composite of these components for a particular vegetation description

10.2. Relation of portion of soil surface covered to surface residue mass

10.2.1. Size criteria for counting residue

To be counted as ground cover, soil surface material must remain in place, not be moved downslope by surface runoff during a rainstorm, and not be moved away by wind. The minimum size required to be counted as ground cover for RUSLE2 purposes must meet this criteria. **No single size should be used for all ground cover material in all situations**. For example, small pieces of residue will stay in place at the upper end of an overland flow path that would be moved at the lower end of a long overland flow path. Similarly, residue will be stable on a very flat overland flow path that would be moved on a steep overland flow path. Small residue pieces can be stable among a gradation of residue sizes but be unstable when the residue is uniformly composed of the small pieces. Small residue pieces that are stable at high residue surface covers may be unstable at low residue surface covers.

Equations that compute the hydraulic stability of mulch and crop residue were considered for RUSLE2 but were rejected because the equations were judged not to be sufficiently robust for RUSLE2 purposes (Foster et al., 1982a, 1982b).

Rock fragments on the soil surface require special consideration. The same stability considerations for other surface residue also apply to counting surface rock fragments as surface cover. Another factor is whether the rock fragments are a part of the soil matrix or simply "loose" rock on the soil surface that acts like surface cover. An approximate guideline is that rock fragments must be larger than 5 mm on coarse textured soils in arid and semi-arid regions where runoff is low and larger than 10 mm in other regions to be counted as ground cover.

10.2.2. Equation for computing residue cover from residue mass

RUSLE2 tracks surface residue (material in direct contact with the soil surface) on a dry mass basis (mass/area). However, the portion of the soil surface covered is the major variable used in equation 6.6 to compute how ground cover (surface residue) affects rill-interrill erosion. The RUSLE2 equation that computes portion of the soil surface covered by surface residue is:

$$f_g = 1 - \exp(-\alpha B_s) \qquad [10.1]$$

where: f_g = fraction of the soil surface covered by residue when no other residue type is present and B_s = surface residue mass (dry mass/area). RUSLE2 computes a value for the coefficient α using equation 10.1 rearranged and user entered values for the residue mass that provides 30, 60, or 90 percent soil cover.

A typical example of surface residue mass-cover data is illustrated in Figure 10.1. A common feature of these data is their high variability, which in turn greatly affects the variability in computed erosion estimates. For example, cover ranges from 0.70 to 1.0 percent in Figure 10.1 at a mass of 150 g/m^2. This range in cover gives ground cover subfactor values for g_c in equation 6.6 (**b** = 0.04 percent^{-1}and R_a = 0.24 inches) that range from 0.018 to 0.061. The portion of the soil surface covered ranges from 0.55 to 0.85 percent for a residue mass of 50 g/m^2, which gives values of 0.033 to 0.11 for g_c. In both cases, erosion

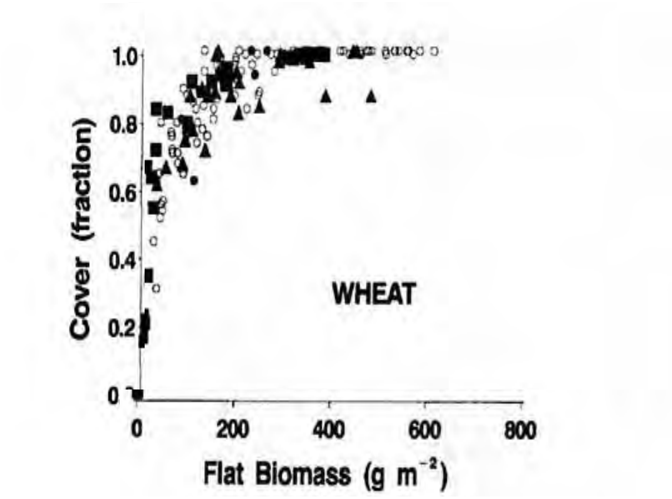

Figure 10.1. Measured data for relationship of residue cover to surface residue mass. (Source: Steiner et al., 2000).

can differ by a factor of 3 for a given surface residue mass. Therefore, even if RUSLE2 could estimate surface residue mass perfectly, RUSLE2's estimated portion of the soil surface covered, and its corresponding estimated erosion, could be significantly in error when compared to an individual measurement of soil surface cover.

Given this variability, the best that RUSLE2 can represent is differences in major residue types. Expecting RUSLE2 to accurately estimate percent residue cover at a particular location on a landscape at a particular point in time is unreasonable.

Data reported in the literature for residue cover as a function of residue mass vary greatly from study to study and even within a particular study as illustrated in Figure 10.1. The values used in the RUSLE2 Core Database were chosen as representative values for conservation and erosion control planning, realizing that numerous studies give values that differ from the RUSLE2 values. For example, surface cover ranged from about 65 percent to 100% for a flat wheat residue mass of about 1500 lbs/acre (168 g/m^2) in the Steiner et al. (2000) study, which is significantly greater than the 58 percent that the RUSLE2 Core Database values compute for the same residue mass. The RUSLE2 Core Database values for wheat straw are based on AH537 (Wischmeier and Smith, 1978) values, which were primarily derived from data reported by Mannering and Meyer (1963), Meyer and Mannering (1967) and Meyer et al. (1970).

The variation among some plant varieties is so great than different mass-cover relationships should be used for major variety types. For example, Stott (1995) noted that α values for corn varied from about 0.00023 to 0.00045 $(lbs/acre)^{-1}$ for corn residue based on her measurements and data reported in the literature. Stott recommended that the 0.00023 acre/lbs value (60 percent cover at 4000 lbs/acre flat corn residue mass) be used for corn grown after the mid 1980's and that the RUSLE2 Core Database value of 0.00038 $(lbs/acre)^{-1}$ (60 percent cover at 2400 lbs/acre corn residue mass) be used for corn grown before the mid 1980's. RUSLE2 satisfactorily estimates flat residue cover at planting for a wide range of soil and conservation tillage methods as Table 10.1 shows, with the recognition that the corn in these studies was grown before the mid 1980's.

Another example is that soybean varieties grown in the Midwest US differ from those grown in the Mid-South US. The RUSLE2 Core Database mass-cover value for soybeans varieties grown in the Midwestern US is that 600 lbs/acre of soybean residue gives 30 percent soil surface cover [AH703 (Renard et al., 1997)] while the mass-cover value for the variety of soybeans grown in the Mid-South US is that 1460 lbs/acre of soybean residue gives 30 percent soil surface cover (Mutchler and Greer, 1984).[67]

The RUSLE2 Core Database values for surface residue mass-cover relationships should be used for routine RUSLE2 applications. When RUSLE2 users wish to use values for residue mass-cover other than those in the RUSLE2 Core Database, users should review and analyze data from multiple sources because of the great variability in these data within a study as illustrated in Figure 10.1 and between studies. RUSLE2 was calibrated to measured erosion values using the values in the RUSLE2 Core Database. That is, RUSLE2 was calibrated to give expected erosion values. **Unexpected serious error in RUSLE2 computed erosion estimates can occur when input residues values are improperly changed from those in the RUSLE2 Core Database (see the RUSLE2 User's Reference Guide). If a change is made in residue input values, RUSLE2 computed erosion values with the new input values should be compared against erosion measured with the residue represented in the new input values.**

10.2.3. Reasons for variability in the surface residue mass-residue cover relationship

A major reason for the variability in the residue mass-residue cover relationship is that crop residue, plant litter, and similar materials are composed of multiple plant components (e.g., leaves, stems, seed pods, and chaff) and pieces that vary in composition, geometry, size, mass, and surface area covered per unit dry mass. RUSLE2 uses a single residue description to represent residue as a composite of multiple components. Consequently, α in equation 10.1 is a function of the relative mass of each residue component in the composite and varies temporally as the relative mass of each residue component varies temporally. For example, the α value for corn and soybean residue immediately after harvest differs significantly from the α value several months later because leaves cover more area than do stems per unit mass and leaves decompose much more rapidly than do the stems. In contrast to corn and soybeans, field measured data at Bushland, Texas showed that α values for barley, oats, spring wheat, and winter wheat did not vary from 24 to 400 days after harvest (Steiner et al., 2000). However, data variability, as in all studies of residue mass-residue cover, may have masked temporal changes in the residue mass-residue cover relationship.

The RUSLE2 assumption is that residue properties such as α in equation 10.1 are time invariant for the period represented by a residue description in a RUSLE2 computation. Consequently, equation 10.1 is a compromise and the values in the RUSLE2 Core Database used to compute α were chosen to compute erosion values appropriate for conservation and erosion control planning (see RUSLE2 User's Reference Guide). The input values that RUSLE2 uses to compute α values should be carefully selected to ensure that equation 10.1 gives the best erosion estimates for the time periods that have the greatest effect on average annual erosion. User entered values for a new residue description being added to a RUSLE2 database should be consistent with values in the RUSLE2 Core Database. Procedures described in the RUSLE2 User's Reference Guide must be followed.

In some cases, temporal changes in residue properties can be represented in RUSLE2 by using multiple residue descriptions during the RUSLE2 computation period. Using multiple residue descriptions requires using an operation that includes a **remove residue/cover process** to remove the existing material and another operation that includes an **add other cover process** that adds the removed material back to the soil surface using a new residue description. The computer mechanics of using RUSLE2 in this way are not convenient for routine conservation and erosion control planning. However, the procedure is mentioned to illustrate RUSLE2's capability for computing the effects of temporal variations of residue properties. Technical specialists for agencies using RUSLE2 in routine conservation planning can use this technique to evaluate the uncertainty in RUSLE2 erosion estimates resulting from the assumption that residue properties do not vary temporally (see RUSLE2 User's Reference Guide).

10.2.4. Overlap of residue

The user assigns a single residue description to each vegetation description and to each operation description in a cover-management description that adds material to the soil surface (see RUSLE2 User's Reference Guide). For example, a corn-soybeans crop rotation involves two residue descriptions, one for corn and one for soybeans. The mass for each residue description is tracked separately. A daily ground cover value is computed with equation 10.1 for each residue description. A net ground cover value is used in equation 6.6 to compute a value for the ground cover subfactor, not the sum of the ground cover values computed with equation 10.1 for each residue description when multiple residue descriptions are involved. RUSLE2 takes into account the overlap of residue applications to compute net ground cover. The RUSLE2 assumption is that the portion of material that overlaps underlying material has no effect on rill-interrill erosion. The computation of net ground cover is illustrated for crop residue or mulch applied to a soil surface with existing rock cover. The net ground cover for these two residue descriptions (e.g., crop residue or mulch and rock) is computed as:

$$f_{gn} = f_{gr} + f_{gm}(1 - f_{gr}) \qquad [10.2]$$

where: f_{gn} = net ground cover (fraction), f_{gr} = ground cover (fraction) computed with equation 10.1 provided by the rock surface residue cover assuming no other material is present, and f_{gm} = ground cover (fraction) computed with equation 10.1 for crop residue or mulch assuming no other material is present. Equations 10.1 and 10.2 are used repeatedly to account for each residue description used in a particular RUSLE2 computation to compute a net ground cover value. The overall net ground cover value is used in equations 6.6, 6.7, and related equations to compute the effect of surface residue cover on rill and interrill erosion. A ground cover subfactor g_c is not computed for each residue description.

10.2.5. Inputs for non-organic residue

In some cases, a material is applied to the soil surface that significantly affects erosion but has less effect on erosion when incorporated into the soil than routine plant residue. The mass values entered in the residue description for cover-mass data points can be scaled to be so small that the mass values used for the material when incorporated in the soil are so small that they have no effect on soil biomass subfactor values (see **Section 6.5**). Input values for mass of these materials applied to the soil must be accordingly scaled. The objective in these RUSLE2 applications is that RUSLE2 uses desired ground cover values to compute ground cover subfactor values using equation 6.6 but uses such small residue mass values that soil biomass factor values computed with equation 6.48 are hardly affected if the material is incorporated into the soil (see RUSLE2 User's Reference Guide).

The importance of using recommended RUSLE2 inputs and following RUSLE2 procedures described in the RUSLE2 User's Reference Guide can not be over-emphasized, especially when making comparisons with the USLE, RUSLE1, and much of the historical data used to develop those models as well as RUSLE2. However, crop characteristics and yield, especially for corn, has changed greatly from the 20 bu/ac corn yield common in the 1930's data used to determine the AH282 and 537 soil loss ratio values, which were used to calibrate RUSLE2, to modern 200 bu/ac high production corn yields. The values in the RUSLE2 Core Database are considered adequate for evaluating modern crops and cropping practices, especially when RUSLE2 erosion computed values are being compared with values computed with the USLE or RUSLE1.

Consideration should be given to changing input values to represent modern crops and cropping practices in certain RUSLE2 applications. In doing so, the procedures described in the RUSLE2 User's Reference Guide should be carefully followed, and input values must be based on multiple data sources, not a single source. RUSLE2 was calibrated to compute expected erosion rates as a function of the principal variables affecting erosion. Therefore, RUSLE2's computation of what appears to be an erroneous cover value does not necessarily mean that RUSLE2's computed erosion values are erroneous.

Improper inputs without consideration of RUSLE2's calibration can result in very serious errors in RUSLE2 computed erosion values.

10.3. Decomposition of residue and dead roots

10.3.1. Description of equations

Both residue and dead roots are assumed to be lost over time as a result of decomposition and other processes related to precipitation and temperature. The basic RUSLE1 decomposition equations are used in RUSLE2 [AH703 (Renard et al., 1997); Yoder et al., 1997; Stott et al., 1990; Stott et al., 1995], which are a simplification of the decomposition equations used in the erosion prediction model WEPP (Laflen et al., 1991b; Flanagan and Nearing, 1995).[68] The main decomposition equation is:

$$B = B_p \exp(-\beta D) \quad [10.3]$$

where: B = the mass in a particular residue/dead root pool after decomposition B_p= the mass in the pool on the previous day, and D = the number of days in the period over

[68] Also, see references listed in the **Decomposition Subsection** of the **References Section**.

which decomposition is being computed, which is a single day in RUSLE2 (i.e., D = 1 day). A daily value for the coefficient β is computed from:

$$\beta = \phi[\min(W_f, T_f)] \qquad [10.4]$$

where: ϕ = a decomposition coefficient (day^{-1}) that is a function of biomass type, W_f = a moisture function, and T_f = a temperature function. Equation 10.4 is based on the assumption that decomposition on a particular day is limited by either moisture or temperature on that date.

Moisture must be present for decomposition to occur. Daily precipitation is used in RUSLE2 as an indicator of moisture available for decomposition. RUSLE2 does not compute moisture in residue/dead root pieces or in the soil that contacts residue/dead roots. Decomposition rate decreases if moisture decreases below the moisture content for optimum decomposition. RUSLE2 does not take into account reduced decomposition at excessively high moisture contents. Daily values for the moisture function W_f are computed from:

$$W_f = (P+I)/P_b \quad if[(P+I)/P_b > 1]: W_f = 1 \qquad [10.5]$$

where: P = daily precipitation (inches), I = daily amount (inches) of water added by irrigation, and P_b = base daily precipitation (inches) at which optimum decomposition occurs. A value of 0.173 inch (4.4 mm) was determined by fitting the RUSLE2 decomposition equations to the field data identified in Table 10.2.

Decomposition also varies with temperature. Decomposition decreases as temperature decreases below 32 ^oC, the optimum temperature at which decomposition rate is maximum. Similarly, decomposition decreases as temperature increases above 32 ^oC. Daily values for the temperature function are computed from:

$$T_f = \frac{2(T+A)^2(T_o+A)^2 - (T+A)^4}{(T_o+A)^4} \quad if(T < -10): T_f = 0 \qquad [10.6]$$

where: T = daily air temperature (^oC), T_o = the optimum temperature (^oC) for decomposition (32 ^oC), and A = 8 ^oC. The value for A was set so that when air temperature becomes less than – 10 ^oC, the temperature function is set to zero.[69] The reason that the temperature function does not become zero at a higher temperature, such as near 0 ^oC, is that temperature varies between a minimum and maximum during the day and average temperature on a given day varies about the long-term average temperature for that day. Air temperature rather than soil temperature is used in the temperature

[69] An adjustment should have been made to equation 10.6 to flatten the top of the curve around the 32 ^oC temperature for maximum decomposition to account for within day and year-to-year variation in temperature about the average daily temperature used in RUSLE2. See Schomberg et al. (2002).

function because soil temperature data are not readily available for use in RUSLE2. Like precipitation, air temperature is an indicator variable rather than the actual temperature that the decomposing material experiences. Values for the RUSLE2 decomposition coefficient ϕ differ from values for decomposition coefficient in similar equations used in other erosion prediction models such as WEPP (Stott et al., 1995), WEPS (Steiner et al., 1995), and RWEQ (Schomberg and Steiner, 1997).

The RUSLE2 composition coefficient ϕ can be expressed in terms of residue half life, which is defined as the time required for half of the residue mass to decompose at optimum temperature and moisture (i.e., $W_f = 1$ and $T_f = 1$). The relation of residue half life $D_{1/2}$ to the decomposition coefficient ϕ is given by:

$$D_{1/2} = -\ln(0.5)/\phi \qquad [10.7]$$

where: $D_{1/2}$ = residue half life (days) and ln(0.5) = 0.693.

The same decomposition coefficient ϕ values and moisture (W_f) and temperature (T_f) functions are used in RUSLE2 for buried and surface residue and dead roots (see **Section 10.3.3** for discussion of the reasons for this decision). Also, RUSLE2 decomposition coefficient ϕ values and the W_f and T_f functions are assumed not to vary with depth in the soil, soil texture, soil management, or residue mass. The same W_f and T_f functions are used to estimate decomposition of standing residue, but the RUSLE2 decomposition coefficient ϕ value for standing residue is 0.3 of that for surface and buried residue because moisture available for decomposition of standing residue is assumed to be much less than moisture available for decomposition of surface and buried residue (Douglas et al., 1980; Ghidey and Alberts, 1993; Steiner et al., 1994) (see **Section 10.3.3** for discussion of the reasons for this decision).

10.3.2. Calibration of equations

Values for the daily base precipitation P_b in equation 10.5 and values for the decomposition coefficient ϕ were determined by fitting the decomposition equations to measured data. Resulting P_b and ϕ values are given in Table 10.2.

The decomposition equations were fitted to the field data using daily average precipitation and temperature values disaggregated (see **Section 3.1**) from long term average monthly precipitation and temperature rather than actual precipitation and temperature values. Using long term-averages in these computations had a smoothing effect. Also, RUSLE2 uses average daily precipitation regardless of whether precipitation actually occurs, and thus values determined for P_b and ϕ are a function of RUSLE2's mathematical structure. Furthermore, the RUSLE2 purpose is to

capture the main differences in decomposition between locations rather than to precisely compute decomposition as a function of soil and cover-management. Furthermore, empirical data available to calibrate RUSLE2's decomposition equations were not sufficient to empirically determine coefficient values that are functions of soil and cover-management.

The RUSLE2 decomposition equations should be calibrated with several years of data at a location for a particular residue type and placement so that the data represent the expected range of climatic conditions at that site over a 10 to 30 year period. Unfortunately, most residue decomposition studies involve only a single year. Even when only single years of data were available, the RUSLE2 average daily precipitation and temperature values were used to calibrate the RUSLE2 decomposition equations.

Data sets were assembled from as many locations for each residue type as were available. Field residue mass-area and decomposition data are highly variable. Multiple sets of data for the same residue type were used as much as possible. The RUSLE2 decomposition equations were fitted to averages of these data by residue type and location.

Calibration of the RUSLE2 decomposition equations involved fitting them to field data to determine values for the base precipitation P_b and the decomposition coefficient ϕ. The first step in the fitting was to allow both P_b and ϕ to vary. The results for some of those fittings are shown in Table 10.2 for the P_b entries other than "4.4 assumed." A consideration was whether both P_b and ϕ varied by residue type and location. Based on an inspection of the fitted P_b and ϕ values, the conclusion was that a constant value of 4.4 mm (0.173 inches) could be used for P_b for the entire US except in the Palouse region (Req region, see **Section 3.2.5**) in the Northwestern US.

The use of a constant $P_b = 4.4$ mm value also was evaluated qualitatively by making computations for numerous locations across the US for several residue types. The 4.4 mm value worked well everywhere except for the Req region where a 0.5 mm value worked better. As Table 10.2 shows for the Pullman, WA location, use of the 0.5 mm P_b value gave ϕ values of 0.01 day^{-1} for wheat residue that are comparable to 0.008 day^{-1} values determined in other parts of the country. The reason for the low P_b values in the Req region is that the soil is highly saturated during the winter months when almost all of the erosion occurs and moisture does not limit decomposition even though daily precipitation is not high. If the 4.4 mm P_b value is used in the Req region, the ϕ value for wheat is 0.017 day^{-1} rather than the 0.008 day^{-1} for other parts of the US (see **Section 10.3.3.9**).

Table 10.3. Recommended values for the decomposition coefficient Φ in RUSLE2 with A = 8 °C and P_b = 4.4 mm (0.173 inches) based on fitting decomposition equations to measured data.

Crop	Decomposition Coefficient Φ (day^{-1})
Alfalfa	0.015
Blue stem hay	0.012
Corn	0.016
Cotton	0.015
Sorghum	0.016
Soybeans (Midwest US)	0.025
Soybeans (Mid South US)	0.015
Wheat in Eastern US (soft white wheat)	0.008
Wheat in Northwest Wheat and Range Region (NWRR) (hard red wheat)	0.017

Note: If P_b = 0.5 mm, then Φ = 0.01 day^{-1} for NWRR wheat

Once the P_b value was set at 4.4 mm, the calibration was repeated where values of ϕ were determined by fitting the decomposition equations to the field data. Table 10.2 entries for the "4.4 assumed" value for P_b are where the decomposition equations were fitted to the data with the P_b value fixed at 4.4 mm. The fitted values for ϕ were inspected and the ϕ values chosen for the RUSLE Core Database are shown in Table 10.3. Figure 10.2 shows how well RUSLE2 decomposition equations fit field data using the 4.4 mm P_b value and Table 10.2 ϕ values for surface residue. Decomposition of buried residue is discussed in **Section 10.3.3.3**.

The ϕ value for the Eucalypt litter was determined using a different calibration approach from the one used to determine the ϕ values shown in Table 10.2.

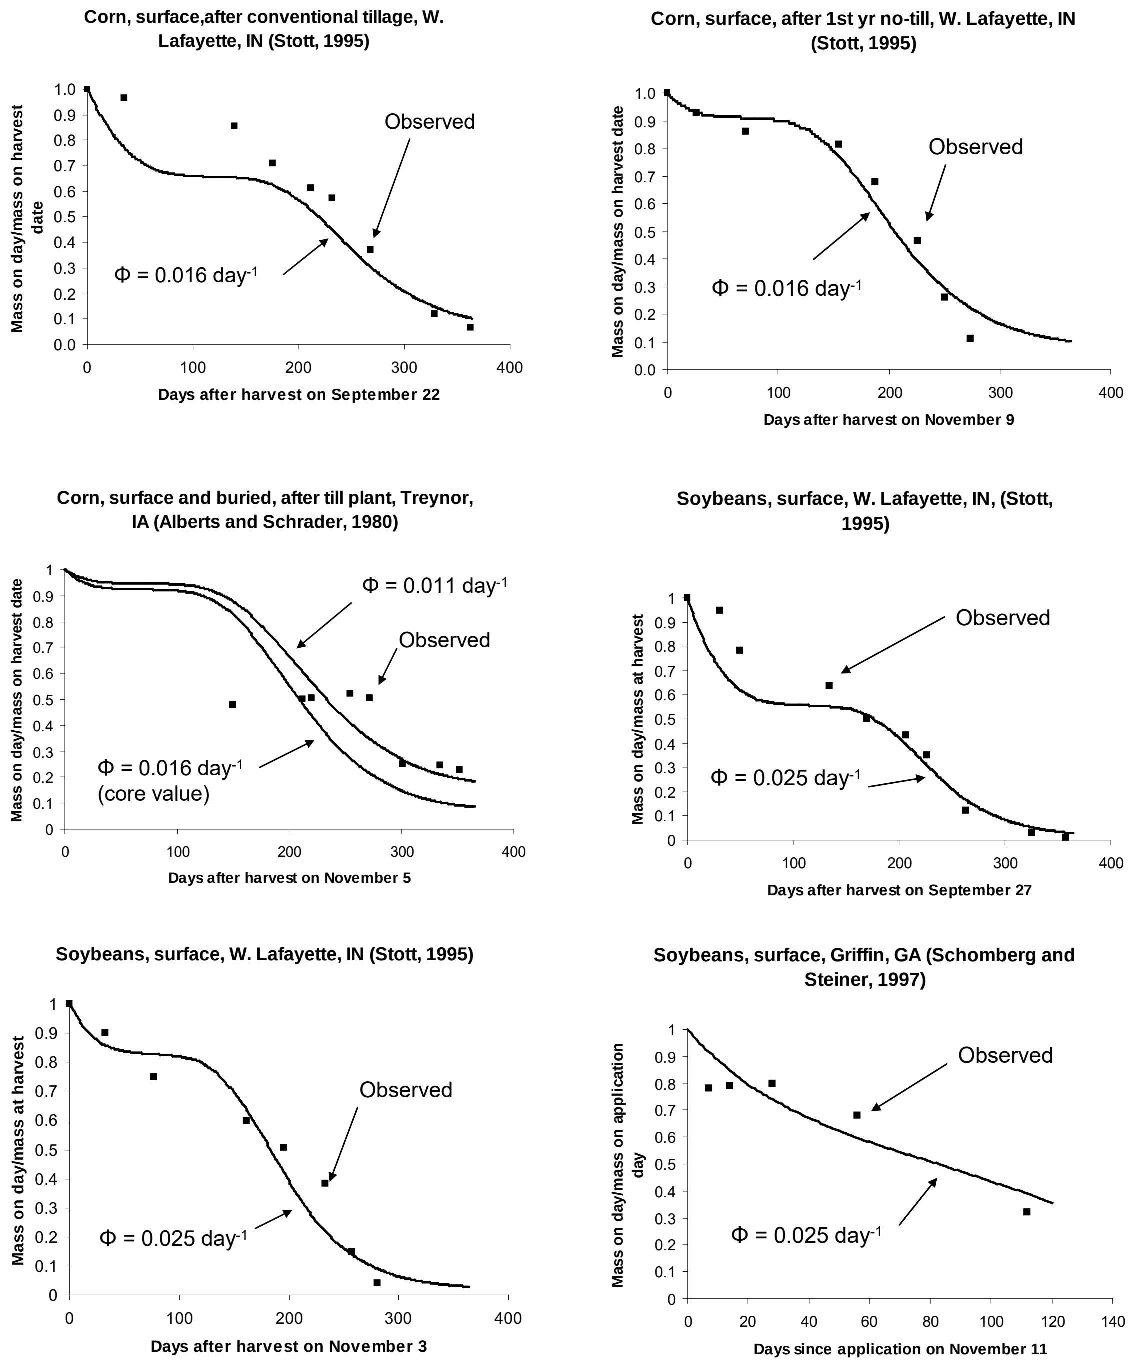

Figure 10.2. Comparison of RUSLE2 decomposition estimates using RUSLE2 Core Database values in comparison with field data.

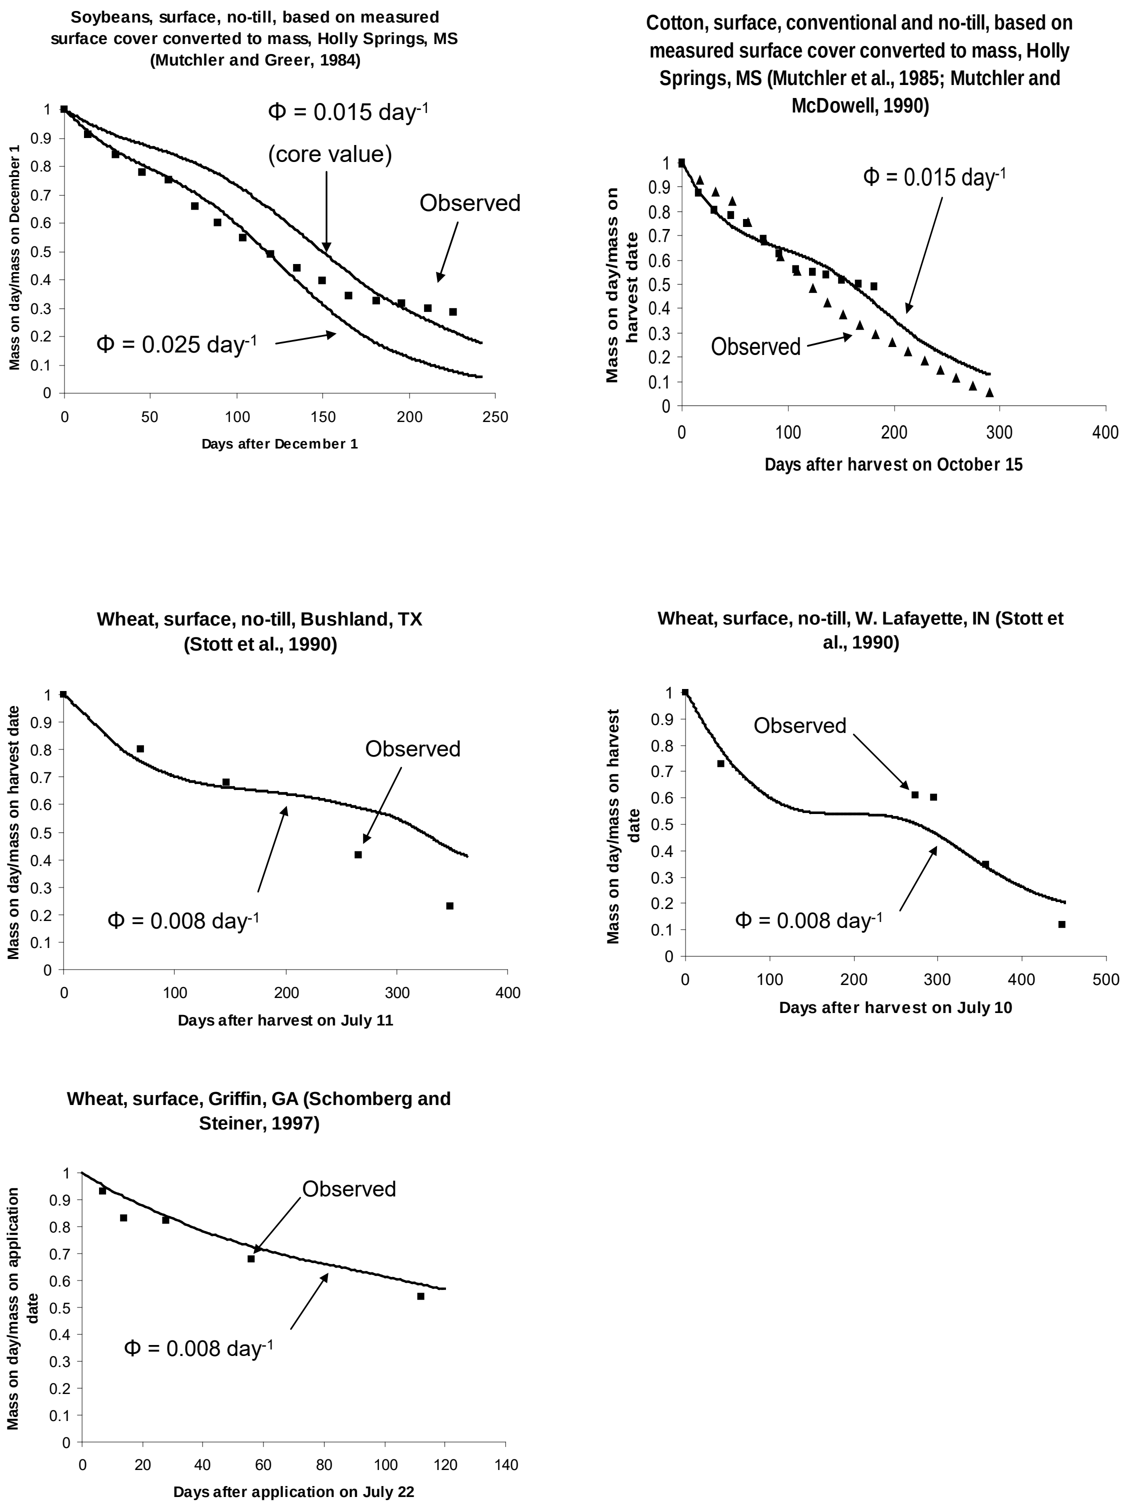

Figure 10.2. Comparison of RUSLE2 decomposition estimates using RUSLE2 Core Database values in comparison with field data. (continued)

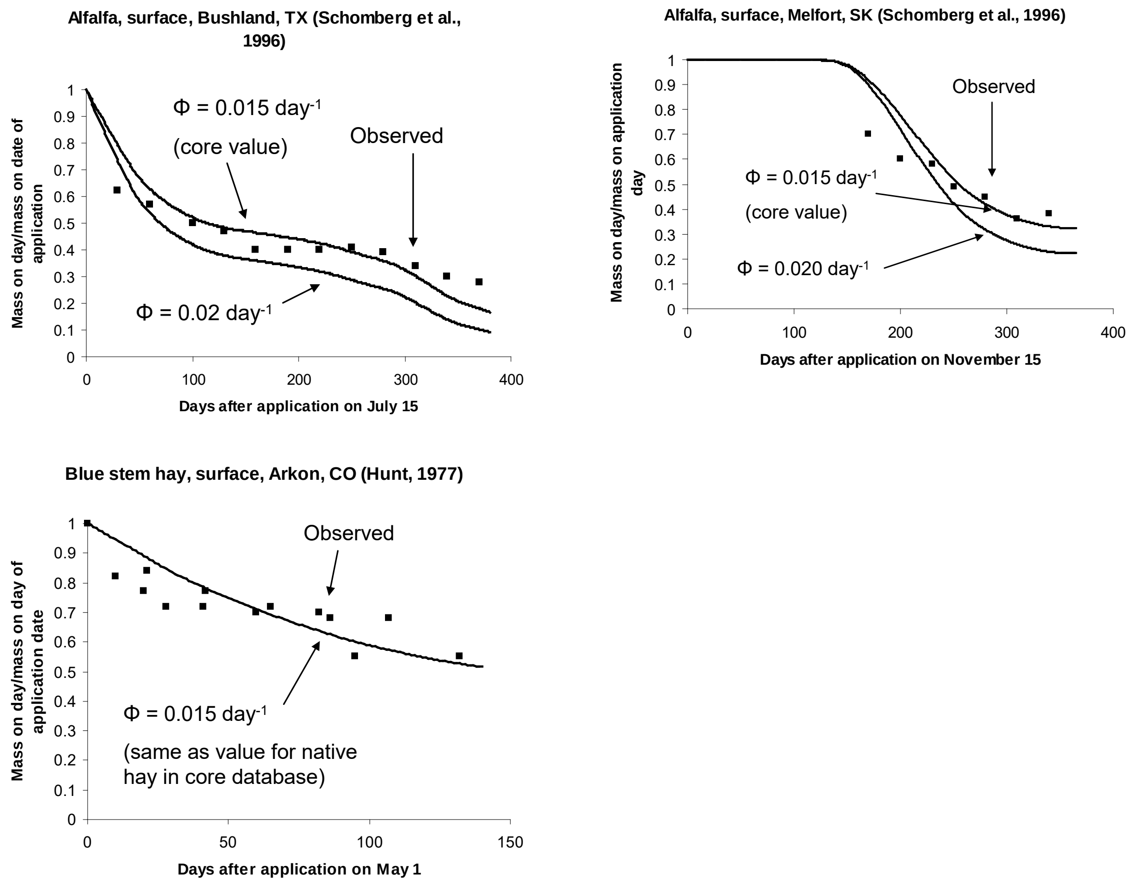

Figure 10.2. Comparison of RUSLE2 decomposition estimates using RUSLE2 Core Database values in comparison with field data. (continued)

Rather than fitting the RUSLE2 decomposition equations to the loss of residue mass over time, a ϕ value was determined for the Eucalypt litter by fitting RUSLE2 decomposition equations to an increasing residue mass over time until the mass reached a stable maximum. The Eucalypt litter data shown in Figure 10.3 are for surface residue (litter) accumulation following a forest fire in the Southwestern Australian Eucalypt forest (Birk and Simpson, 1980). This application illustrates RUSLE2's capability for computing both the accumulation of a surface litter layer where the biomass input is produced by aboveground senescence and the accumulation of a similar below ground biomass pool produced by root growth and death (root senescence, turnover).

An inspection of Figure 10.2 shows that RUSLE2 captures well the effect of location and material type on residue decomposition over time. A constant P_b value over almost all of the US works surprisingly well. Also, assuming the same ϕ value for a residue type works well for locations where climate differs greatly. For example, compare the results for alfalfa at both Griffin, Georgia and Melfort, Saskatchewan.

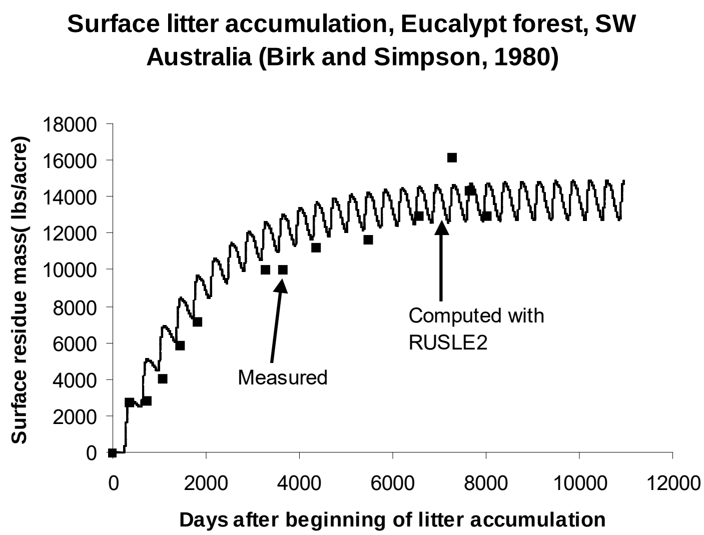

Figure 10.3. Computing the accumulation of a litter layer for an Eucalypt forest in Southwestern Australia.

An expectation is that RUSLE2 database developers can use values in the RUSLE2 Core Database to guide assignment of decomposition coefficient ϕ values for other residue types based on a comparison of residue characteristics. This procedure works but it requires more thought that initially expected. For example, a ϕ value of 0.02 day^{-1} was originally assigned for alfalfa before the ϕ value of 0.015 day^{-1} illustrated in Figure 10.2 was obtained by fitting measured field data. A ϕ value of 0.012 day^{-1} was assigned for native hay before the same ϕ value was determined by fitting measured data for the blue stem hay illustrated in Figure 10.2. The procedure of using values in the RUSLE2 Core Database as a guide in selecting decomposition coefficient values for other residue types will give reasonable RUSLE2 results for erosion control planning provided a careful comparison is made between residue types. The role of stems seems to be a major factor to consider in selecting ϕ values.

10.3.3. Basis for RUSLE2 decomposition decisions

RUSLE2's computation of residue loss is based on decomposition principles even though residue loss occurs by other processes besides decomposition. RUSLE2 is calibrated to field data representative of actual conditions as much as possible. RUSLE2 computations of residue and soil biomass loss are consistent with RUSLE2's purpose to be a **guide** to erosion control planning. Many decisions involved judgment during the formulation and calibration of RUSLE2's residue loss (decomposition) equations. This section describes the basis for those decisions.

10.3.3.1. User expectations

RUSLE2 computes residue decomposition and portion of the soil surface covered essentially using RUSLE1 procedures. Based on the RUSLE1 experience, some users will scrutinize RUSLE2's computed values for ground (surface, flat) residue cover more closely than RUSLE2's computed erosion values. RUSLE2 users are well aware of the importance of ground cover for controlling erosion. RUSLE2 users can not visually estimate erosion rates but they can visually measure ground (surface) cover. If RUSLE2's computed ground cover values do not meet their expectations, they assume that RUSLE2's erosion computations must also be wrong, which is often a false assumption.

Surface residue cover is a major variable used in judging the adequacy of cropland erosion control measures. USDA-Natural Resources Conservation Service (NRCS) standards and specifications for certain conservation practices require a minimum surface residue cover at planting (e.g., 30 percent). The RUSLE2 decomposition procedures were carefully constructed to ensure that RUSLE2 computes appropriate surface residue cover values for conservation planning, as demonstrated by the values shown in Table 10.1. The RUSLE2 decomposition procedures were designed specifically for RUSLE2's use as a conservation planning tool, not for residue management and certainly not to advance residue decomposition science and modeling. The RUSLE2 intent is to capture main differences in loss of residue/dead roots between material types and locations in the context of estimating average annual erosion rates for comparison against a criteria such as the USDA-NRCS soil loss tolerance (T) values (Toy et al., 2002).

While RUSLE2 users can easily measure residue cover, which they can compare with RUSLE2 computed values, they must exercise great caution in their measurements and evaluations of RUSLE2's adequacy for computing residue cover and corresponding erosion estimates. Residue mass-cover data are highly variable as illustrated in Figure 10.1. The cotton data in Table 10.2 illustrates the variability in decomposition data among multiple data sets collected under near identical conditions for the same residue type. Making a few field measurements is not the proper way to evaluate RUSLE2's computed residue cover values. The RUSLE2 User's Reference Guide provides information on how to adjust RUSLE2 inputs to obtain particular RUSLE2 computed residue cover values.

10.3.3.2. Residue sampling method

RUSLE2's computation of residue loss is based on dry mass, which requires field measurements of residue mass over time are needed to calibrate RUSLE2. The mesh bag and the "grab" sample are the two techniques used most often to determine surface residue mass in decomposition experiments. The mesh bag method involves inserting residue in a mesh bag and placing the bag on the soil surface or in the soil. The grab sample method involves removing amd unconfined residue from a sample area. Each method has significant drawbacks (Dabney, 2005).

The residue loss measured by the mesh bag method is a function of mesh size (Dabney, 2005). The mesh bag method tends to underestimate residue loss. The residue loss determined using the common 1 mm mesh bags has to be multiplied by a factor that ranges from 1 to greater than 2 to represent the loss of unconfined residue.

Conversely, the grab sample method tends to overestimate residue loss and has its own shortcomings including the difficulty of removing soil particles attached to the residue. Another difficulty is retrieving the entire residue from the sample area because fragile residue pieces can be broken and not recovered.

The difference in measured residue loss by sampling methods is very significant as illustrated in Figure 10.4. Using the RUSLE2 Core Database values, RUSLE2 computes that a 150 bu/acre corn crop produces 8200 lb/acre of residue. The corn residue mass remaining after 12 months at Bushland, Texas measured by the bag method would be 4100 lbs/acre (Schomberg et al., 1995, 1997) (see Figure 10.4). The percent soil surface cover provided by this residue mass is 79 percent and the ground cover subfactor value computed with equation 6.6 is 0.042.

The RUSLE2 decomposition equations were fitted to corn residue loss at W. Lafayette, Indiana measured using the grab sample method (Stott, 1995). The RUSLE2 computed value for residue mass remaining after 12 months using climate data for Bushland, Texas is 1480 lbs/acre. The percent soil surface cover provided by this residue mass is 43 percent and the ground cover subfactor value is 0.18, which is four times the value based on mesh bag measurements. Consequently, RUSLE2 computes greatly different erosion estimates depending on which set of data is used to calibrate RUSLE2's residue loss (decomposition) equations.

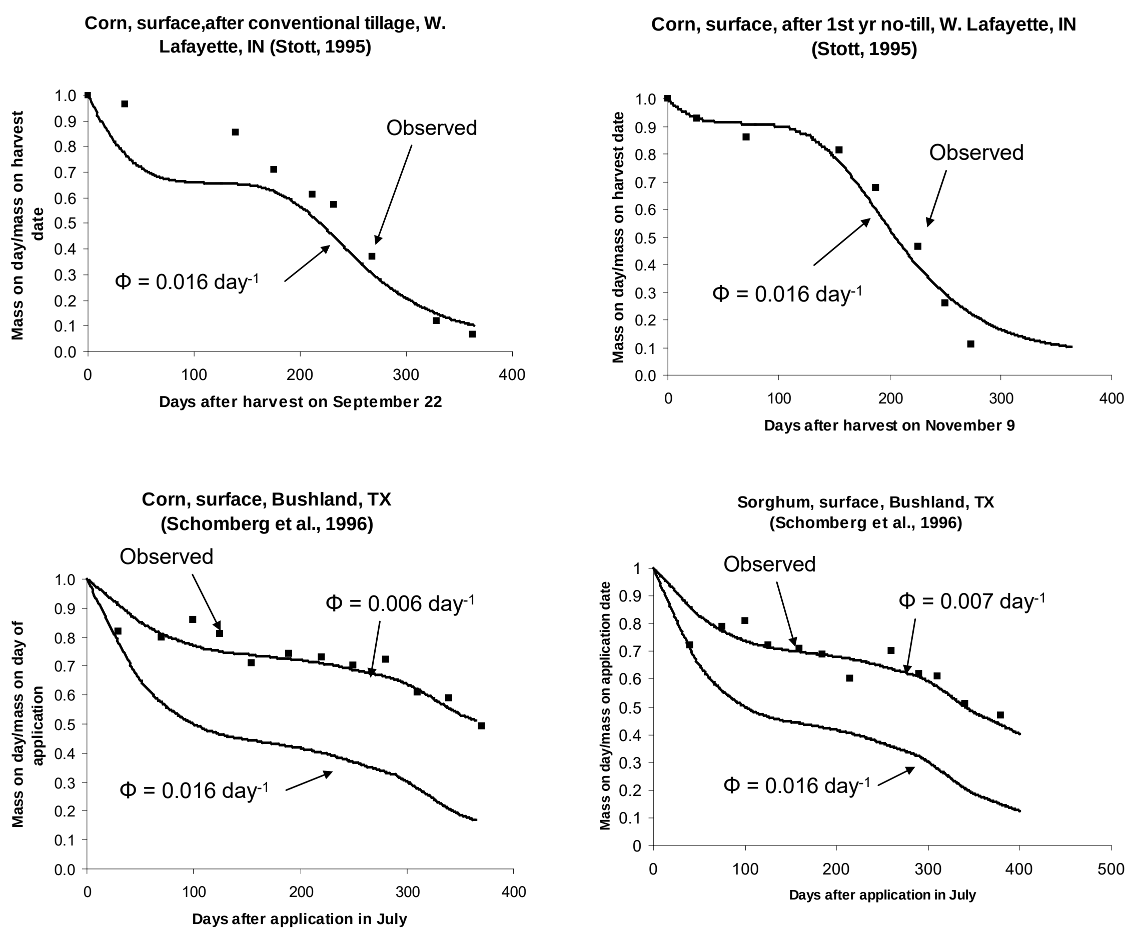

Figure 10.4. Comparison of observed and RUSLE2 computed decomposition of corn residue at W. Lafayette, Indiana and corn and sorghum residue at Bushland, Texas.

The difference in the measured Bushland, Texas data for corn and the RUSLE2 computed values based on a calibration to corn data measured at W. Lafayette, Indiana is not attributable to the RUSLE decomposition equations not performing equally well at the two locations. When wheat straw decomposition was measured by grab sampling from the soil surface (Stott et al., 1990; Stott, 1995; Stenier et al., 1999), measured decomposition at Bushland, Texas was consistent with data collected at W. Lafayette, Indiana and the RUSLE2 decomposition equations performed equally well at both locations (see Figure 10.2).

The difference in measured residue loss between the mesh bag and the grab sampling method is too large too ignore, which required a choice of one sampling method over the other. The grab sampling method was chosen for the development of RUSLE2. The conditions represented by this method, including the loss of residue by wind and other processes besides decomposition, better represent actual field conditions than does the mesh bag method. The differences between the two sampling methods seemed to be greatest for corn and wheat and much less for soybeans and forage crops. Decomposition coefficient ϕ values were determined for corn and wheat from the grab sample method while decomposition coefficient values were determined for forage crops from the mesh bag method.

Surface residue cover data were used to determine decomposition coefficient ϕ values for cotton and soybeans at Holly Springs, Mississippi. These data are field measured values for ground cover, which are the values most important in computing the effect of surface residue on rill-interrill erosion. These field data were considered to be superior to residue loss data measured with the mesh bag method.

The RUSLE2 decomposition coefficient ϕ value determined for corn is assumed to apply to grain sorghum based on the similarity in decomposition of corn and sorghum residue measured at Bushland, Texas by the mesh bag method. While the absolute decomposition values determined by the mesh bag method are not considered acceptable for RUSLE2 use, the mesh bag method is useful for determining relative differences in decomposition among residue types.

Other experimental procedures besides use of the mesh bag can affect decomposition results. The Ghidey and Alberts (1993) dataset includes decomposition values for roots and buried, surface, and above surface residue. Their data differ significantly from data considered best for RUSLE2 as illustrated in Figure 10.5. Oven drying the residue at 65 ^{o}C for 24 hours before placing the residue in the field may have contributed to the differences illustrated in Figure 10.5 in addition to mesh bags being used to measure residue loss.

10.3.3.3. Residue placement

RUSLE2 considers three placements of residue: (1) standing above ground, (2) soil surface, and (3) buried in the soil.

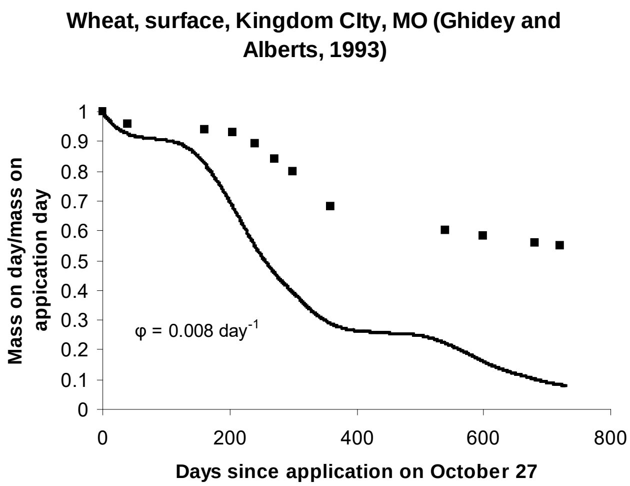

Figure 10.5. Difference in decomposition between that measured by Ghidey and Alberts (1993) and other data considered better for RUSLE2.

The RUSLE2 decomposition coefficient ϕ value used for above ground biomass is 0.3 times the ϕ value used for surface and buried residue. The decomposition coefficient ϕ value for above ground residue should be about 0.75 times the surface/buried residue ϕ value based on data collected by Douglas et al. (1980) and Ghidey and Alberts (1993). However, these data are questionable because the bundled residue samples used in these experimental studies do not represent individual pieces of standing stubble residue. Standing residue would retain much less moisture than the bundled residue samples. The 0.3 value performed satisfactorily in RUSLE2's computation of loss of standing residue (see **Section 10.4.1**)

The RUSLE2 assumption is that buried residue is lost at the same rate that soil surface residue is lost, although the common assumption is that buried residue decomposes more rapidly than does surface residue (Dabney, 2005). An example of measured data illustrating this apparent difference is shown in Figure 10.6. Like other residue aspects, the difference in decomposition rates for surface and buried residue varied greatly in the data reviewed by Dabney (2005) with no clear trend. Overall, the apparent decomposition rate for buried residue, regardless of residue type, was 1.3 times the decomposition rate of surface residue. Additional adjustment is required to obtain decomposition estimates of unconfined residue because the mesh bag sampling method was used in 10 out of 12 studies reviewed by Dabney (2005).

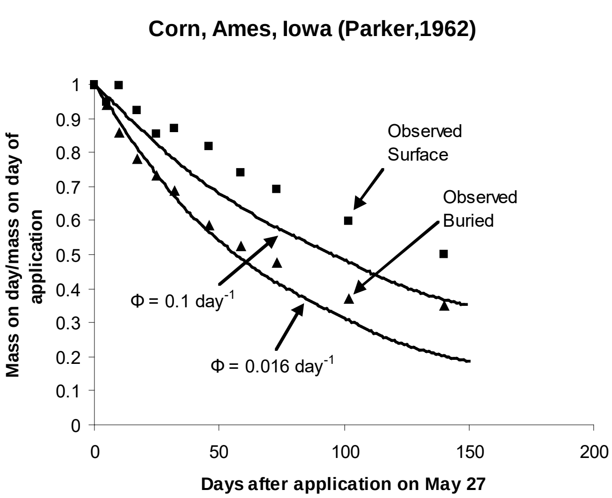

Figure 10.6. Difference in decomposition of residue in bags buried in the soil and placed on the soil surface.

Just as discussed in **Section 10.3.3.2** for surface residue, an adjustment also must be made for the mesh size effect on measured buried residue decomposition.

Instead of multiplying the mesh bag measured residue loss by 2 to obtain an estimate of unconfined surface residue loss, the measured mesh bag buried residue loss should be multiplied by 1.3 to estimate unconfined buried residue loss. Assume that the mesh bag measured surface residue loss is 1000 lbs/acre. The estimated actual loss is 2·1000 = 2000 lbs/acre. The measured mesh bag loss for buried residue is 1.3·1000 = 1300 lbs/acre based on the data reviewed by Dabney (2005), where the 1.3 factor accounts for the apparent higher decomposition rate for buried residue than for surface residue. Next, the 1300 value needs to be multiplied by the 1.3 factor to account for mesh bags underestimating the loss of unconfined buried residue. The buried residue loss of unconfined residue is therefore 1.3·1300 = 1700 lbs/acre. Consequently, these computations show that surface residue is lost at a greater rate (2000 lbs/acre versus 1700 lbs/acre) than is buried residue when the different effect of mesh size on decomposition of surface and buried residue is properly considered. The problem with these computations and with the mesh bag sampling method is the uncertainty involved in adjusting for mesh size and other factors related to how well decomposition in mesh bags represents actual field conditions.

The RUSLE2 intent is not to capture soil differences or placement within soil differences because RUSLE2 does not use soil moisture accounting routines. The buried residue studies cited by Dabney (2005) involved residue mesh bags placed 6 inches deep, which only partly simulates residue burial with a moldboard plow. A moldboard plow distributes residue throughout the disturbed soil layer even though most of the residue is buried in the lower half of the disturbed soil depth (see **Section 8.2.5.2**). Conservation tillage tools like disks, chisel plows, and field cultivators used for primary tillage leave most of the residue in the upper half of the disturbed soil depth (see **Section 8.2.5.2**), which residue buried at six inches does not represent. Furthermore, RUSLE2 uses the residue mass buried in the upper two or three inches to compute the effect of buried residue on erosion (see **Section 6.5**). The soil is drier at this shallow depth than at the six-inch measurement depth, and thus decomposition in this surface layer would be more like decomposition of surface residue than decomposition of residue buried at six inches. Therefore, mesh residue bags buried six inches deep do not represent typical field conditions.

Similarly, the placement of residue filled mesh bags on the soil surface does not represent typical field conditions. As Parker (1962) noted, a distinct boundary between surface residue and the soil surface does not exist in many cropland situations. For example, many residue pieces are both partially buried and exposed in conventional and mulch-till forms of cropping systems where tillage buries a portion of the residue left from the previous year's harvest. Soil splash by raindrop impact and local deposition behind residue pieces bonds the residue to the soil (Brenneman and Laflen, 1982; Toy et al., 2002). Also, the boundary between residue and the soil is not distinct in long-term no-till cropping systems. These effects are not captured by mesh bags placed on the soil surface.

The RUSLE2 objective is to produce reliable erosion estimates for conservation and erosion control planning. Increasing RUSLE2's decomposition rate for buried residue would not improve its erosion estimates but in fact would degrade them. The RUSLE2 computed ratio of erosion during the seedbed period for cropland going from turned sod to conventionally tilled 112 bu/ac yield corn to erosion for the same yield corn continuously cropped is 0.42, whereas the observed value is 0.40 [Table 5-D. AH537 (Wischmeier and Smith, 1978)].[70] However, the RUSLE2 computed ratio value is 0.95 for the second year while the observed value is 0.85. RUSLE2 computes this residual effect from turned sod using buried residue and dead root biomass values in equations 6.48 and 6.49. The first year erosion ratio value is computed well as a function of soil biomass before significant soil biomass loss by decomposition is computed. The fact that an accurate erosion ratio value is computed for the first year indicates that RUSLE2 is computing the proper effect of soil biomass when the estimated soil biomass is accurate. However, the fact that RUSLE2 computes too little soil biomass effect the second year indicates that RUSLE2 is computing too little soil biomass and a corresponding erosion that is too high. Consequently, increasing the decomposition coefficient ϕ value to represent buried residue decomposing more rapidly than surface residue will further degrade RUSLE2's performance for computing the effect of soil biomass.

These RUSLE2 erosion ratio values were computed using a decomposition coefficient ϕ value of 0.0017 day^{-1} for permanent grass vegetation residue. This decomposition coefficient value was originally selected based on comparison with other decomposition coefficient values in the RUSLE2 Core Database. However, recent analysis shown in Figure 10.2 for the blue stem hay shows that 0.012 day^{-1} is an appropriate value for decomposition coefficient ϕ value for blue stem hay. The erosion ratios computed with this ϕ value are now 0.36 compared to the observed 0.4 for the first year and 0.84 compared to the 0.85 observed for the second year, which is a significant improvement.

These results illustrate that the greater requirement is to accurately capture main effects before trying to capture minor effects. No basis exists for RUSLE2 computing decomposition of buried residue at a faster rate than surface residue. The RUSLE2 assumption that surface and buried residue decomposes at the same rate is strongly supported by both data, consideration of actual field conditions, increased accuracy of computed erosion values, and increased RUSLE2 robustness.

10.3.3.4. Roots

Fine roots are the most important roots in RUSLE2. A reasonable assumption is that the decomposition of fine roots is the same as buried residue. This assumption may need

[70] In this case, conventional tillage refers to a spring moldboard plow used for primary tillage followed two weeks later with a tandem disk and harrow or a tandem disk and field cultivator for secondary tillage used to create a seedbed.

reconsideration. Having the decomposition coefficient values the same for residue and roots gives RUSLE2 increased robustness, especially until additional information is learned about the distribution of root sizes and other root properties in the soil, the birth and death of roots, and how roots affect rill-interrill erosion. The RUSLE2 intent is to empirically capture the main effect of roots as an index rather than be a full description of how roots affect erosion.

10.3.3.5. Interdependence among calibration inputs for residue

No reliable data were found where both soil biomass and erosion were measured in the same experiment. Consequently, observed values for buried residue, dead root, and live root biomass were not used to calibrate the soil biomass subfactor equations 6.48 and 6.49 (see **Section 6.5**). Instead, RUSLE2 computed values for soil biomass were used to calibrate the soil biomass subfactor equations. In addition, “observed” soil biomass subfactor values were back-calculated from observed soil loss ratio values given in Table 5, AH537 (Wischmeier, and Smith, 1978) using RUSLE2 computed subfactor values for ground cover, soil surface roughness, ridge height, and soil consolidation for the seedbed crop stage of a silt loam soil at Columbia, Missouri, the RUSLE2 reference (base) location. Equation 6.1 was rearranged to compute values for s_b, the soil biomass subfactor. Soil loss ratio values from Table 5, AH537 are substituted for c in equation 6.1. Values for the other subfactors in equation 6.1 were RUSLE2 computed for the conditions listed in Table 6.5.

This soil biomass subfactor calibration approach has several consequences. The soil biomass subfactor absorbs the error and uncertainty in the other subfactors for the calibration conditions. The seedbed crop stage is the best crop stage for calibrating the soil biomass subfactor. Calibrating the soil biomass subfactor for this crop stage minimizes errors in the other subfactors because they deviate less from unit-plot conditions for the seedbed crop stage than for any other crop stage.

The only independent cover-management input in the calibration of the soil biomass subfactor, equations 6.48 and 6.49, is crop yield. All other cover-management inputs involved in the calibration are derived from yield, RUSLE2 Core Database values, and RUSLE2 procedures such as residue loss by decomposition and redistribution of soil biomass by mechanical soil disturbance. Therefore, a change in either RUSLE2 Core Database values or a RUSLE2 procedure used to compute subfactor values involved in the soil biomass subfactor calibration invalidates the calibration. **Consequently, a change in one of these items without recalibration produces erroneous RUSLE2 computed erosion estimates**.

The RUSLE2 assumption is that buried residue and dead roots decompose at the same rate as surface residue. This calibration approach has the advantage that it is partially self correcting if these assumptions are wrong. The empirically determined coefficient values in equations 6.48 and 6.49 compensate for erroneous soil biomass estimates used in the calibration as long as the relative values are accurate.

RUSLE2 has been developed and carefully validated to ensure that it computes the desired erosion values across the full range of conditions where RUSLE2 is expected to be used. Therefore, a change made to one RUSLE2 procedure, such as residue decomposition, requires a second change to ensure that RUSLE2 continues to compute expected erosion values.

Interdependence among RUSLE2 residue variables must be considered when changes are made so that RUSLE2 computes different ground (surface) cover values. To illustrate, What if RUSLE2 computed surface cover values seem questionable (see the **RUSLE2 User's Reference Guide** for additional discussion)? What RUSLE2 variable should be changed to improve surface cover estimates? The first step is to ensure that the data or observations being used as the basis for a change represent main effects rather than a minor effect or unexplained variability that RUSLE2 is not designed to capture.

The next step is to assess RUSLE2's computed erosion estimates to determine if these values should be changed along with the change in surface cover values. RUSLE2 was calibrated to give expected erosion estimates with an assumed set of values. A difference between an observed surface cover value and a RUSLE2 computed surface cover value does not necessarily mean that RUSLE2 is computing erroneous erosion estimates. What evidence, other than surface cover values, shows that RUSLE2 erosion estimates also need changing? An independence assessment should be made to determine if different erosion values should also be computed.

Changing decomposition coefficient ϕ values changes RUSLE2 computed surface cover values, but changing ϕ values also affects RUSLE2 computed soil biomass values and even soil surface roughness values that are a function of soil biomass. Therefore, a change in a ϕ value affects erosion in more ways than just changing surface cover. The question that should be asked before changing a ϕ value is: What evidence indicates that different soil biomass values should be computed along with different surface cover values?

Another way to change RUSLE2 computed surface cover values is to change above ground biomass as a function of yield. In addition to changing surface cover values, this change also affects soil biomass and soil surface roughness values. Once again, RUSLE2 computed erosion values are affected by changes in other variables besides surface cover.

The simplest way to change RUSLE2 computed surface cover values is to change surface residue mass-cover input values in the residue description (i.e., values for α in equation 10.1). Changing this relationship directly changes surface cover without changing other residue variables that affect erosion.

RUSLE2 changes should be carefully thought out to avoid unintended consequences.

10.3.3.6. Dealing with multiple component residue descriptions

A single RUSLE2 residue description is assigned to each vegetation description. A residue description represents a composite of the residue components produced by the particular vegetation.

Residue produced by vegetation includes: (1) pieces having a wide range in geometry that affect decomposition (e.g., fine and coarse roots and stems); (2) multiple components (e.g. leaves, stems, seed pods, and chaff); (3) variation in composition within a component (e.g., corn stalks having decomposition resistant exterior shells and easily decomposed interior material); (4) components, especially stems, that decompose from the inside out without changing outside dimensions (e.g., wheat straw); (5) decomposition properties that vary with growth stage (e.g., tender young leaves that decompose much more rapidly than mature leaves); (6) differences between above ground and below ground plant components (e.g., leaves that decompose more rapidly than roots); and (7) multiple species within a plant community (e.g., multiple plant species on rangelands and multiple weed species on permanent, unimproved pasture lands and landfills). RUSLE2 uses a single mass-cover coefficient α and decomposition coefficient ϕ to represent residue even though residue is composed of multiple components, each having its own α and ϕ values.

Effective RUSLE2 mass-cover coefficient α and decomposition coefficient ϕ values vary temporally as the residue decomposes. Values for these coefficients are functions of the relative composition of residue components that decompose at different rates. Consequently, the assigned RUSLE2 mass-cover and decomposition coefficient values are a compromise. The result is that RUSLE2 computes decomposition rates that are too slow in the beginning and too fast at the end. However, a review of Figure 10.2 shows that a single value decomposition coefficient ϕ works satisfactorily for a year for residue produced by typical agricultural crops, especially considering the unexplained variability in residue data.

Priority was given to fitting RUSLE2 computed decomposition values to observed values within the first year after residue application. Thus, RUSLE2 most accurately estimates decomposition of the easily and rapidly decomposable portions of the residue and not the residue that remains after one year, as illustrated in Figure 10.7. Most RUSLE2 applications involve a substantial annual input of biomass from crop production or senescence by permanent vegetation, which minimizes errors in RUSLE2 decomposition estimates beyond one year after residue application.

An example of a multiple component residue is the residue produced by a cover crop bi-culture of hairy vetch and rye that is killed at corn planning time in central Illinois (Ruffo and Bollero, 2003). The hairy vetch cover crop residue component (ϕ = 0.032 day^{-1}) decomposes much more rapidly than does the rye cover crop component (ϕ = 0.017 day^{-1}).

Figure 10.8 shows RUSLE2 decomposition computations for hairy vetch and rye grown as mono-culture cover crops and a 1:1 bi-culture cover crop based on dry mass on the day that the cover crop is killed. The curve labeled “by-component” is the decomposition that should be computed for the bi-culture. The “by-component” values shown in Figure 10.8 were computed outside of RUSLE2.

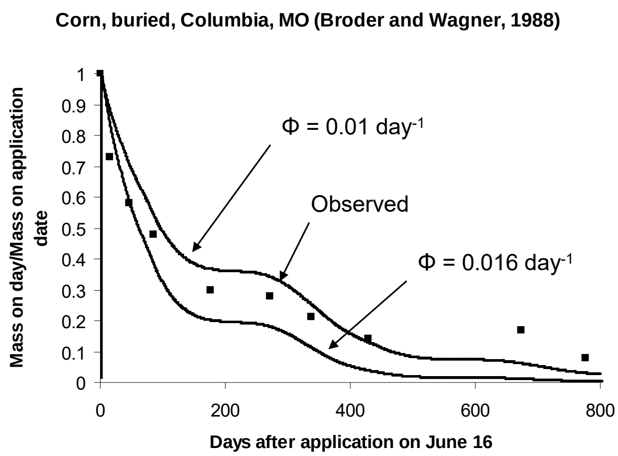

Figure 10.7. RUSLE2’s estimate of residue decomposition over a 2-year period.

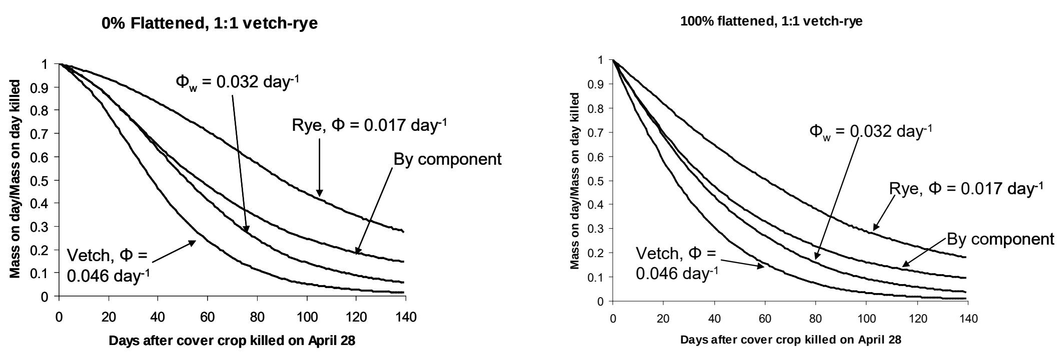

Figure 10.8. RUSLE2 computed decomposition of a 1:1 vetch-rye cover crop killed on April 28 in central Illinois. The Φ_w value is a weighted value based on dry mass on the date that the vegetation was killed.

A single value for the decomposition coefficient ϕ must be entered in the single composite RUSLE2 residue description that must be used to represent the combined residue produced by the hairy vetch and rye. One approach is to enter a weighted ϕ value based on dry mass of the hairy vetch and rye at the time that the cover crop vegetation is killed. As Figure 10.8 shows, initially RUSLE2 accurately computes decomposition but soon computes too much decomposition. The effective decomposition coefficient ϕ value should approach the ϕ value for rye over time as the hairy vetch decomposes much more rapidly than does the rye. An alternative input value for ϕ is an average of the weighted ϕ_w value at the time that the bi-culture cover crop is killed and the ϕ value for rye. RUSLE2 computes too little decomposition initially but computes much improved decomposition values after most of the vetch has decomposed.

Rather than developing a RUSLE2 procedure that adjusts the decomposition coefficient value as decomposition progresses, the best approach would be to modify RUSLE2 to accommodate multiple residue descriptions being assigned to a single vegetation description. In fact, the original RUSLE2 plan was to describe residue by its component parts. Using a residue description for each residue component would significantly improve RUSLE2's computations of residue decomposition and surface residue cover as a function of residue mass. Insufficient data existed for determining decomposition coefficient values for each plant residue component for the vast array of vegetations involved in RUSLE2 applications as a land use independent model.

The large decomposition coefficient ϕ values in Figure 10.8 for the hairy vetch and rye cover crops, 0.046 and 0.017 day^{-1}, respectively, illustrate how the decomposition coefficient ϕ is a function of crop stage. The ϕ value for mature hairy vetch residue is 0.020 day^{-1} while the ϕ value for mature rye is 0.0080 day^{-1}. The RUSLE2 decomposition coefficient values are about twice the values when the vegetation is killed as a cover crop when it is approximately half mature in comparison to the decomposition coefficient values for the vegetation after it reaches full maturity.

10.3.3.7. Effect of loading (application) rate

The decomposition coefficient ϕ seems to be a function of residue mass initially added to the soil surface as illustrated in Figures 10.9 and 10.10 (Steiner et al., 1999; Stott et al., 1990). **If initial surface residue mass affects the decomposition coefficient, the decomposition coefficient ϕ must also be a function of surface residue mass at any time after the residue is added to the soils surface.** The trend in both Figures 10.9 and 10.10 is that the decomposition coefficient ϕ decreases as surface residue mass increases. Therefore, Figure 10.9 and 10.10 imply that decomposition accelerates as surface residue mass decreases. However, this implication is inconsistent with the expectation that decomposition slows as the readily decomposable residue components disappear first, leaving the residue components that resist decomposition.

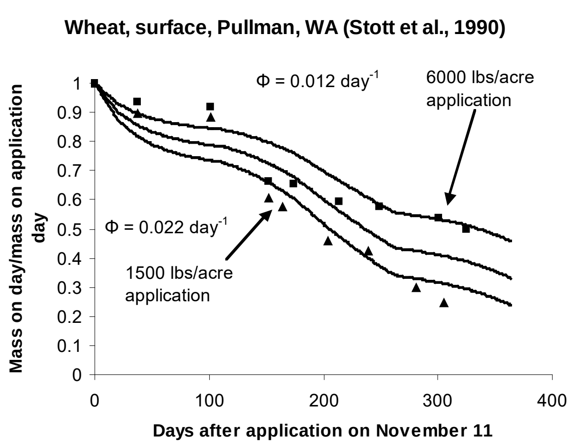

Figure 10.9. Effect of residue application rate on the decomposition coefficient ϕ.

Another concern is the great variability in decomposition coefficient values as illustrated in Figure 10.10. The RUSLE2 decomposition coefficient ϕ is proportional to the k decomposition coefficient in Figure 10.10. The comparable range in

ϕ for the range in k in Figure 10.10 for wheat straw is from 0.004 to 0.012 day^{-1}. RUSLE2 computes that 2100 and 600 lbs/acre of residue remain after 1 year for a 4000 lbs/ace wheat straw application at Columbia, Missouri for the ϕ values of 0.004 and 0.012 day^{-1}, respectively. The respective surface covers are 72 and 30 percent and the respective ground cover subfactor values, assuming **b** = 0.04 $percent^{-1}$ in equation 6.6 (see **Section 6.3**), are 0.0561 and 0.301, which is a 5:1 erosion ratio. The uncertainty in decomposition coefficient ϕ values is much greater than the variation in ϕ as a function of application rate and surface residue mass as shown in Figure 10.10, especially for residue mass less than 6000 lbs/acre (600 g/m^2).

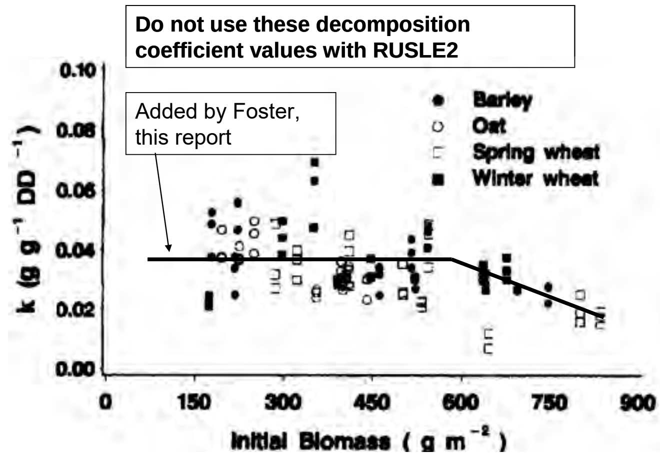

Figure 10.10. Variation of decomposition coefficient k (comparable to ϕ) values from another decomposition model with residue application rate. (Data source: Steiner et al., 1999; Line added by Foster, this report)

Furthermore, are the results illustrated in Figure 10.9 and 10.10 indicative of decomposition of the wide array of vegetation residue including vegetables, corn, wheat, hay, litter on rangelands, Eucalypt forest litter, and erosion control materials used on construction sites? Are the results illustrated in these figures indicative of application conditions that range from wheat straw being blown onto a construction site to wheat straw left in conventionally, reduced, and no-tilled fields?

The conclusion for RUSLE2 purposes is that the decomposition coefficient ϕ is not a function of residue application rate or surface residue mass. The uncertainty illustrated in Figure 10.10 reinforces the conclusion that RUSLE2 represents decomposition differences between major residue and erosion control material types, but not difference in small grain types, for example. An improvement in RUSLE2's decomposition computations can be gained by representing residue components such as legume and grasses and stems, leaves, seed pods, and chaff. Much more research is needed before the RUSLE2's decomposition coefficient ϕ can be made a function of application rate or surface residue mass. Furthermore, a standardized set of decomposition data for a wide range of materials are needed to determine RUSLE2 ϕ values.

10.3.3.8. Effect of irrigation on residue decomposition

RUSLE2's accuracy for estimating increased decomposition caused by irrigation was assessed using data reported by Schomberg et al. (1994) for decomposition of surface and buried alfalfa, wheat, and sorghum residue in mesh bags. Water varying in amounts from 5 to 336 mm was added by sprinkler irrigation during the study year in addition to 305 mm of natural precipitation. The long term average annual precipitation at Bushland, TX is 480 mm. The monthly precipitation and temperature distributions during the study are shown in Figure 10.11. Although monthly temperatures during the study were close to the long term values, the study's monthly precipitation distribution differed significantly from the long average distribution. The water added in each irrigation is given in Figure 10.12.

The objective of this analysis was to determine how well RUSLE2 computes the effect of added irrigation water on residue decomposition, not to determine decomposition coefficient ϕ values. The first step in the analysis was to adjust the decomposition coefficient ϕ value until a good fit was obtained between computed decomposition and

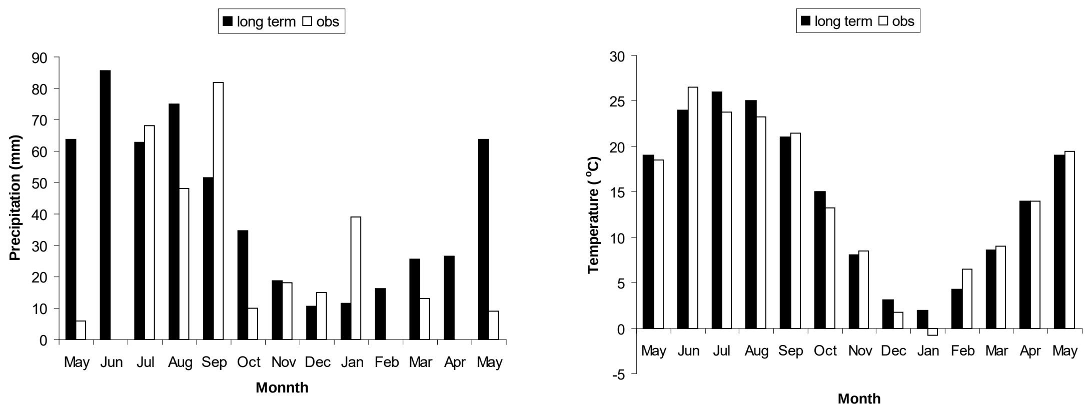

Figure 10.11. Long term average monthly precipitation (480 mm annual) and actual monthly precipitation (305 mm annual) and long term average monthly temperature and actual monthly temperature for Schomberg et al. (1994) study

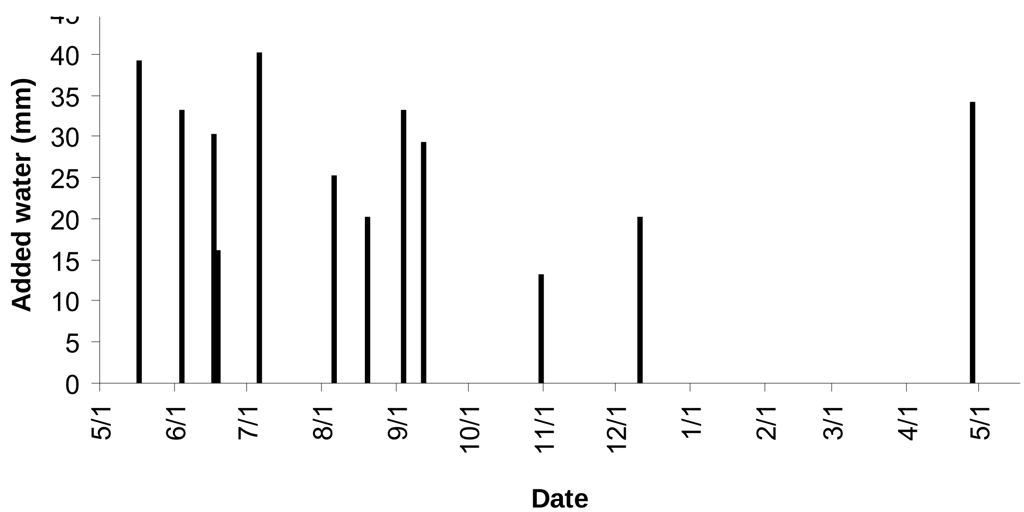

Figure 10.12. Water applied by sprinkler irrigation (total application of 336 mm) in Schomberg et al. (1994) study.

observed decomposition for the no-irrigation (only natural precipitation) condition.

Observed monthly precipitation and temperature values shown in Figure 10.11 were used in the analysis.

The decomposition coefficient ϕ value determined for natural precipitation alone was used to compute decomposition for the 305 mm natural precipitation plus 336 mm of added irrigation water distributed as shown in Figure 10.12. The results of those computations are shown in Figure 10.13.

Variability is a common problem in decomposition data. The data in Schomberg et al. (1994) study also was highly varied. For example, the fraction of surface sorghum residue remaining on December 10 was 53 percent while the fraction remaining on March 10 was 70 percent, which is an obvious error because residue mass does not increase over time. Another problem with these data is that the range in decomposition of surface residue as a function of added irrigation water is not consistent with the range in the observed data for surface sorghum and wheat residue.

As Figure 10.13 shows, the conclusion is that RUSLE2 described well how sprinkler irrigation affects decomposition of both surface and buried residue in the Schomberg et al. (1994) study. Furthermore, RUSLE2 described decomposition well for the natural

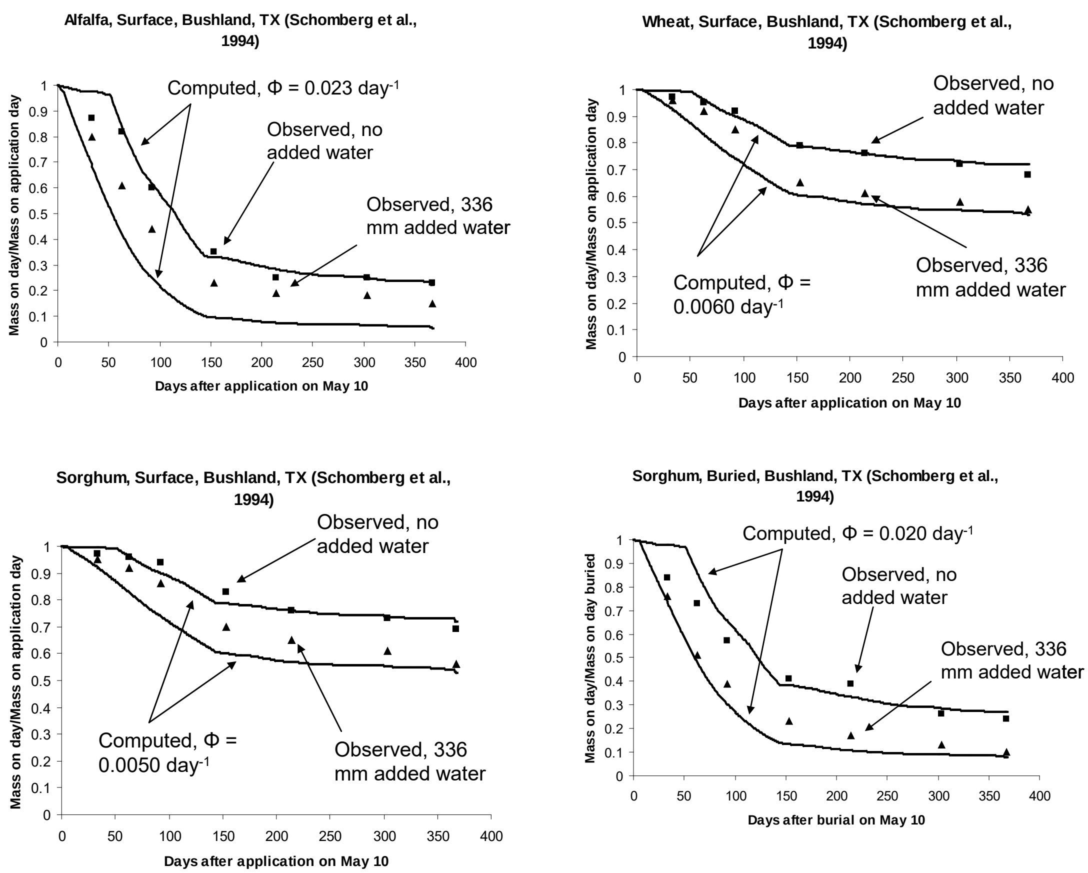

Figure 10.13. Effect of irrigation of buried and surface residue (data source: Schomberg et al., 1994)

precipitation without irrigation even though the actual monthly precipitation distribution did not vary smoothly month to month.

