11.1.6. Relative moisture depletion

A value for the variable **relative moisture depletion** is entered in vegetative descriptions used when RUSLE2 is applied to Req zones (see **Section 6.9**). This variable describes how a previous crops depletes soil moisture, which reduces runoff and erosion in subsequent periods in a crop rotation.[96] Recommended values for relative moisture depletion are given in Table 11.5.

A value of 0.00 for relative moisture depletion means that the vegetation (crop) does not remove sufficient water to significantly affect erosion. In comparison, a crop such as winter wheat is assigned the maximum value of 1.00. See **Section 9.2.7** for discussion on how this variable affects erosion computed by RUSLE2.

Table 11.5. Recommended value for relative moisture depletion for vegetation description used in applying RUSLE2 to Req zones. (Source: AH703)

Crop	Relative moisture depletion input value
Winter wheat and other deep rooted crops	1.00
Spring wheat and barley	0.75
Spring peas and lentils	0.67
Shallow-rooted crops	0.50
Summer fallow	0.00

11.1.7. Growth chart variables

A **vegetation description** includes arrays of input values for the **temporal variables** of age (time), live root biomass, canopy cover, effective fall height, and live surface (ground) cover. The collection of these values is referred to as the **growth chart** for a vegetation description. A value for each variable is entered for each **time** in the growth chart. Each entered value is the value for a variable on that day, not an average or representative value over a time interval.

RUSLE2 uses a descriptive procedure to input values for vegetation variables that affect erosion rather than using a plant model to compute values for those variables. The focus in creating and using vegetation descriptions is to describe, not to model. This RUSLE2 feature gives RUSLE2 great power and flexibility.

A vegetation description is just that, a description of the vegetation condition over the time represented in the growth chart. This description is for the composite field condition on each day. RUSLE2 can not combine vegetation descriptions from multiple

[96] Contact Donald K. McCool, USDA-Agricultural Research Service, Pullman, WA for additional information.

plant communities into a new vegetation description for a plant community composed of multiple components. That is, a single set of vegetation values are used to describe intercropping, where two or more plant types are growing at the same time, rather than combine values for the component parts. For example, the input values for canopy cover and fall height are the values that you want RUSLE2 to use to represent the composite field condition on each day. See **Section 10.2.3.**

11.1.7.1. Age

Age in days is the time variable used in the growth chart. The first entry in a growth chart is always for **day zero (0),** which represents conditions on the date that this **vegetation description** begins to apply. RUSLE2 references day 0 to the date in the **cover-management description** for the **operation description** with a **begin growth process** that instructs RUSLE2 to begin using this particular vegetation description. A set of time (age) values are chosen to describe the temporal variables in the vegetation description. RUSLE2 assumes that variables are linear between each time value. Only a time at the beginning and a time at the end of a period are entered if values for all of the temporal variables do not change over the time period. Similarly, only times at the beginning and end of a period are entered if the temporal variables vary linearly over the time period. Additionally, closely spaced times are used to represent periods when one or more of the temporal variables change non-linearly. A sensitivity analysis (see **Section 17.3**) may be needed to determine the spacing of the times in these non-linear periods.

The growth chart for a RUSLE2 vegetation description often uses days on a 10-day or 15-day internal for convenience.[97]

The days in the growth chart for a vegetation description need not be on a fixed interval.

Day zero in a vegetation description is not necessarily the date that the vegetation is seeded. The values on day 0 describe conditions that exist on the day that RUSLE2 begins to use this vegetation description. Value for day 0 should be entered very carefully. RUSLE2 compares the root biomass and canopy cover values on day 0 with corresponding values for the last day that the previous vegetation description is used. RUSLE2 assumes that a decrease in live root biomass between two vegetation descriptions represents an event where the decrease in live root biomass should be added to the dead root biomass pool. An example is the wheat-legume intercropping cover-management description discussed in **Section 10.2.3.** The live root biomass on day 0 for

[97] Vegetation descriptions in RUSLE1 must be on a 15-day time interval. Although that 15-day time interval is often retained where RUSLE1 data files are imported into RUSLE2, day values in RUSLE2 can be on any interval and the interval can vary throughout a RUSLE2 vegetation description.

the legume vegetation description that represents conditions after the wheat harvest is less than the live root biomass of the combined wheat-legume vegetation on the day of wheat harvest. The effect represented by this decrease is that the wheat harvest killed the wheat and transferred the wheat's live root biomass to the dead root biomass pool. A harvest operation with a **kill vegetation process** is not used in this cover-management description because that process would have transferred the entire live root biomass, not just the wheat live root biomass, to the dead root biomass pool.

The last day in the vegetation description should be carefully selected as discussed in **Section 11.1.3.2.** The last day in the vegetation description should be later than the date in the cover-management description for the operation description that kills the vegetation. In special cases, the last day in the vegetation description and date of the kill vegetation operation should be the same or nearly the same to ensure that RUSLE2 uses a particular value for aboveground biomass at maximum canopy cover. However, if the last day in the vegetation description is less than the date of the kill vegetation operation, RUSLE2 uses values for the last day in the vegetation description until RUSLE2 begins to use the next vegetation description.

No time limit exists for the last day in a vegetation description. Many vegetation descriptions are for a year or less.[98] For example, the duration of vegetation descriptions vary from 60 days for spring broccoli, 120 days for corn grain, 255 days for winter wheat, and 365 days for a mature pasture. In RUSLE2, the time can be as long as desired to represent the full duration of the vegetation, which can be multiple years. For example, the vegetation description for seeding and establishment of permanent vegetation on a landfill or reclaimed mine may be 10 years that includes the initial three-year establishment period and an addition seven years required for a stable litter and soil biomass pool to develop. The RUSLE2 long term vegetation tool described in **Section 11.2.6** can be used to construct these multi-year vegetation descriptions. A set of three vegetation descriptions can be used in this example rather than using one long 10-year vegetation description. Three 1-year vegetation descriptions would be used, one for the first year starting at seeding, one for development during the second year, and one for the third year and every year thereafter, which represents maturity. An operation with a begin growth process is used each year to tell RUSLE2 which vegetation description to use for that year.

Another example where multiple vegetation descriptions are used is to represent mowing permanent vegetation and hay harvests (see **Section 11.1. 3.2**). The main use of the multiple vegetation description is to represent regrowth of the vegetation following mowing or hay harvest. Simultaneous with the representation of mowing and harvest, multiple vegetation descriptions can be used to represent both the increase and decrease of vegetative production between renovations of the vegetation. See **Section 10.2.3** for a

[98] The duration of a vegetation description in RUSLE1 is limited to 1 year. Vegetation descriptions in RUSLE2 can be of any duration.

discussion of an alfalfa cover-management description where multiple vegetation descriptions are used.

11.1.7.2. Live root biomass

Live roots reduce erosion by mechanically protecting and holding soil in place, producing exudates that reduce soil erodibility, becoming a part of the soil dead root biomass by root sloughing (death) or the vegetation being killed, and indirectly representing increased infiltration, reduced runoff, and reduced erosion (see **Section 9.2.5**). The most important roots are the fine ones very near the soil surface. Coarse roots, especially tap roots, have much less effect on erosion than the fine roots. A value for **live root biomass per unit area in the upper four inches (100 mm) of soil** is entered for each time in the **growth chart**. RUSLE2 uses each value in the array to estimate live root biomass values for the entire rooting depth according to the distribution illustrated in Figure 9.14.

Live root biomass values for annually seeded plants, such as the corn and winter wheat illustrated in Figure 11.4, start from zero on day zero (0) in the growth chart and increase through time to a maximum value. In the case of spring planted corn, the values increase as an S-shaped curve and level off at a maximum. The pattern for fall planted winter wheat differs from that for the spring planted corn. The winter wheat experiences early growth during the fall and dormancy during the winter, reflected by the plateau from about day 50 to day 170 in Figure 11.4. The degree of fall growth for the winter wheat and the length of dormancy is climate dependent. RUSLE2 does not adjust vegetation descriptions to account for those climatic differences. Instead, users create multiple vegetations by climatic regions, such as cropping zones. Figure 11.4 illustrates vegetation descriptions for annually seeded crops. Figure 11.5 illustrates vegetation descriptions for permanent vegetation. Two types of erosion analysis are made for permanent vegetation. One analysis is to compute erosion from the date of seeding until the vegetation becomes mature, fully established along with a fully developed litter layer and soil biomass pool. The other analysis is to estimate erosion for a fully established permanent vegetation (see **Section 10.2.8**).

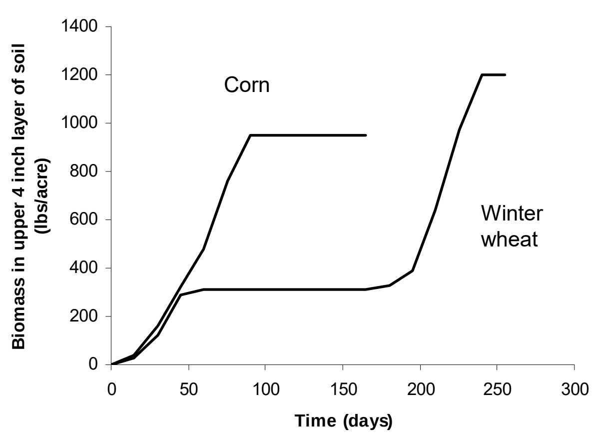

Figure 11.4. Live root biomass values for corn and winter wheat.

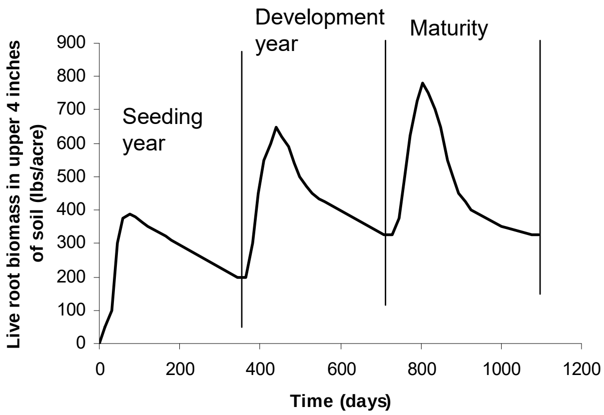

Figure 11.5. Live root biomass for three vegetation descriptions used in series to represent the establishment of permanent vegetation

A single **vegetation description** can be created to describe the vegetation from seeding through complete establishment. The vegetation can also be described with a set of three vegetation descriptions as illustrated in Figure 11.5. The time period for each vegetation description is an entire year. The ending live root biomass for one vegetation description matches the live root biomass at the beginning of the next vegetation description. In the mature year, the beginning live root biomass matches the ending live root biomass. The vegetation description for the mature year is repeated for as many years as necessary for RUSLE2 to compute a stable litter layer and soil biomass pool. This **cover-management description** is a **no-rotation** with a **duration** sufficiently long for fully established conditions to be represented.

Only the vegetation description for the mature year is used to compute erosion for a vegetation completely established. This cover-management description is a **rotation** with a 1-year **duration**. RUSLE2 automatically repeats the computations for as many years as necessary to compute the development of a stable litter layer and soil biomass pool.

The value for live root biomass on day 0 begins at zero for plants started from seed. However, live root biomass on day 0 begins at a value greater than zero when describing vegetable transplants, for example, to reflect the presence of live root biomass is when RUSLE2 begins to use this vegetation description.

Live root biomass is the source of the dead root biomass pool represented by RUSLE2. An **operation description** with a **kill vegetation process** transfers the entire live root biomass that exists on the date of the kill vegetation operation description to the dead root biomass pool. Live root biomass becomes zero on that day and the dead root biomass pool is increased by this amount of live root biomass.

A kill vegetation process in an operation description transfers the entire live root biomass to the dead root biomass pool. Sequential vegetation descriptions without a kill vegetation operation description are used to transfer only a portion of an existing live root biomass pool to the dead root biomass pool.

Root sloughing (death) is also a major source of dead root biomass for permanent vegetation on range, pasture, landfills, and reclaimed mine lands. Up to 40 percent of the annual root biomass can be sloughed (see **Sections 9.2.5.1 and 9.2.5.3.2**). RUSLE2 assumes that a decrease in live root biomass, as illustrated in Figure 11.5, during the time represented by a vegetation description is root sloughing. RUSLE2 can also compute death of root biomass during growth periods by assuming that daily root biomass death is a fraction of the daily live root biomass. The decrease in live root biomass between days is added each day to the dead root biomass pool. Using a constant live root biomass in a permanent vegetation description prevents RUSLE2 from computing an accumulation of dead root biomass, which can result in a serious overestimate of erosion.[99]

Time varying root biomass values should be used in vegetation descriptions for permanent, multiple year forage crops, and similar vegetation.

Situations, such as intercropping, exist where only a portion of an existing live root biomass pool should be transferred to the dead root biomass pool. An example is the small grain-legume **cover-management description** discussed in **Section 10.2.3.** A similar situation is winter weed growth in southern US regions. The canopy of crops like corn, soybeans, and cotton decrease before harvest so that volunteer weeds begin to grow and continue to grow after crop harvest. These weeds provide vegetative cover during the winter to significantly reduce erosion, which is especially important because of the high erosivity during winter months in this region.

Sequential vegetation descriptions are used in RUSLE2, such in these cover-management descriptions, when only a portion of an existing live root biomass pool is to be transferred to the dead root pool. Three vegetation descriptions are used: (1) the wheat only period from seeding until the legume is seeded (corn only), (2) the period when the wheat and legume grow together until wheat harvest (corn and weeds together), and (3) the period after wheat harvest where the legume continues to grow (also, weeds after corn harvest). RUSLE2 makes no change to the dead root biomass pool between periods 1 and 2 because the live biomass values at the end of period 1 equals the live root biomass at the beginning of periods. RUSLE2 adds to the dead root biomass pool between periods 2 and 3 because the live root biomass decreases from that at the end of period 2 to the live biomass at the beginning of period 3. The addition to be dead root biomass pool is the amount of the decrease in the live root biomass. This procedure represents harvest

---

[99] The time-invariant C-factor procedure in RUSLE1 does not directly account for the effect of dead root biomass on erosion.

killing one vegetation while allowing growth of another vegetation to continue.

Figure 11.5 illustrates a situation where no live root biomass should be transferred to the dead root biomass when RUSLE2 switches vegetation descriptions in the cover-management description. The vegetation descriptions for Figure 11.5 were constructed with the biomass value at the end of one vegetation description matching the live root biomass value at the beginning of the next vegetation description in the sequence so that a smooth continuous condition in live root biomass is represent between vegetation descriptions.

Hay harvest of forage crops that regrow after harvest and permanent vegetation that regrows after mowing are cover-management descriptions where an event causes a major change to occur in the aboveground biomass but no change in the live root or dead root biomass pools. Principally two vegetation descriptions are used, one to represent conditions through the day of the hay harvest/mowing and one to represent regrowth conditions after hay harvest/mowing. The live root biomass value at the end of the first vegetation description matches the live root biomass value at the beginning of the second vegetation description. The two live root biomass values should be equal on the day of harvest and the day after harvest so that no change in the dead root biomass occurs. Multiple vegetation descriptions can be created to shows a progression of live root biomass over time where a hay (pasture) crop reaches maximum production and then declines until the hay (pasture) crop is renovated.

RUSLE2 makes no change in the dead root biomass when the live root biomass increases either within a vegetation description or between vegetation descriptions.

Inspect the vegetation descriptions used in a cover-management description to avoid an unintended decrease in live root biomass and addition to dead root biomass between vegetation descriptions.

The recommended approach for selecting input values for live root biomass is to use the values listed in the **RUSLE2 core database** as a guide. Start by selecting a vegetation description in the RUSLE2 core database that is similar to the plant community for which you are selecting input live root biomass values. Modify the live root biomass values for the selected core database plant community based on how you think differences between the two plant communities would affect live root biomass. This approach for selecting live root biomass values is far better than making field measurements of live root biomass values. Measuring root biomass is very difficult and time consuming, which is evident by the huge range of values given in the literature for wildland type plant communities (see **AH703**). The variability is much less for agricultural and pasture land crops, but is still significant. If input values for live root biomass are to be selected based on field measurements, make many measurements, being careful to measure the fine roots, which have the greatest effect on erosion.

The research literature is a source of live root biomass values that are reliable for vegetable and field crops but not for wildland plant communities. Be very careful in selecting live root biomass values based on literature sources. Many data sources should to be reviewed to determine overall main effects. The best way to select live root biomass values for wildland plant communities is to use the ratio of effective root biomass to average annual aboveground biomass production listed in **Section 17.4.1.4**. These values were obtained by using measured erosion data to back calculate effective live root biomass values using the subfactor equations described in **Section 9**.

A major problem with using measured root biomass values for wildland type plant communities is knowing the credit to give to fine roots versus the credit to give to coarse roots. The input values for live root biomass should be based primarily on the annual production of fine roots. However, erosion and root research has not provided definitive information on how to measure root biomass for use in RUSLE2, which was overcome in the RUSLE2 approach that back calculates effective live root biomass values from measured erosion data.

A major requirement is that input values for live root biomass values are consistent with values in the RUSLE2 core database to ensure that RUSLE2 computes the expected erosion values. RUSLE2 was calibrated with the values given in the RUSLE2 core database to give expected average annual erosion estimates. If input values are not consistent with the core values used to calibrate RUSLE2, then RUSLE2 may give erroneous results. Do not use live root biomass values without checking them for consistency with RUSLE2 core values.

11.1.7.3. Canopy cover

Canopy cover is the portion of the soil surface covered by plant material that is above the soil surface. Canopy cover intercepts raindrops but has no effect on surface runoff, (see **Section 9.2.1**). Canopy cover is a major variable in the canopy subfactor, and it is also used by RUSLE2 to estimate live aboveground biomass during the time represented by a **vegetation description** (see **Section 11.1.3.1**).

Canopy cover values are entered for each time value in the **growth chart**. RUSLE2 interprets an increase in canopy cover as plant growth adding aboveground biomass. Conversely, RUSLE2 interprets a decrease in canopy cover as a transfer of live aboveground biomass to the soil surface. Senescence and litter fall are natural processes where leaves fall from mature plants to the soil surface and become surface (flat) cover. Most permanent vegetation and some agricultural crops like soybeans experience senescence. Also, a senescence type process is chemically induced in cotton just before harvest. Not all decreases in canopy cover represent a transfer of biomass from the live aboveground biomass to surface residue. For example, mature corn leaves droop without falling to the soil surface. RUSLE2 uses data are entered in the **senescence tool** in the vegetation description to calibrate equation 11.2 that computes values for live aboveground biomass as a function of canopy cover.

A decrease in canopy cover between the last day of the previous vegetation description and the canopy cover on day zero of the next vegetation description has no significance to RUSLE2. RUSLE2 makes no changes in residue cover when canopy cover changes between vegetation descriptions. In contrast, RUSLE2 assumes that a decrease in live root biomass between vegetation descriptions is dead root biomass that is added to the dead root biomass pool. **Operation processes**, such as **kill vegetation**, in **operation descriptions** to explicitly describe changes in standing and surface residue between vegetation descriptions.

A **kill vegetation process** in an **operation description** converts the entire live aboveground biomass to standing reside rather than just a part. **Understanding this feature is important** for describing intercropping represented in the wheat-legume cover-management description discussed in **Section 10.2.3**. The wheat harvest creates a large pool of standing and flat wheat straw residue. However, the live aboveground biomass for the legume should remain unchanged after the wheat harvest.

A similar situation is hay crops that regrow after hay harvest and permanent vegetation that regrows after mowing. These **cover-management descriptions** typically involve a harvest operation description that includes a **remove live biomass process** to manipulate the live aboveground biomass amounts to add the desired amount of surface (flat) residue and a **begin growth process** to identify the vegetation description that RUSLE2 is to use immediately after harvest. **The value that RUSLE2 uses for standing residue needs to be checked to ensure that RUSLE2 is leaving the proper amount of standing residue. This check is critically important in cover-management descriptions like wheat-legume intercropping because of the large mass of residue left by the wheat harvest.**

Input values for canopy cover should be selected by comparing your vegetation description with vegetation descriptions contained in the **RUSLE2 core database**. Select canopy cover values by adjusting core database values based on differences in characteristics between your vegetation and the core database description being used as a guide.

The literature is a source of canopy cover values. However, make especially sure that the canopy cover values reported in the literature are consistent with **RUSLE2 definitions**. For example, literature values often includes leaves touching the ground as **canopy cover** that the RUSLE2 definitions require counting as **live ground cover** (see **Sections 9.2.2.1 and 11.1.7.5**). Review as many data sources as possible because of data variability. The data should be reviewed to determine overall main effects rather than focusing on the data for a single location.

In some cases, field measurements may be necessary. One way to estimate canopy cover is to sum the open space between plants and open space within the perimeter of the plant canopy and subtract this sum expressed as a percent of the total area from 100. Canopy cover can be estimated from plan view photographs for certain plant communities like corn where live vegetation does not touch the soil surface. A better approach for measuring canopy cover of permanent vegetation on range, pasture, landfills, and reclaimed mine land where some of the live vegetation touches the ground is to lay a transect across the field slope, lower a pointed rod vertically to the soil surface, and count the number of hits for canopy cover, surface (flat) residue (litter), and live parts of the vegetation touching the soil surface (live ground cover). Make sure that a large number of measurements are taken to properly deal with spatial and temporal variability, such as that associated with hillslope position.

11.1.7.4. Canopy Fall Height

Canopy fall height is the effective height from which intercepted rainwater forms drops that fall from the plant canopy (see **Section 9.2.1.1**). **Effective fall height** is less than the canopy height but greater than the height to the canopy bottom. Effective fall height is also a function of canopy shape and the vertical density distribution within the canopy. Some plant communities like grass growing under shrubs on rangelands have two distinct canopies. The understory is the main determinant of effective fall height if the understory is dense. Enter an effective fall height value for each time in the **growth chart**.

Several procedures are available for selecting effective fall height values. One approach is to compare characteristics of your vegetation with **vegetation descriptions** in the **RUSLE2 core database** and assign effective fall height values based on that comparison. Another approach is to inspect plants in the field or in photographs and assign effective fall height values. Another approach is to measure the height to the lowest part of the canopy at locations along a transect. Effective fall height is the average of those values. A fourth approach is to use the **fall height tool** in a RUSLE2 vegetation description to estimate effective fall height. This procedure uses height values to the top and bottom of the canopy, canopy shape, and the density gradient within the plant canopy to estimate effective fall height (see **Section 9.2.1.3**).

Review effective fall height values to ensure consistency among vegetation descriptions so that RUSLE2 computes expected differences in erosion among plant communities.

11.1.7.5. Live ground cover

Live ground cover is live vegetation that touches the soil surface to affect raindrop impact and surface runoff as does other ground cover (see **Section 9.2.2.1**). Live ground cover is one form of ground cover along with crop residue, plant litter, and rock fragments. The portion of the soil surface covered by live ground cover can be very high in early plant growth when the vegetation is composed almost entirely of very low leaves. As the vegetation grows and stems develop, live ground cover can decrease, even to the point that no part of the plant, other than the stems, touches the soil surface to provide live ground cover. Live ground cover inputs also include basal area of the vegetation. A value for live ground cover is entered for each time value in the **growth chart**.

The best way to select live ground cover input values for a vegetation description is to make comparisons with **vegetation descriptions** in the **RUSLE2 core database**. Field measurements can also be made. Many measurements are needed to deal with both temporal and spatial variability. Field measurements can be made using points along a transect. Live ground cover is measured even if it lies on top of plant litter, crop residue, rock, or other types of ground cover. RUSLE2 accounts for overlap of ground cover from different sources. Input values for live ground cover should be reviewed for consistency among the vegetation descriptions in the RUSLE2 database. Also, field inspections of plant communities are helpful, especially if field measurements of live ground cover are not made.

The mass in live ground cover is included in the live aboveground biomass inputs. RUSLE2 does use a relationship between cover and mass for live ground cover as it does for crop residue, plant litter, or applied residue.

11.2. Tools used to develop input values for vegetation descriptions

11.2.1. Develop growth chart for a new production (yield) level

Each **vegetation description** in the RUSLE2 database is for a particular **production (yield) level**. Adjustments are required in a vegetation description to apply RUSLE2 to other production (yield) levels (see **Section 9.2.1.6**). Two options are available to make the adjustments.

One option is to enter the desired production (yield) level value in the **cover-management description** where the vegetation descriptions are selected. RUSLE2 can adjust any vegetation description to a production (yield) level greater than the assigned value for the selected vegetation description. However, the maximum canopy cover must be less than 100 percent in the selected vegetation description for RUSLE2 to adjust to a production (yield) level less than the assigned value for the selected vegetation description. RUSLE2 adjusts values for aboveground biomass at maximum canopy; live root biomass, canopy cover, effective fall height, and live ground cover in the growth chart; and retardance index values to represent the new value entered for production (yield) level. Live aboveground biomass at maximum canopy is assumed to vary with yield according to equation 9.5. RUSLE2 assumes that live root biomass varies linearly with aboveground biomass at maximum canopy cover; canopy and live ground cover vary with the square root of live aboveground biomass at maximum canopy cover; and effective fall height varies with the 0.2 power of live aboveground biomass at maximum canopy. RUSLE2 varies the retardance index as a linear function (retardance index = a + b·yield) (see **Section 11.2.5**).

The second option is to use the RUSLE2 tool **develop growth chart for new production (yield) level** to create a new vegetation description for the desired production (yield) level. This RUSLE2 tool starts with the selection of a base vegetation description at its assigned production (yield) level. A value is entered for the new production (yield) level and RUSLE2 creates a new vegetation description for the new production (yield) level. This new vegetation can be saved in the RUSLE2 database and used in other RUSLE2 computations. The same requirements and equations discussed above for entering a new production (yield) level in a cover-management description apply in the **develop new growth chart tool**. The advantage of using the develop new growth chart tool is that the adjustments do have to be made by hand and manually entered in a new vegetation description in the RUSLE2 database.

11.2.2. Estimate effective fall height based on canopy characteristics

As discussed in **Section 9.2.1.2, effective fall height** varies with heights to the top and bottom of the canopy, canopy shape, and the vertical density gradient of plant material within the canopy that affects fall height. The RUSLE2 tool that estimates **effective fall heights as a function based on canopy characteristics** can be useful in assigning effective fall height values and improves consistency among users assigning effective fall height values.

Effective fall height varies temporally during plant growth and senescence. Input values for canopy characteristics are entered into the fall height tool at selected times during the period represented by a **vegetation description**. These inputs include values for heights to the top and bottom of the canopy, selection of a canopy shape from those illustrated in Figure 9.2, and selection of a canopy density gradient. The canopy density gradient refers to whether canopy material affecting fall height is uniformly distributed with height in the canopy, concentrated near the bottom of the canopy, or concentrated near the top of the canopy. The base condition is for a uniform canopy density gradient where effective fall height is one third of the difference in heights between the top and bottom of the canopy plus the height to the bottom of the canopy as illustrated in Figure 9.1. The effective fall height is adjusted up or down with respect to canopy shape as illustrated in Figure 9.1 and adjusted up if the plant material affecting fall height is concentrated near the top of the canopy or down if the material is concentrated near the bottom of the canopy.

RUSLE2 computes an effective fall height at each of the times where values are entered for canopy characteristics. RUSLE2 then linearly interpolates between these effective fall height values to assign effective fall height values for each time value in the **growth chart**.

11.2.3. Live aboveground biomass at maximum canopy as a function of production (yield) level

The input for **live aboveground biomass at maximum canopy cover** determines the mass of vegetative material that becomes standing and surface (flat) residue, both of which have a major effect on erosion (see **Sections 9.2.2, 9.2.5, and 11.1.3**). The amount of live aboveground biomass varies with production (yield) level as illustrated in Figure 11.6. RUSLE2 uses equation 9.5, represented by the fitted line in Figure 11.6, to estimate live aboveground biomass at maximum canopy cover as a function of **production (yield) level** (see **Section 9.2.1.6**).

The **biomass-yield tool** [live aboveground biomass at maximum canopy as a function of production (yield) level] is used to input values that define the fitted line illustrated in Figure 11.6 for a particular vegetation description. The procedure is to plot observed data for live aboveground biomass at maximum canopy as a function of production (yield) level and fit a straight line to the data. The production (yield) level units in this relationship are the ones created for this particular **vegetation description** (see **Section 11.1.2**).

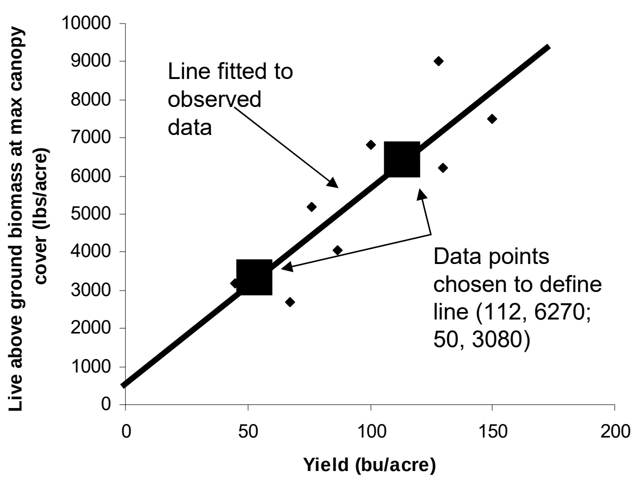

Figure 11.6. Fitting line to aboveground biomass data as a function of yield.

Values for two data points on the line are chosen and entered in the biomass-yield tool. RUSLE2 uses these two data points to compute values for the coefficients M_0 and b_a in equation 9.5. The data point for the higher production (yield) level is the production (yield) level for which the vegetation description applies and the second data point is at a lower production (yield) level. If the same values are entered for both data points, RUSLE2 assumes that the value for the intercept M_0 is zero (0) and that the slope b_a equals the value entered for live aboveground biomass live divided by the production (yield) level. This procedure can be used to describe forage crops and permanent vegetation. Otherwise, this procedure should only be used within a limited production (yield) range. See the discussion later in this section related to the variation of the ratio of live aboveground biomass to production (yield) level.

The value for the intercept (coefficient M_0) represents the live aboveground biomass at maximum canopy at zero production (yield) level. The intercept value is greater than zero for grain and vegetable crops like corn, soybeans, wheat, green beans, and cucumbers, while the intercept value is zero for the typical production (yield) level definitions used for forage crops and permanent vegetation. The value for the coefficient b_a is the slope of the line fitted to the data illustrated in Figure 11.6. It represents the increase in the live aboveground biomass at maximum canopy for a unit increase in production (yield) level.

The input values for live aboveground biomass at maximum canopy must be on a dry basis. The input values are for the live aboveground biomass at maximum canopy cover, not the live aboveground biomass at harvest. RUSLE2 accounts for loss of live aboveground biomass by senescence using the live aboveground biomass at maximum canopy cover as its starting point. Input values used by RUSLE2 to calibrate equation 11.4 to compute loss of live aboveground biomass by litter fall and senescence tool are entered in the senescence tool (see **Section 11.2.4**).

The two input values for live aboveground biomass provide RUSLE2 with the information it uses to compute the mass of above ground plant material that influences erosion. The objective is not to account for all of the biomass in the system but only that biomass that affects erosion. For example, harvested soybean grain does not end up on the soil surface to affect erosion, but pods around the grain do and should be counted in the live aboveground biomass input. Another example is woody-type vegetation such as shrubs on rangelands. The amount of aboveground biomass that becomes litter fall is the only important biomass under most permanent vegetation conditions. However, if the woody-type material becomes surface residue, perhaps as a part of rangeland renovation, then the woody-type biomass must be accounted for in the vegetation description and in the **residue description** selected for the vegetation description.

The values entered for live aboveground biomass at maximum canopy must be consistent with values entered in the senescence tool in a vegetation description.

Input values for the biomass-yield tool can be obtained in several ways. One way is to compare your vegetation with vegetation descriptions in the **RUSLE2 core database** and select input values based on this comparison. A data source is residue-yield research data published by agricultural experiment stations to which you can use to fit equation 9.5. Ensure that yield definitions used in these data are consistent with the RUSLE2 yield definition used in the vegetation description. Also, adjustments may be needed in crop residue data measured at harvest where senescence has occurred. The input values used by RUSLE2 are for the live aboveground biomass at maximum canopy, which is different from the aboveground biomass at harvest after senescence has occurred and surface residue has been lost by decomposition.

Research data vary greatly from study to study. Assemble as much data as possible and choose values that best represent the data as a whole rather than focusing on data from a single location or localized region. Also, be careful about attempting to represent differences between crop varieties. RUSLE2 was calibrated to represent main effect differences between plant communities such as between corn and wheat and not differences between crop varieties.

Rule of thumb values for residue:yield ratios can be used to estimate values for the two input data points in the RUSLE2 biomass-yield tool (see **Section 11.1.3.3**). Values for residue:yield ratios are given in Appendix D of Agriculture Handbook (AH) 703 for particular crops for a range of yields. Assume that the residue:yield ratio value applies to the middle of the yield range. Enter the yield value for the midpoint of the yield range and the residue:yield ratio for the first residue-yield data point. For the second data point, enter the yield for the lower end of the yield range in AH703 and the residue:yield ratio times 1.1. For example, the value for the residue:yield ratio value for corn in AH703 is 1.0. The residue to yield ratio value that would be entered for a 50 bu/ac yield, the lower end of the yield range in AH703, would be 1.0·1.1=1.1.

The assumption of a constant residue:yield ratio only applies over an upper range of yield values for vegetation descriptions where the intercept M_0 value is greater than zero. The equation for residue:yield ratio derived from equation 9.5 is:

$$M_a / Y = M_0 / Y + b_a \qquad [11.8]$$

where: M_a/Y = the ratio of live aboveground biomass at maximum canopy to production (yield) level, which is equivalent to residue:yield ratio after proper consideration for senescence. Residue:yield ratio values for the data illustrated in Figure 11.6 are shown in Figure 11.7. Note that residue:yield ratio values approach infinity at a zero yield and decrease to almost a constant value for yield greater than 50 bu/acre. The change in residue:yield ratio for these data is sufficiently small that a constant residue:yield ratio value could be assumed for yields greater than 50 bu/acre. A constant residue:yield ratio can be used in vegetation descriptions provided the production (yield) level does not vary too widely. However, the best approach is to enter values for live aboveground biomass at maximum canopy at two production (yield) levels rather than residue:yield ratio values. If the intercept M_0 for equation 9.5 is zero, the ratio of live aboveground biomass at maximum canopy to production (yield) level is constant and equal to the b_a coefficient in equation 9.5, which is appropriate for forage crops and permanent vegetation.

Crop residue cover immediately after planting is used as an indicator of the level of erosion control provided by conservation tillage systems. If RUSLE2 does not compute expected residue cover values, users can make changes in RUSLE2 inputs so that RUSLE2 computes the expected cover values. These changes should be made very carefully to avoid unexpected consequences. For example, change the live aboveground biomass at maximum canopy cover does affect the residue cover after planting computed by RUSLE2. Changing this value also affects the amount of belowground biomass computed by RUSLE2, which can have a significant effect on RUSLE2's erosion computations. Consider the following variables, their interactive effects, and their effects on other variables that affect erosion estimates in making changes to RUSLE2 inputs related residue cover after planting:

1. **Amount of live aboveground biomass at maximum canopy cover**
2. **Relationship between portion of soil surface covered for a given residue mass (mass-cover relationship in residue description)**
3. **Decomposition coefficient (half life) value in the residue description selected for the vegetation description**
4. **Flattening, burial, and resurfacing ratio values entered for the operation descriptions used in the cover-management description**

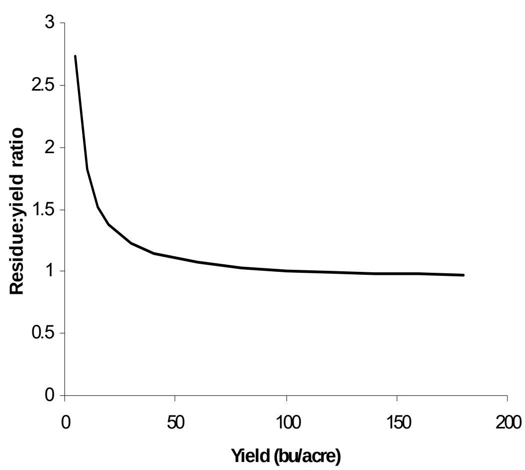

Figure 11.7. Residue:yield ratio for data illustrated in Figure 11.6.

11.2.4. Senescence

Values are entered in the **senescence tool** that RUSLE2 uses to calibrate equation 11.4 to represent senescence and litter fall as a transfer of live aboveground biomass to the surface (flat) residue pool. RUSLE2 computes senescence and litter fall as a function of a decrease in canopy cover (see **Section 11.1.3.1**). The two inputs entered in the senescence tool are portion of the live aboveground biomass at maximum canopy that is subject to senescence (litter fall) and canopy cover after complete senescence has occurred.

As permanent vegetation and agricultural crops like soybeans approach maturity, leaves fall from the plant canopy to the ground, which is senescence and litter fall. The decrease in live aboveground biomass results in a corresponding increase in biomass in the surface (flat) residue pool. In most cases, the entire live aboveground biomass is not subject to senescence. The value entered for portion of the live aboveground biomass subject to senescence is greater than the actual amount that falls to account for the fact that most of this plant material is leaves. A value of 0.6 for the ratio of biomass that falls during senescence to the aboveground biomass at maximum canopy seems to work well for crops like soybeans and cotton. A high value, perhaps up to 0.9, is appropriate for some grass-type vegetation. RUSLE2 multiplies this fraction by the live aboveground biomass at maximum canopy cover to estimate the potential biomass that will be transferred to the soil surface. RUSLE2 distributes the transfer over time using equation 11.2 and the decrease in canopy cover values entered in the **growth chart** of the **vegetation description**. The input in the senescence tool for canopy cover after complete senescence should be less than the minimum canopy cover that occurs after maximum canopy cover in the growth chart.

The standard assumption in RUSLE2 is that senescence occurs during the period of decreasing canopy cover. However, litter fall can also occur during growth periods when canopy cover is increasing, especially for perennial vegetation. RUSLE2 computes the daily litter fall by death during growth periods by multiply the live aboveground biomass on each day by a fraction that is typically 0.01, unless more specific information is available. If RUSLE2 is not to compute litter fall during growth periods, a zero (0) is entered for the death coefficient. Similarly RUSLE2 can compute death of the live root biomass during growth periods entering a non-zero (0) value for the death coefficient for live roots. Generally the same value (0.01) should be used for both live aboveground and root biomass.

Some plants lose canopy cover without aboveground biomass falling to the soil surface. An example is corn where the leaves droop as the plant approaches maturity. For this and similar types of vegetation that lose canopy cover without losing canopy mass, enter a zero for the portion of the aboveground biomass that experiences senescence. This entry prevents RUSLE2 from computing a decrease in aboveground biomass along with an increase in surface (flat) residue when canopy cover decreases.[100]

The objective is to account for the dead biomass that reaches the soil surface in association with a decrease in canopy cover rather than perfectly model senescence as a process.

The reason that a high value is entered for the portion of the live aboveground biomass subject to senescence is related to RUSLE2 using a single **residue description** to represent a composite of plant components that vary greatly in their properties. Above ground plant material is composed of leaves, stems, seed pods, chaff, and other

[100] This input in RUSLE2 is comparable to the input in RUSLE1 for no senescence in the table where operations are entered for each vegetation in the time variant C factor.

components. Leaves cover a much greater portion of the soil surface per unit mass than do stems. Leaves decompose much more rapidly than do stems. The value for a property in a residue description depends on the relative mass of the plant components in the residue. This distribution changes through time because the components decompose at greatly different rates, which means that residue properties change through time even though RUSLE2 assumes constant residue properties.

Consequently, the input for the portion of the live aboveground biomass subject to senescence is a compromise. The values entered in the residue description for the mass-cover relationship often gives priority to stems because the stems remain long after the leaves have disappeared. Entering a value for the actual amount of fallen plant material significantly underestimates the ground cover provided by senescence and litter fall because most of this material is leaves that provides high ground cover for their mass. To offset the underestimation in ground cover, an artificially high value is entered for the portion of live aboveground biomass subject to senescence to give ground cover values that more closely match actual field ground cover values during the senescence period. This approach works satisfactorily for agricultural and vegetable crops like soybeans, cotton, and green beans because of the importance in the portion of the soil surface covered in the erosion computations and the relatively short time between the beginning of senescence and harvest that converts live aboveground biomass to standing and flat residue.

Both the portion of the soil covered by plant material transferred by senescence and litter fall and the biomass amount must be considered when selecting inputs for permanent vegetation. The residue description for permanent vegetation should represent the composite of plant material that reaches the soil surface during an annual growth cycle. Similarly, the input values for live aboveground biomass at maximum canopy and the portion of this biomass that reaches the soil by senescence and litter fall should represent the actual biomass transfer rather than the artificially high values used for agricultural and vegetable crops discussed above. The residue description for permanent vegetation that is never mowed can be different from the residue description for permanent vegetation that is periodically mowed. The decomposition rate for biomass reaching the soil surface by mowing could be greater than the biomass from the same vegetation that reaches the soil surface by litter fall after plant maturity because of differences in decomposition properties of plant material at different growth stages. These residue descriptions are similar to having a residue description for wheat grown a cover crop that is killed well before maturity and different from the residue description for wheat grown to maturity and harvested for grain.

An approach that sometimes can be used to better represent differences among residue properties at certain times is to use multiple vegetation and residue descriptions for the same vegetation. For example, the residue description assigned in the vegetation description that applies to the senescence period reflects residue being mostly composed of the leaves that fall during senescence. The residue description assigned to the vegetation description for the period that begins immediately after the end of senescence reflects a high proportion of coarse plant parts like stems.

The best guidance for selecting input values to describe senescence and litter fall is to compare your vegetation with the vegetation descriptions in the **RUSLE2 core database**. Consistency between your values for a particular vegetation description and values in the RUSLE2 core database and values for other vegetation descriptions in your database is very important to ensure that RUSLE2 computes expected erosion values. Assigning these input values involves judgments that may seem counter intuitive.

11.2.5. Retardance

Retardance describes the degree that vegetation slows overland flow. RUSLE2 uses information on vegetation retardance, along with information on ground cover and soil surface roughness, to compute values for Manning's n, a hydraulic roughness index. The retardance index and Manning's n are used to compute the contouring effectiveness of rows of closely spaced vegetation, transport capacity used to compute deposition caused by dense vegetation strips, and critical slope length associated with contouring (see **Section 14**). Retardance depends primarily on the type, stiffness, and density of vegetation parts that touch the soil surface to slow surface runoff. Retardance is two dimensional, having a value for vegetation grown in strips on the contour perpendicular to the overland flow and a value for the same vegetation grown in rows up and down slope parallel to the overland flow direction.

Retardance for vegetation in contour strips is specified using one of eight classes listed in Table 11.6. These eight retardance classes represent the entire range in retardance from no retardance where the vegetation hardly slows the runoff to maximum retardance produced by a dense, sod forming grass. **The eighth class, retardance index 7, is a special case used to represent exceptionally dense, erect, stiff grass strips, fabric (silt) fences, gravel dams, straw bales, and similar erosion control measured used on overland flow areas.**

A retardance class is selected for a vegetation description along this scale based on the degree that the vegetation is judged to slow runoff considering vegetation type, stiffness, and density. Crops at typical yields are listed with each retardance class to guide the selection of a retardance class.

Table 11.6. RUSLE2 retardance classes for overland flow through vegetation in strips on the contour.

Retardance class at maximum canopy cover	Class index value	Comment

No retardance	0	Vegetation has no appreciable effect on slowing runoff
Low retardance	1	Slightly slows runoff, much like corn at 125 bu/acre
Moderate low retardance	2	Slows runoff somewhat, much like soybeans at 35 bu/acre, cotton at 1 ½ bales/ac, corn at 200 bu/acre
Moderate retardance	3	Slows runoff moderately, much like wheat at 45 bu/acre
Moderately high retardance	4	Slows runoff significantly, much like a moderate yield (3 tons/acre) legume hay before mowing
High retardance	5	Slows runoff very significantly, much like moderate yield (3 tons/acre) legume-grass hay before mowing, dense bunch grass
Very high retardance	6	Slows runoff almost to the maximum degree, like a dense, sod forming grass
Extreme retardance	7	Used as a special class to represent the retardance of stiff, erect, very dense grass strips (hedges), fabric (silt) fences, gravel dams, and straws bales used on overland flow areas

Retardance is also a function of plant growth stage and production (yield) level. The **retardance tool** is used to enter retardance classes at two production (yield) levels for a vegetation description at maximum canopy cover. RUSLE2 uses these inputs to calibrate a linear equation that computes retardance as a function of production (yield) level as illustrated in Figure 11.8. RUSLE2 internally treats the retardance as a continuous variable rather than an integer that changes stepwise. Thus, computed erosion values affected by retardance vary in a continuous fashion rather than in a stepwise fashion between retardance classes. RUSLE2 computes a base hydraulic roughness index value as a function of retardance at maximum canopy cover. RUSLE2 uses this base values to compute a daily hydraulic roughness index that varies with the 0.3 power of daily effective fall height.

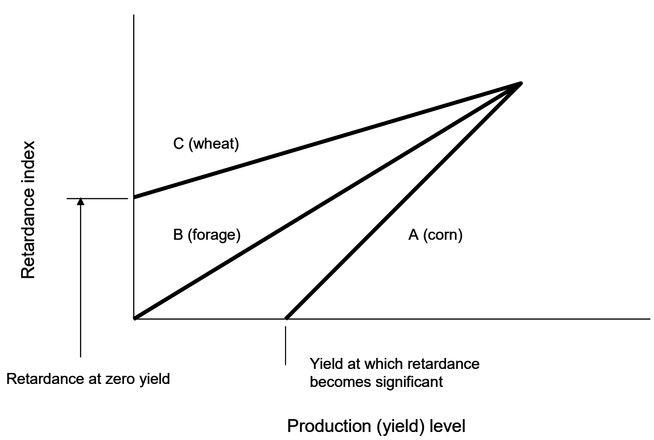

Figure 11.8. Retardance index relationships for different vegetation types

Figure 11.8 shows retardance index-yield relationships for three types of vegetation. Type A vegetation is where plant population must increase to a significant level before retardance becomes significant. For example, corn yield must exceed 100 bu/acre before retardance becomes significant. The entry for this condition in the retardance tool is **Yes** for **Does no retardance apply for a yield greater than zero?** and the second entry is the **Maximum yield at which no retardance applies**, which is 100 bu/acre in this example. RUSLE2 assumes that corn provides no retardance for yields less than 100 bu/acre and that retardance increases linearly for yields greater than 100 bu/acre as illustrated in Figure 11.8

The question **Does no retardance apply to a yield greater than zero?** is answered **No** for vegetation types B and C. RUSLE2 then asks that a retardance class be selected for a zero yield. Type B vegetation is forage-type vegetation grown on hay, pasture, landfills, and reclaimed mine lands. This vegetation is sufficiently dense and stiff to provided retardance that begins to develop at a zero yield. The **no retardance** class is selected for a zero yield, even for a dense sod forming grass that provides maximum retardance at a high yield. Type C vegetation is vegetation like wheat that provides significant retardance at zero yield. The retardance selection for Type C vegetation at zero yield depends on the stiffness and density of the vegetation at zero yield. The type of vegetation and the retardance entries at zero yield are related to the yield definition used in the vegetation description.

Information on retardance at a high yield is entered in the retardance tool for a second data point. The input for this data point along with the entry for the first data point discussed above are used by RUSLE2 to determine values for the coefficients that define the linear equations depicted in Figure 11.8. This second yield point need not correspond with the yield for which the vegetation description applies. In fact, the best yield for the second data point is the highest yield for which this vegetation description might possibly be applied.

Vegetation type in relation to retardance and the entries used to describe the retardance-yield relationship depend on the yield definition used in the vegetation description. For example, a woody-type vegetation could have a significance retardance index for a zero yield where the yield definition is based on annual production rather than the accumulation of biomass over several years.

The second major input in the retardance tool is used by RUSLE2 to define retardance when the vegetation is grown in rows parallel with the assumed flow direction (up and down slope). Row spacing is used as an indicator of this retardance. The retardance for up and down hill rows ranges from no retardance for widely spaced rows and for vegetation grown on ridges where the vegetation does not contact the down slope overland flow to maximum retardance when the vegetation is in a random pattern. The retardance for the random pattern (i.e., no orientation effect) is assumed to be the same as the retardance for the vegetation grown in a contour strip perpendicular to the overland flow. A retardance class for a particular vegetation description is selected from the six classes listed in Table 11.7 between these extremes using row spacing as an indicator.

Although row spacing is used as an indicator, the selection is actually the degree that the vegetation affects retardance at maximum canopy when rows of the vegetation are oriented in an up and down hill direction.

Table 11.7. Row spacing classes used to indicate retardance for vegetation at maximum canopy cover in rows oriented up and down slope.

Row spacing class	Comment
Wide row	Vegetation provides no retardance to overland flow. Row spacing for typical agricultural crops would be 30 inches or wider.
Vegetation on ridges	Vegetation is on ridges sufficiently high that vegetation does not come in contact with overland flow and provides no retardance to the flow. Actual spacing is unimportant.
Moderate	Rows of vegetation and vegetation characteristics such that the vegetation provides a slight but significant retardance relative to the same vegetation in a random pattern. Row spacing for typical agricultural crops would be 15 inches.
Narrow	Rows of vegetation and vegetation characteristics provide moderate retardance relative to the same vegetation in a random pattern. Row spacing for typical agricultural crops would be 7 inches.
Very narrow	Rows of vegetation and vegetation characteristics provide major retardance so that retardance in the down slope direction is almost as great as retardance when the vegetation is in a random pattern. Row spacing for typical agricultural crops would be 3 inches.
No rows, random, broadcast	Characteristics of the vegetation are such that orientation has no effect on retardance because the vegetation is grown in a random pattern.

RUSLE2 adjusts retardance between the value for vegetation grown in rows up and down slope and retardance for contour vegetation strips based on relative row grade to take into account row orientation of the vegetation. For example, if row grade is up and down slope and the vegetation has been assigned a wide row spacing, RUSLE2 will compute no retardance for the vegetation and no deposition will be computed if the vegetation in grown in strips with an up and down hill row orientation.

The best approach for selecting input values for retardance is to use values in the **RUSLE2 core database** as a guide. Maintaining consistency with the RUSLE2 core database is critically important because RUSLE2 was calibrated and validated against values in the RUSLE2 core database.

11.2.6. Long-term vegetation

The **long-term vegetation tool** is useful for creating multiple year duration **vegetation**

descriptions for permanent vegetation. In many cases, the long term vegetation tool can create a vegetation description that can be used without manual adjustments. Even when manual adjustments are required, the long term vegetation tool greatly facilitates the creation of long duration vegetation descriptions. A graph of canopy cover in a vegetation description created with the long term vegetation tool is illustrated in Figure 11.9. This 10-year vegetation description covers the time from seeding, through development, and into full maturity. The long term vegetation tool is most useful for creating vegetation descriptions for permanent vegetation like that on pasture, range, landfills, reclaimed mine, and similar lands.

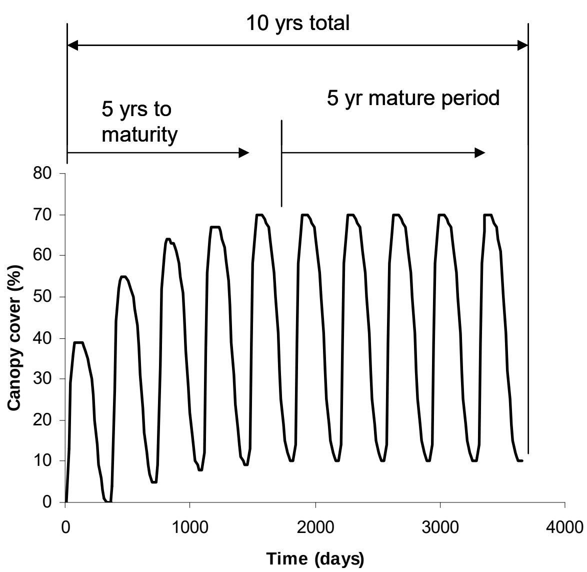

Figure 11.9. 10-year long term vegetation description created with long term vegetation tool.

The inputs entered in the long term vegetation tool are listed in Table 11.8. RUSLE2 uses spline-type equations to temporally distribute values between those entered for the minima and maxima of the variables in the **growth chart** of a vegetation description based on duration and annual timing inputs.

11.2.6.1. Duration inputs

The first set of inputs in the long term vegetation tool is related to **duration** of the vegetation description. The duration of a vegetation description is one year when RUSLE2 is used to estimate erosion for mature vegetation (see **Section 10.2.8**). The **yes-no** input for **rotation** in the **cover-management description** is set to **Yes** with a **1-year duration**. A value of **0** is entered for the **number of years to maturity** and a value of **1 year** is entered for the duration of the vegetation description **(# of years to include in growth pattern**) in the long term vegetation tool to create a vegetation description for mature vegetation.

The long term vegetation tool can also be used to create a vegetation description that starts on the seeding date and continues through the development phase and into the completely mature phase, like the vegetation description illustrated in Figure 11.9. This vegetation description can be used in RUSLE2 to analyze erosion during the establishment period for permanent vegetation on landfills, construction sites, and reclaimed mine lands. The duration of this vegetation description includes a mature period sufficiently long for RUSLE2 to compute a stable litter layer and soil biomass pool.[101] In the example illustrated in Figure 11.9, the development period is five years (time to maturity), and the mature period is five years. A value of **5 years** is entered for the time required for the vegetation to reach maturity (the development phase) and a value of **10 years** is entered for the entire duration.

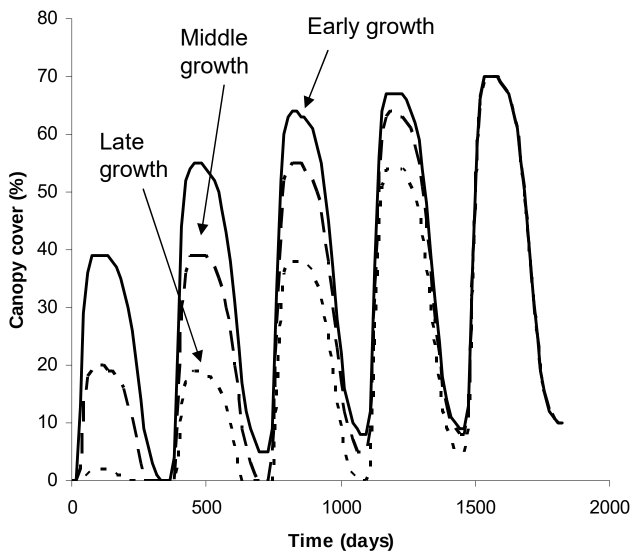

Figure 11.10. Fast growth in the early, middle, or late part of development stage.

The next input is a selection for the period when overall growth is most rapid during the development phase. The choices of **early**, **middle**, and **late** are illustrated in Figure 11.10. Values for all three choices converge in the mature year. Choose the entry appropriate for your vegetation considering seeding date and environmental conditions related to climate, soil, and management at the location where RUSLE2 is being applied. An input of **early** was selected for the vegetation description illustrated in Figure 11.9.

11.2.6.2. Annual timing inputs

The next set of inputs are the **annual timing inputs** related to dates of annual maximum and minimum live aboveground biomass and when most rapid growth and decline occur during the year.

The first timing input is the date of the annual maximum live aboveground biomass, which is also the date when all other temporal variables, including live ground cover, are at a maximum. This date for the example illustrated in Figure 11.9 is July 1. The maximum values occur on this date for every year in the vegetation description created with the long term vegetation tool.

The second timing input is the date that live annual aboveground biomass is minimal, which is also the date that the values for all temporal variables are minimal. RUSLE2 assumes this date for day zero for the vegetation description. The values for all temporal variables are zero on day zero unless the vegetation description has been created for

[101] Stability is defined in terms of litter and soil biomass daily values repeating each year.

mature vegetation.[102] In the example illustrated in Figure 11.9, the date of annual minimum live aboveground biomass is April 1. The date of the **operation description** in the **cover-management description** that uses this vegetation description should be April 1.

Inspect the main vegetation description, including all of the support tools discussed in Section 11.2, to ensure that the proper values are entered and displayed. The long-term vegetation does not transfer all required information into the main vegetation description and the supporting tools.

The time between the dates for maximum and minimum biomass can be any value. Six months between these dates gives a symmetrical distribution during the year. The long term vegetation tool creates non-symmetrical distributions when dates are more or less than six months apart as illustrated in Figure 11.9.

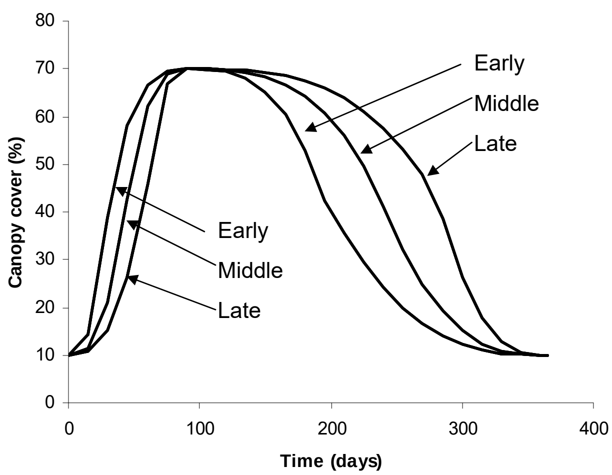

Figure 11.11. Timing of rapid growth and senescence during year.

An important consideration is whether the date of minimum live aboveground biomass corresponds with the seeding date. In the example illustrated in Figure 11.9, the seeding date and date of minimum biomass are the same. However, that assumption is not true for fall seeding when the annual minimum live aboveground biomass occurs in the spring. The long term vegetation tool has no provision for dealing with situations where seeding date and date of minimum live above ground do not correspond. However, the long term vegetation tool is still useful for developing a vegetation description even though manual adjustments are required for these situations. For example, assume that the seeding date is September 1 rather than April 1. The same input values would be used as in the example illustrated in Figure 11.9, but with a change in the selection for the **time that most rapid growth occurs during the development period** and **the time to maturity**. Rather than entering **early,** as in the example, a **middle** selection is made. The time to maturity would be six rather than five years. The

102 This statement applies to vegetation descriptions created with the **long-term vegetation tool**. RUSLE2 can also use multiple annual vegetation descriptions. The temporal values would not be zero on day zero for these vegetation descriptions. However, such annual vegetation descriptions can not be created with the **long-term vegetation tool**.

user manually make changes to values in the vegetation description **growth chart** to correspond to a September 1 seeding date. The manually adjusted values are blended into the values created by the long term vegetation tool. Manual entry of the entire vegetation description is not required.

The third and fourth timing inputs are the times during the year when most rapid growth (gain in live aboveground biomass) and senescence (litter fall, decline in live aboveground biomass) occur. The choices are **early**, **middle**, and **late**. These choices are illustrated in Figure 11.11. One selection can be made for the growth period, such as **early** in the example illustrated in Figure 11.9, and another selection can be made for the senescence period, such as **middle** for the example illustrated in Figure 11.9.

11.2.6.3. Biomass inputs

The **biomass inputs**, which must be on a dry basis, in the **long term vegetation tool** are the same as those in the main part of the **vegetation description** and the **growth chart** discussed in **Section 11.1**. However, a few of the inputs are in a different form. The values entered for **maximum annual live ground biomass** and the corresponding **canopy cover** are for the date of annual maximum canopy cover after the vegetation has reached maturity, which is the date entered in the **annual timing inputs** for maximum biomass. The values entered for **minimum annual live ground biomass** and the corresponding **canopy cover** are for the date of annual minimum canopy cover after the vegetation has reached maturity, which is the date entered in the **annual timing inputs** for minimum biomass.

The input value for annual minimum live aboveground biomass is similar to, but different from, the inputs entered in the senescence tool (see **Section 11.2.4**). The input entered in the long term vegetation tool for annual minimum live aboveground biomass is the ratio f_{mx} of annual minimum live aboveground biomass to annual maximum live aboveground biomass after the vegetation has reached maturity. The value for annual minimum live aboveground biomass is given by:

$$B_{amn} = f_{mx} B_{amx} \qquad [11.9]$$

where: B_{amn} = annual minimum live aboveground biomass at maturity, B_{amx} = annual maximum live aboveground biomass at maturity, and f_{mx} = the ratio of the annual minimum live aboveground biomass at maturity to annual maximum live aboveground biomass at maturity. Essentially the same information must be entered in the **senescence tool**, and it must correspond to the information entered in the long term vegetation tool. The entry in the senescence tool related to biomass is the portion f_s of the annual maximum live aboveground biomass that is available for senescence. The annual minimum live aboveground biomass computed with f_s is given by:

$$B_{amn} = B_{amx} - f_s B_{amx} \quad [11.10]$$

$$B_{amn} = B_{amx}(1 - f_s) \quad [11.11]$$

Combining equations 11.9 and 11.11 shows that the fraction of maximum live aboveground biomass available for senescence that is entered in the senescence tool is related to the ratio of annual minimum live aboveground biomass to annual maximum live aboveground biomass as:

$$f_s = 1 - f_{mx} \quad [11.12]$$

That is, the value entered in the senescence tool equals one minus the ratio of annual minimum live aboveground biomass to annual maximum live aboveground biomass, which is the value entered in the long term vegetation tool for minimum annual live aboveground biomass.

The value entered for canopy cover after full senescence in the senescence tool should be the same as the canopy cover value entered in the long-term vegetation tool for canopy cover for annual minimum live aboveground biomass at maturity.

A value of zero (0) for the **death rate coefficient** for the death of live aboveground is entered biomass when the process of litter fall during the growth period is not be represented. Enter a value of approximately 0.01 when this process is to be represented. A value of 0.01 seems appropriate for a wide range of plant communities.103

The production (yield) level definition, value for production (yield) level and the biomass-yield relationship inputs should be entered in the vegetation description. These values should be carefully checked to ensure that the live aboveground biomass value displayed in the vegetation description is the maximum live aboveground biomass intended from the inputs made in the long term vegetation tool.

Thomas, R.J. and N.M. Asakawa. 1993. Decomposition of leaf litter from tropical forage grasses and legumes. Soil Biology and Biochemistry. 25:1351-1361.

Enter the value for **effective fall height** for the annual maximum live aboveground biomass at maturity. See **Sections 9.2.2.2 and 11.1.7.4** for guidelines for selecting effective fall height values as a function of heights to top and bottom of the canopy, canopy shape, and density gradient within the canopy. Also, the **effective fall height tool** discussed in **Section 11.2.2** can be used to adjust the temporal effective fall height values created by the long term vegetation tool.

Values for **live ground cover** should be entered for most permanent vegetation on range, pasture, landfills, reclaimed mine and similar lands. Enter values to represent live (green) leaves, the basal area, and other live vegetative parts that slow runoff during a rainfall event. The temporal pattern of the live ground cover values created by the long term vegetation tool is exactly the same as the temporal pattern for canopy cover values. This pattern may not be appropriate for live ground cover. For example, live ground cover may develop early in the annual growth period ahead of canopy cover and then decrease while canopy cover is still developing. The values created by the long term vegetation tool can be manually adjusted in the vegetation description as desired.

The long-term vegetation tool multiples the input value for the **ratio of live root biomass to live aboveground biomass** by the value for live aboveground biomass to create values for live root biomass. This ratio is for the biomass (dry basis) of predominantly fine roots in the upper 4 inches (100 mm) of soil to the average annual production of aboveground biomass. RUSLE2 assumes that the ratio of live root biomass to live aboveground biomass is constant over time, which means that live root biomass values follow exactly the same pattern as the live aboveground biomass values. In the field, annual live root development usually precedes development of the live aboveground biomass and root sloughing usually precede senescence and litter fall. The RUSLE2 assumption that the two are the same is considered adequate for erosion estimates used in conservation and erosion control planning. RUSLE2 is designed to be an easy-to-use tool for conservation and erosion control planning rather than a model of actual processes. However, RUSLE2 is quite flexible. The live root biomass values can be manually adjusted in the growth chart to represent any desired pattern.

Obtaining reliable information on live root biomass values is very difficult as discussed in **Section 11.1.7.2**. The recommendation is that the ratio values previously stored in RUSLE2 by plant community be used rather than selecting values from the literature or making field measurements. Selecting a plant community in the long term vegetation tool selects the ratio value stored in RUSLE2 for that plant community. A RUSLE2 previously stored plant community ratio value can be overridden by entering another value. The values for ratio of live root biomass to live aboveground biomass stored in RUSLE2 by plant community types are based on field simulated rainfall erosion experiments where values for these ratios were back calculated using RUSLE2 subfactor equations and measured erosion values. Values for these ratios are given in **Section**

17.4.1.4.[104]

RUSLE2 assumes that a daily decrease in live root biomass represents root sloughing where this decrease represents live roots that become dead roots that is added to the dead root pool. RUSLE2 can also compute root death during the growth period when live root biomass is increasing. If this root death process is not to be represented enter a zero (0) for the daily fraction of live root biomass that becomes dead roots during the growth period. If this process is to be represented, enter a value of 0.01, which is the daily fraction of the live root biomass that becomes dead roots during the growth period. In general, the value selected for this fraction should the same as the value for the comparable fraction of daily live aboveground biomass that becomes surface litter.

Table 11.8. Inputs in the long-term vegetation tool used to create vegetation descriptions for permanent vegetation on pasture, range, landfills, reclaimed mine, and similar lands.

Input	Comment
Duration inputs	
Number of years to maturity (development phase)	If a vegetation description for mature vegetation is being created, enter 0; otherwise, enter the number of years required for the vegetation to reach a stable annual pattern (5 yrs for example in Figure 11.9)
Total number of years in the vegetation description (duration)	Enter total number of years in the vegetation description; should include enough years after maturity for a stable litter layer and soil biomass pool to develop at the location where vegetation description is being used; (10 yrs for example in Figure 11.9)
Fastest growth in development period occurs when? (early, middle, late)	Select the time period during the development phase when most rapid development occurs; (Early for example in Figure 11.9); see Figure 11.10 for illustrations of each period.)
Annual timing inputs	
Annual day of maximum live aboveground biomass at maturity (month/day)	Select date of annual maximum canopy cover, which is also the date of annual maximum live aboveground biomass; maximum of all temporal variables is assumed to occur same date; same date assumed for all years in vegetation description; (7/1 for example in Figure 11.9)

[104] The time invariant C factor procedure in RUSLE1 is frequently used to estimate erosion for permanent vegetation. Single values that represent temporal conditions over the year are used as input rather than the temporal values used in RUSLE2. Also, this RUSLE1 procedure does not include the accumulation of a soil biomass pool or the effect of decomposition of the litter layer at the soil surface. Both RUSLE1 and RUSLE2 can give comparable results if the recommended procedures for each model are carefully followed.

Annual day of minimum annual biomass (month/day)	Select date of annual minimum canopy cover, which is also the date of annual minimum live aboveground biomass; minimum of all temporal variables is assumed to occur on same date; same date assumed for all years in vegetation description; (4/1 for example in Figure 11.9)
Fastest growth occurs when during year? (early, middle, late)	Select early to describe vegetation where most rapid growth occurs early in annual cycle; select late to describe vegetation where early development is slow and most rapid development occurs just before maximum live aboveground biomass is reached; (early for example in Figure 11.9); see Figure 11.11 for illustration.
Fastest decline in growth occurs when during year? (early, middle, late)	Select early to describe vegetation where most canopy is lost immediately after senescence (litter fall) begins in annual cycle; select late to describe vegetation where loss of canopy mass is very slow after maximum aboveground biomass is reached and is very high just before the end of senescence; (middle for example in Figure 11.9); see Figure 11.11 for illustration.
Biomass inputs	
Maximum annual live aboveground biomass at maturity (dry basis)	Enter the live aboveground biomass at maximum canopy for the vegetation when it is mature; in general, annual biomass production rather than long term accumulation of biomass is used for this input; the yield value in main vegetation description where yield is defined must correspond with this value; (1000 lbs/acre for example in Figure 11.9)
Canopy cover at maximum biomass (maximum canopy) at maturity	Enter the canopy cover at annual maximum live aboveground biomass at maturity; (70% for example in Figure 11.9)
Effective fall height at maximum canopy cover at maturity	Enter the effective fall height value at annual maximum canopy cover at maturity; (0.3 ft for example in Figure 11.9)
Live ground cover at annual maximum live aboveground biomass at maturity	Enter the live ground cover at annual maximum live ground cover; check live ground cover computed by tool; values may need adjustment so that live ground cover develops earlier than canopy cover; (15% for example in Figure 11.9)
Ratio of annual minimum live aboveground biomass at maturity to annual maximum live aboveground biomass at maturity (dry basis)	The amount for the annual minimum live aboveground biomass is the product of the ratio entered and the annual maximum live aboveground biomass; this value must correspond to the value entered in the senescence tool for amount of annual live aboveground biomass that is available for senescence; (20 % for example in Figure 11.9)
Canopy cover at minim live	Enter the minimum canopy cover provided the annual

aboveground biomass	minimum live aboveground biomass; value must correspond with value entered in senescence tool; (10% for example in Figure 11.9)
Death fraction for live above ground biomass	Enter the fraction of live aboveground biomass that becomes daily surface litter by death during the growth period when canopy cover is increasing (use 0.01 unless other information is available)
Mechanical loss coefficient	Fraction of live aboveground that is added daily to the surface litter biomass; represents mechanical processes such as animal trampling and vehicular traffic
Plant community	Select the plant community that this vegetation description represents; selection of a plant community causes RUSLE2 to select a ratio of live root biomass to live aboveground biomass; select **Enter root mass/live aboveground biomass** if your plant community is not in the list so that you can enter your own value for this ratio; (southern grasses selected for example in Figure 11.9)
Ratio for live root biomass in upper 4 inches (100 mm) of soil/live aboveground biomass ratio (dry basis)	Selection of a plant community causes RUSLE2 to use the ratio value assigned and stored in RUSLE2 for this plant community; user can override value by entering a new value; (4.5 is stored in RUSLE2 for plant community in the example in Figure 11.9)
Death fraction for live root biomass	Enter the fraction of live root biomass that becomes daily dead root biomass by death during the growth period when live root biomass is increasing (use 0.01 unless other information is available, value should generally be the same as that used for comparable fraction for live aboveground biomass)
Grazing/haying/mowing inputs	
Dates	Enter dates that operations begin
Duration	Enter duration (days) of operation
Regrowth period	Enter days in regrowth period
Fraction live aboveground biomass remaining after operation	Enter the fraction of the live aboveground biomass that remains at the end of the operation; fraction is based on live aboveground biomass that exists on day that operation begins

12. RESIDUE DATABASE COMPONENT

Residue descriptions in the **residue component** of the RUSLE2 database contain values that RUSLE2 uses to compute how residue affects erosion. A residue description is assigned to each **vegetation description** and to **external residue**. A residue description assigned to a vegetation description describes the material that remains after the vegetation is killed with an **operation description** having a **kill vegetation process**. A residue description represents a composite of all plant components including leaves, stems, seed pod, and roots present in a sufficient amount to affect erosion. Thus, the values in a residue description for vegetation depend on the relative mass of each plant component in the residue.

The **residue description** selected for an **operation description** that adds **external residue** is used to describe materials added to the soil surface or placed in the soil that affect erosion. External residue includes applied mulch (e.g., straw), manure, gravel, compost, papermill waste, pine needles, roll erosion control products, and other similar materials. The materials represented by residue descriptions are assumed to be organic and decompose much like natural plant materials. Non-organic materials require special considerations that are described in this section.

The variables used to describe residue are listed in Table 12.1.

Table 12.1. Variables used to describe residue

Variable	Comment
How residue responds to mechanical disturbance (residue type)	Describes fragility (how easily material fractures into smaller pieces) to mechanical disturbance and the size and stiffness of the residue pieces in relation to how well the residue conforms to the soil surface to affect erosion
Decomposition coefficient	A variables that determines the rate that residue decomposes under the standard condition of non-limiting moisture and a temperature of 90 ^{o}F (32.2 ^{o}C)
Decomposition half life (days)	Time required for one half of the residue mass to decompose under the standard conditions of non-limiting moisture and a temperature of 90 ^{o}F (32.2 ^{o}C)
Mass-cover relationship	Portion of the soil surface covered by a given mass on a dry weight basis

12.1. How residue responds to mechanical soil disturbance (residue type)

RUSLE2 includes five predefined residue types listed in Table 12.2. Residue type represents two important residue properties that are related. One is the fragility and size of residue pieces that determine how much residue is flattened, buried, and resurfaced by an operation and the size and stiffness of residue pieces that determine how closely the residue conforms to the soil surface. Assigning a residue type to a residue description requires consideration of both properties.

Table 12.2. RUSLE2 predefined residue types.	
Residue type	Comment
Fragile-very small	Small pieces (about 1 inch, 25 mm), easily broken into smaller pieces, moderate conformity to soil surface, similar to soybean residue
Moderately tough-short	Short to moderate pieces (1 to 5 inch, 25-125 mm), moderately tough (resistant) to being broken into smaller pieces, moderate conformity to soil surface, similar to wheat residue run through a straw chopper
Non fragile-medium	Moderate length pieces (3 to 10 inch, 75- 250 mm), non fragile, not easily broken into smaller pieces, low conformity to soil surface, similar to corn residue run through a combine
Woody-large	Long pieces (> 10 inch, 250 mm), very tough, only breaks into smaller pieces with a very aggressive machine, low conformity to soil surface, similar to woody debris left on disturbed forest land by logging, debris left by aggressive mechanical renovation of shrub dominated rangelands
Gravel	Small to moderate sized pieces with gradation of sizes to fill voids, pieces are not reduced in size by mechanical operations, high conformity to soil surface, similar to gravel and crushed stone about ¾ inch (20 mm) used on driveways.
Note: Woven and netting type erosion control products like erosion control blankets are assigned a residue type based primarily on their conformity to the soil surface micro-topography.	

Mechanical soil disturbance by tillage, construction, logging, and similar equipment break residue into smaller pieces. The susceptibility to residue being broken into smaller pieces is referred to as residue fragility. Conversely, the resistance of residue to size reduction is referred to as residue toughness. The size, length, and fragility of residue pieces affect residue flattening, burial, and resurfacing by operations. Consequently, the ratio values for these processes assigned in operation descriptions (see **Section 13.1**) vary with residue properties represented by the five residue types. Fragile residue like soybeans is more easily buried and conforms more to the soil surface than tough residue like woody debris. Long, stiff, and tough residue is not easily buried and does not conform to the soil surface. Gravel and rock fragments conform very closely to the soil surface.

The residue type assigned to roll erosion control products like blankets that are woven or bound together with netting is determined by their conformity to the soil surface. Similarly, a residue type is assigned to spray products used to control erosion on construction sites. The mechanical fragility of these erosion control products is not important unless mechanical operations are performed on the soil after these materials are placed that affects their coverage of the soil surface. The size and nature of residue pieces is not important in assigning a residue type to these products. For example, a gravel residue type can be assigned to these products where the material conforms very closely to the soil surface and perfect contact with the soil exists.

The degree that residue conforms to the soil surface is the other factor considered in selecting a residue type for a residue description. Small, flexible, stable residue pieces that closely conform to the soil surface provide greater erosion control than do long, stiff residue pieces that bridge soil clods. Runoff can partially or completely flow under the residue pieces with greater erosivity than when residue fully contacts the soil surface.

Selection of a residue type assigns one of three conformity index classes to the residue description to describe how the residue conforms to and is in contact with the soil surface. The three residue conformity index classes are low, moderate, and high. The **gravel** residue type listed in Table 12.2 are assumed to provide high conformity (contact with the soil surface), **fragile-very small** (e.g, chopped soybean residue) and **moderately tough-short** (e.g., chopped wheat straw) residue types are assumed to provide moderate conformity, and **non fragile-medium** (e.g., not-chopped corn stalks) and **woody** (e.g., slash on a logged site) residue type is assume to provide low conformity. The conformity class associated with each residue type is internal in RUSLE2 and can not be changed by the user.

The residue conformity index is most important when applying RUSLE2 to steep (greater than 33%), bare construction-type slopes. For example, the residue conformity index makes only about 14 percent difference in RUSLE2 erosion estimates between the low and high residue conformity class for corn residue in a no-till **cover-management description** applied to a 6 percent steep slope. The effect of residue conformity decreases as soil biomass increases. In contrast, the residue conformity makes about 110 percent difference in RUSLE2 estimated erosion between a residue type with low conformity and one with high conformity for a fully consolidated, cut slope with no soil biomass on 33 percent steepness. The difference in RUSLE2 estimated erosion between residue types with low and high conformity class is 40 percent for recently graded fill material on a 33 percent steep slope. RUSLE2 assumes better contact between soil and residue on recently graded fill material than on hard, fully consolidated soil.

The relative effectiveness of residue for controlling erosion decreases as slope steepness increases above about 33%. The loss of erosion control effectiveness is greater for residue types that provide low conformity than for those residue types that provide high conformity.

Residue types in terms of fragility (toughness) are defined only by the values entered for flattening, burial, and resurfacing ratios in the operation descriptions. However, conformity classes for each residue type are internally assigned in RUSLE2 and can not be changed by the user.

12.2. Decomposition coefficient (decomposition half life)

The decomposition rate of organic residue depends on the organic properties of the material, area and thickness of residue pieces, mechanical fracturing (e.g., fine chopping) of residue pieces to expose easily decomposed material inside a decomposition-resistant outer shell (e.g., corn stalks), and the relative composition of plant parts including leaves, seed pods, chaff, stems, and coarse and fine roots. Residue decomposition rate changes through time as these characteristics change through time. For example, leaves decompose at a much faster rate than stems, which leaves residue main composed of stems that slowly decompose.

The decomposition coefficient value assigned to each residue description is used by RUSLE2 to compute residue loss as a function of daily precipitation and temperature at the location where RUSLE2 is being applied. The decomposition coefficient ϕ value for a residue description is determined by fitting the RUSLE2 decomposition equations to empirical field data. A residue with a large decomposition coefficient ϕ value decomposes more rapidly than does a residue with a low decomposition ϕ value for particular environmental conditions.

Decomposition half-life is another way to express the decomposition coefficient ϕ. Half-life is the time required for half of the residue to be lost under the standard condition of 90 ^{o}F (32.2 ^{o}C) temperature with plentiful, non-limiting moisture. A residue with a long half-life is lost more slowly than residue with a short half-life. The relationship between half-life and the decomposition coefficient is an inverse one where half-life values increase as the decomposition coefficient values decrease. The mathematical relationship between the two is give by:

$$d_{1/2} = 0.693/\phi \qquad [12.1]$$

where: $d_{1/2}$ = residue decomposition half-life (days) and ϕ = residue decomposition coefficient (days^{-1}).

Decomposition computations are based on residue mass. Residue cover is computed using the mass-cover relationship assigned to the residue description. Half-life refers to residue decomposition under the standard condition of 90 ^{o}F (32.2 ^{o}C) and plentiful moisture, which differs from residue decomposition under actual field conditions.

Figure 12.1 illustrates how RUSLE2 computes residue decomposition as a function of location and residue half-life. Decomposition occurs more rapidly in central Mississippi than in central Missouri because of increased precipitation and temperature, especially in the fall and winter. The 43 day half-life residue decomposes much more rapidly than does the 86 day half life residue. Field decomposition rates are slower than the optimum decomposition conditions used to express half-life values.

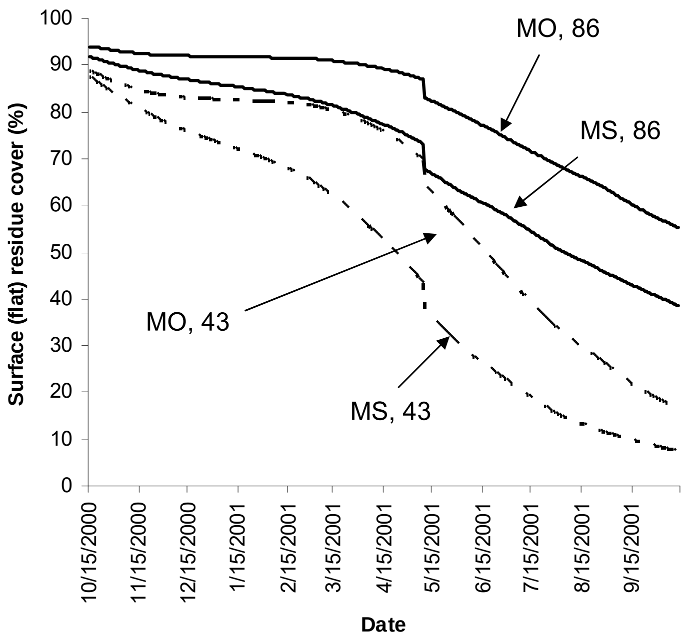

Figure 12.1. Effect of location (Columbia, MO, Jackson, MS) and decomposition half life (43, 86 days) on decomposition of corn residue in a no-till cover-management description.

The intent in RUSLE2 as an erosion control and conservation planning tool is to reflect the main effects of the material (as represented by the decomposition coefficient) and location (represented by precipitation amount and temperature that varies with location) on decomposition. By intent, RUSLE2 does not capture everything that affects decomposition. The following comments discuss particular areas where RUSLE2 represents a compromise and adjustments that users might make to partially overcome the RUSLE2 limitations while retaining RUSLE2's utility.

12.2.1. Soil Moisture

RUSLE2 does not directly consider the effect of soil moisture on decomposition other than how soil moisture is empirically related to precipitation in the decomposition data used to determine RUSLE2 decomposition coefficient ϕ values. Soil moisture is influenced by both cover-management and soil texture. Decomposition coefficient ϕ values can be increased for soil and cover-management conditions that retain water because soil moisture increases decomposition when moisture, rather than temperature, limits decomposition. Thus, the effect of soil texture and cover-management on soil moisture affecting residue decomposition can be partially captured in RUSLE2 by adjusting decomposition coefficient ϕ values. Decomposition coefficient ϕ values are assigned to residue descriptions based on how soil texture and soil moisture are assumed to affect decomposition at that location. A residue description having a decomposition coefficient ϕ value that reflects site-specific field conditions is chosen. However, based on comparisons with the WEPS and WEPP models, the effect of soil moisture as influenced by soil texture and cover-management is so small that the effect is best ignored in RUSLE2. Therefore, the same decomposition coefficient ϕ value is used for soil, cover-management, and climatic conditions except in the Northwestern US (Req region).

12.2.2. Above ground and below ground biomass decomposition

Buried residue is expected to decompose more rapidly than flat residue on the soil surface. However, research data used to derive decomposition coefficient ϕ values for RUSLE2 were inconclusive regarding this expected difference, especially when adjustments are taken into account for how residue confined in mesh bags used in decomposition measurements decomposes at a different rate than unconfined residue typical of field conditions. Therefore, RUSLE2 uses the same decomposition coefficient ϕ value for residue lying flat on the soil surface and residue buried in the soil. Most error, if any) that exists because RUSLE2 uses the same decomposition coefficient ϕ value for buried residue as surface residue is minimized because the RUSLE2 equation for the soil biomass subfactor (equation 9.12) is calibrated using RUSLE2 computed soil biomass values, not measured values (see the **RUSLE Science Documentation**).

RUSLE2 computes decomposition at the base of standing residue at the same rate as residue lying on the soil surface. RUSLE2 uses decomposition rate at the base of standing residue to compute the rate that standing residue is flattened by natural processes (see **Section 9.2.2.3**). However, RUSLE2 assumes that the decomposition coefficient value for standing residue is three tenth of the decomposition coefficient value for surface (flat) residue. Standing residue is assumed to decompose much more slowly than surface residue because of the lack of moisture that soil contact provides to surface residue.

The RUSLE2 user can not change decomposition coefficient values to reflect decomposition differences between surface and buried residue or between above ground plant components and roots. Also, the user can not change the ratio of the decomposition coefficient for standing residue to the decomposition coefficient for surface residue. Decomposition coefficient values can not be entered for individual plant components.

12.2.3. Differences in decomposition among plant components

Individual plant components of leaves, pods, stems, stalks, coarse roots, and fine roots decompose at different rates. For example, leaves decompose much more rapidly than stems, and finely chopped stems decompose more rapidly than intact stems. RUSLE2 uses a single residue description with a single decomposition coefficient ϕ value to represent a composite of plant components. The single, constant decomposition coefficient ϕ value for a residue description causes RUSLE2 to compute decomposition rates that are too low immediately after harvest before the leaves decompose and too high after most of the residue has decomposed. Residue decomposition slows over time as the residue becomes increasingly composed of decomposition-resistant plant parts, which RUSLE2 does not take into account with its constant decomposition coefficient value. Differences between computed and observed residue mass are illustrated in Figure 12.2.[105]

The RUSLE2 composite residue structure and its equations for computing decomposition are a compromise. Separately tracking individual plant components such as leaves and stems with their own decomposition coefficient value would be better scientifically than the RUSLE2 composite approach. However, the RUSLE2 developers' judged that data were not available to derive the decomposition coefficient values for individual plant components for the wide range of residue descriptions needed by RUSLE2 when used as a conservation and erosion control planning tool.

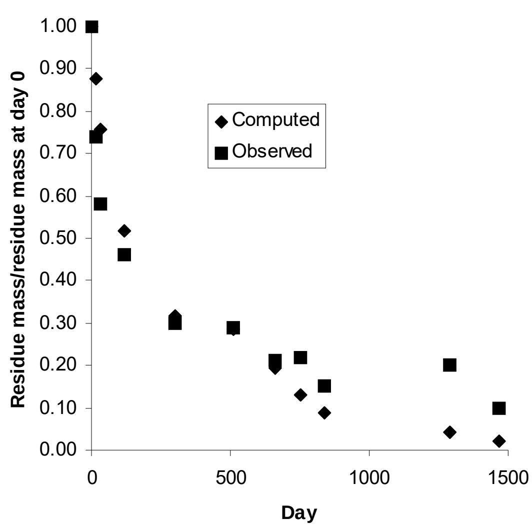

Figure 12.2. Comparison of computed residue mass with observed residue mass for corn in Missouri. (Parker, 1962)

The RUSLE2 composite residue structure must be considered when evaluating residue cover values computed by RUSLE2. Decomposition coefficient values were determined by empirically fitting the RUSLE2 decomposition equations to field residue data to give the best overall fit during the first year after harvest. In many agricultural cropping systems, the annual harvest residue input is much larger than the residue mass immediately before harvest. Errors in residue mass immediately before harvest has little effect on the overall residue mass. Also, errors in residue cover immediately before harvest are often not significant because of low erosion rates at that time. Residue cover should be accurately estimated during the most erosive period,

---

105 Parker, D.T. 1962. Decomposition in the field of buried and surface-applied cornstalk residue. Soil Science Society of America Proceedings. 26:559-562.

which is the late spring and early summer before complete canopy develops for most US row crops. The most important RUSLE2 residue cover estimates at a point in time are those immediately after planting. The RUSLE2 residue decomposition may be too high for times longer than a year for agricultural crops where harvest does not provide a large residue mass input. Overall decomposition coefficient values are chosen to give good residue cover estimates during the most erosive period rather than residue cover values at particular points in time, especially if residue cover errors at those times have little effect on estimated erosion.

These concerns with estimating residue mass over time are much less significant for construction sites where mulch and erosion control products are much more uniform than the residue pieces associated with agricultural crops. However, the problem can be very significant on disturbed forest land where residue ranges from leaves to fine branches to coarse limbs.

Decomposition coefficient ϕ values for a particular residue are preferably location independent, but that objective is not always achieved. For example, the decomposition half-life is 28 days for soybeans grown in the Midwestern US while it is 53 days for soybeans grown in the Southern US. Differences in the vegetative properties of soybeans grown in the two regions partly contribute to the difference in decomposition half-life. The other contributor is climatic differences. The climate in the Southern US is warm and wet during the winter so that the leaves decompose very rapidly after harvest leaving residue in the spring that is primarily composed of stems that decay much more slowly than leaves. In contrast, the climate in the Midwestern US is cold so that little decomposition occurs after harvest during the winter, as illustrated in Figure 12.1. Thus, soybean residue has a higher ratio of leaves to stems in the spring in the Midwestern US than in the Southern US, which gives an apparent higher decomposition coefficient.

Another example where decomposition coefficient ϕ values differ between regions is for wheat residue. The decomposition half-life for wheat grown in the Northwest Wheat and Range Region (NWRR) is 40 days while it is 87 days for wheat grown in other parts of the US. Wheat residue seems to decompose much more rapidly in the NWRR than in other regions.[106] A contributing factor is the difference in climate between the NWRR where precipitation is very low immediately after harvest in comparison to the central Midwestern US. Although the reasons for this difference are not fully understood, the empirical data are more than sufficient to substantiate the difference.

The objective is to obtain the best average annual erosion estimate for conservation and erosion control planning.

---

[106] The NWWR is a major portion of the region where the Req RUSLE2 relationships are used. **See Section 6.9.**

12.2.4. Decomposition coefficient ϕ values based on stage of growth

The organic properties that affect decomposition of plant materials vary with stage of growth. For example, the residue from a wheat cover crop killed well before maturity decomposes at a much faster rate than does the residue from a wheat crop harvested for grain. The decomposition half-life for wheat cover crop residue is 41 days while it is 87 days for residue from wheat harvested for grain. Therefore, two residue descriptions are created for wheat, one for wheat used as a cover crop that is killed well before maturity and one for wheat harvested for grain. The data inputs into RUSLE2 are always to create a description rather than to model a process. The residue description that best fits the situation is assigned to the vegetation description or selected for external residue.

12.2.5. Decomposition coefficient ϕ values for manure

Manure ranges widely from being almost entirely composed of straw used for bedding to liquid slurry. The important properties of manure include its dry matter biomass content and its decomposition properties. The residue descriptions for manure represent a composite of straw, wood shavings, manure, and other materials that may be present. The decomposition half-life assigned to a particular manure depends on the relative mass of individual components and the decomposition properties of each component, including the type of manure. Four classes of manure are recommended for use in RUSLE2. These classes are listed in Table 12.3.

Table 12.3. Recommended classes for residue descriptions for manure.

Class	Decomposition half-life (days)	Comment
Slow decomposition	87	Manure with high content of straw bedding
Moderately slow decomposition	41	Manure from open lots
Moderately rapid decomposition	23	Manure stored in settling basins
Rapid decomposition	14	Poultry litter

12.2.6. Decomposition coefficient ϕ values for erosion control products used on construction sites

Straw mulch is widely used on construction sites to control erosion. A decomposition half-life of 87 days is recommended for straw mulch. The decomposition half life for other erosion control materials used on construction sites can be determined by comparing their longevity with the longevity of wheat straw and adjusting the decomposition half life accordingly. For example, the decomposition half-life for native hay would be shorter than for wheat because of the greater proportion of leaves and fines in the native hay than in the wheat straw. Manufacturers' literature for roll products often includes information that can be used to estimate a decomposition half-life relative to that for wheat straw.

12.3. Mass-cover relationship

Although RUSLE2 tracks residue by mass, RUSLE2 computes the effect of surface (flat) residue on erosion using portion of the soil surface that the residue covers (see equation 9.6). RUSLE2 uses equation 9.9 to convert surface (flat) residue mass to portion of the soil surface cover by residue. User entered values in the residue description for data points (residue mass, cover) are used by RUSLE2 to determine values for the coefficient α in equation 9.9. These data points are the mass of residue that provides 30, 60, and 90 percent ground cover, respectively. RUSLE2 will use a single data point or an average of multiple data points to compute a value for α based on the data points for which values have been entered. Enter a mass value for 60 percent cover if only a single value is entered. The next best choice is a mass value for 30 percent cover. A single data point for 90 percent should be avoided because the mass-cover curve is very flat at high cover for many residue types, as Figure 9.5 illustrates. The best combination of two data points is 30 and 60 percent cover, and the poorest combination is one that involves a data point for 90 percent ground cover. Cover is very insensitive to a change in mass at high cover values where the curve is nearly flat. A value at this high cover is very poor for computing a value for α in equation 9.9 because residue mass value can vary over a wide range without affecting cover, which can result in great error when extrapolated to small cover values.

A RUSLE2 residue description is a composite that represents the net cover provided by the combined mass of the individual plant components of stems, leaves, pods and other plant parts. Leaves cover much more of the soil surface for a given mass per unit area than do stems, as illustrated in Figure 12.3. Thus, the mass-cover relationship for the composite residue depends on the relative mass of each plant component in the residue. A given residue mass covers much more of the soil surface immediately after harvest before the leaves decompose than later after the leaves have decomposed and only stems remain. For example, leaves decompose very rapidly and only stems are left soon after harvest for soybeans in the Southeastern US where fall and winter temperature and precipitation are high. In contrast, soybean leaves persist longer in the upper Midwestern US, and thus the leaves should be given greater consideration in selecting input values for the residue mass-cover relationship in the upper Midwestern US than in the Southeastern US.

RUSLE2 underestimates percent cover for a given mass per unit area immediately after harvest and overestimates percent cover late in the first year and beyond, as illustrated in

Figure 12.2. Refer to **Section 12.2.3** for information on how to best represent cover-mass for time periods that extend beyond one year after residue is added to the soil surface.
.

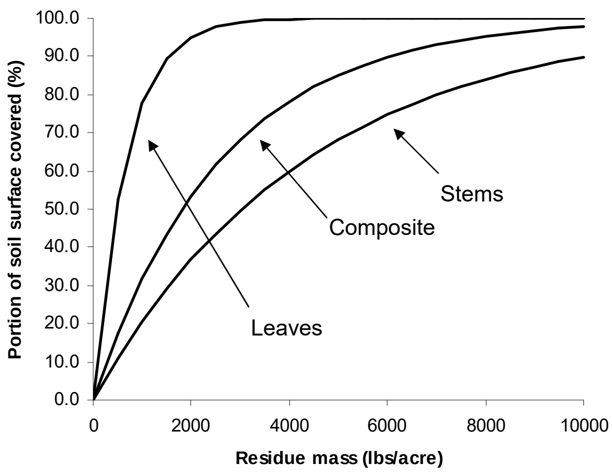

Figure 12.3. The relationship of cover to mass for leaves, stems, and the composite.

12.4. Non-organic residue

Non-organic materials, including stone, are used as mulch applied to the soil or incorporated into the soil. These materials are treated as **external residue** in RUSLE2. Input values in the residue descriptions for these materials must be carefully selected, especially if the materials are manipulated by operations.

12.4.1. Stones (rock fragments, gravel)

Stone, rock fragments, and gravel on the soil surface act as ground cover to reduce erosion (see **Sections 7.6, 9.2.2.1**). Values for rock cover can be entered in the **soil descriptions** in the **soil component** of the RUSLE2 database. RUSLE2 treats the rock cover value entered in a soil description as a constant that is not changed by operations.

Rock cover can also be added to the soil surface as an **external residue** by using an **operation description** that includes an **add other cover process** in a **cover-management description.** Rock cover added as an external residue is affected by soil disturbing operations (operation descriptions that include a **disturb soil process**). RUSLE2 treats rock added as an external residue as biomass that has the same effect on erosion as soil biomass described in **Section 9.2.2.1**. Adjustments should be made in the residue descriptions for rock added as external residue to prevent RUSLE2 from computing a soil biomass effect for rock.

Two special considerations are required to represent rock as external residue. The first step is to assign zero (0) for the decomposition coefficient value.[107] If the rock is not incorporated (buried) in the soil by a soil disturbing operation, no further adjustments are needed.

A second step is required if the rock is incorporated into the soil with a soil disturbing

[107] A very small value like 0.00001 should be entered rather than 0 to avoid a mathematical error in RUSLE2.

operation so that RUSLE2 does not treat rock as soil biomass. An index that has values less than 1 is used to represent the mass of the applied rock. For example, an index value of 0.2 could be used to represent 200,000 lbs/acre of applied rock cover. Values entered in the residue description to define the mass-cover relationship would be based on this index. The biomass subfactor equation (equation 9.12) in **Section 9.2.5.2** will use the index value as if the rock is biomass, but the equation will compute essentially no effect because the index indicates a very small biomass. Should you wish for RUSLE2 to compute an erosion reduction caused by rock incorporated into the soil, adjust the rock mass index until RUSLE2 computes the desired effect.

Be very careful in making these adjustments. See *Section 7.6.* The effect of rock in the soil on erosion is not well understood.

12.4.2. Non-organic erosion control materials that decay

Non-organic materials that decay by ultra-violet radiation are sometimes used at construction sites to control erosion. This decay process differs from the decomposition process assumed for **external residue**. Several special steps are required to develop **residue descriptions** for these materials.

Step 1 involves determining a decomposition coefficient value. RUSLE2 computes decomposition as a function of temperature and precipitation, whereas the decay of these materials is related to ultra-violent (u-v) radiation. Decomposition coefficient values must be determined by location or climatic region because the decomposition of these materials varies by location as u-v radiation, temperature and precipitation conditions that vary by location but are not internally represented in RUSLE2. Decomposition coefficient values are selected by running RUSLE2 and changing decomposition coefficient values until a value is determined that gives the desired loss of erosion control material over time.

Step 2 involves making adjustments for the fact that RUSLE2 adds a portion of the computed decomposed mass to the upper two inches of the soil (see **Section 9.2.5.3**). The decay products of these materials are assumed to have no effect on erosion. The adjustment for these non-organic materials that decay is like the one used for rock. An index is chosen for the erosion control product mass that numerically has values less than 1. The value entered in the **cover-management description** for the mass of the applied materials must be based on this index, and the values entered in the **residue description** for the cover-mass relationship must be consistent with the index definition.

Some erosion control materials are a combination of organic material and non-organic materials, such as compressed straw mulch between a plastic netting. The input values in the residue description should represent a composite of the material, much like residue with multiple plant components is represented as a composite. For example, the mass of the netting could be entirely ignored.

12.5. Selecting input values

The recommended approach for selecting input values for **residue descriptions** is to compare characteristics of the given residue with those in the residue descriptions in the RUSLE2 **core database.** The values in the core database are based on research data and have been evaluated to ensure that RUSLE2 computes erosion estimates appropriate for conservation and erosion control planning.

If the input values can not be selected based on a comparison with residue descriptions in the RUSLE2 core database, research literature may be a data source that can be used to derive RUSLE2 input values for residue descriptions. Otherwise field measurements may be required. Data used to determine RUSLE2 input values should meet certain conditions regardless of source. Data from multiple data sets, sources, locations, and measurements at a location are needed to deal with both spatial and temporal variability. Residue data, especially mass-cover values, are highly variable. The measurements should be made over at least a three year period at various times during the year. The objective is to capture main effects and trends rather than the details or differences between individual measurements. Differences often represent unexplained variability rather than characteristics of a particular residue.

The best measurements are from actual field conditions rather than from laboratory or specialized field experiments. This empirical approach also captures residue loss by other means besides decomposition such as by wind and worms. The purpose of RUSLE2 is not to be an accurate representation of processes but to be an easy-to-use conservation planning tool. Input values determined from measured data for residue descriptions should be compared among themselves and with those in the RUSLE2 core database for consistency. Such consistency is especially important for agencies implementing RUSLE2 on a national basis where fairness is an important requirement for those impacted by RUSLE2 estimates.

The input values in residue descriptions should reflect the most erosive period for the conditions where RUSLE2 is being applied. The values listed in the RUSLE2 core database were chosen to best fit the first year of the data, which is most important for agricultural cropping systems where annual harvest provides a relatively large biomass input. RUSLE2 tends to overestimate residue cover immediately after harvest and underestimate residue cover for periods longer than a year. Fitting the first year of data overall was considered more important than fitting the residue cover at end of the first year or fitting residue cover values beyond the first year. However, certain conditions exist where fitting over a longer period is important. Non-uniformity in the residue such as plant components that range from leaves to stems contributes significantly to RUSLE2 not fitting residue values beyond one year as well as during the first year. RUSLE2 fits residue data much better when residue pieces are uniform.

Surface residue cover values estimated by RUSLE2 are frequently used to judge the adequacy of RUSLE2. The first requirement in making these judgments is to ensure that the residue cover values being used to evaluate RUSLE2 values meet the requirements discussed above.

If RUSLE2 computed surface residue cover values do not match field measurements sufficiently well, do not immediately conclude that the residue decomposition coefficient value (half-life) should be modified. Numerous factors affect the surface residue cover values computed by RUSLE2. Changing the value for a single variable like the decomposition coefficient ϕ can have unexpected consequences that result in seriously erroneous erosion estimates even if the expected surface residue cover values are computed. That is, numerous other factors besides residue (ground) cover affect erosion. For example, changing the decomposition coefficient ϕ value, which affects residue cover, also affects buried residue and dead roots, which can significant affect computed erosion, especially for high yield, no-till corn cropping systems.

Several factors in addition to decomposition affect surface residue cover. These factors include the residue mass at harvest, the distribution between standing residue at harvest and surface (flat) residue, the rate that standing stubble falls, the relationship between residue cover to mass, and flattening, burial, and resurfacing of residue by operations. All of these factors should be systematically considered in correcting a surface residue cover problem.

13. OPERATION DATABASE COMPONENT

The **operation descriptions** in the **operation component** of the RUSLE2 database contain the information that RUSLE2 uses to compute how operations affect erosion. An **operation** is an event that affects the **soil**, **vegetation**, and/or **residue**. Operations play a major role in determining the values for variables used in the subfactor equations described in **Section 9**.

The variables used to describe an operation are given in Table 13.1. Speed of the operation is one of the variables used to describe an operation. Speed affects residue burial, much like disturbance depth. These two variables are discussed together in **Section 13.1.5.3**.

Table 13.1. Variables used to describe an operation

Variable	Comment
Recommended speed	The speed for which values in the operation description apply. The usual input value is the speed recommended by the manufacturer if the operation represents a machine
Minimum speed	RUSLE2 can adjust values in the operation description if the operation occurs at a speed that differs from the recommended speed. The minimum speed is the slowest speed that RUSLE2 will allow for the adjustment
Maximum speed	RUSLE2 can adjust values in the operation description if the operation occurs at a speed that differs from the recommended speed. The maximum speed is the fastest speed that RUSLE2 will allow for the adjustment
Sequence of processes	A set of processes is used to describe the operation. The processes must be listed in the proper order to have the desired effect. The variables used to describe processes are listed in Table 13.2.
List of processes that can be used to describe an operation	
No effect	Process has no effect. Typically used to cause RUSLE2 to display information on particular dates
Begin growth	Identifies the vegetation description that RUSLE2 is to begin using on the date of the operation description in the cover-management description. RUSLE2 references day zero in the vegetation description to the date of the operation
Kill vegetation	Converts live aboveground biomass and live root biomass to dead biomass that decomposes
Flatten standing residue	Transfer biomass from the standing residue pool to the surface (flat) residue pool. Does not affect live biomass
Disturb soil	Represents a mechanical disturbance of the soil. Creates roughness and ridges. Buries and resurfaces buried residue. Redistributes buried

	residue and dead roots in the soil. Does not affect live roots.
Live biomass removed	Takes a portion of above ground live biomass from the site. The removed biomass is no longer involved in RUSLE2's biomass accounting
Remove residue/cover	Removes residue (dead biomass) and other material from the soil surface.
Add other (external) cover	Adds external residue (e.g., mulch, manure, rolled erosion control materials) to soil surface. Also used to place materials like manure in the soil, which must be accompanied by a disturbed soil process in the operation description
Add non-erodible cover	Adds non-erodible cover including plastic used in vegetation production, water used to flood rice fields, and snow cover. RUSLE2 computes no erosion for portion of soil surface covered by non-erodible cover
Remove non-erodible cover	Removes non-erodible cover.

Some processes like **disturb soil** use additional variables to describe them. Those processes and variables and the variables used to describe them are listed in Tables 13.2.

Table 13.2. Variables used to describe particular operation processes

Process	Variables	Comment
Flatten standing residue	Flattening ratio	Portion of the standing residue mass (dry basis) that is flattened by the operation. Value entered for each residue type
Disturb soil	Tillage type	Describes where operation places buried material in soil and how it redistributes buried residue and dead roots in the soil
	Tillage intensity	Describes the degree that operation obliterates existing roughness
	Recommended depth	Typical depth of disturbance. Use value recommended by manufacturer if operation represents a machine
	Minimum disturbance depth	RUSLE2 adjusts values in operation description if disturbance depth differs from recommended depth. Minimum depth is the shallowest depth that RUSLE2 will use to make an adjustment.
	Maximum disturbance depth	RUSLE2 adjusts values in operation description if disturbance depth differs from recommended depth. Maximum depth is the deepest depth that RUSLE2 will make an adjustment.
	Ridge height	Height of ridges created by operation

	Initial roughness	Roughness left by operation when used on a smooth, silt loam soil when surface and soil biomass are very great
	Final roughness	Roughness after roughness has fully decayed
	Portion of surface area disturbed	Portion of the surface disturbed when disturbance occurs in strips.
	Burial ratios	Portion of surface (flat) residue (dry basis) that is buried. Value entered for each residue type
	Resurfacing ratios	Portion of buried residue in the disturbance depth brought to the soil surface and added to surface (flat) residue pool. Value entered for each residue type
Live biomass removed	Biomass affected	Portion of live aboveground biomass (dry basis) affected by operation
	Amount left on surface	Portion of the affected live biomass (dry basis) added to the surface (flat) residue pool by operation
	Amount left as standing residue	Portion of the affected live biomass (dry basis) added to the standing residue pool by operation
Remove residue/cover	All residue affected	Determines whether operation applies to all residue that is present or to the last residue added
	Flat residue removed	Portion of surface (flat) residue (dry basis) removed by operation
	Standing residue removed	Portion of standing residue (dry basis) that is removed by operation
Add other cover	Portion of external residue added to soil surface	Distributes added external residue between soil surface and placement in the soil over lower half of soil disturbance depth
Add non-erodible cover	Cover added	Portion of soil surface receiving non-erodible cover. Erosion is zero on the portion of the soil surface covered by the non-erodible cover
	Cover half life (days)	Time in days that half of the cover disappears by any process. Value entered must be appropriate for location because RUSLE2 does not consider environmental variables in computing loss of non-erodible cover.
	Cover permeability	Determines the degree that the non-erodible cover affects infiltration and runoff. 100% permeability means that the cover has no effect on infiltration. 0% permeability means that all precipitation on the non-

		erodible cover portion runs off
Remove non-erodible cover	Portion of non-erodible cover removed	Portion of current non-erodible cover removed by the operation.

13.1. Processes Used to Describe Operations

Operations are **discrete events** that change properties of **vegetation**, **residue**, and/or the **soil** that affect erosion. Examples of operations include tilling, planting, harvesting, grazing, burning, frost, ripping, blading, and applying mulch. Operations are described using a **sequence of processes**. Both the processes themselves and their sequence determine an operation's effect. Additional variables are used to describe some processes.

13.1.1. No Effect

The **no effect process** has no effect on RUSLE2 computations. It's main use is in a ***no operation*** **operation-description** to cause RUSLE2 to display output information on certain dates and for certain periods. **Section 10.2.1.3** discusses how to use a *no operation* operation-description to set the starting point for RUSLE2's tracking of time in an erosion computation. Also, users will sometimes place *no operation* operation-descriptions in a **cover-management description** where other users will later substitute other operation descriptions.

13.1.2. Begin growth

The **begin growth process** is used in an **operation description** to identify the **vegetation description** that RUSLE2 is to begin using on the date of the operation description in a **cover-management description**. RUSLE2 references day zero in the vegetation description to the date of the operation description containing the **begin growth process**. **Section 10.2.3** describes how a **begin growth process** is used in RUSLE2.

RUSLE2 uses only a single vegetation description at any time during its computations (i.e., only one vegetation description is **current** and being used at any time). RUSLE2 begins using a new vegetation description at each occurrence of an operation description with a **begin growth** process in a cover-management description. RUSLE2 does not combine information from multiple vegetation descriptions.

RUSLE2 uses certain rules regarding the **begin growth process** when an operation description with a begin growth process occurs where the previous vegetation description was not ended with a **kill vegetation process**. RUSLE2 adds the decrease between live root biomass on the last day the previous vegetation description was used and the live root biomass on day zero of the new vegetation description to the dead root biomass pool. RUSLE2 makes no change in the dead root biomass pool if live root biomass increases between vegetation descriptions.

RUSLE2 does not adjust residue pools as a result of differences in canopy cover or live aboveground biomass between vegetation descriptions. Any changes to these biomass pools must be explicitly represented using processes in operation descriptions. However, RUSLE2 DOES adjust the dead root biomass pool between vegetation descriptions. RUSLE2 assumes that a decrease in live root biomass between two vegetation descriptions is dead root biomass that is added to the dead root biomass pool on the date that the change in vegetation description occurs.

13.1.3. Kill vegetation

The **kill vegetation process** converts live aboveground biomass to standing residue and live roots to dead roots and sets values for live root biomass and live ground cover to zero. This process is used in most tillage and harvest **operation descriptions** that end vegetative growth. It is also used in frost killing operation descriptions and in burning operation descriptions if burning entirely kills the vegetation. If an operation such as burning or harvest kills only a portion of the vegetation, the procedure described below is used (see **Section 11.1.3.2**).

Because RUSLE2 uses a descriptive approach and is not a process model, an *operation description* using the *kill vegetation process* must be used to end vegetation growth.

The **kill vegetation process** "kills" all vegetation represented by the current vegetation description. A **kill vegetation process** also ends RUSLE2's use of information from the current vegetation description. If RUSLE2 computations extend beyond the last date represented in a vegetation description, RUSLE2 uses the values on the last date in the vegetation description until an operation description with either a **kill vegetation process** or a **begin growth process** occurs in the **cover-management description**.

Two processes are used in an operation description to represent a partial kill of vegetation. These processes transfer only a portion of the live aboveground biomass to the standing and surface (flat) residue pools and a portion of the live root biomass to the dead root biomass pool. The **first process** is **remove live biomass**, which determines how much of the live aboveground biomass that is affected by the operation and the portion of the affected biomass that is transferred to the standing and surface (flat) residue pools. The **next process** in this operation description is a **begin growth process** that identifies the vegetation description that follows the current vegetation description. RUSLE2 compares the live root biomass on day zero in the new vegetation description with the live root biomass in the current vegetation description on the transfer date. RUSLE2 transfers a **decrease** in live root biomass between the vegetation descriptions to the dead root biomass pool. An increase does not change the dead root biomass pool.

A *kill vegetation process* transfers all live aboveground biomass for the current vegetation to the standing residue pool and all live root biomass to the dead root biomass pool. Use *remove live biomass* and *begin growth processes* to transfer only a portion of live biomass to dead biomass.

13.1.4. Flatten standing residue

Biomass is transferred from the standing residue pool to the surface (flat) residue pool by natural and mechanical processes that flatten the standing residue (see **Section 9.2.2.3**).[108] Flattening of standing residue by natural processes is represented internally in RUSLE2 based on decomposition at the standing residue base. The **flatten standing residue process** is used in **operation descriptions** to represent mechanical flattening of standing residue. For example, this process is used in operation descriptions that describe flattening of standing residue by foot or vehicular traffic. Also, this process is used in operation descriptions for tillage operations that bury crop residue because standing residue must first be flattened before it can be buried according to RUSLE2 rules. This process is also used in harvest operation descriptions to describe the distribution between standing and flat residue after harvest. For example, about 50 percent of wheat residue is left standing after harvest, while only 5 percent of soybean residue is left standing. The difference is primarily related to combine cutter bar height. The amount of residue left standing for corn harvest can range from about 15 to 85 percent depending on combine snapper height or whether the corn was harvested by combine, picker, grazing, or hand. This process can be used in operation descriptions to represent wind flattening standing residue where the RUSLE2 internal procedures for natural processes do not compute sufficient fattening. To flatten live vegetation, a **begin growth process** is used to call a new vegetation description to describe characteristics of the live vegetation after flattening. **A flatten standing residue process** can not be used to descrbe flattening of live vegetation because a RUSLE2 rule is that only standing residue can be flattened..

Two rules apply in using the **flatten standing residue process** in an operation description. The **first rule** is only standing residue can be flattened. Live vegetation must first be converted to standing residue using a **kill vegetation process** or a **remove live biomass process** in an operation description. The **flatten standing residue process** has no effect on live vegetation. Live vegetation can be flattened and continue to live

[108] The companion values for burial and resurfacing ratios are entered in the **disturb soil process**.

(e.g., wheat blown over by wind before maturity). An operation description that includes a **begin growth process** and associated vegetation description that represents flattened live vegetation is used to describe this condition. The **second rule** is that standing residue can not be buried by an operation until the standing residue has been converted from standing residue to surface (flat) residue. Therefore, a tillage operation description that buries standing residue must include a **flatten standing residue process** before a **disturb soil process**. Sequence of processes is important.

Flattening ratio is the input used to describe the **flatten standing residue process**. This ratio is defined as the portion of mass (dry basis) of standing residue that is flattened to the mass (dry basis) of standing residue before flattening. A flattening ratio of 0 means that no standing residue was flattened, and a value of 1 means that the entire standing residue was flattened. The portion of standing residue flattened by a mechanical process depends on both residue type (e.g., the standing residue of some vegetation types resists flattening), type of mechanical process (e.g., vehicular traffic versus harvest, corn combine versus corn picker), and properties of the process (e.g., cutter bar height). A value for the flattening ratio in an operation description is entered for each residue type (see **Section 12.1**). The values must also represent the particular process (e.g., type of machine) and the properties of the process (e.g., how the machine is operated). Multiple operations are required for a particular machine operated in different ways (e.g., cutter bar set at different heights). Values for the flattening ratio are largest for residue types most easily flattened by mechanical action and cutter bar height close to the ground, such as for soybeans.

Values entered for flattening ratio in an operation description should be based on a comparison with operation descriptions in the RUSLE2 **core database**. If a selection can not be made on that basis, research literature may provide data that can be used to determine flattening ratio values. The third possibility is to make field measurements. Data used to determine flattening ratio values should be sufficient to deal with variability, and the emphasis should be on capturing main effects rather than details that may well be unexplained variability. Values determined from the literature or from actual measurements should be checked for consistency with values in the RUSLE2 core database.

13.1.5. Disturb Surface (Soil)

The **disturb surface (soil) process** represents a mechanical disturbance of the soil that, with one exception, resets the soil consolidation subfactor to 1 for the portion of the soil surface that is disturbed (see **Section 9.2.6**). RUSLE2 assumes that the soil must be disturbed to bury surface (flat) residue, to create soil surface roughness and ridges, to mechanically smooth the soil, and to place material in the soil. The exception is the compression tillage type that buries residue without loosening the soil (see **Table 13.3**).

Also, RUSLE2 assumes that a infinitely thin surface layer of soil can be cut away without disturbing the underlying soil. The **operation description** that describes this action would **not** include a **disturb soil process** but would include a **Remove residue/cover process** that removes all above ground and surface vegetation and cover. This operation description does not affect any soil biomass.

Input values for the variables listed in Table 13.2 are required to described the **disturb soil process** for a particular **operation description**.

13.1.5.1. Tillage type

Assigning a **tillage type** from the list in Table 13.3 for an **operation description** provides information to RUSLE2 how a **soil disturbing** operation vertically distributes surface residue when it is buried. This input also provides information on how the operation vertically redistributes existing buried residue and dead roots. The **disturb soil process** has no effect on the distributions of live roots. Live root biomass must be transferred to the dead root biomass pool before root biomass can be redistributed in the soil by a soil disturbing operation. The distribution and redistribution functions represented by the tillage types are described in **Sections 9.2.5.3.3 and 9.2.5.3.4.**

The **inversion+some mixing** tillage type is used to describe machines like moldboard plows and manual operations that bury residue by inverting the soil. These operations bury most of the residue in the lower one half of the disturbance depth as illustrated in Figure 9.15. One way to represent how a soil disturbing operation redistributes buried residue and dead roots is to describe the pattern that results after the operation is applied repeatedly. Repeated applications of the inversion+some mixing tillage type operation results in buried residue and dead roots being nearly uniformly distributed as illustrated in Figure 9.17.

The **mixing with some inversion** tillage type is used to describe machines like heavy offset disks, tandem disks, chisel plows, and field cultivators and manual operations that primarily bury residue by mixing but also bury some residue by soil inversion. These operations bury most of the residue in the upper one half of the disturbance depth as illustrated in Figure 9.15. The second application of an operation of this tillage type mixes the residue fairly uniformly in the upper one half of the disturbance depth as illustrated in Figure 9.18. Subsequence applications result in a moderate bulge of material that moves downward in the soil.

The **mixing only** tillage type is used to describe machines like rotary powered tillers and manual operations that incorporate residue by mixing with hardly any soil inversion. These operations tend to bury residue in the upper one third of the soil depth as illustrated in Figure 9.15 rather than uniformly over the disturbance depth as commonly assumed. Repeated applications of this tillage types results in a well defined bulge of material that moves downward in the soil.

The **lifting, fracturing** tillage type is used to describe machines like fertilizer and manure injectors, subsoilers, and sacrifiers and manual operations that have a similar effect on the soil and residue. This tillage type assumes almost no mixing or inversion, and an operation of this tillage type buries residue in the upper one third of the disturbance depth. The residue distribution and redistribution relationships for **mixing only** are used to describe this tillage type.

An **add other residue/cover process** is used to place external residue in the soil. This process must be followed by a **disturb soil process** in the **operation description**. The lifting, fracturing tillage type is selected for the operation. RUSLE2 places the inserted material in the lower one half of the disturbance depth as illustrated in Figure 9.16. This procedure assumes that the material is placed in the soil by injection. Material can be also placed in the soil by applying it to the soil surface and incorporating it using machines like disks, chisel plows, field cultivators, or rotary powered tillers or manual implements. The operation description for this method of incorporation includes an **add other residue/cover process** followed by a **disturb soil process**.

Table 13.3. Tillage types used in RUSLE2			
Tillage type	Burial pattern	Redistribution characteristics with repeated applications	Comment
Inversion + some mixing	Most of material is placed in lower 1/2 of disturbance depth	Material is nearly uniformly distributed	Used to represent soil disturbing machines like moldboard plows that invert soil
Mixing with some inversion	Most of material is placed in upper 1/2 of disturbance depth	2nd application results in a fairly uniform pattern in the upper ½ of soil disturbance depth after which a moderate bulge develops that moves downward in soil	Used to represent soil disturbing machines like chisel plows, field cultivators, and disks
Mixing only	Most of material placed in upper 1/3 of disturbance depth	A well defined bulge rapidly develops that moves downward in soil	Used to represent powered rotary tillers
Lifting, fracturing	Most of material placed in upper 1/3 of disturbance depth	A well defined bulge rapidly develops that moves downward in soil	Used to represent fertilizer injectors, manure injectors, subsoilers, and sacrifiers
Compression	Most of material placed in upper 1/3 of disturbance depth	No redistribution	Used to represent sheep's foot roller and animal traffic that presses residue into the soil. The soil consolidation subfactor is not reset to 1
Note: When external residue is placed in the soil, the **add other residue/cover process** must be followed with a **disturb soil process** in the operation description, which places the inserted material in the lower one half of the disturbance depth			

The **compression** tillage type is used to describe cattle trampling, a sheep foot's roller, and similar operations pressing residue into the soil without loosening the soil. The **mixing only** distribution relationship is used to vertically distribute the buried residue. Operations of this tillage type are assumed to not redistribute buried residue or dead roots. **An important difference between this tillage type and the other tillage types is that the soil consolidation subfactor is not reset to 1.**

The best way by far for assigning tillage types to soil disturbing operations is to base the selection on Table 13.3 in conjunction with comparisons with tillage types assigned in the RUSLE2 **core database**. Consistency between the assigned tillage type and those in the core database is essential.

A very important feature of the soil mixing relationships used in RUSLE2 is that material does not become uniformly mixed in the soil with repeated applications of the operation except for the *inversion+some mixing* tillage type. The distribution becomes more non-uniform with repeated applications of operations described with the other tillage types.

13.1.5.2. Tillage intensity

Tillage intensity refers to the degree that a soil disturbing operation obliterates existing roughness. Tillage intensity relates to the aggressiveness of the soil disturbance. A tillage intensity value of 1 means that existing soil roughness has no effect on the roughness created by the operation. A tillage intensity value of 0 means that roughness after the operation is the same as before the operation, unless the existing roughness is smoother than the roughness created by the operation on a smooth soil.

A moldboard plow and a rotary powered tiller are both assigned tillage intensity values of 1 because these aggressive machines totally eliminate any signs of existing roughness. In contrast, a spike tooth harrow, which is non-aggressive, is assigned a tillage intensity of 0.4 because the harrow hardly changes existing roughness. For example, soil surface roughness is greater when the harrow follows a moldboard plow than when it follows a tandem disk because of differences in existing roughness and the minimal effect that the harrow has on roughness. The harrow does some smoothing but does not totally work the soil to eliminate all existing soil surface roughness to create a totally new soil surface roughness. Tillage intensity values range from 0.5 to 0.9 machines like field cultivators, tandem disks, and chisel plows depending on the machine's "aggressiveness."

When the roughness immediately before an operation is smoother than the roughness created by the operation on a smooth soil, the tillage intensity variable has no effect on the roughness value estimated by RUSLE2. The roughness value for the operation is set to the **input (initial) roughness value** for the operation, adjusted for soil texture and soil biomass (see **Section 9.2.3**).

Tillage intensity is not necessarily related to the initial roughness created by an operation. For example, both a moldboard plow and a rotary powered tiller are assigned 1 for tillage intensity but the soil surface roughness left by the two machines is very different. The moldboard plow leaves a very rough surface and the powered rotary tiller leaves a very smooth surface. Both machines are very aggressive and completely disturb the soil. Machines that have low tillage intensity values also tend to leave a relatively smooth surface when used on a smooth soil.

Tillage intensity values should be assigned using values in the RUSLE2 **core database** as a guide. The selection is the operation's aggressiveness for obliterating signs of existing soil surface roughness, not the soil surface roughness left by the operation. The RUSLE2 assumption is that tillage intensity is not a function of soil properties. However, different intensity values can be assigned based on soil properties. The RUSLE2 user then chooses the operation description having the tillage intensity values most appropriate for the site-specific condition.

13.1.5.3. Recommended, minimum, and maximum speed and disturbance (tillage) depths

The portion of the surface (flat) residue mass buried by a **soil disturbing operation** (e.g., tillage) increases as disturbance depth and speed increase as illustrated in Figures 13.1 and 13.2. These relationships were derived from analysis of research data. The manufacturer of tillage implements and soil disturbing machines often specify a recommended disturbance depth and speed along with working ranges where the machine operates satisfactorily. The input burial ratio values are for the **recommended disturbance depth and speed**.[109] No other variable, including residue resurfacing, is affected by disturbance depth and speed in RUSLE2.

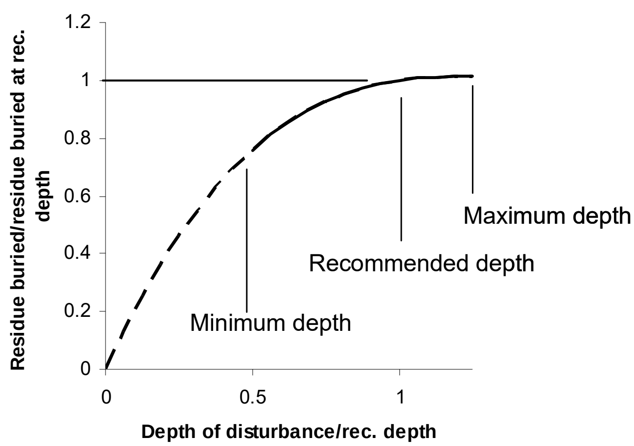

Figure 13.1. Effect of disturbance depth on residue burial (mass basis).

Increasing disturbance depth at shallow depths significantly increases residue burial, but increasing disturbance depth to depths deeper than the recommended depth does not greatly increase residue burial. Increasing speed does not significantly increase residue burial. The effect of speed on residue burial is generally less than the effect of disturbance depth.

[109] Disturbance depth in RUSLE2 is for the entire disturbance (tillage) depth, which differs from the incorporation depth used in RUSLE1. The RUSLE1 incorporation depth is the effective depth of residue burial assuming that residue is buried uniformly with depth. The RUSLE1 incorporation depth is shallower than the RUSLE2 disturbance depth.

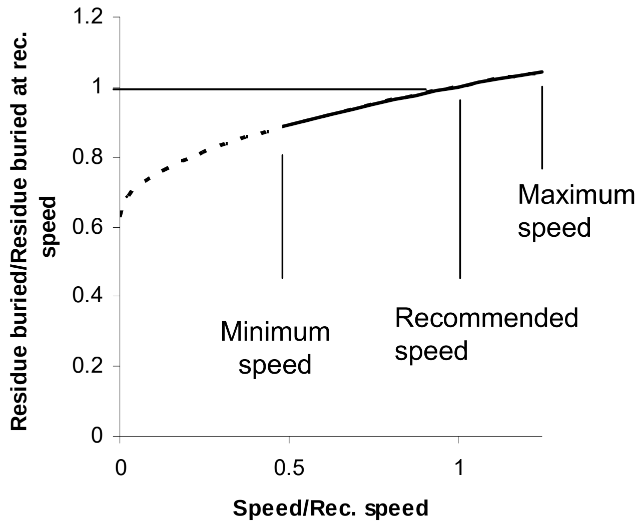

Figure 13.2. Effect of speed on residue burial (mass basis)

In most RUSLE2 applications, the recommended disturbance (tillage) depth and speed are accepted as default values.[110] Input values for disturbance depth and speed entered in **cover-management descriptions** must be within the minimum and maximum values entered in each **operation description.**

The common belief is that practically any surface residue cover can be achieved by varying how a machine is operated. Disturbance depth and speed are the two machine variables that can be changed easily. The assumption that a particular residue cover can be achieved by varying machine operation should be checked. The range in residue cover that can be achieved by varying disturbance depth and speed is determined by making RUSLE2 computations at the minimum and maximum disturbance depth and speed values. If RUSLE2 shows that the desired residue cover is not obtained by varying disturbance depth or speed, another change in the machine such as changing shovel type is required.

Input values for disturbance depth and speed can often be obtained from manufacturer's literature. Also, values given in the RUSLE2 **core database** can be used as a guide to selecting input values. The preferred approach is to select a tillage depth based on the implement type rather than selecting value specific to an individual machine or operator. The disturbance depth and speed values shown in the RUSLE2 core database were chosen to give the desired differentiation between implement types. Input values should be reviewed for consistency among themselves and with values in the RUSLE2 core database.

Input values for disturbance depth and speed should not deviate significantly from those in the RUSLE2 core database for a particular type of machine.

[110] Depth and speed of operations in a **cover-management description** may not be displayed by the RUSLE2 template used to configure your RUSLE2 screen. Choose an alternate RUSLE2 template that displays additional variables so that disturbance depth and speed can be entered for each operation in a **cover-management description**.

13.1.5.4. Ridge height

Ridge height has two effects in RUSLE2. One effect is that increased ridge height increases erosion when the ridges are oriented up and down hill perpendicular to the contour. This ridge effect is considered in the subfactors used to compute **cover-management** effects (see **Section 9.2.4**). The other effect is that increased ridge height decreases erosion when the ridges are on the contour (parallel to the contour). This ridge effect is considered in **support practice** relationships used to compute the **contouring** effect (see **Section 14.1**). The overall ridge height effect, which is the net between these effects, also varies with row grade (grade along the furrows between the ridges).

Operation descriptions that include a **disturb soil process** must be used in a **cover-management description** to create ridges for RUSLE2 to compute a contouring support practice effect. RUSLE2 assumes that ridges can not be created without disturbing the soil, which resets the soil consolidation subfactor to 1 for the portion of the soil surface that is disturbed by the operation that creates the ridges.

Input values for initial ridge height are entered in operation descriptions that include a **disturb soil process**. Ridge height created by an operation is not affected by ridge height that existed before the operation. In effect, an operation obliterates any ridge height that existed prior to the operation even when the operation minimally disturbs the soil. The ridge height entered for an operation should reflect the ridge height that exists when the operation is used in combination with other operations. RUSLE2 computes loss of ridge height over time as a function of precipitation amount and interrill erosion.

The best way, by far, to assign ridge height values is to use the values in the RUSLE2 **core database** as a guide. RUSLE2's estimate of the contouring effect on erosion is RUSLE2's most uncertain estimate. Too frequently, initial ridge height values are entered that are too low, which results in RUSLE2 not computing the expected contouring effect (see **Section 14.1**). Field measured ridge height values may be lower than the corresponding values in the RUSLE2 core database. Also, important ridges are also overlooked when field measurements are made.

If RUSLE2 is not computing as much contouring effect as expected, initial ridge height values in key operation descriptions may need to be increased.

13.1.5.5. Initial roughness

As described in **Section 9.2.3**, RUSLE2 computes decreased sediment production (i.e., detachment, see equations 5.4, 8.1, 9.1, 9.10) as soil surface roughness increases. RUSLE2 also computes decreased runoff rates as soil surface roughness increases (see **Section 5.4**). RUSLE2 uses runoff rate to compute how contouring affects erosion (see **Section 14.1**) and to compute sediment transport capacity (see equation 5.3). RUSLE2 uses sediment transport capacity to compute deposition, sediment yield, and enrichment of the sediment in fines on rough surfaces; on concave shaped slopes; upslope of strips of dense vegetation, rough soil surfaces, and heavy ground cover; and in low grade terrace/diversion channels (see **Section 14**).

RUSLE2 assumes that the soil must be disturbed to create roughness, which resets the soil consolidation subfactor to 1 for the disturbed portion of the soil surface, with one exception. The exception is a **compression tillage type** that creates soil surface roughness but does not reset the soil consolidation subfactor to 1 (see **Section 13.1.5.1**). Therefore, **operation descriptions** that include a **disturb (soil) surface process** must be included in **cover-management descriptions** to describe surface roughness. The input value for **initial roughness** in the disturb soil process in an operation description is an index for the roughness that the operation creates for a standard condition. **This standard condition is a smooth, silt loam soil, where the amount of soil biomass from buried residue and dead roots is very high in the soil disturbance depth after the operation** (see **Section 9.2.3.3**). RUSLE2 adjusts the input initial roughness value to obtain an **adjusted roughness** value for its erosion computations.

These adjustments are for:
soil texture (increased roughness for fine textured soils, decreased for coarse textured soils),

soil biomass in disturbance depth after operation (decreased roughness with decreased soil biomass), and

tillage intensity if the existing roughness is greater than the roughness created by operation on a smooth soil (resulting roughness is least affected by existing roughness as tillage intensity increases).

The initial roughness input value applies only to the **portion of the soil surface disturbed** and not to the entire soil surface. **The input value is not a net for the entire surface.**[111] RUSLE2 does not arithmetically average the roughness values for the disturbed and undisturbed portions of the soil surface. Instead, RUSLE2 computes a roughness subfactor value (see equation 9.10) for both the disturbed and undisturbed portions. These subfactor values are averaged based on the portion of the soil surface disturbed. This average roughness subfactor value is used to compute an **equivalent roughness** value for the entire surface that gives the proper net erosion for the entire surface.[112] This equivalent roughness value is decayed over time by precipitation amount and interrill erosion.

---

[111] The roughness input is different from the inputs for residue burial and resurfacing in the **disturb (soil) surface process** description. Burial and resurfacing input values are net for the entire soil surface.
112 Proper erosion is the net erosion that is computed to occur based on the undisturbed and disturbed surfaces. An equivalent roughness is determined that gives this net erosion.

The best approach for selecting input values for initial roughness is to base them on values in the RUSLE2 **core database**. Like other variables, the values in the RUSLE2 core database were selected to represent operation classes and types to ensure that RUSLE2 computes main effect erosion differences among operations based on research data and professional judgment. User selected initial roughness input values should be reviewed for consistency among implements, machines, and manual types of soil disturbance and for consistency with RUSLE2 core database values. The requirement is that RUSLE2 estimate expected erosion rather than exactly reproducing a field roughness measurement.

The scientific literature is a source of initial roughness input values, but literature values require modification using equations in **Section 9.2.3.3** before using them in RUSLE2. For example, the RUSLE2 initial roughness input values are often higher than comparable values used in other erosion models because of the standard condition used to define RUSLE2 initial roughness. The internal RUSLE2 adjusted roughness values are often similar to input values used in other models.

The RUSLE2 standard condition used to define initial roughness is the same as the one used in RUSLE1 (AH703). However, the RUSLE2 initial roughness input values differ from the RUSLE1 values because of the RUSLE2 tillage intensity effect that is not used in RUSLE1. RUSLE2 initial roughness values are less than comparable RUSLE1 values where tillage intensity is less than 1.

RUSLE1 initial roughness values can not be used directly in RUSLE2 without adjusting for the tillage intensity effect

Field measurements can be made to determine RUSLE2 input initial roughness subfactor values (see **Section 9.2.3.2**). The measurements are on a 1 inch (25 mm) grid using pins lowered to the soil surface or elevations determined using a non-contact method. The chain method should not be used to determine roughness values for RUSLE2. Elevations related to ridges should be removed, and a plane should be fitted to the data to remove land slope effects. The roughness measure used in RUSLE2 is the standard deviation of elevations about this plane. Equations described in **Section 9.2.3.3** must be used to adjust measured values for a particular field condition to the RUSLE2 standard condition for initial roughness. Sufficient measurements are made to account for both temporal and spatial variability. The intent is to characterize main effects of roughness using a diverse data set rather than representing a single, specific site condition.

13.1.5.6. Final roughness

The RUSLE2 subfactors described in **Section 9**, including the roughness discussed in **Section 9.2.3**, are relative to the unit plot conditions used to determine soil erodibility factor values (see **Section 7.2**). The value for each subfactor is 1 for unit plot conditions. A roughness value of 0.24 inches (6 mm) is assumed to represent unit plot roughness. This roughness is similar to the roughness at harvest of a row crop where a moldboard plow, tandem disk, field cultivator, and row cultivator were used to till the soil. A 0.24-inch (6 mm) roughness is nearly but not completely smooth. A perfectly smooth soil surface has a roughness value of 0 inches (0 mm).

The 0.24-inch (6 mm) roughness represents the effect of a few erosion resistance clods on erosion. Even though **final roughness** represents the effect of a few erosion resistant clods, the input value for final roughness is not a function of soil texture. The effect of soil texture on final roughness is empirically represented in the soil erodibility factor values derived from unit plot conditions.

This empirical effect of soil texture on final roughness being included in the soil erodibility factor is but one reason why RUSLE2 definitions must be understood and followed.

A final roughness value of 0.24 inches (6 mm) is typically used in RUSLE2 for operation descriptions that create a roughness greater than 0.24 inches (6 mm) on a smooth soil. However, some operations leave a smoother surface than 0.24 inches (6 mm). A rotary powered tiller used to prepare a very fine seedbed is an example. This tiller creates almost uniform, small-sized soil aggregates (clods) and leaves almost no large clods in comparison to a moldboard plow, heavy offset disk, or chisel plow. Another example is a bulldozer or a road grader that cuts away soil leaving a very smooth surface. A 0.15-inch value is used for final roughness for these operations.

If the input value for final roughness is greater than or equal to 0.24 inches (6 mm), RUSLE2 decays roughness from a starting value to the final roughness value based on daily precipitation and daily erosion. If the input value for final roughness is less than 0.24 inches (6 mm), the input value for initial roughness should be the same as the input value for final roughness. RUSLE2 does not decay this roughness value.

Similarly, RUSLE2 does not decay roughness when the input values for both initial and final roughness are the same, even when the input value for final roughness is greater than 0.24 inches (6 mm). These inputs cause RUSLE2 to use a specific roughness value. An example of this application is representing roughness created by animal traffic, which also involves selecting compression for tillage type (see **Section 13.1.5.1**).

***Long term natural roughness*, discussed in *Section 10.2.7*, is the soil surface roughness that develops over time to soil consolidation after a soil disturbance. Final roughness and long term roughness are not the same, and the values entered for the two variables are not the same.**

13.1.5.7. Surface area disturbed

Some operations like planters disturb only a portion of the soil surface. The variable **portion of soil surface disturbed** directly affects the soil consolidation and soil surface roughness subfactors and indirectly affects the soil biomass subfactor, the effect of distance along an overland flow path on erosion, the effect of surface cover on erosion, and runoff (see **Section 9.2.6**).

Selecting proper values for the portion of the soil disturbed requires an understanding of the definition of soil disturbance, knowing the effect of soil disturbance on erosion, and recognizing indicators of soil disturbance. The definition of soil disturbance is given in **Section 9.2.6.3.**

Soil disturbance, as used in RUSLE2, occurs when an operation fractures and loosens the soil, displaces soil, mixes soil and surface residue so that the interface between the residue and the surface soil is no longer distinct, and disrupts a high organic matter layer at the soil surface.

The portion of the soil surface disturbed includes a **soil source area** and the **soil receiving area** that collects soil displaced from the soil source area. The soil source area is mechanically disturbed (disrupted) where the soil disturbing tool (e.g., disk blade, shank, or shovel) fractures, loosens, and displaces soil. This area is considered disturbed if the tool action penetrates below the residue (litter)-soil interface to mix underlying soil and residue (litter) and expose and displace mineral soil. The area disrupted by the tool should be considered to be disturbed if the disturbance depth exceeds an inch (25 mm) or two (50 mm).

Some tools run beneath the residue (litter)-soil interface and do little more than fracture and loosen the soil. This action is also soil disturbing even though mineral soil may not be exposed. However, the input value for the portion of the soil surface disturbed may be less that the actual field width of disturbance for conditions where the residue (litter)-soil interface remains largely intact and undisturbed. Selecting an input value for portion of the soil surface disturbed by undercutting involves comparing the surface high organic soil layer left after undercutting with this layer where no disturbance occurs.

The soil receiving area receives mineral soil displaced from the soil source area. The soil receiving area is considered disturbed if the residue (litter)-soil interface is disturbed and

Assigning input values for portion of the soil surface disturbed requires judgment. The effect being represented in RUSLE2 needs to be understood. A set of rules is highly useful to ensure that consistency is achieved in assigning input values among types of soil disturbances.

soil and residue (litter) are mixed. If the displaced soil is sufficiently deep that rill erosion does not penetrate the displaced soil layer, the buried residue (litter) has little direct effect on erosion and the entire receiving area should be considered disturbed. In this case, the portion of the soil surface disturbed includes the soil source area and all of the soil receiving area. A displaced soil depth of ½ inch (12 mm) or more is used as a guide in making this determination. The input value for the portion of the soil surface disturbed is reduced where rill erosion erodes through the displaced soil layer to the underlying intact reside (litter). The residue (litter) reduces erosion only after it becomes exposed.

Ridges are evidence of soil disturbance. Ridge creation requires a soil source area, and the receiving (ridge) area is soil of sufficient depth that erosion is unaffected by the underlying residue (litter). Ridges higher than ½ to 1 inch (12 to 50 mm) are considered to be disturbed areas.

The degree of soil disturbance is highly important considerations in determining the effectiveness of no-till cropping systems for controlling erosion. The two characteristics of these systems most responsible for their high erosion control effectiveness are the continuous presence of surface residue and a surface soil layer of high organic matter content, both of which are reduced by soil disturbance. **Both conditions must be present; high residue cover alone is not sufficient for the full no-till effect.** RUSLE2 uses **portion of the soil surface disturbed** along with the **soil consolidation subfactor** and **soil biomass** in the upper 2-inch (50 mm) soil layer to compute the effect of the upper high organic matter soil layer on erosion (see **Section 9.2.6**).

Portion of the soil surface disturbed by an operation and the **time since the last mechanical disturbance** are key variables. According to RUSLE2, surface residue cover is restored quickly in three years or less for much of the Eastern US after a single major disturbance such as moldboard plowing that buries almost the entire surface residue. About three to five years are required in much of the Eastern US to restore soil biomass in the upper 2-inch layer based on decomposition. This determination can be made by setting the **time to soil consolidation** to 1 year, which eliminates the effect of soil consolidation on the accumulation of soil biomass.

The accumulation of soil biomass in the upper 2-inch (50 mm) layer and the effect of this soil biomass on erosion are functions of the soil consolidation subfactor. Consequently, the total time for the no-till effect to be fully regained after a soil disturbance is about the same as the time entered in the **soil description** for the **time to soil consolidation**. The standard assumption for **time to soil consolidation** is seven years in most of the Eastern

US. RUSLE2 computes that most of the no-till effect is regained in about five years, as Table 13.4 illustrates for no-till 112 bu/ac corn **cover-management description** for Columbia, MO. This RUSLE2 estimate is consistent with the rule of thumb that five years is required for the full effect a no-till cropping system to be realized.

RUSLE2 computes a loss of the no-till effect that is almost as great with undercutting blade, chisel plow, field cultivator, and disk-type implements that disturb 100 percent of the soil as with soil inversion implements like moldboard plows. About one half of the no-till effect is lost directly through changes in the soil consolidation subfactor and the other half is lost through the effect of the soil consolidation subfactor being used as a variable in the soil biomass subfactor (see Figure 7.3 and equation 9.12).

Table 13.4. No-till effect after long term no-till is moldboard plowed in one year

Time (years) in no-till after moldboard year	Annual no-till effect (soil consolidation subfactor·soil biomass subfactor) weighted by erosivity distribution
1	0.61
2	0.49
3	0.39
4	0.32
5	0.28
6	0.25
7	0.24
8	0.23

All operations in a **cover-management description** are important in determining the degree of the no-till (lack of soil disturbance) effect. A single operation, such as a fertilizer/manure injector that disturbs as much as 50 percent of the soil surface causes RUSLE2 to compute a significantly reduced no-till effect (i.e., values closer to 1 for the product of the soil consolidation and soil biomass subfactors means a reduced no-till effect). The no-till effect is 0.54 where an injector that disturbs 50 percent of the surface is used with a planter that disturbs 15 percent of the surface for no-till 112 bu/acre corn at Columbia, MO. The no-till effect is 0.22 if the injector is not used for.

Multiple occurrences of an operation that minimally disturbs the soil surface in a cover-management description reduce the no-till effect. For example, the no-till effect is 0.22, 0.32, and 0.40 for one, two, and three occurrences, respectively, of a no-till planter on the same day in the Columbia, MO no-till corn example. **Section 9.2.6.4** describes the mathematical procedure that RUSLE2 uses where only a portion of the soil surface is disturbed by an operation. The net effect is similar to RUSLE2 assuming that most, but not all, of the soil disturbance is in an undisturbed area. RUSLE2 does not assume that a planter runs in the same place each year. However, the overlap effect was empirically considered by fitting RUSLE2 to no-till field data so that the expected erosion estimate is computed.

The large effect of the portion of the soil surface disturbed on estimated erosion is illustrated in Figure 9.19. This difference is significant when using RUSLE2 to estimate erosion for wide row (e.g., 30-inch width) no-till planters and narrow row no-till drills (e.g., 7-inch width). The no-till effect is 0.22, 0.30, 0.57, and 0.62 for 15, 25, 65, and 85 percent for portion of the soil surface disturbed, respectively, for a no-till 112/bu/acre corn cropping system at Columbia, MO. These values illustrated that a small change in portion of the soil surface disturbed has a greater effect on estimated erosion when little of the soil surface is disturbed in comparison to when most of the soil surface is disturbed. The soil disturbance characteristics for both wide row and narrow row seeding implements should be very carefully considered in assigning values for **portion of the soil surface disturbed**. The tendency is to assign values that are too low for wide row implements and values that are too high for narrow row implements.

The effect of no-till cropping on soil erosion was analyzed in depth during the development of RUSLE2. To achieve maximum benefits from no-till cropping, the portion of the soil surface disturbed must be minimized.

13.1.5.8. Burial and resurfacing ratios

RUSLE2 assumes that an **operation description** with a **disturb soil process** buries **surface residue** and resurfaces **buried residue** as described in **Sections 9.2.5.3.3 - 9.2.5.5**. RUSLE2 only buries surface residue because standing residue must be flattened before it can be buried. Therefore, if an operation is being used to bury **standing residue**, the operation description must include a **flatten standing residue process** followed by a **disturb soil process**. RUSLE2 only resurfaces buried residue; it does not resurface **live** or **dead roots**.

The processes in an operation description must be entered in the proper sequence. To bury standing residue, proper sequence is flatten standing residue and disturb soil. A reverse order of these processes in an operation description will give a very different result.

The residue mass left on the soil surface after a soil disturbing operation is the **net** between the residue that is buried and the residue that is resurfaced. Having both residue burial and resurfacing components allows RUSLE2 to compute an increase in surface residue after an operation in certain conditions. An example is a field cultivator following a tandem disk and a moldboard plow in a high yield corn **cover-management description**.[113]

Input values for burial and flattening ratios are on a **mass basis** rather than on the

[113] RUSLE1 does not include a resurfacing component in its residue equations. Consequently, RUSLE1 can not compute an increase in residue cover following an operation like a field cultivator. RUSLE1 can not duplicate the residue burial values computed by RUSLE2. The residue burial ratio values used in RUSLE2 differ from those used in RUSLE1 because of the resurfacing component in RUSLE2.

portion of the soil surface covered even though RUSLE2 uses portion of soil surface covered to estimate erosion. RUSLE2 displays values for portion of the soil surface covered (e.g., percent cover) that are useful in conservation and erosion control planning.

The best information for selecting input values for burial and resurfacing ratios is the RUSLE2 **core database**. The values in the RUSLE2 core database have been carefully selected based on research data and the validation of RUSLE2 to ensure that it computes good estimates of surface residue cover immediately after planting and that it computes good estimates of average annual erosion.

Values for net residue burial ratio are widely available in the technical literature. Unfortunately, much of this literature fails to specify whether the values are based on residue mass or portion of the soil surface covered by residue. In many cases, a mixture of the two was unknowingly included because original sources failed to describe the basis for the values. Consequently, many of the widely available and accepted burial ratio values are not appropriate for RUSLE2 use.

Residue burial values based on mass are very different from those based on percent cover because of the strong non-linear relationship between residue mass and the portion of the soil surface covered by a given residue mass.

Residue burial ratio values in the technical literature almost always represent net burial (net effect of burial and resurfacing combined) rather than burial alone as required by RUSLE2. Consequently, RUSLE2 residue burial ratio values are higher than the common values in technical literature.

The net residue burial ratio computed by RUSLE2 for an operation depends on the operations and their sequence in the cover-management description and the soil biomass in the operation's disturbance depth. For example, RUSLE2 computes 17 percent for the net burial ratio for a tandem disk for a 150 bu/acre corn cover-management description where the tandem disk follows a moldboard plow. In contrast, RUSLE2 computes 53 percent for the net burial ratio for the same tandem disk following a chisel plow with straight points. This illustrates a reason for variability in field observed residue net burial ratio values.

Residue burial and resurfacing ratio values must be assigned to operation descriptions not in the RUSLE2 core database. Sometimes adjustments to the values in the RUSLE2 core database may be desired. The value RUSLE2 computes for surface residue mass after a soil disturbing operation is very sensitive to the resurfacing ratio value. Unfortunately, very little research data are available for determining values for the resurfacing ratio. **The best approach is to accept the resurfacing ratio values in the RUSLE2 core database without adjustments.** Residue burial ratio values are adjusted until RUSLE2 computes the desired residue cover following a particular operation.

The proper field data required to determine RUSLE2 residue burial and resurfacing ratio values are where as operation has been repeated three or more times in the same area.[114] A value for the resurfacing ratio can not be determined from a single occurrence of an operation. Repeated occurrences of an operation establish the equilibrium surface residue mass as illustrated in Figure 13.3. The first occurrence of the operation can be used to estimate a residue burial ratio value provided soil biomass is insignificantly low in the operation's disturbance depth.

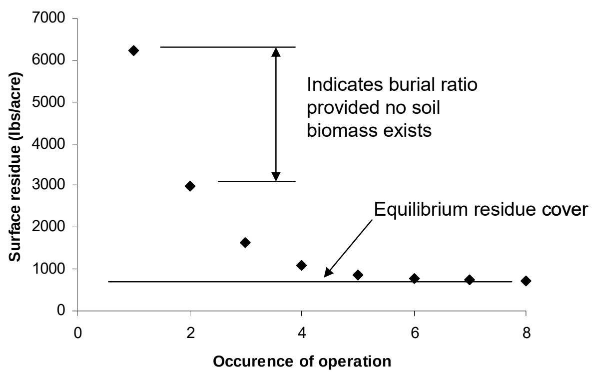

Figure 13.3. Residue burial by repeated occurrences of a field cultivator.

This residue burial ratio value along with the equilibrium surface residue mass can be used to estimate a resurfacing ratio value. The proper procedure for determining values for residue burial and resurfacing ratios is to fit RUSLE2's complete set of residue equations to field data.

Both residue burial and resurfacing ratios are a function of residue type discussed in **Section 12.1**. In general, residue burial ratio values are larger for residue that is in small, fragile pieces that break easily from the forces of a soil disturbing operation. Conversely, resurfacing ratio values are typically larger for residue composed of long, tough pieces. Therefore, size, shape, and fragility (inverse of toughness) all must be considered in selecting both burial and resurfacing ratio values. Rock/gravel is a special case where size and shape is a major factor.

The values in the RUSLE2 core database have been selected to represent the main classes of implements and machines that bury and resurface residue rather than describing specific machines operated in a specific way. The intent with RUSLE2 is to capture main effects within the overall accuracy of RUSLE2. The assigned burial and resurfacing ratio values, regardless of how they were obtained, should be consistent with values in the RUSLE2 core database and with values in the user's working database so that RUSLE2 computes the expected relative effects of the operation on erosion.

[114] Two excellent examples of the type of data needed to determine burial and resurfacing ratio values are: Brown, L.C., R.K. Wood, and J.M. Smith. 1992. Residue management, demonstration, and evaluation. Applied Engineering in Agriculture. 8:333-339.
Wagner, L.E. and R.G. Nelson. 1995. Mass reduction of standing and flat crop residues by selected tillage implements. Transactions of the ASAE. 38:419-427.

The common assumption is that machines can be adjusted to produce almost any desired residue cover. This assumption is often erroneous. RUSLE2 includes relationships discussed in **Section 13.1.5.3** that describe how speed and disturbance depth affect residue burial based on research data. **Input residue burial ratio values outside of the range computed by RUSLE2 on the basis of varying disturbance depth or speed are highly questionable.**

13.1.6. Live biomass removed

The **remove live biomass process** removes live aboveground biomass without **killing** the current vegetation. This process is used in **operation descriptions** used to represent such operations as silage harvest, hay harvest, and mowing permanent vegetation. It's most important use is where a portion, but not all, of the live aboveground biomass is converted to standing and/or surface (flat) residue without killing the current vegetation. Examples include intercropping where one crop is harvested and a second crop continues to grow, volunteer weeds and cover crops that continue to grow after a main crop is harvested, and vegetation that regrows after a mowing or hay harvest. In these cases, some or all of the live root biomass remains, and some or all of the live aboveground biomass remains. The **kill vegetation process** can not be used in **cover-management descriptions** for these vegetation systems because this process converts **all** live aboveground biomass to standing residue and **all** live roots to dead roots, rather than portions of these biomass pools.

RUSLE2 assumes that live aboveground biomass can not be removed without substantially affecting the vegetation. Therefore, RUSLE2 requires that a **begin growth process** or a **kill vegetation process** follow the **remove live biomass process** in an **operation description**. The **begin growth process** identifies the **vegetation description** that RUSLE2 is to use immediately after the operation. If the live root biomass on day zero of the new vegetation description is less than the live root biomass on the last day that the previous vegetation description was used, **the difference is added to the dead root biomass pool because the operation is assumed to have killed a portion, but not all, of the current vegetation.**

Changes in aboveground biomass caused by the operation are described using the input values for the variables that describe the remove live biomass process. These variables are portion of live aboveground biomass **affected** by the operation, portion of the affected biomass left as **surface (flat) residue**, and portion of the affected biomass left as **standing residue**. Although the biomass removed from the local area (field, site) is not important to RUSLE2, this variable is used for user input convenience. RUSLE2 needs a description of the biomass at the site at any particular time to compute erosion. Thus, the biomass left behind either as remaining live biomass and residue after the operation are key variables. The values in the vegetation description identified by the **begin growth process** in the operation description describe the vegetation variables that affect erosion after the operation. Therefore, the remove live biomass process tells RUSLE2 how much residue is left behind for an operation that affects the current vegetation but does not kill it.

Table 13.5 illustrates the input values for three typical operation descriptions where the **remove live aboveground biomass process** is used. The first example is mowing permanent vegetation where the biomass above the cutting height is left as surface residue and the vegetation regrows after the mowing. The amount of live biomass affected is the biomass above the cutting height. The affected biomass is assumed to be 50 percent of the total live aboveground biomass at the time of the mowing. All of the cut (affected) biomass is assumed to become surface residue. Thus, the input for portion of the affected biomass that becomes surface residue is 100 percent. The input is zero for the portion of affected biomass that is left as standing residue because the operation creates no standing residue. A **begin growth process** follows the **remove live biomass process** in the operation description to identify the vegetation description that RUSLE2 uses immediately after mowing. The canopy cover is reduced to reflect the mowing but the live root biomass remains the same between the current vegetation description and the new one.

Table 13.5. Input values for three operation descriptions that use the remove live aboveground biomass process (values on a dry matter basis)

Operation	Live aboveground biomass at time of operation (lbs/ac)	Live aboveground biomass affected (%)		Surface residue left by operation		Standing residue left by operation	
		Portion (%)	Mass (lbs/ac)	Portion (%)	Mass (lbs/ac)	Portion (%)	Mass (lbs/ac)
Mowing permanent vegetation that regrows	3,000	50	1,500	100	1,500	0	0
Legume hay harvest, hay regrows	2,000	95	1,900	5	95	0	0
Harvest small grain in a small grain-legume hay intercropping system	5,000	80	4,000	50	2,000	50	2,000

Note: Values for Portion are user entered input values. Mass values are computed by RUSLE2.

The second example is a legume hay harvest that removes live aboveground biomass and where the legume hay crop regrows after the hay harvest. In this example, 95 percent of the live aboveground biomass on the day of the operation is assumed to be affected. Only a small amount of stubble is left unaffected. The amount of the live aboveground biomass that is affected is 1,900 lbs/acre (= 2,000·95/100). All of the affected biomass is removed from the field except for five percent, which is 95 lbs/acre (= 1,900·5/100), that remains as surface residue. None of the affected biomass is left as standing residue. The surface residue left in the field is from leaf shatter and inefficiencies of the harvesting machines. The operation description includes a **begin growth process** immediately after the **remove live biomass process**. The **begin growth process** identifies the vegetation description that RUSLE2 is to use after the hay harvest. The canopy cover on day zero will be very low because the harvest left nothing but very short stubble. The root biomass does not change between the two vegetation descriptions because the hay harvest has no effect on live root biomass.

The third example is for an intercrop of small grain and legume hay. The small grain is seeded in the fall and the legume hay is seeded in late winter. The small grain is harvested in late spring, which kills that portion of the vegetation. The legume continues to grow after the small grain harvest to be killed by a hay harvest in late summer. The small grain harvest is represented with an operation description that includes a remove live biomass process followed by a **begin growth process**. The total live aboveground biomass at the time of the small grain harvest is 5,000 lbs/acre. Eighty percent (= 5,000·80/100 lbs/acre) of the total live aboveground biomass is affected by the small grain harvest. Half (50 percent) of the affected biomass is left as surface residue, which represents the straw discharged by the combine that harvested the small grain. The other half (50 percent) of the affected biomass is left as standing residue, which represents the standing small grain stubble left by the harvest. The **begin growth process** identifies the vegetation description that applies after the small grain harvest. Both the canopy cover and effective fall height values on day zero in the new vegetation description are reduced slightly from the values on the last day that the previous vegetation description was used. The legume already has a sufficient understory by the time of the small grain harvest that the legume is the major determinant of canopy cover and effective fall height (see **Section 9.2.1**). The live root biomass on day zero in the new vegetation description is significantly reduced from that on the last day for the previous vegetation description, which represents the combined small grain-legume hay vegetation. RUSLE2 assumes this difference to be dead root biomass created by the small grain harvest.

Relative (fractions, percents) rather than absolute variables are used to describe the remove live biomass process. Using an absolute variable like height above which the biomass is removed (e.g., cutting height) could be used for common machine operations like mowing and hay harvest. However, using an absolute height as an input variable also requires user entered values for vegetation height and user entered values or user selected relationships that describe the distribution of the vegetation's biomass within the plant height. The judgment of the RUSLE2 developers was that users could more easily estimate the portion of total plant biomass involved in a remove live aboveground biomass process than users could determine the distribution of biomass within the plant height. Furthermore, relative variables generalize RUSLE2, which gives RUSLE2 additional power and broadens its applicability. For example, RUSLE2 can be used to evaluate operations like hand picking of leaves over the entire canopy, which can not be described using an absolute height approach where all biomass above a given height is affected. Also, this approach gives the user direct control of aboveground biomass values that RUSLE2 uses in its computations.

Unfortunately the relative variable approach means that input values that describe the remove live biomass process are functions of the height above which the biomass is removed, vegetation type, and stage of growth. For example, a particular mower is operated at the same height regardless of the vegetation and its stage of growth. The portion of the biomass affected might be 90 percent for mature, tall weeds but less than 50 percent for early growth weeds and some grasses. Users should develop typical operations that use the remove live biomass process for several vegetation types and conditions.

Values in the RUSLE2 **core database** can be used as a guide for selecting input values for the remove live biomass process. Input values should be checked by making RUSLE2 computations to ensure that the values give expected standing and surface residue amounts. Input values should also be checked for consistency with values in the RUSLE2 core database and values in the user's working database.

Input values for the remove live biomass process are selected considering that the RUSLE2 objective is to describe a field condition rather than to model (simulate) the condition.

13.1.7. Remove residue/cover

The **remove residue/cover process** removes standing and surface (flat) residue. This process is used in **operation descriptions** such as burning and baling straw where a preceding operation description has created standing and/or surface (flat) residue. This process is also used in operation descriptions to represent silage and hay harvests where the current vegetation is live at the time of the operation. A **kill vegetation process** must precede the **remove residue/cover process** in a silage or hay harvest operation description to convert the live aboveground biomass to standing residue and/or surface (flat) residue. **The remove residue/cover process only removes standing and surface (flat) residue**; it does not remove live aboveground biomass. See **Section 13.1.6** for information on how to remove live aboveground biomass.

The three variables used to describe the remove residue cover process are: (1) are all residues affected, (2) portion of surface (flat) residue removed, and (3) portion of standing residue removed.

The first variable is related to how many residue applications on the surface that are to be removed. A **cover-management description** may involve several **residue descriptions** when multiple vegetation descriptions are involved. (e.g., corn, soybean, wheat). Multiple residue descriptions may also be involved when residue is added with the **add other cover process** (see **Section 13.1.8**). Added residues include manure spread on the soil surface and surface applied mulch, such as wheat straw, woodchips, erosion control blankets, and rock.

The input **yes** for the variable **are all residues affected** tells RUSLE2 to remove the same portion of all residues regardless of source, age, or how the residue was placed on the soil surface. An example operation description for this **yes** input is a burning operation that removes some of all residues that are present at the time of the operation.

An example of a **no** input is for a baling straw operation description in a cover-management description for a corn-soybean-wheat crop rotation. The baling straw operation description follows a wheat harvest operation description that kills the wheat to create standing and surface (flat) residue.[115] The **no** input tells RUSLE2 to only remove a portion of the wheat residue, which is the **last** residue description considered by RUSLE2 before the baling straw operation. Residue from previous crops of corn, soybeans, and wheat would not be removed. That is, the **no** input causes only the most recent residue application to be affected.

Inputs for the second and third variables are for the portions of the surface (flat) and standing residue that are removed by the remove residue/cover process. **These variables are on a dry mass basis**. In the baling straw operation description, a zero (0) is entered for the portion of the standing stubble removed because the baling operation has no effect on the standing straw stubble left after the wheat harvest other than to flatten it. If the **flatten standing residue process** occurs in the operation description before the remove residue/cover process, RUSLE2 will remove a portion of the surface (flat) residue created by the **flatten standing residue process** along with the same portion of the other surface (flat) residue.

In the burning operation description, a value of 90 percent is entered for the portion of the standing stubble removed by burning and 25 percent is entered for the portion of the

[115] The processes that describe the wheat harvest and the baling straw operations could be combined into a single operation description provided the harvest and straw baling operations occurred within a few days of each other before residue biomass decreases significantly by decomposition.

surface (flat) residue removed. The reason for the different input values is that the standing residue is assumed to be dry and to burn much more completely than the surface residue that is in contact with soil.

RUSLE2 can remove **buried residue**, but the residue must first be resurfaced with an operation description that includes a **disturb soil process** (see **Section 10.26**). Once the buried residue has been resurfaced as surface (flat) residue, it can be removed with an operation description that includes a remove residue/cover process. Dead roots can not be removed because RUSLE2 has no direct way to remove dead roots and dead roots can not be brought to the surface with a disturb soil process.

Values in the RUSLE2 **core database** can be used to guide the selection of input values for the remove residue/cover process. RUSLE2 computations should be made with the selected input values to ensure that RUSLE2 computes the expected residue cover left by the operation with a remove residue/cover process. Also, input values for the process should be checked for consistency with comparable values in the RUSLE2 core database and the user's working database.

13.1.8. Add other cover

The **add other cover process** is used in **operation descriptions** to place material that affects erosion on the soil surface and in the soil.[116] Typical operations descriptions using this process describe applying mulch on construction sites and in strawberry fields and manure and organic municipal and industrial waste (e.g., papermill waste) to crop and other lands.

The **add other cover process** involves three variables. Two variables are the description of the material added and the amount (dry mass basis) of the material added. These inputs are entered in the **cover-management description** that contains the operation description that uses the add other cover process (see **Section 10.6**). The entry for the type of material added, referred to as **external residue**, is selected from the list of **residue descriptions** in the **residue component** in the RUSLE2 database (see **Section 12**). The material added by this process has sufficient size to reduce the erosive forces of raindrop impact and runoff. Also, the material is generally assumed to be organic (biomass) that decomposes and affects erosion similarly to the decomposition of crop residue and plant litter. The procedure for handling non-organic material such as rock and synthetic erosion control blankets applied to the soil surface to control erosion is described in **Section 12.4**.

The third input, which describes the **add other cover process** itself, is the portion (dry

---

[116] This process is **not** used to add irrigation water (e.g., see **Sections 6.3.4, 10.2.4**). Also, this process is **not** used to represent the addition of chemical compounds that affect soil erodibility. That effect must be represented by adjusting soil erodibility factor values (see **Section 7.3**)

mass basis) of the material that is added to the soil surface. RUSLE2 places the remainder of the added material in the soil. A 100 percent value is used to represent applying straw mulch at a construction site, for example, where none of the material is incorporated into the soil. A value less than 100 percent instructs RUSLE2 to place some of the material in the soil. A zero (0) value places all of the added material in the soil.

If the **add other cover process** places some of the added material within the soil, a companion **disturb soil process** must immediately follow the **add other cover process** in the operation description. RUSLE2 assumes that the soil must be disturbed for material to be placed in the soil, which resets the soil consolidation subfactor to 1 for the portion of the soil surface disturbed except when a **compression tillage type** is assumed.[117] Material placed in the soil using the **add other cover process** is placed in the lower one half of the disturbance depth as illustrated in Figure 9.16. The value for disturbance depth is entered in the **disturb soil process** that follows the **add other cover process** in the operation description.

13.1.9. Add non-erodible cover

RUSLE2 describes the effect of both erodible cover and non-erodible cover. **Erodible cover** is surface cover provided by residue and live ground cover. Residue includes material left by vegetation growth, applied mulch, erosion control blankets, and rock. These materials are referred to as erodible covers because RUSLE2 computes erosion even when these materials completely cover (100 percent cover) the soil surface.

> **The *add non-erodible cover process* can not be used to represent the application of erosion control blankets and similar materials. That effect is represented using the *add other cover process*.**

In contrast, RUSLE2 computes no erosion for **non-erodible cover** for the portion of the soil surface covered by these materials. Consequently, RUSLE2 computes no erosion when these materials completely cover the soil surface. Examples of non-erodible cover include plastic sheeting used in vegetable production, a water depth produced by flooding rice fields, and deep snow.

RUSLE2 assumes a linear relationship between erosion and non-erodible cover, in contrast to the non-linear relationship illustrated in Figure 9.4 for surface residue. Therefore, erosion varies linearly with non-erodible cover as it disappears over time.

[117] An exception is that a **compression tillage type** can be selected in the **disturb soil process** to place material in the soil without resetting the soil consolidation subfactor value to 1. However, this tillage type is specifically meant to describe the effects of animal traffic, sheep's foot soil compaction machines, and similar operations and not meant to describe injection of manure and fertilizer by typical machines used in these operations.

A non-erodible cover is also used to “shut off” RUSLE2’s erosion computations for certain periods. An example is turning off erosion computations during winter periods during frozen soils and/or snow cover. Another example is turning off erosion computations for periods when the RUSLE2 annual computational period does not correspond with the erosion control planning period. Some erosion control regulations for constructions sites require a certain level of erosion control between the date of final grading and the date that vegetation reaches a particular canopy cover. The assumption is that erosion control is adequate once the vegetation reaches a certain canopy cover. Thus, erosion computations are turned off for dates beyond the end date based on canopy cover.

13.1.9.1. Applications of add non-erodible cover process

The **add non-erodible cover process** is used in **operation descriptions** to cause RUSLE2 to compute no (zero) erosion for the portion of the soil surface covered by the non-erodible cover. Example applications include applying strips of plastic mulch in vegetable production, applying ponded water in rice production, representing no erosion during snow cover, and setting computed erosion to zero for computational purposes.[118] An operation description with a **remove non-erodible process** is used to remove non-erodible cover when the period of no erosion ends.

An example of using the **add non-erodible cover process** for computational purposes is a construction site where the overland flow path changes during construction and reclamation. The first analysis period represents the exposed hillslope from clearing and scalping until the topography is reshaped. The second analysis period represents the time after the hillslope is reshaped and erosion control practices are applied before permanent vegetation becomes established. The third analysis period is for mature, fully established vegetation.

Reshaping the hillslope creates a new overland flow path, which requires multiple sets of RUSLE2 computations because RUSLE2 can not change overland flow paths during a **cover-management description**. In this example, a cover-management description is created for each analysis period, and a RUSLE2 computation is made for each overland flow path using the corresponding **soil**, **cover-management**, and **support practice descriptions**. Table 13.6 outlines the three RUSLE2 computations for this example.

The date that RUSLE2 starts its computations must be set first. RUSLE2 operates and accounts for erosion on an annual basis. In this example, the 9/1/0 start date is set one year before the day that the hillslope is reshaped that creates a new overland flow path. The date that the hillslope is reshaped is the reference date in this example. **Section**

[118] This procedure is used in RUSLE2 to set erosion to zero. The comparable procedure used in RUSLE1 to set erosion to zero was to enter a 100 percent canopy cover at a zero fall height. This RUSLE1 technique can not be used in RUSLE2 (see **Section 9.2.1**).

10.2.1.3 describes procedures that can be used to cause RUSLE2 to start tracking time on a particular date.

The first RUSLE2 computation must end on the day before the new overland flow path is created. The erosion that RUSLE2 computes between 9/1/0 and 4/15/1 must be excluded from RUSLE2's accounting of erosion. This erosion is excluded by using an operation description that adds non-erodible cover on 9/1/0 and an operation description that removes the non-erodible cover on 4/15/1. The non-erodible cover causes RUSLE2 to set erosion to zero during this preliminary period. This approach starts RUSLE2's erosion accounting on 4/15/1 with the clearing and scalping of the hillslope.

Table 13.6. RUSLE2 computations for a construction site example where the overland flow path changes during construction and reclamation

RUSLE2 computation	Date	Event	Overland flow path	Cover-management description	Soil descriptio n
1	9/1/0	RUSLE2 starts tracking time	Natural topography	Non-erodible cover	Natural soil profile
	4/15/1	Cleared and scalped		Bare soil, freshly disturbed	
2	9/1/1	Reshaped, temporary erosion control, permanent vegetation seeded	Reshaped topography	Graded, temporary erosion control applied, permanent vegetation seeded	Highly disturbed
3	9/1/4	Permanent vegetation becomes established		Mature vegetation conditions	

Notes:

1. The first date is set so that RUSLE2's annual erosion accounting for the first period ends on the last day before the topography is reshaped that creates a new overland flow path.
2. NRCS soil survey data applies to the natural topography. Soil conditions after reshaping are highly disturbed, which requires use of the RUSLE2 modified soil erodibility nomograph.
3. Cover-management conditions after reshaping could be described with a single cover-management description rather than two as illustrated.

The second analysis period begins on the date (9/1/1) that the hillslope is reshaped and a new overland flow path is established. The third analysis period begins when the vegetation has become mature and fully established (see **Section 11.2.6**). The last two analysis periods can also be combined into a single period using a single cover-management description.

An alternative approach is to start RUSLE2's tracking time on the clearing and scalping date (4/15/1). However, because of RUSLE2's annual accounting, it will include erosion computed from 4/15/1 through 4/14/2 using the first overland flow path. The computed erosion from 9/1/1 through 4/14/2 must be excluded in RUSLE2's erosion accounting to obtain an erosion estimate for just the 4/15 to 9/1 period. This erosion can be excluded by using an operation description that adds non-erodible cover on 9/1/1.

The accounting date in RUSLE2 computations for the second analysis period can start on 9/1 by having the first date in the cover-management description be on 9/1 or it can start on 4/15 if an erosion estimate is needed for each year starting on 4/15. To start RUSLE2's accounting on 4/15/1 for the second analysis period, use an operation description that adds non-erodible cover on 4/15/1 and an operation description that removes the non-erodible cover on 9/1/1. RUSLE2 will set erosion to zero during this period when non-erodible cover is present. The estimated erosion for the period 4/15/1 to 4/14/2 can be obtained by adding the annual erosion from these two RUSLE2 computations.

13.1.9.2. Variables used to describe add non-erodible process

The variables used to describe the **add non-erodible cover process** are the portion of the soil surface covered by the non-erodible cover, half-life of the cover, and permeability of the cover. The value entered for the **portion of the soil surface covered** is the portion of the total area having zero erosion because of the non-erodible cover. This value is 100 percent for applying ponded water on rice fields or for the computational purpose described above where erosion is to set to zero for the entire area. Erosion is set to zero on the entire area. The value is less than 100 percent when strips of plastic are applied in a vegetable field resulting erosion being set to zero for only a portion of the total area.

Half-life is the time required for half of the non-erodible cover to disappear based on a simple exponential relationship involving time. RUSLE2 does not compute the loss of non-erodible material as a function of environmental conditions as it does for residue. The value entered for half-life must represent how local site conditions, such as ultraviolet radiation, temperature, or precipitation, affect loss of the non-erodible cover. Thus, input values for half-life for non-erodible cover can vary with location.

The loss of non-erodible cover is computed solely on an area basis, although mass per unit should be considered in assigning half-life input values. RUSLE2 does not use a mass-cover relationship for non-erodible cover like it does in residue descriptions.

A very large value, such as 1,000,000 days is input for half-life where non-erodible cover does not disappear over time. Refer to manufacture's literature for selecting input values for plastic and similar products. A half-life value can be used to approximate the loss of snow cover, but using RUSLE2 to compute erosion by snowmelt is questionable (see **Sections 6.9.1 and 6.11**). Selected input half-life values should be checked by making RUSLE2 computations to ensure that RUSLE2 computes the expected non-erodible cover over time for the conditions where RUSLE2 will be applied.

Although RUSLE2 computes no erosion for the portion of the soil surface covered by the non-erodible cover, RUSLE2 needs information on how non-erodible cover affects runoff. Deposition computed by RUSLE2 on concave-shaped overland flow paths, behind dense strips of vegetation, and in terrace channels is a function of runoff. If non-erodible cover significantly increases runoff, the computed deposition amount may be significantly reduced. RUSLE2 uses the value entered for non-erodible cover permeability and portion of the soil surface covered by the non-erodible cover to compute runoff.

The input value entered for **non-erodible cover permeability** is the portion of the precipitation that passes through the cover. Many non-erodible covers, such as plastic used in vegetable production and ponded water in rice fields, are impermeable. A value of zero (0) is entered for those materials. If all of the precipitation passes through the cover, 100 percent is entered. An input value less than 100 percent is entered when some but not all of the precipitation passes through the non-erodible cover. For example, 50 percent is entered if half of the precipitation passes through the non-erodible cover and the other half runs off the cover onto the soil surface.

Non-erodible cover such as plastic on the top of beds in vegetable fields completely eliminates both interrill and rill erosion. However, significant rill erosion can occur where runoff accumulates and flows onto the portion of the soil surface not covered. Also, runoff can accumulate under non-erodible cover to cause erosion. Therefore, the presence of non-erodible is not sufficient *alone* to completely eliminate erosion in all situations.

13.1.10. Remove non-erodible cover

The **remove non-erodible cover process** is used in **operation descriptions** to remove part or all existing non-erodible cover. The single variable used to describe this process is the portion of the non-erodible cover that is removed by the process. An input value of 100 percent completely removes non-erodible cover. An input value less than 100 percent removes that portion of the non-erodible cover. For example, assume that non-erodible cover is 62 percent and 50 percent is the input value for portion removed. The non-erodible cover after the removal operation will be $62\% \cdot 50\%/100 = 31\%$. The non-erodible cover may have covered 100 percent of the soil surface when it was initially applied, but it only covers 62 percent of the soil surface on the removal date because of loss by ultraviolet radiation or other processes.

14. SUPPORT PRACTICES DATABASE COMPONENTS

Support practices include contouring (ridges around the hillslope), filter and buffer strips (strips of dense vegetation on the contour), rotational strip cropping (a system of equal width cropping strips that are annually rotated with position along the overland flow path), terraces and diversions (ridges and channels that divide the overland flow path, collect runoff, and redirect it around the hillslope), and small impoundments (impoundment terraces and sediment traps). These practices are referred to as support practices because they are used to support primary cultural erosion control practices based on vegetation, crop residue, plant litter, and applied mulch. The effect of cultural erosion practices on erosion is described with the cover-management variables (see **Section 10**). Most support practices affect rill and interrill erosion and sediment delivery by reducing runoff's erosivity and transport capacity by redirecting the runoff around the hillslope; dividing the overland flow path that reduces the accumulation of runoff; slowing the runoff with strips of rough soil surface, heavy surface residue, or dense vegetation; and capturing and ponding runoff.

RUSLE2 computes how support practices affect **interrill** and **rill erosion** and **sediment yield** at the end of the flow path represented in a RUSLE2 computation (see **Sections 5.1, 5.3.1, 8.2.5**). Most properly designed, installed, and maintained support practices also reduce ephemeral gully erosion. However, RUSLE2 is not a conservation or erosion control planning tool for ephemeral gully erosion because RUSLE2 does not estimate ephemeral gully erosion.[119] RUSLE2 gives partial, indirect credit for reduction of ephemeral gully erosion by contouring and rotational strip cropping. Some of the data used to empirically derive RUSLE2's contouring relationships were measured on small watersheds, less than about 5 ac in size, where ephemeral gully erosion occurred on the non-contoured experimental watershed.

The benefits of support practices for controlling ephemeral gully can only be considered using a procedure other than RUSLE2.

Each support practice affects erosion and sediment delivery in a unique way. Therefore, each major support practice is discussed individually.

14.1. Contouring (ridge orientation relative to overland flow path)

14.1.1. Description of practice

[119] Conservation planners sometimes assume that the USLE and RUSLE1 describe all erosion that occurs within farm fields, which is not the case with these prediction technologies or with RUSLE2. Ephemeral gully erosion is not estimated with any of these technologies and can amount to one half or more of the total sediment production that occurs within field sized areas.

Contouring is the creation of ridges and furrows by tillage equipment, earth moving machines, and other soil disturbing operations to redirect runoff from a path directly downslope to a path around the hillslope.[120] Grade along the furrows is zero when contouring is “perfectly on the contour,” which results in runoff spilling uniformly over the ridges along their length. If furrow grade is not level, runoff flows along the furrows until it reaches low ridge heights or local low areas on the hillslope. The runoff break over ridges in these locations as illustrated in Figure 8.13.

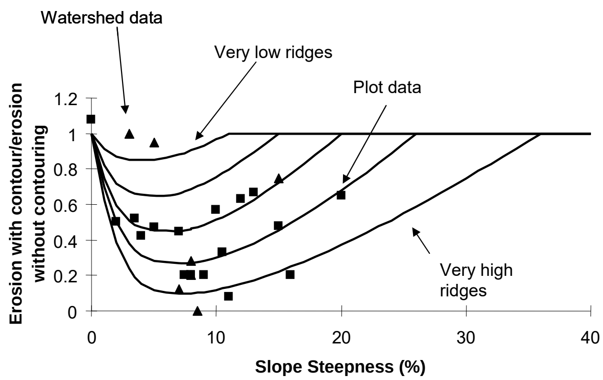

Figure 14.1. Experimental data on how contouring affects erosion.

Section 8.3.6 describes the three RUSLE2 methods that can be used to estimate how contouring affect erosion. The first two methods apply where the ridges are so high, well defined, and on a sufficiently uniform grade that runoff flows to major concentrated flow areas on a hillslope before overtopping the ridges. Application of these two methods is based on a detailed overland flow path description. The **third method** is for typical ridges left in farm fields by tillage equipment like tandem disks, chisel plows, and field cultivators and on reclaimed mined land and other highly disturbed lands by ridgers. This method uses the RUSLE2 relationships that describe contouring (ridging) as a support practice and a overland flow path description based on a flat soil surface.

14.1.2. Basic principles

RUSLE2 uses a daily value for the contouring factor p_c in equation 8.1 to compute the effect of contouring. This subfactor is the ratio of erosion with contouring to erosion without contouring. A value of 1 means that contouring has no effect on erosion. The value for the contouring subfactor is lowest when contouring has its greatest effect on erosion.

The effect of contouring on erosion that was measured on research plots and watersheds is illustrated in Figure 14.1. The effect of contouring varied greatly among the studies.

[120] Contouring in RUSLE2 refers to how orientation of ridges with respect to the overland flow path affects erosion. Standards for erosion control practices published by organizations like the USDA-Natural Resources Conservation Service require that ridging meet certain specifications to be considered the specific erosion control practice of contouring.

For example, contouring reduced erosion as much as 90 percent in one study but did not reduce erosion in another study also conducted on a 6 percent slope steepness.

Information from the research studies represented in Figure 14.1 and from other research studies was not sufficient to empirically derive RUSLE2 contouring relationships. The data were sufficient, however, to identify the main variables that determine how contouring affects erosion. That basic information, along with accepted erosion scientific knowledge and scientific and technical judgment were used to develop the mathematical relationships used in RUSLE2 to compute how contouring affects rill and interrill erosion.

14.1.2.1. Steepness

The first variable considered in developing the equations used to describe the contouring effect illustrated in Figure 14.1 was slope steepness. Contouring does not affect erosion at a flat slope because no preferred runoff path exists. Contouring also has no effect at very steep slopes because the ridge top is at a lower elevation than the ridge base (furrow) on the upper side of the ridge as illustrated in Figure 14.2. The ridge top elevation relative to the elevation of the upslope furrow is a function of both slope steepness and ridge height, which determine the slope steepness that contouring loses its effectiveness.

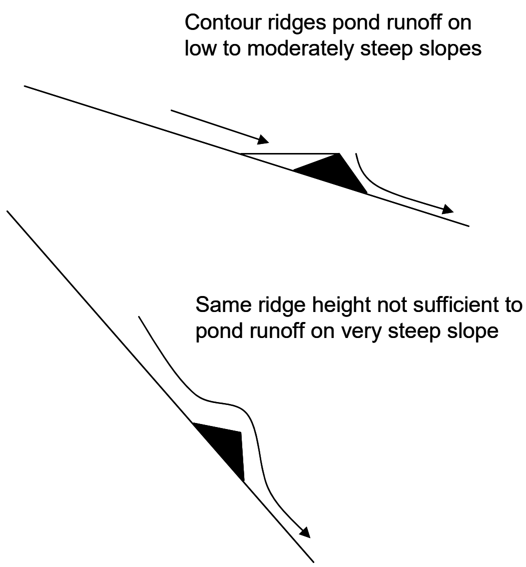

Figure 14.2.Effect of slope steepness and ridge height on contour ridges ponding runoff.

The general shape of the RUSLE2 relationship for contouring's effect on erosion is illustrated in Figure 14.1. The curve decreases from a value of 1, which means that contouring has no effect on erosion, for a flat slope (zero steepness) to a minimum value at a moderate slope steepness, which is the slope steepness that contouring has its greatest reduction on erosion. The curve increases from the minimum value to 1 (no effect) at a steep slope based on the concept that the steepness is so great that no runoff is ponded as illustrated in Figure 14.2 (see AH537, AH703).[121]

14.1.2.2. Ridge height

[121] The relative effect of slope steepness on contouring in RUSLE2 is the same as that in the USLE. The middle curve in Figure 14.1 is very similar to the contouring-slope steepness effect in the USLE (AH537).

The second variable considered was ridge height. The basic concept is that contouring's effect on runoff and erosion is a function of ridge height. Figure 14.2 illustrates the concept for steep slopes. Field data from research plots also showed that erosion decreased as ridge height increased. The ridges on these plots were perfectly on the contour on a moderate slope steepness. The overall variability illustrated in Figure 14.1 for the effect of contouring on erosion was interpreted as being caused by a variation in ridge height.

Contouring is assumed to lose its effectiveness over time as ridge height decays. In RUSLE2, ridge height decays after it is created because water from precipitation causes the soil to subside and as interrill erosion erodes the ridges (see **Section 9.2.4.3**).

Experimental data involving wheat and soybeans showed that closely spaced stems in rows on the contour affect erosion much like soil ridges on the contour. Therefore, RUSLE2 adds an effective vegetative ridge height to the soil ridge height to give an overall ridge height that is used by RUSLE2 to compute the effect of contouring on erosion. The effective vegetative ridge height increases as vegetative retardance increases, which is a function of the retardance class assigned in the vegetation description (see **Section 11.1.4**), yield (production) level, and growth stage.

14.1.2.3. Storm severity and runoff

Experimental plot data showed that contouring's effectiveness (p_c) is greater for small storms than for large storms (i.e., p_c values are less for small storms than for large storms). One reason for this difference in effectiveness is that a higher percentage of the excess rainfall (rainfall in excess of infiltration) is stored in ponded runoff behind the ridges for small storms than for large storms. Similarly, contouring reduces erosion more for low runoff amounts than for high runoff amounts. Therefore, RUSLE2 computes values for the contouring subfactor p_c that decrease as runoff depth decreases.

The minimum contouring factor value at the low point of each curve illustrated in Figure 14.1 is reduced linearly with runoff depth. Also, the slope steepness above which contouring has no effect on erosion is computed as a function of runoff depth raised to the 0.857 power. This power is based on the assumption that the maximum slope steepness at which contouring is effective for a given ridge height is a function of the shear stress that the runoff applies to the soil. The runoff variable used by RUSLE2 to compute contouring subfactor values is the ratio of runoff computed for the site specific condition to runoff computed for the base condition of a moldboard plowed, clean tilled, low yielding corn grown on a silt loam soil in Columbia, MO (see **Section 8.1.2**).

Field data from contouring on small watersheds (less than five acres) in the south central US showed that the effectiveness of contouring is related to storm severity. The data showed that erosion with contouring can be greater for very intense storms than for a comparable non-contoured situation. The intense storms caused much ridge breakovers, concentration of overland flow in a few rills which causes increased rill erosion, and a cascading effect similar to dam failures releasing water. These effects partially accounts for contouring subfactor values being greater than 1 in Figure 14.1. Also, moderate and large storms cause most of the erosion. The 24-hour precipitation amount with a 10-year return period rather than a precipitation amount based on an average annual return period is used in RUSLE2 to compute runoff depth. The 10-year return period captures how a more severe than average annual storm has a dominant effect on how much contouring reduces erosion.

The RUSLE2 computed contouring subfactor values vary daily as cover-management conditions change. The runoff curve number is a key variable in the NRCS runoff curve number method. RUSLE2 computes values for the curve number as a function of surface roughness, ground cover, soil biomass, and soil consolidation, which in turn means that runoff and contouring subfactor values vary daily in RUSLE2.

14.1.2.4. Relative row grade (ridge-furrow orientation relative to overland flow path)

In this RUSLE2 procedure for computing how contouring affects erosion, the overland flow path is determined assuming a flat soil surface without ridges. The contouring subfactor p_c value is 1 by definition for a ridge-furrow orientation directly **up and down hill** (parallel to the overland flow path). Contouring subfactor values are less than 1 when the ridge-furrow orientation is **perfectly on the contour** (perpendicular to the overland flow path).[122] **Relative row grade**, which is the ratio of absolute row (furrow) grade to the overland flow path steepness, is RUSLE2's measure of ridge-furrow orientation to the overland flow path.[123] A relative row grade of 1 means that the ridge-furrow orientation is up and down hill parallel to the overland flow path, and a relative row grade of zero (0) means that the ridge-furrow orientation is perfectly on the contour and perpendicular to the overland flow path. A 0.1 relative row grade means that the ridge-furrow orientation is slightly off contour, and a 0.5 relative row grade means that the ridge-furrow orientation is half way between being perfectly on the contour and up and down hill.

---

[122] The **cover-management description** must include a **soil disturbing operation description** that creates ridges with a greater than zero height for RUSLE2 to compute a contouring subfactor value less than 1. That is, ridges with a height greater than zero must be present for RUSLE2 to compute a contouring effect.
[123] Even though absolute row grade can be entered into RUSLE2, RUSLE2 uses relative row grade to compute how ridge-furrow orientation to the overland flow path affects erosion.

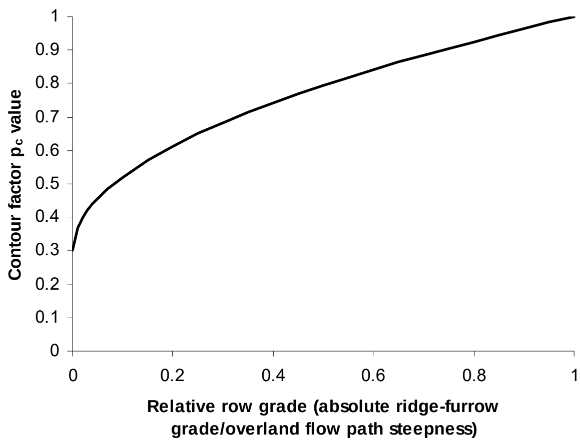

Figure 14.3. Effect of relative row grade on the contouring subfactor p_c.

RUSLE uses the empirical relationship illustrated in Figure 14.3 to compute contouring subfactor p_c values for ridge-furrow orientations between these two extremes. The assumption implicit in Figure 14.3 is that contouring rapidly loses effectiveness as ridge-furrow orientation deviates from being perfectly on the contour (i.e., as relative row grade increases from zero). This assumption is supported by the limited research data available for validation.

14.1.2.5. Contouring failure (critical slope length)

Contouring fails and totally loses its effectiveness when the combination of runoff rate and steepness along the overland flow path becomes too great for the given cover-management condition. The high contouring subfactor values in Figure 14.1 represent such failure based on the description of the field conditions in the research report. On simple uniform overland flow paths where soil, steepness, and cover-management do not vary spatially, a **critical slope length** is defined as the location along the path where contouring fails from that location through the end of the overland flow path. The contouring subfactor value for the upper portion of the overland flow path from its origin to the critical slope length location is the RUSLE2 computed values for contouring (i.e., contouring is fully effective). The contouring factor value is set to 1 for the portion of the overland flow path from the critical slope length location to the end of the path (i.e., contouring has completely failed). The contouring subfactor makes a step increase, rather than a gradual increase, at the critical slope length location as illustrated in Figure 14.4. Contouring subfactor values do not vary with distance along the overland flow path because RUSLE2 contouring subfactor values are based on runoff depth, not runoff rate.

RUSLE2 does not compute contouring failure and a critical slope length if the overland flow path length is sufficiently short. ***Also, contouring failure and critical slope length are not a function of ridge height or soil erodibility properties.***

RUSLE2 assumes contouring failure when the runoff applies a shear stress to the soil in the ridges that exceeds a critical shear stress related to ridge stability.[124] The shear stress

[124] Shear stress applied to the soil is a frictional type force per unit area much like the frictional force felt

applied to the soil by runoff **increases** as runoff rate and steepness of the overland flow path increase and **decreases** as total hydraulic roughness provided by cover-management increases.[125] Runoff rate is a function of both runoff depth and location along the overland flow path (see **Section 8.1.2**). Shear stress applied to the soil decreases as cover-management intensity increases because of the effect of cover-management on both runoff depth (hence, runoff rate) and the total hydraulic roughness (see **Section 14.2.3**).[126] Contouring failure increases and critical slope length decreases for a given cover-management condition as steepness of the overland flow path increases. Contouring failure increases with a change in location where storm erosivity represented by the 10-year, 24 hour precipitation amount increases. Conversely, contouring failure is reduced by increased soil surface cover, soil-surface roughness, and vegetation retardance and cover-management practices that reduce runoff, all of which reduce runoff's shear stress that causes contouring failure. Contouring failure on long overland flow paths is reduced by changing cover-management conditions that reduce runoff's shear stress and/or by dividing the overland flow path with terraces/diversions.

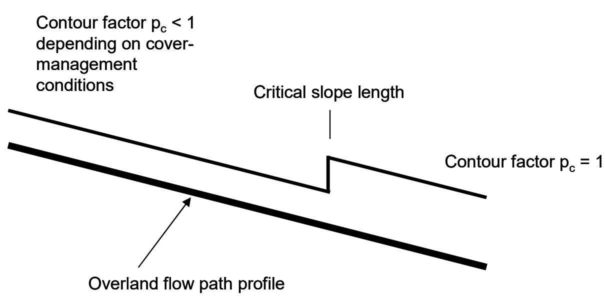

Figure 14.4. Illustration of critical slope length and contouring subfactor values for a uniform overland flow path.

Depending on conditions, RUSLE2 computes zones of contour failure along complex overland flow paths, like that illustrated in Figure14.5. Contouring failed in the mid-portion of the overland flow path because of the combination of runoff rate (represented by distance from the path origin) and steepness. Runoff's shear stress acting on the soil exceeds the soil's critical shear stress in this zone. Contouring does not fail on the upper portion of the overland flow path. The combination of runoff rate and steepness is low because distance is short even though steepness becomes large. Contouring failure ends on the lower portion of the overland flow path because the combination of runoff rate and steepness decrease so that the runoff's shear stress acting on the soil decreases below the soil's critical shear stress even though distance is large.

when your hand is rubbed by sandpaper.

[125] Total hydraulic roughness is composed of two parts, the part related to the shear stress that the flow exerts on the soil particles (referred in channel hydraulics as grain roughness) that causes erosion and sediment transport and the part related to the shear stress applied to hydraulic elements (referred to as form roughness) including soil surface roughness (e.g., clods), ground cover (e.g., surface residue and live ground cover), and plant stems.

[126] An increase in cover-management intensity refers to an overall increase in soil surface roughness, surface residue cover, aboveground biomass, soil biomass, vegetative retardance, and soil consolidation.

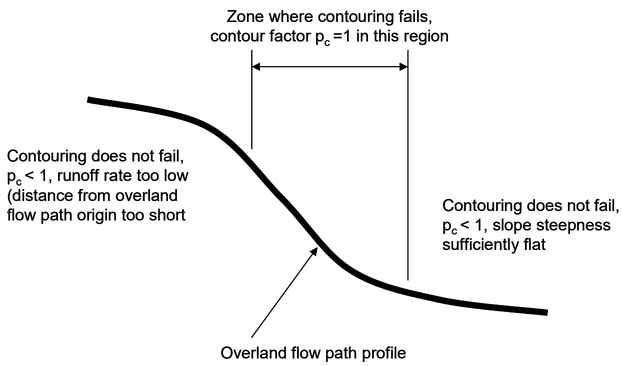

Figure 14.5. Zone on a complex shaped overland flow path where contouring fails because the combination of distance and steepness.

Figure 14.6 illustrates how RUSLE2 handles an overland flow path with an intense cover-management strip upslope from the end of the overland flow path. Several zones are identified in Figure 14.6. Contouring does not fail and the contouring subfactor value is less than 1 in Zone 1 because the combination of runoff rate (represented by distance from the path origin) and steepness is not sufficient for runoff's shear stress applied to the soil to exceed the soil's critical shear stress for the given cover-management condition. The applied shear stress equals the critical shear stress at the boundary between Zones 1 and 2 and exceeds the critical shear stress in Zone 2. Contouring fails and the contouring subfactor value equals 1 in Zone 2. The intense cover-management in Zone 3 greatly reduces the runoff's shear stress applied to the soil to less than the soil's critical shear stress. Contouring does not fail and contouring subfactor values are less than 1 in Zone 3.

Zone 4 is a special situation. The cover-management condition in Zone 4 is the same as in Zones 1, 2, and 5. Because contouring failed in Zone 2, the expectation is that contouring also fails in Zone 4 based on runoff rate, steepness, and cover-management condition. However, the difference is that the intense cover-management strip in Zone 3 is assumed to spread the runoff so that it leaves the strip in a very thin flow. The flow's shear stress applied to the soil is less than soil's critical shear stress in Zone 4. RUSLE2 assumes that the shear stress applied to the soil at the upper end of Zone 4 equals the shear stress applied to the soil at the lower end of Zone 3. The runoff's shear stress increases over Zone 4 and becomes equal to the soil's critical shear stress at the boundary between Zones 4 and 5. Contouring does not fail and the contouring subfactor value is less than 1 in Zone 4.

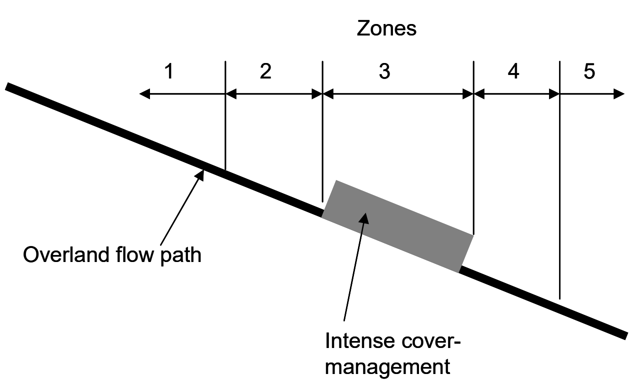

Figure 14.6. Zones along an overland flow part with an intense cover-management strip.

Runoff leaves the intense cover-management strip spread in a thin flow across the slope. The runoff becomes concentrated again in rill flow with distance in Zone 4.

This flow concentration increases the shear stress that the runoff applies to the soil and equals the soil's critical shear stress at the boundary between Zones 4 and 5. Contouring fails in Zone 5 because the runoff's shear stress applied to the soil exceeds the soil's critical shear stress and the contouring subfactor value equals 1 in Zone 5.[127]

14.1.2.6. Temporal changes in contouring subfactor values and contouring failure

RUSLE2 computes a daily value for the contouring subfactor p_c. The value changes daily because the soil ridge height decays daily and the effective vegetation ridge height changes as vegetative retardance changes daily. Cover-management conditions change daily to influence runoff depth that RUSLE2 uses to compute daily contouring subfactor p_c values. The daily contouring subfactor p_c value also changes on days that soil disturbing operations occur that creates ridges with a new height.

Runoff rate and shear stress applied to the soil by runoff change daily as cover-management conditions change. Runoff rate also changes as daily erosivity changes, which captures the likelihood of an intense storm occurring when the cover-management condition is vulnerable to contouring failure. The daily erosive precipitation amount used to compute runoff rate is the product of the 10 year, 24 hour precipitation amount and the ratio of daily erosivity to the maximum daily erosivity.[128]

This effect of combining a vulnerable cover-management condition for contouring failure with the likelihood of an intense storm is illustrated in Figure 14.7 for a conventionally tilled corn **cover-management description** at Lincoln, NE. This example is for a uniform overland flow path where the contouring fails beyond the critical slope length on the lower portion of the overland flow path. The most vulnerable period to contouring failure is from the first secondary tillage operation (tandem disk) on May 1 until harvest on October 15 because the soil surface is smooth with very little surface residue and the vegetation provides little retardance, even at maturity.

---

[127] Equation 8.1 is used to compute detachment in each zone in Figure 14.6. The contouring subfactor p_c value for Zone 4 is computed based on runoff depth, steepness, cover-management condition, and relative row grade assuming no contouring failure. Even though runoff is spread in a thin sheet flow that has reduced erosivity, the values of no other factor are changed in equation 8.1 because the intense cover-management strip spreads runoff. That is, the only erosion reduction computed by RUSLE2 for Zone 4 is from the contouring subfactor value being less than 1 for Zone 4 because the intense cover-management strip spreads the runoff. The contouring subfactor value would equal 1 because of contouring failure if the intense cover-management was not on Zone 3.

[128] The daily erosive precipitation amount used to compute runoff rate is not the same as the daily precipitation amount determined by disaggreagtion of the monthly precipitation amounts in a location's **climate description**.

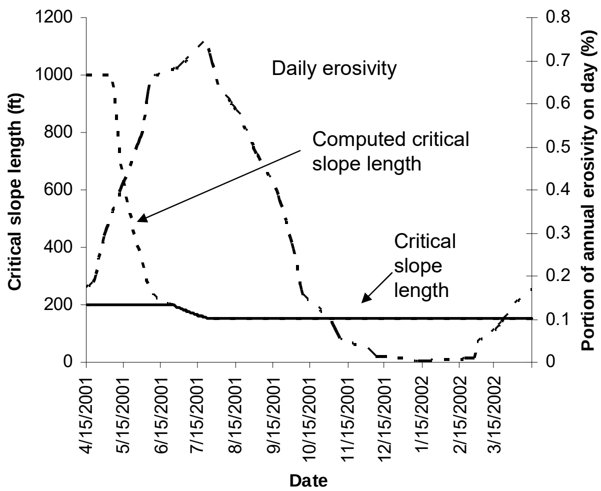

Figure 14.7. Daily critical slope length.

The critical slope length shown in Figure 14.7 is 200 ft, which is the overland flow path length, from April 15 to June 25.[129] A RUSLE2 displayed critical slope length that equals the overland flow path length means that the computed critical slope length is longer than the overland flow path length. A computed critical slope length longer than the overland path length has no consequence because contouring does not fail within the actual overland flow path length. The RUSLE2 computed critical slope length starts at 1000 ft, which is the longest overland flow path that RUSLE2 considers. The computed critical slope length becomes less than 1000 ft on May 7 and steadily decreases to 200 ft on June 25. The reason for the decrease is the increase in the daily erosive precipitation amount used to compute shear stress, which is indicated by the increase in the daily erosivity to July 22 in Figure 14.7. The vulnerability of the cover-management condition to contouring failure in this example does not change significantly during this period. However, in other cases, vulnerability to contouring failure can increase significantly over time as roughness and surface residue decay.

After June 25, the computed critical slope length decreases to a value less than 200 ft, which means that RUSLE2 has computed contouring failure and has set the contouring subfactor p_c value to 1 on the lower portion of the overland flow path. The critical slope length ultimately decreases to a minimum of 154 ft on July 22, the date of peak erosivity. Even though the site condition was slightly more vulnerable to contouring failure earlier, the shortest critical slope length did not occur until later when the combination of cover-management vulnerability and daily erosive precipitation was maximal.

The potential for contouring failure decreased significantly after July 22 because the daily erosivity decreased as illustrated in Figure 14.7. However, the critical slope length did not increase. Similarly, harvest on October 15 added a very heavy surface residue cover that greatly reduced the vulnerability for contouring failure, but the critical slope length did not increase at harvest. Once contouring fails, contouring effectiveness is not

[129] The actual critical slope length before June 25 is longer than 200 ft, but RUSLE2 does not display critical slope length value longer than the overland flow path length. The computed critical slope length can be seen by entering 1000 ft for the overland flow path length, which is the longest value that can be entered in RUSLE2.

restored until the next **operation description** that includes a **disturb soil process** to create new ridges. In RUSLE2, contouring failure is assumed to occur by runoff breaking through ridges; consequently ridges must be recreated to restore contouring effectiveness. Critical slope length is reset when new ridges are created. See **Section 14.1.2.5** for discussion on the importance of critical slope length in conservation planning.

In this example, the first soil disturbing operation after the critical slope length reached its minimum on July 22 is a moldboard plowing operation on April 15. This operation resets computed critical slope length, which is the reason for the increase in critical slope from 154 ft on April 14 to 1000 ft on April 15. The contouring subfactor p_c value remains at 1 for the portion of the slope beyond the critical slope length until new ridges are created to restore contouring effectiveness.

This example is for a uniform overland flow path. The same concepts apply to a non-uniform overland path. Contouring fails on portions of the overland flow path where runoff's shear stress applied to the soil exceeds the soil's critical shear stress for contour failure. That area expands as the combination of vulnerable cover-management and erosive conditions increase. Once contouring fails on an area, RUSLE2 sets the contouring subfactor value to 1, and contouring effectiveness is not restored until a soil disturbing operation occurs that creates new ridges.

Dates **for** ***operation descriptions*** **must be carefully selected for** ***no rotation cover-management descriptions*** **where critical slope length is important. Operations that occur together to create a particular field condition should be combined into a single operation, or the same date should be used for the operation descriptions. An example is creating ridging and applying mulch that occur together on a construction site. These two operation descriptions should either be combined into a single operation description or occur on the same date to prevent RUSLE2 from computing erroneous contouring failure (critical slope length) values.**

14.1.2.7. Use of critical slope length information in conservation planning

The usual conservation and erosion control planning objective is to avoid contouring failure anywhere along the overland flow path. In the case of uniform overland flow paths, this objective corresponds to the critical slope length not being less than the overland flow path length.

If contouring failure occurs, the two frequently used corrective measures are to change the cover-management practice or add terraces/diversions along the overland flow path. Reducing land steepness is a possible alternative on landfills, construction sites, reclaimed mine, and other similar highly disturbed lands where topography can be modified. An average erosion rate for the erodible portion of the overland flow path less than the planning criteria, such as soil loss tolerance, is usually not sufficient for adequate erosion control when contouring fails. Local erosion can be too high where contouring fails on an overland flow path even though the average erosion for the erodible portion of the overland flow path is sufficiently low.

14.1.3. Calibration

RUSLE2's contouring equations, which capture these contouring principles, were calibrated to the experimental field data illustrated in Figure 14.1.[130] The middle curve in Figure 14.1 was assumed to represent the overall, main effect of contouring on erosion. This curve is comparable to the contouring subfactor values in AH537. The calibration procedure required assuming a base condition to represent this overall, main effect curve in Figure 14.1.

Most of the experimental data illustrated in Figure 14.1, which includes the data that were the basis for the AH537 contouring subfactor values, are from research studies conducted from the early 1930's to the mid 1950's.[131] The base condition used in the RUSLE2 contouring calibration represented those conditions rather than modern conditions.[132] The assumed base condition was a conventionally tilled, low yield (60 bu/ac) corn cover-management description at Columbia, MO (see **Footnote 23**). The operations in this cover-management description included a moldboard plow in the spring for primary tillage, two secondary tillage operations to prepare the seedbed, row planter to seed the crop, row cultivation to control weeds, and harvest .

A second cover-management description used in the calibration was conventionally tilled soybeans and wheat added to the base corn cover-management description. This cover-

---

[130] The data sources are listed in Tables 6-1 and 6-2, AH703.
[131] Using modern data to calibrate RUSLE2 contouring computations was preferred, but unfortunately adequate modern data do not exist. The important output from RUSLE2 for most conservation and erosion control planning is average annual erosion rather than erosion for individual storms. Also, erosion is highly variable and data over several years are needed to obtain good average annual erosion estimates. This requirement is especially important for calibrating RUSLE2 for contouring because the effectiveness of contouring is strongly related to major storms that occur at vulnerable times. The best data for calibrating RUSLE2 are from natural runoff events on small watersheds (less than 5 ac). Natural runoff plot data supplement these data. Rainfall simulator plot data are not especially useful for calibrating RUSLE2, although these data are extremely important for developing principles, concepts, and basic equations.

The calibration data should be from a wide range of climatic, soil, topographic, and cover-management conditions to capture main effects and to deal with the extreme variability in contouring data. Unfortunately, by the end of the 1970's, many studies involving natural runoff plots were discontinued and the emphasis shifted to rainfall simulator studies. Similarly the number of small watershed studies decreased and remaining studies did not have common study conditions needed to calibrate RUSLE2.
[132] The common assumption is that AH537 contouring subfactor values from the 1930's to 1950's data apply to modern cropping practices. That assumption is highly questionable, if not invalid, because of differences in cropping practices in the two eras. For example, row cultivation is used much less in modern practices than in older practices and yields for most crops have increased significantly since the 1930's.

management description was used to calibrate RUSLE2's effective vegetative ridge height. Research data from a location in Illinois and a location in Oklahoma were used in the calibration. Another important study in the RUSLE2 contouring calibration was a 1960's field study in Northern Mississippi on the effect of relative row grade.

Two very important calibration inputs were ridge height and relative row grade (ratio of row grade along furrows to average steepness of overland flow path). The calibration input values for these variables must be followed when RUSLE2 input values are selected for conservation and erosion control planning. A 3 inches (75 mm) ridge height was input for the row cultivation operation, which had the greatest contouring effect among the operation in the base cover-management description. The second important input was the 10 percent relative row grade used to represent contouring on the small research watersheds and farm fields, which is in contrast to a zero (0) relative row grade used to represent contouring on research plots.

Ridge heights assigned to operation descriptions must be consistent with the 3-inch (75 mm) ridge height assigned to the row cultivation used in the RUSLE2 contouring calibration.

The second major calibration of the RUSLE2 contouring computations was for critical slope length on uniform overland flow paths and contouring failure in general on complex overland flow paths. RUSLE2 was calibrated to AH537 critical slope length values for contouring alone without strip cropping using the base condition described above.[133] AH537 critical slope lengths values for strip cropping were doubled from those for contouring alone. Instead, RUSLE2 computes contouring failure as a function of cover-management conditions along the overland flow path rather than using a multiple of critical slope length values for contouring alone.[134] A cover-management description involving a conventionally tilled corn, alfalfa-timothy hay rotational strip cropping system was used to calibrate RUSLE2's computation of contouring failure, especially as it relates to a hydraulically rough strip spreading runoff. Research strip cropping data from the 1930's to mid 1950's for LaCrosse, Wisconsin were used to partially validate these RUSLE2 computations. The validation was based on the ratio of average sediment yield from the strip cropping system to sediment yield from the same rotational cropping system not in strips. Measured values for this ratio were compared to RUSLE2 computed values.

[133] No explicit research data exist for critical slope length. Contouring failure has been observed and described in research reports, especially at locations in Arkansas and Texas, where severe runoff events occurred. Critical slope length values given in AH282 and AH537 were based on these and other visual field evidence of contouring failure from the early 1930's to mid 1950's. The critical slope length concept and the assigned values based on scientific and technical judgments continue to be accepted by conservation and erosion control planners and were, therefore, used in the RUSLE2 calibration.

[134] RUSLE1 assumes that strip cropping and buffer strips have critical slope lengths that are 1 ½ times those for contouring alone.

14.1.4. Interpretation of RUSLE2 contouring relationships

Of all the variables that affect erosion, contouring is easily the most difficult one to accurately represent, especially at a specific site. Slight, non-obvious differences seem to greatly affect how contouring affects erosion. Consequently, RUSLE2 erosion estimates affected by contouring are more uncertain than erosion estimates influenced by any other RUSLE2 factor. **Therefore, special care should be exercised in interpreting RUSLE2 erosion estimates in relation to contouring.**

RUSLE2 describes the established main effects of contouring in relation to major variables. These effects are valid in general, but an effect at a specific site may be quite different from the general effect. For example, the statement that contouring reduces erosion by 50 percent for a given condition is true in general, but the reduction may be 10 percent at one site and 90 percent at another site. Contouring is a good conservation practice but its effectiveness at a specific site is more uncertain than for other erosion control practices. RUSLE2 is designed to capture broad trends related to contouring. For example, use of the 10 -year, 24-hour precipitation amount is intended to capture differences in general contouring effectiveness by geographic region. Similarly, the relationship of contouring to runoff is meant to capture general trends of how cover-management conditions affect runoff that in turn affect how contouring affects erosion. These RUSLE2 estimates are not meant to explicitly describe how cover-management affect runoff and contouring's effectiveness at a specific site. RUSLE2 is a tool to assist conservation and erosion control planning.