The Schomberg et al. (1994) data show major differences in decomposition rate between surface and buried residue. These differences seem to be a direct result of experimental procedures. That issue is discussed in detail in **Section 10.3.3.2**.

These results also show that decomposition of both surface and buried residue is a dampened process that does not react quickly to changes or irregularities in precipitation or temperature. Surface residue apparently continues to decompose longer after a water-application event that seems to have been assumed in some decomposition models (Schomberg and Steiner, 1997; Steiner et al., 1999). Decomposition of surface residue seems much more related to local soil moisture at the contact between the residue and soil than was previously considered.

An important question is whether residue decomposes the same per unit water added by irrigation as it does by unit water added by natural rainfall. Decomposition may be less per unit water applied by sprinkler irrigation than applied by natural rainfall. Water droplets in the irrigation-applied water have very low impact energy in comparison to natural rainfall. Thus, natural rainfall splashes many more soil particles that increase the contact between the soil and the residue (Foster et al., 1985a) than does sprinkler irrigation applied water. Irrigation-applied water may wash away soil particles previously bonded to the residue by rainfall. Also, deposition of sediment produced interrill-rill erosion (Brenneman and Laflen,1982) increases soil bonding between residue and soil at low residue application rates that does not occur with irrigation-applied water.

The type of irrigation should be considered in selecting irrigation inputs for RUSLE2. This decomposition analysis was based on sprinkler irrigation. The irrigation input values for sprinkler irrigation should be based on the water that actually reaches the soil. This amount can be significantly less than the amount discharged from the irrigation nozzles because of wind and evaporation losses.

Also, decomposition may be less on ridges when furrow irrigation is used than with flood irrigation on a smooth surface. Similarly, decomposition of surface residue may be reduced with drip irrigation. However, be careful in making adjustments to irrigation amounts because RUSLE2 uses the same amount in computing decomposition of both surface and buried residue. Also, RUSLE2 uses irrigation input values to compute temporal soil erodibility (see **Section 4.5**).

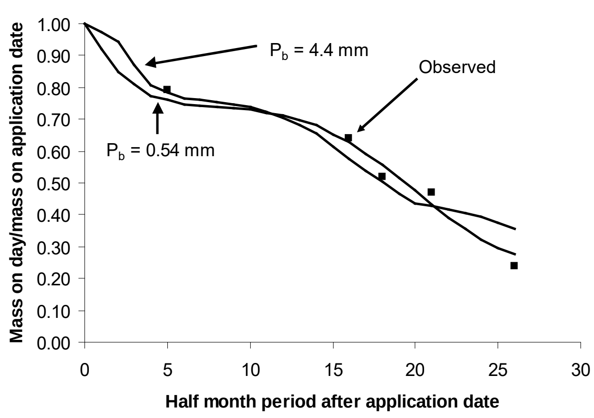

Figure 10.14. Effect of changing the base daily precipitation P_b value in the moisture function used to compute wheat straw residue decomposition at Pullman, Washington.

10.3.3.9. Special considerations for the NWRR and Req zones

The climate in the Northwest Wheat and Range Region

(NWRR), which is within the larger Req zone (see RUSLE2 User's Reference Guide), differs significantly from the climate in non-Req areas. An example is the relationship of monthly precipitation amount relative to number of precipitation events (see **Section 10.3.4.2**). Consequently, should the decomposition equations and coefficient values differ for the NWRR and the entire Req zone from those for other regions? To evaluate this possibility, the base moisture P_b value in the moisture function (W_f, equation 10.5) was determined by fitting the decomposition equations specifically to decomposition data collected at Pullman, Washington. A P_b value of 0.54 mm produced improvement for some data sets as illustrated in Figure 10.10, but not for all data sets. When 0.54 mm is used for P_b in equation10.5, RUSLE2 computes decomposition being controlled throughout the year by the temperature function (T_f, equation 10.6) at Pullman, Washington. When P_b = 4.4 mm, RUSLE2 computes that decomposition is controlled by the moisture function from May through October. Computing that decomposition is controlled by moisture when average monthly precipitation is as low as 0.45 inches (11 mm) in July and 0.64 inches (16 mm) in August seems more appropriate than the temperature function controlling decomposition during these dry months.

Decomposition coefficient ϕ values determined for wheat using P_b = 0.54 mm are essentially the same as decomposition coefficient values determined for wheat in other regions using P_b = 4.4 mm. Consequently, the difference in decomposition coefficient values in Table 10.2 between the NWRR and other regions may not be related to wheat varieties as implied in Table 10.2, but related to having an appropriate description of the moisture function W_f for the NWRR.

The recommendation is that 4.4 mm be used for P_b for the NWRR and Req zone along with the Req specific decomposition coefficient values given in Table 10.3 until additional research is conducted. This additional decomposition research for the Req zone, including the NWRR, can be conducted simultaneously with additional research needed on other RUSLE2 Req relationships throughout the Req zone, especially for locations outside of the central Washington to northern Idaho and Northeastern Oregon region.

10.3.4. Comparison of RUSLE2, RWEQ, WEPP, and WEPS decomposition

The RUSLE2 water erosion and RWEQ (Fryrear et al., 1998) wind erosion prediction technologies use comparable empirical structures involving long-term average monthly climate and management inputs and both were originally intended for conservation planning in USDA-Natural Resources Conservation Service (NRCS) field offices. The NRCS initially placed a high priority on RUSLE2 and RWEQ using the same equations and parameter values for computing residue mass values. Later the NRCS adopted WEPS (Hagan et al., 1996) instead of RWEQ for field office conservation planning. WEPS is a process-based simulation model that uses stochastic climate inputs. The comparable water erosion prediction model is WEPP (Flanagan and Nearing, 1995).

RUSLE2 and WEPS should compute comparable residue mass values because these models are being implemented by NRCS for routine conservation planning, and WEPP may be implemented in the future. Although erosion prediction clients may not know the residue mass values that these models should compute, clients readily recognize differences in values computed by the models and question differences when none should exist. Such differences reduce the creditability of the models and the conservation plans developed using them.

Decomposition estimates of surface applied residue were computed using RUSLE2, RWEQ, WEPP, and WEPS at the locations listed in Table 10.4.

Table 10.4. Locations for RWEQ, WEPP, and WEPS decomposition computations

Location	Annual precipitation (inches)	Model	Comments
Jefferson City, Missouri	37.8	All	Near Columbia, Missouri
Minneapolis, Minnesota	27.0	ALL	
W. Lafayette, Indiana	37.0	RWEQ	
Scottsbluff, Nebraska	15.1	WEPP/WEPS	
Jamestown, North Dakota	18.3	RWEQ	Used in Figure 10.19
Amarillo, Texas	20.1	RWEQ	Near Bushland, Texas
Borger, Texas	20.7	WEPP/WEPS	Near Bushland, Texas
Denton, Texas	33.1	WEPP/WEPS	
Dallas, Texas	36.0	WEPP/WEPS	
Houston, Texas	46.4	WEPP/WEPS	
Galveston, Texas	39.8	WEPP/WEPS	
Holly Springs, Mississippi	54.2	WEPP/WEPS	
Jackson, Mississippi	53.8	RWEQ	
Gulfport, Mississippi	60.0	WEPP/WEPS	
Mobile, Alabama	62.3	All	
Spokane, Washington	16.0	RWEQ	
Tucson, Arizona (Davis)	11.2	RWEQ	Davis-Monthan Air Force Base
Tucson, Arizona (Campbell)	12.4	WEPP/WEPS	University of Arizona Agricultural Experiment Station on Campbell Avenue
Albuquerque, New Mexico	9.3	RWEQ	Used in Figure 10.19

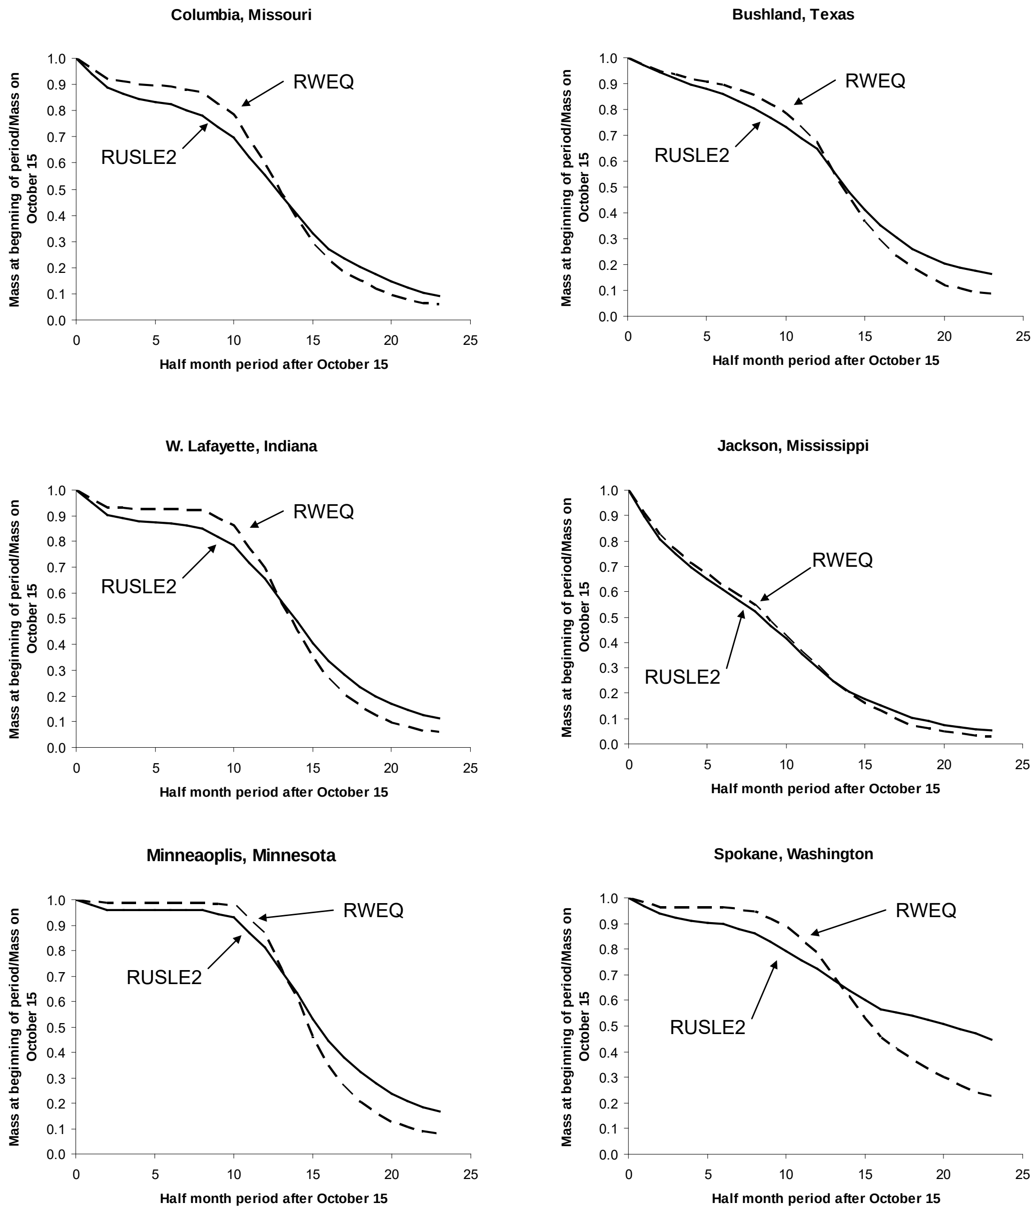

Figure 10.15. Residue decomposition computed with RUSLE2 and RWEQ

For the RWEQ computations, mulch was assumed to be surface applied on October 15 at 4500 lb/acre to a seedbed condition with no existing above ground or below ground biomass for all locations except Tucson, Arizona. The mulch was assumed to be applied on January 1 at Tucson.

The RWEQ decomposition coefficient value was adjusted to give the best fit of computed residue mass to RUSLE2 computed values at Columbia (Jefferson City), Missouri. This RWEQ decomposition coefficient value was used for all other locations, and the same RUSLE2 decomposition value was used for all locations.

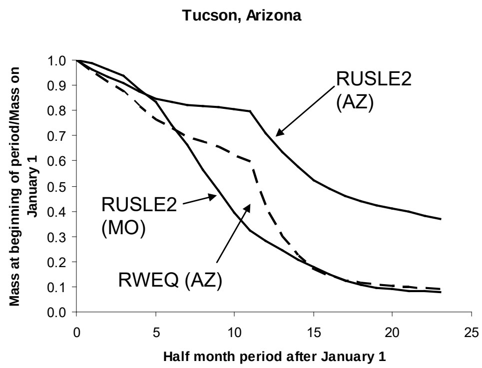

Figure 10.16. Residue decomposition computed with RUSLE2 and RWEQ at Tucson, Arizona

For the WEPP computations,[71] the same 4500 lbs/acre mulch rate was assumed to be applied on May 10, except for Tucson where the mulch was assumed to be applied on January 1. The mulch was applied to a soil that had not been tilled for a year. No above ground or below ground biomass was assumed. WEPP was run for 10 years with the same mulch amount applied each year with no soil disturbance throughout the 10 year simulation period.

WEPP computes daily residue mass for each annual mulch application. Daily computed surface residue mass for each mulch application was averaged for the 10 year simulation period. The WEPP computed residue mass values are equivalent to conducting annual experiments where the fate of mulch applied each year is determined. The WEPP computations represent each annual application placing new mulch on mulch remaining from previous years rather than mulch being applied each year to bare soil.

The RUSLE2 decomposition coefficient ϕ value was adjusted to give the best fit of RUSLE2 computed residue values to WEPP computed values for Columbia (Jefferson City), Missouri for a silt loam soil. This RUSLE2 decomposition coefficient value was used for all locations and the same WEPP decomposition coefficient value was used for the same silt loam soil for all locations.

Decomposition was computed with WEPP at the locations listed in Table 10.4. RUSLE2 computed decomposition values compared well with WEPP computed values for locations where temperature rather than moisture was the factor limiting decomposition. At locations where RUSLE2 computed that moisture limited decomposition, WEPP conputed decomposition amounts that were significantly greater than RUSLE2 computed, which was especially evident a Tucson, Arizona where the WEPP computed decomposition was essentially the same as decomposition computed at Columbia, Missouri even though average annual precipitation at Tucson as only 12 inches in comparison to 38 inches at Columbia, Missouri. Consequently, WEPP seems to be computing too much decomposition in dry locations.[72]

---

[71] The WEPP version used in these computations was dated May 18, 2006, which was downloaded from the USA-ARS WEPP Internet site in April 2008. This version is the most recent version available to the public.

[72] These results have been reported to Dennis Flanagan, lead WEPP developer, USDA-Agricultural Research Service, W. Lafayette, Indiana. WEPP developers are investigating whether WEPP may be

The WEPS compuations were made using the WEPS hydrology component rather than WEPS with the WEPP hydrology component.[73] The same 4000 lbs/acre mulch rate was assumed to be annually applied on October 15 at all locations. The management practice used to make the compuations represented a soil tilled with a moldplow plow and a tandem disk that buried all of the previous year's mulch and did not resurface any buried residue. WEPS was run for 15 years. Daily surface residue mass values were averaged

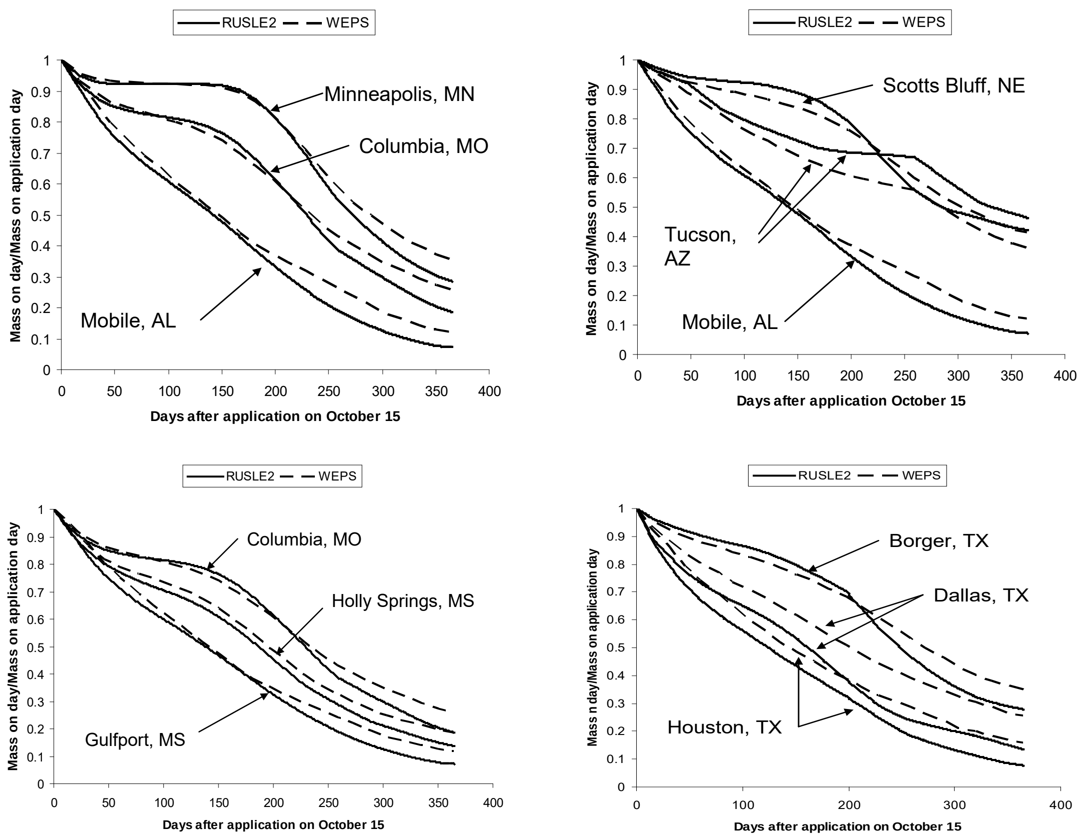

Figure 10.17. Residue decomposition computed with RUSLE2 and WEPS

for the 15 year simulation. The results are plotted in Figure 10.17.

The same WEPS decomposition coefficient value was used for all WEPS computations. The RUSLE2 decomposition coefficient ϕ value was adjusted to give the best fit of

---

computing too much decomposition at Tucson and other dry locations. Possible WEPP changes may made sometime soon (May 10, 2008).

[73] The WEPS version used in these computations was dated April 14, 2006, which was provided by Larry Wagner, lead WEPS developer, USDA-Agricultural Research Service, Manhattan, Kansas.

RUSLE2 computed residue values to WEPS computed values for Columbia (Jefferson City), Missouri for the Morley silty clay loam soil. This RUSLE2 decomposition coefficient value was used for all subsequent RUSLE2 computations.

10.3.4.1. Structure of decomposition computations

All four models (RUSLE2, RWEQ, WEPP, and WEPS) use moisture and temperature functions to compute decomposition. RUSLE2, WEPS, and WEPP use equation 10.4 that takes a minimum of the moisture and temperature functions instead of the product of these functions used in RWEQ. The differences in computed decomposition resulting from the RUSLE2 minimum structure and the RWEQ product structure are illustrated in Figures 10.15 and 10.16. With the exception of the Tucson location, the consistent trend is that the product structure computes reduced decomposition during cool periods and increased decomposition during warm periods.

Using a minimum of the moisture and temperature functions was judged to be better than the product of the functions based on an inspection of Figures 10.2 and 10.15.

The minimum of the moisture and temperature functions, which is equation 10.4, is also used in WEPP and WEPS. The Gregory et al. (1985) decomposition model was originally used in RUSLE1, but it was replaced with a modification of the WEPP decomposition model (Stott, 1991; Stott et al., 1995) because the Gregory et al. model also was judged to compute too little decomposition during cool periods and too much decomposition during warm periods.

10.3.4.2. Moisture function

10.3.4.2.1. Comparison with RWEQ

RUSLE2's moisture function used to compute decomposition is given by equation 10.5. The RWEQ moisture function is given by (Fryrear et al., 1998; Schomberg and Steiner, 1997):

$$W_{fwe} = 1.25 N_p / D_p \qquad [10.8]$$

where: W_{fwe} = the RWEQ moisture function used to compute decomposition, N_p = the number of precipitation events in the period D_p (days). The Schomberg and Steiner (1997) justification for using number of precipitation events is that surface residue does not remain moist long after a precipitation event, which conceptually implies that residue moisture content following a precipitation event is independent of the event's precipitation amount, which seems questionable. The moisture retained by residue depends greatly on residue type and mass and its contact with the soil mass. Similarly, the Schomberg-Steiner assumption seems questionable for mulch-till and no-till cropping systems where the soil-residue interface is not well defined and surface residue pieces are partially covered by soil. The assumption also seems questionable during fall and spring periods when evaporation is reduced. Dew may provide a significant moisture source, even on very hot days (Heilman et al, 1992).

Decomposition was computed with RUSLE2 and RWEQ at the locations identified in Table 10.4, and the computed values are shown in Figures 10.15 and 10.16. Except for the Tucson location, the RUSLE2 and RWEQ moisture functions performed similarly. The reason for the similar performance is that number of precipitation events in a given period in the RWEQ moisture function actually serves as a surrogate for precipitation amount used in the RUSLE2 moisture function. Precipitation amount in a given period is highly correlated with number of precipitation events in the period and the relationship is essentially the same across the eastern US as shown in Figure 10.18. However, a disadvantage of the RWEQ moisture function even in this region is that number of precipitation event is more spatially varied than precipitation amount. Also, data on number of precipitation events are much less available than long term monthly precipitation values, such as those that were easily found and used to compute decomposition in Canada (see Figure 10.2) and SW Australia (see Figure 10.3).

The RUSLE2 and RWEQ decomposition estimates differ greatly for Tucson, Arizona as shown in Figure 10.16. In this figure, decomposition was computed at Columbia, Missouri with RWEQ for mulch applied on January 1, the same as for Tucson. RWEQ computed the same decomposition for both Tucson and Columbia even though annual rainfall at Tucson (Davis) was only 11 inches in comparison to 38 inches at Columbia (see Table 10.4). The reason that RWEQ computes the same decomposition at the two locations is that the number of storms is comparable for the two locations even though annual precipitation differs significantly between the locations. Similarly, the number of storms per month in relation to monthly precipitation amount is high at Spokane Washington during the cool period, which is the reason for the difference between decomposition computed by RUSLE2 and RWEQ Spokane being greater than at the other locations in Figure 10.15.

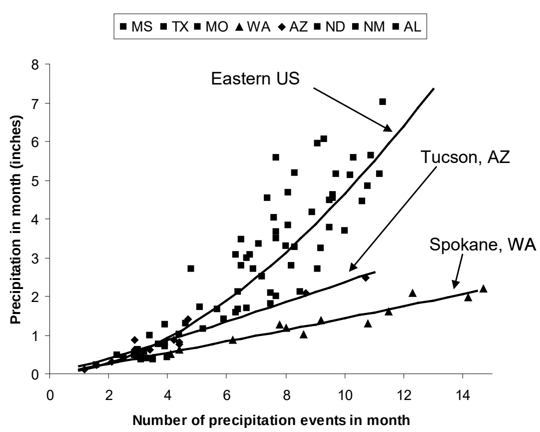

Figure 10.18. Relation of average monthly precipitation to number of precipitation events in a month.

Use of the RWEQ moisture function in RUSLE2 would require varying the decomposition coefficient value with location in the western US. This requirement is similar to the base precipitation value P_b in equation 10.5 needing to be changed so that the same RUSLE2 decomposition coefficient values can be used in the Palouse Region and in the eastern US (see **Sections 3.2.5 and 10.3.2**).

Overall, using precipitation in the RUSLE2 moisture function is judged superior to using number of precipitation events as in RWEQ. Using number of precipitation events would provide no fundamental improvement in RUSLE2's decomposition estimates. Precipitation amount appears to be superior in low precipitation regions in the western

US. Precipitation amounts are much more readily available and spatially stable than number of precipitation events in a given period.

10.3.4.2.2. Comparison with WEPP

The WEPP moisture function is given by (Stott et al., 1995):

$$W_{fwp} = \theta_t / \theta_o \quad [10.9]$$

where: W_{fwp} = the WEPP moisture function used to compute decomposition of surface residue, θ_t = water content (volume of water/volume of bulk soil)[74] of the tilled soil layer and θ_o = the optimum water content (volume water/volume of bulk soil) for decomposition. The WEPP assumption is that the optimum moisture content for decomposition is 0.6 times the soil's pore space (volume pore space/volume of bulk soil). Consequently, the decomposition computed by WEPP should be a function of soil, tillage, and other factors that affect infiltration (e.g., precipitation, soil properties, and cover-management), soil water retention (e.g., soil properties), and soil water extraction (e.g., drainage and evapo-transpiration) (Alberts et al., 1995).

The present WEPP version does not computes the same decomposition amount at Tucson, Arizona as it does in Columba, Missouri, even average annuaj precipitation at Tucson is 12 inches in comparison to 38 inches at Columbia. These WEPP computations were judged tgo be erroneous, thus further computations were not made with WEPP. Changes are anticipated in WEPP to deal with this apparent problem (May 10, 2008).

10.3.4.2.3. Comparison with WEPS

The WEPP moisture function is given by (Hagan et al., 1996):

$$W_{fws} = \theta_s / \theta_f \quad [10.10]$$

where: W_{fws} = the WEPP moisture function used to compute decomposition of surface residue, θ_s = water content (volume of water/volume of bulk soil) of the surface soil layer, which is thinner than the WEPP tilled soil layer, and θ_f = field capacity water content of the surface soil layer (volume water/volume of bulk soil), which is considered to be the optimum water content for decomposition. Soil water content in the surface soil layer is affected by precipitation, infiltration, drainage, and extraction. Consequently, WEPS decomposition should be a function of soil and cover-management.

As illustrated in Figure 10.17, RUSLE2 computed decomposition values compared well with WEPS computed values for locations where temperature rather than moisture was the factor limiting decomposition. However, a difference in trend between the RUSLE2 and WEPS compuated values was apparent at these locations where computed

---

[74] Bulk soil includes the volume of both soil particles and pore space.

decomposition rates were less for WEPS than for RUSLE2 during the maximum precipitation period. WEPS computed decomposition was significantly less than RUSLE2 computed decomposition at Tucson, Arizona. RUSLE2 computed less decomposition during the dry periods at Tucson than did WEPS. WEPS computed much less decomposition than did RUSLE2 at Dallas, Texas. The distinguishing feature at Dallas is a double peaked precipitation pattern. Precipitation (≈ 2.1 inches/month) in July and August is about half the precipitation in April and May (≈ 4.6 inches) and September and October (≈ 3.6 inches/month). In contrast to Tucson where RUSLE2 computed less decomposition than did WEPS, RUSLE2 computed more decomposition at Dallas than did WEPS.

Apparently the WEPS soil moisture values are dampened more than are the RUSLE2daily precipitation values used to compute decomposition, even at locations where precipitation is moderately high and greater such as Columbia, Missouri; Holly Springs and Gulfport, Mississippi; and Mobile, Alabama. This same dampening may be responsible for the differences at Tucson and Dallas.

These differences raise questions about the adequacy of the WEPS computed soil moisture values at all locations, but especially at locations where monthly precipitation changes greatly in a short time, and how well the RUSLE2 moisture function performs in dry regions. The decomposition data illustrated in Figure 10.2 are inadequate to definively make a determination about RUSLE2's moisture function used to compute decomposition or to show whether RUSLE2 or WEPS better computes decomposition.

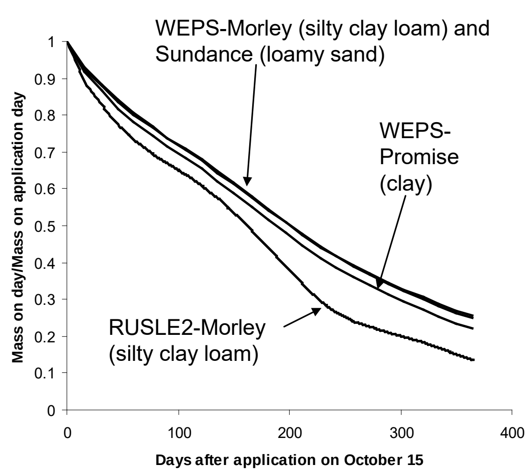

Figure 10.19. Effect of soil texture on WEPS computed decomposition at Dallas, Texas.

Figure 10.19 shows WEPS computed decomposition values for three soil textures at Dallas, Texas. The effect of soil texture on WEPS computed decomposition values are not great. RUSLE2 does not consider soil textue in its decomposition computations.

Figure 10.20 shows the effect of soil disturbance on WEPS computed decomposition. Whether the soil was only moldboard plowed or was moldboard plowed and disked had no effect on WEPS computed decomposition. However, WEPS computed increased decomposition for a soil not disturbed, which is the appropriate direction for computing decomposition for no-till farming practices.

10.3.4.3. Temperature function

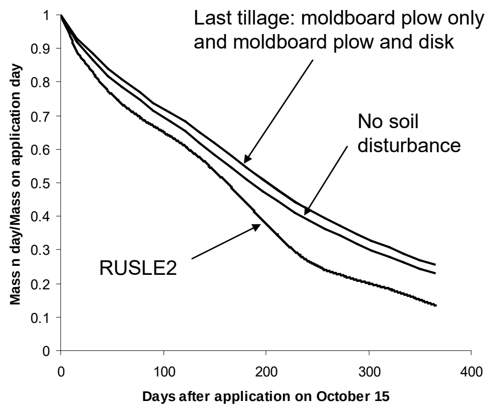

Figure 10.20. Effect of soil disturbance on WEPS computed decomposition

The same basic temperature function, equation 10.6, is used in RUSLE2, WEPP, WEPS, and RWEQ. Both RUSLE2 and WEPP compute a daily temperature function value using average daily temperature computed as the average of the maximum and minimum temperature for the day. RWEQ and WEPS compute a daily temperature function value by computing a temperature function value for both the daily maximum and minimum temperatures and averaging those two temperature function values. RUSLE2 and RWEQ use long term daily and monthly temperature values, respectively, whereas WEPP and WEPS uses stochastically generated daily temperature values.[75]

Each model uses slightly different values for the variables A and optimum temperature T_o in equation 10.6. For example, RWEQ and WEPS use A = 0 ^oC whereas RUSLE2 uses A = - 8 ^oC to compensate for using long-term average daily temperature in RUSLE2. RUSLE2 computes decomposition for a long term average daily temperature as low as -10 ^oC. In WEPP, A = -6.1 ^oC, which compensates for use of daily average temperature in computing a daily temperature function value. The optimum temperature value use in RUSLE2, RWEQ, and WEPS is 32 ^oC while 33 ^oC is used in WEPP.

RUSLE2 and WEPP compute almost identical long term average decomposition for conditions where the temperature function entirely controls rather than the moisture function. Little of the differences between RUSLE2 and WEPS in Figure 10.17 appear to be caused by differences in the temperature functions used to compute decomposition.

The RWEQ/WEPP temperature function approach is superior at high temperatures to the RUSLE2 approach. Flattening the temperature function around the optimum temperature, T_o in equation 10.6 would improve the RUSLE2 temperature function. The best approach would be to replace the RUSLE2 temperature function as described by Schomberg et al. (2002).

The end result is that RUSLE2 computed temperature function values at high temperatures were not a significant factor in fitting the measured decomposition data illustrated in Figure 10.2. In each case, the moisture function was limiting rather than the temperature function when temperatures were high. At low temperatures, the

[75] The RUSLE2 input is long term average monthly that RUSLE2 disaggreagtes into daily temperatures.

temperature function was limiting, where RUSLE2's temperature function is judged adequate.

Schomberg et al. (2002) found no improvement in the fit of RUSLE2 computed decomposition to measured data with their improved temperature function. However, their new temperature function required a decomposition coefficient ϕ value of 0.0048 day^{-1} in comparison to 0.0041 day^{-1} for the temperature function described by equation 10.6. Thus, decomposition coefficient values are moisture and temperature function dependent and model dependent in other ways including how soil moisture is computed for example.

10.3.4.4. Summary comments on RUSLE2 decomposition computations

For RUSLE2, WEPS, WEPP to give comparable long term surface residue cover estimates, decomposition data that best represents field conditions must be identified and used to calibrate all these models.

The RUSLE2 decomposition equations use simple inputs so that RUSLE2 is convenient for use in conservation and erosion control planning. The RUSLE2 purpose is not to accurately model residue decomposition processes in a research context. RUSLE2 users must be aware of RUSLE2 procedures and how to select RUSLE2 inputs to best represent residue for each particular application. Input values described in the RUSE2 User's Reference Guide and in the RUSLE2 Core Database were chosen to ensure that RUSLE2 is adequate for conservation and erosion control planning. RUSLE2 is a complex procedure that involves many mathematical relationships with numerous interactions. Input values must be carefully selected to avoid RUSLE2 computing erroneous erosion values when adjusting RUSLE2 inputs to obtain a desired value for a particular variable such as the portion of the soil surface covered by residue. Avoid changing a single variable such as the decomposition coefficient so that RUSLE2 computes an expected surface residue cover immediately before harvest.

The RUSLE2 decomposition procedures are better than those in RWEQ, a comparable model for wind erosion. Also, RUSLE2 computes decomposition values that are comparable to those computed by WEPS and WEPP, process-based models for wind and water erosion, respectively, when all three models are calibrated to the same data. The soil moisture computations in both WEPS and WEPP should be reveiwed for dry regions and regions when monthly precipitation is double peaked. Decomposition values computed by WEPS do not appear to vary much with soil texture or soil disturbance. Conquently, decomposition computed by RUSELE2 will not differ significantly from the values computed for WEPS when soil and cover-management vary at a location. Advantages of RUSLE2 are that it is robust, uses simple inputs, gives good results, and is easy to use, important attributes for its intended purpose of guiding conservation and erosion control in local field offices.

The RUSLE2 User's Reference Guide describes steps that should be observed in adjusting RUSLE2 input related to values computed for soil surface residue covered.

10.4. Standing residue

10.4.1. Decomposition

Certain operations convert live vegetation to standing residue (see **Section 8**). A portion of the standing residue is assumed to fall each day and become surface residue. Also, standing residue decomposes daily. This decomposition is computed using equations 10.3-10.6 but with a decomposition coefficient ϕ value that is 0.3 of that used to compute surface residue decomposition because reduced moisture is available for decomposition of standing residue.

RUSLE2 computes the decomposition of a unit stem mass assumed to represent decomposition at the base of standing residue stems. This decomposition is computed using equations 10.3 - 10.6 and the same decomposition coefficient ϕ value used to compute surface residue decomposition. That is, decomposition at the stem base is assumed to occur at the same rate as surface residue decomposition.

The portion of the standing residue mass that remains standing over time is assumed to be related to the portion of the remaining unit stem base mass. The RUSLE2 equation for this relationship is:

$$\gamma_t = -2.62\gamma_s^3 + 4.57\gamma_s^2 - 0.95\gamma_s \qquad [10.11]$$

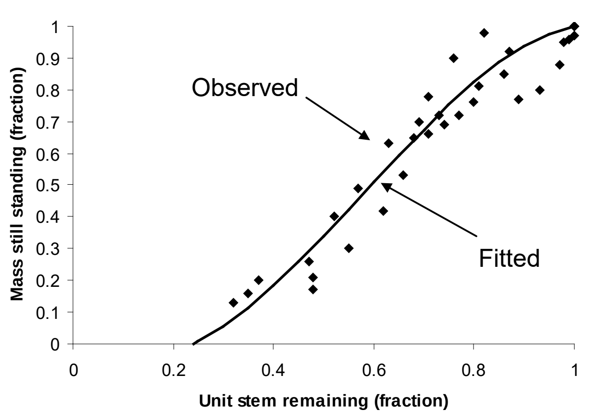

Figure 10.21. Relation of standing residue mass to computed unit stem base mass. (Data source: Steiner et al., 1994)

where: γ_t = portion (fraction) of original standing residue mass that remains and γ_s = portion (fraction) of the original unit stem base mass that remains at any given time. Equation 10.11 was derived by fitting to measured wheat data collected in Texas, Oregon, and North Dakota as illustrated in Figure 10.21 (Steiner et al., 1994). No similar data were found for other vegetation communities. However, equation 10.11 is considered to be adequate for other plant types besides small grain.

10.4.2. Canopy cover-mass relationship

During the live period for a vegetation description, canopy cover is known directly from user input. These canopy cover values are used to estimate temporal values for live above ground biomass (see **Section 9.2.5**).

Once live above ground biomass is transferred to standing residue, the known variable is standing residue mass. This biomass is computed from standing live above ground biomass converted to standing residue on the conversion date, decomposition of standing residue over time, and the amount of the standing residue that has become surface residue computed with equation 10.11.

RUSLE2 computes canopy cover for standing residue using:

$$f_t = \mu B_t^{2/3} \qquad [10.12]$$

where: f_t = canopy cover provided by the standing residue and B_t = daily standing residue biomass (dry mass/area). The value for the coefficient μ is determined from:

$$\mu = f_{to} / B_{to}^{2/3} \qquad [10.13]$$

where: f_{to} and B_{to} = canopy cover and biomass (dry mass/area), respectively, when the standing residue is created from live above ground biomass.

10.4.3. Manning's n, effective vegetation ridge height, and effective fall height for standing residue

Values for the Manning's n and effective ridge height for standing residue are computed using:

$$n_t = n_{to}(B_t / B_{to}) \qquad [10.14]$$

$$H_t = H_{to}(B_t / B_{to}) \qquad [10.15]$$

where: n_t = the daily standing residue Manning's n, n_{to} = the live vegetation Manning's n on the day that the standing residue was created, H_t = daily effective standing residue ridge height (inches), and H_{to} = effective ridge height (inches) of the live vegetation on the day that the standing residue was created. The effective ridge height for standing residue is computed from:

$$h_f = h_{fo}(f_t / f_{to}) \qquad [10.16]$$

where: h_f = the daily effective fall height, h_{fo} = the effective fall height for the vegetation on the day that the standing residue was created, f_t = daily canopy cover, and f_{to} = the canopy cover of the vegetation on the day that the standing residue was created.

Although RUSLE2 uses a single vegetation description on any given day, RUSLE2 tracks multiple standing residue descriptions. RUSLE2 assumes that the overall Manning's n for standing residue and the overall effective ridge height for each standing residue description are the sums of the respective values for each standing residue description. The net effective fall height of the standing residue is weighted by the canopy cover for each standing residue description. These values are independent of corresponding values for live vegetation.

This approach for representing a composite of vegetation and multiple standing residue descriptions should involve interactions similar to those assumed for overlapping ground cover. However, the RUSLE2 procedure is judged to be satisfactory for conservation and erosion control planning. Only a few residue descriptions are used in most cover-management descriptions and most standing residue is removed by tillage or other operations.

10.5. List of symbols

A = a reference temperature in temperature function used to compute decomposition (-8 ^{o}C)

b = coefficient that desribes the effectiveness for a particular residue type for reducing erosion ($percent^{-1}$)

B = mass (dry) in a particular residue/dead root pool (mass/area)

B_s = surface residue dry biomass (mass/area)

B_t = standing residue dry biomass (mass/area)

B_{to} = standing residue dry biomass on day when standing residue is created (mass/area)

c = daily cover-management factor

D = time in period over which decomposition is being computed (days)

D_p = period over which N_p precipitation events occur (days)

$D_{1/2}$ = residue half life (time)

f_g = ground (surface) residue cover (fraction)

f_{gm} = ground (surface) cover for crop residue or mulch assuming no other material is present (fraction)

f_{gn} = net ground (surface) cover provided by total surface residue mass (fraction)

f_{gr} = ground (surface) cover provided by the rock surface residue cover assuming no other surface residue is present (fraction)

f_t = canopy cover provided by the standing residue (fraction)

f_{to} = canopy cover provided by standing residue on day that standing residue is created (fraction)

g_c = daily ground cover subfactor

h_{fi} = effective fall height of standing residue (feet)

h_{fo} = effective fall height for the vegetation on day that the standing residue was created (feet)

H_t = effective standing residue ridge height (inches)

H_{to} = effective ridge height of live vegetation on day that the standing residue was created (inches)

n_t = standing residue Manning's n

n_{to} = live vegetation Manning's n on day that the standing residue was created

I = daily amount of water added by irrigation (inches)

N_p = Number of precipitation events in the period D_p

P = daily precipitation (inches)

P_b = base daily precipitation in moisture function used to compute decomposition (inches)

s_b = daily soil biomass subfactor

T = daily air temperature (^oC)

T_f = daily temperature function used to compute decomposition

T_o = optimum temperature for decomposition (^oC)

W_f = daily moisture function used to compute decomposition in RUSLE2

W_{fwe} = RWEQ moisture function used to compute decomposition

W_{fwp} = WEPP moisture function used to compute decomposition

W_{fws} = WEPS moisture function used to compute decomposition

α = coefficient in equation used to compute surface residue cover for a given residue mass [(mass/area^{-1})]

β = coefficient used to compute residue decomposition (day^{-1})

γ_s = portion of the unit stem base mass (dry basis) that remains

γ_t = portion of standing residue mass (dry basis) that remains

θ_f = field capacity moisture content (volume water/volume bulk soil)

θ_o = optimum soil moisture content for residue decomposition (volume water/volume bulk soil)

θ_s = soil moisture content for the surface soil layer (volume water/volume bulk soil)

θ_t = soil moisture content of the tilled soil layer (volume water/volume bulk soil)

μ = coefficient in equation used to compute canopy cover from standing biomass $(mass/area)^{-2/3}$

ϕ = decomposition coefficient that is a function of biomass type (day^{-1})

ϕ_w = weighted decomposition coefficient for residue description composed of two or more distinct residue types (day^{-1})

Indices

i - day

11. SUMMARY

11.1. RUSLE2 overview

The Revised Universal Soil Loss Equation, Version 2, (RUSLE2) is a tool specifically developed to guide erosion control planning at the local field office. RUSLE2 computes estimates of soil erosion caused by rainfall and its associated overland flow. RUSLE2 computes soil erosion estimates based on site-specific conditions for climate, soil, topography, and land use. Typically, RUSLE2 is used to compute soil erosion estimates for alternative erosion control measures that might be applied at a specific site. The erosion control practices that result in erosion estimates less than the erosion control criteria are considered acceptable. Consequently, erosion control can be tailored to site-specific conditions and requirements by using RUSLE2.

RUSLE2 is land-use independent. It applies to all land conditions where mineral soil is exposed to the erosive forces of raindrop impact and surface runoff produced by Hortonian overland flow. This overland flow occurs when rainfall intensity exceeds the infiltration rate of rainwater into the soil. RUSLE2 applies to cropland; permanent pastureland; construction sites; military training grounds; landfills and similar waste disposal sites; rangelands; disturbed forestlands; right-away along highways, pipelines, and electric transmission lines; and other similar lands.

The basic spatial RUSLE2 computational unit is the overland flow path selected to represent the site. Surface runoff follows this path from its origin to where overland flow becomes collected in a channel. The overland flow path can be divided into segments so that RUSLE2 can capture the effects of soil, steepness, and land use conditions varying along the overland flow path. RUSLE2 computes net erosion or deposition (mass/area) for each segment, sediment load (mass/unit flow width) at the end of each segment and at the end of the overland flow path, and sediment characteristics at the detachment point and in the sediment load at the end of each segment.

RUSLE2 also computes deposition in terrace channels assuming uniform conditions along these channels and deposition in small impoundments used on overland flow areas. RUSLE2 does not compute erosion in concentrated flow areas, referred to as ephemeral gully erosion, that terminate the overland flow path.

The basic temporal RUSLE2 computational unit is the long-term average for each day during the computation period used to represent a site's land-use condition. RUSLE2 management descriptions used to represent land-use conditions can be rotations where land use conditions are repeated in cycles or non-rotations where land-use conditions exist only for a single duration. The rotation cycle duration is the computation period. Rotation-type management descriptions are typically used to represent cropland and similar land uses. Also, rotation-type management practices are used to represent permanent land-use conditions that do not change from year to year.

Non-rotation type management descriptions are used to represent one-time land use conditions, such as reclamation of construction sites and surface mines. The computation period for these examples is from final grading through the number of years required for the site to become stabilized.

RUSLE2 sums long-term average daily erosion values to compute average annual values for the computation period used in the management description, for each year, and other sub-periods within the overall computation period. The average annual erosion value for the overall computation period typically is used in erosion control planning. The RUSLE2 computed average annual erosion for the site is compared to the site's erosion control criteria, which is an allowable average annual erosion rate based on the on-site and off-site damages that soil erosion would cause.

RUSLE2 computes how temporal variability of climate, soil, and land-use conditions affects erosion. Soil erosion is greatest when periods of maximum erosivity coincide with periods when the soil is most susceptible to erosion. Climatic erosivity typically varies greatly during the year. Also, land-use conditions vary during the year, ranging from bare soil after a major mechanical disturbance to dense cover provided by mature vegetation. Even erosion susceptibility of a site in permanent vegetation can vary significantly during the year as above ground and below ground biomass grow and subside. Even if vegetative cover and soil biomass do not vary temporally, soil erodibility varies during the year. Soil erodibility is greatest during periods of high soil moisture.

11.2. RUSLE2 mathematical structure

RUSLE2 is hybrid soil erosion prediction (estimation) technology because it is a combination of the empirical, index-based Universal Soil Loss Equation (USLE) and process-based equations for the detachment, transport, and deposition of soil particles. RUSLE2 computes a long-term average daily sediment production value using the USLE factors for erosivity, soil erodibility, slope length, slope steepness, cover-management, and support practice. Each USLE factor, except the one for slope steepness, is modified in RUSLE2 to compute a daily value rather than the standard USLE average annual value.

The USLE mathematical structure is (Wischmeier and Smith, 1978):

$$A = RKLSCP$$

where: A = average annual erosion (mass/area·year), R = average annual erosivity factor (erosivity units/area·year), K = average annual soil erodibility factor (mass/erosivity unit), L = average annual slope length factor (dimensionless), S = average annual slope steepness factor (dimensionless), C = average annual cover-management factor (dimensionless), and P = average annual support practice factor (dimensionless) . Each USLE factor, except the erosivity factor, has the mathematical structure of:

$$F = \left(\sum_{i=1}^{I} f_i \phi_i \right) \Big/ N$$

where: F = average annual factor, f_i = factor value for the *ith* time period, ϕ_i = the fraction of the annual erosivity that occurs during the *ith* period, I = the number of sub-periods in the computationl period for the management description used to represent a site's land use conditions, N = number of years in the computation period. Thus, the USLE has the mathematical structure of:

$$A = R\left[\left(\sum_{i=1}^{I_k} k_i \phi_i\right)\Big/N_k\right]\left[\left(\sum_{i=1}^{I_l} l_i \phi_i\right)\Big/N_l\right]\left[\left(\sum_{i=1}^{I_s} s_i \phi_i\right)\Big/N_s\right]\left[\left(\sum_{i=1}^{I_c} c_i \phi_i\right)\Big/N_c\right]\left[\left(\sum_{i=1}^{I_p} p_i \phi_i\right)\Big/N_p\right]$$

where: k_i = soil erodibility factor for the *ith* period (mass/erosivity unit), I_k = the number of periods in the N_k years used to determine an average annual soil erodibility factor value, l_i = slope length factor for the *ith* period (dimensionless), I_l = the number of periods in the N_l years used to determine an average annual slope length factor value, s_i = slope steepness factor for the *ith* period (dimensionless), I_s = the number of periods in the N_s years used to determine an average annual slope steepness factor value, c_i = cover-management factor for the *ith* period (dimensionless), I_c = the number of periods in the N_c years used to determine an average annual cover-management factor value, p_i = support practice factor for the *ith* period (dimensionless), and, I_p = the number of periods in the N_p years used to determine an average annual support practice factor value. In practice, the USLE mathematical structure is:

$$A = RKLS\left[\left(\sum_{i=1}^{I_c} c_i \phi_i\right)\Big/N_c\right]P$$

where: temporally constant values for K, L, S, and P are used throughout the computation period.

The basic RUSLE1 mathematical structure is the same as the USLE structure except that a temporal soil erodibility factor is used as (Renard et al., 1997):

$$A = R\left[\left(\sum_{i=1}^{24} k_i \phi_i\right)\Big/24\right]LS\left[\left(\sum_{i=1}^{24N_c} c_i \phi_i\right)\Big/24\,N\right]P$$

where: each year is divided in 24 half month periods and N = years in the overall computation period. Additional sub-periods are added if an operation that disturbs the soil, vegetation, or residue occurs within a half month period.

The RUSLE2 mathematical structure is:

$$A = \left(\sum_{i=1}^{365N} r_i k_i l_i s_i c_i p_i \right) \Big/ N$$

where: r_i = daily erosivity factor (erosivity unit/year), k_i = daily soil erodibility factor (mass/area·erosivity unit), l_i = daily slope length factor (dimensionless), s_i = daily slope steepness factor (dimensionless), c_i = daily cover-management factor (dimensionless), and p_i = daily support practice factor (dimensionless), all long term averages for the *ith* day, and N = number of years in the overall computational period. In practice, a single time-invariant slope steepness S is used instead of a daily s_i slope steepness factor.

The difference in mathematical structure between the USLE, RUSLE1, and RUSLE2 results in the three methods giving different erosion estimates even when each method gives the same average annual values for each USLE factor. Also, RUSLE2 considers much more interdependence between the factors than either the USLE or RUSLE1 considers.

Fundamentally, the USLE applies to a uniform overland flow path where neither soil, steepness, cover-management, nor support practice vary along the flow path. A mathematical procedure is available to apply the USLE to non-uniform overland flow paths where deposition does not occur. The USLE can not be applied to overland flow paths where steepness along the flow path decreases sufficiently to cause deposition.

The same mathematical structure used in process-based erosion prediction technologies to compute deposition along non-uniform overland flow paths is used in RUSLE1 and RUSLE2. Deposition is computed at locations along the flow path where the sediment load exceeds surface runoff's sediment transport capacity. RUSLE2 computes deposition using the equation:

$$D_p = \left(\alpha V_f / q\right)\left(T_c - g\right)$$

where: D_p = deposition rate (mass/area·time), α = an empirically determined deposition coefficient (dimensionless), V_f = the sediment's fall velocity (length/time), q = surface runoff rate (volume/unit overland flow width·time), T_c = surface runoff's sediment transport capacity (mass/unit overflow width·time), and g =sediment load (mass/unit overflow width·time) being transported by surface runoff.

Five sediment classes (primary clay, primary silt, small aggregate, large aggregate, and primary sand) are used in RUSLE2 to represent sediment characteristics. RUSLE2 computes the distribution of the sediment among these classes and the diameters of the aggregate classes at the point of detachment as a function of soil texture. The specific gravity of the aggregate classes is about 65 percent of that for the primary particle classes. RUSLE2 computes how deposition changes sediment characteristics along the overland flow path by applying the deposition equation to each sediment class. RUSLE2 also computes an enrichment ratio based on the specific surface of the sediment load and the specific surface area of the surface soil.

Both the deposition and sediment transport capacity equations are functions of runoff rate. A daily runoff rate index is computed using the NRCS runoff curve number method and the 10 year-24 hour precipitation amount. RUSLE2 computes a daily curve number value as a function of daily cover-management variables.

RUSLE2 computes how soil surface conditions affect runoff's sediment transport capacity. The computation is based on a division of runoff shear stress between that acting on roughness elements, including live vegetation, standing residue, surface residue cover and soil surface roughness, and that acting on the soil grain roughness, which is the part responsible for sediment transport. A daily division of shear stress is computed using daily cover-management variables.

RUSLE2's erosivity and soil erodibility definitions and variables are the same as those used by the USLE, which are based on the unit-plot concept. Also, RUSLE2 can use the standard USLE soil erodibility nomograph to compute soil erodibility factor values for undisturbed soil profiles or a modified nomograph for highly disturbed soil conditions. RUSLE2 computes a daily erodibility factor value that is varied about the base soil erodibility factor values using daily precipitation and temperature values. Daily erosivity is computed as the product of average annual erosivity and the fraction of the annual erosivity that occurs on each day.

The RUSLE2 slope length factor, which is the same as the USLE and RUSLE1 slope length factor, is given by:

$$l_x = (x/\lambda_u)^m$$

where: l_x = slope length factor used to compute erosion at any location x along an overland flow path (dimensionless), λ_u = unit plot length, and m = a slope length factor exponent. Sediment is detached from the soil mass on overland flow area by impacting raindrops (interrill erosion) and surface runoff (rill erosion). Interrill erosion is uniform along a uniform overland flow path, in which case the exponent m = 0. Rill erosion increases along an overland flow path as runoff increases, in which case m = 1. RUSLE2 computes a daily exponent value (between 0 and 1) that depends on the ratio of rill-to-interrill erosion. This ratio is computed as a function of how soil texture, slope steepness, and surface cover affects rill erosion relative to interrill erosion. The rill-to-interrill erosion ratio changes daily as cover-management changes daily.

The RUSLE2 slope steepness factor is the same as the one used in RUSLE1. This factor is time invariant in RUSLE2.

11.3. Land use subfactors

11.3.1. Cover-management subfactors

The use of basic cover-management variables to compute daily cover-management factor and runoff curve number values gives RUSLE2's its land-use independence. Cover-management factor values are computed as the product of several subfactors. These subfactors are canopy, ground (surface) cover, soil surface roughness, soil ridging, soil consolidation, soil biomass, and ponding. An additional soil moisture subfactor is used when RUSLE2 is applied to cropland in certain areas of the northwestern US.

The canopy subfactor describes how above ground canopy (cover that does not touch the soil surface) affects rainfall erosivity. The variables used in this subfactor include fraction of the soil surface covered by canopy and effective fall height of water drops falling from the canopy. RUSLE2 includes equations that estimate effective fall height based on top and bottom canopy heights, canopy shape, and the vertical gradient of canopy mass.

In contrast to canopy cover, ground (surface) cover rests directly on the soil surface. The main component of the equation that computes ground cover subfactor is:

$$c_g = \exp(-bf_g)$$

where: c_g = the subfactor for ground cover. **b** = coefficient for effectiveness of ground cover for reducing erosion (percent^{-1}), and f_g = ground cover (percent). The **b** coefficient, which is a measure of the effectiveness of ground cover for reducing erosion, is a function of the rill-to-interrill erosion ratio. RUSLE2 computed **b** values vary from 0.025 when the erosion is entirely interrill erosion to 0.06 when the erosion is entirely rill erosion. An additional soil surface roughness term is added to this equation in RUSLE2 to account for surface cover having less effect as soil surface roughness increases.

The soil surface roughness subfactor represents how soil surface roughness influences erosion by reducing runoff's erosivity, by causing deposition in local depressions, and by ponding water that protects a portion of the soil surface from direct raindrop impact. Daily soil surface roughness subfactor values are computed as a function of the daily soil surface roughness index. Soil surface roughness decreases daily from the initial soil surface roughness left by a mechanical soil disturbance. RUSLE2 computes the daily decrease in the soil surface roughness index using values for daily precipitation and daily interrill erosion. The soil surface roughness index value left after a mechanical soil disturbance is computed as a function of the soil surface roughness index that exists at the time of the soil disturbance, the soil surface roughness index created by the mechanical soil disturbance applied to a standard soil condition, soil texture, soil biomass, and the degree that the mechanical soil disturbance obliterates existing soil surface roughness.

The soil ridging subfactor represents the effect of ridge side slope on interrill erosion. The soil ridging subfactor is a function of daily ridge height, which is a surrogate for ridge side slope. RUSLE2 decreases daily ridge height from an initial ridge height left by a mechanical soil disturbance as a function of daily precipitation and daily interrill erosion.

The soil consolidation subfactor represents how a bare soil without soil biomass becomes less erodible over time as the soil experiences wetting and drying cycles. Soil consolidation in RUSLE2 refers to the re-bonding of soil particles after a mechanical soil disturbance. The RUSLE2 assumption is that mechanical soil compaction (increase in soil bulk density) does not decrease erosion. RUSLE2 computes soil consolidation subfactor values as a function of the time since the last mechanical soil disturbance. The RUSLE2 time to soil consolidation is seven years but increases to 20 years where average annual precipitation is less than 30 inches.

The soil biomass subfactor represents how soil biomass reduces erosion. RUSLE2 computes daily soil biomass subfactor values as a function of the daily amounts of live roots, dead roots, and buried biomass in the soil and the soil consolidation subfactor. Plant litter, crop residue, manure, and other types of biomass on the soil surface that is incorporated in the soil by mechanical soil disturbance adds to buried soil biomass. Also, injection of manure, sewage sludge, and other organic materials into the soil adds soil biomass. The runoff and erosion reduction computed by the soil biomass subfactor significantly increases as the soil becomes “consolidated” after a mechanical soil disturbance.

The ponding subfactor accounts for how a water layer on the soil surface decreases raindrop impact erosivity in high rainfall regions where land is nearly flat. The variables used to compute ponding subfactor values are land steepness and daily runoff depth, which in turn is a function of the 10 year-24 hour precipitation amount, soil properties, and cover-management.

The antecedent soil moisture subfactor, which is used only on cropland in the northwestern US, accounts for how previous cropping reduces soil moisture that in turn reduces erosion in subsequent cropping periods.

11.3.2. Support practice subfactors

The contouring subfactor computes how contour ridging affects rill erosion and sediment transport by redirecting surface runoff. Contouring subfactor values are computed as a function of daily runoff rate, overland flow path steepness, and ridge-furrow grade

RUSLE2 computes the location along an overland flow path (critical slope length) beyond which contour ridges fail. This computation is a function of the daily runoff rate, daily cover-management conditions, and land steepness.

RUSLE2 computes how profile shape(uniform, convex, concave, and complex) along the overland flow path affects erosion, deposition, and sediment yield from the overland flow path represented in a RUSLE2 computation. RUSLE2 computes the amount of deposition on concave portions of the overland flow path, how this deposition affects sediment characteristics by enriching the sediment in fine and less dense particles.

Strips of dense vegetation placed along overland flow paths can significantly reduce erosion and sediment yield. RUSLE2 computes the reduction in sediment production, the amount of deposition caused by the dense vegetation strips, and the change in sediment characteristics.

Terraces and diversions placed along an overland flow path reduce erosion by decreasing overland flow path length. RUSLE2 also computes deposition and its effect on sediment characteristics in low grade terraces assuming a uniform terrace grade. RUSLE2 does not compute erosion by flow in these channels.

RUSLE2 computes deposition in small impoundments such as small sediment basins used on construction sites and small impoundments created by parallel tile outlet terrace systems. A simple settling-type equation is used to compute deposition by sediment particle class.

The deposition computed by RUSLE2 depends on the characteristics of the sediment reaching the deposition area. Sediment characteristics at the point of detachment are computed as a function of soil texture, but deposition along the overland flow path enriches the sediment in fines and less dense particles that are deposited less readily. Consequently, less deposition is computed in dense grass strips, terrace channels, and in impoundments if upstream deposition has been computed.

RUSLE2 computes how irrigation affects erosion caused by rainfall and its associated overland flow. RUSLE2 takes into account increased yield and increased soil moisture, which increases biomass decomposition and soil erodibility, caused by the irrigation. RUSLE2 does not compute the erosion directly caused by irrigation itself.

The subsurface drainage subfactor represents how subsurface drainage reduces erosion by reducing surface runoff. This subfactor is based on how much subsurface drainage reduces a soil's runoff potential. The runoff potential (permeability) subfactor in RUSLE2's computation of unit-plot soil erodibility is used to adjust the soil erodibility value to account for the subsurface drainage effect.

11.4. Biomass accounting

Biomass on and in the soil has a great effect on soil erosion. The input value for production (yield) level provides the starting point for RUSLE2's biomass accounting. RUSLE2 tracks the conversion of live standing vegetation to dead standing residue by natural and mechanical processes. RUSLE2 accounts for soil surface biomass accumulation from standing residue becoming surface residue caused by standing residue falling by natural processes and mechanical events, by litter fall, and by events that add surface biomass such as straw mulch applications. RUSLE2 estimates the biomass in litter added to the soil surface by senescence based on the decrease in canopy cover.

The RUSLE2 sources of soil biomass are live and dead roots, soil surface biomass that is buried by mechanical soil disturbance, decomposed soil surface biomass that is added to soil, and biomass injected into the soil. RUSLE2 adds the daily decrease in live root biomass to dead root biomass. Live roots decrease annually as a part of the growth cycle of perennial vegetation, and live roots become dead roots when vegetation is killed by a mechanical operation or a natural process such as frost.

RUSLE2 computes the daily decomposition loss of standing residue, surface residue, buried residue, and dead roots as a function of daily precipitation and temperature. The same decomposition coefficient value is used for all plant parts and whether the material is on the soil surface or buried in the soil. However, the decomposition coefficient for standing dead vegetation is assumed to be 30 percent of that for surface and buried material.

RUSLE2 uses a specific set of rules to transfer biomass between standing residue, surface residue, and buried residue pools. For example, live above ground biomass must be converted first to standing residue before live vegetation biomass can become surface residue. Next, standing residue must be converted to soil surface residue. Only surface residue can be buried. That is, standing residue can not be directly buried without first being converted to surface residue. A mechanical soil disturbing operation is required to bury or place residue in the soil, and a mechanical soil disturbing operation is required to resurface previously buried residue.

11.5. Cover-management descriptions

Users provide a cover-management description that RUSLE2 uses to compute how cultural practices affect erosion. A RUSLE2 cover-management description is a list of operations by date, vegetation descriptions and production levels (yields), and residue descriptions and amounts for material added to the soil surface or injected into the soil. A cover-management description is a rotation when the list of operations are repeated in a cycle with a particular duration, which is typical for cropland and permanent vegetation, or a non-rotation when each operation occurs only once over a particular duration, which is typical of construction sites.

11.6. Operation descriptions

Operations are events that affect the soil, vegetation, or residue. The user selects from several processes to describe the effects of an operation. **Begin growth** is the process that tells RUSLE2 to begin using data in a particular vegetation description on a particular date. **Add residue** is used to apply mulch. A residue description that describes the mulch characteristics is assigned in the cover-management description. **Kill vegetation** is the process used to convert live vegetation to standing residue and live roots to dead roots. It is used to describe harvest of an annual crop and to describe frost killing annual vegetation.

The **disturb soil** process describes a mechanical soil disturbance. For example, the operation description for a heavy offset disk includes a **disturb soil** process. The **disturb soil** process includes inputs for burial and resurfacing values for each of the five RUSLE2 residue types, the fraction of the standing residue that is converted to surface residue, the fraction of surface residue that is buried, and the fraction of the buried residue that is resurfaced by the operation. The **disturb soil** process includes a designation for whether the operation buries residue by inverting the soil, by mixing the residue with the soil, by a combination of mixing and inversion, or by pressing the residue into the soil. The **disturb soil** process also includes values for soil disturbance depth, surface roughness left by the operation for a standard condition, and ridge height left by the operation, the degree that the operation obliterates existing soil roughness , and fraction of the soil surface disturbed by the operation.

An operation such as straw baling may include a **remove residue** process to describe reduction in surface residue cover after a small grain harvest, for example.

An operation description can include multiple processes. The sequence of the processes is critically important. For example, having an **add residue** process before a **disturb soil** process gives a very different surface residue cover than if the **add residue** process comes after the **disturb soil** process.

11.7. Vegetation descriptions

Computing the effects of vegetation on erosion is an important RUSLE2 feature. RUSLE2 uses values for vegetation variables including temporal canopy cover, effective fall height, live above ground biomass, and root biomass to compute cover-management subfactor and runoff values. Values for these variables are entered in vegetation descriptions.

RUSLE2 does not model vegetation growth as a function of environmental conditions. Instead RUSLE2 vegetation descriptions apply in particular ecological zones. Each vegetation description is for a particular base production (yield) level. The RUSLE2 user chooses the vegetation description for the site where RUSLE2 is being applied and a appropriate yield for the site is entered in the cover-management description. RUSLE2 adjusts the base vegetation description values according to the input yield value for the site.

11.8. Residue descriptions

A residue description is assigned to each vegetation description to describe the characteristics of residue produced by the vegetation. Also, a residue description is used to describe material added to the soil surface (e.g., straw mulch) and material (e.g., sewage sludge) injected into the soil. The residue description includes a decomposition coefficient value that describes how rapidly the residue decomposes under a standard condition, the fraction of the soil surface covered by a given residue mass, and designation of residue type that denotes the fragility of the residue and how well the residue conforms to the soil surface.

11.9. Climate descriptions

Climate descriptions contain the data on long term average monthly precipitation, temperature, and erosivity values that RUSLE2 uses to compute erosion. Each climate description is for a particular location, county, or rainfall zone.

11.10. Soil descriptions

Soil descriptions contain data on soil properties that RUSLE2 uses to compute erosion and deposition. These properties include soil texture, soil erodibility, runoff potential, rock cover, and time to soil consolidation, all for the reference unit plot condition. RUSLE2 includes soil erodibility nomographs that are used to estimate soil erodibility values from values for basic soil properties.

11.11. RUSLE2 databases

The user runs RUSLE2 by making menu selections from the RUSLE2 database. Each description in the database is stored by an identifier name. In a typical RUSLE2 application, the user selects a climate description by location, soil description by soil mapping unit or some other designator, cultural practice by a cover-management description identifier, and support practices by their identifiers, all appropriate for the site specific conditions. The user enters overland path steepness and length values based on the overland flow path chosen to represent the site.

A wide array of RUSLE2 descriptions, especially for cropland, is available from the USDA-Natural Resources Conservation Service (NRCS). Information can be downloaded and imported into your working RUSLE2 database from the NRCS National RUSLE2 Database and from the database of other RUSLE2 users.

Users can adjust values stored in their working RUSLE2 database to better match site conditions. Also, users can create new database entries. New user chosen values must be consistent with values in the RUSLE2 **Core Database**. RUSLE2 was calibrated using a particular set of **core values**. User input values must be consistent with these **core values** in order to obtain good results with RUSLE2 regardless of how much a user may disagree with the **core values**. If a **core value** were to be changed, other RUSLE2 internal or input values would have to be changed as well, because RUSLE2 has been calibrated to give desired erosion estimates with the **core value**. These core values are contained in the RUSLE2 **Core Database**.

11.12. RUSLE2 validation

The equations for the subfactors were primarily calibrated using data from Agriculture Handbook 537 (Wischmeier and Smith, 1978), which is a summary of more than 10,000 plot-years of data. Additional data from the literature were used to calibrate the equations for conditions not represented by the AH537 data. Erosion values were computed with RUSLE2 for a wide range of conditions, including conditions not represented by existing research data. These values were inspected to ensure that they were consistent with the available research data and consistent with professional judgment.

Ground (surface) cover is perhaps the single most important RUSLE2 variable, at least for cropland conditions. The surface cover left by a cropping system immediately after planting in a key variable used by soil conservationists in judging the effectiveness of a particular cropping system. The adequacy of RUSLE2 for estimating surface cover was very carefully evaluated. An extensive array of literature was reviewed in this evaluation. Scientists have reported differences in RUSLE2 estimates with those made by other comparable erosion models. When RUSLE2 is fitted to the same data used to fit other methods, RUSLE2's estimates of surface cover are almost the same as those estimated by other methods for long term average conditions. The differences were primarily caused by variability in residue data and by differences in techniques used to measure residue mass as it decomposes.

11.13. List of symbols

A = average annual erosion (mass/area·year)

b = coefficient for effectiveness of ground cover for reducing erosion ($percent^{-1}$)

c_g = the subfactor for ground cover (dimensionless)

c_i = cover-management factor for the *ith* period (dimensionless)

C = average annual cover-management factor (dimensionless)

D_p = deposition rate (mass/area·time)

f_g = ground cover (percent)

f_i = factor value for the *ith* time period

F = average annual factor

g =sediment load (mass/unit overflow width·time)

I = the number of sub-periods in the computation period for the management description used to represent a site's land use conditions

I_c = the number of periods in the N_c years used to determine an average annual cover-management factor value

I_k = the number of periods in the N_k years used to determine an average annual soil erodibility factor value

I_l = the number of periods in the N_l years used to determine an average annual slope length factor value

I_p = the number of periods in the N_p years used to determine an average annual support practice factor value

I_s = the number of periods in the N_s years used to determine an average annual slope steepness factor value,

k_i = soil erodibility factor for the *ith* period (mass/erosivity unit)

K = average annual soil erodibility factor (mass/erosivity unit)

l_i = slope length factor for the *ith* period (dimensionless)

l_x = slope length factor used to compute erosion at any location x along an overland flow path (dimensionless)

L = average annual slope length factor (dimensionless)

m = a slope length factor exponent

N = number of years in the computation period

N_c = number of years used to determine an average annual cover-management factor value

N_k = number of years used to determine an average annual soil erodibility factor value

N_l = number of years used to determine an average annual slope length factor value

N_s = number of years used to determine an average annual slope steepness factor value

p_i = support practice factor for the *ith* period (dimensionless)

P = average annual support practice factor (dimensionless)

q = surface runoff rate (volume/unit overland flow width·time)

r_i = erosivity factor for the *ith* period (erosivity unit/area·year)

R = average annual erosivity factor (erosivity unit/area·year)

s_i = slope steepness factor for the *ith* period (dimensionless)

S = average annual slope steepness factor (dimensionless)

T_c = surface runoff's sediment transport capacity (mass/unit overflow width·time)

V_f = the sediment's fall velocity (length/time)

x = distance along overland flow path (length)

α = an empirically determined deposition coefficient (dimensionless)

ϕ_i = the fraction of the annual erosivity that occurs during the *ith* period

λ_u = unit plot length (72.6 ft, 22.1 m)

Indices

i - time period (days)

USER'S REFERENCE GUIDE

Revised Universal Soil Loss Equation
Version 2

(RUSLE2)

Prepared for
USDA-Agricultural Research Service
Washington, D.C.

May 15, 2008

Acknowledgements

RUSLE2 was developed cooperatively by the USDA-Agricultural Research Service (ARS), the USDA-Natural Resources Conservation Service (NRCS), and the Biosystems Engineering and Environmental Science Department of the University of Tennessee. Each project participant maintains a RUSLE2 Internet site directed toward their specific interests. Consult these sites for a list of the employees of these organizations who contributed to the development of RUSLE2. Contributors from several other organizations also participated in the development of RUSLE2.

The USDA-ARS was responsible for providing the erosion science on which RUSLE2 is based including the mathematical equations used in RUSLE2, core data values used to calibrate RUSLE2, scientific documentation, and a user's reference guide for RUSLE2.

The USDA-NRCS was the principal client for RUSLE2. The NRCS provided information to ensure that RUSLE2 could be easily used in their local field (district) offices. The NRCS also developed an extensive RUSLE2 operational (working) database, primarily for cropland. The NRCS has developed RUSLE2 templates and user guides specifically for their purposes.

The interests and needs of a wide variety of other users were considered during RUSLE2's development. RUSLE2 was developed to be land-use independent to give RUSLE2 the wide applicability range possible and to accommodate the needs of these users.

The University of Tennessee participated in the development of the mathematical equations used in RUSLE2, developed the computer science used in RUSLE2, and developed the RUSLE2 computer program. They also developed user guides and other RUSLE2 information for their clients.

This RUSLE2 User's Reference Guide was reviewed by USDA-Natural Resources Conservation Service technical specialists from several disciplines; Kenneth G. Renard (retired), USDA-Agricultural Research Service, Tucson, Arizona, and Seth Dabney, USDA-Agricultural Research Service, Oxford, Mississippi.

Preface

This RUSLE2 User's Reference Guide describes RUSLE2 in detail in semi-technical language. This Guide describes how RUSLE2 works, how to select input values, how to apply RUSLE2 to make erosion estimates for the wide range of conditions represented by RUSLE2, how to interpret values computed by RUSLE2, how to evaluate RUSLE2's adequacy for conservation and erosion control planning, RUSLE2's accuracy, and how to conduct sensitivity analysis with RUSLE2. This Guide also describes similarities and differences between RUSLE2 and the USLE and RUSLE1, widely used predecessor technologies, and how to select input values and make interpretations when comparing erosion values estimated by these technologies.

RUSLE2 is land use independent and applies to all land uses where soil erosion occurs by erosive forces applied to exposed mineral soil by raindrop impact and surface runoff produced by Hortonian overland flow. This User's Reference Guide is targeted to technical specialists, who in turn, can use the information in this Guide to develop application-specific RUSLE2 user guides.

This User Reference Guide provides information on contact agencies that can provide additional information on RUSLE2.

A companion RUSLE2 Science Documentation describes the mathematical procedures used in RUSLE2.

Disclaimer

The purpose of RUSLE2 is to guide and assist erosion-control planning. Erosion-control planners should consider information generated by RUSLE2 to be only one set of information used to make an erosion-control decision. RUSLE2 has been verified and validated, and every reasonable effort has been made to ensure that RUSLE2 works as described in RUSLE2 documentation available from the USDA-Agricultural Research Service. However, RUSLE2 users should be aware that errors may exist in RUSLE2 and exercise due caution in using RUSLE2.

Similarly, this RUSLE2 User's Reference Guide has been reviewed by erosion scientists and RUSLE2 users. These reviewers' comments have been faithfully considered in the revision of this document.

Every reasonable effort has been made to ensure that this document is accurate. The USDA-Agricultural Research Service alone is responsible for this document's accuracy and how faithfully the RUSLE2 computer program represents the information in this document.