Although, research data are sufficient to identify the main variables that affect contouring, the amount and quality of the data are insufficient to empirically derive and calibrate mathematical relationships for the effect of contouring on erosion except in the general sense. In addition, the contouring data used to develop RUSLE2 do not represent modern agronomic conditions. The RUSLE2 developers significantly extended contouring relationships beyond the main effect of slope steepness normally represented in contouring subfactor values (see AH537). Because research data are not available to validate these extensions, RUSLE2 computations were very carefully examined to ensure that computed values reflect the current scientific knowledge, are acceptable based on modern scientific and technical judgment, and are reasonable for use in conservation and erosion control planning.

14.1.5. Contouring inputs

The **contour systems description** in the RUSLE2 database involves the two inputs of **how row grade is specified** and the **input value for row grade**. The other important input for contouring is the **ridge heights** for the **operation descriptions** in the **cover-management description.**

14.1.5.1. Method of specifying row grade

Row grade can be entered in a **contour system description** using the methods listed in Table 14.1. When a contour system description is used to represent to represent contouring, the assumption is that the overland flow path input represents the flow path perpendicular to contour lines, not a flow path along the ridges and furrows.

The first method of **up and down slope** represents a no-contouring effect. RUSLE2 gives the same result obtained with the other three methods by inputting an **absolute row grade** that equals the overland flow path steepness or inputting 1 for **relative row grade**. This selection tells RUSLE2 to compute erosion without considering any contouring effect.

The method **set absolute row grade** is where a value for the actual furrow (row) grade at the site is entered. This method should be used only where ridges and furrows are well defined and runoff flows to major concentrated flow areas before breaking over the ridges.

Using the *set absolute row grade* input method for ordinary contouring provided by most typical agricultural implements is a *misuse* of RUSLE2.

Table 14.1. Ways to specify row grade.

Row grade specification method	Comment
Up and down slope	Specifically sets relative row grade to 1, i.e., absolute row grade equals overland flow path steepness
Set absolute row grade	Value entered for absolute row grade as measured in the field. **Should only be used in special cases**.
Set relative row grade	Relative row grade is the ratio of the absolute row grade to steepness of overland flow path. Should be used to represent most ordinary contouring situations.
Use management relative row grade	RUSLE2 uses relative row grade input in the cover-management description used in the particular RUSLE2 application.

The **set relative row grade** is the appropriate way to enter row grade for ordinary contouring that affects runoff as illustrated in Figure 8.13 (see **Section 8.3.6**). Relative row grade is the ratio of absolute row grade to overland flow path steepness. As discussed in **Section 14.1.4**, RUSLE2's estimates of how contouring affect erosion are more uncertain than for any other variable. **Contouring system descriptions** based on relative row grade can be developed, stored in the RUSLE2 database, and used so that

RUSLE2 computes the proper relative differences in erosion in relation to contouring. The proper relative difference related to contouring between field situations is not achieved when the absolute row grade entry method is used. Contouring effectiveness is related to how closely the ridge forming operation follows the actual field contours. Equal values for relative row grade imply the same contouring quality in relation to following field contours regardless of land steepness.[135]

The following example illustrates how inputting absolute row grade gives too much credit for contouring on steep land. Assume that an absolute row grade of 1 percent is entered for both a 6% and a 30% overland flow path (land) steepness. The relative row grade is 1/6 = 0.17 for the 6% slope, which gives a contouring subfactor value of 0.70 if the contouring subfactor value is 0.50 for perfect contouring. The relative row grade is 0.033 for the 30% slope, which gives a contouring subfactor value of 0.59 if the contouring subfactor value for perfect contouring is also 0.50. Assuming the same row grade regardless of land steepness computes a much greater relative benefit for contouring on steep slopes than on moderately steep slopes. Achieving this increased contouring benefit requires extra care, which is unlikely, with the ridge forming operation to maintain the 1 percent row grade on steep slopes. Furthermore, such precision implied by varying absolute row grade on steep slopes is unwarranted given RUSLE2's accuracy and quality of the contouring data used to calibrate RUSLE2.

The entry method **use management relative row grade** requires the same inputs as the set relative row grade selection. When this selection is made, RUSLE2 uses the relative row grade entered in the **cover-management description** (see **Section 10.2.10**). The advantage of this method is that contouring and cultural erosion control can be combined into a single erosion control practice described by a cover-management description, which is useful in erosion inventory analysis. The relative row grade should be set to 10% in the cover-management description for ordinary contouring.

14.1.5.2. Row grade

The **set absolute row grade** entry method requires that the **absolute row grade** along the ridges-furrows be entered. As discussed in **Section 14.1.5.1**, this entry method should only be used where the ridges-furrows are so well defined that runoff travels in the furrows to major concentrated flow areas before breaking over the ridges. An alternative method for applying RUSLE2 to this condition is discussed in **Section 8.3.6.**

Absolute row grade is the value that is determined by measuring a decrease in elevation over distance along the furrows (rise/run). In many cases row grade varies along the ridges-furrows, particular on either side of concentrated flow areas to reduce sharp bends in the ridges and to facilitate the ridge forming operation. A representative row grade

---

[135] Regardless of input method, RUSLE2 uses relative row in its computations.

must be selected because non-uniform row grades along the ridges-furrows can not be entered into RUSLE2.

Relative row grade is the ratio of row grade to overland flow path steepness. However, a more appropriate way to consider relative row grade is that values for relative row grade represent contouring classes, which are actually classes for ridge-furrow orientation with respect to the overland flow path. Five classes are listed in Table 14.2.[136] Additional classes are not warranted given RUSLE2's accuracy. The classes in Table 14.2 are **contour system descriptions** that have been created and placed in a RUSLE2 database.

Perfect contouring is where the ridges-furrows are oriented parallel to the contour. The row grade is perfectly flat and the ridge tops are level so that runoff spills over the ridge uniformly along the ridge. This condition is obtained in the field when a surveying instrument is used to lay out contour lines. This contouring class is used with high quality rotational strip cropping where row grade is level across concentrated flow areas. Strip cropping in the LaCrosse, Wisconsin area with its smooth sweeping curves with no evidence of ephemeral gully erosion is an example of perfect contouring.

Sometimes row grade associated with rotational strip cropping and buffer strips (see **Section 14.2**) is increased in the vicinity of concentrated flow areas to avoid sharp bends that hinder farming operations.[137] **Contouring with strips** (5% relative row grade) or **standard contouring** (10% relative row grade) should be selected for this situation. If the contouring subfactor value is 0.50 with perfect contouring, a 5% relative row grade gives a contouring subfactor value of 0.61.

Standard contouring (10% relative row grade) should be selected for contouring where no vegetative strips are present to guide ridge forming operations. Unless the topography is quite uniform, creating ridges and furrows perfectly on the contour is practically impossible. Also, row grade is often increased on either side of concentrated flow areas to facilitate ridge forming operations. If the contouring subfactor value is 0.5 with perfect contouring, a 10% relative row grade gives a contouring subfactor value of 0.66.

---

[136] The classes listed in Table 14.2 are names used for **contour system descriptions** in the RUSLE2 database that is downloaded from the RUSLE2 Internet site at the USDA-Agricultural Research Service-National Sedimentation Laboratory, Oxford, MS (http://msa.ars.usda.gov/ms/oxford/nsl/rusle/index.html) ARS reviewer, check this). The values for relative row grades in Table 14.2 are the important information. Users may change the names of the contour system descriptions to other names for convenience.

[137] Row grade should remain level across concentrated flow areas. Increasing row grade from level on either side of concentrated flow areas ensures that concentrated areas will persist and may require a grassed waterway to control ephemeral gully erosion. Contour strip cropping that does not have level row grades across concentrated flow areas will not eliminate concentrated flow areas and ephemeral areas as occurred so effectively with level grade contour strip cropping in the LaCrosse, WI area.

RUSLE2 has two contouring (ridge-furrow orientation) classes to represent “cross slope” ridging. The two classes are **moderately off contour**, which is a relatively row grade of 25%, and **half off contour**, which is a relative row grade of 50%. If the contouring subfactor value is 0.50 for perfect contouring, the contouring subfactor values are 0.75 and 0.93, respectively, for these two ridge-furrow orientations.

The last class is **up and down slope** (hill) where the ridge-furrow orientation is parallel to the land slope. The relative row grade is 100% and the contouring subfactor value is 1 for this class.

Table 14.2. Classes of relative row grades to represent contouring (ridge-furrow orientation to land slope)

Contouring (ridge-furrow orientation) class	Relative row grade	Comment
Perfect contouring	0	Ridges-furrows are exactly on the contour (orientation is parallel to contour), use with strips that exactly follow the contour laid out with surveying instruments
Contouring with strips	5%	Use with strips laid out on the contour with survey instruments but with row grade adjustments when approaching concentrated flow areas
Standard contouring	10%	Typical contouring that was initially laid out with survey instruments. Row grade adjustments are made when approaching concentrated flow areas
Cross slope-moderately off contour	25%	Ridge-furrow orientation ¼ off contour. Sufficiently close to the contour to merit significant credit for reducing rill-interrill erosion
Cross slope-half off contour	50%	Ridge-furrow orientation is ½ off contour (half way between on-the-contour and up and down slope). Merits some but not much credit for reducing rill-interrill erosion
Up and down slope	100%	Ridge-furrow orientation is parallel to land steepness. Merits no credit for reducing rill-interrill erosion

Note: The effect of ridge-furrow orientation on ephemeral gully erosion, which RUSLE2 does not estimate, should be considered in developing a complete erosion control plan.

Being able to enter a non-zero row grade in RUSLE2 does not imply that use of such row grades is encouraged or even acceptable. It is recognition that contouring can not be perfect in most field situations and that some credit should be given for rill-interrill erosion reduction for ridge-furrow orientations that are not directly up and down hill. Ridge-furrow grades greater than flat (zero) should be avoided so runoff does not flow along the furrows to concentrated flow areas on the landscape, which promotes ephemeral gully erosion. In fact, a slight row grade may cause more ephemeral gully erosion because the ridges and furrows discharge runoff in a concentrated flow area much further upslope than with a steep relative row grade. RUSLE2 does not consider ephemeral gully erosion; RUSLE2 only deals with rill-interrill erosion.

Conversely, effective erosion control is to place ridges-furrows on a continuous grade with a sufficiently high ridge to ensure that runoff flows to a concentrated flow area protected by a grassed waterway.

A complete erosion control plan includes consideration of both rill-interrill and ephemeral gully erosion.

14.1.5.3. Input ridge heights in relation to contouring

At least one **operation description** that includes a **disturb soil process** to create ridges must be in the **cover-management** description for RUSLE2 to compute a contouring effect (see **Section 9.2.4**). The RUSLE2 assumption is that ridges oriented at an angle to the overland flow path must be present for a contouring effect on erosion. The degree that contouring (ridging) reduces rill-interrill erosion depends on ridge height and row grade.[138] Input ridge height values are entered in the operation descriptions (see **Section 13.1.5.4**).

Ridge height (along with row grade) is the single most important variable that determines the effectiveness of contouring (ridge-furrow orientation to the overland flow path) in RUSLE2. If RUSLE2 computes less contouring effect than expected, ridge heights may be too low.

Ridge height after an operation is totally determined by the operation description, and the ridge height that existed before the operation has no effect on ridge height left by an operation, even when the operation minimally disturbs the soil. The ridge height input in a particular operation description should reflect the ridge height that exists when that operation is used in combination with other operations.

---

[138] The total effect of ridges on rill-interrill involves two parts. One part is the contouring effect which is related to the orientation of the ridge-furrows with respect to the overland flow path and the other part is the increased detachment caused by increased ridge height as described in **Section 9.2.4**.

After an operation description creates a ridge, ridge heights decay with precipitation amount and interrill erosion. RUSLE2 does not consider the loss of ridge height caused by deposition in the furrows. Daily ridge height used by RUSLE2 to compute the contouring effect can be much less than the input ridge height value.[139]

Ridge height values input in an operation description must be referenced to the initial 3-inch (75 mm) ridge height assigned to row cultivation used to calibrate the RUSLE2 contouring relationships for Columbia, MO (see **Section 14.1.3**). In assigning a ridge height to an operation description, ask the question of how the operation affects contouring in relation to row cultivation used for corn from the early 1930's to the mid 1950's? Measured ridge heights are a guide because RUSLE2 has been calibrated as much as possible to use ridge heights that are measured in the field. However, measured ridge heights may not always capture how RUSLE2 should compute contouring effectiveness for a particular operation description or for a cover-management description overall. Input ridge height values must be consistent with the ridge height values in the RUSLE2 **core database** because those values were selected to ensure that RUSLE2 computes the desired contouring effect.

Consequently, the best approach by far is to use ridge height values in the RUSLE2 **core database** as a guide in selecting an input value for an operation description. Consistency of ridge height values among operation descriptions is critically important so that RUSLE2 computes the expected relative erosion differences among contouring conditions. This requirement is especially important given the high variability and uncertainty in the research data used to develop RUSLE2 and the high variability in site specific contouring performance.

14.2. Porous Barriers

14.2.1. Description of practices

Porous barriers are support practices that do not terminate the overland flow path because runoff flows through these barriers. These practices must be placed on the contour or else their effectiveness is greatly reduced because runoff flows along them rather than through them. Examples include filter strips (dense vegetation strips at the end of overland flow paths), buffer strips (multiple narrow strips of dense permanent vegetation along the overland flow path), rotational strip cropping (equal width strips including some dense vegetation strips grown in a rotating and alternating fashion in time and space along the overland flow path), and fabric fences, gravel dams, and straw bales used on construction sites and similar lands.

---

[139] The ridge height values used in RUSLE2's contouring computations do not correspond with those in RUSLE1 because ridge heights change daily in RUSLE2. The RUSLE2 input values for ridge height are similar to the ridge height values used in RUSLE1 computations.

14.2.2. Basic principles

The high flow retardance of the most effective porous barriers slows runoff and ponds water on the upper side of the barrier. Runoff leaves the barrier spread across the slope in a uniform thin depth, which significantly reduces the potential for contouring failure immediately downslope of the barrier (see **Section14.1.2.5**).

14.2.2.1. Description of actual processes

Ponding (**backwater**) immediately upslope of a barrier reduces runoff's transport capacity, which can cause deposition. As much as 90 percent of the incoming sediment load can be deposited in the backwater until deposited sediment accumulates so much that the lower edge of the sediment wedge reaches the upper edge of the barrier as illustrated in Figure 14.8. Narrow width, dense, high retardance barriers less than 18 inches (500 mm) wide produce wide backwater that causes much deposition. **However, vegetation type barriers must be sufficiently wide to protect against localized failure and short circuiting of the runoff through the barrier that are caused by poor non-uniform plant stands, for example.**

As deposited sediment accumulates during runoff events, the upper edge of the backwater and deposited sediment combined advance upslope as illustrated in Figure 14.8. The upslope advancement of the deposited sediment increases transport capacity in the backwater and fills the ponded area with sediment. Sediment is transported into the barrier itself where sediment is deposited because the barrier's high flow retardance greatly reduces runoff's sediment transport capacity. Eventually both the backwater and barrier, such as a grass strip, become filled with sediment. The barrier becomes almost ineffective because it no longer causes deposition and does little to reduce sediment load. Vegetation strips regain flow retardance during reduced erosion periods if vegetation growth is not overly hindered by sediment.

14.2.2.2. RUSLE2 description

RUSLE2's representation of these very complex processes is simplified as illustrated in Figure 14.9. **RUSLE2 bases its computations solely on the hydraulics within the effective width of the barrier itself.** RUSLE2 does not compute backwater hydraulics and deposition in the backwater. Instead RUSLE2 represents the backwater by computing an additional width that is added to the actual width to create a total effective width for the strip/barrier. **Temporal changes in the backwater effect are not considered. Section 8.1.4** describes the RUSLE2 computational procedures for porous barriers.

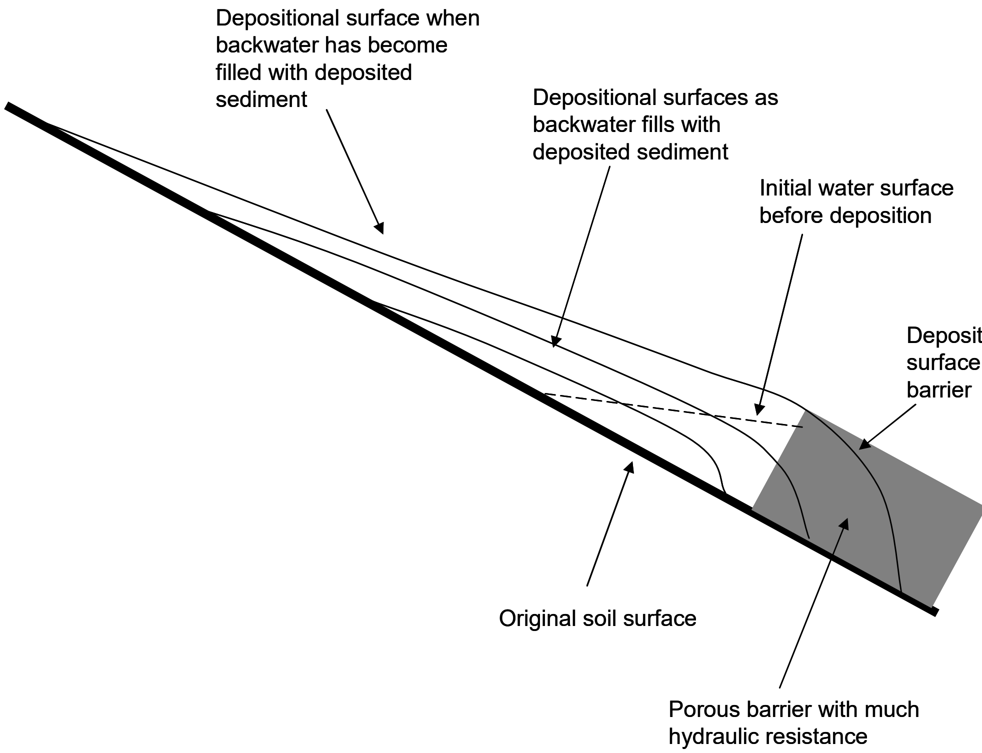

Figure 14.8. Deposition in backwater upslope of a porous barrier as deposition develops over time.

Neglecting deposition in the backwater and temporal changes is insignificant in most cases where barrier are wide such as with most grass buffer and filter strips.

The porous barrier's flow retardance must reduce runoff's sediment transport capacity to less than the incoming sediment load for RUSLE2 to compute deposition. If a barrier's retardance is low, the barrier will hardly slow runoff and transport capacity will not be sufficiently reduced at the barrier's upper edge for RUSLE2 to compute deposition. Also, RUSLE2 will not compute deposition by a barrier if the incoming sediment load is less than the transport capacity at the barrier's upper edge.

Deposition caused by a barrier reduces sediment load along the overland flow path, especially if a high retardance barrier is located at the end of the overland flow path. Detachment (sediment production) is typically low within high retardance barriers, but sediment production will not be greatly reduced if barriers are narrow with respect to the overland flow path length.

RUSLE2 computes deposition ending within a barrier as illustrated in Figure 14.9 where runoff's sediment transport capacity increases within the barrier, which is the usual case, and the barrier (e.g., grass buffer strip) is sufficiently wide. Increasing barrier width when RUSLE2 computes that deposition ends within a barrier does not significantly increase the fraction of the incoming sediment load that is trapped by the barrier. The decrease in sediment yield from the overland flow path that occurs as barrier width is increased results from the barrier occupying an increased portion of the overland flow path. Increasing barrier width reduces sediment yield more because of very low detachment (sediment production) within the barrier than sediment yield is reduced by increased sediment trapping.

However, increasing barrier width increases sediment trapping if RUSLE2 computes deposition over the entire barrier width (i.e., deposition does not end within the barrier). RUSLE2 computes reduced sediment yield because of both increased deposition and reduced sediment production in this case.

Figure 14.9 illustrates the usual case where transport capacity increases within the barrier after a step decrease at the upper edge of a barrier. This increase in transport capacity occurs where runoff rate increases within the barrier because rainfall rate exceeds infiltration rate (see **Sections 8.12 and 8.1.3**). Runoff rate and transport capacity decrease within a barrier where infiltration rate is greater than rainfall rate. RUSLE2 does not compute deposition ending within a barrier when transport capacity decreases within the barrier. Runoff ends within a barrier when infiltration rate exceeds rainfall rate if the barrier is sufficiently wide.

The width required for runoff to end within a barrier depends on discharge rate of the upslope runoff where it enters the barrier as well as rainfall rate and infiltration rate within the barrier. If runoff ends within a barrier, runoff begins at the next location on the overland flow path where infiltration rate is less than rainfall rate, which is often at the upper edge of the strip immediately downslope of the barrier as illustrated in Figure 14.10. An example of runoff ending within a barrier is a high residue strip, left rough by a moldboard plow throwing soil upslope in the Northwest Wheat and Range Region (NWRR, see **Section 6.9.1**). The rainfall rate and flow rate of upslope runoff entering the strip is very low, about 0.25 in/hr (6 mm/h) and infiltration rate in the strip is relatively high.

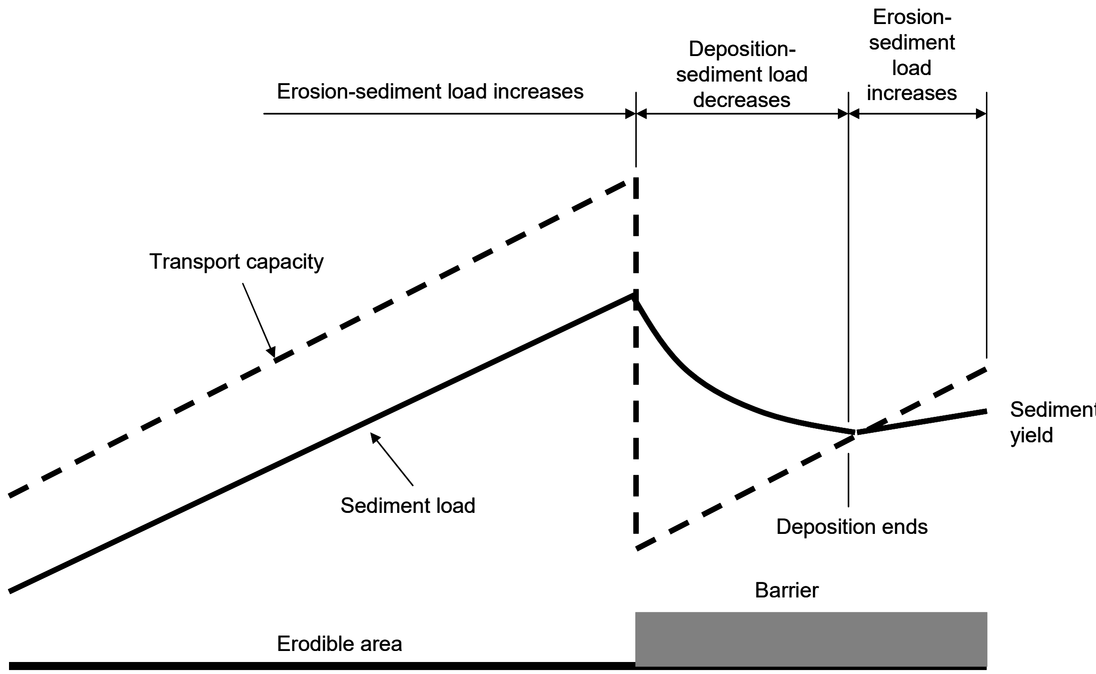

Figure 14.9. RUSLE2 hydraulic representation of a porous barrier.

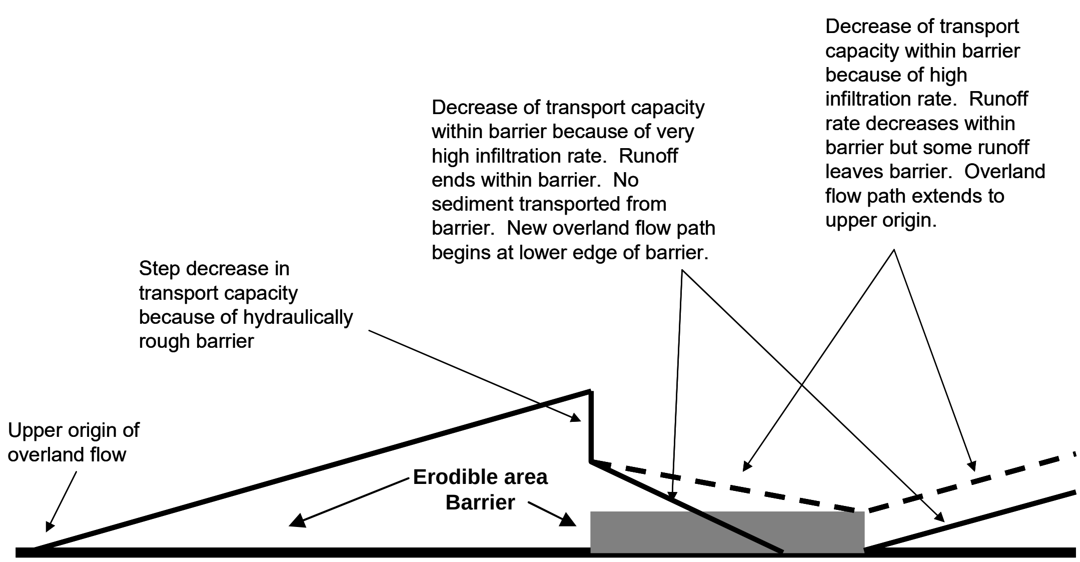

Figure 14.10. Effect of high infiltration rate within barrier that causes runoff date to decrease within barrier.

Most of the deposition caused by a porous barrier occurs in the backwater on the upper side of a strip/barrier. The length of this depositional area must be included with the actual physical width of the strip. Otherwise, RUSLE2 will overestimate sediment yield, especially if the strip is very narrow like a silt fence. RUSLE2 estimates a backwater width based on runoff rate and flow retardance of the strip. RUSLE2 computes the backwater/depositional length along the overland flow path and add this length to the input value for actual strip/barrier width. To simplify the computations, RUSLE2 adds the backwater/depositional width to the lower edge of the barrier/strip, which increases the overland flow path length by the same amount. RUSLE2 computes the backwater/depositional length by first computing flow depth at the upper edge of the strip/barrier using the total Manning's n for the barrier, discharge rate at the upper edge of the barrier, and steepness of the barrier segment. This computation was calibrated based on erosion plot studies involving 1.5 ft wide (0.46 m) stiff grass hedges at Holly Springs, Mississippi. The backwater/depositional length is computed from this flow depth and the steepness of the segment immediately upslope of the barrier assuming a level water surface.

RUSLE2 uses the retardance classes assigned to **vegetation descriptions** to compute the flow depth at the upper edge of the strip/barrier.[140] The maximum width that RUSLE2 adds for any retardance and hydraulic resistance is 15 ft (5.0 m). RUSLE2 only sets a minimum for the retardance class 7 condition, where the minimum backwater/deposition width that is added is 3 ft (1.0 m). Retardance class 7 represents stiff grass hedge, silt fence, or similar porous barrier that have an especially high retardance (see **Section 11.2.5**). If the retardance of these barriers is similar to the retardance of vegetation, an appropriate vegetation retardance class is assigned. The width added for the other retardance classes is computed value, except that it can not exceed 15 ft (5.0 m).

The backwater/depositional length increases as the hydraulic resistance (retardance, ground cover, surface roughness) of the strip/barrier increases. Also, the backwater/depositional length increases as discharge rate increases. RUSLE2 uses the same temporally varied discharge rate to compute backwater/depositional length that it uses to compute contouring failure (critical slope length). The backwater/depositional width decreases as steepness upslope of the strip/barrier and slope steepness of the segment that contains the barrier increases.

The RUSLE2 overland flow path begins at the origin of overland flow assuming that rainfall rate exceeds infiltration rate everywhere along the possible overland flow path based on topography. This choice of an overland flow path includes situations where discharge rate decreases within a barrier placed along the overland flow path, including situations where runoff ends within the barrier. RUSLE2 properly takes into account variations in infiltration and runoff along the overland flow path because of barriers and other changes in cover-management along the overland flow path. However, if the cover-management upslope of an erodible area is known not to produce runoff, the overland flow path can be started at the upper edge of the erodible area where runoff

---

[140] A **vegetation description** is used to describe the retardance of mechanical porous barriers. The canopy cover should be 100 percent and the effective fall height should be set to 0 to minimize the detachment computed over the effective width for the strip/barrier. See **Section 14.2.5.1**.

begins. **Section 8.3.4** describes selecting RUSLE2 overland flow paths for porous barriers.

Barriers most effectively induce deposition and reduce sediment load when perfectly on the contour. Runoff may flow along but not through a barrier when the barrier's upper edge is on a grade. Runoff flows along the barrier until the runoff reaches a concentrated flow area where the runoff flows through and over the barrier. Porous barriers designed for overland flow generally perform very poorly in concentrated flow areas. The sediment trapping capacity of a barrier such as a grass strip is rapidly lost by becoming inundated with deposited sediment, or a barrier such as a fabric fence loses its sediment trapping capacity by structural failure. A ridge of soil can develop on the upper side of a barrier because of the combination of high rates of deposition and vegetation re-growing on top of the deposited sediment. Also, tillage in cropped fields and other soil disturbing operations can leave a ridge of soil at the upper edge of a barrier that causes runoff to flow along the barrier rather than entering it. Runoff may not reach a barrier when row grade is steep and ridges high on the inter-barrier area. The runoff flows along the ridges and furrows to concentrated flow area, where the concentrated flow causes the barriers to rapidly fail. [141]

Porous barriers should be analyzed as flow interceptors (e.g., terraces or diversions) when runoff flows along the upper edge of the barrier without entering the barrier.

When porous barriers are selected from the *strips-barriers component* of the *RUSLE2 database*, RUSLE2 requires that relative row grade (see *Section 14.1.5.2*) be 10 percent or less.

Sediment delivery ratio, which is the ratio of sediment leaving the overland path having porous barriers to sediment leaving the overland flow path without barriers is a measure of the degree that the barriers cause deposition. Values for the sediment delivery ratio determined from the RUSLE2 computed sediment yield values depend on the sediment load reaching a porous barrier relative to runoff's transport capacity within the barrier. That is, the sediment delivery ratio is near one, which means little deposition, when the incoming sediment load is only slightly greater than the transport capacity within the porous barrier. In contrast, deposition is much greater and the sediment delivery is much less than 1 when the incoming sediment load is much greater than the transport capacity

[141] RUSLE2 requires that a relative row grade of 10 percent or less be used when porous barriers are selected from the **strips-barriers RUSLE2 database component**. However, this restriction can be bypassed by selecting a **RUSLE2 template** that displays the three layer profile schematic (see **Section 8**), dividing the cover-management layer of the overland flow into segments, and selecting appropriate **cover-management descriptions** for each segment.

within the barrier. Therefore, the RUSLE2 sediment delivery ratio for a particular porous barrier depends on the erosion environment in which the porous barrier is placed as well as characteristics of the barrier itself.

The sediment delivery ratio based on RUSLE2 computations is not constant in general. For example, the sediment delivery ratio for a vegetation strip of moderate retardance is larger for no-till than for clean-till cropping on the inter-barrier area. The vegetation strip traps a smaller portion of the incoming sediment load from the no-till area than from the clean-till area because the incoming sediment load from the no-till area is only slightly higher than the transport capacity within the strip. Detachment and sediment production, which determine the incoming sediment load, is low with no-till cropping in comparison with clean-till cropping. Even though the sediment delivery ratio is higher for the clean-till cropping, overall erosion is less with the no-till cropping.

The RUSLE2 computed sediment delivery ratio for a porous barrier depends on the characteristics of the sediment that reaches the barrier. Sediment characteristics are determined by the properties of soil from which the sediment is eroded (see **Section 7.5**) and upslope deposition. For example, a high portion of sediment eroded from sandy soils is large, easily deposited particles. The RUSLE2 sediment delivery ratio for this sediment is much lower than for sediment eroded from high silt soils that produce a high portion of small, not easily deposited particles. A high portion of the sediment eroded from high clay soils is large, easily deposited aggregates. Clay is a bonding agent that contributes to sediment being eroded as aggregates. The RUSLE2 computed sediment delivery ratio is lower than is commonly assumed for sediment eroded from clay soils because of the high portion of large aggregates in the sediment eroded from these soils.

The RUSLE2 computed sediment delivery ratio for a porous barrier is high where much upslope deposition occurs. An example is a grass strip at the end of a concave-shaped overland flow path where much deposition occurred because of reduced steepness. This deposition removes a high portion of the coarse, easily deposited particles from the sediment load so that the sediment reaching the barrier is largely composed of fine, not easily deposited particles.

Sediment delivery ratio values for porous barriers do not depend very much on the erosion environment, except for sediment characteristics, where runoff's sediment transport capacity is near zero within the barriers. Dense grass strips are an example of this porous barrier.

Deposition is a selective process that enriches the sediment in fines because coarse, dense sediment like sand and large aggregates are more easily deposited than is fine sediment like clay, silt, and small aggregates (see **Sections 5.4 and 7.5**). RUSLE2 computes an **enrichment ratio** that is a measure of the degree that deposition enriches the sediment in fines. The enrichment ratio is the ratio of the specific surface area of the sediment leaving the RUSLE2 overland flow path to the specific surface area of the soil subject to erosion. The enrichment ratio for a porous barrier increases as portion of the incoming sediment load that is deposited increases. That is, enrichment ratio values increase as values for the sediment delivery ratio decrease.

A major question is the credit given to sediment deposited by porous barriers as **soil saved**. This deposition is referred to as **remote deposition** where the deposition is localized in contrast to **local deposition** that occurs over most of the overland flow area. As discussed in **Section 8.1.5.4**, the credit given to remote deposition as soil saved is a matter of scientific and technical judgment. Keeping the sediment on the overland flow path is clearly preferred to the sediment leaving the overland flow path. Furthermore, sediment deposited upslope is preferred to the sediment deposited near the end of the overland flow path. Also, sediment deposited in localized, semi-permanent locations, such as above grass buffer strips, is less desirable than sediment deposited where soil disturbing operations, such as tillage operations associated with rotational strip cropping, routinely spread the deposited sediment. An increased portion of the overland flow path (i.e., hillslope) benefits when the deposited sediment is spread.

The **conservation planning soil loss** discussed in **Section 8.1.5** gives partial credit for the deposition that occurs with porous barriers as soil saved that benefits the landscape. The credit taken for deposition reduces the soil loss used in conservation planning. The credit taken for this deposition depends on both the location and amount of deposition. For example, RUSLE2 takes little credit for deposition that occurs near the end of the overland flow path, but can take more than 80 percent credit for deposition that occurs on the upper one third of the overland flow path. Rotation strip cropping (see **Section 14.2**) is a special case where full credit is taken for deposition.[142]

Erosion on the inter-barrier area is not greatly affected by the barrier, except for the immediate area downslope of the barrier where erosion may be reduced. Even though the infiltration rate within a porous barrier may be substantially higher than on the inter-barrier area, RUSLE2 does not consider how erosion below a barrier is affected by reduced runoff exiting the barrier. RUSLE2 does compute how reduced runoff affects contouring failure and sediment transport capacity downslope of a porous barrer. High retardance porous barriers spread the exiting runoff so that rill erosion is reduced for a distance downslope before the runoff becomes concentrated once again in rills. This distance has not been defined in research studies. Based on field observations, rill erosion and runoff concentrated in rills occurs immediately downslope of the barrier if the soil is highly susceptible to rill erosion. In other cases, rill erosion and runoff

[142] A rotational strip cropping support practice must be selected through the **strips/barriers component** of the RUSLE2 database in order for RUSLE2 to give full credit (i.e., set **conservation planning soil loss** value to the **sediment yield** value) for deposition associated with rotational strip cropping. Rotational strip cropping can be represented in RUSLE2 by dividing the **management layer** of the **overland flow path schematic** (see **Section 8**), but this procedure takes only partial credit for deposition.

concentrated in rills has been observed not to occur until beyond 3 ft (1 m) on soils moderately resistant to rill erosion. A 10 ft (3m) and greater distance is required for visible evidence of rill erosion downslope of porous barriers on soils highly resistant to rill erosion. Runoff exiting a porous barrier has a very low sediment load and, therefore, has increased erosivity, which increases rill erosion. The RUSLE2 assumption is that these effects offset each other. Consequently, RUSLE2 computes the same erosion rate below a barrier regardless of the presence or absent of the barrier, except for conditions where RUSLE2 computes no contouring failure immediately downslope of a barrier as discussed in **Section 14.1.2.5**.

14.2.3. Calibration

Calibrating RUSLE2 for porous barriers required determining mathematical relationships and numerical values for the K_T coefficient in equation 5.3, which is RUSLE2's equation for runoff's sediment transport capacity (see **Section 8.1.3**). . Equation 5.3 is based on the concept that total overland flow shear stress is divided into the two components of shear stress applied to soil and sediment particles (grain roughness) and shear stress applied to ground cover, soil surface roughness, and standing vegetation (form roughness) (see **Section 14.1.2.5**). The shear stress applied to the soil and sediment particles is used to compute runoff's sediment transport capacity. The shear stress applied to the soil and sediment particles is related to the ratio of the hydraulic resistance of a smooth soil to total hydraulic resistance.

The K_T coefficient involves two parts. One part represents the combined effects of sediment transportability with the hydraulic resistance (grain roughness) of a smooth soil surface and the second part represents the effect of total hydraulic roughness (resistance). Although sediment transportability is related to diameter and density of sediment particles, RUSLE2 uses the same transportability value for all soils even though sediment characteristics vary. **However, RUSLE2 captures the main effects of sediment characteristics on deposition by using equation 5.2, which involves sediment fall velocity that is a function of sediment particle diameter and density (see Section 7.5).** A single Manning's n value is used for all smooth soil; it does not vary as a function of soil particle diameter.

The RUSLE2 developers judged that using constant representative values for sediment transportability and grain resistance improved RUSLE2's robustness as a conservation and erosion planning tool.

A combined base value for grain roughness (resistance) of a smooth soil and sediment's transportability was determined by calibrating RUSLE2 to measured sediment load on a concave overland flow path profile. The RUSLE2 assumption is that sediment transport capacity equals sediment load at the location where deposition begins on a concave profile. The calibration data were from a simulated rainfall field study on a concave plot

35 ft (10.7 m) long where slope steepness decreased continuously from 18 percent at the upper end to 0 percent at the lower end. The bare silt loam soil was smooth so that the only hydraulic resistance was grain roughness. The slope profile was cut from a deep soil profile so that soil characteristics were uniform along the overland flow path. Deposition began at the location where steepness equaled 6 percent. A base value for the K_T coefficient for grain roughness only was determined by adjusting its value until RUSLE2's sediment transport capacity equaled measured sediment load at the 6 percent steepness location. Additional evaluations of the calibrated K_T value were made by comparing RUSLE2 estimates with measured values in laboratory deposition studies, visual field evidence of deposition, and scientific and technical judgments.[143]

The second part of the K_T variable involves the mathematical equation that computes K_T values as a function of the ratio of grain hydraulic resistance to total hydraulic resistance. This equation was derived from sediment transport theory. The Manning's n, which is widely used in hydraulic analyses, is used in RUSLE2 as the measure of total hydraulic resistance. A RUSLE2 total Manning's n value is the sum of the Manning's n values for ground cover, soil surface roughness, and standing vegetation. Values for Manning's n for ground cover and surface roughness were developed from field overland flow velocity measurements.[144]

Manning's n for standing vegetation is based on a retardance concept where seven retardance classes are used to describe the hydraulic resistance provided by standing vegetation (see **Section 11.1.4**). RUSLE2 uses an equation that converts retardance values to Manning's n values. The retardance classes and the empirical equation that computes Manning's n as a function of retardance class were based on both field velocity measurements and scientific judgment of how standing vegetation affects overland flow velocity and hydraulic resistance.

The next step was to calibrate the equations used to compute sediment characteristics as a function of deposition. The coefficient value involved in these equations was calibrated by comparing RUSLE2 computation of sediment yield and sediment class distributions for very dense grass strips of 3, 6, and 9 feet (0.9, 1.8, and 2.6 m) widths where sediment transport capacity within the grass strips can be considered to be zero (0).

The final step in the calibration was to validate the equations as a complete set. These equations involve complex interactions, which prevents calibration of coefficient values except for very special conditions. The equations and coefficient values, therefore, had to be validated as a set over the conditions where RUSLE2 would likely be applied in conservation and erosion control planning. RUSLE2 computed values for sediment load and sediment particle distributions along and at the end of concave shaped overland flow paths were compared to measured values for both field and laboratory studies. Similar comparisons were made for sediment yield from the end of slopes involving mulch strips of different hydraulic resistance and placement along the overland flow path and contour strip cropping at several locations.[145] In all cases, evaluations were made to ensure that RUSLE2 computed values for sediment load and sediment class distribution are reasonable and consistent with accepted scientific knowledge and available data.

14.2.4. Interpretation

RUSLE2's erosion, deposition, and sediment load computations for porous barriers are for conservation and erosion control planning purposes. Numerous assumptions were made in that context to derive simple, robust RUSLE2 equations that give reasonable values consistent with research data and accepted scientific and erosion control principles. With the possible exception of contouring, porous barrier erosion control varies more with site-specific condition than any other factor. For example, a barrier not perfectly on the contour can result in runoff flowing along the barrier, collecting in a concentrated flow area, breaking over the barrier, and causing the barrier to fail and trap almost no sediment. The effectiveness of vegetative strips depends on a ridge of soil not accumulating along the barrier's upper edge that prevents runoff from entering the barrier. Also, vegetation uniformity and a high quality and dense plant stand must be maintained for vegetative barriers to be fully effective. Installation and maintenance of fabric fences is more important than any other factor in determining their effectiveness.

Having and enforcing a good set of installation and maintenance specifications and standards is essential.

RUSLE2 **core database** values for porous barriers represent values that should be used in RUSLE2 applications in the judgment of RUSLE2 developers. RUSLE2 represents the general, overall main effects of these practices as they are judged to be commonly installed in the field. The effectiveness of porous barriers under ideal laboratory conditions is almost always much better than under typical field conditions. RUSLE2 input values for porous barriers values should reflect local conditions and the judgment of designers and regulatory officials for fabric fences, gravel dams, straw bales, and similar porous barriers typical of those used on construction sites.

14.2.5. Inputs

The inputs used to represent porous barriers in RUSLE2 include overland flow path description, a contouring description, and the specific inputs for the strip/barrier system. Porous barriers do not affect the overland flow path description because overland flow is assumed to pass through porous barriers. RUSLE2 accounts for infiltration variations along the overland flow path, including strips where infiltration is so high that runoff ends within the strip, to compute sediment transport capacity and contouring failure (critical slope length). The overland flow path length is selected as if runoff is produced along the entire overland flow path.

The upper edge of a strip/barrier system should be as close as possible to perfectly on the contour (zero row grade) for maximum effectiveness. Figures 14.11 and 14.12 illustrate the importance of a strip/barrier's upper edge being on the contour. If the upper edge is placed parallel to the site boundary as illustrated in Figure 14.11, a grade exists along the upper edge. This grade results in overland flow collecting and running along the upper edge of the strip/barrier to a concentrated flow area, where the flow can overwhelm the barrier. A much better layout is where the upper edge is on the contour as illustrated in Figure 14.12. Runoff enters the barrier uniformly along its length, and the barrier is much less likely to fail in concentrated flow areas. An advantage of having the upper edge of strips/barriers on the contour on cropland is that concentrated flow and ephemeral gully erosion can be greatly reduced.

Selecting a **strip/barrier description** from the RUSLE2 **strip/barrier database component** requires that relative row grade be 10 percent or less except for up and down slope (100 percent relative row grade) where runoff flows perpendicular into the strip/barrier. This restriction can be circumvented by using a RUSLE2 screen **template** that displays the three-layer profile schematic (see **Section 8**). In both input approaches, RUSLE2 assumes that the runoff flows into the porous barrier and that the only effect of the barrier being off grade is in the contouring effect described in **Section**

14.1. See **Section 14.1.5** for additional guidance on selecting contouring inputs for porous barriers.

Inputs specific to a strip/barrier system can be entered in one of two ways. Selecting a **strip/barrier description** from the RUSLE2 database is the intended approach for routine conservation planning. These descriptions involve simplifying assumptions such as uniform strip/barrier widths for convenience and consistency with RUSLE2's accuracy. However, the **three layer profile schematic** can be used to circumvent the 10 percent relative row grade rule when flexibility is needed to represent a complex field situation. The **management layer** in the profile schematic is divided into segments and **cover-management descriptions** are selected for each segment to represent the strips and barriers along the overland flow path.

The inputs for strip/barrier descriptions in the strip/barrier component of the RUSLE2 database are listed in Table 14.3.

Table 14.3. Input variables for strip/barrier descriptions

Input variable	Comment
Strip barrier type	Type refers to filter strip/barrier, buffer strip/barrier, or rotation strip cropping. A filter strip/barrier is permanent at end of overland flow path. Buffer strip/barrier type involves multiple permanent barriers along overland flow path. Rotational strip cropping involves multiple, equal width strips that alternate in time along the overland flow path
Number of strips/barriers crossing overland flow path	Assumption is that strips/barriers are equally spaced along overland flow path
How strip/barrier width is specified	Width can be specified in absolute units or as the portion of the overland flow path length
Absolute strip width	Strip/barrier width if input for width is specified in absolute units
Strip/barrier width relative to overland flow path length	Strip/barrier width if input for width is specified as the portion of the overland flow path length
Strip/barrier cover-management description	Select the cover-management description for the filter and buffer strip/barrier system. Cover-management description selected for profile is cover-management input for non-strip portion of the overland flow path. The cover-management description selected for the profile is the cover-management description that RUSLE2 uses for rotational strip cropping.
Strip/barrier at bottom of overland flow path	Selecting **yes** places a strip/barrier at the end of the overland flow path. Remaining strips are uniformly spaced along the overland flow path. Selecting **no** places the last strip/barrier

	the same distance above the end of the overland flow path that strips/barriers are spaced along the overland flow path.
Is strip/barrier used for water quality	For USDA-NRCS conservation planning. NRCS specifies require that last strip width be twice as wide as the other strips when explicit purpose is to improve water quality.

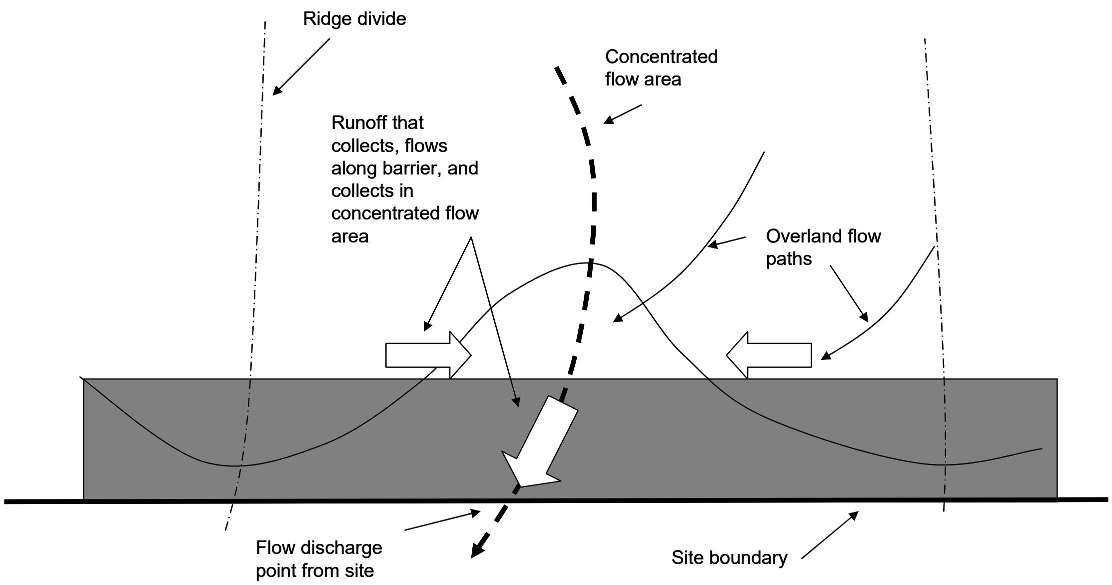

Figure 14.11. A strip where upper edge is parallel to site boundary.

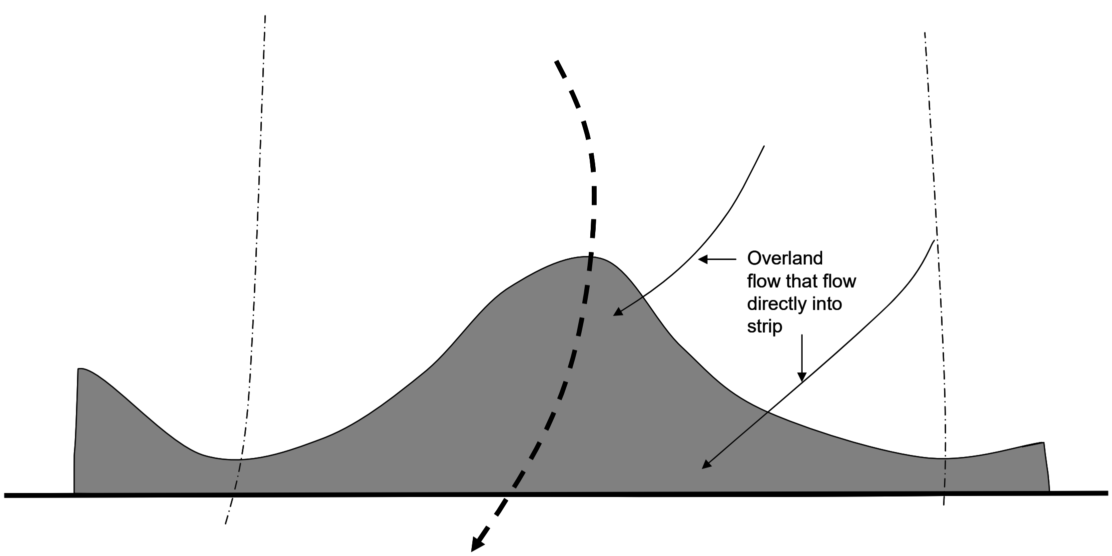

Figure 14.12. A strip where upper edge is perfectly on the contour.

14.2.5.1. Inputs for filter strip/barrier

A filter strip porous barrier is a single barrier at the end of the overland flow path. Four examples of a filter strip porous barrier are a wide strip of dense vegetation (e.g., grass strip) on cropland, a narrow strip of erect, stiff, dense grass (stiff grass hedge) on cropland, an undisturbed strip left along concentrated flow areas on disturbed forestland, and a fabric (silt) fence on a construction site. The specific inputs for a filter strip-type porous barrier are: strip/barrier type (select **filter strip**), how strip/barrier width is specified, strip/barrier width, and cover-management description for strip/barrier.

The general recommendation for conservation and erosion planning is to specify **strip/barrier width** as the portion of the overland flow path length. A strip width of 10 percent of the overland flow path length is commonly assumed for general conservation and erosion control planning. An alternate is to specify the actual widths in absolute units instead of a portion of the overland flow path length.

Figure 14.12 illustrates that the portion of the overland flow path occupied by a filter strip/barrier of a fixed width varies by overland flow path. This variation means that the relative filter strip/barrier width depends on the overland flow path assumed in applying RUSLE2 to a particular site. The recommended approach is to choose an overland flow path and a representative filter strip/barrier width that are consistent with the conservation and erosion control planning objectives for the site. For example, a typical RUSLE2 application is to protect the eroding portion of the hillslope from excessive erosion so that the soil resource is protected. The one third portion of the hillslope having the highest erosion potential is typically selected as the area where RUSLE2 will be applied when conservation planning objective is to protect the soil resource. An overland flow path is assumed through this hillslope area, and the filter strip/barrier width for that overland flow path is used as the input width. However, if this width is not representative of the filter strip/barrier as a whole, use a representative filter strip width even if it does not match the actual width for the selected overland flow path.[146]

Filter strips/barriers are often used to reduce sediment yield from a site. RUSLE2 computes sediment yield from the area represented in a RUSLE2 computation. This area can include the entire overland flow area, diversions/terrace channels having deposition, and small impoundments, but it does not include concentrated flow areas where additional deposition and ephemeral gully erosion can occur (see **Sections 5.1 and 5.2**).

RUSLE2 computations should be made for a collection of overland flow paths when computing sediment yield where conditions vary over the area of interest. The sediment yield value for each overland flow path is weighted by the area represented by that path to obtain a sediment yield estimate for the entire area represented by the RUSLE2 computations. The **plan component** of the **RUSLE2 database** can assist in this computation where the sediment yield values are weighted by the sub-area that each overland flow path represents relative to the total area.

---

[146] RUSLE2 computes erosion and deposition values for porous barriers that are consistent with erosion science and research data. RUSLE2 is not meant to displace erosion control practice standards and specifications issued by agencies like the USDA-Natural Resources Conservation Service. However, such standards sometimes compromise erosion control performance for convenience of certain farming operations. RUSLE2 does not consider all factors important in conservation and erosion control planning. Use RUSLE2 values to guide developing an appropriate site-specific plan.

RUSLE2 only computes sediment yield from the overland flow area, diversion/terrace channels where deposition occurs, and small impoundments. RUSLE2 does not compute sediment yield from the site unless the flow paths represented by RUSLE2 end at the site boundary (see *Sections 5.1 and 5.2*).

RUSLE2 computes a backwater/deposition width and adds that value to the input width for the strip/barrier. This approach takes into account type and porosity of the barrier based on the retardance value assigned in the **vegetation description** used to represent the barrier (see **Sections 11.1.4 and 11.2.5**). This approach also takes into account how location, soil, and cover-management affect runoff and backwater/deposition width.

A **cover-management description** is selected to describe the filter strip/barrier, even for mechanical barriers like silt fences. The cover-management description for permanent vegetation strips should be a **no-rotation** type cover-management description (see **Section 10.2.8**). If the cover-management description on the upslope portion of the overland flow path is also a no-rotation type cover-management description, then consistency of the dates between the cover-management descriptions is not required. Similarly, consistency of dates between the cover-management descriptions is not important when cover-management description is a rotation type for the strip/barrier even though the upslope cover-management description is a no-rotation type. **However, if the cover-management descriptions are a no-rotation type for both the upslope area and the strip/barrier, then the dates in the two cover-management descriptions must be consistent.**

Strips/barriers can be added and removed at particular times over the computational period using operations in the cover-management description for the strip/barrier.[147] This RUSLE2 capability allows the use of a single cover-management description to describe a strip/barrier to compute erosion over the pre-construction, construction, and post construction phases.

A **vegetation description** is used to describe mechanical barriers such as fabric fences, gravel dams, straw bales, berms, and similar erosion control porous barriers used on construction sites. A selection is made from the **retardance classes** defined for vegetation plus the additional retardance class for silt fences and stiff grass hedges to describe the porosity of the barrier (see **Section 11.2.5**). Retardance class 7 for stiff grass hedges and silt fences is selected if the material provides extremely high retardance. Another retardance classes is used for more porous barriers. Also, the **production**

---

[147] A **begin growth process** in an **operation description** is used to install (put in place) a mechanical barrier (e.g., silt fence) because a vegetation description is used to represent the barrier. A **kill vegetation** and a **remove residue processes** are used in an operation description to remove a mechanical barrier.

(yield) level can be changed to alter the retardance (porosity) of the strip/barrier unless the **extremely high retardance class** is selected for the strip/barrier.

The canopy cover should be set to 100 percent and the effective fall height should be set to zero in the vegetation description used to describe a mechanical barrier to minimize detachment that RUSLE2 computes for the portion of the overland flow path occupied by the barrier.

High quality filter strips/barriers can greatly reduce sediment yield, but they do not significantly reduce the conservation planning soil loss (see **Section 8.1.5.4**). The deposition caused by the strip/barrier is near the end of the overland flow path unless the strip is very wide such as a strip that occupyies more than 40 percent of the overland flow path.

Porous barriers must be perfectly on the contour for effective performance. RUSLE2 assumes well designed, installed, and maintained barriers.

14.2.5.2. Inputs for buffer strips/barriers

A **buffer strip/barrier** type porous barrier is a set of equal width strips/barriers spaced uniformly along the overland flow path and having the same cover-management description and width. The same base **cover-management description** applies to all of the inter-strip/barrier areas. Examples include permanent grass strips on cropland and silt fences on a construction site.

The specific inputs for a buffer strip type porous barrier are:

barrier type (select **buffer strip**),
number of strips/barriers crossing the overland flow path,
how strip/barrier width is specified,
strip/barrier width,
cover-management description for strip/barrier,
whether a strip/barrier is at the end of the overland flow path, and
is the buffer strip system for water quality.

The **buffer strip/barrier description** in the **strip/barrier component** of the RUSLE2 database is for routine conservation and erosion control planning. A RUSLE2 template (see **Section 8**) that displays the three layer profile schematic can be used to apply RUSLE2 to complex, non-uniform conditions.

Several inputs for a buffer strip/barrier system are the same as for a filter strip barrier description. See **Section 14.2.5.1** for a description of the common inputs. Only the additional inputs required to describe a buffer strip/barrier system are discussed in this section.

The number of strips/barriers is not the number of strips/barriers on the hillslope or in the field, but the number of strips/barriers that cross the overland flow path used in the RUSLE2 computation.

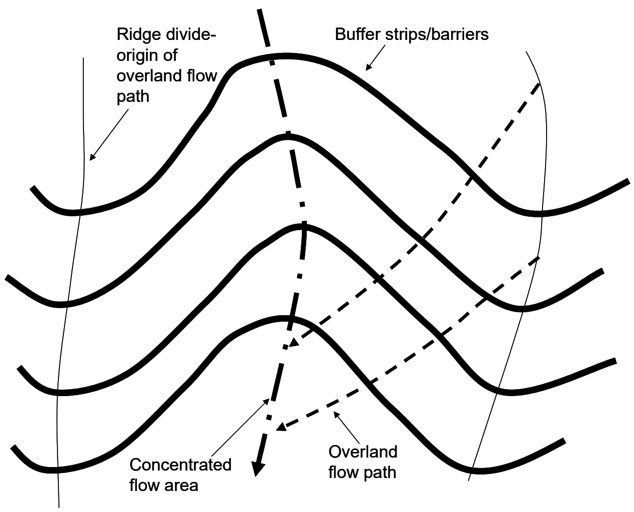

Figure 14.13. A buffer strip/barrier system on a typical hillslope illustrating various overland flow paths.

Enter a representative value for the number of strips/barriers that cross the overland flow path. The number will vary depending on the overland flow path that is chosen for the RUSLE2 computation as illustrated in Figure 14.13. Apply the guidelines described in **Section 14.2.5.1** regarding filter strip width for selecting a value for the number of strips/barriers that cross the overland flow path.

If a strip/barrier is placed at the end of the overland flow path, select **yes** for the input of **strip/barrier at the end of the overland flow path**. RUSLE2 divides the overland flow path into a number of barrier-interbarrier intervals equal to the number of strips/barriers crossing the overland flow path. This arrangement is illustrated in Figure 14.14.

The strip/barrier arrangement where a strip/barrier is not at the end of the overland flow path is also illustrated in Figure 14.14. In this case, the number of inter-strip/barrier intervals along the overland flow path is one greater than the number of strips/barriers. Consequently, the strips/barriers are more closely spaced than when a strip/barrier is at the end of the overland flow path. Sediment yield is increased when a strip/barrier is not at the end of the overland flow path to trap the sediment eroded on the last inter-strip/barrier area. Although sediment yield is reduced when a strip/barrier is at the end of the overland flow path, the conservation planning soil loss (see **Section 8.1.5.4**) may not differ greatly with strip/barrier placements.

As Figure 14.13 illustrates, the relationship of the last strip/barrier to the end of the overland flow path varies. Either chose the input that best represents the overall field situation or make RUSLE2 computations for both strip/barrier placements. The conservation or erosion control plan could be based on an average of the two computations or on the one where the erosion and sediment yield potential is greater.

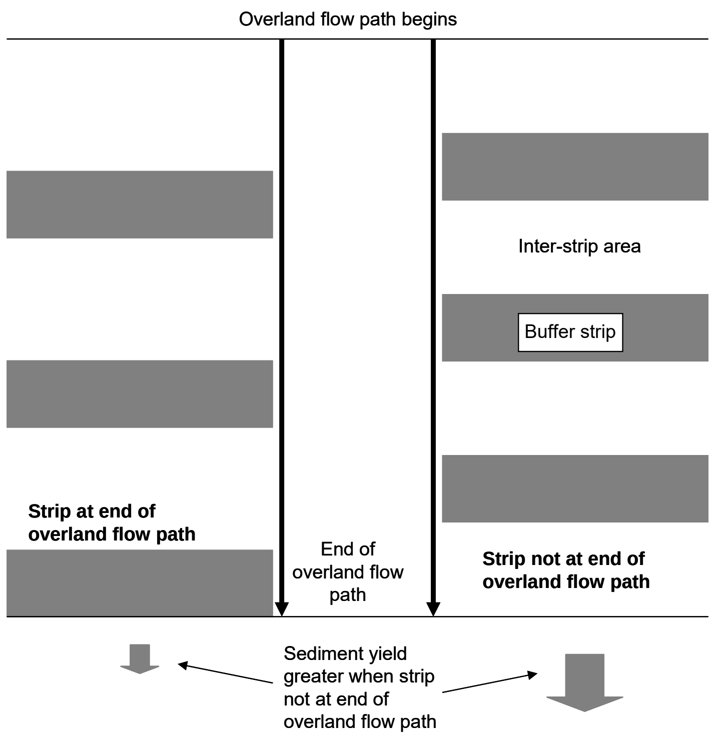

Figure 14.14. Illustration of a buffer strip systems where strip is at end of overland flow path and one where strip is not at end of overland flow path.

Select **yes** for the input **used for water quality** if the buffer strip/barrier description is being used for water quality purposes according to USDA-NRCS standards. Also, select **yes** for the input **to place a strip/barrier at the end of the overland flow path**. These selections cause the width of the strip at the end of the overland flow path to be twice the width of the other strips.

14.2.5.3. Inputs for rotational strip cropping

A rotational strip cropping system is a set of equal width strips that are annually rotated on the overland flow path in a sequence determined by a **cover-management description**. The cover-management description includes erodible periods and dense vegetations periods. Rotational strip cropping's effectiveness is from the deposition caused by the dense vegetation strips. The specific inputs for a rotational strip cropping type porous barrier are barrier type (select **rotational strip cropping**), number of strips/barriers crossing the overland flow path, the cover-management description, and the sequencing of the strips along the overland flow path.

Select a representative value for the number of strips that cross the overland flow path. The number of strips that cross the overland flow path varies with the overland flow path as described in **Section 14.2.5.2** for buffer strip systems. Also, the field overland flow path does not always begin and end on a strip boundary as assumed by RUSLE2. The idea is to a chose a number that best represents the overall field situation where RUSLE2 is being used as a conservation and erosion control planning tool. A RUSLE2 **template** that displays the three layer profile schematic can be used to estimate erosion on more complex situations that can be represented with the **rotation strip cropping description** in the **strip/barrier component** of the RUSLE2 database.[148] For example, this template

[148] If a RUSLE2 template with the three layer profile schematic is used to represent rotational strip cropping

is required to compute erosion for a rotational strip cropping system combined with a filter strip system because a filter strip description and a rotational strip cropping description from the RUSLE2 strip/barrier database component can not be combined.

The number of strips is not the number of strips on the hillslope or in the field, but the number of strips that cross the overland flow path used in the RUSLE2 computation.

Select a cover-management description that includes periods of dense vegetation that provide substantial flow retardance to cause deposition. The cover-management description, which is applied to all strips along the overland flow path, must include dense vegetation or other high hydraulic resistance conditions to cause deposition. The effectiveness of rotational strip cropping is achieved by having alternating strips of dense vegetation that cause deposition.

These alternating strips of dense vegetation are described by sequencing the cover-management description among the strips. The sequencing procedure used in RUSLE2 is to **offset** the starting date of the cover-management description by a particular number of years for each strip.

The following examples illustrate how to offset a cover-management description, which must be a rotation, to describe a rotational strip cropping system in RUSLE2. Assume a simple cover-management description of two years of corn followed by three years of hay represented by corn 1 - corn 2 - hay 1 – hay 2 – hay 3. Multiple years of each crop are grown together for convenience. Assume four strips along the overland flow path. The number of strips along an overland flow path need not match the years in the rotation as illustrated in this example. The number of strips will often be less than the number of years in the rotation.

Table 14.4 illustrates a rotation strip cropping description where the cover-management description is not offset for any strip. The result is that the same cover-management condition exists on all strips in any year. This system only reduces the conservation planning soil loss by reducing erosion that results from the three years of hay being much less erodible than is the corn. No deposition occurs among the strips because the hydraulic resistance does not increase between any two adjacent strips. This system is not rotational strip cropping because the dense vegetation (i.e., hay) are not alternated among the erodible (i.e., corn) strips.

Table 14.4. Example of no offset for a corn-corn-hay-hay-hay cropping rotation.

Strip	Years of	Year 1	Year 2	Year 3	Year 4	Year 5

and similar strip conditions where the strips must be sequenced along the overland flow path, the inputs to describe strip sequencing are entered in the **cover-management tab**.

Number	Offset					
1 (upper end of overland flow path	0	corn 1	corn 2	hay 1	hay 2	hay 3
2	0	corn 1	corn 2	hay 1	hay 2	hay 3
3	0	corn 1	corn 2	hay 1	hay 2	hay 3
4	0	corn 1	corn 2	hay 1	hay 2	hay 3

To achieve strip cropping, the cover-management description on some of the strips needs to be offset as illustrated in Table 14.5. The 2-year offset on strips 2 and 4 shifted the cover-management description by two years so that runoff from at least one corn strip runs through at least one hay strip. Sediment yield is reduced in the first two years because of a hay strip at the end of the overland flow path. However, sediment yield is increased in years 4 and 5 because the erodible corn strip is the last strip on the overland flow path. Both erosion and sediment yield are low in year 3 because the entire overland flow path is in the low erodible hay condition and only slight deposition occurs in this year.

Table 14.5. Example of a rotational strip cropping system where cover-management conditions are alternated by strip along the overland flow path.

Strip Number	Years of Offset	Year 1	Year 2	Year 3	Year 4	Year 5
1	0	corn 1	corn 2	hay 1	hay 2	hay 3
2	2	hay 1	hay 2	hay 3	corn 1	corn 2
3	0	corn 1	corn 2	hay 1	hay 2	hay 3
4	2	hay 1	hay 2	hay 3	corn 1	corn 2

Table 14.6 illustrates another possible strip cropping system described with a different set of offset years from the set illustrated in Table 14.5. The system illustrated in Table 14.6 is not as effective as the one illustrated in Table 14.5. In an example computation for Columbia, MO, the conservation planning soil loss for the system illustrated in Table 14.4 is 5.8 tons/acre. The conservation planning soil loss for the system illustrated in Table 14.5 is 2.6 ton/acre while it is 3.9 tons/acre for the system illustrated in Table 14.6. The major deficiency of the system illustrated in Table 14.6 is that it has fewer alternating strips of hay among corn strips than in the system illustrated in Table 14.5.

Table 14.6. Example of a rotational strip cropping system where the rotation is delayed a year on each subsequent strip.

Strip Number	Years of Offset	Year 1	Year 2	Year 3	Year 4	Year 5
1	0	corn 1	corn 2	hay 1	hay 2	hay 3
2	1	hay 3	corn 1	corn 2	hay 1	hay 2

3	2	hay 2	hay 3	corn 1	corn 2	hay 1
4	3	corn 2	hay 1	hay 2	hay 3	corn 1

RUSLE2 gives full credit to all deposition in the conservation planning soil loss for rotational strip cropping in contrast to the partial credit given for deposition caused by filter and buffer strip/barrier systems.

14.3. Flow Interceptors (diversions/terraces, sediment basins)

The conservation planning soil loss for rotational strip cropping is the same as the sediment yield when the *rotation strip cropping description* in the *strip/barrier component* of the RUSLE2 database is used. The two are not equal when the three layer profile schematic is used to represent rotational strip cropping by directing the overland flow path into segments.

14.3.1. Description of practices

Flow interceptors are topographic features that end the overland flow path (see **Sections 8.2 and 8.3**). Flow interceptors include diversions, terraces, and sediment basins. Diversions and terraces are constructed specifically to intercept overland flow and redirect the runoff around the hillslope in a low gradient channel. Terraces are constructed on a sufficiently low grade to cause deposition and even on a level grade with a closed outlet to conserve soil moisture in dry climates. Diversions are constructed on a sufficiently steep grade so that deposition does not occur but on a sufficiently flat grade so that erosion does not occur. Constructed terraces and diversions typically involve ridges and accompanying channels that convey the runoff to a protected open channel or an underground pipe that conveys the runoff downslope to a safe outlet. Disposal channels must be lined with vegetation, stone, or other material to prevent erosion because flow erosivity can be quite high in these channels.

The two major terrace types used on cropland are gradient and parallel tile outlet (PTO). Grade along a gradient terrace is nearly uniform, which requires plan curvature to fit the hillslope as illustrated in Figure 14.15. This curvature and the resulting non-uniform spacing between terraces along their length inconvenience farming operations. Gradient terraces generally divide the overland flow path length in shorter nearly uniform length overland flow paths between the terraces.

Parallel tile outlet terraces are relatively straight and are nearly uniformly spaced along their length. The terraces create small impoundments where they cross concentrated flow areas as illustrated in Figure 14.15. Impounded runoff drains through a vertical riser connected to an underground tile line (pipe). Grade along parallel terraces is typically non-uniform requiring that the grade be limited to prevent erosion. A variety of overland

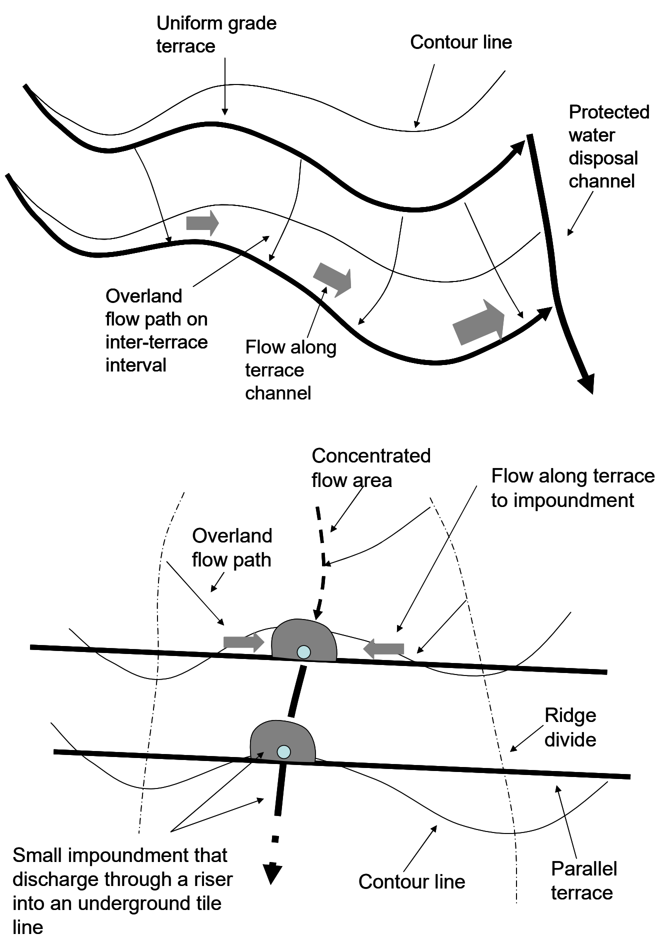

Figure 14.15. Illustration of a gradient terrace (top sketch) and parallel tile outlet (PTO) terrace systems (bottom sketch) and associated flow paths.

flow path lengths exist between parallel terraces. In contrast, to gradient terraces that almost always divide the overland flow path length, the longest overland flow path between parallel terraces may not be affected if the terraces are widely spaced. Sediment yield is low because of deposition in the small impoundment (sediment basin) in the concentrated flow areas.

Diversions, terraces, and sediment basins are also used on construction sites, reclaimed mine land, landfills, and other highly disturbed lands to shorten the overland flow path as illustrated in Figure 8.12 and reduce sediment yield, especially during periods when cover-management erosion control methods can not be used during soil disturbing operations.

Other features, including windrowed forest debris on disturbed forest land following site preparation for reseeding, act as diversion/terraces. Another example is a ridge of soil left by grading operations at the top of a cut or embankment on a construction site (see **Section 8.3.3**). Another example is an off-contour stiff grass hedge where tillage leaves a ridge of soil along the hedge that diverts the runoff rather than allowing it to flow through the hedge. A similar example is an off-contour silt fence on a construction site.

14.3.2. Basic principles

Flow interceptors involve two basic **hydraulic elements**, which are a **channel** and an **impoundment**. Diversions/terraces reduce rill and interrill erosion by shortening the overland flow path length, which is considered in the **topographic description** of the overland flow path (see **Section 8**).

Terraces also reduce sediment yield by causing deposition in the terrace channel. The basic principles described in **Section 5.4** for computing deposition on overland flow areas are used to compute deposition in diversion/terrace channels. The basic concept is that deposition occurs when the sediment load delivered to the diversion/terrace channel by overland flow on the inter-terrace interval exceeds transport capacity in the terrace channel. Deposition is computed with:

$$D = [\phi/(1+\phi)](dT_c/dx - D_o) \qquad [14.1]$$

where: D = deposition rate (mass/time·unit channel width), T_c = transport capacity in the diversion/terrace channel (mass/time), x = distance along the channel, dT_c/dx = change of transport capacity along the channel (mass/time·distance), and D_o = sediment delivered to the channel from the overland flow area (mass/time·unit distance along channel). The variable φ is given by:

$$\phi = aV_f / q_c \qquad [14.2]$$

where: α = a coefficient to be determined by calibration, V_f = fall velocity of the sediment particles, and q_c = discharge rate in channel per unit channel width, which is the discharge rate from the overland flow path that ends at the diversion/terrace channel. Transport capacity in the channel is computed by:

$$T_c = K_{Tc} Q_c s \qquad [14.3]$$

where: K_{Tc} = a coefficient to be determined by calibration, $Q_c = q_c x$ = discharge rate in the channel, and s = sine of the grade angle of the channel.

Simplifying assumptions consistent with RUSLE2's purpose to serve as a guide for conservation and erosion control planning were made in solving these equations. The equations are applied to each sediment particle class assuming no interaction among the particle classes. Grade along the channel is assumed to be uniform, which gives the mathematical result that deposition is uniform along the channel. Consequently, channel length is not a factor in the computations and, therefore, is not an input.

Transport capacity for a sediment particle class is assumed to be proportional to its portion in the sediment load that reaches the channel. Deposition among the particle classes varies according to the particle class's fall velocity. RUSLE2 computes the particle class distribution and the sediment load leaving the channel. RUSLE2 computes an enrichment ratio that is a measure of how deposition enriches the sediment load in fines (see **Section 7.5.1**). The enrichment ratio increases as deposition increases (i.e., as the sediment delivery ratio decreases).

RUSLE2 also assumes a smooth, bare soil surface in a diversion/terrace channel. Deposition in these channels is highly localized, typically along the channel edge where overland flow enters the channel flow. Deposition covers most soil surface roughness and crop residue to leave a bare, smooth soil surface. RUSLE2 does not accurately compute deposition where vegetation in the channel retards the flow to cause deposition. This limitation is not especially important because most erosion and deposition occur during the cropping season before vegetation develops.

RUSLE2 does not consider channel cross section shape in its computations.

Sediment delivery ratio is a measure of deposition. In RUSLE2, the sediment delivery ratio for a given diversion/terrace channel varies with several factors including channel grade and runoff, sediment load, and sediment characteristics entering the channel from the inter-diversion/terrace area. For example, very little or no deposition occurs when the channel grade is steep because transport capacity is high. Very little deposition occurs when sediment delivery is low and runoff is high from the overland flow area. Deposition is reduced when incoming sediment is mostly fine particles caused by the source soil properties or deposition on the overland flow path, particularly near its end (e.g., deposition by a grass strip or a flat concave overland flow path segment at the channel edge). Consequently, the sediment delivery ratio computed by RUSLE2 for a diversion/terrace is not constant for a particular channel grade, but depends on the conditions on the inter-diversion/terrace area as well.[149]

RUSLE2 computes deposition in a small impoundment (sediment basin) using:

$$g_{out} = g_{in} \exp(-\beta V_f) \quad [14.4]$$

where: g_{in} = sediment load coming into the sediment basin, g_{out} = sediment load leaving the sediment basin, and α = a coefficient determined by calibration. This equation is fundamentally for a simple settling tank where transport capacity is assumed to be zero and the effective length is determined by calibration. RUSLE2 computed deposition depends only on the characteristics of the incoming sediment. RUSLE2 typically computes large deposition amounts and fine sediment leaving the basin. RUSLE2 computes reduced deposition if the incoming sediment is fine, which is why RUSLE2 computes significantly less deposition by a second sediment basin than by the first basin in a series. RUSLE2 computes an enrichment ratio, which is a measure of deposition enriching the sediment in fines, for the outgoing sediment (see **Section 7.5.1)**.

---

[149] The RUSLE1.06 computes deposition by diversions/terraces similar to RUSLE2. However, RUSLE1.05 computes sediment delivery ratio solely as a function of diversion/terrace grade.

RUSLE2 computed deposition is not a function of basin geometry, hydraulics, or remaining basin capacity. That is, RUSLE2 does not consider design or maintenance in its impoundment (sediment basin) computations.

RUSLE2 takes partial credit for the deposition caused by terraces and impoundments as soil saved in protecting the soil resource. The amount of deposition credited as soil saved in computing the conservation planning soil loss depends on diversion/terrace spacing and location of the diversion/terrace along the overland flow path. Deposition in a terrace located near the end of the overland flow path gets very little credit as soil saved. Deposition in a terrace located about half way along the overland flow path gets approximately half credit as soil saved when diversion/terrace spacing is less than 90 ft (30 m). The credit decreases as spacing increases beyond 90 ft (30 m) to essentially no credit for spacing greater than 300 ft (100 m).

RUSLE2 is a conservation and erosion control planning tool. It is not a hydraulic design tool. See *Haan et al. 1994. Design Hydrology and Sedimentology for Small Catchments. Academic Press* for a description of procedures that can be used to design channels and impoundments. Also, RUSLE2 is not meant to displace standards used by agencies such as the USDA-NRCS, although those standards sometime compromise practice performance for farming convenience and other reasons not considered by RUSLE2.

14.3.3. Calibration

Calibrating RUSLE2 for flow interceptors involves two sets of calibration, one for deposition in terrace channels and one for deposition in small impoundments (sediment basins). The erosion component of the CREAMS and the RUSLE1.05 equation that computes sediment delivery as a function of terrace grade were major tools used in this RUSLE2 calibration.[150] The CREAMS erosion component represents experimental field data involving gradient terraces on a range of grades at numerous locations, which were also used to derive the RUSLE1.05 equation. Another data set used in the RUSLE2 calibration was from a study of deposition in a ridge-furrow system.[151] The first step in

[151] Meyer, L.D. and W. C. Harmon. 1985. Sediment losses from cropland furrows of different gradients. Trans. ASAE. 28: 448-453, 461.

the calibration was to determine a value for the $\mathbf{K_{TC}}$ coefficient in the sediment transport capacity equation, equation 14.3, for a terrace channel. The value for this coefficient was adjusted until sediment transport capacity matched sediment load at the point that deposition was judged to begin based on field data as channel grade was reduced. Sediment transport capacity equals sediment load at the point that deposition begins according to RUSLE2 theory. The next step in the calibration was to determine a value for the coefficient $\boldsymbol{\beta}$ in equation 14.2. This equation determines the RUSLE2 computed particle class distribution in the sediment leaving the channel and determines deposition amount to a much lesser extent. Both the experimental field data and computed values from the CREAMS erosion component were used in this calibration.

The second set of calibrations was to determine a value for the coefficient **a** in equation 14.4 that RUSLE2 uses to compute deposition by particle class for a small impoundment. Once again, the CREAMS erosion component was used in the calibration because it had been calibrated using data from several field studies of impoundment, tile outlet terraces in Iowa. The primary calibration was to adjust values for the coefficient $\boldsymbol{\beta}$ until the RUSLE2 computed sediment delivery ratio matched experimental values. Also, the RUSLE2 computed values were evaluated against experimental values determined from sediment basins used on construction sites and mined land. The RUSLE2 computed sediment delivery ratio values matched the experimental values for sediment basins on highly disturbed land where the basins were well designed and constructed and were clear of sediment, i.e., functioning at optimum performance.[152]

14.3.4. Interpretation

RUSLE2 computations for **hydraulic elements** are for conservation and erosion control planning, **not for design**. RUSLE2 computes deposition in channels typical of diversions, terraces, and similar channels that intercept overland flow. RUSLE2 does not consider channel shape or hydraulic resistance in its computations. Although RUSLE2 computes average annual deposition, the computations represent an approximate 10 year return period. The channels are assumed to be in an environment, typically cropland and construction sites, where failure does not cause major damage and routine maintenance and repair are readily available.

Vol. I: Model Documentation. Conservation Research Report No. 26. USDA-Science and Education Administration. pp. 36-64.

Toy, T.J. and G.R. Foster (coeditors). 1998. Guidelines for the use of the Revised Universal Soil Loss equation (RUSLE1.06) on mined lands, construction sites, and reclaimed lands. USDI-Office of Surface Mining. Denver, CO.

However, a different environment exists in other RUSLE2 applications where a diversion failure causes major problems. Diversions are sometimes used on the steep side slopes of landfills and hazardous waste sites to reduce rill erosion. Deposition in the diversions should be avoided because it reduces flow capacity, which can cause overtopping, very serious gully erosion, and major failure of the diversion. Maintaining a uniform grade and avoiding adverse grades along these diversions is especially important to prevent overtopping. Also, differential settling on the overland flow area between diversions can cause overland flow to become concentrated flow that causes serious gully erosion and overwhelms downslope diversions. RUSLE2 provides no information on such localized failures.

Similarly, RUSLE2 computes average annual deposition by small impoundments (sediment basins) assuming optimum performance without considering basin geometry, hydraulics, or water and sediment chemistry. RUSLE2 computed values apply to small sediment basins similar in size and hydraulic performance to the impoundments created by parallel tile outlet terraces where impounded water is drained by a perforated riser pipe that discharges into an underground pipe. Retention time in these basins is about 24 hours and the maximum water depth is about 4 to 6 ft (1 to 2 m).

These sediment basins often have a life expectancy less than five years, which means that the probability of an extreme event occurring while they are in place is low. Therefore, RUSLE2's estimate of average annual deposition is reasonable for conservation and erosion control planning. Damages are likely to be minor if failure occurs. Construction cost is low and maintenance and repair are readily available. Cleaning the basin after major storms may be more cost effective than building a large basin based on an extreme event.

All hydraulic structures including channels and impoundments should be based on proper engineering design. *RUSLE2 IS NOT AN ENGINEERING DESIGN TOOL.* Good professional judgment should always be used in making final decisions rather than relying solely on RUSLE2. RUSLE2 is to be used as a guide to supplement other information.

14.3.5. Inputs

The **hydraulic element (open channel-impoundment) systems component** of the RUSLE2 database is used in routine conservation and erosion control planning to evaluate the effect of diversions/terraces and small impoundments (sediment basins) on erosion and sediment yield from the flow path represented in the RUSLE2 computation. The hydraulic element systems database component contains **diversions/terraces and sediment basin systems descriptions** that are applied to the overland flow path without the hydraulic elements in place. Each hydraulic element system description involves a **hydraulic element (channel/impoundment) flow path description** that is applied at one or more equally spaced intervals along the overland flow path. A channel/impoundment flow path description lists the **hydraulic elements** (i.e., channels, impoundments) in the channel/impoundment flow path. Each diversion/terrace and sediment basin is assumed to be thin and to take up no space on the hillslope. This approach does not take into account how back and front slope characteristics of a diversion/terrace or sediment basin affect erosion.

A RUSLE2 **template** having the **three layer profile schematic** should be used (1) for complex conditions where the channel/impoundment flow paths are not equally spaced along the overland flow path, (2) where the individual channel/impoundment flow path differ, (3) where the soil, topography, and cover-management conditions of the embankment/channel should be described because of their effect on erosion, and (4) where soil, steepness, or cover-management vary along the overland flow path.

An example where the hydraulic element flow paths are non-uniformly spaced along the overland flow path is illustrated in Figure 8.12 where a diversion is placed at the top of a landfill sideslope. Figure 8.11 illustrates a detailed description of embankment/channel topography. Grass is often used on steep backslope terraces to prevent excessive erosion. The detailed soil, topography, and cover-management of such embankment/channels can be represented as described in **Sections 8.3.3 and 8.3.4**.

14.3.5.1. Inputs for a hydraulic element (channel/impoundment) system description

The inputs for a **hydraulic element (channel/impoundment) system description** are (1) number of hydraulic element (channel/impoundment) flow paths that cross the overland flow path, (2) whether a channel/impoundment flow path is located at the end of the overland flow path, and (3) the **hydraulic element (channel/impoundment) flow path description**.

When a hydraulic element (channel/impoundment) system description is used in RUSLE2, the overland flow path length is described without the hydraulic elements present. RUSLE2 uses the input for number of channel/impoundment flow paths that cross the overland flow path to determine the overland flow path length between the hydraulic element flow paths. This overland flow path length is the overall overland flow path length divided by number of channel/impoundment flow paths (diversion/terraces) if a channel/impoundment path is located at the end of the overland flow path. If a channel impoundment path is not located at the end of the overland flow path, the overland flow path length between channel/impoundment paths is computed as the overall overland flow path length divided by the number of channel/impoundment paths plus one.

The number of channel/impoundment flow paths that cross the overall overland flow path varies with the overland flow path chosen for the RUSLE2 computation. A representative number should be chosen based on the conservation and erosion control planning objective, which is similar to choosing the number of porous barriers that cross the overland flow path (see **Sections 14.2.5.1 and 14.2.5.2**).

Extra consideration should be given to selecting the number of channel/impoundment flow paths that cross the overall overland flow path when representing parallel impoundment terraces. The overland flow path length between parallel impoundment terraces varies greatly as illustrated in Figure 14.15. The RUSLE2 computed overland flow path length should be checked to determine if this overland flow path length is appropriate. The RUSLE2 computed overland flow path length can sometimes be too short. An improvement in the erosion computation can be made by decreasing the number of channel/impoundment flow paths that cross the overall overland flow path. Also, the overall overland flow path can be lengthened for the hydraulic element computation but not for the computation when the hydraulic elements are not present. Another alternative is to apply RUSLE2 to a single inter-terrace interval.

The number of channel/impoundment paths is not the total number on the hillslope but the number that cross the selected overland flow path used in the RUSLE2 computation.

The input of whether a channel/impoundment (diversion/terrace) flow path is at the end of the overland flow path significantly affects computed sediment yield. A diversion/terrace at the end of the overland flow path is unnecessary when the sole purpose of the diversion/terrace system is to control rill-interrill erosion. In that case, a **no** input is selected for whether a channel/impoundment flow path is located at the end of the overland flow path. When **no** is selected, the sediment eroded on the last overland flow path interval leaves the RUSLE2 overall overland flow path without passing through the selected channel/impoundment flow path. If a channel/impoundment flow path is placed at the end of the overland flow path to trap sediment and control sediment yield from the site, select **yes** for whether a channel/impoundment flow path is located at the end of the overland flow path. This selection causes RUSLE2 to compute that sediment eroded on all overland flow path intervals passes through the selected channel/impoundment flow path.

The last input is to select a **hydraulic element (channel/impoundment) flow path description** from previously created entries in the RUSLE2 database.

14.3.5.2. Inputs for a hydraulic element (channel/impoundment) flow path description

A **hydraulic element (channel/impoundment) flow path description** gives the sequence of hydraulic elements (i.e., channel and impoundment) along the flow path.

Table 14.7 lists the possible sequences that can be used in RUSLE2.[153]

DO NOT ENTER SEQUENCES OTHER THAN THOSE LISTED IN TABLE 14.8.

Table 14.7. Possible sequences of channel and impoundment hydraulic elements used to represent hydraulic element (channel/impoundment) flow paths.	
Sequence	Comment
Impoundment	Overland flow drains directly into impoundment. Typical application is a sediment basin on a construction site.
Impoundment-impoundment	Overland flow drains directly into the first impoundment, which in turn drains directly into the second impoundment. Typical application is two sediment basins in series on a construction site where sediment yield leaving the site must be very low.
Channel	Overland flow drains uniformly into channel along its length. No inflow at upper end of the channel can occur. Typical application are gradient terraces on an agricultural field or a diversion on a construction site or landfill.
Channel-impoundment	Overland flow area drains uniformly into channel along its length. No inflow at upper end of the channel can occur. Discharge from channel flows directly into impoundment. Typical applications are impoundment parallel terraces on an agricultural field and a diversion used to divert overland flow into a sediment basin on a construction site.
Channel-impoundment-impoundment	Same as a channel-impoundment sequence except that discharge from the first impoundment flows directly into the second impoundment. An example application is a diversion channel discharging overland flow into a series of two sediment basins on a construction site.
Note: When a segment on the overland flow path is adjacent to a segment with an adverse (negative) steepness, RUSLE2 assumes a channel hydraulic element at the intersection of the segments (see **Section 8.3.3**). The default channel assumed by RUSLE2 is steep so that no deposition occurs. A hydraulic element (channel/impoundment) flow path description from the RUSLE2 database can be substituted for the default channel, which allows RUSLE2 to compute deposition in channels at the intersection of the backslope and frontslope of a bench terrace system (see Figure 14.16) and in furrows separating ridges (see Figure 8.14), for example.	

An impoundment element can be the single element in the sequence, which represents overland flow discharging directly into an impoundment without first flowing through a channel. This sequence represents a sediment basin on a construction site.

[153] Other sequences besides those listed in Table 14.8 can be entered, but RUSLE2 does not properly compute deposition for other sequences.

Outflow from an impoundment is assumed to be a point discharge that can only flow into another impoundment. It can not discharge into a channel because a channel can not accept inflow at its upper end. Two or more impoundments can be placed in series to represent sediment basins in series.

A RUSLE2 channel hydraulic element is a channel of uniform grade that receives runoff uniformly along its length from the adjacent overland flow area. No inflow occurs at the upper end of the channel (i.e., discharge is zero at the upper end of the channel). **Only a single channel can be in the sequence of hydraulic elements used to describe a hydraulic element (channel/impoundment) flow path. If a channel is in the sequence, it must be the first hydraulic element in the sequence.**

RUSLE2 does not compute erosion in a channel. Ensure that the channel's lining is sufficient to prevent erosion for the channel's field grade.

A single channel is used to represent gradient terraces, illustrated in Figure 14.15, on an agricultural field, a diversion on a construction site, and a diversion at the top of the landfill sideslope illustrated in Figure 8.12. The discharge from a channel is a point discharge that can only flow into an impoundment element because of the no inflow requirement for a channel. A channel-impoundment sequence is used to represent parallel impoundment terraces illustrated in Figure 14.15.

The no inflow requirement for channels means that a sequence of channels can not be used to describe a variable grade diversion or terrace system, for example. A single grade must be entered to represent a variable grade channel. If the profile along the channel is concave, enter the grade over the last one fourth to one third of the channel. If the profile along the channel is convex, enter the grade over the first one third to one half of the channel.

Notes:
Grade along a RUSLE2 channel is uniform.
No inflow can occur at the upper end of a RUSLE2 channel, i.e., channels can not be in series to represent non-uniform grade channels.
RUSLE2 does not compute erosion in channels.
RUSLE2 is not a hydraulic design procedure. Proper hydraulic procedures should be used to design channels and impoundments.
The impoundments considered by RUSLE2 are small impoundments like sediment basins and impoundments associated with parallel tile outlet terraces.
RUSLE2 does not consider the disposal channel system associated with diversions and gradient terraces.

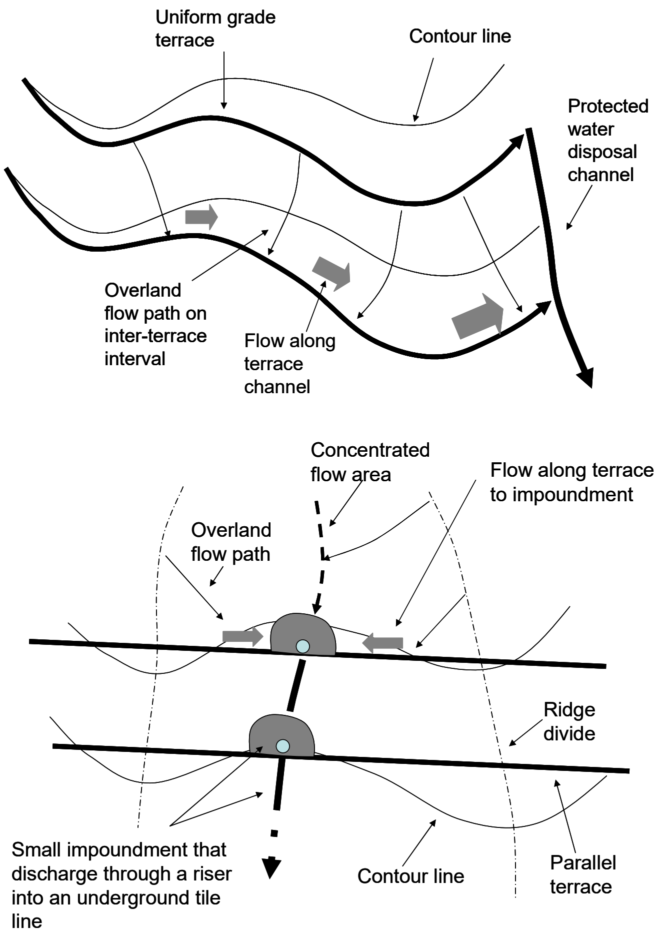

Figure 14.15. Illustration of a gradient terrace (top sketch) and parallel tile outlet (PTO) terrace systems (bottom sketch) and associated flow paths.

No inputs are required to describe an impoundment hydraulic element. Grade is the single input used to describe a channel hydraulic element. A typical RUSLE2 database contains channel descriptions over a range of grades from which selections can be made in describing channel/impoundment flow path systems.

RUSLE2 makes no distinction between a diversion or a terrace channel. Both are represented by the same channel hydraulic element. If a channel is intended to behave as a diversion where no deposition is expected, the RUSLE2 output should be reviewed for deposition. If deposition is computed in the diversion channel, a channel with an increased grade should be selected.

14.3.5.3. Inputs for the RUSLE2 default channel description

RUSLE2 automatically inserts a **default channel** when an overland flow path segment intersects with an overland flow path segment having an adverse (negative) steepness (see **Section 8.3.3**). Also, RUSLE2 may automatically assign a default channel at the end of the overland flow path. The grade of this default channel is already entered in the RUSLE2 database, and it can be changed. The grade is usually set at a very high steepness (e.g., 100 percent) so that RUSLE2 does not compute deposition in the default channel. Another channel that represents the field condition can be selected to replace the default channel in a particular RUSLE2 computation by selecting a channel/impoundment flow path description from the RUSLE2 database. By making this substitution, RUSLE2 can compute deposition in the channels that RUSLE2 assigns for inward sloping bench terraces illustrated in Figure 14.16, in the furrows between ridges illustrated in Figure 8.14, and in a concentrated flow areas that separates two overland flow areas, which are created by dividing an overland flow path into two segments and entering a negative steepness for the second segment.

14.3.5.4. Inputs for bench terraces

Figure 14.16 illustrates bench terraces that can be represented by RUSLE2. The hydraulic element system component of the RUSLE2 database is not used in this RUSLE2 application. A RUSLE2 template having the three layer profile schematic is used to describe bench terraces.

The first bench terrace system is an outward sloping bench terrace where the benches slope outward away from the hillslope. The overland flow path is divided into segments where steepness values are entered into appropriate segments to represent the steep backslope and the relative flat bench. Runoff as overland flow is assumed from the top of the benches across each bench through the last bench. Different cover-management descriptions are selected for the backslope and bench segments.

The same procedure is used to describe inward sloping bench terraces where the benches slope inward to the hillslope. A negative steepness is entered for the inward sloping bench segments. Using this information, RUSLE2 determines the overland flow path lengths for each segment. RUSLE2 treats each backslope-bench combination as a separate catchment. RUSLE2 also assigns a default channel at the intersection of the backslope and bench. A channel on a low grade can be selected from the RUSLE2 database to replace the default channel so that RUSLE2 can compute deposition in the runoff that flows around the hillslope at the base of each backslope. Appropriate cover-management descriptions are selected for the backslope and bench segments.

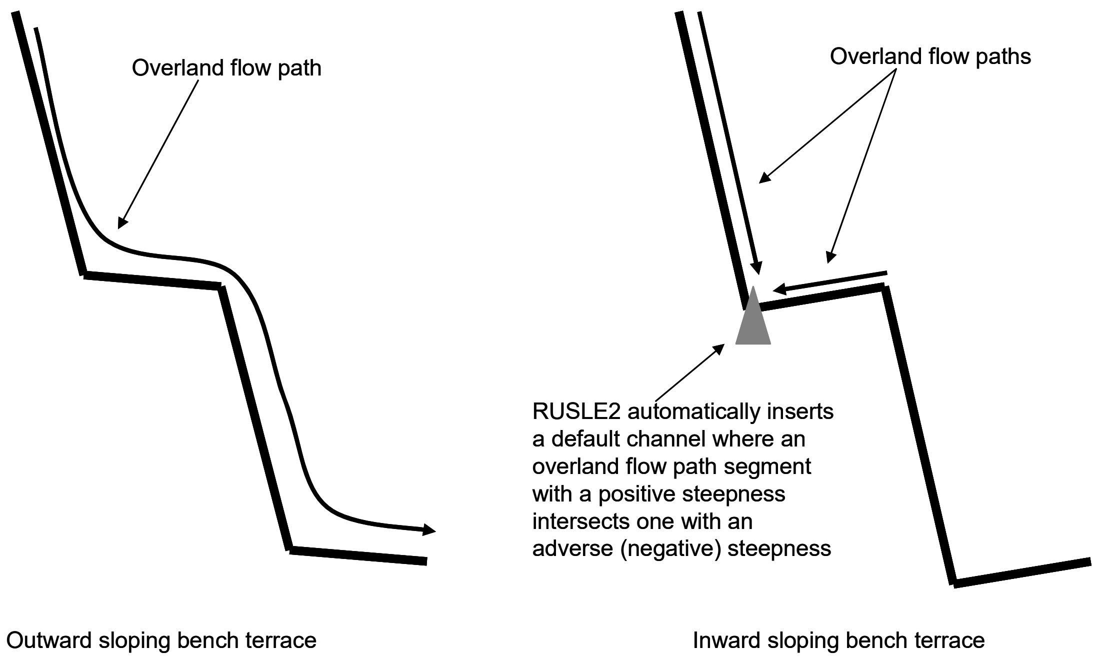

Figure 14.16. Overland flow paths for outward and inward sloping bench terraces.

14.4. Subsurface Drainage

14.4.1. Description of practice

Subsurface drainage is where lateral ditches or perforated pipe (tile line) placed about 2 to 3 ft (0.5 to 1 m) below the soil surface are used to reduce soil wetness to facilitate farming operations and improve crop yield. Subsurface drainage is most often used on relative flat slopes, less than 3 percent steepness, where the water table is near the soil surface over most of the site. Subsurface drainage lowers the water table and reduces soil water content, which in turn reduces runoff and erosion. Localized areas can also be subsurface drained. Examples include where a restricting layer causes a perched water table or in swales where the water table is high at the toe of hillslopes.

Installing tile drainage can be expensive, and therefore, a tile drainage system should be well designed based on site-specific conditions. The two major variables in a subsurface drainage system are depth and spacing of the tile lines and drainage ditches. Increasing depth and decreasing spacing improves subsurface drainage performance but also increases costs. Therefore, most subsurface drainage systems represent a balance between benefits and costs.

14.4.2. Basic principles

Subsurface drainage reduces rill-interrill erosion because it reduces surface runoff and increases vegetation production (crop yield) level. RUSLE2 uses the permeability subfactor equation in its soil erodibility nomographs to estimate how runoff potential reduced by subsurface drainage affects soil erodibility. The effect of increased production (yield) level is considered by inputting a production (yield) level value appropriate for the drained condition.

The two RUSLE2 soil erodibility nomographs include a permeability subfactor that adjusts soil erodibility based on the soil's runoff potential. The six permeability classes used in the nomographs describe runoff potential. Choice of a soil erodibility nomograph permeability class is based on texture and other surface soil properties, soil profile characteristics, presence of a naturally occurring restrictive layer, landscape position, location, and other factors that affect runoff potential under the unit plot condition (see **Sections 7.2 and 7.3.2**). Soil erodibility factor values increases as runoff potential increases.

Each **soil description** in the RUSLE2 database includes a hydrologic soil group designation, which is an index of runoff potential, for the undrained and drained conditions (see **Section 7.7**). RUSLE2 uses this index in the NRCS curve number method to estimate runoff (see **Section 8.1.2**).[154] A **D** hydrologic soil group represents the highest runoff potential while an **A** hydrologic soil group represents the lowest runoff potential. The same factors that determine a permeability class in a RUSLE2 soil erodibility nomograph also determine a hydrologic soil group.

The degree that subsurface drainage changes the hydrologic soil group depends on site specific conditions. A very fine texture undrained soil may be assigned a **D** hydrologic soil group. Subsurface drainage will decrease the soil's runoff potential, but not greatly, resulting in a change of hydrologic soil group from **D** to **C** or **B**. Soil texture is a limiting factor in being able to economically drain this soil.

A coarse texture soil may be assigned a **D** hydrologic soil group because of a restrictive subsoil layer or being in a low position on the landscape. Subsurface drainage can greatly improve internal drainage of this soil resulting in the hydrologic soil group changing from a **D** to an **A**. A coarse soil texture does not limit internal drainage nearly as much as does a fine texture.

Subsurface drainage does not always change the hydrologic soil group designation to an A hydrologic soil group. Internal soil properties, especially texture, also affect the assigned hydrologic soil group for the drained condition.

RUSLE2 uses the permeability subfactor in its soil erodibility nomographs to compute how subsurface drainage affects erosion. RUSLE2 computes permeability subfactor values for the soil erodibility factor based on the hydrologic soil group assigned for the undrained and the drained conditions. RUSLE2 uses the permeability subfactor values and the soil erodibility factor for the undrained condition to compute an **effective soil erodibility factor** value for the drained condition. The four hydrologic soil group classes are scaled to match the six permeability classes used in the permeability subfactor so that a hydrologic soil group can be converted to a soil erodibility nomograph permeability class. RUSLE2 computed values for the effect of subsurface drainage on rill-interrill erosion are illustrated in Table 14.8.

RUSLE2 computes the greatest effect of subsurface drainage when soil erodibility factor (K) values are low. For example, RUSLE2 computes a 60 percent reduction in erosion for subsurface drainage that reduces runoff potential from a **D** to **A** hydrologic soil group for a silty clay soil with a 0.20 US units soil erodibility factor (**K**) value. This runoff potential reduction is too high for a fine textured soil. A more likely runoff reduction potential would be either from a **D** to **C** or **B** hydrologic soil group. RUSLE2 computes

---

[154] The permeability classes used in the RUSLE2 soil erodibility nomographs are essentially a runoff potential index in much way that the hydrologic soil group is a potential runoff index. The permeability class index is used in RUSLE2's soil erodibility nomograph to compute soil erodibility values and the hydrologic soil group index is used in RUSLE2 in the NRCS curve number runoff estimation method to estimate runoff in RUSLE2.

about a 20 percent reduction in erosion for this silty clay soil when runoff potential decreased from a **D** to **C** hydrologic soil group. RUSLE2 computes about a 25 percent reduction in erosion when the runoff potential decreases from **D** to **A** hydrologic soil group for a silt soil having a **K** value of 0.55 US units. These computations are based on the same crop yield for all cases.

The additive, rather than multiplicity, mathematical structure of the soil erodibility nomograph accounts for the much greater relative reduction in erosion by subsurface drainage at low soil erodibility factor values than at high soil erodibility factor values.