Table of Contents

Glossary of Terms 1
1. WELCOME TO RUSLE2 16
2. WHY UPGRADE FROM RUSLE1 TO RUSLE2? 17
3. ABOUT RUSLE2 USER'S GUIDES AND DATABASES 18
3.1. RUSLE2 User Instructions 18
3.2. RUSLE2 Database 18
3.4. RUSLE2 Slide Set 19
3.5. RUSLE2 User Reference Guide 19
3.6. Getting Started 19
3.7. Scientific and Technical Documentation 20
4. CUSTOMER SUPPORT 21
5. ABOUT RUSLE2 22
5.1. Fundamental Definitions 22
5.2. Hillslope Overland Flow Path (Hillslope Profile) as the Base Computational Unit in RUSLE2 22
5.3. Does RUSLE2 Not Apply to Certain Conditions? 27
5.3.1. Rill erosion or concentrated flow erosion? 27
5.3.2. Can RUSLE2 be Used to Estimate Sediment Yield from Large Watersheds? 27
5.3.3. Estimating Soil Loss with RUSLE2 for Large Areas 29
5.4. Equation Structure of RUSLE2 30
5.5. Major Factors Affecting Erosion 33
5.5.1. Climate 33
5.5.2. Soil 34
5.5.3. Topography 34
5.5.4. Land Use 34
5.6. Computing Soil Loss with RUSLE2 35
5.6.1. Computational Database Components 35
5.6.2. RUSLE2 Database Components 36
5.6.3. Templates 37
5.6.4. Access/Permission Files 38
5.6.5. Computer Program Mechanics 38
6. CLIMATE DATABASE COMPONENT 39
6.1. Major Climate Variables 39
6.2. Basic Principles 42
6.2.1. Computing Erosivity for Individual Storms 42
6.2.2. Why New Erosivity Values were Computed from Modern Data 44
6.2.3. Erosivity Density Values 45
6.2.4. Monthly Erosivity Values 47
6.3. Input Values for Monthly Erosivity Density, Precipitation, and Temperature 47
6.3.1. Selecting Climate Input Values for Continental US 47
6.3.2. Climate Input Values Outside of Continental US 48
6.3.3. Erosivity Values for High Elevation, Snow Cover, Snow Melt, and Req Zone 56

6.3.4. Erosivity Values for Irrigation ... 56
6.3.5. Erosivity Values for Subsurface Drainage ... 57
6.4. Disaggregation of Monthly Values into Daily Values ... 57
6.5. Ten Year Storm ... 58
6.5.1. 10 Year-24 Hour Storm ... 58
6.5.2. 10-Year EI Storm ... 59
6.6. Distribution of Erosivity During the Year ... 61
6.7. Varying Soil Erodibility with Climate ... 62
6.8. RUSLE2 Reduces Erosivity for Ponding ... 62
6.9. Req Erosivity Relationships ... 63
6.9.1. Req Definition, Zones, and Values ... 63
6.9.2. Req distribution ... 66
6.9.3. Should Req Zone be Selected? Yes or No? ... 67
6.10. Applying RUSLE2 at High Elevations in Western US ... 68
6.11. Snowmelt Erosivity ... 69
7. SOIL DATABASE COMPONENT ... 70
7.1. Major Soil Variables ... 70
7.2. Basic Principles ... 71
7.3. Selection of Soil Erodibility K Values ... 73
7.3.1 From NRCS soil survey ... 73
7.3.2. Estimating K values with the RUSLE2 soil erodibility nomographs ... 74
7.3.2.1. Background on nomographs. ... 74
7.3.2.2. Nomograph inputs. ... 75
7.3.2.3. Special nomograph considerations. ... 76
7.4. Temporal Variability in K ... 77
7.5. Soil Texture ... 79
7.6. Sediment Characteristics at the Point of Detachment ... 81
7.6.1. RUSLE2 computes sediment characteristics ... 81
7.6.2. User entered values. ... 84
7.7. Rock Cover ... 85
7.8. Hydrologic Soil Group ... 86
7.9. Time to Soil Consolidation ... 87
7.10. Soil Loss Tolerance (T) ... 88
7.10.1. Purpose of "T-value" input ... 88
7.10.2. NRCS-assigned soil loss tolerance values ... 89
7.10.3. Taking hillslope position into account ... 90
8. TOPOGRAPHY ... 93
8.1. Basic Principles ... 93
8.1.1. Detachment ... 93
8.1.2. Runoff ... 96
8.1.3. Sediment transport capacity ... 97
8.1.4. Sediment routing ... 98
8.1.4.1. Case 1: Detachment over the entire segment ... 98
8.1.4.2. Case 2: Deposition over the entire segment ... 99
8.1.4.3. Case 3: Deposition ends within the segment ... 101
8.1.4.4. Case 4: Deposition begins within the segment ... 101

8.1.5. Computing sediment yield, soil loss from eroding portion, total detachment, conservation planning soil loss, and erosion by segment 102
8.1.5.1. Sediment yield 102
8.1.5.2. Soil loss from eroding portion 102
8.1.5.3. Total Detachment.. 103
8.1.5.4. Conservation planning soil loss 103
8.1.5.5. Erosion by segment.. 104
8.1.5.6. General comments 106
8.2. Representing Overland Flow Path Profiles.. 107
8.2.1. General considerations.. 107
8.2.2. Profile shapes 108
8.2.3. Importance of representing non-uniform profile shapes in RUSLE2........... 110
8.2.4. Implications of using uniform profiles to represent non-uniform profiles for conservation and erosion control planning 112
8.2.5. Implications for using RUSLE2 for estimating sediment yield for watersheds 114
8.2.6. Importance of properly representing steepness at end of concave profiles where deposition occurs... 115
8.3. Applying RUSLE2 to particular profile shapes 115
8.3.1. Uniform profile 115
8.3.2. Complex:convex-concave profile 119
8.3.3. Complex:concave-convex profile 120
8.3.4. Overland flow path with porous barriers (e.g., vegetative strips, fabric fences) and flow interceptors (e.g., diversions, terraces) 123
8.3.5. Overland flow path for diversions that intercept runoff above steep slopes 126
8.3.6. Overland flow path for contouring (ridging) 127
8.3.6.1. Overland flow path for ordinary contouring, ridging, and bedding....... 129
8.3.6.2. Overland flow path for a ridge (bed)-furrow description 129
8.3.6.3. Summary comments... 130
8.4. Influence of Upslope Areas on Overland Flow Path 131
9. COVER-MANAGEMENT SUBFACTORS 133
9.1. Basic Principles... 133
9.2. Cover-Management Subfactors 135
9.2.1. Canopy 135
9.2.1.1. Canopy effects 135
9.2.1.2. Canopy cover (f_c) 136
9.2.1.3. Effective fall height (h_f) 137
9.2.1.4. Understory 138
9.2.1.5. Interaction with ground cover... 139
9.2.1.6. Effect of production level (yield)... 139
9.2.1.7. Senescence and other canopy losses... 142
9.2.1.8. Assigning values for canopy 142
9.2.2. Ground Cover.. 143
9.2.2.1. Ground cover effect 143
9.2.2.2. Equation for ground cover subfactor 145
9.2.2.3. How ground cover is added to and removed from the soil surface 147

9.2.2.4. Conversion of residue mass to portion of soil surface that is covered .. 150
9.2.2.5. Spatially non-uniform ground cover 152
9.2.2.6. What to do when RUSLE2 computes a ground cover value that is not the expected value.. 153
9.2.3. Soil (Surface) Roughness.. 156
9.2.3.1. Soil (surface) roughness effect 156
9.2.3.2. Roughness measure.. 157
9.2.3.3. Soil surface roughness subfactor 158
9.2.3.4. Effect of existing roughness (tillage intensity effect)........................... 162
9.2.3.5. How RUSLE2 handles roughness when soil disturbance is in strips 163
9.2.3.6. Assigning roughness values.. 163
9.2.3.7. Roughness decay.. 164
9.2.3.8. Long term roughness... 165
9.2.3.9. Overriding RUSLE2 roughness values 165
9.2.4. Ridges 165
9.2.4.1. Ridge subfactor effect 166
9.2.4.2. Effect of ridge orientation on ridge subfactor...................................... 167
9.2.4.3. Ridge formation and decay 168
9.2.4.4 Assignment of input ridge height values 168
9.2.5. Soil biomass 169
9.2.5.1. Soil biomass effect.. 169
9.2.5.2. Soil biomass subfactor 171
9.2.5.3. How biomass is added to and removed from the soil 173
9.2.5.3.1. Live root biomass.. 173
9.2.5.3.2. Dead root biomass.. 174
9.2.5.3.3. Buried residue 177
9.2.5.4. Redistribution of dead roots and buried residue in soil by soil disturbing operations.. 179
9.2.5.5. Spatial non-uniformity of soil biomass... 181
9.2.5.6. Assigning input values that determine soil biomass............................. 181
9.2.5.7. Comments 182
9.2.6. Soil consolidation 182
9.2.6.1. Soil consolidation effect 183
9.2.6.2. Importance of soil consolidation subfactor to other variables.............. 184
9.2.6.3. Definition of mechanical soil disturbance 185
9.2.6.4. How RUSLE2 handles strips 186
9.2.6.5. Assigning values for portion of soil disturbed..................................... 187
9.2.7. Ponding effect 188
9.2.8. Antecedent soil moisture 188
9.2.8.1. Antecedent soil moisture subfactor effect 189
9.2.8.2. Assigning input values.. 189
10. COVER-MANAGEMENT DATABASE COMPONENT.................................... 190
10.1 Creating a cover-management description 193
10.2. Discussion of variables used in a RUSLE2 cover-management description..... 196
10.2.1. Dates 196
10.2.1.1. Operations as discrete events and representing continuous activity.... 196

10.2.1.2. Representing the year in dates ... 197
10.2.1.3. Tracking time in RUSLE2 ... 197
10.2.1.5. Allowing RUSLE2 to set duration ... 197
10.2.1.6. Initial conditions ... 198
10.2.2. Operations ... 199
10.2.3. Vegetation ... 199
10.2.4. Yield ... 202
10.2.5. Operation depth and speed ... 203
10.2.6. External residue and amount added ... 204
10.2.7. Long term roughness ... 205
10.2.8. Rotation and duration ... 206
10.2.9. Build new rotation with this management ... 208
10.2.10. Relative row grade ... 208
10.2.11. Management alignment offset ... 209
11. VEGETATION DATABASE COMPONENT ... 210
11.1. Variables in a RUSLE2 vegetation description ... 212
11.1.1. Base production (yield) level ... 212
11.1.2. User definition of production (yield) level units ... 213
11.1.3. Live Aboveground biomass at maximum canopy cover ... 214
11.1.3.1. Basic principles ... 214
11.1.3.2. Consistency between inputs for aboveground biomass at maximum canopy cover with processes in operation descriptions ... 219
Example 1. Corn ... 220
Example 2. Harvesting hay and mowing permanent vegetation ... 221
Example 3. Cover crop. ... 224
Example 4. Green beans. ... 225
11.1.3.3. Residue:yield ratio ... 225
11.1.3.4. Selecting input value for aboveground biomass at maximum canopy cover ... 226
11.1.4. Vegetative retardance ... 227
11.1.5. Residue ... 227
11.1.6. Relative moisture depletion ... 229
11.1.7. Growth chart variables ... 229
11.1.7.1. Age ... 230
11.1.7.2. Live root biomass ... 232
11.1.7.3. Canopy cover ... 236
11.1.7.4. Canopy Fall Height ... 238
11.1.7.5. Live ground cover ... 238
11.2. Tools used to develop input values for vegetation descriptions ... 239
11.2.1. Develop growth chart for a new production (yield) level ... 239
11.2.2. Estimate effective fall height based on canopy characteristics ... 240
11.2.3. Live aboveground biomass at maximum canopy as a function of production (yield) level ... 241
11.2.4. Senescence ... 244
11.2.5. Retardance ... 247
11.2.6. Long-term vegetation ... 250

11.2. 6.1. Duration inputs 251
11.2. 6.2. Annual timing inputs 252
11.2.6.3. Biomass inputs 254
12. RESIDUE DATABASE COMPONENT 261
12.1. How residue responds to mechanical soil disturbance (residue type) 261
12.2. Decomposition coefficient (decomposition half life) 264
12.2.1. Soil Moisture 265
12.2.2. Above ground and below ground biomass decomposition 266
12.2.3. Differences in decomposition among plant components 266
12.2.4. Decomposition coefficient values based on stage of growth 269
12.2.5. Decomposition coefficient values for manure 269
12.2.6. Decomposition coefficient for erosion control products used on construction sites 269
12.3. Mass-cover relationship 270
12.4. Non-organic residue 271
12.4.1. Stones (rock fragments, gravel) 271
12.4.2. Non-organic erosion control materials that decay 272
12.5. Selecting input values 273
13. OPERATION DATABASE COMPONENT 275
13.1. Processes Used to Describe Operations 278
13.1.1. No Effect 278
13.1.2. Begin growth 278
13.1.3. Kill vegetation 279
13.1.4. Flatten standing residue 280
13.1.5. Disturb Surface (Soil) 281
13.1.5.1. Tillage type 282
13.1.5.2. Tillage intensity 285
13.1.5.3. Recommended, minimum, and maximum speed and disturbance (tillage) depths 286
13.1.5.4. Ridge height 288
13.1.5.5. Initial roughness 288
13.1.5.6. Final roughness 290
13.1.5.7. Surface area disturbed 292
13.1.5.8. Burial and resurfacing ratios 295
13.1.6. Live biomass removed 298
13.1.7. Remove residue/cover 301
13.1.8. Add other cover 303
13.1.9. Add non-erodible cover 304
13.1.9.1. Applications of add non-erodible cover process 305
13.1.9.2. Variables used to describe add non-erodible process 307
13.1.10. Remove non-erodible cover 308
14. SUPPORT PRACTICES DATABASE COMPONENTS 310
14.1. Contouring (ridge orientation relative to overland flow path) 310
14.1.1. Description of practice 310
14.1.2. Basic principles 311
14.1.2.1. Steepness 312

14.1.2.2. Ridge height 312
14.1.2. 3. Storm severity and runoff 313
14.1.2.4. Relative row grade (ridge-furrow orientation relative to overland flow path) 314
14.1.2.5. Contouring failure (critical slope length) 315
14.1.2.6. Temporal changes in contour factor values and contouring failure..... 318
14.1.2.7. Use of critical slope length information in conservation planning...... 320
14.1.3. Calibration 321
14.1.4. Interpretation of RUSLE2 contouring relationships................................. 323
14.1.5. Contouring inputs 323
14.1.5.1. Method of specifying row grade 324
14.1.5.2. Row grade 325
14.1.5.3. Input ridge heights in relation to contouring 328
14.2. Porous Barriers 329
14.2.1. Description of practices 329
14.2.2. Basic principles 330
14.2.2.1. Description of actual processes.. 330
14.2.2.2. RUSLE2 description 330
14.2.3. Calibration 338
14.2.4. Interpretation 340
14.2.5. Inputs 341
14.2.5.1. Inputs for filter strip/barrier 344
14.2.5.2. Inputs for buffer strips/barriers 347
14.2.5.3. Inputs for rotational strip cropping 349
14.3. Flow Interceptors (diversions/terraces, sediment basins)................................ 352
14.3.1. Description of practices 352
14.3.2. Basic principles 353
14.3.3. Calibration 356
14.3.4. Interpretation 357
14.3.5. Inputs 358
14.3.5.1. Inputs for a hydraulic element (channel/impoundment) system description 359
14.3.5.2. Inputs for a hydraulic element (channel/impoundment) flow path description 360
14.3.5.3. Inputs for the RUSLE2 default channel description 363
14.3.5.4. Inputs for bench terraces 364
14.4. Subsurface Drainage 366
14.4.1. Description of practice 366
14.4.2. Basic principles 366
14.4.3. Calibration/validation 368
14.4.4. Interpretation 369
14.4.5. Input 370
14.5. Irrigation 371
14.5.1. Description of practice 372
14.5.2. Basic principles 372
14.5.3. Calibration 374

14.5.5. Inputs 374
14.5.4. Interpretation.. 375
15. APPLICATION OF RUSLE2 TO PARTICULAR LAND USES 377
15.1. Additional RUSLE2 Related Documents 378
16. CORE DATABASE.. 379
17. EVALUATION OF RUSLE2... 380
17.1. Verification/Validation 380
17.2. Interpretations in the context of conservation and erosion control planning..... 382
17.2.1. Principle 1: Fit main effects.. 382
17.2.2. Principle 2: Don't custom fit to local data or to specific data 384
17.2.3. Principle 3: Follow RUSLE2 definitions, rules, procedures, guidelines, and core database values.. 384
17.2.4. Principle 4: Don't evaluate RUSLE2 based on how well it fits secondary variables 385
17.2.5. Principle 5: Avoid fine tuning parameter and input values 386
17.2.6. Principle 6: Make sufficient temporal and spatial field measurements according to RUSLE2 requirements 386
17.2.7. Principle 7. Avoid too much detail 387
17.2.8. Principle 8. Computing erosion with RUSLE2 for historical events and individual storm events is an advanced application.. 388
17.2.9. Principle 9. Always evaluate the adequacy of the data.............................. 390
17.2.9.1 An ideal dataset.. 390
17.2.9.2. Natural rainfall versus simulated rainfall... 390
17.2.9.3. Measurement area size.. 391
17.2.9.4. Modern data 392
17.2.9.5. Data record length.. 393
17.2.9.6. Dividing the data into development and evaluation parts................... 393
17.2.9.7. Users must make their own judgments 394
17.2.10. Principle 10. Make sure that the inputs are proper 394
17.2.11. Principle 11. Be alert for RUSLE2 users who believe RUSLE2............. 395
17.2.12. Principle 12. RUSLE2 is only in error when it leads to a poor conservation or erosion control plan 395
17.3. Sensitivity analysis 396
17.4. RUSLE2 Accuracy.. 399
17.4.1. Comparison of RUSLE2 erosion estimates with USLE erosion estimates. 399
17.4.1.1. Average annual erosion values for cropland...................................... 399
17.4.1.2. Soil loss values by crop stage for cropland....................................... 403
17.4.1.3. Crop residue cover immediately after planting.................................. 405
17.4.1.4. Erosion values for range, pasture, and similar lands 405
17.4.1.5. Erosion values for construction sites 413
17.4.1.6. Erosion values for disturbed forestland 413
17.4.2. Accuracy of RUSLE2 by statistical measures 413
17.4.3. Qualitative assessments of RUSLE2's accuracy 415
17.4.3.1 Temporal values.. 415
17.4.3.2. Soils 417
17.4.3.3. Topography.. 417

17.4.3.4. Geographic Region ... 418
17.4.3.5. Land Use ... 418
17.4.3.6. Irrigation ... 419
17.5. Relation of RUSLE2 to other USLE/RUSLE erosion prediction technologies. 419
17.5.1. Erosivity ... 420
17.5.2. Soil erodibility ... 421
17.5.3. Topography ... 422
17.5.4. Cover-management ... 423
17.5.5. Support practices ... 425
17.5.5.1. Contouring ... 425
17.5.5.2. Strips/barriers ... 426
17.5.5.3. Diversions/terraces/sediment basins ... 427
17.5.6. Computing erosion ... 428
18. HOW RUSLE2 CAME TO BE ... 430

Glossary of Terms

Term	Description
10 yr EI	Storm EI with a 10-year return period
10 yr-24 hr EI	Storm EI for the 10 yr-24 hr precipitation amount
10 yr-24 hr precipitation	24 hour precipitation amount having a 10-year return period
Antecedent soil moisture subfactor	See cover-management subfactors.
Average annual, monthly, period, and daily erosion	RUSLE2 computes average daily erosion for each day of the year, which represents the average erosion that would be observed if erosion was measured on that day for a sufficiently long period. Average period, monthly, and annual erosion are sums of the average daily values.
Average erosion	Average erosion is the sediment load at a given location on the overland flow path divided by the distance from the origin of overland flow path to the location.
b value, also b_f value	Coefficient in equation for effect of ground cover on erosion; values vary daily with rill-interrill erosion ratio and residue type
Birth of biomass	Refers to the addition of live aboveground and root biomass simultaneous with the death during growth periods when canopy cover and root biomass is increasing
Buffer strips	Dense vegetation strips uniformly spaced along overland flow path; can cause much deposition
Burial ratio	Portion of existing surface (flat) cover mass that is buried by a soil *disturbing* operation; dry mass basis-not area covered basis
Calibration	Procedure of fitting an equation to data to determine numerical values for equation’s coefficients
Canopy cover	Cover above soil surface; does not contact runoff; usually provided by vegetation
Canopy shape	Standard shapes used to assist selection of effective fall height values for waterdrops falling from canopy
Canopy subfactor	See cover-management subfactors.
Channel order	Relative position of a channel in a concentrated flow network
Climate description	Input values for variables used to represent climate (primarily temperature, precipitation, and erosivity density); stored in RUSLE2 climate database component under a location name
Concentrated flow area	Area on landscape where channel flow occurs; ends overland flow path
Conservation planning soil loss	A conservation planning erosion value that gives partial credit to deposition as soil saved; credit is function of location on overland flow path where deposition occurs
Contouring	Support erosion-control practice involving ridges-furrows that

	reduces erosion by redirecting runoff around hillslope
Contouring failure	Contouring effectiveness is lost where runoff shear stress exceeds a critical value
Contouring description	Row grade (steepness) used to describe contouring; stored in RUSLE2 contouring component database under name for contouring practice; ridge height in *operation* description used in cover-*management* description also key input in addition to row grade
Core database	RUSLE2 database that includes values for base conditions used to validate RUSLE2; input values for a new condition must be consistent with values in core database for similar conditions
Cover-*management* description	Values for variables that describe cover-management; includes dates, *operation* descriptions, *vegetation* descriptions, yields (vegetation production level), applied external residue (*residue* description) and amount applied; named and saved in RUSLE2 management component database
Cover-management subfactors (subfactors used in RUSLE2 listed below in italics)	Cover-management subfactor values used to compute detachment (sediment production) by multiplying subfactor values, subfactor values vary through temporally
Canopy	Represents how canopy affects erosion, function of canopy cover and effective fall height
Ground cover	Represents how ground cover affects erosion; primarily function of portion of soil surface covered
Surface roughness	Represents how soil surface roughness and its interaction with soil biomass affect erosion
Soil biomass	Represents how live and dead roots in upper 10 inches of soil and buried residue in upper 3 inches and less of soil affects erosion
Soil consolidation	Represents how a mechanical disturbance and it interaction with soil biomass affect erosion, erosion decreases over time after last disturbance as the soil consolidates (a soil bonding effect that occurs with wetting and drying of the soil-not a mechanical effect)
Ridging	Represents how ridges increase detachment (sediment production)
Ponding	Represents how a water layer on soil surface reduces erosion
Antecedent soil moisture	Represents how previous vegetation affects erosion by reducing soil moisture, used only in Req zone
Critical slope length	Location along a uniform overland flow path where contouring fails
Cultural practice	Erosion control practice, such as no-till cropping, where cover-management is used to reduce erosion
Curve number	An index used in NRCS curve number method to compute runoff; RUSLE2 computes curve number value as function of hydrologic

	soil group and cover-management conditions
Database	RUSLE2 database stores both input and output information in named descriptions
Dead biomass	Represents live above ground and root biomass that has been converted to dead biomass by *kill vegetation* process in an *operation* description; dead biomass decomposes
Dead root biomass	A *kill vegetation* process in an *operation* description converts live root biomass to dead root biomass, dead roots decompose at the same rate as surface and buried residue
Dead standing biomass	Represents live aboveground biomass converted to dead standing biomass by a *kill vegetation* process in an *operation* description; dead standing biomass does not contact soil surface; dead standing biomass decomposes more slowly than surface and subsurface dead biomass
Dead surface biomass	Represents surface biomass that resulted from live aboveground biomass being killed and flattened to become surface biomass, buried residue that has been brought to the soil surface by a soil disturbing process in an operation description, and material that has been applied as external residue; in contact with soil surface
Death of biomass	Refers to the loss of live aboveground and root biomass simultaneous with birth of live biomass during growth periods when canopy cover and root biomass is increasing; daily death of live aboveground biomass adds to surface residue pool and daily death of root biomass adds to dead root biomass pool
Decomposition	Loss of dead biomass as a function of material properties, precipitation, and temperature; decomposition rates for all plant parts and buried and surface biomass are equal; decomposition rate for standing residue is significantly decreased because of no soil contact
Deposition	Transfers sediment from sediment load being transported by runoff to soil surface; net deposition causes sediment load to decrease with distance along overland flow path; depends on sediment characteristics and degree that sediment load exceeds sediment transport capacity; enriches sediment load in fines; computed as a function of sediment particle class fall velocity, runoff rate, and difference between sediment load and transport capacity
Deposition portion	Portion of overland flow path where net deposition occurs
Detachment	Process that separates soil particles from soil mass by raindrops, waterdrops falling from vegetation, and surface runoff; net detachment causes sediment load to increase along overland flow path; detachment is non-selective with respect to sediment characteristics; computed as function of erosivity, soil erodibility, distance along overland flow path, steepness of overland flow path, cover-management condition, and contouring

Disaggregation	Mathematical procedure used to covert monthly precipitation and temperature values to daily values assuming that values vary linearly; daily precipitation values sum to monthly values; average of disaggregated daily temperature equal average monthly value
Diversion/terrace/ sediment basin	A set of support practices that intercept overland flow to end overland flow path length.
Diversions	Intercepts overland flow and directs it around hillslope in channelized flow; grade is sufficiently steep that deposition does not occur but not so steep that erosion occurs in the diversion
EI_{30}	Storm (rainfall) erosivity; product of storm energy and maximum 30-minute intensity; storm energy closely related to rain storm amount and partly to rainfall intensity
Enrichment	Deposition is selective, removing the coarse and dense particles, which leaves the sediment load with an increased portion of fine and less dense particles
Enrichment ratio	Ratio of specific surface area of sediment after deposition to specific surface area of soil subject to erosion
Ephemeral gully erosion	Erosion that occurs in concentrated flow areas
Eroding portion	Portion of overland flow path where net detachment (erosion) occurs
Erosivity	Index of rainfall erosivity at a location; closely related to rainfall amount and intensity; monthly erosivity is average annual sum of individual storm erosivity values in month; annual erosivity is average sum of values in year; storm rainfall amount must be ½ inch (12 mm) or more to be included in computation of erosivity
Erosivity density	Ratio of monthly erosivity to monthly precipitation amount
External residue	Material, usually biomass, added to soil surface or placed in the soil; affects erosion same as surface residue and buried residue from vegetation
Fabric (silt) fence	Porous fabric about 18 inches wide placed against upright posts on the contour; these barriers pond runoff and cause deposition; widely used on construction sites
Fall height (effective)	Effective fall height is the effective height from which waterdrops fall from canopy; depends on canopy shape, canopy density height gradient, and top and bottom canopy heights
Filter strip	A single strip of dense vegetation located at the end of an overland flow path; can induce high amounts of deposition
Final roughness	Soil surface roughness after roughness has decayed to unit plot conditions, primarily represents roughness provided by soil resistant clods
Flattening ratio	Describes how much standing residue that an operation flattens; ratio of standing residue mass before operation to standing residue mass after operation; depends on operation and residue; dry mass

	basis
Flow interceptors	Topographic features (ridges, channel) on an overflow path that collect overland flow and direct the runoff around hillslope; end overland flow path; diversions, terraces, and sediment basins are flow interceptors
Form roughness	Represents the hydraulic roughness provided by soil surface roughness, vegetation, and residue; reduces detachment and sediment transport capacity of runoff
Gradient terraces	Terraces on a uniform grade (steepness)
Grain roughness	Represents the hydraulic roughness provided by the soil; responsible for detachment and sediment transport by flow
Ground cover	Represents the portion of the soil surface covered by material in direct contact with soil; includes plant litter, crop residue, rocks, algae, mulch, and other material that reduces both raindrop impact and runoff (surface flow) erosivity
Ground cover subfactor	See cover-management subfactors
Growth chart	The collection of values that describe the temporal vegetation variables of live root biomass in upper 4 inches (100mm), canopy cover, fall height, and live ground cover; values are in a vegetation description
Hortonian overland flow	Overland flow generated by rainfall intensity being greater than infiltration rate; although flow may be concentrated in micro-channels (rills), runoff is uniformly distributed around hillslope
Hydraulic (roughness) resistance	Degree that ground cover, surface roughness, and vegetation slow runoff; varies daily as cover-management conditions change
Hydraulic element	RUSLE2 hydraulic elements are a channel and a small impoundment
Hydraulic element flow path description	Describes the flow path through a sequence of hydraulic elements, named and saved in RUSLE2 hydraulic element component database
Hydraulic element system description	Describes a set of hydraulic element paths that are uniformly spaced along the overland flow path described without the hydraulic element system being present; named and saved in RUSLE2 hydraulic path component database
Hydrologic soil group	Index of runoff potential of a soil profile at a given geographic location, at a particular position on the landscape, and with the presence or absence of subsurface drainage
Impoundment	A flow interceptor; impounds runoff; results in sediment deposition, represents typical impoundment terraces on cropland and small sediment basins on construction sites
Impoundment parallel terrace	Parallel terraces-impoundments (PTO) where terraces cross concentrated flow areas; impoundment drains through a riser into

	underground pipe
Incorporated biomass	Biomass incorporated (buried) in the soil by a *soil disturbing* operation; also biomass added to the soil from decomposition of surface biomass; amount added by decomposition of surface material is function of soil consolidation subfactor
Inherent organic matter	Soil organic matter content in unit-plot condition
Inherent soil erodibility	Soil erodibility determined by inherent soil properties; measured under unit-plot conditions (see soil erodibility)
Initial conditions	Cover-management conditions at the beginning of a no-rotation cover-management description
Initial input roughness	Soil surface roughness index value assigned to *soil disturbing* operation that occurs on the base condition of a silt loam soil with a large amount of biomass on and in the soil; actual initial roughness value used in computations is a function of soil texture, soil biomass, existing roughness at time of soil disturbance, and tillage intensity
Injected biomass	Biomass placed in the soil using an *add other residue/cover* process in a *soil disturbing* operation description (see *operation* processes); biomass is placed in lower half of disturbance depth
Interrill erosion	Erosion caused by water drop impact; not function of distance along overland flow path unless soil, steepness, and cover-management conditions vary; interrill areas are the spaces between rills where very thin flow occurs
Irrigation	Water artificially added to the soil to enhance seed germination and vegetation production
Land use independent	RUSLE2 applies to all situations where Hortonian overland flow occurs and where raindrop impact and surface runoff cause rill and interrill erosion of exposed mineral soil; the same RUSLE2 equations are used to compute erosion regardless of land use
Live aboveground biomass	Live aboveground biomass (dry matter basis); converted to standing residue (dead biomass) by a *kill vegetation* process in an *operation* description.
Live ground (surface) cover	Parts of live aboveground biomass that touches the soil surface to reduce erosion.
Live root biomass	RUSLE2 distributes input values for live root biomass in upper four inches of soil profile over a constant rooting depth of 10 inches for all vegetation types and growth stages. A *kill vegetation* process in an *operation* description converts live root biomass to dead root biomass. Primarily refers to fine roots that are produced annually; RUSLE2 uses live and dead root biomass in the upper 10 inches of soil profile to compute a value for the soil biomass subfactor
Local deposition	Deposition that occurs very near, within a few inches, from the point of detachment in surface roughness depressions and in

	furrows between ridges; given full credit for soil saved
Long term roughness	Soil surface roughness that naturally develops over time; specified as input in cover-*management* description; depends on vegetation characteristics (e.g., bunch versus sod forming grasses, root pattern near soil surface) and local erosion and deposition, especially by wind erosion; RUSLE2 computes roughness over time; develops fully by time to soil consolidation
Long term vegetation	Permanent vegetation like that on pasture, range, reclaimed mined land, and landfills; vegetation description can include temporal values starting on seeding date through maturity, any arbitrary date after seeding date, or only for the vegetation at maturity
Management alignment offset	Used to sequence cover-*management* descriptions along an overland flow path to create alternating strips
Mass-cover relationship	Equation used to compute portion of soil surface covered by a particular residue mass (dry basis)
Mass-yield relationship	Equation used to compute standing biomass (dry basis) of vegetation as a function of production (yield) level
Maximum 30-minute intensity	Average rainfall intensity over the continuous 30 minutes that contains the greatest amount in a rain storm
Non-erodible cover	Cover such as plastic, standing water, snow, and other material that completely eliminates erosion, material can be porous and disappear over time
Non-uniform overland flow path	Soil, steepness, and/or cover-management vary along an overland flow path; path is divided into segments where selections are made for each segment
NRCS curve number method	Mathematical procedure used in RUSLE2 to compute runoff using precipitation amount; a daily runoff value is computed using the 10 yr-24 hr precipitation amount. Daily runoff amount varies as daily curve number varies based on temporally varying cover-management conditions
NWWR	Northwest Wheat and Range Region; a region in the Northwestern US covering eastern Washington and Oregon, northern Idaho; see Req zone
Operation	An operation changes soil, vegetation, or residue; typically represents common farm and construction activities such as plowing, blading, vehicular or animal traffic, and mowing; also represents burning and natural processes like killing frost and germination of volunteer vegetation
Operation disturbance depth	Surface residue buried by a soil disturbing operation is a function of depth of soil disturbed by operation (operation disturbance depth)
Operation description	Information used to describe an operation; named and stored in the operation component of the RUSLE2 database
Operation processes	Processes used to describe an operation; describes how an operation changes cover-managements and soil conditions that affect erosion,

(processes used in RUSLE2 listed below in italics)	net result of an operation depends on sequence of processes used to describe a particular operation
No effect	Has no effect on computations; commonly used to reference dates in a cover-*management* description and to cause RUSLE2 to display information for a particular set of dates
Begin growth	Tells RUSLE2 when to begin using data from a particular *vegetation* description
Kill vegetation	Converts live aboveground biomass to standing residue and to convert live root biomass to dead root biomass
Flatten standing residue	Converts a portion of the standing residue to surface residue
Disturb (soil) surface	Mechanically disturbs soil (removes consolidation effect for portion of soil surface disturbed); required to bury surface residue; resurfaces buried residue; creates soil surface roughness and ridges; required to inject external residue directly into the soil
Add other cover	Adds external residue to the soil surface and/or places it in the soil
Remove live above ground biomass	Removes a portion of the live aboveground biomass, leaves a portion of the affected biomass as standing and surface (flat) residue
Remove residue/cover	Removes a portion of standing and surface (flat) residue
Add nonerodible cover	Adds nonerodible cover such as plastic, standing water, snow, or other material that allows no erosion for portion of soil surface covered; nonerodible cover disappears over time, cover can be porous; nonerodible cover has no residual effect, not used to represent erosion control blankets and similar material.
Remove nonerodible cover	Removes nonerodible cover, nonerodibile cover has no residual effect
Operation speed	Surface residue buried by a *soil disturbing* operation is a function of operation speed.
Overland flow path	Path taken by overland flow on a smooth soil surface from its point of origin to the concentrated flow area that ends the overland flow path; runoff is perpendicular to hillslope contours
Overland flow path description	Described by steepness values, *soil* descriptions, and cover-*management* descriptions for segments along an overland flow path; a uniform profile (overland flow path) is where steepness, soil, and cover-management do not vary with distance along overland flow path, a convex profile is where steepness increases with distance along the overland flow path; a concave profile is where steepness decreases with distance along the overland flow

	path; a complex profile is a combination of convex, concave, and/or uniform sub-profiles; description involves segment lengths and segment steepness; Soil and cover-management can vary along overland flow paths
Overland flow path length	Distance along the overland flow path from the origin of overland flow to the concentrated flow area (channel) that intercepts runoff to terminate overland flow; does not end where deposition begins (see USLE slope length and steepness)
Overland flow path segments	Overland flow path is divided into segments to represent spatial variability along an overland flow path; conditions are considered uniform within each segment
Overland flow path steepness	Steepness along the overland flow path; not hillslope steepness (see USLE slope steepness)
Permeability index	Index for the runoff potential of the unit-plot soil condition; used in RUSLE2's soil erodibility nomographs; inversely related to hydrologic soil group
Plan description	Collection of RUSLE2 *profile* (overland flow path) descriptions; used to computed weighted averages for a complex area based on the portion of the area that each profile represents; description named and saved in plan component of RUSLE2 database
Ponding subfactor	See cover-management subfactors
Porous barriers	Runoff flows through a porous barrier; does not affect overland flow path length; typically slows runoff to cause deposition; examples are stiff grass hedges, grass filter strips, fabric (silt) fences, gravel dams, and straw bales
Precipitation amount	Includes all forms of precipitation; RUSLE2 disaggregates input monthly values into daily values to compute residue decomposition and temporal soil erodibility
Production (yield) level	A measure of average annual vegetation live aboveground biomass production; user defines yield measure and preferred units on any moisture content basis; input value used to adjust values in a *vegetation* description at a base yield; maximum canopy cover in *base vegetation* description must be less than 100 percent
Profile (overland flow path) description	Information used to describe profile (overland flow path); includes names for location, topography, soil, cover-management, and support practices used to make a particular RUSLE2 computation; *profile* descriptions are named and stored in the profile component of the RUSLE2 database
Profile shape	See overland flow path description
Rainfall (storm) energy	Computed as sum of products of unit energy and rainfall amount in storm intervals where rainfall intensity is assumed uniform; storm energy is closely related to rain storm amount
Rainfall intensity	Rainfall rate express as depth (volume of rainfall/per unit area) per unit time

Relative row grade	Ratio of row grade to average steepness of overland flow path
Remote deposition	Deposition that occurs a significant distance (tens of feet) from the point where the sediment was detached; examples include deposition by dense vegetation strips, terraces, impoundments, and toe of concave overland flow paths; only partial credit is given to remote deposition as soil saved; credit depends on location of deposition along overland flow path; very little credit is given for deposition near end of overland flow path
Req	Equivalent erosivity for the winter months in the Req zone, used to partially represent Req effect
Req effect	Refers to Req equivalent erosivity; erosion per unit rainfall erosivity in the winter period in the Req zone is much greater than in summer period; increased Req winter effect is mainly because of a greatly increased soil erodibility; effect partially results from an elevated soil water content, increased runoff, and soil thawing
Req zone	Region where erosion is elevated in the winter months because of the Req effect, region is primarily in eastern WA and OR, portions of ID, CA, UT, CO, and limited area in other western US states
Residue	Has multiple meanings in RUSLE2; generally refers to dead biomass, such as crop residue, created when vegetation is killed; plant litter from senescence; and applied mulch material such as straw, wood fiber, rock, and erosion control blankets used on construction sites; material is assumed to be biomass that decomposes; also used to represent material like rock that does not decompose by setting a very low decomposition coefficient value
Residue description	Values used to describe residue; named and stored in the residue component of the RUSLE2 database
Residue type	Refers to fragility and geometric residue characteristics; affects residue amount buried and resurfaced by of an operation; affects degree that residue conforms to surface roughness; affects erosion control on very steep slopes
Resurfacing ratio	Portion (dry mass basin) of the buried residue in the soil disturbance depth that a *soil disturbing* operation brings to the soil surface; function of residue and operation's *soil disturbing* properties
Retardance	Degree that vegetation (live aboveground biomass) and standing residue slows runoff; varies with canopy cover; function of production (yield) level; part of vegetation description
Ridge height	Height of ridges created by a *soil disturbing* operation; major variable, along with row grade, that determines contouring effectiveness; decays as a function of precipitation amount and interrill erosion
Ridge subfactor	See cover-management subfactors
Rill erosion	Caused by overland flow runoff; increases with distance along the

	overland flow path
Rill to interrill erosion ratio	Function of slope steepness, rill to interrill soil erodibility, and how cover-management conditions affect rill erosion different from interrill erosion
Rock cover entered in *soil* description	Rock cover entered in the soil description; represents naturally occurring rock on soil surface; operations do not affect this rock cover, rock cover created by an operation that *adds other cover* (rock residue) is treated as external residue; *soil disturbing* operations bury and resurface rock added as external residue
Root biomass	See dead and live root biomass
Root sloughing	Annual decrease in root biomass; RUSLE2 adds the decrease in live root biomass to dead residue biomass pool
Rotation	Refers to whether a list of *operation* descriptions in a cover-*management* description is repeated in a cycle; length of cycle is rotation duration; list of *operation* descriptions are repeated until average annual erosion value stabilizes; eliminates need to specify initial conditions for rotations; operation descriptions in a no-rotation cover-management descriptions are sequentially processed a single time; first operation descriptions in cover-*management* description establish initial conditions in a no-rotation cover-*management* description
Rotation duration	Time (cycle duration) before the list of operation descriptions in a rotation type cover-*management* description repeats; rotation duration is time period over which RUSLE2 makes its computations in a no-rotation cover-*management* description
Rotational strip cropping	A rotation type cover-*management* description that involves periods of dense vegetation that are sequenced along the overland flow path to create strips of alternating dense vegetation that cause deposition
Row grade	Grade along furrows separated by ridges; usually expressed as relative row grade
Runoff	Computed using NRCS curve number method and the 10 yr-24 hour precipitation amount; used to compute contouring effect, contouring failure (critical slope length), and deposition by porous barriers, flow interceptors, and concave overland flow paths
Sediment basin	Small impoundment typical of those used on cropland and construction sites; discharge is usually through a perforated riser that completely drains basin in about 24 hours
Sediment characteristics	Deposition computed as a function of sediment characteristics, which are particle class diameter and density and the distribution of sediment among particle classes
Sediment particle classes	RUSLE2 uses sediment particle classes of primary clay, silt, and sand and small and large aggregate; diameter of aggregate classes and the distribution of sediment among particle classes at point of detachment are computed as function of soil texture; RUSLE2

	computes how deposition changes the distribution of sediment particle classes
Sediment load	Mass of sediment transported by runoff per unit hillslope width
Sediment transport capacity	Runoff's capacity for transporting sediment, depends on runoff rate, overland flow path steepness, and hydraulic roughness; deposition occurs when sediment load is greater than transport capacity
Sediment yield	Sediment load at the end of the flow path represented in a RUSLE2 computation; flow path ends at overland flow path unless hydraulic elements (channel or impoundment) are represented in RUSLE2 computation; sediment yield for site only if RUSLE2 flow path ends at site boundary
Segments	The overland flow path divided into segments to represent spatial variation of steepness, soil, and cover-management
Senescence	Decrease in vegetation canopy cover; senescence adds biomass to surface (flat) residue unless RUSLE2 is instructed that a decrease in canopy cover, such as leaves drooping, does not add to surface residue
Shear stress applied by overland flow	Function of runoff rate and steepness of overland flow path; total runoff shear stress is divided into two parts of shear stress acting on the soil (grain roughness) and shear stress acting on surface residue, surface roughness, live vegetation, and standing residue (form roughness); shear stress acting on the soil is used to compute sediment transport capacity, total shear stress is used to compute contouring failure
Short term roughness	Roughness created by a soil disturbing operation; decays over time as a function of precipitation amount and interrill erosion
Slope length exponent	Exponent in equation used to compute rill-interrill erosion as a function of distance along overland flow path; function of rill to interrill erosion ratio.
Soil biomass subfactor	See cover-management subfactors
Soil consolidation effect	Represents how wetting/drying and other processes cause soil erodibility to decrease over time following a mechanical soil disturbance; increase in soil bulk density (mechanical compaction) not the major cause; affects accumulation of biomass in upper 2 inch (50 mm) soil layer and effect of soil biomass on runoff and erosion
Soil consolidation subfactor	See cover-management subfactors
Soil description	Describes inherent soil properties that affect erosion, runoff, and sediment characteristics at point of detachment; named and saved in soil component of RUSLE2 database
Soil disturbance width	Portion of the soil surface disturbed; weighted effects of disturbance computed as a function of erosion on disturbed and

	undisturbed area used to compute effective values for time since last disturbance, effective surface roughness, and effective ground cover
Soil disturbing operation	*Operation* description that contains *disturb soil* process
Soil erodibility	RUSLE2 considers two soil erodibility effects, one based on inherent soil properties and one based on cover-management; inherent soil erodibility effect represented by K factor value empirically determined from erosion on unit plot; part related to cover-management is represented in cover-management subfactors
Soil erodibility nomograph	Mathematical procedure used to compute a K factor value, i.e., inherent soil erodibility
Soil loss	Proper definition is the sediment yield from a uniform overland flow path divided by the overland flow path length; loosely used as the net removal of sediment from an overland flow path segment
Soil loss from eroding portion	Net removal of sediment from the eroding portion of the overland flow path
Soil loss tolerance (T)	Erosion control criteria; conservation planning objective is that "soil loss" be less than soil loss tolerance T value; special considerations must be given to non-uniform overland flow paths to avoid significantly flawed conservation and erosion control plans
Soil mechanical disturbance	Mechanical soil disturbance resets soil consolidation effects; *disturb soil* process must be included in an operation description to create surface roughness and ridges and to place biomass into the soil
Soil saved	Portion of deposited sediment that is credited as soil saved; computed erosion is reduced by soil saved to determine a conservation planning soil loss value; credit depends on location of deposition along overland flow path
Soil structure	Refers to the arrangement of soil particles in soil mass; used to compute soil erodibility (K) factor values
Soil texture	Refers to the distribution of primary particles of sand, silt, and clay in soil mass subject to erosion
Standing residue	Created when live vegetation is killed; decomposes at a reduced rate; falls over at a rate proportional to decomposition of surface residue
Strip/barrier description	Support practice; describes porous barriers; named and stored in the strip/barrier component of the RUSLE2 database
Subfactor method	See cover-management subfactors
Subsurface drainage description	Support practice that lowers water table to reduce soil water content, runoff, and erosion; RUSLE2 uses difference between hydrologic soil groups for drained and undrained conditions to compute erosion as affected by subsurface drainage
Support practices	Erosion control practice used in addition to cultural erosion control

	practices, hence a support practice; includes contouring, filter and buffer strips, rotational strip cropping, silt (fabric) fences, stiff grass hedges, diversions/terraces, gravel dams, and sediment basins
Surface (flat) residue	Material in direct contact with the soil surface, main source is plant litter, crop residue, and applied mulch (external residue).
Surface roughness	Random roughness; combination of soil peaks and depressions that pond runoff; created by a *soil disturbing* operation, decays as a function of precipitation amount and interrill erosion
Surface roughness index	A measure of soil surface roughness; standard deviation of surface elevations measured on a 1 inch grid about mean elevation; effect of ridges and land steepness removed from measurements
Surface roughness subfactor	See cover-management subfactors
Temperature	Input as average monthly temperature; disaggregated into daily values; used to compute biomass decomposition and temporal soil erodibility
Template	Determines the computer screen configuration of RUSLE2 and inputs and outputs; determines the complexity of field situations that can be described with RUSLE2
Terraces	Flow interceptors (channels) on a sufficiently flat grade to cause significant deposition
Three layer profile schematic	Some RUSLE2 templates include a overland flow path schematic having individual layers to represent cover-management, soil, and topography; used to graphically divide the overland flow path into segments to represent complex conditions
Tillage intensity	Degree that existing soil surface roughness affects roughness left by a *soil disturbing* operation
Tillage type	Identifies the relative position within soil profile where a soil disturbing operation initially places buried residue, also relates to how operation redistributes buried residue and dead roots
Time to soil consolidation	Time required for 95 percent of the soil consolidation effect to be regained after a soil disturbing operation
Topography	Refers to steepness along the overland flow path and the length of the overland flow path
Uniform slope	Refers to an overland flow path where soil, steepness, and cover-management do not vary along the overland flow path
Unit rainfall energy	Energy content of rainfall per unit of rainfall; function of rainfall intensity
Unit plot	Base condition used to determine soil erodibility; reference for effects of overland flow path steepness and length; cover-management, and support practices; continuous tilled fallow (no vegetation; tilled up and downhill, maintained in seedbed conditions; topographic, cover-management, support practice factor values equal 1 for unit plot condition; land use independent, i.e.,

	applies to all land uses including undisturbed land such as pasture, range, and forest lands
USLE slope length and steepness	Distance from origin of overland flow to a concentrated flow area (e.g., terrace or natural waterway) or to the location where deposition occurs; USLE soil loss is sediment yield from this length divided by length (mass/area); USLE steepness is steepness of the slope length; uniform actual overland flow path is often represented with uniform steepness
Validation	Process of ensuring that RUSLE2 serves its intended purpose as a guide to conservation and erosion control planning.
Vegetation description	Information used by RUSLE2 to represent the effect of vegetation on erosion; includes temporal values in growth chart, retardance, and biomass-yield information; named and stored in vegetation component of RUSLE2 database
Verification	Process of ensuring RUSLE2 correctly solves the mathematical procedures in RUSLE2
Worksheet description	Form in RUSLE2 program; used to compare conservation and erosion control practices for a given site; used to compare *profile* descriptions; named and saved in the worksheet component of the RUSLE2 database

1. WELCOME TO RUSLE2

Version 2 of the Revised Universal Soil Loss Equation (**RUSLE2**) estimates soil loss, sediment yield, and sediment characteristics from rill and interrill (sheet and rill) erosion caused by rainfall and its associated overland flow. **RUSLE2** uses factors that represent the effects of climate (erosivity, precipitation, and temperature), soil erodibility, topography, cover-management, and support practices to compute erosion. RUSLE2 is a mathematical model that uses a system of equations implemented in a computer program to estimate erosion rates. The other major component of RUSLE2 is a database containing an extensive array of values that are used by the RUSLE2 user to describe a site-specific condition so RUSLE2 can compute erosion values that directly reflect conditions at a particular site.

RUSLE2 is used to evaluate potential erosion rates at specific sites, guide conservation and erosion control planning, inventory erosion rates over large geographic areas, and estimate sediment production on upland areas that might become sediment yield in watersheds. **RUSLE2 is land use independent. It can be used on cropland, pastureland, rangeland, disturbed forestland, construction sites, mined land, reclaimed land, landfills, military lands, and other areas where mineral soil is exposed to raindrop impact and surface overland flow produced by rainfall intensity exceeding infiltration rate (i.e., Hortonian overland flow)**.

The RUSLE2 computer program, a sample database, user instructions, a slide set that provides an overview of RUSLE2, and other supporting information are available for download from the USDA-Agricultural Research Service (ARS) Official RUSLE2 Internet Site at http://www.ars.usda.gov/Research/docs.htm?docid=6010. The University of Tennessee also maintains a RUSLE2 Internet site where older versions of the RUSLE2 can be downloaded and where additional RUSLE2 information is available. The address is www.rusle2.org. The USDA-Natural Resources Conservation Service (NRCS) also provides and distributes information on RUSLE2 including databases and other materials that it uses to apply RUSLE2 in each of its county level offices across the US. Contact the NRCS Internet site at http://fargo.nserl.purdue.edu/rusle2_dataweb/RUSLE2_Index.htm or contact the NRCS state agronomist in your state to obtain NRCS information on RUSLE2. The NRCS Internet site contains an extensive RUSLE2 database that must be used in NRCS-related applications involving RUSLE2. Information in this database can also be downloaded for other RUSLE2 applications as well. Other organizations that use RUSLE2 may also have RUSLE2 Internet sites that contain databases for their specific RUSLE2 applications.

2. WHY UPGRADE FROM RUSLE1 TO RUSLE2?

RUSLE2 is a second generation of RUSLE1, but it is not simply an enhancement of RUSLE1. **RUSLE2** is a new model with new features and capabilities. If you are using any version of RUSLE1, you should upgrade to **RUSLE2.** **RUSLE2** uses a modern, powerful graphical user interface instead of the text-based interface of RUSLE1. ***RUSLE2** can be used in either US customary units or SI units.* **RUSLE2** can globally switch between the two systems of units or the units on individual variables can be changed to one of several units. Those who work with metric units will find **RUSLE2** much easier to use than RUSLE1. **RUSLE2** can also manipulate attributes of variables, which includes graphing, changing units, and setting number of significant digits. **RUSLE2** is much more powerful than RUSLE1, has improved computational procedures, and provides much more output useful for conservation planning than does RUSLE1.

Even though **RUSLE2** appears quite different on the computer screen from RUSLE1, it has many similarities with RUSLE1. The general approach is the same and many of the values in the database are the same for **RUSLE2** and RUSLE1. Thus, conversion from RUSLE1 to **RUSLE2** should be relatively easy.

3. ABOUT RUSLE2 USER'S GUIDES AND DATABASES

3.1. RUSLE2 User Instructions

RUSLE2 is a straight forward, easily used computer program that is best learned by using it. A set of user instructions is available on the **USDA-Agricultural Research Service (ARS)** RUSLE2 Internet site http://www.ars.usda.gov/Research/docs.htm?docid=6010 to help you get started with RUSLE2. A self-guided tutorial is available on the **University of Tennessee** http://bioengr.ag.utk.edu/rusle2/tutorial.htm to help you learn the mechanics and operation of the **RUSLE2** computer program. The **USDA-Natural Resources Conservation Service (NRCS)** Internet site http://fargo.nserl.purdue.edu/rusle2_dataweb/RUSLE2_Index.htm provides instructional material and database information that helpful for any RUSLE2 user, but is required for NRCS-related **RUSLE2** applications. Also, other organizations provide training and instructional materials targeted to a specific land use such as construction sites that you can also use to learn RUSLE2.

3.2. RUSLE2 Database

The **RUSLE2** download on the USDA-ARS RUSLE2 Internet site includes a sample database. This sample database should only be used to help you become acquainted with **RUSLE2** and how it works. This database is not intended for use in actual **RUSLE2** applications. You can obtain that database information by downloading from the USDA-Natural Resources Conservation Service (NRCS) national **RUSLE2** database or from another database having values that have been properly established for your purpose. You can download information from the NRCS national **RUSLE2** database by contacting the Internet site http://fargo.nserl.purdue.edu/rusle2_dataweb/RUSLE2_Index.htm. Additional information can be obtained by contacting the State Agronomist in each NRCS State Office.

Values in your **RUSLE2** operational database must be based on the **RUSLE2 core database** (see **Section 16**). Values in your operational database must be consistent with those in the core database to ensure that **RUSLE2** give expected results and to ensure consistency in **RUSLE2** applications among clients, locations, and other situations where similar erosion estimates are expected. This consistency is very important when **RUSLE2** is used by a national agency where adequacy of the erosion prediction technology is partly judged on consistency of estimates. The NRCS national **RUSLE2** database has been extensively reviewed to ensure consistency, minimal error, and expected erosion values computed with **RUSLE2**. Make sure that the same quality control has been used in the preparation of other **RUSLE2** databases that you might use for the source of data in your **RUSLE2** operational database.

Some values in the RUSLE1 database can be used in **RUSLE2** and directly transferred to the **RUSLE2** database using procedures included in **RUSLE2.** However, the best approach is download values from a quality-controlled **RUSLE2** database, such as the NRCS national **RUSLE2** database, rather than transfer values from a RUSLE1 database. Values for several input variables are different in **RUSLE2** from those in RUSLE1. Also, new input variables have been added to **RUSLE2** that are not in RUSLE1. Furthermore, core values, including those for rainfall erosivity, in the **RUSLE2** database have updated based on new analysis.

3.3. RUSLE2 HELP

The **RUSLE2** computer program contains an extensive set of **HELP** information. Most of the **HELP** information is arranged by variable within **RUSLE2**. Information on a particular variable can be obtained at the location within **RUSLE2** where the variable occurs.

3.4. RUSLE2 Slide Set

A **slide set** is available with the **RUSLE2** download at the ARS RUSLE2 Internet site. This **slide set** provides an extensive overview of **RUSLE2**. The speaker notes that accompany many of the slides provide additional background. Also, slides can be used for **RUSLE2** training and for making presentations on **RUSLE2**.

3.5. RUSLE2 User Reference Guide

This **User's Reference Guide** describes **RUSLE2**, its factors, selection of input values, and application of **RUSLE2**. The **Table of Contents** lists the topics covered by the **User's Guide.** Rather than reading the entire **User's Guide**, specific topics can be selected from the **Table of Contents** and individually reviewed. Also, the **Glossary of Terms** provides information on specific topics.

This **User's Reference Guide** is intended to serve as a **reference** for RUSLE2 technical specialists rather than a guide for the routine RUSLE2 user. User guides and manuals for these users should be developed for specific applications based on information in this **Guide**.

3.6. Getting Started

Like all other hydrologic models, **RUSLE2** requires a proper approach for selecting input values, running the model, and interpreting its output values. **RUSLE2** has particular limitations that must be considered. Before applying **RUSLE2,** you should become well acquainted with **RUSLE2** and its factors by reviewing the **RUSLE2 Slide Set**. After installing **RUSLE2**, run the sample database that can be downloaded with **RUSLE2** that includes several example overland flow path profiles. Change selected variables including location, soil, overland flow path length and steepness, and cover-management and support practices in these examples to help learn the mechanics of the **RUSLE2** computer program and to help learn how main inputs affect computed erosion and other output variables. Start out with the uniform slope templates rather than the complex slope templates.

3.7. Scientific and Technical Documentation

The **RUSLE2** Scientific Documentation describes the equations and mathematical procedures used in RUSLE2. It is available from the USDA-Agricultural Research Service
http://www.ars.usda.gov/SP2UserFiles/Place/64080530/RUSLE/RUSLE2_Science_Doc.pdf.

4. CUSTOMER SUPPORT

If needed information is not available in **RUSLE2** documentation, contact one of the **RUSLE2** experts. The USDA-Agricultural Research Service (ARS) is the lead research agency, in cooperation with the University of Tennessee, that developed **RUSLE2**. The USDA-Natural Resources Conservation Service (NRCS), the major user of **RUSLE2,** has much experience in RUSLE2 applications and developed extensive database information for many different types of applications of **RUSLE2** across the US and other locations. Contact your NRCS State Agronomist to obtain additional databases, information, and direct assistance on **RUSLE2** applications.

5. ABOUT RUSLE2

5.1. Fundamental Definitions

RUSLE2 uses several important terms to describe erosion (see **Glossary of Terms**). In the mid-1940's, W. D. Ellison defined erosion as, "... a process of detachment and transport of soil particles."[1] **Detachment** is the separation of soil particles from the soil mass and is expressed in units of mass/area. Soil particles separated from the soil mass are referred to as **sediment**. Sediment movement downslope is sediment transport, described as **sediment load** expressed in units of mass/width of slope. The sediment load at the end of the **RUSLE2** hillslope profile is defined as sediment yield or sediment delivery. **Deposition**, expressed as mass/area, is the accumulation of sediment on the soil surface.

Detachment transfers sediment from the soil mass to the sediment load so that sediment load increases along the hillslope where detachment occurs. Conversely, deposition transfers sediment from the sediment load to the soil mass with a corresponding accumulation of sediment on the soil surface. Deposition is a selective process that **sorts** sediment. This process **enriches** the sediment load in fines in comparison to the soil where detachment originally produced the sediment.

RUSLE2 considers two types of deposition, local and remote. **Local deposition** is sediment deposited very near, within a few inches of where it was detached. Deposition in micro-depressions (**surface roughness**) and in low gradient furrows is an example of local deposition. The difference between local detachment and local deposition is called **net detachment** (or **net deposition**). **Remote deposition** is sediment deposited some distance, 10's of feet (several meters) from the origin of the sediment. Deposition on the toe of a concave slope, at the upper side of vegetative strips, and in terrace channels is an example of remote deposition. **Full credit for soil saved** is taken in **RUSLE2** for local deposition. Only **partial credit** that depends on the location of the deposition is given to remote deposition for soil saved. Sediment deposited at the end of an overland flow path is given very little credit as soil saved.

5.2. Hillslope Overland Flow Path (Hillslope Profile) as the Base Computational Unit in RUSLE2

The base **RUSLE2** computational unit is a single overland flow path along a hillslope profile as illustrated in Figure 5.1. An **overland flow path** is defined as the path that runoff flows from the origin of overland flow to where it enters a major flow concentration. **Major flow concentrations** are locations on the landscape where sides of a hillslope intersect to collect overland flow in defined channels. **Ephemeral or**

[1] Ellison, W.D. 1947. Soil erosion studies. Agricultural Engineering. 28:145-146.

classical gully erosion occurs in these channels. These defined channels are distinguished from **rills** in two ways. Rills tend to be parallel and are sufficiently shallow that they can be obliterated by typical farm tillage and grading operations as a part of construction activities. When the rills are reformed, they occur in new locations determined by **microtopograpy** left by soil disturbing operations like tillage. In contrast, concentrated flow areas occur in the same locations, even after these channels are filled by tillage. Location of these channels is determined by **macrotopography** of the landscape.

An infinite number of overland flow paths exist on any landscape. A particular overland flow path (**hillslope profile**), such as the one labeled **A** in Figure 5.1, is chosen for the one on which the conservation plan is to be based. The overland flow path (profile) that represents the 1/4 to 1/3 most erodible part of the area is often the profile selected for

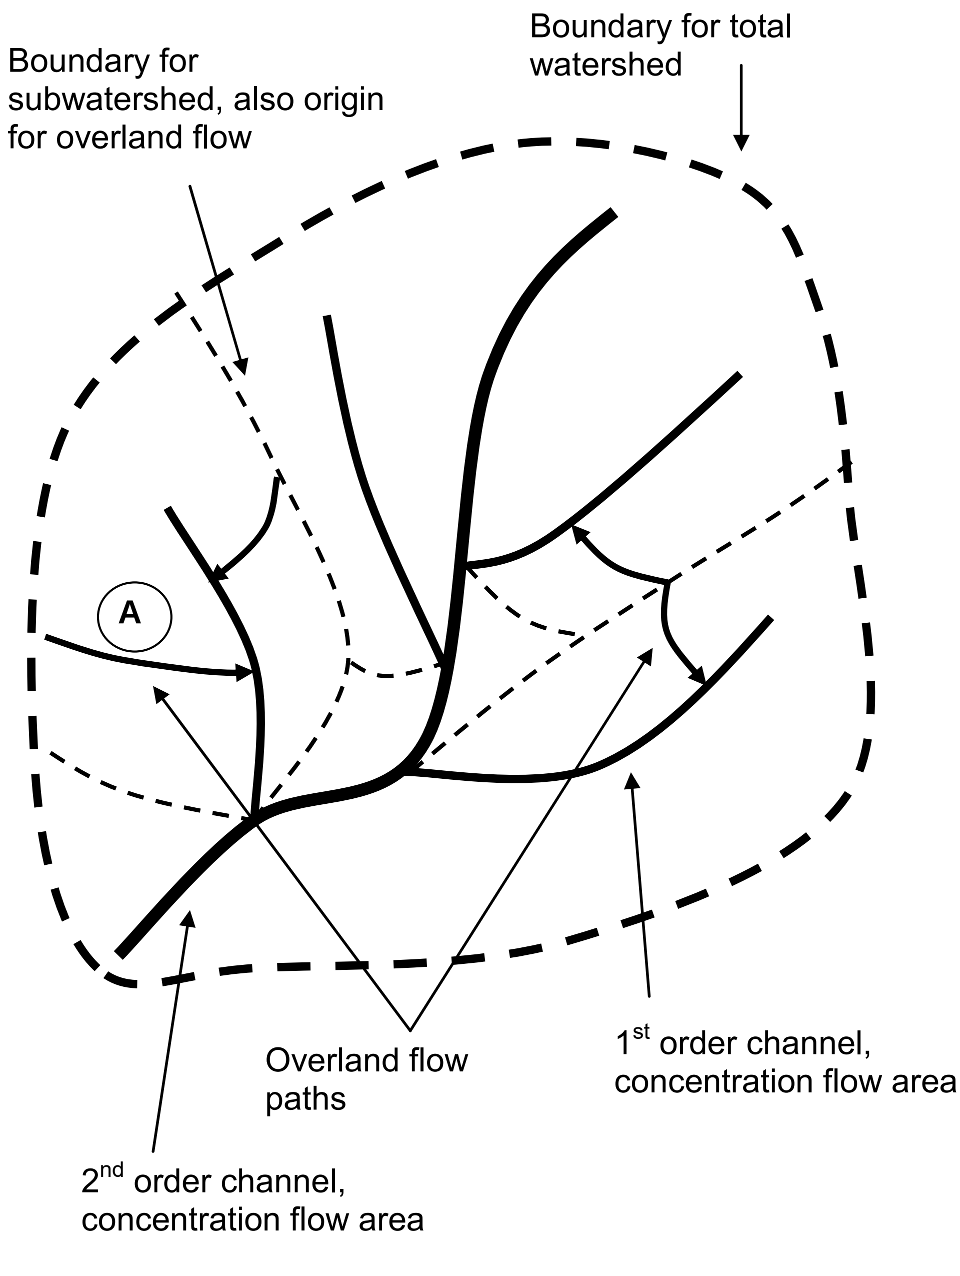

Figure. 5.1. Overland flow paths in a typical application of RUSLE2

applying RUSLE2 when the **conservation planning** objective is to protect the soil resource from degradation by excessive erosion. **RUSLE2** is used to estimate erosion for this profile for each of several alternative land use practices that might be used at the site. Those practices that give a RUSLE2 estimated soil loss that meets the **conservation planning** criteria are considered to provide acceptable erosion control. Organizations such as the NRCS have specific guidelines on how **RUSLE2** is to be used in their programs.

The first step in describing the selected profile is to identify a base point on the hillslope through which the overland flow path is passes. The overland flow path through that point, such as profile **A** in Figure 5.1, is described by dividing the slope into segments and specifying distance and steepness for each segment. The overland path is traced from the origin of overland flow through the base point to where the overland flow is terminated by a concentrated flow channel as illustrated in Figure 5.1.

Figure 5.2 shows the shape of a typical overland flow path on a common natural landscape. This **complex** hillslope profile has an upper **convex** section and a **concave** lower section. This profile has two important parts. The upper part is the **eroding portion** where **net erosion** occurs, and the lower part is the **depositional portion** where **net deposition** occurs. The average erosion rate on the eroding portion of the hillslope is defined as **soil loss** (mass/area). Soil loss on the eroding portion of the landscape degrades the soil on that portion of the landscape and the landscape itself. A typical conservation planning objective is to reduce soil loss to a rate less than **soil loss tolerance (T)** or another quantitative planning criterion. Keeping soil loss to less than T protects the soil so that its productive capacity is maintained and the landscape as a whole is protected from excessive erosion.

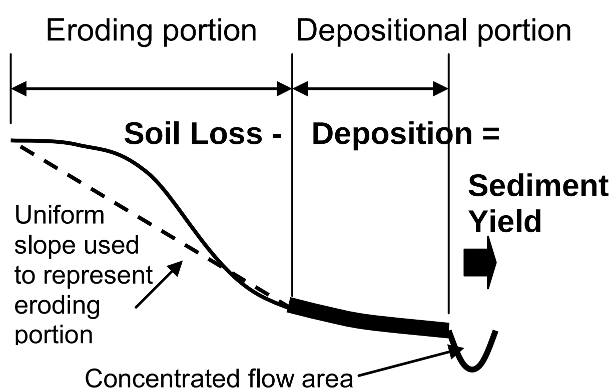

Figure 5.2. Complex hillslope, convex-concave profile

Sediment yield from the hillslope profile and the site is also an important conservation planning consideration. Excessive sediment leaving a site can cause downstream sedimentation and water quality problems. Sediment yield is less than soil loss by the amount of deposition. The sediment yield computed by **RUSLE2** is the sediment leaving the overland flow path represented in **RUSLE2**. This sediment yield will be the sediment yield for the site only if the **RUSLE2** flow path ends at the boundary of the site.

Many conservation-planning applications involve only the eroding portion of the hillslope, which can be approximated by a **uniform slope** as illustrated in Figure 5.2. The **slope length (overland flow path length)** in this application is the distance from the origin of overland flow to where deposition begins, which is the traditional definition of **slope length** in the USLE and RUSLE1. However, soil loss estimated using a uniform slope of the same average steepness and slope length as a non-uniform shaped profile will differ from the average erosion rate for the non-uniform profile, sometimes by as much as 15%. The difference is especially important on convex shaped hillslopes where the erosion rate near the end of the overland flow path can be much larger than the erosion rate at the end of a uniform profile. Deposition like that in Figure 5.2 for concave hillslope sections does not occur on the **uniform** and **convex** shaped hillslopes illustrated in Figure 5.3. Sediment yield equals soil loss on those profiles.

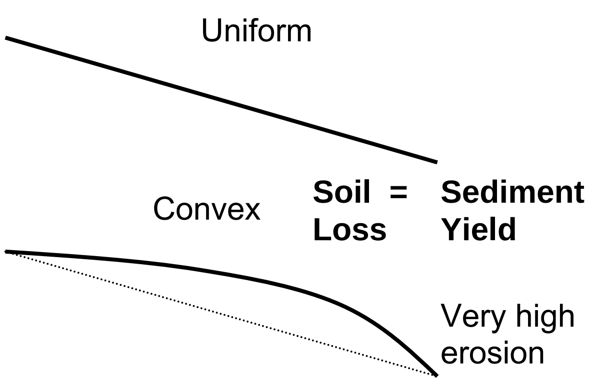

Figure 5.3. Sediment yield equals soil loss on uniform and convex slopes

Another important **complex** hillslope shape is shown in Figure 5.4 where a **concave** section occurs in the middle of the hillslope. A field example is a cut slope-road-fill slope that is common in hilly terrain being logged. **Deposition** can occur on the mid-section of the hillslope where the roadway is located if steepness of the roadway is sufficiently flat. Soil loss occurs on the cut slope and downslope on the fill slope in situations where overland flow from the cut slope continues across the roadway onto the fill slope. Although the steepness and length of the fill slope is the same as that for the upper cut slope, erosion rate is much greater on the fill slope than on the cut slope because of increased overland flow. Although the USLE and RUSLE1 cannot easily describe this hillslope, **RUSLE2** easily determines appropriate **overland flow path lengths**, and computes **erosion** on the two **eroding portions** of the overland flow path, **deposition** on the **depositional portion** of the overland flow path, and **sediment yield** from the overland flow path. Note that the **overland flow path** used in RUSLE2 does not end where deposition begins for this overland flow path.

In addition to computing how slope shape affects erosion, RUSLE2 can also compute how variations in soil and management along a hillslope profile affect erosion.

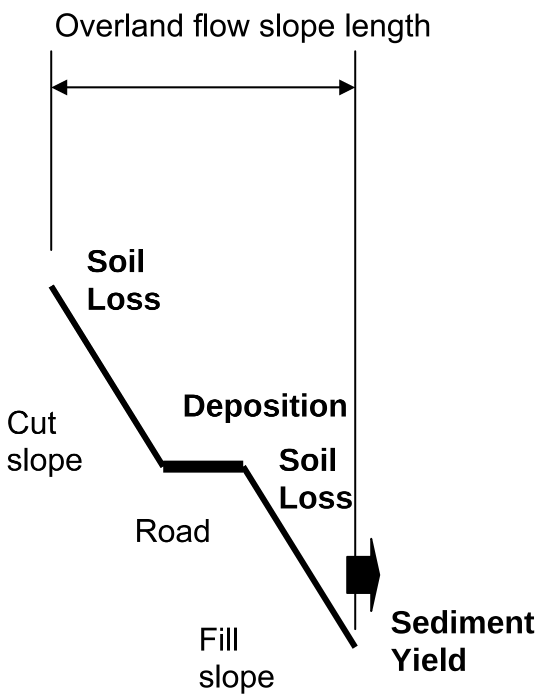

Figure 5.4. Soil loss, deposition, and sediment yield from a complex slope, concave-convex shape.

5.3. Does RUSLE2 Not Apply to Certain Conditions?

5.3.1. Rill erosion or concentrated flow erosion?

RUSLE2 does not apply to concentrated flow areas where ephemeral gully erosion occurs. **Whether or not RUSLE2 applies to particular eroded channels is not determined by size or depth of the channels.** The determination depends on whether the channels in the field situation would be included if RUSLE2 plots were to be placed on that landscape. The core part of **RUSLE2** that computes **net detachment** (**sediment production**) is empirically derived from data collected from plots like those illustrated in Figures 5.5 and 5.6. The length of these plots typically was about 75 ft (25 m) and width ranged from 6 ft (2 m) to about 40 ft (13 m) wide with plots as wide as 150 ft (50 m) at one location. These plots were always placed on the sides of the hillslope where overland flow occurred, not in the swales where concentrated flow occurs. Thus, RUSLE2 can estimate soil loss for rills 15 inches (375 mm) deep on sides of hillslopes because these rill would be in plots placed on this part of the landscape but not erosion from a 4 inch (100 mm) deep ephemeral gully or 10 ft (3 m) deep classical gully in a concentrated flow area because plots were not be placed in these locations.

5.3.2. Can RUSLE2 be Used to Estimate Sediment Yield from Large Watersheds?

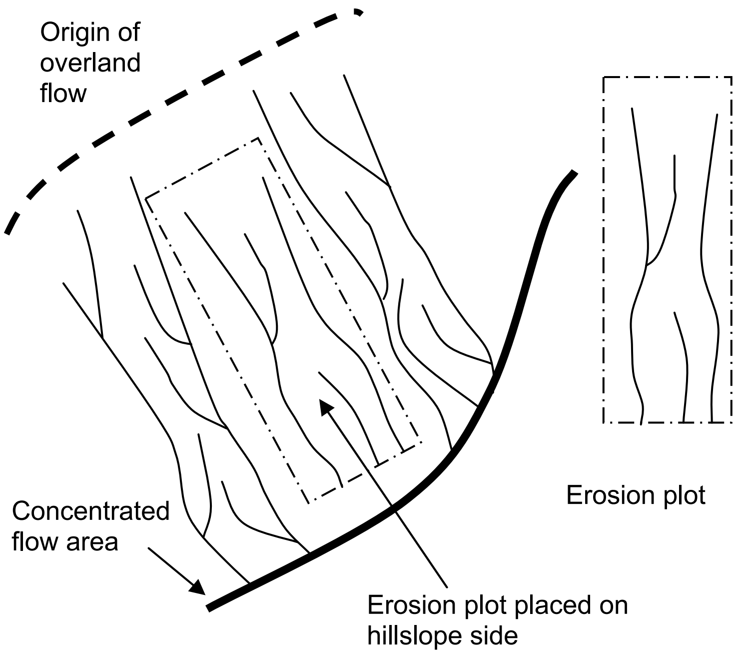

Figure 5.5. Relation of erosion plots to landscape

Sediment yield from most large watersheds is often less than sediment production within the watershed. Thus, much sediment is deposited within a typical watershed. **RUSLE2**, in contrast to the USLE and RUSLE1, can estimate the deposition that occurs on the overland flow portion of the landscape. This deposition, up to 75 percent of the sediment produced on the eroding portion of the hillslope, can be substantial on many hillslopes. **If RUSLE2 is used to estimate sediment yield in watersheds, it should be applied only to the eroding portion of the landscape to compute a soil loss comparable to that computed by the USLE. Otherwise, a different set of sediment delivery ratio values from those used by the USLE would have to be used with RUSLE2 to take into account deposition on overland flow areas.**

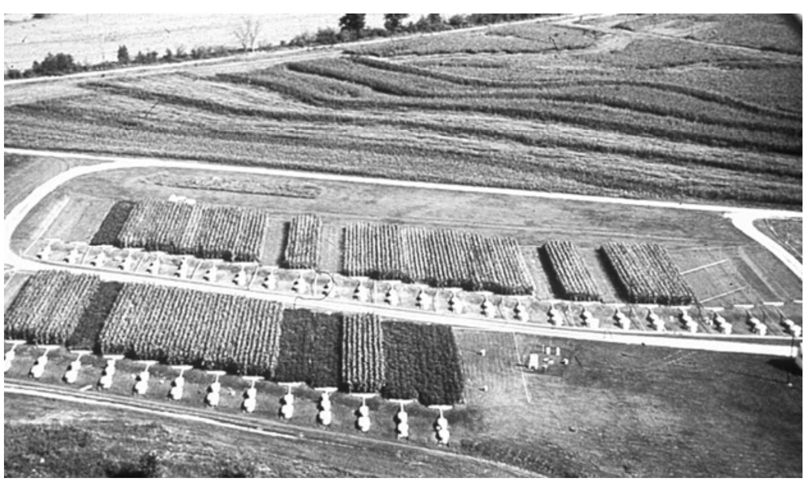

Figure 5.6. Erosion plots 12 ft wide (3.65 m) and 72.6 ft (22.1 m) long near Columbia, MO.

In addition to the sediment produced by interrill and rill erosion on upland areas (estimated by **RUSLE2)**, erosion in concentrated flow areas (ephemeral gullies), classical gullies, stream channels, and mass movement of material into channels are other major sources of sediment that contribute to sediment yield, which are not estimated by **RUSLE2**.

5.3.3. Estimating Soil Loss with RUSLE2 for Large Areas

RUSLE2 can be used to estimate soil loss for large areas. The approach is to select sample points over the inventory area where RUSLE2 will be applied to compute soil loss. These sample points should be selected according to the requirements of the inventory, giving special attention to required accuracy and how soil loss estimates will be aggregated according to soil, topography, land use, and conservation practice. RUSLE2 can be applied in several ways. One way is to estimate a "point" soil loss at the sample point. A slope length[2] to the point and values for steepness, soil, and cover and management at each sample point are determined. A slope segment 1 ft (0.3 m) long at the end of the slope length along with the other RUSLE2 input values for the segment are used in RUSLE2 to compute soil loss at the point.

Another approach is to determine a slope length through the point that extends to the location that deposition begins or to a concentrated flow area if deposition does not occur. Values for conditions along the slope length are used in RUSLE2 to compute a soil loss for the slope length. A limitation of this approach is that soil loss values cannot be aggregated based on conditions that vary along a slope length, such as multiple soil types.
A third approach, which was used by USDA-NRCS for the National Resources Inventory (NRI), uses the slope length through the point to either deposition or a concentrated flow area and conditions at the point to compute soil loss. This approach does not provide an estimate of soil loss at the point. Soil loss values cannot be aggregated for variables that are related to position on the slope. For example, the same soil loss is computed at the top of slope as at the bottom of slopes when slope steepness is the same for both locations.[3] A major advantage of computing soil loss for the entire slope length is that the number of sample points needed to obtain an accurate estimate of average soil loss for the area is significantly reduced. However, this procedure can not be used where the main variables, such soil erodibility or steepness, depend on landscape position.

An approach that absolutely should not be used is to determine spatially averaged values for slope length and steepness, soil, and cover-management conditions for the inventory area and use these values in RUSLE2 to compute a single soil loss value for the area. Soil loss estimates by this method are inaccurate because of nonlinearities in the RUSLE2 equations. No simple, universally applicable method can be developed to select the proper input values for this method. The issue is directly related to the proper

---

2 Slope length refers to the traditional USLE definition of slope length, which applies to the eroding portion of the RUSLE2 overland flow path length.

3 For discussion of the mathematics related to this approach, see Foster, G.R. 1985. Understanding ephemeral gully erosion (concentrated flow erosion). In: Soil Conservation, Assessing the National Resources Inventory. National Academy Press. Washington, D.C. pp. 90-125.

mathematical procedures for spatial integration, which is exactly the reason why RUSLE2 is much superior mathematically to the USLE or RUSLE1 as discussed below.

5.4. Equation Structure of RUSLE2

RUSLE2 uses an equation structure similar to the Universal Soil Loss Equation (USLE) and RUSLE1. RUSLE2 computes long-term average soil loss on each *ith* day as:

$$a_i = r_i k_i l_i S c_i p_i \qquad \textbf{[5.1]}$$

where: a_i = long-term average soil loss for the *ith* day, r_i = erosivity factor, k_i = soil erodibility factor, l_i = soil length factor, S = slope steepness factor, c_i = cover-management factor, p_i = supporting practices factor, all on the *ith* day.[4] The slope steepness factor S is the same for every day and thus does not have a subscript. To emphasize, values for these factors are long–term averages for a particular day—not for the year, which is the reason that lower case symbols are used rather than upper case as in RUSLE1 and USLE. Equation 5.1 is exactly like the USLE except that it computes soil for a given day rather than an annual soil loss.

RUSLE2 computes deposition when sediment load exceeds transport capacity on overland flow profiles like the one illustrated in Figure 5.2 using:

$$D_p = (V_f / q)(T_c - g) \qquad \textbf{[5.2]}$$

where: D_p = deposition, V_f = fall velocity of the sediment in still water, q = overland flow (runoff) rate per unit width of flow, T_c = sediment transport capacity, and g = sediment load. **RUSLE2** computes runoff rate using the 10-yr, 24 hr storm amount, the NRCS curve number method, and a runoff index (curve number) computed from cover-management variables. **RUSLE2** computes sediment transport capacity using:

$$T_c = K_T q s \qquad \textbf{[5.3]}$$

where: s = sine of the slope angle and K_T = a transport coefficient computed as a function of cover-management variables. The steady state conservation of mass equation is to compute sediment load as:

$$g_{out} = g_{in} + \Delta x D \qquad \textbf{[5.4]}$$

where: g_{out} = sediment load leaving the lower end of a segment on the slope, g_{in} =

4 Lower case letters are used to denote daily variables in comparison to the upper case letters used in the USLE and RUSLE1 that denote average annual values.

sediment load entering the upper end of the segment, Δx = length of segment, and D = net detachment or deposition within the segment. The sign convention is "+" for detachment because detachment adds to the sediment load, and "-" for deposition because it reduces the sediment load. Equation 5.4 is graphically illustrated in Figure 5.7.

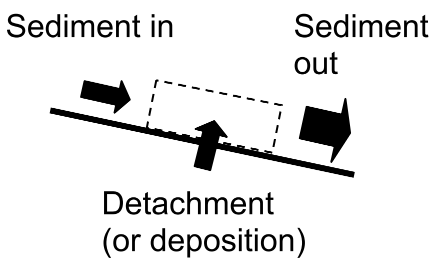

Figure 5.7. Schematic of conservation of mass equation for computing sediment load along the slope

Equations 5.2-5.4 are solved for each of the five particle classes of primary clay, primary silt, small aggregate, large aggregate, and primary sand. The distribution among these classes at the point of detachment is computed by RUSLE2 as a function of soil texture. The wide range in fall velocity for sediment particle classes allows equation 5.2 to compute the sorting of sediment where coarse and dense sediment are deposited first, which enriches the sediment load in fines and less dense particles.

Average annual soil loss is computed as:

$$A = \left(\sum_{i=a}^{365m} a_i \right) \Big/ m \qquad \textbf{[5.5]}$$

where: A = average annual soil loss, m = number of years in the analysis period, and 365m = the number of days per year. The value for m is 1 for continuous vegetation on range, pasture, and other lands where conditions are the same year after year, while m = the number of years of cropping-management rotations on cropland and the number of years following a disturbance such as construction, logging, grading of a reclaimed surface mine, or closing of a land fill where conditions are changing year to year.

For comparison, RUSLE1 is:

$$A = RLSP \left\{ \left[\sum_{k=1}^{24m} \left(f_k k_k \right) \right] \Big/ m \right\} \left[\sum_{k=1}^{24m} \left(f_k c_k \right) \right] \Big/ m \qquad \textbf{[5.6]}$$

where: R = average annual erosivity, f_k = distribution of erosivity by half month period, L = slope length factor, P = supporting practices factor, and k = index for the half month period. The 24 in equation 5.6 is the number of half month periods in a year. Values for the terms K and C are computed from:

$$K = \left[\sum_{k=1}^{24m} \left(f_k k_k \right) \right] \Big/ m \qquad \textbf{[5.7]}$$

and:

$$C = \left[\sum_{k=1}^{24m} \left(f_k c_k \right) \right] \Big/ m \qquad \textbf{[5.8]}$$

Values for K and C were computed and placed in tables so that RUSLE1 could be used in a “paper version” as A=RKLSCP. A computer program for RUSLE1 is also available to compute K, C, and P factor values from basic subfactor variables along with a procedure for computing soil loss for non-uniform shaped overland flow paths.

The USLE is:

$$A = RKLSP \left[\sum_{j=1}^{N} \left(f_j c_j \right) \right] \Big/ m \qquad \textbf{[5.9]}$$

where: j = the index for crop stage periods and N = the number of crop stages over the analysis period. A crop stage period is one where the cover-management factor c can be assumed to be constant. Values for C were computed from:

$$C = \left[\sum_{j=1}^{N} \left(f_j c_j \right) \right] \Big/ m \qquad \textbf{[5.10]}$$

Values for C were placed in tables so that the USLE could be used easily in a “paper version” as A=RKLSCP.

The numerical integration used in RUSLE2 to solve equations 5.1 and 5.5 is much superior to the approximations used in RUSLE1 and the USLE. The difference in soil loss estimates between RUSLE2 and the other equations can be as much as 15 percent because of differences in the mathematical integration procedures. Modern computers are readily available to solve complex equations to eliminate the need for a “paper version” of RUSLE2. The equations and procedures in RUSLE2 are too complex for a “paper version.” Although RUSLE2 can compute C factor values, RUSLE2 does not use the standard RKLSCP factor values to compute erosion.

The USLE, introduced in the early 1960's and revised in 1978,[5] was totally empirical, having been derived from more than 10,000 plot years of data from natural runoff plots and an estimated equivalent of 2,000 plot-years of data from rainfall simulator plots. The strength of the USLE is its empiricism, which is also its weakness. The USLE cannot be applied to situations where empirical data are not available for a specific field condition to derive appropriate factor values. Also, the USLE subfactor procedure for non-cropland (Table 10, AH537) is missing important variables including soil surface roughness and biomass production level.

Federal legislation in the 1980's required erosion prediction technology applicable to almost every cropland use, a requirement that the USLE could not meet. A "subfactor" method that estimates values for the cover-management factor C allows RUSLE1 to be applied to any land use. Process-based equations were also added to estimate the values for the support practice factor P so that soil loss could be estimated for modern strip cropping systems that could be estimated with the USLE. Data needed to derive USLE P factor values were not available for these systems. This hybrid approach of starting with an empirical structure and then adding process-based equations where empirical data were limited greatly increased the power of RUSLE1 over the USLE.

RUSLE2 significantly expands on this hybrid approach by combining the best of empirical-based and process-based erosion prediction technologies. Modern theory on erosion processes of detachment, transport, and deposition of soil particles by raindrop impact and surface runoff was used to derive **RUSLE2** relationships where the required equations could not be derived from empirical data. **RUSLE2** is well-validated erosion prediction technology that builds on the success of the USLE and RUSLE1. **RUSLE2** validation is described in **Section 17**.

5.5. Major Factors Affecting Erosion

The four major factors affecting interrill and rill erosion are: (1) climate, (2) soil, (3) topography, and (4) land use.

5.5.1. Climate

Rainfall drives interrill and rill erosion. The most important characteristics of rainfall are rainfall intensity (how hard it rains) and rainfall amount (how much it rains). Soil loss is high in Mississippi where much intense rainfall occurs, whereas soil loss is low in the deserts of Nevada where very little rainfall occurs. Thus, rainfall erosivity varies by location. Specifying the location of a site identifies the erosivity at the site.

---

5 Wischmeier, W.H. and D.D. Smith. 1978. Predicting rainfall-erosion losses: A guide to conservation planning. U.S. Dept. of Agriculture, Agriculture Handbook # 537.

5.5.2. Soil

Some soils are naturally more erodible than are other soils. Erosion by raindrop impact is not easily seen, but varying degrees of rilling indicate differing erodibility among soils. Knowledge of basic soil properties such as texture provides an indication of erodibility. For example, soils high in clay and sand have low erodibilities while soils high in silt have high erodibilities. Soils are mapped and named as map units and components that make up map units. Soil properties, including erodibility, are assigned by soil component and map unit. These properties are, in effect, specified when the name of a soil mapping unit is selected. Soils on highly disturbed lands like reclaimed mine sites can not be mapped and require special considerations to determine erodibility.

5.5.3. Topography

Topography, especially steepness, affects soil loss. Intense rilling is evidence that steep slopes like road cuts and fills experience intense erosion when bare. Runoff that accumulates on long slopes (overland flow path lengths) is also highly erodible, especially when it flows onto steep slopes. Thus, slope steepness and overland flow path length, to a lesser extent, are major indicators of how topography affects erosion. Slope shape (steepness along the overland flow path), illustrated in Figure 5.2, 5.3, and 5.4, also affects erosion and deposition as evidenced by both erosion and deposition on concave slopes.

5.5.4. Land Use

Erosion occurs when soil is left bare and exposed to raindrop impact and surface runoff. Vegetative cover greatly reduces soil loss. Two types of practices are used to control soil loss. One type is cultural practices like vegetative cover, crop rotations, conservation tillage, and applied mulch. The other type is supporting practices like contouring, strip cropping, and terraces that “support” cultural management practices. Of the factors of climate, soil, topography, and land use, land use is most important. It has the greatest range of effect on soil erosion, and it is the one that can be changed most readily to control soil loss and sediment yield.

A powerful feature of RUSLE2 is that it is land use independent. By using fundamental variables to represent cover-management effects, RUSLE2 can be applied to any land use. These variables include percent canopy cover; fall height; ground cover provided by live vegetation, plant litter, crop residue, and applied materials; surface roughness; soil biomass; degree of soil consolidation, and ridge height. RUSLE2 applies to cropland, rangeland, disturbed forestland, construction sites, reclaimed mined land, landfills, military training sites, and other areas where “mineral” soil is exposed to the forces of raindrop impact and overland flow produced by rainfall in excess of infiltration.

5.6. Computing Soil Loss with RUSLE2

RUSLE2 computes soil loss and other erosion values using inputs for climate, soil, topography, and use practices and conditions. These values stored in the RUSLE2 database under names for locations, which identify climatic variables; soil; cover-management conditions and practices; and supporting practices. The user selects a name from a menu list for each of these factors to compute erosion. RUSLE2 “pulls” the values associated with each input name from the RUSLE2 database. The user changes values of particular variables from those stored in the database as needed to represent site-specific conditions related to topography, yield (production level), rock cover, and type and amount of applied materials like manure and mulch.

In many ways, RUSLE2 is a set of database components that operate like a spreadsheet. Values are stored in each database component for the variables that RUSLE2 uses in its computations. When the user changes a particular value to represent a site-specific condition, RUSLE2 immediately updates its computations, much like a spreadsheet updates its computations when a change is made in a cell.

RUSLE2 is never started from a “blank sheet.” It always starts with information already stored in a database component. The user changes the values for particular variables if the values stored in the database are not appropriate for the field conditions where RUSLE2 is being applied.

5.6.1. Computational Database Components

All RUSLE2 database components accept input and make computations. However, three RUSLE2 database components are the primary computational components. These components are the (hillslope) **profile**, **worksheet**, and **plan view** components.

The overland flow path along a hillslope **profile** is the basic computational unit of RUSLE2. Information on the location (climate), soil, cover-management, supporting practices, and topography of a specific overland flow path describes a particular hillslope **profile**. Once this information has been entered in RUSLE2 to describe a particular hillslope profile, the profile can be named and saved in the **profile** component of the RUSLE2 database.

The RUSLE2 **worksheet** component is used to facilitate conservation planning by computing erosion for a set of alternate conservation practices for a **uniform** hillslope profile for a particular location, soil, and topography. The worksheet provides a convenient way to compare alternatives. Another RUSLE2 worksheet is available that can be used to compare hillslope profiles where conditions including location, soil, topography, cover-management, and supporting practice can vary along hillslope profiles and among the profiles.

The RUSLE2 **plan view** component can be used to compute average soil loss and other erosion variables for a spatial area like a field or watershed where profiles vary over the area.

Individual profile, worksheets, and plan views can be named and saved.

5.6.2. RUSLE2 Database Components

The major components of the RUSLE2 database are listed in Table 5.1. With the exception of a few site-specific inputs, RUSLE2 uses values stored in its database to make its computations. Later sections discuss the major variables in each RUSLE2 database component. Information on each variable and how it is used along with information on how to select input values is provided.

Table 5.1. RUSLE2 database components

Components	Comment
Plan view	Computes average erosion for a spatial area like a field or watershed
Worksheet	Computes erosion for alternative management practices and alternative hillslope profiles (overland flow paths)
Profile	Computes soil loss for a single hillslope profile (overland flow path), the basic computational unit in RUSLE2
Climate	Contains data on erosivity, precipitation amount, and temperature
Storm erosivity	Contains data on the distribution of erosivity during the year
Soil	Contains soil data including erodibility, texture, hydrologic soil group, time to consolidation, sediment characteristics, soil erodibility nomographs
Management	Contains descriptions of cover-management systems; includes dates, operations, vegetation, type and amount of applied materials
Operation	Contains data on operations, which are events that affect soil, vegetation, and residue; includes the sequence of processes used to describe each operation; whether an operation places residue in the soil; includes values for flattening, burial, and resurfacing ratios; ridge heights; and initial soil roughness
Vegetation	Contains data on vegetation; includes residue types associated with particular vegetations, yield, amount of aboveground biomass at maximum canopy, senescence, flow retardance, root biomass, canopy cover, fall height, live ground cover
Residue	Contains data that describe the residue description assigned to each vegetation description; includes values for decomposition, mass-cover

	relationship, how residue responds to tillage
Contouring	Contains values for row grade used to describe degree of contouring
Strips/barriers	Contains data that describes filter strips, buffer strips, and rotational strip cropping; includes cover-management in strips, width of strips, number of strips across slope length, whether or not a strip is at the end of the slope; and offset of rotation by strip; includes information on barriers used on construction sites.
Hydraulic system	Identifies the hydraulic elements and their sequence used to describe hydraulic systems of diversions, terraces, and impoundments; includes number across overland flow path length and whether or not a system is at the end of the slope; includes specific locations of practice on the overland flow path length
Hydraulic element	Contains data on grade of named channel for terraces and diversions
Subsurface drainage system	Contains data on the percent of the area covered by optimum drainage

5.6.3. Templates

RUSLE2 uses **control files** known as **templates** and **access/permission files** that control the RUSLE2 computer screen and the variables accessible to the user. **Templates** determine the appearance of the computer screen and the complexity of the problems that can be analyzed. **Templates** can be customized by the user to change the appearance of the screen. Two standard templates, **uniform slope** and **complex slope**, are available for download from the **USDA RUSLE2 Internet site** at http://www.ars.usda.gov/Research/docs.htm?docid=6038. The **uniform slope** template is for application of RUSLE2 to uniform slopes where all conditions are the same along the slope except for regularly spaced strips such as buffer strips and strip cropping. The **uniform slope** template should be used to learn RUSLE2. It is also the template that makes RUSLE2 most comparable to the USLE and RUSLE1 for estimating soil loss. The **complex slope** template can be used to analyze slopes where conditions such as soil, steepness, cover-management conditions, and certain support practices vary along the slope.

RUSLE2 can display information on many more variables than is displayed on the **uniform slope** and **complex slope** templates. Contact your RUSLE2 administrator for information on how to obtain templates that display additional output. Also, you can edit templates yourself to add a display of certain variables to your current templates. The revised template can be saved under an existing name or saved with a new name. **Of course, saving a template under an existing name means that the template as it existed before the change is lost.** Templates can be transferred among users.

5.6.4. Access/Permission Files

RUSLE2 uses **access/permissions** files that can be named and saved. These files determine the variables that are seen and the variables that are seen but cannot be edited. A main benefit of **access/permissions** files is to protect users from making unauthorized changes in a database. Contact your RUSLE2 administrator for information on changing RUSLE2 access control especially if you find that you cannot manipulate key variables because you are apparently locked out of them. In some cases, you can change values and store the information under a new name. Also, don't be surprised to learn that RUSLE2 has many other variables of interest that someone "upstream" has chosen to keep hidden from you.

5.6.5. Computer Program Mechanics

Information on RUSLE2 computer interface mechanics is summarized in documents available on the USDA-ARS (http://www.ars.usda.gov/Research/docs.htm?docid=6010), University of Tennessee (www.rusle2.org), and USDA-NRCS (http://fargo.nserl.purdue.edu/rusle2_dataweb/RUSLE2_Index.htm) Internet sites.

When the RUSLE2 program is first started, the opening screen provides two choices. Select either a **profile** or **worksheet** to perform erosion computations or select one of the other **database components** to work on stored input values such as those for cover-management and support practices, vegetation, operation, residue, and soil properties, and climate inputs. The second choice is to select a **template**. Templates control the appearance of the RUSLE2 interface and determine the complexity of the field problems that can be analyzed. RUSLE2 is easiest to use for a simple uniform slope, which is the **uniform slope** template. As you become familiar with RUSLE2, move to the **complex slope** and other templates to analyze complex slopes. Also, once you learn the program, you can change the program so that the program starts with alternative screens and **default profiles, worksheets, and plan views**.

Input values in the database can be changed during a particular RUSLE2 analysis. However, you may be locked out of certain database elements because of settings in the RUSLE2 **access control file**.

6. CLIMATE DATABASE COMPONENT

This section describes the variables in the **climate database component**, the role of each variable, and how to determine values for key variables. Values on erosivity, precipitation amount, and temperature are the principal information in the climate database component.

Three types of erosivity inputs can be used in RUSLE2. The preferred method is to enter values for **erosivity density**, which is the ratio of monthly erosivity to monthly precipitation. Erosivity density values were recently determined from analysis of modern weather data as a part of the RUSLE2 development. The second method is to enter monthly erosivity values. The third method is to enter an average annual erosivity value along with an erosivity distribution curve for the EI zone containing the site where RUSLE2 is being applied. The third method is the same as that described in AH703 for RUSLE1. However, do not use values from AH703 because those values are based on old data from the 1930's to 1950's period. **Erosivity values determined from the modern data are about 10 percent larger on average than values based on the older data.**[6]

RUSLE2 uses a storm with a 10 year recurrence interval in its runoff computations. **Two types of inputs for this storm can be used in RUSLE2 (see Section 6.5.2).** One option, which is recommended, is to enter a value for the 10 year-24 hour precipitation amount. RUSLE2 computes a corresponding 10 yr EI. The other option is to enter a 10 yr EI value. RUSLE2 computes a corresponding 10 yr-24 hr precipitation amount. Although the two options yield similar results in the eastern US, entering the 10 yr-24 hr precipitation amount yields significantly improved results in the western US.

6.1. Major Climate Variables

Table 6.1 lists the variables in the RUSLE2 **climate database component** for the **preferred erosivity density** approach, which should be used when applying RUSLE2 to locations within the continental US. Table 6.2 lists the erosivity variables for the annual

6 This overall 10 percent increase in average annual erosivity should not be attributed necessarily to climate change. The increase could be related to differences in measurement techniques and equipment and analytical procedures used to determine erosivity values from the measured data. Data limitations including temporal and spatial variability, missing data, and errors in weather data do not allow conclusions contribute to the difference. In general, the monthly distributions of erosivity changed less than the overall increase in erosivity. The erosivity values produced by this analysis are superior to previous erosivity values, especially for the Western US, for conservation and erosion control planning using RUSLE2. This 10 percent difference in erosivity values must be interpreted along with RUSLE2's accuracy in the context of the particular RUSLE2 application (see **Section 17**).

R and EI distribution zone approach, which may be convenient when applying RUSLE2 outside of the US.

Table 6.1. Variables in climate database component for **erosivity density** procedure		
Variable	**Symbol**	**Comment**
Monthly erosivity density	α_m	Ratio of monthly erosivity to monthly precipitation; RUSLE2 uses these values and monthly precipitation to compute monthly erosivity
Annual erosivity	R	RUSLE2 sums monthly erosivity values to determine an annual erosivity value (not an input)
Monthly erosivity	R_m	RUSLE2 computes monthly erosivity using monthly values for erosivity density and precipitation (not an input)
Daily erosivity	r_i	RUSLE2 "disaggregates" monthly erosivity values into daily values (not an input)
Monthly precipitation	P_m	Average annual monthly precipitation (rainfall plus snow), used to compute monthly erosivity, the temporal variation of soil erodibility, and decomposition of dead plant materials (litter, residue, roots)
Daily precipitation	p_i	RUSLE2 "disaggregates" monthly precipitation values into daily values (not an input)
Annual precipitation	P_t	RUSLE2 computes annual precipitation from the monthly precipitation values; used to compute time to soil consolidation (not an input)
10 yr 24 hr precipitation	$P_{10y,24h}$	This precipitation, representative of a moderately infrequent erosive rain, is used to compute a storm erosivity and runoff; these variables, in turn, are used to compute transport capacity and deposition for concave slopes, vegetative strips, and channels; reduction of erosion by ponding; effectiveness of contouring; and critical slope length for contouring
EI for 10 yr 24 hr precipitation	$EI_{10y,24h}$	RUSLE2 determines this values from 10 yr 24 hr precipitation and maximum monthly erosivity density value (not an input)
Monthly temperature	T_m	Average annual monthly temperature, used to compute the temporal variation of soil erodibility and decomposition of dead plant materials (litter, residue, roots)
Daily temperature	T_i	RUSLE2 "disaggregates" monthly temperature values into daily temperature values (not an input)
In Req Area?	Yes or no	The Req area is a region in the Northwestern part of the US where the erodibility of certain cropland and other highly disturbed soils is greatly increased during winter months; answer **Yes** to use Req relationships for these land uses

Use Req distribution?	Yes or no	Wintertime adjustment for increased erodibility does not apply to land uses like pasture and rangeland; if answered no, Req relationships will not be used
R equivalent	R_{eq}	The effect of the greatly increased erodibility is accounted for in the Req region by using an equivalent erosivity value based on annual precipitation (not an input)
EI distribution for Req	-	An erosivity distribution that describes the greatly increased erodibility during the winter
Adjust for soil moisture	Yes or no	An adjustment is made for soil moisture when the Req relationship is selected for cropland and other situations of highly disturbed soil, only applies to Req zone
Vary soil erodibility with climate	Yes or no	With the exception of when the Req relationships are used, select **Yes** to vary soil erodibility values through time as a function of monthly precipitation and temperature (may not be available on most templates)
Note: Not all of these Req-type variables are available on some templates. For example, if **No** is the input for **In Req area?,** then RUSLE2 automatically varies soil erodibility with climate.		

Table 6.2. Variables in climate database component for monthly or annual R and EI distribution procedure. Note: Refer to AH703 for information on these variables.

Variable	**Symbol**	**Comment**
Average annual erosivity	R	An erosivity index that indicates how the erosivity of rainfall varies by location
Erosivity distribution	EI zone identifier	Describes how erosivity varies during the year by half-month periods. Not an input when monthly erosivity values are entered.
Monthly erosivity	R_m	RUSLE2 computes monthly erosivity using annual erosivity value and erosivity (EI) distribution by half month period when method of entering annual erosivity is used.
Daily erosivity	r_i	RUSLE2 "disaggregates" half month erosivity values into daily values (not an input)
10 year storm erosivity	EI_{10yr}	This storm represents a moderately infrequent erosive rain; EI_{10yr} value is used to compute runoff, which along with the storm erosivity, is used to compute transport capacity and deposition for concave slopes, vegetative strips, and channels; reduction of erosion by ponding; effectiveness of contouring; critical slope length for contouring

6.2. Basic Principles

RUSLE2 is based on the assumption that net **detachment** caused by a single storm is directly proportional to the product of a storm's **energy E** and its **maximum 30-minute intensity I_{30}**. **The relationship between detachment and storm erosivity EI is linear**, which means that individual **storm EI** values can be summed to determine monthly and annual erosivity values. This linear relationship also means that average annual erosion can be mathematically computed for each day as represented by Equation 5.1 even though erosion does not occur on every day during a year.

The **average annual erosivity value R** is an index of erosivity at a location. For example, R-values in central Mississippi are about 10 times those in Western North Dakota. If all things are equal, erosion in central Mississippi is 10 times that in Western North Dakota. Erosivity reflects the effects of both rainfall amount and rainfall intensity on erosion. Thus, erosivity values can vary significantly among locations having nearly equal rainfall amounts because of difference in rainfall intensity among locations.

6.2.1. Computing Erosivity for Individual Storms

Storm erosivity EI is the product of a storm's total **energy E** and its **maximum 30-minute intensity I_{30}**. A storm's total energy is most related to the total amount of rainfall in a storm. It is also partially related to intensity because the energy content per unit rainfall (**unit energy**) is related to rainfall intensity. Rainfall intensity also has a direct affect on erosion besides its effect on storm energy. The **maximum 30-minute intensity** is a better measure of the intensity effect than either **average intensity** or **peak intensity**. The 30-minute time period over which to average intensity was determined from analysis of empirical erosion data for the continental US. Other time periods such as 15 minutes are better in other places of the world where rainfall characteristics differ from those in the continental US. **The EI product for storm erosivity captures the effects of the two most important rainfall variables that determine erosivity; how much it rains (rainfall amount) and how hard it rains (rainfall intensity).**

Total energy for a storm is computed from:

$$E = \sum_{k=1}^{m} e_k \Delta V_k \qquad \textbf{[6.1]}$$

where: e = unit energy (energy per unit of rainfall), ΔV = rainfall amount for the *kth* period, k = an index for periods during a rain storm where intensity can be considered to be constant, and m = number of periods. Unit energy is computed from:

$$e = 0.29[1 - 0.72\exp(-0.082i)]$$ **[6.2]**

where: unit energy e has units of MJ/(ha·mm) and i = rainfall intensity (mm/h).[7] Table 6.3 illustrates computation of total energy for a storm. The total energy for the example storm is 8.90 MJ/ha.

The next step is to determine the maximum 30-minute intensity I_{30}. Maximum 30-minute intensity is the average intensity for the continuous 30 minutes with the maximum rainfall. (Also, I_{30} = 2·amt of rain in the 30 minutes having the maximum rainfall amt) Plotting cumulative rainfall for the storm as illustrated in Figure 6.1 is helpful for determining maximum 30-minute rainfall. This storm is unimodal (single peak), which means that the 30 minutes with the most rainfall contains the time that the peak intensity occurs. The amount of rainfall is 27.4 mm for the 30 minutes with the most rainfall, which gives an intensity of 57.4 mm/h for I_{30}.

Table 6.3. Sample computation of erosvity EI for an individual storm

Time (hrs:min)	Duration of interval (minutes)	Cumulative rain depth (mm)	Rainfall in interval (mm)	Intensity (mm/h)	Unit energy (MJ/ha* mm)	Energy in interval (MJ/ha)
4:00		0.0				
4:20	20	1.3	1.3	3.8	0.137	0.17
4:27	7	3.0	1.8	15.2	0.230	0.41
4:36	9	8.9	5.8	38.9	0.281	1.64
4:50	14	26.7	17.8	76.2	0.290	5.15
4:53	3	30.5	3.8	76.2	0.290	1.10
5:05	12	31.8	1.3	6.4	0.166	0.21
5:15	10	31.8	0.0	0.0	0.081	0.00
5:30	15	33.0	1.3	5.1	0.152	0.19
Total	90		33			8.88

The erosivity for the storm is the product of 8.90 MJ/ha (storm energy) and 57.4 mm/h (maximum 30-minute intensity) = 512 MJ·mm/(ha·h). **The computation of storm erosivity in US customary units is similar, except that storm erosivity values are divided by 100 to provide convenient working numbers.**

---

7 Equation 6.2 differs from the corresponding equation used in RUSLE1 (AH703). The 0.082 coefficient in equation 6.2 was 0.05 in AH703. For additional discussion, see McGregor, K.C., R.L. Bingner, A.J. Bowie, and G.R. Foster. 1995. Erosivity index values for northern Mississippi. Transactions of the American Society of Agricultural Engineers. 38(4):1039-1047.

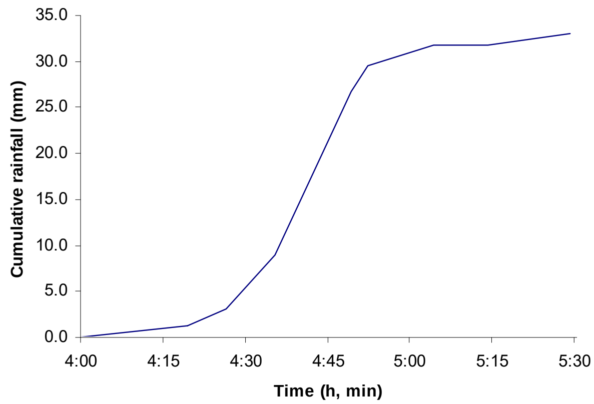

Figure 6.1. Cumulative rainfall for a storm.

Rains less than 0.5 inch (12.5 mm) and separated from other rains by more than 6 hours are not included in the computations unless the maximum 15-minute intensity exceeds 0.5 inch/hour (12.5 mm/h). When erosivity values were first computed in the late 1950's, these small storms were omitted to significantly reduce the amount of rainfall data that must be processed in an era before data could be processed with computers. These storms add little to the total annual erosivity. However, storms less than 0.5 inch (12.5 mm) were also deleted in computing erosivity for RUSLE2 to give some effect of computing reduced erosion at low rainfall amounts and intensities because of little or no runoff.

Average annual erosivity is the sum of the storm erosivities over M number of year as:

$$R = \left[\sum_{m=1}^{M} \sum_{j=1}^{J(m)} (EI_{30})_j \right] \Big/ M \qquad \textbf{[6.3]}$$

where: R = average annual erosivity, EI_{30} = the erosivity of an individual storm, j = an index for each storm, J(m) = number of storms in the *mth* year, and m = an index for year.[8]

6.2.2. Why New Erosivity Values were Computed from Modern Data

A concern has existed for sometime that erosivity values for the eastern US needed to be recomputed based on modern precipitation data. Average annual erosivity values in AH703 for the Eastern US, as well as erosivity values in AH282 and AH537, were based on data collected in the approximate period of 1935 to 1957. This period included two major droughts in large regions of the US. Also, a possible climate change over the last 70 years may have increased rainfall amounts and intensities and caused a corresponding increase in erosivity. To address these concerns, precipitation data from the 1960's through 1999 were analyzed to develop a modern set of erosivity values.[9] **Based on this**

---

[8] The R factor has units. In this guide, the US customary units for R are hundreds of (ft tons in)/(ac yr hr). Metric units in the SI system are (MJ mm)/(ha∗h) for erosivity and (t h)/(MJ mm). See AH703 for additional information.

[9] Precipitation data from 15-minute stations across the US were assembled by the Illinois State Water Survey (ISWS), who computed storm energy and maximum 30-minute intensity for the qualifying

analysis, modern average annual erosivity is about 10% greater over much of the eastern US than that for the1935-1957 period.

Differences in erosivity values derived from the 1930's-1950's data and those derived from the 1960's-1990's data should not be interpreted as having been caused by climate change. Differences in record length, analysis procedures, and interpretation at different points in time and by different people prevent such a direct comparison of values.

Erosivity values described in this RUSLE2 User Reference Guide determined from the modern data should be accepted as representing the best erosivity values currently available for applying RUSLE2 at the local field office level for conservation and erosion control planning—nothing more, nothing less.

6.2.3. Erosivity Density Values

The erosivity density method used to derive erosivity values was developed to maximize the precipitation data that could be used to compute erosivity values and to provide a consistent set of erosivity value for conservation and erosion control planning. **Erosivity density** is the ratio of the monthly erosivity to monthly precipitation. Erosivity density values were computed across the US at about 1610 stations. Statistical analysis showed that erosivity density is independent of elevation, which means that the erosivity density could be smoothed and mapped using GIS techniques for the entire continental US as a spatial unit (See the RUSLE2 Scientific Documentation for additional information). Precipitation data with intensity values needed to compute erosivity are very limited

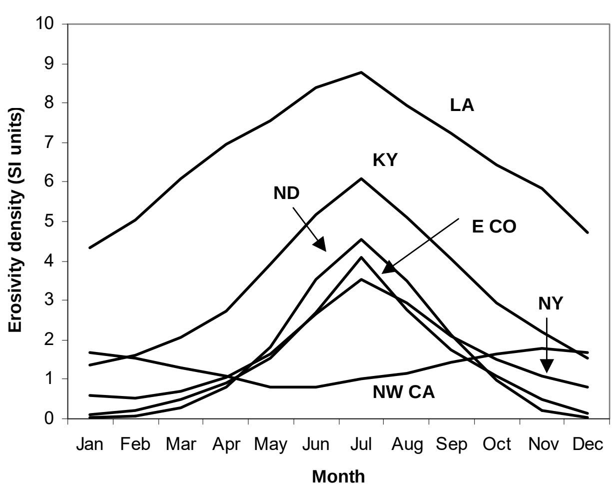

Figure 6.2. Erosivity density at selected locations. LA-Louisiana, KY-Kentucky, ND-North Dakota, E CO-Eastern Colorado, NY-New York, NW CA-Northwestern California

---

rainstorms. The ISWS and the USDA-NRCS National Water and Climate Center (NWCC) analyzed the data to remove storms with greater than a 50-yr return period, snow events, and invalid data because of equipment failure, a short record length, or other reasons. University of Tennessee personnel performed the spatial analysis of the data.

at higher elevations. The applicability of erosivity density values is limited at elevations higher than about 3,000 m (10,000 ft), especially in the winter months.[10]

Erosivity density is a measure of erosivity content per unit of precipitation. Erosivity density is low during the winter months and high during the summer months with the exception of the western most portion of the US. Erosivity density is greater in the southern part of the US than in the northern part. Erosivity density is more uniform over the year in the southern part of the US than in other parts of the US.

Unsmoothed erosivity density values directly computed from the weather data at individual stations are both spatially and temporally irregular. Trends are sometimes difficult to discern when comparing data among individual weather stations. However, patterns like those in Figure 6.2 emerge when data from several stations are averaged over areas like the quadrants of Indiana.[11] The erosivity density values were spatially smoothed using GIS techniques to provide spatial and temporal consistency required by conservation and erosion control planning applications of RUSLE2. The objective in RUSLE2 is to represent the main geographic trends in the historical data and not the details in historical weather data. Preferably the probability of weather events, both dry and wet, would be the same at all locations in the climate data used by RUSLE2.

Erosivity density values for the continental US are shown in Figure 6.3-6.14. RUSLE2 users can read values from these figures to create entries in their RUSLE2 operational database. However, RUSLE2 users are advised to download values for their RUSLE2 application from the NRCS RUSLE2 National Database rather than to create their own RUSLE2 entries by reading values from these Figures. However, some users may wish to create an entry in their database for a specific site rather than use the NRCS database values. Values for erosivity density can be read from these figures with sufficient accuracy to apply RUSLE2.

The principal application of RUSLE2 is for conservation and erosion control planning. The objective is to capture main effects and consistency so that farmers, contractors, and others impacted by RUSLE2 are treated fairly, especially where costs, benefits, and regulatory impacts are involved. No one should be penalized or rewarded based on unusual events occurring at a location.

---

[10] Erosivity density values are highly variable in the western US. Also, the number of locations is very limited. Because of these data limitations, statistical tests that show that the hypothesis that erosivity density values are not a function of elevation are not robust. Obviously erosivity density values decrease with elevation in the winter because of increasing amounts of snow at higher elevations. Also, erosivity density values probably decrease slightly with elevation in the summer.

11 See RUSLE2 Science Documentation, USDA-Agricultural Research Service.

6.2.4. Monthly Erosivity Values

RUSLE2 computes a monthly erosivity by multiplying monthly erosivity density by monthly precipitation as:

$$R_m = \alpha_m P_m \quad \textbf{[6.4]}$$

where: R_m = monthly erosivity, α_m = monthly erosivity density, and P_m = monthly precipitation. Annual erosivity is computed as the sum of the monthly erosivity values. Figures 6.15 and 6.16 illustrate average annual R-values for the continental US. The values in these figures are for illustration only. Actual values used in RUSLE2 should be downloaded from the NRCS national RUSLE2 database. Average annual erosivity values for the western US and the mountainous regions of the eastern US are much more variable than indicated in these figures. Nevertheless, these figures can be compared to similar figures in AH282, AH537, and AH703.

6.3. Input Values for Monthly Erosivity Density, Precipitation, and Temperature

6.3.1. Selecting Climate Input Values for Continental US

RUSLE2 requires monthly values for erosivity density, precipitation, and temperature appropriate for the site where RUSLE2 is being applied. A sample set of these values are included with the download of RUSLE2. A complete set of these values can be obtained from the NRCS national RUSLE2 database or by contacting the NRCS state agronomist in your particular state of interest.

The climate values in the NRCS national RUSLE2 database have been assigned by county for those counties in the US where the values can be considered to be uniform over the county. In mountainous areas, the RUSLE2 weather inputs vary over space because of elevation effects. In those regions, NRCS has organized the data by precipitation depth zones that vary with elevation. The precipitation and temperature values in the NRCS national RUSLE2 database are based on 1961-1990 data.

RUSLE2 users in the US should generally use RUSLE2 climate input values from the NRCS national RUSLE2 database. However, in some cases, climate values may be needed for a specific location rather than for the precipitation depth zones used in the NRCS national RUSLE2 database. Erosivity density values at a particular location can be read from Figure 6.3-6.14. Precipitation and temperature values at a specific location can be obtained from the PRISM database available from the USDA-NRCS. PRISM monthly and precipitation values are on a 4 km by 4 km grid throughout the continental US.[12]

Current PRISM values are based on historical data from 1961-1990. The data were not processed to remove unusually dry or wet events. That is, the return periods (probability) of events vary significantly by location, resulting in spatial variability that is inappropriate for conservation and erosion control planning. The PRISM model, considered state-of-the-art, produces precipitation values that can vary greatly over a relatively short distance, which can result in a corresponding wide variation in erosion estimates.

6.3.2. Climate Input Values Outside of Continental US

When RUSLE2 is applied outside of the continental US, input climate data should be assembled using procedures outlined above if possible.[13] However, RUSLE2 is frequently applied where detailed weather data are not available.

Several points should be considered in developing input values for RUSLE2 where weather data are limited. RUSLE2 is a conservation and erosion control planning tool that captures main effects of the variables that affect rill and interrill erosion and general spatial trends. Weather data can be very irregular between locations, especially if the period of record is short. While short records may have to be used out of necessity, the values should be carefully inspected and smoothed based on technical judgment by those knowledgeable of local and regional weather and climate conditions.

Estimating erosivity as outlined above requires precipitation data that include rainfall intensity values. However, these intensity data may not be available. Erosivity can be estimated from monthly and daily precipitation data, provided sufficient data are available to calibrate the procedures.

[12] These PRISM-based values were developed by the NRCS, Oregon State University, and other cooperators using the PRISM model that takes measured precipitation and temperature station (point) data and spatially distributes these values taking into account effects of elevation, proximity to a major water body, atmospheric inversions, and other factors (see Daly, C., G. Taylor, and W. Gibson. 1997. The PRISM approach to mapping precipitation and temperature, 10th Conf. on Applied Climatology, American. Meteorological Society.)

[13] The NRCS National RUSLE2 Database contains values for Alaska, Hawaii, Puerto Rico and US Territories in the Pacific Basin and Virgin Islands.

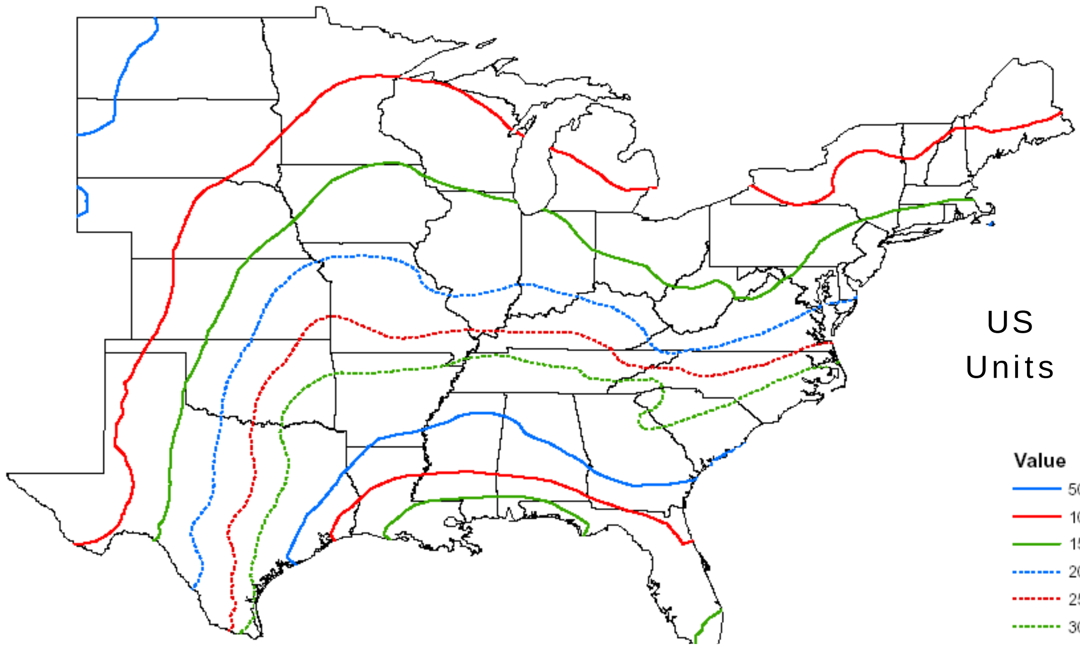

Figure 6.15. Average annual erosivity R-values for the eastern US in customary US units (See Foster, G.R., D.K. McCool, K.G. Renard, and W.C. Moldenhauer. 1981. Conversion of the universal soil loss equation to SI metric units. Journal of Soil and Water Conservation 36(6):355-359.

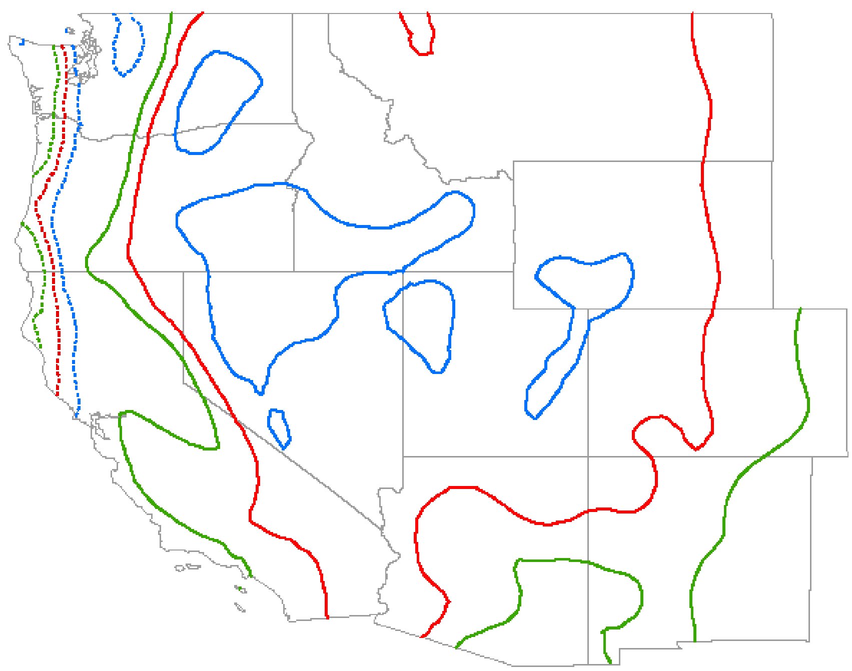

Figure 6.16.Average annual erosivity R values for western US. (For illustration to show broad trends. Local values vary greatly.)

When storm data are used to estimate erosivity, storm erosivity can be computed from storm rainfall amount using the non-linear equations:

$$R_s = aP_s^b \qquad \textbf{[6.5]}$$

where: R_s = storm erosivity, P_s = storm precipitation amount, and values for coefficients **a** and **b** are determined by **nonlinear** analysis of empirical data. A logarithmic transform and linear regression does not return the proper values for the **a** and **b** coefficients in equation 6.5. The coefficient **a** and exponent **b** varies by season of the year and by location as represented by the different shaped curves in Figure 6.2.

Monthly precipitation can also be used to estimate monthly erosivity from empirically derived equations. Equation 6.4 implies a linear relationship between monthly precipitation and monthly erosivity. However, the relationship between monthly erosivity and monthly precipitation is actually non-linear. A linear equation can only be used to estimate monthly erosivity using monthly precipitation when the year is divided into months and having erosivity density values that vary by location and by month in sufficient spatial resolution to stepwise approximate non-linear temporal and spatial variations in erosivity. That is, linear equations can be used in a stepwise fashion to approximate non-linear equations if the temporal and spatial steps have sufficient resolution.

6.3.3. Erosivity Values for High Elevation, Snow Cover, Snow Melt, and Req Zone

Applying RUSLE2 to high elevations, periods when a snow cover is present, and snow melt are discussed below in **Section 6.9** related to applying RUSLE2 in the special **Req** zone.

6.3.4. Erosivity Values for Irrigation

The major types of irrigation are surface applied and sprinkler applied water. RUSLE2 can not be used to estimate erosion from surface irrigation systems because runoff and erosion decrease along the flow path for surface irrigation, whereas RUSLE2 assumes an increase.

Most sprinkler irrigation systems apply water at a sufficiently low intensity that erosion does not occur. Thus, the applied water has little or no erosivity. However, irrigation does affect rill-interrill erosion by increasing soil moisture, and increasing vegetation production (yield) level, which decreases erosion. The increased soil moisture increases runoff and erosion when rainfall occurs during irrigation periods, and the added water increases decomposition of biomass on and in the soil. **Section 14.5** describes how to use RUSLE2 to estimate how irrigation affects rill-interrill erosion caused by rainfall.

6.3.5. Erosivity Values for Subsurface Drainage

Subsurface drainage reduces both soil moisture, which reduces runoff and erosion. RUSLE2 uses a soil erodibility factor value for the drained situation that differs from the soil erodibility value for the undrained condition to compute how subsurface drainage affects erosion. Subsurface drainage also increases vegetation production (yield) level, which reduces erosion. **Section 14.4** describes how to use RUSLE2 to estimate how subsurface drainage affects erosion.

6.4. Disaggregation of Monthly Values into Daily Values

As indicated by Equation 5.1, RUSLE2 uses long term average daily values in its computations. RUSLE2 uses a disaggregation procedure to compute long term average daily weather values from long term daily monthly values. This procedure uses linear equations that interpolate between the monthly values. The RUSLE2 disaggregation equations compute daily values that preserve monthly averages in the input data. The resulting daily values are sometimes not smooth, especially for rainfall values that vary up and down from month to month in comparison to the smooth trends in temperature. Preserving average monthly values was considered to be more important than having a smooth curve. Disaggregation of the monthly erosivity and temperature values for Birmingham, AL is shown in Figure 6.17.

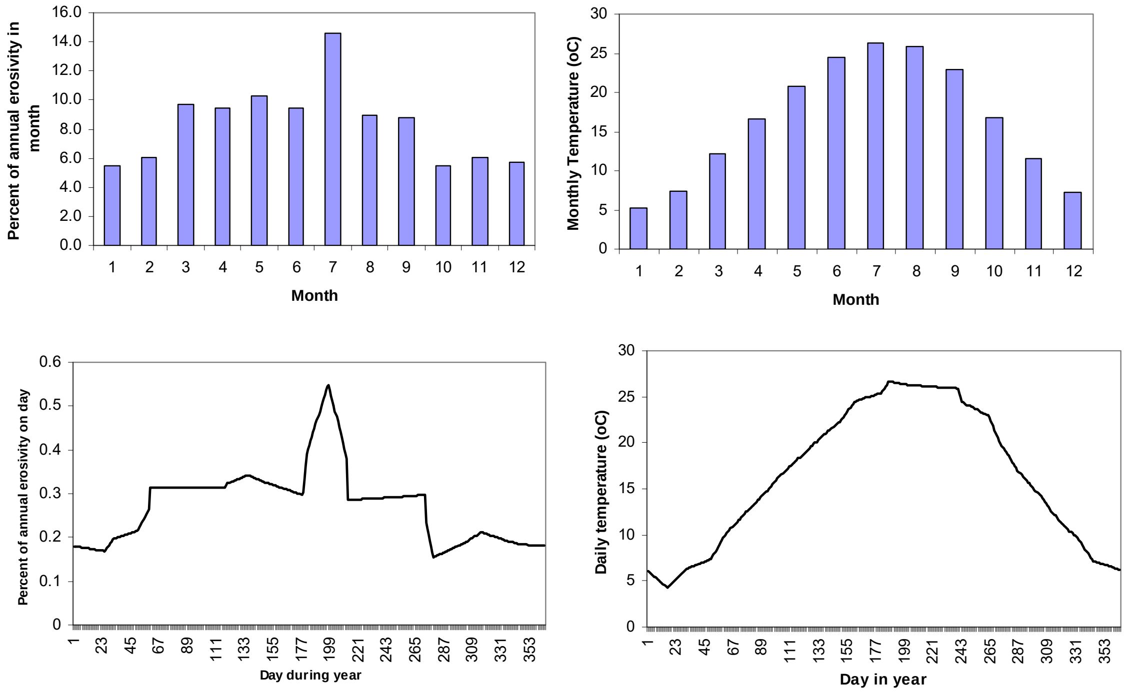

Figure 6.17. Disaggregation of monthly erosivity and temperature into daily values for Birmingham, AL.

6.5. Ten Year Storm

RUSLE2 uses a storm having a 10 year recurrence interval in its runoff computations. Two ways are provided in RUSLE2 for obtaining values for this storm. The strongly recommended way, especially for the eastern US, is to enter values for the 10-year-24 hour precipitation amount. The second way is to enter values for the 10 year EI event like that used in RUSLE1. The 10 year EI event is the storm erosivity that a 10 year recurrence interval.

6.5.1. 10 Year-24 Hour Storm

RUSLE2 uses the 10 year-24 hour (P_{10y24h}) storm to compute storm erosivity and runoff values that are used to compute factor values for contouring, critical slope length for contouring, sediment transport capacity, and the effect of ponding on reducing erosivity. Sediment transport capacity is used to compute deposition by runoff entering slope segments with a concave shape, dense vegetation, high ground cover, or rough soil surface. The 10 year-24 hour precipitation value is the storm amount that occurs in a 24 hour period that has the probability of occurring once every 10 years (a 10-year return period). Values for the 10 year-24 hour precipitation amounts in the NRCS national RUSLE2 database are by county in the eastern US and by precipitation depth zone in the eastern US. Those values were taken from the most recent National Weather Service published values. Values for the 10 yr-24 hour precipitation are illustrated in Figure 6.18 for the eastern US and for New Mexico in Figure 6.19 as an example of the values available for the western US. These figures are taken from older publications (national maps have not been updated) and are for illustration purposes only. More recent data are available that should be used. The modern data are available at http://hdsc.nws.noaa.gov/hdsc/pfds/.

Figure 6.18. (Full illustration only) 10 yr-24 hour precipitation for the US

The P_{10y24h} value is used to compute an erosivity value associated with this precipitation. The procedure used by RUSLE2 computes an EI_{10y24h} value as:

$$EI_{10y24h} = 2\alpha_m P_{10y24h} \quad \textbf{[6.6]}$$

where: m = the month with the largest erosivity density value.

6.5.2. 10-Year EI Storm

Although use of the 10 year-24 hour storm is the preferred storm input in RUSLE2, the 10-year EI storm has been retained in RUSLE2 as an option. The 10-year EI method gives good results in the eastern US but not in the western US. The 10-year EI value is used to estimate a precipitation amount that is used in the same way that the 10 year-24 hour precipitation amount is used in RUSLE2. The reason that this method does not work well in the western US is that the precipitation amount for this storm is underestimated because the erosivity density (erosivity content per unit precipitation) is much less in the western US than in the eastern US.

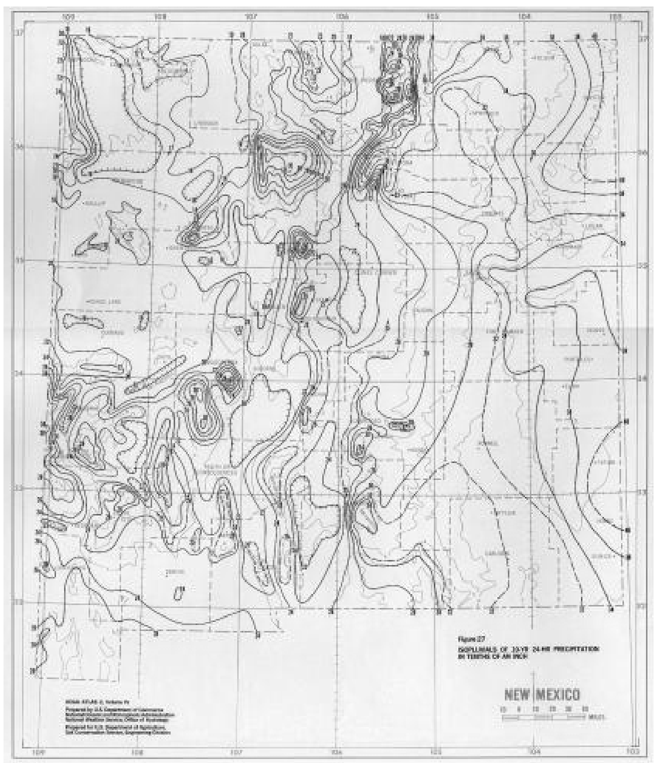

Figure 6.19. (For illustration only) 10 yr 24 hr precipitation for New Mexico.

The map of 10-year EI values has been revised from that in AH703 to greatly smooth the lines to only capture the major trends across the eastern US rather than local variations that reflect unexplained variability in the data rather than "real" differences. The 10-year EI values shown in Figure 6.20 should be used in RUSLE2 and in RUSLE1 rather than the values given in AH703.

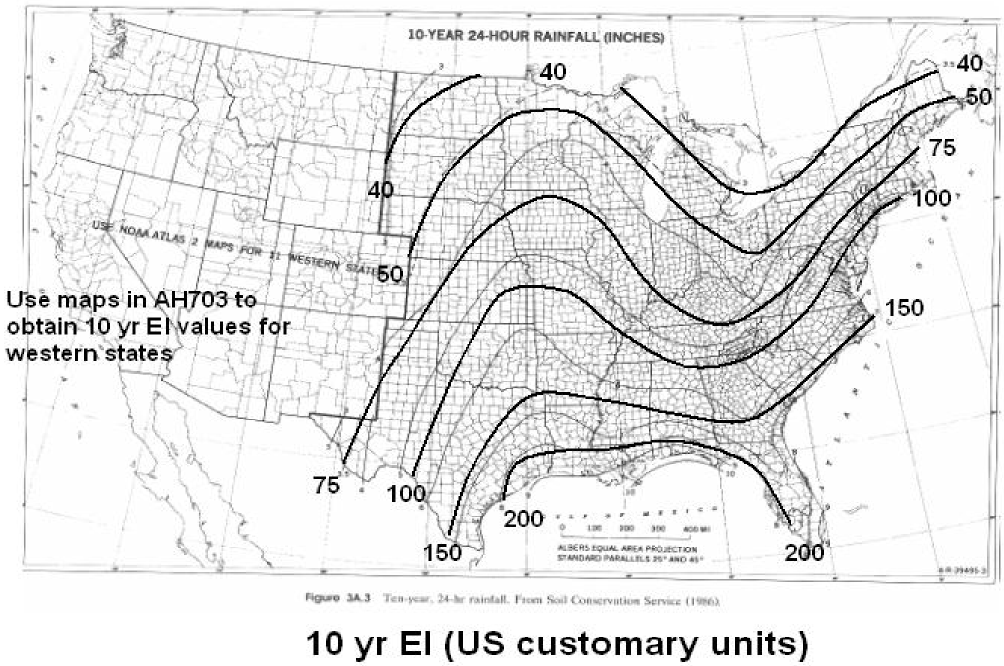

Figure 6.20. 10-year EI values.

6.6. Distribution of Erosivity During the Year

Figure 6.2 illustrates how erosivity density varies temporally by location. Monthly erosivity is computed as the product of erosivity density and precipitation values. Daily erosivity values are computed from the monthly values using the disaggregation procedure discussed in **Section 6.4**. Figure 6.21 illustrates how daily erosivity varies by locations. In central Louisiana, erosivity is nearly the same throughout the year. In contrast, erosivity is very peaked in North Dakota and in eastern Colorado, but the peak occurs at different times of the year. The erosivity density in central Kentucky and New York is similar, but the erosivity tends to be concentrated later in the year in New York than in Kentucky. The climate in northwest California, and other parts of the western continental US, is quite different from that for the eastern US. In this western region of the US, erosivity is highest in the winter months and lowest in the summer months.

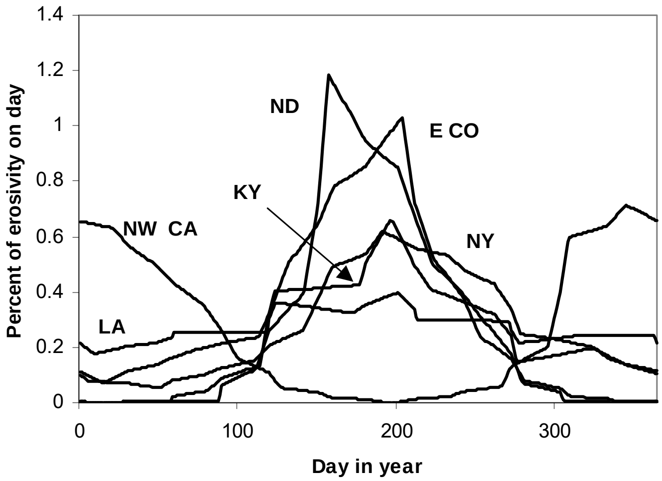

Figure 6.21. Temporal erosivity distribution for several US locations.

The temporal distribution of erosivity significantly affects soil erosion if the soil is exposed during the peak erosivity periods. For example, almost 60% of the annual erosivity in North Dakota occurs in June and July, a period when clean tilled row crops are especially susceptible to erosion because little cover is present. Therefore, on a relative basis, greater erosion occurs with clean tilled crops like corn per unit **annual erosivity R** in North Dakota than in New York because much of the erosivity in New York occurs after a significant canopy cover has developed, leaving the soil less susceptible to erosion. Growing a crop like wheat, rather than corn, that provides the greatest protection during peak erosivity can significantly reduce erosion. Thus, an erosion control practice is to change crops to ones that provide maximum protection during the most erosive period. Similarly, one way to reduce erosion on construction sites is to perform operations that expose the soil at times other than periods of peak erosivity.

6.7. Varying Soil Erodibility with Climate

RUSLE2 varies soil erodibility as a function of monthly precipitation and temperature. This capability is used for all locations and conditions where the standard erosivity relationships are used. However, RUSLE2 does not vary the soil erodibility with climate for the Req zone described in **Section 6.9**. This variation is taken into account in the temporal erosivity distribution used in the Req zone.

6.8. RUSLE2 Reduces Erosivity for Ponding

Intense rainfall on slopes less than about 1 percent steepness causes ponded water that reduces the erosivity of raindrop impact, an effect very important in the Mississippi Delta Region where both precipitation amount and intensity are high. RUSLE2 automatically computes the effect of ponding on erosivity using a cover-management sub-factor (See **Sections 9.1 and 9.2.7**). The reduction is computed as a function of slope steepness and the 10 yr-24 precipitation amount. The 10 yr-24 hr storm captures the effect of a moderately intense and moderately infrequent storm where ponding is most likely to have its greatest effect. In contrast to RUSLE1, RUSLE2 assumes that ponding reduces erosivity on both flat and ridged surfaces. The adjustment for ponding in RUSLE2 cannot be "turned off" as it could in RUSLE1.

6.9. Req Erosivity Relationships

6.9.1. Req Definition, Zones, and Values

The erosion processes in the Northwestern Wheat and Range Region (NWRR),[14] adjacent areas with similar climate, and certain other areas of the western US differ from those in other regions. Erosion from rainfall and/or snowmelt on thawing cropland, construction sites, and other sites of highly disturbed soils in this region is much greater than expected based on standard **R**-values computed according to Equations 6.1 and 6.2. Therefore, equivalent **R**-values, $\mathbf{R_{eq}}$ values, are used to apply **RUSLE2** to these special conditions. In addition, a modified erosivity distribution and special equations for the topographic and cover-managements factors are also used. The Req erosivity distribution is described in this section and the topographic and cover-management relationships are described in **Sections 8 and 9.**

These conditions occur in the Req zones illustrated in Figures 6.22 and 6.23. Northwestern Colorado, southwestern Colorado, southeastern Utah, and northern California are special transitional areas that use different relationships from those in the Req zone. Values for R_{eq} are used instead of standard R-values in the Req zones. Values for Req are computed from annual precipitation as:

$$R_{eq} = 7.86P_a - 50.5 \qquad \textbf{[6.7]}$$

[14]The Northwest Wheat and Range Region (NWRR) includes about 10 million acres of non-irrigated cropland in parts of eastern Washington, north central Oregon, northern Idaho, southeastern Idaho, southwestern Montana, western Wyoming, northwestern Utah, northern California, and other western US regions. Runoff and erosion processes in this area are dominated by winter events. Many of these events involve rainfall and/or snowmelt on thawing soils. The thawing soils remain quite wet above the frost layer and are highly erodible until the frost layer thaws allowing drainage and soil consolidation. The transient frost layer near the surface limits infiltration and creates a super-saturated moisture condition such that almost all rainfall and snowmelt runs off. This condition occurs most intensively on cropland where the soil has been finely tilled and a well defined interface exists between the tilled soil and the untilled soil. In addition, mechanical soil disturbance (tillage in most cases) has mechanically broken the soil matrix into small soil aggregates. This mechanical soil disturbance breaks bond within the soil and greatly reducing its strength under super-saturated thawing conditions. The effect seems less under cropping management systems like no-till and pasture where little mechanical disturbance has occurred or if mechanical disturbance has not occurred for three or more years. Also, the Req region is characterized by frequent periodic, wide swings in temperature above and below freezing during the winter months. Another important feature is the probability of having rainfall during a thaw of the soil surface when the soil has low strength and is highly vulnerable to erosion.

where: R_{eq} = the equivalent erosivity (US units) and P_a = average annual precipitation (in). Equation 6.7 is an empirical equation developed primarily for the Req zone illustrated in Figure 6.22 across eastern Washington into Idaho. Equation 6.7 should not be applied to situations that give an R_{eq} value greater than 200 US erosivity units. Similarly, an R_{eq} value greater than 200 US erosivity units should not be used in RUSLE2. See **Section 6.10** for guidance on applying RUSLE2 to high elevations where Req > 200 US units.

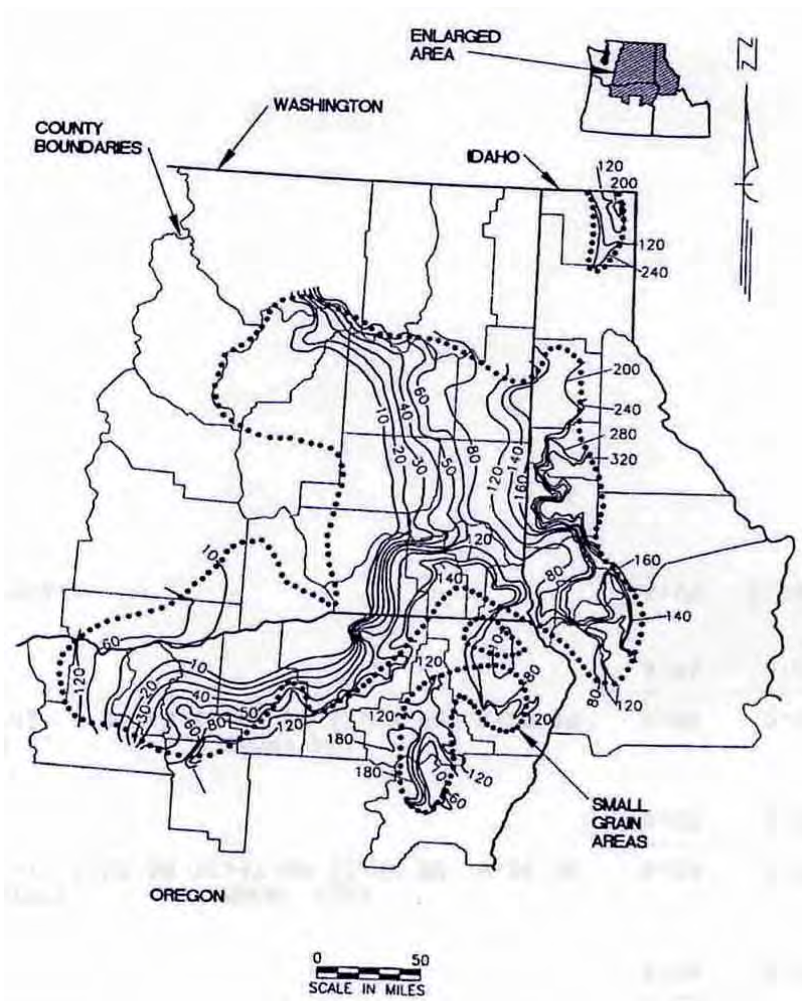

Figure 6.22. Outline of Req zone in Washington, Oregon, and northern Idaho. Only the boundary of area is important. Disregard contour lines.

The Req procedure using equation 6.7 in RUSLE2 can probably be applied to the Req zone illustrated in Figure 6.23. However, the temporal erosivity distribution has to be adjusted to account for differences in temporal precipitation patterns between the Req zones illustrated in Figures 6.22 and 6.23. Also, the Req procedure using equation 6.7 can not be used in the transitional zones in Colorado, Utah, and other areas.

Another consideration in applying the Req approach in the transitional zones is the topographic and cover-management equations. The RUSLE2 equations for the effect of topography and cover-management for the "standard" erosivity regions differs from those for the Req zones.[15] RUSLE2 uses a single set of these equations for the year. That is, RUSLE2 does not apply one set to the winter months when the Req effect occurs and another set to the summer months when the “standard” erosivity effect occurs. This selection of equation is made when the Req choice is made.

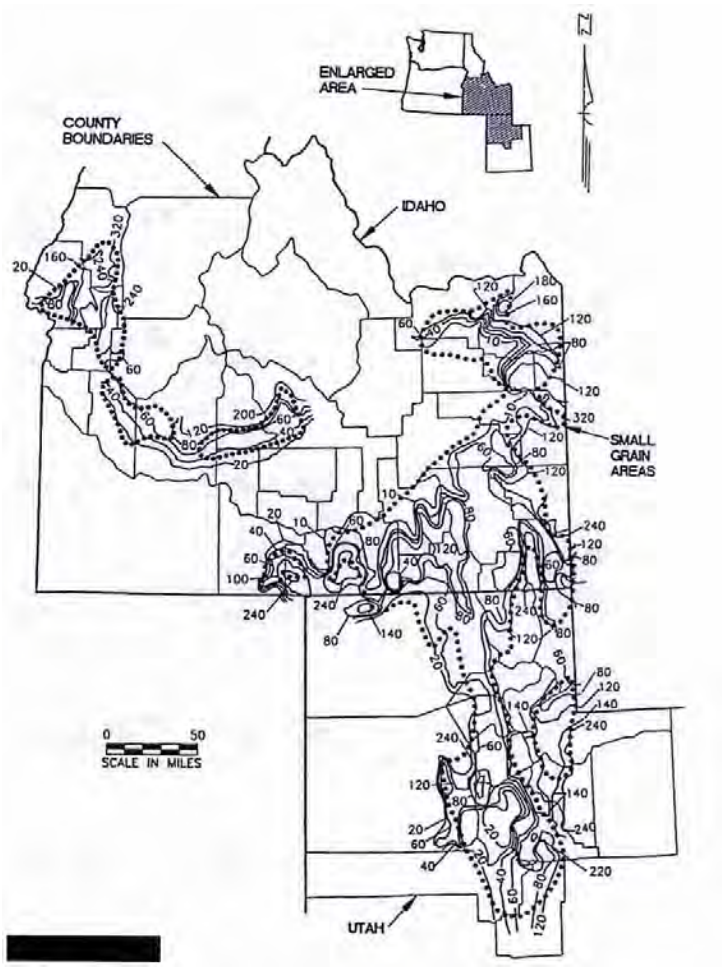

Figure 6.23. Req zone in southern Idaho and northern Utah. Only the boundary of the area is important. Disregard contour lines.

A value for R_{eq} can be entered directly into the RUSLE2 climate database for a particular location, or RUSLE2 can compute it from average annual precipitation using equation 6.7.

At first, the $\mathbf{R_{eq}}$ effect may appear to apply to areas beyond the Req zones illustrated in Figures 6.22 and 6.23 where frozen soils and runoff from snowmelt occurs, such as the northern tier of states in the U.S. However, that region does not experience the repeated freezing and thawing that is characteristic of the Req zone. Instead, the freezing, thawing, and runoff on thawing soils in those areas is limited to about one month instead of occurring repeatedly throughout the winter months as occurs in the Req zones. Research at Morris, Minnesota showed that only about seven percent of the annual erosion at that location is associated with erosion during the spring thaw. The soil is much more susceptible to erosion during the thawing period. That effect is partially considered in the

[15] Req-type effects occur in many locations of the western US. Also, these effects vary greatly within a local region. The Req procedures in RUSLE2 should be used very carefully when used in regions outside of the Req zone illustrated in Figure 6.22. Consult with ARS or NRCS RUSLE2 support personnel for advice on a recent RUSLE2 version to represent Req-type effect.

temporally varying soil erodibility factor **K** for all areas of the US except for the Req region. The Req value and the Req erosivity distribution account for the temporal variation of soil erodibility.

Rainfall and runoff on thawing soil is common to the upper Mid-South, lower Midwest regions, and similar regions of the US that experience repeated freezing and thawing events and where rainfall routinely occurs during the winter. Even though repeated freezing and thawing is experienced, the soil is not super-saturated by a restricting frost layer several millimeters (a few inches) below the soil surface as in the Req zone. The temporally varying soil erodibility factor **K** partially takes into account the increased erosion during freezing and thawing in the non-Req regions. In contrast to the western US, the increased erosion in late winter and early spring is small relative to the total annual erosion. As mentioned above, erosion during this period at Morris, Minnesota, where annual erosivity is low relative to other parts of the eastern US, is only seven percent of the annual soil loss.

6.9.2. Req distribution

A special erosivity distribution is needed for the Req zone to account for the greatly increased erosion that occurs during the winter months. The Req erosivity distribution is shown in figure 6.24 along with the erosivity distribution based on standard erosivity computations. The distribution shown in Figure 6.24 is for the Pullman, WA area where about 87% of the erosion on the unit plot[16] condition occurs during the winter months. This Req distribution is referred to as an 87-13 Req distribution. This distribution can be used throughout the Req zone illustrated in Figure 6.22. A different distribution should be used in the Req zone illustrated in Figure 6.23 and in the transitional Req zones like north and southwestern Colorado, northern

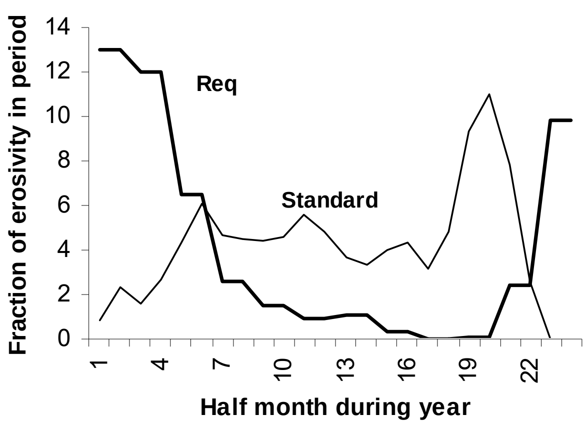

Figure 6.24. 87-13 Req erosivity distribution compared to distribution for standard erosivity at Pullman, WA.

[16] See **Section 7.2** for a definition of unit plot.

California, southeastern Utah, northern Arizona, and northern New Mexico. Less erosivity is concentrated in the winter in these areas. Contact ARS or NRCS personnel for information on Req values and Req erosivity distribution values for these regions.

6.9.3. Should Req Zone be Selected? Yes or No?

Several considerations are necessary in applying RUSLE2 in the Req zone. The first consideration is whether or not to use the Req relationships. Definitely the Req relationships are used for cropland where annual tillage disturbs 100 percent of the soil surface. The Req relationships also apply to certain recently disturbed areas where a well defined soil interface exists just below the soil surface and the upper soil layer is much like a finely tilled cropped soil. However, if the last disturbance occurred more than three years ago, the Req relationships should not be used. Thus, the Req relationships do not apply to undisturbed lands like pasture and rangelands.

Special consideration is required for hay and similar lands where mechanical soil disturbance (cultivation) occurs infrequently. Also, special consideration is required as time elapses after landfill closure or final grading of a reclaimed mine site. Erosion is computed assuming both the Req relationships and the standard erosivity relationships. A soil loss is interpolated between these two values depending on how frequently a mechanical soil disturbance occurs or how much time has elapsed since a disturbance. These same interpolations can be used in the transitional Req zones. RUSLE2 does not make smooth transitions in its computations between Req and standard zones or conditions, which requires professional judgment in applying RUSLE2. These considerations in applying RUSLE2 emphasizes that RUSLE2 is a guide to conservation and erosion control planning.

If the Req relationships, including those for topography and cover, are to be used, answer **Yes** to the question **In Req area?** and **Yes** to the question **Use Req EI distribution**. The standard Req erosivity distribution that is in the RUSLE2 sample database should be used throughout the Req zone illustrated in Figure 6.22. Contact ARS and NRCS personnel regarding Req values and Req distributions for locations outside of the zone illustrated in Figure 6.22.

Answer **Yes** to the question **adjust for soil moisture** when the Req relationships are used in RUSLE2. The amount of moisture in the soil profile during the winter months greatly affects erosion in the Req zone. Certain management practices and crops grown ahead of the winter greatly reduce soil moisture, runoff, and erosion. Answering **Yes** instructs RUSLE to take these effects into account. Answer **No** to the question **Vary soil erodibility with climate** when the Req relationships are used. Answer **Yes** for **varying soil erodibility with climate** when the standard erosivity is used, including all other

The soil moisture relationships are unique to the Req zone and should not be used outside of the Req zone.

areas of the US, including the Western US.

6.10. Applying RUSLE2 at High Elevations in Western US

Special considerations are required when applying RUSLE2 at high elevations in the western continental US. A major consideration involves snow. **If snow is continuously present on the soil surface, RUSLE2 does not apply to those months that the snow cover is present.** RUSLE2 can be applied to the non-winter months by using the standard erosivity relationships and by **turning RUSLE2 off** during the winter period. The way to **turn erosion off** is to use an operation that **adds a non-erodible cover** on the date that the winter period begins and an operation that **removes the non-erodible cover** on the date that the winter period ends. The choice of dates can be based on local observations or long term weather data for snow cover. An alternate approach is to use the date that RUSLE2 computes that the average daily temperature decreases to 1.7 ^{o}C (35 ^{o}F) temperature in late fall or early winter as the beginning date for the non-erdoble winter period. The ending date of the non-erodible winter period date in late winter or early spring is the date that RUSLE2 computes that average daily temperature increases to 7.2 ^{o}C (45 ^{o}F).

Special consideration is required where annual precipitation gives Req values greater than 200 US units. The first factor to consider is whether the Req relationships should be applied to the particular land use. Unless the land use is cropland or a particular type of highly disturbed land condition, the Req relationships probably do not apply. Also, if the precipitation is sufficiently high that a snow cover is present much of the winter and rarely disappears during the winter, the Req relationships do not apply. Even if all of the conditions are met for using the Req relationships but the Req value exceeds 200 US units, RUSLE2 should not be used during the winter months at that location. RUSLE2 is not considered sufficiently accurate to extrapolate it to Req values greater than 200 US units.

A statistical analysis of the erosivity density values showed that erosivity is not a function of elevation. **This statistical result is valid based on the data.** Unexplained variability in the data and the lack of precipitation data at elevations much above 3000 m (10,000 ft) prevent a rigorous testing of the hypothesis that erosivity density does not vary with elevation. This assumption of no elevation effect on erosivity density values is sufficient in the eastern US, but not in the western US during the winter for elevations higher than 3000 m (10,000 ft). The assumption is accepted as valid during the summer months at all locations in the continental US, with the understanding that erosivity is probably being slightly over estimated at elevations above 3000 m (10,000 ft) in the western US.

6.11. Snowmelt Erosivity

RUSLE2 is not designed to estimate erosion caused by snowmelt. The Req relationships do not apply to conditions where snow covers the soil for most of the winter months nor does it estimate the erosion that occurs when the snow melts. RUSLE2 can be **turned off** during the winter period by applying a non-erodible cover at the start of the snow cover and **turned on** after the snowmelt has ended by removing the non-erodible cover using operation descriptions described in **Sections 13.1.9 and 13.1.10.**

However, empirical values that account for snowmelt erosivity can be added to the standard monthly erosivity values to obtain effective monthly erosivity values. These effective monthly erosivity values can be entered in RUSLE2 using the monthly erosivity procedure when the standard topographic and cover-management relationships are being used. An Req value and an appropriate temporal Req erosivity distribution is developed if the Req topographic and cover-management relationships are used. Consult ARS or NRCS personnel for guidance.

7. SOIL DATABASE COMPONENT

This section describes the variables in the **soil database component**, the role of each variable, and how to determine values for key variables. Values for soil erodibility, soil texture, hydrologic soil group, rock cover, and time to soil consolidation are the principal information in the soil database component. These values are available from the local NRCS office in their soil survey database for cropland and similar land uses. These values are also included in the NRCS national RUSLE2 database. Values for most highly disturbed lands like construction sites and reclaimed mined lands must be obtained from on-site determinations.

7.1. Major Soil Variables

The values included in the RUSLE2 **soil database component** are listed in Table 7.1.

Table 7.1. Variables in soil component of RUSLE2 database

Variable	**Symbol**	**Comment**
Soil erodibility factor	K	Obtain from NRCS soil survey for cropland and similar lands; must be determined from on-site measurements for highly disturbed lands; **includes no effect of rock surface cover, but includes effect of rock in soil profile**
Soil texture		USDA soil texture class. If sand, silt, and clay content entered, RUSLE2 assigns appropriate textural class
Sand, silt, clay content		Based on USDA classification; if texture entered, RUSLE2 selects values for sand, silt, and clay % in mid-point of textural class
Hydrologic soil group (undrained)		Index for potential of undrained soil to produce runoff under unit plot conditions; a (lowest runoff potential), B, C, D (highest runoff potential)
Hydrologic soil group (drained)		Index for potential of soil to produce runoff under unit plot conditions with a high performing subsurface drainage system; **hydrologic soil group not automatically an A for drained conditions because soil properties may limit drainage**
Rock cover		Portion of soil surface covered by rock fragments sufficiently large not to be moved by runoff; rock diameter generally must be larger than 10 mm (3/8 inch) to qualify as cover
Calculate time to soil consolidation		Answer **Yes** for RUSLE2 to compute time to soil consolidation
Time to soil		Time for soil erodibility to decrease and level out after a soil

consolidation		mechanical disturbance. Enter a value or have **RUSLE2** compute based on average annual precipitation.
T value	T	Value used as criteria in conservation or erosion control planning; NRCS soil loss tolerance T value is typically used for protecting soil; another value besides T may be used for highly disturbed lands based on local regulatory or other requirements; criteria for sediment yield control depend on off-site conditions affected by sediment delivery

7.2. Basic Principles

Soils vary in their inherent susceptibility to erosion. The soil erodibility **K** factor is a measure of erodibility for the **unit plot** condition. The unit plot is 72.6 ft (22.1 m) long on a 9 percent slope, maintained in continuous fallow, tilled up and down hill periodically to control weeds and break crusts that form on the soil surface. Unit plots are plowed, disked, and harrowed, much like for a clean tilled row crop of corn or soybeans except no crop is grown. The first two to three years of erosion data after a unit plot is established are not used to determine a K value. Time is required for residual effects from previous cover-management to disappear, especially following high production sod, forest conditions with lots of roots and litter, or any condition with high levels of soil biomass. About 10 years of soil loss data are required to obtain an accurate estimate of K. The data record should be sufficiently long to include moderate and large storms.

The K value for a soil is the slope of a straight line passing through the origin for measured erosion data plotted versus storm erosivity as illustrated in Figure 7.1. The equation for this line is:

$$A_u = EI_{30}K \quad \textbf{[7.1]}$$

where: A_u = the soil loss from the unit plot measured for an individual storm and EI_{30} = the erosivity of the storm that produced the storm soil loss. Data from storms less than 12.5 mm (0.5 inch) are not included in the analysis.

The unit plot procedure determines empirical K values for specific soils where the effect of cover-management on soil erodibility has been removed. Not all soils occur where erosion can be measured under unit plot conditions. The equations used by RUSLE2 for topographic and cover-management can be used to adjust measured erosion data to unit plot conditions. These equations are discussed in later sections.

The soil erodibility factor **K** represents the combined effect of susceptibility of soil to detachment, transportability of the sediment, and the amount and rate of runoff per unit rainfall erosivity for unit plot conditions. Fine textured soils high in clay have low **K** values, about 0.05 to 0.15 tons per US erosivity unit, because they are resistant to detachment.[17] Coarse textured soils, such as sandy soils, have low **K** values, about 0.05 to 0.2 tons per US erosivity unit, because of low runoff even though these soils are easily detached. Medium textured soils, such as silt loam soils, have moderate **K** values, about 0.25 to 0.45 tons per US erosivity unit, because they are moderately susceptible to detachment and they produce moderate runoff. Soils having very high silt content are especially susceptible to erosion and have high **K** values. Sediment is easily detached from these soils, which also tend to crust, produce large amounts and rates of runoff, and produce fine sediment that is easily transported. Values of **K** for these soils typically exceed 0.45 tons/acre per US erosivity unit and can be as large as 0.65 tons per US erosivity unit.

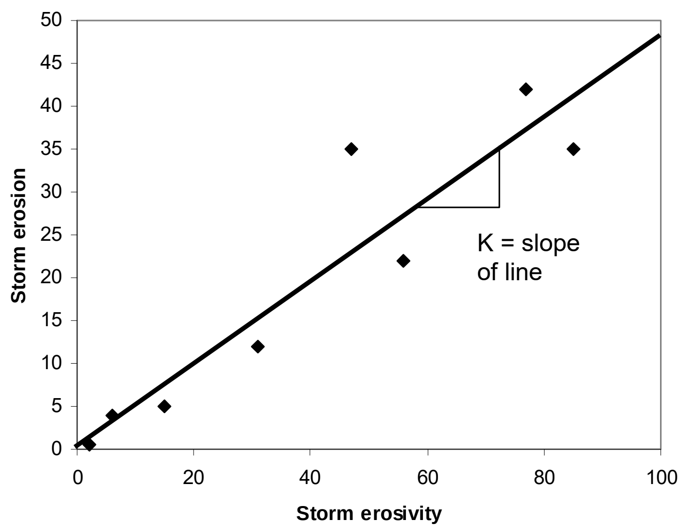

Figure 7.1. Determining a value for the soil erodibility K factor from measured erosion data for unit plot conditions.

The RUSLE2 soil erodibility factor is an **empirical measure** defined by the erosivity variable EI_{30} (product of storm energy and maximum 30 minute intensity) used in RUSLE2. It is not directly related to specific erosion processes, and it is not a soil property like texture. RUSLE2 K values are unique to this definition, and erodibility values based on other erosivity measures, such as runoff, must not be used for K. Values for K are not proportional to erodibility factor values for other erosivity measures. Also, K values may not increase or decrease in the same sequence as other definitions of soil erodibility. For example, the RUSLE2 K value for a sandy soil is low whereas an erodibility factor value based on runoff is high for sand.

---

[17] The R and K factors have units. In this guide, the US customary units for R are hundreds of (ft tons in)/(ac yr hr). The corresponding US customary units on K are tons /[(hundreds of ft tons in)/(ac hr)]. Metric units in the SI system are (MJ mm)/(ha∗h) for erosivity and (t h)/(MJ mm) for erodibility. See AH703 for additional information.

Soil organic matter reduces the K factor value because it produces compounds that bind soil particles and reduce their susceptibility to detachment by raindrop impact and surface runoff. Also, organic matter increases soil aggregation, which increases infiltration and reduces runoff and erosion. Permeability of the soil profile affects **K** because it affects runoff. Soil structure affects **K** because it affects detachment and infiltration. Soil structure refers to the arrangement of soil particles, including primary particles and aggregates, in the soil. Soil mineralogy has a significant effect on **K** for some soils, including subsoils, soils located in the upper Midwest of the US, and volcanic soils in the Tropics.

Many factors affect soil erodibility. Values for the RUSLE2 soil erodibility K factor, which is a measure on inherent soil erodibility, are for unit plot conditions where the effects of management have been removed. These RUSLE2 definitions were also used in the USLE and RUSLE1.

Values for **K** for several "benchmark" soils have been determined from experimental erosion data. Values for **K** can be estimated for other soils by comparing their properties with those of the benchmark soils and assigning K values based on similarities and differences in properties that affect K values. As a part of its soil survey program, the USDA-NRCS has determined K values for cropland and other similar lands where the soil profile has not been disturbed or the soil mixed.[18] RUSLE2 includes two soil erodibility nomographs, discussed in **Section 7.3.2.,** that can be used to estimate K values. See AH703 for additional information on the soil erodibility factor K.[19]

7.3. Selection of Soil Erodibility K Values

7.3.1 From NRCS soil survey

Values for **K** should be selected from the USDA-Natural Resources Conservation Service (NRCS) soil survey for RUSLE2 applications where the soil profile has not been disturbed and mixed. Values for K for both topsoil and subsoil layers are available for most US soils. The greatest detail is for cropland soils and less for rangeland and forestland soils. Values for K are not available for soils on construction sites, landfills, and reclaimed surface mines because of soil mixing and soil-like materials associated

[18] The USDA-NRCS has mapped most US soils on cropland and other land uses where the soil profile has not been disturbed. Soils were mapped as soil map units (names). Descriptions and properties of each soil map unit are published in soil surveys by US county or other survey area. Soils information is available in a computer database and paper form at local USDA-NRCS offices. The soils data required by RUSLE2 have been extracted from the NRCS soil survey database and included in the NRCS national RUSLE2 database.

[19] Renard, K.G., G.R. Foster, G.A. Weesies, D.K. McCool, and D.C. Yoder. 1997. Predicting soil erosion by water: A guide to conservation planning with the Revised Universal Soil Loss Equation (RUSLE). U.S. Dept. of Agriculture, Agriculture Handbook 703, 404 pp. Much of the information in AH703 on soil erodibility applies to RUSLE2, except for the part on temporal variability of K.

with surface mining. The RUSLE2 modified soil erodibility nomograph can be used to estimate K values for these soils.

Make sure that K values extracted from the NRCS soil survey are the ones where no adjustment has been made for rock on the soil surface and where the effect of rock in the soil profile has been considered.

Multiple K values for a given soil mapping unit are given in the NRCS soil survey database. Select the K value where no adjustment has been made for rock fragments on the soil surface. Using a K value that has been adjusted for surface rock fragments can cause a major error in RUSLE2 erosion estimates. RUSLE2 uses a single composite ground cover that takes into account overlap of rock by crop residue and plant litter. The RUSLE2 mathematical relationships used to compute the effect of ground cover on erosion are nonlinear. Treating each ground cover individually causes errors because of this nonlinearity.

7.3.2. Estimating K values with the RUSLE2 soil erodibility nomographs

7.3.2.1. Background on nomographs.

RUSLE2 includes two soil erodibility nomographs that can be used to estimate soil erodibility K factor values. One nomograph is the **standard nomograph** described in AH703.[20] This nomograph is used to estimate soil erodibility values for cropland and similar soils where the soil profile has not been disturbed. The other nomograph is the **RUSLE2 modified nomograph**. This nomograph is used to estimate soil erodibility K factor values for highly disturbed lands where the soil profile has been disturbed and the soil mixed.

The difference between the standard and the modified soil erodibility nomographs is in the structure effect. The standard nomograph gives K values that decrease as structure changes from a blocky, platy structure to a granular structure. This trend is inconsistent with accepted science on how erosion varies with soil structure. The standard nomograph was derived from about 55 soils, primarily in Indiana, that were mostly medium textured soils without a wide, uniform sample of soil textures and soil structures. The result is that K values from the standard erodibility nomograph are too high for very high clay soils and too low for very high silt soils. The **standard nomograph** is satisfactory for most cropland soils.

---

[20] For background information, see Wischmeier, W.H., C.B. Johnson, and B.V. Cross. 1971. A soil erodibility monograph for farmland and construction sites. J. Soil Water Conservation. 26:189-193. However, information provided in this RUSLE2 User Guide determines the RUSLE2 application of the nomograph rather than information from other sources.

The **RUSLE2 modified soil erodibility nomograph** should be used to estimate K factor values for highly disturbed lands like constructions sites, landfills, military training sites, and reclaimed mined land. The RUSLE2 modified nomograph gives more credit to the effect of soil structure than does the standard nomograph. The RUSLE2 modified soil erodibility nomograph is exactly the same as the standard nomograph except that the equation for soil structure has been reversed. The two nomographs give the same K values for a moderate to coarse granular soil structure.

AH703 lists equations for estimating K factor values for special cases. Those equations were not included in RUSLE2 because some input values can not be obtained easily or K values computed by some of the equations seemed questionable. Carefully examine those equations and review original source materials before using values from those equations in RUSLE2.

7.3.2.2. Nomograph inputs.

The inputs for both the **RUSLE2 modified** and the **standard** soil erodibility nomographs are the same. Therefore, the single set of inputs listed in Table 7.2 applies to both nomographs. The definitions and variable descriptions used in the nomograph must be carefully followed.[21]

Table 7.2. Variables used in RUSLE2 soil erodibility nomographs

Variable	**Symbol**	**Comment**
Sand content		Based on mass (weight), proportion of the total for the clay, silt, and sand, 0.050 mm < sand dia ≤ 2.0 mm
Silt+very fine sand content		Based on mass (weight), proportion of the total for the clay, silt, and sand, 0.002 mm < silt dia ≤ 0.050 mm, 0.050 mm < very fine sand dia ≤ 0.10 mm; RUSLE2 can estimate very fine sand content.
Inherent organic matter content		Based on mass (weight), proportion of the total clay, silt, sand, and organic matter; **organic matter content is for unit plot conditions; do not use organic matter content in nomograph to reflect management different from the unit plot conditions.**
Structure class		Arrangement of primary particles and aggregates in soil
Permeability class		Used to indicate runoff potential under unit plot conditions. Represents the entire soil profile, not just soil surface layer. Should not be determined from a pereameter measurement.
Is		Select **Yes** and RUSLE2 assumes that the permeability class

[21] See the USDA-NRCS soil survey manual for a description of the terms used in the soil erodibility nomograph and procedures for determining values for the nomograph variables. This manual is available on the NRCS Internet site www.nrcs.usda.gov.

permeability with coarse fragments present		has been chosen giving consideration to rock in the soil profile. **Strongly recommend selecting permeability based on professional judgment rather than allowing RUSLE2 to adjust for rocks in soil profile.** Select **No** and RUSLE2 will adjust the permeability class for rock in the soil profile. This adjustment does not apply to soils with large rock fragments like mined land.
Coarse fragment content		Based on mass (weight) proportion of total soil made up of rock fragments > 3 in (75 mm) diameter

7.3.2.3. Special nomograph considerations.

Organic matter content is a major variable in the soil erodibility nomographs. **The input value for this variable is the organic matter content of the soil in the unit plot condition after previous land use effects have disappeared.** RUSLE2 has an upper limit of 4% for this organic matter content input. Applying animal manure, plowing under "green" manure, improving residue management, and other management practices that add biomass significantly reduce erosion. **RUSLE2 considers this important effect using equations for cover-management effects rather than the soil erodibility factor.** The soil erodibility factor is for a base condition where the effects of management have been removed.[22]

Adjusting K to account for organic matter as influenced by land use is double accounting and is a misuse of RUSLE2. Similarly, the permeability class in the soil erodibility nomographs is not adjusted to represent how cover-management and support practices affect runoff.

The permeability effect in the nomographs is based on how the **entire soil profile** affects runoff for unit plot conditions. The input permeability code **should not** be based only on the upper 4 inches (100 mm) to 6 inches (150 mm) of soil. Permeability tests on soil samples from this layer should not be the sole basis for determining the permeability input to the nomographs. The input permeability code entered in the nomograph should take into account how restricting layers, such as a rock, fragipan, caliche, or clay layer, below the soil surface affect runoff. The input permeability code should also reflect how

[22] Considering how land use affects organic matter and soil erosion by adjusting the organic matter input in the soil erodibility nomographs to compute K values seems possible because the nomographs include an organic matter variable. However, the erodibility nomographs must not be used for this purpose. RUSLE2 is an empirical equation based on certain definitions that must be carefully followed. Adjusting K to account for the effect of cover and management on organic matter and runoff is inconsistent with RUSLE2 definitions, structure, and equations.

restricting layers, such as a plow pan or a dense compacted layer created by construction traffic, if these layers that are not routinely broken up by ordinary tillage or other soil distributing operations. RUSLE2 takes into account how subsoiling affects erosion by breaking up these layers.