A lower limit of 0.2 is set in RUSLE2 for the ratio of erosion with subsurface drainage to erosion without subsurface drainage to prevent RUSLE2 from computing unreasonably low erosion estimates with subsurface drainage.

The RUSLE2 computed values for the effect of subsurface drainage on erosion is essentially not a function of location as illustrated in Table 14.8. Subsurface drainage should affect erosion more at a low precipitation location that at a high precipitation location, especially for coarse texture soils. Values for the hydrologic soil group for the drained condition entered in the **soil descriptions** in the RUSLE2 database can be selected to take this effect into account (see **Section 14.4.5**).

The runoff reduction provided by subsurface drainage depends on drain depth and spacing. This effect can be considered by the values entered in the soil descriptions for the drained condition (see **Section 14.4.5**).

Cover-management condition interacts with surface drainage to affect runoff. That effect is considered by the production (yield) level value for the drained condition entered in the **cover-management descriptions** in the RUSLE2 database (see **Section 10.2.4**). The production (yield) value in a RUSLE2 computation should be appropriate for the subsurface drainage condition.

The other effect of subsurface drainage that RUSLE2 considers is how reduced runoff affect contouring, contouring failure (critical slope length), and sediment transport capacity and deposition. A reduced runoff, which is used in these computations, is computed because of the reduced hydrologic soil group for subsurface drainage. Therefore, because of this reduced runoff, RUSLE2 computes less erosion and sediment yield for situations where contouring and deposition is involved.

If a subsurface drainage support practice is selected, the production (yield) level value should be changed accordingly from the undrained condition.

14.4.3. Calibration/validation

A rule of thumb is that tile drainage reduces rill-interrill erosion by about 40 percent.[155] RUSLE2 computations based on the principles described in **Section 14.2** were made for a wide range of soil textures and drainage intensities to ensure that RUSLE2 gives this result overall. Based on a review of the values listed in Table 14.8 and other values, RUSLE2 was judged to adequately capture the main effects of subsurface drainage on rill-interrill erosion for conservation and erosion control planning. The values shown in Table 14.8 do not consider how subsurface drainage affects yield and its consequent effect on erosion, which is an additional subsurface drainage effect.

14.4.4. Interpretation

Just as for other support practices, RUSLE2 erosion estimates for subsurface drainage represent broad, general effects more than site specific effects. RUSLE2 captures how factors related to site location, vegetation production (yield) level, soil properties, soil position on the landscape, and characteristics of the drainage system affect erosion. RUSLE2 results are much better than the rule of thumb that subsurface drainage reduces erosion by 40 percent. The accuracy of RUSLE2 erosion estimates for subsurface drainage is similar to that for other support practices, including contouring.

Sometimes subsurface drainage is given little consideration as an erosion control practice. It is seldom installed solely for erosion control because of its expense. However, research clearly shows that subsurface drainage significantly reduces erosion in certain conditions, and, therefore, erosion reduction should be recognized as an important benefit of subsurface drainage. Sometimes subsurface drainage is considered to be environmentally detrimental because it is used to drain wetlands, for example.

However, subsurface drainage should be recognized for its merits in appropriate situations.

Perhaps more than any other practice, the subsurface drainage component in RUSLE2 is subject to misuse. For example, subsurface drainage is most effective on relatively flat hillslope areas less than 3 percent steep and in localized areas of wet soils. RUSLE2 does not identify where subsurface drainage should not be used. Technical standards should be consulted for information on subsurface drainage applications.

14.4.5. Input

The **deep (subsurface) soil drainage system descriptions** in the RUSLE2 database have a single input of **portion of the hillslope that is well drained.** The other RUSLE2 inputs to represent subsurface drainage are the hydrologic soil groups in the **soil description** for the undrained and drained conditions (see **Section 7.7**) and the production (yield) level input in the **cover-management description**s used for the drained and undrained conditions (see **Section 10.2.4**).

The hydrologic soil group input represents the degree that subsurface drainage reduces runoff potential of the soil under the unit plot condition given the site location, the soil's position on the landscape, soil profile properties, naturally occurring soil restrictive layers, and subsurface drain depth and spacing. Multiple **soil descriptions** for the same soil profile can be created for various drain depths and spacings. The input for the hydrologic soil group for the drained condition should reflect the site's location. For example, subsurface drainage may have a greater effect on the reduction of runoff potential on a coarse texture soil at a low precipitation location when compared to a high precipitation location. The input for hydrologic soil group for the undrained and drained conditions reflects soil profile properties, especially texture. As discussed in **Section 14.2**, subsurface drainage does not automatically reduce the hydrologic soil group to **A** for all soils, especially fine textured soils.

The NRCS soil survey database and the NRCS RUSLE2 database may have a hydrologic soil group assigned for drained conditions. Check the criteria that NRCS used to select hydrologic soil groups to ensure consistency with RUSLE2 criteria.

Vegetation production (yield) level is usually increased by subsurface drainage because increasing crop production is the major reason for subsurface drainage. Use appropriate yield values for both the undrained and drained conditions.

Subsurface drainage was installed decades ago in many farm fields. When applying RUSLE2 to these fields, the easiest approach is to ignore subsurface drainage if no assessment is being made on how subsurface drainage affects erosion. Make sure that the hydrologic soil group input for the undrained condition and the input for vegetation production (yield) level represents the current field condition. RUSLE2 computes a subsurface drainage effect only if the hydrologic soil group input for the drained condition differs from the corresponding input for the undrained condition, and different vegetation production (yield) level inputs are not entered for the drained and undrained conditions.

The input for **portion of the hillslope that is well drained** is used to compute erosion for an overland flow path where only a portion of it is subsurface drained. An overland flow path having a complex:convex-concave profile is an example. The lower concave portion of this profile can have high soil wetness because of a low landscape position. Localized subsurface drainage is used to eliminate this soil wetness. Soil wetness is not a problem on the upper part of the overland flow path. An input value less than 100 percent for **portion of the hillslope that is well drained** represents this situation. RUSLE2 uses this input to weight its detachment (sediment production) computations and the curve numbers it uses to computes runoff for the undrained and drained conditions.

Also, this input can be used to reduce the effect that RUSLE2 computes for subsurface drainage. For example, if RUSLE2 is judged to compute too much erosion reduction, a value less than 100 percent can be input to reduce the subsurface drainage effect computed by RUSLE2. If the trivial input of zero (0) is entered, RUSLE2 computes no subsurface drainage effect on erosion, unless different yield values are used for the undrained and drained conditions.

RUSLE2 does not notify the user when it computes questionable erosion estimates for subsurface drainage. The RUSLE2 user must know where and how subsurface drainage is used and must make the proper inputs.

14.5. Irrigation

14.5.1. Description of practice

Irrigation adds water to the soil to increase vegetation (crop) production or to dispose of waste. The principal irrigation types are surface, sprinkler, and subsurface applied water. Surface irrigation discharges water in a line source at an upslope field edge and water infiltrates along the flow path, which results in discharge rate decreasing with downslope distance.[156] Although surface irrigation can cause high erosion, RUSLE2 does not estimate this erosion because RUSLE2 assumes an increasing discharge rate along its flow path.

RUSLE2 can not be used to estimate erosion directly caused by irrigation.

Sprinkler irrigation applies water through a system of pipes and overhead spray nozzles. Water is applied to only a portion of the area at a time. The water application is moved through time to cover the entire area. A two week cycle might be used, for example, to cover the entire area with multiple applications over a crop production season. Water is applied at a sufficiently low rate so that no runoff, and thus no erosion, occurs.

Subsurface (drip) irrigation applies water through a system of underground pipes and emitters. This type of irrigation does not cause rill-interrill erosion.

Although RUSLE2 is not used to estimate rill-interrill erosion caused by any type of irrigation, it can be used to estimate erosion caused by rainfall to reflect how irrigation changes the field conditions that affect rill-interrill erosion.

14.5.2. Basic principles

A main effect of irrigation captured by RUSLE2 is increased soil moisture that increases soil erodibility, increases biomass decomposition, and decreases soil surface roughness and soil ridge height. The main inputs to represent irrigation in RUSLE2 are the vegetation production (yield) level appropriate for the irrigation management, amount of water added by irrigation, and amount of biomass added in the irrigation water.

[156] The erosion mechanics of surface irrigation are described by Toy, T.J., G.R. Foster, and K.G. Renard. 2002. Soil Erosion: Processes, Prediction, Measurement, and Control. John Wiley and Son, New York, NY.
.

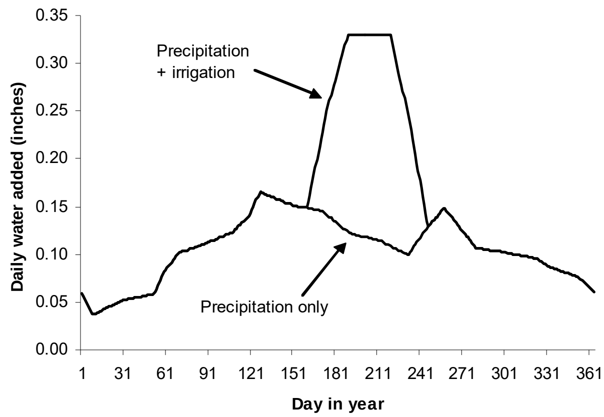

Figure 4.17. Precipitation and water added by irrigation for a 112 bu/ac corn crop at Columbia, Missouri.

RUSLE2 computations for the effect of irrigation were made for a 112 bu/ac conventionally tilled and a 112 bu/ac no-till corn crop at Columbia, Missouri. The results are summarized in Figure 14.17-14.20. In this example, irrigation water was added at the rate to just meet daily consumptive use, which is illustrated in Figure 14.17. The daily water added by irrigation is summed with daily precipitation, which is used to compute daily soil erodibility, daily decomposition, and daily loss of soil surface roughness and ridge height.

A major effect of irrigation computed by RUSLE2 is the increased soil erodibility during the irrigation period, which is illustrated in Figure 14.18. An upper limit is placed on how much added irrigation water can increase soil erodibility. No daily soil erodibility value can be greater than twice the soil erodibility value computed by a RUSLE2 nomograph.

The other major effect of irrigation is that it increases residue decomposition. Figure 10.19 shows the increase in decomposition computed by RUSLE2 for the 112 bu/ac no-till corn at Columbia, Missouri. The increase in decomposition was not great. The relative increase will be significantly greater in dry regions, such as Scotts Bluff, Nebraska. Very little of the decomposition effect continues beyond harvest because of the large amount of residue added by harvest.

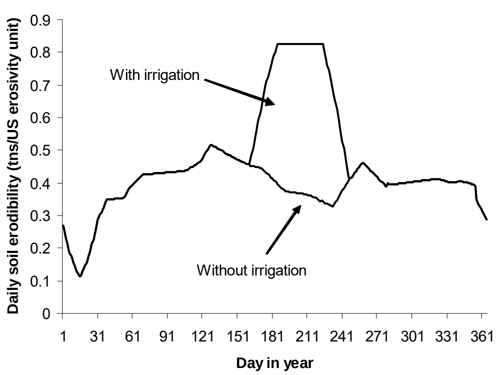

Figure 14.18. Effect of irrigation on daily soil erodibility at Columbia, Missouri.

Most of the effect of irrigation on erosion is during the irrigated period, as shown in Figure 10.20 by daily erosion rates computed for the 112 bu/ac conventionally tilled corn. The computed annual increase in erosion was from 24 to 30 tons/acre·year and 1.5 to 2.4 tons/acre·year, for the conventionally tilled and no-till crops, respectively. This difference in erosion is for the same yield. These computations illustrate how irrigation affects RUSLE2 computed erosion if nothing changes other than adding irrigation. The proper calculation would have been to input a yield value appropriate for the irrigated conditions. The RUSLE2 computed erosion is 26 tons/acre·year if the irrigation is assumed to increase yield from 112 bu/ac to 150 bu/ac. Further erosion reduction would have occurred if the applied irrigation had a significant content of bio-solids.

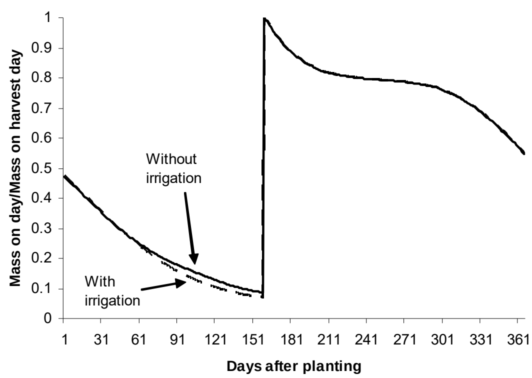

Figure 14.19. RUSLE2 computed decomposition for no-till corn at Columbia, Missouri.

14.5.3. Calibration

The RUSLE2 procedure that describes how irrigation affects erosion caused by natural precipitation (rainfall) and its associated runoff was not calibrated. Computed erosion values were not compared to measured values. However, erosion values were computed for a range of conditions and reviewed to ensure that RUSLE2 gives values acceptable for conservation planning.

14.5.5. Inputs

The input yield values should be appropriate for the irrigated management system (see **Section 10.2.4**). The effect of the increased yield that reduces erosion is just as important as the increased soil moisture that increases erosion. The best way to input yield values for irrigation is to create vegetation descriptions specifically for irrigated conditions. These vegetation descriptions include consumptive use values. A vegetation description is selected that is appropriate for the region, soil, and irrigation management system. Yield values in the cover-management descriptions using these vegetation descriptions can be varied to accommodate site-specific conditions. The RUSLE2 yield adjustment procedure for vegetation descriptions adjusts consumptive use values along with the other values.

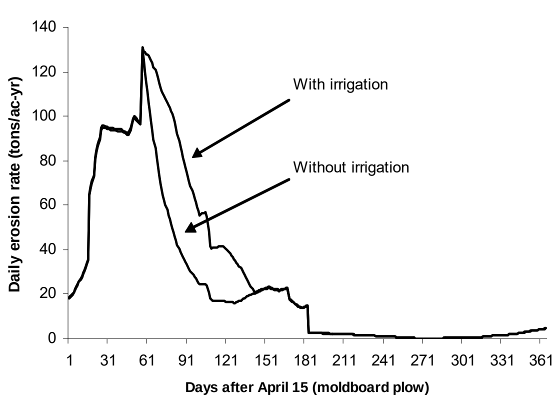

Figure 14.20. RUSLE2 computed effect of irrigation on daily erosion rate for 112 bu/ac conventionally corn at Columbia, Missouri.

The amount of water added by irrigation can be input using either of: (1) consumptive use through time, (2) dates and application rates on those dates, and (3) and period application depths. Irrigation systems are typically designed to supply water at the daily consumptive use of the crop being grown. Therefore, the consumptive use input method is preferred for inputting irrigation amount values in RUSLE2. Daily consumptive use values are entered in the vegetation description for the irrigated system, soil, and region. Consumptive use values depend on the crop and its yield, location, soil, and perhaps other factors.[157] If consumptive use is less than natural precipitation, such as for supplemental irrigation in the southeastern US, one of the other two input methods can be used to input irrigation amounts.

The other two input methods for irrigation amount are to enter application rates on particular days or to enter irrigation amounts (depths) by period. These periods are at the user's choice, which can be monthly, biweekly, or arbitrary non-uniform periods. Consideration should be given to reducing added water amounts for irrigation systems, such as drip irrigation, that do wet the surface soil.

The effect of added biomass that is applied by irrigation (e.g., for example waste disposal of bio-solids) is represented by including an **operation** that **adds external residue** in cover-management descriptions (see **Section 10.2.6**). Biomass added by irrigation is represented in a cover-management description having an **operation description** that applies **external residue** (see **Section 10.2.6**). This cover-management description involves the date of the operation that applies the biomass, biomass amount (dry matter basis) added by the operation (not the average annual mass applied), and the selection of a **residue description** that represents the applied biomass (see **Section 12**). RUSLE2 applies external residue by event rather than on a continuous daily rate. If biomass is applied by an irrigation system that operates on a cycle, the dates of the **add biomass** operation should be on the same frequency as the irrigation cycle. If the biomass is applied daily, the application can be approximated by applying a two week biomass amount once every two weeks. A sensitivity analysis (see **Section 17.3**) can be conducted to determine if the biomass can be applied in monthly intervals rather than in biweekly or other intervals. Decomposition characteristics of the biomass mainly determine the frequency of the biomass applications when approximating daily applications.

14.5.4. Interpretation

[157] Values for consumptive use and other information related to irrigation application rates can be obtained from local offices of the USDA-NRCS and Extension Service affiliated with Land Grant Universities in each state.

The RUSLE2 intent is to capture broad, main effects of increased soil moisture caused by the addition of water by irrigation. RUSLE2 does not capture hydrologic and hydraulic detail. The purpose of RSULE2 is to provide information useful for conservation and erosion control planning, not for irrigation system design. RUSLE2 estimated erosion for the effect of irrigation is comparable in accuracy to RUSLE2 computed values for other support practices, including contouring. Using RUSLE2 to evaluate the effect of irrigation on rill-interrill erosion by rainfall is much better than disregarding the effect.

15. APPLICATION OF RUSLE2 TO PARTICULAR LAND USES

RUSLE2 is **land use independent**, which means that RUSLE2 estimates rill-interrill erosion caused by rainfall and its associated Hortonian-type overland flow any where mineral soil is exposed (see **Section 5**). This capability is a major advantage when applying RUSLE2 to reclaimed mined land, waste disposal sites, disturbed forest land and mechanically disturbed military lands, and other lands where climate, soil, topography, and cover-management variables that affect erosion traverse the spectrum of conditions on common land use classifications such as cropland, rangelands, grazing lands, pasture lands, and disturbed forest lands. Erosion conditions on a common land use like cropland vary from a bare, highly erodible soil to a highly erosion resistant, well maintained pasture. Similarly, erosion conditions on rangeland vary from a highly erodible, recent mechanically disturbed pipeline construction site to a site never mechanically disturbed other than by wild animal presence. Well designed erosion prediction technology like RUSLE2 is based on a description of the fundamental variables that are land use independent. Erosion is a mechanical process where soil particles are detached and transported when the forces on them from raindrop impact and surface runoff become sufficiently strong.

Erosion prediction technologies designed for specific land uses like rangelands are much more limited than is RUSLE2, even when applied to that land use. RUSLE2's land-use independence allows it to be applied anywhere mineral soil is exposed to the erosive forces of raindrop impact and surface runoff produced by Hortonian overland flow.

However, many RUSLE2 users' applications will be limited to specific land uses such as construction sites. Easy-to-use RUSLE2 user guides targeted to specific land uses are needed. This RUSLE2 User's Reference Guide provides reference information on which to base user guides for specific land uses. Such RUSLE2 user guides will include input data and other land use specific information not available in this RUSLE2 User's Reference Guide. Also, user guides are needed that describe RUSLE2 computer program mechanics and operations for specific land uses.

An example of user guides for a specific land use includes a workbook and a user manual for construction sites and other highly disturbed lands. These documents are available from the International Erosion Control Association.

A primary source of RUSLE2 information is the USDA-ARS RUSLE2 Internet site http://www.ars.usda.gov/Research/docs.htm?docid=6010. The University of Tennessee and the USDA-Natural Resources Conservation Service, both of whom participated in the RUSLE2 development, also maintain RUSLE2 Internet sites.

Several RUSLE2 related documents are helpful for developing land use specific RUSLE2 user guides. Not all information in these and other RUSLE2 related documents applies to RUSLE2. Always check information from other sources to ensure that it is consistent with the RUSLE2 User's Reference Guide before using it in RUSLE2 applications.

16. CORE DATABASE

A core database was used to develop, verify, and validate RUSLE2 for a base set of conditions. Values selected for new entries in a user's RUSLE2 working database should be selected based on information in this **RUSLE2 User's Reference Guide** and values in the **RUSLE2 core database**. Values for new entries must follow RUSLE2 definitions and be consistent with RUSLE2 core database values. Also, the **RUSLE2 core database** values must be used when RUSLE2 is being evaluated against the USLE, RUSLE1, and other erosion prediction technologies, against research data, and other analyses.

The **RUSLE2 core database** can be obtained from the official USDA-Agricultural Research Service Internet site http://www.ars.usda.gov/Research/docs.htm?docid=6010 maintained at the National Sedimentation Laboratory in Oxford, Mississippi. The **RUSLE2 core database** is named **RUSLE2 core data**.

17. EVALUATION OF RUSLE2

17.1. Verification/Validation

Verification is the process of ensuring that RUSLE2 makes its calculations as intended. Verification ensures that the equations, parameter values, and logic that links the equations have been programmed as designed and give the expected results. Verification involves running the model for the range of: research data used to derive the model, the RUSLE2 core database, and field conditions for which RUSLE2 might be used. Also, verification involves running the model for special conditions to make sure that every equation and every logic step in the model is exercised. The objective is to test every element of the model to find and fix all errors.[159] This verification process was extensively and fully followed in developing RUSLE2.

No guarantee is made that RUSLE2 contains no computational errors, only that an aggressive effort was made to find and fix errors.

Validation is the process of ensuring that RUSLE2 serves its intended purpose as described…"[160]

The stated purpose of RUSLE2 is to guide conservation and erosion control planning by users at the field office level, such as the field offices of the USDA-Natural Resources Conservation Service (NRCS). RUSLE2 was designed to be land use independent and is to apply to all conditions where rainfall and its associated Hortonian overland flow cause rill-interrill erosion of exposed mineral soil (see **Section 5**). RUSLE2 does not apply to erosion caused by runoff during irrigation (see **Section 14.5**) or snow melt (see **Section 6.3.3**). RUSLE2 is not a process representation of erosion, and RUSLE2 is not a tool for discovering new, original scientific knowledge about erosion. RUSLE2 represents its developers' interpretation of research data, accepted scientific and technical information, and judgments about use of erosion prediction technology in conservation and erosion control planning (see **Section 17.2**).

The most important part of RUSLE2's validation is whether RUSLE2 leads to the desired erosion control decision, not how well RUSLE2 estimates compare to measured data. Validation certainly involves evaluating RUSLE2's accuracy, but many other considerations are also important in judging how well RUSLE2 serves its stated purpose. For example, a model could perfectly compute erosion, but if the resources required to use the model exceed available resources, the model is invalid, (i.e., it does not serve its intended purpose).

---

[159] Essentially a quote from Toy, T.J., G.R. Foster, and K.G. Renard. 2002. Soil Erosion: Processes, Prediction, Measurement, and Control. John Wiley and Son, New York, NY. p. 146.
[160] Essentially a quote from Toy et al., 2002. p. 146. Also, see pp. 146-149 regarding model validation.

RUSLE2 should be easy and convenient to use, including when it is used infrequently. RUSLE2 must not require excessive resources including: time required to learn the model; time to actually run the model in developing a conservation or erosion control plan; acquisition, assembly, and entry of input data; computer skills; and technical expertise required to run RUSLE2. Support documents, training, and assistance when problems arise must be available.

Are the benefits gained from using RUSLE2 worth its costs, especially in comparison to using alternative methods to develop conservation and erosion control plans? How does the quality of conservation and erosion control plans developed with RUSLE2 compare with those developed from use of other erosion prediction technologies? If two erosion prediction technologies result in the same conservation and erosion control plan, each technology performs equally well. The choice of a specific erosion prediction technology is, therefore, determined by preferences and resources required to use each technology.

RUSLE2 must accurately represents scientifically accepted trends of how major variables such as precipitation amount and intensity, soil texture, overland flow path length and steepness, ground cover, soil biomass, and contouring affect erosion. Research data available to develop erosion prediction technology are unavoidably incomplete and biased. The data do not represent all of the conditions where RUSLE2 will be applied, and consequently, numerous RUSLE2 applications will be extrapolations beyond the data used to derive RUSLE2. Therefore, whether RUSLE2 accurately represents scientifically accepted trends is a key factor in how well RUSLE2 performs when extrapolated. RUSLE2 was also developed to be robust so that extrapolations are conservative and conform to obvious, defined limits, (i.e., if RUSLE2 estimates are erroneous, the estimates will not be unreasonable).

Erosion data have a high degree of explained variability and bias. For example, regression fitting of an equation to a particular experimental data set gives the nonsensical results that the fitted equation computes increased erosion with increased ground cover. The data are obviously flawed or biased by incompleteness, measurements not based on RUSLE2 definitions, or measurement error. RUSLE2 describes accepted scientific trends even though the fit to particular observed data may be compromised.

RUSLE2 developers envisioned themselves in the position of land users impacted by RUSLE2. Given their knowledge of both erosion science and RUSLE2's representation of that science, RUSLE2 developers asked themselves the question, do they have sufficient confidence in RUSLE2 erosion estimates in particular situations to be willing to implement RUSLE2 based erosion control practices?

Users should assure for themselves the validity of RUSLE2. This RUSLE2 User's Reference Guide describes in detail how RUSLE2 was derived, what it represents, and how RUSLE2 represents accepted scientific and technical information.

17.2. Interpretations in the context of conservation and erosion control planning

The RUSLE2 developers followed several fundamental principles to interpret research data used to empirically derive and calibrate RUSLE2 equations and to validate RUSLE2. Whether or not RUSLE2 is considered valid depends on the acceptance of these principles.

17.2.1. Principle 1: Fit main effects

The first step in applying the **main effects principle** is to assemble the largest possible dataset for the erosion control practice or other condition being analyzed. These datasets are seldom ideal because of incomplete, non-uniform, and biased coverage, and much unexplained variability.[161] The second step is to identify the variables and equation form based on erosion theory and fundamental erosion process studies that will be used to describe the main effects. Analyzing erosion data for no-till cropping provides a case study for illustrating the main effects principle.

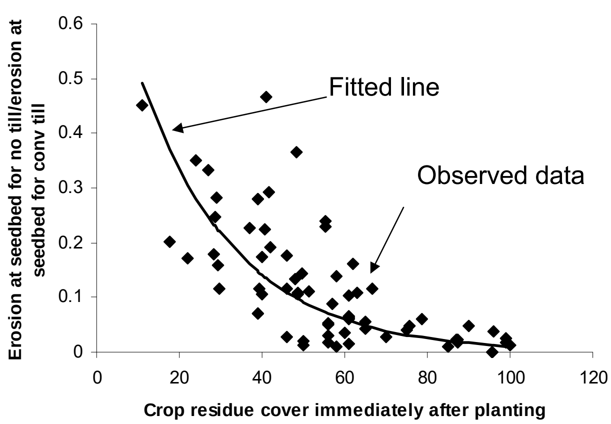

Figure 17.1. Relation of erosion with no-till cropping to erosion with conventional tillage for seedbed period.

Conservation tillage, including no-till, is widely used to control erosion on cropland. Experimental erosion data for no-till cropping are plotted in Figure 17.1 where the dependent variable is ratio of erosion with no-till to erosion with conventional till for the seedbed period. Results from many fundamental erosion studies involving applied mulch show that erosion decreases rapidly as ground cover increases as represented by Equation 9.6.[162]

[161] Nearing, M.A., G. Govers and L.D. Norton. 1999. Variability in soil erosion data from replicated plots. Soil Sci. Soc. Amer. J. 63: 1829-1835.

[162] See, for example,

Manering, J.V. and L.D. Meyer. 1963. Effects of various rates of surface mulches on infiltration and erosion. Soil Science Society of America Proceedings 27:84-86.

Therefore, ground cover is assumed to be a main effect variable for no-till's effect on erosion.

The deviation in erosion from the main effect is large in Figure 17.1. For example, the fitted value at 50 percent ground cover (crop residue cover) is 0.1 while the experimental values ranged from about 0.02 to 0.4. Other variables have a significant effect, which is captured in RUSLE2 by varying the coefficient **b** in equation 9.6.

Erosion theory and fundamental experimental erosion studies show that the coefficient **b** varies with the rill to interrill erosion ratio because of difference between rill erosion and interrill erosion mechanics. Ground cover reduces rill erosion more than it reduces interrill erosion.[163] Values for **b** are larger where rill erosion is dominant on bare soils, such as on relatively steep overland flow paths (greater than 12 %), than where interrill erosion is dominant, such as on relatively flat overland flow paths (less than 3%).

Fundamental erosion studies show that **b** values are increased when added ground cover increases infiltration, which in turn reduces runoff and rill erosion. Increased biomass in the upper soil layer accompanies increased ground cover in long term no-till cropping but not in short term no-till cropping or in mulch applied to freshly graded construction sites. Consequently, **b** values are a function of land use. Rather than making **b** values a function of land use classification, RUSLE2 computes **b** values as a function of cover-management variables.[164] For example, RUSLE2 detects the difference between a construction site and a no-till cropped field using the soil consolidation factor and the amount of soil biomass in the upper soil layer.

This approach of using equations to represent main effects of major universal climate, soil, topographic, and cover-management variables rather associating equations and coefficient values with a land use classification gives RUSLE2 its land use independence.

The concept in RUSLE2 is to describe the main effect that major variables have on erosion and then compute deviations about the main effect using secondary variables. RUSLE2 properly represents trends apparent from an overall analysis of the experimental data and erosion science even though RUSLE2 may not faithfully reproduce individual

---

[163] Foster, G.R. and L.D. Meyer. 1975. Mathematical simulation of upland erosion by fundamental erosion mechanics. *In:* Present and Prospective Technology for Predicting Sediment Yields and Sources. ARS-S-40 USDA-Science and Education Administration. pp. 190-204.

[164] RUSLE1.06 assigns **b** values as a function of land use classification. RUSLE1.05 assigns b_g values according to a user selected classification for rill to interrill erosion ratio.

data values in an experimental dataset. The RUSLE2 approach increases robustness, which means that RUSLE2 can be more confidently extrapolated beyond the data used to derive it than can regression equations involving a large set of variables fitted to the data.

Selecting equations and coefficient values based on best statistical fits to experimental field data can produce very flawed results for conservation and erosion control planning. The results can be especially flawed if the experimental data have a high degree of unexplained variability and are non-uniform in coverage, incomplete, and biased, problems impossible to avoid in erosion data. For example, the regression approach can result in nonsensical results where erosion is computed to increase as ground cover increases. RUSLE2 faithfully reproduces trends proven by erosion science rather than simply providing the best fit to experimental data that are almost always flawed.

17.2.2. Principle 2: Don't custom fit to local data or to specific data

Some users adjust RUSLE2 parameter and input values to fit a particular data point because that data point is considered more valid that other data points. Increased value is placed on that data point because the data came from a particular locale or because of familiarity with the investigator who collected the data. RUSLE2 adjustments and evaluations based on how well RUSLE2 fits a single data point are generally improper.

RUSLE2 is designed to fit main effects as described in **Section 17.2.1**. Erosion data are highly variable and have a high degree of uncertainty for unknown reasons, especially if the measured erosion rates are low (less than 1 ton/acre per year). The validity of any single data point is, therefore, highly questionable. The validity of a single data point must be judged against the dataset as a whole.

If a particular data point is judged to be valid, fitting RUSLE2 to the single data point should still be avoided. Calibrating RUSLE2 to a data point could well result in RUSLE2 estimates that are seriously erroneous because RUSLE2 no longer will fit the main effect. Either RUSLE2's fit of this single data point should be considered in a particular RUSLE2 application, or another erosion prediction procedure should be used instead of RUSLE2.

17.2.3. Principle 3: Follow RUSLE2 definitions, rules, procedures, guidelines, and core database values

RUSLE2 uses specific definitions, rules, procedures, and core database values that must be followed. RUSLE2 definitions, rules, and procedures were chosen for specific reasons that are sometimes not obvious. For example, adjusting RUSLE2 soil erodibility K factor values to account for increased organic matter resulting from organic farming or applying manure is improper and gives erroneous results. Similarly, soil erodibility factor values adjusted for surface rock fragments should not be used. RUSLE2 considers the effect of rock cover and increased soil biomass in its cover-management computations. The soil erodibility factor applies specifically and only to unit plot conditions.

Similarly, RUSLE2 core database values must be followed because RUSLE2 was calibrated based on those values. The core database values were selected to represent main effects adequately supported by research data and erosion science. The values were selected to be consistent with accuracy of RUSLE2 and the data used to derive RUSLE2. Input values for database entries not represented in the RUSLE2 core database must be consistent with core database values for similar conditions.

While you as a user may not agree with the RUSLE2 definitions, rules, procedures, and core database values, they must be observed. Do not assume that USLE and RUSLE1 definitions, rules, procedures, and input values apply to RUSLE2, because many do not.

17.2.4. Principle 4: Don't evaluate RUSLE2 based on how well it fits secondary variables

RUSLE2 was developed, calibrated, and validated to ensure that it gives good average annual erosion estimates, even if the fit of RUSLE2 computed values for secondary variables (e.g., crop residue) is less than expected. For example, RUSLE2 typically under estimates residue cover for periods longer than about 1 year, but this underestimate does not mean that the average annual erosion estimate is erroneous, especially in rotation-type cover-management descriptions where a large amount of residue is added annually. The adequacy of RUSLE2 computed values for secondary variables is based on RUSLE2 computing the expected erosion estimate, not on how RUSLE2 computed values for secondary variables are used for non-RUSLE2 purposes.

RUSLE2 estimates of crop residue cover immediately after planting can be used in routine conservation planning and compliance activities.

However, situations arise where the RUSLE2 accuracy of a secondary variable is insufficient in a particular RUSLE2 application. An example is applying RUSLE2 to a construction site two or more years after only a single mulch application. Separate RUSLE2 computations using different input residue values for each year may be required to accurately compute erosion in particular years.

Users should use this RUSLE2 User's Reference Guide to determine where RUSLE2 erosion estimates may need special interpretations or RUSLE2 inputs may need adjustment.

17.2.5. Principle 5: Avoid fine tuning parameter and input values

If you must adjust parameter and input values, be sure that you understand the variable being adjusted and how it is used in RUSLE2. Carefully read and follow this RUSLE2 User's Reference Guide to avoid unintended consequences.

Adjusting input values so that RUSLE2 computes an expected residue cover is an example where adjustments are sometimes made. Because RUSLE2 has many interacting variables, changing the value for a single variable may affect several computations. For example, changing the value for the residue decomposition coefficient affects surface residue cover and soil biomass as well. Soil biomass affects computed values for the soil biomass subfactor, surface roughness, and runoff. If the change is only to affect surface residue cover, the residue decomposition coefficient value is not the input variable that should be changed.

Another example where changing the value of a single variable can have unexpected results is the width of soil disturbance. Changing the value for this variable affects more than the soil consolidation subfactor value because several RUSLE2 computations are a function of the soil consolidation subfactor.

Section 12.5 describes a procedure for adjusting input values to obtain an expected residue cover. This procedure is a guide for changing input values for other variables to achieve a particular result.

Make sure that the proper variables are being changed to achieve the desired result.

17.2.6. Principle 6: Make sufficient temporal and spatial field measurements according to RUSLE2 requirements

Canopy, surface cover, surface roughness, and yield are variables that are sometimes field measured as a part of evaluating RUSLE2 and collecting field data for RUSLE2 input. Measuring root biomass should not be attempted except in a very carefully managed research environment, and even then the results are questionable. Soil biomass as used in RUSLE2 should be back calculated from other variables because it is almost impossible to measure.

Field measured values vary randomly and systematically (e.g., a combine leaving residue in strips) in both space and time. Field measurements must be proper and in sufficient number to account for variability keeping in mind that RUSLE2 is designed to represent main effects. Canopy cover, surface cover, fall height, and other RUSLE2 variables must be measured based on RUSLE2 definitions, rules, and procedures to accurately evaluate

RUSLE2 and properly selected input values. Also, many RUSLE2 relationships are nonlinear, which affects how field measurements are made, analyzed, and interpreted. Follow this RUSLE2 User's Reference Guide closely in making field measurements.

Field measurements of residue surface cover are often made and used in the conservation planning and compliance determination on cropland. Given the importance of residue surface cover, special precautions should be observed in making residue cover

Field measurements must be made in accordance with RUSLE2 definitions, rules, and procedures.

measurements.

Both high residue and low residue cover is difficult to measure and convert to residue mass values, partly because of the non-linear residue mass-cover relationship (see **Section 12.3**). Residue samples must be carefully collected and processed (e.g., soil particles carefully removed). The residue mass to cover relationship varies within the field and during the year as the relative composition of plant parts (leaves, stems, and other components) vary in the residue. The relationship also varies from year to year as weather, yield, and field operations vary. Residue measurements should be made over a minimum of three years to obtain values that can be compared to RUSLE2 estimates. Experience also shows that when residue surface cover is accurately measured, cover is often less than assumed based on visual observations.

Soil surface roughness values used in RUSLE2 computations are not the input values because RUSLE2 adjusts the input values for soil texture and soil biomass (see **Section 9.2.3.2**). Also, field measured values for soil surface roughness only match input values when roughness is measured for the base condition used to define RUSLE2 soil surface roughness input values.

The terminology and definitions of plant cover used in vegetation surveys may be quite different from the very specific definitions of canopy cover, ground cover, live ground cover, and fall height used in RUSLE2. Also, the definitions of vegetation production (yield) level may be quite difference from RUSLE2 definitions and input values in the RUSLE2 core database.

Before using information from vegetation surveys, ensure that the values taken from these survey are proper when using them for RUSLE2 input.

17.2.7. Principle 7. Avoid too much detail

Difference between RUSLE2 computed erosion estimates may not be significant. Significance in this context is not the same as statistical significance discussed in **Section 17.4**. In this context, significance refers to a sufficient difference resulting in a conservation planning or compliance decision being altered.

The general guideline is that difference in estimated erosion values should exceed 10 percent because the difference is considered practically significant.

RUSLE2 is not designed to capture the difference between machine adjustments on particular tillage machines, unless the effect of the adjustment is sufficiently great. RUSLE2 is designed to distinguish between machine classes such as straight, sweep, and twisted shovel type chisel plows. Some of the differences in residue burial that are often claimed to be achievable by machine adjustment are questionable (see **Section 13.1.5.3**). Input values should be for machine classes and not varied to reflect individual machine configuration or operation.

Similarly, RUSLE2 is not designed to capture differences between crop varieties other than major differences such as between popcorn and field corn, for example. When differences between crop varieties grown in different regions are sufficiently great to give erosion estimates that differ by more that 10 percent (i.e., the 10 percent rule), differences in crop varieties should be represented. Likewise, dates in cover-management descriptions should be selected to represent major differences such as early, mid, and late season planting and/or harvest, not to represent operations on particular dates. Also, RUSLE2 is not intended to capture how annual variation in operation dates within a cover-management description affects erosion.

RUSLE2 users, especially those who prepare RUSLE2 databases, have the responsibility of determining when difference are sufficiently great to warrant creating new entries in the RUSLE2 database with different input values. Differences in erosion estimates because of difference in inputs values for similar conditions are a partial measure of uncertainty and precision in RUSLE2 erosion estimates.

17.2.8. Principle 8. Computing erosion with RUSLE2 for historical events and individual storm events is an advanced application

RUSLE2 is a conservation planning tool, not a model that reproduces historical erosion events. RUSLE2 is not designed to be evaluated or calibrated by inputting historical data to compute erosion values that are compared to values measured at a particular site. Also, RUSLE2 is not designed to evaluate how historical events such as an unusually dry or wet season or year affected erosion. The uncertainty in RUSLE2 erosion estimates for these applications is much greater than in average annual erosion estimates.

RUSLE2 is not structured to readily accommodate input of historical data, especially weather data for multiple years. Also, RUSLE2 does not represent temporal variations in soil moisture that can greatly affect runoff from individual storm events. RUSLE2 does not conveniently represent residual effects from a previous year, although expert RUSLE2 users can capture much of the effects of these initial conditions. RUSLE2 does not model how vegetation responds to environmental conditions, but values that represent the vegetation and operations for a specific historical period can be input into RUSLE2.

The adequacy of the historical experimental data against which RUSLE2 is being evaluated must be considered. Are the historical, experimental data comparable to the data used to develop RUSLE2 parameter and input values? If not, RUSLE2 computed erosion may not compare well with the measured erosion. A poor fit does not necessarily indicate that RUSLE2 performs poorly, but that the historical experimental data are not representative of the main effects represented by RUSLE2.

A short record, such as three years, often produces data that differ significantly from average annual erosion values measured over an extended period or estimated by RUSLE2. The cover-management data used to develop RUSLE2 were analyzed to compute ratios of erosion values for a given cover-management condition to erosion values for a base condition. The advantage of the RUSLE2 approach is that these ratio values varied much less year to year than did absolute erosion values. RUSLE2 does not reflect how year to year variation in soil moisture, runoff, plant yield, and other variables affects erosion.

RUSLE2 has similar limitations when used to estimate how an especially dry or wet season or year affects erosion. In these extremes, the ratio of runoff to precipitation usually differs significantly from average annual values. Extreme storm events sometimes occur in dry years. Although annual rainfall may be quite low in a dry year, a few very intense rainfall events can cause exceedingly high erosion per unit precipitation. Conversely, a wet year can involve many relatively low intensity storms that cause reduced erosion per unit precipitation. Although RUSLE2 captures some but not all of these effects, RUSLE2 is limited because it does not compute runoff by individual storm event.

Input data for the climate, operation, vegetation, residue, and cover-management descriptions can be entered to represent a particular year. RUSLE2 computes erosion estimates that partially reflect how departure of these input values from average annual conditions affects erosion. Also, expert users can set up RUSLE2 to capture most residual effects from a previous year where conditions differed greatly from those for the year being analyzed. The RUSLE2 computed erosion is likely to be less than it should be for a wet year and greater than it should be for a dry year.

RUSLE2 can be configured to estimate erosion for a single storm by inputting values to represent conditions on the day of the storm. However, RUSLE2 does not estimate soil moisture and how runoff is affected by soil moisture on the day of the rainfall event. Thus, RUSLE2 erosion estimates will be low or high depending on how soil moisture departs from its average annual value for the particular event. Although RUSLE2 is not intended to estimate erosion from individual storms, its accuracy for individual storm event erosion estimates may be comparable to estimates from complex, process-based models.[165] **RUSLE2 is better for estimating individual event erosion than is commonly assumed.**

These RUSLE2 applications are quite advanced. Proper procedures must be followed. For example, no-rotation type cover-management descriptions should be used in most cases rather than using standard rotation-type cover-management descriptions, even when representing crop rotations. This RUSLE2 User's Reference Guide should be carefully studied and followed in applying RUSLE2 in these special applications.

If users understand how RUSLE2 works regarding individual storms and representing historical events and they have the expertise and other resources to apply RUSLE2, then RUSLE2 is valid in these applications if these RUSLE2 users consider RUSLE2 estimates to be useful.

17.2.9. Principle 9. Always evaluate the adequacy of the data

17.2.9.1. An ideal dataset

All measured erosion data available for developing and evaluating RUSLE2 are questionable in some way.[166] An ideal dataset represents modern climatic and land use conditions, soils and topography as they occur on actual hillslopes, and the full range of conditions where RUSLE2 is applied. Record length is sufficient to provide accurate average annual estimates and probability distributions. The dataset is complete, un-biased, and without measurement error. Replications and treatments are sufficient to define RUSLE2 relationships with a high degree of statistical accuracy. Measurements must be made according to RUSLE2 definitions, rules, and procedures.

17.2.9.2. Natural rainfall versus simulated rainfall

[165] Although RUSLE2 is not intended for estimating erosion for specific storm events, RUSLE2 is fundamentally an event-based procedure. The linearity between storm erosivity and storm erosion simplifies the RUSLE2 mathematical integration for estimating average annual erosion. See **Sections 5.4 and 7.2**.

[166] Toy, T.J., G.R. Foster, and K.G. Renard. 2002. Soil Erosion: Processes, Prediction, Measurement, and Control. John Wiley and Son, New York, NY.

Data from natural rainfall events are much preferred over data from simulated rainfall because simulated rainfall does not perfectly match natural rainfall. Most erosion data collected with rainfall simulators are for standard, uniform intensity storms in comparison with natural rainstorms having greatly varying intensities and amounts. Measured infiltration, runoff, and erosion are functions of temporal rainfall intensity pattern and its interaction with spatially varied soil conditions.[167] Energy for some rainfall simulators is much less than that of natural rainfall. **Data were not used in the development of RUSLE2 that were collected using simulated rainfall where energy was less than about 75 percent of that in natural rainfall.** Rainfall simulators having energies approaching natural rainfall typically apply water intermittently on a cycle ranging from about 5 seconds to 30 seconds, which affects infiltration, runoff, erosion, sediment transport, deposition, and sediment characteristics.

The standard storm set is typically applied only at a few times during the year, usually when the study condition is most vulnerable to erosion condition. In some erosion studies on rangelands involving rainfall simulators, the applied erosivity was much greater than typical annual rainfall erosivity at some locations.[168]

These differences between natural and simulated rainfall raise questions about the advisability of using simulated rainfall erosion data to develop and evaluate RUSLE2. The RUSLE2 developers judged that these data were useful in the context of RUSLE2 being a conservation and erosion control planning tool. Erosion data from simulated rainfall would be interpreted against erosion data from natural rainfall. Erosion data from simulated rainfall were primarily analyzed, except for the soil erodibility nomographs, by forming ratios of erosion for a given condition to erosion for a base condition, realizing that these ratios vary with storm characteristics and other factors (see Figure 17.1).

17.2.9.3. Measurement area size

Erosion plots that are either 35 ft long or 72.6 ft long and 6, 10, or 12 ft wide were widely used to measure the effect of climate, soil, land steepness, and cover-management on erosion. Plots of about 36, 72.6, and 150 ft long (plots as long as 370 ft were used in one study and 650 ft in another study) were used in multiple studies to determine the effect of overland flow path length on erosion. Small watersheds ranging in size from about 2 ac to 5 ac were used to measure the effect of contouring, rotational strip cropping, and terracing on erosion.

[168] See:
Simanton, J.R., L.T. West, M.A. Weltz, and G.D. Wingate. 1987. Rangeland experiments for Water Erosion Prediction Project. Paper No. 87-2545. American Society of Agricultural Engineers. St. Joseph, MI.
Spaeth, Jr., K.E., F.B. Pierson, M.A. Weltz, and W.H. Blackburn. 2003. Evaluation of USLE and RUSLE estimated soil loss on rangelands. J. Range Management 56:234-246.

Do these erosion plots tilled manually or with small equipment adequately represent typical land use practices and non-uniform overland flow paths having lengths that range from 1 ft to 1,000 ft.? Do these small watersheds with their spatial variability of soil, topography, and cover-management conditions provide data suitable for developing RUSLE2?

Even though these and other questions can be raised about these measurement areas, the RUSLE2 developers judged that these measurement areas were appropriate for developing RUSLE2 as a conservation and erosion control planning tool. RUSLE2 users must interpret RUSLE2 erosion estimates in terms of how well these plots and small watersheds represent erosion on the field area where RUSLE2 is being applied (see **Sections 5.1, 5.2, and 5.3**). RUSLE2 developers judged that erosion data from small measurement areas about 3 ft by 3 ft (1 m by 1m) where essentially only interrill erosion occurs are not suitable for developing RUSLE2 or evaluating its estimates of rill and interrill erosion combined for typical overland flow paths.[169] This small measurement area is not suitable for determining RUSLE2 soil erodibility factor values or making relative comparisons of soil erodibility and erosion control practices. Erosion data from plots shorter than 35 ft were not used in the development of RUSLE2 where both interrill and rill erosion were being considered. However, data from interrill erosion type areas were used to develop RUSLE2 interrill erosion relationships.

Finding a suitable area on a natural hillslope for a set of erosion plots having uniform soil and steepness is difficult. A minimum of three replications along with a base treatment, and three treatments are needed, for example, in a simple study to evaluate mulch application rate for a particular mulch type. A set of 12 rainfall simulator plots are needed for this study, which requires a total width of about 220 ft. Finding a uniform area that wide is difficult on natural landscapes. The problem is especially acute on rangelands where erosion rates are low and spatial variability is great. The scale of the variability is on the order of the plot width and length. A slight shift in the placement of a plot can result in significantly different measured erosion rates.

17.2.9.4. Modern data

Modern data representative of current land use practices and climate conditions should be used to develop and evaluate RUSLE2. Modern climate data were used to develop RUSLE2 input erosivity, precipitation, and temperature values. However, the underlying natural rainfall erosion data used to calibrate the soil biomass subfactor equation (equation 9.12) were from the mid 1930's to the mid 1950's. Few natural rainfall erosion

---

[169] Foster, G.R., J.R. Simanton, K.G. Renard, L.J. Lane, and H.B. Osborn. 1981. Discussion of "Application of the Universal Soil Loss Equation to Rangelands on a Pre-Storm Basis." Journal of Range Management 34:161-165.

plot data were collected after the 1970's. Most modern erosion data were collected using simulated rainfall.

Therefore, a question is how well does RUSLE2 estimate erosion for modern conditions? Applying RUSLE2 to modern conditions represents an extrapolation from conditions quite different from current ones. RUSLE2 developers addressed this question and judged that RUSLE2 performs satisfactorily for modern conditions. They also judged that the cover-management subfactor procedure allows RUSLE2 to be extrapolated to conditions significantly beyond those represented in the underlying data.

17.2.9.5. Data record length

About 10 years are usually required to obtain representative average annual values for erosion data measured from natural rainfall for one- and two-year crop rotations. Erosion data for cropped conditions are available from only two locations where the record length exceeded a decade. However, interpretation of a long term data is difficult because of temporal weather variability and changes in farming practices over time. None of the data available for analyzing rotational strip cropping involving five-year and longer crop rotations are fully adequate because of short record length even though record length is about 10 years. A five-year rotation requires 20 or more years to obtain reasonable average annual data and even longer when the crop rotation is used in strip cropping. Collecting such data is often not feasible, which is the reason that these data do not exist.

Data having record lengths as short as three years for natural rainfall events were used in the development of RUSLE2. These data were primarily analyzed to determine ratios, which vary less temporally than do absolute values (see Figure 17.1). Data having a short record length are more susceptible to interpretation problems caused by extreme events occurring during the measurement period and to measurement equipment failure than data having a long record length.

Missing data can be a serious problem. An example is the high erosion rates that can occur during late winter and early spring thaws when soil erodibility is significantly increased. Too few events were measured to adequately represent them in the temporal erodibility equation (see **Section 7.3**). Few locations were adequately equipped to measure runoff and erosion in these environmental conditions, and the need to make those measurements was probably not recognized at the time.

17.2.9.6. Dividing the data into development and evaluation parts

Developers of models sometimes divide data into two parts, one part is used to develop the model and the other part is used to evaluate the model. The entire dataset was used to develop RUSLE2 rather than dividing the data. The best approach is to use the largest dataset possible to develop erosion models given the variability, incompleteness, bias, and other shortcomings in erosion data.

Reports are sometimes published where measured data at a single location for a small, specific set of conditions are compared with RUSLE2 estimates. Such data should first be evaluated to determine how they fit with the RUSLE2 dataset as a whole to ensure that the specific study data are not outliers. Given the unexplained variability in erosion data (e.g., see Figure 17.1), either a good or poor fit of RUSLE2 to a single data point is by chance. Evaluations involving essentially a single data point usually provide very little information about RUSLE2's adequacy.

A main criterion in developing RUSLE2 is that it describes well established main effects. Fitting an erosion prediction equation to incomplete and biased data can produce nonsensical results such as erosion increasing as ground cover increases. The fit of RUSLE2 to experimental data as determined by statistical goodness of fit measures was sometimes compromised so that RUSLE2 accurately represents established main effects. Getting the best statistical fit to reduced quality data may not produce the best result for conservation and erosion control planning.

17.2.9.7. Users must make their own judgments

All developers of erosion prediction technology make judgments about erosion data used to derive equations, parameter values, and input values. Different people reach different conclusions when evaluating a particular dataset and in evaluating RUSLE2's adequacy relative to the dataset. The RUSLE2 developers' judgments are described in this RUSLE2 User's Reference Guide.

Users must make their own judgments about RUSLE2. Users should only use RUSLE2 when they are satisfied that RUSLE2 is suitable for their purposes.

17.2.10. Principle 10. Make sure that the inputs are proper

When RUSLE2 users obtain poor results, they often suspect a problem with RUSLE2, while RUSLE2 developers often suspect improper inputs. Always double check input values when evaluating and applying RUSLE2, and especially ensure that input values are consistent with the core database values. Do not use input values from other erosion models. RUSLE2 input values sometimes differ from values used for similar variables in other erosion prediction technologies, including the USLE and RUSLE1.

Ensure that RUSLE2 rules and procedures are followed. Errors in the sequence of processes used in an **operation description** can easily occur, for example. If a **flatten standing residue process** is used in a soil disturbing operation description, the results will differ significantly depending on whether the flattening process is placed in the operation description before or after the **disturb soil process**. Another example of an input error is where the live root biomass value on day zero in a **vegetation description** is much less than the live root biomass on the last day in this vegetation description when it is used to represent mature vegetation. RUSLE2 adds the difference in the live root biomass between the ending and beginning dates to the dead root biomass pool when none should be added in this situation.

RUSLE2 results can be no better than the inputs.

17.2.11. Principle 11. Be alert for RUSLE2 users who believe RUSLE2

RUSLE2 estimates contain error and uncertainty. All RUSLE2 estimates should be examined, interpreted, and carefully considered before using them. Conservation and erosion control planners should always make planning decisions using RUSLE2 estimates as a guide.

17.2.12. Principle 12. RUSLE2 is only in error when it leads to a poor conservation or erosion control plan

RUSLE2's accuracy (see **Section 17.4**) should be evaluated in the context of conservation and erosion control planning.[170] Does RUSLE2 result in the desired conservation and erosion control planning decision? For example, RUSLE2 could compute annual erosion estimates of 50, 200, and 400 tons/acre for a particular highly erodible site given the uncertainty in RUSLE2 estimates. The range in these values represents significant numerical error. However, RUSLE2 leads to the correct conservation decision with each estimate; that is; erosion is excessive and needs to be significantly reduced. In fact, RUSLE2 probably is not needed in this situation because the erosion hazard is easily recognized from general erosion knowledge.

Similarly, RUSLE2 could compute an annual erosion estimate between 0.001 and 0.1 tons/acre for a rangeland site given the uncertainty in RUSLE2 estimates. Nevertheless, RUSLE2 leads to the desired conservation planning decision; erosion is low. Making erosion measures using plots that are 35 ft long and 12 ft wide to determine the "correct" value is difficult for low erosion rates, especially on rangelands. The 0.001 tons/acre value could have been 0.05 tons/acre if a gopher hole had been near the plot end or the soil had been slightly disturbed and exposed when placing a plot border or installing a plot end. The 0.1 tons/acre value could have been 0.01 tons/acre had the plot had been located differently because of non-uniform spatial variability within the plot and on the hillslope.

---

[170] For additional discussion, see Toy, T.J., G.R. Foster, and K.G. Renard. 2002. Soil Erosion: Processes, Prediction, Measurement, and Control. John Wiley and Son, New York, NY.

RUSLE2's accuracy is most important when erosion estimates are sufficiently close to the erosion control criteria such that errors result in substantial expense to apply unnecessary erosion control. RUSLE2 is typically used in conservation planning to compute a soil loss value that is compared against a soil loss tolerance value **T** or another erosion control criteria value. If the computed soil loss value is less than the erosion control criteria, erosion control is assumed to be adequate.

Assume that the erosion control criterion is an annual 5 tons/acre. If the RUSLE2 annual erosion estimate is 10 tons/acre, the RUSLE2 based conservation planning decision is that erosion is excessive and additional erosion control is needed. However, if the "correct" erosion estimate is an annual 5 tons/acre, the proper conservation planning decision is that erosion control is acceptable and no further erosion reduction is needed. The significance of the error is determined by the expense of additional erosion control when none was needed.

Fortunately RUSLE2 is most accurate in the critical range of annual estimates between about 2 to 20 tons/acre. Annual erosion greater than 20 tons/acre is usually considered excessive and annual erosion less than 1 ton/acre is generally considered to be acceptable. If RUSLE2 computes an annual erosion of 10 tons/acre with one practice and 20 tons/acre with a second practice, the erosion control planner can be confident that erosion with the first practice will be substantially less than with the second practice. However, if RUSLE2 computes 1 and 2 tons/acre annual erosion estimates for two practices, especially on pasture land, the difference between the two practices is not great, and the most that can be said is that erosion will likely be less with one practice than with the other practice and that erosion will be low with both practices.

RUSLE2 erosion estimates for support erosion control practices, especially contouring, are much more uncertain than those for cultural erosion control practices based on cover-management variables. RUSLE2 accurately represents the global effects of support practices but not their performance on specific sites. The uncertainty in the estimated erosion reduction by support practices on a specific site is much greater than the uncertainty in estimated erosion reduction by cultural erosion control practices.

17.3. Sensitivity analysis

A RUSLE2 sensitivity analysis is very helpful in understanding how RUSLE2 computes erosion, determining how a particular practice or condition affects erosion, determining the effect of a particular variable on erosion, and detecting input errors. The general procedure for conducting a sensitivity analysis is to change a single input while holding other inputs constant. For example, a sensitivity analysis can be conducted on how location affects erosion by making RUSLE2 computations for a set of locations using a single set of inputs for soil, topography, cover-management, and support practices. Likewise, a sensitivity analysis can be conducted on cover-management practices by making erosion computations for a set of practices for a given location, soil, topography, and support practices.

A sensitivity analysis can also be conducted on a single variable such as overland flow path length. Changing input values from 10 to 1000 ft for the overland flow path length has little effect on RUSLE2 computed erosion where steepness is 1 percent or less. Therefore, carefully selecting a precise input value for overland flow path length on very flat slopes is not critical.

A sensitivity analysis for the single variable overland flow path length can be easily conducted by changing input values on the main RUSLE2 **profile** screen. Sensitivity analyses conducted on other individual variables usually requires changing values in the **RUSLE2 database description** that contains the values for that variable. For example, conducting a sensitivity analysis on canopy cover requires changing values in a **vegetation description**.

The effect of a single variable or a set of variables, such as those in cover-management descriptions, on erosion varies with the situation. For example, overland flow path length has little effect on erosion on very flat slopes. However, it has a moderate effect on steep slopes. Therefore, more care is needed in selecting input values for overland flow path lengths on moderate and steep slopes than on very flat slopes. Furthermore, the effect of overland flow path length also depends on soil and cover-management conditions. Similarly, the effect of a particular cover-management practice depends on location, soil, and topography.

Some variables are used in multiple RUSLE2 equations, which results in complex interactions that complicate sensitivity analyses. Surface biomass, soil biomass and the soil consolidation subfactor are examples of such variables. Each variable has a primary effect and several secondary effects. Surface (flat) cover is often assumed to be the most important RUSLE2 variable, which is true for many but not all conditions. Soil biomass can have a much greater effect on erosion than surface biomass in certain conditions. Surface biomass, soil biomass, and soil consolidation strongly interact so that the combined effect is more than expected based on the primary effect of each variable. Special inputs must be used in sensitivity analyses to isolate the primary effect of individual variables separate from their interactive effects.

Be very careful about generalizing results from a sensitivity analysis. Sensitivity analyses should be conducted over a wide range of conditions before drawing conclusions about the effect of a particular variable on erosion.

Inputs must be changed carefully to conduct sensitivity analyses on surface (flat) cover, which is an important variable in conservation planning on cropland. An input must be selected to change surface cover to conduct a sensitivity analysis on surface cover. An obvious input is vegetation production (yield) level. Changing yield does change surface biomass, but it also changes soil biomass and canopy values. Changing yield is an important sensitivity analysis but not for conducting a sensitivity analysis on surface cover. Is the surface cover analysis to study the effect of surface biomass or is it to study the effect of the portion of the soil surface covered? If the purpose of the sensitivity analysis is to study the effect of surface biomass, inputs for the relationship of aboveground biomass to yield in a vegetation description can be changed. If the sensitivity analysis is to study the effect of how the portion of the soil covered affects erosion, inputs in a **residue description** that relate portion of the soil surface covered to the surface biomass can be changed.

An important sensitivity analysis is the effect of soil disturbance width on erosion (see **Section 9.2.6**). The soil disturbance width effect of a particular soil disturbing operation depends greatly on whether the operation is the only soil disturbing operation in the **cover-management description**. The soil disturbance width effect can be great if only one **soil disturbing operation** is in a cover-management description. The soil disturbance width effect for a particular operation is much less if other soil disturbing operations, especially ones that disturb the full soil width, are included in the cover-management description.

Although soil disturbance width has a minor effect on surface roughness, its major effect is on the soil consolidation subfactor and its secondary effects. The soil consolidation primary effect is illustrated in Figure 7.3. Its secondary effects are from being a variable in several other computations including the soil biomass subfactor, decomposition's transfer of surface biomass to soil biomass, runoff, and the rill-interrill erosion ratio that affects the slope length exponent in equation 8.1 and **b** value in equation 9.6 used to compute ground cover effect. A sensitivity analysis on soil disturbance width and on the soil consolidation effect requires sorting through an array of complex, interacting variables.

Care must also be taken in sensitivity analyses to ensure that the effect of a variable being studied is not being masked by another variable. An example is disturbance depth of secondary tillage. A primary tillage operation with a deep disturbance depth typically precedes secondary tillage operations in many cropland cover-management descriptions. Disturbance depth of secondary tillage operations has very little effect on erosion because primary tillage buries most of the residue below the disturbance depth of the secondary tillage operation. The effect of disturbance depth of the same secondary tillage operation can be significant when no primary tillage operations are in the cover-management description.

RUSLE2 uses a description of field conditions to compute erosion. Most variables in a RUSLE2 description are not automatically changed when input values for key variables are changed. For example, RUSLE2 does not change vegetation production (yield) level when a new location (which changes precipitation and temperature), soil, or management is selected that affects yield. Therefore, a sensitivity analysis that involves changes in variables that affect yield requires changing the yield input value in the cover-management descriptions used in the analysis.

The value entered for yield must be consistent with the selected location's climatic, soil, and management.

17.4. RUSLE2 Accuracy

The assumption in developing RUSLE2 was that the widely accepted and used USLE and RUSLE1 were valid models for conservation and erosion control planning. RUSLE2 was developed to improve these technologies by significantly extending their applicability to practically every field situation where rill and interrill erosion occurs, increasing their power, and improving their underlying supporting science. Therefore, one assessment of RUSLE2's accuracy is to compare RUSLE2 and USLE computed erosion values. A second assessment is the fit of the USLE, and thus RUSLE2, to the research data from which the USLE was derived. A third assessment is identifying where RUSLE2 is most, (and least) accurate.

17.4.1. Comparison of RUSLE2 erosion estimates with USLE erosion estimates

Determining the accuracy of RUSLE2 for estimating how cover-management affects erosion is perhaps the most important assessment of RUSLE2 because of the major role of cover-management in conservation and erosion control planning. The soil loss ratio values in Table 5, AH537 represent measured values.[171] These values are a summary of a large mass of research data, 10,000 plot-years, as analyzed and interpreted by Wischmeier and Smith (AH537). The fully empirical USLE directly uses measured values to compute cover-management's effect on erosion. In contrast, RUSLE2 uses a set of equations that were fitted to the soil loss ratio values in Table 5, AH537 and other data (see **Section 9**). Therefore, one part of the assessment is how well the RUSLE2 subfactor equations fit measured soil loss ratio values.

17.4.1.1. Average annual erosion values for cropland

Table 17.1 shows erosion values computed with the USLE and RUSLE2 for a wide range of cover-management practices for Columbia, MO and for two cotton cover-management practices for Holly Springs, MS.[172] The values in AH537 represent a summary of

[171] Soil loss ratio values in AH537 are the ratio of soil loss with a given cover-management condition at a particular crop stage period to soil loss from the unit plot for the same crop stage.
[172] Columbia, MO is used as a base location in RUSLE2. AH537 values for slope length and steepness, soil loss ratio, and support practice factors are assumed to apply at Columbia, MO. RUSLE2 adjusts its values for these factors about the Columbia, MO base values. The weather at Columbia, MO is near the "middle"

measured values for the eastern US. Measured soil loss ratio values varied greatly among

Table 17.1. Estimated average annual erosion values (tons/acre) for the USLE and RUSLE2 (overland flow path length = 150 ft, steepness = 6%)

4. erosion values computed for Columbia, MO except for two cotton management where values are for Holly Springs, MS
5. meadow refers to hay production
6. Same R value and K value used in USLE and RUSLE2 comptuations
7. LS = 0.824 for USLE while "net" LS value for RUSLE2 varied from 0.73 for no-till corn to 1.01 for conv cont 50 bu/ac silage corn

locations. For example, the soil loss ratio value for the seedbed crop stage for conventionally tilled corn varied from about 0.2 to 0.8 in data collected in the 1970's at several locations.[173] The reasons for this variation could not be empirically determined

of the data for the Eastern US. Holly Springs, MS was used in RUSLE2 as the base location for cotton cover-management because research at that location and other nearby locations provided most of the data used to derive AH537soil loss ratio values for cotton.

[173] The seedbed crop stage is when the soil is finely tilled in preparation for crop seeding. No vegetation

because of unexplained variability in the data. However, fundamental research conclusively shows that erosion decreases as soil biomass increases. Therefore, the seedbed soil loss ratio value for conventionally tilled continuous corn at a particular yield should be higher in the southern US than in the northern US because increased precipitation and temperature significantly increase decomposition, which reduces soil biomass. RUSLE2 captures this and other effects in its cover-management subfactor equations that are not captured by the USLE.

The soil loss ratio values computed by RUSLE2 vary by location, soil, and topography in contrast to the USLE soil loss ratio values that do not vary with these factors. Therefore, a comparison between RUSLE2 and USLE estimated erosion values must be for a representative condition. Columbia, MO (a central location), a silt loam soil, and a uniform overland flow path 150 ft (50 m) long, 6 percent steep were chosen to compute the estimates shown in Table 17.1. Differences in RUSLE2 and USLE erosion estimates vary with location, generally becoming greater with distance from Columbia, MO as climatic conditions differ from those at Columbia, MO.

Even at Columbia, MO, RUSLE2 and the USLE do not compute the same erosion estimates because of differences in equation structure. The daily topographic length factor in RUSLE2 varies with cover-management, while the corresponding USLE L factor does not vary. RUSLE2 computes a “net” LS value that is a temporal integration of daily values weighted by the temporal distribution of erosivity. Values for the RUSLE2 “net” LS factor vary from a low of 0.73 for the 112 bu/ac no-till corn to 1.01 for the 50 bu/ac corn silage whereas the USLE LS value is 0.82 for all conditions in Table 17.1.

Even when the RUSLE2 “net” LS value is the same as the USLE LS factor value, RUSLE2 and the USLE likely will not compute the same erosion values because of differences in temporal integration. RUSLE2 multiplies its daily factors values to determine a daily erosion estimate and sums these values for an annual erosion estimate. The only temporal integration in the USLE is by crop stage period where the soil loss ratio values are weighted by the temporal erosivity distribution to compute a cover-management factor value, which is multiplied by the other factor values to determine an annual erosion estimate.

RUSLE2 does not use “net” factor values to compute annual erosion. These values are only for comparison with USLE factor values and for use in the USLE for conditions where empirical erosion data are not available to determine USLE factor values. **Multiplication of the RUSLE2 computed “net” factor values according to the USLE equation structure does not compute the same erosion estimate as that computed by RUSLE2 (see *Section 5.4*)**.

---

and very little surface residue cover are present in conventional moldboard plowed cropping systems that bury almost the entire residue from the previous year’s crop.

An assessment of RUSLE2 based on a comparison of estimated erosion values with USLE estimates must consider differences in equation structure and the additional effects represented by RUSLE2 (see *Section 17.2*).

As illustrated in Table 17.1, RUSLE2 computed erosion values compare well with USLE values. Biomass is the principal factor that affects erosion for the conditions listed in Table 17.1. Biomass differences primarily account for the difference in erosion values from the high biomass meadow (hay) to the low biomass in 50 bu/ac corn silage. Biomass differences also principally account for the differences in erosion between the 50 and 112 bu/ac corn practices. A land use residual effect results from soil biomass loss over time after large amounts of biomass are buried in the soil and a large amount of roots are killed. Erosion increases over two years of corn following a high production meadow (hay) as soil biomass is lost.

Vegetation characteristics and vegetation management affect erosion (e.g., corn, wheat, and hay and hay versus grain production). As the values in Table 17.1 show, RUSLE2 captures the effect of these variables on erosion.

Other factors besides cover-management must be considered when evaluating the RUSLE2 values in Table 17.1. The topographic length factor discussed above is one of those factors. RUSLE2 does not vary the topographic steepness factor; it is constant just as in the USLE. However, the RUSLE2 topographic steepness factor differs from the USLE one. The RUSLE2 steepness factor value for a 6 percent steepness is 18 percent greater than the corresponding USLE value. Consequently, all RUSLE2 erosion estimates in Table 17.1 are systematically increased by 18 percent larger relative to the corresponding USLE values. The difference between the RUSLE2 and USLE steepness factors decreases for steepness less than 6 percent except for very flat steepness where the RUSLE2 values are greater than the USLE values. The RUSLE2 and USLE steepness factor values are equal at 9 percent steepness. Above 9 percent, the USLE values become progressively greater than the RUSLE2 values.[174]

Even when the RUSLE2 “net” soil erodibility value equals the USLE soil erodibility factor value and all other factors are the same, the erosion estimates computed by RUSLE2 and the USLE can differ. The daily RUSLE2 soil erodibility values temporally vary, which affects estimated erosion, especially when comparisons are made for

multiple locations and soils. Also, the rill erodibility to interrill soil erodibility ratio

Therefore, differences in RUSLE2 and USLE erosion estimates can not be generalized on the basis of computations for a single location, soil, or topography.

varies among soils, which also affects results.

Conservation tillage, including no-till, mulch till, and ridge till, is a major erosion control practice used on cropland. However, no USLE erosion estimates are given in Table 17.1 for conservation tillage because AH537 soil loss ratio values for conservation tillage are considered unreliable. The AH537 values were based on research conducted early when conservation tillage was beginning to be adopted and do not represent modern conservation tillage. Other data on conservation tillage besides the AH537 values were used to develop the RUSLE2 cover-management subfactor equations. Data from a large number of references were reviewed and analyzed to give special attention to no-till because the USLE and RUSLE1 were highly criticized for not accurately computing erosion for no-till. As Figure 17.1 shows, the effectiveness of no-till varies greatly, even more than erosion with conventional tillage. A very detailed analysis of the empirical data did not provide the information required to describe the variability in the no-till data. RUSLE2 captures the main effect illustrated in Figure 17.1 and computes values about this line as a function of location, slope steepness, soil, crop, and yield.

The cover-management subfactor approach used in RUSLE2 computes erosion values that compare well with values computed by the USLE and, therefore, with the experimental data on which the USLE is based.

17.4.1.2. Soil loss values by crop stage for cropland

An additional assessment of RUSLE2's accuracy is how well it reproduces the soil loss ratio values in Table 5, AH537 for crop stage periods.[175] Tables 17.2, 17.3, and 17.4 show RUSLE2 computed soil loss ratio values for corn and cotton. The soil loss ratio values for the fallow crop stage period shows that RUSLE2 captures the effects of surface roughness and the values for crop stages 1, 2, and 3 shows that RUSLE2 captures the effect of a developing and mature crop. Differences between values in Tables 17.3 and 17.4 confirm that RUSLE2 captures the effect of ridges where repeated tillage operations bury almost the entire residue for a low residue cotton crop.

Comparisons for soil loss ratios were made for the other cover-management conditions listed in Table 17.1. The values in Tables 17.2, 17.3, and 17.4 and from the other comparison between RUSLE2 soil loss ratio estimates and the AH537 values indicate that RUSLE2 accurately computes the temporal variation in soil loss ratio values.

RUSLE2 is judged to accurately compute temporal cover-management effects during the year.

Table 17.2. Soil loss ratios for 112 bu/ac conv cont corn from AH537 and values computed with RUSLE2		
Crop stage (defined in AH537)	AH537 Soil loss ratio	RUSLE2 Soil loss ratio

Jan 1 to Feb. tillage	32	27

17.4.1.3. Crop residue cover immediately after planting

Crop residue cover immediately after planting is an important variable used in conservation planning and compliance determination on cropland. RUSLE2 is expected to accurately estimate this cover, which it does as illustrated in Table 17.5 for a wide range of conservation tillage systems and the major crops of corn and soybeans.

RUSLE2 accurately estimates crop residue cover immediately after planting for a wide range of tillage systems.

17.4.1.4. Erosion values for range, pasture, and similar lands

Both RUSLE1 and RUSLE2 apply to range and similar lands, although the USLE poorly estimates erosion for these lands.[176] The major problem is with Table 10, AH537, entitled "Factor C for permanent pasture, range, and idle land" used to apply the USLE to these lands. This table does not include a soil surface roughness effect, and it improperly links below ground biomass to ground cover. Table 10, AH537 does not allow rock cover to be considered separately from biomass ground cover, it does not properly account for production (yield) level, and the **b** value in equation 9.6 for the ground cover effect is about 0.026 rather than a much more preferred value of 0.035. Also, values for the USLE slope steepness are too large for steepness greater than 25 percent.

Differences between the RUSLE2 and RUSLE1.06 soil biomass subfactor equations required that new RUSLE2 values for the ratio of effective root biomass to annual above ground production be developed. Two major datasets known as the WEPP rangeland data[177] and the USDA Rangeland Study Team data[178] are available for determining these RUSLE2 ratio values and evaluating RUSLE2 for rangelands.

Only the WEPP data set was used because of problems with the USDA Range Study Team data. The USDA Range Study Team dataset was carefully analyzed to compute effective root biomass values or to evaluate RUSLE2. When the data were divided into plant type categories of sagebrush, bunch, sod, and tall grass, the relationship between surface cover and erosion empirically derived from the data showed that erosion increased as surface cover increased for some of the

plant types, which is unacceptable based on well accepted fundamental research. Measurements were taken at too few sites for the number of variables affecting erosion, and perhaps measurements of input variables were not made according to RUSLE definitions. In several cases, the plant litter cover was inconsistent with the production level (e.g., far too much litter cover for the annual production). Also, in the few cases when experimental sites for the WEPP and Range Study Team studies coincided or were close together much of the data for the basic cover-management variables from these common sites values did not agree. Some of these differences may have been caused by temporal differences because the experiments were conducted in different years.

The first step in determining these ratio values was to classify the WEPP data by plant community. The standard RUSLE2 soil erodibility, topographic, canopy, ground cover, surface roughness, and soil consolidation factor values were assumed to apply to these data, which reflects RUSLE2 land use independence. Measured erosion values were divided by the product of these factor values to compute a soil biomass subfactor value for each experimental site. A value for effective root biomass was next obtained by substituting the soil biomass subfactor value computed from the experimental data in equation 9.12, where a zero buried residue biomass was assumed. The effective root biomass value computed by solving equation 9.12 was divided by the annual aboveground biomass production (yield) level to determine a value for the ratio of effective root biomass in the upper 4 inch (100 mm) soil depth to annual aboveground production. A non-linear procedure that fitted predicted erosion to measured (observed) erosion was used to determine ratio values for plant communities that occurred at multiple sites. The resulting values are shown in Table 17.6.

Table 17.6. Values for ratio of effective root biomass to annual above ground biomass production for vegetation typical of range, pasture, and similar lands.

Plant community	ratio effective root biomass in upper 4 inches (100 mm)/annual above ground production
N mixgrass	2.5
S mixgrass	3.1
tallgrass prairie	1.0
shortgrass prairie	3.0
desert grassland	6.1
southern grasses	6.4
CA annual grass	2.6
cold desert shrub	5.9
southern desert shrub	6.6
shinnery oak w/herb interspace	2.6
chaparral	1.3
pasture, sod grasses	6.0
pasture, bunchgrasses	3.7
pasture, weeds	2.3

The values shown in Table 17.6 may not be consistent with known rooting and other characteristics of these plant communities. One reason for the lack of expected trends is variability in the measured data, too few measurement sites for each plant community, and too few replications. A sufficient number of sites to obtain a reasonably accurate overall effective root biomass ratio value for a plant community were available for only the southern desert shrub and southern mixed grass prairie plant communities. With these two exceptions, the Table 17.6 values for each plant community were derived from data for a single site. The Table 17.6 value for a plant community could differ from the expected value by a factor of two based on data for the two plant communities that occurred at multiple sites.

The Table 17.6 values are also affected by applying the standard RUSLE2 soil erodibility factor and the soil consolidation factor values to rangeland conditions. Tilling coarse texture rangeland soils in the southwestern US to create unit plot conditions greatly increases infiltration and reduces runoff and erosion (see **Section 7.2**). The low erosion immediately after tillage is related to land use residual effects (see **Section 9.2.5**). For example, soil plowed out of high production meadow is only one fourth as erodible immediately after tillage as it is after two years of tillage for row crop production (AH537). This land use residual effect disappears over time as a soil is continuously maintained in a unit plot condition. Research on these southwestern US rangeland soils showed that erosion increased over about three years after an initial tillage but no subsequent tillage, which indicates a strong land use residual effect in these soils.[179] The RUSLE2 assumption that standard erodibility values apply to rangeland conditions seem reasonable.

The soil consolidation effect assumes that tillage increases erosion by about 55 percent (see **Section 7.8**). This effect seems to have been masked in the land use residual effect in the research described above. The soil consolidation effect surely varies with soil properties and climate. However, research has not defined the relationship between the soil consolidation effect with these variables, even for cropland conditions and certainly not for rangeland conditions. The RUSLE2 soil consolidation relationship was empirically derived from data collected on a single soil at Zanesville, Ohio.

In any case, discrepancies between RUSLE2 soil erodibility and soil consolidation relationships and those for rangeland conditions were empirically incorporated in the Table 17.6 values. These soil and climate effects, along with data variability, account for any inconsistency in Table 17.6 values with vegetation characteristics.

Until research provides improved information, the values in Table 17.6 should be used even if they do not seem consistent with vegetation characteristics.

The Table 17.6 values were derived assuming the time invariant cover-management (C factor) procedure (AH703). Therefore, these values represent buried residue and dead roots as well as live roots. Vegetation, residue, and cover-management descriptions can be created so that RUSLE2 computes erosion using a time invariant C factor procedure similar to that in RUSLE1.06c. The **vegetation description** has a single entry in the **growth chart** on day zero. The entered value for live root biomass is the product of the site average annual production level and the ratio value in Table 17.6 for the plant community. Entered values for canopy cover, effective fall height, and live ground cover are representative values chosen to compute average annual erosion. The **cover-management description** includes an **operation description** having a **begin growth process** that tells RUSLE2 to use the single entry vegetation description and an **add other residue/cover process** that applies an **external residue** to give the desire ground cover. The **residue description** uses a zero value for the **decomposition coefficient** so

that the residue does not decompose to properly represent the time invariant approach. The cover-management description is a **no-rotation type** with one year **duration**.

Rather than use this time invariant approach, the recommended procedure is to use RUSLE2's full temporal capability when applying it to range and similar lands. Two options are available for determining input values for live root biomass in the vegetation descriptions. One option is to use literature values or to make field measurements. The literature values are highly variable. For example, the reported ratio for root biomass to aboveground biomass ranged from 0.6 to 120 for the northern mixed grass prairie plant community (AH537). A problem with literature values and with field measuring roots, which are very difficult to measure, is knowing the root size above which to discard roots because large roots have little effect on erosion. The most important roots are the fine ones near the soil surface. Even if roots are accurately measured, research has not established the relationship of erosion to root characteristics.

The best option for determining live root biomass input values is to use the RUSLE2 **long-term vegetation tool** to construct vegetation descriptions (see **Section 11.2.6**). This tool uses Table 17.6 values to estimate live root biomass values. A major advantage of using Table 17.6 values is that they have been empirically determined directly from measured erosion data using RUSLE2 definitions and equations.

Although the Table 17.6 values include a buried residue and dead root effect when used in the time invariant C factor procedure, these values give good results when they are used to estimate live root biomass values for temporal vegetation descriptions. The RUSLE2 full temporal method using live root biomass developed from Table 17.6 values gave comparable erosion estimates to those from the RUSLE1.06c time invariant C factor procedure.

The RUSLE2's temporal procedures should be used when applying RUSLE2 to range, pasture, and similar lands rather than the time invariant C factor method.

WEPP data collected for plant communities that occurred at multiple sites provided a limited indication of the uncertainty in RUSLE2 erosion estimates. The south desert shrub plant community occurred at six sites and the southern mixed grass prairie plant community occurred at five sites.[180] Estimated (predicted) and measured (observed) erosion values are shown in Figures 17.2 and 17.3. RUSLE2 estimated erosion values compare reasonably well with measured erosion values for the south desert shrub plant community except for one data point in Figure 17.2 where the predicted erosion was

[180] Data from two additional sites for the south desert shrub plant community and from an additional site for the southern mixed grass prairie plant community were not used in the analysis because these data points were judged to be outliers.

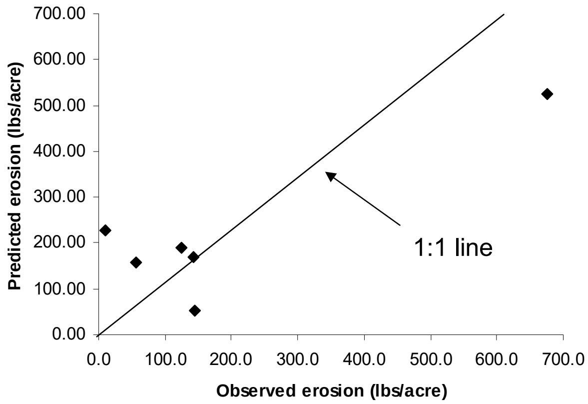

Figure 17.2. Predicted and observed erosion for south desert shrub plant community.

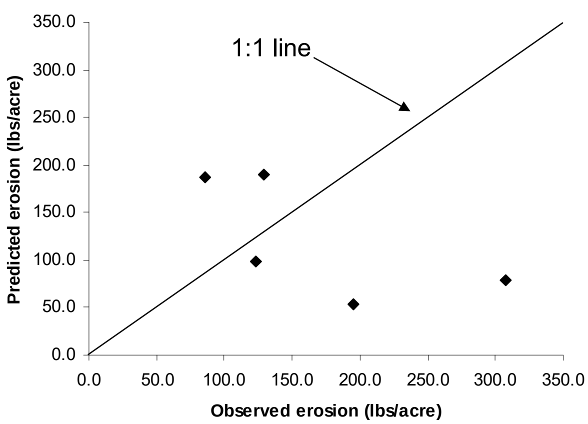

Figure 17.3. Predicted and observed erosion for southern mixed grass plant community.

about 220 lbs/acre while observed erosion was about 10 lbs/acre. However, other than this data point, the data are comparable to scatter in erosion data for cropland at such low erosion rates. Data for the southern mixed grass prairie plant community are shown in Figure 17.3. The error is large for two data points. Based on these results, a RUSLE2 erosion estimate for a particular rangeland site could be in error by a factor of five.

Even a modest evaluation of RUSLE2's accuracy for range and similar lands is essentially impossible because of limited research data (See **Section 17.2)**. The WEPP and Range Study Team datasets are the best available, but these data were produced using rainfall simulators and involved rainfall application at a single point in time rather than at several times during the year and over several years. The WEPP and Range Study Team data do not account for average annual seasonal changes or year to year changes. Even though above and surface ground cover can be measured, below ground measurements can not be easily made to determine the land use residue effect at the time of the experiments. Weather, vegetation, and soil conditions over several years preceding the experiments can greatly affect erosion measured at a single point in time.

The similarity of erosion generated by simulated rainfall and that produced by natural rainfall on western US rangelands is highly questionable. For example, the erosivity of single simulated storm in both the WEPP and Range Study Team experiments was about 50 US erosivity units whereas the average annual erosivity in much of the western US, where most rangeland occurs, is less than 20 US erosivity units. The data used to determine the Table 17.6 values were from a single simulated storm applied to dry soil conditions. These experiments also involved a second simulated storm applied to moist conditions. Table 17.6 values and results of RUSLE2 evaluations depend greatly on whether one or two storms are used in the analysis. Also, the simulated rainfall was applied in a uniform intensity that can give significantly different erosion when infiltration rates are high and spatially varied than erosion from temporally varied intensity.[181] Applying multiple simulated rainfall multiple times during the year affects the conditions being studied because of the additional rainfall. This effect is very important in the dry climates where most rangeland occurs where the simulated rainfall is a significant portion of the annual rainfall.

Accurately measuring the low erosion rates typical of rangeland conditions (e.g., 50 lbs/ac in Figure 17.3) and having small differences, especially on a percentage basis, between replications is almost impossible. Table 17.7 shows a range of the ratio of measured erosion for the two replications in the WEPP study. These ratio values are not particularly meaningful given the low erosion rates. A slight soil disturbance near the end of a plot or a slight shift in the placement of plots could have easily produced significantly different measured erosion values. Expecting RUSLE2 or any other model to precisely fit data for individual sites is unrealistic and unreasonable because of the low erosion rates, spatial and temporal variability, and the difficulty of measuring low erosion rates. These data issues must be considered when evaluating RUSLE2 for its applicability to range and similar lands. RUSLE2 may perform better than the experimental data used to evaluate it.

Is RUSLE2 adequate for conservation and erosion control planning for range, pasture, idle, and similar lands? VERY DEFINITIVELY. RUSLE2 describes the main effects of how the major physical, biological, and ecological variables, affect erosion as conclusively proven by fundamental erosion research. RUSLE2 computes the low erosion rates that have been measured on range, pasture, idle, and similar lands. RUSLE2 accurately represents how changing major variables such as plant community, production level, removal of biomass, and mechanical soil disturbance affects erosion.

[181] Flanagan, D.C., G.R. Foster, and W.C. Moldenhauer. 1988. Storm pattern effect on infiltration, runoff, and erosion. Transactions of American Society of Agricultural Engineers 31(2):414-420.

RUSLE2 can be used as a conservation and erosion control planning tool for rangelands, pasturelands, idle, and other similar lands.

17.4.1.5. Erosion values for construction sites

Published data related to erosion control on construction sites using straw and other mulch types were extensively reviewed during the development of RUSLE1.06.[182] New RUSLE1.06 relationships were developed to describe the reduced effectiveness of mulch on construction sites relative to cropland. These new relationships also describe how mulch conformance to soil surface roughness affects erosion control on construction sites. Also, the effectiveness of simple sediment basins, surface roughness, ridging, and porous barriers on reducing erosion and trapping sediment was also extensively reviewed during the RUSLE1.06 development. Equations, input values, and other information developed for RUSLE1.06, along with information developed since the RUSLE1.06 release were used in the development and evaluation of RUSLE2 for its applicability to construction sites and similar conditions. RUSLE2 works significantly better for construction site conditions than does RUSLE1.06.

17.4.1.6. Erosion values for disturbed forestland

The Dissmeyer-Foster subfactor method used to estimate erosion on disturbed forestland is widely recognized and accepted.[183] The basic subfactor relationships used in that method are used in the RUSLE2. Therefore, RUSLE2 estimates erosion with comparable accuracy as does the Dissmeyer-Foster method. RUSLE2 is substantially better than the USLE with the Dissmeyer-Foster method because of RUSLE2's increased power and capability, such as applying to non-uniform overland flow profiles and improved relationships for computing revegetation of disturbed forestland following mechanical disturbance. RUSLE2 can also be applied to road construction in forested areas and can estimate erosion on logging roads where the runoff occurs as overland flow. RUSLE2 can also be used to evaluate how alternative burning treatments and forest fire affects erosion. Burning removes surface biomass and some buried biomass and roots. RUSLE2 represents burning removing surface and buried biomass, but it does not represent the removal of either live or dead root biomass by burning.

17.4.2. Accuracy of RUSLE2 by statistical measures

[182] Toy, T.J. and G.R. Foster (coeditors). 1998. Guidelines for the use of the Revised Universal Soil Loss equation (RUSLE1.06) on mined lands, construction sites, and reclaimed lands. USDI-Office of Surface Mining. Denver. CO.

[183] Dissmeyer, G.E. and G.R. Foster. 1980. A guide for predicting sheet and rill erosion on forest land. Technical Publication SA-TP-11. USDA-Forest Service-State and Private Forestry-Southeastern Area. 40 pp.

An analysis of the statistical fit of the USLE to the experimental natural runoff plot data used to develop the USLE showed that the USLE computes average annual erosion within 25 percent for average annual erosion between 4 and 30 tons/acre and within 50 percent for average annual erosion between about 0.5 and 4 tons/acre.[184] The uncertainty increases rapidly for average annual erosion less than 1 ton/acre and can exceed 500 percent for average annual soil loss less than 0.1 tons/acre (see **Section 17.4.1.4**). The uncertainty also increases, but not greatly, for average annual erosion greater than 30 tons/acre. The uncertainty in RUSLE2's estimates erosion are slightly greater than that for the USLE based on an evaluation of RUSLE1 using the same data and the similarities between RUSLE1 and RUSLE2.[185]

RUSLE2 (and RUSLE1) not fitting the data as well as the USLE is expected. The AH537 soil loss ratio values used in the USLE are essentially direct summaries of the experimental data whereas the soil loss ratio values used by RUSLE2 (and RUSLE) are computed with equations fitted to the AH537 values. As expected, the fitted equations do not exactly fit the data (see **Section 17.4.1.1)**.

Even though the fit of RUSLE2 to the experimental data is slightly less than the USLE fit, RUSLE2 is superior to the USLE because of RUSLE2's increased power and capability. In contrast to the USLE, RUSLE2 can be applied to conditions where experimental data have not been collected to empirically determine soil loss ratio values. Although the USLE has a cover-management subfactor procedure for "undisturbed, pasture, and idle lands," the procedure is deficient and should not be used. The RUSLE2 subfactor procedure is much better than the USLE procedure.

A statistical analysis of the fit of the USLE to the experimental data is not particularly robust because the natural runoff plot data have a high degree of unexplained variability.[186] A difference of 30 percent in measured erosion between adjacent plots is common for conditions where little difference would be expected. The difference in measured erosion between replicate plots can not be explained by measured differences in soil, topography plot preparation, or plot condition. Data quality must often be compromised in finding a hillslope where an adequate number of replications can be installed without excessive variation in soil or topographic properties that affect erosion

Tiwari, A.K., L.M. Risse, and M.A. 2000. Evaluation of Wepp and its comparison with USLE and RUSLE. Trans. ASAE 43:1129-11135. (Based on this paper, RUSLE is slightly better than the process-based model WEPP.)
[186] Nearing, M.A., G. Govers. and L.D. Norton. 1999. Variability in soil erosion data from replicated plots. Soil Sci. Soc. Amer. J. 63: 1829-1835.

(see **Section 17.2**). Too few replications at individual locations, non-uniform coverage of the major variables that affect erosion and differences in statistical designs between locations in numerous studies prevent the use of common statistical methods to evaluate RUSLE2's statistical accuracy. The number of variables affecting erosion is very large, which in turn requires a large and high quality database to statistically evaluate RUSLE2. If the database is too small and does not uniformly cover the range of variables affecting erosion, erroneous conclusions are drawn. For example, Risse et al.[187] concluded that contouring does not affect erosion. However, when a proper dataset on contouring is assembled and analyzed, the analysis shows that contouring has a major effect on erosion although its effect is highly variable (see **Section 14.1**).[188]

Because RUSLE2 is, for the most part, empirically derived, RUSLE2's adequacy is determined by the data used to derive it. Therefore, RUSLE2's adequacy for a particular application is largely determined by how well the plots and small watersheds (<5 acres) used to derive RUSLE2 represent actual field conditions.

RUSLE2 provides an accurate representation of how major variables affect erosion as measured by plots and small watersheds (<5 acres).

17.4.3. Qualitative assessments of RUSLE2's accuracy

Qualitative assessments of RUSLE2's accuracy are useful in guiding conservation planning decisions. The following sections provide qualitative assessments of where RUSLE2 works best and where it is less well suited.

17.4.3.1 Temporal values

RUSLE2 is designed to estimate average annual erosion. It is not designed to estimate erosion from individual storms, specific time periods, probability distributions of erosion by storm, season, or year. Also, it is not designed to estimate erosion for a storm with a given recurrence interval. Information in AH537 can be used to construct probability

[187] Risse, L.M., M.A. Nearing, A.D. Nicks, and J.M. Laflen. 1993. Error assessment in the Universal Soil Loss Equation. Soil Sci. Soc. Am. J. 57: 825-833.

[188] The Risse et al. and Tiwari et al. papers are considered definitive papers on statistical evaluations of the USLE and RUSLE. However, these papers' shortcomings affect interpretation of their results. The evaluations described in both papers used only a portion of the available data (e.g., Tiwari et al. used only 1600 plot-years of data for 20 locations while Risse et al. used only 1700 plot-years of data at 23 locations out of more than 10,000 plot-years of data at 43 locations used to develop the USLE and RUSLE). The natural runoff plot data used to develop the USLE are not uniformly distributed for the main variables that affect rill-interrill erosion. Choosing an unbiased 20 percent sample from the entire dataset is difficult. For example, the evaluation dataset chosen by Risse et al. was biased. The dataset included 2 plots from Morris, MN, 13 plots at Guthrie, OK, and 18 plots from LaCrosse, WI. Neither paper provides information to show that the evaluation results were unbiased. Such statistical evaluations are not robust and their validity is questionable.

distributions for annual erosivity at individual locations that can be used in RUSLE2 to compute probability distributions of annual erosion for average soil and cover-management conditions. **RUSLE2** can not consider deviations in cover-management conditions by day, season, or year from the average condition.

An advanced user can compute erosion with RUSLE2 for a single storm. The erosion computed for this storm represents the average erosion produced by the storm occurring in many years on the storm's date.[189] Although RUSLE2 is not recommended for estimating erosion for individual storms, RUSLE2's accuracy for individual storms is comparable to that for process-based models like WEPP.[190] Other research has also shown that simple empirical models fitted to observed data perform as well as or better than process-based hydrologic models.

The USLE equation structure, which is used in RUSLE2, is said to underestimate erosion when average annual erosion and erosion from individual storms is large.[191] However, this statement does not accurately represent this equation structure. The USLE equation structure is fitted to estimate average annual erosion values. Consequently, it is self evident that this equation structure, when properly fitted to the data, both underestimates and overestimates large erosion. This equation structure underestimates erosion when a large storm produces an unusually high runoff relative to storm amount because the storm occurred on very moist soil. RUSLE2 has no explicit runoff term to represent increased runoff for a given rainstorm. Conversely, the equation structure overestimates erosion when the same storm occurs on very dry soil that produces low runoff. Estimating runoff is more difficult than estimating erosion based on W.H. Wischmeier's experience.[192] Process-based models' equation structure should give them an inherent advantage over RUSLE2 for estimating erosion for single storms, but that capability is barely realized in practical applications. The advantage of process-based models is lost because of

---

[189] The RUSLE2 is designed for conservation and erosion control planning where average annual erosion is used in the planning process. As a consequence, the RUSLE2 computer program is not designed to accept inputs for specific storms and, therefore, is inconvenient for computing erosion for individual storms.

[191] Risse, L.M., M.A. Nearing, A.D. Nicks, and J.M. Laflen. 1993. Error assessment in the Universal Soil Loss Equation. Soil Sci. Soc. Am. J. 57: 825-833. (In fact, Figure 1 in this paper shows that the USLE does not underestimate erosion for measured high erosion relative to moderate erosion. Figure 1 does show that the USLE overestimates erosion for low measured erosion. The overestimation occurs for annual erosion less than 1 ton/acre.)

[192] **Wischmeier**, W.H. 1966. Relation of field plot runoff to management and physical factors. Soil Sci. Amer. Proc. 30:272-277.

Wischmeier, W.H. mid 1970's. personal communication.

estimation errors in runoff and the many variables that are functions of environmental variables in these models.[193] The cumulative effect of having many more variables to calibrate in process-based models than in the USLE equation structure diminishes process-based model performance. Too often calibration of process-based models results in fitting unexplained variability rather than main effects.

17.4.3.2. Soils

Difficulty in estimating runoff from input climate data is the major reason why an explicit runoff term is not used in RUSLE2 except for computing the effect of support practices on erosion where an index-based approach is used to capture main effects.

RUSLE2 is most applicable to medium textured soils. It works moderately well for fine textured soils and acceptably for coarse textured soils and least well for high sand soils. Errors can be large when applied to rangeland coarse textured soils in the Southwestern US and to soils on reclaimed mined land having a very high content of large rock fragments. Technical judgment can be used in assigning soil erodibility factor values to overcome some of these difficulties (see **Section 7**).

RUSLE2 should not be applied to organic soils, such as peat.

17.4.3.3. Topography

RUSLE2 works best for overland flow path lengths between 50 (15 m) and 300 ft (100 m) long. It works moderately well for overland flow path lengths less than 20 ft long, including overland flow path lengths as short as 1 inch (25 mm), and for overland flow path lengths between 300 and 600 ft (100 and 200 m). It works acceptably for overland flow path lengths between 600 and 1000 ft long (200 and 300 m).

RUSLE2 should not be applied to overland flow path lengths greater than 1000 ft (300 m). The RUSLE2 program will not accept input values greater than 1000 ft (305 m).

RUSLE2 works best for overland flow path steepness between 3 and 20 percent. It works moderately well for steepness less than 3 percent and between 20 and 35 percent. It works acceptably for steepness between 35 and 100 percent. It should not be applied to steepness greater than 100 percent.

---

[193] Tiwari, A.K., L.M. Risse, and M.A. Nearing. 2000. Evaluation of Wepp and its comparison with USLE and RUSLE. Trans. ASAE 43:1129-11135.

RUSLE2 should not be used for overland flow path steepness greater than 100 percent. The RUSLE2 program does not accept input values greater than 100 percent

RUSLE2 can be applied to all overland flow path profile shapes, including those where deposition occurs (see **Section 5.2**). Its erosion estimates for the eroding portions of overland flow paths are significantly more accurate than deposition estimates for the depositional portions. Accurately estimating deposition by overland flow is very difficult because a slight change in overland flow hydraulics can greatly affect deposition. RUSLE2 estimates are most accurate for uniform cover-management along an overland flow path. RUSLE2 is less accurate where cover-management varies enough along the overland flow path to significantly affect runoff because RUSLE2 does not explicitly consider runoff in its detachment computations. Overland flow path segment lengths can be adjusted to partially to account for this RUSLE2 limitation (see **Section 8.4**).

17.4.3.4. Geographic Region

RUSLE2 works best where rainfall occurs regularly, rainfall is the dominant precipitation, and average annual rainfall exceeds 20 inches. **RUSLE2** works acceptably in low rainfall regions like the western US. In these areas, RUSLE2 results should be interpreted as representing average erosion for sites having conditions like the field site rather than representing erosion on the actual field site. RUSLE2 erosion estimates are more accurate for actual field sites in high than in low rainfall regions. RUSLE2's accuracy is significantly reduced in low rainfall regions where annual erosion is low, especially if it is less than 1 ton/acre. **RUSLE2** can be used to estimate erosion in the special winter condition represented by the Northwest Wheat and Range Region. Special adjustments are needed for other regions where Req-type effects occur (see **Section 6.3.3**).

RUSLE2 does not explicitly estimate erosion caused by snowmelt.

17.4.3.5. Land Use

RUSLE2 is land use independent. It applies to all land uses where mineral soil is exposed to the erosive forces of raindrop impact and Hortonian overland flow. RUSLE2 works best for all land uses where annual erosion exceeds 1 ton/acre. **RUSLE2** works best for cropland, construction sites, land fills, and moderate to highly disturbed military training sites. It works moderately well on pastureland, mine spoil and disturbed forestland. It works acceptably on rangeland, abandoned crop and pastureland, and similar wildlife lands with few trees.

RUSLE2 should not be used for undisturbed forestland.

17.4.3.6. Irrigation

RUSLE2 can be used to estimate erosion by rainfall on lands where irrigation is used.

RUSLE2 cannot estimate erosion by furrow, flood, or similar types of surface irrigation.

17.4.3.7. Processes

RUSLE2 estimates rill and interrill erosion from rainfall and its associated runoff produced as Hortonian overland flow. It estimates sediment yield from overland flow paths, from diversion/terrace type channels where deposition occurs, and from impoundments like small sediment basins and impoundment terraces (see **Section 5.2**).

RUSLE2 does not estimate erosion or deposition in concentrated flow areas like within-field ephemeral gullies, incised gullies, and stream channels. RUSLE2 does not estimate erosion by mass wasting or by piping (i.e., water flowing through "pipes" in the soil).

17.5. Relation of RUSLE2 to other USLE/RUSLE erosion prediction technologies

The USLE was first used for local field office conservation planning by the USDA-Soil Conservation Service in the early 1960's. AH282, published in 1965, documented this USLE version. The next version of the USLE was documented in AH537, and it remains the standard USLE version. RUSLE1 was first released in 1992. The NRCS officially adopted RUSLE1.05 for local field office conservation planning in the mid 1990's. RUSLE1.05 is documented in AH703. RUSLE1.06, intended to replace RUSLE1.05, was released in 1998 and documented in the OSM manual for applying RUSLE1.06 to construction, mine, and reclaimed lands.[194] An erroneous impression is that RUSLE1.05 should be applied to cropland and RUSLE1.06 to disturbed lands. All versions of RUSLE1.06 apply to all lands. RUSLE1.06c was released in 2003. Changes were made so that RUSLE1.06c erosion estimates more closely correspond with RUSLE2's estimates than those from previous RUSLE1.06 versions.

[194] Toy, T.J. and G.R. Foster (coeditors). 1998. Guidelines for the use of the Revised Universal Soil Loss equation (RUSLE1.06) on mined lands, construction sites, and reclaimed lands. USDI-Office of Surface Mining. Denver. CO.

Foster et al. describe major differences in these technologies.[195]

17.5.1. Erosivity

The erosivity values given in AH282, AH537, and AH703 were determined from precipitation data collected from the mid 1930's to mid 1950's for the eastern US. The RUSLE2 erosivity values were determined from precipitation data collected from 1960 through 1999 for the entire continental US (see **Section 6.2**). Overall, the erosivity values from the recent data are about 10 percent higher in the Eastern US than erosivity values from the early data. The RUSLE2 erosivity values for the western US are much better than the erosivity values in AH537 or AH703.

RUSLE2 erosivity values should be used in all USLE/RUSLE versions.

Erosivity values in AH537 were reduced along the US Gulf Coast to account for high intensity rainfall ponding water that creates a water depth and reduces raindrop impact erosivity. Erosivity values in AH703 were not reduced to account for this effect. Instead, a ponding subfactor that is a function of the 10 year EI value and slope steepness was used in all RUSLE1 versions, but the ponding subfactor was used only with ridges. RUSLE2 uses a similar ponding subfactor (see **Section 9.2.7**) that is applied regardless of the presence of ridges.

The AH703 10 yr EI values were also based on the 1930's to 1950's precipitation data. The 10 yr EI values were contoured in great detail, which resulted in a 10 yr EI map with long narrow ridges-valleys in the equal value lines. A 10 yr EI map was developed for RUSLE1.06c that eliminated these ridges-valleys to represents main trends across the US appropriate for computing how support practices affect erosion.

The new RUSLE1.06c 10 yr EI map should be used in all RUSLE1 versions.

RUSLE2 uses 10 yr-24 hr precipitation values, which are based on data collected from before the 1960's, rather than 10 yr EI values. Smoothed 10 yr-24 hr precipitation values used in RUSLE2 are shown in Figure 6.18. These values capture the main trends across the Eastern US, much like the new 10 yr EI map developed for RUSLE1.06c.

RUSLE2 uses modern precipitation and temperature data that should also be used in all RUSLE1versions.

---

[195] Foster, G.R., T.J. Toy, and K.G. Renard. 2003. Comparison of the USLE, RUSLE1.06c, and RUSLE2, for application to highly disturbed land. In: First Interagency Conference on Research on Research in the Watersheds. USDA-Agricultural Research Service. Washington, D.C. pp. 154-160.

Use the smoothed 10 year EI map developed for RUSLE1.06c for all RUSLE1 versions.

17.5.2. Soil erodibility

All USLE/RUSLE versions use the same base soil erodibility factor value. RUSLE1.05 and RUSLE1.06b temporally vary the soil erodibility factor value while RUSLE1.06c does not. The resulting erosion difference can be 20 percent in some Midwestern US and Northeastern US location. RUSLE2 uses a new procedure to temporally vary soil erodibility factor values that is much better than the old RUSLE1 procedure, especially in the western US outside of Req type regions. The net soil erodibility factor value computed by RUSLE2 can also differ from RUSLE1.05 and RUSLE1.06 net erodibility factor value by 20 percent. The net soil erodibility value computed by RUSLE2 is close to the base soil erodibility value used by RUSLE1.06c for most of the Eastern US.