Values computed with the RUSLE2 soil erodibility nomographs apply to a central, base location, which is Columbia, Missouri.[23] Soil erodibility K factor values vary by location even when soil properties are exactly the same between locations. The K factor values are higher (or lower) at those locations where rainfall amount and frequency and other factors caused increased (or decreased) runoff per unit rainfall in relation to climatic conditions at Columbia, Missouri. This effect is taken in account by computing temporal soil erodibility factor values that are referenced to the climate at Columbia, Missouri (see **Section 7.4**)

The K factor values computed by the RUSLE2 nomographs are solely a function of soil properties. Theoretically, these K values should be increased or decreased as the ratio of runoff to rainfall varies by location. Although, this adjustment is seldom made, RUSLE2 takes the effect into account in its computation of temporal soil erodibility values.

The soil erodibility nomograph does not apply to soils of volcanic origin, organic soils such as peat, Oxisols, low activity clay soils, calcareous soils, and soils high in mica. Also, the nomograph is less accurate for subsoils than for topsoils. Professional judgment is used to assign K values for those soils. Contact the NRCS State Soil Scientist in your state for assistance.

7.4. Temporal Variability in K

Soil erodibility K factor values vary during the year. The values tend to be high during and immediately following thawing and other periods when the soil is wet. The values tend to be low when soil moisture and runoff is low because of increased soil evaporation caused by high temperatures. The input K value is a base value that is assumed to represent an average value during the "frost free" period, which is defined as the time that the temperature is above 4.4 ^{o}C (40 ^{o}F). Temporal soil erodibility values computed by RUSLE2 are shown in Figure 7.2 for Columbia, Missouri; St. Paul, Minnesota; Birmingham, Alabama; and Tombstone, Arizona.

---

[23] Columbia, Missouri is used as a base location in both RUSLE1 and RUSLE2. USLE values for slope length and steepness effect, soil loss ratio, and support practice factors are assumed to apply at Columbia, MO. RUSLE2 adjusts its values for these factors about the Columbia, MO base values. The weather at Columbia, Missouri is near the "middle" of the data for the Eastern US.

RUSLE2 computes the ratio of daily **K** values to the base K value as a function of the ratio of daily temperature to the base average frost free temperature at Columbia, Missouri and the ratio of daily precipitation to the base average frost free precipitation at Columbia, Missouri. The ratio of daily K to base K increases as the ratio of daily precipitation to base average frost free precipitation increases. This effect represents the increased runoff per unit precipitation caused by increased soil moisture during high precipitation periods. The ratio of daily K to base K decreases as the ratio of daily temperature to base average frost free temperature increases. This effect represents decreased runoff per unit precipitation because of decreased soil moisture on the unit plot conditions during periods when soil evaporation is high. The relative effect of precipitation is greater than that of temperature in these computations. The effect of cover-management on soil erodibility is computed using equations described in **Sections 7 and 9** for cover-management effects.

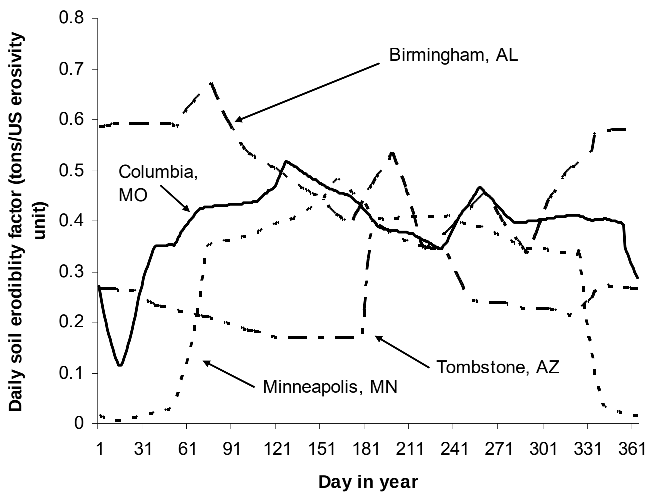

Figure 7.2. Temporal soil erodibility factor values. Base K is 0.42 US units.

When temperature decreases below -1.1 °C (30 °F), RUSLE2 reduces K values exponentially as a function of temperature until the K factor value becomes very close to zero at a temperature of -9.4 °C (15 °F). The very low K values for Minneapolis, Minnesota during the winter months represent frozen soil that is nonerodible. The same effect is seen for Columbia, Missouri where K values are partially reduced during the winter.

RUSLE2 does not represent increased erodibility during and immediately after the thawing period. The observed data are too few to empirically determine a relationship for this period. Also, the increased erosion during this period is small relative to the total annual erosion for the eastern US. For example, research measurements at Morris, Minnesota showed that erosion during this period was less than 7% of the total annual erosion. This percentage decreases for locations further south. However, the increased erodibility during this period is important in southwestern Colorado, Southeastern Utah, and similar locations in the western US where annual erosivity is low. The relative contribution of the erosion during and immediately after the thawing period is much greater in the western US than in the eastern US. Adjustments can be made in the monthly erosivity values to account for the increased erosion during this period. See **Sections 6.9 and 6.10**.

The peak in erodibility values for Birmingham, AL in March results from increased rainfall, not from the thawing effect. The main influence of temperature on temporally varying K values is in late summer when increased temperature increases soil evaporation and reduces runoff and erosion. The peak erodibility occurs during the summer for Tombstone, AZ because most of the annual rainfall at this location occurs during this period.

As described in Section 7.3.2.3, the RUSLE2 soil erodibility nomographs computes soil erodibility values solely as a function of soil properties. These nomographs do not take into account how soil erodibility factor values are increased in wet locations such as Birmingham, Alabama and are decreased in dry locations such as Tombstone, Arizona. The temporal soil erodibility equations used in RUSLE2 take this effect into account. For example, Figure 7.2 illustrates how the annual average soil erodibility value is much lower at Tombstone than at Birmingham even though the base soil erodibility factor value computed with a RUSLE2 soil erodibility nomograph is the same at both locations.

A constant erodibility value that does not vary during the year can be used in RUSLE2 by answering **No** to the question **Vary erodibility with climate** in the Climate database component. Assuming that soil erodibility varies temporally is recommended for all areas except the Req zones because the Req procedure captures the increased erodibility during the winter in these regions (See **Section 6.9**). The fit of the equation that computes temporal soil erodibility K factor values is weak, and statistically the hypothesis that soil erodibility does not vary with time can not be rejected.[24]

In contrast to RUSLE1 where the time varying soil erodibility relationships were not used in the Western US, the temporally varying erodibility relationships should be used in the Western US for RUSLE2, except in Req applications.

7.5. Soil Texture

Soil texture is the distribution of the primary particles of sand, silt, and clay in the soil. RUSLE2 uses values for sand, silt, and clay fractions to compute soil erodibility, the

[24] A major difference between RUSLE2 and RUSLE1 is in the temporal soil erodibility computations. The differences in erosion between the models can be as large as 25% in the central Midwest and in the New England regions because of the difference in erodibility computations. The RUSLE1 equations (See AH703) were heavily influenced by data from the Morris, MN and Holly Springs, MS locations. While the relationship for temporal erodibility was well defined at these locations, it was not well defined at eight other locations. Given the overall data, a new temporal erodibility relationship was developed for RUSLE2. The current recommendation is that a constant K value be used in RUSLE1.

distribution of the sediment particle classes at the point of detachment, and the diameter of the small and large aggregate particle classes. See **Section 7.5** for a description of the RUSLE2 sediment classes used.

The fractions for soil texture are based on mass (weight) of the total of these three primary particle classes. The sizes of these classes, which are based on the USDA classification, are given in Table 7.3. Refer to the USDA-NRCS soil survey manual for procedures to determine soil texture from soil samples.[25] These procedures involve dispersing a soil sample to breakup soil aggregates into their constituent primary particles. Sieves are typically used to determine the size distribution of the sand classes and the total sand content. Sieves are screens having various sized openings that sort particles by size. A hydrometer or pipette is typically used to determine clay content. This technique is based on fall velocity. Strongly aggregated soils, including some Tropic soils of volcanic origin, may be difficult to disperse and require special procedures. Silt content is 1.0 minus the clay and sand contents.

Table 7.3. Diameter of primary particle classes. Based on USDA classification.

Primary particle class	**Diameter (mm)**
Clay	dia ≤ 0.002
Silt	0.002 < dia ≤ 0.05
Sand	0.05 < dia ≤ 2
Very fine sand	0.05 < dia <0.1
Fine sand	0.1 ≤ dia < 0.5
Coarse sand	0.5 < dia < 1
Very coarse sand	1 ≤ dia < 2

Primary particles are the smallest, discrete mineral soil particles. Obviously, aggregates are larger than the primary particles that form them. The density of aggregates is less than the density of primary particles because of open space within aggregates. This open space can be partially filled with water, and the rate that pore space becomes filled (rate of soil wetting) greatly affects aggregate stability, soil erodibility, and sediment aggregate size. Rapid wetting significantly reduces aggregate stability and increases soil erodibility. Difference in rate of soil wetting is partially why erosion varies greatly between similar storms.

RUSLE2 input values for sand, silt, and clay content (soil texture) are for the upper soil layer susceptible to erosion. This layer is usually assumed to be 4 inches (100 mm) thick depending on the degree and depth of rill erosion. Soil texture values in the NRCS soil survey database can be used as input in RUSLE2 without processing soil samples from the site **provided the soil profile has not been disturbed and soil mixing has not occurred.** The site is located on a soil survey map to identify the soil map unit at the site. Texture values for that soil map unit are given in the NRCS soil survey database.

If the soil profile has been disturbed and the soils mixed, such as at a construction site or reclaimed mine, soil samples from the site must be processed to determine RUSLE2 soil input values.

[25] Soil Survey Manual available on the Internet site www.ftw.nrcs.usda.gov/tech_ref.

RUSLE2 assigns the appropriate textural class when values are entered for sand, silt, and clay content.

If the sand, silt, and clay content is not known, select the soil textural class as the RUSLE2 input if it is known or can be determined by professional judgment such as from feel of the soil. RUSLE2 assigns central values for sand, silt, and clay content for the input textural class based on the textural triangle. The values assigned by RUSLE2 are shown in Table 7.4.

Sometimes the sand, silt, and clay of a soil are known, but the very fine sand content is not known. RUSLE2 can estimate the very fine sand content using the equation:

$$f_{vfsandt} = 0.74 f_{sand} - 0.62 f_{sand}^{2} \quad [7.2]$$

where: $f_{vfsandt}$ = the fraction of the total primary particles (sand+silt+sand) that is composed of very fine sand and f_{sand} = the fraction of the primary particles that is sand. This equation was derived by regression analysis using data in the NRCS soil survey database for Lancaster County in southeastern Nebraska.

7.6. Sediment Characteristics at the Point of Detachment

RUSLE2 uses values for sediment characteristics to compute deposition. Values used to describe sediment can be computed by RUSLE2, which is the recommended approach, or values can be user entered to create a custom sediment distribution.

.

7.6.1. RUSLE2 computes sediment characteristics

Rill and interrill erosion produces sediment that is a mixture of primary particles and aggregates. RUSLE2 uses the five particle classes of primary clay, primary silt, small aggregate, large aggregate, and primary sand to represent sediment. The sediment distribution for many soils has two peaks, one in the silt size range and one in the sand size range. Comparison of sediment size distributions before and after dispersion shows that much of the sediment in these peaks is aggregates. The two aggregate classes represent this sediment. The primary clay, silt, and sand classes represent the sediment that is eroded as primary particles.

RUSLE2 computes the distribution of these five particle classes and the diameters of the small and large aggregate classes at the point of detachment as a function of soil texture.[26]

[26] The equations used by RUSLE2 are described by Foster, G.R., R.A. Young, and W.H. Neibling. 1985. Sediment composition for nonpoint source pollution analyses. Trans. ASAE 28(1):133-139, 146.

Cover-management also affects sediment characteristics. Increased soil biomass increases the fraction of the sediment composed of aggregates and the size of the aggregates. However, sufficient experimental data are not available to derive equations to describe how cover-management affects sediment characteristics.

In general, the fractions and diameters for the aggregate classes increase as the soil's clay content increases. Clay is assumed to be a binding agent that increases aggregation. .

Table 7.4. Sand, silt, and clay contents assigned for a textural class. Based on USDA classification.

Textural class	**Sand (%)**	**Silt (%)**	**Clay (%)**
Clay	20	20	60
Clay loam	33	33	34
Loam	41	41	18
Loamy sand	82	12	6
Sand	90	6	4
Sandy clay	51	5	44
Sandy clay loam	60	13	27
Sandy loam	65	25	10
Silt	8	87	5
Silt loam	20	65	15
Silty clay	6	47	47
Silty clay loam	10	56	34

Table 7.5. Characteristics of sediment classes assume

Sediment class	**Density (specific gravity)**	**Diameter (mm)**	
Primary clay	2.6	0.002	Fraction = 0.2
Primary silt	2.65	0.01	Fraction strong
Small aggregate	1.8	0.03 to 0.1	Fraction and d
Large aggregate	1.6	0.3 to 2	Fraction and d
Primary sand	2.65	0.2	Fraction strong

Values assumed by RUSLE2 for each sediment class are listed in Table 7.5. Fall velocity V_f of each sediment class is used in equation 5.2 to represent sediment "depositability." Fall velocity is a function of diameter and density of the sediment particles. RUSLE2 computes fall velocity using Stokes law for the small particle classes and standard drag relationships for the large particle classes assuming that the sediment particles are spheres.

Table 7.6. Sediment characteristics for a silt loam soil (20% sand, 60% silt, 20% clay) at detachment and (0% sand, 56% silt, 44% clay) after deposition by a dense grass strip on the lower 10% of slope length.

Sediment class	Diameter (mm)	% at detachment	% after deposition
Primary clay	0.002	5	43
Primary silt	0.01	24	54
Small aggregate	0.03	36	3
Large aggregate	0.4	28	0
Primary sand	0.2	7	0

Deposition enriches the sediment load in fines, which RUSLE2 computes as illustrated in Table 7.6. Deposition changes the distribution of the sediment classes from that at the point of detachment. RUSLE2 also computes the sand, silt, and clay content in the sediment leaving the RUSLE2 hillslope profile. RUSLE2 computed that the fraction of primary clay sediment class leaving the grass filter strip after deposition is 43% in comparison to 5% at the point of detachment in the example illustrated in Table 7.6. Also, the total clay content in the sediment was 44% versus 20% in soil surface layer.

RUSLE2 assumes that small aggregates are composed of clay and silt primary particles and that large aggregates are composed of clay, silt, and sand primary particles. RUSLE2 computes the distribution of these particles in each aggregate class as a function of soil texture. RUSLE2 also computes an enrichment ratio as specific surface area of the sediment at the lower end of the last RUSLE2 element divided by the specific surface area of the sediment at the point of detachment. The enrichment ratio for the Table 7.6 example is 1.9, which means that the specific surface area of the sediment is almost twice that of the soil. The specific surface areas assumed in RUSLE2 for primary particles are 20 m^2/g for clay, 4 m^2/g for silt, and 0.05 m^2/g for sand. Specific surface area indicates the relative importance of each primary particle class as a binding agent and for transporting soil-absorbed chemicals. The specific surface area of each aggregate class depends on the composition of primary particles.

7.6.2. User entered values.

Although the RUSLE2 names assigned the five sediment classes are arbitrary, the names of the classes and the number of classes can not be changed. However, values for fraction, diameter, and density assigned to each class can be user overwritten to create a custom sediment description. RUSLE2 does not properly compute enrichment if these values are manually overwritten.

7.7. Rock Cover

Rock cover on the soil surface acts as ground cover and reduces erosion much like plant litter, crop residue, and applied mulch, except that rock does not decompose and add biomass to the soil. RUSLE2 combines rock cover with other ground cover to obtain a single composite ground cover value, taking into account the overlap of plant and applied materials on the rock cover. This single ground cover value is used in the equations that compute cover-management effects on erosion (See **Section 9.2.2**.). This overlap of cover is the reason that values for rock cover and other ground cover cannot be added to obtain the total cover. Also, the effects of rock and other ground cover cannot be computed separately and then combined to determine the total ground cover effect because of the nonlinearity in the equation used to compute the ground cover effect on erosion.

The nonlinearity in the equations used to compute the ground cover effect is the reason that a K factor value cannot be used in RUSLE2 where an adjustment has already been made for rock cover.

RUSLE2 handles "rock cover" entered as a soil input differently than ground cover added through a cover-management input. The soil input rock cover remains constant through time, is not buried, and does not decompose. The rock cover variable can also be used to represent mosses, which provide substantial ground cover on rangelands, and other types of ground cover that can be assumed remain constant through time.

See Section 12 for special considerations needed when a mechanical soil disturbance is used to bury rock or other material that does not decompose.

The soil rock cover input is a site-specific entry based on field measurements. The same technique used to measure other ground cover like plant litter and crop residue can be used to measure rock cover.[27] To be counted as ground cover, rock must be sufficiently large not be moved by raindrop impact or surface runoff. The minimum rock size that is measured is site specific, but as a guideline, the minimum rock size is 10 mm (3/8 inch) diameter except on coarse texture rangeland soils where the minimum size is 5 mm (3/16 inch).

[27] A typical procedure used to measure ground cover is to lay a line transect, such as a knotted string or measuring tape, across the soil surface diagonal to any cover orientation. An estimate of ground cover is the percentage of knots or markings on a tape that contact ground cover. Another approach is to photograph the surface, lay a grid over the photograph, and count the intersection points that touch ground cover.

Do not use rock cover values or rock content in the soil profile from the NRCS soil survey database to determine rock cover. The definitions of rock cover in that database do not correspond with RUSLE2 definitions.

The appropriate time to measure rock cover is during the 1/4 to 1/3 period of the year or crop rotation when the hillslope is most susceptible to erosion. Measure rock cover on cultivated land after rainfall has exposed the rock so that the rock and its influence can be readily seen.

7.8. Hydrologic Soil Group

Hydrologic soil group is an index of the runoff potential of the soil under unit plot conditions. These designations are A (lowest potential), B, C, and D (highest potential). **RUSLE2** uses the hydrologic soil designation in the NRCS curve number method to compute runoff. Hydrologic soil group designations are available by map unit and component in the NRCS soil survey database. The USDA-NRCS hydrology manual provides information on assigning hydrologic soil group designations for those soils not included in the NRCS soil survey.[28] The soils with the lowest runoff potential, such as deep sandy soils, are assigned an A hydrologic soil group. The soils where almost all of the rainfall becomes runoff are assigned a D hydrologic soil group. Examples of hydrologic group D soils include high clay soils and silt soils that readily crust causing significantly reduced infiltration. Soils having a restrictive layer like a fragipan, rock, plow pan, or traffic pan near the soil surface also are assigned a D hydrologic soil group.

RUSLE2 uses the hydrologic soil group designations for drained and undrained conditions to compute the soil loss reduction caused by tile and other drainage practices. The equation used in the soil erodibility nomographs for the effect of permeability on soil erodibility are used to compute the effect of drainage on erosion. The four hydrologic soil groups are scaled over the six permeability classes so that a hydrologic soil group designation can be converted to a permeability class to use the erodibility nomograph equation.[29]

Two hydrologic soil group designations are entered for a soil. One is for the **undrained** condition and one for the **drained** conditions. Runoff potential can be high because of a perched water table or the soil occupying a low-lying position on the hillslope even though soil properties would indicate a low runoff potential. Artificially draining these

---

[28] Contact the NRCS Internet site at www.nrcs.usda.gov for additional information

[29] Although hydrologic soil group and the permeability class are directly related, RUSLE2 requires separate inputs for these two variables. Therefore, the user needs to ensure that the inputs for these variables are consistent when one of the nomograph is used to compute a K value.

soil with deep parallel ditches or buried tile lines can greatly increase internal drainage and reduce surface runoff and erosion.

The hydrologic soil group assigned for the drained condition represents runoff potential under drained conditions based on soil properties and assuming a high performance drainage system. A drained soil does not imply that an A hydrologic soil group should be assigned. For example, a drained sandy soil might be assigned an A hydrologic soil group whereas a drained clay soil might be assigned a C hydrologic soil group because the clay limits internal drainage and infiltration.

7.9. Time to Soil Consolidation

RUSLE2 assumes that the soil is 2.2 times as erodible immediately after a mechanical disturbance than after the soil has become "fully consolidated."[30] Erosion decreases with time and "levels out" as illustrated in Figure 7.3. A double exponential decay curve is used to describe this decrease in erodibility. The equation used in RUSLE2 for this curve was derived from erosion data at Zanesville, OH that were collected over time after tillage stopped on a fallow plot. The time required for the erosion rate to "level out" after a mechanical disturbance is the **time to soil consolidation**. Erodibility of a fully "consolidated" soil is 45 percent of that immediately after mechanical disturbance. The time to consolidation is at the time when 95 percent of the decrease in erodibility has occurred.[31]

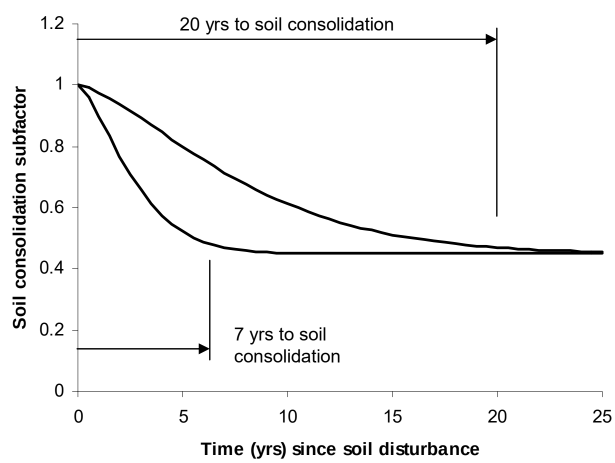

Figure 7.3.Effect of time on decrease in soil erodibility following a mechanical disturbance.

This decrease in erodibility occurs because of soil wetting and drying and biological soil activity. RUSLE2 assumes seven years for the **time to soil consolidation,** but another value can be entered. Also, RUSLE2 can compute the time to soil consolidation based on average annual precipitation as describe below.

---

[30] Soil consolidation does not refer to the physical process of the bulk density of the soil increasing over time. Instead, it refers to a change in erodibility over time.

31 The 95 percent is used rather than 100 percent because the equation from is such that an infinitely long time is required for the computed values to actually reach the fully consolidated condition.

Time to soil consolidation is a function of soil properties. However, insufficient data are available to derive a relationship between soil properties and time to soil consolidation and soil properties and the degree of soil consolidation. The degree of soil consolidation (i.e., the increase in erodibility because of a mechanical disturbance, is less for a high sand soil than for a high clay soil. Also, the relative effect of mechanical disturbance seems to be greater for rill erosion than for interrill erosion.

Answering **Yes** to the question, **Calculate time to consolidation from precipitation**, causes RUSLE2 to compute a **time to soil consolidation** that is a function of average annual precipitation. RUSLE2 assumes seven years for the **time to soil consolidation** where average precipitation exceeds 30 inches (760 mm) and computes a **time to soil consolidation** that increases to 20 years in the driest areas of the Western US, as illustrated in Figure 7.3. The time to soil consolidation increases linearly from 7 years to 20 years between as average annual precipitation decreases from 30 inches (760 mm) to 10 inches (250 mm). A value of 20 years for time to soil consolidation is assumed for average annual precipitation less than 10 inches (250 mm). This increased time to soil consolidation reflects how the effects of a mechanical soil disturbance persist longer in low precipitation areas where reduced water is available and less frequent wetting and drying cycles occurs.

7.10. Soil Loss Tolerance (T)

The objective in conservation and erosion control planning is to control average annual erosion to an acceptable level.

7.10.1. Purpose of "T-value" input

The "T-value" in the RUSLE2 soil database component is the acceptable average annual rill-interrill erosion rate for a particular situation. RUSLE2 is used to identify erosion control practices that give estimated rill-interrill erosion equal to or less than the "T-value" assumed in the particular conservation planning application. In many cases, the T-value used in conservation planning will the NRCS-assigned soil loss tolerance value.

The "T-value" varies with the situation. For example, the "T-value" can be increased from the standard soil loss tolerance T-value for construction sites where the soil is exposed to erosion for a relatively short time. The standard soil loss tolerance T-value is used for cropland where long term productivity must be maintained or landfills where the buried waste must be protected from exposure by erosion over hundreds of years. An especially low "T-value" may be required to control off-site sediment delivery to protect a sensitive downstream resource such as a fish habitat. In many RUSLE2 applications, the "T-value" is determined by applicable government program or regulations.

The "T-value" entered in the RUSLE2 soil database component should be appropriate for the particular application.

Rather than reducing erosion to an absolute "T-value," the erosion control objective in some applications is to reduce erosion by a certain percentage relative to a base condition. Although a "T-value" is not needed in those applications, a nonzero "T-value" must be entered so that RUSLE2 can compute the ratio of segment erosion to the "T-value" adjusted for slope position, as discussed below.

7.10.2. NRCS-assigned soil loss tolerance values

Soil loss tolerance values assigned to each soil map unit by NRCS as a part of its soil survey program are often entered in RUSLE2 as the "T-value." Soil loss tolerance values range from 1 tons/acre (2 t/ha) per year to 5 tons/acre (11 t/ha) per year based primarily on how erosion is judged to harm the soil and to cause other damage. Shallow and fragile soils that can not be easily reclaimed after serious erosion are assigned low soil loss tolerances values. Limiting erosion rate to soil loss tolerance protects the soil as a natural resource and maintains the soil's long term productive capacity. Soil loss tolerance values consider the damages caused by erosion and the benefits of soil conservation. Also, soil loss tolerance values include a socio-economic element by considering the availability of reasonable and profitable erosion control technology.[32]

Although soil loss tolerance values were principally developed for cropland soils, soil loss tolerance values are also used for erosion control planning for reclaimed surface mines, landfills, and military training sites. Applying mulch controls erosion and promotes seed germination and early growth of vegetation. Erosion control facilitates establishing and maintaining vegetation, which is essential to long term site protection and similar to cropland requirements. Reclaimed land regulations require that excessive rill erosion be prevented. A rule of thumb is that rill erosion begins when soil loss for the eroding portion of the overland flow path exceeds about 7 tons/acre (15 t/ha) per year. A major concern on waste disposal sites is that buried waste not be exposed by rill erosion. Controlling soil loss to less than 5 tons/acre (11 t/ha) per year significantly reduces the likelihood of rill erosion. A well designed surface runoff collection system in addition to the rill and interrill erosion control practice is also required to prevent incised gully erosion.

Soil loss tolerance values are primarily for protecting the soil as a natural resource and not for protecting offsite resources from excessive sedimentation or water quality degradation. The criteria for controlling sediment yield from a site should be based on potential off-site sediment damages.

---

[32] The factors considered in assigning soil loss tolerance values are discussed by Toy, T.J., G.R. Foster, and K.G. Renard. 2002. Soil Erosion: Processes, Prediction, Measurement, and Control. John Wiley and Son, New York, NY. The definition for soil loss tolerance given in AH537 implies that erosion can occur indefinitely at soil loss tolerance even though soil loss tolerance values exceed soil formation rates by about a factor of ten.

7.10.3. Taking hillslope position into account

A uniform slope for the **eroding portion** of the overland flow path is usually assumed in analyses where soil loss tolerance values are used in erosion control planning. See **Section 5.2** and Figures 5.2 and 5.3 for illustrations of overland flow paths and the eroding portion of an overland flow path. **Soil loss** is computed for this uniform profile and compared to the soil loss tolerance value. A satisfactory erosion control practice is one that reduces soil loss to the "T-value" or less.

However, special considerations should be given to applying soil loss tolerance values where steepness varies along the overland flow path. Average erosion for the profile is underestimated when a uniform profile is assumed for convex shaped profiles and overestimated for concave profiles. This difference is illustrated in Table 7.7 were average erosion is computed for uniform and convex profiles of the same length and average steepness. The average erosion for the convex profile is about 25% greater than the average erosion for the uniform profile. The difference in the erosion between the profiles increases as the degree of curvature of the convex profile increases. The ratio of steepness at the end of the convex slope to average steepness is a measure of curvature. In this example, the steepness at the end of the convex slope is about 1.7 times the average steepness of the profile.

An erosion control approach is to reduce the average erosion for the convex profile to the "T-value," which is illustrated in the two right hand columns of Table 7.7. Average erosion rate does not adequately account for the high erosion rate at the end of convex profiles. The erosion rate on the last segment at the end of the convex profile illustrated in Table 7.7 is more than twice the average erosion rate for the profile. The erosion rate at the very end of the convex profile is higher yet. Therefore, average erosion for the entire profile is not a satisfactory erosion control measure for a convex profile, especially one with significant curvature. Extra protection is needed on the lower end of the convex profile to provide comparable erosion control to that on the uniform profile.

Table 7.7. Soil loss along uniform and convex profiles of same length and average steepness. A = average erosion for entire profile and Adj T = T-value adjusted for position on profile. Assume "T-value" = 5.0.

	Uniform			Convex				
				Same practice as uniform profile			Practice changed to give same A as for uniform profile	
Segment	Steepness (%)	Segment erosion	Erosion/ Adj T	Steepness (%)	Segment erosion	Erosion/ Adj T	Segment erosion	Erosion/ Adj T
1	6	2.50	0.99	2	1.09	0.32	0.88	0.26
2	6	4.22	1.00	4	2.85	0.65	2.29	0.52
3	6	5.29	1.00	6	5.29	1.00	4.26	0.81
4	6	6.12	1.00	8	8.44	1.40	6.81	1.10
5	6	6.84	1.00	10	13.10	1.80	10.50	1.50
		A = 5.0			A = 6.2		A = 5.0	

An erosion control approach for convex profiles could be to reduce erosion rate on the last segment to the "T-value." However, erosion rate for each segment is a function of the segment length. Basing erosion control on segment erosion would make erosion control a function of segment length, which is improper. An alternative approach is to reduce "point" erosion rate to be less than the "T-value," but this approach provides greater protection for the convex profile than is considered necessary for the uniform profile having the same average steepness as the convex profile. Thus, the two profiles are not being compared on an equal basis.

Erosion rate increases along a uniform profile so that the erosion rate at the end of the uniform profile is substantially higher than the "T-value" when average erosion for the profile equals the "T-value." The erosion rate on the last segment on the uniform profile illustrated in Table 7.7 is 6.8, which is about 35% greater than the "T-value." Therefore, a procedure is needed that puts non-uniform profiles on the same basis as uniform profiles when comparing segment erosion to "T-values."

RUSLE2 computes the ratio of segment erosion to T adjusted for position to put erosion on an equal basis when comparing non-uniform shaped profiles.

RUSLE2 computes a **ratio of segment erosion to a "T-value" adjusted for position along the profile** so that erosion on non-uniform shaped profiles can be compared on an equal basis to erosion on uniform profiles when selecting erosion control practices.[33] The reason for having the comparison on an equal basis is that the soil loss tolerance concept is based on a uniform profile. The erosion control objective is that the ratio of segment erosion to "T-value" adjusted for position should be one or less. Note that this ratio is 1

[33] See AH703 for a discussion of this adjustment, including the mathematics used to make the adjustment.

everywhere along the uniform profile illustrated in Table 7.7, which shows that the ratio takes out the position effect along the profile in comparing segment erosion values to “T-values.”

The analysis involving the ratio of segment erosion to “T-values” adjusted for position along the profile should be for the eroding portion of the profile and not include depositional portions of concave profiles.

The same level of erosion control is achieved on the convex profile as on the uniform profile when the ratio of segment erosion to “T-value” adjusted for slope position is one or less for all segments. In the example in Table 7.7, the convex profile requires increased erosion control on the last two segments than is required on the uniform profile of the same average steepness as the convex profile because the convex profile accelerates erosion near its end. Similarly, less erosion control is needed on the upper three segments than on the uniform profile because the ratio of segment erosion to “T-value” adjusted for position is less than 1. In this example, the average erosion for the convex profile must be reduced to 3.3 tons/acre to provide the same level of erosion control on the last segment of the convex profile as provided on the last segment of the uniform profile.

8. TOPOGRAPHY

Topographic information is stored in the profile and worksheet components of the RUSLE2 database. Topography is a part the overall description of an **overland flow path** that includes information on cover-management, soil, and steepness along the flow path. This description involves three layers of information, illustrated in Figure 8.1. An overland flow path is also referred to as a RUSLE2 **hillslope profile**.

Segments are created for each layer by specifying the locations where cover-management, soil, or steepness changes along the flow path. Inputs are selected from the RUSLE2 database for each management and soil segment, and values for segment break locations and steepness are user entered. Thus, RUSLE2 computes how change in cover-management, soil, and steepness along the overland flow path affect erosion and deposition. Segment break locations need not coincide among the layers as illustrated in Figure 8.1.

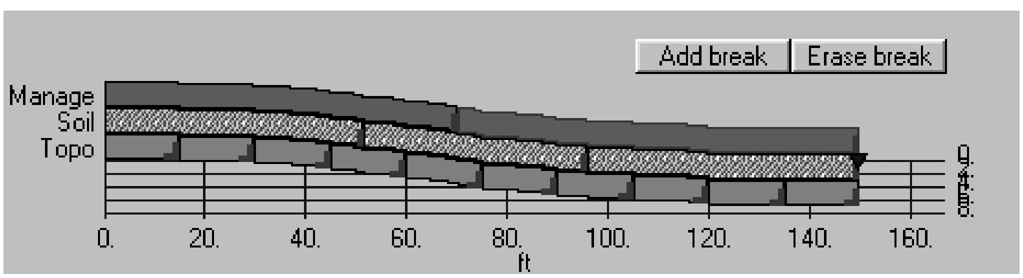

Figure 8.1. Schematic of the three layers that represent an overland flow path (a RUSLE2 hillslope profile).

8.1. Basic Principles

RUSLE2 uses equation 5.4 to compute erosion along an overland flow path. For generality, assume that all RUSLE2 profiles are composed of multiple segments, like Figure 8.1. Each layer (management, soil, topography) has its own segments. RUSLE2 assembles the segments for each layer into a composite set of segments. A composite segment end is located at a change in any one of the three layers.

8.1.1. Detachment

The computations that solve equation 5.4 start at the upper end of the overland flow path and step down slope segment by segment, which "routes" the water and sediment down slope. The sediment load g_{in} entering a particular segment is known from the computation of the sediment load g_{out} leaving the adjacent upslope segment. No sediment enters the first segment because it is at the origin of the overland flow.

The amount, expressed as mass per unit area, of net detached sediment (sediment produced) within the *ith* segment is computed with:

$$D_i = rkScp_c(x_i^{m+1} - x_{i-1}^{m+1}) / \lambda_u^m (x_i - x_{i-1}) \qquad \textbf{[8.1]}$$

where: D_i = net detachment (mass/area), r = erosivity factor, k = soil erodibility factor, S = slope steepness factor, c = cover-management factor, p_c = contouring factor, x_i = distance to lower end of the segment, x_{i-1} = distance to the upper end of the segment, λ_u = length of the unit plot (either 72.6 ft or 22.1 m), and m = slope length exponent. All variables are for a particular day and for the *ith* segment.34 Equation 8.1 is equation 5.1 applied to a segment.

The slope length exponent **m** for the *ith* segment is computed from:

$$m = \beta/(1+\beta) \qquad \textbf{[8.2]}$$

where: β = ratio of rill to interrill erosion for the *ith* segment, which in turn is given by:

$$\beta = \left[\frac{k_r}{k_i}\right]\left[\frac{c_{pr}}{c_{pi}}\right]\left[\frac{\exp(-0.05 f_g)}{\exp(-0.025 f_g)}\right]\left[\frac{(s/0.0896)}{3s^{0.8}+0.56}\right] \qquad \textbf{[8.3]}$$

where: k_r/k_i = the ratio of rill erodibility to interrill erodibility; c_{pr}/c_{pi} = the ratio for below ground effects for rill and interrill erosion, respectively, which is a prior land use type effect; exp(-0.05f_g/exp(-0.025 f_g) = the ratio of the ground cover effect on rill and interrill erosion, respectively; (s/0.0896)/(3$s^{0.8}$+0.56) = the ratio of slope effects for rill and interrill erosion, respectively; s = sine of the overland flow path slope angle; and f_g = percent ground cover.[35] All variables in equation 8.3 are for the *ith* segment. The ratio k_r/k_i is computed as a function of soil texture where the ratio decreases as clay increases because clay makes the soil resistant to rill erosion. The ratio increases as silt increases because silt decreases the resistance of soil to rill erosion. The ratio c_{pr}/c_{pi} represents how rill erosion decreases relative to interrill erosion as both soil consolidation and soil biomass increase. The term exp(-0.05f_g)/exp(-0.025f_g) represents how ground cover has a greater effect on rill erosion than on interrill erosion. The term (s/0.0896)/(3$s^{0.8}$+0.56) represents how slope steepness has a greater effect on rill erosion than on interrill erosion.

---

[34] See the RUSLE Science Documentation for a complete description of the equations used in RUSLE2. The equations in this RUSLE2 User's Reference Guide are for illustration only and are not the complete equations.

[35] Equation 8.3 replaces the selection of an LS "Table" in RUSLE1.05 and earlier RUSLE1 versions and replaces having to select a land use in RUSLE1.06. RUSLE2, in effect, selects the proper LS relationship based on cover-management conditions.

A constant value of 0.5 is used for m in the Req zone.

The RUSLE2 slope length effect from equation 8.1 is:

$$L_i = (x_i^{m+1} - x_{i-1}^{m+1}) / \lambda_u^m (x_i - x_{i-1}) \qquad \textbf{[8.4]}$$

where: L_i = the slope length factor for the *ith* segment. The slope length effect in RUSLE2 adjusts soil loss from the unit plot up or down depending on whether the ith segment position is located less or greater than the unit-plot length λ_u of 72.6 ft (22.1 m) from the upper end of the overland flow path. Values for the slope length effect are less than 1 when location of the segment is less than the unit plot length and greater than 1 when the location is greater than the unit plot length.

The slope length effect in RUSLE2 is a function of rill erosion relative to interrill erosion except in the Req zone. Interrill erosion is assumed to be caused by raindrop impact and therefore independent of location along the overland flow path, assuming that the variables that affect interrill erosion are constant along the overland flow path. Rill erosion is assumed be caused by surface runoff and to vary linearly along the overland flow path because of runoff accumulation. The slope length exponent **m** in equation 8.2 varies between 0 and 1 and reflects the relative contribution of rill and interrill erosion. The exponent m is near 0 when almost all of the erosion is by interrill erosion, such as on a flat slope, and m is near 1 when almost all of the erosion is from rill erosion, such as on a bare, steep slope. Slope steepness, cover-management, and soil affect RUSLE2's slope length effect because of their different effect on rill erosion relative to interrill erosion. The RUSLE2 slope length effect varies daily as cover-management conditions change. The USLE slope length factor is independent of the other USLE factors, except for slope steepness. The RUSLE1 slope length factor only partially varies with the other RUSLE1 factors.

RUSLE2 spatially integrates equation 5.4 in its computations. A spatial integration of the USLE and RUSLE1 is possible for a limited set of conditions, but the integration must be done manually and is laborious. Few users perform the integration. RUSLE2 performs the integration internally without extra steps required of the user other than to divide the overland flow path into segments and specify the inputs for each segment. Just as RUSLE2 differs from RUSLE1 and the USLE in temporal integration, RUSLE2 also differs from them in spatial integration and interaction among factors. Although RUSLE2 uses fundamentals from the USLE and RUSLE1, RUSLE2 is essentially a new model. These mathematical differences give RUSLE2 much more power than the other equations.[36]

---

[36] The difference in temporal integration can result in as much as 20% differences in erosion estimates between RUSLE2 and the USLE and RUSLE1. The difference in spatial integration between RUSLE2 and RUSLE1 is generally not great provided the proper selections are made in RUSLE1. However, few users

The RUSLE2 slope steepness factor is computed with:

$$S = 10.8s + 0.03 \qquad \text{slope} < 9\% \qquad \textbf{[8.5]}$$

$$S = 16.8s - 0.50 \qquad \text{slope} \geq 9\% \qquad \textbf{[8.6]}$$

for all areas except the Req zone, where equation 8.7 is used.

$$S = (s / 0.0896)^{0.6} \qquad \text{slope} \geq 9\% \qquad \textbf{[8.7]}$$

where: slope = slope steepness in percent.[37] The slope steepness factor S has a value of 1 for a 9% slope. Values for the S factor are less than 1 for slope steepness less than 9 percent and greater than 1 for slope steepness greater than 9 percent. The slope steepness factor in RUSLE2 adjusts the soil loss values from the unit plot up or down depending on whether the field slope is steeper or flatter than the 9 percent steepness of the unit plot.

The slope steepness S factor should be a function of the soil and cover-management similar to equation 8.3. However, neither the empirical data nor theory is sufficient for incorporating those effects into RUSLE2.

8.1.2. Runoff

RUSLE2 uses discharge (flow) values for runoff to compute sediment transport capacity, contouring effectiveness, and critical slope length for contouring. Discharge rate at a location is computed from:

$$q = q_{i-1} + \sigma_i (x - x_{i-1}) \qquad \textbf{[8.8]}$$

where: q = discharge rate (volume/width·time) at the location x between the segment ends x_{i-1} and x_i, q_{i-1} = discharge rate at x_{i-1}, and σ_i = excess rainfall rate (rainfall rate - infiltration rate) on the *ith* segment. Excess rainfall rate is computed using the NRCS runoff curve number method that computes runoff depth. RUSLE2 assumes that runoff rate is directly proportional to runoff depth. RUSLE2 computes curve number values, the major parameter in the NRCS curve number method, as a function of hydrologic soil group, soil surface roughness, ground cover, soil biomass, and soil consolidation to represent the effect of cover-management on runoff. In general, RUSLE2 computes reduced runoff as these variables increase, except for soil consolidation that interacts with soil biomass. If soil biomass is very low, soil consolidation increases runoff, typical of a bare construction site. If soil biomass is high, typical of high production pasture, soil

---

properly select inputs for RUSLE1 to achieve this similarity in results.

[37] The slope factor equations are the same in RUSLE2 and RUSLE1.

consolidation decreases runoff.[38] The curve number method is configured within RUSLE2 to compute negative values for rainfall excess (σ) so that RUSLE2 can compute decreasing discharge along a segment having very high infiltration that receives run-on from upslope.

Discharge in RUSLE2 is typically used as a ratio of discharge computed for a given condition to a base runoff computed for moldboard plowed, clean tilled, low yielding corn grown on a silt loam soil in Columbia, MO. RUSLE2 starts with empirical erosion factor values taken from AH537, which is a summary of data collected over a wide range of conditions at many locations. RUSLE2 uses ratios, such as the one involving discharge, in process-based equations to adjust the empirical erosion factor values up or down from a base value. RUSLE2 often computes a departure from a base value rather than an absolute value. Computing departures is more stable and robust than computing absolute values. This approach combines the best of empirically based and process based variables and equations.

Columbia, MO is used as a base because it is centrally located in the US and represents "typical" weather values in the eastern US. The moldboard plowed, clean-tilled, row cultivated corn best represents the condition for contouring and critical slope length values in AH537. These AH537 values are directly related to runoff and serve as calibration data.

8.1.3. Sediment transport capacity

Sediment transport capacity ($T_{c,up}$ and $T_{c,low}$) is computed at both the upper (x_{i-1}) and lower (x_i) ends of each segment using equation 5.3 and the discharge rates and slope steepness of the segment. This approach results in a step change in sediment transport capacity at segment ends, even when steepness varies smoothly in continuous fashion. Slope steepness values for adjacent segments could have been averaged to obtain a smoothly varing transport capacity along the slope. However, such an approach would have increased the difficulty for users to represent sharp changes in steepness, such as the flat top and steep sideslope of a landfill. Transport capacity is also a step function where cover-management conditions, such as at the upper end of a grass strip change as a step function, or slope steepness changes as a step function, such as the change in steepness from the top of a landfill to the sideslope. RUSLE2 computes transport capacity at the lower end of a segment based on conditions for that segment and at the upper end of the adjacent segment using the conditions for that segment to capture step changes. These step changes in transport capacity are illustrated in Figure 8.2.

The product qs in Equation 5.3 represents runoff erosivity. It is proportional to runoff's total shear raised to the 3/2 power. Total shear stress is divided between that acting on the soil (skin friction) and that acting on form roughness elements (form friction). The

[38] Soil consolidation is used as an indicator variable, not as a cause and effect variable.

shear stress acting on the soil is assumed to be responsible for runoff transporting sediment. The coefficient K_T is a measure of the fraction of the flow's total shear stress that acts on the soil to transport sediment. Values for K_T and transport capacity decrease as form hydraulic roughness increases even though total hydraulic roughness increases..

Manning's n is a measure of form and grain (skin) roughness combined. RUSLE2 uses Manning's n values to compute K_T values. In turn, RUSLE2 computes values of Manning's n as a function of standing live and dead vegetation, ground cover, and surface roughness, which are form roughness elements.

The variable K_T is also a calibration coefficient that represents transportability of the sediment. RUSLE2 does not vary K_T as a function of sediment properties, which means that sediment transport capacity is not a function of sediment characteristics. A base value for K_T was determined by calibrating RUSLE2 to a field plot experiment of deposition on a concave slope. The steepness of this concave slope decreased from 18% at the its upper end to 0% at its lower end. Deposition began at the location where steepness was 6%. This condition was assumed to represent moldboard plowed, clean tilled, low yield corn on a silt loam soil at Columbia, MO. The calibration was checked against general field observations and data from laboratory experiments on sediment transport and deposition.

8.1.4. Sediment routing

Several cases must be considered in routing the sediment down slope (i.e., solving equation 5.4 sequentially by segment starting at the upper end of the overland flow path).

8.1.4.1. Case 1: Detachment over the entire segment

Detachment occurs over the entire segment when the transport capacity $T_{c,up}$ at the upper end of the segment is greater than the incoming sediment load g_{in} and the transport capacity $T_{c,low}$ at the lower end of the segment is greater than the maximum possible sediment load at the lower end of the segment. The maximum possible sediment load is the incoming sediment load plus the sediment produced within the segment by detachment. This case occurs on uniform and convex shaped slopes and the upper portion of a concave slope.

Sediment load at the lower end of the segment is given by:

$$g_{out} = g_{in} + D_i(x_i - x_{i-1}) \qquad \textbf{[8.9]}$$

where: D_i = net detachment (sediment production) computed with equation 8.1 for the *ith* segment.

Another possibility is that the potential sediment load computed with equation 8.9 exceeds transport capacity at the lower end of the sediment while the potential sediment load based on interrill erosion is less than transport capacity. If this condition exists, RUSLE2 computes a reduced rill erosion so that the sediment load at the end of the segment just fills transport capacity without overfilling it.

RUSLE2 assumes that interrill erosion always occurs at a "capacity" rate. Interrill erosion is computed like net detachment (equation 8.1) except for an interrill erosion slope steepness factor, the slope length factor being 1 (i.e., interrill erosion does not vary by location along the overland flow path), and multiplying by 0.5 based on the assumption that interrill erosion equals rill erosion for unit-plot conditions. The RUSLE2 equation for interrill erosion rate is:

$$D_{ir,i} = 0.5rk(3s^{0.8} + 0.56)cp_c \qquad \textbf{[8.10]}$$

No local deposition occurs for **Case 1** conditions when slope steepness is sufficiently steep.[39] However, at low steepness, interrill erosion can be greater than sediment transport capacity, which causes local deposition. Local deposition occurs where interrill erosion rate exceeds the increase in transport capacity with distance (i.e, $D_{ir} > dT_c/dx$). Equation 8.1 empirically includes local deposition in its computation of net detachment. Local deposition is selective causing coarse particles to be deposited and the sediment load to be enriched in fine particles. RUSLE2 uses the procedure that computes deposition in **Case 2** to compute sediment characteristics and the enrichment ratio for this local deposition (See **Section 7.5**).

The distribution of the sediment added to the sediment load by detachment is the sediment distribution at the point of detachment described in **Section 7.5**. The particle class distribution in the sediment load is the same as that at the point of detachment unless local deposition or remote deposition is computed.

8.1.4.2. Case 2: Deposition over the entire segment

Deposition occurs along an entire segment when the sediment load exceeds transport capacity at both the upper and lower ends of the segment. An example of this case is deposition in a narrow grass strip illustrated in Figure 8.2. Table 7.6 shows values computed by RUSLE2 for an example like this case.

---

[39] **Local deposition** is deposition very close (few inches, tens of millimeters) to the detachment point. Deposition in the depressions on a rough soil surface is an example of local deposition. **Remote deposition** is deposition a considerable distance (tens of feet, several meters) from the detachment point.

Equation 5.2, which computes deposition, is applied to each particle class. Sediment characteristics used in these computations are described in **Section 7.5.** The transport capacity for each particle class is computed by dividing the total sediment transport capacity computed with equation 5.3 among the particles in proportion to the mass distribution of the sediment classes in the total sediment load. The distribution of sediment transport capacity among the particle classes changes as deposition occurs along the overland flow path because each particle class is deposited at a different rate based on fall velocity

Equation 5.2 has two unknowns, deposition rate and sediment load. Equation 5.2 is combined with the continuity equation to solve for deposition rate and sediment load. The continuity equation for **Case 2** is:[40]

$$\Delta g / \Delta x = D_{ir} + D_p \qquad \textbf{[8.11]}$$

where: $\Delta g/\Delta x$ is the change in sediment load Δg over the distance Δx, D_{ir} = interrill erosion and D_p = deposition rate.

An important assumption involves interrill erosion in equation 8.11. **Does interrill erosion occur simultaneously with deposition?** CREAMS assumes that rill erosion **does not** occur simultaneously with deposition, while RUSLE2 assumes that interrill erosion **does** occur simultaneously with deposition. This assumption is valid for interrill erosion on ridges where deposition occurs in the furrows between the ridges. However, the assumption is not clear-cut where deposition occurs on flat soil surfaces, such as the toe of a concave slope. Deposition is dynamic and spatially varied. Flow depth and transport capacity vary considerably across the slope leaving "exposed" areas where interrill erosion occurs. Deposition and flow patterns change during deposition.[41]

While not a perfect assumption, RUSLE2 assumes that interrill erosion occurs simultaneously with deposition. A consequence of this assumption is that less enrichment of sediment in fines is computed than when no interrill erosion is assumed.

Equations 5.2 and 8.11 and transport capacity being distributed among particles classes based on their distribution in the sediment load creates a very complex and interactive set of equations to be solved. The equations are solved numerically in RUSLE2 because simple, closed form solutions were not found. The RUSLE2 numerical solution divides the portion of the overland flow path where deposition occurs into small sub segments. Decreasing sub segment length increases computational accuracy but noticeably

[40] The sign convention is that detachment is positive (increases the sediment load) and deposition is negative (decreases the sediment load).
[41] See Toy et al. (2002) for additional discussion.

increases computational time, which required a compromise between the two. The procedure was carefully designed to minimize differences related to how a user segments the overland flow path. The user will seldom see much effect of segment division on RUSLE2 results. The accuracy of the deposition computation with respect to the numerical solution matching the "true" mathematical solution is well within the overall accuracy of RUSLE2.

RUSLE2 computes deposition rate, total sediment load, and the sediment load of each particle class along each segment. The sediment load g_{out} leaving the segment is the sediment load computed at the end of the segment, which is the sediment load g_{in} entering the next downslope segment. The distribution of the particle classes in the sediment load indicates how deposition enriches the sediment in fines. RUSLE2 computes an enrichment ratio based on specific surface area of the sediment at the end of the last segment on the overland flow path (See **Section 7.5**). The value computed for enrichment ratio is related to the fraction of the sediment load that is deposited. The enrichment ratio increases as the deposition fraction increases.

8.1.4.3. Case 3: Deposition ends within the segment

Deposition ends within a segment when deposition occurs at the upper end of the segment and transport capacity increases within the segment at a rate greater than interrill erosion rate if the segment is sufficiently long as illustrated in Figure 8.3. Sediment load exceeds transport capacity at the upper end of the segment and decreases within the segment while transport capacity increases within the segment. The two become equal within the segment, which is the location x_e that deposition ends. RUSLE2 computes deposition and the sediment load on the upper portion of the segment using the deposition procedure described for **Case 2.**

The same conditions described for **Case 1** exist for the lower portion of the segment beyond the location x_e where deposition ends. Net detachment is computed using equation 8.1 where x_e is substituted for x_{i-1}. Rill erosion is reduced, if necessary, to avoid the sediment load "overfilling" transport capacity. Sediment load at the end of the segment is computed from:

$$g_{out} = g_{xe} + D_{>xe}(x_i - x_e) \qquad \textbf{[8.12]}$$

where: g_{xe} = sediment load at the point where deposition ends and $D_{>xe}$ = net detachment on the lower portion of the segment beyond the location where deposition ends.

8.1.4.4. Case 4: Deposition begins within the segment

Deposition begins within a segment when the transport capacity at the upper end of a segment is greater than sediment load, and transport capacity decreases within the segment to become less than sediment load. This case occurs on a segment where cover-management and/or soil change so that infiltration rate is so high that runoff and transport capacity decrease within the segment. This case is illustrated in Figure 8.4.

Deposition begins at the location where sediment load and transport capacity become equal. RUSLE2 computes the deposition on the lower portion of the segment using the procedure described for **Case 2.**

8.1.5. Computing sediment yield, soil loss from eroding portion, total detachment, conservation planning soil loss, and erosion by segment

RUSLE2 displays several values produced by these computations. These output values are used in conservation and erosion control planning to select erosion control measures appropriate for the site conditions.

8.1.5.1. Sediment yield

Sediment yield is the amount of sediment leaving the overland flow path.[42] It is used in erosion control planning where the objective is to reduce the amount of sediment leaving the site. RUSLE2 computes sediment yield as sediment load at the end of the overland flow path divided by the overland flow path length. That is:

$$SY = g_{out,I} / \lambda_{ofpl} \qquad \textbf{[8.13]}$$

where: SY = sediment yield from the overland flow path length (mass/area), $g_{out,I}$ = the sediment load at the end of the last segment on the overland flow path, I = the index of the last segment, and λ_{ofpl} = the overland flow path length.

8.1.5.2. Soil loss from eroding portion

The eroding portions of an overland flow path are where no deposition occurs, except for local deposition. Figure 5.2 illustrates the eroding portion of a complex shaped profile for an overland flow path. The **soil loss from eroding portion** is used in conservation planning where the objective is to protect eroding areas from excessive erosion to maintain soil productivity, prevent rilling, and reduce sediment yield.

The soil loss for the eroding portion of the overland flow path is computed from:

$$A_{ep} = \sum (g_{out,k} - g_{in,k}) \Big/ \sum (x_{out,k} - x_{in,k}) \qquad \textbf{[8.14]}$$

---

[42] This sediment yield is the sediment yield for the site only if the overland flow path ends at the site boundary.

where: A_{ep} = soil loss (mass/area) for the eroding portions of the overland flow path and the index k refers to each portion of the overland flow path that is an eroding rather than a depositional area. Soil loss for the eroding portions of the overland flow path is the total sediment produced on the eroding portions divided by the total length of the eroding portions.

8.1.5.3. Total Detachment

Total detachment represents the sediment produced for the entire overland flow path, including depositional areas. In contrast, soil loss for the eroding portion of the overland flow path excludes depositional areas.

Total detachment for the overland flow path is the sum of the detachment amount (sediment production) for each segment divided by the overland flow path length. That is:

$$D_T = \sum D_{f,i}(x_i - x_{i-1}) / \lambda_{ofpl} \qquad \textbf{[8.15]}$$

where: D_T = the total detachment (mass/area) for the overland flow path length and D_f = the sediment production for each segment. Sediment production for a segment is the value computed by equation 8.1 if rill erosion is not limited as described in **Section 8.1.4.1** or remote deposition does not occur as described in **Sections 8.1.4.2-8.1.4.4.** If rill erosion is limited, the sediment production is the sum of the interrill erosion and the rill erosion required to just fill transport capacity. If remote deposition occurs, sediment production equals interrill erosion.

8.1.5.4. Conservation planning soil loss

Neither **soil loss for the eroding portion** or **total detachment** take any **credit** for **remote deposition** as "**soil saved**," although RUSLE2 gives full credit to **local deposition** as "soil saved" because local deposition is empirically considered in equation 8.1 that computes net detachment. **Giving credit to remote deposition is a matter of judgment.** In the USLE (AH282, AH537), half credit was given to deposition by gradient terraces and full credit was given to deposition by rotational strip cropping.[43] No credit was given to deposition on the toe of concave slopes because this deposition ended the USLE slope length. RUSLE1 gave credit to deposition by terraces based on

---

[43] Gradient terraces are terraces on a uniform grade less than about 1% and may be level for moisture conservation. These terraces reduce overland flow path length and "save" soil by causing deposition uniformly along their length. The deposited sediment is spread by periodic mechanical operations required to maintain flow capacity. Rotational strip cropping is a system of alternating uniform width strips of dense vegetation that deposit sediment and strips where erosion is significantly higher than with the dense vegetative strips. The strips are systematically rotated by position on the hillslope over the crop rotation cycle.

terrace spacing. If the terraces were close together, about half credit was taken, and the credit was reduced to none as terrace spacing increased to 300 ft (100 m). Credit for deposition with narrow permanent vegetative strips (e.g., buffer and filter strips) was not discussed in AH282 or 537. In RUSLE1, the amount of credit given to deposition depended on the location of the deposition. Deposition near the end of the overland flow path was given very little credit. The credit increased to more than 60% for deposition near the origin of the overland flow path.

The **conservation planning soil loss** computed by RUSLE2 gives full credit for deposition with rotational strip cropping, i.e., the **conservation planning soil loss equals sediment yield**. RUSLE2 gives partial credit to deposition that occurs with permanent vegetative strips based on the location of the deposition. Very little credit is given to deposition at the end of the overland flow path, and the credit increases to about 60% for deposition located close to the overland flow origin. The same credit is given to deposition on concave portions of an overland flow path. Very little credit is given for the deposition if it is near the end of the overland flow path like that illustrated in Figure 5.4 and increased credit is given to deposition near the origin of the overland flow path.

The justification of the conservation planning soil loss in RUSLE2 is based on the following principles.

1. Deposition is beneficial. The quality of the soil, hillslope, and landscape is better with the deposition than without it. That is, deposition has a **soil saved** benefit.
2. Deposition that occurs and remains on very small areas relative to the entire hillslope area provides much less benefit that deposition that occurs on and is spread over a significant sized area by mechanical operations such as tillage and terrace maintenance.
3. Deposition that occurs near the end of the overland flow path has almost no value for maintaining the quality of the overall hillslope. Deposition in these locations is essentially “lost” from the hillslope with little chance for recovery.
4. Deposition upslope on the hillslope represents soil that is captured and not “lost” from the hillslope. A benefit can be gained by spreading the deposited sediment using common mechanical operations without having to physically transport the sediment upslope.

In general, the **conservation planning soil loss** is greater than **sediment yield**, except for rotational strip cropping where the conservation planning soil loss equals sediment yield. The conservation planning soil loss is less than the **total detachment** for the slope. The difference between total detachment and the conservation planning soil loss represents the **credit taken for deposition**. **Soil loss on the eroding portion** of the slope is the highest value of the set.

8.1.5.5. Erosion by segment

RUSLE2 computes erosion along the overland flow path. The user can obtain these erosion values by dividing the overland flow path into segments. The average **erosion for a segment** depends on segment length because point erosion varies with distance within the segment.

Point erosion at a can be computed with RUSLE2 using a very short segment such as 1 ft (0.3 m) at the location where the point erosion is desired.

Net erosion for a segment is computed as:

$$a_i = (g_{out,i} - g_{in,i})/(x_i - x_{i-1}) \qquad \textbf{[8.16]}$$

where: a_i = erosion for the *ith* segment (mass/area). A positive value means that the segment experiences a net loss of sediment (detachment) and a negative value means that the segment experiences a net gain of sediment (deposition). Even though either net detachment or net deposition occurs overall for a segment, a part of the segment can

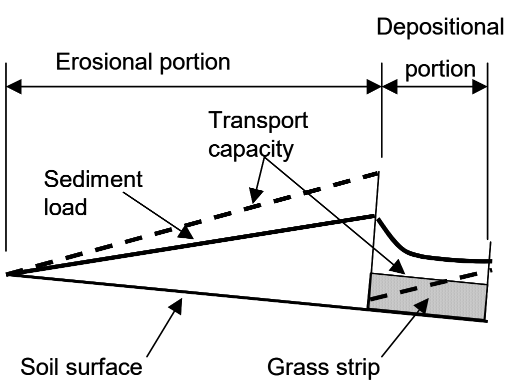

Figure 8.2. Narrow grass where deposition occurs over entire segment

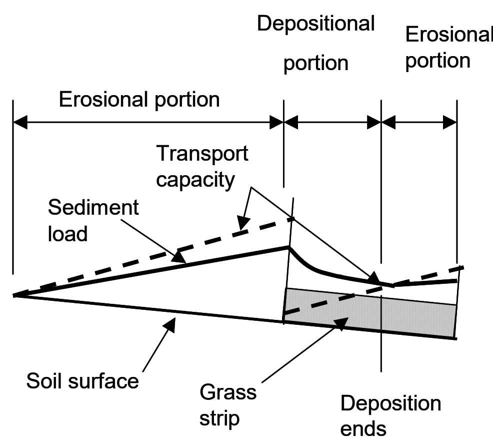

Figure 8.3. Grass strip sufficiently wide that deposition ends within segment and erosion occurs on lower portion of segment

experience net detachment while another part experiences net deposition, such as illustrated in Figures 8.3 and 8.4.

The segment erosion values must be carefully interpreted with respect to the erosion control planning criteria. **Is the erosion control criterion for point erosion or for average erosion for a uniform shaped slope, such as the soil loss tolerance value?**

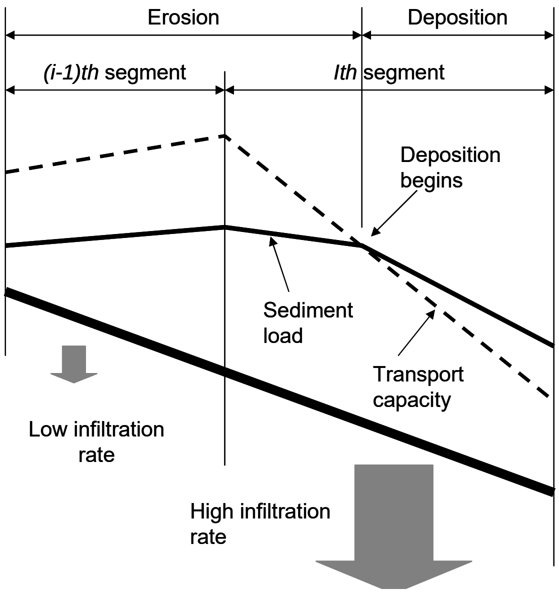

Figure 8.4. Deposition begins within a segment on a segment with a very high infiltration rate

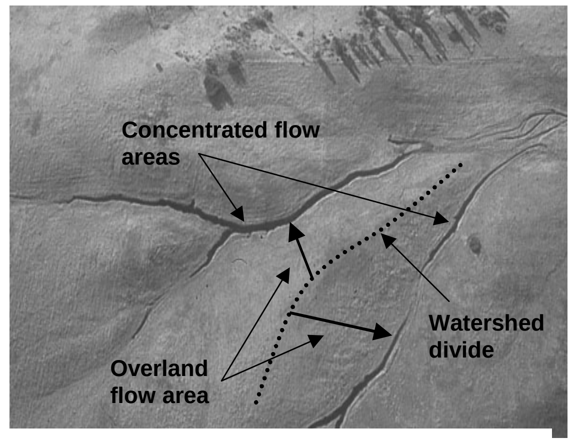

Figure 8.5. A natural landscape with concentrated flow areas and divides where overland flow originates

Comparing a point erosion value computed by RUSLE2 with an erosion control criteria based on average erosion for a uniform slope can produce misleading results and under designed erosion control practices that do not provide sufficient protection or over designed erosion control practices that are too costly. See **Section 7.9** for information on how to interpret RUSLE2 segment erosion values with respect to erosion control criteria based on average erosion for a uniform slope.

8.1.5.6. General comments

RUSLE2 displays a variety of erosion values that can be used in conservation and erosion control planning. Also, RUSLE2 can be applied in variety of ways to a field site. For example, RUSLE2 can be applied in the traditional USLE way by assuming a uniform slope and that deposition ends slope length. The erosion values computed by RUSLE2 can be compared with soil loss tolerance values or other erosion control criteria just as USLE soil loss values were used.

The other option is to apply RUSLE2 to an overland flow path that passes through depositional areas and is terminated by a concentrated flow area. The effect of variability in soil, steepness, and cover-management on erosion along the overland flow path can be analyzed. The RUSLE2 sediment yield estimates are greatly superior to the USLE soil loss estimates for estimating the sediment amount leaving a site. RUSLE2 provides detailed information about how erosion varies along the overland flow path so that a cost effective erosion control practice can be tailored to the specific site conditions better than could be done with the USLE.

Users must understand how to apply RUSLE2 and interpret its computed values. The user must be aware of differences between the USLE, RUSLE1, and RUSLE2 when comparing these models and values from by them. The user must not assume that USLE and RUSLE1 procedures apply automatically to RUSLE2.

8.2. Representing Overland Flow Path Profiles

8.2.1. General considerations

Applying RUSLE2 requires selecting and describing an overland flow path. A hillslope involves an infinite number of overland flow paths. **Section 5.2** describes how to choose overland flow paths for applying RUSLE2 in conservation and erosion control planning.[44]

A point on the hillslope is selected through which the overland flow path passes. The overland flow path is traced from its origin through the point to the concentrated flow area that ends that particular overland flow path as illustrated in Figures 5.1 and 8.5. This flow path is traced perpendicular to the contour lines assuming that the soil surface is flat and ignoring how ridges or micro topographic features affect flow direction.

Overland flow paths are best determined by visiting the site, pacing flow paths, and making measurements directly on the ground. Contour map intervals greater than 2-ft (1-m) should be used cautiously, if at all, to determine overland flow paths. Contour map intervals of 10-ft (3-m) should not be used because concentrated flow areas that end overland flow paths cannot be adequately delineated. Also, these maps do not provide the detail needed to identify depositional areas and the slope steepness with sufficient precision to accurately compute deposition (See **Section 8.2.5**). Overland flow paths are generally much too long when contour intervals greater than 10 ft (3 m) are used to determine them.

Overland flow path lengths on many landscapes generally are less that 250 ft (75 m), and usually do not exceed 400 ft (125 m). Path lengths longer than 1000 ft (300 m) can not be used in **RUSLE2** because the applicability of **RUSLE2** at these long path lengths is questionable. Overland flow often becomes concentrated flow on most landscapes before

[44] See AH703 for additional discussion on identifying, selecting, and describing overland flow paths.

such lengths are reached. The maximum of 1000 ft (300 m) is an extrapolation from the longest plot of about 650 ft (200 m).

RUSLE2 applies to overland flow path lengths as short as zero, which means that RUSLE2 can be applied to ridges and beds like those used in vegetable production as discussed in **Section 8.3.6.2**.

RUSLE2 applies to steepness between flat (0%) and a 100% (1:1) maximum. This maximum of 100% is an extrapolation from 30%, the maximum steepness of the plots used to derive RUSLE2.

Length values like overland flow path segment lengths, distance from the origin of overland flow to lower segment end, overland flow path length, and land area are based on a horizontal measure for internal computations in **RUSLE2**. However, such length values can be input into RUSLE2 based on measuring along the hypotenuse (i.e., parallel to the soil surface). Field measurement parallel to the land surface is easier than measuring horizontally. The difference between horizontal and hypotenuse measurements is insignificant for slope steepness less than 20 percent. Distance and areas measured from maps is a horizontal measure. All references to land areas in RUSLE2 are horizontally based, even if the overland flow path length values were entered on a hypotenuse basis.

Overland flow profiles are segmented to represent differences in steepness, soil, and cover-management along the overland flow path. Topographic segments can be entered in RUSLE2 by distance from the origin of the overland flow path to the lower end of the segment or by segment length. The choice of entry method is based on user preference.

8.2.2. Profile shapes

The profiles for overland flow paths have various shapes as illustrated in Figure 8.6.[45] Simple shapes are uniform, concave, and convex. A uniform shaped profile is one where steepness is the same everywhere along the overland flow path. A convex profile is one where steepness increases everywhere along the overland flow path. RUSLE2 computes net detachment everywhere along uniform and **convex** profiles such that the entire profile is an **eroding portion** (See **Section 5.2**). A **concave** profile is one where steepness decreases everywhere along the overland flow path. If the lower part of a concave profile is sufficiently flat, transport capacity is less than sediment load and deposition occurs. These profiles have an upper **eroding portion** and a lower **depositional portion,** as

[45] Although the terms **hillslope profile** and **overland flow path profile** are often used interchangeably, the two terms are different. A RUSLE2 overland flow path profile does not start at the top of a hill and run to the bottom of the hill. Instead, a RUSLE2 overland flow path profile starts at the origin of overland flow, which is a runoff divide, and perpendicularly crosses contour lines. A RUSLE2 overland flow path is ended by a concentrated flow area.

illustrated in Figure 5.2. However, if the profile does not flatten sufficiently, deposition will not occur and the entire profile is an **eroding portion**.

Deposition does not occur on all concave shaped profiles. A decrease in steepness is not enough by itself to cause deposition.

Simple profile shapes are combined to form complex shaped overland flow profiles. A complex:convex-concave profile is one where the upper part is convex and the lower part is concave. Deposition occurs on the concave portion if steepness flattens sufficiently for transport capacity to become less than sediment load. If deposition occurs, the upper part of the profile is an eroding portion and the depositional area is the depositional portion as illustrated in Figure 5.2. Another complex shaped profile is complex:concave-convex. Deposition occurs on the concave portion if it flattens sufficiently. Runoff can continue as overland flow across the depositional area onto the lower convex portion. If deposition occurs, this profile has both an upper and lower eroding portion separated by the depositional portion. Erosion on the lower eroding portion is directly related to runoff that originates on the upper portion of the overland flow path. Therefore, the path length used to compute erosion on the lower eroding portion of the profile must include the entire path that generates runoff that flows onto the lower eroding portion.

Deposition does not end an overland flow path in RUSLE2.

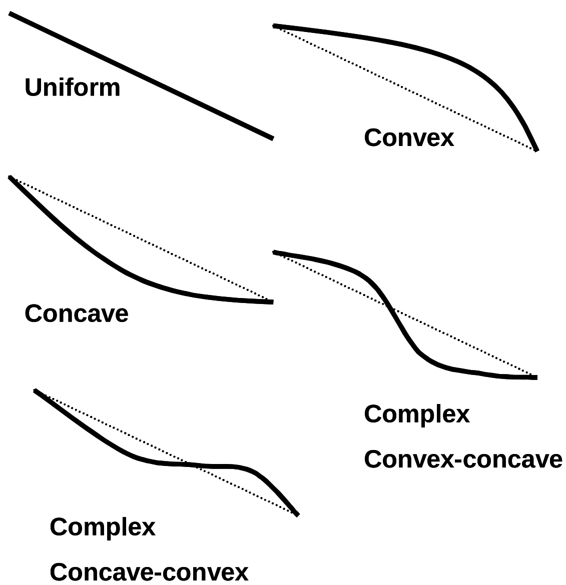

Figure 8.6. Overland flow path profiles

8.2.3. Importance of representing non-uniform profile shapes in RUSLE2

Many conservation and erosion control planners using USLE and RUSLE1 assumed uniform profiles even though procedures were available for applying these models to irregular slopes. This section discusses how profile shape affects RUSLE2 erosion estimates.

The overland flow path profile is a complex:convex-concave shape for many natural landscapes. This profile is illustrated in Table 8.1 along with RUSLE2 computed erosion values. The length of this profile is 250 ft (76 m) and has an average steepness of 4.1%. RUSLE2 computed erosion values are also shown for uniform and convex profiles having the same length and average steepness as the complex profile.

Table 8.1. Computed erosion by segment for three profle shapes, all having the same length and average steepness

			Convex-Concave			Uniform			Convex		
Segment Number	Distance to lower end of segment (ft)	Segment length (ft)	Steepness (%)	Erosion (tons/acre)	Sediment load (lbs/ft width)	Steepness (%)	Erosion (tons/acre)	Sediment load (lbs/ft width)	Steepness (%)	Erosion (tons/acre)	Sediment load (lbs/ft width)
1	28	28	2	4	5	4.1	7	8	0.5	1	2
2	64	36	4	10	22	4.1	11	26	1.5	4.2	9
3	107	43	8	28	78	4.1	14	53	2.8	9	27
4	149	42	6	25	125	4.1	16	84	4.2	16	58
5	181	32	4	-1	125	4.1	17	109	5.4	24	94
6	218	37	2	-28	77	4.1	19	141	6.6	34	151
7	250	32	1	-21	46	4.1	20	170	7.7	44	216
Average			4.1	4		4.1	15		4.1	19	

The computed erosion values differ greatly for the three profile shapes. The average erosion on the complex profile is 4 tons/acre (8.8 t/ha) while the average erosion on the uniform profile is 15 tons/acre (33 t/ha). Negative segment erosion values indicate net deposition for the segment. The reason for the large difference is deposition on the complex profile. Although the average erosion for the complex profile is much lower than average erosion for the uniform profile, the maximum segment erosion of 28 tons/acre (62 t/ha) for the complex profile is significantly larger than the maximum segment erosion of 20 tons/acre (44 t/ha) for the uniform profile. Figures 8.7 and 8.8 illustrate the variation in segment erosion and sediment load along the complex profile.

Another comparison is between the convex profile and the uniform profile. As expected, deposition is not computed for either the uniform or the convex profile. However, the average erosion of 19 tons/acre (42 t/ha) for the convex profile is significantly higher than the average erosion of 15 tons/acre (33 t/ha) for the uniform profile. This difference illustrates that uniform profiles underestimate average profile erosion when a uniform profile is assumed to represent a convex profile. The maximum segment erosion on the convex profile is 44 tons/acre (97 t/ha) while the maximum segment erosion is 20 tons/acre (44 t/ha) for the uniform profile. The uniform profile seriously underestimated maximum segment erosion for the convex profile.

Another comparison involves the average erosion for the eroding portion of the profile. The eroding portion of the profile represented in Table 8.1 is between the origin of overland flow and 165 ft (50 m), where deposition begins. The eroding portion of the slope can be approximated with a uniform profile with a length of 165 ft (50 m) on a steepness of 5.2%, which is the average steepness of the eroding portion. The average erosion for the uniform profile is 16 tons/acre (35 t/ha), while the erosion computed with

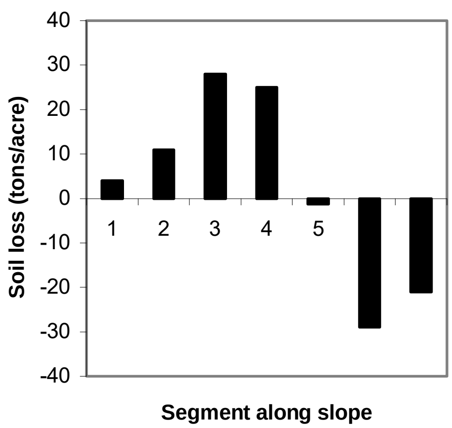

Figure 8.7. Segment erosion along a complex convex-concave hillslope profile

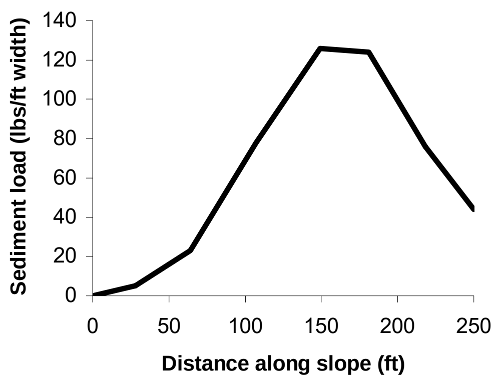

Figure 8.8. Sediment load along a complex convex-concave hillslope profile

the actual non-uniform profile is 18 tons/acre (40 t/ha) for the eroding portion. The average erosion for the eroding portion is about the same with these two methods. However, the maximum segment erosion computed with the non-uniform profile is 28 tons/acre (62 t/ha) while it is 23 tons/acre (51 t/ha) computed with the uniform profile approximation. The uniform profile approximation significantly underestimates the potential for rill erosion on the convex portion of the overland flow path

8.2.4. Implications of using uniform profiles to represent non-uniform profiles for conservation and erosion control planning

Assuming a uniform profile is common when the USLE and RUSLE1 were used in conservation and erosion control planning. A uniform profile is easy to describe, requiring only a length and steepness. The computational procedure for applying the USLE to non-uniform profiles is cumbersome and laborious. The non-uniform slope procedure in RUSLE1 is easy to use, but it only considers the effect of non-uniform steepness. It does not consider variation of soil erodibility or cover-management along the overland flow path.

Interpreting segment erosion values along non-uniform profiles (overland flow paths) is complex where using an erosion control criteria based on average erosion for a uniform profile. RUSLE2 is much more powerful than either the USLE or RUSLE1. RUSLE2 considers the interactive effects of spatial variation in soil and cover-management relative to position along non-uniform profiles. The RUSLE2 inputs are easy to enter, and RUSLE2 provides aids for interpreting segment erosion values (See **Section 7.9)**.

Based on the discussion in **Section 8.2.3**, the implications of using uniform profiles of the same length and average steepness to represent non-uniform profiles are:

1. Uniform profiles underestimate profile (average erosion over the profile length) for convex profiles depending on degree of curvature of the convex profile. The difference can easily be as large as 20%.
2. Uniform profiles seriously underestimate local (segment) erosion for convex profiles and results in inadequate erosion control for rill erosion on the lower end of the convex profile. The difference can easily be as high as a factor of two or more.
3. Uniform profiles overestimate profile erosion for concave profiles. The error can be very large if most of the eroded sediment is deposited on the concave profile. The difference can be large as a factor of five or more.
4. Uniform profiles applied to the eroding portion of concave profiles overestimate profile erosion. The difference can be as large as 20%.
5. Uniform profiles applied to the eroding portion of a concave profile give maximum erosion that is comparable to maximum erosion on the concave profile.
6. Uniform profiles applied to complex:convex-concave profiles overestimate average profile erosion if deposition occurs on the concave portion.
7. Uniform profiles applied to the eroding portion of a complex:convex-concave profile can give about the same average erosion for the eroding portion as representing the non-uniform profile.
8. Uniform profiles applied to the eroding portion of a complex:convex-concave profile can significantly underestimate maximum erosion on the eroding portion of the profile.
9. Deposition does not end the overland flow part on complex:concave-convex profile.
10. Dividing a complex:concave-convex into two separate uniform profiles seriously underestimates erosion on the lower convex portion of the profile.

The strong recommendation is that non-uniform overland flow profiles be represented in RUSLE2, especially convex shaped profiles. Users should recognize that representing a convex profile with a uniform profile will result in erosion control being less than needed (under-designed). Using a uniform profile to represent the eroding portion of a concave profile will result in erosion control being greater than needed (over-designed).

8.2.5. Implications for using RUSLE2 for estimating sediment yield for watersheds

RUSLE2 computes deposition on overland flow areas and the sediment leaving the overland flow path represented in the RUSLE2 computations. For example, RUSLE2 computes a sediment delivery of 4 tons/acre (8.4 t/ha) from the overland flow path as Table 8.1 illustrates. That sediment delivery is the sediment yield for the site only if the overland flow path ends at the site boundary. RUSLE2 overland flow profiles end in concentrated flow areas illustrated in Figures 5.1 and 8.5. These concentrated flow areas are typically within the site boundary. Both erosion (ephemeral gully) and deposition can occur in the concentrated flow areas so that the sediment delivered from site can differ significantly from the RUSLE2 computed sediment delivered from the end of the overland flow profile. That is, sediment leaving the overland flow portion of the site may only be a portion of the site sediment yield because of erosion and/or deposition that occurs in concentrated flow areas.

The USLE is widely used to estimate sediment yield from watersheds by multiplying USLE soil loss estimates by a sediment delivery ratio (SDR).[46] Sediment delivery ratios are typically less than one to account for the deposition that occurs in many watersheds. The sediment mass leaving the watershed is typically less than the sediment produced by rill and interrill erosion. Much of this deposition occurs on the overland flow areas of the watersheds.[47] Although RUSLE2 can compute the deposition on overland flow areas, RUSLE2 should be used to compute erosion on the eroding portion of the overland flow profile because the sediment delivery ratio values already reflect the deposition on overland flow areas as well as deposition by concentrated and channel flow areas.

[46] The USLE soil loss has a particular meaning. It is sediment mass delivered to the end of the uniform slope assumed to represent the eroding portion of the overland flow path. The USLE soil loss is expressed as mass delivered to the end of the ULSE slope length per unit width divided by the USLE slope length.
[47] See Toy et al. (2002) for a discussion of this deposition.

Thus, the proper way to use sediment delivery ratio values with USLE soil loss estimates is to use RUSLE2 to compute erosion on the eroding portion of the overland flow profile. That erosion value, which is comparable to the USLE soil loss value, is multiplied by the sediment delivery ratio to obtain a sediment yield for the watershed. For example, assume that the sediment delivery ratio is 0.15 for a particular watershed that contains the representative profile described in Table 8.1. Sediment yield is computed by multiplying the 18 tons/acre (39.6 t/ha) erosion value for the eroding portion of the overland flow path by the sediment delivery ratio of 0.15 to give a sediment yield of 2.7 tons/acre (5.9 t/ha). Multiplying the RUSLE2 computed sediment yield value of 4 tons/acre (8.8 t/ha) for the overland flow path by sediment the delivery ratio value based on a USLE type soil loss value gives a sediment yield that is much too low.

8.2.6. Importance of properly representing steepness at end of concave profiles where deposition occurs

The deposition computed by RUSLE2 is directly related to sediment transport capacity. Accurately computing deposition is very difficult because slight variability in the flow hydraulics on a depositional surface can greatly affect sediment transport capacity. The error in deposition computations is much greater than error in detachment computations.

Even if the computations could be made perfectly, an accurate description of the steepness along the flow path where deposition is needed. For example, the sediment yield from the complex profile illustrated in Table 8.1 is 4.0 tons/acre (8.8 t/ha ac). If the steepness for the last segment, which covers a relatively small portion of the profile, had been estimated at 2%, the estimated sediment yield would have been 7.8 tons/acre (17.2 t/ha). If the steepness had been estimated at 0.5%, the estimated sediment yield would have been 2.6 tons/acre (5.7 t/ha). These differences illustrate the importance of carefully determining the steepness at the end of the overland flow path on concave profiles where deposition occurs.

Deposition estimates are much less accurate than detachment estimates. Also, obtaining accurate deposition estimates requires a more carefully measured steepness than does detachment, especially where deposition occurs at the end of an overland flow profile.

8.3. Applying RUSLE2 to particular profile shapes

This section describes how to apply RUSLE2 to particular overland flow profile shapes commonly encountered in conservation and erosion control planning.

8.3.1. Uniform profile

Uniform profiles (slopes) are often assumed because only a slope steepness and slope length are required to topographically describe them.[48] Uniform slopes are used to represent the eroding portion of overland flow paths, not the entire path (See **Section 5.2**). The **slope steepness** of the uniform slope is set to the average steepness of the eroding portion of the overland flow path.

Slope length, as used in the USLE, is the distance from the origin of overland flow to the upper edge of deposition for concave profiles, illustrated in Figure 5.2, or to concentrated flow areas for convex profiles, illustrated in Figure 5.3. See AH703 for additional illustrations.

The best approach for determining slope length and steepness is to make measurements during a site inspection.

Determining the upper edge of deposition is easy on cropland, construction sites, and other land areas that readily erode. However, deposition may not be apparent where rill erosion does not occur and deposition is low, where heavy vegetative cover obscures the soil surface, or where recent mechanical soil disturbance has mixed deposited sediment with underlying soil.

A rule of thumb is that deposition begins where steepness is one half of the average steepness of the concave portion of the profile.

Two examples illustrate the procedure. The first example is a concave profile that decreases from 18 percent steepness at the upper end to 2 percent steepness at the lower end. The average steepness is 10 percent and one half of the average steepness is 5 percent. Deposition begins at the location where the flow path has flattened to 5 percent steepness as shown in Figure 8.7.

The second example is a concave profile that decreases from 4 percent at the upper end to 2 percent at the lower end. The average steepness is 3 percent and one half of the average steepness is 1.5 percent. Deposition does not occur because the steepness at the lower end of this profile is greater than the steepness where deposition would be expected to occur.

This procedure only captures how degree of profile curvature affects deposition. Other factors also affect deposition. Deposition occurs when

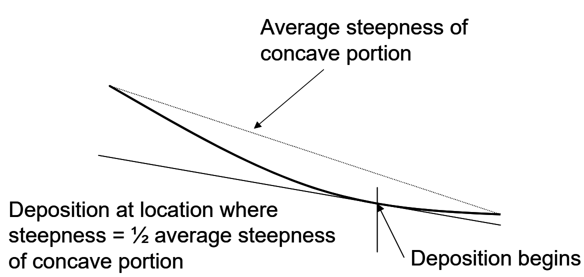

Figure 8.7. Rule of thumb for location of upper edge of deposition on a concave profile

4… Reference Guide. It is the length of the
u… overland flow path. Slope steepness
s…

sediment load produced by upslope erosion exceeds transport capacity of the runoff. If the sediment load produced by upslope erosion is low relative to transport capacity, deposition begins further downslope than when sediment load is high relative to transport capacity.

RUSLE2 can estimate the location of deposition by segmenting the overland flow profile and entering steepness values for each segment. Negative segment erosion values indicate deposition. RUSLE2 computes erosion for the eroding portion of the overland flow path that can be used in conservation and erosion control planning (See **Section 8.1.5.2**).

Terraces, diversions, grassed waterways, ephemeral gullies, and similar concentrated flow areas are easily identified as ending slope length. Slope length can often be easily determined on cut and fill slopes involved in construction, landfills, and surface mine reclamation. Many landscapes include converging areas where overland flow is collected in defined channels, which are areas where ephemeral gully erosion occurs. These channels are illustrated in Figures 5.1 and 8.5. Slope length ending concentrated flow areas on natural landscapes, such as western rangelands, may not be obvious because the concentrated flow areas are not eroding channels.

The fact that experts can look at the same landscape and choose different slope lengths may seem troubling. Determining slope length involves judgment, and the variability in slope length among RUSLE2 users is a part of the uncertainty in RUSLE2 erosion estimates (See **Section 17.4**). One element in the judgment is how well plots used to derive RUSLE2 represent the specific field site where RUSLE2 is being applied. The data used to determine RUSLE2 were collected from plots that ranged in width from about 6 ft (2 m) to 12 ft (4 m), with some as wide as 75 ft (25 m). Plots lengths were as long as 350 ft (100 m) in two cases, but most plots were about 75 ft (25 m). These plots are illustrated in Figures 5.5 and 5.6. Slope length should not extend beyond the hillslope location where plots of these dimensions and flow conditions would represent erosion.

The depth of an eroded channel on a hillslope does not determine whether RUSLE2 applies. Is this channel parallel to other channels and of comparable size to neighboring channels as illustrated in Figure 5.6? Or is the channel much larger than neighboring channels because runoff has been collected rather than being spread uniformly across the hillslope?

Fortunately RUSLE2 erosion estimates are not sensitive to slope length for slope steepness less than 2 percent. For example, slope length being off by a factor of two for a 0.5 percent steepness has almost no effect on estimated erosion. Estimated erosion is less sensitive to slope length than to slope steepness for steepness between 2 and 20 percent. Above 20 percent steepness, estimated erosion is almost as sensitive to slope length as to slope steepness. Therefore, the uncertainty in estimating slope length does not have a major effect on estimated erosion for steepness less than 10 percent. Much more careful attention should be given to estimating slope steepness than to slope length.

Slope length and steepness values should be determined from field measurements, but site inspections may not be feasible. Problems associated with using contour maps and digital elevation data are discussed in **Section 8.2.1**. In general, those data are seldom satisfactory for determining slope lengths and often are not satisfactory for determining slope steepness because the data do not have sufficient resolution.

Slope length and steepness values have been assigned to soil map units in some cases.[49] These values may be acceptable for large scale regional analyses, but they should not be used for site-specific conservation and erosion control planning. The range in slope steepness across soil map units can give widely different estimated erosion values. For example, the land steepness of a soil map unit can range from 1 percent to 5 percent. The average steepness is 3 percent, which might give an estimated erosion rate of 12 tons/acre (26 t/ha). The estimated erosion values for the extremes of the slope steepness for the soil map unit are 4 tons/acre (9 t/ha) and 22 tons/acre (48 t/ha) for the 1 percent and 5 percent steepness, respectively. The importance of profile shape, especially if the profile is convex, should not be overlooked.

A principle in applying RUSLE2 is that a similar level of precision be used for all inputs for a specific site. Therefore, if a uniform slope is assumed, then a single soil and a single cover-management should be assumed for the slope. Uniform width and uniform spaced cover-management strips can be placed on the uniform slope to represent filter and buffer strip and rotational strip cropping support practices. However, soil and cover-management (e.g., to represent the variation of yield along the slope) should not be varied along a uniform slope that is being used to represent a non-uniform profile, especially a convex profile shape. For example, high soil erodibility at the end of a convex profile can give far higher erosion rates than will be computed assuming a uniform slope.

Not using the same level of precision for all inputs can result in very seriously flawed conservation plans when the planning criteria is to an absolute standard such as soil loss tolerance.[50] This problem is reduced but not eliminated for conservation planning to a relative standard, such as an 80 percent erosion reduction. Profile (overland flow path) averages can be very misleading for both concave and convex profiles because of non-linearity in the RUSLE2 equations. Soil map units sometimes involve multiple soil components where soil erodibility differs significantly among the components.

---

[49] Griffin, M.L., D.B. Beasley, J.J. Fletcher, and G.R. Foster. 1988. Estimating soil loss for topographically nonuniform field and farm units. J. Soil and Water Conservation 43:326-331.

[50] An analogy is using a micrometer to measure the sand grain roughness in a concrete pipe while guessing at the diameter of the pipe and expecting an estimate of discharge rate to be of comparable precision to the sand grain measurements.

Sometimes one of the components is chosen as the dominant component if it occupies more than 50 percent of the soil map unit. An alternative is to take averages. However, a soil component that occupies about 25 percent of the overland flow path with a very high soil erodibility located at the lower end of a convex shaped profile is the dominant soil in terms of the erosion on the profile. The soil component that occupies most of the profile is not necessarily the dominant soil in terms of erosion, although it may be the dominant soil for other processes such as crop production.

If the spatial variation in soil and/or cover-management is sufficient to warrant dividing the overland flow profile into segments, then the variation in steepness along the overland flow path should be entered as well.

The problem is not limited to convex profiles. A uniform profile computes maximum erosion at the end of the profile whereas maximum erosion occurs on a concave profile in the upper part of the profile, not at the end. The positioning of soil components along the profile strongly interacts with profile shape. The result is that erosion computed with uniform slopes and assuming a spatially average soil erodibility or a dominant soil component based on occupying the highest fraction of the profile can produce erosion estimates that greatly differ from those computed using a non-uniform profile shape and the proper placement of the soil and cover-management conditions along the profile.

RUSLE2 users must be aware of the importance of precision in the inputs and the importance of spatial interaction among variables. The same level of precision should be applied to all RUSLE2 inputs. Even though uniform slopes have long been standard practice in conservation planning, most conservation planners have little awareness of the impact of that assumption on the adequacy of the resulting plans.

8.3.2. Complex:convex-concave profile

The profile for overland flow paths on many natural landscapes is complex:convex-concave (See **Section 8.2.2**). The potential for deposition always exists on concave shaped profile sections. The segments used to represent the profile must be carefully chosen to ensure that RUSLE2 correctly make its computations, especially where deposition occurs. The critical choices are number of segments and steepness of the last segment experiencing deposition.

Segments can be long where steepness changes slowly. Segments should be shorter where steepness changes most rapidly. The deposition computations are more sensitive to changes in steepness than are the detachment computations. Therefore, shorter segments are needed in depositional areas than in the detachment areas. The rule of thumb given in **Section 8.3.1** can be used as a first approximation where deposition begins to help in initially choosing segments for the depositional portion of the profile.

A minimum of three, preferably four, segments should be used in the depositional area. If segments are too long in the depositional area, RUSLE2 will incorrectly show no or much too little deposition. A minimum of three segments, preferably four, should be used to describe the eroding portion of the profile. However, each non-uniform profile behaves differently depending on degree of curvature of the convex and concave sections of the profile.

As discussed in **Section 8.2.6,** steepness of the last segment experiencing deposition has a major impact of estimated sediment yield. Make sure that this segment is not too long to help avoid entering a steepness at the end of the profile that is too steep resulting in computed sediment yield being too high. The difference between 1 percent steepness and 2 percent steepness can affect sediment yield by a factor of two.

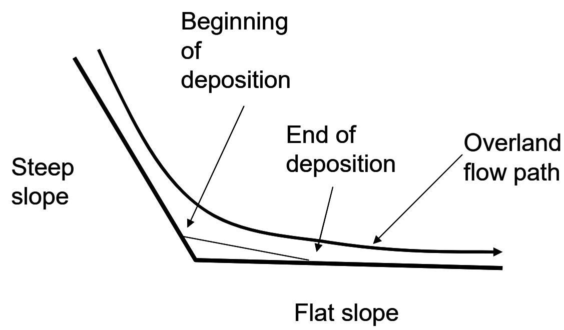

Figure 8.10. Flat uniform slope at toe of uniform steep slope.

Varying segment length is more efficient than using uniform segment lengths for the entire profile. Profile sections of uniform steepness do not need to be divided into segments. A relatively flat slope at the toe of a steep slope is a special case of a concave slope that illustrates that profiles sections of uniform steepness do not need to be divided into segment. This profile is illustrated in Figure 8.10. This profile can be described with two segments, one for the steep slope and one for the flat slope. RUSLE2 computes deposition over a short distance on the upper portion of the flat slope and erosion over the lower portion of the flat slope. RUSLE2 correctly makes these computations without dividing the flat slope into segments.

The most important factor in selecting segments to represent profiles where steepness varies along the profile is that shorter segments are needed where steepness changes most rapidly. Also, shorter segments are needed in depositional than in detachment areas.

8.3.3. Complex:concave-convex profile

Deposition potentially occurs on the lower end of the concave part of the profile provided steepness is sufficiently flat. The guidelines in **Section 8.3.1** can be used to initially estimate whether deposition will occur on the profile and where the depositional area might be as a guide to choosing segments to represent the profile. The same guidelines above for the complex:convex-concave profile (See **Section 8.3.2**) apply for choosing segments to represent a complex:concave-concave profile. An increased number of segments is needed in the depositional area and where steepness is changing most rapidly. An easily made mistake on this profile is to choose segments that are too long in the depositional area. If the segment are too long, RUSLE2 will incorrectly show no deposition when deposition should have been computed.

Deposition on the concave portion of the profile does not end the overland flow path assuming that the flow continues across the depositional area onto the lower part of the slope as overland flow.

The cut-roadway-fill profile illustrated in Figure 8.10 is a special case of a complex: concave-convex profile. Runoff from the cut slope is assumed to flow across the roadway onto the fill slope. If the roadway slopes outward at a sufficient steepness, erosion rather than deposition occurs on an earthen roadway. The overland flow path begins at the top of the cut and extends across the roadway to the bottom of the fill slope assuming that the flow remains as overland flow.

The roadway can be on a sufficiently flat steepness that deposition occurs on the roadway. If the runoff continues across the roadway as overland flow onto the fill slope, the overland flow path begins at the upper end of the cut slope, continues across the roadway, and ends at the bottom of the fill slope. The flow on the fill slope is composed of runoff generated from the cut slope above the roadway so far as runoff produced on the fill slope. The overland flow path length reflects the amount and rate of runoff, which is the reason that it includes the fill slope in this case even though deposition may occur on the roadway. Deposition on the roadway does not end slope length so far as computing soil loss from the fill slope provided the runoff flows across the roadway onto the fill slope as overflow and does not become concentrated flow, perhaps because of a ridge left by a road grader on the outer edge of the road.

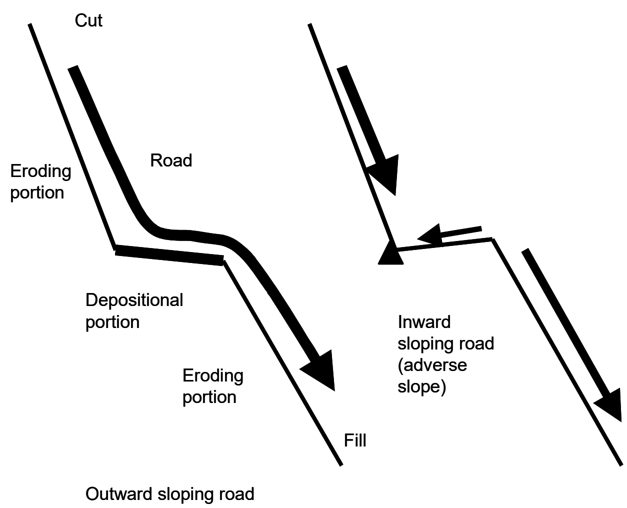

Figure 8.10. Cut-road-fill hillslope illustrating how an inward and outward sloping road section affects overland flow path lengths and that deposition on the outward sloping road does not end overland flow path length

Erosion on the cut slope can be significantly reduced by intercepting and diverting runoff so that the runoff from the cut slope and the roadway do not flow onto the fill slope. A diversion could be placed at the top of the fill slope to intercept the runoff, which is illustrated in **Section 8.3.5**. Placing the diversion at the top of the fill slope reduces erosion on the fill slope, but deposition still occurs on the roadway, which is objectionable.[51]

A better solution is to slope the roadway inward on an adverse steepness back toward the cut slope, as illustrated in Figure 8.10. This profile configuration can be represented very simply in RUSLE2 by entering a negative value for steepness on the roadway to represent an adverse slope. This profile configuration can be described in RUSLE2, as illustrated in Table 8.2, by entering a negative steepness value for the roadway segment. Sloping the road inward creates three overland flow path lengths, one each for the fill slope, roadway, and cut slope segments. RUSLE2 analyzes both profiles illustrated in Figure 8.10 without having to break the analysis into parts. Segments that describe each portion of the profile are entered into RUSLE2, and RUSLE2 automatically determines and handles the overland flow path lengths.

[51] Diversions are considered to be support practices in RUSLE2. Support practices include contouring (ridging), diversions, terraces, vegetative strips, porous barriers, and small sediment basins. See **Section 14** that discusses diversions.

Entering an adverse slope for the roadway causes RUSLE2 to create a channel at the intersection of the cut slope and the roadway. This channel intercepts runoff from the cut slope and collects runoff from the roadway. The sediment yield computed by RUSLE2 is the total sediment yield for the entire profile.

RUSLE2 automatically places a channel where a profile segment with a positive steepness intersects with a profile segment with a negative steepness (an adverse slope). This channel can be described with a grade to compute deposition if the grade is sufficiently flat. RUSLE2 does not compute erosion in channels. This channel ends the overland flow path.

Table 8.2. Erosion on a cut-road-fill slope

Segment #	Distance to lower end of segment (ft)	Segment length (ft)	Segment type	Steep-ness (%)	Soil loss (tons/acre)	Segment type	Steep-ness (%)	Soil loss (tons/acre)
1	75	75	fill	33	162	fill	33	162
2	95	20	outward sloping	2	-493	inward sloping	-2	5.8
3	170	75	cut	33	353	cut	33	162
			Sediment yield = 169 tons/acre			Sediment yield = 143 tons/acre		

8.3.4. Overland flow path with porous barriers (e.g., vegetative strips, fabric fences) and flow interceptors (e.g., diversions, terraces)

RUSLE2 represents two major types of flow barriers. One type is porous barriers where the overland flow is assumed to continue through the barrier onto the portion of the profile downslope of the barrier. Examples of porous barriers include vegetative strips (filter, buffer, stiff grass), fabric fence, gravel bags, and straw bales. The other type of barrier is flow interceptors that cut off the runoff and redirect it around the slope in defined channels. Examples of flow interceptors are diversions and terraces. Diversions and terraces function exactly the same way in terms of intercepting runoff. The difference is that diversions are defined in RUSLE2 as channels that are placed on a sufficiently steep grade that no deposition occurs in them but the grade is not so steep that erosion occurs in the channel. Conversely, terraces are intentionally placed on a sufficiently flat grade that deposition does occur in them. Diversions are placed at critical places on the overland flow profile to intercept runoff and prevent it from flowing onto a steep part of the profile, such as on the landfill example illustrated in Figure 8.12. In contrast, terraces are typically installed as system of uniform spaced channels.

Both diversions and terraces required a runoff disposal system to move the collected runoff down the slope without causing channel erosion. RUSLE2 does not consider the water disposal channel system.

The purpose of porous barriers is to cause substantial deposition. Even though these barriers induce deposition, the overland flow path length does not end at the deposition because the runoff continues through the strip as overland flow. A profile with multiple grass strips that induce deposition has only one overland flow path length as illustrated in figure 8.11b.

Deposition at a grass strip does not end the path length with a new one beginning below the strip. Cover-management segments do not end the overland flow path.

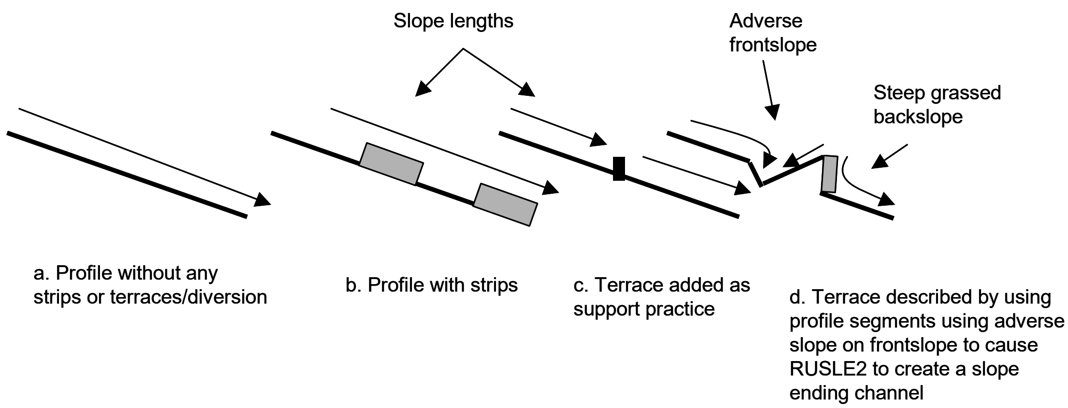

Figure 8.11. How vegetative strips and terraces are described in RUSLE2 and how these practices affect slope lengths assumed by RUSLE2

In contrast, terrace and diversion channels intercept runoff in concentrated flow areas that end the overland flow path. A new overland flow path begins at the terrace/diversion ridge because that is where overland flow originates that flows across the next portion of the profile.

Terraces and diversions can be described in one of two ways in RUSLE2. One approach is used in most conservation planning. RUSLE2 assumes that the terrace/diversion channel and ridge are infinitely thin as illustrated in Figure 8.11c. This approach is used in RUSLE2 where terraces/diversions are represented as a support practice. The other approach is to describe the actual hillslope profile configuration, including the cover-management on each segment such as the grass on a steep backslope of a terrace/diversion.

The overland flow path that is entered in RUSLE2 is the path without the terraces/diversions. The segments are added to create the profile illustrated in Figure 8.11d. RUSLE2 automatically creates a channel where segments with a positive and a negative (adverse) steepness intersect. Such channels end the overland flow path. RUSLE2 determines the appropriate overland flow path lengths without the analysis having to be broken into parts.

8.3.5. Overland flow path for diversions that intercept runoff above steep slopes

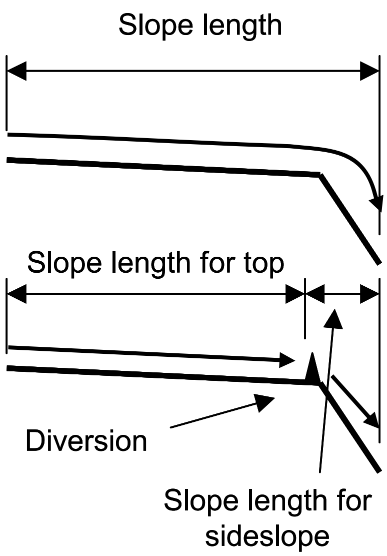

Figure 8.12. Landfill with relatively flat top and steep side slope, with and without a diversion

Table 8.3. Soil loss on a landfill with and without a dversion at the top of the steep sideslope

Segment	Distance to end of segment (ft)	Steep-ness (%)	Soil loss(tons/acre) Without diversion	With diversion
1	250	2	9	9
2	300	33	538	130

Erosion is high at the end of convex shaped hillslope profiles and where runoff from a long slope flows onto a steep slope like the sideslope of a landfill. Placing a diversion at the top of the sideslope as illustrated in Figure 8.12 is an effective practice for reducing erosion on the steep sideslope as shown in Table 8.3. The entire profile description is entered into RUSLE2 and then a diversion is applied at the top of the steep sideslope. RUSLE2 automatically ends the overland flow path for the relatively flat top slope and begins a new overland flow path at the top of the steep sideslope. As expected, the diversion did not reduce erosion on the top of the landfill but significantly reduced erosion on the sideslope.

8.3.6. Overland flow path for contouring (ridging)

The effect of contouring, ridging, and bedding on erosion can be represented in three ways in RUSLE2.[52] The **first method** is that the surface can be represented using a ridge (bed)-furrow description where the overland flow path length is from the top of the ridge (bed) to the furrow that separates the ridges or beds **provided** the ridges and beds are so well defined, so high, and on a sufficiently uniform grade that the runoff flows in the furrows separating the ridges or beds that the flow flows in the furrows along their total length until reaching the end of the furrow or a defined concentrated flow area. The **second method** to describe an overland flow path along the ridges-furrows when the ridges are well defined and flow stays within the ridges as just described.

[52] The effect of contouring on erosion is highly variable and is very difficult to accurately predict. Slight variations can result in wide variations in erosion. For example, under certain conditions, contouring can actually increase erosion, while in other similar conditions, the same contouring can be highly effective. The high variability in effectiveness is partly related to storm severity. The contouring relationships in RUSLE2 represent the main effects that supported by the data. See **Section 14.1** for additional discussion.

The **third method** is to describe an overland flow path assuming a flat soil surface without the ridges and without considering how the ridges affect the flow pattern. This method is used in ordinary cases of ridges like those left in farm fields by tillage equipment such as tandem disks, chisel plows, and field cultivators or those left by ridgers on highly disturbed lands such as reclaimed mine sites.

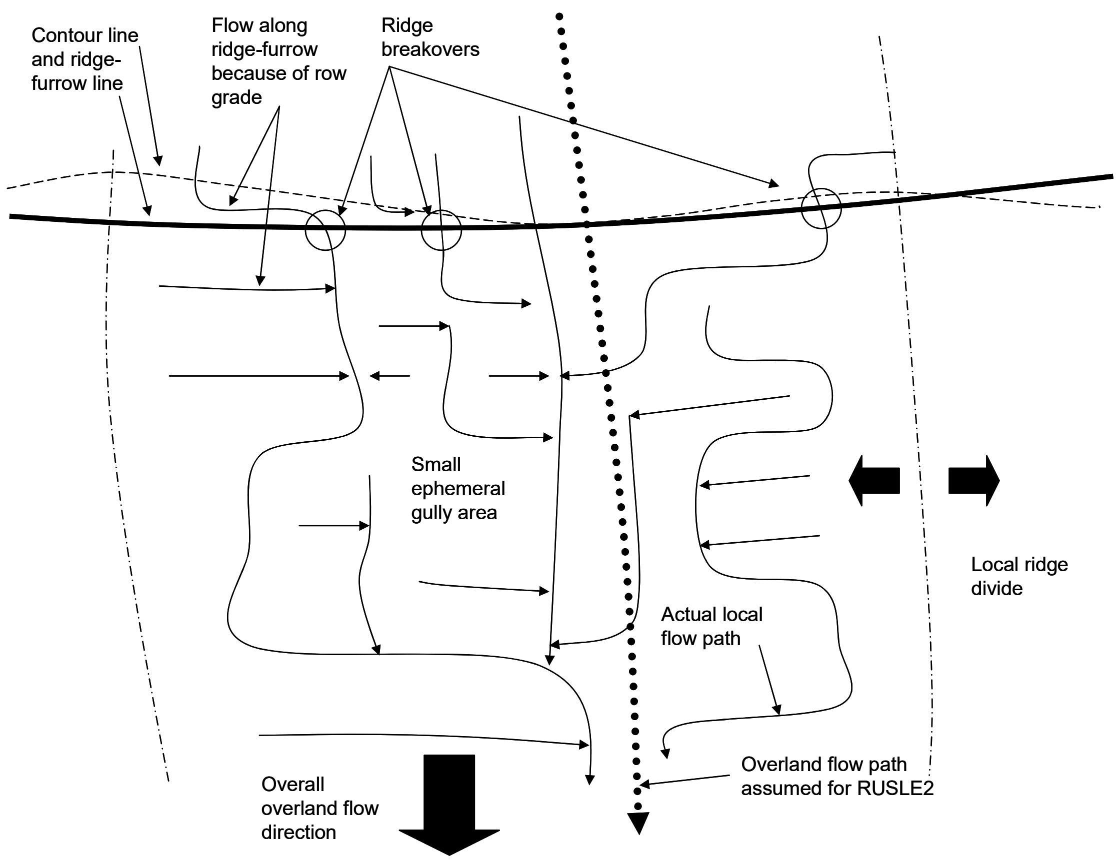

Figure 8.13. Overland flow patterns in a typical field where local runoff flows along ridge-furrows because of a row grade, breaks over in local areas, and accumulates in small local ephemeral gully areas.

These field situations are illustrated in Figure 8.13. Runoff flows along the furrows a distance [a few to several ft (m)] before breaking over one or more ridges before the runoff is intercepted by a sufficiently large ridge to direct runoff along a furrow. The breakovers are located randomly between the major concentrated flow areas. Breakover locations are random and can not be determined after the ridge forming operation in advance of the erosion event because of non-uniform ridge height and non-uniform grade along the furrows. **The first two methods should not be used for the conditions illustrated in Figure 8.13**.

These three methods can give significantly different results, which partially reflects the great difficulty of accurately estimating the effect of contouring (ridging). Use RUSLE2 as a guide to conservation and erosion control planning rather than considering it to provide absolute erosion estimates for any particular site.

8.3.6.1. Overland flow path for ordinary contouring, ridging, and bedding

Contouring, including ridging and bedding, is normally treated as a support practice in RUSLE2. See **Section 14.1** for a description of contouring as a support practice. To treat contouring, ridging, and bedding as a support practice, enter the overland path description in RUSLE2 as the path that the overland flow would follow as if the soil surface is flat and no ridges are present to influence the flow pattern.

8.3.6.2. Overland flow path for a ridge (bed)-furrow description

RUSLE2 can directly compute erosion on ridges and beds and the deposition in the furrows that separate them. RUSLE2 can accommodate overland flow path lengths as short as a zero length. Thus, RUSLE2 can be applied to ridge-furrow and bed systems, like those illustrated in Figure 8.14 for vegetable production.[53] RUSLE2 can also be applied where plastic is added and removed on the beds (See **Section 13.1.9** for a description on how to use RUSLE2 to describe the effect on erosion of adding and removing plastic to beds).

[53] Actually a finite, small number like 0.001 ft (0.5 mm) must be entered, which gives the same result as entering a zero. The erosion rate at a zero overland flow path length is entirely interrill erosion. An erosion rate exists for a zero overland flow path length but the amount of erosion is zero because erosion amount for a uniform profile is the product of average erosion rate for the overland flow path and the overland flow path length.

Representing ridges and beds as the overland flow path and "hillslope profile" is used when the ridges and beds are so high that flow is unquestionably contained in the furrows between the ridges and beds until it reaches a well defined concentrated flow area. RUSLE2 can also compute deposition that occurs in the furrows but not erosion by flow in them.

The overland flow path length is one half of the spacing of the ridges and beds. In this example, 20% is assumed for the steepness of the bed sideslope, and 1% is assumed for the steepness of the top of the beds and 50% is assumed for the steepness of the bed

Table 6.14. Soil loss for ridges and beds

Ridges				Beds			
Segment #	Segment length (ft)	Steepness (%)	Soil loss (tons/acre)	Segment #	Segment length (ft)	Steepness (%)	Soil loss (tons/acre)
1	1.5	20	20	1	0.9	1	3
2	1.5	-20	20	2	0.6	50	27
				3	0.6	-50	3
				4	0.9	-1	27
Soil loss = 20 tons/acre				Soil loss = 13 tons/acre			

sideslope. An adverse steepness (negative values), illustrated in Table 6.14 is used for the segments on either side of the beds. The positive steepness of one sideslope intersecting with the negative (adverse) steepness on the adjacent ridge or bed causes RUSLE2 to create a channel that ends the overland flow path length. The grade that RUSLE2 automatically assumes for the default channel is so steep that no deposition occurs. However, the actual grade can be entered so that RUSLE2 can compute deposition that occurs in the furrows between the ridges or beds.

8.3.6.3. Summary comments

RUSLE2 does not give the same results for all these three approaches for representing ridges-furrows. The approach of explicitly describing the configuration of the ridges and beds works when the ridges contain the flow until a major well-defined concentrated flow area is reached. Although RUSLE2 can estimate deposition in furrows on a relatively flat grade, RUSLE2 can not estimate erosion in the furrows, which RUSLE2 has represented as channels.

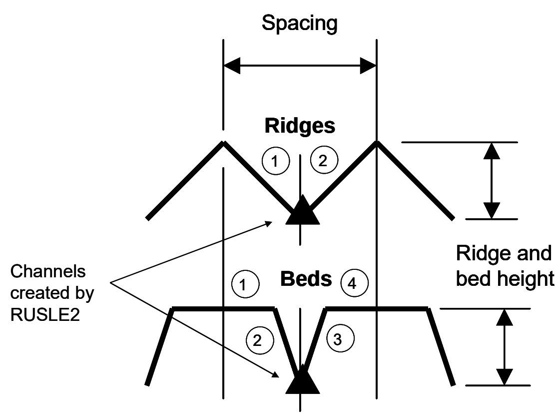

Figure 8.14. Ridge and bed systems.

The approach of representing the overland flow path as if the ridges-furrows are not present works best when the flow pattern is irregular as illustrated in Figure 8.13.

8.4. Influence of Upslope Areas on Overland Flow Path

RUSLE2 is sometimes applied to a field site that is downslope from an area that contributes runoff to the site. The recommended approach is to represent the entire overland flow path even though the upslope area is not a part of the analysis area. The soil loss computed for the downslope area should not be compared to soil loss tolerance, but the procedure described in **Section 7.9.3** where a ratio of soil loss to T value adjusted for position on the slope is computed. A conservation practice should be chosen that reduces this ratio to 1.

RUSLE2 takes into account cover-management conditions on an upslope area for computing transport capacity on downslope segments where cover-management is quite different from the upslope area. However, RUSLE2 does not fully take into account how reduced runoff from the upslope area reduces detachment on the downslope segment. In some applications, **RUSLE2** is applied to a field downslope from an upslope area that is very different from the field. The following approach can be used to take into account how reduced runoff from the upslope segment affects detachment on the downslope segment. If runoff production on the upslope segment is less than that on the downslope segment, the overland flow path length to the upper edge of the downslope segment should be shortened. An example is an undisturbed forest on the upslope area where the overland flow path length begins at the upper edge of the site because no surface runoff is assumed to occur from the undisturbed forest. If the upslope area is pasture and only produces half the runoff that a downslope field produces, the overland flow path length at the upper edge of the field should be one half the distance of the slope length across the pasture area.

Conversely, if the upslope area produces more runoff than does the field, the overland flow path length at the upper edge of the field should be greater than the actual distance in proportion to the differences in runoff potential for the two areas.

9. COVER-MANAGEMENT SUBFACTORS

Cover-management refers to how vegetation, soil condition, and material on and in the soil affect erosion. RUSLE2 describes the effects of cover-management using basic variables applicable to any cover-management system. The basic cover-management variables used in RUSLE2 are canopy (vegetative material not in contact with soil surface), ground (surface) cover (material in contact with soil surface), soil surface roughness, soil ridge height, below ground biomass (live and dead roots and incorporated material), and soil consolidation and antecedent soil moisture in the Req zone (see **Section 6.9**).

RUSLE2 is land use independent, which means that it can be applied to any land use where mineral soil is exposed to raindrop impact and Hortonian overland flow. RUSLE2 can be applied to crop, pasture, hay, range, disturbed forest, mined, reclaimed, construction, landfill, waste disposal, military training, park, wild, and other lands. RUSLE2 does not apply to undisturbed forestlands and lands where no mineral soil is exposed and surface runoff is produced by a mechanism other than rainfall intensity exceeding infiltration rate.

Because RUSLE2 is land use independent, it applies to transitions between land uses. For example, a lightly disturbed military training site may behave much like a pasture or rangeland, a moderately disturbed site may behave like a cropped field, and a highly disturbed site may behave like a very rough construction site. A "fresh" landfill and a recently reclaimed mine site not yet vegetated may behave like a freshly graded construction site but behave like pasture or range land over time. Pasture and rangeland may be periodically converted to and from cropland.

Erosion models based on specific land uses typically do not produce the same erosion values at a common point between land uses resulting in uncertainty between erosion estimates. RUSLE2 does not have this problem.

9.1. Basic Principles

Equation 7.1 estimates soil loss for the unit plot, which is a fallow (no vegetation) condition periodically tilled up and down slope to break the crust and to control weeds. This special condition is used to define and determine soil erodibility factor values (see **Section 7.2**). The daily cover-management factor **c** in equations 5.1 and 8.1 "adjusts" the unit-plot erosion to site-specific field conditions as affected by cover-management.

The cover-management factor c describes how cover-management affects both erosivity and erodibility. For example, vegetation and ground cover affect erosivity by reducing the erosive forces applied to the soil by raindrop impact and surface runoff. Both live and dead roots and organic material in the soil increase infiltration, which reduces erosivity by reducing runoff. These materials reduce erodibility by decomposing in the soil to produce chemical bonding agents that increase the soil's resistance to detachment. Soil mechanical disturbance, which creates a very rough soil surface that ponds water, reduces the erosivity of both raindrop impact and surface runoff. Large soil clods that form the roughness peaks reduce erodibility by being resistant to detachment in comparison to a mechanical disturbance that finely pulverizes the soil. Thus, the effects of both erosivity and erodibility are included in other RUSLE2 factors besides just the erosivity and erodibility factors in equation 8.1.

RUSLE2 uses an index-based method to estimate soil loss without mimicking (explicitly modeling) erosion processes. RUSLE2 involves specific definitions and rules that must be followed, even when logic suggests something different.

A subfactor method used in RUSLE2 to compute values for the cover-management factor c gives RUSLE2 its land use independence.[54] This method uses subfactors that are universally important in how any cover-management system affects rill and interrill erosion. The RUSLE2 subfactors, listed in Table 9.1, are canopy, ground cover, soil roughness, ridge height, soil biomass, soil consolidation,[55] and antecedent soil moisture used in the Req zone. RUSLE2 computes a value for each subfactors for each day and uses equation 9.1 to compute a daily c factor value in equation 8.1.

$$c = c_c g_c s_r r_h s_b s_c p_p a_m \qquad [9.1]$$

where: c_c = canopy subfactor, g_c = ground cover subfactor, s_r = soil surface roughness subfactor, r_h = ridge height subfactor, s_b = soil biomass subfactor, s_c = soil consolidation subfactor, p_p ponding effect subfactor, and a_m = antecedent soil moisture subfactor.

Cover-management variables also affect the RUSLE2 topographic and support practice factors. Thus, the topographic, cover-management, and support practice factors must be examined to see the entire effect of land use and management on RUSLE2 erosion estimates.

---

[54] The RUSLE2 daily cover-management factor c is comparable to the soil loss ratio used in the USLE and RUSLE1. Soil loss ratios in the USLE applied to a crop stage period and to a 15-day period in RUSLE1. The C factor in the USLE and RUSLE1 is an average soil loss ratio value weighted by the temporal distribution of erosivity (EI distribution). Although RUSLE2 can compute a C factor value, RUSLE2 does not use a C factor value and a C factor value from another source can not be entered into RUSLE2 to compute erosion. The RUSLE2 subfactor method involves more variables and a different set of equations than used in the USLE or RUSLE1.

[55] Soil consolidation refers to how erosion decreases with time after a mechanical soil disturbance. Soil consolidation includes how the increase in soil bulk density after a mechanical soil disturbance affects erosion, but the major effect is how wetting and drying and other processes cement soil particles.

Table 9.1. Cover-management subfactors used in RUSLE2.		
Subfactor	Symbol	Comment
Canopy cover	c_c	Influence of above-ground vegetative material not in contact with soil surface; includes both live and dead vegetation
Ground cover	g_c	Material in contact with soil surface; includes both live and dead plant material and other material like manure, mulch, and "roll" erosion control materials applied to the soil surface
Soil (surface) roughness	s_r	Random roughness created by a mechanical soil disturbance; includes peaks and depressions that are randomly shaped and located without an orientation to runoff direction
Ridge height	r_h	Ridges formed by a mechanical soil disturbance; ridges and furrows between ridges redirect flow if not oriented up and down hill
Soil biomass	s_b	Includes plant and other organic material in the soil that has been incorporated by a mechanical soil disturbance, grown there as live roots that become dead roots, or moved into the soil by worms or other organisms
Soil consolidation	s_c	Refers to how a mechanical soil disturbance loosens the soil to increase erosion and the degree to which erosion has decreased following a mechanical soil disturbance
Antecedent soil moisture	a_m	Used in the Req zone; refers to how previous vegetation reduces soil moisture so that subsequent runoff and erosion is decreased

9.2. Cover-Management Subfactors

This section describes each cover-management subfactor and how RUSLE2 computes a value for each subfactor.

9.2.1. Canopy

Canopy is live and dead vegetative cover above the soil surface that **intercepts raindrops** but does not contact the **surface runoff**. The portion of the **above ground plant biomass** touching the soil surface is treated as **live ground cover**.

9.2.1.1. Canopy effects

Canopy intercepts raindrops. Some of the intercepted rainfall reforms as waterdrops that fall from the canopy. The erosivity of these drops is directly related to their impact energy. The impact energy of a waterdrop is one half of the product of mass (determined by drop diameter) and the square of impact velocity (determined by fall height). In contrast to raindrops that vary over a wide size range, all water drops falling from canopy are nearly of an equal size (about 3 mm) that is significantly larger than the median raindrop size (about 1.5 mm). Even though the mass of each waterdrop falling from canopy is greater than the mass of most raindrops, the impact velocity of waterdrops falling from canopy is generally much lower than the impact velocity of raindrops because of the low fall heights from plant canopy. However, if the bottom of the canopy is greater than about 30 ft (10 m), the erosivity of waterdrops falling from canopy is greater than that of raindrops because of the increased mass of the drops falling from canopy.

Some of the rainwater intercepted by canopy flows along plant stems to the soil surface. While this water has no erosivity to detach soil particles by waterdrop impact, it provides water for runoff, but the delay caused by the water flowing along the stems to the soil surface reduces peak runoff rate, which in turn reduces runoff erosivity. Dense canopies retain a significant amount of water that never reaches the ground because it is evaporated after the storm. While this water is not significant for large storms, it can significantly reduce runoff for small storms.

The equation used to compute a value for the canopy subfactor is:

$$c_c = 1 - f_c \exp(-0.1 h_f) \qquad [9.2]$$

where: f_c = canopy cover (fraction) and h_f = effective fall height (ft). The two canopy variables of **canopy cover** and effective **fall height** are used to describe the effect of canopy on erosion.

9.2.1.2. Canopy cover (f_c)

Canopy cover is the portion of the soil surface covered by canopy in a horizontal plan view. The fraction of the soil surface covered by canopy is 1 minus the fraction of open space, which is the space through which a raindrop can fall to the soil surface without being intercepted by the plant canopy. Open space can be seen by looking down on the canopy from above and identifying the open space between the outer perimeter of the individual plant canopies and the open space within the outer perimeter of individual plant canopies. The

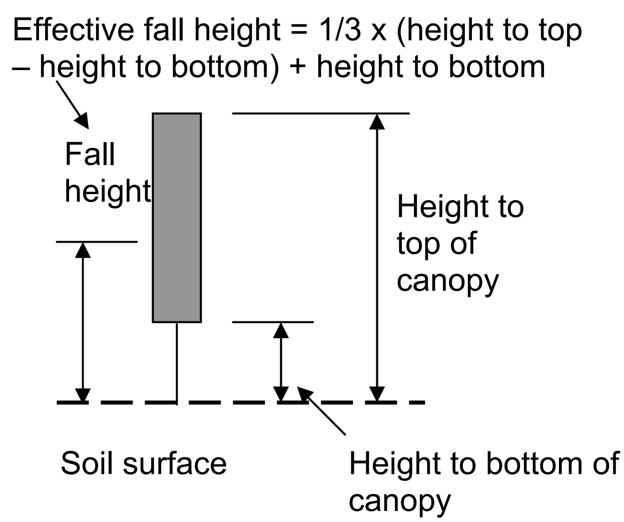

Figure 9.1. Effective fall height for a cylindrical shaped canopy of uniform density

effect on wind on the erosivity of raindrops or on how canopy intercepts raindrops is not considered in RUSLE2.

9.2.1.3. Effective fall height (h_f)

Waterdrops fall from various heights within the plant canopy, and some of the drops are intercepted by lower canopy. The total impact energy of these waterdrops is the sum of the impact energy of each drop on the soil surface. Effective fall height is the single fall height that gives the total energy if all drops fell from a single height. Effective fall height varies with plant maturity and shape, density gradient within the canopy, and heights to the top and bottom of the canopy. If the canopy shape is cylindrical and canopy density is uniform with height, the fall height is assumed to be one third of the way up from the bottom of the canopy as illustrated in Figure 9.1. The lower than average height reflects the likelihood that waterdrops falling from higher in the canopy are intercepted by lower canopy.

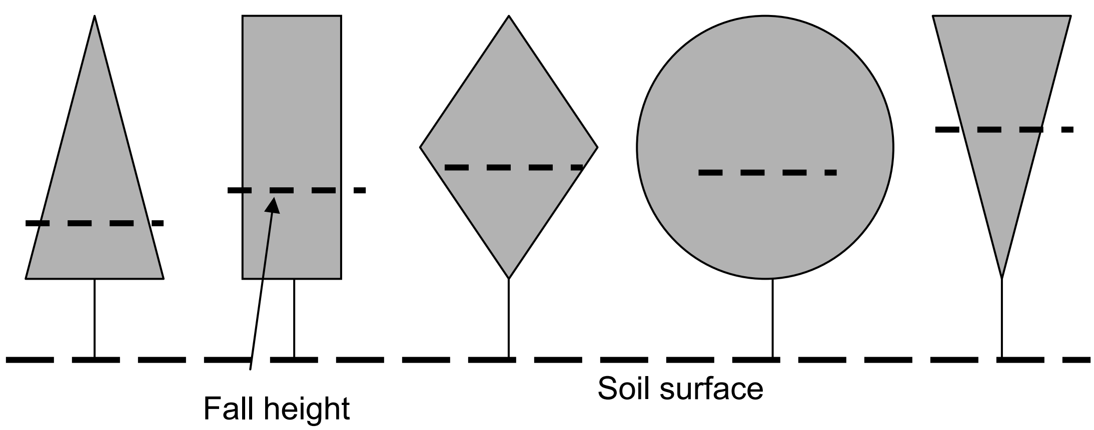

Figure 9.2. Effect of canopy shape on fall height

Canopy shape and density gradient of the canopy material with height influence effective fall height because lower canopy can intercept waterdrops that fall from higher in the canopy. Effective fall height is low when the canopy material is concentrated low in the canopy because of shape and density gradient as illustrated in Figures 9.2 and 9.3. If most of the leaves and branches of the plant are concentrated in the upper portion of the canopy, the effective fall height is one half to two thirds of the distance from the bottom to the top of the canopy. RUSLE2 includes a procedure that uses graphical shapes of these figures to assist in assigning effective fall height values for any particular vegetation throughout its growth.

Fall height assigned to a vegetation (plant community) should be assigned based on how the canopy of the particular plant community affects erosion relative to other plant communities. Fall height must be consistent among vegetations in the RUSLE2 database and consistent with fall heights in the Core Database.

Because the effect of fall height in equation 9.2 is nonlinear, the heights cannot be averaged to determine an effective fall height.

Fall height can be measured at regular intervals along a transect where a rod is lowered through the canopy to the ground. The height to the lowest part of the canopy touching the rod is measured. Rather than averaging these values, the proper approach is to compute a canopy subfactor value by using equation 9.2 for each height and assuming that $f_c = 1$. These subfactor values are averaged and the effective fall height is computed from:

$$h_{fe} = -\ln(1 - c_{ca})/0.1 \qquad [9.3]$$

where: h_{fe} = effective fall height (ft) and C_{ca} = average canopy subfactor.

9.2.1.4. Understory

RUSLE2 uses a single vegetation description at any point in time. The values in this description are for the composite of the plant community that exists at the given point in time. RUSLE2 cannot take components of a plant community and aggregate values for each component into a composite value. The user directly assigns and enters a composite value for each RUSLE2 variable used to describe a particular vegetation.

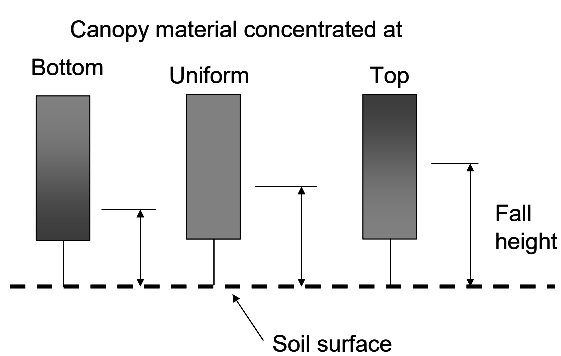

Figure 9.3. Effect of canopy density distribution on fall height

Some plant communities have distinct canopy components of over and understories. Examples include grass under shrubs on a rangeland, grass under vines on a vineyard, a legume interseeded in a small grain, a rye cover crop interseeded in corn, and volunteer weeds that begin to grow as crops approach maturity. Consideration must be given to overlapping canopies in determining an effective fall height. **The understory is often dominant in determining fall height especially if the understory is dense.**

9.2.1.5. Interaction with ground cover

Canopy that is directly above ground cover is assumed not to affect erosion. Thus, the effective canopy cover is computed from:

$$f_{ce} = f_c(1 - f_g) \qquad [9.4]$$

where: f_{ce} = effective canopy cover (fraction) and f_g = portion of soil surface cover by ground cover (fraction).[56] Also, RUSLE2 compares the canopy subfactor value with the ground cover subfactor value computed with the canopy cover value. RUSLE2 does not allow the canopy subfactor value to be less than this ground cover subfactor value. The effect of this comparison is that canopy cover behaves as ground cover as fall height approaches zero.

9.2.1.6. Effect of production level (yield)

RUSLE2 does not "grow" vegetation like a plant model "grows" vegetation. The user describes vegetative growth by entering values for retardance and above-ground biomass at maximum canopy, and values for root biomass, canopy cover, fall height, and live ground cover that vary through time. These values are entered in the vegetation component of the RUSLE2 database to describe a particular vegetation.

Variables used in RUSLE2 to describe vegetation are a function of production level (yield). **RUSLE2** can vary these values for these variables as a function of yield so that a vegetation description does not have to be created for each production (yield) level. A single vegetation description is created for a base yield, which RUSLE2 adjusts to the site specific yield.[57]

The purpose of entering a site-specific production (level) yield is so that RUSLE2 can determine values for biomass on and in the soil. Sources of biomass are **above-ground biomass** and **root biomass** from the vegetation grown on site and from **external residue**

---

[56]The RUSLE2 interaction between canopy and ground cover is similar to the one assumed in the USLE (AH537). No interaction between canopy cover and ground cover was assumed in RUSLE1 (AH703). As a result, the effect of canopy at low fall heights was too great in RUSLE1. In fact, RUSLE1erroneously computed a zero erosion for a 100% percent canopy cover when fall height was zero, rather than erosion for 100% ground cover. The RUSLE1 technique of using a zero fall height to shut off erosion for special purposes such as plastic mulch can not be used in RUSLE2. The **add** and **remove nonerodible cover processes** used to describe **operations** serves this purpose in RUSLE2.

[57] RUSLE2 differs from RUSLE1 in this regard. Different yields could only be accommodated In RUSLE1 by creating a vegetation description for each yield. A single base vegetation description is created In RUSLE2 for a base yield. RUSLE2 adjusts the base vegetation description to fit the specific site yield entered. However, a vegetation description for specific yields can be used in RUSLE2 just as in RUSLE1.

applied to the soil surface and/or incorporated into the soil. External residue includes straw, wood fiber, wood chips, organic-based roll erosion control materials, compost, leaves and forest debris, manure, and other similar materials that are typically applied to control erosion.[58]

Biomass values must be on a dry weight basis. The dry weight of external residue is known at the time of application from the user input value. The dry weight values for the above-ground and root biomass is determined from the production (yield) level entered by the user to represent a particular field site. RUSLE2 adjusts the aboveground biomass value at maximum canopy as a function of yield according to:

$$M_a = M_0 + b_a Y \qquad [9.5]$$

where: M_a = dry weight aboveground biomass at maximum canopy for the site specific yield, M_0 = the aboveground biomass at maximum canopy for a zero yield, and Y = yield in units chosen by the user. RUSLE2 determines values for M_0 and the slope term b_a from values entered by the user for two different yields. RUSLE2 uses a similar relationship to vary retardance with yield (see **Section 11.1.4**).

Dry weight values for root biomass are entered in RUSLE2 for a vegetation description at the base yield. RUSLE2 assumes that dry weight root biomass varies directly with yield, that canopy and live ground cover vary with the square root of yield, and that effective fall height varies with yield to the 0.2 power.

The base vegetation used to create vegetation descriptions at a new yield should be for a base yield where maximum canopy cover is less than 100 percent. The base maximum canopy cover must be less than 100 percent for the RUSLE2 yield adjust function to fully work. If the maximum canopy cover is 100 percent, RUSLE2 can adjust only for yield values greater than the base yield. RUSLE2 does not directly adjust vegetation values as a function of seeding rate, population, or row spacing. RUSLE2 can indirectly adjust for seeding rate and population by assuming a relationship between yield and these variables. Row spacing can only be considered in RUSLE2 by having a vegetation description for each row spacing. If canopy characteristics vary significantly between crop varieties, plant communities, or management practices, a vegetation description must be constructed to reflect each significant difference.

RUSLE2 computes the variation of above-ground biomass through time by assuming that above-ground biomass varies with the 1.5 power (see **Section 11.1.3.1**) of canopy cover.[59] RUSLE2 calibrates this relationship using the user entered values for above-

---

[58] External residue also includes inorganic materials such as rock and roll erosion control materials applied to the soil surface. These materials require special consideration. See **Section 12**.

[59] RUSLE2 tracks aboveground biomass through time, which is different from RUSLE1. A biomass value entered in RUSLE1 had to correspond to the date of an operation that affected aboveground biomass.

ground biomass at maximum canopy and the amount of above-ground biomass remaining after full senescence has occurred. This approach allows an operation to be entered at any date during a cover-management system without the user having to explicitly enter the biomass at that point in time. In some cases, the assumed relationship between canopy and aboveground biomass may not give the proper value for the aboveground biomass when an operation with a **kill** vegetation process occurs before the vegetation reaches maturity.[60] A vegetation description can be created where the above-ground biomass at maximum canopy is the aboveground biomass at the time that the vegetation is killed rather than the above-ground biomass at maximum canopy as the vegetation approaches maturity.

The yield entered in RUSLE2 for the vegetation at a particular field site must be consistent with the site climatic, soil, and management conditions. **RUSLE2 assumes that the user has selected a vegetation description and yield appropriate for the site.** Because RUSLE2 does not model vegetation growth, it can not determine the appropriateness of a vegetation description for a particular site nor does RUSLE make adjustments based on climatic, soil, or management conditions. For example, an operation description must be used to tell RUSLE2 to represent frost killing vegetation.

In RUSLE2, the users define production (yield) level in any terms that they choose, although customary usage is recommended. For example, yield can be expressed in terms of a "fresh" weight or a "dry" weight. Equation 9.5 converts the specified yield, which might be in fresh weight units, to the dry weight values that RUSLE2 needs for biomass.

Accounting for all of the biomass involved in a particular cover-management system is not necessary. **The amount of biomass left in the field to affect erosion is the critical variable.** The amount of biomass that leaves a field is unimportant.

RUSLE2 does not have this requirement. The biomass values are entered at maximum canopy and RUSLE2 tracks biomass through time. An operation can be entered in RUSLE2 at any time in a cover-management system without having to specify (enter) a biomass value in the vegetation description on the date of the operation.

[60] **Kill vegetation** has a particular definition in RUSLE2. Kill vegetation is one of several processes used to describe an operation. Killing vegetation converts live vegetation to dead vegetation. See **Section 13** for the RUSLE2 rules regarding manipulation of vegetation. A **kill vegetation process** must be used in an operation description to tell RUSLE2 that vegetation has died by maturity or has been killed by frost.

RUSLE2 uses a description of site specific conditions to compute erosion. The user carefully follows the RUSLE2 definitions and procedures to create this description. Multiple approaches can often be used to create a description. In general, RUSLE2 was designed so that vegetation descriptions can be created independently of the operations used to manipulate vegetation. For example, this approach allows RUSLE2 to use a single description for corn grown for grain and corn grown for silage. However, some cases may occur where a vegetation description is created to reflect the manipulations of an operation that can not be conveniently created using an operation. The important consideration is that RUSLE2 gets the values that it needs for its computations.

9.2.1.7. Senescence and other canopy losses

Canopy cover increases during the growth period when plants accumulate aboveground biomass. As plants become maturity, some vegetation, such as soybeans and perennial grasses, lose canopy cover by senescence. Other plants, such as cotton, lose canopy cover by being defoliated with chemicals. This loss of canopy cover transfers biomass from standing vegetation to plant litter (residue) on the soil surface. Once canopy material falls to the soil surface, RUSLE2 begins to compute its decomposition. Some plants, like corn, lose canopy cover by leaves drooping without falling to the soil surface, which RUSLE2 also considers (see **Section 11.2.4**).

Plants such as hay and pasture crops and permanent vegetation on rangeland, closed landfills, and other undisturbed areas experience a simultaneous birth and death of aboveground biomass during the growth period while cover is increasing. The death of live aboveground biomass adds a substantial amount of biomass to the surface litter (residue) pool. The daily death of live aboveground biomass is approximately one percent of the live aboveground biomass on that day.

The other way that canopy is lost is by **operations** that **remove live biomass**. Harvest, shredding, mowing, grazing, and burning are typical operations that reduce canopy cover (see **Section 13.1**).

9.2.1.8. Assigning values for canopy

Canopy values assigned to represent a particular vegetation must be consistent with those in the **RUSLE2 Core Database** and with values for other plant communities in the **vegetation component** of the RUSLE2 database. Core values are used to guide assigning values to new vegetation descriptions entered in the RUSLE2 vegetation database. Using consistent values with those in the Core Database helps ensure that RUSLE2 gives the expected erosion estimate and that erosion estimates are consistent between plant communities.

9.2.2. Ground Cover

Ground cover, which is material in contact with the soil surface, slows surface runoff and intercepts raindrops and waterdrops falling from canopy. Ground cover includes all material that touches the soil surface. Examples are rock fragments, portions of live vegetation including basal area and plant leaves that touch the soil, cryptogams (mosses), crop residue, plant litter, and applied materials including manure, mulch, and roll erosion control materials. Ground cover is probably the single most important variable in RUSLE2 because it has more effect on erosion than almost any other variable, and applying ground cover is the simplest, easiest, and most universal way of controlling erosion.

To be counted as ground cover, the material must remain in place and not be moved downslope by surface runoff during a rainstorm. Also, the material must contact the soil surface so that runoff does not flow between the material and the soil to cause erosion.

Operations in RUSLE2 do not affect rock cover entered in the soil component of the RUSLE2 database. Rock fragments added as an external residue are manipulated just like any other "residue" by operations in RUSLE2. See *Section 12* for special consideration regarding treating rock as an external residue

Rock fragments on the soil surface require special consideration. Generally rock fragments must be larger than 5 mm on coarse textured soils in arid and semi-arid regions where runoff is low and larger than 10 mm in other regions to be counted as ground cover. Rock fragments on the soil surface can be treated in one of two ways. They can be considered to be a part of the soil where a rock cover value is entered in the **soil component** of the RUSLE2 database (see Section 7.6). Rock fragments can also be "applied" as an **external residue**.[61]

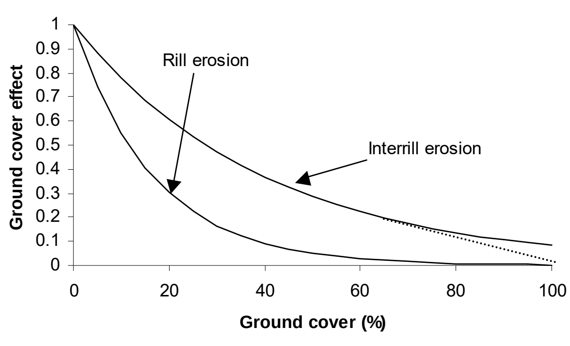

Figure 9.4. Effect of ground cover on rill and interrill erosion

9.2.2.1. Ground cover effect

Ground cover reduces erosion by protecting the soil surface from direct raindrop impact, which reduces **interrill erosion**. Ground cover also slows surface runoff and reduces its detachment and transport capacity, which reduces **rill erosion**. If

[61] **External residue** is RUSLE2 nomenclature that refers to any material added to the soil surface or placed in the soil from a source other than vegetation grown on site.

ground cover is low (less than about 15%) and ground cover pieces are long and oriented across slope, ground cover reduces soil loss by causing deposition in small ponds above ground cover pieces. As ground cover increases, deposition ends and ground cover reduces runoff detachment capacity, which reduces rill erosion. The ground cover effect for both interrill and rill erosion is illustrated in Figure 9.4.

Ground cover reduces rill erosion more than interrill erosion. That is, the ground cover subfactor is less for rill erosion than for interrill erosion for a given ground cover percent as illustrated in Figure 9.4. The net or overall effectiveness of ground cover depends on the relative contributions of rill and interrill erosion. The ground cover subfactor value is less when rill erosion makes the greater contribution to total erosion than when interrill erosion makes the greater contribution.

Factors that affect the relative contributions of rill and interrill erosion affect the ground cover subfactor. These variables include ratio of soil erodibility for rill erosion to soil erodibility for interrill erosion, soil biomass, soil consolidation, ground cover type, and the anchoring and bonding of ground cover to the soil. Obviously ground cover provides the greatest erosion control when it is well anchored and bonded to the soil. Conversely, ground cover is least effective where mulch pieces bridge across soil roughness so that runoff flows under the ground cover and where runoff moves poorly anchored ground cover. RUSLE2 partially represents these effects by reducing erosion for a given amount of ground cover when increased soil biomass is present.

These mechanical effects reduce the forces applied to the soil by waterdrop impact and surface runoff. An indirect effect is ground cover's effect on infiltration and runoff. Infiltration rate can be very high and runoff low on a freshly tilled soil without a surface seal.[62] If ground cover is placed on the soil before a crust is formed, the ground cover will reduce seal formation and help maintain high infiltration and low runoff. Therefore, ground cover has a lesser effect on reducing erosion when placed on a soil after it becomes crusted or placed on a soil where internal soil properties, such as a high clay content or high bulk density, reduce infiltration. A given amount of ground cover reduces erosion more for cover-management systems, such as no-till cropping, that maintain high soil biomass, improve soil quality, and reduce crusting because of increased infiltration. An interaction between soil biomass and soil consolidation is a major variable used by RUSLE2 to compute values for the ground cover subfactor.

Size and shape of ground cover material vary widely. Sizes and shapes include round rock fragments; thin, flat leaves; long slender pieces of unchopped wheat reside; long and increased diameter unchopped corn stalks; large pieces of woody debris left by logging operations; and continuous roll erosion control blankets. The portion of the soil surface

---

[62] A surface seal is a thin, dense layer of soil particles at the soil surface caused by soil particle dispersion associated with raindrop impact and other processes. This thin layer, which reduces infiltration, is known as a surface **seal** when wet and a **crust** when dry.

covered is used as a single variable to describe the effect of ground cover on erosion. Even though the geometry of individual ground cover pieces can vary greatly, even for the same type of ground cover, the portion of the soil surface covered integrates the effects of varying geometry of ground cover pieces on erosion, as illustrated in Figure 9.4. Ground cover (crop residue) provided by above-ground biomass from a typical agricultural crop includes leaves, pods, hulls, cobs, stems, and stalks and fine and coarse roots for below-ground biomass. Ground cover (slash) on a disturbed forest ranges from leaves and needles to broken tree limbs. Furthermore, certain operations, especially harvest operations, frequently reduce size of biomass pieces that becomes ground cover. Even though size and shape of residue pieces vary over a wide range for a particular residue, a single **residue type** is selected to represent the residue. **Residue type** is an entry in the **residue component** of the RUSLE2 database that is selected based on size and toughness of the residue.

Several types of ground cover may occur at a specific site and overlap each other. Examples include rock fragments, live ground cover (basal area and plant leaves), and plant litter. RUSLE2 assumes that ground cover produced by vegetative biomass and ground cover from external residue overlap rock cover represented in the soil description. RUSLE2 also assumes that live ground cover overlaps all other types of ground cover. RUSLE2 assumes that the last ground cover that arrives on the soil surface overlaps existing ground cover, except for live ground cover. RUSLE2 accounts for the overlap of individual ground cover pieces instead of adding the cover provided by each ground cover type.

The important consideration is the net effect of the composite ground cover, not how the individual ground cover materials affect erosion. RUSLE2 uses the net ground cover to compute a value for the ground cover subfactor. The best way to visualize the net ground cover is to determine the fraction of bare, exposed soil and subtract that value from one.

RUSLE2 accounts for ground cover on a mass per unit area basis (e.g., tons/acre, t/ha). RUSLE2 converts mass (weight) values to a percent (fraction) of the soil surface covered (see **Section 12**), accounts for overlap, and uses a net (effective) ground cover value to compute a value for the ground cover subfactor.

Although RUSLE2 tracks ground cover by mass, RUSLE2 displays ground cover in percent (fraction) to aid conservation planning that if often based on maintaining a certain ground cover percent.

9.2.2.2. Equation for ground cover subfactor

The main equation used in RUSLE2 to compute a value for the ground cover subfactor is:

$$g_c = \exp(-bf_g) \qquad [9.6]$$

where: **b** = a coefficient that describes the relative effectiveness of ground cover and f_g = ground cover (percent). The effectiveness of ground cover varies with the site-specific condition. For example, a 50% ground cover can reduce soil loss by 95% under some conditions while only reducing soil loss by 65% under other conditions. Values for **b** in RUSLE2 range from about 0.025 for the interrill erosion ground cover effect to 0.06 for the rill erosion ground cover effect, illustrated in Figure 9.4, to represent this variation in ground cover effectiveness.

Therefore, the net **b** value depends how interrill erosion varies relative to rill erosion. Consequently, the **b** value used by RUSLE2 in equation 9.6 varies daily with the ratio of rill to interrill erosion. RUSLE2 computes a net **b** value using equations based on rill and interrill erosion as:

$$a_t = a_r \exp(-0.06 f_g) + a_i \exp(-0.025 f_g) \qquad [9.7]$$

$$b = -\ln[(a_t /(a_i + a_r)]/ f_g \qquad [9.8]$$

where: a_t = total relative erosion with ground cover, a_r =relative rill erosion on the same bare soil with all other conditions the same as when ground cover is present, and a_i = relative interrill erosion on a bare soil with all other conditions the same as when cover is present. Values for relative interrill and rill erosion in equations 9.7 and 9.8 are computed using the variables in equation 8.3. These equations compute daily **b** values daily that capture the main effects of how the net effectiveness of ground cover on rill-interrill erosion is affected by soil, cover-management, and by slope steepness. These effects are described in **Section 9.2.2.1**.[63]

In Req applications, a constant **b** value of 0.046 is used because the majority of the erosion is assumed to occur from rill erosion. The 0.046 value is based on analysis of plot data.

---

[63] RUSLE2 eliminates the need to choose a **b** value for the effectiveness of ground cover required in RUSLE1.05 or the choice of a land use required in RUSLE1.06. RUSLE2 automates a manual selection of **b** required in RUSLE1. RUSLE2 computes **b** values as cover-management conditions vary through time that RUSLE1 did not compute.

RUSLE2 does not compute a composite ground cover subfactor value by computing a subfactor value for each ground cover type and then multiplying those values. That procedure would be an improper mathematical operation. Therefore, rock fragment cover must be combined with other ground cover considering overlap rather than using a soil erodibility factor value already adjusted for rock cover.

RUSLE2 reduces the effect of ground cover on steep slopes with little soil biomass. This feature represents how mulch is less effective on steep construction sites than crop residue and plant litter on crop, range, pasture, and disturbed forestland. RUSLE2 takes into account how small ground cover pieces that conform closely to the soil surface reduce erosion more than long pieces of ground cover that bridge across roughness elements like soil clods. This effect is greatest on steep, construction-like soil and slope conditions.

RUSLE2 assumes an interaction between soil surface roughness and ground cover such that the effectiveness of ground cover is reduced as surface roughness increases. For example, ground cover in the bottom of a depression filled with ponded water does not reduce erosion as much as does the same ground cover on a flat soil surface.
RUSLE2 computes a low **b** value for flat slopes where interrill erosion dominates, a high **b** value on steep slopes where rill erosion dominates, and an increased **b** value on no-till and other soils conditions where ground cover increases infiltration. The interaction of soil consolidation and soil biomass is used to indicate conditions where ground cover increases infiltration. RUSLE2 also compute increased **b** values for soils susceptible to rill erosion based on soil texture and decreased **b** values for increased soil consolidation that is assumed to reduce rill erosion more than interrill erosion.

RUSLE2 b values are not always comparable to b values reported in scientific literature. In many cases, literature b values are based on plotting soil loss versus percent ground cover without considering other variables such as soil surface roughness, soil biomass, and soil consolidation. Values determined on that basis cannot be compared with RUSLE2 b values because RUSLE2 represents those effects in other variables. Also, reported b values are as large as 0.1, which are larger than can be obtained by RUSLE2. These high b values represent extremes rather than the typical condition represented by RUSLE2.

9.2.2.3. How ground cover is added to and removed from the soil surface

RUSLE2 biomass residue pools:
1. Standing (canopy cover)
2. Flat (ground cover)
3. Buried

Ground cover is added to the soil surface by live vegetation (live ground cover), senescence causing canopy material to fall to the soil surface, natural processes causing standing residue to fall over, an operation (e.g., harvest)[64] flattening standing residue, an operation (e.g., tillage) resurfacing previously buried residue, or an operation applying **external residue** (e.g., mulch, manure, roll erosion control product) to the soil surface. Ground cover is removed when plant growth reduces leaves or other live plant parts from touching the soil surface, an operation (e.g., tillage) buries ground cover, or an operation (e.g., straw baling, burning) removes ground cover.

Live ground cover values are entered in the **vegetation descriptions** in the **vegetation component** of the RUSLE2 database (see **Section 11**). Live ground cover is controlled entirely by these values, and live ground cover does not decompose. **The mass of live ground cover is accounted for in the above-ground biomass of the live vegetation.** Senescence transfers material from the live above-ground biomass (canopy) to the soil surface where it is treated as ground cover (flat residue). Once on the soil surface, this residue decomposes as a function of daily rainfall, daily temperature, and decomposition half life (coefficient) assigned in the **residue description** entered in the **residue component** of the RUSLE2 database (see **Section 12**).
.
When live vegetation is **killed**, it becomes **standing residue**. Over time this residue falls over because of natural processes and becomes ground cover (i.e., becomes surface residue). The rate that standing residue "falls" (i.e., mass is converted from standing residue to surface residue) is proportional to the decomposition rate at the base of the dead standing residue. The base of the standing residue is assumed to decompose at the same rate as the **flat (surface) residue**.

Standing residue, which is not in contact with the soil surface, decomposes at a much slower rate than flat or buried residue because of no soil contact to provide moisture to accelerate decomposition.[65] Standing residue can also be converted to ground cover (flat residue) by an **operation** that includes a **flattening process**. **Flat residue** is lost by decomposition and burial by operations. **Buried residue** is also reduced by decomposition at the same rate as flat residue, and buried residue can be resurfaced by an operation that includes a **(mechanically) disturb soil process**, which adds material to ground cover. **External residue** can also be added to the soil surface by an operation that includes an **add other cover process**. External residue decomposes at the rate determined by the decomposition half life (coefficient) entered for the **residue description** in the **reside component** of the RUSLE2 database**.** See **Section 13** for a description of how operations manipulate ground cover.

---

[64] An operation is an event that mechanically disturbs the soil, changes the vegetation, or changes the residue.

[65] RUSLE2 assumes that flat residue, buried residue, and dead roots all decompose at the same rate. Standing residue is assumed to decompose at a much slower rate than residue in the other pools. Decomposition rate at the base of standing residue, which determines the rate that standing residue falls, is the same as the decomposition rate for flat residue.

The information in each RUSLE2 database component and the rules for manipulating RUSLE2 variables are a "language" and procedure used to describe field conditions through time. The objective in RUSLE2 is to describe field conditions as they exist, not to model processes as a way to describe field conditions. A check should always be made before making a RUSLE2 computation to verify that the user created description matches the actual field situation. RUSLE2 uses your field description to estimate erosion.

Nonerodible cover can be added to the soil surface to represent adding a plastic mulch used in vegetable production, a water layer used in rice production, a snow cover in winter months, and to shut off erosion for particular computational reasons. Nonerodible cover acts like other kinds of ground cover except that it completely shuts off erosion for the portion of the soil surface that it occupies. Half life and permeability are parameters used to describe nonerodible cover (see **Section 13.1.9**).

Most types of ground cover can be removed from the soil surface. Live ground cover is removed controlled by the values assigned through time in the **vegetation description**. Rock cover assigned in the **soil description** can not be removed. Other forms of ground cover can be removed by using an **operation** that has a **remove residue/cover process.** Buried residue biomass in the soil can be removed by using an operation to **resurface** the residue to become ground cover and then using another operation that removes this ground cover. Neither live nor dead roots can be removed from the soil. **RUSLE2**

RUSLE2 rules for transfer of residue among pools:
1. Residue is added to the soil surface by senescence, standing residue falls over by natural processes, standing residue that is flattened by an operation, or application of external residue
2. Senescence transfers biomass from live canopy to the soil surface, adding ground cover (flat residue)
3. Live vegetation cannot be flattened or buried
4. Killing live vegetation creates standing residue (dead plant material)
5. Standing residue becomes flat residue by falling over from natural processes or by being flattened by an operation
6. Only flat residue can be buried (standing residue must first be flattened by natural processes or by an operation before it can be buried)
7. Flat residue can only be buried by an operation that mechanically disturbs the soil
8. Twenty five percent of the daily decomposed flat (ground cover) residue becomes buried residue in the upper 2 inch (50 mm) soil layer where it decomposes again
9. Only buried residue can be resurfaced; roots can not be resurfaced
10. Buried residue can only be resurfaced by an operation mechanically disturbs the soil

assumes that a decrease in the live root biomass in the vegetation description represents root sloughing that becomes a part of the dead root biomass pool (see **Section 11.2.6.3**). **Also, RUSLE2 can represent daily additions to the dead root pool by root death during growth periods (i.e., when live root biomass is increasing).**

9.2.2.4. Conversion of residue mass to portion of soil surface that is covered

RUSLE2 uses the following equation to convert ground cover (residue) mass to portion of the soil surface that is covered:

$$f_g = 1 - \exp(-\alpha M_g) \qquad [9.9]$$

where: α = a coefficient that is a function of residue characteristics (units depend on the units of M_g) and M_g = residue mass per unit area (e.g., lbs/acre, kg/ha) expressed on a dry matter (weight) basis. Figure 9.5 shows a plot of equation 9.9 for four residue types.

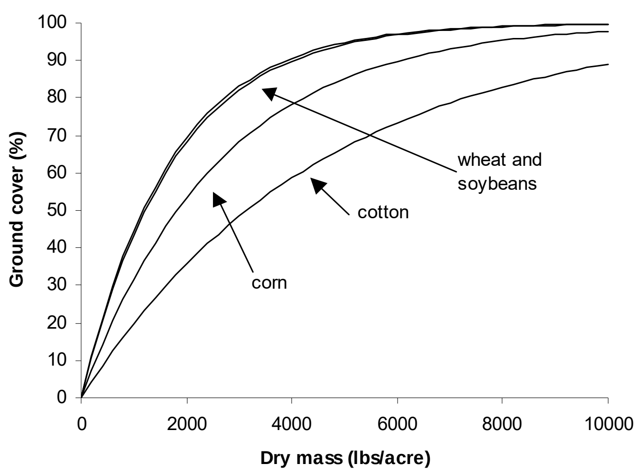

Figure 9.5. Relationship of ground cover to dry mass for four types of residue.

RUSLE2 uses data points entered in the **residue description** in the **residue component** of the RUSLE2 database to determine a value for α in equation 9.9 for each residue description in the residue component of the RUSLE2 database (see **Section 12.3**).

Figure 9.5 illustrates differences in residue types. Cotton residue is mainly composed of very coarse, woody stems, which requires a large mass of these residue pieces to produce a given ground cover. The other extreme is soybean residue, which is a mixture of several plant components including leaves, stems, and seed pods. The curve for wheat residue is similar to the one for soybean residue, but in this case, not a particularly large mass of hollow wheat stems is required to provide significant ground cover. Also, a significant amount of wheat residue is composed of leaves. Corn residue is intermediate. Much of the corn residue is large stalks that are solid but less dense than cotton stems. Also, much of the corn residue is composed of leaves.

The portion of the soil surfaced covered by residue does not change greatly as residue mass (weight per unit area) changes at high amounts of ground cover. For example, reducing the mass of the ground cover material by 50% has little effect on ground cover if mass of material on the soil surface is very large. In contrast, a slight change in mass per unit area at low mass values can significantly change ground cover. The small change in ground cover at large mass values is a major reason that RUSLE2 computes burial and resurfacing of material based on mass rather than on percent cover.

The best approach for selecting values for a residue description in the RUSLE2 database is to choose values based on information in the **core database** rather than making site specific field measurements. Field data are highly variable and should be avoided unless a large mass of data collected under research conditions are available (see **Section 9.2.2.6**).

Be cautious in developing residue descriptions for different crop varieties. Differences reported in scientific literature often represent unexplained variability rather than real differences.

RUSLE2 uses a single composite residue description for a particular residue although crop residue and plant litter are composed of a wide variety of plant components of different sizes. This approach is a compromise. A small mass of leaves gives a much greater percent ground cover than does the same mass of stems. Therefore, the relationship between cover and mass depends on the relative proportion of leaves and stems, or other plant components. This relationship changes through time because the residue components decompose at different rates. For example, leaves decompose much more rapidly than do stems. Consequently the mass-cover relationship is very different immediately after harvest when many leaves are present than later after the leaves have decomposed with only stems remaining. Also, the mass-cover relationship for a residue type can appear to differ by location for a particular plant community, when in reality the mass-cover relationship is reflecting how the proportion of leaves to stems varies by time and location.

The mass-cover values for the residue descriptions in the RUSLE2 core database were primarily chosen so that RUSLE2 computes erosion estimates that compare well with measured erosion values in research studies.[66] Also, the core database residue descriptions were chosen to represent the overall mass-ground cover relationship for the first year after harvest rather than fitting ground cover values at a specific point in time, such as one year after harvest. The result is that RUSLE2 may underestimate cover

[66] The major reason for having and using a RUSLE2 **core database** is to help ensure consistency in RUSLE2 estimates, especially by cover-management system and by location. Consistency is a major requirement when RUSLE2 is used to implement cost sharing and regulatory type programs so that all clients are treated fairly.

beyond about 12 months. The core database values were chosen to compute average annual erosion as a function of main effects rather than secondary effects associated with residue components decomposing at different rates. Fitting secondary effects, especially with limited data, is often fitting unexplained variability. The core database values represent several data sets rather than focusing on a single data set.

9.2.2.5. Spatially non-uniform ground cover

This section describes how to apply RUSLE2 where ground cover is concentrated in strips and patches. Examples of non-uniform ground cover are narrow strips mechanically disturbed by tillage and planting equipment, residue strips left by harvest operations, natural processes that cause residue to collect in strips, "patches" of highly disturbed soil left by logging and military training operations, and grass/shrub "clumps" on rangeland.

RUSLE2 uses different **cover-management descriptions** along the overland flow path to compute erosion for these conditions. Segments are created in the **management layer** illustrated in Figure 8.1. Cover-management descriptions are assigned to segments to represent non-uniform ground cover and disturbed soil along the flow path.

RUSLE2 assumes that ground cover is uniformly distributed for a particular cover-management description. RUSLE2 values for flattening, burial, and resurfacing ratios used to describe the manipulation of residue by operations are based on the entire area, not the local area where the residue is manipulated, such as in a tilled strip where seeds are planted.

The first example is the patchiness common to disturbed forest lands and military training sites where ground cover and soil disturbance vary randomly. The boundaries between the patches are the location of segment breaks. Cover-management descriptions are applied to each segment to represent each cover-management condition along the flow path.

A second example is landfills where vegetation and ground cover vary along the flow path because of soil differences. Segments are created in both the soil layer and the management layer in Figure 8.1. Appropriate soil and cover-management descriptions are assigned to each segment.

A third example is residue strips left by a combine without a straw spreader. Two cover-management descriptions are used to represent this condition. One description is for the strip that has standing residue with no flat residue from the vegetation just harvested. An operation with a **remove residue/cover process** is used to remove the flat residue that RUSLE2 assumes to be uniformly distributed. The cover-management description for the other strip is the same except it **applies external residue** to add the residue removed in the first cover-management description. The management layer in Figure 8.1 is divided into segments based on the width of each cover-management strip and the appropriate cover-management description is applied to each strip.

A fourth example is for mechanically disturbed strips, such as in vineyard or orchard where clean tilled strips are maintained within a relatively undisturbed area. A cover-management description is created for each strip and the management layer in Figure 8.1 is divided into segments to represent each of these strips along the overland flow path. If the strips are uniform along the flow path, the **strip/barrier descriptions** can be used to facilitate dividing the flow path into segments (see **Section 8**). Dividing the profile illustrated in Figure 8.1 into many segments can be tedious and laborious. The important variable is the ratio of the sum of the segment lengths of one strip type to the entire overland flow path length. This variable is more important than the actual number of strips along the flow path provided the number of strips exceeds a total of about 20 for the combination of strips (10 of one strip type and 10 of the other strip type). The inputs for number of strips and width of strips must be coordinated to ensure that the relative portion of the flow path occupied by each strip type is maintained.

A RUSLE2 template that includes the profile schematic illustrated in Figure 8.1 must be used to apply this procedure. This template allows non-uniform segment lengths. Also, strips are not constrained to be on the contour.

HOWEVER, CARE SHOULD BE TAKEN IN APPLYING RUSLE2 TO STRIPS. THE POSSIBILITY OF RUNOFF RUNNING ALONG THE UPPER EDGE OF HIGH RETARDANCE STRIPS BELOW ERODIBLE AREAS MUST BE CONSIDERED.

9.2.2.6. What to do when RUSLE2 computes a ground cover value that is not the expected value

Ground cover is a key variable used in conservation and erosion control planning and in determining whether a conservation or erosion control plan has been properly implemented. Residue ground cover immediately after planting is often the key value for conservation planning on cropland. RUSLE2 is expected to provide a good estimate of this ground cover value. The acceptability of RUSLE2 is sometimes judged on the basis of this value. Comparisons are made between the RUSLE2 estimated residue cover values with research data, site-specific field measurements, and professional judgment. This section provides guidance on making these comparisons and how to adjust RUSLE2 inputs if ground cover estimates do not meet expectations.

Several factors must be considered in comparing RUSLE2 residue ground cover values with field observations. RUSLE2 computes "typical," average annual daily residue cover values rather than residue cover at any specific time. Residue cover values measured at a particular site vary greatly from year to year, requiring at least three years of data where a range of production (yield) levels and weather conditions occurred to obtain measured values comparable to RUSLE2 estimates. Also, residue cover varies greatly from location to location within a field site requiring numerous measurements at a site depending on the measurement procedure (e.g., a beaded string versus photographs of a meter (yard) square area).