The RSULE2 temporal soil erodibility equation also computes average annual soil erodibility values that vary with location, even when soil properties are the same between locations. This effect is greatest in the Western US where soil erodibility values can vary as much as 50 percent from base soil erodibility values.

Do not temporally vary soil erodibility factor values in any RUSLE1 version.

RUSLE2 includes the standard USLE soil erodibility nomograph (AH537, AH703) widely used to estimate soil erodibility values. RUSLE2 also includes a modified version of the USLE soil erodibility nomograph that computes a greater effect of soil structure on soil erodibility than does the standard USLE nomograph (see **Section 7.3.2**). The trend of soil erodibility with soil structure in the standard USLE nomograph is not consistent with the trend identified by fundamental research.

The RUSLE2 modified soil erodibility nomograph should be used in all USLE/RUSLE versions when applied to highly disturbed lands. The standard USLE soil erodibility nomograph can be used on cropland.

The USLE does not consider sediment characteristics. RUSLE1.05 uses a single value deposition coefficient that does not vary with soil properties or upslope deposition. RUSLE1.06b and c use a deposition coefficient that is computed as a function of soil texture, but it does not change with upslope deposition. RUSLE2 computes sediment characteristics values for five sediment classes at the point of detachment as a function of soil texture. RUSLE2 computes how deposition changes the distribution among the sediment classes as deposition occurs. RUSLE2 computed deposition depends on how much upslope deposition has enriched the sediment in fines. RUSLE2 computes an enrichment ratio based on specific surface area, which is a function of soil texture and the portion of the detached sediment that is deposited.

17.5.3. Topography

The USLE slope length exponent varies only with slope steepness for steepness less than 5 percent. The RUSLE1.05 slope length exponent varies with slope steepness over the full range of steepness from zero to 100 percent. Also, the RUSLE1.05 slope length exponent is a function of the rill to interrill erosion ratio where the user selects from one three classes. In RUSLE1.06b and c, the slope length exponent is computed from the rill to interrill erosion ratio where the user selects from land use classes. Also, the RUSLE1.06 slope length exponent is a function of the rill soil erodibility to interrill soil erodibility ratio computed from soil texture. RUSLE2 computes the slope length exponent as a function of soil, steepness, and cover-management variables that affect the rill to interrill erosion ratio (see **Section 8.1.1**).

The slope length exponent used in the USLE and all RUSLE1 versions is constant over the computational period (i.e., duration in cover-management description). In contrast, RUSLE2 computes a slope length exponent value that varies daily as cover-management conditions change daily.

As a minimum, the RUSLE1.05 slope length relationship (AH703) should be used in the USLE.

The slope steepness relationship in the USLE has a quadratic form empirically derived from data collected at La Crosse, WI. This equation does not apply well to slope steepness less than about 2 percent or to slope steepness greater than about 25 percent. The RUSLE1 and RUSLE2 slope steepness relationship is based on a wide ranging dataset and is much more linear than the USLE quadratic relationship. No USLE, RUSLE, or RUSLE2 version varies the slope steepness relationship with any variable including time, soil, or cover-management.

The RUSLE slope steepness relationship (AH703) should be used in the USLE.

The USLE irregular slope procedure works well for determining how overland flow path profile shape affects erosion on the eroding portion of the flow path. It is not easily used where cover-management varies along the flow path. **The USLE does not compute deposition on concave flow path profiles.** RUSLE1.05, 1.06b, and 1.06c compute deposition on concave overland flow path profiles but do not vary the deposition coefficient along the overland flow path as deposition changes sediment characteristics. These models are not easily used where cover-management varies along the overland flow path except for rotational strip cropping. RUSLE2 computes how deposition changes sediment properties along the overland flow path that in turn affect downslope deposition. RUSLE2 is easily applied where cover-management varies along the overland flow path in any pattern (see **Section 17.4.3.3**)

17.5.4. Cover-management

RUSLE2 computes soil loss ratio values that can be compared to AH537 values. Also, RUSLE2 can be used to compute soil loss ratio values to use where experimental research has not determined values for the USLE. However, a much better approach is to use RUSLE1.06c rather than the USLE. The cover-management relationships in RUSLE1.06c are comparable to those in RUSLE2 and an error in the RUSLE1.05 and RUSLE1.06b computer programs in the soil biomass subfactor was corrected in RUSLE1.06c. The erosion reduction computed for no-till was reduced between RUSLE1.06b and RUSLE1.06c to be consistent with analysis conducted during the RUSLE2 development. Also, the interaction between canopy cover and ground cover used in the USLE and RUSLE2 is used in RUSLE1.06c but not in other RUSLE1 versions.

The AH537 soil loss ratio values for "conventional tillage" were used to calibrate **RUSLE2** so that the soil loss ratio values computed by **RUSLE2** match, as closely as possible, AH537 values.[196] The AH537 values for conservation tillage were not used in the **RUSLE** calibration because the AH537 values were based on research data collected in the late 1960's and early 1970's that do not represent modern conservation tillage. An extensive set of data from a literature survey was assembled and used to validate **RUSLE2** for no-till and other conservation tillage types.

Several considerations are important to ensure proper comparisons of RUSLE2 computed soil loss ratio values with AH537 and other soil loss ratio values.

RUSLE2 uses a ridge subfactor that is not used by RUSLE1. The effect of ridges is not represented in the AH537 soil loss ratio values except in Table 5-A. for cotton. Daily values of the RUSLE2 C and the ridge subfactors must be multiplied and integrated using the temporal erosivity distribution to compute a RUSLE2 soil loss ratio that can be compared to AH537 soil loss ratios.

The AH537 soil loss ratio values for crop stage four, the period following harvest, were not used to calibrate RUSLE2. Most of the data used to develop AH537 soil loss ratio

---

[196] Soil loss ratio is the ratio of erosion in a given period, like a crop stage, to erosion from the "unit plot" for the same period where all other conditions are the same. A crop stage is a period where cover-management conditions can be assumed to be constant. Equation 5.9 shows how soil loss ratios and crop stage periods are used to compute a cover-management factor value in the USLE.

values for cropland, except for conservation tillage and cotton, were from about 1935 to 1955. Farming practices in this period left corn stalks standing more erect after harvest than do modern combines that shred and spread the stalks. Also, AH537 soil loss ratio values for flat residue are based on a surface cover effect (mulch subfactor) having a b_f value of 0.026 (see equation 9.6), much lower than the now accepted value of 0.035. The data used to determine and evaluate **b** values in **RUSLE2** included the data used to develop the AH537 mulch subfactor curve plus additional data.

Many of the AH537 soil loss ratio values are for yields lower than modern yields, especially for corn. For example, the AH537 yield for high production corn is 112 bu/ac, whereas a modern corn yield is easily 150 bu/ac or more.

Soil loss ratios in AH537 are independent of location, whereas **RUSLE2** computed soil loss ratio values vary with location. For example, **RUSLE2** soil loss ratio values for corn are significantly lower in the upper Midwestern US than in the lower part of the Mid-South US because of the low soil biomass in the Mid-South where a humid, warm climate greatly increases biomass decomposition in comparison with the climate of the upper Midwest. Climate data at Columbia, Missouri were used to calibrate **RUSLE** and to represent typical conditions that would produce soil loss ratio values to compare with AH537 values, except for cotton where climate data from Holly Springs, MS were used.

To make comparisons between RUSLE2 soil loss ratio values and AH537 values, use Columbia, MO climate to compute RUSLE2 soil loss values for all AH537 conditions, except for cotton where the Holly Springs, MS location should be used. Climate data from Pullman, WA or Pendleton, OR should be used to compute RUSLE2 soil loss ratio values and other values to compare with research determined values in the Northwest Wheat and Range Region.

RUSLE2 was calibrated with the RUSLE2 core database. RUSLE2 soil loss ratio values should be computed using the RUSLE2 core database when making comparisons with AH537 values. Also, the RUSLE2 production (yield) level adjustment procedure should be used when comparing RUSLE2 computed soil loss ratio values with AH537 values for different production levels.

Table 10, AH537 is widely used in the USLE to compute erosion on range, pasture, idle, and undisturbed lands. **This procedure should not be used because it has major shortcomings (see Section *17.4.1.4*).** RUSLE2 and RUSLE1.06c provide much better estimates than the USLE for these conditions.[197] Also, RUSLE1.06c is much improved over RUSLE1.05 and earlier RUSLE1.06 versions for these conditions.

[197] Spaeth, Jr., K.E., F.B. Pierson, M.A. Weltz, and W.H. Blackburn. 2003. Evaluation of USLE and RUSLE estimated soil loss on rangelands. J. Range Management 56:234-246.

A major advantage of RUSLE2 and RUSLE1.06c is their land use independence that allows them to be applied to conditions that vary from highly disturbed to undisturbed over the period of interest. Examples include construction sites, reclaimed mine land, disturbed forestland, and landfills from the time of the last disturbance through recovery and stabilization. Also, RUSLE2 and RUSLE1.06c work well for military training sites and similar areas where conditions at the site range from highly disturbed to undisturbed and for rangeland sites that move back and forth with cropland depending on farming economics. If different models are applied to different time periods or to different land use conditions, the likelihood is almost 100 percent that erosion estimates from the different models will differ significantly at common point in time when common estimates are expected. These erosion estimate differences complicate interpretation of the values and raise questions about the validity of one or more of the models. Users may not know the correct erosion estimate, but they can easily recognize that differences are being computed where values should not be different.

RUSLE2 can be used to compute soil loss ratio values for any land use where RUSLE2 applies. These values can be used in the USLE for conditions where experimentally derived soil loss ratio values are not available. *RUSLE1.06c should be used rather than the USLE.*

17.5.5. Support practices

17.5.5.1. Contouring

The AH537 contouring subfactor values typically used in the USLE vary only with steepness of the overland flow path. All RUSLE1 versions compute contouring subfactor values that vary with the major variables that affect the relation between erosion and contouring. RUSLE1 uses input values for cover-management condition and ridge height that represent the entire computational period. These inputs are selected to compute average annual erosion. RUSLE2 uses equations similar to those in RUSLE1 to compute daily contouring subfactor values (**see Section 14.1**). A relative row grade of 10 percent and climate data for Columbia, MO should be used when comparing RUSLE2 and RUSLE1 contouring subfactor values with AH537 values. Also, cover-management conditions, including yield, used in RUSLE2 and RUSLE1 should be chosen to represent farming practices in the 1930' to mid 1950's to compute contouring subfactor values to compare with AH537 values.

RUSLE2 computes a net contouring subfactor value by integrating daily contouring factor values with the temporal erosivity distribution values. However, RUSLE2 net contour values are not the proper values to compare with AH537 values. The proper RUSLE2 contouring subfactor value to compare with an AH537 value is the ratio of RUSLE2 computed average annual erosion for a 10 percent relative row grade to average annual erosion for an up and downhill (100 percent) relative row grade. This RUSLE2 contouring subfactor is comparable to AH537 contouring subfactor values computed as the ratio of measured average annual erosion with contouring to measured average annual erosion with up and downhill tillage. Values for this RUSLE2 contouring subfactor value differs from the RUSLE2 net contouring subfactor (see **Section 17.5.6** for a discussion of the reason for this difference).

A difficulty with RUSLE1 is that representative input values for the entire computational period must be chosen. RUSLE2 computes daily contouring subfactor values based on the daily values for cover-management variables. RUSLE2 and RUSLE1 should give similar contouring subfactor values but the values will not compare exactly.

All RUSLE versions describe how major variables affect contouring failure (critical slope length). AH537 values only vary with slope steepness and whether or not strip cropping is used. AH537 gives a single adjustment for conservation tillage conditions. All RUSLE versions were calibrated to give AH537 critical slope lengths for the base Columbia, MO condition (see **Section 14.1.2.5**).

RUSLE2 can be used to compute contouring subfactor values for use in the USLE. The value should be computed as a ratio of average annual erosion values with and without contouring computed by RUSLE2. Actually, RUSLE1.06c should be used rather than the USLE.

17.5.5.2. Strips/barriers

Although Table 14, AH537 list factor values for several rotational strip cropping conditions, AH537 provides no factor values for narrow strips of permanent vegetation or mechanical barriers like fabric (silt) fences. To compare RUSLE2 and RUSLE1 factor values with AH537 values, make RUSLE2 and RUSLE1 computations with and without rotational strip cropping for Columbia, MO using input values that represent farming practices, including yield, in the 1930' to mid 1950's. Compute ratio values using RUSLE2 estimated average annual sediment yield, not detachment or erosion, to compare with AH537 values that were computed as measured sediment yield with strip cropping to measured sediment yield without strip cropping. Similarly, RUSLE1 sediment yield values should be used rather than the P factor values. The RUSLE1 P factor values do not give full credit for deposition as soil saved, whereas the AH537 and RUSLE2 values give full credit for deposition as soil saved for rotational strip cropping.

The AH537 strip cropping factor values do not apply to modern farming practices, including conservation tillage, that leave rough soil surfaces and high residue cover that induce deposition much like dense vegetation strips. The effectiveness of strips is related to sediment production on the more erodible strips relative to transport capacity in the strips having a high hydraulic resistance (see *Section 14.2*).

All RUSLE versions capture how major variables affect the relationship between sediment yield and strips/barriers. RUSLE1 uses inputs for cover-management condition for each strip that represents each year of the computational period. RUSLE2 computes daily factor values as a function of daily cover-management variables. Just as with contouring, RUSLE2 and RUSLE1 factor values for strips/barriers will not agree because of this difference in input even though similar equations are used in both models. Another reason for differences is that RUSLE1.05 uses a single deposition coefficient value, RUSLE1.06 uses a deposition coefficient that is a function of soil texture, and RUSLE2 uses sediment characteristics that are a function of soil texture and upslope deposition.

See **Sections 14.2 and 17.5.5.3** for a discussion of RUSLE2's conservation planning soil loss that gives credit for deposition as soil saved.

RUSLE2 can compute factor values for strips/barriers that can be used in the USLE, but a better approach is to use RUSLE1.06c rather than the USLE.

17.5.5.3. Diversions/terraces/sediment basins

Factor values for diversions, terraces, and small sediment basins reported by Foster and Highfill and the RUSLE1.06 OSM manual are the best values for comparing with RUSLE values.[198] The value of terraces as a soil conservation practice has been debated for several years. The benefit of terraces for shortening the overland flow path length to reduce sediment production and deposition in terrace channels and small sediment basins reducing sediment yield reduction is universally accepted. However, the value of deposition as soil saved is debated. For example, credit was given to deposition in 1965 in AH282 as soil saved but no credit was given in 1978 in AH537. The credit given is a matter of judgment. USDA-NRCS agronomists tend to claim no credit for deposition with terraces but prefer to claim credit for deposition caused by narrow permanent vegetation strips, while USDA-NRCS engineers prefer to claim credit for deposition caused by terraces.[199]

---

[198] See:
Foster, G. R. and R. E. Highfill. 1983. Effect of terraces on soil loss: USLE P factor values for terraces. Journal of Soil and Water Conservation 38:48-51.

Toy, T.J. and G.R. Foster (coeditors). 1998. Guidelines for the use of the Revised Universal Soil Loss equation (RUSLE1.06) on mined lands, construction sites, and reclaimed lands. USDI-Office of Surface Mining. Denver. CO.

[199] This debate among these NRCS disciplines involves a certain amount of self-interest. NRCS agronomists have technical oversight for permanent vegetation strips while NRCS engineers have technical oversight for terraces.

The RUSLE2 developers consider deposition in terrace channels and above permanent vegetation strips to have a similar benefit as soil saved. In fact deposition in terrace channels could perhaps merit increased credit because tillage redistributes this deposited sediment over a larger landscape area than tillage redistributes sediment deposited by permanent vegetation strips. RUSLE2 gives consistent credit to deposition as soil saved between terraces and permanent vegetation strips based on location along the overland flow path, except for rotational strip cropping where full credit is given to deposition. Also, the credit given to deposition as soil saved with terraces decreases as terrace spacing increases (see **Section 14.3**). Giving full credit to deposition associated with rotational strip cropping is consistent with AH282 and AH537 values. The RUSLE2 soil conservation planning soil loss value is the RUSLE2 output that reflects credit for deposition as soil saved (see **Section 8.1.5.4**).

RUSLE1.05 computes sediment yield from diversion/terrace channels as a function of channel grade only. That is, the fraction of the sediment load that is deposited in a diversion/terrace channel is independent of the sediment load coming into the channel or transport capacity in the channel. RUSLE2 and RUSLE1.06 compute deposition as a function of sediment characteristics, sediment transport capacity in the channel, and sediment load reaching the channel. If incoming sediment load is less than transport capacity, no deposition is computed. RUSLE1.05 assumes that 95 percent of the sediment that reaches a small sediment basin is deposited. RUSLE2 and RUSLE1.06c compute deposition in small sediment basins as a function of characteristics of the incoming sediment.

RUSLE2 can be used to compute diversion/terrace/sediment basin P factor values for use in the USLE. However, a better approach than using the USLE is to use RUSLE1.06c, which computes diversion/terrace/sediment basin P factors using equations that are similar to those used in RUSLE2.

17.5.6. Computing erosion

RUSLE2 computes net values for the soil erodibility factor K, topographic factor LS, cover-management factor C without the ridging effect, ridge subfactor, ponding subfactor, and contouring subfactor by weighting daily values with the temporal erosivity distribution, exactly in the same way that these computations are made in the USLE for the C factor and in RUSLE1 for the K and C factors.

These RUSLE2 computed factor values can be compared with those for the USLE and RUSLE1. These comparisons give insight into differences among RUSLE2, RUSLE1, and the USLE. The comparisons should be properly made. For example, the RUSLE2 net factor values for cover-management and ridging should be multiplied to obtain a C factor that can be compared with the USLE and RUSLE1 C factor values. Also, the proper RUSLE2 values for the contour and strip cropping factors is to divide the average annual sediment yield for contouring and contouring/contouring/strip cropping on a uniform overland flow path by estimated sediment yield without contouring or strip cropping. The RUSLE2 net contouring subfactor value differs from this RUSLE2 factor value for contouring because the net contouring subfactor only involves the temporal integration of the erosivity distribution while the ratio values involves the temporal integration of the product of all the RUSLE2 factors.

The RUSLE2 computed values for these factors can be multiplied as the USLE and RUSLE1 factor values are multiplied to estimate average annual erosion. However, this erosion value differs from the value computed by RUSLE2 because of differences in the mathematic integration among these models (see **Section 5.4**). RUSLE2 does not compute erosion by multiplying average annual values for individual factors; RUSLE2 computes average annual erosion by computing daily erosion as the product of the daily factor values and summing the daily erosion values. The difference in these mathematical procedures for computing average annual erosion can be as much as 15 percent, depending on cropping-management system and location.

Even if RUSLE2 were to produce net factor values that equaled USLE and RUSLE1 factor values, RUSLE2's computed average annual erosion would not match USLE and RUSLE1's computed average annual erosion. RUSLE2's mathematics properly integrate the temporally and spatially varying governing equations. The USLE and RUSLE1 procedures are approximations.

18. HOW RUSLE2 CAME TO BE

The Universal Soil Loss Equation (USLE) was developed in the late 1950s and became widely used in conservation planning on cropland in the 1960s. Beginning in the 1970s, the USLE was applied to many other land uses in addition to cropland and to other applications besides conservation planning.

The USLE was updated in 1978, but by 1985 the USLE needed another update with passage of the Farm Bill and to incorporate new research information. A project led by USDA-Agricultural Research Service was initiated at a workshop in Lafayette, Indiana in 1985 to update the USLE. This workshop attended by leading U.S. erosion research scientists and USLE users from the USDA-Natural Resources Conservation Service (formerly, Soil Conservation Service) and Forest Service, USDI-Bureau of Land Management, and U.S. Army Corps of Engineers set objectives and approaches for the update.

By 1987, much of the background work on updating the USLE was well underway and some had been completed. The project evolved into much more than an updating of the USLE. The USLE was undergoing a major revision, and hence the updated USLE became what is now referred to as **RUSLE1**, the **R**evised **USLE**. Also, another major addition to the project was the development of a computer program to implement RUSLE1.

Development of **RUSLE2** began in 1993 using RUSLE1 as the starting point. RUSLE2 uses the basic USLE equation structure to compute sediment detachment but differs greatly from the USLE in almost every other way. RUSLE2 is similar to RUSLE1, but RUSLE2 uses new equations, a new mathematical integration procedure, new database values, and is implemented in a modern graphical user interface computer program. Almost all of the mathematical relationships in RUSLE2 have been revised from corresponding relationships in RUSLE1.

RUSLE2 is much more powerful than either the USLE or RUSLE1. The interface for the RUSLE2 computer program, the underlying modeling engine of this computer program, its computational routines, and RUSLE2's mathematical equations make RUSLE2 the most modern, powerful, and easy-to-use erosion prediction technology available for use in conservation and erosion control planning at the local field office level.

RUSLE2 was developed by a group of experienced and nationally recognized erosion scientists, erosion control specialists, and soil conservationists. Data needed to develop and validate RUSLE were incomplete in some cases, which necessitated scientists and users using judgment to fill gaps. USDA-Agriculture Handbook 703 and other RUSLE1 publications, which was the starting point for RUSLE2, have been reviewed by peer scientists in a process typical of the reporting of rigorous research. Erosion scientists, NRCS technical specialists, and many others have made many computations with RUSLE2 to ensure that RUSLE2 works well for every imaginable situation where RUSLE2 will be applied. The scientific documentation for RUSLE2 has been peer reviewed according to standard procedures of the USDA-Agricultural Research Service.

RUSLE2 can be used with full confidence that it meets high scientific standards and produces reliable results for conservation and erosion control planning for all lands where rill and interrill erosion occur by rainfall and Hortonian overland flow.

EXECUTIVE SUMMARY ES-1

BACKGROUND ES-1
SUMMARY OF MAJOR CONCLUSIONS ES-2
SUPPORT FOR MAJOR CONCLUSIONS ES-6
KEY FINDINGS FOR MAJOR CONCLUSIONS ES-7
CLOSING COMMENTS ES-15

CHAPTER 1. INTRODUCTION 1-1

1.1 Purpose 1-1
1.2 Scientific Context 1-2
1.2.1 Concepts of Connectivity in Hydrology and Ecology 1-2
1.2.2 Connectivity Gradients and Descriptors 1-3
1.2.3 Cumulative Effects of Streams and Wetlands on Downstream Waters 1-10
1.2.4 Effects of Human Activities on Connectivity 1-11
1.3 Report Approach 1-14
1.3.1 Selection and Screening of Scientific Materials 1-16
1.3.2 Report Structure 1-18
1.4 Summary 1-18

CHAPTER 2. AN INTEGRATED SYSTEMS PERSPECTIVE ON INTERACTIONS OF WATERSHEDS, STREAMS, WETLANDS, AND DOWNSTREAM WATERS 2-1

2.1 Introduction 2-1
2.2 An Introduction to River Systems 2-2
2.2.1 River System Components 2-2
2.2.2 River System Hydrology 2-8
2.2.3 River Network Expansion and Contraction 2-18
2.3 Influence of Streams and Wetlands on Downstream Waters 2-22
2.3.1 Effects of Streams and Wetlands on Material Fluxes 2-22
2.3.2 Connectivity and Transport of Materials to and from Streams and Wetlands 2-26
2.3.2.1 Connectivity and Isolation 2-26
2.3.2.2 Spatial and Temporal Variability of Connectivity 2-29
2.4 Factors Influencing Connectivity 2-30
2.4.1 Climate-Watershed Characteristics 2-31
2.4.2 Spatial Distribution Patterns 2-38
2.4.3 Biota 2-40
2.4.4 Human Activities and Alterations 2-44
2.4.5 Interactions Among Factors 2-47
2.4.6 Quantifying Connectivity 2-49
2.4.6.1 Hydrologic and Chemical Connectivity 2-49
2.4.6.2 Biological Connectivity 2-50
2.4.6.3 Summary 2-51

CHAPTER 3. STREAMS: PHYSICAL, CHEMICAL, AND BIOLOGICAL CONNECTIONS TO RIVERS 3-1

3.1 Abstract 3-1
3.2 Introduction 3-2
3.3 Physical Connections 3-5
3.3.1 Water 3-5
3.3.2 Sediment 3-13

3.3.3 Wood 3-17
3.3.4 Temperature (Heat Energy) 3-19
3.4 Chemical Connections 3-21
3.4.1 Nutrients 3-23
3.4.2 Dissolved and Particulate Organic Matter 3-28
3.4.3 Ions 3-32
3.4.4 Contaminants and Pathogens 3-33
3.5 Biological Connections 3-37
3.5.1 Invertebrates 3-38
3.5.2 Fishes 3-40
3.5.3 Genes 3-43
3.6 Streams: Synthesis and Implications 3-45

CHAPTER 4. WETLANDS: PHYSICAL, CHEMICAL, AND BIOLOGICAL CONNECTIONS TO RIVERS 4-1
4.1 Abstract 4-1
4.2 Introduction 4-3
4.3 Riparian/Floodplain Wetlands 4-3
4.3.1 Introduction 4-3
4.3.2 The Physical Influence of Riparian Areas on Streams 4-7
4.3.2.1 Hydrology 4-7
4.3.2.2 Geomorphology (Sediment-vegetation Interactions) 4-8
4.3.2.3 Temperature and Sunlight 4-9
4.3.3 The Chemical-nutrient Influence of Riparian Areas on Streams 4-10
4.3.3.1 Hyporheic/Soil Processing of Nutrients 4-11
4.3.3.2 Nitrogen 4-11
4.3.3.3 Phosphorus 4-12
4.3.3.4 Carbon and Allochthonous Inputs 4-13
4.3.3.5 Pesticides 4-14
4.3.3.6 Mercury 4-14
4.3.4 Biological Connections Between Riparian Areas and Streams 4-15
4.3.4.1 Vascular Plants and Phytoplankton 4-15
4.3.4.2 Vertebrates 4-17
4.3.4.3 Invertebrates 4-19
4.4 Non-floodplain Wetlands 4-20
4.4.1 Introduction 4-20
4.4.2 The Physical Influence of Non-floodplain Wetlands on Streams 4-21
4.4.2.1 Surface-water Connections 4-21
4.4.2.2 Ground-water Connections 4-22
4.4.2.3 Effects of Non-floodplain Wetlands on Streamflow 4-24
4.4.3 Effects of Non-floodplain Wetlands on Water Quality 4-26
4.4.3.1 Non-floodplain Wetlands as Sources for Downstream Waters 4-27
4.4.3.2 Non-floodplain Wetlands as Sinks and Transformers for Downstream Waters 4-29
4.4.4 Biological Connections Between Non-floodplain Wetlands and Streams 4-30
4.4.5 Geographic Isolation of Non-floodplain Wetlands 4-35
4.5 Wetlands: Synthesis and Implications 4-39
4.5.1 Riparian/Floodplain Wetlands 4-39
4.5.2 Non-floodplain Wetlands 4-39

CHAPTER 5. APPLICATIONS AND DISCUSSION: CONNECTIVITY CASE STUDIES 5-1
5.1 Introduction 5-1
5.2 Carolina and Delmarva Bays 5-2
5.2.1 Connectivity and Consequences on Downstream Waters 5-2
5.2.2 Effects of Human Alteration 5-3
5.3 Oxbow Lakes 5-3
5.3.1 Connectivity and Consequences on Downstream Waters 5-3

5.3.2 Effects of Human Alteration 5-4
5.4 Prairie Potholes **5-4**
5.4.1 Connectivity and Consequences on Downstream Waters 5-4
5.4.2 Effects of Human Alteration 5-5
5.5 Prairie Streams **5-6**
5.5.1 Connectivity and Consequences on Downstream Waters 5-6
5.5.2 Effects of Human Alteration 5-7
5.6 Southwestern Intermittent and Ephemeral Streams **5-7**
5.6.1 Connectivity and Consequences on Downstream Waters 5-7
5.6.2 Effects of Human Alteration 5-8
5.7 Vernal Pools **5-8**
5.7.1 Connectivity and Consequences on Downstream Waters 5-8
5.7.2 Effects of Human Alteration 5-9
5.8 Synthesis **5-9**

CHAPTER 6. CONCLUSIONS **6-1**
6.1 Major Conclusions and Key Findings **6-1**
6.1.1 Conclusion 1: Streams 6-1
6.1.1.1 Conclusion 1, Key Findings 6-2
6.1.2 Conclusion 2: Riparian/Floodplain Wetlands and Open Waters 6-3
6.1.2.1 Conclusion 2, Key Findings 6-4
6.1.3 Conclusion 3: Non-floodplain Wetlands and Open Waters 6-5
6.1.3.1 Conclusion 3, Key Findings 6-6
6.1.4 Conclusion 4: Degrees and Determinants of Connectivity 6-8
6.1.4.1 Conclusion 4, Key Findings 6-9
6.1.5 Conclusion 5: Cumulative Effects 6-10
6.1.5.1 Conclusion 5, Key Findings 6-11
6.2 Strength of Evidence for Conclusions and Data Gaps in the Available Literature **6-12**

PREFACE

This report was prepared by the National Center for Environmental Assessment, the National Health and Environmental Effects Research Laboratory, and the National Exposure Research Laboratory, in the U.S. Environmental Protection Agency's (U.S. EPA's) Office of Research and Development. It reviews and evaluates evidence from peer-reviewed sources that were published or in press by December 2014. Throughout this document, terms are used with their generally recognized scientific meaning. We have provided definitions of technical terms in the Glossary (Appendix A). Two previous drafts prepared on 1 February 2011 and 12 July 2011 were reviewed by U.S. EPA and U.S. Army Corps of Engineers staff. Additional comments were received from scientists in government, academic, nonprofit, and private industry organizations listed in the **Reviewers** section who reviewed all or part of the 1 February 2011 preliminary draft. A draft prepared on 11 October 2011 was independently peer reviewed by a panel of 11 topic experts, listed in the **Reviewers** section, on 30 January 2012. An external review draft released in September 2013 (600/R-11/098B) was reviewed by U.S. EPA staff and a panel of the U.S. EPA's Science Advisory Board (SAB) that convened 16−18 December 2013 (SAB report number EPA-SAB-15-001, available online at www.epa.gov/sab). The 27 topic experts comprising the SAB panel are listed in the **Reviewers** section. In addition, comments from the public were received through the docket or at the SAB panel meeting. Comments from these sources were considered and used to improve the clarity and scientific rigor of the document.

ACKNOWLEDGMENTS

We gratefully acknowledge support provided by ICF International in Durham, NC and Tetra Tech, Inc. in Owings Mills, MD for preparation and production of draft and final reports; Eastern Research Group, Inc. in Lexington, MA for organizing and managing an independent peer review of a draft report; and Ms. Iris Goodman, Dr. Thomas Armitage, and Dr. Angela Nugent at the U.S. Environmental Protection Agency, Science Advisory Board (SAB) in Washington, DC for their service as Designated Federal Officers for the SAB review of this report.

EXECUTIVE SUMMARY

BACKGROUND

The objective of the Clean Water Act is to restore and maintain the chemical, physical, and biological integrity of the nation's waters. The U.S. Environmental Protection Agency's (U.S. EPA's) Office of Research and Development developed this report to inform rulemaking by the U.S. EPA and U.S. Army Corps of Engineers (U.S. ACE) on the definition of "waters of the United States" under the Clean Water Act (CWA). Its purpose is to summarize current scientific understanding about the connectivity and mechanisms by which streams and wetlands, singly or in aggregate, affect the physical, chemical, and biological integrity of downstream waters. The focus of the review is on surface and shallow subsurface connections of small or temporary streams, nontidal wetlands, and certain open waters. Because this report is a technical review of peer-reviewed scientific literature, it neither considers nor sets forth legal standards for CWA jurisdiction, nor does it establish EPA policy.

The report is organized into six chapters. Chapter 1 outlines the purpose, scientific context, and approach of the report. Chapter 2 describes the components of a river system and watershed; the types of physical, chemical, and biological connections that link those components; the factors that influence connectivity at various temporal and spatial scales; and methods for quantifying connectivity. Chapter 3 reviews literature on connectivity in stream networks in terms of physical, chemical, and biological connections and their resulting effects on downstream waters. Chapter 4 reviews literature on the connectivity and effects of nontidal wetlands and certain open waters on downstream waters. Chapter 5 applies concepts and evidence from previous chapters to six case studies from published literature on Carolina and Delmarva bays, oxbow lakes, prairie potholes, prairie streams, southwestern streams, and vernal pools. Chapter 6 summarizes key findings and conclusions, identifies data gaps, and briefly discusses research approaches that could fill those gaps. A glossary of scientific terms used in the report and detailed case studies of selected systems (summarized in Chapter 5) are included in Appendix A and Appendix B, respectively.

SUMMARY OF MAJOR CONCLUSIONS

Based on the review and synthesis of more than 1,200 publications from the peer reviewed scientific literature, the evidence supports five major conclusions. Citations have been omitted from the text to improve readability; please refer to individual chapters for supporting publications and additional information.

Conclusion 1: Streams

The scientific literature unequivocally demonstrates that streams, individually or cumulatively, exert a strong influence on the integrity of downstream waters. All tributary streams, including perennial, intermittent, and ephemeral streams, are physically, chemically, and biologically connected to downstream rivers via channels and associated alluvial deposits where water and other materials are concentrated, mixed, transformed, and transported. Streams are the dominant source of water in most rivers, and the majority of tributaries are perennial, intermittent, or ephemeral headwater streams. Headwater streams also convey water into local storage compartments such as ponds, shallow aquifers, or stream banks, and into regional and alluvial aquifers; these local storage compartments are important sources of water for maintaining baseflow in rivers. In addition to water, streams transport sediment, wood, organic matter, nutrients, chemical contaminants, and many of the organisms found in rivers. The literature provides robust evidence that streams are biologically connected to downstream waters by the dispersal and migration of aquatic and semiaquatic organisms, including fish, amphibians, plants, microorganisms, and invertebrates, that use both upstream and downstream habitats during one or more stages of their life cycles, or provide food resources to downstream communities. In addition to material transport and biological connectivity, ephemeral, intermittent, and perennial flows influence fundamental biogeochemical processes by connecting channels and shallow ground water with other landscape elements. Physical, chemical, and biological connections between streams and downstream waters interact via integrative processes such as nutrient spiraling, in which stream communities assimilate and chemically transform large quantities of nitrogen and other nutrients that otherwise would be transported directly downstream, increasing nutrient loads and associated impairments due to excess nutrients in downstream waters.

Conclusion 2: Riparian/Floodplain Wetlands and Open Waters

The literature clearly shows that wetlands and open waters in riparian areas and floodplains are physically, chemically, and biologically integrated with rivers via functions that improve downstream water quality, including the temporary storage and deposition of channel-forming sediment and woody debris, temporary storage of local ground water that supports baseflow in rivers, and transformation and transport of stored organic matter. Riparian/floodplain wetlands and open waters improve water quality through the assimilation, transformation, or sequestration of pollutants, including excess nutrients and chemical contaminants such as pesticides and metals, that can degrade downstream water integrity. In addition to providing effective buffers to protect downstream waters from point source and nonpoint source pollution, these systems form integral components of river food webs, providing nursery habitat for breeding fish and amphibians, colonization opportunities for stream invertebrates, and maturation habitat for stream insects. Lateral expansion and contraction of the river in its floodplain result in an exchange of organic matter and organisms, including fish populations that are adapted to use floodplain habitats for feeding and spawning during high water, that are critical to river ecosystem function. Riparian/floodplain wetlands and open waters also affect the integrity of downstream waters by subsequently releasing (desynchronizing) floodwaters and retaining large volumes of stormwater, sediment, and contaminants in runoff that could otherwise negatively affect the condition or function of downstream waters.

Conclusion 3: Non-floodplain Wetlands and Open Waters

Wetlands and open waters in non-floodplain landscape settings (hereafter called "non-floodplain wetlands") provide numerous functions that benefit downstream water integrity. These functions include storage of floodwater; recharge of ground water that sustains river baseflow; retention and transformation of nutrients, metals, and pesticides; export of organisms or reproductive propagules to downstream waters; and habitats needed for stream species. This diverse group of wetlands (e.g., many prairie potholes, vernal pools, playa lakes) can be connected to downstream waters through surface-water, shallow subsurface-water, and ground-water flows and through biological and chemical connections.

In general, connectivity of non-floodplain wetlands occurs along a gradient (Conclusion 4), and can be described in terms of the frequency, duration, magnitude, timing, and rate of change of water, material, and biotic fluxes to downstream waters. These descriptors are influenced by climate, geology, and terrain, which interact with factors such as the magnitudes of the various functions within wetlands (e.g., amount of water storage or carbon export) and their proximity to downstream waters to determine where wetlands occur along the connectivity gradient. At one end of this gradient, the functions of non-floodplain wetlands clearly affect the condition of downstream waters if a visible (e.g., channelized) surface-water or a regular shallow subsurface-water connection to the river network is present. For non-floodplain wetlands lacking a channelized surface or regular shallow subsurface connection (i.e., those at intermediate points along the gradient of connectivity), generalizations about their specific effects on downstream waters from the available literature are difficult because information on both function and connectivity is needed. Although there is ample evidence that non-floodplain wetlands provide hydrologic, chemical, and biological functions that affect material fluxes, to date, few scientific studies explicitly addressing connections between non-floodplain wetlands and river networks have been published in the peer-reviewed literature. Even fewer publications specifically focus on the frequency, duration, magnitude, timing, or rate of change of these connections. In addition, although areas that are closer to rivers and streams have a higher probability of being connected than areas farther away when conditions governing the type and quantity of flows—including soil infiltration rate, wetland storage capacity, hydraulic gradient, etc.—are similar, information to determine if this similarity holds is generally not provided in the studies we reviewed. Thus, current science does not support evaluations of the degree of connectivity for specific groups or classes of wetlands (e.g., prairie potholes or vernal pools). Evaluations of individual wetlands or groups of wetlands, however, could be possible through case-by-case analysis.

Some effects of non-floodplain wetlands on downstream waters are due to their isolation, rather than their connectivity. Wetland "sink" functions that trap materials and prevent their export to downstream waters (e.g., sediment and entrained pollutant removal, water storage) result because of the wetland's ability to isolate material fluxes. To establish that such functions influence downstream waters, we also need to know that the wetland intercepts materials that otherwise would reach the downstream water. The literature we reviewed does provide limited examples of direct effects of wetland isolation on downstream waters, but not for classes of wetlands (e.g., vernal pools). Nevertheless, the literature we reviewed enables us to conclude that sink functions of non-floodplain wetlands, which result in part from their relative isolation, will affect a downstream water when these wetlands are situated between the downstream water and known point or nonpoint sources of pollution, and thus intersect flowpaths between the pollutant source and downstream waters.

Conclusion 4: Degrees and Determinants of Connectivity

Watersheds are integrated at multiple spatial and temporal scales by flows of surface water and ground water, transport and transformation of physical and chemical materials, and movements of organisms. Although all parts of a watershed are connected to some degree—by the hydrologic cycle or dispersal of organisms, for example—the degree and downstream effects of those connections vary spatially and temporally, and are determined by characteristics of the physical, chemical, and biological environments and by human activities.

Stream and wetland connections have particularly important consequences for downstream water integrity. Most of the materials—broadly defined as any physical, chemical, or biological entity—in rivers, for example, originate from aquatic ecosystems located upstream or elsewhere in the watershed. Longitudinal flows through ephemeral, intermittent, and perennial stream channels are much more efficient for transport of water, materials, and organisms than diffuse overland flows, and areas that concentrate water provide mechanisms for the storage and transformation, as well as transport, of materials.

Connectivity of streams and wetlands to downstream waters occurs along a continuum that can be described in terms of the frequency, duration, magnitude, timing, and rate of change of water, material, and biotic fluxes to downstream waters. These terms, which we refer to collectively as connectivity descriptors, characterize the range over which streams and wetlands vary and shift along the connectivity gradient in response to changes in natural and anthropogenic factors and, when considered in a watershed context, can be used to predict probable effects of different degrees of connectivity over time. The evidence unequivocally demonstrates that the stream channels and riparian/floodplain wetlands or open waters that together form river networks are clearly connected to downstream waters in ways that profoundly influence downstream water integrity. The connectivity and effects of non-floodplain wetlands and open waters are more variable and thus more difficult to address solely from evidence available in peer-reviewed studies.

Variations in the degree of connectivity influence the range of functions provided by streams and wetlands, and are critical to the integrity and sustainability of downstream waters. Connections with low values of one or more descriptors (e.g., low-frequency, low-duration streamflows caused by flash floods) can have important downstream effects when considered in the context of other descriptors (e.g., large magnitude of water transfer). At the other end of the frequency range, high-frequency, low-magnitude vertical (surface-subsurface) and lateral flows contribute to aquatic biogeochemical processes, including nutrient and contaminant transformation and organic matter accumulation. The timing of an event can alter both connectivity and the magnitude of its downstream effect. For example, when soils become saturated by previous rainfall events, even low or moderate rainfall can cause streams or wetlands to overflow, transporting water and materials to downstream waters. Fish that use nonperennial or perennial headwater stream habitats to spawn or rear young, and invertebrates that move into seasonally inundated floodplain wetlands prior to emergence, have life cycles that are synchronized with the timing of flows, temperature thresholds, and food resource availability in those habitats.

Conclusion 5: Cumulative Effects

The incremental effects of individual streams and wetlands are cumulative across entire watersheds and therefore must be evaluated in context with other streams and wetlands. Downstream waters are the time-integrated result of all waters contributing to them. For example, the amount of water or biomass contributed by a specific ephemeral stream in a given year might be small, but the aggregate contribution of that stream over multiple years, or by all ephemeral streams draining that watershed in a given year or over multiple years, can have substantial consequences on the integrity of the downstream waters. Similarly, the downstream effect of a single event, such as pollutant discharge into a single stream or wetland, might be negligible but the cumulative effect of multiple discharges could degrade the integrity of downstream waters.

In addition, when considering the effect of an individual stream or wetland, all contributions and functions of that stream or wetland should be evaluated cumulatively. For example, the same stream transports water, removes excess nutrients, mitigates flooding, and provides refuge for fish when conditions downstream are unfavorable; if any of these functions is ignored, the overall effect of that stream would be underestimated.

SUPPORT FOR MAJOR CONCLUSIONS

This report synthesizes a large body of scientific literature on the connectivity and mechanisms by which streams, wetlands, and open waters, singly or in aggregate, affect the physical, chemical, and biological integrity of downstream waters. The major conclusions reflect the strength of evidence currently available in the peer-reviewed scientific literature for assessing the connectivity and downstream effects of water bodies identified in Chapter 1 of this report.

The conclusions of this report were corroborated by two independent peer reviews by scientists identified in the front matter of this report.

The term connectivity is defined in this report as the degree to which components of a watershed are joined and interact by transport mechanisms that function across multiple spatial and temporal scales. Connectivity is determined by the characteristics of both the physical landscape and the biota of the specific system. Our review found strong evidence supporting the central roles of the physical, chemical, and biological connectivity of streams, wetlands, and open waters—encompassing varying degrees of both connection and isolation—in maintaining the structure and function of downstream waters, including rivers, lakes, estuaries, and oceans. Our review also found strong evidence demonstrating the various mechanisms by which material and biological linkages from streams, wetlands, and open waters affect downstream waters, classified here into five functional categories (source, sink, refuge, lag, and transformation; discussed below), and modify the timing of transport and the quantity and quality of resources available to downstream ecosystems and communities. Thus, the currently available literature provided a large body of evidence for assessing the types of connections and functions by which streams and wetlands produce the range of observed effects on the integrity of downstream waters.

We identified five categories of functions by which streams, wetlands, and open waters influence the timing, quantity, and quality of resources available to downstream waters:

- Source: the net export of materials, such as water and food resources;
- Sink: the net removal or storage of materials, such as sediment and contaminants;
- Refuge: the protection of materials, especially organisms;
- Transformation: the transformation of materials, especially nutrients and chemical contaminants, into different physical or chemical forms; and
- Lag: the delayed or regulated release of materials, such as stormwater.

These functions are not mutually exclusive; for example, the same stream or wetland can be both a source of organic matter and a sink for nitrogen. The presence or absence of these functions, which depend on the biota, hydrology, and environmental conditions in a watershed, can change over time; for example, the same wetland can attenuate runoff during storm events and provide ground-water recharge following storms. Further, some functions work in conjunction with others; a lag function can include transformation of materials prior to their delayed release. Finally, effects on downstream waters should consider both actual function and potential function. A potential function represents the capacity of an ecosystem to perform that function under suitable conditions. For example, a wetland with high capacity for denitrification is a potential sink for nitrogen, a nutrient that becomes a contaminant when present in excessive concentrations. In the absence of nitrogen, this capacity represents the wetland's potential function. If nitrogen enters the wetland (e.g., from fertilizer in runoff), it is removed from the water; this removal represents the wetland's actual function. Both potential and actual functions play critical roles in protecting and restoring downstream waters as environmental conditions change.

The evidence unequivocally demonstrates that the stream channels and riparian/floodplain wetlands or open waters that together form river networks are clearly connected to downstream waters in ways that profoundly influence downstream water integrity. The body of literature documenting connectivity and downstream effects was most abundant for perennial and intermittent streams, and for riparian/floodplain wetlands. Although less abundant, the evidence for connectivity and downstream effects of ephemeral streams was strong and compelling, particularly in context with the large body of evidence supporting the physical connectivity and cumulative effects of channelized flows that form and maintain stream networks.

As stated in Conclusion 3, the connectivity and effects of wetlands and open waters that lack visible surface connections to other water bodies are more difficult to address solely from evidence available in the peer-reviewed literature. The limited evidence currently available shows that these systems have important hydrologic, water-quality, and habitat functions that can affect downstream waters where connections to them exist; the literature also provides limited examples of direct effects of non-floodplain wetland isolation on downstream water integrity. Currently available peer-reviewed literature, however, does not identify which types or classes of non-floodplain wetlands have or lack the types of connections needed to convey the effects on downstream waters of functions, materials, or biota provided by those wetlands.

KEY FINDINGS FOR MAJOR CONCLUSIONS

This section summarizes key findings for each of the five major conclusions, above and in Chapter 6 of the report. Citations have been omitted from the text to improve readability; please refer to individual chapters for supporting publications and additional information.

Conclusion 1, Streams: Key Findings

- Streams are hydrologically connected to downstream waters via channels that convey surface and subsurface water either year-round (i.e., perennial flow), weekly to seasonally (i.e., intermittent flow), or only in direct response to precipitation (i.e., ephemeral flow). Streams are the dominant source of water in most rivers, and the majority of tributaries are perennial, intermittent, or ephemeral headwater streams. For example, headwater streams, which are the smallest channels where streamflows begin, are the cumulative source of approximately 60% of the total mean annual flow to all northeastern U.S. streams and rivers.

- In addition to downstream transport, headwaters convey water into local storage compartments such as ponds, shallow aquifers, or stream banks, and into regional and alluvial aquifers. These local storage compartments are important sources of water for maintaining baseflow in rivers. Streamflow typically depends on the delayed (i.e., lagged) release of shallow ground water from local storage, especially during dry periods and in areas with shallow ground-water tables and pervious subsurfaces. For example, in the southwestern United States, short-term shallow ground-water storage in alluvial floodplain aquifers, with gradual release into stream channels, is a major source of annual flow in rivers.
- Infrequent, high-magnitude events are especially important for transmitting materials from headwater streams in most river networks. For example, headwater streams, including ephemeral and intermittent streams, shape river channels by accumulating and gradually or episodically releasing stored materials such as sediment and large woody debris. These materials help structure stream and river channels by slowing the flow of water through channels and providing substrate and habitat for aquatic organisms.
- There is strong evidence that headwater streams function as nitrogen sources (via export) and sinks (via uptake and transformation) for river networks. For example, one study estimated that rapid nutrient cycling in small streams with no agricultural or urban impacts removed 20–40% of the nitrogen that otherwise would be delivered to downstream waters. Nutrients are necessary to support aquatic life, but excess nutrients lead to eutrophication and hypoxia, in which over-enrichment causes dissolved oxygen concentrations to fall below the level necessary to sustain most aquatic animal life in the stream and streambed. Thus, the influence of streams on nutrient loads can have significant repercussions for hypoxia in downstream waters.
- Headwaters provide habitat that is critical for completion of one or more life-cycle stages of many aquatic and semiaquatic species capable of moving throughout river networks. Evidence is strong that headwaters provide habitat for complex life-cycle completion; refuge from predators, competitors, parasites, or adverse physical conditions in rivers (e.g., temperature or flow extremes, low dissolved oxygen, high sediment); and reservoirs of genetic- and species-level diversity. Use of headwater streams as habitat is especially critical for the many species that migrate between small streams and marine environments during their life cycles (e.g., Pacific and Atlantic salmon, American eels, certain lamprey species). The presence of these species within river networks provides robust evidence of biological connections between headwaters and larger rivers; because these organisms also transport nutrients and other materials as they migrate, their presence also provides evidence of biologically mediated chemical connections. In prairie streams, many fishes swim upstream into tributaries to release eggs, which develop as they are transported downstream.

- Human alterations affect the frequency, duration, magnitude, timing, and rate of change of connections between headwater streams, including ephemeral and intermittent streams, and downstream waters. Human activities and built structures (e.g., channelization, dams, groundwater withdrawals) can either enhance or fragment longitudinal connections between headwater streams and downstream waters, while also constraining lateral and vertical exchanges and tightly controlling the temporal dimension of connectivity. In many cases, research on human alterations has enhanced our understanding of the headwater stream-downstream water connections and their consequences. Recognition of these connections and effects has encouraged the development of more sustainable practices and infrastructure to reestablish and manage connections, and ultimately to protect and restore the integrity of downstream waters.

Conclusion 2, Riparian/Floodplain Wetlands and Open Waters: Key Findings

- Riparian areas and floodplains connect upland and aquatic environments through both surface and subsurface hydrologic flowpaths. These areas are therefore uniquely situated in watersheds to receive and process waters that pass over densely vegetated areas and through subsurface zones before the waters reach streams and rivers. When pollutants reach a riparian or floodplain wetland, they can be sequestered in sediments, assimilated into wetland plants and animals, transformed into less harmful or mobile forms or compounds, or lost to the atmosphere. Wetland potential for biogeochemical transformations (e.g., denitrification) that can improve downstream water quality is influenced by local factors, including anoxic conditions and slow organic matter decomposition, shallow water tables, wetland plant communities, permeable soils, and complex topography.
- Riparian/floodplain wetlands can reduce flood peaks by storing and desynchronizing floodwaters. They can also maintain river baseflows by recharging alluvial aquifers. Many studies have documented the ability of riparian/floodplain wetlands to reduce flood pulses by storing excess water from streams and rivers. One review of wetland studies reported that riparian wetlands reduced or delayed floods in 23 of 28 studies. For example, peak discharges between upstream and downstream gaging stations on the Cache River in Arkansas were reduced 10−20% primarily due to floodplain water storage.
- Riparian areas and floodplains store large amounts of sediment and organic matter from upstream and from upland areas. For example, riparian areas have been shown to remove 80−90% of sediments leaving agricultural fields in North Carolina.
- Ecosystem function within a river system is driven in part by biological connectivity that links diverse biological communities with the river system. Movements of organisms that connect aquatic habitats and their populations, even across different watersheds, are important for the survival of individuals, populations, and species, and for the functioning of the river ecosystem. For example, lateral expansion and contraction of the river in its floodplain result in an exchange of matter and organisms, including fish populations that are adapted to use floodplain habitats

for feeding and spawning during high water. Wetland and aquatic plants in floodplains can become important seed sources for the river network, especially if catastrophic flooding scours vegetation and seed banks in other parts of the channel. Many invertebrates exploit temporary hydrologic connections between rivers and floodplain wetland habitats, moving into these wetlands to feed, reproduce, or avoid harsh environmental conditions and then returning to the river network. Amphibians and aquatic reptiles commonly use both streams and riparian/floodplain wetlands to hunt, forage, overwinter, rest, or hide from predators. Birds can spatially integrate the watershed landscape through biological connectivity.

Conclusion 3, Non-floodplain Wetlands and Open Waters: Key Findings

- Water storage by wetlands well outside of riparian or floodplain areas can affect streamflow. Hydrologic models of prairie potholes in the Starkweather Coulee subbasin (North Dakota) that drains to Devils Lake indicate that increasing the volume of pothole storage across the subbasin by approximately 60% caused simulated total annual streamflow to decrease 50% during a series of dry years and 20% during wet years. Similar simulation studies of watersheds that feed the Red River of the North in North Dakota and Minnesota demonstrated qualitatively comparable results, suggesting that the ability of potholes to modulate streamflow could be widespread across eastern portions of the prairie pothole region. This work also indicates that reducing water storage capacity of wetlands by connecting formerly isolated potholes through ditching or drainage to the Devils Lake and Red River basins could increase stormflow and contribute to downstream flooding. In many agricultural areas already crisscrossed by extensive drainage systems, total streamflow and baseflow are increased by directly connecting potholes to stream networks. The impacts of changing streamflow are numerous, including altered flow regime, stream geomorphology, habitat, and ecology. The presence or absence of an effect of prairie pothole water storage on streamflow depends on many factors, including patterns of precipitation, topography, and degree of human alteration. For example, in parts of the prairie pothole region with low precipitation, low stream density, and little human alteration, hydrologic connectivity between prairie potholes and streams or rivers is likely to be low.
- Non-floodplain wetlands act as sinks and transformers for various pollutants, especially nutrients, which at excess levels can adversely impact human and ecosystem health and pose a serious pollution problem in the United States. In one study, sewage wastewaters were applied to forested wetlands in Florida for 4.5 years; more than 95% of the phosphorus, nitrate, ammonium, and total nitrogen were removed by the wetlands during the study period, and 66−86% of the nitrate removed was attributed to the process of denitrification. In another study, sizeable phosphorus retention (0.3 to 8.0 mg soluble reactive P m^{-2} d^{-1}) occurred in marshes that comprised only 7% of the lower Lake Okeechobee basin area in Florida. A non-floodplain bog in Massachusetts was reported to sequester nearly 80% of nitrogen inputs from various sources, including atmospheric deposition, and prairie pothole wetlands in the upper Midwest were found to remove >80% of the nitrate load via denitrification. A large prairie marsh was found to remove 86% of nitrate, 78% of ammonium, and 20% of phosphate through

assimilation and sedimentation, sorption, and other mechanisms. Together, these and other studies indicate that onsite nutrient removal by non-floodplain wetlands is substantial and geographically widespread. The effects of this removal on rivers are generally not reported in the literature.

- Non-floodplain wetlands provide unique and important habitats for many species, both common and rare. Some of these species require multiple types of waters to complete their full life cycles, including downstream waters. Abundant or highly mobile species play important roles in transferring energy and materials between non-floodplain wetlands and downstream waters.
- Biological connections are likely to occur between most non-floodplain wetlands and downstream waters through either direct or stepping stone movement of amphibians, invertebrates, reptiles, mammals, and seeds of aquatic plants, including colonization by invasive species. Many species in those groups that use both stream and wetland habitats are capable of dispersal distances equal to or greater than distances between many wetlands and river networks. Migratory birds can be an important vector of long-distance dispersal of plants and invertebrates between non-floodplain wetlands and the river network, although their influence has not been quantified. Whether those connections are of sufficient magnitude to impact downstream waters will either require estimation of the magnitude of material fluxes or evidence that these movements of organisms are required for the survival and persistence of biota that contribute to the integrity of downstream waters.
- Spatial proximity is one important determinant of the magnitude, frequency and duration of connections between wetlands and streams that will ultimately influence the fluxes of water, materials and biota between wetlands and downstream waters. However, proximity alone is not sufficient to determine connectivity, due to local variation in factors such as slope and permeability.
- The cumulative influence of many individual wetlands within watersheds can strongly affect the spatial scale, magnitude, frequency, and duration of hydrologic, biological and chemical fluxes or transfers of water and materials to downstream waters. Because of their aggregated influence, any evaluation of changes to individual wetlands should be considered in the context of past and predicted changes (e.g., from climate change) to other wetlands within the same watershed.
- Non-floodplain wetlands can be hydrologically connected directly to river networks through natural or constructed channels, nonchannelized surface flows, or subsurface flows, the latter of which can travel long distances to affect downstream waters. A wetland surrounded by uplands is defined as "geographically isolated." Our review found that, in some cases, wetland types such as vernal pools and coastal depressional wetlands are collectively—and incorrectly—referred to as geographically isolated. Technically, the term "geographically isolated" should be applied only to the particular wetlands within a type or class that are completely surrounded by uplands. Furthermore, "geographic isolation" should not be confused with functional isolation, because

geographically isolated wetlands can still have hydrologic, chemical, and biological connections to downstream waters.

- Non-floodplain wetlands occur along a gradient of hydrologic connectivity-isolation with respect to river networks, lakes, or marine/estuarine water bodies. This gradient includes, for example, wetlands that serve as origins for stream channels that have permanent surface-water connections to the river network; wetlands with outlets to stream channels that discharge to deep ground-water aquifers; geographically isolated wetlands that have local ground-water or occasional surface-water connections to downstream waters; and geographically isolated wetlands that have minimal hydrologic connection to other water bodies (but which could include surface and subsurface connections to other wetlands). This gradient can exist among wetlands of the same type or in the same geographic region.
- Caution should be used in interpreting connectivity for wetlands that have been designated as "geographically isolated" because (1) the term can be applied broadly to a heterogeneous group of wetlands, which can include wetlands that are not actually geographically isolated; (2) wetlands with permanent channels could be miscategorized as geographically isolated if the designation is based on maps or imagery with inadequate spatial resolution, obscured views, etc.; and (3) wetland complexes could have connections to downstream waters through stream channels even if individual wetlands within the complex are geographically isolated. For example, a recent study examined hydrologic connectivity in a complex of wetlands on the Texas Coastal Plain. The wetlands in this complex have been considered to be a type of geographically isolated wetland; however, collectively they are connected both geographically and hydrologically to downstream waters in the area: During an almost 4-year study period, nearly 20% of the precipitation that fell on the wetland complex flowed out through an intermittent stream into downstream waters. Thus, wetland complexes could have connections to downstream waters through stream channels even when the individual wetland components are geographically isolated.

Conclusion 4, Degrees and Determinants of Connectivity: Key Findings

- The surface-water and ground-water flowpaths (hereafter, hydrologic flowpaths), along which water and materials are transported and transformed, determine variations in the degree of physical and chemical connectivity. These flowpaths are controlled primarily by variations in climate, geology, and terrain within and among watersheds and over time. Climate, geology, and terrain are reflected locally in factors such as rainfall and snowfall intensity, soil infiltration rates, and the direction of ground-water flows. These local factors interact with the landscape positions of streams and wetlands relative to downstream waters, and with functions (such as the removal or transformation of pollutants) performed by those streams and wetlands to determine connectivity gradients.
- Gradients of biological connectivity (i.e., the active or passive movements of organisms through water or air and over land that connect populations) are determined primarily by species

assemblages, and by features of the landscape (e.g., climate, geology, terrain) that facilitate or impede the movement of organisms. The temporal and spatial scales at which biological pathways connect aquatic habitats depend on characteristics of both the landscape and species, and overland transport or movement can occur across watershed boundaries. Dispersal is essential for population persistence, maintenance of genetic diversity, and evolution of aquatic species. Consequently, dispersal strategies reflect aquatic species' responses and adaptations to biotic and abiotic environments, including spatial and temporal variation in resource availability and quality. Species' traits and behaviors encompass species-environment relationships over time, and provide an ecological and evolutionary context for evaluating biological connectivity in a particular watershed or group of watersheds.

- Pathways for chemical transport and transformation largely follow hydrologic flowpaths, but sometimes follow biological pathways (e.g., nutrient transport from wetlands to coastal waters by migrating waterfowl, upstream transport of marine-derived nutrients by spawning of anadromous fish, uptake and removal of nutrients by emerging stream insects).
- Human activities alter naturally occurring gradients of physical, chemical, and biological connectivity by modifying the frequency, duration, magnitude, timing, and rate of change of fluxes, exchanges, and transformations. For example, connectivity can be reduced by dams, levees, culverts, water withdrawals, and habitat destruction, and can be increased by effluent discharges, channelization, drainage ditches and tiles, and impervious surfaces.

Conclusion 5, Cumulative Effects: Key Findings

- Structurally and functionally, stream-channel networks and the watersheds they drain are fundamentally cumulative in how they are formed and maintained. Excess water from precipitation that is not evaporated, taken up by organisms, or stored in soils and geologic layers moves downgradient by gravity as overland flow or through channels carrying sediment, chemical constituents, and organisms. These channels concentrate surface-water flows and are more efficient than overland (i.e., diffuse) flows in transporting water and materials, and are reinforced over time by recurrent flows.
- Connectivity between streams and rivers provides opportunities for materials, including nutrients and chemical contaminants, to be transformed chemically as they are transported downstream. Although highly efficient at the transport of water and other physical materials, streams are dynamic ecosystems with permeable beds and banks that interact with other ecosystems above and below the surface. The exchange of materials between surface and subsurface areas involves a series of complex physical, chemical, and biological alterations that occur as materials move through different parts of the river system. The amount and quality of such materials that eventually reach a river are determined by the aggregate effect of these sequential alterations that begin at the source waters, which can be at some distance from the river. The opportunity for transformation of material (e.g., biological uptake, assimilation, or beneficial transformation) in intervening stream reaches increases with distance to the river.

Nutrient spiraling, the process by which nutrients entering headwater streams are transformed by various aquatic organisms and chemical reactions as they are transported downstream, is one example of an instream alteration that exhibits significant beneficial effects on downstream waters. Nutrients (in their inorganic form) that enter a headwater stream (e.g., via overland flow) are first removed from the water column by streambed algal and microbial populations. Fish or insects feeding on algae and microbes take up some of those nutrients, which are subsequently released back into the stream via excretion and decomposition (i.e., in their organic form), and the cycle is repeated. In each phase of the cycling process—from dissolved inorganic nutrients in the water column, through microbial uptake, subsequent transformations through the food web, and back to dissolved nutrients in the water column—nutrients are subject to downstream transport. Stream and wetland capacities for nutrient cycling have important implications for the form and concentration of nutrients exported to downstream waters.

- Cumulative effects across a watershed must be considered when quantifying the frequency, duration, and magnitude of connectivity, to evaluate the downstream effects of streams and wetlands. For example, although the probability of a large-magnitude transfer of organisms from any given headwater stream in a given year might be low (i.e., a low-frequency connection when each stream is considered individually), headwater streams are the most abundant type of stream in most watersheds. Thus, the overall probability of a large-magnitude transfer of organisms is higher when considered for all headwater streams in a watershed—that is, a high-frequency connection is present when headwaters are considered cumulatively at the watershed scale, compared with probabilities of transport for streams individually. Similarly, a single pollutant discharge might be negligible but the cumulative effect of multiple discharges could degrade the integrity of downstream waters. Riparian open waters (e.g., oxbow lakes), wetlands, and vegetated areas cumulatively can retain up to 90% of eroded clays, silts, and sands that otherwise would enter stream channels. The larger amounts of snowmelt and precipitation cumulatively held by many wetlands can reduce the potential for flooding at downstream locations. For example, wetlands in the prairie pothole region cumulatively stored about 11−20% of the precipitation in one watershed.
- The combination of diverse habitat types and abundant food resources cumulatively makes floodplains important foraging, hunting, and breeding sites for fish, aquatic life stages of amphibians, and aquatic invertebrates. The scale of these cumulative effects can be extensive; for example, coastal ibises travel up to 40 km to obtain food from freshwater floodplain wetlands for nesting chicks, which cannot tolerate salt levels in local food resources until they fledge.

CLOSING COMMENTS

The structure and function of downstream waters highly depend on materials—broadly defined as any physical, chemical, or biological entity—that originate outside of the downstream waters. Most of the constituent materials in rivers, for example, originate from aquatic ecosystems located upstream in the drainage network or elsewhere in the drainage basin, and are transported to the river through flowpaths illustrated in the introduction to this report. Thus, the effects of streams, wetlands, and open waters on rivers are determined by the presence of (1) physical, chemical, or biological pathways that enable (or inhibit) the transport of materials and organisms to downstream waters; and (2) functions within the streams, wetlands, and open waters that alter the quantity and quality of materials and organisms transported along those pathways to downstream waters.

The strong hydrologic connectivity of river networks is apparent in the existence of stream channels that form the physical structure of the network itself. Given the evidence reviewed in this report, it is clear that streams and rivers are much more than a system of physical channels for efficiently conveying water and other materials downstream. The presence of physical channels, however, is a compelling line of evidence for surface-water connections from tributaries, or water bodies of other types, to downstream waters. Physical channels are defined by continuous bed-and-bank structures, which can include apparent disruptions (such as by bedrock outcrops, braided channels, flow-through wetlands) associated with changes in the material and gradient over and through which water flows. The continuation of bed and banks downgradient from such disruptions is evidence of the surface connection with the channel that is upgradient of the perceived disruption.

Although currently available peer-reviewed literature does not identify which types of non-floodplain wetlands have or lack the types of connections needed to convey functional effects to downstream waters, additional information (e.g., field assessments, analysis of existing or new data, reports from local resource agencies) could be used in case-by-case analysis of non-floodplain wetlands. Importantly, information from emerging research into the connectivity of non-floodplain wetlands, including studies of the types identified in Section 4.5.2 of this report, could close some of the current data gaps in the near future. Recent scientific advances in the fields of mapping, assessment, modeling, and landscape classification indicate that increasing availability of high-resolution data sets, promising new technologies for watershed-scale analyses, and methods for classifying landscape units by hydrologic behavior can facilitate and improve the accuracy of connectivity assessments. Emerging research that expands our ability to detect and monitor ecologically relevant connections at appropriate scales, metrics to accurately measure effects on downstream integrity, and management practices that apply what we already know about ecosystem function will contribute to our ability to identify waters of national importance and maintain the long-term sustainability and resiliency of valued water resources.

CHAPTER 1. INTRODUCTION

1.1 Purpose

The objective of the Clean Water Act is to restore and maintain the chemical, physical, and biological integrity of the nation's waters. The U.S. Environmental Protection Agency's (U.S. EPA's) Office of Research and Development developed this report to inform rulemaking by the U.S. EPA and U.S. ACE on the definition of "waters of the United States" under the Clean Water Act (CWA). Its purpose is to summarize current scientific understanding about the connectivity and mechanisms by which streams and wetlands, singly or in aggregate, affect the physical, chemical, and biological integrity of downstream waters. Because this report is a technical review of peer-reviewed scientific literature, it does not consider or set forth legal standards for CWA jurisdiction. Rather, the report evaluates, summarizes, and synthesizes the available peer-reviewed scientific literature to address three questions:

1. What are the physical, chemical, and biological connections to and effects of ephemeral, intermittent, and perennial streams on downstream waters (e.g., rivers, lakes, reservoirs, estuaries)?
2. What are the physical, chemical, and biological connections to and effects of riparian or floodplain wetlands and open waters (e.g., riverine wetlands, oxbow lakes) on downstream waters?
3. What are the physical, chemical, and biological connections to and effects of wetlands and open waters in non-floodplain settings (e.g., most prairie potholes, vernal pools) on downstream waters?

These questions were developed in collaboration with the U.S. EPA's Office of Water to translate regulatory questions and terminology into more scientifically relevant questions and terms (Table 1-1).

This report focuses on the physical, chemical, and biological connections (or lack thereof) by which small or temporary streams, nontidal wetlands, and certain open waters can affect the integrity of downstream waters.

In addition to a broad survey of literature responding to the three questions above, the U.S. EPA's Office of Water asked the Office of Research and Development to create six case studies with more detailed reviews of published literature on Carolina and Delmarva bays, oxbow lakes, prairie potholes, prairie streams, southwestern streams, and vernal pools.

Table 1-1. Translating connectivity-related questions between policy and science. This table presents a crosswalk of regulatory and scientific questions this report addresses. Policy questions use regulatory terms (shown in quotation marks) that lack scientific definitions or are defined differently in scientific usage. All terms used in this report reflect scientific definitions and usage.

Policy question	Science question
What tributaries have a "significant* nexus" to "traditional navigable waters"?	What are the connections to and effects of ephemeral, intermittent, and perennial streams on downstream waters?
What "adjacent" waters have a "significant* nexus" to "traditional navigable waters"?	What are the connections to and effects of riparian or floodplain wetlands and open waters on downstream waters?
What categories of "other waters" have a "significant* nexus" to "traditional navigable waters"?	What are the connections to and effects of wetlands and open waters in non-floodplain settings on downstream waters?

* "Significant," as used here, is a policy determination informed by science; it does not refer to statistical significance.

1.2 Scientific Context

1.2.1 Concepts of Connectivity in Hydrology and Ecology

Streams, wetlands, and other surface waters interact with ground water and terrestrial environments throughout the landscape, from the mountains to the oceans. Thus, an integrated perspective of the landscape, described in this section, provides the appropriate scientific context for evaluating and interpreting evidence about the physical, chemical, and biological connectivity of streams, wetlands, and open waters to downstream waters.

Connectivity has long been a central tenet for the study of aquatic ecosystems. The River Continuum Concept (Vannote et al., 1980) viewed the entire length of rivers, from source to mouth, as a complex hydrologic gradient with predictable longitudinal patterns of ecological structure and function. The key pattern is that downstream communities are organized, in large part, by upstream communities and processes (Vannote et al., 1980; Battin et al., 2009). The Serial Discontinuity Concept (Ward and Stanford, 1983) built on the River Continuum Concept to improve our understanding of how dams and impoundments disrupt the longitudinal patterns of flowing waters with predictable downstream effects.

The Spiraling Concept (Webster and Patten, 1979; Newbold et al., 1981; Elwood et al., 1983) described how river network connectivity can be evaluated and quantified as materials cycle from dissolved forms to transiently stored forms taken up by living organisms, then back to dissolved forms, as they are transported downstream (Section 3.4.1). These three conceptual frameworks focused on the longitudinal connections of river ecosystems, whereas the subsequent flood pulse concept (Junk et al., 1989) examined the importance of lateral connectivity of river channels to floodplains, including wetlands and open waters, through seasonal expansion and contraction of river networks. Ward (1989) summarized the importance of connectivity to lotic ecosystems along four dimensions: longitudinal, lateral, vertical (surface-subsurface), and temporal connections; he concluded that running water ecosystems are open systems that are highly interactive with both contiguous habitats and other ecosystems in the surrounding landscape. As these conceptual frameworks illustrate, scientists have long recognized the hydrologic connectivity that the physical structure of river networks represents.

More recently, scientists have incorporated this connected network structure into conceptual frameworks describing ecological patterns in river ecosystems and the processes linking them to other watershed components, including wetlands and open waters (Power and Dietrich, 2002; Benda et al., 2004; Nadeau and Rains, 2007; Rodriguez-Iturbe et al., 2009). The Network Dynamic Hypothesis (Benda et al., 2004) is a physically based framework for predicting patterns of habitat heterogeneity observed along a river, based on dynamics that generate potential biological "hotspots" at tributary confluences. It essentially reexamines earlier, linearly driven frameworks given the patchy and stochastic nature of lotic ecosystems (e.g., Resh et al., 1988; Townsend, 1989; Rice et al., 2001), and thus reflects a more realistic river network perspective. Bunn and Arthington (2002) identified natural flow variability and associated lateral and longitudinal connectivity of stream channels and floodplains as two principal mechanisms linking hydrology to aquatic biodiversity of riverine species (also Leigh et al., 2010). In addition, application of metapopulation theory and population genetic theory to natural populations has greatly improved our understanding of the role of dispersal and migration in the demographic persistence, community assembly, and evolution of aquatic species (Hastings and Harrison, 1994; Moilanen and Hanski, 1998; Hanski, 1999; Pannell and Charlesworth, 2000; Fagan, 2002; Bohonak and Jenkins, 2003; Waples, 2010; Fronhofer et al., 2012). Sheaves (2009) emphasized the key ecological connections—which include process-based connections that maintain habitat function (e.g., nutrient dynamics, trophic function) and movements of individual organisms—throughout a complex of interlinked freshwater, tidal wetland, and estuarine habitats as critical for the persistence of aquatic species, populations, and communities over the full range of time scales.

1.2.2 Connectivity Gradients and Descriptors

The landscape and flowpath perspectives illustrated in Figure 1-1 draw heavily from the connectivity frameworks described in Section 1.2.1. These perspectives are essential to understanding connections from streams, wetlands, and open waters that affect the integrity of downstream waters. **Connectivity** is defined here as the degree to which components of a watershed are joined and interact by **transport mechanisms** that function across multiple spatial and temporal scales (Section 2.3.2.1). The primary transport mechanisms considered in this report are surface-water and shallow ground-water flows,

Table 1-2. Dimensions of watershed connectivity.	
Dimension	**Examples and flowpaths in Figure 1-1 or Figure 1-2**
Longitudinal	Streamflow and downstream transport of materials, organisms (1-1A); hyporheic flow (1-1A); ground-water flow through local and larger scale aquifers (1-1A), aquatic or overland movement of organisms in or along stream channels (1-1B); biogeochemical transport and transformation (1-1B) (Alexander et al., 2007; Freeman et al., 2007)
Lateral	Overbank flow and transport from channels into banks, floodplains, and riparian areas (1-1A); spillage and transport from wetlands and open waters into streams (1-1A); overland flow and interflow (1-1A); ground-water recharge from streams and wetlands (1-1A); bank storage (1-1A); transport or movement of organisms between streams and wetlands or open waters (1-1B) (Ward, 1989; Stanford and Ward, 1993)
Vertical	Surface-subsurface exchange of water, materials, organisms (1-1A and 1-1B); ground-water recharge from streams and wetlands (1-1A); atmospheric losses (1-1A) (Amoros and Bornette, 2002; Banks et al., 2011)
Temporal	Variable source area (1-2); seasonal cycles of wetland inundation and outflow to streams (1-1A); migration or diapause of aquatic organisms (1-1B) (Hewlett and Hibbert, 1967; Bohonak and Jenkins, 2003; Zedler, 2003)

transport and transformation of physical and chemical materials, and movements of aquatic and semiaquatic organisms, all of which connect watersheds in four dimensions (Table 1-2). Figure 1-1 illustrates the continuous hydrologic flowpaths (Figure 1-1A) and biological pathways (Figure 1-1B) that connect watershed components spatially; Figure 1-2 illustrates the temporal dynamics of hydrologic flowpaths (Sections 2.2.3 and 2.3.2.2).

Although all parts of a watershed are connected to some degree—by the hydrologic cycle or dispersal of organisms, for example—the degree of connectivity among aquatic components varies along a continuum from highly connected to highly isolated. This continuum can be described in terms of the **frequency, duration, magnitude, timing,** and **rate of change** (Poff et al., 2007) of physical and chemical fluxes to and biological exchanges with downstream waters. These terms, which we refer to collectively as **connectivity descriptors**, characterize the range over which streams and wetlands vary and shift along the connectivity gradient in response to changes in natural and anthropogenic factors and, when considered in a watershed context, can be used to predict probable effects of different degrees of connectivity over time. These and similar descriptors are used in hydrology and disturbance ecology to characterize the variability and alteration of natural flow regimes (Resh et al., 1988; Poff, 1992; Poff et al., 1997; Lake, 2000; Leibowitz et al., 2008). For example, in hydrology, magnitude is the amount of water moving past a fixed location per unit time, frequency is how often a particular flow magnitude occurs, duration is a measure of how long a particular flow magnitude persists, and rate of change is how quickly one type of flow changes to another. Because the presence of water determines hydrologic connectivity, these descriptors also can be used to describe the timing and magnitude of hydrologic connections. Further, they can describe other types of connections. The number of individuals immigrating or emigrating during a dispersal event, for example, could be used to determine

Figure 1-1A. Hydrologic flowpaths. Arrows are representative of surface-water and ground-water flows occurring throughout the watershed. Subsurface flows are shown within the cross section, and by faded arrows outside the cross section.

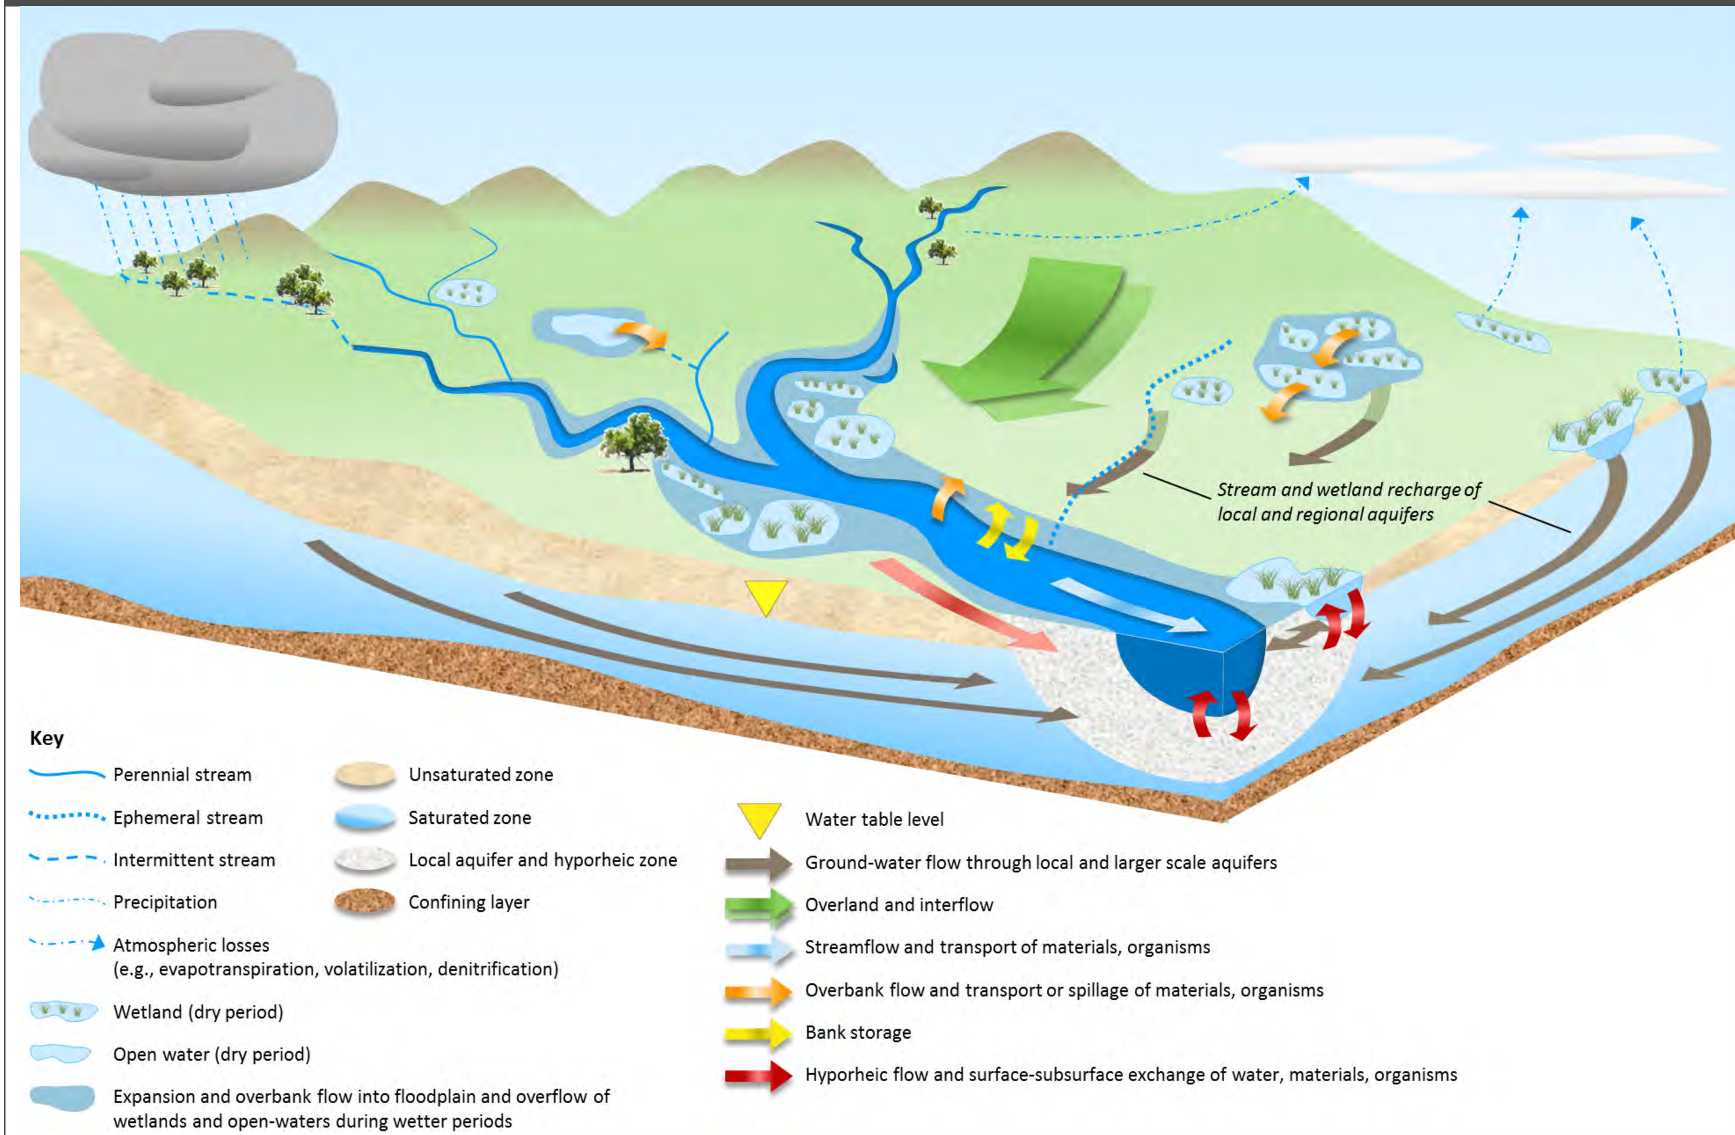

Figure 1-1B. Biological flowpaths. Arrows are representative of biological pathways occurring throughout the watershed. This figure also includes representative biogeochemical pathways occurring in streams and floodplains.

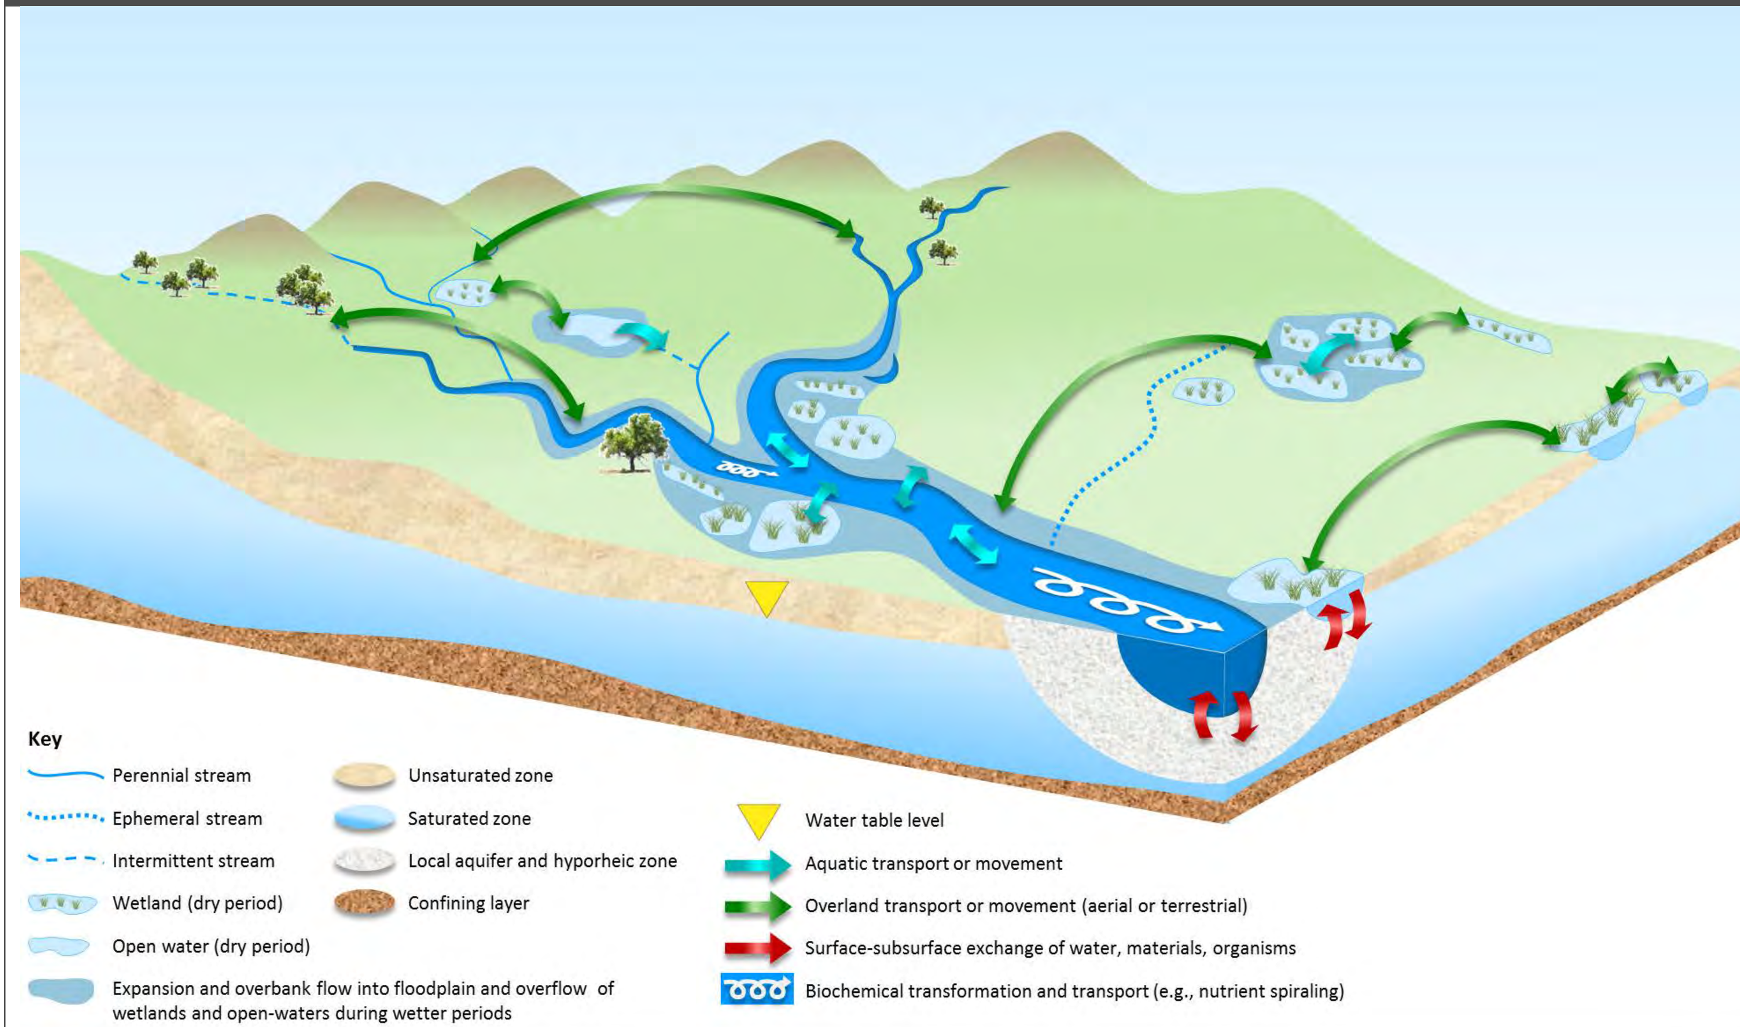

Figure 1-2. Temporal dynamics of hydrologic flowpaths. (A) A riverscape at peak hydrologic expression. (B) The same riverscape in a dry period. Intermittent and ephemeral streams, and some wetlands, are dry.

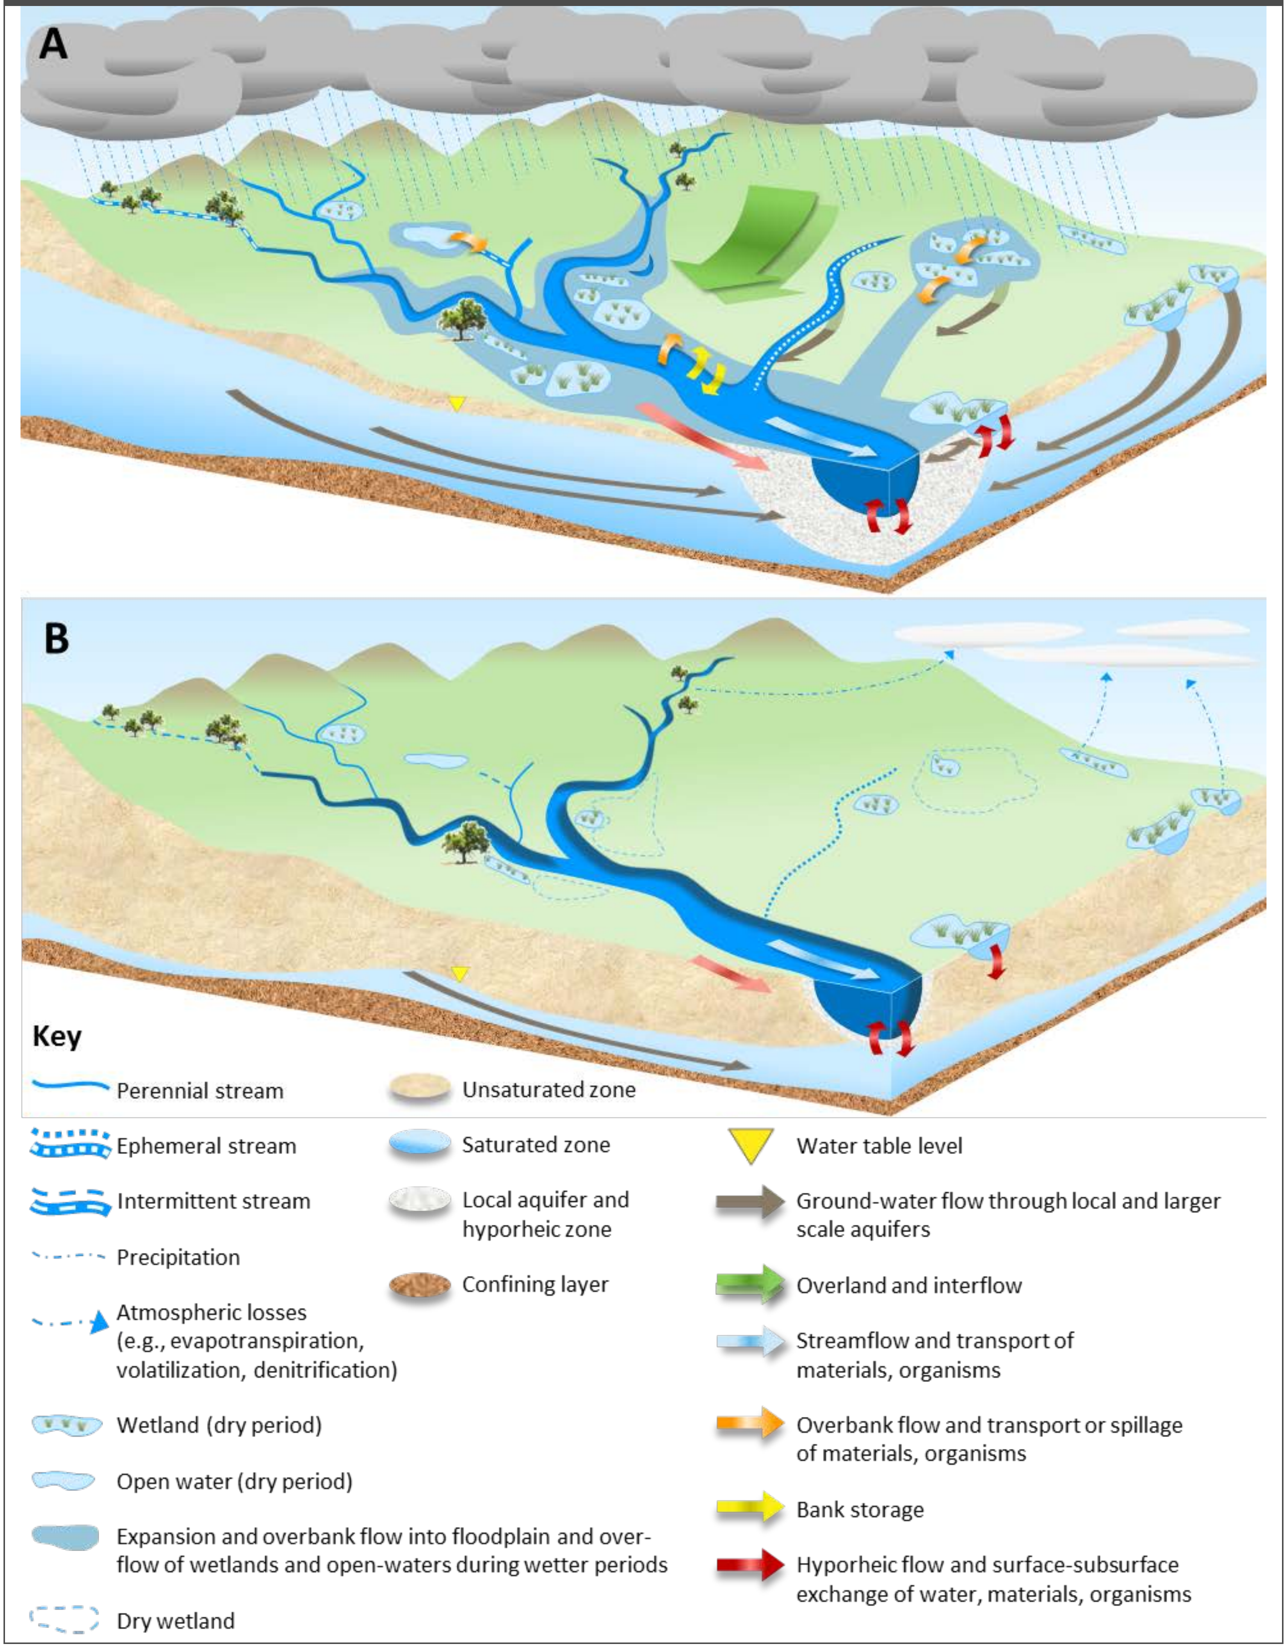

the magnitude of the event; the probability, length, and predictability of similar events could be expressed in terms of their frequency, duration, and timing; and fluctuations in dispersal could be described as the rate of change through time (e.g., across seasons or years).

Stream and wetland connections have particularly important consequences for downstream water integrity. Longitudinal flows through ephemeral, intermittent, and perennial stream channels (Figure 1-1A, blue lines and arrows) are much more efficient for transport of water, materials, and organisms than diffuse overland flows and interflows (Figure 1-1A, green arrows). Over time, stream transport pathways are reinforced by recurrent flows that maintain channel form. Areas that concentrate water also provide mechanisms for storage, transformation, and transport of materials. Differences in flow frequency, duration, magnitude, timing, and rate of change (e.g., rapid flow in mountain streams, slow flow through glacial ice or bedrock, intermittent flow in seasonal streams, ephemeral flow in arid rivers) create conditions needed for a range of ecosystem functions that affect downstream waters. Such functions include short- and long-term storage of water and sediment, transformation or sequestration of contaminants, recycling of excess nutrients, provision of habitat for aquatic and semiaquatic species, recharge of river baseflow, and provision of drinking water for humans and wildlife. For example, areas that are prone to wetting and drying cycles in response to seasonal conditions (e.g., stream and wetland perimeters shown in Figure 1-1A) are "hotspots" for chemical transformations (Vidon et al., 2010).

Ultimately, differences in the frequency, duration, magnitude, timing, and rate of change of physical, chemical, and biological connections describe different positions along the connectivity gradient and produce different types of downstream effects. For example, highly connected stream channels convey water and channel-forming sediment to rivers, whereas highly isolated wetlands can reduce flooding and store excess sediment. Connections with low values of one or more descriptors (e.g., low-frequency, short-duration flooding) can have important downstream effects when values for other descriptors are high (e.g., large-magnitude downstream transfer of floodwaters, sediment, large woody debris, and organisms). At the other end of the frequency gradient, high-frequency, low-magnitude vertical and lateral flows (Table 1-2) contribute to aquatic biogeochemical processes, including nutrient and contaminant transformation and organic matter accumulation (e.g., Brunke and Gonser, 1997; Karwan and Saiers, 2012; Lawrence et al., 2013).

In addition, timing is a key connectivity descriptor that can influence downstream waters. For example, when soils are saturated by previous rainfall events, even low or moderate rainfall can cause streams or wetlands to overflow, transporting water and materials to downstream waters. The same wetland or wetland type can attenuate floods or generate floods, depending on hydrologic conditions (Acreman and Holden, 2013). Predictable events also can profoundly influence the effects of connections. Wetlands and river networks expand and contract in response to seasonal and decadal cycles and longer term changes in environmental conditions. In wet conditions (Figure 1-2A), streams and rivers expand longitudinally into headwaters and laterally into floodplains or riparian areas, wetlands inundate and connect via surface water and ground water to other wetlands and the stream network, the water table rises, and local aquifers are recharged. In dry conditions (Figure 1-2B), the river network is limited to perennial streams, wetlands dry down, and the water table level lowers. Seasonal flooding and drying events over an annual cycle are formative processes of physical, chemical, and biological attributes of streams in the western United States (Gasith and Resh, 1999). Large seasonal waterfowl migrations can move nutrients, plants (seeds), and invertebrates between wetlands and downgradient waters (Figuerola and Green, 2002; Green and Figuerola, 2005; Frisch et al., 2007). Fish that use nonperennial or perennial headwater stream habitats to spawn or rear young, and invertebrates that move into seasonally inundated floodplain wetlands prior to emergence, have life cycles that are synchronized with the timing of flows and flood pulses, temperature thresholds, and food resource availability in those habitats (Junk et al., 1989; Falke et al., 2010).

The surface-water and ground-water flowpaths along which water and materials are transported and transformed (Sections 2.2.2, 3.3, 3.4, 4.3.2, 4.3.3, 4.4.2, and 4.4.3; Figure 1-1A) determine variations in the degrees of physical and chemical connectivity. These flowpaths are controlled primarily by variation in climate, geology, and terrain within and among watersheds and over time. These factors have been used to group watersheds into hydrologic landscapes units that, although not necessarily spatially contiguous, are predicted to exhibit similar hydrologic function (Wolock et al., 2004; Wigington et al., 2013). Climate, geology, and terrain are reflected locally in factors such as rain and snowfall intensity, soil infiltration rates, and the direction of ground-water flows. These local factors interact with stream and wetland function and landscape position to influence degrees of connectivity through time and across space. When considered together with these local factors, hydrologic landscapes could provide a regional context for evaluating the physical and chemical connectivity of streams and wetlands in a particular watershed or group of watersheds (Section 2.4.1).

Gradients of biological connectivity (i.e., the active or passive movements of organisms through water and air and over land that connect populations of aquatic species; Sections 3.5, 4.3.4, and 4.4.4; Figure 1-1B) are determined primarily by species assemblages and by landscape features, including the factors discussed above, that facilitate or impede the movement of organisms. Organisms move across the landscape to colonize new habitats, avoid inbreeding, escape predation or competition, locate mates, and acquire resources needed to survive and reproduce. The temporal and spatial scales at which biological pathways connect aquatic habitats depend on characteristics of both the landscape and species, and overland transport or movement can occur across watershed boundaries. Dispersal is essential at higher levels of biological organization for population persistence, maintenance of genetic diversity, and evolution of aquatic species (Labbe and Fausch, 2000; Fagan, 2002; Malmqvist, 2002; Bohonak and Jenkins, 2003; Armsworth and Roughgarden, 2005). Consequently, dispersal strategies reflect aquatic species' responses and adaptations to biotic and abiotic environments, including spatial and temporal variation in resource availability and quality (e.g., Clobert et al., 2009). Dispersal-related traits and behaviors (e.g., habitat specialization, dispersal mode, behavioral response to environmental cues) therefore encompass species-environment relationships over time and provide an ecological and evolutionary context for evaluating biological connectivity in a particular watershed or group of watersheds.

Pathways for chemical transport and transformation largely follow hydrologic flowpaths (Figure 1-1A), but sometimes follow biological pathways (e.g., nutrient transport from wetlands to coastal waters by migrating waterfowl, upstream transport of marine-derived nutrients by anadromous fish, uptake and removal of nutrients by emerging stream insects; Figure 1-1B). The transport and transformation of nutrients (e.g., sequential transformations, Section 2.3.2.1; and nutrient spiraling in streams, Section 3.4.1) and other chemicals associated with water integrate physical, chemical, and biological connectivity of streams and wetlands to downstream waters (Figure 1-1B).

1.2.3 Cumulative Effects of Streams and Wetlands on Downstream Waters

Stream and wetland connectivity to downstream waters, and the resulting effects on downstream water integrity, must be considered cumulatively. First, when considering the effect of an individual stream or wetland, including the cumulative effect of all the contributions and functions that a stream or wetland provides is essential. For example, the same stream transports water, removes excess nutrients, mitigates flooding, and provides refuge for fish when conditions downstream are unfavorable; ignoring any of these functions would underestimate the overall effect of that stream.

Secondly, stream channel networks and the watersheds they drain are fundamentally cumulative in how they are formed and maintained. Excess precipitation that is not evaporated, taken up by organisms, or stored in soils and geologic layers moves downgradient as overland flow or through channels, which concentrate flows and carry sediment, chemical constituents, and organisms (Sections 3.3, 3.4, and 3.5). As flows from numerous headwater channels combine in larger channels, the volume and effects of those flows accumulate as they move through the river network. As a result, the incremental contributions of individual streams and wetlands accumulate in the downstream waters. Important cumulative effects are exemplified by ephemeral flows in arid landscapes, which are key sources of baseflow for downgradient waters (Sections 5.6 and B.5; Schlesinger and Jones, 1984; Baillie et al., 2007; Izbicki, 2007), and by the high rates of denitrification in headwater streams (Section 3.4.1). The amount of nutrients removed by any one stream over multiple years or by all headwater streams in a watershed in a given year can have substantial consequences for downstream waters (Alexander et al., 2007; Alexander et al., 2009; Böhlke et al., 2009; Helton et al., 2011). Similar cumulative effects on downstream waters have been documented for other material contributions from headwater streams (Chapter 3). For example, although the probability of a large-magnitude transfer of organisms from any given headwater stream in a given year might be low (i.e., a low-frequency connection when each stream is considered individually), headwater streams are the most abundant type of stream in most watersheds (Section 3.2). Thus, the overall probability of a large-magnitude transfer of organisms is higher when considered for all headwater streams in a watershed—that is, there is a high-frequency connection when considered cumulatively at the watershed scale, compared with probabilities of transport for streams individually. Similarly, a single pollutant discharge might be negligible but the cumulative effect of multiple discharges could degrade the integrity of downstream waters.

Evaluating cumulative contributions over time is critical in streams and wetlands with variable degrees of connectivity. For example, denitrification in a single headwater stream in any given year might not affect downstream waters; over multiple years, however, this effect could accumulate. Western vernal pools provide another example of cumulative effects over time. These pools typically occur as complexes in which the hydrology and ecology are tightly coupled with the local and regional geological processes that formed them (Section B.6). When seasonal precipitation exceeds wetland storage capacity and wetlands overflow into the river network and generate stream discharge, the vernal pool basins, swales, and seasonal streams function as a single surface-water and shallow ground-water system connected to the river network.

1.2.4 Effects of Human Activities on Connectivity

Human activities alter naturally occurring gradients of physical, chemical, and biological connectivity by modifying the frequency, duration, magnitude, timing, and rate of change of fluxes, exchanges, and transformations. For example, all dimensions of connectivity (Table 1-2) can be reduced by dams and levees (Ward and Stanford, 1983; Ligon et al., 1995; Collier et al., 1996; Wohl, 2005; Franklin et al., 2009), water withdrawals (Haag and Pfeiffer, 2012), and habitat destruction. Alternatively, connectivity can be increased by point source discharges (Brooks et al., 2006); channelization, drainage ditches, and tiles (Randall et al., 1997; Min et al., 2010); and storm drains and impervious surfaces (Booth, 1990; Paul and Meyer, 2001; Elmore and Kaushal, 2008; Walsh et al., 2012). The effects of human activities on connectivity are often complex. For example, a levee will decrease connectivity between a river channel and its floodplain at the levee site, but might increase connectivity of the channel and floodplain farther downstream, due to increased flow. Similarly, drainage ditches that increase hydrologic connectivity between isolated aquatic systems also can decrease biological connectivity through habitat loss and fragmentation.