Great care must be taken in measuring residue cover when the cover is spatially non-uniform in strips and patches to ensure that the sample density is sufficient when measuring residue cover using the bead-string or similar method, especially if the strips are narrow and residue cover is heavy in one strip type. In fact, the best way to measure residue cover for this condition is to use transects within each strip type rather than diagonally across strips and weight the values based on area represented by each strip type.

The RUSLE2 mass-cover and erosion equations are highly nonlinear. As a consequence, using residue cover averaged over the entire area to estimate erosion with RUSLE2 likely will not give the same result as that obtained when the spatially non-uniform cover is analyzed using segments as described in **Section 9.2.2.5**. Remember, the purpose of RUSLE2 is to serve as a tool to guide conservation and erosion control planning rather than being a scientific tool.

The error in residue cover measurements can be large for residue cover less than about 20 percent. Sometimes residue mass is estimated based on field measurements of residue cover percent converted to a mass using curves like those in Figure 9.5. The error in mass can be large, sometimes by as much as a factor of two, for residue cover values greater than 75 percent. The residue mass can change by a large amount with only a small change in ground cover because of the flatness of the mass-cover curve at high cover values. Also, the data used to develop curves like those in Figure 9.5 are highly variable based on the relative portion of leaves to stems and other factors.

Very carefully compare the values determined from site-specific field measurements with values in the **core database** and values reported in the literature. Ask the question, "Are the field measured values consistent with commonly accepted values and reasonable when the data as a whole are considered? If the measured values differ significantly from other values, can the differences be reasonably explained?"

Getting a good comparison between the RUSLE2 residue cover estimate and a measured value at a particular point in time, such as immediately before harvest, does not ensure a good average annual erosion estimate. The best average annual erosion is obtained from a good estimate of residue cover over the two to three month period during the most erodible part of the year. The most erodible period is determined by a combination of peak erosivity and peak susceptibility of the field condition to erosion. RUSLE2 templates that display erosion through time can be used to identify the most erodible period.

RUSLE2 was constructed and calibrated, and values in the core database were carefully chosen to ensure that RUSLE2 produces average annual erosion estimates consistent with commonly accepted erosion scientific knowledge and the uncertainty in the research erosion measurements (see **Section 17** for a discussion of the uncertainty in erosion data and RUSLE2 erosion estimates). RUSLE2 was developed to capture main effects rather than secondary variability, which often reflects statistically unexplained viability. Thus, fitting RUSLE2 to data from a specific research study or measurements made at a specific field site often does not improve RUSLE2 estimates and in fact may degrade the quality of estimates. Residue cover can vary greatly from year to year as yield and weather vary.

Don't make changes just to get a better fit to local conditions. Always compare against a broad data set. Look at RUSLE2 estimates as representing main effects and typical conditions in a conservation planning context, not in a research context. Make sure that data being fitted are high quality, and collect as much supplemental data as possible, including yield, residue mass, and how residue cover varies during the year.

ALWAYS CHECK RUSLE2'S ESTIMATED EROSION. CHANGING INPUTS THAT AFFECT RESIDUE COVER ALSO AFECTS OTHER RUSLE2 COMPUTATIONS. DO NOT AUTOMATICALLY ASSUME THAT A RESIDUE COVER VALUE AT A PARTICULARLY TIME, SUCH AS IMMEDIATELY AFTER PLANTING OR BEFORE HARVEST, CORRECTLY COMPUTED BY RUSLE2 ENSURES A CORRECT AVERAGE ANNUAL EROSION ESTIMATE.

If one concludes that RUSLE2 is not computing the desired residue cover values, how does one change input values to obtain the desired residue cover values? The main factors that affect residue cover must be considered in a systematic, stepwise manner. The factors that affect residue cover affect many other RUSLE2 computations. Adjusting a particular RUSLE2 input may give the expected residue cover but adversely affect the RUSLE2 erosion estimate because other RUSLE2 computations were affected. The main variables to consider and the order to consider them are: (1) the amount of residue at harvest, (2) the distribution between standing and flat residue at harvest, (3) the mass-ground cover relationship, (4) values for the burial and resurfacing ratios of the operations, and (5) the decomposition half life (coefficient) value. Estimated residue cover and erosion values should be checked at each step. Sometimes changing a particular variable gives unexpected results. For example, changing the value for the decomposition half life affects not only ground cover, but standing residue, buried residue, and dead roots as well.

9.2.3. Soil (Surface) Roughness

Soil (surface) roughness, illustrated in Figure 9.6, refers to the random peaks and depressions left by soil disturbing operations. This random roughness does not affect general overland flow direction in contrast to oriented roughness (ridges and furrows) that redirects runoff. Roughness characteristics at the time that the roughness is created depend on soil disturbing operation that creates the roughness, soil properties including texture and soil moisture, live vegetation, standing and flat residue, and soil biomass. Different types of soil disturbing operations produce widely differing distributions of aggregates and clod sizes depending on soil conditions, which affect roughness. Surface roughness decays over time to a smooth surface, except for a few persistent clods on some soils.

Figure 9.6. Soil surface with a 1.0 inch roughness just created by a mechanical disturbance.

9.2.3.1. Soil (surface) roughness effect

Soil surface roughness affects erosion in several ways. The depressions formed by surface roughness pond water and slow runoff, which reduce the erosivity of raindrops, waterdrops falling from vegetation, and surface runoff. Runoff's transport capacity through the depressions is very low, which causes local deposition. Soil surface roughness decays over time as deposition fills the depressions with sediment, interrill erosion wears away the roughness peaks, and the presence of water and weathering cause the soil to subside.

Soil clods resistant to detachment primarily form the roughness illustrated in Figure 9.6. Surface roughness is a partial measure of clodiness left by a soil disturbance. Large clods also produce deep depressions. Fine soil particles produced during the creation of the roughness are often left in the depressions where they are protected from erosion. Thus, erodibility of a rough soil surface is less than that of a smooth, finely pulverized soil surface. The degree that a soil forms clods depends on soil texture and soil moisture at the time of the soil disturbance. RUSLE2 does not consider the effect of soil moisture on soil roughness, mainly because RUSLE2 is an average annual model. Clods are smaller and less stable for coarse textured soils than for fine textured soils (see **Section 7.4**).

Soil surface roughness increases infiltration, which reduces runoff. Also, cloddy, rough soils resist sealing and crusting in comparison to finely pulverized soils that readily seal and crust, especially if soil biomass is low. Thus, rough soils reduce erosion because of decreased runoff.

RUSLE2 considers a **short term roughness** and a **long term roughness**. Short term roughness is created by tillage equipment, earth moving machines, and similar operations that mechanically disturb the soil. Long term roughness evolves over time after the last mechanical soil disturbance on pasture, range, landfills, and reclaimed land. Long term roughness is related to vegetation type (bunch versus sod forming), plant roots near the soil surface, local erosion and deposition by both water and wind, and animal traffic. RUSLE2 simultaneously keeps track of the decay of short term roughness and the natural development of long term roughness over the **time to soil consolidation** (see **Section 7.8**). Daily short term roughness decay is computed as a function of daily precipitation and daily interrill erosion. The effect of soil conditions at any point in time is captured by the effect of soil conditions on the initial roughness discussed in Section 9.2.3.3. Long term roughness is computed as a function of time and the final roughness roughness value that is a user input.

9.2.3.2. Roughness measure

RUSLE2 uses a roughness index that is the standard deviation of the micro-surface elevations about the mean elevation as a measure of soil surface roughness. Machines like scarifiers, moldboard plows, and heavy offset disks create rough soil surfaces [e.g., $R_m > 1.5$ inch (35 mm), R_m = field measured roughness value] while machines like rotary tillers pulverize the soil and leave a smooth soil surface [e.g., $R_m < 0.2$ in (5 mm)]. Machines, like bulldozers and road graders having blades that cut the soil also leave a smooth surface with a low roughness value.

The method of laying a roller chain on the soil surface and estimating roughness by how much the horizontal measurement between the ends of the chain is shorter than the chain length should not be used to measure roughness for RUSLE2. This procedure does not capture all roughness features important in RUSLE2.

Micro-relief meters are used in research to measure surface roughness. These meters measure micro-surface elevations over a grid by lowering pins to the soil surface or by using a laser system.[67] Because roughness index values depend on grid spacing, a standard spacing of 1 inch (25 mm) should be used to determine roughness index values for RUSLE2. Also, a plane should be fitted to the elevation data, and deviations taken

[67] Toy, T.J., G.R. Foster, and K.G. Renard. 2002. Soil Erosion: Processes, Prediction, Measurement, and Control. John Wiley and Son, New York, NY.

with respect to the plane to remove the effects of land slope. Also, the effect of ridges (oriented roughness) should be avoided or taken out of the data by analysis as well.

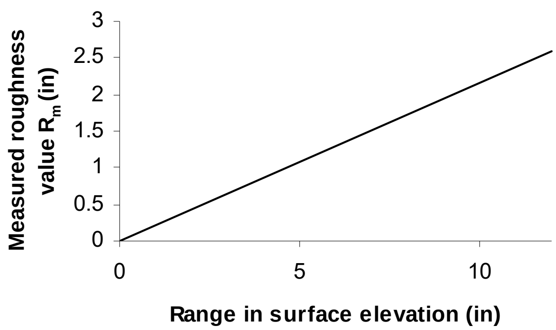

Figure 9.7. Relation of measured surface roughness value to range in elevation from highest roughness peak to deepest depression

Figure 9.7 provides an approximate estimate of surface roughness if a micro-relief meter is not available. The range in surface elevation from the highest roughness peak to the bottom of the deepest depression is measured by laying a 6 ft (2 m) straight edge across the roughness peaks.[68] A third approach for estimating surface roughness is to compare the appearance of the soil surface with photographs for soil surfaces having measured roughness values.[69]

Roughness values used in *operation descriptions* in the *operation component* of the RUSLE2 database are selected from the core database, not from field measurements at the site where RUSLE2 is being applied.

9.2.3.3. Soil surface roughness subfactor

Values for the RUSLE2 soil surface roughness subfactor are computed from:

$$s_r = \exp[-0.66(R_a - 0.24)] \qquad [9.10]$$

where: R_a = adjusted roughness value (inches) and 0.24 inches (6 mm) = the adjusted roughness value assigned to unit plot conditions (see **Section 7.2** for a description of unit plot conditions). The value for the roughness subfactor for the unit plot conditions is 1 by definition. Roughness subfactor values are less than 1 when the surface roughness effect of the site-specific condition is greater than on the unit plot and greater than 1 when the site-specific surface roughness effect is less than on the unit plot. An example of a soil surface that is smoother than the unit plot is a soil finely tilled with a rotary tiller for vegetable seeding. A soil surface with an adjusted roughness greater than the 0.24 in (6 mm) of the unit has roughness subfactor values less than 1. Roughness subfactor

[68] See Figure C-10, AH703 for details.
[69] See AH703.

values can range from almost 1.2 for a perfectly smooth surface to lower than 0.3 for an exceptionally rough surface as illustrated in Figure 9.8.

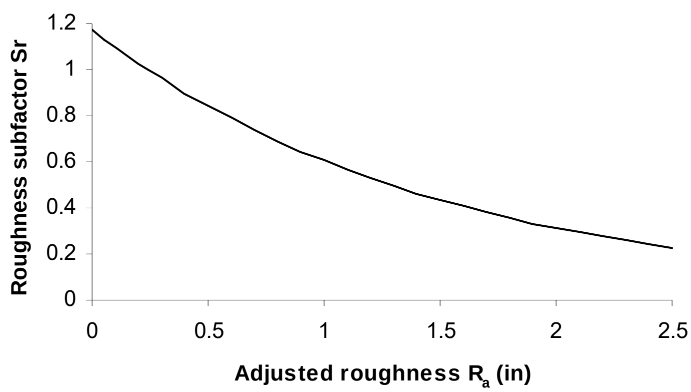

Figure 9.8. Relation of roughness subfactor to adjusted roughness

Computation of the adjusted roughness R_a starts with the initial base R_{ib} roughness assigned to **operation descriptions** having a **disturb soil process** in the **operations component** of the RUSLE2 database. The **initial base roughness** is assigned according to the roughness that the operation would produce for a smooth silt loam soil having a high soil biomass similar to a soil with a dense sod grass cover.

The input roughness value assigned to an operation is the roughness that the operation would create on a silt loam soil where the soil biomass is very high.

The first step in computing an adjusted roughness value to use in equation 9.10 is to adjust the initial roughness value R_{ib} for the effect of soil texture by multiplying by a soil texture adjustment factor. Soil texture adjustment factor values computed with the RUSLE2 equations for the midpoint of the soil texture classes are shown in Table 9.2.

The roughness adjustment factor is greater for high clay soils than for high sand soils. Consequently, RUSLE2 uses a higher roughness value for high clay soils than for high sand soils for a given initial (input) base roughness values, which means that soil surface roughness reduces erosion more on high clay soils than on high sand soils for a given operation. The adjustment factor for a silt loam soil is 1.0 because it is the base condition.[70]

The next adjustment is for soil biomass computed with:

$$R_a = 0.24 + (R_{it} - 0.24)\{0.8[1 - \exp(-0.0015 B_{ta})] + 0.2\} \qquad [9.11]$$

70 The difference between 1.0 and the 1.02 value in Table 9.1 results from rounding and not being able to fit the equation to exactly 1.0 for the mid-point of the silt loam texture.

where: R_{it} (inches) = the initial (input) roughness adjusted for soil texture and B_{ta} = the total mass (dry weight basis) of buried residue and dead roots averaged over the soil disturbance depth after the operation (lbs/acre per inch depth). Figure 9.9 illustrates how the input roughness value is adjusted for soil biomass for a range of input roughness values.

Table 9.2. Factor to adjust input roughness as a function of soil texture

Soil texture class	Adjustment factor
clay	1.39
clay loam	1.22
loam	1.05
loamy sand	0.78
sand	0.69
sandy clay	1.25
sandy clay loam	1.13
sandy loam	0.90
silt	0.81
silt loam	1.02
silty clay	1.33
silty clay loam	1.23

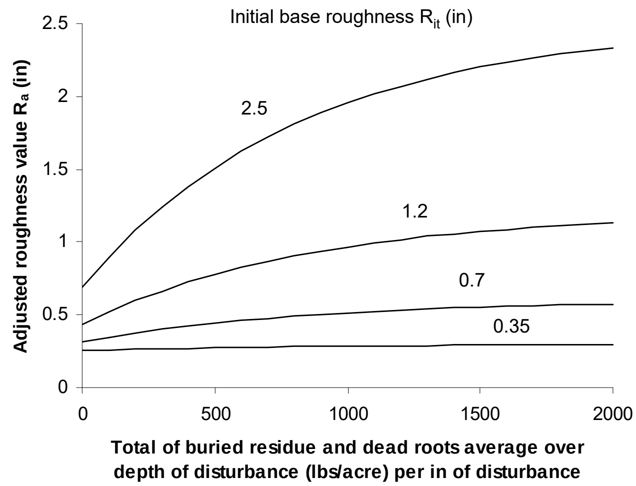

Figure 9.9. Roughness value adjusted from input value for soil biomass effect.

The effect of soil biomass on roughness can be observed in the field by comparing roughness after sod field is plowed with the roughness after a field in continuous low residue vegetable cropping is plowed. The difference in roughness can also be observed when a permanent grass strip beside a continuously cropped field is plowed. Soil surface roughness is much larger on the sod field and grass strip than on the continuously cropped fields having much lower biomass than the sod and grass conditions. The soil plowed out of sod turns up in "chunks" as if it is held together by roots. A similar effect occurs in chisel plowed wheat stubble fields.

The effect of roughness in a sod, meadow, and hay fields on erosion is very significant. According to Table 5-D, AH537[71] erosion immediately after moldboard plowing a high biomass condition is one fourth of that immediately after moldboard plowing a continuous row cropped field where biomass is reduced. The biomass effect on erosion depends on the sod, meadow, or hay production (yield) level, which determines the biomass of roots and buried residue. The roughness effect for moldboard plowing in a continuous cropped corn is also a function of yield as illustrated in Table 5, AH537. For example, the roughness subfactor value is about 0.55 for a 110 bu/ac yield and about 0.75 for a 50 bu/ac yield. A roughness related to biomass effect is also illustrated in Table 5,

[71] Wischmeier, W.H. and D.D. Smith. 1978. Predicting rainfall-erosion losses: A guide to conservation planning. U.S. Dept. of Agriculture, Agriculture Handbook # 537.

AH537 where the residue is removed, which reduces soil biomass. For example, the soil surface roughness subfactor is about 0.90 where the residue is removed for a 110 bu/acre corn yield while it is about 0.55 where the residue is not removed. The values in Tables 5 and 5-D, AH537 are based on measured soil loss data. Another illustration of how soil biomass affects the soil surface roughness is that a soil surface is noticeably smoother after tillage following soybeans than tillage following corn.

When roughness data from field research are analyzed to develop input roughness values for RUSLE2, field measured roughness R_m values must be adjusted for soil texture using Table 9.2 and for soil biomass using Figure 9.10. The best approach is to make roughness measurements under high soil biomass conditions to minimize the amount of adjustment required for biomass. As illustrated in Figure 9.10, biomass does not have much effect on the soil surface roughness value for soil biomass values (buried residue plus dead roots) greater than about 1000 lbs/acre per inch depth of disturbance.

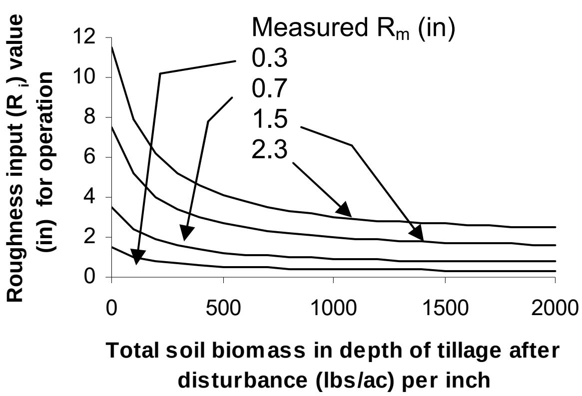

Figure 9.10. Conversion of a measured roughness value (R_m) to a roughness input value (R_i) (silt loam soil)

Roughness measurements made with yields of 200 bu/acre corn, 70 bu/acre wheat, and 4 tons/acre on hay or pasture land are conditions where measured roughness values need little if any adjustment for soil biomass.

The following example illustrates how to use Figure 9.10 to adjust a measured roughness value for biomass. Assume that the measured roughness is 1.5 inches (40 mm) and the average soil biomass is 500 lb/ac per inch depth of disturbance after the operation. A value of about 3.2 in (80 mm) is read from Figure 9.10, which would be the input roughness value for the operation that produced this roughness on a silt loam soil.

The input roughness values in the **operation descriptions** in the **operation component** of the RUSLE2 database are greater than are typically measured in the field because of the biomass effect. Roughness values computed by RUSLE2, rather than input values, should be compared to measured roughness values. Even then, field measured roughness values may not match those computed by RUSLE2. As described in **Section 9.2.3.1,** the RUSLE2 soil surface roughness subfactor captures more than just the physical effect of roughness geometry on soil loss. It also captures the effect of soil management as represented by soil biomass on aggregate size distribution and stability and their effect on infiltration and erodibility. The roughness input value and the roughness subfactor have been developed together to reflect these effects. Priority is given to capturing these effects rather than reproducing roughness values that can be measured in the field.

Perhaps more than any other RUSLE2 variable, roughness values from the *core database* should be used rather than using roughness values measured at the specific site specific for input into RUSLE2.

9.2.3.4. Effect of existing roughness (tillage intensity effect)

The input roughness values represent the roughness that a particular operation creates when used on a smooth soil surface of silt loam texture and having high soil biomass as discussed in **Section 9.2.3.3.** The field roughness left by an operation depends on the roughness existing at the time of the operation. For example, the roughness left by a spike tooth harrow following a moldboard plow is much greater than the roughness left by the spike tooth harrow following a tandem disk. The spike tooth harrow has relatively little effect on roughness such that the roughness left by the harrow strongly depends on the existing roughness at the time of the operation. The roughness is only slightly greater when a tandem disk follows a moldboard plow than when it follows another tandem disk. The roughness following a moldboard plow is independent of existing roughness.

The influence of existing roughness is represented by the **tillage intensity** variable in RUSLE2. A soil disturbing operation where existing roughness has no effect on the roughness created by the operation is assigned a tillage intensity of 1. That is, the operation "wipes" out all effects of the existing roughness. Operations are assigned a tillage intensity less than 1 based on the degree that the roughness left by an operation is influenced by existing roughness at the time of the operation. For example, tillage intensity values of 0.4, 0.75, and 1 are assigned to spike harrows, tandem disks, and moldboard plows, respectively.[72]

A tillage intensity of 0.4 means that the operation converts 40 percent of the existing roughness to the operation's assigned roughness and leaves 60 percent of the existing roughness. A tillage intensity of 1 means that that 100 percent of the existing roughness

[72] RUSLE1 does not use a tillage intensity effect. RUSLE1 uses an absolute concept where an operation is assumed to create a particular roughness regardless of the existing roughness. That is, the roughness following a spike tooth harrow in RUSLE1 is the same regardless of whether the harrow follows a moldboard plow or a tandem disk. Input roughness values are the same for RUSLE1 and RUSLE2 for operations where the tillage intensity is 1. However, input roughness values for operations where tillage intensity is less than 1 are smaller in RUSLE2 than in RUSLE1 to achieve comparable roughness values in both models. However, the two models can not compute the same roughness values for all situations because of the tillage intensity factor effect.

is “wiped out,” and the resulting roughness is 100 percent of the operation’s assigned roughness.

Tillage intensity does not indicate the roughness left by an operation performed on a smooth surface. Soil disturbing operations like moldboard plows and heavy offset disks are assigned 1 for tillage intensity and leave a very rough surface. In contrast, a rotary tiller is also assigned 1 for tillage intensity value but leaves a very smooth surface. The key factor in both cases is that existing roughness has no effect on the resulting roughness, which is the basis for assigning a tillage intensity value of 1, not the roughness left by the operation.

If existing roughness is less than that created by an operation on a smooth soil surface, the surface roughness computed by RUSLE2 is not affected by the tillage intensity factor.

9.2.3.5. How RUSLE2 handles roughness when soil disturbance is in strips

Some operations like strip tillage, manure injection, and planting only disturb a portion of the soil surface. **The input roughness base value for these operations applies only to the portion of the soil surface that is disturbed.** RUSLE2 does not average the roughness values for the disturbed and undisturbed portions to determine an average roughness value because of non-linearity in equation 9.10 used to compute the roughness subfactor value. Instead RUSLE2 computes a roughness subfactor value using equation 9.10 for each strip (disturbed and undisturbed) and computes a composite roughness subfactor value based on the portion of the surface disturbed by the operation. This composite roughness subfactor value is used in a rearrangement of equation 9.10 to compute an effective roughness value for the entire surface. This effective roughness is then decayed based on rainfall amount and interrill erosion as described in **Section 9.2.3.7.**

The approach used to handle roughness with strips differs from the way that ground cover in strips is handled. Input roughness values only apply to the portion disturbed whereas input values for flattening, burial, and resurfacing ratios apply to the entire area.

9.2.3.6. Assigning roughness values

Input roughness base values for soil disturbing operations are assigned by selecting a value from the RUSLE2 “core database” by comparing characteristics of an operation with characteristics of operations in the “core database.” Basing input values on the “core database” values helps ensure consistency between RUSLE2 applications. Consult the research literature if no operations are in the “core database” that are sufficiently close to your operation,. Use the largest possible database to estimate input roughness values and apply the adjustment procedures described in **Section 9.2.3.3.** Make sure that field measurements were carefully made and that sufficient measurements were taken to deal with spatial and temporal variability.

Field measurements should not be made at the specific site where RUSLE2 is being applied to determine an input roughness value for RUSLE2. Rather, values based on the RUSLE2 core database should be used.

9.2.3.7. Roughness decay

RUSLE2 decays the adjusted roughness, R_a in equation 9.10, each day based on daily precipitation and interrill erosion. About 40 percent of the roughness decay is by rapid subsidence and the remainder is by interrill erosion. Precipitation amount is used to compute the rapid subsidence of roughness that is assumed to be caused by soil wetting. Roughness decay by interrill erosion represents impacting waterdrops wearing away soil peaks and filling depressions with sediment. Interrill erosion is computed using the terms in the denominator of equation 8.3. The result is that roughness persists longer in dry climates than in wet climates and longer when the soil is protected from interrill erosion than when the soil is exposed to raindrop impact.

Roughness decays over time to a "final" roughness that is entered as an input for each **operation description** having a **disturb soil process** (see **Section 13.1.5**). A value of 0.24 inches (6 mm) is typically used for **final roughness** to represent the long term persistence of a few exceptionally stable soil clods. Although the final roughness value would seem to be a function of soil texture, a value of 0.24 inches (6 mm) is used for all soils. The reason for applying the 0.24 in (6 mm) value to all soils is to compute a surface roughness subfactor value of 1 for the unit plot condition for all soils when all roughness has decayed.

The expectation is that the final roughness value should be higher for high clay soils where clods persist than for sand soils that have no clods. However, such an adjustment should not be made because that effect is empirically considered in the K factor value.

However, an input final roughness other than 0.24 inches (6 mm) is used in RUSLE2 to represent conditions where an operation leaves the soil smoother than the unit plot condition. For example, rotary tiller and blading operations leave a smoother soil surface than exists for unit plot conditions. When a **final roughness** value less than 0.24 in (6 mm) is entered, an **initial roughness** value equal to the **final roughness** value must be entered. RUSLE2 does not compute a change in roughness when the final roughness value is less than 0.24 inches (6 mm). Also, if the input initial roughness is greater than 0.24 inches (6 mm) and the input final roughness is less than 0.24 inches (6 mm), RUSLE2 will not decay the roughness to less than 0.24 inches (6 mm).

The rate of roughness decay is not a function of soil conditions in RUSLE2. RUSLE2 captures the effect of soil conditions on roughness at any time by making the initial roughness a function of soil conditions.

9.2.3.8. Long term roughness

As described in **Section 9.2.3.1**, RUSLE2 computes a long term development of soil roughness to an input natural roughness value. The development of long term roughness is assumed to be directly proportional to the soil consolidation subfactor value. The starting point for the development of long term roughness is 0.24 inches (6 mm). Long term roughness is reset to this value each time a soil disturbing operation occurs. If only a portion of the soil surface is disturbed, a weighted value for the long term roughness is computed as described in **Section 9.2.3.5.**

9.2.3.9. Overriding RUSLE2 roughness values

Sometimes the way that RUSLE2 computes roughness needs to be overridden for research purposes. Set the initial and final input roughness values to the same value and RUSLE2 will use this roughness value in equation 9.10 to compute roughness subfactor values. This procedure can be used in RUSLE2 so that RUSLE2 can use measured roughness values directly in its computations. However, RUSLE2 does not compute roughness decay when this procedure is used.

The adjustments that RUSLE2 makes for soil texture and soil biomass can not be easily overridden while retaining the RUSLE2 procedure for computing roughness decay. The only approach that can be used is to adjust RUSLE2 input values until RUSLE2 computes adjusted roughness values that correspond to the measured field values. A special template must be obtained to display the adjusted roughness values.

The proper approach for applying RUSLE2 in conservation and erosion control planning is to use roughness values from the core database and allow RUSLE2 to make its adjustments for soil texture and soil biomass rather than attempt to use field measured roughness values.

9.2.4. Ridges

Ridges affect soil erosion in two ways. One effect is on sediment production, which is discussed in this section, and the other effect is runoff flow direction, which is discussed in **Section 14.1**. Ridges, and the furrows that separate them, are referred to as oriented roughness because they redirect runoff from a direct, downslope direction (perpendicular to the contour) when the ridges are oriented in direction besides directly up and down slope. Orienting ridges parallel with the contour is an important conservation (support) practice known as contouring that can significantly reduce soil loss if the ridges are sufficiently high.

9.2.4.1. Ridge subfactor effect

The ridge subfactor describes how ridges affect sediment production by increased interrill erosion on steep ridge sideslopes. Erosion can be as much as twice that from a level soil surface for land slopes up to 6 percent.[73] The increase in soil loss caused by ridges is related to ridge sideslope steepness where interrill erosion increases according to $3s^{0.8}+0.56$ where s_i = sine of the ridge sideslope angle. This equation computes interrill erosion from a 30 percent steep ridge sideslope that is about three times the interrill erosion from a flat, level soil surface. Even when land slope is flat, the local ridge sideslope can be very steep, such as 30 percent so that interrill erosion is very high on the ridge sideslope.[74]

Figure 9.11. Ridge subfactor values as a function of ridge height for land slopes less

Figure 9.11 shows RUSLE2 ridge subfactor values as a function of ridge height when the land slope is less than 6 percent and the ridges are oriented up and down hill. Ridge height is used to represent ridge sideslope steepness because ridge height values can be easily visualized and measured for ridge forming operations. Using ridge sideslope steepness in RUSLE2 would require that a value for ridge spacing be entered, which is not always available, in addition to a ridge height value. Also, more ridges are often present than is often recognized. For example, the ridge spacing assumed for row crops is often the spacing of the rows. However, the planter may leave several small, but very important ridges besides the ridges directly associated with the

[73] Young, R.A. and C. K. Mutchler. 1969. Soil and water movement in small tillage channels. Trans. ASAE. 12(4):543-545. Also, personal communication with K.C. McGregor and C.K. Mutchler, USDA-Agricultural Research Service, National Sedimentation Laboratory, Oxford, MS.

[74] RUSLE1 does not include a ridge sufactor. RUSLE2 can compute up to twice the erosion for high ridges on slope less than six percent than that computed by RUSLE1.

plants. Determining ridge height is much easier for construction machines like scarifiers and bulldozer treads than determining ridge spacing.

A value of 1 corresponds to the ridge subfactor value for a unit plot. The unit plot condition based on being tilled up and down slope with a harrow is assumed to have a 1 inch (25 mm) ridge height. Thus, values for the ridge height subfactor as less than 1 for ridge heights less than 1 inch (25 mm) because of the unit plot condition being the reference in RUSLE2 and the unit plot having a 1 inch (25 mm) ridge.

The effect of ridges on sediment production diminishes in RUSLE2 as land slope steepness increases above 6 percent because the local steepness of the ridges becomes almost equal to the land slope at steepness above 30 percent. For example, the local steepness of the ridge sideslopes is 42 percent when the ridge sideslope is 30 percent and the land slope is 30 percent. Figure 9.12 shows ridge subfactor values as landslope increases above six percent. As illustrated, ridge subfactor values converge to 1 at steep land slopes. The values in Figure 9.11 were derived from experimental data while the values in Figure 9.12 were derived from a simple rill-interrill erosion model where rill erosion varies linearly with land slope steepness and interrill erosion with $3s^{0.8}+0.56$.

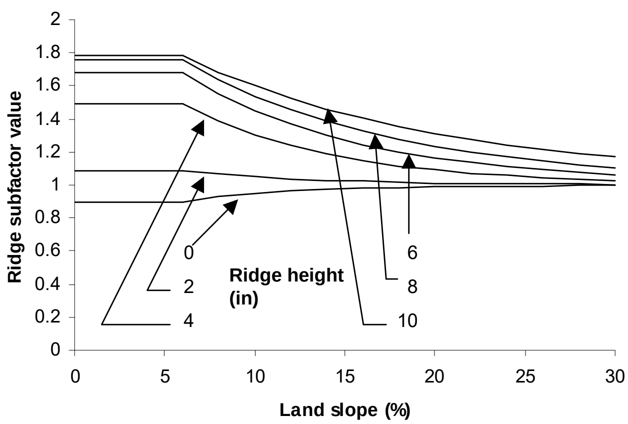

Figure 9.12. Ridge subfactor values as a function of ridge height and land slope steepness

9.2.4.2. Effect of ridge orientation on ridge subfactor

The ridge subfactor values in Figures 9.11 and 9.12 apply when ridges are oriented up and down slope. When the ridges are oriented on a direction different from up and down slope, ridge subfactor values decrease to 1 as ridge orientation approaches the contour. The relationship used to adjust ridge subfactor values as a function of ridge orientation (row grade) is shown in Figure 9.13. This relationship is a mirror image of Figure 14.3, the one used to adjust contouring factor values for ridge orientation, which is discussed in **Section 14.1**. The net effect of ridges is a composite of Figure 9.13 and Figure 14.3.

The need for Figure 9.13 seems questionable. Why does ridge orientation with respect the land slope affect sediment production? It doesn't. The reason for these adjustments is related to the empirical structure of RUSLE2 and constructing RUSLE2 so that it gives the expected erosion values with contouring.

9.2.4.3. Ridge formation and decay

Ridges are described in RUSLE2 by using a **soil disturbing operation**. An input ridge height value is entered in the **operation** component of the **RUSLE2 database** for each soil disturbing operation. This input value is the "typical" (representative) ridge height created by the operation. A "typical" ridge height is used because ridge height can vary with soil and cover-management condition, factors not considered in RUSLE2 in contrast to random roughness that RUSLE2 computes as a function of soil texture and soil biomass. The assumption is that ridge height is far more controlled by the physical mechanics of the operation than by soil conditions. Operations having different ridge heights for different soil conditions can be created for RUSLE2 to compute how ridge height affected by soil condition affects erosion.

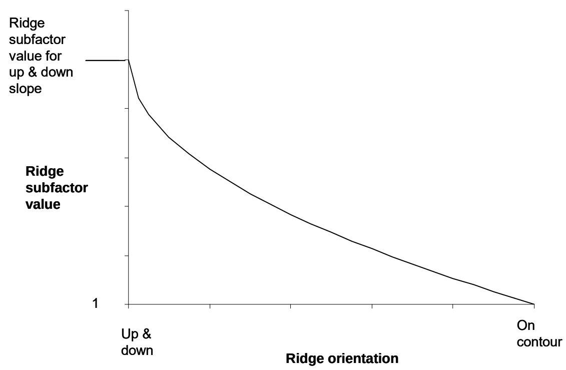

Figure 9.13. Effect of ridge orientation (row grade) on ridge subfactor

RUSLE2 computes a daily decay of ridge height as a function of daily precipitation and interrill erosion. The decay in ridge height by precipitation is independent of soil and cover-management conditions. The decay of ridge height by interrill erosion depends on rainfall erosivity, canopy cover, and ground cover. About 40 percent of the ridge height decay is from precipitation, which represents how the presence of water causes soil settlement. The remainder is from interrill erosion, which represents the wearing away of the ridge by raindrop impact.

The only way that ridges exist in RUSLE2 is to create them with a soil disturbing operation.

9.2.4.4 Assignment of input ridge height values

RUSLE2 input values for ridge height for an operation should be selected by comparing the characteristic of the operation with operations having ridge height values assigned in the RUSLE2 "core database." Ridge heights should not be selected based on field measurements. Ridge heights should be assigned very carefully to ensure consistency. Keep in mind that ridge heights affect both sediment production and contouring on erosion. Ridge height values in the RUSLE2 **core database** were selected very carefully to ensure that RUSLE2 computes the proper contouring effect. The tendency is to assign ridge height values that are too low and then be surprised that RUSLE2 computes too little contouring effect. Although RUSLE2 has been constructed to use easily measured field values, ridge heights is a situation where assigning values based on the **core database** gives far better results than can be obtained by entering field measurements of ridge height.

The effectiveness of contouring in RUSLE2 depends on ridge height: no ridge height, no contouring effect. To have a contouring effect, ridges must be present.

9.2.5. Soil biomass

Soil biomass in RUSLE2 includes live and dead roots, buried plant litter and crop residue from vegetation "grown" on-site, and added materials (external residue) that were buried or directly placed in the soil. These materials, including rock added as an "external residue," are assumed to be organic materials that decompose and reduce soil erodibility.

Buried inorganic materials including rock require special consideration. An extremely low value is entered for the decomposition coefficient for materials, such as rock, that do not decompose so that essentially no mass is lost by decomposition. RUSLE2 assumes buried inorganic material has the same effect as buried organic material, which may be too much effect.[75] For example, non-organic materials do not produce compounds that reduce soil erodibility. This problem can be accounted for in RUSLE2 by reducing the amount of inorganic material that is entered as having been added to an amount that has the expected effect on erosion. However, if this adjustment is made, the mass-cover relationships for the inorganic material must be adjusted so that RUSLE2 uses the proper ground cover percent in computing how a surface application of this material would affect erosion.

9.2.5.1. Soil biomass effect

---

[75] Rock cover entered in the **soil descriptions** in the **soil component** of the RUSLE2 database remains constant and is not subject to burial or decomposition. This rock cover is unaffected by operations in contrast to rock added as an external residue that is manipulated by operations.

Live roots affect soil loss by mechanically holding the soil in place, resisting erosive forces if the roots are exposed, and producing exudates that reduce soil erodibility. Also, live roots are a measure of plant transpiration that reduces soil moisture, which in turn increases infiltration and reduces runoff and soil loss.

When vegetation is "killed" in RUSLE2 by an operation that has a **kill process**, live roots becomes **dead roots** and begin to decompose. The physical presence of dead roots reduces erosion by reducing runoff erosivity if the dead roots are exposed, and dead roots also seem to hold the soil in "clumps" when the soil is mechanically disturbed.[76] Also, dead roots decompose to produce organic compounds that reduce soil erodibility and increase infiltration and reduce runoff.

Exposed **buried residue**[77] acts similar to exposed dead roots by physically reducing runoff's erosive forces applied to the soil, but buried residue does not mechanically hold the soil like roots hold the soil. Residue decomposes and produces organic compounds that reduce soil erodibility and increase infiltration and decrease runoff and erosion. Overall, buried residue is less effective than roots on reducing erosion because buried residue does not mechanically hold the soil in place, and buried residue is not associated with plant transpiration like roots.

Although buried residue occurs in a wide range of sizes and types of vegetative and organic material, the effect of all buried residue is treated the same based on experimental research that compared how crop residue, "green" manure, compost, animal manure, hardwood litter, and pine needles affected erosion.[78] However, preference is given to fine roots instead of coarse roots when root biomass values are entered in a **vegetation description** in the **vegetation component** of the **RUSLE2 database**. Fine roots have greater surface area per unit mass than coarse roots and often are very close to the soil surface where they have a greater effect on runoff and erosion than coarse roots. Fine roots readily slough and become a part of the soil organic matter pool. Not much of

---

[76] Some of the effect may well be roots mechanically holding the soil together. Another effect is that roots produce compounds that have caused a local increased in soil strength. Another effect is that the soil fractures along lines that expose the roots as if they are holding the soil in place. The fact is clearly obvious that soil roughness is increased with high levels of soil biomass when soil is disturbed.

[77] Buried residue is RUSLE2 nomenclature for organic material in the soil that affects soil loss that has been buried or placed in the soil by an operation. Buried residue also includes non-organic material in the soil, but this material requires special considerations.

Copley, T.L., L.A. Forrest, A.G. McCall, and F.G. Bell. 1944. Investigations in erosion control and reclamation of eroded land at the Central Piedmont Conservation Experiment Station, Statesville, North Carolina, 1930-40. USDA Technical Bulletin 873.

Hays, O.E., A.G. McCall, and F.G. Bell. 1949. Investigations in erosion control and reclamation of eroded land at the Upper Mississippi Valley Conservation Experiment Station near LaCrosse, Wisconsin, 1933-43. USDA-Technical Bulletin 973.

the mass of coarse roots is entered for root biomass because coarse roots are assumed to have relatively little effect on erosion.

9.2.5.2. Soil biomass subfactor

Equation 9.12 is used in RUSLE2 to compute values for the soil biomass subfactor.

$$s_b = c_b \exp(-0.0026B_{rt} - 0.00066B_{rs} / s_c^{0.5}) \qquad [9.12]$$

where: s_b = soil biomass subfactor, c_b = 0.951,[79] B_{rt} = the sum of the live and dead root biomass averaged over a 10 inch (250 mm) depth (lbs/acre per inch of depth), B_{rs} = the amount of buried residue averaged over a depth that linearly ranges from 3 inches (75 mm) if the soil is not consolidated (i.e., c_s = 1) to 1 inch (25 mm) if the soil is fully consolidated (i.e., s_c = 0.45), and s_c = the soil consolidation subfactor (see **Sections 7.8 and 9.2.6** for discussion of the soil consolidation subfactor). The coefficients 0.0026 for root biomass B_{rt} and 0.00066 for buried residue B_{rs} are multiplied by 1.65 for Req applications. Most of the erosion in Req situations is assumed to be caused by rill erosion. Soil biomass has a much greater effect on rill erosion than on interrill erosion.

All soil biomass variables are on a dry weight basis.

Equation 9.12 was empirically derived by fitting it to soil loss ratio values for the seedbed crop stage period[80] in Table 5 and accompanying tables in AH537.[81] These soil loss ratio values were for a wide range of soil biomass and soil consolidation conditions, including pasture and hay lands; no-till and reduced-till forms of conservation tillage for corn grain; and conventional clean-till corn grain, corn silage, soybean, and wheat cropping over a range of yields. Also, soil loss data on the effect of incorporation of green manure, animal manure, compost, hardwood litter, and pine needles into the soil were analyzed. Erosion data from rainfall simulator studies were used to determine values for effective root biomass for rangeland (see **Section 17.4.1.4**).

---

[79] Equation 9.12 also has a second part for very low soil biomass where c_b increases from 0.95 to 1 so that the soil biomass subfactor equals 1 when no soil biomass is present.

[80] Soil loss ratio values in AH537 are the ratio of soil loss with a given cover-management system at a particular crop stage period to soil loss from the unit plot for the same crop stage. The seedbed crop stage period is when the soil has been tilled to prepare a relatively smooth surface for seeding a crop so that the major effect is from soil biomass.

[81] The soil loss ratio values in AH537, except for conservation tillage and "undisturbed" land, are a summary of field measured soil loss for more than 10,000 plot-years of data. Erosion data are quite variable for unexplained reasons. Also, the length of record often varied between studies and locations, and the number of treatments and replications and other variables differed between locations, which prevents the data from being analyzed by common statistical procedures. Instead, the data must be analyzed and interpreted for main effects, which was expertly done by W.H. Wischmeier and D.D. Smith in AH537. The soil loss ratio values in AH537 are the most comprehensive available by far for calibrating RUSLE2 and are much better for calibrating and validating RUSLE2 than the original soil loss data.

The 10-inch (250 mm) depth over which root biomass is averaged was the best of several depths analyzed. A 3-inch (75 mm) depth over which buried residue is averaged also was the best of several depths analyzed. This 3 inches (75 mm) depth is linearly reduced in RUSLE2 to 1 inch (25 mm) as the soil consolidation subfactor c_s decreases from 1 to 0.45 to give increased credit to buried residue B_{rs} in the upper soil layer with no-till cropping and other cover-management systems that leave residue at the soil surface and do not disturb the entire soil surface. A similar feature is the division of the variable buried residue B_{rs} by the square root of the soil consolidation subfactor c_s, which also gives increased credit to buried residue as the soil consolidates. A major advantage of no-till cropping is the accumulation of organic matter in the upper two inches (50 mm) of soil. This layer promotes earthworm burrowing and other processes that decrease runoff and soil erodibility. Tillage and other mechanical soil disturbances disrupt this layer and cause an immediate increase in soil erosion. This zone requires about 5 years to develop in the eastern US, which is consistent with using 7 years for the time to soil consolidation to represent this time.

Soil consolidation refers to lack of soil disturbance and the soil becoming less erodible over time after a soil disturbance rather than the soil necessarily becoming dense.

Table 9.3. Effect of corn yield and tillage system on the soil biomass subfactor at Columbia, MO

	Soil biomass subfactor		
	Type tillage system		
Yield (bu/acre)	Clean till	Reduced till	No till
50	0.78	0.74	0.57
100	0.66	0.60	0.38
200	0.48	0.40	0.16

Table 9.4. Effect of production level of a grass on the soil biomass subfactor

	Soil biomass subfactor		
Yield (lbs/acre)	St. Paul, MN	Columbia, MO	Baton Rouge, LA
1000	0.47	0.51	0.56
2000	0.22	0.27	0.33
4000	0.05	0.08	0.11

Tables 9.3 and 9.4 illustrate values for the soil biomass subfactor for the three corn tillage systems at different yield levels and grass at three production levels. The values for the soil biomass subfactor computed by equation 9.12 decrease as yield increases as illustrated in Table 9.3 because of increased buried residue and live and dead roots. The difference between the clean-till and reduced-till systems is that the reduced-till system leaves additional residue near the soil surface where it has greater effect than residue buried more deeply by the moldboard plow in the clean-till system. The major difference in the no-till system from the other systems is from additional residue near the soil surface and the additional credit given in equation 9.12 for buried residue B_{rs} because of a reduced soil consolidation subfactor c_s. The reduced soil consolidation subfactor has even greater effect in the grass system that has no soil disturbance than in the no-till system where narrow strips are disturbed to plant the seeds. Another factor that reduces the soil

biomass subfactor s_b in the grass system is greater live and dead root biomass at the high grass production level than for the high corn yield. More dead root biomass is produced by root sloughing (death) with the grass than is left after the corn harvest.

The soil biomass subfactor is a function of location as illustrated in Table 9.4 because decomposition of buried residue and dead roots is related to monthly precipitation and temperature, which vary by location. For example, the soil biomass subfactor for the 2000 lbs/acre grass production level is 0.22, 0.27, and 0.33 at St. Paul, MN; Columbia, MO; and Baton Rouge, LA, respectively. Decomposition is much higher at Baton Rouge, LA than at St. Paul, MN because of increased temperature and precipitation, especially during winter at Baton Rouge, LA where temperatures are sufficiently high for significant decomposition to occur. The relative effect of location increases as production level (i.e., biomass level) increases.

Values for the soil biomass subfactor are significant and comparable in magnitude to values for other subfactors. Although ground cover is frequently considered to be the single most important variable in RUSLE2, the soil biomass subfactor can be equally important. Perhaps most important is the total amount of biomass in a cover-management system and how that biomass is distributed between the biomass pools.

All features of cover-management systems should be considered rather than focusing on a single variable such as ground cover as a measure of erosion control effectiveness.

9.2.5.3. How biomass is added to and removed from the soil

9.2.5.3.1. Live root biomass. RUSLE2 obtains values for live root biomass from the **vegetation description** in the **vegetation component** of the RUSLE2 database for the **current vegetation**. A name for a vegetation description is entered for each operation with a **begin growth process** in each **cover-management description** in the RUSLE2 database. RUSLE2 begins to use values for this vegetation description on the date of the operation that contains the begin growth process.

The live root biomass values in a vegetation description are for the upper 4 inches (100 mm), whereas equation 9.12 uses live root biomass values for the upper 10 inches (250 mm). RUSLE2 uses the live root distribution illustrated in Figure 9.14 to compute live root biomass in the upper 10-inch (200 mm) depth from the input values for the 4 in (100 mm) depth.[82] The distribution in Figure 9.14 is used for all vegetations[83] and all time.

[82] RUSLE2 divides the soil into 1-inch (25 mm) layers to account for soil biomass. Depths of disturbance are rounded to the nearest 1-inch (25 mm) so that the depth of disturbance corresponds with the bottom of a soil layer. The number of layers considered in an operation depends on the number of 1-inch (25 mm) in the depth of disturbance. Thus, an operation with a 2-inch disturbance depth only involves two layers. The

Figure 9.14 shows that most of the live root biomass is in the upper 4 inches (100 mm) of soil, which is a major reason for the 4-inch (100 mm) depth used for the root biomass input values in the RUSLE2 database.[84]

An input for rooting depth is not required by RUSLE2, which does not consider how rooting depth varies with vegetation or plant maturity.

9.2.5.3.2. Dead root biomass. Live roots become dead roots in one of three ways. One way is by including an operation in the **cover-management description** that has a **kill process**. The live root biomass for the **current vegetation** on the date of this operation is added to the dead root biomass pool and the live root biomass becomes zero.

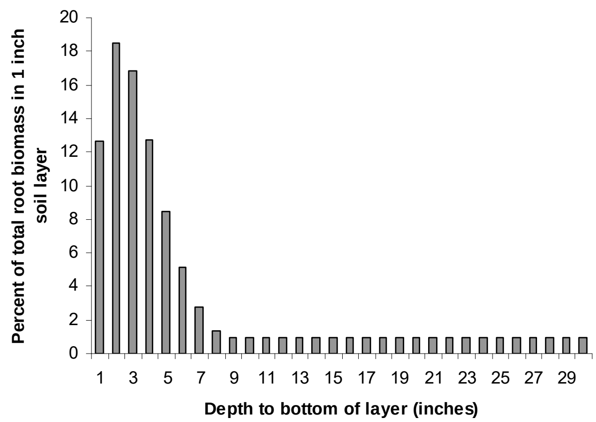

Figure 9.14. Distribution of live root biomass assumed for RUSLE2.

The second way that live root biomass becomes dead root biomass is by root sloughing and root death during growth periods, similar to canopy senescence (and live aboveground death during growth periods). Root death and sloughing is an important source of dead root biomass for perennial and similar types of vegetation to create a soil organic pool. The amount of root sloughing in a year ranges from about 25 to 40 percent of the root biomass.[85]

---

minimum depth that RUSLE2 recognizes is 1 inch (25 mm).

[83] Data from several literature sources for major agricultural crops of corn, soybeans, wheat, and cotton, several hay and pasture crops, and for selected vegetable crops were reviewed to determine the distribution in Figure 9.14 at plant maturity. The relative shape of the root distribution was very nearly the same for all crops. The rooting depth for the fine roots judged to have the most effect on soil loss did not vary among crops, except that the rooting depths for field and pasture crops was about twice that for vegetable crops. Even though rooting depth differs among plant types and with plant development, RUSLE2 empirically captures the main effect of roots on soil loss.

[84] The root distribution in RUSLE2 differs between from the one used in RUSLE1. RUSLE1 assumes that the root biomass in the second 4 inch (100 mm) soil layer is 75 percent of that in the top 4 inch (100 mm) layer and that no roots occur below 8 inches (200 mm). Based on Figure 9.14, RUSLE1 assumed significantly too much root biomass below the 4 inch (100 mm) soil layer below the upper 4 inches (100 mm) of soil.

[85] For additional information, see Reeder, J.D., C.D. Franks, and D.G. Michunas. 2001. Root biomass and microbial processes. In: The Potential of U.S. Grazing Lands to Sequester Carbon and Mitigate the Greenhouse Effect. R.K. Follett, J.M. Kimble, and R. Lal (eds). Lewis Publisher, Boca Raton, FL.

RUSLE2 represents daily root death during growth periods by multiplying daily live root biomass by a fraction. RUSLE2 represents root sloughing by a decrease in the root biomass during the year, much like RUSLE2 determines senescence by a reduction in canopy. Input values for root biomass increase when growth occurs and decrease after plant maturity when live root biomass is being lost by root sloughing.[86] Roots develop more rapidly than does canopy and reach maturity while the canopy is still adding biomass. Root sloughing can be assumed to either precede or parallel canopy senescence. Values for the temporal distribution of root biomass can be manually developed and entered for vegetations in the RUSLE2 database. Also, RUSLE2 includes an easy-to-use procedure that can be used to construct temporally varying root biomass values based on dates of maximum and minimum root biomass and root biomass values at those dates. RUSLE2 also has a procedure that estimates root biomass using built-in values for the ratio of root biomass to aboveground biomass production for selected plant communities. See **Section 11** that describes the vegetation component of the RUSLE2 database for additional information.

RUSLE2 determines the amount of root sloughing on each day by comparing the live root biomass values on a given day with the live root biomass on the previous day. RUSLE2 assumes that a decrease in live root biomass from one day to the next is caused by root sloughing and adds the decrease to the dead root biomass pool. RUSLE2 computes daily root biomass death by multiply daily root live biomass by a fraction. Daily root death biomass is added to the dead root biomass pool.

Using a single root biomass for the entire year for perennial type plants, including pasture and hay crops grown for several years, causes RUSLE2 to over estimate erosion because the dead root biomass pool that accumulates from root sloughing is not represented.

The third way that live root biomass becomes dead root biomass is when the live root biomass on the first day of a new **vegetation description** is less than the live root biomass on the last day when the current vegetation is used. The difference in live root biomass is added to the dead root biomass. This procedure is used when only a portion of the live root biomass is to be transferred to the dead root biomass pool because the **kill process** in an operation transfers the entire live root biomass to dead root biomass.

---

[86] The time invariant C factor in RUSLE1 uses a single representative value for root biomass for the entire year and does not consider root sloughing and the accumulation of a dead root biomass pool that can significantly reduce soil loss. Also, the time invariant C factor in RUSLE1 does not consider the accumulation of a buried residue biomass pool that can significantly reduce soil loss. Although the time invariant C factor in RUSLE1 was easy to use, it could seriously over estimate soil loss by not considering these important soil biomass pools. Thus, RUSLE2 does not include a time invariant cover-management computation, but it does include many of the easy to use features of the RUSLE1 time invariant C factor so that root sloughing can be easily considered using simple inputs that mimic RUSLE1 inputs. RUSLE1 can consider these soil biomass pools by using its time variant C factor with temporally varying canopy and root biomass values.

This procedure is used to apply RUSLE2 to intercropping type situations. Intercropping involves growing multiple crops at the same time where they typically have different seeding and harvest dates. Examples include planting a cover crop before silage harvest, planting a legume in small grain where the legume is harvest for hay after the grain is harvested, and weeds that develop before a crop is harvested. The procedure is illustrated where a cover crop is seeded before a silage corn crop is harvested. The cover crop provides vegetative cover to control erosion after the silage crop is removed by harvest. Values for live root biomass for this cover-management description are given in Table 9.5.

This **cover-management description** involves three **vegetation descriptions**. The first one is for the silage corn. The second one is for the composite of the rye, which is seeded on June 8, and the silage corn growing together. The third vegetation description is for the rye after the silage corn is harvested on August 8.

RUSLE2 detects that the live root biomass for the new vegetation, which is the rye after the silage has been harvested on August 8, is less than the live root biomass of the current vegetation, which is the composite of the corn and rye, on August 8. The difference of 950 lbs/acre in the upper 4 inches between the 1380 lbs/acre on August 8 for the current vegetation and the 430 lbs/acre for the new vegetation is the amount of live root biomass that is put in the dead root biomass. This 950 value represents the live root biomass of the silage corn on the date that it was harvested and killed. The live root biomass value for the rye vegetation immediately after the silage harvest represents conditions on the first day that this particular **vegetation description** is used, not the date that the vegetation was seeded.

Root biomass and other values used in the vegetation description can start at any time as required to describe the vegetative conditions for a cover-management system. The values for day zero and beyond describe conditions on the day that RUSLE2 is to begin using that vegetation description.

The **silage harvest operation** does not include a **kill process** to kill the corn. If a kill process had been included in the operation, the entire live root biomass would have been transferred to the dead root biomass. Only the corn live root biomass is to be transferred to the dead root biomass. The difference of 950 lbs/acre in the upper 4 inches represents the change in live root biomass from "killing" the corn and allowing the rye to continue "growing." RUSLE2 adds this difference to the dead root biomass pool.

Dead root biomass is lost by decomposition, which is a function of daily precipitation and temperature, and the decomposition half life for the roots. RUSLE2 uses the same decomposition half life for the dead roots as for aboveground biomass. RUSLE2 maintains a biomass pool for dead roots, much like a litter layer on the soil surface. The amount of biomass that RUSLE2 computes is a function of location. The biomass in these pools is greater at locations where decomposition is less because of reduced temperature and rainfall, such as the Northern US in comparison to the Southern US. The accumulation of biomass in the dead root biomass pool can significantly reduce erosion as computed by equation 9.12.

Although operations that include a disturb soil process resurface buried residue, these operations do not resurface dead roots. The dead roots that are most important for influencing rill and interrill erosion are fine roots that are assumed to be tightly bound to the soil so that they are not resurfaced.

Table 9.5. Values for two vegetations: silage corn interseeded with rye to provide cover after the silage is harvested

Calendar date	Days since begin growth	Root biomass (lbs/acre in top 4 inches)	Comment
10-Mar	0	0	Operation with begin growth process that uses silage corn vegetation description
25-Mar	15	40	
9-Apr	30	160	
24-Apr	45	320	
9-May	60	480	
24-May	75	760	
8-Jun	0	950	Operation with begin growth process that uses a vegetation description for the composite of the silage and rye; rye seeded on this day
23-Jun	15	980	
8-Jul	30	1080	
23-Jul	45	1280	
8-Aug	60	1380	Silage harest operation, silage corn harvested which removes the corn vegetative cover, kills corn roots, rye continues to grow
8-Aug	0	430	Silage harvest operation contains a begin growth process as last process in list of processes used to describe that operation. This begin growth process begins to use the rye vegettion description having values on day 0 appropriate for the date of the silage harvest
22-Aug	15	530	
7-Sep	30	610	

actual vegetation description includes additional dates to complete growth of the rye

9.2.5.3.3. Buried residue. Buried residue is added to the soil in three ways: (1) a fraction of the decomposed ground cover biomass is added, (2) a fraction of the ground cover biomass is buried by certain operations, and (3) biomass is placed directly into the soil with certain operations.

Each day, RUSLE2 arbitrarily adds a fraction of the surface (flat) layer of biomass (i.e., crop residue, plant litter) that decomposes on that day to the upper 2 inch (50 mm) soil layer. The fraction varies from zero if the soil has been recently mechanically disturbed to 0.25 if the soil is fully consolidated as a function of the soil consolidation subfactor s_c. RUSLE2 uses this procedure to accumulate organic matter at the soil surface on pastureland, rangeland, no-till cropland, and other lands not regularly tilled or mechanically disturbed.

Operations with a **disturb soil process** transfer (bury) a portion of the surface (flat) layer of biomass to the buried residue pool. The amount of residue that is buried is the product of the surface residue mass and a **burial ratio**. Values for the burial ratio are entered for each **operation description** having a disturb soil process in the **operation component** of the RUSLE2 database. RUSLE2 distributes the residue that it buries according to one of **three mixing distributions** illustrated in Figure 9.15. A distribution is selected when a **tillage type** is selected to describe an operation having a disturb soil process. The distributions **inversion with some mixing** is for operations like a moldboard plow that invert the soil. Most of the buried residue is placed in the lower half of the depth of disturbance. The distribution **mixing with some inversion** is for operations like a tandem disk, chisel plow, and field cultivator that place most of the residue in the upper half of the depth of disturbance. These operations bury residue primarily by mixing but involve some burial by inversion. The distribution **mixing only** applies where almost all of the burial is by mixing with very little burial by inversion for operations like rotary tillers, subsoilers, and manure and fertilizer injectors that place most of the residue in the upper one third of the depth of disturbance. One of these three mixing distributions is assigned to each operation with a **disturb soil** process when data for the operation are entered into the RUSLE2 database. The placement distribution for the **lifting and fracturing** and **compression** tillage types place the buried residue using the **mixing only** distribution.

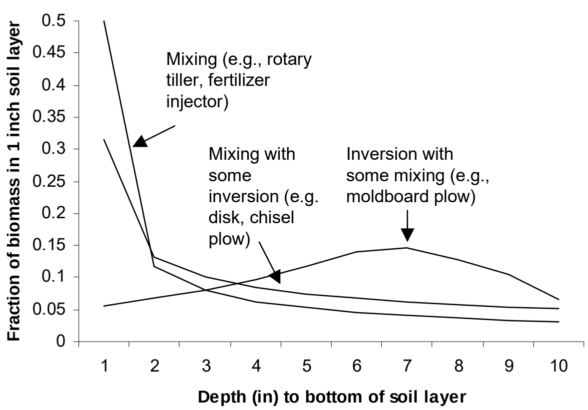

Figure 9.15. The initial distribution when residue is buried by an operation.

Buried residue can also be added to the soil in RUSLE2 by placing **external residue** in the soil with an operation that includes an **add residue process**. A disturb soil process must be included in the operation description to place external residue in the soil because the assumption is that the soil must be disturbed to place material in it. External residue is placed in the lower half of the disturbance depth as illustrated in Figure 9.16.

Buried residue is lost from the soil by being resurfaced by an operation that includes a **disturb soil process** and by decomposition. Buried residue is removed from the soil by being resurfaced and transferred to the surface (flat residue) pool by soil disturbing operations. The amount of **resurfaced residue** is the product of the amount of buried residue in the depth of disturbance at the time of the operation and a **resurfacing ratio** value assigned to the operation description in the RUSLE2 database. The resurfaced residue is extracted layer by layer by first taking out the entire buried residue in the layer, if necessary, from the top soil layer and then moving to the next and succeeding layers until the total mass of resurfaced residue is obtained. In many cases, only a portion of the buried residue in the top 1-inch (25 mm) layer is extracted. Extraction seldom extends beyond the second layer. RUSLE2 does not resurface dead roots as discussed in **Section 9.2.5.3.2.**

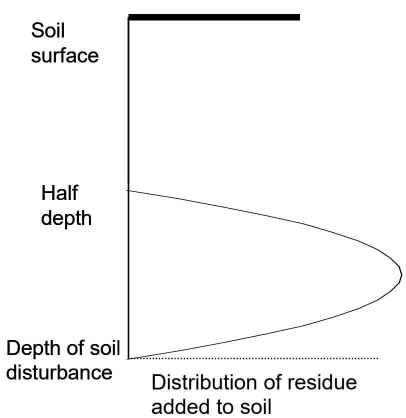

Figure 9.16. Distribution of residue placed in by an operation that has an "add residue" process.

Buried residue lost by decomposition as function of daily precipitation and temperature and the decomposition half life of the buried residue. RUSLE2 assumes that the decomposition half life is the same for buried residue as for the surface, flat residue. RUSLE2 maintains biomass pools for buried residue like it does for dead roots and a litter layer on the soil surface that is a function of location. The biomass in these pools is greater at locations where decomposition is less because of reduced temperature and rainfall, such as the Northern US in comparison to the Southern US. The accumulation of biomass in the buried residue pool can significantly reduce erosion as computed by equation 9.12.

Table 9.6. Retention coefficient values for redistributing residue among soil layers

Layer	Mixing distribution: Inversion w/mixing	Mixing w/inversion	Mixing
1 (top)	0.40	0.32	0.50
2	0.40	0.39	0.56
3	0.40	0.47	0.61
4	0.40	0.54	0.67
5	0.40	0.62	0.72
6	0.40	0.69	0.78
7	0.40	0.77	0.83
8	0.40	0.84	0.89
9	0.50	0.92	0.94
10	1.00	1.00	1.00

9.2.5.4. Redistribution of dead roots and buried residue in soil by soil disturbing operations

Operations with a **disturb soil process** redistribute buried residue and dead roots according to the **mixing distribution** assigned to that operation. When a soil disturbing operation occurs, RUSLE2 first redistributes the buried residue and dead roots and then buries the residue. Two steps are involved for an operation that has an **inversion with some mixing** distribution. The first step is to invert the soil layers with their buried residue and dead roots by layer so that the biomass in the bottom layer becomes the biomass in the top layer, the biomass in the next to bottom layer becomes the biomass in the next to the top layer, and so forth. The second step transfers biomass between soil layers. A **filtering** concept is used in RUSLE2 where each soil layer is **sifted** so that some of the biomass in each layer is retained in the layer and the remainder of the biomass moves down to the next layer. The amount retained is the product of the biomass in the layer and a retention coefficient having values shown in Table 9.6.[87] The retention values for the **inversion with some mixing** distribution are all equal except for the values for the bottom two layers. The value for the bottom layer must be 1 so that no biomass passes through the bottom layer and the slightly higher value for the next to bottom layer was empirically determined to give a good fit between experimental data and computed values. The equal retention values imply that the biomass is equally likely to move downward in the lower part of the disturbance depth as in the upper part. In effect, the soil is uniformly "stirred, mixed, and sifted" over the disturbance depth.

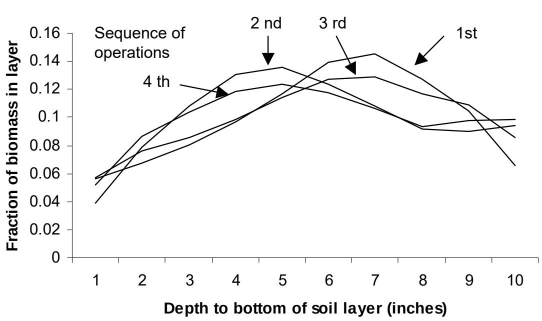

Figure 9.17. Initial burial and redistribution of residue by repeated operations with an inversion mixing distribution (e.g., moldboard plow)

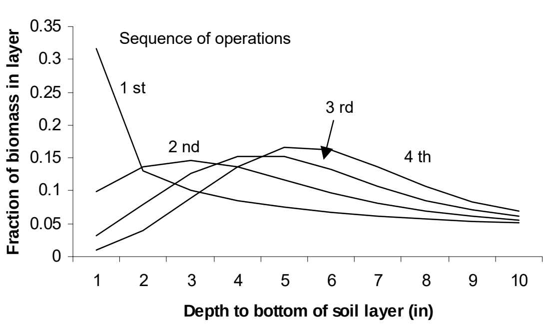

Figure 9.18. Initial burial and redistribution of residue by repeated operations with a mixing and some inversion mixing distribution (e.g., tandem disk)

Only one step is involved in redistributing biomass with the two mixing distributions that minimally involve inversion. The retention coefficient for the top layer is assumed to be same as the fraction of residue placed in the top layer by burial. The values for the retention coefficients for the remaining layers are linearly increased with depth to a value of 1 as shown in Table 9.6. The value of 1 for the last layer prevents biomass from passing through the bottom layer. The increase in retention values with depth means that biomass is more likely to move down in the upper part of the disturbance depth than in the bottom part and that stirring and mixing decrease with depth.

Figure 9.17 shows the buried residue distributions after each of four repeated

dure used to distribute buried residue in the soil
ts is described in **Section 13**. The RUSLE2
here material becomes uniformly distributed in
RUSLE1 assumes that the material is uniformly

operations for a moldboard plow that has an **inversion with some mixing** distribution where no additional residue is buried after the first operation. The buried residue distribution gradually becomes more uniform with each operation. Figure 9.18 shows buried residue distribution with repeated operations with a tandem disk where residue burial is mainly by mixing. After repeated operations, a bulge of biomass develops that moves downward in the soil. The bulge becomes increasingly concentrated with each operation and moves downward less with each operation. Thus rather than the distribution becoming increasingly uniform as assumed in some models, RUSLE2 computes an increasingly non-uniform distribution for the mixing type distributions. Implements like tandem disks and rotary tillers are assumed to bury residue uniformly in the soil, but in fact they only bury residue uniformly under certain conditions, which occurs with about two passes as can be seen from Figure 9.18.

9.2.5.5. Spatial non-uniformity of soil biomass

The soil biomass for live and dead roots and buried residue is spatially non-uniform for row crops, widely disperse plants like clumps of shrubs and grass on rangelands, and tree seedlings in a forest. However, RUSLE2 assumes that all soil biomass is uniformly distributed, even when the operation only disturbs a portion of the soil surface.

9.2.5.6. Assigning input values that determine soil biomass

The amount of soil biomass is a critical variable in determining how a cover-management system affects erosion. The three principal sources of soil biomass are from live root biomass, plant litter and crop residue, and externally added residue. The mass of external residue is based on dry matter basis and is known. Root biomass values for a **vegetation description** should be selected by comparing the vegetation's characteristics with those of vegetation descriptions in the RUSLE2 **core database**. When selecting root biomass values for a particular vegetation description, the role of fine roots versus coarse roots must be considered. For example, even though carrots and potatoes make up root biomass, their mass is not considered in assigning root biomass values because those "coarse roots" have little effect on erosion. In cases where some credit is to be taken for coarse roots, some, but not all, of their biomass is entered along with the biomass of the fine roots.

A key factor in selecting input root biomass values is to account for the temporal variation in root biomass so that the effect of root sloughing is captured by RUSLE2.

Do not make field measurements of root biomass values to determine input values for RUSLE2. Measuring root biomass is very difficult, tedious, and tiresome and should only be done in a research setting. Large errors are common unless extreme care is taken and even then the results may show much variability. The ratio values in the RUSLE2

core database used to determine root biomass values for rangeland plant communities have been chosen based on measured soil loss values obtained during rainfall simulator experiments.[88] Other root biomass values in the RUSLE2 **core database** have been selected from the scientific literature and these values were used when equation 9.12 was fitted to erosion data.

Use of root biomass values that have not been checked for consistency with values in the RUSLE2 *core database* can cause serious errors in RUSLE2.

The other major source of soil biomass is from decomposition of plant litter and crop residue on the soil surface and from the incorporation of crop residue into the soil. The amount of plant litter is determined by senescence of the plant canopy and the amount of biomass associated with that loss of canopy. The amount of residue produced by a crop is determined by the residue to yield relationships defined for the crop and is entered in the vegetation component of the RUSLE2 database. The other important factor that determines the amount of buried residue is the flattening, burial, and resurfacing ratios used to describe operations in the operation component of the RUSLE2 database.

Even though a plant community may be a mixture of species, RUSLE2 represents the plant community as a single vegetation description where input values are selected to describe the composite effects of the vegetation. RUSLE2 "grows" only one vegetation at a time. RUSLE2 cannot take data from two vegetation descriptions, such as corn and rye, and combine them into a single composite vegetation.

9.2.5.7. Comments

RUSLE2 does not consider how soil texture or other soil properties affect the distribution of residue and roots in the soil. Although RUSLE2 adjusts amount of biomass buried by a soil disturbing operations as a function of speed and depth, RUSLE2 does not adjust the distribution of the residue as a function of operation speed or depth.

9.2.6. Soil consolidation[89]

A mechanical disturbance loosens soil and increases its erodibility, which in turn increases erosion. After a mechanical soil disturbance, soil erodibility decreases as soil

---

[88] The data used to calibrate RUSLE2 to rangelands were collected as a part of the Water Erosion Prediction Project (WEPP) by R. Simantion and others, USDA-ARS, Tucson, AZ. See Table 5-4 in AH703.

[89] A prior land use (PLU) subfactor was used in RUSLE1. This subfactor was the product of the soil consolidation subfactor and the soil biomass subfactor. This same product is used to display RUSLE2 subfactor values in some of the templates.

primary particles and aggregates become cemented together by wetting and drying and

Soil consolidation in RUSLE2 refers to the decrease in soil erodibility following a mechanical soil disturbance rather than an increase in bulk density.

other soil processes, which is the main soil consolidation effect. A mechanical soil disturbance decreases the bulk density of soil. Increases in soil bulk density do not greatly reduce soil erodibility, except when compaction is extreme.

9.2.6.1. Soil consolidation effect

Figure 7.3 is a plot of the soil consolidation subfactor s_c as it decreases with time after a mechanical soil disturbance. The soil is assumed to be 0.45 times as erodible at full consolidation as it is immediately after a disturbance. A soil disturbance resets the soil consolidation subfactor to 1 and it begins to decrease again with time. Seven (7) years is normally assumed for the time for the soil to become fully consolidated after a mechanical disturbance in the Eastern US where rainfall events are sufficiently frequent for the soil to experience repeated wetting and drying cycles required for the cementing process (See **Section 7.8**). RUSLE2 computes an increased **time to soil consolidation** up to 20 years as annual precipitation decreases from 30 inches (760 mm) to 10 inches (250 mm). A constant 20 years for time to soil consolidation is used where annual precipitation is less than 10 inches (250 mm). This increased time to soil consolidation reflects how the effects of a mechanical soil disturbance persist longer in low precipitation areas where reduced water is available and less frequent wetting and drying cycles occur.

The soil consolidation effect is greatest for those soils that have the greatest and most active cementing agents. These agents are most closely related to clay and organic matter particles because of their high specific surface area. Thus, the soil consolidation effect is greatest for soils having a high organic matter content, characteristic of cover-management systems involving a high level of soil biomass. The effect of organic matter content as affected by cover-management system is captured in the soil biomass subfactor s_b computed with equation 9.12.

The soil consolidation effect is also a function of soil texture because of the role of clay in cementing soil particles. The soil consolidation effect is greatest for fine textured soils with a high clay content and least for coarse textured soils with a low clay content. However, RUSLE2 does not consider the effect of soil texture on the soil consolidation subfactor.[90]

[90] The soil consolidation subfactor in RUSLE2 is one of the variables least well defined by scientific research. Its effect varies with many factors, but the research data are not sufficient to derive an empirical equation for the effect of soil conditions on the time to soil consolidation. Although, the soil consolidation

9.2.6.2. Importance of soil consolidation subfactor to other variables

The soil consolidation subfactor has indirect effects in RUSLE2 by being a variable in equations used to compute values for other cover-management subfactors. For example, the consolidation subfactor s_c is used in equation 9.12 to compute values for the soil biomass subfactor s_b. The soil consolidation subfactor is used to compute the rill-to-interrill erosion ratio in equation 8.3 where soil consolidation is assumed to reduce rill erosion much more than interrill erosion. The ratio of rill-to-interrill erosion affects the slope length effect and the ground cover subfactor g_c. Mulch is assumed to have reduced effectiveness on steep, cut construction slopes, which are detected in RUSLE2 by a low soil consolidation subfactor and low soil biomass values.

The soil consolidation subfactor is also a variable in RUSLE2 equations used to compute runoff index values (curve numbers) and runoff, which is used to compute how support practices affect soil loss (see **Section 14**). For example, when the soil is consolidated (i.e., s_c values near 0.45), infiltration is assumed to be low and runoff high if no soil biomass is present. A construction site where a surface soil layer was cut away without disturbing the underlying soil represents this condition. However, if the soil is undisturbed, which is indicated by a low s_c value, and contains a high level of soil biomass, infiltration is assumed to be high and runoff low. A high production permanent pasture represents this condition.

An undisturbed soil is required for a layer of high organic matter to develop at the soil surface on range, pasture, and no-till cropland. The soil consolidation subfactor is used as an indicator of the potential for this layer to develop. This effect is captured in equation 9.12 for the soil biomass subfactor s_b.

The portion of the soil surface that is mechanically disturbed during a cover-management system determines the overall effect of soil consolidation. The effects of the portion of the soil surface disturbed and the soil consolidation subfactor are illustrated in Figure 9.19 for a no-till corn cropping system at Columbia, MO.[91] One of the curves in Figure 9.19 is where the only soil disturbance is by a no-till planter that disturbs the soil in strips for a place to plant the seeds. The portion of the soil surface disturbed by the planter was varied from none to full width disturbance. No other variable such as burial ratio that would normally vary with the portion of the soil surface disturbed was changed. Thus the only effect represented is the effect of soil consolidation as reflected by portion of the soil surface disturbed. The other curve is where a fertilizer injector that disturbs 50

---

subfactor equation was primarily derived from soil loss measured at the single location Zanesville, OH, limited data from other locations indicate that the equation is valid in general.

[91] The effects computed for the soil consolidation subfactor differ between the non-Req and Req applications. The Req applications give increased credit for soil biomass, which is affected by the soil consolidation subfactor, but the Req applications do not adjust the slope length factor and the ground cover subfactor values as a function of the rill-to-interrill ratio that are used in non-Req applications.

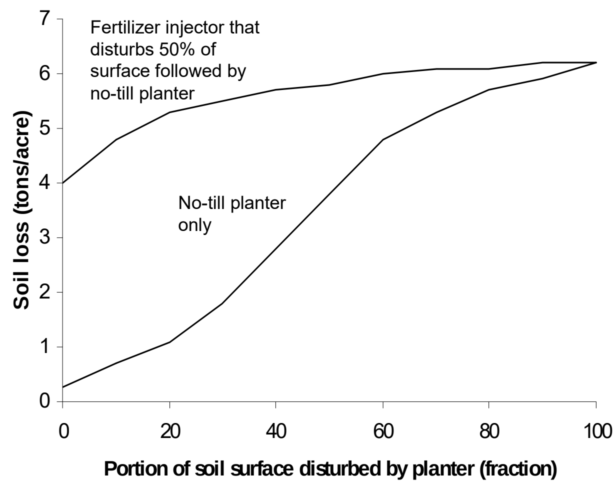

Figure 9.19. Effect of portion of soil disturbed on soil loss at Columbia, MO for no-till corn at 110 bu/acre. Fertilizer injector does not bury or resurface residue.

percent of the soil surface precedes the planter. Portions of the soil surface disturbed by the planter were varied while the 50 percent portion disturbed by the fertilizer injector was fixed.

The ratio of soil loss for the no-till planter with no disturbance and without the fertilizer injector to soil loss with full disturbance in Figure 9.19 is 0.04, which is much more effect than the 0.45 value for the full soil consolidation subfactor for no disturbance. Several variables cause additional effects beyond the 0.45 value directly associated with the soil consolidation subfactor. The soil consolidation affects the soil biomass subfactor as computed with equation 9.12. Another variable is the soil depth over which buried residue mass is averaged for equation 9.12 is reduced as the soil consolidation subfactor decreases. Another variable is the reduced slope length effect that is computed as a function of the rill to interrill erosion ratio that RUSLE2 computes as the soil consolidation subfactor decreases (see **Section 8.1.1**). Another variable is a decreased ground cover subfactor that is computed as a function of the rill-interrill erosion ratio that is a function of the soil consolidation subfactor (see **Section 9.2.2**).

The second curve in Figure 9.19 where a fertilizer injector precedes the no-till planter illustrates the importance of considering all soil disturbing operations in a cover-management system instead of giving attention solely to a single operation like a planter or drill. Varying the portion of the soil surface disturbed by the planter when it follows the fertilizer injection that disturbs a relative large portion of the soil surface had relatively little effect on erosion. The fertilizer injector is the dominant operation in terms of the soil consolidation subfactor effect. Most of the benefits of no-till cropping are lost by the fertilizer injector. The fertilizer injector disturbs the soil more than the no-till planter that follows the fertilizer injector. Consequently, adjusting the portion of the soil surface disturbed by the planter had little effect on the RUSLE2-computed soil loss..

9.2.6.3. Definition of mechanical soil disturbance

Soil disturbance, as used in RUSLE2, occurs when an operation fractures and loosens the soil, displaces soil, mixes soil and surface residue so that the interface between the residue and the surface soil is no longer distinct, and disrupts a high organic matter layer at the soil surface.

Operations that seed crops like corn, soybeans, and wheat in rows and that inject fertilizer and manure with thin shanks disturb only strips of soil and not the entire soil surface. An important input value, as illustrated in Figure 9.19, is the portion of the soil surface disturbed by each operation. A definition of mechanical soil disturbance is required to assign values for the portion of the soil surface that is disturbed by an operation.

A lower limit of 15% for portion of the soil surface disturbed should be used for no-till implements. This limit is related to the computational accuracy of RUSLE2; it is not related to definitions of no-till as used by NRCS or others.

When an operation displaces soil, the source area of the soil is included in the soil surface disturbed and the receiving area is included under certain conditions. The receiving area **is not** included in the area disturbed if the resulting soil depth from the displaced soil is so thin, less than 0.5 inch (10 mm) as a guide, that it has little effect on detachment by raindrop impact (interrill erosion) or detachment by runoff (rill erosion). The soil surface should be essentially level after an operation to assign a low value to the portion of the soil surface disturbed. The receiving area **is** included in the disturbed area if the surface residue and soil were mixed by the operation or any high organic matter soil layer at the soil surface was disrupted. The receiving area **is** included in the area disturbed, even though the surface residue has not been mixed with soil or high organic matter layer at the soil surface has not been disrupted, if displaced soil is deeper than about 0.5 inches (10 mm) such that significant amounts of interrill and rill erosion occurs because of exposed bare soil. Ridges and furrows are an indication of a high portion of the soil surface disturbed, especially where soil thrown from either side meets to form the ridge. Machines and implements, like scarifiers and hoe drills that involve shanks and shovels typically disturb a greater portion of the soil surface than implements that involve straight coulters. However, concave coulters and disks can throw large amounts of soil, resulting in almost the entire surface being disturbed.

New input values for portion of soil disturbed by an operation should be carefully examined for consistency and guidelines established so that input values are consistently assigned for other new operations.

9.2.6.4. How RUSLE2 handles strips

RUSLE2 does not keep track of individual strips of disturbed areas through time. RUSLE2 computes only a single composite soil consolidation subfactor value at any time. When an operation occurs that disturbs only a portion of the soil surface, RUSLE2 computes a composite soil consolidation subfactor value based on the portion of the soil surface that is disturbed by using a subfactor value of one (1) for the portion of the soil surface disturbed and the subfactor value at the time for the undisturbed portion at the time of the operation. This composite soil consolidation subfactor value is used in the RUSLE2 soil consolidation subfactor equation, represented by Figure 7.3, to compute an effective time after last soil disturbance. RUSLE2 accounts for time after a soil disturbance by starting with this effective time after last disturbance and proceeds.

9.2.6.5. Assigning values for portion of soil disturbed

A value of one (1) is assigned to the portion of the soil surface disturbed for most full width operations like scarifiers, moldboard plows, offset disks, tandem disks, chisel plows, and field cultivators. The portion of the soil surface disturbed by implements like row cultivators, planter, drills, and fertilizer and manure injectors that disturb strips of soil may be, but are not necessarily, less than one (1). Values for the portion of the soil surface disturbed selected for these operations should be consistent with values assigned to comparable operations in the RUSLE2 **core database**, which should be consulted first before values are assigned to new operations being put in the operation component of the RUSLE2 database. However, the portion disturbed can depend on local conditions, specific machines, and individual operators. Thus, input values may need to be adjusted from the **core values** based on the guidelines in **Section 9.2.6.3.**

Blading and grading used in construction operations must be carefully considered when a value for the portion of the soil disturbed is assigned to these operations. A grading operation for fill material should include a **disturb soil** process that uses a value of one (1) for the portion of the soil surface disturbed, even if the soil has been compacted with a roller or other compaction device. Compaction of the soil does not greatly reduce soil erodibility. Repeated wetting and drying and related soil processes must occur to cement the soil particles for the soil to be **consolidated**. A zero (0) is assigned to portion of the soil surface disturbed for a grading operation that cuts and removes a soil layer and leaves the underlying soil undisturbed. Thus, RUSLE2 assigns a value of one (1) for the soil consolidation subfactor for a fill slope and a value of 0.45 to a cut slope. However, if the cut slope has been ripped with a scarifier, disked for a seedbed, or mulch crimped in, a value is assigned to the portion of the soil disturbed according to the guidelines in **Section 9.2.6.3.**

Important RUSLE2 rules:
Surface material cannot be buried without using an operation with a *disturb soil* process
Material cannot be placed in the soil (e.g., manure injection) without an operation with a *disturb soil* process
Roughness cannot be created without an operation with a *disturb soil* process
Select values for portion of soil surface disturbed based on guidelines in section 9.2.6.3.

9.2.7. Ponding effect

Water ponds on flat lands during intense rainfall. The ponded water depth reduces rainfall erosivity. The effect is greatest along the Gulf Coast and the lower Atlantic Coast of the US. For example, RUSLE2 computes that the ponding effect reduces erosion by 46 percent at New Orleans, Louisiana on a 0.5 percent slope.

RUSLE2 computes values for the ponding sub-factor as a function of the 10 yr-24 hr precipitation amount and land steepness. The ponding effect sub-factor decreases as the 10 yr-24 hr precipitation amount increases, which is indicative of increased rainfall intensity. The ponding effect sub-factor increases as land steepness increases. For example, RUSLE2 computes only a 6 percent reduction in erosion because of the ponding effect for a 5-percent land steepness at New Orleans.

The RUSLE2 assumption is that the ponding effect is not affected by soil-surface roughness or soil ridges.

9.2.8. Antecedent soil moisture

The level of soil moisture affects infiltration and runoff to some degree at all locations. However, the effect is least where large amounts of rainfall frequently occur such as in the humid Southeastern US. The effect is more pronounced in the Western portion of the Great Plains in the US. Soil moisture is removed by growing crops depending on the type of crop and its production level. Soil loss is less following a crop that extracted much of the soil moisture in a low rainfall area. This effect is especially pronounced in the NWRR where rainfall is relatively low and environmental conditions associated with timing of rainfall and the freezing and thawing of soil under either high or low soil moisture content. A soil moisture subfactor is needed in the NWRR for Req applications to account for these special effects.

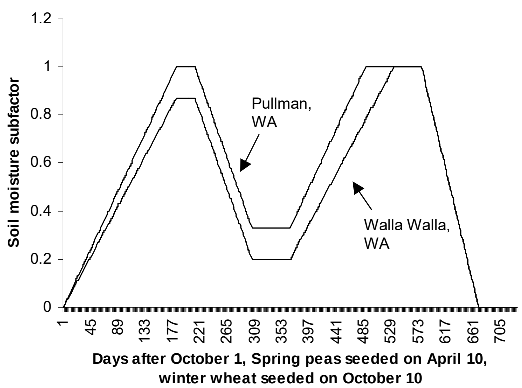

Figure 9.20. Antecedent soil moisture subfactor values for two locations in Washington for a winter wheat-spring pea rotation. The first peak is the effect of the winter wheat and the second one is the effect of spring peas.

9.2.8.1. Antecedent soil moisture subfactor effect

Values for the antecedent soil moisture subfactor s_m are illustrated in Figure 9.20. Subfactor values are 1 when the soil profile is “filled” relative to the unit plot and less than 1 when the soil profile is depleted of moisture relative to the unit plot.

As Figure 9.20 illustrates, the effect is a function of both location and type of crop. Antecedent soil moisture subfactor values are lower at Walla Walla, WA than at Pullman, WA because of less precipitation. Also, the values are lower following wheat than following spring peas because of the water usage difference between the two crops. As always, the values for the antecedent soil moisture subfactor are one (1) for unit plot conditions.

9.2.8.2. Assigning input values

An input value is assigned to each **vegetation description** in the **vegetation component** of the RUSLE2 database. Values are listed in **Section 11.1.6** and in the RUSLE2 **core database** that can be used as a guide for assigning input values used in the antecedent soil moisture subfactor.

The antecedent soil moisture subfactor must only be used in the NWRR for Req applications.

10. COVER-MANAGEMENT DATABASE COMPONENT

The **cover-management component** of the RUSLE2 database contains the **cover-management descriptions** that RUSLE2 uses to compute how cultural practices such as tillage systems for cropped fields, temporary erosion control practices for construction sites, and long term vegetation on a reclaimed mine sites affect erosion.

A **RUSLE2** cover-management description is primarily a list of operations and the dates on which each operation occurs. An **operation** is an event that changes the vegetation, residue, and/or soil in some way. Examples of operations are given in Table 10.1.

Table 10.1. Examples of operations

Operation	Effects	Comment
Moldboard plow	Kills vegetation, disturbs soil, buries residues, redistributions biomass in soil	Primary tillage, first step in growing a crop
Planting	Disturbs a strip of soil, seeds a crop	Includes a **begin growth** process. The name for the appropriate vegetation description is entered to represent the crop being grown
Broadcast seeding	Seeds a particular vegetation. This seeding operation does not disturb the soil.	Includes a **begin growth** process. The name for the appropriate vegetation description is entered to represent the vegetation that is seeded.
Volunteer weeds	Starts growth of volunteer weeds	Includes a **begin growth** process. The name for the appropriate vegetation description is entered to represent the volunteer weeds
Harvest	Kills vegetation and flattens some of the standing residue	Typical operation for crops like corn, soybeans, and wheat
Baling straw	Removes residue, flattens standing residue	Removes residue and flattens remaining standing residue
Silage harvest	Removes live biomass, kills vegetation	Leaves a portion of the live biomass in the field to represent harvest losses
Mowing	Removes live biomass, add cut material back as external residue, regrow vegetation	Cuts the live biomass but leaves it in the field. Does not kill vegetation. **Begin growth** process calls vegetation description that regrows vegetation after mowing
Baling hay	Remove live biomass,	**Begin growth** process calls vegetation

	regrows hay	description for vegetation that regrows after the hay harvest
Frost kills vegetation	Uses a **kill vegetation** process	RUSLE2 does not model plant growth. Must tell RUSLE2 when vegetation is killed, even if it occurs naturally
Fire	Remove residue/cover	RUSLE2 can not remove dead roots from the soil
Apply mulch	Add other residue/cover	Use to apply mulch to represent construction sites
Apply plastic mulch in a vegetable field, water in a rice field, or deep snow at a construction site in mountains	Apply non-erodible cover	Shuts off erosion for period that non-erodible cover is present. Use a **remove non-erodible cover** process to remove cover and to restart erosion.

The cover-management description includes the names of vegetation and residue descriptions needed by certain operations. An operation that includes a **begin growth** process requires that a vegetation description be specified for that operation. The **begin growth** process signals RUSLE2 to begin using information from the specified vegetation description on the operation's date. Similarly, operations with an **add other residue/cover** process require specifying a residue description and the amount of the material being added for the operation. RUSLE2 adds the cover at the specified amount on the date of the operation.

Additional non-event based information is also entered as a part of the cover-management description. For example, the user specifies whether the list of operations is repeated in a cycle (rotation) with a particular frequency or whether RUSLE2 is to compute erosion based on a single occurrence of each operation.

The variables in a cover-management description associated with the list of operations are listed in Table 10.2. The non-event variables that apply to a cover-management description are listed in Table 10.3.

Table 10.2. Variables in a cover-management description

Variable	Comment
List of dates	List of dates for the operations used to describe the cover-management condition (practice)
List of operations	Name of operation description in operation component of the RUSLE2 database containing values that RUSLE2 uses to

	describe the effect of the operation on erosion. Operations are events that change vegetation, residue, and/or soil. The list of operations is the main part of a cover-management description, which represent how cultural practices affect erosion.
List of vegetation descriptions	Name of vegetation description in the vegetation component of the RUSLE2 database containing values used by RUSLE2 to represent the effect of vegetation on erosion. Only one vegetation description is used at a time by RUSLE2. That is, RUSLE2 can not combine multiple vegetation descriptions into a single description.
Yield	Identifies production (yield) level in user defined units
Operation depth	Specifies the disturbance depth of operations that disturbs the soil. Default value is "recommended" value in operation description in operation component of RUSLE2 database. RUSLE2 will adjust for a depth value different from the default value.
Operation speed	Specifies the speed of operations that disturbs the soil. Default value is "recommended" value in operation description in operation component of RUSLE2 database. RUSLE2 will adjust for a speed value different from the default value.
External residue	Name of material (residue description in residue component of RUSLE2 database) added to soil surface and/or placed in soil. RUSLE2 uses values in residue description to compute how material affects erosion. Vegetation produces plant litter and crop residue. That material is considered by operations that manipulate vegetation and its biomass. External residue is material other than that associated with the vegetation descriptions in the cover-management description. Typical external residue includes manure and mulch (applied erosion control materials),
Residue added/removed	User entered mass value (dry weight basis) for material added when external residue is applied. Value shown is for the amount of plant material added from the "current" vegetation is computed by RUSLE2.
Cover from residue addition	Portion of soil surface covered by the added external or vegetation material. Value is computed by RUSLE2. This value is only for the added material and does not include existing surface (flat) cover.
Vegetative retardance	Refers to the degree that the vegetation slows surface runoff. RUSLE2 computes value based on user enter information in the vegetation description.

Table 10.3. Non-event variables used in a cover-management description

Rotation and duration	Is RUSLE2 to process the list operations multiple times in a cycle (rotation) with a certain frequency to represent steady state conditions for the cycle? Duration is the time for the cycle to be repeated. Crops are frequently grown in a crop rotation. The same crop grown each year (e.g., continuous corn) has a one-year rotation. Constructions sites are typically analyzed as a no-rotation. That is, the list of operations in the cover-management description are processed as a single pass through them.
Long term roughness	The soil surface roughness index value that evolves over time after the last soil disturbance.
Build new rotation with this management	Use this procedure to combine existing cover-management descriptions to create a new cover-management description.
Relative row grade	Can be used to specify cover-management description used as a part of a contouring system
Management alignment offset	Specifies the timing of operations when the same cover-management description is used on multiple segments along the overland flow profile.

10.1 Creating a cover-management description

The cover-management description provides information that RUSLE2 uses to compute values for the cover-management subfactors described in **Section 9**.[92] Table 10.4 illustrates a cover-management description for a corn-soybean-wheat rotation while Table 10.5 illustrates a cover-management description for a construction site where mulch is applied, a temporary cover crop is seeded, and permanent vegetation is seeded.

Table 10.4. List of operations for a corn-soybean-wheat 3-yr rotation

Date	Operation	Vegetation	Yield
4/15/1	Twisted shovel chisel plow		
5/1/1	Tandem disk		
5/5/1	Field cultivator		
5/10/1	Planter	Corn 112 bu/ac base yield	150 bu/ac
6/10/1	Row cultivator		
10/15/1	Harvest		
4/15/2	Moldboard plow		
5/1/2	Tandem disk		
5/5/2	Field cultivator		

[92] See Section 17.4.1.4 for information on creating a cover-management description for range, pasture, idle, undisturbed, and similar lands using a time invariant approach.

5/10/2	Planter	Soybeans 25 bu/acre base yield	35 bu/ac
9/10/2	Harvest		
9/15/2	Tandem disk		
9/20/2	Double disk drill	Wheat 35 bu/acre base yield	50 bu/ac
7/1/3	Harvest		
Non-event variable	Long term roughness	0.24 inches (6 mm)	
Non-event variable	Rotation	Yes	
Non-event variable	Duration	3 years	
Non-event variable	Management alignment	Not applicable	
Non-event variable	Relative row grade	10 percent	

Table 10.5. Cover-management description for applying straw mulch, seeding spring barley as temporary vegetation, and seeding a local native grass for permanent cover at a construction site

Date	Operation	Vegetation	Yield	External residue	Amount external residue added/removed
4/1/1	Blade fill material				
4/2/1	Broadcast seed	Spring barley 35 bu/ac base yield	25 bu/ac		
4/3/1	Apply mulch			Wheat straw	4000 lbs/ac
9/15/1	Killing frost				
9/16/1	Shred standing vegetation				
9/17/1	Double disk drill	Local native grass	1000 lbs/ac		
Non-event variable	Long term roughness	0.6 inches (15 mm)			

Non-event variable	Rotation	No			
Non-event variable	Duration	10 years			
Non-event variable	Management alignment	Not applicable			
Non-event variable	Relative row grade	Not applicable			

The first step in creating a RUSLE2 **cover-management description** is to list the dates and events that affect the soil, vegetation, and/or residue. A RUSLE2 **operation description** is selected from the **operation component** (see **Section 13**) of the RUSLE2 database to describe each of these events, even if the event is a natural occurrence such as frost killing vegetation. In general, the list of operations mimics actual events. However, only events that affect erosion are included in the list. For example, an aerial pesticide application would not be included. Be careful not to overlook an important natural event, such as a killing frost. The second step is to add supporting information such as the names for required **vegetation and external residue descriptions** and **application rates** for external residue. RUSLE2 procedures and definitions must be followed in creating a cover-management description to describe a field situation, keeping mind that RUSLE2 is not a simulation model. The input is a description for the field conditions that affect erosion.

A cover-management description can involve as many operations and vegetation descriptions as required. A field description can often be created in multiple ways. An example is the development of permanent, perennial vegetation from seeding to maturity after erosion has stabilized. The **duration** of the cover-management description is longer than the time for the vegetation to reach maturity to allow time for a stable litter layer and soil biomass pool to develop. Assume that three years is required for the vegetation to reach maturity and that an additional three years is needed for the litter layer and soil biomass pool to fully develop. The additional time for the litter layer and soil biomass pool to fully develop depends on temperature and precipitation at the location. The duration of the cover-management description is six years to include time for RUSLE2 to compute the effect on erosion of a fully developed litter layer and soil biomass pools.

The vegetation for this condition can be described with a single vegetation description that covers the entire six year period where the last four years involve duplicate values. A second way to apply RUSLE2 is to create three vegetation descriptions, one for the first year, one for the second year, and one for the third and subsequence year. Each of the six years represented in the cover-management description includes an operation description with a **begin growth** process where the appropriate vegetation description is assigned to the particular year.

RUSLE2 is often used to evaluate erosion for the maturity period alone without concern for erosion during establishment of the permanent vegetation. Examples include estimating erosion on pasture, range, reclamined mine, and waste disposal lands. In this case, a vegetation description of one year is created to represent the vegetation at maturity. Values at the end of the year equal those at the beginning of the year to represent a complete annual cycle. The cover-management description is a 1-year rotation. RUSLE2 cycles through the annual vegetation description a sufficient number of times so that RUSLE2 computes a stable litter layer and soil biomass pool and thus computes a stable erosion rate representative of condition where the permanent vegetation is fully established.

The same agricultural crop such as corn, soybeans, or wheat can be grown year after year (continuous cropping). The same crops can also be grown in a rotation such as a corn-soybean rotation. A cover-management description can be created for each possible combination, although the number of cover-management descriptions becomes large and difficult to manage.

An alternative is to use the **rotation builder** in RUSLE2. The rotation builder is used to combine multiple cover-management descriptions into a single cover-management description. The rotation builder most often is used to combine annual cover-management descriptions to create multiple year cover-management descriptions. The rotation builder can also be used to combine partial year cover-management descriptions for a single crop to create a single year cover-management description such as for vegetable cropping. Another example is using the rotation builder to combine a one-year wheat cover-management description with a two-year corn-soybean cover-management description to create a three-year corn-soybean-wheat cover-management description. In general, the rotation builder can also be used to combine cover-management descriptions of any duration.

The RUSLE2 rules must be carefully followed.

10.2. Discussion of variables used in a RUSLE2 cover-management description[93]

10.2.1. Dates

10.2.1.1. Operations as discrete events and representing continuous activity

Operations are discrete events that occur on a particular day. More than one operation can occur on a given day. Having each operation occur on individual days in RUSLE2

[93] The variables displayed in RUSLE2 depend on the template used to configure the RUSLE2 computer screen. Variables are discussed that you may not see displayed in RUSLE2 depending on the template you are using.

rather than on the same day is sometimes useful for seeing the effect of individual operations and for locating errors in cover-management descriptions. **However, this procedure can cause very serious errors in certain situations.** An example is creating ridges and applying mulch on a construction site. These two operations should be on the same day to avoid erroneous critical slope length values (see **Section 14.1.2.5**).

Representing continuous activity like grazing requires applying an operation multiple times over the period that the activity occurs. For example, a grazing operation description might be used once a week for each week that the grazing occurs. A sensitivity analysis should be conducted to determine how best to represent a continuous activity with a set of discrete events. In many cases, such as grazing, the best way to represent a continuous activity is to create vegetation descriptions that include the effect of the activity rather than using multiple operations.

Keep in mind that RUSLE2 uses descriptions to compute erosion. In many cases, the desired description can be created in multiple ways.

10.2.1.2. Representing the year in dates

The year of the operation can be any integer provided the years are in sequential order (e.g., 1, 2, 3, …; 2004, 2005, 2006, …; 75, 76, 77). The years 1, 2, 3 were used in Tables 10.4 and 10.5 to represent the calendar year of the rotation.

10.2.1.3. Tracking time in RUSLE2

RUSLE2 begins tracking time on the date of the first operation in the cover-management description. RUSLE2 computes average annual erosion based on the date of the first operation. Sometimes annual erosion estimates are needed on a calendar year basis or time needs to start at the same point when erosion estimates from alternative cover-management descriptions are being compared. A **no operation** operation description, which is described with a single **no effect process**, is used as the first operation in each cover-management description. A no operation only marks time and has no effect on the RUSLE2 computations. The date of a no operation is set to **January 1, 1** so that RUSLE2 will display erosion estimate on an actual calendar year basis. The no operation can also be placed on another date such as September 1 as the starting point for annual erosion accounting.

10.2.1.5. Allowing RUSLE2 to set duration

RUSLE2 scans the dates in the list of operations to determine the **duration** of the cover-management description. Using a no operation in the last year of the duration ensures that RUSLE2 makes the correct determination of duration. See **Section 10.2.8** for a discussion of rotation and duration.

A value for the duration can be entered in the cover-management description. RUSLE2 may over ride this duration based on the dates in the list of operations. An inadvertent error can occur that will not be noticed. To avoid this error, include a *no operation* in the list of operations to ensure that RUSLE2 determines the proper duration from the dates for the list of operations.

10.2.1.6. Initial conditions

The operations must always be in the proper sequence. The starting operation is unimportant for a rotation because RUSLE2 loops through the list of operations until the erosion computations become stable. Because of this computational feature, values for initial conditions for RUSLE2 are not required for rotations.

However, initial conditions are needed where the cover-management description is a **no rotation** such as applying RUSLE2 to a construction site. In this case, initial conditions must be set in RUSLE2. The first set of operations in the cover-management description are selected to create the desired initial condition. The default initial condition assumed by RUSLE2 is that the soil is bare, fully consolidated, and has no soil biomass. This condition is like that created by a blade and cutting away the surface layer of soil below the root zone without disturbing the underlying soil. If this situation is applicable to the actual field situation, no operations are needed to set initial conditions. Start with the first operation, which might be an application of mulch on a construction site. A common condition on construction sites is placing mulch on a freshly graded fill. An operation description named **blade fill material** can be used as the first operation description in the list of operations. This operation includes a **disturb soil** process with the result that the soil is not consolidated in contrast to the cut, default condition. Erosion on the fill slope will be twice that on the cut slope because of the soil consolidation effect. An initial condition of a rough soil can be created by using an operation description to create a rough surface keeping in mind that a disturb soil process is required in the operation to create the roughness that also eliminates soil consolidation at the time of the operation.

The initial condition may also involve soil biomass, a litter cover, and growing vegetation. The appropriate initial conditions are created by using an initial set of operations that create the desired description. A **no operation** can be used before and after the initial set of operations used to create the initial conditions to mark time so that RUSLE2 displays erosion on the desired date. Be sure to set up operations so that RUSLE2 displays average annual erosion starting on the desired date. Keep in mind that the average annual erosion displayed by RUSLE2 is for the entire cover-management description including the operation descriptions used to establish initial conditions.

RUSLE2 displays average annual erosion for each year that provides the erosion values that can be used to compute average annual erosion for any period during the entire duration of the cover-management description.

10.2.2. Operations

Operations are events that affect soil, vegetation, and/or residue. RUSLE2 uses the information in **operation descriptions** to compute how operations effect erosion.

Many RUSLE2 operations are created and named to represent actual events such as tilling, seeding, harvesting, burning, frost, grading, and applying mulch. A single operation description can often be created to represent an event such as tillage. However, cases arise where multiple RUSLE2 operations are used to represent a single actual field event. An example is a harrow drawn behind a tandem disk through the field as a single unit. A more accurate representation of how the composite implement buries residue can be obtained in RUSLE2 by representing the effects of tandem disk separate from the effects of the harrow. Thus, two operation descriptions are used on the same day, one to represent the tandem disk and one to represent the harrow, to represent a single actual field event. The operation descriptions can be put on two consecutive dates so that the effects of the tandem disk can be seen separate from the effects of the harrow in a test computation, but the two operations should be on the same day for the erosion control planning computation..

Having the operations in the proper sequence is an absolute necessity.

Operations represent discrete events. Representing a continuous activity like grazing is discussed in **Section 10.2.1.1**.

See **Section 13** for a complete discussion of operation descriptions.

10.2.3. Vegetation

RUSLE2 uses the information in a **vegetation description** in the **vegetation component** of the RUSLE2 database to compute erosion when vegetation is present. **Operation descriptions** with a **begin growth** process in a **cover-management description** instruct RUSLE2 to begin using data from a particular vegetation description in its computations. Thus, the name of a vegetation description must be entered for each operation that includes a **begin growth** process. RUSLE2 begins using data from the selected vegetation description on the date of the operation and references the first date, day zero, in the vegetation description to this date.

Various approaches are used in RUSLE2 to create cover-management descriptions involving vegetation. In the case of annual crops, a vegetation description for each crop is used, which requires an operation description with a **begin growth** process to call a vegetation description for the appropriate crop in a **rotation** like a corn-soybeans-wheat rotation. The vegetation descriptions for annual crops like corn, soybeans, and wheat represent a year or less.

Multiple vegetation descriptions can also be used during a year. An example is using multiple vegetation descriptions to represent sequential planting and harvesting of two or more vegetable crops during the year.

A particular plant community can be divided into multiple vegetation descriptions. For example, the following sequence of vegetation descriptions can be used to represent a hay crop. The first vegetation description is for the period from fall seeding of alfalfa and through early growth, senescence, dormancy through the winter, and spring growth to the first harvest in the first harvest year. The second vegetation description describes the regrowth following the first and second harvests in the first harvest year. The third vegetation description describes the regrowth after the last harvest in the first harvest year, senescence, winter dormancy, and spring regrowth to first harvest in the second harvest year. The fourth vegetation description describes regrowth after the first and second harvests in the second harvest year. Additional vegetation descriptions are used as required to complete the rotation. Each vegetation description should represent the progression of growth in terms of **yield**, **canopy**, **live ground cover**, and **live root biomass**. For example, yield typically increases in the early years of a hay rotation while it may decrease in latter years.

Another example of using multiple vegetation descriptions is when RUSLE2 is applied to **intercropping**. Intercropping is when two crops grow together at the same time. An example is planting a legume crop in late winter in a small grain crop. The small grain is harvested in early summer. The legume crop continues to grow after the small grain is harvested until the legume is harvested for hay in late summer. Another example is planting a rye cover crop in corn before it is harvested for silage so that vegetative cover will be present after the vegetative cover is removed when the corn is harvested for silage. Another example of intercropping is ally-way cropping in commercial tree production and grass growing in the alley ways in vineyards and orchards. Another example is volunteer weeds that grow in crops like corn, soybeans, or cotton, especially in the southern US, as the canopy cover decreases after the crop matures. The weeds continue to grow after the crop is harvested.

The small grain-legume cropping system illustrates use of multiple vegetation descriptions. The cover-management description starts in the fall with primary tillage followed by secondary tillage and seeding of the small grain. The first vegetation description is for the period between the time that the small grain is seeded and the time that the legume is seeded. The second vegetation description is for the period between the time that the legume is seeded and the small grain is harvested when the combined growth of both the small grain and legume is represented. The values for canopy, live ground cover, and live root biomass on day zero in this vegetation description should be the same as the same as the corresponding values on the last day that the previous vegetation description is used. The third vegetation description used in this 1-year rotation is for the period between the small grain harvest and the harvest of the legume. The values for canopy, live ground cover, and live root biomass on day zero in this vegetation description are less than corresponding values on the last day that the previous vegetation description was used to reflect the dead above ground and root biomass that was created with the harvest of the small grain.

RUSLE2 is often used to estimate erosion for a perennial plant community like that on a range, pasture, landfill, or reclaimed mine lands. The cover-management description to represent this condition is a 1-year rotation involving a single vegetation description. The **vegetation description** describes the vegetation over an entire year.

Another important application of RUSLE2 is to estimate erosion during the period immediately following grading of a construction site, landfill, or reclaimed mine to when the permanent vegetation becomes fully established. Temporary vegetation is seeded in the spring followed by seeding of the permanent vegetation in the fall. The vegetation description for this **no-rotation** cover-management description can be represented in two ways.

The first approach uses two **vegetation descriptions**. The first **vegetation description** represents the period between when the temporary vegetation is seeded and the permanent vegetation is seeded. The second vegetation description is for the period after the permanent vegetation is seeded until a stable litter layer and soil biomass pool has developed. The values for each year over the last few years of the description are repeats where the vegetation has matured and become stable on an annual cycle. The **long-term vegetation tool** discussed in **Section 11.2.6** can be used to create these vegetation descriptions.

The second approach uses multiple **vegetation descriptions** of the permanent vegetation. The first **vegetation description** is for the temporary vegetation. The second **vegetation description** is for the first year of the permanent vegetation. The third **vegetation description** is for the second year of the permanent vegetation. The fourth **vegetation description** is for the third year of the permanent vegetation, which represents maturity for this particular vegetation. The third year **vegetation description** is used as many years as necessary for the litter layer and soil biomass to become stable.

The RUSLE2 rules related to **vegetation descriptions** must be carefully observed. In particular RUSLE2 only uses a single **vegetation description** at a time, which is referred to as the **current** vegetation description. An **operation description** with a **begin growth** process is required to tell RUSLE2 when to begin using data from a particular vegetation description. A vegetation description can start at anytime during the growth cycle of the vegetation. A vegetation description is simply that, a description of the vegetation at a given time. The first date in the vegetation description is day zero, which is referenced to the date that an operation calls that vegetation description. Decreases in **live root biomass** are assumed to become dead biomass that are put in the **dead root biomass** pools, respectively. Thus, the ending values of one vegetation description must properly match those of the next vegetation description used in a cover-management description. For example, the **canopy**, **live ground cover**, and **live root biomass** values at the end of a vegetation description used to represent a mature perennial plant community should be the same as corresponding values at the beginning (day zero) of that vegetation description.

Important RUSLE2 rules related to vegetation

1. **RUSLE2 uses only one vegetation description at a time. This vegetation description is referred to as the *current* vegetation.**
2. **A vegetation description describes the *composite* of plants present at a given time.**
3. **The length of time in a vegetation description should be as long as that vegetation description is used in a cover-management description. If the length of the vegetation description is too short, RUSLE2 uses the values on the last date in the vegetation description until a new current vegetation description is established.**
4. **A new, current vegetation is established by using an operation having a *begin growth* process.**
5. **A *decrease* in *live root biomass* between the first day (day zero in the vegetation description) of the new current vegetation description and the last day that the previous vegetation was used is considered to be dead roots and is added to the *dead root biomass* pool.**

The vegetation descriptions selected in a cover-management description must be consistent with site conditions. RUSLE2 does not check appropriateness of a vegetation description based on environmental conditions or other factors. RUSLE2 simply uses the values in the selected vegetation description. For example, RUSLE2 uses the same values for non-irrigated corn grown in a humid area as in a desert area.

Must be sure that the selected vegetation description is appropriate for the cover-management description and for the site specific environmental conditions.

See **Section 11** for a complete discussion of vegetation descriptions.

10.2.4. Yield

Each **vegetation description** is created for a particular **yield**. Multiple vegetation descriptions can be created for various yield values. A vegetation description having the desired yield can be selected when creating a **cover-management description**. RUSLE2 does not adjust yield based on environmental, management, or other factors. The input yield value must be consistent with site specific conditions, including precipitation, irrigation, temperature, soil, fertility, pest control, plant variety, and management, where RUSLE2 is being applied,.

Instead of selecting a vegetation description created for the desired yield, a vegetation description at a base yield can be selected. RUSLE2 assumes the base yield as the default yield, which the user can change to a value appropriate for the specific RUSLE2 application. RUSLE2 will adjust values in the base vegetation description to the input yield value. The base vegetation should be chosen so that maximum yield is less than 100 percent cover. The RUSLE2 yield adjusting equations, described in **Section 11.2.1**, can not adjust to yield values less than the base yield if maximum canopy of the base vegetation description is 100 percent. However, RUSLE2 can adjust to yield values greater than the base yield when maximum canopy is 100 percent.

The input yield value is in the user defined units for that particular vegetation description. Vegetation descriptions are typically created to use customary units. However, units vary among users applying RUSLE2 to various land uses. Open the vegetation description to determine how yield is defined for a particular vegetation description. If the units defined for that particular vegetation description are not the preferred units, create a new yield unit definition. The input yield units can be wet weight, dry volume, or number of items per unit area, for example. Also, the units can be non-customary and even original units created specifically for a particular RUSLE2 application. When defining units, the user enters values that RUSLE2 uses to convert input units values to dry mass values needed to compute subfactor values in equation 9.1 and related equations.

The input yield value must match site specific conditions.

10.2.5. Operation depth and speed

Operation **depth** refers to the **depth of disturbance** for those **operation descriptions** that include a **disturb soil** process. The default depth of disturbance is the recommended depth entered in the operation description. Similarly, operation **speed** refers to the speed of operation descriptions that include a disturb soil process. The default speed is the recommended speed entered in the operation description.

The amount of surface (flat) cover, crop residue in cropping-management systems, that is buried depends on machine depth of disturbance and speed. In general, **recommended** depth and speed values should be accepted and used in RUSLE2 computations. However, varying input values for depth and speed provides an indication of how residue cover can be affected by depth and speed of soil disturbing implements. Input values must fall within **limits** entered in the operation description.

A common assumption is that residue cover, especially in conservation tillage systems, can be easily manipulated by how tillage implements are operated. The two variables easiest to vary are depth and speed. The RUSLE2 relationships for the effect of these variables on residue burial are based on a very careful study of the research data. If RUSLE2 does not produce the desired residue ground cover value over the range of depths and speeds that are possible in the RUSLE2 inputs, then a particular ground cover can not be reasonably achieved by changing depth and/or speed.

The adjustments that RUSLE2 makes for operation depth and speed are discussed in **Section 13.1.5.3**.

Be very careful in assuming that practically any residue cover can be achieved with any implement based on changes in depth and speed. The RUSLE2 values are based on sound research. Assumptions for varying residue cover by adjusting implement depth and speed that are inconsistent with RUSLE2 computations should be rejected.

10.2.6. External residue and amount added

External residue refers to material added to the soil surface or placed in the soil. This material is usually organic material such as straw mulch, certain erosion control roll products, manure, and compost. In general, RUSLE2 assumes that external residue is organic material that produces organic compounds that reduce soil erodibility when the external residue decomposes. Some materials like rock such as gravel mulch do not decompose. Other materials, such as some roll erosion control products, deteriorate by a different process than the one assumed in RUSLE2. See **Section 12** for a discussion on how to handle these situations.

External residue can be placed entirely on the soil surface, entirely in the soil, or divided between the two. An **operation description** that includes an **add other cover** process tells RUSLE2 that external residue is being added. When an operation description having this process is in the list of operation descriptions in a **cover-management description**, a **residue description** from the **residue component** (see **Section 12**) of the RUSLE2 database is selected to identify the external residue being added. RUSLE2 uses the information in the selected residue description to compute how that external residue affects erosion. Important residue variables include residue type that affects how soil disturbing operations bury the residue and the degree that the residue conforms to the micro-topography of the soil surface, the portion of the soil surface covered by a given residue mass, and a decomposition coefficient that determines how rapidly that the material decomposes as a function of daily precipitation and temperature at the location.

When external residue is placed in the soil, a **disturb soil** process must follow the **add other cover** process in the operation description used to apply the external residue. The information for this process determines the depth in the soil that the external residue is placed. RUSLE2 assumes that external residue placed in the soil is placed in the lower half of the disturbance depth with most of the residue concentrated near the three fourths disturbance depth as illustrated in Figure 9.16.

The value entered for amount of external residue added must be a mass value based on dry weight. Also, the value must be consistent with the mass values used in the residue description to describe the relationship for portion of the soil surface covered by a given residue mass.

Residue, including residue from vegetative growth and applied external residue, can be removed from the soil surface by using an operation description that includes a **remove residue/cove**r process. This process removes standing and flat residue but not buried residue. Operation descriptions use this process to represent burning and straw baling for example. **Buried residue** in the soil can be removed, by burning for example, by using an operation description that includes two steps. The first step is to resurface the desired amount of buried residue with a **disturb soil** process and then remove the resurfaced residue from the soil surface with a **remove residue/cover** process. The **resurfacing coefficient** in the disturb soil process is set so that the desired amount of buried residue is resurfaced. The value for the **portion of the soil surface disturbed** for this soil disturb process is usually set to 100 percent, which sets the **soil consolidation** subfactor to 1 (a fully disturbed soil) because RUSLE2 assumes that buried residue can not be removed from the soil without disturbing the soil. However, resetting the soil consolidation effect can be eliminated by setting the portion of the soil surface disturbed in the disturb soil process disturbed to 1 percent.

RUSLE2 does not resurface dead roots in the soil because the fine roots, which are the most important roots in affecting erosion, are assumed to be so tightly bound to the soil that a mechanical disturbance can not resurface them.

See **Section 12** for a detailed discussion of residue descriptions.

10.2.7. Long term soil surface roughness

Long term soil surface roughness is the roughness that develops over time by natural processes such as local erosion and deposition by both wind and water erosion (See

Section 9.2.3.1.) Long term soil surface roughness is also a function of vegetation characteristics such as grasses being bunch or sod forming grasses and the density of the vegetation.

Long term soil surface roughness begins to develop after the last soil disturbing operation. The time over which this roughness is assumed to develop is the **time to soil consolidation** (See **Section 7.8**.).

Entering an appropriate value for long term soil surface roughness is most important for range, pasture, reclaimed mine, and landfills lands where permanent vegetation exists. Recommended values for long term soil surface roughness are given in Table 10.6. Long term soil surface roughness is generally set to 0.24 inch (6 mm) for cropping-management systems.

Table 10.6. Long term roughness values for range and similar lands. (Source: AH703)

Condition	Long term soil surface roughness	
	(inches)	(mm)
California annual grassland	0.25	6
Tallgrass prairie	0.30	8
Shortgrass, desert	0.80	20
Mixed grass, prairie	1.00	25
Natural shrub	0.80	20
Pinyon/Juniper interspace	0.60	15
Sagebrush	1.10	28
Bare with rock fragments	0.6	15
Moderate pitted	1.10	28
Deep pitted	2.00	50
Root plowed	1.30	32

10.2.8. Rotation and duration

Rotation in RUSLE2 refers to whether or not the list of operations in the **cover-management description** is to be repeated as a cycle (rotation). The length of the cycle is the **duration** of the rotation.

Designating a cover-management description as a rotation causes RUSLE2 to cycle through the list of operations until average annual erosion for the cycle (rotation) becomes stable. Most RUSLE2 cropland applications involve cover-management descriptions that are rotations. The value entered for duration for a rotation-type cover-management description is the number of years from the first operation in the list of operation descriptions until that operation is repeated in the next cycle. Continuous cropping, such as for corn, has a 1-year duration. Also, a rotation-type cover-management description for three vegetable crops grown in the same year has a 1-year duration. A 1-year duration is used to apply RUSLE2 to permanent vegetation on range, pasture, reclaimed mine, landfill, and similar lands. A 2-year rotation applies to corn and soybeans grown in subsequent years. A corn-soybean-wheat rotation is an example of a 3-year rotation. Three years elapses from the date of the first operation in the rotation until that operation is repeated in the next cycle.

Duration is not the same as the number of calendar years over which the operations occur. For example, operations for the corn-soybean-wheat rotation occur in four calendar years while 3 years is the duration for the rotation.

An actual field event need not occur in each year of a rotation. For example, corn could be grown in a 2-year corn-fallow rotation where no operations occur in the fallow year. This rotation is a 2-year duration because two years elapses between an occurrence of the first operation in the list of operations until its occurrence when the cycle is next repeated.

The listing of operation descriptions in a rotation can begin with any operation in the list. RUSLE2 cycles through the list until the average annual erosion rate becomes stable. Specifying initial conditions for rotations is not required because of this feature.

A **no-rotation** designation for a cover-management description instructs RUSLE2 to start its computations with the first operation in the list of operation descriptions and proceed through the list. The time period over which RUSLE2 computes erosion begins on the date of the first operation and continues through the number of years specified for duration. Cover-management descriptions for construction sites, establishment periods for vegetation on reclaimed mine and landfills, and recovery from disturbances on range, pasture and disturbed forest land are typically designated as no-rotations. RUSLE2 computes an average annual erosion for the duration, as well as average annual erosion for each year of the duration. See **Section 10.2.1.3** for guidance on how to use an operation description with a **no effect** process to set RUSLE2's starting point in its computations and to display output at desired times.

In a no-rotation cover-management description, the first few operations are used to establish initial conditions, which is discussed in **Section 10.2.1.6.**

RUSLE2 scan the dates in the list of operation descriptions to determine the duration of the cover-management description. In several cases, this computation needs to be over ridden by the user entering a different value for duration. An example is the corn-fallow rotation mentioned above where operations only occur in the first year of the rotation but the actual duration is two years. Another example is a construction site where mulch is applied and the site is temporarily seeded. An average annual erosion estimate is needed over the next two years before the final grading and seeding occur. In these examples, RUSLE2 sets the duration to 1 year when the proper value is 2 years.

Even when proper values are entered for duration, RUSLE2 can unexpectedly change the duration, which causes serious errors. To prevent such errors, enter a *no-operation* operation description (an operation using a single *no effect* process) in each year (*not each calendar year*) of the duration for the cover-management description.

10.2.9. Build new rotation with this management

The **rotation builder** is a RUSLE2 tool that can be used to combine individual cover-management descriptions, including both rotation and no-rotation type cover-management descriptions, into a single cover-management description. The combined cover-management description can be named, saved, and used later in a RUSLE2 erosion computation. Also, the combined cover-management description can be used directly in a RUSLE2 erosion computation without naming and saving it. This tool is most often used in RUSLE2 cropland applications where the combination of single year cover-management descriptions into multi-year rotations is almost limitless. Having a cover-management description for each combination results in a large and cumbersome set of cover-management descriptions in the RUSLE2 database.

RUSLE2 has editing capability for copying and pasting between cover-management descriptions, which can be used to combine cover-management descriptions. The disadvantage of this approach is that the year in the dates must be changed for each individual cover-management description except for the first one. The rotation builder greatly facilitates the manipulation of these dates.

Refer to the RUSLE2 Summary User Manual at http://www.ars.usda.gov/SP2UserFiles/Place/64080530/RUSLE/RUSLE2_User_Manual.exe for information on the mechanics of using the rotation builder.

10.2.10. Relative row grade

Contouring is a support practice used in conjunction with cover-management practices to reduce erosion, especially on cropland. **Ridging** is a comparable practice used on reclaimed mined land and similar lands. The effectiveness of contouring (ridging) depends on ridge height and row grade, two major variables directly related to the cover-management practice. Ridge height is determined by values entered in **operation descriptions** that include a **disturb soil** process (soil disturbing operations). See **Section 13.1.5.4** for information on specifying ridge heights. Thus, one of the most important variables that determines effectiveness of contouring is actually specified in the **cover-management descriptions** rather than in a **support practice description**.

Row grade is the grade along the ridge-furrows created by soil disturbing operations. Contouring is most effective when row grade is perfectly level, but level row grades are seldom obtained in actual field contouring. The effectiveness of contouring decreases as row grade increases.

The recommended row grade input in RUSLE2 is **relative row grade**, which is the ratio of row grade to land steepness along the overland flow path assuming that the soil surface is flat (no ridges to redirect flow) so that runoff flows perpendicular to the topographic contours. Inputting relative row grade according to the guidelines in **Section 14.1.5** provides a more accurate RUSLE2 estimate of how contouring affects erosion than inputting absolute row grade. A major advantage of inputting relative row grade in a cover-management description is that the contouring effectiveness of a cover-management practice can be represented within a cover-management description. A cover-management description using relative row grade can be applied to any overland flow path without considering site-specific topography. This capability is advantageous for applying RUSLE2 in erosion inventories.

See **Section 14.1.5** for information on how to specify relative row grade to represent various conditions.

10.2.11. Management alignment offset

Rotational contour strip cropping is a support practice that uses a rotation cover-management practice having a combination of erodible and dense vegetation conditions. The hillslope is divided into a series of contour strips where the same rotation cover-management practice is applied to each strip. However, the rotation is sequenced differently among the strips along the overland flow path so that dense vegetation strips are alternated with erodible strips. The dense vegetation strips induce deposition to reduce net erosion.

The **management alignment offset** is the years that the rotation cover-management description is offset (delayed) relative the starting date in the cover-management description on the base strip, which is typically the uppermost strip but can be any of the strips. RUSLE2 applies the offset assigned to each strip to achieve the alternating pattern of erodible-dense vegetation strips along the overland flow path.

See **Section 14.2** for detail discussion of rotational contour strip cropping.

11. VEGETATION DATABASE COMPONENT

The **vegetation descriptions** in the **vegetation component** of the RUSLE2 database provide RUSLE2 with the information that it uses to compute how vegetation affects rill-interrill erosion. The RUSLE2 descriptions do not contain all of the information commonly used to describe vegetation. For example, RUSLE2 assumes the same rooting depth for all growth stages, plant types, and soil profiles. Even though rooting depth may affect erosion, the empirical erosion data used to develop RUSLE2 are not adequate for determining how rooting depth affects erosion. The main rooting effect captured in the data is the effect of root biomass.

RUSLE2 does not model vegetation growth. Instead, the RUSLE2 user explicitly describes the vegetation at the site where RUSLE2 is being applied. RUSLE2 does not compute how climate, soil, or management affects production (yield) level, canopy cover, height, or any other vegetative property that affect erosion.

When RUSLE2 users create vegetation, residue, operation, and cover-management descriptions, they should choose input values that ensure that RUSLE2 is using expected values for the variables that affect rill-interrill erosion. These variables include canopy cover, effective fall height, live ground cover, live root biomass, surface residue added by litter fall, standing and surface residue created at harvest, and dead roots created by root sloughing (death) and harvest.

Accounting for all of the biomass produced by the vegetation is not important in RUSLE2. The important biomass is the biomass that affects erosion. For example, the biomass left in the field after a hay harvest is a critical variable, not how much biomass left the field. Yield is only important as it is used to determine values for the biomass variables used in its computations.

RUSLE2 users create vegetation descriptions using RUSLE2 rules and procedures. These descriptions contain values for the variables that RUSLE2 uses to compute erosion. RUSLE2 vegetation descriptions are created with the focus on the information needed by RUSLE2 to compute erosion. The focus is not on accounting for biomass that leaves the site and has economic value.

Thee variables in a RUSLE2 vegetation description are listed in Table 11.1. The RUSLE2 vegetation descriptions also include **tools** listed in Table 11.2 used to develop input values for some of the variables listed in Table 11.2.

Table 11.1. Variables in a RUSLE2 vegetation description

Variable	Comment
Base production (yield) level	Production (yield) level for which a particular vegetation description applies. Value units defined by user.

Production (yield) level definition	User provided information that defines units for production (yield) level.
Amount of biomass at maximum canopy	RUSLE2 uses this information to determine amount of aboveground biomass based on canopy percent over the time represented in the growth chart. Value important in determining the amount of crop residue available at harvest and the amount of senescence (litter) fall. Values are on a dry weight basis.
Retardance	Indicates degree that vegetation retards (slows) runoff to affect critical slope length and transport capacity.
Residue	Name for residue description that applies to this vegetation description.
Relative moisture depletion rate	**Used only for Req applications.** Describes the degree that the vegetation extracts moistures during growth that affects erosion after the vegetation.
Growth chart involves the following variables	
Age (days)	Points through time used to describe temporal variation of vegetation. Starts at zero. RUSLE2 references day zero to the calendar date of the operation containing the begin growth process that tells RUSLE2 to begin using this vegetation description.
Root biomass	Mass (dry weight basis) of roots in upper 4 inch (100 mm) of soil.
Canopy cover	Portion of soil surface covered by canopy that intercept raindrops falling vertically.
Fall height	Effective height from which water drops fall where canopy has intercepted rainfall.
Live surface cover	Portion of the soil surface covered by live plant parts that touch the soil surface and affect erosion.

Table 11.2. Tools used to input values in vegetation description.	
Tool	Comment
Develop growth chart for a production (yield) level other than base level	Used to create a growth chart for a new production (yield) level that can be used in a vegetation description.
Estimate fall height	A graphical tool that estimates fall height values based on heights to the top and bottom of canopy and a graphical description of canopy.
Develops the relationship between aboveground biomass and production (yield) level	User inputs aboveground biomass values at two yield values so that RUSLE2 can develop a relationship between aboveground biomass and production (yield) level.
Develops the relationship for senescence	User inputs canopy values that RUSLE2 uses to develop a relationship between canopy cover and aboveground biomass that is used to compute the mass of plant material

	that falls to the soil during senescence.
Develops a relationship between retardance and production (yield) level	User inputs retardance values at two production (yield) levels that RUSLE2 uses to determine a relationship for retardance as a function of production (yield) level.
Develops a growth chart for long term vegetation	Used to develop temporal values for perennial and permanent vegetation on range, pasture, reclaimed mine, wastes disposal, and similar lands.

11.1. Variables in a RUSLE2 vegetation description

11.1.1. Base production (yield) level

The RUSLE2 vegetation variables are a function of production (yield) level. Therefore, each **vegetation description** in the **vegetation component** of the RUSLE2 database is for a particular **production (yield) level**. When RUSLE2 is applied to a particular site, the vegetation's production (yield) level must match site-specific conditions. The vegetation and its production (yield) level must be consistent with the location's climate, irrigation, soil, fertility, pest control, and other management conditions. Because RUSLE2 is not a plant growth model, it does not adjust vegetation variables to match site-specific conditions. Production (yield) level is a user site-specific input that reflects long-term production levels rather than production in any specific year. Although RUSLE2 can indicate how erosion varies between dry and wet years, it is not intended for such applications.

The RUSLE2 production (yield) level input can be handled in one of two ways. One way is to create a vegetation description for a set of production (yield) levels where the user selects a vegetation description for the production (yield) level that is appropriate for the site. The second way is for the user to select a vegetation description at a base production (yield) level and input the site production (yield) level value. RUSLE2 will then adjust values in the base vegetation description to ones appropriate for the input production (yield) level value.

RUSLE2 can adjust to a production (yield) level value that is higher than the production (yield) level of the base vegetation description. However, the maximum canopy cover in the base vegetation must be less than 100 percent for RUSLE2 to adjust to a production (yield) level lower than the base production (yield) level. This restriction is related to the RUSLE2 equations used to adjust for production (yield) level. The user can alternately create a new vegetation description for a new production (yield) level if the RUSLE2 adjustments are not satisfactory.

The units for the production (yield) level are user defined (see **Section 11.1.2)** and can be almost any units that a user prefers.

Yield is important in RUSLE2 only to indicate the yield to which a particular vegetation description applies or as a variable that can be used to adjust values in a given vegetation description to the desired yield. The biomass associated with a harvestable part of vegetation and its yield are important only if that biomass in the harvestable part directly affects erosion and is represented by a RUSLE2 vegetation variables. For example, accounting for the biomass in the harvestable corn grain is not important. Accounting for the biomass in a harvestable hay crop is only important until the hay is harvested. The biomass in watermelons before harvest is not important, but the ground cover provided by watermelons may be important. The biomass left behind in the field after harvest is important, not the biomass taken from the field. RUSLE2 procedures are used to create a field description of the variables that affect erosion, not to account for vegetation in its entirety.

11.1.2. User definition of production (yield) level units

Almost any user preferred units can be created for inputting values for **production (yield) level** in RUSLE2. These units can be on any basis including dry or wet, mass (weight), volume, standard moisture such as 14 percent for corn grain, number such as bales of hay or straw, or even an original user created basis. The production (yield) level input must be on a per unit area basis. These units should be common usage for intended RUSLE2 users, convenient, and a reliable indicator of how values for RUSLE2 vegetation variables change with production (yield) level.

Two inputs are used to define the production (yield) level units. The first input is the displayed yield unit, typically a common unit such as bushels per acre (liters/ha), lbs per acre (kg/ha), tons per acre, or hundred weight per acre.

The second input is a **conversion factor.** RUSLE2 multiplies the user production (yield) level input value by this conversion factor to convert the input value, which may be a mass, volume, or number per unit area value, to a mass value. Converting the production (yield) level input to a mass value facilitates using rules of thumb for estimating crop residue at harvest. The production (yield) level value expressed as a mass is multiplied by a residue:yield ratio to estimate residue at harvest.

To illustrate, the conversion factor for corn is 56 lbs/bushel at the standard 14 percent moisture content. Multiplying a 100 bu/acre corn yield by this conversion factor gives a corn grain yield of 5600 lbs/acre in terms of mass. Multiplying this mass value by the 1:1 to the residue:yield rule of thumb gives an estimate of 5600 lbs/acre of corn residue at harvest. A linear equation, discussed in **Section 9.2.1.6** is used in RUSLE2 to estimate residue at harvest rather than a simple residue:yield ratio because the residue:yield ratio varies with yield. The input data needed for this equation are discussed in **Section**

11.2.1.

The conversion factor value for converting production (yield) level inputs to a mass value is plant specific. The conversion factor for corn is 56 lbs/bushel while it is 32 lbs/bushel for oats. The input units for some plants, such as hay, are already a mass value. The conversion factor for those plants can be one (1) or it may be different from 1 if a conversion from a wet to dry basis is involved. A conversion of dry basis can either be made in this conversion factor on in the computation of aboveground biomass as a function of production (yield) level.

RUSLE2 uses the production (yield) level input to compute aboveground biomass values. This computation involves two steps. One is to multiply the input production (yield) level value by a conversion factor to obtain a mass value and the second is to convert the production (yield) level value to aboveground plant biomass values on a dry basis. The user arranges these two steps as desired to end up with the appropriate aboveground biomass values. For example, a wet to dry basis conversion can be made in the first step or the second step. The input and conversion values must be consistent so that the final result is a mass on a dry basis.

11.1.3. Live Aboveground biomass at maximum canopy cover

RUSLE2 computes daily values for live aboveground biomass as a function of daily canopy cover. Coefficient values in the equation for this computation value are determined from user input values for **live aboveground biomass at maximum canopy cover** and the value for **live above ground biomass at minimum canopy cover.**

11.1.3.1. Basic principles

The input values entered in a **vegetation description** are selected to provide RUSLE2 with the values that it needs to compute erosion. Consequently, not all of a plant's aboveground biomass is necessarily included in the input for **aboveground biomass at maximum canopy cover**. Only that plant material that becomes litter fall or that will become standing, surface, or incorporated residue is included in the input. For example, harvestable grain is not included in this input because the grain is removed from the field without affecting erosion. If a harvestable product is left in the field to provide standing or surface (flat) residue or is incorporated into the soil to provide soil biomass, it should be included in the aboveground biomass input.

RUSLE2 uses the input for aboveground biomass at maximum canopy cover to estimate daily live aboveground biomass during the time period represented by a vegetation description. Three stages of vegetation growth are represented in RUSLE2. These stages are: (1) new growth, (2) senescence/regrowth, and (3) stem growth, which are illustrated in Figure 11.1.

The general equation for all three stages is:

$$B = B_0 + \alpha(C - C_0)^{1.5} \qquad [11.1]$$

where: B = live aboveground biomass (mass/area), B_0 = live aboveground biomass at the canopy cover C_0, C = canopy cover (percent), and α = a coefficient. Figure 11.1 represents these growth stages for a plant community that reaches is already or reaches maturity in a single growth cycle. RUSLE2 determines values for B_0, C_0, and α from user input values.

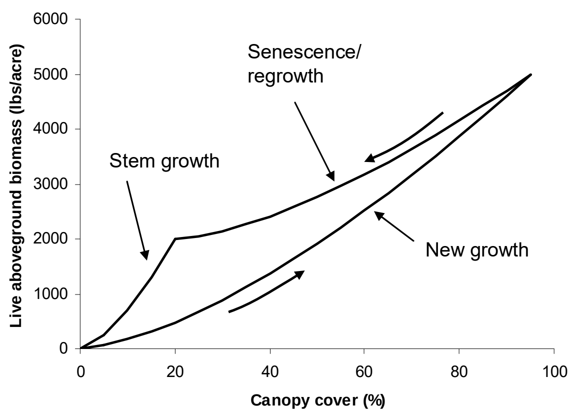

Figure 11.1. Canopy cover-live aboveground biomass relationship for a plant community that reaches maturity in a single growth cycle.

Equation 11.1 works best where maximum canopy cover is less than 100 percent. It works less well for conditions where aboveground biomass increases significantly after canopy cover reaches 100 percent. Equation 11.1 was chosen for its simplicity, robustness, and ability to be calibrated with minimal user inputs after an evaluation of alternate equation forms, including exponential forms.

A plant community well represented by Figure 11.1 is soybeans. The new growth period represents the relation between canopy cover and live aboveground biomass from plant emergence after seeding until full maturity and senescence begins. Equation 11.1 for the new growth period is:

$$B_n = \alpha_n C_n^{1.5} \qquad [11.2]$$

where: B_n = live aboveground biomass and C_n = canopy cover during the new growth stage. RUSLE2 computes a value for α_n using:

$$\alpha_n = B_{mx} / C_{mx}^{1.5} \qquad [11.3]$$

where: B_{mx} = the user entered value for live aboveground biomass at maximum canopy cover C_{mx}.

Senescence occurs during the period of decreasing canopy after the plant community has reached maturity. Equation 11.1 during the senescence stage is:

$$B_r = B_{mn} + \alpha_r (C_r - C_{mn})^{1.5} \quad [11.4]$$

where: B_r = live aboveground biomass and C_r = canopy cover during the senescence period and B_{mn} = the user entered value for live aboveground biomass at minimum canopy cover C_{mn}.

RUSLE2 computes a value for α_r using:

$$\alpha_r = (B_{mx} - B_{mn})/(C_{mx} - C_{mn})^{1.5} \quad [11.5]$$

In general, RUSLE2 assumes that any decrease in canopy cover within a vegetation description represents senescence, except for special plants like corn. Leaves droop on those plants that reduce canopy cover but do not fall to the soil surface. A user input tells RUSLE2 to not apply equation 11.4 to those plant communities.

The stem growth stage represents conditions when canopy cover is less than the minimum canopy cover that results after senescence is completed. This growth stage is important, for example, when a plant community is mowed or hay is harvested, which leaves a canopy cover that is less than the minimum canopy cover after full senescence. Equation 11.1 for the stem growth stage is:

$$B_s = \alpha_s C_s^{1.5} \quad [11.6]$$

where: B_s = the live aboveground biomass and C_s = the canopy cover during the stem growth stage. RUSLE2 computes a value for the coefficient α_s using:

$$\alpha_s = B_{mn} / C_{mn}^{1.5} \quad [11.7]$$

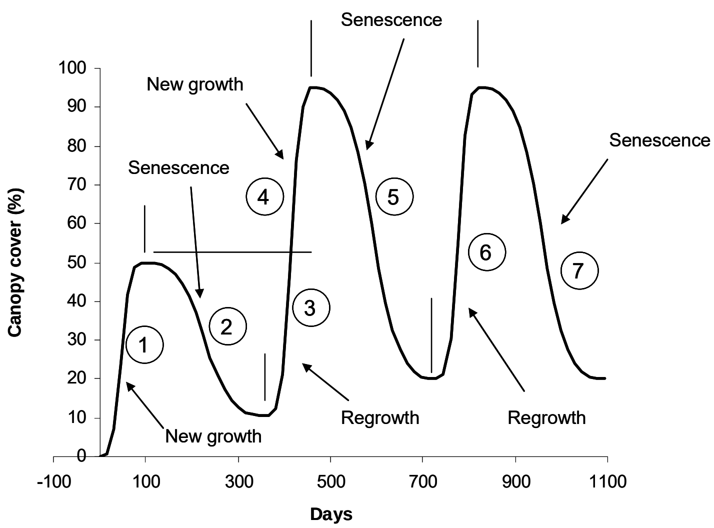

Figure 11.2. Canopy cover for a plant community that requires two cycles to reach maturity

Figure 11.2 illustrates canopy cover for a plant community that takes two growth cycles to reach maturity. The third growth cycle in Figure 11.2 represents full maturity. The plant community can be described in RUSLE2 by using the **long-term vegetation tool** or by creating a vegetation description for each growth cycle. The principles that are used in the long-term vegetation tool should be used in creating individual vegetation descriptions for plant communities like those represented in Figure 11.2.

Period 1 is new growth that begins on day zero and continues to the date of the maximum canopy cover in the first growth cycle. Period 2 is senescence that begins at maximum canopy cover in the first growth cycle and continues until minimum canopy cover at the end of the first growth cycle. Period 3 is regrowth that begins at the minimum canopy cover at the beginning of the second growth cycle and ends on the date that the canopy cover in the second growth cycle reaches the maximum canopy cover in the first growth cycle. Period 4 is new growth that begins at the date that canopy cover in the second growth cycle reaches maximum canopy cover in the first growth cycle and continues until maximum canopy cover in the second growth cycle. Period 5 is senescence that begins at maximum canopy cover in the second growth cycle and continues until minimum canopy cover at the end of the second growth cycle. Period 6 is regrowth that begins at minimum canopy cover at the beginning of the third growth cycle, which is the first full mature growth cycle. The regrowth period 6 continue until the maximum canopy cover of the third growth cycle. Period 7 is senescence that begins at maximum canopy cover in the third growth cycle and continues until the minimum canopy cover at the end of the third growth cycle. A growth cycle that represents full maturity does not contain any new growth periods.

Figure 11.3 shows the canopy cover-live aboveground biomass relationships for the plant community illustrated in Figure 11.2. Period 1 represents the new growth period in the first growth cycle. Period 2 represents senescence in the first growth cycle. Period 3 represents regrowth in the second growth cycle. Plant regrowth stage is assumed to retrace canopy loss during the previous senescence. Consequently, the same equation is used for the regrowth stage that follows the immediately previous senescence stage. That is, the same equation is used to describe both periods 2 and 3. Another equation is used to describe both periods 5 and 6.

Once canopy cover reaches the maximum canopy cover in the previous growth cycle, plant growth shifts from regrowth to new growth. Plant growth "rejoins" the previous new growth. The same equation is used for new growth in all growth cycles. Plant communities that have three or more growth cycles to reach maturity are represented using these same principles. These principles are repeatedly applied to each growth cycle until maturity is reached. New growth stages are not involved in the growth cycle that represents plant maturity.

The user inputs in the RUSLE2 **long-term vegetation tool** are **live above ground biomass for maximum canopy cover at maturity** and **live above ground biomass at minimum canopy cover at maturity**. RUSLE2 uses these inputs and the canopy cover

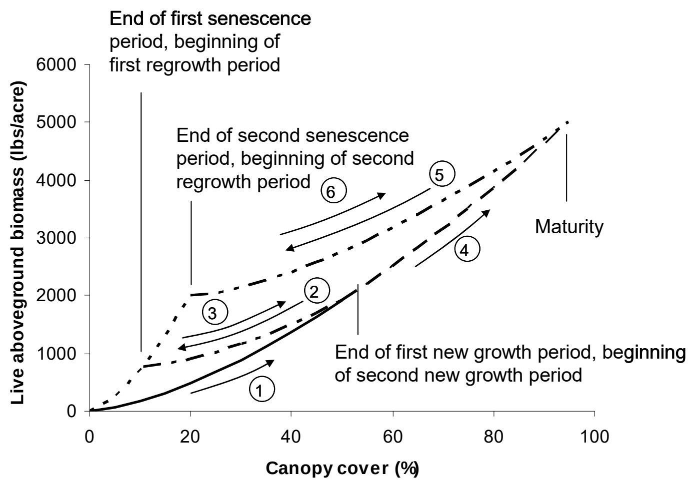

Figure 11.3. Canopy cover-live aboveground biomass relationship for a plant community that reaches maturity in two growth cycles.

values entered by the user to determine similar values for local maxima and minima canopy covers for growth cycles before plant maturity. A RUSLE2 assumption is that canopy cover for the local minimum canopy cover at the end of a growth cycle equals the product of minimum canopy cover at maturity and the ratio of local maximum canopy cover for the growth cycle to the maximum canopy cover at maturity. Another RUSLE2 assumption is that the live aboveground biomass, minimum canopy cover data point for each growth cycle must lay on the stem growth curve given by equations 11.6 and 11.7.

The other RUSLE2 option for describing plant communities having multiple growth cycles is to create a vegetation description for each growth cycle. The assumptions used in the RUSLE2 **long-term vegetation tool** should be used in creating these vegetation descriptions to ensure continuity between the individual vegetation descriptions.

Maintaining continuity between vegetation descriptions in a cover-management description is very important.

Equation 11.1 allows RUSLE2 to use the same **vegetation description** in different **cover-management descriptions** where the vegetation is killed on different dates.[94] For example, a wheat cover crop used to provide winter erosion control is killed on different spring dates depending on the main crop (e.g., corn versus cotton) and early or late planting. RUSLE2 needs an aboveground biomass estimate on the date that the wheat crop is killed and the main crop is planted. RUSLE2 estimates a value for that biomass by substituting the canopy cover value in the vegetation description on the date that the

[94] RUSLE1 differs from RUSLE2 regarding the input value for biomass when the vegetation is killed. The RUSLE1 vegetation descriptions contain the values for residue mass at the time that the vegetation is killed. Separate RUSLE1 vegetation descriptions are required for each date that the vegetation is killed. Also, two separate RUSLE1 vegetation descriptions are required for silage corn and grain corn. In RUSLE2, the same vegetation description can be used for both silage and grain corn, and the same vegetation description can be used when the vegetation is killed on different dates.

wheat is killed into equation 11.1. Without equation 11.1, RUSLE2 would require a vegetation description for each date that the wheat is killed in alternative cover-management descriptions.

RUSLE2 can also use vegetation descriptions that end on the date that the vegetation is killed where the input for aboveground biomass is for the maximum canopy cover on that day. This input technique can be used to ensure that RUSLE2 uses a particular value for aboveground biomass on the date that the vegetation is killed rather than the one computed with equation 11.1. This procedure can be used when equation 11.1 is considered to be a poor representation of the canopy cover-live aboveground biomass.

Perennial vegetation including hay and pasture crops and plant communities on rangelands, closed landfills, and other undisturbed areas exhibit a simultaneous birth and death of live aboveground biomass during new and regrowth periods. RUSLE2 computes a daily death amount of aboveground biomass as a fraction, approximately 0.01, of the live aboveground biomass on that day (see **Section 11.2.6**). This daily biomass amount is added to the surface litter (residue) biomass on that day.

RUSLE2 also considers a daily "mechanical" loss of live aboveground biomass that is added to surface litter. This daily addition is a fraction of the daily live aboveground biomass. This computation represents the loss of live aboveground biomass by mechanical processes such as animal traffic or by vehicular traffic (see **Section 11.2.6**).

11.1.3.2. Consistency between inputs for aboveground biomass at maximum canopy cover with processes in operation descriptions

RUSLE2 inputs for cover-management, vegetation, residue, and operation are descriptions based specifically on RUSLE2 rules and procedures. A particular field condition can often be described in multiple ways. However, the individual vegetation, residue, and operation descriptions used to create a cover-management description must be consistent with each other. A key element in this consistency is ensuring that the input value for aboveground biomass at maximum canopy cover in the vegetation description is consistent with the operation descriptions.

The value entered in a *vegetation description* for *aboveground biomass at maximum canopy cover* must be consistent with the *processes* in the *operation descriptions* in the *cover-management description* to ensure that RUSLE2 has the proper biomass values for standing residue, flat residue, and soil biomass for its computations.

Four examples are used to illustrate selecting values for aboveground biomass that are consistent with operation descriptions.

Example 1. Corn
Corn is grown for grain or silage. When corn is grown for harvestable grain, all of the aboveground biomass, except for the grain, is left in the field as standing and flat residue. When corn is grown for silage, almost all of the aboveground biomass is removed from the field as a harvestable product. Only a small amount of plant material is left in the field as standing and flat residue.

Table 11.3 lists **processes** that would be used in a **harvest operation description** for alternative input values for aboveground biomass at maximum canopy cover. Alternative 1 for corn grain is where the input value for aboveground biomass at maximum canopy cover is the amount of biomass that will be left in the field after the actual harvest removes the harvestable grain from the field. Alternative 2 is where the input value for aboveground biomass includes the entire aboveground plant material (i.e., fodder and grain). The harvest operation description for this vegetation description must include either a **remove live biomass process** before the **kill process** or a **remover residue/cover process** after the **kill process** to remove the grain. These processes are not required in Alternative 1 because the biomass for the grain is not included in the accounting. If the grain is not removed in Alternative 2, the amount of residue assumed by RUSLE2 after the harvest will be too high. Alternative 1 is the recommended procedure for corn grain.

The RUSLE2 objective is not to fully account for all of the biomass, but to describe only the biomass that affects erosion.

The alternatives for corn silage are similar to those for corn grain. Alternative 1 is where the aboveground biomass includes only the fodder without the grain, which is the same vegetation description as Alternative 1 for the corn grain. The harvest operation for this alternative includes a remove live biomass process before the kill process. Just as in Alternative 2 for the corn grain, a remove residue/cover process can be used after a kill process. In any case, plant material must be removed so that RUSLE2 has the proper value for the residue left in the field after the actual field operation. Alternative 2 for the corn silage is where the input value for aboveground biomass value at maximum canopy cover is the amount of residue that exists in the field after the actual field harvest operation.

Table 11.3. Harvest operation descriptions for corn grain and corn silage production			
Grain		Silage	
Alternative 1		Alternative 1	
Process	Comment	Process	Comment
Alternative 1 Aboveground biomass at max canopy does not include grain		Alternative 1 Aboveground biomass at max canopy includes all of the aboveground plant material except the grain	
Kill vegetation	Converts live aboveground biomass to standing residue, amount of standing residue directly related to input for aboveground biomass at maximum canopy	Remove live biomass	Removes most of live aboveground biomass from RUSLE2's accounting of aboveground biomass but leaves behind a small portion as flat residue
Flatten standing residue	Converts a portion of the standing residue to flat residue	Kill vegetation	Converts the remaining live aboveground biomass to standing residue
		Flatten standing residue	Converts a portion of the standing residue to flat residue
Alternative 2 Aboveground biomass at max canopy includes grain		Alternative 2 Aboveground biomass at max canopy is only the residue that will be left after the harvest operation	
Remove live biomass	This process removes the grain and leave the remaining as material that will become residue	Kill vegetation	Converts live aboveground biomass to standing residue
Kill vegetation	Converts live aboveground biomass to standing residue	Flatten standing residue	Flatten the portion of the standing residue that is to be left as flat residue
Flatten standing residue	Flatten the portion of the standing residue that is to be left as flat residue		

Example 2. Harvesting hay and mowing permanent vegetation.
Forage crops such as alfalfa regrow after each hay harvest. Similarly, permanent vegetation such as that on a landfill regrows after it is mowed. The objective is to provide RUSLE2 with inputs so that it can determine the amount of surface residue added by a hay harvest or mowing operation. Two alternatives, illustrated in Table 11.4, can be used for the hay harvest/mowing operation descriptions. In Alternative 1, the input value for the aboveground biomass at maximum canopy cover includes all of the aboveground plant material. RUSLE2 uses equation 11.1 to compute the aboveground biomass on each day, including the date of the hay harvest/mowing. Given a particular aboveground biomass on the date of the hay harvest or mowing, what is the amount of

this biomass that is added to the surface residue? The two processes of **remove live biomass process** and a **begin growth process** are used in both the hay harvest and mowing operation descriptions. The begin growth process identifies the vegetation description that RUSLE2 is to use immediately after the hay harvest/mowing operation. In addition to the input for aboveground biomass at maximum canopy cover, the other key inputs are the **portion of the aboveground biomass that is affected** and the **portion of the affect biomass that is left as surface residue** for the remove live biomass process.

To illustrate, assume that the aboveground biomass on the date of the hay harvest is 3600 lbs/acre. The input for the portion affected in the remove live biomass process in the hay harvest operation is 98 percent, which means that 3528 lbs/acre of biomass is affected. The input for the portion of the affected biomass that is left is 5 percent, which means that 176 lbs/acre is added to surface residue as a result of the hay harvest operation.

The inputs used to describe mowing a short grass permanent vegetation are similar to those used to describe the hay harvest. Assume that the amount of aboveground biomass on the date of the mowing is also 3600 lbs/acre. The input value is assumed to be 50 percent for the portion of the aboveground biomass affected by the mowing, which is 1800 lbs/acre. The input value for the portion of the affected biomass that is left as added surface residue is 100 percent, which means that 1800 lbs/acre is added to the surface residue as a result of the mowing.

The input values for these operation descriptions are both machine and vegetation specific. For example, assume that the permanent vegetation is a tall grass at the same production 3600 lbs/acre level as the short grass. Assume that 75 percent of the aboveground biomass is affected by the mowing with the tall grass in comparison with the short grass because of differences in vegetation characteristics even though the mower is operated at the same height with both vegetations. The amount of affected aboveground biomass is 2700 lbs/acre. The portion of the affected biomass that is added to the surface residue is still 100 percent, which means that 2700 lbs/acre of biomass is added to the surface residue for the tall grass mowed at the same height as the short grass where aboveground biomass was the same for both grasses. The portion of the aboveground biomass that is affected depends on the vegetation, the machine, and its cutting height.

These inputs, which can be cumbersome and confusing, must be handled very carefully according the RUSLE2 rules and procedures to avoid errors. The intent in RUSLE2 is not to mimic machines, their operations, and settings, but to provide a way to enter information that RUSLE2 needs to determine the surface residue cover and the vegetation conditions after the operation. The operation and vegetation descriptions must be consistent and considered together to ensure that RUSLE2 has the desired values for its computations.[95]

Alternative 2 applies when RUSLE2 is to use a user-entered value for the surface residue added by a hay harvest or mowing operation. The input value for aboveground biomass at maximum canopy is only important in determining the litter fall and the aboveground biomass on the date that the vegetation is killed. In contrast to Alternative 1, it plays no role in determining the surface residue added by the hay harvest/mowing operation. The **processes** in the hay harvest/mowing operation descriptions are **remove live biomass**, **add external residue/cover**, and **begin growth**. The input values for the **remove live biomass process** are 100 percent for the portion of the aboveground biomass affected and 0 percent for the portion of the affected biomass that is left behind as added surface residue. This process removes all of the aboveground biomass on the date of the hay harvest/mowing operation. The **add external residue/cover process** is used to add a specific user entered value for the biomass added to the surface residue by the hay harvest/mowing operation. The inputs for the **add external residue process** are a residue description for the material that is to be added to the soil surface by the operation and the amount of the material that is added. In the mowing example, the value entered for amount of external residue added might be 2000 lbs/acre.

An advantage of this approach is that the effect of cutting height can be quickly and easily evaluated by changing the input value for amount of external residue added. A disadvantage of Alternative 2 is that RUSLE2 does not automatically change this input value as production (yield) level changes because the effect of yield can only be accommodated by manually entering different values for the amount of external residue added. The value for surface residue added that RUSLE2 computes in Alternative 1 does vary with yield as expected.

Table 11.4. Alternative descriptions for hay harvest/mowing operations.			
Alternative 1. Operation description uses aboveground biomass to estimate surface residue added by operation		Alternative 2. Operation description assigns surface residue added by a direct input	
Process	Comment	Process	Comment
Remove live biomass	Removes a portion of the live aboveground biomass at the time of harvest and leaves a part of it in the field as surface residue added	Remove live biomass	Removes all of the live aboveground biomass from the system

[95] RUSLE2 was not designed to use absolute cutting height for hay harvest and mowing operations so that user-entered information is not required on the vertical biomass distribution for each vegetation description and how that changes through time. Such inputs for describing vegetation are not readily available. A major advantage of the RUSLE2 approach, which may seem crude, is that practically any situation can be represented with simple, easy-to-understand inputs.

Begin growth	Identifies the vegetation description that RUSLE2 to use after the hay harvest/mowing operation	Add other cover	Adds external residue in a user entered amount to represent the surface residue added by the operation
		Begin growth	Identifies the vegetation description that RUSLE2 is to use after the hay harvest/mowing operation
Note: A kill vegetation process was not used. A kill vegetation process transfers the live root biomass into the dead root biomass pool, which does not occur in a hay harvest or mowing operation for vegetation that regrows following the operation.			

Example 3. Cover crop.
Vegetation such as rye can be used as a cover crop to reduce erosion over the winter after harvest of the main crop until it is replanted in the spring. A **vegetation description** for a cover crop can be created in either of two ways.

The preferred approach is to develop a vegetation description that extends beyond the last possible date when the cover crop would be killed. The input value for above-ground biomass at maximum canopy cover is for the day in the vegetation description having the maximum canopy cover. This vegetation description can be used in **cover-management descriptions** where the date of the **operation description** that kills the cover crop can vary from day zero until the last day in the vegetation description. RUSLE2 uses equation 11.1 to estimate aboveground biomass on the date on the cover crop killing operation description.

Another approach is to describe the cover crop from its seeding date to the date that the cover crop is killed. The input value for the aboveground biomass at maximum canopy is the amount of aboveground biomass on the date that the cover crop is killed, assuming that the cover crop has not reached maturity and canopy cover is still increasing. The ending date of this vegetation description should coincide with or be within a few days of the date for the cover crop killing operation description. A disadvantage of this approach is that getting these dates to coincide is cumbersome and inconvenient. Another disadvantage is that a separate vegetation description is needed for each date that the cover crop might be killed, which varies according to main vegetation (e.g., cotton is planted later than corn) and early or late planting. The advantage of this approach is that the user can control the amount of biomass at the time that the vegetation is killed instead of letting RUSLE2 use equation 11.1 to estimate aboveground biomass at the date that the cover crop is killed. If the cover crop killing date occurs before the last date in the vegetation description, RUSLE2 will still use equation 11. 1 or 11.2 to estimate aboveground biomass on the date that the cover crop is killed. A few days difference in the killing date and the last date in the vegetation description has only a minimal effect on the results. If the date of the cover crop killing operation occurs after the last day in the vegetation description, RUSLE2 assumes the value on the last day of the vegetation description for all later days. Make a careful check to avoid this condition.

Example 4. Green beans.
Green beans can be cropped in several ways. Mechanically harvested green beans often involve a single harvest that kills the green beans. A vegetation description for green beans can be developed specifically for this cover-management description where the last date in the vegetation description corresponds with the mechanical harvest date. The input value for the above-ground biomass at maximum canopy cover would be for the harvest date, assuming that plant maturity and maximum canopy cover are not reached before the harvest.

A second way of cropping green beans is to hand pick them multiple times before the green beans are mechanically killed by tillage or chemically killed to plant the vegetable crop that follows the green beans. A vegetation description for the green beans is constructed that ends on the date of the operation description that kills the green beans. The input for above-ground biomass at maximum canopy cover would differ in this vegetation description from corresponding input in the vegetation description for the mechanically harvest green beans because the green beans would be killed later than with the single mechanical harvest green beans.

A third way that green beans can be grown is to hand pick the green beans multiple times and let the green beans grow until they die naturally. A vegetation description for this cropping method describes the green beans from seeding until the date that the green beans are assumed to die naturally. An operation description with a kill vegetation process must be included in the cover-management description on the date that the green beans are assumed to die naturally. This operation is needed to convert the live aboveground biomass and live roots to standing residue and dead root biomass.

The input for aboveground biomass at the natural maximum canopy cover is the aboveground biomass amount just before senescence begins. This vegetation description can also be used for the other two types of green bean production methods. This vegetation description has the advantage of not requiring a vegetation description for each production method and also has the advantage of not requiring the cumbersome process of matching the last date in the vegetation description with the date in the cover-management description for the operation description that kills the green beans. The advantage of ending the vegetation description on the date that the green beans are killed is that the user can control the value that RUSLE2 uses for aboveground biomass on the date that the green beans are killed rather than relying on RUSLE2 to use equation 11.1 to estimate the live aboveground biomass value on that date.

11.1.3.3. Residue:yield ratio

The value for aboveground biomass at maximum canopy cover can be entered in one of two ways. The recommended way is to directly enter a value for biomass in terms of dry biomass per unit area. The alternative is to enter a value for residue:yield ratio. RUSLE2 multiplies the value for this ratio by the input yield value and the conversion factor that computes a yield mass (see **Section 11.1.2**) to compute a value for aboveground biomass at maximum canopy cover. See Section **11.2.1** for a discussion on how RUSLE2 adjusts aboveground biomass as a function of production (yield) level.

Make sure that when the residue:yield ratio, yield, and conversion factor are all combined, the resulting aboveground biomass value is on a dry basis.

Residue:yield ratios are primarily rules of thumb, which are useful if values for aboveground biomass are not available. Residue:yield ratio values are a function of yield. Assuming a constant residue:yield ratio value over a working range is acceptable for several crops, but residue yield ratio values can be significantly larger at low yield than at high yields.

The residue:yield ratio values can vary by crop variety. Some of the common rule of thumb residue:yield ratio values were developed 40 or more years ago. Make sure that those values, although widely used, apply in your situation.

Be slow in having different residue:yield ratios in an attempt to compute how crop variety affects erosion. RUSLE2 is not sufficiently accurate for basing conservation planning on such differences. The main intent of RUSLE2 is to represent how main plant types, such as wheat, affect erosion in relation to another crop type, such as corn. The same is true for capturing the differences between plant community types for permanent vegetation on pasture, range, reclaimed mine, and landfills.

11.1.3.4. Selecting input value for aboveground biomass at maximum canopy cover

The input for aboveground biomass at maximum canopy is one of the most important inputs in RUSLE2 because this value determines the amount of litter fall and crop residue that ends up on the soil surface as ground cover to affect erosion. In most situations involving disturbed land, ground cover has more effect on erosion than any other variable. The input value for this aboveground biomass should be chosen very carefully and must be consistent with the values in the **RUSLE2 core database**. The values shown in the RUSLE2 core database were used to calibrate RUSLE2. If a user assumes different values for the RUSLE2 core database conditions than were used by the RUSLE2 developers in their calibration of RUSLE2, then RUSLE2 will give erroneous results.

Consistency between inputs and the RUSLE2 core database must be followed.

Scientific literature is a source of data for values for aboveground biomass at maximum canopy cover. These data can be quite variable. Assemble as much data as possible and review the data as a whole. Select input values that represent the data as a whole rather than trying to capture the effects of individual studies. Some or even most of the differences between individual studies can be unexplained by variability that occurs between particular years and locations.

11.1.4. Vegetative retardance

Vegetative retardance refers to the degree that vegetation slows runoff to reduce its erosivity and transport capacity. Vegetative retardance depends on type, growth stage, and density of the vegetation. For example, the retardance of dense, sod forming grasses is much greater than that of vines in a vineyard. The retardance of sod forming grasses is greater than that for bunch grasses. The retardance of a sod forming grass is very low if its production (yield) level is very low. Retardance increases during the growing season as plant material develops. Plant material must be in contact with the soil surface and slow the runoff to affect vegetation retardance. Additional factors such as soil surface roughness, surface residue cover, and live ground cover are considered by RUSLE2 to determine the overall retardance as it varies through time in a RUSLE2 computation.

Eight retardance classes ranging from none to the greatest, which is for a dense sod forming grass, are used to represent the vegetation retardance at maximum canopy cover at the base yield. RUSLE2 adjusts the class selected to represent the vegetation description as canopy cover changes during the time and as yield varies from the base yield represented by the vegetation description.

The input for retardance class for a **vegetation description** is discussed in **Section 11.2.5**. The retardance class that RUSLE2 assigns to the vegetation description at the input yield value is displayed in the **cover-management description** window of the RUSLE2 computer program for certain **user template** RUSLE2 program configurations. The purpose for giving the user access to vegetation retardance class during a RUSLE2 computation is to allow the user to manually override RUSLE2's selection of the retardance class for the input yield, if desired.

11.1.5. Residue

As described in **Section 11.1.3,** aboveground plant material can reach the soil surface as litter fall or by mechanical operations such as mowing and harvesting. RUSLE2 uses data on plant material properties to compute how this material, referred to as **residue** in RUSLE2 terminology, affects erosion. These properties include how well the material conforms to the soil surface, resists breaking into smaller pieces when the soil surface is mechanically disturbed (fragility), the portion of the soil surface cover by a given mass of material, and the rate that the material decomposes under a standard environmental condition.

Data for these properties are input for **residue descriptions** contained in the **residue component** in the RUSLE2 database. A residue description is selected and assigned to each **vegetation description** depending on how a vegetation description is used in a **cover-management description**. Plant litter (residue) is typically composed of several plant components including leaves, seed pods, chaff, and fine and coarse stems that vary greatly in their properties. A residue description represents a composite of all plant components present in the residue at the time that residue description is being used in RUSLE2. Assigning a residue description to a vegetation description is almost always a compromise. For example, immediately after harvest, the leaves in soybean residue provide a high degree of soil cover, but these leaves decompose very rapidly so that the residue becomes composed primarily of stems. The stems cover a far smaller area than do the leaves for a given mass, and the stems decompose far more slowly than do the leaves. Thus, the net properties of the soybean residue change greatly through time as the relative mass of the residue components change through time.

RUSLE2 does not consider how the properties of a residue description change through time.

Select a residue description to obtain the best overall results, which is usually an estimate of average erosion rather than erosion for a particular period. Values for residue and other variables in the RUSLE2 core database were chosen to give good estimates for average annual erosion.

However, cases arise where a different residue description should be selected for a particular plant community, such as wheat, depending on how the vegetation description is used in a cover-management description. Mature wheat straw decomposes much more slowly than does wheat residue when the wheat is killed in its early growth stage. Thus, two wheat residue descriptions should be developed, one for wheat grown to maturity where the grain is harvested and wheat straw remains and one for wheat grown as a cover crop that is killed before the wheat reaches maturity. Thus, the residue assigned to wheat depends on whether the wheat vegetation description is used in a cover-management description for grain or in a cover-management description where the wheat is used as a cover crop that is killed before reaching maturity.

The same residue description can be used for multiple vegetation descriptions. For example, several vegetation descriptions can be developed for corn based on days to maturity. The same residue description can be used for all of these corn descriptions.