Human activities modify the natural biological processes, material fluxes, and energy fluxes that link watershed components, resulting in a suite of stressors with measurable effects on downstream ecosystems. Some of these activities are illustrated in a hypothetical watershed (Figure 1-3). In Figure 1-3 (A), buried and ditched streams have eliminated aquatic habitat, increased downstream export of runoff and contaminants, and eliminated stream functions that could benefit downstream water quality. Figure 1-3 (B) shows a dam and reservoir that have constrained natural river expansion and contraction cycles by increasing water storage, trapping sediment, and regulating the volume and timing of river discharge. Dams and reservoirs also block upstream movement of migrating fish and other organisms, alter riparian areas, and impair riparian and floodplain wetland functions. In Figure 1-3 (C), levees and channelization have disconnected the river from its floodplain; decreased exchange of water, materials, and biota between the channel bed and hyporheic zone; and eliminated stream and wetland habitats. In addition, levees decrease the volume of river discharge at the levee site, but increase discharge downstream of the levee site. In Figure 1-3 (D), urban stormwater drainage has increased export of runoff and contaminants from impervious surface areas, altered stream temperature, and impaired instream habitats. In Figure 1-3 (E), drained and ditched wetlands have impaired wetland habitat and functions; increased downstream export of excess nutrients and

Figure 1-3. Effects of human alterations on watershed connectivity. See Section 1.2.4 for description of alterations illustrated in A-G.

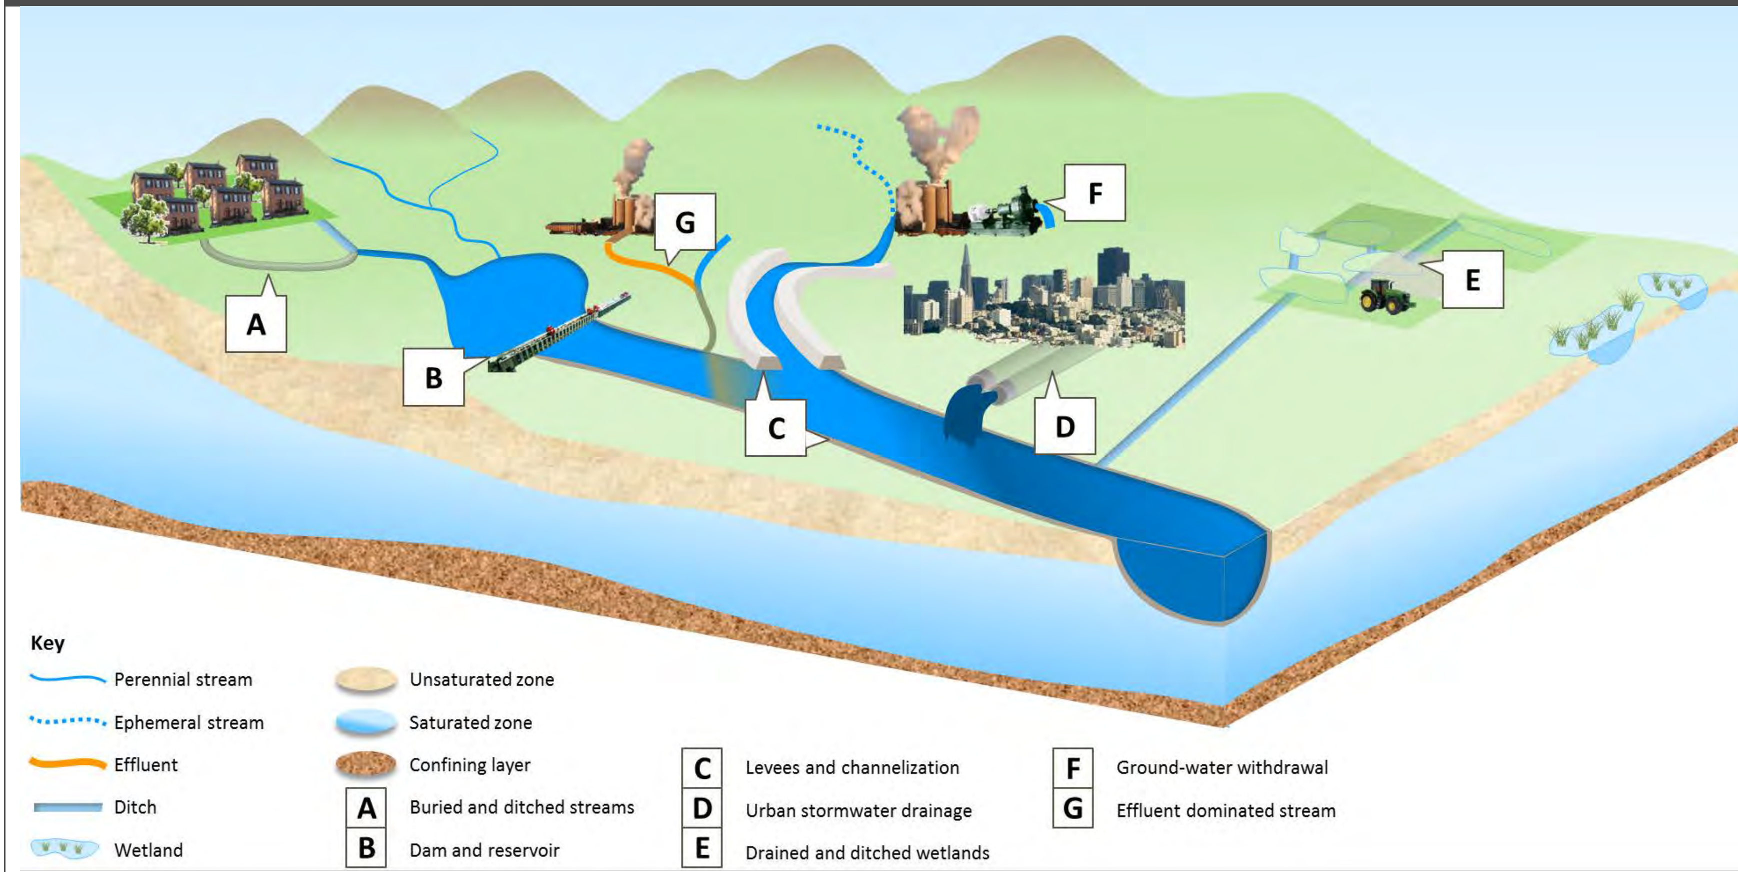

Figure 1-4. The role of connectivity in maintaining the physical, chemical, and biological integrity of water. Climate, landscape, and species' traits (Influencing Factors) interact to form Connections (hydrologic, chemical, and biological) that control the frequency, duration, magnitude, timing, and rate of change of material and energy fluxes, and biological dynamics (Processes) linking watershed components. The Functions by which these connections affect downstream waters modify the timing of transport and the quantity and quality of resources available to downstream communities. Biomonitoring programs have developed structural metrics for assessing physical habitat, water quality, and biological assemblages as indicators of the physical, chemical, and biological integrity of downstream waters (Assessment Endpoints and Metrics).

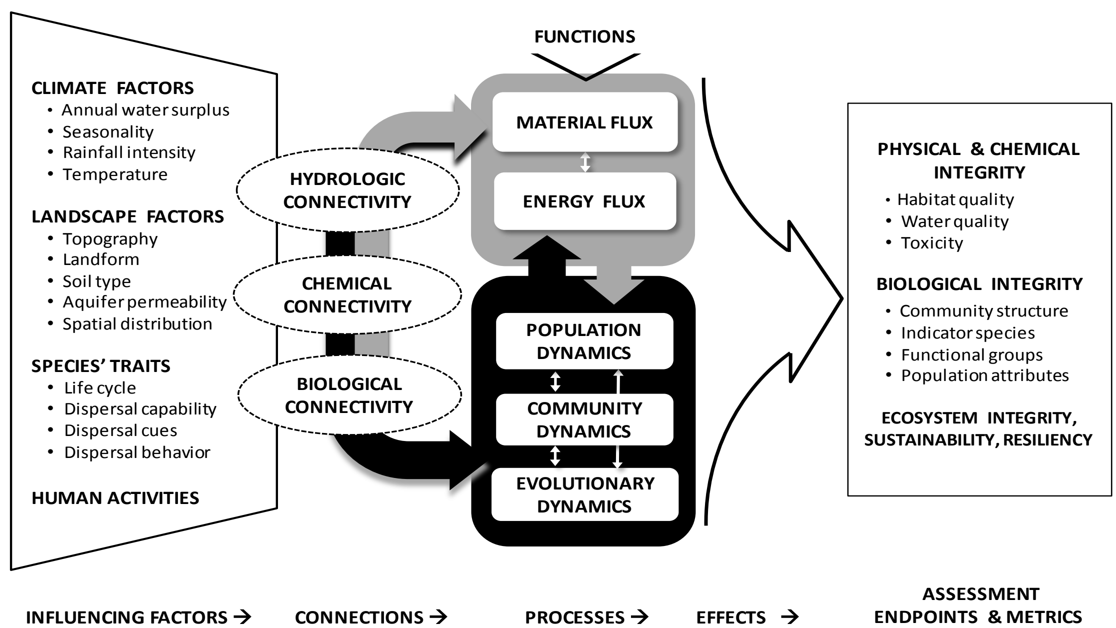


other contaminants; and decreased recharge of local and regional aquifers. In Figure 1-3 (F), groundwater withdrawal has lowered the water table, disconnecting surface water and ground water, thereby causing local streams and wetlands to dry. Finally, in Figure 1-3 (G), pollutant discharges into effluent-dominated streams have altered the volume and timing of streamflow, and increased the export of contaminants into streams. Because watersheds typically experience multiple covarying stressors, determining the cause of a specific downstream effect can be difficult. Relating observed effects to probable causes requires not only reliable measures of candidate stressors and observed effects, but also a clear understanding of the intermediate processes that link them mechanistically (U.S. EPA, 2010; Farrar et al., 2014).

Multiple indicators and measures have been proposed for detecting and quantifying changes in connectivity associated with human activities (With et al., 1997; Tischendorf and Fahrig, 2000; Moilanen and Nieminen, 2002; Calabrese and Fagan, 2004; Martin and Soranno, 2006; Fullerton et al., 2010; Hermoso et al., 2012). Impairments that result from structural alteration of landscape attributes (e.g., dam construction, channel incision, loss of overland dispersal corridors) are relatively easier to detect and quantify than impairments of functional processes (e.g., altered nutrient dynamics, reduced gene flow), but both have important consequences for the short- and long-term integrity of freshwater ecosystems. Palmer and Febria (2012) proposed that ecosystem impairment can be better identified and diagnosed by a combination of structural and functional metrics than by either type alone. Because connectivity can be defined in both structural and functional terms and is an integral component of aquatic ecosystem integrity, this approach is more appropriate for detecting and assessing effects of altered connectivity. To this end, systematic approaches that are rooted in landscape analysis and which incorporate hydroecological dynamics present in streams and wetland complexes (Section 2.4.6) are likely to provide useful information for inferring when and where altered connectivity is a cause of impairment to water resources.

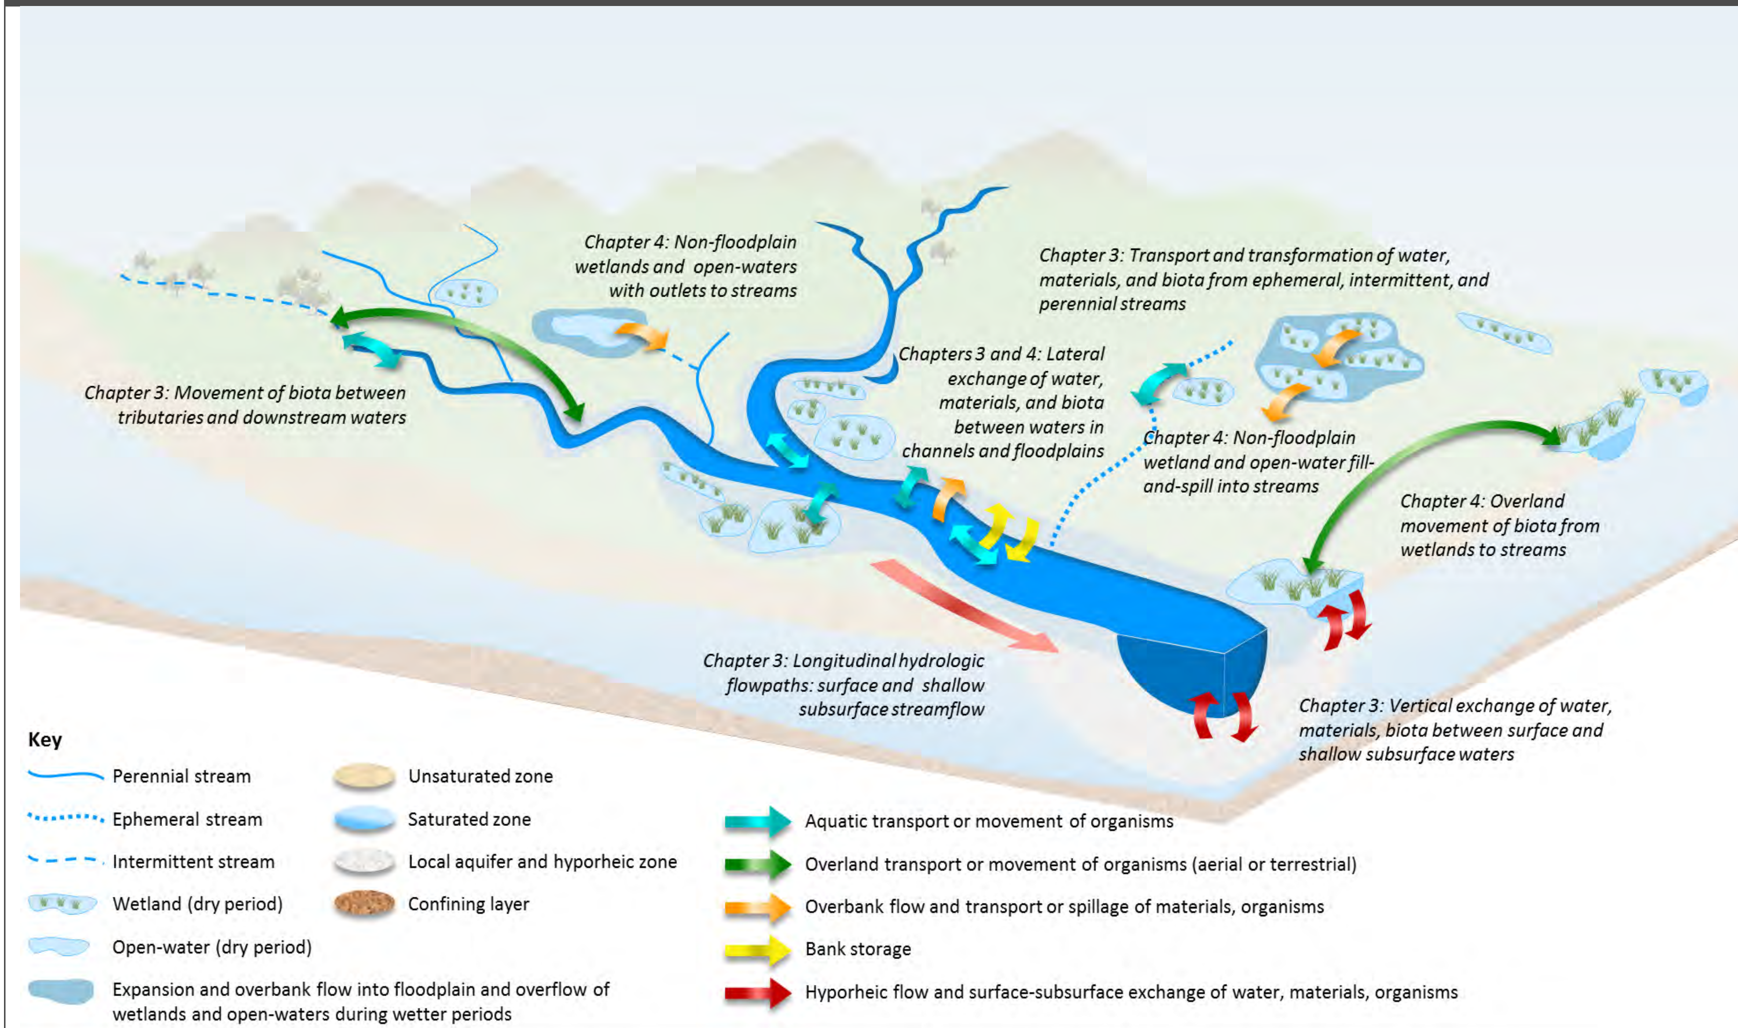
1.3 Report Approach

In this report, we focus entirely on peer-reviewed, publicly accessible sources of information about surface-water and ground-water (particularly shallow ground-water) connections and interactions from streams, wetlands, and open waters that influence the function and condition of downstream surface waters (Figure 1-5). Information about connections among water bodies of the same type (e.g., wetland-to-wetland or headwater stream-to-headwater stream connections) and connections from terrestrial systems to downstream waters are considered out of scope (Figure 1-5).

The topical scope of this report was chosen to consider waters that often fall under the purview of the CWA. As a scientific review, however, this report does not consider or make judgments regarding legal standards for CWA jurisdiction. Our review of subsurface flows emphasizes shallow (local) ground water, because flows in this category have the greatest interchange with surface waters (Winter et al., 1998) although relevant surface-subsurface exchanges occur at depths ranging from centimeters to tens of meters, depending on geographic location, stream channel geometry, and other factors (Woessner, 2000). As with any literature review, readers should refer to the cited publications for quantitative information, such as flow distance, depth, duration, timing, and magnitude, about specific surface-water and ground-water connections, and for other details about the systems and studies discussed in this report.

To identify connections and effects of streams, wetlands, and other water bodies on downstream waters, we used two types of evidence from peer-reviewed, published literature: (1) direct evidence that demonstrated a connection or effect (e.g., observed transport of materials or movement of organisms from streams or wetlands to downstream waters) and (2) indirect evidence that suggested a connection or effect (e.g., presence of environmental factors known to influence connectivity, a gradient of impairment associated with cumulative loss of streams or wetlands). In some cases, an individual line of evidence demonstrated connections along the entire river network (e.g., from headwaters to large rivers). In most cases, multiple sources of evidence were gathered and conclusions drawn via logical inference—for example, when one body of evidence shows that headwater streams are connected to downstream segments, another body of evidence shows those downstream segments are linked to other

Figure 1-5. Waters and connections considered to be within scope for this report.



segments farther downstream, and so on. This approach, which borrows from weight-of-evidence approaches in causal analysis (Suter et al., 2002; Suter and Cormier, 2011), is an effective way to synthesize the diversity of evidence needed to address questions at larger spatial and longer temporal scales than are often considered in individual scientific studies.

1.3.1 Selection and Screening of Scientific Materials

We searched the scientific literature for information on the types of waters, connections, and downstream effects identified in the report objectives and scope (Section 1.1; Figure 1-5). We conducted keyword searches using terms inclusive of the types of waters, connections, and downstream effects of interest (e.g., [wetland* AND [river* OR stream*] AND [connect* OR isolat*]]). Because simple keyword searches would have omitted relevant publications, we also searched for literature on related topics. Topics included conceptual frameworks of watershed and landscape connectivity; hydrologic flowpaths among watershed components; biogeochemical transformation and cycling in streams and wetlands; natural or artificial tracers of difficult-to-observe flows (e.g., ground-water flow, gene flow); chemical and biological processes associated with aquatic habitat fragmentation and spatial isolation; and climate or landscape factors that influence connectivity or isolation. We also reviewed citations provided by peer-review panels and in public comments on drafts of the report. We then screened those results and selected the most relevant publications for review and synthesis in this report, based on the criteria in Figure 1-6.

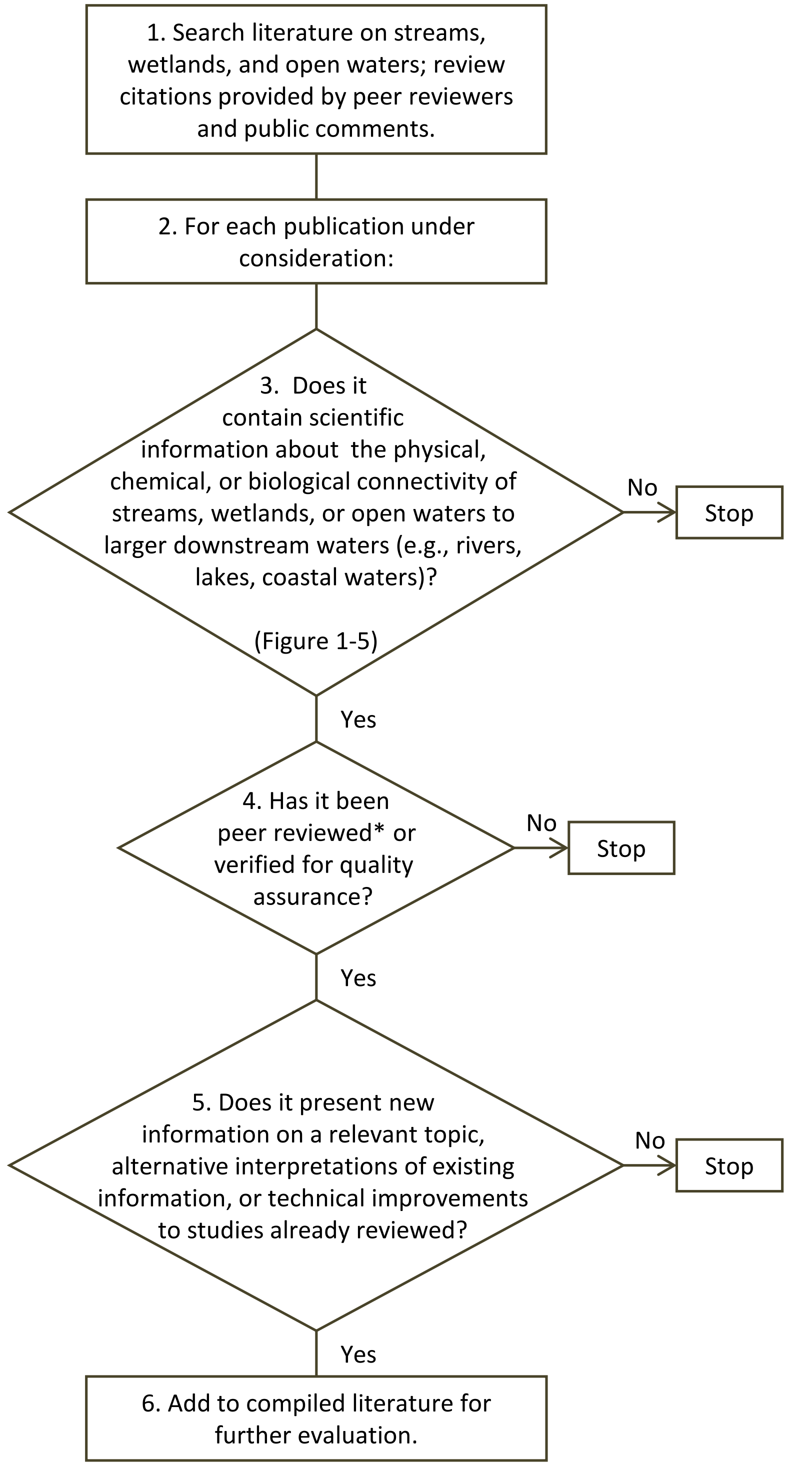
We used science citation databases and search engines available through Web of Science™ and Google Scholar™ to search primary (original research) and secondary (review) literature. These searches included examination of references citing or cited in relevant publications obtained through specific searches.

Because the breadth and depth of topics covered in this report made an exhaustive literature review impractical, we emphasized highly influential papers on relevant topics, review papers that summarized multiple studies in narrative form, meta-analyses that used statistical methods to combine results from multiple independent studies into a single evaluation of evidence, and superseding editions or versions of published research. Publications that did not provide new information, an alternative perspective or interpretation of evidence, or a technical improvement (e.g., improved accuracy or better study design) were not summarized in the report to avoid redundancy and excessive length and detail.

We summarized the relevant literature in narrative form and organized each chapter into lines of evidence pertaining to different types of connections (physical, chemical, biological) for different types of systems (streams, riparian/floodplain wetlands, non-floodplain wetlands). Lines of evidence were evaluated for strength, consistency, mechanistic plausibility, and relevance to the endpoints identified in the report objectives. Finally, conclusions for each of the report's three questions were derived from the key findings, and placed in context with concepts and evidence provided in each chapter.

Cited in this report are 1,353 references. Most were published in refereed scientific journals (86%), as scientific reports by federal agencies that follow peer-review guidelines of the Office of Management and

Figure 1-6. Flow chart for screening and compiling literature.



* Peer review is the formal evaluation of scientific information by independent experts who were not involved in the work but have equivalent scientific and technical expertise. Its purpose is to ensure that materials accepted for publication have been critically reviewed and revised as needed to meet the documented standards of scientific integrity and quality for specific journals or organizations. All reports published by the U.S. EPA Office of Research and Development meet or exceed peer-review requirements established by the Office of Management and Budget (OMB, 2004).

Budget (4%), or scientific books (~9%). The remaining citations refer to photographs, maps, non-federal reports, or websites (<1%) that provide supplemental information.

1.3.2 Report Structure

The report is organized into six chapters. Chapter 1 outlines the purpose, scientific context, and approach of the report. Chapter 2 describes the components of a river system and watershed; the types of physical, chemical, and biological connections that link those components; the factors that influence connectivity at various temporal and spatial scales; and methods for quantifying connectivity. Chapter 3 reviews literature on connectivity in stream networks in terms of physical, chemical, and biological connections and their resulting effects on downstream waters. Chapter 4 reviews literature on the connectivity and effects of nontidal wetlands and certain open waters on downstream waters. Chapter 5 applies concepts and evidence from previous chapters to the case studies detailed in Appendix B. Chapter 6 presents the five major conclusions of this report, with a summary of key findings from the literature synthesized to develop these conclusions. It also discusses the relative abundance of literature on topics reviewed in this report, and briefly discusses emerging research that can close some current data gaps identified in the report. A glossary of scientific terms used in the report and detailed case studies of selected systems (summarized in Chapter 5) are included in Appendix A and Appendix B, respectively.

1.4 Summary

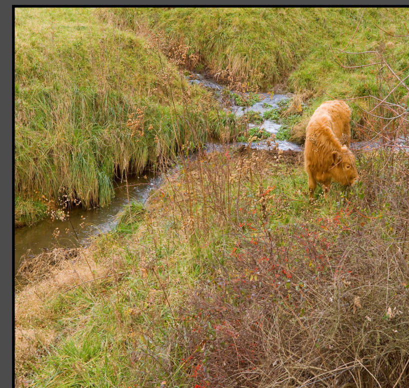
This report evaluates, summarizes, and synthesizes available peer-reviewed scientific literature on the connectivity and mechanisms by which streams, wetlands, and open waters, singly or in aggregate, affect the physical, chemical, and biological integrity of downstream waters.

Connectivity has long been a central tenet for the study of aquatic ecosystems. Watersheds are integrated at multiple spatial and temporal scales by flows of surface water and ground water, transport and transformation of physical and chemical materials, and movements of organisms. Although all parts of a watershed are connected, the degrees and downstream effects of those connections vary; the effects also are influenced by characteristics of the physical environment, the biological environment, and by human activities in the watershed.

Variation in the degree of connectivity is critical to the integrity and sustainability of downstream waters, and can be described in terms of the frequency, duration, magnitude, timing, and rate of change of fluxes to and biological exchanges with downstream waters. These descriptors characterize the range over which streams and wetlands vary and shift along connectivity gradients and the probable effects of different types (hydrologic, chemical, biological) and degrees of connectivity over time. Gradients of physical, chemical, and biological connectivity are controlled primarily by variation in climate, geology, terrain, aquatic organisms, and human activities within and among watersheds, and over time.

Ultimately, differences in the frequency, duration, magnitude, timing, and rate of change of physical, chemical, and biological connections describe different positions along the connectivity gradient and produce different types of downstream effects. Connections with low values of one or more descriptors (e.g., low-frequency, short-duration floods) can have important downstream effects when values for other descriptors are high (e.g., large-magnitude transfers of floodwaters, sediment, large woody debris, and organisms downstream). At the other end of the frequency gradient, the effects of high-frequency, low-magnitude vertical and lateral flows strongly contribute to biogeochemical functions, including nutrient and contaminant transformation and organic matter accumulation.

Stream channel networks and the watersheds they drain are fundamentally cumulative in how they are formed and maintained. The downstream consequences (e.g., the amount and quality of materials that eventually reach a river) are determined by the aggregate effect of contributions and sequential alterations that begin at the source waters and function along continuous flowpaths to the watershed outlet. Cumulative effects across a watershed must therefore be considered when quantifying the frequency, duration, and magnitude of connectivity, to evaluate the downstream effects of streams, wetlands, and open waters.



CHAPTER 2. AN INTEGRATED SYSTEMS PERSPECTIVE ON INTERACTIONS OF WATERSHEDS, STREAMS, WETLANDS, AND DOWNSTREAM WATERS

2.1 Introduction

A river is the time-integrated result of all waters contributing to it, and connectivity is the property that spatially integrates the individual components of the watershed. In discussions of connectivity, the watershed scale is the appropriate context for interpreting technical evidence about individual watershed components (Newbold et al., 1982b; Stanford and Ward, 1993; Bunn and Arthington, 2002; Power and Dietrich, 2002; Benda et al., 2004; Naiman et al., 2005; Nadeau and Rains, 2007; Rodriguez-Iturbe et al., 2009). Such interpretation requires that freshwater resources be viewed within a landscape—or systems—context (Baron et al., 2002). Addressing the questions asked in this report (Section 1.1), therefore, requires an integrated systems perspective that considers both the components contributing to the river and the connections between those components and the river. This chapter describes this integrated systems perspective. Section 2.2 outlines the basic hydrologic foundation of river systems. Section 2.3 provides a general overview of how streams and wetlands affect downstream waters, focusing on functions within streams and wetlands and how they are connected to downstream waters. Finally, Section 2.4 examines key factors that affect connectivity between streams and wetlands and rivers. Although we focus our discussion here on interactions between streams, wetlands, and rivers, similar exchanges of water, influenced by many of the same factors, also occur between rivers, lakes, estuaries, and marine waters.

2.2 An Introduction to River Systems

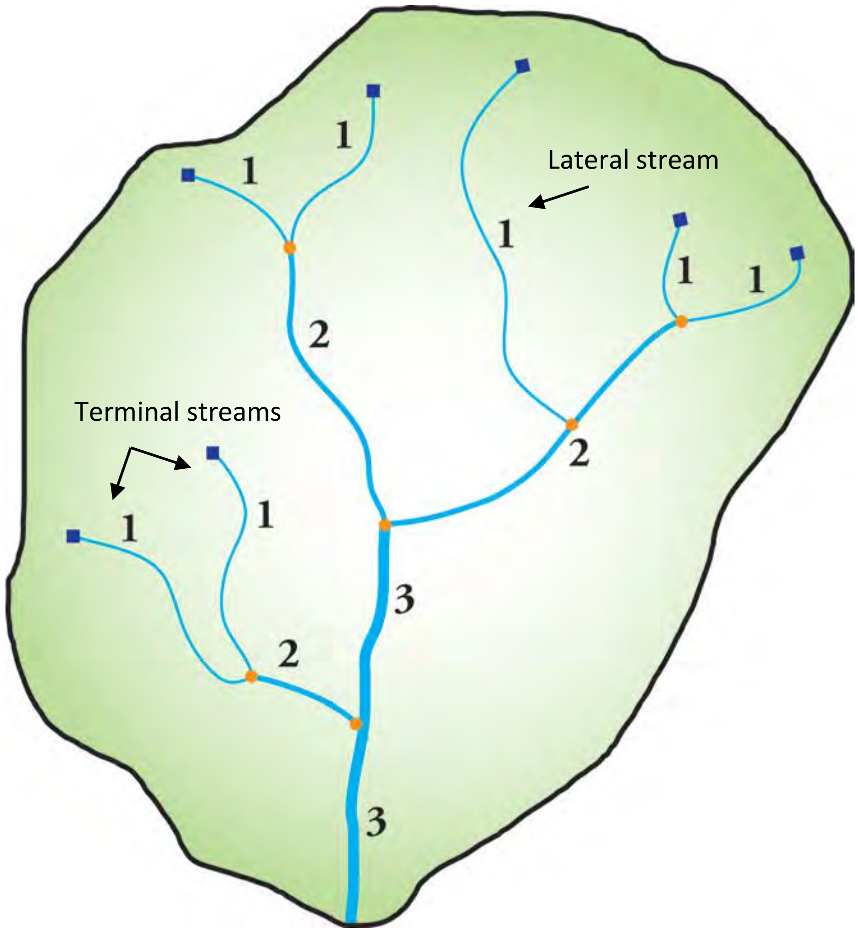
2.2.1 River System Components

In this report, the term **river** refers to a relatively large volume of flowing water within a visible channel, including subsurface water moving in the same direction as the surface water and lateral flows exchanged with associated floodplain and riparian areas (Naiman and Bilby, 1998). **Channels** are natural or constructed passageways or depressions of perceptible linear extent that convey water and associated materials downgradient. They are defined by the presence of continuous bed and bank structures, or uninterrupted (but permeable) bottom and lateral boundaries. Although bed and bank structures might in places appear to be disrupted (e.g., bedrock outcrops, braided channels, flow-through wetlands), the continuation of the bed and bank downgradient from such disruptions is evidence of the surface connection with the channel that is upgradient of the perceived disruption. Such disruptions are associated with changes in the gradient and in the material over and through which the water flows. If a disruption in the bed and bank structure prevented connection, the area downgradient would lack a bed and bank, be colonized with terrestrial vegetation, and be indiscernible from the nearby land. The concentrated longitudinal movement of water and sediment through these channels lowers local elevation, prevents soil development, selectively transports and stores sediment, and hampers the colonization and persistence of terrestrial vegetation. **Streams** are defined in a similar manner as rivers: a relatively small volume of flowing water within a visible channel, including subsurface water moving in the same direction as the surface water and lateral flows exchanged with associated floodplain and riparian areas (Naiman and Bilby, 1998).

A **river network** is a hierarchical, interconnected population of channels that drains surface and subsurface water (Sections 2.2.2 and 2.2.3) from a watershed to a river and includes the river itself. Watershed boundaries traditionally are defined topographically, such as by ridges, but ground-water sources and losses can occur outside of topographic boundaries (Winter et al., 2003). These channels can convey water year-round, weekly to seasonally, or only in direct response to rainfall and snowmelt (Frissell et al., 1986; Benda et al., 2004). The smallest of these channels, where streamflows begin, are considered **headwater streams**. Headwater streams are first- to third-order streams (Vannote et al., 1980; Meyer and Wallace, 2001; Gomi et al., 2002; Fritz et al., 2006b; Nadeau and Rains, 2007), where stream order is a classification system based on the position of the stream in the river network (Figure 2-1; Strahler, 1957). The point at which stream or river channels intersect within a river network is called a **confluence** (Figure 2-1). The confluence of two streams with the same order results in an increase of stream order (i.e., two first-order streams join to form a second-order stream, two second-order streams join to form a third-order stream, and so on); when streams of different order join, the order of the larger stream is retained.

One weakness of classification based on stream order is that it disregards the contributions of lower order streams where they join a higher order stream. Link magnitude, an alternative method for classifying streams, resolves this issue. Link magnitude is the sum of all source streams draining into a given stream segment (Scheidegger, 1965; Shreve, 1967). Therefore, unlike stream order, the link

Figure 2-1. A generalized example of a river network within its watershed. Blue lines illustrate the river network, within the light green area of its watershed. Numbers represent Strahler stream order, with streams increasing in order when two streams of equal order join. Blue squares indicate channel heads, and orange dots depict confluences.



magnitude of a segment accounts for all contributing lower order streams regardless of their position in river networks. For some properties, link magnitude might better reflect the aggregate upstream contributions to downstream waters.

Mock (1971) presented a classification of the streams comprising stream or river networks. He designated first-order streams that intersect other first-order streams as sources. We refer to these as **terminal source streams**. Mock defined first-order streams that flow into higher order streams as tributary sources, and we refer to this class of streams as **lateral source streams** (Figure 2-1)**.**

Terminal and lateral source streams typically originate at channel heads (Dietrich and Dunne, 1993), which occur where surface-water runoff is sufficient to erode a definable channel. The channel head denotes the upstream extent of a stream's continuous bed and bank structure (Figure 2-1). Channel heads are relatively dynamic zones in river networks, as their position can advance upslope by overland or subsurface flow-driven erosion, or retreat downslope by colluvial infilling. Source streams also can originate at seeps or springs and associated wetlands.

When two streams join at a confluence, the smaller stream (i.e., that with the smaller drainage area or lower mean annual discharge) is called a **tributary** of the larger stream, which is referred to as the **mainstem**. A basic way of classifying tributary contributions to a mainstem is the **symmetry ratio**, which describes the size of a tributary relative to the mainstem at their confluence, in terms of their respective discharges, drainage areas, or channel widths (Roy and Woldenberg, 1986; Rhoads, 1987; Benda, 2008).

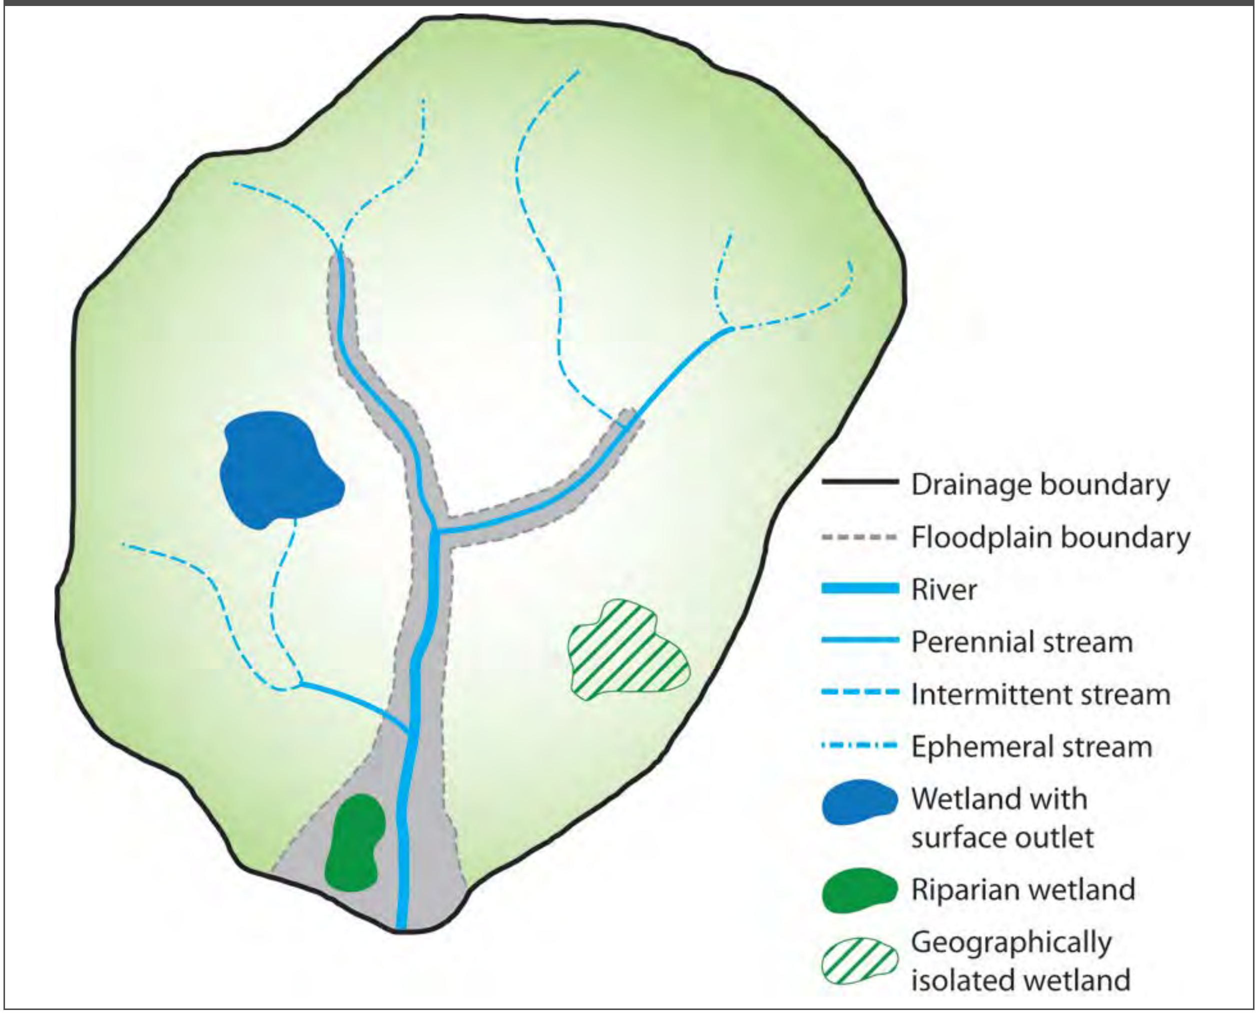
Surface-water hydrologic connectivity within river network channels occurs, in part, through the unidirectional movement of water from channels at higher elevations to ones at lower elevations—that is, hydrologic connectivity exists because water flows downhill. In essence, the river network represents the aboveground flow route and associated subsurface-water interactions, transporting water, energy, and materials from the surrounding watershed to downstream rivers, lakes, estuaries, and oceans (the River Continuum Concept; Vannote et al., 1980).

A **river system** (Figure 2-2) consists of a river network and its entire watershed. It includes all connected or isolated surface-water bodies (e.g., lakes and wetlands), any ground-water flow systems connecting the drainage basin with the river network and surface-water bodies, and terrestrial ecosystems (Stanford and Ward, 1993; Naiman et al., 2005).

Streamflow and the quantity and character of sediment—interacting with watershed geology, terrain, soils and vegetation—shape morphological changes in the stream channel that occur from river network headwaters to lower rivers (Montgomery, 1999; Church, 2002). Headwater streams are typically erosion zones in which sediment from the base of adjoining hillslopes moves directly into stream channels and is transported downstream. As stream channels increase in size and decrease in slope, a mixture of erosion and deposition processes usually is at work. At some point in the lower portions of river networks, sediment deposition becomes the dominant process and floodplains form. **Floodplains** are level areas bordering stream or river channels that are formed by sediment deposition from those channels under present climatic conditions (Figure 2-3). These natural geomorphic features are inundated during moderate to high water events (Leopold, 1994; Osterkamp, 2008). Floodplain and associated river channel forms (e.g., meandering, braided, anastomosing) are determined by interacting fluvial factors, including sediment size and supply, channel gradient, and streamflow (Church, 2002, 2006). **Terraces** are historical floodplains, formed under different climatic conditions, that are no longer connected to the river or stream channel that formed them (Figure 2-3).

Both riparian areas and floodplains are important components of river systems (Figure 2-3). **Riparian areas** are transition zones between terrestrial and aquatic ecosystems that are distinguished by gradients in biophysical conditions, ecological processes, and biota. They are areas through which surface and subsurface hydrology connect water bodies with their adjoining uplands, and they include those portions of terrestrial ecosystems that significantly influence exchanges of energy and matter with aquatic ecosystems (National Research Council, 2002). Riparian areas often have high biodiversity (Naiman et al., 2005). They occur near lakes and estuarine-marine shorelines and along river networks,

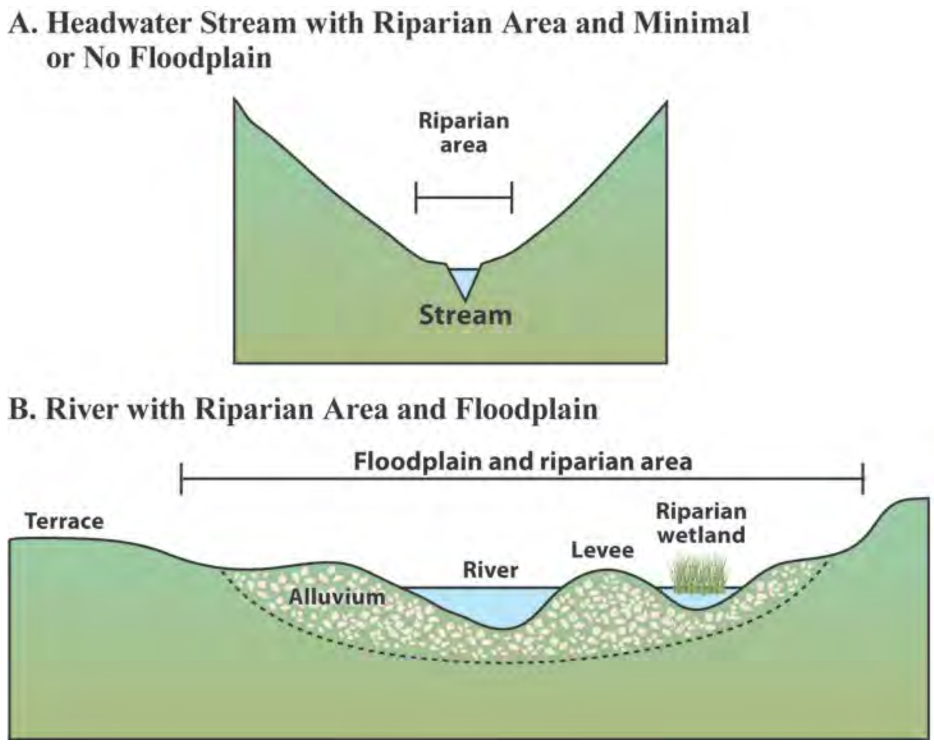
Figure 2-2. Elements of a river system. These elements include: the drainage basin (light green area), river network (rivers and streams), and other water bodies (riparian/floodplain wetlands, lakes, and wetlands in non-floodplain settings). Note that the non-floodplain wetland that lacks a stream outlet also would be considered "geographically isolated" *sensu* Tiner (2003b).



where their width can vary from narrow bands along headwater streams (Figure 2-3A) to broad zones that encompass the floodplains of large rivers (Figure 2-3B).

Floodplains are also considered riparian areas, but not all riparian areas have floodplains. All rivers and streams within river networks have riparian areas, but small streams in constrained valleys are less likely to have floodplains than larger streams and rivers in unconstrained valleys (Figures 2-2 and 2-3). The Federal Emergency Management Agency defines the area that will be inundated by the flood event having a 1% chance of being equaled or exceeded in any given year as the "Special Flood Hazard Area," also referred to as the "100-year floodplain" (https://www.fema.gov/floodplain-management/flood-zones). The 100-year floodplain can but need not coincide with the geomorphic floodplain. Like riparian areas, wetlands are transitional areas between terrestrial and aquatic ecosystems. According to Cowardin et al. (1979), an area is classified as a wetland if it has one or more of the following three

Figure 2-3. Hypothetical cross-sections of (A) a headwater stream and (B) a large river within a river network. The headwater stream in (A) is a constrained reach with a narrow riparian area and no floodplain; the river in (B) has both a riparian area and a floodplain with the same spatial extent. Examples of other common natural floodplain features are shown in (B). The lateral extent of riparian areas varies depending on the criteria used for delineation.



attributes: (1) the area supports predominantly hydrophytes (i.e., water-loving plants) at least periodically; (2) the land has substrate that is predominantly undrained hydric soil; or (3) the land has nonsoil substrate that is saturated with water or covered by shallow water at some time during the growing season of each year. Note that the Cowardin et al. (1979) definition requires only one of these characteristics, in contrast to the federal regulatory definition, which requires all three (33 Code of Federal Regulations 328.3(b); see also USACE, 1987). Thus, as used in this report, a wetland need not meet the federal regulatory definition. Wetlands include areas such as swamps, bogs, fens, marshes, ponds, and pools (Mitsch et al., 2009).

Many classification systems have been developed for wetlands (Mitsch and Gosselink, 2007). These classifications can focus on vegetation, hydrology, hydrogeomorphic characteristics, or other factors (Cowardin et al., 1979; Brinson, 1993; Tiner, 2003a; Comer et al., 2005). Because this report focuses on downstream connectivity (Section 1.3), we consider two landscape settings in which wetlands occur based on directionality of hydrologic flows. Directionality of flow also is included as a component of hydrodynamic setting in the hydrogeomorphic approach (Brinson, 1993; Smith et al., 1995) and as an element of water flowpath in an enhancement of National Wetlands Inventory data (Tiner, 2011). This emphasis on directionality of flow is necessary because hydrologic connectivity plays a dominant role in determining the types of effects wetlands have on downstream waters (Section 2.3.2).

A **non-floodplain wetland setting** is a landscape setting where the potential exists for unidirectional, lateral hydrologic flows from wetlands to the river network through surface water or ground water. Such a setting would include upgradient areas such as hillslopes or upland areas outside of the floodplain. Any wetland setting where water could only flow from the wetland toward a river network would be considered a non-floodplain setting, regardless of the magnitude and duration of flows and of travel times. In this document, we therefore refer to wetlands that occur in these settings as **non-floodplain wetlands**.

A **riparian or floodplain wetland setting** is a landscape setting (e.g., floodplains, most riparian areas, lake and estuarine fringes) that is subject to bidirectional, lateral hydrologic flows. Wetlands in riparian/floodplain settings can have some of the same types of hydrologic connections as those in non-floodplain settings. In addition, wetlands in these settings also have bidirectional flows. For example, wetlands within a riparian area are connected to the river network through lateral movement of water between the channel and riparian area (e.g., through overbank flooding, hyporheic flow). Given our interest in addressing the effects of wetlands on downstream waters (Section 1.1), we have focused in particular on the subset of these wetlands that occur in riparian areas with and without floodplains (collectively referred to hereafter as **riparian/floodplain wetlands**); we generally do not address wetlands at lake and estuarine fringes. **Riparian wetlands** are portions of riparian areas that meet the Cowardin et al. (1979) three-attribute wetland criteria (i.e., having wetland hydrology, hydrophytic vegetation, or hydric soils); **floodplain wetlands** are portions of the floodplain that meet these same criteria.

Our use of landscape setting to define riparian/floodplain wetlands and non-floodplain wetlands is similar to the use of landscape position by Tiner (2011) to supplement the Cowardin et al. (1979) classification. Our use of riparian/floodplain wetland setting is generally consistent with Tiner's estuarine, lotic, and lentic landscape positions, whereas our non-floodplain setting is similar to his terrene category (Tiner, 2011). One important difference is that Tiner (2011) would consider a wetland to be terrene if it were located along a river but not subject to frequent overflow. Given that even infrequent flooding can have profound effects on wetland development and function, we would consider such a wetland to be in a riparian/floodplain setting.

The terms "riparian/floodplain" and "non-floodplain" are meant to describe the landscape setting in which wetlands occur and do not refer to wetland type or class. Many wetland types occur in both settings. For example, a palustrine emergent wetland (Cowardin et al., 1979) could be located outside a floodplain, or it could be located within a floodplain and subject to bidirectional flows. A wetland that is classified as depressional in the hydrogeomorphic approach could have any combination of inlets and outlets or none at all (Smith et al., 1995). The setting for such a wetland would be riparian/floodplain if it had both an input and output channel because water from the stream flows into and affects the wetland. A depressional wetland with a surface outlet and no inlet or with no outlets and inlets, however, would be considered non-floodplain because water could flow downgradient only from the wetland to the river network, and not from a stream to the wetland. Similarly, a riverine wetland (Smith et al., 1995) that is the origin for a stream would be considered non-floodplain if it had no input channel, even though it occurs in a riparian area. In most cases, however, riverine wetlands would be considered riparian/floodplain. Thus, directionality of hydrologic flow is a function of landscape setting and cannot necessarily be determined from wetland class.

A major consequence of the two different landscape settings is that waterborne materials can be transported only from the wetland to the river network for a non-floodplain wetland, whereas waterborne materials can be transported from the wetland to the river network and from the river network to the wetland for a riparian/floodplain wetland. In the latter case, there is a mutual, interacting effect on the structure and function of both the wetland and river network. In contrast, a non-floodplain wetland can affect a river through the transport of waterborne material, but the opposite is not true. Note that we limit our use of riparian/floodplain and non-floodplain landscape settings to describe the direction of hydrologic flow; the terms cannot be used to describe directionality of geochemical or biological flows. For example, mobile organisms can move from a stream to a non-floodplain wetland (e.g., Subalusky et al., 2009a; Subalusky et al., 2009b). In Alaska, transport of live salmon or their carcasses from streams to riparian areas by brown bears (*Ursus arctos*) account for more than 20% of riparian nitrogen budgets (Helfield and Naiman, 2006). Although this example is in a riparian/floodplain setting, it shows how geochemical fluxes can be decoupled from hydrologic flows.

Both non-floodplain and riparian/floodplain wetlands can include **geographically isolated wetlands**, or wetlands completely surrounded by uplands (Tiner, 2003b). These wetlands have no apparent surface-water outlets, but can hydrologically connect to downstream waters through spillage or ground water. We define an **upland** as any area not meeting the Cowardin et al. (1979) three-attribute wetland criteria, meaning that uplands can occur in both terrestrial and riparian areas. Thus, a wetland that is located on a floodplain but is surrounded by upland would be considered a geographically isolated, riparian/floodplain wetland that is subject to periodic inundation from the river network. Although the term "geographically isolated" could be misconstrued as implying functional isolation, the term has been defined in the peer-reviewed literature to refer specifically to wetlands surrounded by uplands. Furthermore, the literature explicitly notes that geographic isolation does not imply functional isolation (Leibowitz, 2003; Tiner, 2003b). Discussion of geographically isolated wetlands is essential because hydrologic connectivity (an element of connectivity, which is the focus of this document) is generally difficult to characterize for these wetlands. The difficulty arises because hydrologic monitoring or additional information and analyses would be necessary to determine whether surface or subsurface hydrologic connections occur for such wetlands.

2.2.2 River System Hydrology

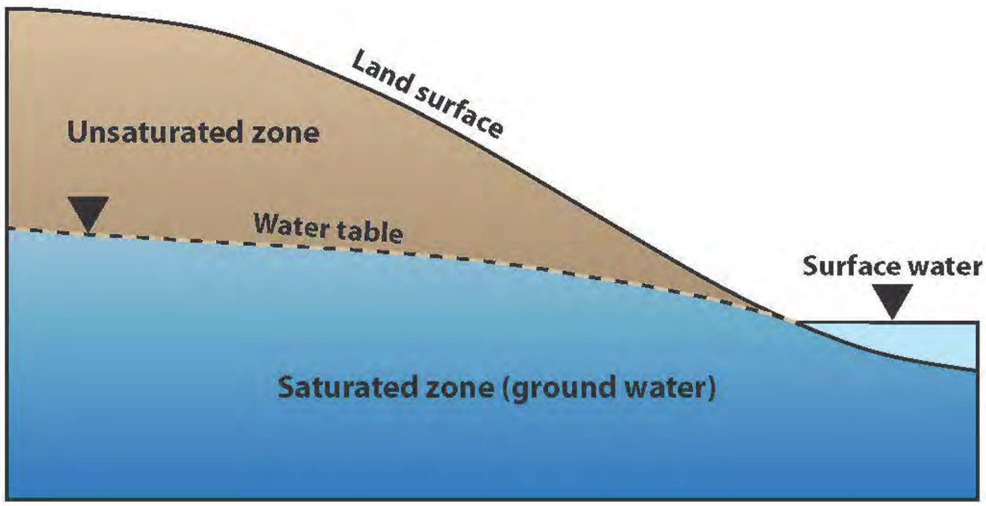
River system hydrology is controlled by hierarchical factors that result in a broad continuum of belowground and aboveground hydrologic flowpaths connecting river basins and river networks (Winter, 2001; Wolock et al., 2004; Devito et al., 2005; Poole et al., 2006; Wagener et al., 2007; Poole, 2010; Bencala et al., 2011; Jencso and McGlynn, 2011). At the broadest scale, regional climate interacts with river-basin terrain and geology to shape inherent hydrologic infrastructure that bounds the nature of basin hydrologic flowpaths. Different climate-basin combinations form identifiable hydrologic landscape units with distinct hydrologic characteristics (Winter, 2001; Wigington et al., 2013). Buttle (2006) posited three first-order controls of watershed streamflow generated under specific hydroclimatic conditions: (1) the ability of different landscape elements to generate runoff by surface or subsurface lateral flow of water; (2) the degree of hydrologic linkage among landscapes by which surface and subsurface runoff can reach river networks; and (3) the capacity of the river network itself to convey runoff downstream to the river-basin outlet. River and stream waters are influenced by not only basin-scale or larger ground-water systems, but also local-scale, vertical and lateral hydrologic exchanges between water in channels and sediments beneath and contiguous with river network channels (Ward, 1989; Woessner, 2000; Malard et al., 2002; Bencala, 2011). The magnitude and importance of river-system hydrologic flowpaths at all spatial scales can radically change over time at hourly to yearly temporal scales (Junk et al., 1989; Ward, 1989; Malard et al., 1999; Poole et al., 2006).

Because interactions between ground waters and surface waters are essential processes in rivers, knowledge of basic ground-water hydrology is necessary to understand the interactions between surface and subsurface water and their relationship to connectivity within river systems. Subsurface water occurs in two principal zones: the unsaturated zone and the saturated zone (Figure 2-4; Winter et al., 1998). In the **unsaturated zone**, the spaces between soil, gravel, and other particles contain both air and water. In the **saturated zone**, these spaces are completely filled with water. **Ground water** refers to any water that occurs and flows (**saturated ground-water flow**) in the saturated zone beneath a watershed surface (Winter et al., 1998). Rapid flow (**interflow**) of water can occur through large pore spaces in the unsaturated zone (Beven and Germann, 1982).

Traditionally, geologic formations in which ground water occurs are divided into two major categories: (1) **aquifers**, which are saturated geologic units capable of transmitting significant amounts of water under ordinary hydraulic gradients; and (2) **aquicludes**, which are saturated geologic units that are *not* capable of transmitting significant quantities of water (aquicludes are also referred to as confining layers or confining units; Freeze and Cherry, 1979). Water flow in an aquifer can take various forms: Water can flow in small voids and pores between the aquifer strata (porous media aquifers), in large voids (karst), or in fractures and cracks within the aquifer formation (fractured flow aquifers). Flow differs in its characteristics between the various aquifer types mentioned, yet follows the same basic rule, by which flow occurs from regions of high hydraulic pressure to regions of lower hydraulic pressure, down the pressure gradient (Jones and Mulholland, 2000).

There are two main types of aquifers (Freeze and Cherry, 1979). **Unconfined aquifers** are underlain by a confining unit but remain open to the atmosphere at their top and exchange gases with the environment. The upper saturated horizon in unconfined aquifers is known as the **water table** (Figure 2-4). Complex geologic conditions can lead to more complex distributions of saturated and unsaturated zones. Discontinuous saturated lenses creating **perched water tables** can occur where low permeability layers (e.g., clay) are present in the midst of highly permeable materials such as sand (Freeze, 1971). **Confined aquifers** are bounded by an underlying confining unit and an overlying confining unit and typically lack a direct connection with current surface and atmospheric conditions (Figure 2-5). Water in confined aquifers is often pressurized, and, consequently, water levels in wells

Figure 2-4. Water below the land surface occurs in either the unsaturated or the saturated zone. The upper surface of the saturated zone is the water table. Ground water and ground-water flow occur in the saturated zone. If a surface-water body is connected to the ground-water system, the water table intersects the water body at or near the surface of its shoreline. Modified from Winter et al. (1998).

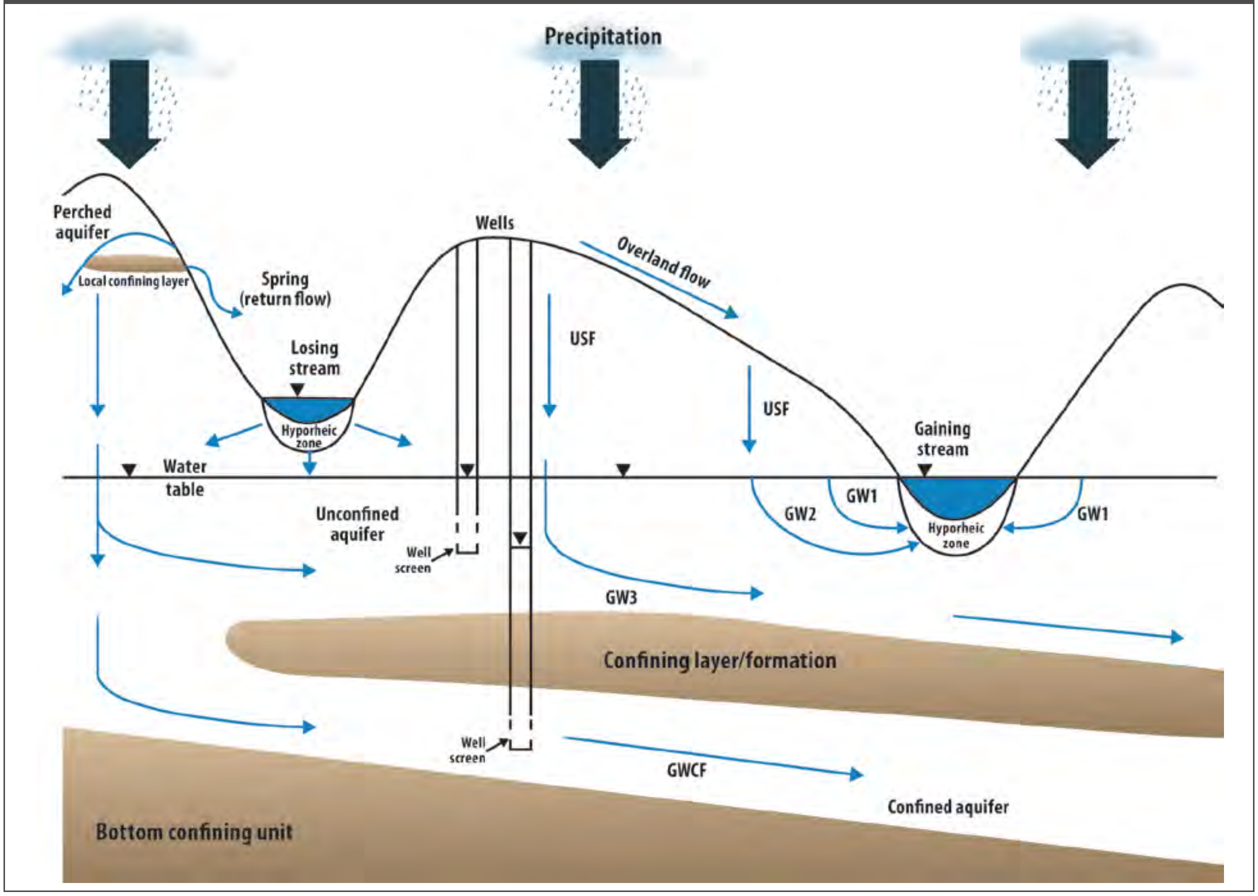


penetrating confined aquifers occur at elevations above the upper confining unit. The surface of the water levels in wells penetrating a confined aquifer is called the **potentiometric surface**. Confined aquifers typically occur deeper below the land surface than unconfined aquifers and generally have less frequent influence on surface waters than unconfined aquifers.

Traditionally, aquifers were identified based solely on their ability to support wells for water production, but in recent years hydrologists studying ground water-surface water interactions have recognized the need for a broader definition that recognizes the importance of low-flow geologic formations to aquatic ecosystems. Payne and Woessner (2010) highlighted the importance of aquifers with varying flow rates on streams and proposed a classification of aquifer flow systems that ranged from high flow to low flow, with low flow aquifers having limited ground-water discharge potential except for small streams and wetlands. Winter et al. (1998) simply defined aquifers as the permeable materials (e.g., soil, rock) through which ground water flows. In this report, we have adopted the Winter et al. (1998) aquifer definition. Unless otherwise noted, our discussion of ground water and aquifers is limited to unconfined systems.

Ground-water **recharge areas** occur where water from land surfaces or surface-water bodies infiltrates and moves into saturated zones. **Discharge areas** occur where water flows from saturated zones into a river network, other water bodies, or onto land surfaces. A **gaining stream (**or **wetland**; also referred to as a **discharge wetland**) within a river network receives inflow of ground water. In this situation, the water table elevation near the stream (or wetland) must be higher than the elevation of the stream water surface. In a **losing stream (**or **wetland**; i.e., **recharge wetland**), water flows from the stream (wetland) to ground water. In this situation, the water table elevation near the stream or wetland is

Figure 2-5. Cross-section showing major hydrologic flowpaths in a regional-scale stream-watershed system. USF = unsaturated flow, GW = ground-water flowpath (saturated flow); GW1, GW2, and GW3 = ground-water flowpaths of varying depth and length. GW1 represents local ground water and GW3 represents regional ground water. GWCF = ground-water flowpath in confined aquifer.



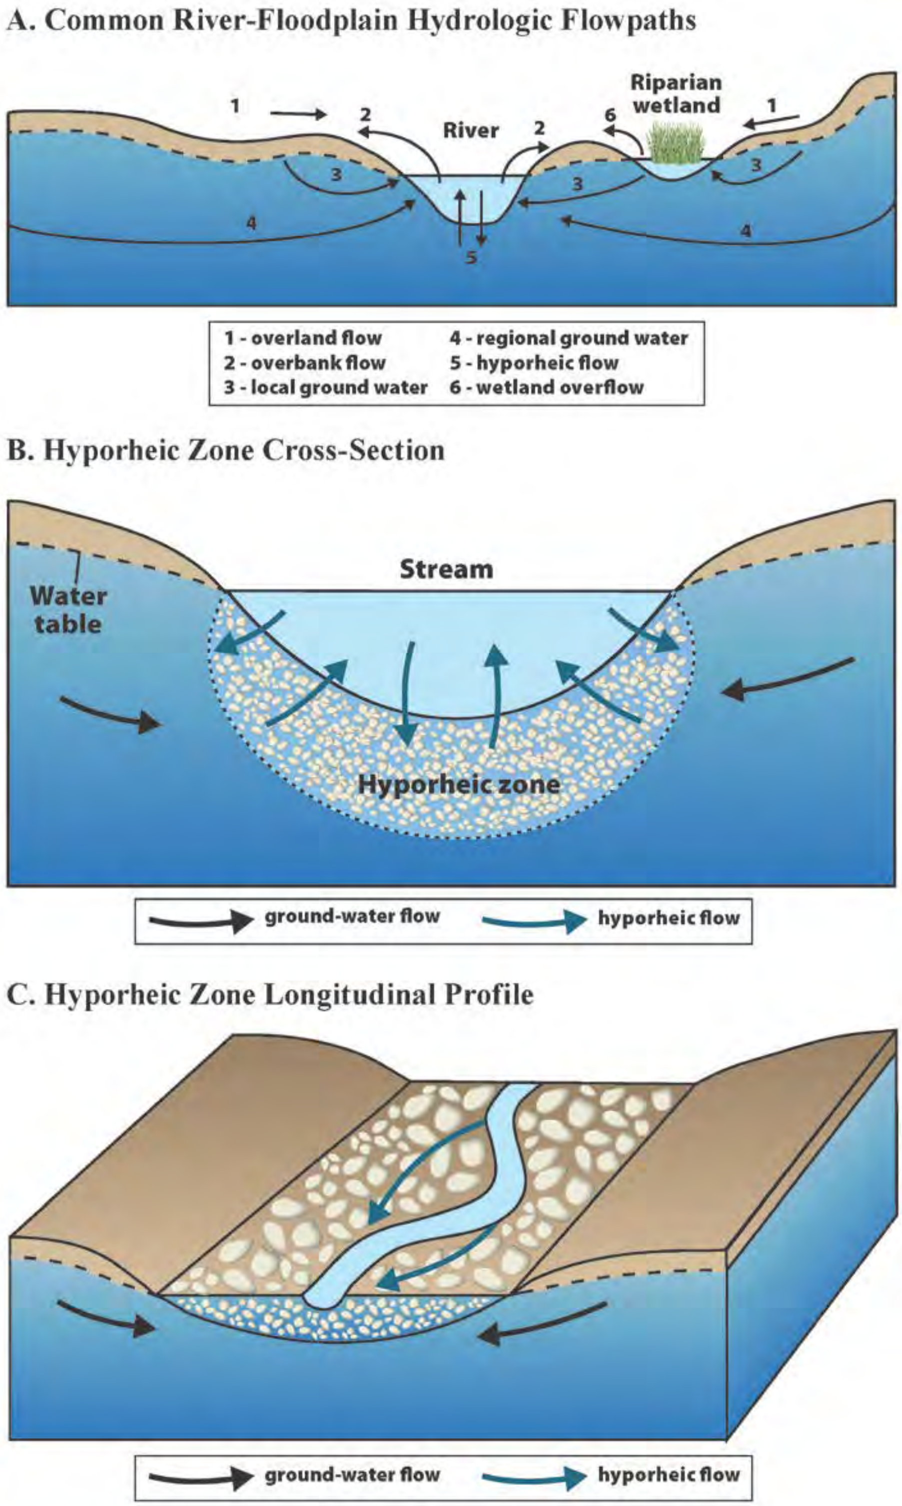
lower than the stream or wetland water surface. Conditions that determine whether streams and wetlands are gaining or losing can change over short periods of time and over short distances within river networks and river basins (Winter et al., 1998; Harrington et al., 2002; Wilson and Guan, 2004; Coes and Pool, 2005; Scanlon et al., 2006; Vivoni et al., 2006; Larned et al., 2008). Overall, however, the volume and sustainability of streamflow within river networks typically depend on contributions from ground water (Winter, 2007), especially in areas with shallow ground-water tables and pervious subsurfaces (de Vries, 1995; Kish et al., 2010).

Ground-water flow systems within river basins can be complex, of varying sizes and depths, and overlie one another (Tóth, 1963; Winter et al., 1998; Haitjema and Mitchell-Bruker, 2005). Although in reality there is a continuum of flowpath lengths that occur within river basins (Bencala et al., 2011), they are commonly grouped into three categories (Figure 2-5). In **local ground-water** flow systems (also referred to as shallow ground-water flow systems), ground water flows from the highest elevations of water tables (water table highs) to nearby lowlands or surface waters (Winter and LaBaugh, 2003). Local ground-water flow is the most dynamic of ground-water flow systems, having the greatest interchange with surface waters. If the depth-to-width ratios of aquifers are sufficiently large, regional flow systems (deepest ground-water flowpaths) also might be present. **Regional ground water** (also referred to as deep ground water) originates from precipitation in distant upland recharge areas and moves long distances, through deep regional-scale aquifers, to river networks (Figure 2-5). The contact times between ground water and subsurface materials are longer for these deep and long flow systems than for local systems. Eventually, deep regional flow systems also discharge to surface waters in the lower portions of river networks where they influence surface-water conditions. An **intermediate ground-water** flow system is one in which ground water flows from a water table high to a lowland that is not immediately adjoining the water table high. Intermediate ground-water flow systems are representative of the wide range of flowpath lengths and depths that occur between local and regional ground-water systems.

Other hydrologic flowpaths are also significant in determining the characteristics of river systems. The most obvious is the downstream water movement within stream or river channels, or **open-channel flow**. River water in stream and river channels can reach riparian areas and floodplains via **overbank flow** (Figure 2-6A), which occurs when floodwaters flow over stream and river channels (Mertes, 1997). **Overland flow** is the portion of streamflow derived from net precipitation that flows over the land surface to the nearest stream channel with (Figure 2-6A; Hewlett, 1982). Overland flow can be generated by several mechanisms. **Infiltration-excess overland flow** occurs when the rainfall rates exceed the infiltration rates of land surfaces (Horton, 1945). **Saturation-excess overland flow** occurs when precipitation inputs cause water tables to rise to land surfaces so that precipitation inputs to the land surfaces cannot infiltrate and flow overland (Dunne and Black, 1970). **Return flow** occurs when water infiltrates, percolates through the unsaturated zones, enters saturated zones, and then returns to and flows over watershed surfaces, commonly at hillslope-floodplain transitions (Dunne and Black, 1970).

Alluvium (Figure 2-3B) comprises deposits of clay, silt, sand, gravel, or other particulate materials that running water has deposited in a streambed, on a floodplain, on a delta, or in a fan at the base of a mountain. These deposits occur near active river systems but also can be found in buried river valleys—the remnants of relict river systems (Lloyd and Lyke, 1995). In this report, we are concerned primarily with alluvium deposited along active river networks. Commonly, alluvium is highly permeable, creating an environment conducive to ground-water flow. **Alluvial ground water** (typically a mixture of river water and local, intermediate, and regional ground water) moves through the alluvium. Together, the alluvium and alluvial ground water comprise **alluvial aquifers**. Alluvial aquifers are closely associated with floodplains and have high levels of **hyporheic exchange** (Stanford and Ward, 1993; Amoros and Bornette, 2002; Poole et al., 2006). Hyporheic exchange occurs when water moves from stream or river into alluvial deposits and then returns to the channels (Figures 2-6B and 2-6C; Bencala, 2005; Leibowitz et al., 2008). Hyporheic exchange allows for the mixing of surface water and ground water. It occurs during both high- and low-flow periods, and typically has relatively horizontal flowpaths at scales of meters to tens of meters (Bencala, 2005) and vertical flowpaths with depths ranging from centimeters to tens of meters (Stanford and Ward, 1988; Woessner, 2000 and references therein).

Figure 2-6. Hyporheic zone flows. (A) Common hydrologic flowpaths by which water flows between watersheds and river networks. (B) and (C) The three-dimensional process of hyporheic flow, or the movement of water from a river or stream to nearby alluvium and then back to the river or stream. Modified from Winter et al. (1998).



Riparian areas and floodplains can have a diverse array of hydrologic inputs and outputs, which, in turn influence riparian/floodplain wetlands. Riparian areas and floodplains receive water from precipitation; overland flow from upland areas; local, intermediate, regional ground water; and hyporheic flows (Figure 2-6A; National Research Council, 2002; Richardson et al., 2005; Vidon et al., 2010). Water flowing over the land surface in many situations can infiltrate soils in riparian areas. If low permeability subsoils or impervious clay layers are present, water contact with the plant root zone is increased and materials in the water are subject to ecological functions such as denitrification before it reaches the stream channel (Section 4.3.2; National Research Council, 2002; Naiman et al., 2005; Vidon et al., 2010).

The relative importance of the continuum of hydrologic flowpaths among river systems varies, creating streams and rivers with different flow duration (or hydrologic permanence) classes (Figures 2-2 and 2-7). **Perennial streams** or stream reaches (Figure 2-7A) typically flow year-round. They are maintained by local or regional ground-water discharge or streamflow from higher in the stream or river network. **Intermittent streams** or stream reaches (Figure 2-7B) flow continuously at certain times of the year (e.g., during certain seasons such as spring snowmelt); drying occurs when the water table falls below the channel bed elevation. **Ephemeral streams** or stream reaches (Figure 2-7C) flow briefly (typically hours to days) during and immediately following precipitation; these channels are above the water table at all times. Streams in these flow duration classes often transition longitudinally, from ephemeral to intermittent to perennial, as drainage area increases and elevation decreases along river networks. Many headwater streams, however, originate from permanent springs and flow into intermittent downstream reaches. At low flows, intermittent streams can contain dry segments alternating with flowing segments. Transitions between flow duration classes can coincide with confluences or with geomorphic discontinuities within the network (May and Lee, 2004; Hunter et al., 2005). Variation of streamflow within river systems occurs in response to **hydrologic events** resulting from rainfall or snowmelt. **Stormflow** is streamflow that occurs in direct response to rainfall or snowmelt (Figure 2-8A), which might stem from multiple ground-water and surface-water sources (Dunne and Leopold, 1978). **Baseflow** is streamflow originating from ground-water discharge or seepage (locally or from higher in the river network), which sustains water flow through the channel between hydrologic events (Figure 2-8A). Perennial streams have baseflow year-round; intermittent streams have baseflow seasonally; ephemeral streams have no baseflow. All three stream types convey stormflow. Thus, perennial streams are more common in areas receiving high precipitation, whereas intermittent and ephemeral streams are more common in the more arid portions of the United States (Figure 2-9; NHD, 2008). The distribution of headwater streams (perennial, intermittent, or ephemeral) as a proportion of total stream length is similar across geographic regions and climates (Figure 2-9C).

Similar to streams, the occurrence and persistence of riparian/floodplain wetland and non-floodplain wetland hydrologic connections with river networks, via surface water (both channelized and nonchannelized) or ground water, can be continuous, seasonal, or ephemeral, depending on the overall hydrologic conditions in the watershed. For example, a non-floodplain wetland might have a direct ground-water connection with a river network during wet conditions but an indirect regional ground-water connection (via ground-water recharge) under dry conditions. Geographically isolated wetlands can be hydrologically connected to the river network via nonchannelized surface flow (e.g., swales or overland flow) or ground water.

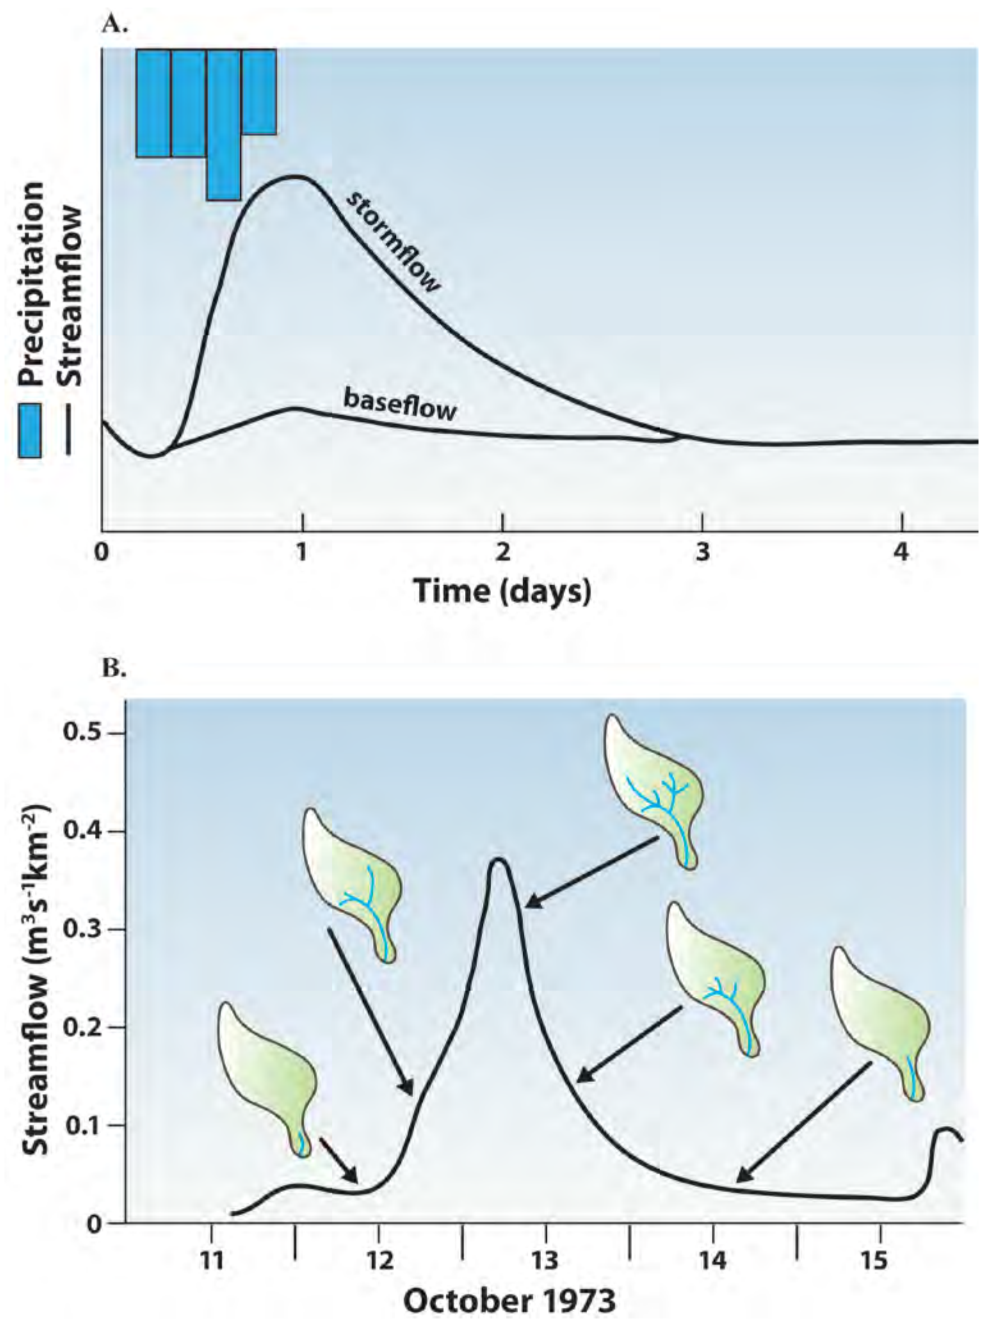

Figure 2-9. Characteristics of U.S. streams by watershed, in terms of percent of total stream length as (A) perennial, (B) intermittent, and (C) headwater streams. Data from the National Hydrography Dataset (NHD) Reach Address Database (RAD) v2.0 at 1:100,000 scale using 8-digit HUC (Hydrologic Unit Code) watersheds. Here, “intermittent” includes streams having intermittent or ephemeral flow. Note that NHD data generally do not capture streams <1.6 km (1 mile) in length, and ranges of color categories are not consistent across maps.

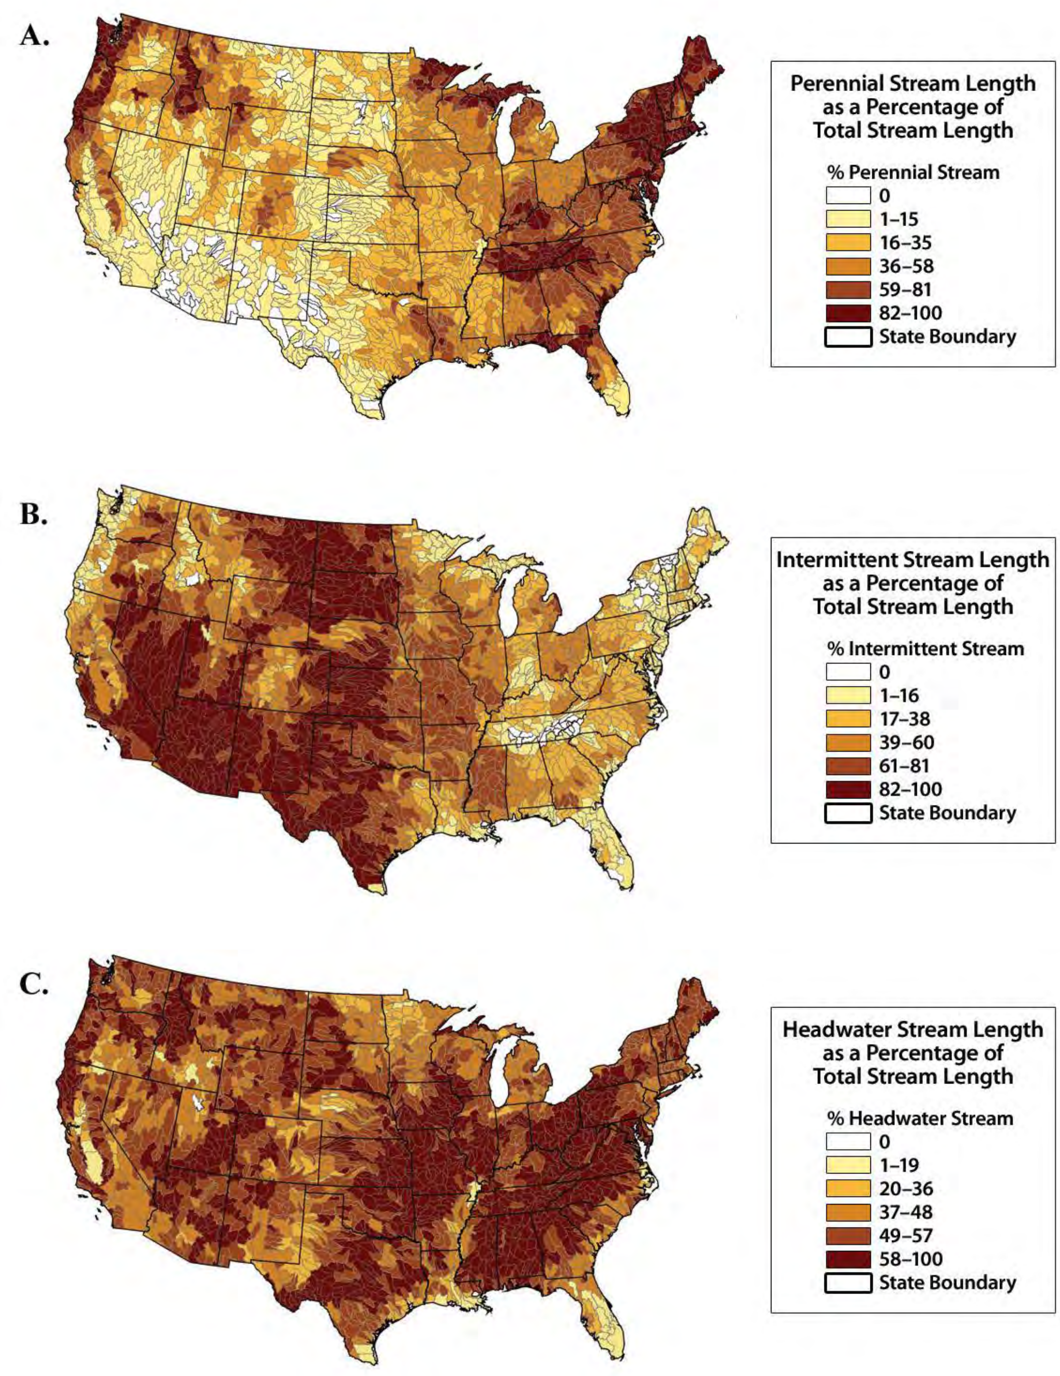

2.2.3 River Network Expansion and Contraction

The portions of river networks with flowing water expand and contract longitudinally (in an upstream-downstream direction) and laterally (in a stream channel-floodplain direction) in response to seasonal environmental conditions and precipitation events (Hewlett and Hibbert, 1967; Gregory and Walling, 1968; Dunne and Black, 1970; Day, 1978; Junk et al., 1989; Hunter et al., 2005; Wigington et al., 2005; Rains et al., 2006; Rains et al., 2008). The longitudinal expansion of channels with flowing water in response to major precipitation events represents a transient increase in the extent of headwater streams. Figure 2-10 shows the expansion of the flowing portion of two stream networks in western Oregon between dry, summer and wet, winter seasons. Intermittent and perennial streams flow during wet seasons, whereas ephemeral streams flow only in response to rainfall or snowmelt. During dry periods, flowing portions of river networks are limited to perennial streams; these perennial portions of the river network can be discontinuous (Stanley et al., 1997; Hunter et al., 2005; Larned et al., 2010) or interspersed with intermittently flowing stream reaches.

The dominant sources of water to a stream can shift during river network expansion and contraction (Malard et al., 1999; McGlynn and McDonnell, 2003; McGlynn et al., 2004; Malard et al., 2006). Rainfall and snowmelt cause a river network to expand in two ways. First, local aquifers expand and water moves into dry channels, which increases the total length of the wet channel (Winter et al., 1998); the resulting intermittent streams will contain water during the entire wet season. Second, stormflow can cause water to enter ephemeral and intermittent streams (Figure 2-8). The larger the rainfall or snowmelt event, the greater the number of ephemeral streams and total length of flowing channels that occur within the river network. Ephemeral flows cease within days after rainfall or snowmelt ends (Figure 2-8B), causing the length of wet channels to decrease and river networks to contract. The flowing portion of river networks further shrinks as the spatial extent of aquifers with ground water in contact with streams contract and intermittent streams dry. In many river systems across the United States, stormflow comprises a major portion of annual streamflow (Hewlett et al., 1977; Miller et al., 1988; Turton et al., 1992; Goodrich et al., 1997; Vivoni et al., 2006). In these systems, intermittent and ephemeral streams are major sources of river water (Section B.5). When rainfall or snowmelt induces stormflow in headwater streams or other portions of the river network, water flows downgradient through the network to its lower reaches. As water moves downstream through a river network, the hydrograph for a typical event broadens with a lower peak (Figure 2-11). This broadening of the hydrograph shape (Figure 2-11A) results from transient storage of water in river network channels and nearby alluvial aquifers (Fernald et al., 2001).

Floodplains and riparian areas can be locations with significant ground-water recharge and discharge (National Research Council, 2002; Naiman et al., 2005). During very large hydrologic events, aggregate flows from headwaters and other tributary streams can result in overbank flooding in river reaches with floodplains; this occurrence represents lateral expansion (Figure 2-12) of the river network (Mertes, 1997). Water from overbank flows can recharge alluvial aquifers, supply water to floodplain wetlands, surficially connect floodplain wetlands to rivers, and shape the geomorphic features of the floodplain

Figure 2-10. Extent and connectivity of streams with flowing water, wetlands, and other water bodies in (A) Spring Valley Creek, OR and (B) Spoon Creek, OR during dry summer (left) and wet winter (right) conditions. (Wolman and Miller, 1960; Hammersmark et al., 2008). Depending on the nature of the hydraulic gradients, ground water within floodplain alluvium can move both parallel and perpendicularly to streams or rivers (National Research Council, 2002) and enter river networks at various discharge points. Bidirectional exchanges of water between ground water and river networks, including hyporheic

Figure 2-11. Stormflow moves downstream through the river network and interacts with lower stream reaches, floodplains, and alluvial aquifers. flow, can occur under a wide range of streamflows, from flood flows to low flows (National Research Council, 2002; Naiman et al., 2005; Vivoni et al., 2006).

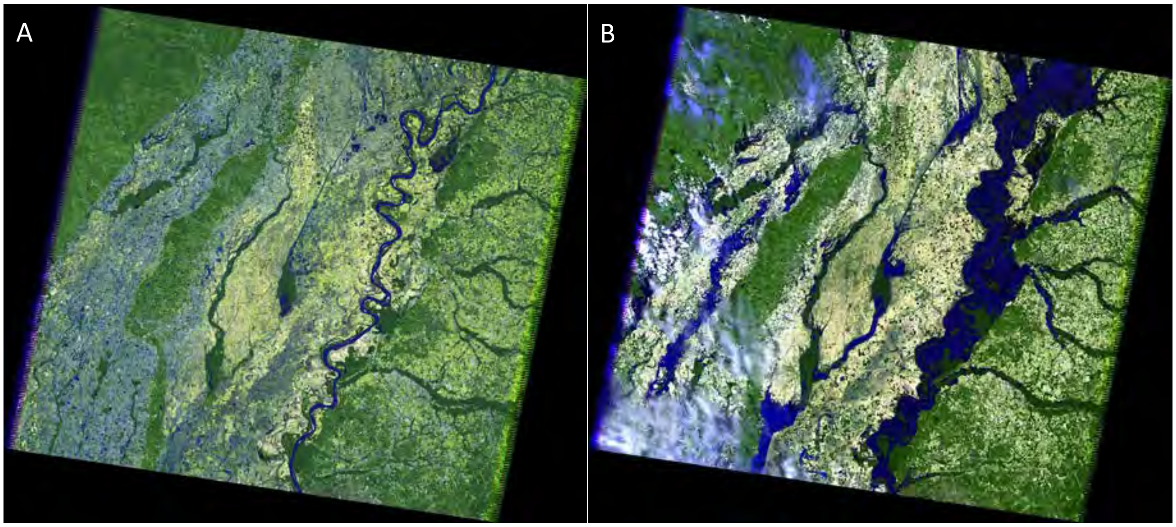
The hydrologic connections with river networks fundamentally differ for riparian/floodplain wetlands and non-floodplain wetlands. Riparian/floodplain wetlands can have bidirectional, lateral hydrologic connections to the river network, either through overbank flooding (i.e., lateral expansion of the network) or hyporheic flow, in addition to unidirectional flows from upland and ground-water sources (Figure 2-6A). In contrast, hydrologic connections between non-floodplain wetlands and river networks originate via surface-water spillage or ground-water flow when water inputs exceed evapotranspiration and available storage. Although wetlands that serve as origins for streams are riparian, we group them with non-floodplain wetlands because they also have unidirectional flow through their outlet streams. In both cases, the degree of hydrologic connectivity between riparian/floodplain and non-floodplain wetlands and the river network varies with lateral expansion and subsequent contraction.

Figure 2-12. Landsat 5 satellite images of the Mississippi River along the borders of Tennessee, Kentucky, Missouri, and Arkansas on (A) May 12, 2006 and (B) May 10, 2011. Images courtesy of U.S. Geological Survey/National Aeronautics Space Administration.



One factor affecting the lateral distance that overbank flow spreads is preexisting moisture conditions on the floodplain (Mertes, 1997; Naiman et al., 2005). River overbank flow that enters a dry floodplain will spread and then infiltrate the soil (Naiman et al., 2005). If inflows from streams, rainfall, or ground water have water tables elevated to the floodplain surface, water entering the riparian area from overbank flow cannot infiltrate soils. The result is standing water on the floodplain and subsequent movement of water to lower elevations of the floodplain. This water can alter the geomorphology of the floodplain (Hupp and Osterkamp, 1996), be biogeochemically transformed (Section 4.3.2; Naiman et al., 2005), be lost by evaporation, or be transpired by vegetation (Meyboom, 1964). As the river and floodplain water table elevations decrease, surface water on the floodplain can flow back into the river, infiltrate floodplain soils, or evapotranspire.

Many studies have documented the fact that riparian/floodplain wetlands can attenuate flood pulses of streams and rivers by storing excess water from streams and rivers. Bullock and Acreman (2003) reviewed wetland studies and reported that wetlands reduced or delayed floods in 23 of 28 studies. For example, Walton et al. (1996) found that peak discharges between upstream and downstream gaging stations on the Cache River in Arkansas were reduced 10–20% primarily due to floodplain water storage. Locations within floodplains and riparian areas with higher elevations likely provide flood storage less frequently than lower elevation areas.

The interactions of high flows with floodplains and associated alluvial aquifers of river networks are important determinants of hydrologic and biogeochemical conditions of rivers (Ward, 1989; Stanford and Ward, 1993; Boulton et al., 1998; Burkart et al., 1999; Malard et al., 1999; Amoros and Bornette, 2002; Malard et al., 2006; Poole, 2010). Bencala (1993; 2011) noted that streams and rivers are not pipes: They interact with the alluvium and geologic materials adjoining and under channels. In streams or river reaches constrained by topography, significant floodplain and near-channel alluvial aquifer interactions are limited (Figure 2-3A). In reaches with floodplains, however, stormflow commonly supplies water to alluvial aquifers during high-flow periods through the process of **bank storage** (Figure 2-13; Whiting and Pomeranets, 1997; Winter et al., 1998; Chen and Chen, 2003). As streamflow decreases after hydrologic events, the water stored in these alluvial aquifers can serve as another source of baseflow in rivers (Figure 2-13C).

In summary, the extent of wetted channels is dynamic because interactions between surface water in the channel and alluvial ground water, via hyporheic exchange, determine open-channel flow. The flowing portion of river networks expands and contracts in two primary dimensions: (1) longitudinally, as intermittent and ephemeral streams wet up and dry; and (2) laterally, as floodplains and associated alluvial aquifers gain (via overbank flooding, bank storage, and hyporheic exchange) and lose (via draining of alluvial aquifers and evapotranspiration) water. Vertical ground-water exchanges between streams and rivers and underlying alluvium are also key connections, and variations in these vertical exchanges contribute to the expansion and contraction of the portions of river networks with open-channel flow. Numerous studies have documented expansion and contraction of river systems (e.g., Gregory and Walling, 1968); the temporal and spatial pattern of this expansion and contraction varies in response to many factors, including interannual and long-term dry cycles, climatic conditions, and watershed characteristics (Cayan and Peterson, 1989; Fleming et al., 2007).

2.3 Influence of Streams and Wetlands on Downstream Waters

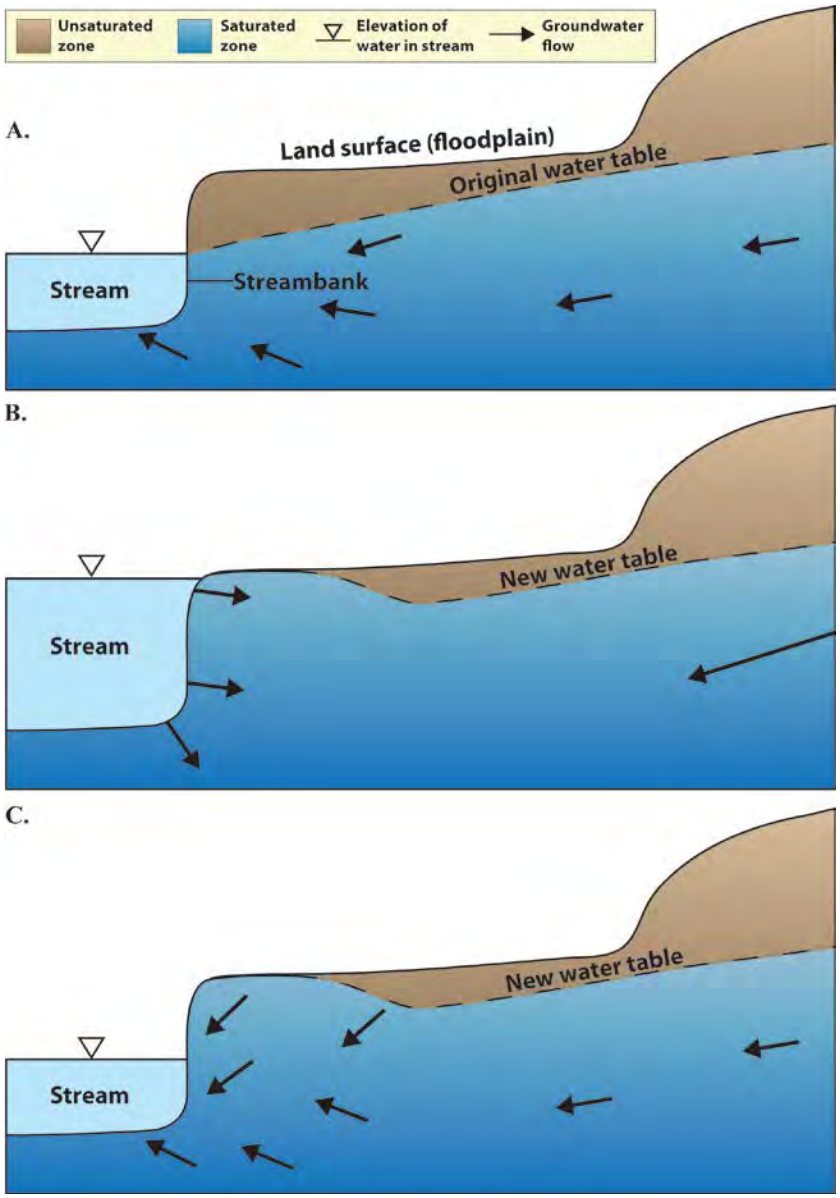
The previous section provided background on river system hydrology. In this section, we present a general overview of how streams and wetlands affect downstream waters, focusing on functions within streams and wetlands and their connectivity to rivers.

The structure and function of rivers are highly dependent on the constituent materials stored in and transported through them. Most of these materials, broadly defined here as any physical, chemical, or biological entity, including water, heat energy, sediment, wood, organic matter, nutrients, chemical contaminants, and organisms, originate outside of the river: They originate from either the upstream river network or other components of the river system, and then are transported to the river by water movement or other mechanisms. Thus, the fundamental way in which streams and wetlands affect river structure and function is by altering fluxes of materials to the river. This alteration of material fluxes depends on two key factors: (1) functions within streams and wetlands that affect material fluxes, and (2) connectivity (or isolation) between streams and wetlands and rivers that allows (or prevents) transport of materials between the systems.

2.3.1 Effects of Streams and Wetlands on Material Fluxes

Streams and wetlands affect the amounts and types of materials that are or are not delivered to downstream waters, ultimately contributing to the structure and function of those waters. Leibowitz et al. (2008) identify three functions, or general mechanisms of action, by which streams and wetlands

Figure 2-13. The direction and magnitude of interactions between surface water and ground water can dramatically change during large hydrologic events, including floods. (A) In a hypothetical stream-floodplain cross-section, ground water flows from the alluvial aquifer to the stream before a major hydrologic event. (B) During the bank-full hydrologic event, surface water moves from the stream and becomes ground water in the alluvial aquifer. (C) After recession of the event, ground water that was stored in the alluvial aquifer during the hydrologic event flows back to the stream. This process is called bank storage, which can sustain baseflow in streams and rivers after the hydrologic event has ended. Modified from Winter et al. (1998).



influence material fluxes into downstream waters: **source**, **sink**, and **refuge**. We have expanded on this framework to include two additional functions: **lag** and **transformation**. These five functions (summarized in Table 2-1) provide a framework for understanding how physical, chemical, and biological connections between streams and wetlands and downstream waters influence river systems.

These five functions (Table 2-1) are neither static nor mutually exclusive, and often the distinctions between them are not sharp. A stream or wetland can provide different functions at the same time. These functions can vary with the material considered (e.g., acting as a source of organic matter and a sink for nitrogen) and can change over time (e.g., acting as a water sink when evapotranspiration is high and a water source when evapotranspiration is low). The magnitude of a given function also is likely to vary temporally: For example, streams generally are greater sources of organic matter and contaminants during high flows.

Leibowitz et al. (2008) explicitly focused on functions that benefit downstream waters, but these functions also can have negative effects—for example, when streams and wetlands serve as sources of chemical contamination (Sections 3.4.4, 4.3.3.5, 4.3.3.6; Table 2-1). In fact, benefits need not be linear with respect to concentration; a beneficial material could be harmful at higher concentrations due to nonlinear and threshold effects. For example, nitrogen can be beneficial at lower concentrations but can reduce water quality at higher concentrations. Although here we focus primarily on the effects of streams and wetlands on downstream waters, these same functions can describe effects of downstream waters on streams and wetlands (e.g., downstream rivers can serve as sources of colonists for upstream tributaries).

Because many of these functions depend on import of materials and energy into streams and wetlands, distinguishing between *actual function* and *potential function* is instructive. For example, a wetland with appropriate conditions (e.g., a reducing environment and denitrifying bacteria) is a potential sink for nitrogen (Sections 4.3.3.2 and 4.4.3.2): If nitrogen is imported into the wetland, the wetland can remove it by denitrification. The wetland will not serve this function, however, if nitrogen is not imported. Thus, even if a stream or wetland does not currently serve a function, it has the potential to provide that function under appropriate conditions (e.g., when material imports or environmental conditions change). Although potential functions do not actively affect downstream waters, they can be instrumental in protecting those waters from future impacts. Ignoring potential function also can lead to the paradox that degraded streams and wetlands (e.g., those receiving nonpoint-source nitrogen inputs) receive more protection than less degraded systems (Leibowitz et al., 2008).

Three factors influence the effect that material and energy fluxes from streams and wetlands have on downstream waters: (1) proportion of the material originating from (or reduced by) streams and wetlands relative to the importance of other system components, such as the river itself; (2) residence time of the material in the downstream water; and (3) relative importance of the material. In many cases, the effects on downstream waters need to be considered in aggregate. For example, the contribution of material by a particular stream or wetland (e.g., a specific ephemeral stream) might be small, but the aggregate contribution by an entire class of streams or wetlands (e.g., all ephemeral streams in the river network) might be substantial. Integrating contributions over time also might be necessary, taking into account the frequency, duration, and timing of material export and delivery.

Table 2-1. Functions by which streams and wetlands affect material and energy fluxes to downstream waters. Arrows indicate material and energy imports to and exports from a stream or wetland, in terms of mass or energy; arrow widths represent relative material mass or energy and differences in arrow shades represent timing (lag) or composition (transformation) changes. Imports to streams and wetlands can come from upland terrestrial areas, other streams and wetlands, or from the river itself. Arrows are meant to be illustrative, and do not necessarily represent upstream/downstream relationships. For example, materials and energy can move downstream, upstream, or laterally into streams and wetlands. Examples of commonly exchanged materials and energy include water, heat energy, nutrients, contaminants, sediment, particulate organic matter, organisms, and reproductive propagules; note that exchange of materials and energy between streams and wetlands and downstream systems can result in positive or negative effects on downstream waters.

Function	Definition	Examples
	Net increase in a material or energy flux (exports > imports)	*Streams*: invertebrate production (Wipfli and Gregovich, 2002) *Wetlands*: phytoplankton production from floodplain (Schemel et al., 2004; Lehman et al., 2008)
	Net decrease in a material or energy flux (exports < imports)	*Streams*: upstream fish populations that are not sustainable without net immigration from downstream areas (Woodford and McIntosh, 2010) *Wetlands*: sediment deposition, denitrification (Johnston, 1991)
	Avoidance of a nearby sink function, thereby preventing a net decrease in material or energy flux (exports = imports)	*Streams*: headwaters as summer coldwater refuges (Curry et al., 1997) *Wetlands*: riparian wetlands as aquatic refuges in dryland rivers (Leigh et al., 2010)
	Temporary storage and subsequent release of materials or energy without affecting cumulative flux (exports = imports); delivery is delayed and can be prolonged	*Streams*: delay of downstream peak flows due to bank storage (Burt, 1997); temporary heat storage within the alluvial aquifer (Arrigoni et al., 2008) *Wetlands*: flood attenuation (Bullock and Acreman, 2003)
	Conversion of a material or energy into a different form; the amount of the base material or energy is unchanged (base exports = base imports), but its composition (e.g., mass of the different forms) can vary	*Streams*: conversion of coarse to fine particulate organic matter (Wallace et al., 1995) *Wetlands*: mercury methylation (Galloway and Branfireun, 2004; Selvendiran et al., 2008)

Considering the cumulative material fluxes that originate from a specific stream or wetland, rather than the individual materials separately, is essential in understanding the effects of material fluxes on downstream waters (Section 1.2.3).

In general, the more frequently a material is delivered to a river, the greater its effect. The effect of an infrequently supplied material, however, can be large if the material has a long residence time in the river (Leibowitz et al., 2008). For example, woody debris might be exported to downstream waters infrequently but it can persist in downstream channels. In addition, some materials are more important in defining the structure and function of a river. Using the same example, woody debris can have a large effect on river structure and function because it affects water flow, sediment and organic matter transport, and habitat (Harmon et al., 1986; Gurnell et al., 1995). Another example is salmon migrating to a river: They can serve as a keystone species to regulate other populations and as a source of marine-derived nutrients (Schindler et al., 2005).

2.3.2 Connectivity and Transport of Materials to and from Streams and Wetlands

2.3.2.1 Connectivity and Isolation

The functions discussed above represent general mechanisms by which streams and wetlands influence downstream waters. For these altered material and energy fluxes to affect a river, however, transport mechanisms that deliver (or could deliver) these materials to the river are necessary. **Connectivity** describes the degree to which components of a system are connected and interact through various transport mechanisms; connectivity is determined by the characteristics of both the physical landscape and the biota of the specific system. This definition is related to, but is distinct from, definitions of connectivity based on the actual flow of materials between system components (e.g., Pringle, 2001). That connectivity among river-system components, including streams and wetlands, plays a significant role in the structure and function of these systems is not a new concept. In fact, much of the theory developed to explain how these systems work focuses on connectivity and linkages between system components (e.g., Section 1.2; Vannote et al., 1980; Newbold et al., 1982a; Newbold et al., 1982b; Junk et al., 1989; Ward, 1989; Benda et al., 2004; Thorp et al., 2006).

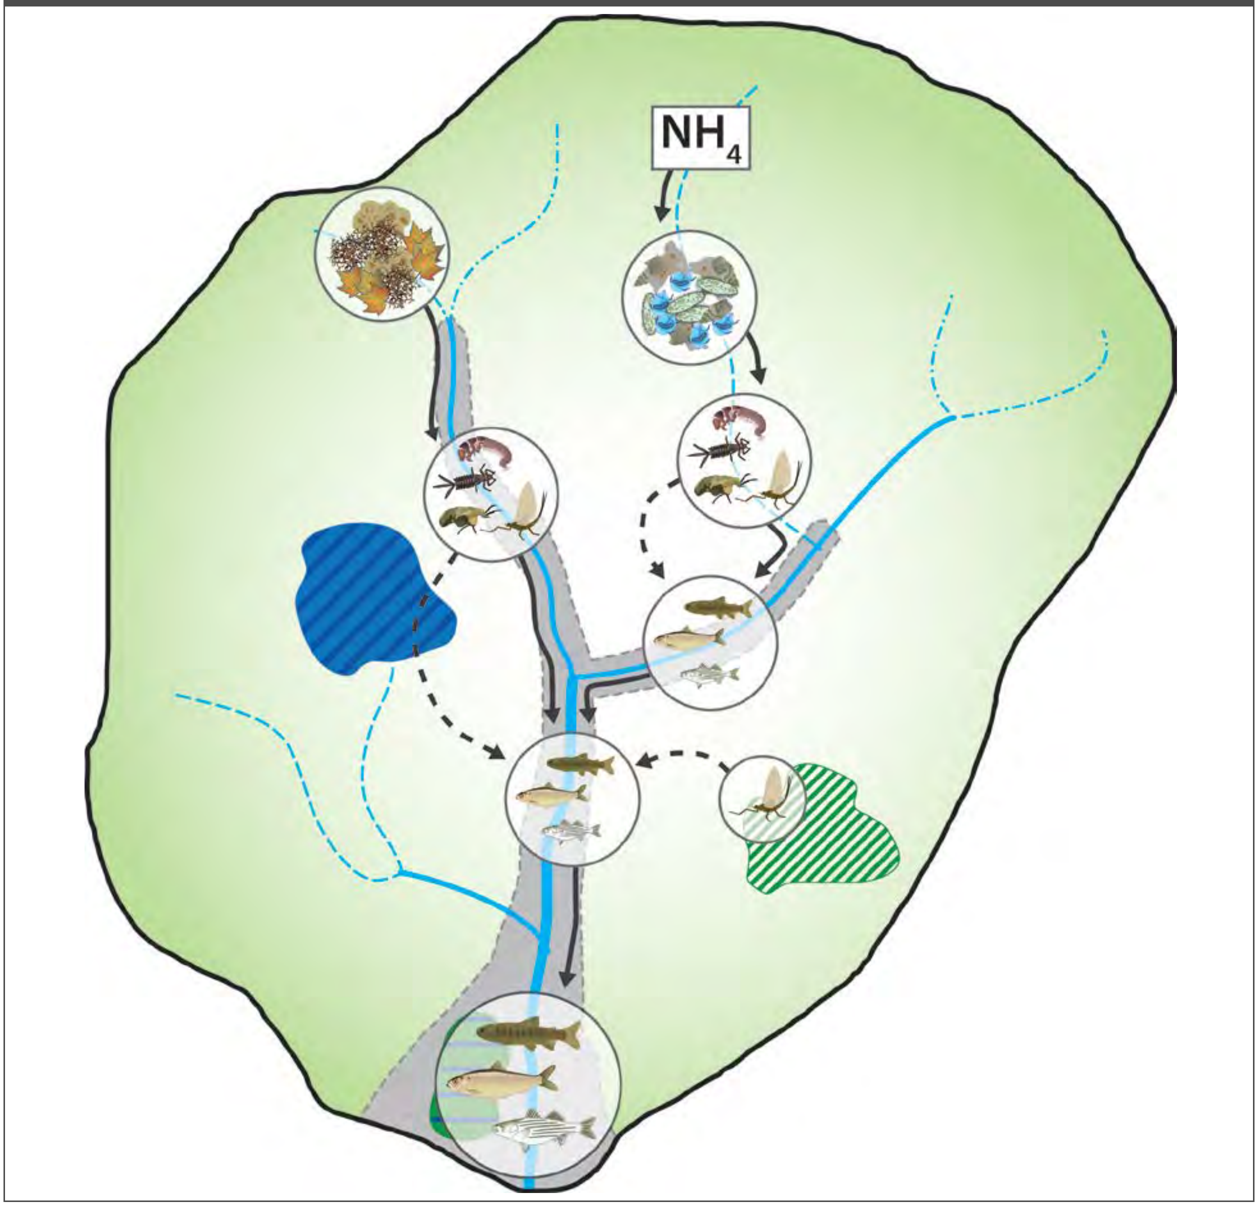
In addition to its central role in defining river systems (Section 2.2.1), water movement through the river system (Figure 2-6) is the primary mechanism providing physical connectivity both within river networks and between those networks and the surrounding landscape (Fullerton et al., 2010). Hydrologic connectivity results from the flow of water, which provides a "hydraulic highway" (Fausch et al., 2002) along which physical, chemical, and biological materials associated with the water are transported (e.g., sediment, woody debris, contaminants, organisms).

Ecosystem function within a river system is driven by interactions between the river system's physical environment and the diverse biological communities living within it (Wiens, 2002; Schroder, 2006). Thus, river system structure and function also depend on biological connectivity among the system's populations of aquatic and semiaquatic organisms. Biological connectivity refers to the movement of organisms, including transport of reproductive materials (e.g., seeds, eggs, genes) and dormant stages, through river systems. These movements link aquatic habitats and populations in different locations through several processes important for the survival of individuals, populations, and species (Sections 3.5, 4.3.4, and 4.4.4). Movements include dispersal, or movement away from an existing population or parent organism; migration, or long-distance movements occurring seasonally; localized movement over an organism's home range to find food, mates, or refuge from predators or adverse conditions; and movement to different habitats to complete life-cycle requirements. At the population and species levels, dispersal and migration contribute to persistence at local and regional scales via colonization of new habitats (e.g., Hecnar and McLoskey, 1996; Tronstad et al., 2007); location of mates and breeding habitats (Semlitsch, 2008); rescue of small populations threatened with local extinction (Brown and Kodric-Brown, 1977); and maintenance of genetic diversity (e.g., Waples, 2010). These movements can result from passive transport by water, wind, or other organisms (e.g., birds, terrestrial mammals); active movement with or against water flow (e.g., upstream fish migration); or active movement over land (for organisms capable of terrestrial dispersal) or through the air (for birds or insects capable of flight; Figure 1-1B). Thus, biological connectivity can occur within aquatic ecosystems or across ecosystem or watershed boundaries, and it can be multidirectional. For example, organisms can move downstream from perennial, intermittent, and ephemeral headwaters to rivers; upstream from estuaries to rivers to headwaters; and laterally between floodplain wetlands, geographically isolated wetlands, rivers, lakes, or other water bodies. Significant biological connectivity can also exist between aquatic and terrestrial habitats (Nakano et al., 1999; Gibbons, 2003; Baxter et al., 2004), but our focus is on connections among components of aquatic systems (Section 1.3).

As noted in Section 2.2.3, streams and rivers are not pipes (Bencala, 1993; Bencala et al., 2011); they provide opportunities for water to interact with internal components (e.g., alluvium, organisms) through the five functions by which streams and wetlands alter material fluxes (Table 2-1). Connectivity between streams and wetlands provides opportunities for material and energy fluxes to be altered sequentially by multiple streams and wetlands as the materials are transported downstream. The aggregate effect of these sequential fluxes determines the proportion of material that ultimately reaches the river. The form of the exported material can change as it moves down the river network (Figure 2-14), however, making quantitative assessments of the importance of individual stream and wetland resources within the entire river system difficult. For example, organic matter can be exported from headwater streams and consumed by downstream macroinvertebrates (Figure 2-14). Those invertebrates can drift farther downstream and be eaten by juvenile fish that eventually move into the mainstem of the river, where they continue to feed and grow.

The assessment of stream and wetland influence on rivers also is complicated by the cumulative time lag resulting from these sequential transformations and transportations. For example, removal of nutrients by streambed algal and microbial populations, subsequent feeding by fish and insects, and release by excretion or decomposition delays the export of nutrients downstream (Figure 2-14).

Figure 2-14. Illustration of the sequential transformation of materials as they move through the river network, via either downstream transport with water flow (solid black arrows) or via aerial or terrestrial movements (dashed black arrows). Here, an ephemeral headwater stream exports organic matter (at left) and an intermittent headwater stream exports ammonium, which is incorporated into algal biomass (at right). Macroinvertebrates consume these basal food resources and transform them into biomass, which in turn is eaten and transformed into fish biomass in both local and downstream reaches.



The opposite of connectivity is **isolation**, or the degree to which transport mechanisms (i.e., pathways between system components) are lacking; isolation acts to reduce material fluxes between system components. Although here we primarily focus on the benefits that connectivity can have on downstream systems, isolation also can have important positive effects on the condition and function of downstream waters. For example, waterborne contaminants that enter a wetland cannot be transported to a river if the wetland is hydrologically isolated from the river, except by nonhydrologic pathways. Increased isolation can decrease the spread of pathogens (Hess, 1996) and invasive species (e.g., Bodamer and Bossenbroek, 2008), and increase the rate of local adaptation (e.g., Fraser et al., 2011). Thus, both connectivity and isolation should be considered when examining material fluxes from streams and wetlands, and biological interactions should be viewed in light of the natural balance between these two factors.

When assessing the effects of connectivity or isolation and the five general functions (sources, sinks, refuges, lags, and transformations; Table 2-1) on downstream waters, dimensions of time and space must be considered. Water or organisms transported from distant headwater streams or wetlands generally will take longer to travel to a larger river than materials transported from streams or wetlands near the river (Section 2.4.2). This can introduce a lag between the time the function occurs and the time the material arrives at the river. In addition, the distribution of streams and wetlands can be a function of their distance from the mainstem channel. For example, in a classic dendritic network, there is an inverse geometric relationship between number of streams and stream order. In such a case, the aggregate level of function could be greater for terminal source streams, compared to higher order or lateral source streams. This is one reason why watersheds of terminal source streams often provide the greatest proportion of water for major rivers. Connectivity, however, results from many interacting factors (Section 2.4.5). For example, the relationship between stream number and order can vary with the shape of the watershed and the configuration of the network (Section 2.4.2). Thus, caution must be exercised when generalizing about these spatial and temporal relationships. Spatial and temporal variability of connectivity is discussed below, and the factors influencing them are considered in Section 2.4.

2.3.2.2 Spatial and Temporal Variability of Connectivity

Connectivity is not a fixed characteristic of a system, but varies over space and time (Ward, 1989; Leibowitz, 2003; Leibowitz and Vining, 2003). Variability in hydrologic connectivity results primarily from the longitudinal (Figures 2-8 and 2-10) and lateral (Figure 2-12) expansion and contraction of the river network and transient connection with other components of the river system (Section 2.2.3). The variability of connectivity can be described in terms of frequency, duration, magnitude, timing, and rate of change (Section 1.2.2).

The expansion and contraction of river networks affect the extent, magnitude, timing, and type of hydrologic connectivity. For example, intermittent and ephemeral streams (Figure 2-7) flow only during wetter seasons (Section 2.4) or during and immediately following precipitation events. Thus, the spatial extent of connectivity between streams and wetlands and rivers increases greatly during these high-flow events because intermittent and ephemeral streams are estimated to account for 59% of the total length of streams in the contiguous United States (Nadeau and Rains, 2007). Changes in the spatial extent of connectivity due to expansion and contraction are even more pronounced in the arid and semiarid Southwest, where more than 80% of all streams are intermittent or ephemeral (Figures 2-9B and B-5; Levick et al., 2008). Expansion and contraction also affect the magnitude of connectivity because larger flows provide greater potential for material transport (e.g., Section 3.3.2).

Besides affecting the spatial extent and magnitude of hydrologic connectivity, expansion and contraction of the stream network also affect the duration and timing of flow in different portions of the network. Perennial streams have year-round connectivity with a downstream river, whereas intermittent streams have seasonal connectivity. The temporal characteristics of connectivity for ephemeral streams depend on the duration and timing of storm events (Figure B-10). Similarly, connectivity between wetlands and downstream waters can range from permanent to seasonal to episodic.

The expansion and contraction of river systems also affect the type of connectivity. For example, during wet periods when input from precipitation can exceed evapotranspiration and available storage, non-floodplain wetlands could have connectivity with other wetlands or streams through surface spillage (Leibowitz and Vining, 2003; Rains et al., 2008). When spillage ceases due to drier conditions, hydrologic connectivity could only occur through ground water (Rains et al., 2006; Rains et al., 2008).

When the flow of water mediates dispersal, migration, and other forms of biotic movement, biological and hydrologic connectivity can be tightly coupled. For example, seasonal flooding of riparian/floodplain wetlands creates temporary habitat that fish, aquatic insects, and other organisms use (Junk et al., 1989; Smock, 1994; Tockner et al., 2000; Robinson et al., 2002; Tronstad et al., 2007). Factors other than hydrologic dynamics also can affect the temporal and spatial dynamics of biological connectivity. Such factors include movement associated with seasonal habitat use (Moll, 1990; Lamoureux and Madison, 1999) and shifts in habitat use due to life-history changes (Huryn and Gibbs, 1999; Gibbons et al., 2006; Subalusky et al., 2009a), quality or quantity of food resources (Smock, 1994), presence or absence of favorable dispersal conditions (Schalk and Luhring, 2010), physical differences in aquatic habitat structure (Grant et al., 2007), or the number and sizes of nearby populations (Gamble et al., 2007). For a specific river system with a given spatial configuration, variability in biological connectivity also occurs due to variation in the dispersal distance of organisms and reproductive propagules (Section 2.4.4; Semlitsch and Bodie, 2003).

Finally, just as connectivity from temporary or seasonal wetting of channels can affect downstream waters, temporary or seasonal drying also can affect river networks. Riverbeds or streambeds that temporarily dry up are used by aquatic organisms that are specially adapted to wet and dry conditions, and can serve as egg and seed banks for several organisms, including aquatic invertebrates and plants (Steward et al., 2012). These temporary dry areas also can affect nutrient dynamics due to reduced microbial activity, increased oxygen availability, and inputs of terrestrial sources of organic matter and nutrients (Steward et al., 2012).

2.4 Factors Influencing Connectivity

Numerous factors affect physical, chemical, and biological connectivity within river systems. These factors operate at multiple spatial and temporal scales, and interact with each other in complex ways to determine where components of a system fall on the connectivity-isolation gradient at a given time. In this section, we focus on four key factors—climate-watershed characteristics, spatial distribution patterns, biota, human activities and alterations. These are by no means the only factors influencing connectivity, but they illustrate how many different variables shape physical, chemical, and biological connectivity. We also examine how interactions among different factors influence connectivity, using as an example wetlands in the prairie pothole region.

2.4.1 Climate-Watershed Characteristics

The movement and storage of water in watersheds varies with climatic, geologic, physiographic, and edaphic characteristics of river systems (Winter, 2001; Wigington et al., 2013). At the largest spatial scale, climate determines the amount, timing, and duration of water available to watersheds and river basins. Key characteristics of water availability that influence connectivity include annual water surplus (precipitation minus evapotranspiration), timing (seasonality) of water surplus during the year that is heavily influenced by precipitation timing and form (e.g., rain, snow), and rainfall intensity.

Annual runoff generally reflects water surplus and varies widely across the United States (Figure 2-15). Seasonality of water surplus during the year determines when and for how long runoff and ground-water recharge occur. Precipitation and water surplus in the eastern United States is less seasonal than in the West (Finkelstein and Truppi, 1991). The Southwest experiences summer monsoonal rains (Section B.5), whereas the West Coast and Pacific Northwest receive most precipitation during the winter season (Wigington et al., 2013). Throughout the West, winter precipitation in the mountains occurs as snowfall, where it accumulates in seasonal snowpack and is released during the spring and summer melt seasons to sustain streamflow during late spring and summer months (Brooks et al., 2012). The flowing portions of river networks tend to have their maximum extent during seasons with the highest water surplus (Section 2.2.3; Figure 2-10), when conditions for flooding are most likely. Typically, the occurrence of ephemeral and intermittent streams is greatest in watersheds with low annual runoff and high water surplus seasonality but also is influenced by watershed geologic and edaphic features (Gleeson et al., 2011).

Rainfall intensity can affect hydrologic connectivity in localities where watershed surfaces have low infiltration capacities relative to rainfall intensities. Infiltration-excess overland flow occurs when rainfall intensity exceeds watershed surface infiltration, and it can be an important mechanism in providing water to wetlands and river networks (Goodrich et al., 1997; Levick et al., 2008). Overland flow is common at low elevations in the Southwest, due to the presence of desert soils with low infiltration capacities combined with relatively high rainfall intensities (Section B.5). The Pacific Northwest has low rainfall intensities, whereas many locations in the Mid-Atlantic, Southeast, and Great Plains have higher rainfall intensities. The prevalence of impermeable surfaces in urban areas can generate overland flow in virtually any setting (Booth et al., 2002).

River system topography and landscape form can profoundly influence river network drainage patterns, distribution of wetlands, and ground-water and surface-water flowpaths. Winter (2001) described six generalized hydrologic landscape forms (Figure 2-16) common throughout the United States. Mountain

Figure 2-15. Map of annual runoff in contiguous United States showing locations of five example streams that illustrate daily runoff patterns and total annual runoff depths. (A) Rapidan River, VA; (B) Noyo River, CA; (C) Crystal River, CO; (D) San Pedro River, AZ; and (E) Metolius River, OR. All data are from http://waterdata.usgs.gov/usa/nwis/sw (downloaded June 27, 2011). Runoff can be conceived as the difference between precipitation and evapotranspiration at the watershed scale. The varied runoff patterns in the five rivers result from divergent climate, geology, and topography.

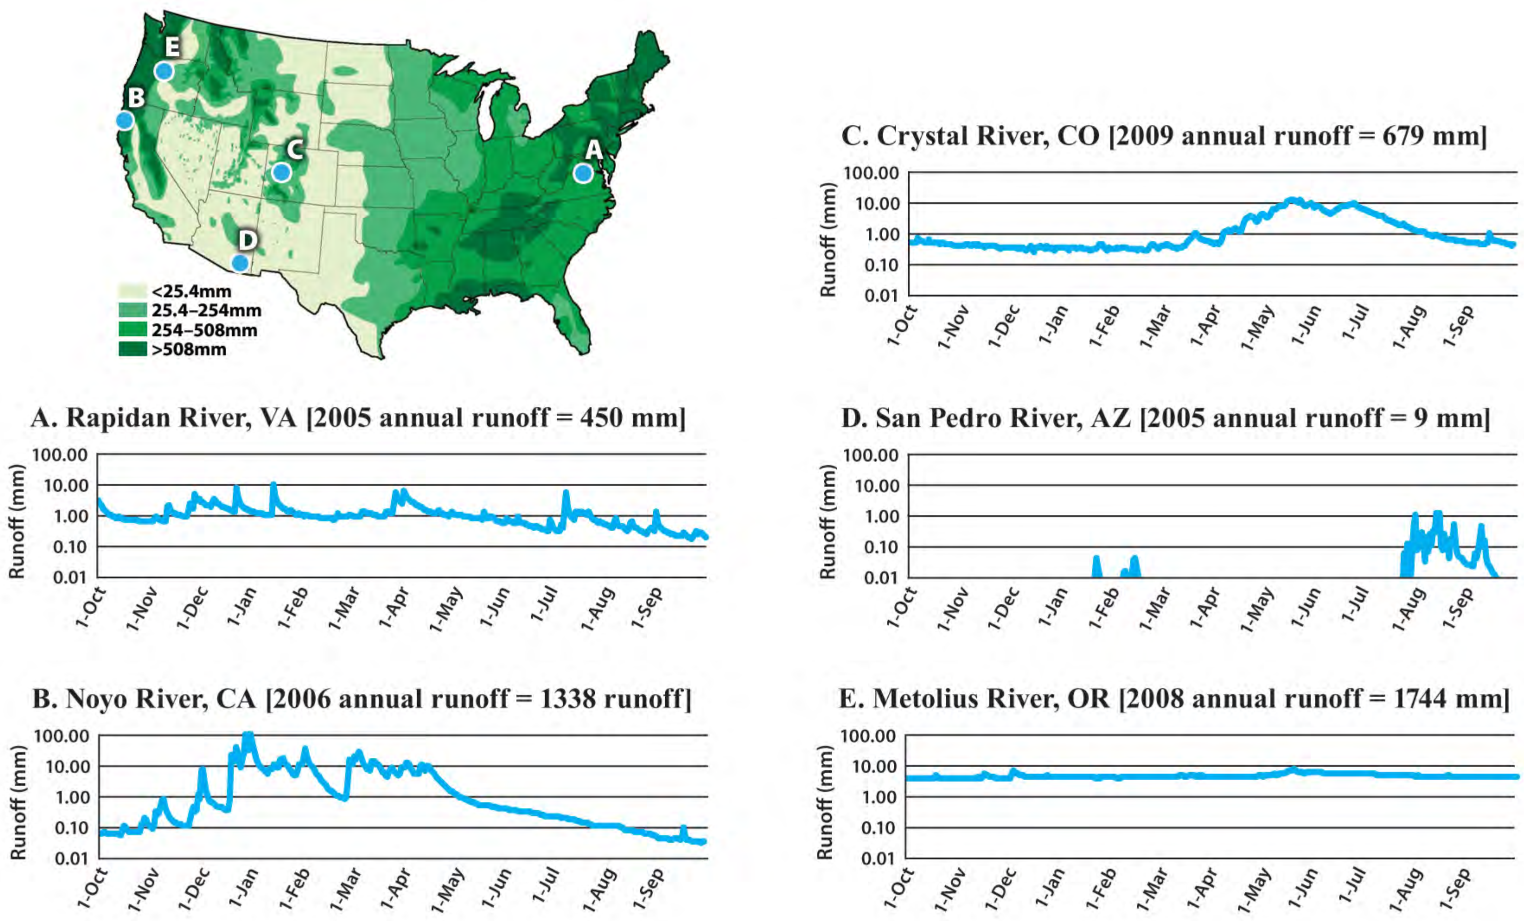


Figure 2-16. Generalized hydrologic landscape forms. (A) Mountain Valley: narrow uplands and lowlands separated by large steep valley sides; (B) Playa: large broad lowland separated from narrow uplands by steeper valley sides (playas and basins of interior drainage); (C) Plateau and High Plains: small narrow lowlands separated from broad uplands by steeper valley sides; (D) Riverine Valley: small fundamental landscape units nested inside broader fundamental landscape unit; (E) Coastal Terrain: small fundamental landscape units nested inside broader fundamental landscape unit (coastal plain with terraces and scarps); and (F) Hummocky Terrain: small fundamental landscape units superimposed randomly on larger fundamental landscape unit. A fundamental hydrologic landscape unit is defined by land-surface form, geology, and climate. Modified from Winter (2001).

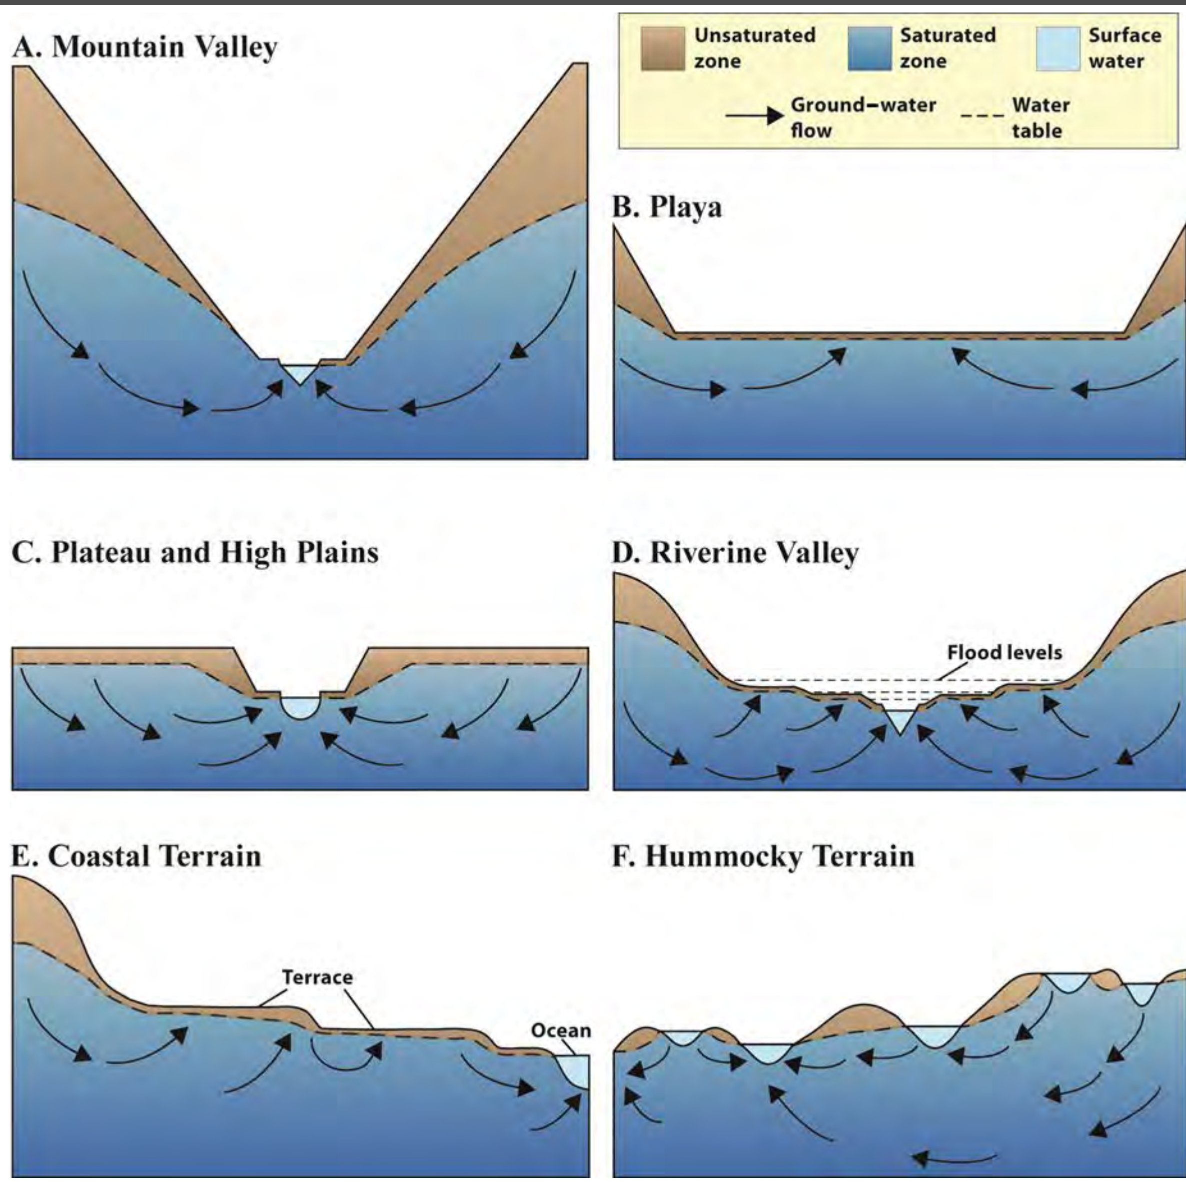
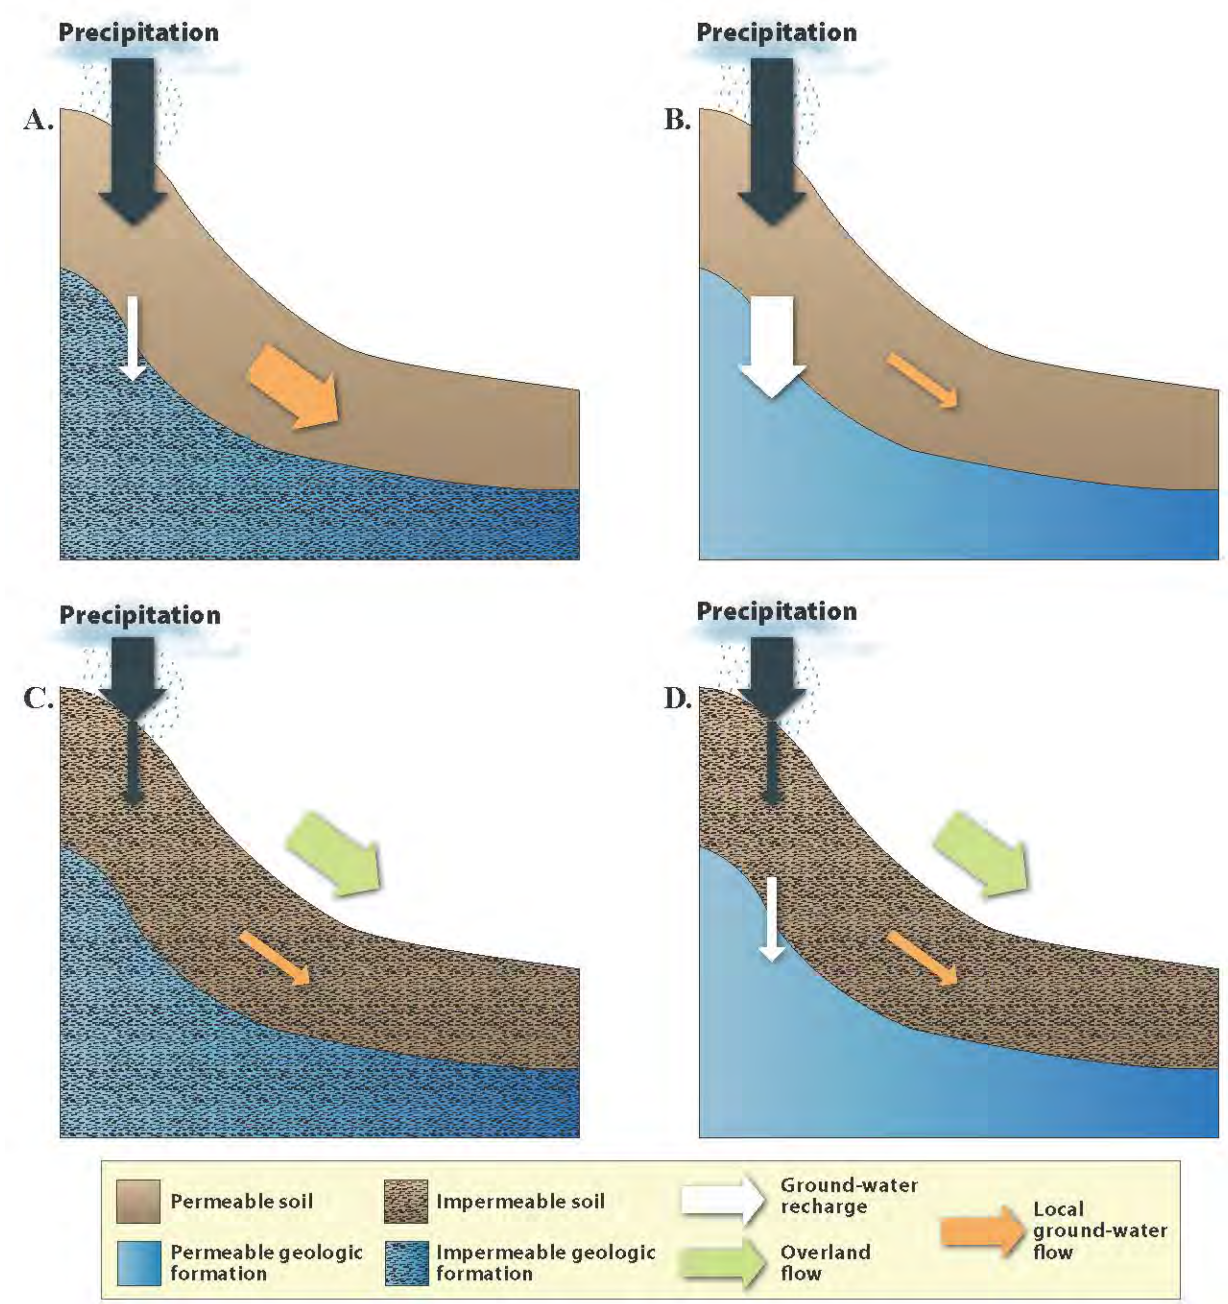


Valleys (Figure 2-16A) and Plateaus and High Plains (Figure 2-16C) have constrained valleys through which streams and rivers flow. The Mountain Valleys form has proportionally long, steep sides with narrow to nonexistent floodplains resulting in the rapid movement of water downslope. In contrast, Riverine Valleys (Figure 2-16D) have extensive floodplains that promote strong surface-water, hyporheic water, and alluvial ground-water connections between wetlands and rivers. Small changes in water table elevations can influence the water levels and hydrologic connectivity of wetlands over extensive areas in this landscape form (Figure 2-16D). Local ground-water flowpaths are especially important in Hummocky Terrain (Figure 2-16F). Constrained valleys, such as the Mountain Valley landform (Figure 2-16A), have limited opportunities for the development of floodplains and alluvial aquifers, whereas unconstrained valleys, such as the Riverine Valley landform (Figure 2-16D), provide opportunities for the establishment of floodplains. Some river basins can be contained within a single hydrologic landscape form, but larger river basins commonly comprise complexes of hydrologic landscape forms. For example, the James River in Virginia, which flows from mountains through the Piedmont to the Coastal Plain, is an example of a Mountain Valley-High Plateaus and Plains-Coastal Terrain-Riverine Valley complex.

Floodplain hydrologic connectivity to rivers and streams occurs primarily through overbank flooding, shallow ground-water flow, and hyporheic flow (Section 2.2). Water-table depth can influence connectivity across a range of hydrologic landscape forms, but especially in floodplains. Rivers and wetlands can shift from losing reaches (or recharge wetlands) during dry conditions to gaining reaches (or discharge wetlands) during wet conditions. Wet, high water-table conditions influence both ground-water and surface-water connectivity. When water tables are near the watershed surface, they create conditions in which swales and small stream channels fill with water and flow to nearby water bodies (Wigington et al., 2003; Wigington et al., 2005). Nanson and Croke (1992) noted that a complex interaction of fluvial processes forms floodplains, but their character and evolution are essentially a product of stream power (the rate of energy dissipation against the bed and banks of a river or stream) and sediment characteristics. They proposed three floodplain classes based on the stream power-sediment characteristic paradigm: (1) high-energy noncohesive, (2) medium-energy noncohesive, and (3) low-energy cohesive. The energy term describes stream power during floodplain formation, and the cohesiveness term depicts the nature of material deposited in the floodplain. The cohesiveness term is also related to the hydraulic properties of alluvial aquifers. Alluvium for Class 1 and 2 floodplains tends to have higher hydraulic conductivity, or a higher rate at which water moves through a saturated, permeable soil or rock layer, than Class 3 floodplains. The higher the hydraulic conductivity of an alluvial aquifer, the greater the exchange rate between the alluvial aquifer and river waters (Whiting and Pomeranets, 1997). In addition, hyporheic and alluvial aquifer exchanges are more responsive to seasonal discharge changes in floodplains with complex topography (Poole et al., 2006).

Within hydrologic landscape forms, soil and geologic formation permeabilities are important determinants of hydrologic flowpaths (Figure 2-17). Permeable soils promote infiltration that results in ground-water hydrologic flowpaths (Figures 2-17A and 2-17B), whereas the presence of impermeable soils with low infiltration capacities is conducive to overland flow (Figures 2-17C and 2-17D). In situations in which ground-water outflows from watersheds or landscapes dominate, the fate of water depends in part on the permeability of deeper geologic strata. The presence of an aquiclude near the watershed surface leads to shallow subsurface flows through soil or geologic materials (Figure 2-17A).

Figure 2-17. Major hydrologic flowpaths for hillslopes with combinations of permeable and impermeable soils and geologic formations. (A) Permeable soil and impermeable underlying geologic formation; (B) permeable soil and permeable underlying geologic formation; (C) impermeable soil and impermeable underlying geologic formation; and (D) impermeable soil and permeable underlying geologic formation. Width of arrow indicates relative magnitude of flow. Note that pavement can be another source of impermeable surfaces and subsequent overland flow in anthropogenically influenced settings.



These local ground-water flowpaths connect portions of watersheds to nearby wetlands or streams (Figure 2-3). Alternatively, if a deep permeable geologic material (an aquifer) is present, water is likely to move farther downward within watersheds and recharge deeper aquifers (Figure 2-17B). The permeability of soils and geologic formations both can influence the range of hydrologic connectivity between non-floodplain wetlands and river networks. For example, a wetland that is the origin of a stream can have a permanent or temporary surface-water connection with downstream waters through a channelized outlet (Figure 2-18A); a wetland can be connected to downstream waters by transient surface-water flows through swales (Figure 2-18B) or by shallow ground-water flows (Figure 2-18C); or a wetland can be hydrologically isolated from downstream waters (Figure 2-18D) because it recharges a deep ground-water aquifer that does not feed surface waters, or it is located in a basin where evapotranspiration is the dominant form of water loss.

The importance of climate-watershed interactions in determining the amount and seasonality of water surpluses, the timing and duration of streamflow, and thus the timing and extent of hydrologic connectivity, is illustrated by annual hydrographs for five rivers in different regions of the United States (Figure 2-15).

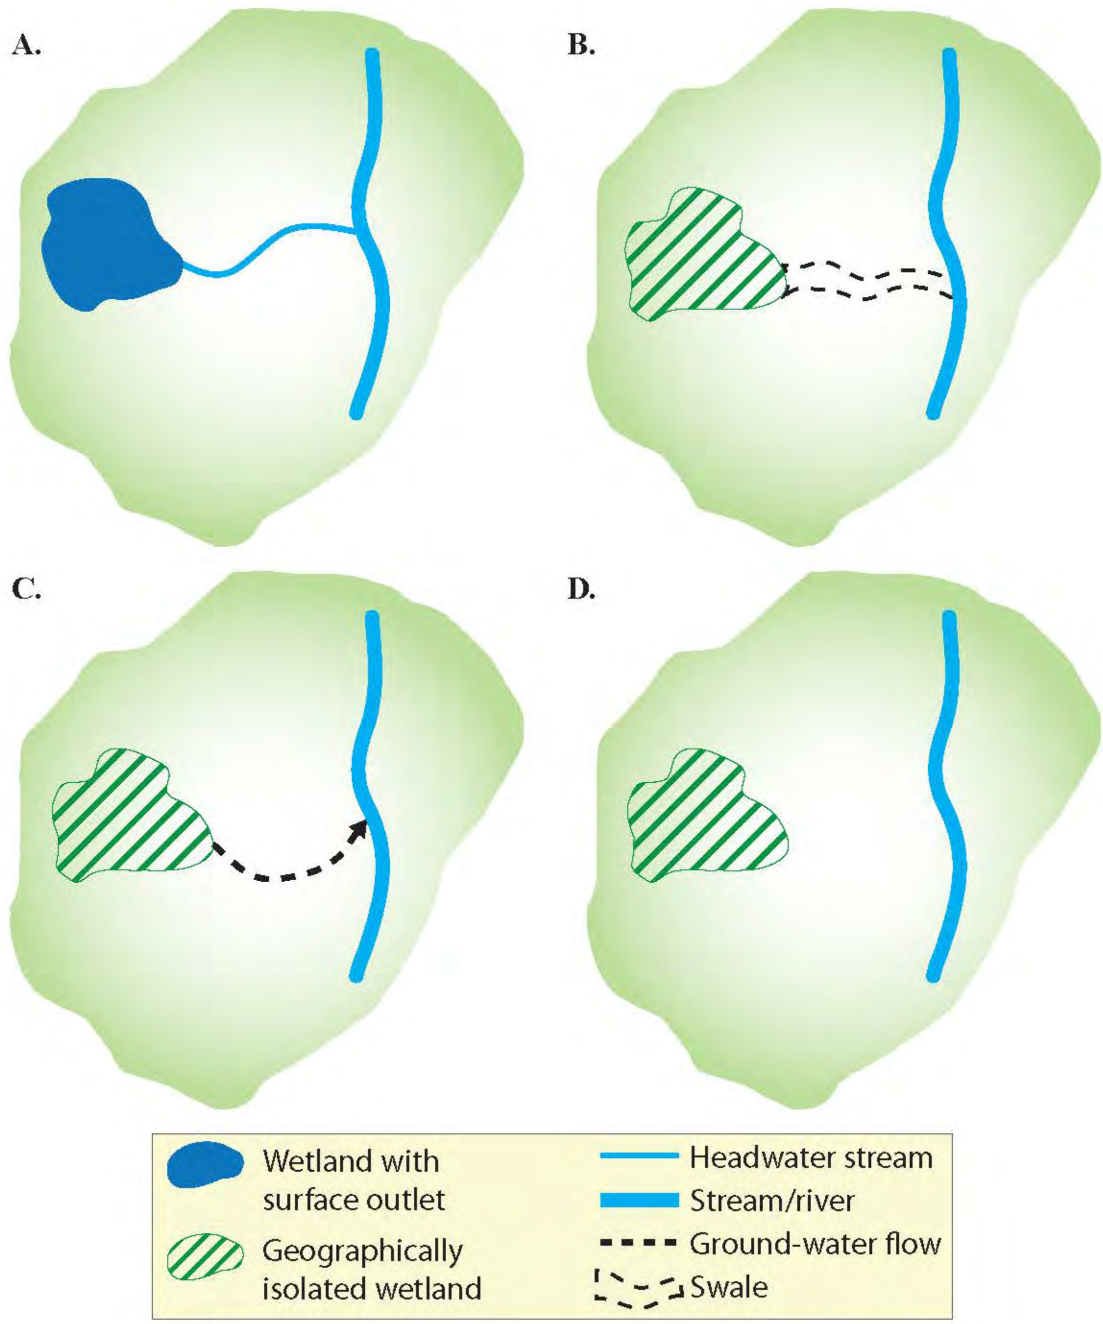
The hydrograph for the Rapidan River in Virginia (Figure 2-15A) illustrates the uniform annual precipitation pattern of the East (with small variations due to increased evapotranspiration in the summer months) interacting with a steep Blue Ridge Mountain watershed comprising metamorphic bedrock with alluvial and colluvial fill in the lower riparian areas (Castro and Hornberger, 1991). Hydrologic events driven by rainfall can occur anytime during the year, but are especially common in winter and spring months; these events result in expansion of the river network as ephemeral streams flow. Baseflow sustains perennial flow over a large part of the network.

Located in a region of steep slopes and impermeable bedrock (Mayer and Naman, 2011), the Noyo River watershed in California (Figure 2-15B) has highly seasonal water surplus because rainfall occurs primarily from November through May and the impermeable bedrock prevents precipitation water from moving to deep ground water. Consequently, runoff timing is similar to precipitation temporal patterns. Total runoff for the basin is high, and baseflow levels are high during the winter and low during the dry summer season. These low baseflow periods create conditions favorable for intermittent flows in streams with significant channel alluvium (Wigington et al., 2006).

The Crystal River of Colorado (Figure 2-15C) drains a glaciated landscape in the upper portion of the Gunnison River in the Colorado Rocky Mountains. It has protracted high flow during the spring that is controlled by the accumulation and melting of snow in the basin's higher elevations during the winter and subsequent melting during spring and summer. This streamflow pattern also promotes the occurrence of intermittently flowing streams due to large water surplus differences between the high-flow and low-flow periods.

Total runoff in the San Pedro River, Arizona is low (Figure 2-15D), and short, intense rainstorms during the summer monsoons commonly drive hydrologic events (Levick et al., 2008). Because a major proportion of water reaching the San Pedro River originates as overland flow to ephemeral streams that ultimately flow to the mainstem river, baseflow is limited (Section B-5). In other San Pedro River

Figure 2-18. Types of hydrologic connections between non-floodplain wetlands and streams or rivers. (A) A wetland connected to a river by surface flow through a headwater stream channel. (B) A wetland connected to a river by surface flow through a nonchannelized swale. Such a wetland would be considered geographically isolated if the swale did not meet the Cowardin et al. (1979) three-attribute wetland criteria. (C) A geographically isolated wetland connected to a river by ground-water flow (flowpath can be local, intermediate, or regional). (D) A geographically isolated wetland that is hydrologically isolated from a river. Note that in A–C, flows connecting the wetland and river may be perennial, intermittent, or ephemeral.



mainstem reaches, ground-water flow from regional and alluvial aquifers supports baseflow (Dickinson et al., 2010). Like the Crystal River, the Metolius River in Oregon (Figure 2-15E) also has snowpack in its higher elevations, but geologic conditions in the watershed alter the climate signal. Meltwaters in the Metolius River flow through long flowpaths in porous bedrock to springs in or near the river (James et al., 2000; Gannett et al., 2001). Although intermittent and ephemeral streams occur in the Metolius basin, most streams are spring-fed and perennial.

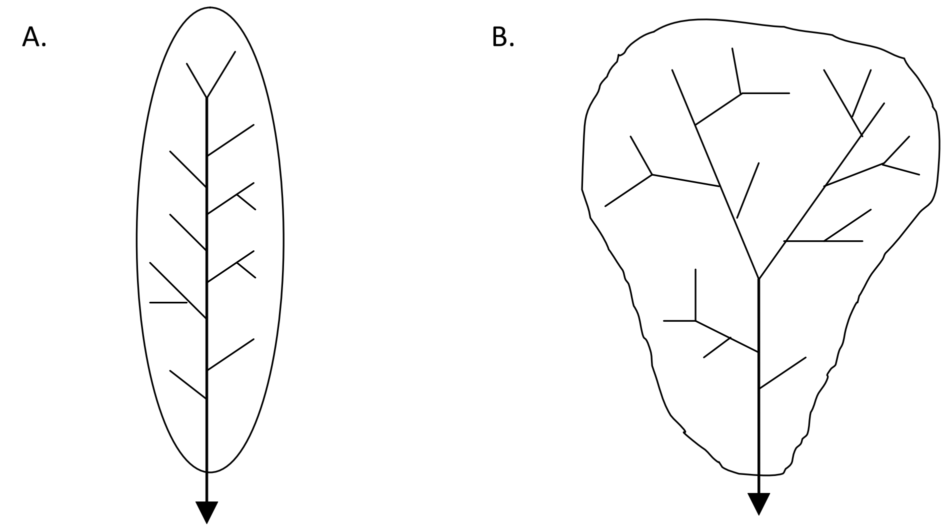
2.4.2 Spatial Distribution Patterns

Climate and watershed characteristics directly affect spatial and temporal patterns of connectivity between streams and wetlands and rivers by influencing the timing and extent of river network expansion and contraction. They also influence the spatial distribution of water bodies within a watershed (e.g., Tihansky, 1999), and in particular, the spatial relationship between those water bodies and the river.

Hydrologic connectivity between streams and rivers can be a function of the distance between the two water bodies (Bracken and Croke, 2007; Peterson et al., 2007). If channels functioned as pipes, this would not be the case, and any water and its constituent materials exported from a stream eventually would reach the river. Because streams and rivers are not pipes (Section 2.2.3; Bencala, 1993), water can be lost from the channel through evapotranspiration and bank storage and diluted through downstream inputs. Thus, material from a headwater stream that flowed directly into the river would be subject to less transformation or dilution. On the other hand, the greater the distance a material travels between a particular stream reach and the river, the greater the opportunity for that material to be altered (e.g., taken up, transformed, or assimilated) in intervening stream reaches; this alteration could reduce the material's direct effect on the river, but it could also allow for beneficial transformations. For example, organic matter exported from a headwater stream located high in a drainage network might never reach the river in its original form, instead becoming reworked and incorporated into the food web (Figure 2-14). Similarly, higher order streams generally are located closer to rivers and, therefore, can have higher connectivity than upstream reaches of lower order. Note that although an individual low-order stream can have less connectivity than a high-order stream, a river network has many more low-order streams, which can represent a large portion of the watershed (Section 3.2); thus, the magnitude of the cumulative effect of these low-order streams can be significant.

The relationship between streams and the river network is a function of basin shape and network configuration. Elongated basins tend to have trellis networks where relatively small streams join a larger mainstem (Figure 2-19A); compact basins tend to have dendritic networks with tree-like branching, where streams gradually increase in size before joining the mainstem (Figure 2-19B). This network configuration describes the incremental accumulation of drainage area along rivers, and therefore provides information about the relative contributions of streams to downstream waters. Streams in a trellis network are more likely to connect directly to a mainstem, compared with a dendritic network. The relationship between basin shape, network configuration, and connectivity, however, is complex. A mainstem in a trellis network also is more likely to have a lower stream order

Figure 2-19. Major types of basin shapes and network configurations. (A) A rectangular basin with trellis network, and (B) a compact basin with a dendritic network.



than one in a dendritic network. For example, the lowest reach in the trellis network in Figure 2-19A is a third-order stream, while that of the dendritic network (Figure 2-19B) is a fourth-order stream.

Distance also affects connectivity between non-floodplain and riparian/floodplain wetlands and downstream waters. Riverine wetlands that serve as origins for lateral source streams that connect directly to a mainstem river have a more direct connection to that river than wetlands that serve as origins for terminal source streams high in a drainage network. This also applies to riparian/floodplain wetlands that have direct surface-water connections to streams or rivers. If geographically isolated non-floodplain wetlands have surface-water outputs (e.g., depressions that experience surface-water spillage or ground-water seeps; Figure 2-18B), the probability that surface water will infiltrate or be lost through evapotranspiration increases with distance. For non-floodplain wetlands connected through ground-water flows, less distant areas are generally connected through shallower flowpaths (Figure 2-5), assuming similar soil and geologic properties. These shallower ground-water flows have the greatest interchange with surface waters (Section 2.2.2) and travel between points in the shortest amount of time. Although elevation is the primary factor determining areas that are inundated through overbank flooding, connectivity with the river generally will be higher for riparian/floodplain wetlands located near the river's edge compared with riparian/floodplain wetlands occurring near the floodplain edge.

Distance from the river network also influences biological connectivity among streams and wetlands. For example, mortality of an organism due to predators and natural hazards generally increases with the distance it has to travel to reach the river network. The likelihood that organisms or propagules traveling randomly or by diffusive mechanisms such as wind will arrive at the river network generally decreases as distance increases.

The distribution of distances between wetlands and river networks depends on both the drainage density of the river network (the total length of stream channels per unit area) and the density of wetlands. Climate and watershed characteristics influence these spatial patterns, which can vary widely. For example, a subset of fens in New York State was located closer to each other, on average, than a subset of Carolina bays at the Savannah River Site: The proportion of wetlands located at distances of 0–100, 100–500, and >500 m was 27, 39, and 35%, respectively, for the fens and 12, 44, and 44% for the Carolina bays, respectively (Bedford and Godwin, 2003; Sharitz, 2003). When interpreting such distributions, however, other factors that affect connectivity (e.g., differences in soils or slope) should be considered.

Figure 2-20 compares the spatial distribution of wetlands and streams to the river network in six different landscape settings. The figure shows landscape settings ranging from no nearby streams and dense small wetlands (Figure 2-20A), to a few nearby streams with high wetland density (Figures 2-20B and 2-20C), to less spatially uniform wetlands (Figure 2-20D), to areas with higher drainage densities and riparian (Figure 2-20E) or larger, more extensive (Figure 2-20F) wetlands. The maps in Figure 2-20 are single examples of these various settings, so they might not be representative. They are useful, however, for illustrating the degree to which landscape setting can affect the interspersion—and thus average distance—between wetlands and the river network, and the large variability that can result. In settings having many wetlands and relatively low drainage density (Figures 2-20B, 2-20C, and 2-20D), the distances between individual wetlands and the stream can vary greatly. In contrast, the distances in areas having a higher drainage density (Figure 2-20E and 2-20F) are shorter and vary less. All factors being equal, wetlands closer to the stream network will have greater hydrologic and biological connectivity than wetlands located farther from the same network.

2.4.3 Biota

Biological connectivity results from the interaction of physical characteristics of the environment—especially those facilitating or restricting dispersal—and species' traits or behaviors, such as life-cycle requirements, dispersal ability, or responses to environmental cues (Section 1.2.2). Thus, the types of biota within a river system are integral in determining the river system's connectivity, and landscape features or species traits that necessitate or facilitate movement of organisms tend to increase biological connectivity among water bodies.

Diadromous fauna (e.g., Pacific and Atlantic salmon, certain freshwater shrimps and snails, American eels), which require both freshwater and marine habitats over their life cycles and therefore migrate along river networks, provide one of the clearest illustrations of biological connectivity. Many of these taxa are either obligate or facultative users of headwater streams (Erman and Hawthorne, 1976; Wigington et al., 2006), meaning that they either require (obligate) or can take advantage of (facultative) these habitats; these taxa thereby create a biological connection along the entire length of the river network. For example, many Pacific salmon species spawn in headwater streams, where their young grow for a year or more before migrating downstream, living their adult life stages in the ocean, and then migrating back upstream to spawn. Many taxa also can exploit temporary hydrologic connections

Figure 2-20. Examples of different landscapes showing interspersion of wetlands and streams or rivers. (A) Prairie potholes within the Missouri Coteau in North Dakota; (B) prairie potholes within the Drift Prairie in North Dakota; (C) playas in Texas; (D) vernal pools in California; (E) bottomland hardwood wetlands in Illinois; and (F) Carolina bays in North Carolina. Note all maps are at the same scale. Wetlands smaller than the minimum mapping unit (currently 0.4 ha) might not appear on maps. between rivers and floodplain wetland habitats caused by flood pulses (Section 1.2.1; Junk et al., 1989; Tockner et al., 2000), moving into these wetlands to feed, reproduce, or avoid harsh environmental conditions and then returning to the river network (Copp, 1989; Smock, 1994; Richardson et al., 2005).

Biological connectivity does not solely depend on diadromy, however, as many nondiadromous organisms are capable of significant movement within river networks (Section 1.2.2). For example, organisms such as pelagic-spawning fish and mussels release eggs or larvae that disperse downstream with water flow (e.g., Platania and Altenbach, 1998; Schwalb et al., 2010); many fish swim significant distances both upstream and downstream (e.g., Gorman, 1986; Hitt and Angermeier, 2008); and many aquatic macroinvertebrates move or drift downstream (e.g., Elliott, 1971; Müller, 1982; Brittain and Eikeland, 1988; Elliott, 2003). Taxa capable of movement over land, via either passive transport (e.g., wind dispersal or attachment to animals capable of terrestrial dispersal) or active movement (e.g., terrestrial dispersal or aerial dispersal of winged adult stages), can establish biotic linkages between river networks and wetlands, as well as linkages across neighboring river systems (Hughes et al., 2009).

The fundamental influence that biological connectivity has on species distributions can last long after a system is disconnected. In a global analysis of freshwater fish diversity, Dias et al. (2014) found that paleoconnected drainage basins (basins that had hydrologic connections during the most recent glacial maximum) currently have greater species richness and lower endemism and beta diversity than paleodisconnected basins. This study indicates that hydrologic connectivity, by allowing dispersal of aquatic organisms, can have a long-lasting legacy effect on the geographic distribution of species.

The examples discussed above illustrate how environmental characteristics provide the physical structure through which biological connectivity occurs, as mediated by biological traits and behavior. The physical structure of the environment is not static, however, and also can be altered by biological behavior. The beaver (*Castor canadensis*) is a keystone species that builds dams that can alter connectivity in several ways. Most obviously, beaver dams reduce hydrologic connectivity by impounding streams and modifying conditions above the dam from lotic to lentic. The area impounded by beaver dams can be large: In the Kabetogama Peninsula of Minnesota, impounded area accounted for up to 13% of the landscape, with an average pond area of about 4 ha (Johnston and Naiman, 1990a, b). In a review of the effects of beaver on stream ecosystems, Collen and Gibson (2001) noted that, although the hydrologic effects of a single beaver dam can be small, the impact of a series of dams on streams can be significant; for example, up to 30% of the water in an Oregon catchment was impounded by beaver dams. Such dams can directly affect material transport (e.g., the ability of the stream to carry sediment is reduced) and alter biogeochemical characteristics (Naiman et al., 1994; Collen and Gibson, 2001). Beaver dams also can affect biological connectivity, for example, by obstructing upstream migration, and cause changes in fish distributions (Collen and Gibson, 2001).

2.4.4 Human Activities and Alterations

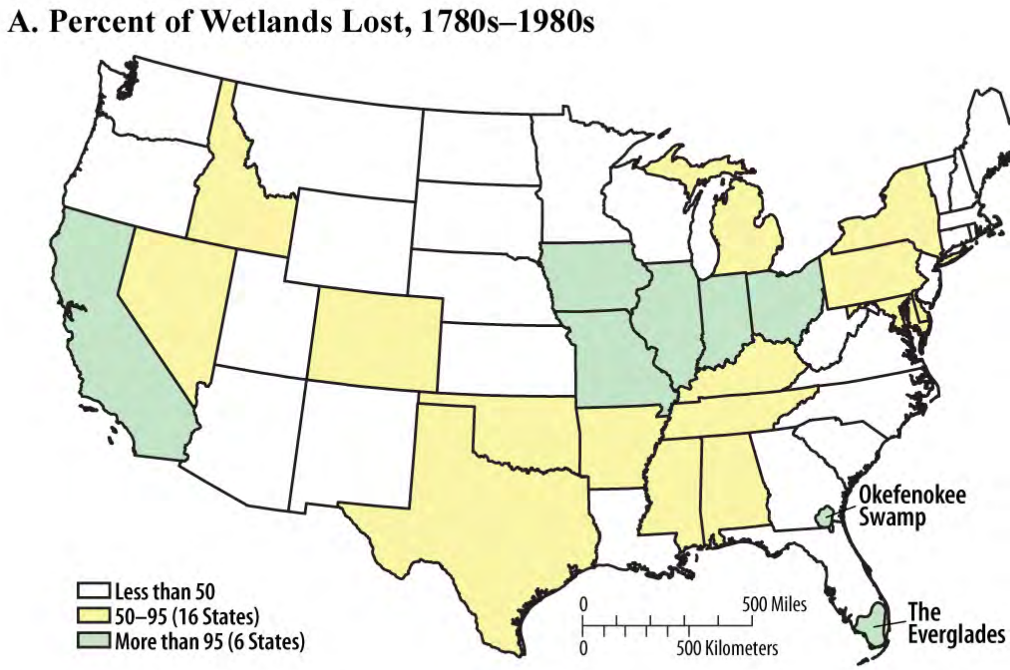
Human activities frequently alter connectivity between headwater streams, riparian/floodplain wetlands, non-floodplain wetlands, and downgradient river networks (Sections 1.2.4, 3.2, 4.3, and 4.4). In doing so, they alter the transfer and movement of materials and energy between river system components. In fact, the individual or cumulative effects of headwater streams and wetlands on river networks often become discernible only following human-mediated changes in degree of connectivity. These human-mediated changes can increase or decrease hydrologic and biological connectivity (or, alternatively, decrease or increase hydrologic and biological isolation). For example, activities and alterations such as dams, levees, water abstraction, piping, channelization, and burial can reduce hydrologic connectivity between streams and wetlands and rivers, whereas activities and alterations such as wetland drainage, irrigation, impervious surfaces, interbasin transfers, and channelization can increase hydrologic connections. Biological connectivity can be affected similarly: For example, dams and impoundments might impede biotic movement, whereas nonnative species introductions artificially increase biotic movement. Further complicating the issue is that a given activity or alteration might simultaneously increase and decrease connectivity, depending on which part of the river network is considered. For example, channelization and levee construction reduce lateral expansion of the river network (thereby reducing hydrologic connections with floodplains), but might increase this connectivity downstream due to increased frequency and magnitude of high flows.

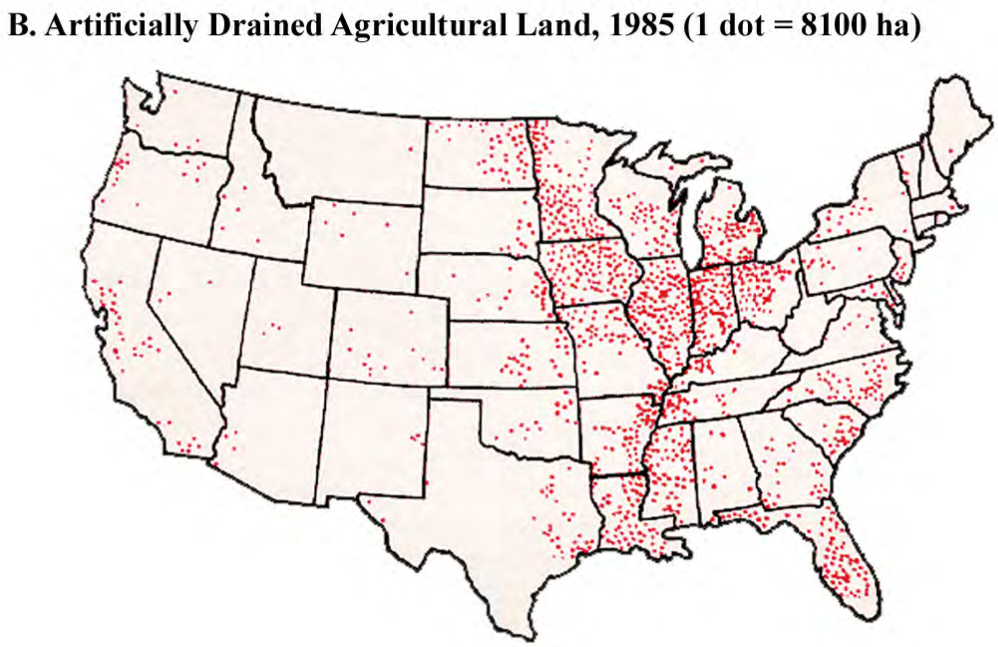
To illustrate, we describe two notable alterations that affect river system connectivity: dams (and their associated impoundments) and wetland drainage. The United States has more than 80,000 dams, over 6,000 of which exceed 15 m in height (USACE, 2009). Numerous studies have shown that dams impede biotic movements, reduce biological connectivity between upstream and downstream locations (e.g., Greathouse et al., 2006; Hall et al., 2011), and form a discontinuity in the normal stream-order-related progression in stream ecosystem structure and function (Stanford and Ward, 1984). Dams, however, can have the opposite effect with respect to natural lakes: increasing their biological connectivity with respect to invasive species by adding impoundments that decrease average distances between lakes and serving as stepping stone habitat (Johnson et al., 2008). Upstream of large dams, riparian areas are permanently inundated, increasing lateral hydrologic connectivity. Downstream, dams decrease peak stream volumes during the normal high-runoff seasons, while increasing minimum flows during normal low-flow seasons—an overall dampening of stream-flow variability (Poff et al., 2007). Because many riverine organisms are adapted (via life history, behavioral, and morphological characteristics) to the seasonality of natural flow regimes, dampening flow variability can have deleterious effects on species persistence where dams have been built (Lytle and Poff, 2004). This reduction in high flows also decreases the connectivity of riparian wetlands with the stream by reducing the potential for overbank lateral flow. Reducing overbank lateral flow can affect downstream water quality, because overbank flow deposits sediment and nutrients that otherwise remain entrained in the river (Hupp et al., 2009).

The greatest human impact on riparian/floodplain wetlands and non-floodplain wetlands has been through wetland drainage (Figure 2-21), primarily for agricultural purposes. Estimates show that, in the conterminous United States, states have lost more than half their original wetlands, with some losing more than 90%; wetland surface areas also have declined significantly (Dahl, 1990).

Drainage causes a direct loss of function and connectivity in cases where wetland characteristics are completely lost. In the Des Moines lobe of the prairie pothole region, where more than 90% of the wetlands have been drained, a disproportionate loss of smaller and larger wetlands has occurred. Accompanying this loss have been significant decreases in perimeter-area ratios—which are associated with greater biogeochemical processing and ground-water recharge rates—and increased

Figure 2-21. Comparison of percent wetland loss between (A) the 1780s and mid-1980s with (B) the distribution of artificially drained agricultural land in 1985. One dot equals 8100 ha. From Blann et al. (2009), as modified from Dahl (1990).





mean distances between wetlands, which reduces biological connectivity (Van Meter and Basu, In press). Wetland drainage also increases hydrologic connectivity between the landscape—including drained areas that retain wetland characteristics—and downstream waters. Effects of this enhanced hydrologic connectivity include (1) reduced water storage and more rapid conveyance of water to the network, with subsequent increases in total runoff, baseflows, stormflows, and flooding risk (Wiskow and van der Ploeg, 2003; Blann et al., 2009); (2) increased delivery of sediment and pollutants to downstream waters; and (3) increased transport of water-dispersing organisms (Babbitt and Tanner, 2000; Baber et al., 2002; Mulhouse and Galatowitsch, 2003). Biological connectivity, however, also can decrease with drainage and ditching, as average distances between wetlands increase and limit the ability of organisms to disperse between systems aerially or terrestrially (Leibowitz, 2003). Ground-water withdrawal can have an effect similar to drainage on some wetlands, which can affect wetland connectivity by reducing the number of wetlands. Of particular concern in the arid Southwest is that ground-water withdrawal can decrease regional and local water tables, reducing or altogether eliminating ground-water-dependent wetlands (Patten et al., 2008). Ground-water withdrawal, however, also can increase connectivity in areas where that ground water is applied or consumed.

Particularly noteworthy is that restoration of hydrologic connectivity, especially in systems with widespread human alterations, also might adversely affect downstream waters (Jackson and Pringle, 2010). For example, dam removal can result in the downstream transport of previously sequestered pollutants (Jackson and Pringle, 2010); dam releases to restore flows, without simultaneous restoration of sediment supplies, can result in downstream channel degradation (Germanoski and Ritter, 1988; Schmidt and Wilcock, 2008). Hammersmark et al. (2008) used a modeling study to show how the restoration of incised stream channels can improve connectivity between streams and floodplains and thus restore predisturbance hydrology (i.e., increased floodplain water storage, reduced peak stormflow, and reduced baseflow).

2.4.5 Interactions Among Factors

Interactions among the factors discussed above can be complex. Here we provide an example of temporary surface-water connections between wetlands in the prairie pothole region (PPR) to illustrate these complex interactions (Leibowitz and Vining, 2003). Further details on wetlands in the PPR are provided in Sections 5.4 and B.3.

During high-water conditions in 1995, a temporary surface-water connection was observed between two geographically isolated prairie potholes in the region’s Drift Prairie. Based on a spatial analysis during similarly wet conditions in 1996, 28% of the wetlands in a 40 km^2 area containing the sites had a temporary surface-water connection to at least one other wetland, including a complex (defined in the study as a group of wetlands interconnected through temporary surface-water connections) of 14 wetlands.

In considering these findings, Leibowitz and Vining (2003) suggested that precipitation and local relief are the primary factors controlling the spatial distribution of these temporary surface connections. Precipitation is the ultimate source of water that fills these wetlands, whereas relief controls how much the water level in a wetland must rise before spillage occurs (water level is also influenced by evapotranspiration and ground water, but ground-water dynamics are difficult to predict for individual wetlands). Relief also controls mixing—which could occur in flatter areas when the boundaries of expanding wetlands overlap—by determining the change in surface area per change in water level. Thus, for a given level of precipitation, the number of surface connections occurring between wetlands should be inversely proportional to local relief. Within the PPR, precipitation generally decreases from east to west, while relief generally increases. The easternmost physiographic region in the PPR is the Red River Valley, a relatively flat ancient lakebed (Lake Agassiz) having deep deposits of silt and clay. Water can pond easily on these deposits, producing shallow wetlands and integrated drainage (i.e., the presence of stream networks). The Missouri Coteau, which forms the western boundary of the PPR, consists of dead-ice glacial moraine. This area has hummocky terrain, and local relief can be as great as 15–45 m in steeper areas (Winter et al., 1998). As a result, the Coteau has deeper wetlands and little to no integrated drainage. The Drift Prairie, located between the Red River Valley and the Missouri Coteau, is an undulating plain formed on ground moraine. Relief, wetland depth, and the level of integrated drainage in the Drift Prairie are intermediate in comparison with the other two regions.

Leibowitz and Vining (2003) hypothesized that the combined effect of these patterns in precipitation and relief should produce a strong east-west gradient across the PPR in the occurrence of intermittent surface-water connections. Both the absolute number of connections and complex size (the number of wetlands contained in a complex) should be highest in the Red River Valley. Given the relative flatness of this area, mixing should be the more common mechanism for temporary connections. The number of temporary connections and complex size should be lower in the Drift Prairie, and spillage might dominate in this hillier terrain. In the Missouri Coteau, where relief is greatest, the occurrence of these temporary connections should be rare and limited to small complex sizes. Human impacts, however, could affect these trends (Section 2.4.4).

Beyond these regional trends in relief and precipitation, local variation in the occurrence of intermittent surface-water connections should be influenced strongly by ground-water dynamics. The ground-water hydrology of prairie potholes has been well investigated at several sites (e.g., Winter et al., 1998; Winter and Rosenberry, 1998). The specific ground-water interactions—and hence the effects of ground-water movement on spillage or mixing, however, are unknown for most prairie potholes. All else being equal, ground-water discharge wetlands should receive more water, and so should have a higher probability of spillage, than ground-water recharge wetlands because recharge should reduce the amount of water available for spillage.

A major factor influencing the temporal distribution of intermittent connections within the PPR is wet-dry cycles. Climatic changes that have occurred throughout the Holocene drive these cycles. Evidence, for example, exists for 20-, 22-, 50-, 100-, and 200-year climatic cycles (Ashworth, 1999). Wetland hydrology responds dramatically to these wet-dry cycles as ground-water levels and precipitation patterns fluctuate. In 1996, the average monthly Palmer Hydrological Drought Index for central North Dakota was 4.02 (88th percentile), compared with a median of 1.00 for annually calculated monthly averages between 1895 and 2001. Moisture levels of this magnitude—and consequently the degree of connectivity observed (Leibowitz and Vining, 2003)—would be expected to occur during wetter portions of wet-dry cycles.

2.4.6 Quantifying Connectivity

As previously discussed, watershed connectivity is a dynamic and scalable quantity that occurs along a gradient from highly connected to highly isolated (Ward, 1989; Euliss et al., 2004). Connectivity can be quantified using *structural* metrics of physical landscape features (e.g., watershed topography, the spatial arrangement of habitat patches), or *functional* metrics of system dynamics, which integrate information about processes and interactions that influence hydrologic flows or biological dispersal. Selection of specific metrics for quantifying connectivity depends on the purpose of the assessment, the environmental context (e.g., humid versus arid), type of connection (e.g., hydrologic, chemical, biological), spatial and temporal scale of interest, and available data (Calabrese and Fagan, 2004; Lexartza-Artza and Wainwright, 2009).

2.4.6.1 Hydrologic and Chemical Connectivity

In hydrology, connectivity research has aimed to understand how and when water volume inputs (e.g., precipitation minus water loss through infiltration, evaporation and transpiration) and moisture thresholds trigger surface and subsurface flow, thereby influencing streamflows in a given watershed (Western et al., 2001; Ali and Roy, 2010; Bracken et al., 2013). Because movement of water is the primary mechanism by which chemical substances are transported downstream, quantifying chemical connectivity is closely related to quantifying hydrologic connectivity (Michalzik et al., 2001; Borselli et al., 2008). Hydrologic connectivity research has focused on relating patterns of soil moisture following precipitation events to stream discharge (Western et al., 2001; James and Roulet, 2007; Ali and Roy, 2010) or measuring flow-process connectivity at the hillslope scale (Knudby and Carrera, 2005; Reaney, 2008; Smith et al., 2010). Although this research provides a critical understanding of how water moves through a watershed, it is only indirectly related to connectivity between small streams and rivers, or between wetlands and streams. Metrics for quantifying hydrologic connections between upstream and downstream waters have started to be explored through research characterizing the hydrologic permanence of streams (Fritz et al., 2008; Fritz et al., 2009) or mapping temporal variation in surface connections between wetlands and streams using field (McDonough et al., 2015) or remotely sensed data (Sass and Creed, 2008; Lang et al., 2012; Huang et al., 2014). More commonly, research efforts have focused on data collection methods that could inform measurement of connectivity (e.g., deriving relationships between connectivity and topography or water quality; hydrologic tracers; geostatistical modeling; and watershed, ground-water, or coupled surface water-ground water modeling).

Structural indices derived from topography can be used to predict patterns of watershed wetness. Examples include the Topographic Wetness Index (Quinn et al., 1995), which is quantified using the upslope contributing area and local slope, as well as quasi-dynamic indices that calculate the effective contributing area (**variable source area**) in a watershed (e.g., Barling et al., 1994; Tarboton, 1997; Creed and Beall, 2009). These indices could be used to predict the location of hydrologic flowpaths and areas of a watershed that might be efficient exporters of nutrients, sediment, or pollutants following heavy rainfall or snowmelt periods (Creed and Beall, 2009; Lane et al., 2009). In flatter landscapes, a more dynamic contributing area model is typically required (Shaw et al., 2013). One example is the fill-and-spill model in which the watershed contributing area expands when wetland storage reaches capacity (fill) and wetlands overflow (spill) onto the land surface and into other surface-water bodies (Tromp-van Meerveld and McDonnell, 2006; Shaw et al., 2013; McCauley and Anteau, 2014). Other researchers have quantified basin-scale hydrologic connectivity as the ratio of flowing stream reaches connected to the outlet to the total potentially flowing stream reaches (Phillips et al., 2011; Spence and Phillips, 2015), or as transport potential in a given direction quantified by a directional connectivity index (Larsen et al., 2012). Similar to this, the volume-to-breakthrough concept quantifies connectivity as actual runoff relative to water inputs, where connectivity decreases with increased infiltration, depression storage, slope length, barriers, or other factors (Bracken and Croke, 2007).

Several other lines of research are contributing to a general understanding of connectivity between water features. Water quality indicators have been used to identify connectivity between wetlands and streams (Johnston et al., 1990; Leibowitz and Vining, 2003). Tracer experiments using ^{15}N, bromide, salt solutions, fluorescing particles, or other conservative compounds have been conducted that can inform flowpaths in aquatic systems (Mulholland et al., 2004; Bencala et al., 2011; O'Brien et al., 2012). Modeling and measuring the mass transfer efficiency of a watershed using a parameter such as the sediment delivery ratio, which describes and predicts the relationship between erosion and sediment yield in a watershed, can indicate the degree of connectivity within a watershed (Atkinson, 1995; Hooke, 2003; Bracken and Croke, 2007). Geostatistical approaches are being developed to consider how connectivity would be quantified within a branched stream network (Fagan, 2002; Ganio et al., 2005; Peterson et al., 2007). In addition, numerous mechanistic modeling and simulation tools can be modified and applied to investigate connectivity dynamics from geographically isolated wetland systems (Golden et al., 2014) and headwaters (e.g., TOPMODEL; Beven and Kirkby, 1979) to downstream surface-water systems.

Although the research community has not reached a consensus regarding the best methods or metrics to quantify or predict hydrologic or chemical connectivity (Lexartza-Artza and Wainwright, 2009; Ali and Roy, 2010; Bracken et al., 2013), future efforts to quantify connectivity using the descriptors discussed in Chapter 1 (frequency, magnitude, duration, timing, and rate of change) or other connectivity metrics will help to further refine and quantify the lines of research summarized above.

2.4.6.2 Biological Connectivity

In the quantification of biological connectivity, species traits (e.g., dispersal mode, habitat requirements, behavior) also must be considered (Calabrese and Fagan, 2004). Structural connectivity can be quantified from the physical landscape (e.g., the size, shape, and arrangement of habitat patches) assuming that the spatial configuration of habitats reflects species' ability to move between them. Functional connectivity directly incorporates information about species' movement obtained from field studies or from models to inform estimates of connectivity (Calabrese and Fagan, 2004; Wainwright et al., 2011).

Indices based on graph theory calculate connectivity using a graph to represent the landscape as a network of nodes (e.g., habitat patches) connected by edges (pathways of movement; Urban and Keitt, 2001). Such connectivity indices include the Minimum Spanning Tree (Urban and Keitt, 2001), Correlation Length (Keitt et al., 1997; Rae et al., 2007), the Integral Index of Connectivity (Pascual-Hortal and Saura, 2006), and the Probability of Connectivity (Saura and Pascual-Hortal, 2007). Graph-theory approaches can be used to assess structural or functional connectivity at multiple spatial scales (Eros et al., 2012). Specific information about habitats and focal species is incorporated by applying node weights (e.g., habitat area or quality, population abundance), edge weights (e.g., Euclidean distance, landscape resistance), or edge characteristics (e.g., direction of movement; Galpern et al., 2011). Indices derived from such graphs seek to characterize connectivity in terms of habitat (e.g., total connected habitat area), dispersal pathways (e.g., relative abundance of individuals using a pathway, path redundancy or vulnerability), or both (Rayfield et al., 2010). The Integral Index of Connectivity, for instance, incorporates patch area, the topological distance between patches and the proportion of connected patches (Pascual-Hortal and Saura, 2006), and has been successfully used to quantify connectivity within a river network at varying spatial scales for otters (Van Looy et al., 2013).

The dendritic nature of stream networks also can be explicitly integrated when considering the biological connectivity for obligate aquatic species, such as fish. The branching structure of a dendritic network (Figure 2-19B), which has a single pathway (the stream channel) between habitat patches (e.g., stream reaches), influences individual movement and population distribution and abundance, and thus the impact of disturbances and fragmentation on connectivity (Fagan, 2002; Grant et al., 2007); this can be reflected in graph-theoretic connectivity indices (Malvadkar et al., 2015). An example of a dendritic metric is the Dendritic Connectivity Index, which uses the number of barriers (e.g., culverts) and the passability of these barriers to quantify the probability that fish can move between two points in a river network (Cote et al., 2009).

2.4.6.3 Summary

This section briefly reviews the growing body of research into testable indices and metrics that represent hydrologic and biological connectivity of functional importance to downstream waters. Data availability is a critical issue, as the information content that connectivity indices provide often is related directly to their data requirements (Calabrese and Fagan, 2004; Bergsten and Zetterberg, 2013). Additionally, the many proposed connectivity indices and approaches discussed in the literature suggest that different metrics are needed to quantify different types of connectivity across diverse environments, scales, and ecosystem functionalities (Rayfield et al., 2010; Galpern et al., 2011; Bracken et al., 2013). With further development and refinement, the utilization of connectivity indices can provide graphical, quantitative assessments of connectivity.

CHAPTER 3. STREAMS: PHYSICAL, CHEMICAL, AND BIOLOGICAL CONNECTIONS TO RIVERS

3.1 Abstract

The physical structure of a river network inherently demonstrates cumulative connectivity (Section 1.2.3) between all streams and their downstream rivers. Substantial evidence supports physical, chemical, and biological connections from headwater streams—including those with ephemeral, intermittent, and perennial flows—to waters immediately downstream through transport of water and associated materials, movement of organisms and their products, and bidirectional geomorphic adjustments. Among the most compelling evidence for the effects of headwater streams on rivers is as sources of water, nitrogen, organic carbon, and sediment (clean and contaminated); as transformers of and sinks for nitrogen, carbon, and contaminants; and as providers of essential habitat for migratory animals such as anadromous salmon. Headwater streams as a class provide substantial quantities of water to larger water bodies. For example, first-order streams cumulatively contribute approximately 60% of the total mean annual flow to all northeastern U.S. streams and rivers. Infrequent, high-magnitude events are especially important for transmitting materials from headwater streams in most river networks. The strongest lines of evidence supporting the effects of headwater streams are from watersheds where headwater streams drain a unique portion of the basin (e.g., hydrology, geology, human alteration). Investigation of connections among river network components continues to be an active area of scientific research, with progress occurring in the development of river network models and connectivity metrics for quantifying connections and their downstream effects. Physical, chemical, and biological connections between headwater streams and downstream waters are fundamental to the structure and function of river networks, and additional empirical data and further breakthroughs that quantify linkages across large spatiotemporal scales will continue to enhance our understanding of river network complexity.

3.2 Introduction

In this chapter, we describe the state of knowledge of stream connectivity and its effects on the physical, chemical, and biological condition of downstream waters. Although we recognize that streams also are important sources of water and other materials to nearby terrestrial systems and deep ground-water systems via lateral and vertical connections (e.g., Gray, 1993; Shentsis and Rosenthal, 2003; Walters et al., 2008), we focus here on longitudinal surface-water connections between streams and rivers, and on shallow subsurface-water interactions integral to surface-water connections and downstream water condition. The evidence primarily focuses on the connections between headwater streams and downstream waters, but we draw some evidence from connections of larger streams to rivers, reservoirs, lakes, and coastal waters. We consider the peer-reviewed evidence for connectivity and its consequent effects on downstream rivers in terms of physical (Section 3.3), chemical (Section 3.4), and biological (Section 3.5) connections between upstream and downstream habitats. Although we recognize that many linkages between streams and downstream waters cross physical, chemical, and biological boundaries, we have chosen this format for ease of presentation. In each section we also consider how human alteration of streams affects their connectivity and resulting effects on downstream rivers (Sections 1.2.4 and 2.4.4). In some cases, connectivity and its effects on downstream waters become more discernable with human alteration (e.g., Chin and Gregory, 2001; Wigmosta and Perkins, 2001); however, when human alterations are widespread and relatively uniform (e.g., Blann et al., 2009) attributing downstream effects to particular tributaries or parts of the river network can be more complex. Coupled human-natural systems are an area of active research (Box 3-1). Section 3.6 closes this general section with a discussion on stream-river connections by synthesizing evidence in terms of the conceptual framework (Chapter 2) and viewing streams in a connectivity gradient context (Section 1.2.2). In addition, two case studies on specific types of stream systems are in Appendix B: prairie streams (Section B.4) and southwestern intermittent and ephemeral streams (Section B.5).

Streams range greatly in size in terms of both drainage area and discharge. In general, their abundance is inversely related to their size. First-order streams typically are most abundant, although individually they have the smallest drainage areas and shortest average stream lengths (Horton, 1945; Schumm, 1956; Ijjasz-Vasquez et al., 1993). When considering drainage area and stream length of headwater streams together, however, they can represent most of the river watershed and network. Thus, despite their small individual size, these headwater streams cumulatively can have a large influence on downstream waters (Section 1.2.3).

Some headwater streams lack channel connections to large downstream water bodies because they drain closed or endorheic basins. Endorheic basins have no surface outflows to oceans, but terminate as inland lakes, seas, playas, or pans (Shaw and Bryant, 2011). Although endorheic streams are common in some areas (Section B.5), endorheic basins represent only approximately 2% of the North American continent (Vörösmarty et al., 2000) and generate 0.15% (9 of 5,892 $km^3\ yr^{-1}$) of its annual discharge (Fekete et al., 2002).

Box 3-1. Urban Streams

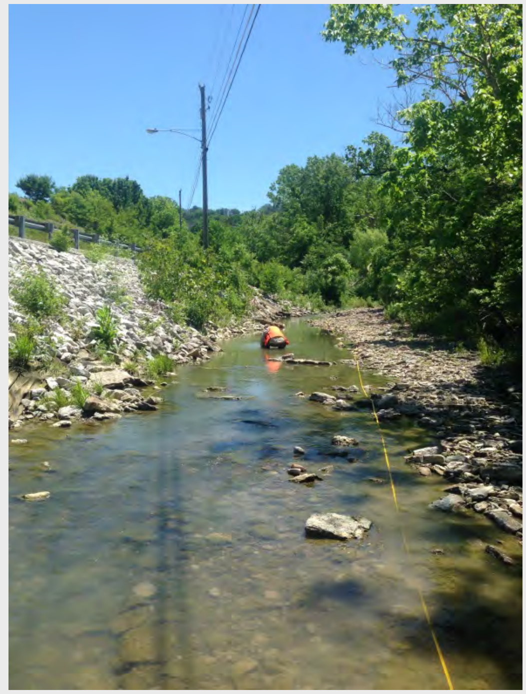
Urban development alters the structure and function of stream ecosystems in numerous ways (Paul and Meyer, 2001; Walsh et al., 2005). Although the specific symptoms of what Walsh et al. (2005) referred to as the “urban stream syndrome” depend on numerous factors, including the location, density, type, and age of urban development, common patterns have emerged. For example, urban streams typically experience increased stormflows (from direct runoff to channels), flashier hydrographs, altered baseflows, increased nutrient and contaminant concentrations, and decreased organic matter retention. Many of these attributes are related to changes in connectivity—that is, alteration of the longitudinal, lateral, and vertical connections between the landscape, headwater streams, and downstream waters.

Connectivity and consequences on downstream waters. One pervasive effect of urban development is the alteration of hydrologic connectivity along river networks. The frequency, duration, magnitude, timing, and rate of change of both stormflows and baseflows are altered via multiple pathways. The highly connected, engineered network of impervious surfaces, pipes, and storm drains increases the volume and rapidity of stormwater runoff into urban streams, resulting in increased frequency, magnitude, and rate of change of stormflows within the river network. This quick delivery of stormwater runoff to streams also means that stormflows tend to recede quickly, shortening stormflow duration. Because impervious surfaces reduce infiltration and watershed storage of water, urban development also can reduce baseflow magnitudes. Together, these patterns result in the typical flashy hydrographs of urban streams and altered hydrologic connections throughout urban river networks. Higher stormflow magnitudes and frequencies also can scour sediments from urban channels, which, in combination with engineered channel straightening, can cause urban channels to enlarge via incision and expansion. Direct wastewater discharges to urban streams (e.g., from wastewater treatment plants, industrial facilities, or combined sewer overflows) and water withdrawals for municipal and industrial uses also can affect the frequency, duration, and magnitude of hydrologic connections in urban streams. Vertical hydrologic connections can be augmented by leaky subsurface sewer and water pipes, or diminished by reduced infiltration due to increased impervious surface area and channel incision, straightening, hardening, and simplification.

Stream burial, or the diversion of streams into pipes, culverts, and other conveyances, is common in urban watersheds, and provides another illustration of how urban development alters connections. For example, more than 60% of all streams in Baltimore City, particularly small headwater streams, have been buried (Elmore and Kaushal, 2008). As a result, most lateral and longitudinal connections along urban river networks have been replaced by urban infrastructure, resulting in greatly expanded headwater drainage areas (Kaushal and Belt, 2012).

These changes in hydrologic connectivity have significant consequences for downstream waters in urban areas. Between rain events, urban landscapes accumulate materials such as organic material, nutrients, and contaminants, which then are delivered quickly to urban streams with surface runoff. As natural stream channels are converted to simplified engineered structures, they lose their ability to retain and transform these materials, resulting in reduced storage and lag time before transport to downstream waters (Nedeau et al., 2003; Carey and Migliaccio, 2009; Kaushal and Belt, 2012).

Box 3-1. Urban Streams (continued)



Longitudinal connectivity in urban streams also influences the movement and distribution of organisms in these systems. Urban stream habitats frequently become fragmented and homogenized, as connectivity is disrupted by road crossings, channel incision, and other impacts associated with urban development. Habitat homogenization reduces complexity, which limits the availability of habitats needed throughout species' life cycles (for reproduction, rearing, refuge from disturbance and predation). Fragmentation can result in reduced movement of mobile organisms, most notably fish, through the river network (Perkin and Gido, 2012). Urban streams also can benefit, however, from connectivity with intact, upstream habitats. For example, Waits et al. (2008) found that immigration from less disturbed upstream areas serving as source habitats maintained central stoneroller populations in an urban stream.

Connectivity and restoration of urban streams. Because so many of the adverse effects associated with urban development are related to changes in lateral, longitudinal, and vertical connections along urban riverscapes, restoration of these systems often involves re-establishing connections that existed before urbanization. For example, detention ponds and green infrastructure (rain gardens, bioswales, permeable pavements, green roofs) are designed to slow stormwater runoff into urban streams, thereby increasing retention and processing of water, nutrients, sediment, and contaminants. Ultimately, the slowing of stormwater runoff can re-establish lateral and longitudinal connections as retention and transformation pathways, rather than the primarily export pathway these connections traditionally served in urban river networks.

The contribution of headwater streams to river networks in terms of stream number, length, or drainage area over large geographic regions has been difficult to determine, even with advances in remote sensing and geographic information systems. The small size of headwater streams makes distinguishing them from surrounding areas and overlying tree canopies difficult in most regions (Gilvear and Bryant, 2003). Numerous studies have shown that existing U.S. hydrographic databases and topographic maps underestimate the extent of headwater streams (Morisawa, 1957; Gregory, 1976; Hansen, 2001; Heine et al., 2004; Stoddard et al., 2005; Roy et al., 2009). Therefore, most streams portrayed on databases and maps as first-order streams are, when ground-truthed, second- or third-order streams. For example, more than 80% of mapped (1:25,000-scale topographic maps) stream terminuses in a Massachusetts watershed underestimated the upstream extent of the channels (Brooks and Colburn, 2011). On average, these unmapped upstream segments were nearly 0.5 km in length, and 40% had one or more upstream tributaries (Brooks and Colburn, 2011). Even with this widely known underestimation by databases and maps, first-order streams recognized in the U.S. Geological Survey (USGS) medium-resolution (1:100,000-scale) National Hydrography Dataset (NHD) represent 53% (2,900,000 km) of total stream length (Nadeau and Rains, 2007). Moreover, approximately 50% of these first-order streams were classified as not having year-round flow (i.e., nonperennial; Section 2.2.2; Nadeau and Rains, 2007). Southwestern and prairie streams are predominantly ephemeral and intermittent

(Sections 5.5, 5.6, B.4, and B.5). Thus, despite the shortcomings of existing national maps and hydrographic databases, it is still clear that headwater streams—including ephemeral and intermittent streams—represent a large fraction of river networks in the United States. Combining their overwhelming extent with their high biogeochemical activity (Section 3.4) means that headwater streams, including ephemeral and intermittent channels, have a large cumulative or aggregate effect on the river network (Benstead and Leigh, 2012).

In the following sections, we consider longitudinal connectivity between streams and downstream waters in terms of the physical, chemical, and biological connections between them.

3.3 Physical Connections

Physical connections result from the transport of nonliving materials that do not chemically change (or change slowly) enroute from streams to downstream rivers. In this section, we discuss factors controlling water, temperature (heat energy), sediment, and wood in streams; how these materials are transported downstream; and evidence that these connections affect the condition of downstream rivers.

3.3.1 Water

The recurrent, concentrated surface flow of water from surface runoff and ground water develops and maintains river networks, and water is the primary medium carrying other materials from streams to rivers (Section 2.3). The temporal dynamics of flow (its frequency, duration, magnitude, timing, and rate of change) within and among river networks vary in space and time and influence the physical, chemical, and biological connectivity between streams and downstream waters (Sections 2.2.2, 2.2.3, and 2.3.2.2). Thus, the physical connection of water flow through river networks largely forms the foundation for chemical and biological connections and where along the dynamic connectivity gradient streams are positioned (Section 1.2.2).

Most rivers receive the majority of their water from tributaries rather than from direct precipitation on or ground-water input to river segments (Winter, 2007; Bukaveckas, 2009). Alexander et al. (2007) modeled flow through river networks in the northeastern United States and estimated that first-order streams (designated on the 1:100,000-scale NHD river network) provide approximately 70% of the mean annual water volume in second-order streams and about 55% and 40% of the mean water volume in fourth- and higher order rivers, respectively. Overall, first-order streams cumulatively contribute about 60% of the total volume of mean annual flow to all northeastern streams (Alexander et al., 2007).

Headwater stream contributions to downstream baseflow vary among river networks, based on several large-scale factors (Section 2.4). For example, headwater streams that have stronger connections to ground water or that consistently receive more precipitation relative to downstream reaches have a larger effect on downstream river baseflows. Hydrologic data from 11 nested gages distributed throughout a watershed (176 km^2) in the Catskill Mountains, NY were used to assess the extent of spatial correlation in baseflow discharge (Shaman et al., 2004). Baseflow discharge in smaller streams (i.e., with watersheds <8 km^2) was more weakly correlated with mainstem discharge than discharge in larger streams; the authors concluded that this pattern reflected greater contributions by deep ground water as drainage area increased (Shaman et al., 2004). Using geochemical tracers and hydrologic data from 32 nested stations in a watershed (1,849 km^2) of the River Dee in Scotland, Tetzlaff and Soulsby (2008) determined that streams draining the upper 54% of the watershed contributed 71% of baseflow. However, the upper watershed received only 58% of the total annual precipitation, indicating that long residence time ground-water flowpaths from the headwater watersheds were also important in maintaining downstream baseflows (Tetzlaff and Soulsby, 2008). In contrast, headwater streams (0.11−3.5 km^2) making up 33% of the total area in a northern Sweden watershed (78 km^2) contributed only 18% of the summer baseflow at the basin outlet (Temnerud et al., 2007). The specific discharge contribution (L s^{-1} km^{-2}) for headwater streams, however, varied by an order of magnitude (~0.5−8.0), reflecting the heterogeneity (i.e., mires, lakes, forest) of the study watershed (Temnerud et al., 2007). Jencso et al. (2009) monitored 24 transects with a total of 84 wells along lower hillslopes, toe-slope, and riparian areas in a northern Rocky Mountains watershed (22.8 km^2) and found that the duration of connectivity from hillslopes to streams was positively correlated (r^2 = 0.95) with the duration of higher than normal downgradient watershed streamflow. This finding demonstrates the strong link between downstream flow conditions and the connectivity of ephemeral and intermittent streamflow from nearby hillslopes, and that the cumulative downstream effect of the hydrologic connections between the hillslope and stream channel is time varying. Hydrologic connections to downstream rivers are often complex, involving longitudinal, lateral, and vertical exchanges that vary over space and time. This means that the flowpath by which headwater streams contribute to downstream waters will vary according to climatic, topographic, and geologic context.

We can also infer the importance of headwater streams from variation in river hydrologic responses over space. Discharge increases with drainage area, and the general assumption, particularly for mesic environments, is that drainage area can be used as a proxy for discharge. The relationship can be written as $Q = kA^c$, where Q is discharge (m^3 s^{-1}), k is a constant representing hydrologic factors such as antecedent moisture and precipitation, A is drainage area (km^2), and c is the scaling power constant. This scaling power reflects how the rate of discharge increases with drainage area, and can be useful for qualitatively assessing headwater contributions to downstream discharge. Where $c \approx 1$, discharge is generated proportionally with increasing drainage area. Where $c < 1$, upstream portions of the watershed (where headwater streams tend to be most abundant) generate more discharge per unit area than downstream portions, suggesting that rivers with $c < 1$ derive a higher proportion of their flow from headwater streams. Where $c > 1$, downstream portions generate more discharge per area than upstream reaches, suggesting that rivers with $c > 1$ might store more water per unit area in upstream vs. downstream areas. Alternatively, urbanization in the lower portions of the watershed can lead to a similar relationship (Galster et al., 2006). Data from multiple USGS gages along large, unregulated rivers showed that mean and peak annual discharge do not always increase proportionally with drainage area (Galster, 2007, 2009). Of the 40 rivers examined, only 16 had linear peak annual discharge-area relationships ($c \approx 1$) throughout their period of record (Galster, 2009). Eleven rivers had relationships where $c < 1$, three rivers had relationships where $c > 1$, and ten showed changes in the relationship over their period of record.

Despite variability in area-discharge relationships, most mesic watersheds have a value of *c* between 0.8 and 1 (Galster, 2007), suggesting that drainage area can be used to roughly estimate the proportion of flow that arises from headwater streams. For example, Alexander et al. (2007) found that the watersheds of first-order streams cumulatively accounted for 57% of the total drainage area and 55% of the total annual river flow of the New England states. In more xeric arid and semiarid watersheds where the ground-water table can be below the stream channel and thunderstorms of limited spatial extent dominate runoff, however, *c* is generally < 1. For instance, in the highly instrumented Walnut Gulch Experimental Watershed (operated by the U.S. Department of Agriculture, Agricultural Research Services [USDA-ARS]) in southeastern Arizona, discharge becomes more nonlinear (*c* decreases) with increasing watershed area, and a critical transition threshold area occurs roughly within 37–60 ha (Goodrich et al., 1997). The primary causes of increasingly nonlinear response are (1) the increasing role of ephemeral channel infiltration losses to the subsurface, unconsolidated alluvium, and (2) the continual decline of fractional storm area coverage as watershed area increases. Caruso and Haynes (2011) reported that first-order watersheds made up 61% of total drainage area of the Upper Colorado River basin. In this case, the first-order streams produced a lower proportion (41%) of the total annual river flow than suggested by their total drainage area, in part because 84% of the streams were intermittent. Both studies used the 1:100,000-scale NHD, in which first-order watersheds generally correspond to second-order watersheds at the 1:24,000 scale (Alexander et al., 2007). These results, representing two very different parts of the United States, strongly suggest that headwater streams, even where seasonally dry, cumulatively generate a large fraction of the nation's stream and river flows.

The propagation of stormflow through river networks provides clear evidence of hydrologic connectivity between headwater streams and rivers, particularly when an intense storm occurs over only the headwater portions of a river network. In these cases, the hydrograph peaks sharply in the headwater streams, indicating a quick response to precipitation (Figures 2-8 and 2-11). Timing of the storm and onset of the peak are increasingly delayed with increasing distance down the network (Figure 2-11; see below for further discussion of hydrologic dispersion). Typically, discharge magnitude increases as stormflow accumulates incrementally over the river network (Allan, 1995). The contribution of tributaries to rivers during widespread floods manifests as stepped increases in discharge immediately below confluences, as water flows accumulate through a river network (Figure 3-1).

Such propagation was recorded following a monsoonal storm event through an arid network of ephemeral channels in the Río Grande, NM (Figure 3-2). The high-intensity storm dropped approximately 18–25% of annual rainfall on the stream's approximately 16,000 km^2 drainage area over a 2-day period. Discharge recorded at two gages on the stream and three gages on the Río Grande downstream of the confluence illustrated lag (residence) time and peak hydrograph broadening at least 127 km downstream (Vivoni et al., 2006). Stormflow contributions from the ephemeral stream

Figure 3-1. Longitudinal pattern of flow along (A) River Derwent and (B) River Trent, illustrating stepped increases in flow associated with tributary inflows. Small arrows indicate location of tributary confluences along the mainstem; bold arrow in (B) indicates the confluence of the two rivers. accounted for 76% of flow at the Río Grande, even though these channels were considered to have a flood return interval of 1.11 to 1.84 years across the USGS gages in the network (Vivoni et al., 2006).

How water flows through the streams in river networks shapes hydrologic responses (time to peak flow, peak-flow magnitude, and recession of peak flow) in downstream rivers (also see Sections 2.2, 4.3.2.1, and B.2 for discussion of hydrologic exchange between main channels and floodplains and associated water bodies). A key effect streams in a network structure have on hydrologic responses is dispersion, or the spreading of water output from a drainage basin over time. Hydrologic dispersion is the combined effect of several mechanisms operating across different spatial scales that influence the travel time (or residence time) and volume of water reaching a river network outlet (Saco and Kumar, 2002).

The components of hydrologic dispersion most relevant to river networks include hydrodynamic dispersion, geomorphologic dispersion, and kinematic dispersion. At the scale of individual channels within the network, hydrodynamic dispersion represents storage, turbulence, and shear stress processes that make portions of a channel's water volume move downstream faster than others, rather than as a single, discrete pulse. Hydrodynamic dispersion, which can be visualized by placing a volume

Figure 3-2. Time series of rainfall and streamflow observations in the Rio Puerco and Rio Grande, 6−18 September 2003. of dye tracer in an upstream location and watching how the dye disperses longitudinally as it moves downstream, takes into account water flowing into and out of recirculating eddies at channel margins, off-channel sloughs, the streambed, and nearby bank sediments (see hyporheic exchange, Section 2.2.2).

These areas, which mix with the main channel flows at relatively slow rates, are collectively part of the stream's transient storage. As streamflow decreases after a storm, water that was temporarily stored in the banks, the floodplain, and other off-channel habitats flows back into the channel and supports stream baseflow (Sections 2.2.3 and 4.3.2.1; Whiting and Pomeranets, 1997; Chen and Chen, 2003; Baillie et al., 2007). Hydrodynamic dispersion is also readily apparent when flow resumes in ephemeral channels. The velocity at the front of flow moving down the dry channel is much slower than upgradient of the front because of higher turbulence and infiltration losses at the front. Flow in these situations, piles up at the front and is reflected as rapid rises in the hydrographs (Figures B-6 and B-10).

Hyporheic flowpaths have been characterized for a variety of situations that affect streambed topography and impede flow across a range of spatial scales (e.g., gravel bars, channel meanders, pool-riffle sequences, and large woody debris; Buffington and Tonina, 2009; Stonedahl et al., 2010; Sawyer et al., 2011) and in varying flow conditions that shift streambed topography (Harvey et al., 2012). The residence time that water spends in the subsurface alluvium before upwelling into streams—that is, the hyporheic residence time—is defined locally by the pressure head, alluvial volume, hydraulic conductivity, bed stability, and near-bed turbulence. For example, because 90% of the stream length in mountainous drainage basins is composed of steep channels with associated bed-form sequencing and limited alluvial volumes, most hyporheic exchange in these systems is expected to be rapid, shallow, and occur over small spatial scales (Buffington and Tonina, 2009). Slower, deeper, and longer hyporheic flowpaths occur in streams in unconfined valleys, with moderate hydraulic gradients and extensive alluvial volumes. In streams of both regions, hydrologic connections exist between shallow ground-water sources and stream channels, but the characteristics of these connections differ. These differences in hydrologic residence time are important, given that residence time reduces downstream flooding, controls various biogeochemical processes, and influences the distribution of stream organisms (Sections 3.4 and 3.5).

Geomorphologic dispersion is the cumulative effect of different travel distances over the larger spatial scale of entire river networks (Rodríguez-Iturbe and Valdes, 1979; Gupta et al., 1980; Rinaldo et al., 1991; Snell and Sivapalan, 1994). Not all points along the river network (or even headwater streams) are equidistant from the network outlet, so water simultaneously entering different parts of the network will not simultaneously arrive at the outlet.

Geomorphologic dispersion assumes water flowing through the network moves at a constant velocity or has varying resistance to downgradient transport. Within river networks, however, water velocity and related hydrodynamics change over space and time (e.g., channel slope and dimensions are not uniform across all pathways through the river network; Saco and Kumar, 2002; Paik and Kumar, 2004). Kinematic dispersion is the cumulative effect of spatially variable water velocity as it moves through river networks (Saco and Kumar, 2002). The physical configuration and variable channel form of streams within a river network, which influence components of hydrologic dispersion at varying scales, are the primary controls dispersing flow from streams to rivers over time and thereby cumulatively mediate the arrival time of stormwater pulses in rivers following rainstorms (Saco and Kumar, 2008).

Another factor that influences hydrologic response is channel transmission loss, or the loss of surface-flow volume due to infiltration into unconsolidated alluvium (Section 2.2). Transmission is another process by which streams, particularly in arid and semiarid regions, can slow or divert from the longitudinal flow of water to downstream rivers and thus minimize downstream flooding. Channel transmission losses are readily apparent from a series of hydrographs recorded in the USDA-ARS Walnut Gulch Experimental Watershed (Figure B-10). These hydrographs are the result of several high-intensity thunderstorms in the upper and lower portions of the watershed. As little or no lateral overland or tributary inflow occurs between the two upstream flumes, the decrease in both peak runoff rate and runoff volume is the result of channel transmission losses and dispersion only. As illustrated in this figure, however, even though runoff transmission losses are large there is sufficient runoff to increase flow in the San Pedro River at the downstream Tombstone USGS gaging station. Over relatively short time frames, infiltration or seepage through channel bed and banks typically dominates transmission losses, although evapotranspiration losses can be significant in stream reaches with prolonged surface flows (Hamilton et al., 2005; Costelloe et al., 2007). In many arid areas, precipitation and the potential for runoff are highest in mountainous regions, where small, ephemeral streams are most abundant (Section B.5). Because streams represent the topographic low points in watersheds that collect and concentrate surface water, they tend to have more water available for infiltration, be more permeable (have coarser sediment) than upland soils, have fewer plants, have higher antecedent moisture, and be closer to shallow ground water—all of which are factors that increase the potential for infiltration. In fact, evidence is mounting that ground-water recharge in hot arid and semiarid areas will occur only where water is concentrated and focused, such as in channels, depressions, or areas of high infiltration (e.g., karst; Brahana and Hollyday, 1988; Hughes and Sami, 1992; Sharma and Murthy, 1995; Scanlon et al., 1997; Scott et al., 2000; Constantz et al., 2002; Coes and Pool, 2005). Infiltrated precipitation in upland portions of alluvial drainage basins rarely reaches the ground-water table as recharge due to high potential evapotranspiration, the adaptation of xeric plants to use available soil moisture efficiently, and upward temperature gradients that transport water vapor upward in thick vadose zones. Relative to their cumulative surface area, an inordinate amount of ground-water recharge occurs in headwater ephemeral and intermittent channels within arid drainage basins (Osterkamp et al., 1994; Goodrich et al., 2004).

Channel bed and bank permeability also governs the degree to which infiltration is an important pathway between streams and ground-water aquifers. Fine bed and bank sediments slow infiltration. In many semiarid and arid streams, bed sediments become finer in the downstream direction because flow competence declines (Dunkerley, 1992), suggesting that lateral and vertical hydrologic connections might be especially important in headwater streams. Sand and gravel mining in ephemeral and intermittent channels and other human alterations that increase fine sediment loading and deposition can further slow percolation (Bull and Scott, 1974). Because fine sediments can concentrate in channels following moderate flows, higher flows that scour fine sediments or submerge more permeable floodplains have higher infiltration rates (Lange, 2005). In the Walnut Gulch Experimental Watershed, cumulative transmission losses over 54 km of channel resulted in a 57% decrease in flow volume associated with a storm (Renard and Keppel, 1966). Infiltration losses accounted for up to half the flow volume along three ephemeral channels in the southwestern United States (Constantz et al., 2002). Chemical and isotopic tracers have confirmed that ephemeral streams are cumulatively important areas for floodwaters to recharge ground-water aquifers in desert regions (Tang et al., 2001). Although transmission losses represent disruptions of surface connectivity between streams and downstream waters, such losses indicate vertical hydrologic connections that reduce downstream flooding and recharge the ground-water aquifers that eventually contribute to flow in downstream waters (Izbicki, 2007).

Human alterations designed to control the spatial and temporal distribution of water have affected the longitudinal, lateral, vertical, and temporal dimensions of hydrologic connectivity in river networks. Structures such as dams, weirs, levees, culverts, and pipes alter longitudinal transport, restrict lateral expansion, and alter vertical exchange (e.g., Gregory, 2006; Hester and Doyle, 2008; Park et al., 2008). Surface-water and ground-water abstraction and diversion can cause tributary segments to dry, thereby severing longitudinal and vertical connectivity and reducing or eliminating lateral connectivity during low-flow periods (e.g., Colvin and Moffitt, 2009; Scanlon et al., 2012). Human alterations that increase fine sediment deposition or microbial biofilm in streambeds also can hamper vertical exchange (Battin and Sengschmitt, 1999; Rehg et al., 2005), causing conditions that can become chronic without periodic floods to flush out deposited sediments and biofilms (Box 3-1).

Human alterations also can affect the temporal dynamics of hydrologic connectivity in river networks. In a predominantly rural river network in central Illinois, the total dispersion of the flow was controlled primarily by geomorphological (~60%) and kinematic dispersion (~35%; Saco and Kumar, 2002). In contrast, hydrodynamic dispersion cumulatively contributed to 72–86% of the total dispersion in highly urbanized watersheds in the Chicago metropolitan area (Cantone and Schmidt, 2011). The rapid hydrologic travel times associated with impervious surface runoff and rapid flow through the sewer and storm drain networks contributed to the predominant influence of hydrodynamic dispersion (Cantone and Schmidt, 2011).

Interbasin water transfer also affects the temporal and spatial dynamics of flow in human-dominated river networks (Meador, 1996). Water is fundamental to human societies for drinking, food production, industry, waste transport and processing, recreation, and aesthetics. Engineered infrastructure moves water (and associated waste products) where and when it is needed (or removes it from where it is unwanted). Many streams in human-dominated watersheds, particularly streams that historically have ephemeral and intermittent flows, receive a significant proportion of their baseflow from municipal and industrial wastewater effluent discharges (Box 3-1). Streams that would be dry in the absence of these discharges are called effluent-dependent streams, whereas those that receive most, but not all, of their flow from effluent are called effluent-dominated streams (Brooks et al., 2006). About 25% of permitted effluent discharges in the United States enter streams with mean annual flows incapable of diluting effluents by more than 10-fold. This percentage of permitted effluent discharges entering streams incapable of diluting effluents by more than 10-fold increases to 60% when low-flow discharge is considered (Brooks et al., 2006). Streams draining human-dominated areas also can derive baseflow from ground water recharged by over-irrigation and leaky infrastructure (Lerner, 1986; Roach et al., 2008; Townsend-Small et al., 2013).

Ultimately, these alterations can increase the frequency, duration, magnitude, and predictability of baseflows when tributaries might otherwise contain little or no water. Because dry periods in intermittent and ephemeral streams contribute to the key transformation, lag, and refuge functions these systems perform (Sections 3.4 and 3.5), loss of these dry periods has consequences for downstream waters. In addition, when water is stored or imported for human use, it is essentially being "borrowed" from another period or location, which then must contend with reduced water availability. Without careful water management and reuse (e.g., Bischel et al., 2013), any benefits of baseflow augmentation can be overshadowed by potential risks, such as increased contaminant and pathogen exposures (Section 3.4.4) and increased success of introduced species (Jackson and Pringle, 2010).

3.3.2 Sediment

Sediment carried with water flow from streams to downstream waters is critical for maintaining the river network. Fluvial sediments scour channels, deposit to form channel features, and influence channel hydrodynamics (Church, 2006). Although sediment is essential to river systems, excess sediment can impair ecological integrity by filling interstitial spaces, reducing channel capacity, blocking sunlight transmission through the water column, and increasing contaminant and nutrient concentrations (Wood and Armitage, 1997).

Sediment in headwater streams originates from nearby hillslopes and enters these streams via overland flow, bank erosion (Grimshaw and Lewin, 1980), and infrequent disturbances such as landslides and debris flows (e.g., Benda and Dunne, 1987; Swanson et al., 1998; Eaton et al., 2003). Sediment transported within river networks can be divided into two major categories: suspended and bedload. Suspended sediment is fine sediment (clay, silt, fine sand) that requires slow velocities and little turbulence to remain entrained in the water column; bedload sediment is coarser particles that slide, roll, and bounce along the streambed during faster, more turbulent flows (Church, 2006; Wilcock et al., 2009).

The dynamic balance between sediment supply and transport capacity (Lane, 1955; Bull, 1991; Trimble, 2010)—with the variables of sediment flux and sediment grain size on one side, and discharge and channel slope on the other—is a principal paradigm of fluvial geomorphology. If one of these variables changes, a compensatory change occurs in at least one of the other variables. For example, if discharge increases, a lower channel slope is needed to transport the same amount of similarly sized sediment; alternatively, less discharge or lower channel slope is needed to move a load of fine sediment than the same load of coarse sediment. Associated with this balance is the relationship between channel geometry (width and depth) and discharge (Leopold and Maddock, 1953), and adjustments to maintain a dynamic balance also can include changes in channel dimensions.

The sediment supply-transport capacity balance is particularly relevant to geomorphologic connectivity in river networks, because these variables typically differ as one moves from headwater streams to downstream rivers (Ferguson et al., 2006; Ferguson and Hoey, 2008). For example, slope and grain size typically decrease, whereas discharge and channel size typically increase, in downstream reaches (Church, 2002). Thus, streams cumulatively and aggregatively affect rivers in part by changing sediment supply or transport capacity locally at confluences over time. Relatively small, local contributions in sediment and discharge from a tributary stream might elicit no detectable change or only a short-lived spike in downstream sediment characteristics, discharge, or channel geometry. In contrast, tributary streams making large relative contributions at mainstem confluences elicit strong, stepped changes in mainstem characteristics. Because headwater streams can make large contributions during infrequent disturbances (e.g., floods, debris flows), the influence of headwater streams on downstream waters can vary significantly over time, and even headwater streams can have long-lasting effects on rivers.

Human alterations can exert considerable influence on the structure and distribution of a watershed's river network, thereby affecting sediment-based connections between headwater streams and downstream waters. For example, road building in steep forested areas in the U.S. Pacific Northwest can cause soil erosion, create concentrated discharge, and increase stream channel network lengths, all of which affect the spatial distribution, intensity, and timing of erosional processes and cumulative sediment delivery to downstream waters (Montgomery, 1994; Wemple et al., 1996; Wemple et al., 2001).

Dams also modify sediment dynamics within river networks. Sediment concentrations and suspended loads can be reduced for hundreds of kilometers downstream of dams, as is especially apparent in the semiarid and arid western U.S. river networks (Williams and Wolman, 1984). The disruption of downstream sediment supply by dams alters the balance between sediment supply and transport capacity (Williams and Wolman, 1984; Kondolf, 1997). Water released from dams lacks sediment load and thus has excess energy. This energy often downcuts channels downstream of dams, causing channel incision and streambed coarsening as finer gravels and sands are transported downstream over time (Williams and Wolman, 1984; Kondolf, 1997). The elimination of floods enables the encroachment of terrestrial vegetation, resulting in channel narrowing and the conversion of complex, multithreaded channels into simple, single-thread channels.

Other human activities also can affect sediment dynamics. Gravel and sand mining locally removes bed sediment and lowers streambed elevation, creating a steep gradient change. Erosion of the streambed can occur both upstream and downstream of the mine. The steep gradient change increases stream power locally, which increases sediment demand and causes the streambed to erode in the upstream direction via headcutting, which often extends far up into tributary channels (e.g., Florsheim et al., 2001; Rinaldi et al., 2005; Rieke-Zapp and Nichols, 2011). Erosion in the downstream direction occurs because most of the sediment being carried by water is deposited in the mining pit, leaving the water that passes over the pit with excess energy that subsequently leads to downstream channel downcutting (Bull and Scott, 1974; Kondolf, 1997). These examples show that the dynamic balance between sediment supply and transport capacity represents a fundamental longitudinal connection along the river network that must be considered to determine the potential repercussions of human alterations.

Streams transport and store sediment. Headwater streams tend to have low competence to transport sediment during baseflow (Gooderham et al., 2007), but they have structures (boulders, woody debris) that entrain and store colluvial sediments between infrequent disturbances (e.g., stormflows) that are the dominant means for downstream sediment transport (e.g., Gomi and Sidle, 2003). Because of their abundance and distribution, headwater streams can have a substantial cumulative effect on downstream waters via sediment storage and transport. Poor soil conservation, drainage of wetlands, deforestation, and tributary channelization associated with the development of agricultural land has long been recognized as being detrimental to downstream waters via their connections with headwater streams (Person et al., 1936). To stem further degradation, government agencies encouraged and funded various soil conservation practices and the construction of small impoundments on headwater streams to trap sediment and provide stable water supplies for livestock, irrigation, and recreation (Person et al., 1936; Renwick et al., 2005). Although most such ponds are small (≤1 ha or 2.5 acre) and represent only ~20% of the total impounded area (or 0.4% of the total watershed area), they can cumulatively have a significant effect. For example, Smith and Kraft (2005) estimated that the approximately 2.3 million ponds distributed primarily on headwater streams of the Mississippi River network cumulatively captured 25–50% of the eroded soil from the landscape.

Ephemeral desert streams are another example of sediment connections between headwater streams and downstream waters. These ephemeral streams can exhibit high sediment export efficiency by having higher bedload per unit stream power than that of forested perennial streams (Laronne and Reid, 1993). Despite infrequent flows of short duration, flood waves (bores) in ephemeral desert streams can carry substantial amounts of sediment downstream (Hassan, 1990). The transport distance associated with these floods, however, often is insufficient to link them directly to perennial rivers. For example, a reach-scale study in the Walnut Gulch Experimental Watershed in Arizona estimated sand transport distances of only 401 and 734 m in nine floods over two consecutive years (Powell et al., 2007). Over longer times spans the episodic nature of flow in ephemeral and intermittent channels transfers sediment in a stepwise manner, depositing sediment some distance downstream and then moving it farther downstream by subsequent events. The frequency, timing, and predictability of stream runoff and therefore sediment transport vary widely with significant seasonal, annual, and interannual variations that depend on elevation, climate, channel substrate, geology and the presence of shallow ground water. Over longer time spans, however, sediment will continue to move downstream and affect downstream waters (Brooks and Lemon, 2007).

Despite increasing bank erosion rates with increasing channel size and discharge, sediment yield from watersheds typically decreases with increasing drainage area, due to increased sediment deposition within channels and on nearby floodplains (Walling, 1983). This storage of sediment contributes to the temporal attenuation or lag in the sediment delivery to downstream waters; it also illustrates that headwater streams are important sediment sources for maintaining channels and floodplains.

Streams also can store substantial amounts of sediment that are released only during rare export events. A series of experimental sediment introductions into steep, ephemeral, second-order streams in southwestern Washington showed that between 30 and 45% of the added sediment (ranging from clay to coarse sand) was exported to the mainstem 95−125 m downstream, during stormflows of 66−69% of bank full discharge (Duncan et al., 1987). Virtually all the added fine clay particles were exported from the ephemeral streams to the mainstem, presumably because this fraction remained suspended at even moderate flows (Duncan et al., 1987). Headwater streams within an Oregon Coastal Range watershed (2.5 km^2 area) stored 23% of total stored sediment within the watershed's river and valley network, compared with only 9% storage within the mainstem channel (May and Gresswell, 2003). Trimble (1999) constructed a long-term sediment budget for the Coon Creek watershed (360 km^2), a Wisconsin stream in the Mississippi River drainage, over periods coinciding with major land-use changes. When agricultural practices caused major soil erosion (1853–1938), streams acted as net sources of sediment (42×10^3 Mg yr^{-1}); after erosion control, streambank stabilization, and revegetation (1975–1993), streams became net sediment sinks (9×10^3 Mg yr^{-1}) (Trimble, 1999).

Several studies identify abrupt changes in sediment size and channel morphology that coincide with stream confluences having sufficiently high symmetry ratios (Knighton, 1980; Rhoads, 1987; Rice and Church, 1998; Rice et al., 2001). Reviews of tributary confluence data have identified that symmetry ratios ranging from 0.2 to 0.7 are needed to create a discernible sediment or channel morphology discontinuity along a mainstem (Rhoads, 1987; Benda, 2008). Suspended particulate matter (inorganic + organic) and bed particle size were measured above and below eight confluences on the Acheron River in Australia to determine stream contributions (Wallis et al., 2008; Wallis et al., 2009). Suspended particulate matter downstream of confluences approximated the sum of mainstem and stream exports during high flows, but stream contributions were negligible during low flows (Wallis et al., 2009). Four of the eight confluences showed expected changes in bed particle size below confluences with streams, but bed particle sizes were similar in the mainstem and stream for the remaining confluences (Wallis et al., 2008).

Streams, through their connections to rivers at confluences, can disrupt longitudinal trends in discharge of water and sediment in rivers (Best, 1988; Benda et al., 2004; Ribeiro et al., 2012). For example, dams often remove much of the sediment from transport, whereas most streams naturally are sediment sources. The objective of a study on the Agigawa River in Japan was to examine contrasting disruptions associated with a dam (sediment removal) and a stream confluence (sediment discharge) downstream of the dam (Katano et al., 2009). Stream sediment contributions to the river reversed many of the dam-related changes to downstream waters, including restoration of turbidity levels and the proportion of sand and gravel substrate in the river bed (Katano et al., 2009). Other upstream land uses can also have an effect on downstream sediment transport. Numerous modeling studies have shown how land use can affect sediment export from headwater streams to downstream waters. For example, Howarth et al. (1991) used the Generalized Watershed Loading Function model in the Hudson River estuary and its associated watershed and demonstrated that urban, suburban, and agricultural land uses in headwater watersheds produced the highest proportion of downstream sediment and organic carbon delivery to the estuary. More recently, Wilson and Weng (2011) applied the Soil and Water Assessment Tool in the Des Plaines River watershed in Illinois to simulate the cumulative effects of headwater streams on downstream total suspended solids concentrations. Their calibrated model projected that expansion of medium- and high-density residential development in place of low-density residential development in headwater subwatersheds would decrease downstream total suspended solid concentrations.

3.3.3 Wood

Large woody debris (typically considered >10 cm diameter and >1 m long) has a strong influence on hydrodynamics, sediment transport and storage, and channel morphology (e.g., Harmon et al., 1986; Nakamura and Swanson, 1993; Abbe and Montgomery, 1996; Naiman and Decamps, 1997; Montgomery et al., 2003). Woody debris dissipates energy, traps moving material, and forms habitat for aquatic plants and animals (Anderson and Sedell, 1979; Harmon et al., 1986; Abbe and Montgomery, 1996; Naiman and Decamps, 1997; Gurnell et al., 2002). In-channel wood can redirect water movements, create pools, and slow water movement through a channel (Nakamura and Swanson, 1993; Abbe and Montgomery, 1996; Naiman and Decamps, 1997). Wood recruitment to forested streams occurs because of chronic tree mortality; episodic disturbances such as fire, debris flows, landslides, and windthrow; and bank erosion. The steeper topography associated with hillslopes along many headwater streams increases the likelihood that trees will fall toward the channel (Sobota et al., 2006), relative to streams in flatter terrain. Environmental setting, including valley slope, influences the supply of wood to streams and therefore the degree of connectivity between streams and downstream waters.

Wood tends to accumulate in, rather than be exported from, most forested headwater streams, due to their low discharge and relatively narrow channel widths (Keller and Swanson, 1979; Bilby and Ward, 1989; Gurnell, 2003). For example, wood was determined to have entered the channel more than 60 years earlier in a North Carolina headwater stream (Wallace et al., 2001); in some Pacific Northwest streams, wood entered the channel more than a century earlier (Swanson and Bachmann, 1976; Keller et al., 1981). Because of the large occurrence of wood and small size of streams, wood has a stronger influence on hydrologic and geomorphic processes in headwater streams than in most larger rivers (Bilby and Bisson, 1998).

Large, infrequent disturbance events are the primary drivers for wood movement from headwater streams (Benda and Cundy, 1990; Benda et al., 2005; Bigelow et al., 2007). Reeves et al. (2003) determined that 65% of the wood pieces and 46% of the wood volume in a fourth-order stream in Oregon's Coastal Range were delivered downstream from headwater streams by debris flows, rather than originating from the riparian zone next to the fourth-order channel. Using data from 131 reservoirs in Japan, investigators identified a curvilinear relationship between watershed area and large woody debris export (Seo et al., 2008); wood export per unit area increased with stream size for headwater streams (6–20 km^2), peaked at intermediate-sized streams (20–100 km^2), and then decreased with stream size for large streams (100–2,370 km^2). The amount of wood in low-gradient midwestern streams was determined to be supply limited mainly because human alteration both depletes large wood sources and results in altered hydrology and channel structure enhancing downstream transport of small wood (Johnson et al., 2006). Topography and topology also govern wood delivery from headwater streams. Downstream segments draining steep, finely dendritic networks receive a greater proportion of wood from headwater streams than networks that are low gradient and weakly dissected (Benda and Cundy, 1990; Reeves et al., 2003).

Additional evidence on wood-mediated connections along the river network comes from studies of wood upstream and downstream of tributary confluences. Several studies have assessed the distribution of wood associated with confluences. Wood volumes were measured upstream and downstream of 13 confluences (symmetry ratios ranged from 0.05 to 0.49) in the Cascade Range of western Washington (Kiffney et al., 2006). Wood volumes tended to peak at or immediately downstream of stream confluences (Kiffney et al., 2006), suggesting that streams are either important sources of wood to mainstems or alter channel form to enhance wood storage at confluences. Elevated wood density, however, was not associated with confluences of eight streams to the Acheron River in Australia (Wallis et al., 2009). The authors concluded that the study streams had insufficient capacity to transport wood to the mainstem, because streams had similar slope to the mainstem but lower discharges (Wallis et al., 2009).

Large wood can shorten sediment transport distances and debris flow runout by entrainment (Lancaster et al., 2003). Woody debris in 13 Coastal Range streams in Oregon had accumulation rates ranging from 0.003 to 0.03 $m^3\ m^{-1}\ yr^{-1}$, largely based on time since the last debris flow (May and Gresswell, 2003). The volume of instream wood was strongly related to the volume of sediment stored. On average, 73% of stream sediment, prone to debris flow transport, was stored behind instream wood (May and Gresswell, 2003). Unlike most human-built dams, natural logjams and beaver dams are temporary structures that do not completely restrict transport of water, sediment, and biology across all discharge levels. Although natural wood accumulations act to restrict longitudinal connectivity by slowing the downstream transport, these features enhance lateral and vertical connectivity with the floodplain and hyporheic zone, respectively (Burchsted et al., 2010; Sawyer et al., 2011). The importance of wood in decreasing longitudinal connectivity, while enhancing lateral connectivity, temporary storage, and habitat diversity has been documented not only locally at unit and reach spatial scales (1–100 m stream length) but along entire networks where valley confinement is an important predictor for wood storage (Wohl and Beckman, 2014). Past and ongoing human activities (timber harvest, beaver trapping, road building along streams, placer mining, log floating, desnagging) have so completely removed in-channel wood and availability of near-channel old-growth wood recruitment, that retention of new wood in channels is unlikely (Wohl and Beckman, 2014). Wood (and associated sediment) movement from headwater streams to downstream segments occurs through infrequent, high-magnitude events (e.g., debris flows, fire). Once in larger streams, wood and sediment can be stored in alluvial fans and floodplains between stormflows that trigger additional downstream movement through the network (Benda et al., 2005). Because of the long distances and infrequent triggers associated with wood transport from most headwater streams to rivers, the relevant periods for governing transport aggregate over decades to centuries (Benda et al., 1998). Wood entering headwater streams can affect the downstream transport of water and materials in headwater streams, but also can be transported downstream from headwater streams where it is important habitat for aquatic life, a source of dissolved and particulate organic matter, and influential in controlling hydrodynamics and channel morphology of rivers.

3.3.4 Temperature (Heat Energy)

Connections between streams and downstream waters can affect heat transfer, and thus water temperature, throughout river networks (Knispel and Castella, 2003; Rice et al., 2008). Heat is thermal energy transferred across a boundary, whereas temperature is the amount of thermal energy per unit volume (Coutant, 1999; Poole and Berman, 2001). Therefore, the amount of heat and the size of the water body (i.e., volume, discharge) are fundamental controls of water temperature. Because water temperature is such a fundamental property that drives physical (e.g., viscosity and density of water), biological (e.g., organism behavior and physiology), and biogeochemical (e.g., nutrient assimilation and mineralization) characteristics of stream ecosystems, it can cumulatively have significant indirect effects on downstream waters via its effects on other forms of connectivity. This influence can occur over even relatively small spatial scales or patches (Sections 3.4 and 4.5; Allan, 1995). For example, water temperature strongly regulates stream ecosystem respiration, which then drives nutrient uptake (Section 3.4.1; Demars et al., 2011). Warmer temperatures exacerbates eutrophication problems such as fish kills, and heat stress can interact with chemicals synergistically or antagonistically making them more or less toxic to organisms, respectively (e.g., Holmstrup et al., 2010).

The total net heat exchange for a stream has several components, including heat flux from solar radiation, evaporation, convection with air, conduction with the streambed sediments, and advection with direct inputs from precipitation, ground water, tributaries, and effluents (Webb, 1996; Coutant, 1999). Given these diverse thermal energy fluxes, numerous direct and indirect factors can change stream temperature. For instance, riparian vegetation directly affects stream temperature by insulation (shading incoming solar radiation and trapping air, reducing wind; Moore et al., 2005) and indirectly affects stream temperature via its influence on channel morphology (e.g., Trimble, 1997) and degree of hyporheic exchange through input of woody debris (e.g., Sawyer et al., 2012). Channel morphology can directly influence stream temperature by affecting bank shading and altering channel width-to-depth ratio, and indirectly influence stream temperature by affecting hyporheic exchange. Hyporheic exchange influences stream temperature via buffering (reducing the diel temperature range) and lagging (offsetting daily temperature patterns relative to surface-water patterns) effects, due to the extended alluvial flowpath and by the advection or conduction of thermal energy or both (Arrigoni et al., 2008).

Over coarse spatial scales, a nonlinear increase in mean daily water temperature typically occurs from headwater streams to large rivers (Caissie, 2006). A unimodal trend occurs in daily variation (i.e., daily maximum-minimum) of water temperature, as stable ground-water temperatures (in headwater streams) and greater depth and volume of water (in large rivers) buffer water temperatures from the daily changes typical in intermediate-sized streams (Caissie, 2006). The steep increase in water temperature immediately downstream of headwater streams is associated with more rapid flux of heat into headwater streams, as shallow water contacts the surrounding air and receives direct radiation (Caissie, 2006). This longitudinal pattern, however, does not hold for all river networks: Some river networks receive substantial deep ground-water contributions at lower reaches or advective inputs from tributaries along the mainstem. Channel network configurations can influence the length, dominant aspect relative to the sun, and distribution of tributaries, which influence the thermal heterogeneity along a stream that might be associated with inflowing surface and hyporheic water. Callahan et al. (2015) illustrated how topographic, geomorphic, riparian, and hyporheic exchange can interact to influence stream temperature in the Kenai Peninsula, AK. Ground-water inputs played important moderating roles in determining stream temperatures in both low-gradient versus steep headwater streams, despite these streams having different channel morphologies, draining contrasting topographies, and having different riparian canopies (Callahan et al., 2015). Although low-gradient headwater streams had fewer channel margin seeps and lower hyporheic exchange than the steep headwater streams, the subsurface-water temperature entering the low-gradient streams was lower during summer than that entering the steep streams (Callahan et al., 2015).

Although many studies have determined that several direct and indirect factors can alter stream temperature, including those listed above, these effects typically have been documented to carry for only short distances downstream. This is in part because most studies measuring stream temperature changes are conducted over reach or subreach scales (<100 m) and because stream-water temperature equilibrates rapidly (~4 hr) to immediate surrounding conditions (e.g., Zwieniecki and Newton, 1999; Rutherford et al., 2004; Hester et al., 2009). Some studies, however, do provide evidence of thermal connections along river networks. The empirical evidence supporting thermal connections between headwater streams and downstream waters includes studies that have gauged the spatial relationship of water temperature over river networks and studies that have detected discontinuities in river temperature associated with stream confluences. Geospatial analyses are used to assess the degree of spatial dependence of a variable across a river network, and are particularly well suited for studying connectivity within these systems. Studies of this type have shown that upstream water temperature is significantly related to downstream water temperature, even over relatively long distances. For example, water temperature data collected at 72 locations throughout a Catskill Mountain, NY watershed were used to predict daily mean summer water temperatures spatially throughout approximately 160 km of channel (Gardner and Sullivan, 2004). Results showed that water temperatures at points along the river network separated by up to nearly 20 km were related. Johnson et al. (2010) similarly used geostatistical analyses to determine the influence of headwater streams on downstream physicochemistry, including water temperature. Water temperature within the eastern Kentucky watershed was correlated across the river network over an average distance of approximately 5 km (Johnson et al., 2010).

Studies that have detected discontinuities in river temperature associated with stream confluences also provide evidence of thermal connections along river networks. Ebersole et al. (2003) identified and characterized cold patches along a river network in northeastern Oregon that largely had summer water temperatures exceeding the tolerance limit of native salmonids. Floodplain springbrook streams were among the cold patches identified and were determined to contribute the coldest water to the river network (Ebersole et al., 2003). A subsequent study in northeastern Oregon determined that tributary confluences typically provided coldwater (≥3 °C colder than mainstem temperatures) patches during the summer (Ebersole et al., 2015). In addition, 39% of these tributary confluences were with streams that contributed cold hyporheic water even when they lacked surface water—that is, they were ephemeral and intermittent streams that were significantly connected to downstream waters even when the streambed surfaces were dry (Ebersole et al., 2015). Unexpectedly, factors such as tributary size, flow presence, and flowpath length were not important in predicting whether a tributary's confluence would be a cold patch. Rather, the probability of a confluence's being a cold patch was largely explained by amount of available water at the end of the snowmelt season (Ebersole et al., 2015).

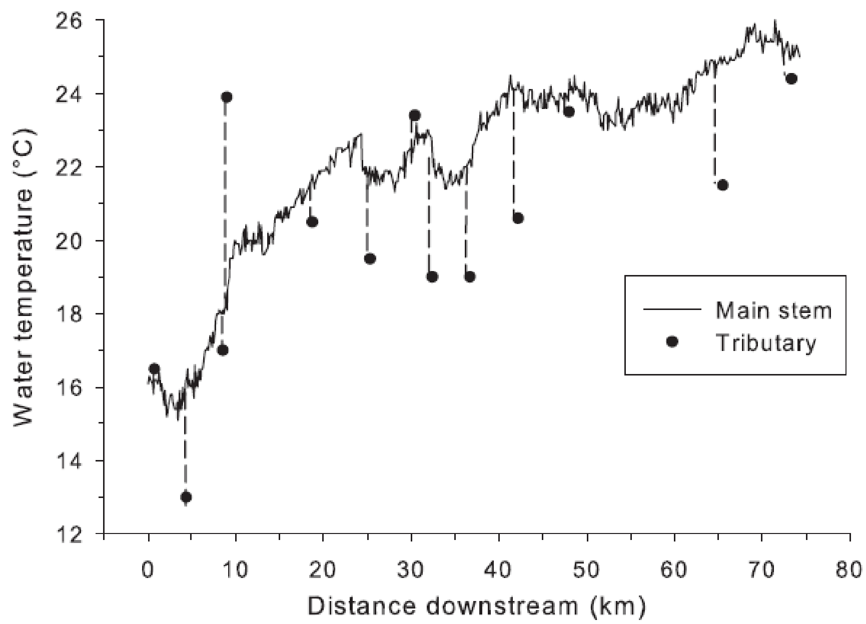
Thermal infrared sensors are a recent remote-sensing tool that can provide snapshots of thermal heterogeneity along river corridors (Torgersen et al., 2001; Torgersen et al., 2008; Cristea and Burges, 2009). Thermal maps and plots of longitudinal profiles overlaid by stream locations show that confluences coincide with distinct peaks and troughs in river temperature (Figure 3-3). The effects of streams were discernible when temperature differences of streams and the mainstem exceeded 1 °C and streams had large symmetry ratios (Cristea and Burges, 2009). In most cases, the effect of the stream on river-water temperature was minor relative to longitudinal changes over the course of the river (Torgersen et al., 2001; Cristea and Burges, 2009). Despite having a relatively minor effect on temperature over the length of entire rivers, however, streams provide persistent coldwater habitats that are less susceptible to meteorological variation than other classes of thermal refuges and therefore are particularly important for aquatic life (Section 3.5.2; Dugdale et al., 2013).

Although headwater stream temperatures are highly responsive to local conditions, they still can have a cumulative effect on downstream waters. The fact that large-scale alteration of headwater streams has been documented to affect downstream water temperature illustrates this point. For example, reductions in baseflow (ground-water inputs) resulting from increased surface runoff from impervious surfaces (Leopold, 1968) and reduced hyporheic exchange through the engineered piping, straightening, and hardening of streambeds contribute to increased average and maximum summer water temperatures and decreased average and minimum winter temperatures in downstream waters. The combination of riparian vegetation removal, increased urban runoff, and storm sewer inputs results in larger temperature swings associated with increased channel width-to-depth ratios and thus air-water surface area available for radiant, evaporative, and convective fluxes (LeBlanc et al., 1997).

3.4 Chemical Connections

Chemical connections are linkages between headwater and other tributary streams and their downstream waters based on the transport of chemical elements and compounds (e.g., nutrients, dissolved and particulate organic matter, ions, and contaminants). Chemical connectivity between streams and rivers involves the transformation, removal, and transport of these substances throughout the river network; these processes, in turn, influence water quality, sediment deposition, nutrient availability, and biotic functions in rivers.

Figure 3-3. Airborne thermal infrared remotely sensed water temperature in the mainstem and at tributary confluences of the North Fork John Day River, OR, on 4 August 1998. Line indicates mainstem, black dots indicate tributary confluences, and dashed vertical lines indicate location of tributary confluences along the mainstem. Reprinted with permission from Torgersen et al. (2008).



Because water flow is the primary mechanism for downstream transport of chemical substances, chemical connectivity is closely related to hydrologic connectivity (Sections 2.2 and 3.3.1). The movement of water across and through landscapes and into river networks integrates potential solute sources and sinks throughout the watershed. Thus, solute concentrations are an integration of upstream mixing processes and transport processes in the stream channel. In simplest terms, streams generally operate in two modes: a high-discharge throughput mode in which solutes and particles entering the stream channel are quickly transported downstream, and a low-discharge processing mode whereby solutes and particles are processed or stored near where they entered the river network (Meyer and Likens, 1979).

Factors that affect hydrologic connectivity (including precipitation patterns and human alterations) modify these upstream-downstream chemical linkages. For example, the spatial and temporal variability of rainfall affects chemical connectivity between streams and rivers. Many headwater streams receive pulsed inputs of water, sediment, organic matter, and other materials during rain events. Periodic flows in ephemeral or intermittent streams can have a strong influence on biogeochemistry by connecting the channel to other landscape elements (Valett et al., 2005), and this episodic connection can transmit substantial amounts of material into downstream rivers (Nadeau and Rains, 2007).

The alternation of dry and flowing periods largely drives the temporal dynamics of chemical connections between ephemeral and intermittent streams and downstream waters. The frequency, duration, magnitude, timing, and rate of change of flow further account for the variable connectivity observed within and across river networks over space and time (Section 1.2.2). Materials accumulate on and within dry streambeds where they are temporarily stored and can undergo transformations (Acuña et al., 2005; Fritz et al., 2006a; Ademollo et al., 2011; Arce et al., 2014). Transmission losses, tributary confluences, various channel forms, and retention structures also can contribute to the spatial distribution of materials and processes in dry streambeds (Marcus, 1987; Graf et al., 1991; Reneau et al., 2004; Taylor and Little, 2013). The onset of flows in ephemeral and intermittent stream channels, particularly those following long dry periods and initiated by floods (i.e., first flushes), are important in transporting and transforming large amounts of unique materials for long distances downstream, which then can have significant effects (e.g., Obermann et al., 2009; Hladyz et al., 2011; David et al., 2012). Human alteration of channel characteristics (e.g., channel shape and depth) and organic matter inputs also affect the ability of streams to temporarily store and cycle materials before transport to downstream waters.

Biogeochemical transformations control the mobility of different chemicals by altering chemical properties, such as form (e.g., dissolved, colloidal, gravitoidal), bioavailability, and toxicity. Thus, transformation is a key process influencing the downstream transport and attenuation of chemicals. Physicochemical (e.g., pH, redox potential, chelator concentration, light, hydrologic residence time) and biological (e.g., extracellular enzymes, physiology, lipid content) conditions control the location, rate, and timing of chemical transformations in streams and downstream rivers. For example, the introduction of stream restoration structures (e.g., small log dams) can affect the spatial distribution of oxic and anoxic zones in streambeds and thus biogeochemical cycling and reaction rates for instream biogeochemical processes throughout the river network (Lautz and Fanelli, 2008). These types of human alterations, in turn, affect the form of chemical substances and the timing of their transport downstream (Box 3-1). Data from the Baltimore Ecosystem Study Long-Term Ecological Research site suggest that increased hydrologic connectivity from urban infrastructure (e.g., pipes, storm drains, ditches) in headwaters increases the frequencies of occurrence and transport rates of nutrients, carbon, and metals to downstream surface waters (Kaushal and Belt, 2012). Urbanization can cause complex downstream responses, however, and sometimes creates longer travel times (i.e., reduced downstream connections). For example, aging infrastructure can leak water and pollutants into ground water rather than transporting these materials directly downstream.

3.4.1 Nutrients

Studies have documented nutrient-based chemical connections along river networks. Alexander et al. (2007) investigated how stream size affected nitrogen transport in a northeastern U.S. river network. First-order headwater streams contributed approximately 65% of the nitrogen mass in second-order streams, and approximately 40% of that mass in fourth-order and higher order streams (Alexander et al., 2007). Alexander et al. (2000) conducted a study of major regional watersheds of the Mississippi River basin, which showed that instream nitrogen loss was inversely related to mean stream depth. This finding most likely resulted from the reduced occurrence of denitrification and settling of particulate nitrogen in deeper channels, due to reduced contact and exchange between stream water and benthic sediments (Alexander et al., 2000). Böhlke et al. (2009) used laboratory-, local-, and reach-scale studies to describe the effect of seasonal and event-based variation of instream properties (e.g., stream depth, flow rates, temperature) on denitrification rates in headwater streams, which can cause interannual variations in rates of nitrate export to downstream waters. A dynamic transport model using a one-dimensional version of the advection-dispersion equation was developed to estimate progressive instream nitrate removal from first- to fourth-order streams (Alexander et al., 2009). Model simulations indicated that denitrification rate constants in headwater tributaries varied strongly by season, based on biogeochemical and hydrologic factors. This in turn had a cumulative effect on downstream nitrate export (Alexander et al., 2009). These studies highlight how stream size affects nitrogen-based chemical connections, with headwater streams within the network affecting downstream water quality.

Phosphorus-based chemical connections also have been documented. Doyle et al. (2003) modeled the relative influence of hydrogeomorphic and uptake processes on longitudinal phosphorus retention through a river network of first- through sixth-order streams. The model revealed greater variation in uptake relative to hydrogeomorphic processes, and the authors concluded that uptake processes influence downstream variation in phosphorus retention at the watershed scale more than hydrogeomorphology.

Research on hydrologic control and seasonality of nutrient export from streams in the Mississippi River basin similarly provides evidence of downstream connectivity (Section B.4.3.2.1). Export of dissolved reactive phosphorus from second- and fourth-order streams in agricultural watersheds occurred mainly during high-discharge conditions, with discharges equal to and greater than the 90th percentile exporting 84% of the dissolved reactive phosphorus, primarily during January and June (Royer et al., 2006). Similar patterns have been documented in total phosphorus concentrations of first- through fourth-order streams from another Mississippi River basin (Bayless et al., 2003). In another study, researchers modeled riverine dissolved reactive phosphorus yield of 73 watersheds within the Mississippi River basin during the January to June period, as a function of nutrient sources and precipitation (Jacobson et al., 2011). Riverine dissolved reactive phosphorus yield was positively related to fertilizer phosphorus inputs, human sources of phosphorus (e.g., sewage effluent), and precipitation, which generates surface runoff that moves fertilizer applied to the landscape into streams and rivers that then transport it downstream (Jacobson et al., 2011). These studies demonstrate the connections and processes by which nutrients exported from streams in the Mississippi River basin contribute to anoxia in the Gulf of Mexico (Rabalais et al., 2002).

Other environmental and biological processes also can affect nutrient-based chemical connections. The underlying geology of the Mokelumne River in California's central Sierra Nevada Mountains affected the spatial and temporal variability in chemical connections. Holloway et al. (1998) examined water quality in that watershed to identify primary sources of nitrate entering downstream reservoirs. They conducted a paired watershed comparison with two ephemeral streams in nearby watersheds that were underlain with different rock types (diorite vs. biotite schist) but had similar land-use, vegetation, topography, and watershed area. Many samples from the diorite watershed had nitrate concentrations below detection limits (<4 μM), with a median concentration of 3.3 μM; concentrations were not strongly associated with the start or end of the high precipitation period. In the biotite schist watershed, maximum stream concentrations of nitrate (>300 μM) occurred at the start of the high precipitation period, and concentrations decreased over time. A nearby perennial stream, also in a biotite schist watershed, displayed this same temporal trend, with highest nitrate concentrations at the beginning of the rainy season and decreasing concentrations during the spring. Holloway et al. (1998) concluded that biotite schist streams contributed a disproportionately large amount of total nitrate to downstream reservoirs, despite draining only a small area of the entire watershed.

In another study, nitrate concentrations were measured at 50 sites across the West Fork watershed of the Gallatin River in southwestern Montana's northern Rocky Mountains under different hydrologic conditions and across two seasons, growing and dormant (Gardner and McGlynn, 2009). Streams ranged from first-order mountain streams to fourth-order streams near the West Fork-Gallatin River confluence. In the dormant season, the distance over which nitrate concentrations were spatially correlated ranged from 3.2 to 5.5 km. In the growing season, this range decreased to 1.9 to 2.7 km. This seasonal difference likely resulted from greater biological uptake and use of nitrate during the growing season, which then limited its downstream transport; during the dormant season, downstream transport increased, resulting in greater spatial dependence in nitrate concentrations (Gardner and McGlynn, 2009).

Seasonal variability in chemical connectivity also was observed in Arizona's San Pedro River. Differences in dissolved organic nitrogen concentration were detected among three segments of the river during the dry season, but stream water was well mixed, the system was hydrologically connected, and no differences in dissolved organic nitrogen concentration were detected during the wet season (Brooks and Lemon, 2007). These seasonal differences occur because nitrogen accumulates locally at varying levels during drier periods but is mixed and transported downstream during large, infrequent storm events, making nitrogen concentrations more longitudinally uniform (Fisher et al., 2001).

Peterson et al. (2001) examined chemical connectivity by studying similar network components across different types of river networks. After measuring nitrogen export from 12 headwater streams distributed throughout the contiguous United States, Alaska, and Puerto Rico, they found that uptake and transformation of inorganic nitrogen were most rapid in the smallest headwater streams (Peterson et al., 2001). Given the prevalence of headwater streams on the landscape (Section 3.2) and their hydrologic connectivity to other river network components (Sections 2.2 and 3.3.1), headwater stream nitrogen processing can improve water quality in downstream waters. Many other studies also highlight the importance of nitrogen processing in headwater streams (e.g., Hill et al., 1998; Hill and Lymburner, 1998; Triska et al., 2007). Mulholland et al. (2008) measured in situ rates of nitrate removal by denitrification in 72 streams across different biomes and used those rates to model how headwater and larger streams in a river network respond to simulated nitrate loading increases. At low loading rates, the biotic removal of dissolved nitrogen from water is high and occurs primarily in headwater streams, which reduces loading to larger streams and rivers downstream. At moderate loading rates, the ability of headwater streams to remove nitrogen is reduced, but larger streams can remove the excess nitrogen. At high loading rates, removal by headwater streams and larger streams in the river network is ineffective, resulting in high nitrogen export to rivers (Mulholland et al., 2008). Similar results were obtained by Wollheim et al. (2008) in the Ipswich River, MA.

Helton et al. (2011) conducted simulation experiments that illustrated the effects of connectivity in the Ispwich River (MA) and Flat Creek (WY) networks, via the use of river-network models of nitrate dynamics. The nitrate models underpredicted nitrogen removal in many reaches, which was attributed to connections between the river channels and neighboring wetlands that were not characterized by the model and that functioned as nitrogen sinks (Section 4.3.3.2). By not representing the fine-scale variability in nitrogen uptake in river-network models and assuming that nitrogen uptake decreases with depth along a river network, simulations can potentially misrepresent the export of nitrogen from headwater streams to downstream waters (Darracq and Destouni, 2005, 2007). The potential for this misrepresentation, however, depends on the spatial scale of the study and the specific characteristics of the river network.

The influences of headwater and other tributary streams on nutrient concentrations in larger downstream waters, as detailed in the numerous examples above, reflect the combined processes of nutrient cycling and downstream transport that occur throughout river networks, albeit most intensively in headwater streams. The concept of nutrient spiraling provides an approach to quantifying these cycling and transport processes and a relatively simple framework for understanding their implications. As nutrients cycle through various forms or ecosystem compartments, being consumed and regenerated for reuse, they complete a “cycle” only after having been displaced some distance downstream, which stretches the cycle into a helix or “spiral” (Webster and Patten, 1979). The stretch of the spiral, or the openness between its loops, is primarily determined by flow, whereas the diameter of the loops is mainly determined by biological activity (Cummins et al., 2006). Nutrients such as dissolved phosphorus and nitrogen, which enter the stream via ground-water or overland flow, are removed from the water column by algae and microbial organisms. These nutrients are then consumed by organisms at higher trophic levels, transported farther downstream as suspended particles, or returned to the dissolved pool through cell death and lysis. Nutrients flowing through the food web also are regenerated to the dissolved pool via excretion and microbial decomposition. Nutrients in the dissolved, particulate, and living tissue phases of the cycling process are subject to downstream transport, such that each phase transition moves some distance downstream. The average downstream distance associated with one complete cycle—from a dissolved inorganic form in the water column, through microbial uptake, subsequent transformations through the food web, and back to a dissolved available form—is termed the “spiraling length.”

Although measurement of total spiraling length requires detailed study of tracer dynamics through multiple compartments of the stream ecosystem, Newbold et al. (1981; 1983a) have shown that it can be approximated by “uptake length” or the distance traveled in the water column before algal and microbial assimilation occurs. Uptake lengths for phosphorus and nitrogen can be estimated precisely only from tracer additions of radioactive or stable isotopes, but they can be roughly estimated from experimental additions that briefly raise the concentration of the natural form of the nutrient. Ensign and Doyle (2006) compiled results of 404 measurements of uptake length of phosphate, ammonium, and nitrate in streams and rivers ranging from first- to fifth-order. For a given stream order, they estimated the number of cycles that each nutrient had undergone as the ratio of median uptake length to the average length of stream for that stream order (from Leopold et al., 1964). They found that the three nutrient forms cycle between roughly 8 (nitrate) and 40 (ammonium) times within the length of a first-order stream, and between roughly 8 and 90 times within the respective lengths of first- to fourth-order streams.

Withers and Jarvie (2008) also compared phosphorus uptake lengths among different streams. Shorter uptake lengths are indicative of more rapid phosphorus cycling and greater efficiency of phosphorus retention. The shortest uptake lengths (2–580 m) were in first-order streams that drained “pristine” watersheds. Uptake lengths were longer (26–3,460 m) in second- to fourth-order streams that drained agricultural watersheds, and longest (4,140–367,000 m) in fifth-order rivers that drained a mixture of urban and agricultural land use (Withers and Jarvie, 2008).

These studies highlight the high nutrient-processing potential of headwater streams. This potential results from their low water volume-to-bed sediment area ratio, which enhances conditions for key nutrient uptake processes (e.g., adsorption, precipitation, assimilation) not only at the water-bed interface but within the streambed sediments (Withers and Jarvie, 2008). Downstream ecosystems depend on processes that occur in headwater streams. Given that roughly half the water reaching larger tributaries and rivers originates from headwater streams (Section 3.3.1), the results of Ensign and Doyle (2006) make clear that phosphorus and nitrogen arrive at downstream waters having already been cycled many times in headwater and smaller tributaries. This cycling is, fundamentally, a complex of ecosystem processes that intensively uses nutrients and then regenerates them for delivery to downstream waters much in their original form. Because nutrients undergo transformations across various forms (e.g., dissolved, particulate, inorganic, or in living organisms) while being transported downstream (i.e., spiraling), explicitly identifying their exact origin in the network can be difficult.

Although headwater nutrient cycling, or spiraling, functions largely to deliver regenerated nutrients downstream, headwater stream processes measurably alter the delivery of nutrients to downstream waters in many ways. For example, if cycling has been seriously impaired such that nutrient regeneration is inhibited or nutrients are generated in biologically unavailable or toxic forms, the downstream effects could be large. Nutrients taken up as readily available inorganic forms can be released back to the water column as organic forms (Mulholland et al., 1988) that are less available for biotic uptake (Seitzinger et al., 2002). Similarly, nutrients incorporated into particles are not entirely regenerated (Merriam et al., 2002; Hall et al., 2009), but rather accumulate and contribute to longitudinally increasing particulate loads (Whiles and Dodds, 2002). The amount of phosphorus and nitrogen delivered downstream by headwater streams cycles seasonally due to the accumulation of nutrients in temporarily growing streambed biomass (Mulholland and Hill, 1997; Mulholland et al., 2004). Such variations affect downstream productivity (Mulholland et al., 1995) and help explain the seasonality in the spatial correlations of nutrient concentrations described above.

Microbially mediated transformations affect the forms of nitrogen transported from headwater streams to downstream waters, and these transformations can influence—and be influenced by—human alterations of the landscape. Nitrification, or the transformation of ammonium to nitrate, occurs naturally in undisturbed headwater streams (e.g., Bernhardt et al., 2002) but increases sharply in response to ammonium inputs (e.g., Newbold et al., 1983b), thereby reducing potential ammonium toxicity from pollutant inputs (Chapra, 1996). Denitrification, which removes nitrate from stream-water through transformation to atmospheric nitrogen, is also widespread among headwater streams, as demonstrated by stable isotope tracer additions to 72 streams in the conterminous United States and Puerto Rico (Mulholland et al., 2008). Mulholland et al. (2008) estimated that headwater streams (<100 L s^{-1}, about third order or less) free from agricultural or urban impacts reduce downstream delivery of nitrogen by 20–40%. Alexander et al. (2007) and Wollheim et al. (2008), using earlier and less extensive measurements of denitrification rates, estimated nitrogen removal of 8 and 16% by stream networks of first to third order and first to fifth order, respectively. In headwater agricultural streams, denitrification in stream sediments might not be effective at removing nitrate from stream water because of altered hydrology. In watersheds with tile drains and channelized headwaters, stream nitrate concentration is positively correlated with stream discharge, suggesting that these altered streams are in throughput mode, whereby nitrate inputs are rapidly transported downstream with little retention or processing (Royer et al., 2004).

Small tributaries also affect the downstream delivery of nutrients through abiotic processes. Meyer and Likens (1979) showed that phosphorus concentrations in a forested first-order New Hampshire stream were reduced by sorption to stream sediments. A much stronger sorption of phosphorus by stream sediments was observed by Simmons (2010) in first- to third-order West Virginia streams impacted by acid mine drainage, where phosphorus sorbed to metal hydroxide precipitates introduced by mine drainage. These examples further illustrate the potential for headwater streams to absorb nutrient impacts to the benefit of downstream waters.

3.4.2 Dissolved and Particulate Organic Matter

Headwater streams supply downstream waters with dissolved and particulate organic carbon, which support biological activity throughout the river network. Organic carbon enters headwater streams from the surrounding landscape, including wetlands (Section 4.3.3.4 and 4.4.3.1), in the form of terrestrial leaf litter and other seasonal inputs, dissolved organic carbon (DOC) in subsurface and surface runoff, and fine particulate organic matter (including eroded soil) in surface runoff. Headwater reaches also export organic carbon produced within the stream by photosynthesis, both as DOC (Kaplan and Bott, 1982) and suspended particles (Marker and Gunn, 1977; Lamberti and Resh, 1987).

Ågren et al. (2007) determined that headwater streams exported the largest amount of terrestrial DOC on a per unit basis in the Krycklan watershed in Sweden. The amount of organic matter exported from headwater streams to downstream waters varies with multiple factors, including surrounding land use. For example, Schelker et al. (2014) developed a mixing-model approach and quantified that forest harvesting at areal proportions of 11% and 23–25% of a northern Sweden watershed induced stepped increases in DOC delivery, due to disturbance of shallow forest soils and subsequent transport from headwaters to downstream locations. Similarly, a 20% increase in downstream DOC concentrations was predicted following forest harvesting in the headwater areas of the H.J. Andrews Long Term Ecological Research site, using the VELMA (Visualizing Ecosystems for Land Management Assessments) model (Abdelnour et al., 2013). In southeast Arizona, Meixner et al. (2007) found that DOC consistently doubled to tripled in the San Pedro River during storm events from a flush of terrestrial organic matter and nutrients. This is comparable to the flush response observed by others (Fisher et al., 1982; Brooks et al., 2007) during monsoon precipitation events in the southwestern United States. These examples further demonstrate connectivity of headwater streams and their cumulative effects on downstream water quality.

Fisher and Likens (1973) followed the fate of these inputs in a forested headwater stream in New Hampshire. They concluded that 34% of inputs were mineralized through respiration by consumers and microbes within the headwater stream, which represented the "ecosystem efficiency" of the reach. The remaining 66% was exported downstream and constituted, as Fisher and Likens (1973) observed, "… inputs to the next stream section where they are assimilated, or passed on (throughput) or both." Other studies have reported similar amounts of export. Webster and Meyer (1997) compiled organic matter budgets from 13 North American first- and second-order streams. The median ecosystem efficiency was 31%, implying a median export of 69% of organic matter inputs. A large body of literature has demonstrated that headwater streams modify and export organic carbon that significantly affects ecosystem processes throughout the river network.

Vannote et al. (1980) recognized that exported carbon was not simply the unutilized fraction but was also greatly modified in character. A basic tenet of their River Continuum Concept is that longitudinal variations in the structure of stream ecosystems reflect, in part, the cumulative effects of upstream organic matter processing. Much or most of the organic carbon exported from headwater streams has been altered either physically or chemically by ecosystem processes within the headwater reaches. Leaf litter contributes an average of 50% of the organic matter inputs to forested headwater streams (Benfield, 1997), but leaves and leaf fragments (>1 mm) account for only 2% or less of organic matter exports (Naiman and Sedell, 1979; Wallace et al., 1982; Minshall et al., 1983). The conversion of whole leaves to fine particles (<1 mm) involves physical abrasion, microbial decomposition, and invertebrate feeding and egestion (Kaushik and Hynes, 1971; Cummins et al., 1973; Petersen and Cummins, 1974). The rate of that conversion is affected by whether the leaves are in an aerobic environment, such as riffles, or an anaerobic environment, such as depositional pools (Cummins et al., 1980). Feeding activities of aquatic invertebrates called "shredders" break down leaves that have entered streams (Cummins and Klug, 1979; Cummins et al., 1989). Invertebrate activity is particularly important, as demonstrated by large reductions of fine particle export following experimental removal of invertebrates from a headwater stream (Cuffney et al., 1990; Wallace et al., 1991). Strong invertebrate influence on fine particle export also has been inferred from analysis of seasonal (Webster, 1983) and daily (Richardson et al., 2009) variations.

Downstream organisms consume organic carbon exported from headwater streams, supporting metabolism throughout the river network. In part, this results from direct consumption of detrital organic matter (Wallace et al., 1997; Hall et al., 2000), but much of the metabolic consumption of organic matter in streams occurs via microbial decomposition (Fisher and Likens, 1973). The microbes themselves are then consumed by other organisms (Hall and Meyer, 1998; Augspurger et al., 2008), whose energy in turn supports the food web through what is known as the "microbial loop" (Meyer, 1994). In addition to transformations associated with microbial and invertebrate activity, organic matter in streams can be transformed through other processes such as immersion (Corti et al., 2011) and abrasion (Paul et al., 2006); photodegradation also can be important in ephemeral and intermittent streams where leaves accumulate in dry channels exposed to sunlight (Dieter et al., 2011; Fellman et al., 2013).

The organic carbon turnover length, derived from the nutrient spiraling concept (Section 3.4.1; Newbold et al., 1982b), is a measure of the downstream fate of exported carbon. Carbon turnover length is the ratio of the downstream flux of organic carbon to ecosystem respiration per length of stream. It approximates the average distance that organic carbon would travel before being consumed and mineralized by aquatic organisms. Carbon turnover length for first-order streams is on the order of 1 to 10 km (Newbold et al., 1982b; Minshall et al., 1983), suggesting that organic carbon exported from headwater streams is likely to be used primarily in the somewhat larger streams to which they are direct tributaries (i.e., second- or third-order streams). The carbon turnover length, however, actually represents a weighted average of widely varying turnover lengths associated with the diverse array of particulate and dissolved forms of organic carbon in stream and river ecosystems (Newbold, 1992). Turnover lengths of specific organic carbon forms can be estimated if their rates of downstream transport and mineralization (or assimilation) are known. For example, Webster et al. (1999) estimated a turnover length of 108 m for whole leaves in a North Carolina second-order stream, but a much longer turnover length of 40 km for fine (<1 mm) organic particles. Newbold et al. (2005) obtained similar estimates of 38 and 59 km for the turnover lengths of two different size fractions of fine organic particles in a second-order Idaho stream. Kaplan et al. (2008) concluded that DOC in a third-order southeastern Pennsylvania stream consisted of a rapidly assimilated "labile" fraction with a turnover length of 240 m, a more slowly assimilated "semilabile" fraction with a turnover length of 4,500 m, and a "refractory" fraction with immeasurably slow assimilation, implying an indefinitely long turnover length sufficient to carry the carbon to coastal waters.

Because turnover length increases with stream size, organic carbon that travels to a larger order stream is likely to travel farther than its original turnover length predicts (Minshall et al., 1983; Webster and Meyer, 1997). For example, the organic carbon turnover length of the Salmon River, ID increased from 3.7 km in a second-order headwater stream to 1,200 km in the eighth-order reach, about 600 km downstream (Minshall et al., 1992). In a modeling study, Webster (2007) estimated that turnover length increased from several hundred meters in the headwater streams to greater than 100 km in a large downstream river. This progression of increasing turnover length from headwater streams to increasingly larger streams and rivers implies that organic carbon exported from headwaters supports metabolism throughout the river network.

Although turnover length reflects the spatial scale over which upstream exports of organic carbon are likely to support downstream metabolism, it does not provide direct evidence for or quantify the actual use of organic carbon in downstream reaches. Studies of transport and mass balance throughout the river network provide such evidence. Shih et al. (2010) applied the SPARROW (SPAtially Referenced Regressions On Watershed attributes) model to organic carbon data from 1,125 monitoring sites throughout the conterminous United States. They estimated that all river reaches (large and small) delivered an annual average of 72 kg C ha^{-1} of incremental drainage area, whereas the river systems as a whole exported 30 kg C ha^{-1}. Thus, 58% of carbon inputs were respired within the river networks, while the rest (42%) were transported downstream. Shih et al. (2010) did not specify the proportion of inputs originating from headwater streams, but using their results (with certain assumptions), we can estimate the amount of organic carbon in river networks that originates from headwater streams. We begin with the proportion of carbon originating from allochthonous sources as 0.78 (Shih et al., 2010). If we assume that the proportion of headwater streams in a drainage area is 0.50 (Section 3.2; Alexander et al., 2007; Caruso and Haynes, 2011), headwater streams then provide 0.39 (= 0.78 × 0.50) of the total organic carbon supply, with the input from the larger downstream network being 0.61 (i.e., 61%) of the carbon supply. Using the ecosystem efficiency for headwater streams of 31% (Webster and Meyer, 1997), the proportion of carbon originating from headwater streams that is delivered downstream is 0.39 × (1 − 0.31) = 0.27. The proportion of carbon exported from headwater streams (0.27), plus the proportion of carbon input directly to the downstream network (0.61), equals the total carbon input to the downstream network (0.88). Thus, 31% (= 0.27/0.88 × 100) of the total carbon supplied to downstream reaches originates from headwater streams.

Most terrestrial organic matter that enters headwater streams is transported downstream (Gomi et al., 2002; MacDonald and Coe, 2007), typically as fine particulate or dissolved organic matter (Bilby and Likens, 1980; Naiman, 1982; Wallace et al., 1995; Kiffney et al., 2000). These headwater streams also can export significant amounts of autochthonous organic matter via the downstream transport of benthic algae (Swanson and Bachmann, 1976). Both allochthonous and autochthonous organic matter can be transported significant distances downstream (Webster et al., 1999), especially during high flows (Bormann and Likens, 1979; Naiman, 1982; Wallace et al., 1995). The importance of discharge in determining organic matter transport dynamics highlights the interdependence of physical and biological connections within the river network. For example, Wallace et al. (1995) examined coarse particulate organic matter export in three headwater streams in North Carolina and found that 63–77% of export over a 9-year period occurred during the 20 largest floods. This finding suggests that headwater streams (including ephemeral and intermittent streams) can provide temporary storage for organic matter (Gomi et al., 2002), which is then transported downstream during storms or snowmelt. Exports also can vary seasonally, increasing in autumn and winter when deciduous trees drop their leaves (Wipfli et al., 2007) and in the spring when flowers and catkins are shed.

The amount of organic matter exported from headwater streams can be large, and often depends on factors such as discharge, abiotic retention mechanisms within the channel (Bilby and Likens, 1980), biological communities (Cuffney et al., 1990), and the quality and quantity of riparian vegetation in headwater watersheds (Wipfli and Musslewhite, 2004). For example, Wipfli and Gregovich (2002) found that organic matter export ranged from <1 to 286 g of detritus (dead organic matter) per stream per day in 52 coastal headwater streams in Alaska. When debris dams were removed from a New Hampshire headwater stream, export of fine particulate organic carbon increased by 632% (Bilby and Likens, 1980). The longitudinal discontinuities created by logjams and beaver dams slow the downstream transport of organic matter, enabling instream organisms to process the carbon and slowly leak material downstream (Wohl and Beckman, 2014). The strong links among organic matter storage, processing, and downstream transport in ephemeral streams of the southwestern United States can be seen in the distribution of organic matter of varying quality and mobility over periods with varying rainfall intensities (Norton et al., 2007). Arroyos or ephemeral channels in northeastern New Mexico are important in transporting and transforming organic matter that enhances the fertility of agricultural areas along downstream alluvial fans. More frequent but low-intensity rainfall was important in driving biochemical transformations that altered organic matter mobility and quality, which was subsequently transported downstream by larger storms (Norton et al., 2007). Traditional farming practices in the region relied on the temporary storage, transformation, and transport of organic matter from ephemeral streams (Norton et al., 2007; Sandor et al., 2007).

Although organic matter clearly is exported from headwater streams, effects on downstream organisms, and the distance over which these effects propagate are difficult to quantify (Wipfli et al., 2007). Many downstream organisms rely on organic matter and its associated microbes for food, but demonstrating where in the river network such material originates presents a challenge. Similarly, the conversion of organic matter to other forms (e.g., invertebrate or fish biomass via consumption), each with its own transport dynamics, makes tracking sources of downstream contributions difficult. Given the prevalence of headwater streams in both the landscape and the river network (Leopold et al., 1964), and their primacy in organic matter collection and processing, a logical conclusion is that headwater streams exert a strong influence on downstream organic matter dynamics. Benstead and Leigh (2012) estimated that headwater streams, including intermittent and ephemeral channels, result in a global carbon efflux of 1.6 Pg C yr^{-1}, making the overall contributions of rivers and streams about equivalent to all inland lakes and wetlands combined. In addition, headwater streams also serve as a source of colonists for downstream habitats (Section 3.5). For example, headwater springs can provide algae a winter refuge from freezing, then serve as a source of propagules for downstream reaches upon spring thaws (Huryn et al., 2005).

3.4.3 Ions

Measurements of ions and conductivity from nested study designs provide additional evidence for connectivity by various transport mechanisms. Rose (2007) collected data at 52 sampling stations in Georgia's Chattahoochee River basin, which includes the heavily urbanized region of Atlanta, over a 2-year period. The study sought to characterize baseflow hydrochemistry across a rural-to-urban land-use gradient. A plot of the major ion (sodium, bicarbonate alkalinity, chloride, and sulfate) concentrations versus downstream river distance showed distinct peaks relative to baseflow measurements, with elevated concentrations persisting downstream.

In a study of mined and unmined streams in the Buckhorn Creek basin in Kentucky, water measurements taken at several locations within the same tributary had similar conductivity values (Johnson et al., 2010). As expected, confluences disrupted this spatial similarity along the river network. Conductivity values along the mainstem decreased at confluences with unmined streams and increased at confluences with mined streams, demonstrating that headwater streams were transporting ions downstream and affecting downstream conductivity. This spatial pattern in conductivity was consistent between spring and summer surveys of the river network.

In a study in Sweden, measurements of pH from the outlets of seven watersheds were statistically related to headwater pH measurements in those watersheds (Temnerud et al., 2010). As pH at outlets increased under low-flow conditions, so did median pH of the headwater streams. This study illustrates the connectivity between the headwater components of the river network and the outlets of the watersheds and the cumulative effects of headwater streams to downstream waters.

3.4.4 Contaminants and Pathogens

The movement of contaminants—that is, substances that adversely affect organisms when present at sufficient concentrations—and waterborne pathogens provides another line of evidence for chemical connectivity between tributaries and the river network. Existing information typically has been derived from either empirical experiments that release tracer substances into streams to monitor movement along a longitudinal gradient or the use of modeled projections and characterization of contaminants. Studies also have examined trace metal data collected at multiple sites throughout a specific watershed, relative to a point source or a complex mixture of point-source inflows (e.g., active mining areas, wastewater treatment plant discharges). These studies provide a way to understand sediment transport in streams and rivers and to determine how metals are spatially and temporally dispersed in the watershed (Rowan et al., 1995).

The degree of surface-water and ground-water mixing or exchange in the hyporheic zone influences the transport and uptake of trace metals. In a 7 km perennial stream segment contaminated by copper mining in Arizona, 20% of the dissolved manganese load was removed by microbial activity that was likely stimulated by the physicochemical conditions and increased residence time (compared with surface channel residence time) associated with hyporheic exchange (Harvey and Fuller, 1998). That oxidation of manganese enhanced the uptake of other trace metals and thereby decreased cobalt, nickel, and zinc loads 12–68% over the 7 km reach (Fuller and Harvey, 2000). Modeling the contributions of hyporheic exchange on contaminant dynamics over entire river networks requires further research.

Another example of chemical connections along the river network is how inputs of water associated with natural gas (coalbed methane) extraction and hardrock mining can influence trace element and dissolved solute concentrations in perennial rivers. Patz et al. (2006) examined trace elements and other water quality parameters in ephemeral streams resulting from coalbed methane extraction activities that are connected to the perennial Powder River, WY. Iron, manganese, arsenic, fluoride, dissolved oxygen, pH, and turbidity differed across sample locations, demonstrating connectivity between wellhead discharge and ephemeral streams. The contribution of ephemeral streams was detected in the Powder River, where pH was consistently elevated downstream of the confluence with a high-pH stream (Patz et al., 2006).

In a broader study, Wang et al. (2007) used retrospective USGS data (1946−2002) to investigate spatial patterns in major cation and anion concentrations related to coalbed methane development in the Powder River basin (33,785 km^2) in Wyoming and Montana. The study indicated that coalbed methane development could have detrimental effects on the Powder River, especially in terms of sodium adsorption ratio (sodicity). Although the authors indicated connectivity and adverse effects in stream quality with increased sodium and stream sodicity, data also revealed inconsistent patterns associated with complex spatial variability within the drainage basin due to the geographic distribution of the coalbed methane wells.

The spatial extent of metal transport has been demonstrated in the upper Arkansas River of Colorado, where the headwaters have been affected by past mining activities (Kimball et al., 1995). Bed sediments sampled from the headwaters to approximately 250 km downstream showed an inverse relationship between sediment cadmium, lead, and zinc concentrations and downstream distance. That same spatial distribution pattern in bed sediment metal concentrations was observed from headwater streams to the downstream Clark Fork River in Montana, which has been impacted by mining and smelting activities in its headwaters (Axtmann and Luoma, 1991). Based on regression models, bed sediment metal concentrations from river sites were inversely related to downstream distance, and predictions from those models indicated that sediments with metals originating from headwater mining and smelting areas were reaching Lake Pend Oreille, more than 550 km downstream. Hornberger et al. (2009) used a 19−year data set from the Clark Fork River, with sites from the headwater streams to 190 km downstream, and found that bed sediment copper concentrations at downstream sites were positively correlated with concentrations at upstream sites.

Lewis and Burraychak (1979) examined the downstream transport of heavy metals from ephemeral and intermittent streams to a downstream perennial stream, due to the impacts of active and abandoned copper mines. Water chemistry in Pinto Creek was monitored biweekly for 2 years at four stations, one above and three below a point discharge associated with the Pinto Valley Mine in east-central Arizona (Lewis and Burraychak, 1979). Surveys of fish, aquatic macroinvertebrates, and vegetation were conducted during the same period at 13 sampling stations along the total stream length. Contaminants from the Pinto Valley Mine entered Pinto Creek via accidental discharge of waste from tailings ponds (Lewis, 1977). Monitoring revealed that mine wastes comprised up to 90% of total flow in Pinto Creek, and that most chemical parameters increased in concentration below the discharge point, then decreased progressively downstream (Lewis and Burraychak, 1979). Increases in sulfate, conductivity, and total hardness between above-mine and below-mine locations were most apparent, although increases in heavy metals and suspended solids were considered most detrimental to organisms.

Suspended solids settled in and buried intermittent channels, which contained up to 50 cm of mine-waste sediment; these sediments were present all the way to the stream terminus. Increased heavy metal concentrations in the food web and sediments also were detected below the discharge point (Lewis and Burraychak, 1979).

Lampkin and Sommerfeld (1986) similarly showed that intermittent streams can contribute highly mineralized, acidic waters to a downstream perennial reach, in a study that characterized acid mine drainage impacts on water and sediment chemistry (particularly major cations, silica, sulfate, selected heavy metals, and acidity) in Lynx Creek, a small intermittent stream in east-central Arizona. Six stations, two above and four below an abandoned copper mine, were monitored (water and sediment samples) monthly for 1 year. Specific conductance, pH, and dissolved ion concentrations varied with proximity to the mining complex. Concentrations of most constituents were higher near the mine and progressively decreased downstream toward the terminus of Lynx Creek, due to precipitation and dilution by headwater streams. All heavy metal and sulfate concentrations were higher at the immediate discharge location versus the above-mine stations; sulfate concentrations downstream of mine-drainage inputs also significantly differed from the rest of the creek. Sediments throughout the creek were high in metals, suggesting downstream transport of contaminated sediments. Acid-mine drainage from the mine had a major but mostly localized impact on Lynx Creek.

As discussed in previous sections, headwater streams are connected to downstream waters through the transport of chemicals but also through transformation processes. Boreal river networks, in which headwater streams are sources of DOC and pH increases downstream, provide these transformations. Iron exported from the acidic headwater tributaries is bound to DOC (mobile form). As pH increases, iron-rich ground water enters the channel, and iron transforms to iron (oxy) hydroxides that aggregate and precipitate out of solution (Neubauer et al., 2013). These iron (oxy) hydroxides can function as carriers of toxic metals and metalloids (e.g., arsenic), thereby removing them from solution and temporarily storing them in and along the river network (Neubauer et al., 2013).

Several studies also have projected the cumulative effect of headwater systems on downstream mercury concentrations and loads in response to land use, climate, and atmospheric deposition. The Water Quality Analysis Simulation Program and the Bioaccumulation and Aquatic System Simulator models were used to predict changes in water, sediment, and fish-tissue mercury concentrations across water bodies with varying upstream headwater drainage areas (Knightes et al., 2009). Simulations predicted that watersheds with high headwater drainage densities would exhibit longer lag times for mercury delivery downstream compared to those with low headwater drainage densities. This work suggests that headwater streams can serve a mercury storage function, and that temporally varying connectivity contributes to the transport of mercury from headwater streams to downstream waters.

The cumulative effects of land-cover change on total and methylmercury fluxes from a North Carolina headwater watershed to the Cape Fear River were simulated using the Grid Based Mercury Model (Golden and Knightes, 2011). The simulations estimated a 95% increase in total mercury fluxes from the landscape to downstream waters in response to new suburbanization and a 7% decrease in total and methylmercury export in response to reforestation. Predicted changes in total mercury fluxes from the landscape to the downstream assessment point resulted primarily from changes in landscape land cover, rather than changes in connections within the river network.

The effects of climate change on total mercury export from headwater tributaries draining a Coastal Plain watershed (79 km^2) in South Carolina were simulated using multiple watershed models (Golden et al., 2014). Results indicated increased total mercury export under the high-precipitation scenario and decreased total mercury export under the low-precipitation scenario, showing that precipitation, and thus hydrologic connections, drive mercury transport from headwater streams to downstream waters.

Contaminants are commonly transported from tributaries to downstream rivers bound to sediments. Using isotopic fingerprinting, Gehrke et al. (2011) identified different tributaries as contributing to downstream mercury contamination of surface sediments in San Francisco Bay. Historic gold mining in the tributary watersheds of the San Joaquin and Sacramento Rivers contributed to contaminated mercury sediments in the northern part of San Francisco Bay, whereas wastes from mercury mine operations were delivered to the southern part of the bay via the Guadalupe River (Gehrke et al., 2011).

Studies of radionuclide (e.g., plutonium, thorium, uranium) distribution, transport, and storage provide convincing evidence for long-distance chemical connections in river networks. Although the natural occurrence of radionuclides is extremely rare, their production, use, and release for military and energy applications have been monitored for more than 50 years. Like metals, radionuclides adsorb readily to fine sediment; thus, the fate and transport of radionuclides in sediment generally mirrors that of fine sediment. From 1942 to 1952, plutonium dissolved in acid was discharged untreated into several intermittent headwater streams that flow into the Rio Grande at the Los Alamos National Laboratory, NM (Graf, 1994; Reneau et al., 2004). These intermittent headwaters drain into Los Alamos Canyon (152 km^2 drainage area), which joins the Rio Grande approximately 160 km upriver from Albuquerque. Also during this time, nuclear weapons testing occurred west of the upper Rio Grande near Socorro, NM (Trinity blast site) and in Nevada. The San Juan Mountains in the northwestern portion of the upper Rio Grande basin (farther upstream from the site where Los Alamos Canyon enters the Rio Grande) is the first mountain range greater than 300 m in elevation east of these test locations. The mountains therefore have higher plutonium concentrations than the latitudinal and global averages because of their geographic proximity to the test sites. The mountain areas are steep with thin soils, so plutonium from testing fallout was readily transported to headwater streams in the upper Rio Grande basin via erosion and subsequent overland movement. The distribution of plutonium within the Rio Grande illustrates how headwater streams transport and store contaminated sediment that has entered the basin through both fallout and direct discharge. Although Los Alamos Canyon represented only 0.4% of the drainage area at its confluence with the Rio Grande, its mean annual bedload contribution of plutonium was almost seven times that of the mainstem (Graf, 1994). Much of this contribution occurred sporadically during intense storms that were out of phase with flooding on the upper Rio Grande. Total estimated contributions of plutonium to the Rio Grande are approximately 90% from fallout to the landscape and 10% from direct effluent at Los Alamos National Laboratory (Graf, 1994). Based on plutonium budget calculations, only about 10% of the plutonium directly discharged into Los Alamos

Canyon and less than 2% of the fallout over the upper Rio Grande basin have been exported to the Rio Grande. Much of the plutonium is adsorbed to sediment and soil that has either not yet been transported to the river network or is stored on floodplains or in tributary channels (Graf, 1994). Approximately 50% of the plutonium that entered the Rio Grande from 1948 to 1985 is stored in the river and its floodplain; the remaining amount is stored in a downriver reservoir. Similar export of radionuclides through a river network has been traced following the Fukushima Dai-ichi Nuclear Power Plant accident in Japan (Chartin et al., 2013). The highest levels of radionuclide fallout were in areas drained by headwater tributaries. Isotopic analysis of sediment-bound radionuclides collected from throughout the river network over time documented the downstream transfer of contaminated sediment during a succession of summer typhoons and spring snowmelt (Chartin et al., 2013).

Waterborne pathogens (bacteria, viruses, protozoa) are another class of contaminants of concern because of the associated risks to human health and well-being. The principal origins of waterborne pathogens to downstream waters are as point and diffuse sources from livestock and municipal wastes via tributaries (Ferguson et al., 2003). Rainfall events and waterborne disease outbreaks in the United States are strongly correlated, pointing to hydrologic connectivity through tributaries and stormwater drains as a key link in transporting pathogens downstream, where they can overwhelm treatment plants and eventually contaminate drinking water sources (Curriero et al., 2001). Ephemeral and intermittent tributaries also transport waterborne pathogens downstream from livestock and human waste (e.g., Parker et al., 2010; Wilkes et al., 2013). Moist sediments in and near ephemeral and intermittent streams can act as temporary pathogen reservoirs (Chase et al., 2012). Survival of fecal indicator bacteria in dry sediments of an intermittent stream was high and remained constant over 1 month, but declined to unculturable levels after 51 days at 20 °C and 163 days at 5 °C (Chahinian et al., 2012). As for contaminants, various physicochemical (e.g., discharge, nutrient concentrations, temperature, humic acids) and biological (predation, competition) conditions in tributaries can mediate the transport or inactivation of pathogens (Ferguson et al., 2003).

3.5 Biological Connections

Biological connections are linkages throughout the river network, from headwater streams (including those with intermittent and ephemeral flow) to their downstream waters, that are mediated by living organisms or their products (e.g., seeds, exudates, or excreta; Lamberti and Resh, 1987).

Because biological connections often result from passive transport of organisms or their products with water flow, biological connectivity often depends on hydrologic connectivity (Section 3.3.1). Many living organisms, however, also can actively move with or against water flow; others disperse actively or passively over land by walking, flying, drifting, or "hitchhiking." All of these organism-mediated connections form the basis of biological connectivity between headwater streams and downstream waters.

Biological connections between upstream and downstream reaches can affect downstream waters via multiple pathways or functions. For organisms capable of significant upstream movement, headwater streams, including ephemeral and intermittent streams, can increase both the amount and quality of habitat available to those organisms. Many organisms require different habitats for different resources (e.g., food, spawning habitat, overwintering habitat), and thus move throughout the river network—both longitudinally and laterally—over their life cycles (Schlosser, 1991; Fausch et al., 2002). For example, headwater streams can provide refuge habitat under adverse conditions, enabling organisms to persist and recolonize downstream areas once adverse conditions have abated (Meyer and Wallace, 2001; Meyer et al., 2004; Huryn et al., 2005). Headwater streams also provide food resources to downstream waters: as Progar and Moldenke (2002) state, "…headwater streams are the vertex for a network of trophic arteries flowing from the forest upland to the ocean."

In this section, we consider longitudinal biological connections in terms of both the aquatic organisms—specifically invertebrates and fishes—that move along river networks and their consequent effects on downstream waters (see Section 3.4.2 for discussion of particulate organic matter dynamics and Section 3.4.4 for discussion of waterborne pathogens). We then discuss the importance of organism movement throughout the river network for genetic connectivity in a separate section. We also recognize the many important biological connections between river networks and terrestrial systems (Lamberti and Resh, 1987), but as discussed in Chapter 1, these connections are outside the scope of this document. Lateral biological connections between the river network and riparian and floodplain habitats are considered in Chapter 4.

3.5.1 Invertebrates

Headwater streams provide habitat for diverse and abundant stream invertebrates (Meyer et al., 2007) and serve as collection areas for terrestrial and riparian invertebrates that fall into them (Edwards and Huryn, 1995; Kawaguchi and Nakano, 2001). These aquatic and terrestrial invertebrates can be transported downstream with water flow and ultimately serve as food resources for downstream organisms. Many fish feed on drifting insects (Nakano and Murakami, 2001; Wipfli and Gregovich, 2002), and these organisms can also settle out of the water column and become part of the local benthic invertebrate assemblage in downstream waters. Drift, however, has been shown to increase invertebrate mortality significantly (Wilzbach and Cummins, 1989), suggesting that most drifting organisms are exported downstream in the suspended detrital load (Section 3.4.2).

The downstream drift of stream invertebrates (Müller, 1982; Brittain and Eikeland, 1988) and the contribution of terrestrial and riparian invertebrates to overall drift (Edwards and Huryn, 1995; Kawaguchi and Nakano, 2001; Eberle and Stanford, 2010) have been well documented. For example, drift estimates in 52 small coastal streams in Alaska ranged from 5 to 6,000 individuals per stream per day (Wipfli and Gregovich, 2002). This export of invertebrates can be especially high in intermittent and ephemeral streams, as terrestrial invertebrates accumulate in these channels during dry periods and are then transported downstream upon channel rewetting (Corti and Datry, 2012; Rosado et al., 2015). The amount of invertebrate drift often is closely related to stream discharge (e.g., Harvey et al., 2006), as well as diel invertebrate behavioral patterns that are independent of flow (Rader, 1997). To compensate for loss of individuals to downstream drift, invertebrate populations in headwater streams are maintained and replenished through a combination of high productivity and upstream dispersal (Hershey et al., 1993; Humphries and Ruxton, 2002). This dispersal creates downstream to upstream biological connections along the river network; for organisms capable of directed movement over long distances (e.g., winged adult forms of aquatic invertebrate larvae), these connections can occur over significant network distances.

Given this evidence, that headwater streams are biologically connected to downstream waters via the active and passive export of invertebrates is clear, and the cumulative export of invertebrates from numerous headwater streams to downstream waters can be substantial. As with organic matter, however, assessing the effect of headwater invertebrate production and export on downstream waters is difficult, given that these resources enter downstream waters at multiple points and times throughout the river network. Nevertheless, some studies have documented the importance of drifting invertebrates for downstream organisms. Wipfli and Gregovich (2002) estimated that drifting insects and detritus (i.e., particulate organic matter; Section 3.4.2) from fishless headwater streams in Alaska supported between 100 and 2,000 young-of-year salmonids per km in a large, salmon-bearing stream. This estimate of headwater importance in systems where juvenile salmonids move into headwater streams to feed and grow is likely conservative (Section 3.5.2). Other studies have shown increased fish growth with increased invertebrate drift (Wilzbach et al., 1986; Nielsen, 1992; Rosenfeld and Raeburn, 2009), indicating that drift does provide a valuable food resource, especially when food is limiting (Boss and Richardson, 2002).

Headwater streams also serve as habitat for invertebrates. Many invertebrate species are well adapted to seasonal or episodic periods of drying (Feminella, 1996; Williams, 1996; Bogan and Lytle, 2007) or freezing temperatures (Danks, 2007) and can be found throughout a range of stream sizes (e.g., Hall et al., 2001b) and flow regimes (intermittent and perennial, e.g., Feminella, 1996). Intermittent streams also can provide refuge from adverse biotic conditions. For example, Meyer et al. (2004) found that native amphipods can persist in intermittent reaches but are replaced by nonnative amphipods in perennial reaches. After disturbance, these upstream habitats can provide colonists to downstream reaches. This phenomenon can be especially important in intermittent streams, where permanent upstream pools can serve as refuges during drying. For example, Fritz and Dodds (2002, 2004) examined invertebrate assemblages before and after drying in intermittent prairie streams and found that initial recovery of invertebrate richness, richness of invertebrate drift, and richness of aerially colonizing insects were negatively related to distance from upstream perennial water. Dry stream channels also can facilitate dispersal of aquatic invertebrates by serving as dispersal corridors for terrestrial adult forms (Bogan and Boersma, 2012; Steward et al., 2012).

Headwater stream invertebrates also provide critical functional roles in maintaining physical and chemical connectivity to downstream waters (Covich et al., 1999). Invertebrates accelerate the breakdown of coarse particulate organic matter (e.g., leaves) to more mobile fine and dissolved forms (Section 3.4.2; Wallace and Webster, 1996); promote algal productivity and microbial activity (and nutrient uptake) by biofilm grazing (Feminella and Hawkins, 1995); and temporarily store and transfer sediments, nutrients, and contaminants through their trophic and physical activity (e.g., via bioconsolidation and bioturbation; Pringle et al., 1993; Walters et al., 2008; Statzner, 2012). The contribution of invertebrates in controlling sediment mobilization can be substantial. For example, Statzner (2012) estimated that the discharge necessary to move approximately 0.4 kg of sediment s^{-1} in the Colorado River would increase by an order of magnitude in response to bioconsolidation by net-spinning caddisflies and would decrease by an order of magnitude in response to bioturbation by crayfish.

Diverse and abundant invertebrate assemblages also inhabit the hyporheic zone of river networks (Stanford and Ward, 1988; Boulton, 2000). Hyporheic assemblages are composed of invertebrate species that inhabit shallow subsurface sediments within streambeds to various degrees. Some taxa spend their entire lives in the hyporheic zone (Boulton, 2000). Other taxa spend only part of their life cycles, typically their earliest larval stages or periods of disturbances, in the hyporheic zone, and others spend their entire aquatic stages in the hyporheic zone then migrate out for their aerial adult stages (Boulton, 2000). These hyporheic assemblages make similar contributions to physical and chemical connectivity with downstream waters as benthic invertebrates do, while also enhancing hyporheic exchange (Section 3.3.1) through movements and migration within the hyporheic zone (Boulton, 2000).

3.5.2 Fishes

Although some fish species maintain resident headwater populations, many species move into and out of headwater streams at some point in their life cycles (Ebersole et al., 2006; Meyer et al., 2007). Some fish species occur only in headwater streams, contributing to regional aquatic biodiversity (e.g., Paller, 1994). As with invertebrates, however, certain fish species can be found throughout a range of stream sizes (Freeman et al., 2007) and flow durations (Schlosser, 1987; Labbe and Fausch, 2000), and the fish species found in headwater streams often are a subset of species found in downstream habitats (Horwitz, 1978). Use of headwater streams as habitat is especially evident for the many diadromous species that migrate between headwater streams and marine environments during their life cycles (e.g., Pacific and Atlantic salmon, American eels, certain lamprey species), and the presence of these species within river networks provides robust evidence of biological connections between headwater streams and larger rivers.

Through their activities, migratory fish can be important in modifying habitat, and transforming and transporting materials (e.g., Taylor et al., 2006; Hassan et al., 2008). Return migration of diadromous fishes provides a feedback loop in which marine-derived nutrients are transported upstream to headwater streams, for subsequent processing and export (Section 3.4.1). This example illustrates how biological connections also can create chemical connections throughout the river network. Migratory fish also can bioaccumulate and transport contaminants long distances between headwater streams and downstream waters (e.g., Krümmel et al., 2003; Morrissey et al., 2011). Fish also can act as transport vectors of other organisms (e.g., seeds, pathogens, glochidia), moving other organisms against flow or extending their dispersal distances (e.g., Chick et al., 2003; Senderovich et al., 2010; Schwalb et al., 2013). Even nonmigratory taxa can travel substantial distances within river networks throughout their life cycles (Gorman, 1986; Sheldon, 1988; Hitt and Angermeier, 2008). As a result, the distribution and movement of fish throughout river networks can be highly variable, both spatially and temporally (Schlosser, 1991; Labbe and Fausch, 2000; Fausch et al., 2002).

The importance of connectivity in structuring fish assemblages provides further evidence of biological connections along river networks. Fish assemblages among connected streams tend to be more similar, in that assemblages in reaches located closer together tend to have more species in common than assemblages in distantly separated reaches (Matthews and Robinson, 1998; Hitt et al., 2003; Grenouillet et al., 2004). Measures of river network structure also can explain fish assemblage structure, with studies showing that metrics such as link magnitude (the sum of all first-order streams draining into a given stream segment) and confluence link (the number of confluences downstream of a given stream segment) are significant predictors of fish assemblages (e.g., Osborne and Wiley, 1992; Smith and Kraft, 2005).

The importance of biological connections along river networks is often highlighted by human alterations that affect these connections. For example, fish assemblages within highly connected river networks were more homogeneous, whereas fragmentation by road crossings resulted in greater dissimilarity of fish assemblages between upstream and downstream habitats (Perkin and Gido, 2012). Many studies have documented statistically significant associations between impoundment of prairie streams and loss of native fishes (e.g., Winston et al., 1991; Luttrell et al., 1999; Schrank et al., 2001; Falke and Gido, 2006; Matthews and Marsh-Matthews, 2007), and fragmentation of river networks has been consistently related to local extinction of salmonid populations (Morita and Yamamoto, 2002; Letcher et al., 2007).

For certain taxa, headwater streams—including intermittent and ephemeral streams— provide critical habitat for specific portions of their life cycles. Many fish, both salmonids and nonsalmonids, spawn in headwater streams, including those with intermittent flow (Erman and Hawthorne, 1976; Schrank and Rahel, 2004; Ebersole et al., 2006; Wigington et al., 2006; Colvin et al., 2009). Kanno et al. (2014) found that many brook trout moved between mainstem and tributary habitats over their life cycles. Because reproductive success varied across these habitats, this movement resulted in substantial gene movement into tributary habitats (Section 3.5.3).

After spawning, fish using headwater streams return downstream for feeding and overwintering. For example, Bonneville cutthroat trout moved from less than 1 km to more than 80 km downstream postspawning, typically within 30 days (Schrank and Rahel, 2004). Many salmonids also grow in headwater streams (Brown and Hartman, 1988; Curry et al., 1997; Bramblett et al., 2002). In some cases, these headwater streams, including intermittent streams, can provide higher quality habitat for juvenile fish, as evidenced by increased growth, size, and overwinter survival in these habitats (Ebersole et al., 2006; Ebersole et al., 2009), perhaps due to warmer temperatures and higher prey and lower predator densities (Limm and Marchetti, 2009).

In prairie streams (Section B.4), the importance of hydrologic connectivity for biological connectivity is especially evident, as many fishes broadcast spawn, or release eggs into the water column, which then develop as they are transported downstream (Cross and Moss, 1987; Fausch and Bestgen, 1997). Platania and Altenbach (1998) estimated that unimpeded eggs could travel as far as 144 km before hatching, and another 216 km as developing protolarvae (i.e., the swim-up stage), illustrating that downstream transport of these drifting organisms can be extensive. Adult fish then migrate upstream prior to egg release (Fausch and Bestgen, 1997). Thus, these fishes require hydrologic connectivity to maintain both upstream and downstream populations (Fausch and Bestgen, 1997).

When abiotic or biotic conditions farther downstream in the river network are adverse, upstream reaches can provide refuge habitat for downstream fishes. Examples of adverse abiotic conditions include temperature (Curry et al., 1997; Cairns et al., 2005) and flow (Pires et al., 1999; Wigington et al., 2006) extremes, low dissolved oxygen concentrations (Bradford et al., 2001), and high sediment levels (Scrivener et al., 1994). Examples of adverse biotic conditions include the presence of predators, parasites, and competitors (Fraser et al., 1995; Cairns et al., 2005; Woodford and McIntosh, 2010).

Because headwater streams often depend on ground-water inputs, temperatures in these ecosystems tend to be warmer in winter (when ground water is warmer than ambient temperatures) and colder in summer (when ground water is colder than ambient temperatures), relative to reaches farther downstream (Section 3.3.4; Power et al., 1999). Thus, these headwater streams can provide organisms with both warmwater and coldwater refuges at different times of the year (Curry et al., 1997; Baxter and Hauer, 2000; Labbe and Fausch, 2000; Bradford et al., 2001), again highlighting the spatial and temporal variability of these fish-based biological connections. In some cases, loss of coolwater refuges can facilitate invasion by species more tolerant of warmwater conditions (Karr et al., 1985).

Headwater streams also can provide refuge from flow extremes. Fish can move into headwater streams, including intermittent streams, to avoid high flows downstream (Wigington et al., 2006); fish also can move downstream during peak flows (Sedell et al., 1990), highlighting the bidirectionality of biological connections within these systems. Low flows can cause adverse conditions for organisms, as well, and residual pools that are often fed by hyporheic flow can enable organisms to survive dry periods within intermittent streams (Pires et al., 1999; May and Lee, 2004; Wigington et al., 2006).

Biotic conditions within the river network—that is, the taxa found in the system—also can create an adverse environment, as the presence of invasive species or other predators and competitors can negatively affect native taxa. In some cases, headwater streams can provide these taxa refuge from other species and enable populations to persist. For example, Fraser et al. (1995) found that prey fish moved downstream when piscivores (fish-eating fish) were excluded, but moved upstream into headwater streams when they were present. The role of headwater streams as refuges from adverse biotic conditions can be closely related to where along the connectivity-isolation continuum these habitats fall, with isolation allowing for persistence of native populations (Letcher et al., 2007). Physical barriers (which reduce connectivity and increase isolation) have been used to protect headwater streams from invasion (Middleton and Liittschwager, 1994; Freeman et al., 2007); similarly, most genetically pure cutthroat trout populations are confined to small, high-elevation streams that are naturally or anthropogenically isolated (Cook et al., 2010).

When adverse conditions have abated and these organisms move back down the river network, they can serve as colonists of downstream reaches (Meyer and Wallace, 2001). For example, Hanfling and

Weetman (2006) examined the genetic structure of river sculpin and found that upstream populations were emigration biased (i.e., predominant movements were out of these reaches), whereas downstream populations were immigration biased (i.e., predominant movements were into these reaches).

3.5.3 Genes

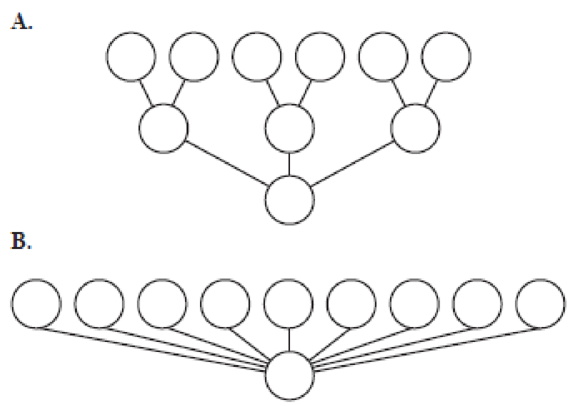
Genetic connectivity results from biotic dispersal and subsequent reproduction and gene flow, or the transfer of genetic material within and among spatially subdivided populations. Populations connected by gene flow have a larger breeding population size, making them less prone to inbreeding and more likely to retain genetic diversity or variation—a basic requirement for adaptation to environmental change (Lande and Shannon, 1996). Genetic connectivity exists at multiple spatial and temporal scales. It can extend beyond a single river watershed (Hughes et al., 2009; Anderson et al., 2010), and in diapausing organisms, can provide a direct link between distant generations (dispersal through time; Bohonak and Jenkins, 2003).

Although physical barriers can protect headwater habitats and populations by isolating them from colonization by and hybridization with invasive species (Section 2.3.2.1), isolation also can have serious adverse effects on native species via reductions in genetic connectivity. For example, Hanfling and Weetman (2006) found that artificial weirs intensified natural patterns of limited headwater immigration, such that headwater (above-barrier) sculpin populations diverged genetically from downstream (below-barrier) populations and lost significant amounts of genetic diversity. This pattern of strong genetic divergence accompanied by loss of headwater genetic diversity above natural and artificial barriers has been documented in multiple fish species and regions (Yamamoto et al., 2004; Wofford et al., 2005; Deiner et al., 2007; Guy et al., 2008; Gomez-Uchida et al., 2009; Whiteley et al., 2010). Loss of headwater-river genetic connectivity might be exerting selection pressure against migrant forms in fish with life cycles requiring movement along the entire river corridor (Morita and Yamamoto, 2002). Ultimately, tradeoffs exist between the risks associated with headwater-river genetic connectivity (e.g., hybridization with nonnative species and hatchery fish) and those associated with genetic isolation (e.g., reduced reproductive fitness, increased risk of local extinction, deterioration of overall genetic variation, and selection against migratory traits; Fausch et al., 2009).

In general, genetic connectivity decreases with increasing spatial distance (Wright, 1943). Genetic connectivity in river networks is also strongly influenced by the hierarchical structure of a river network (Section 2.4.2), the direction of dispersal (upstream, downstream, or both), dispersal modes and pathways used (e.g., swimming, flying), and species' life histories (Hudy et al., 2010).

Computer simulation approaches examine the spatial and temporal processes of genetic connectivity for realistic behaviors and life histories of species inhabiting complex, dynamic landscapes and riverscapes (Epperson et al., 2010). For example, Morrissey and de Kerckhove (2009) demonstrated that downstream-biased dispersal in dendritic river networks (which by definition have more tributaries than mainstems) can promote higher levels of genetic diversity than other geographical habitat structures. Under these conditions, low-dispersing headwater stream populations can act as reservoirs of unique genetic alleles (units of genetic variation) that occasionally flow into and mix with highly dispersing downstream populations. Although the number of headwater streams (i.e., potentially unique genetic reservoirs) is important in maintaining genetic diversity, networks with more complex hierarchical structures (Figure 3-4) are more efficient at maintaining genetic diversity than networks in which all tributaries flow directly into the mainstem (Morrissey and de Kerckhove, 2009). In another simulation, Chaput-Bardy et al. (2009) demonstrated that out-of-network gene flow (e.g., terrestrial dispersal by insects or amphibians) or very high levels of within-network gene flow (e.g., fish that move and reproduce throughout the network) can counteract the effects of network structure; thus, individual species behavior can profoundly affect observed genetic patterns.

Figure 3-4. (A) A dendritic network with multilevel hierarchical structure, and (B) a uninodal network with all headwater streams feeding directly into a river mainstem. Source: Reprinted from The maintenance of genetic variation due to asymmetric gene flow in dendritic metapopulations, (2009) by Morrissey and de Kerckhove with permission of The Univ of Chicago Press.



Most empirical evidence for the role of headwater streams in maintaining genetic connectivity and diversity comes from studies of economically important fish species, but correlations of river network structure or landscape alteration with genetic patterns have been reported for other species. Consistent with the model of Morrissey and de Kerckhove (2009), Fer and Hroudova (2008) found higher genetic diversity in downstream populations of yellow pond-lily (*Nuphar lutea*), which disperses over long distances via water-mediated dispersal of detached rhizomes. Frequent dispersal and high gene flow among headwater and downstream populations of the giant Idaho salamander (*Dicamptodon aterrimus*; Mullen et al., 2010) are expected to contribute to genetic diversity of upstream and downstream populations.

Headwater populations contribute to the maintenance of genetic diversity even in animals capable of overland dispersal. In a field study of the common stream mayfly *Ephemerella invaria*, which emerges into streamside forests to mate and disperse, Alexander et al. (2011) found that regional genetic diversity was strongly correlated with tree cover in first-order (headwater) stream watersheds. Observed loss of genetic diversity in this species could be related to degradation of stream habitats, degradation of out-of-network dispersal pathways, or both (Chaput-Bardy et al., 2009; Grant et al., 2010; Alexander et al., 2011).

In summary, genetic connectivity in river systems reflects the breeding potential of a metapopulation. The maintenance of genetic diversity is directly related to genetic connectivity, and thus is critical to a species' regional persistence. Genetic connectivity is influenced by the landscape, riverscape, and biology of the organisms involved; spatially subdivided stream and river populations can maintain genetic diversity, provided they remain connected by at least low levels of gene flow (Waples, 2010).

3.6 Streams: Synthesis and Implications

Despite widespread human alterations, rivers are not simple conduits draining watersheds. A river, including the water and material it carries and the organisms living in it, represents the cumulative longitudinal, lateral, and vertical connections of its network of channels integrated over time (Section 1.2.3). Although we recognize that streams also exchange water and other materials with nearby terrestrial and deep ground-water systems via lateral and vertical connections, this chapter focused on longitudinal surface-water connections between streams and rivers, as well as shallow subsurface-water interactions integral to surface-water connections and downstream water condition.

A substantial body of evidence unequivocally demonstrates connectivity between streams and downstream rivers via both structural and functional connectivity (as defined in Wainwright et al., 2011). Streams are structurally connected to rivers through the network of continuous channels (beds and banks) that make these systems physically contiguous, and the very existence of a continuous bed and bank structure provides strong geomorphologic evidence for connectivity (Section 2.2.1). A stream must be linked to a larger, downstream water body by a channel for the two to have a surface-water (hydrologic) connection. Although some streams lack a channel connection to larger water bodies (i.e., small endorheic basins), they are the exception. Streams that link larger water bodies through networks of continuous bed and bank are the rule. The network structure reflects the aggregate and cumulative nature of the connections between distant headwater streams and the downstream river.

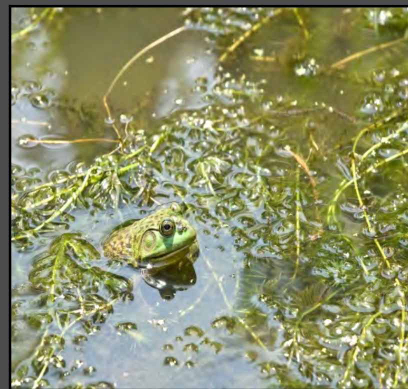
Although not comprehensive or equally studied among all stream types, the existing science indicates that connectivity with downstream waters varies among streams and over time. This variation in connectivity to downstream waters can be described as a connectivity gradient, ranging from highly connected to highly isolated (Section 1.2.2). A stream's position on the gradient is influenced not only by distance to downstream waters but also by the frequency, magnitude, duration, timing, and rate of change of fluxes to downstream waters. Connectivity is dynamic: It changes with immediate, seasonal, and interannual or interdecadal (e.g., climate oscillations) conditions that affect the availability and distribution of water, materials, and biota. Because connectivity is dynamic, a complete understanding of a stream's connections and consequences to downstream waters should aggregate connections over relatively long time scales (multiple years to decades; Section 1.2.3). Although distance between streams and downstream waters vary, other factors such as intervening resistance, relative size or chemical load, and species assemblage also influence the degree of connectivity with and level of consequence on downstream waters. Despite being distant from downstream waters, headwater streams make up the majority of stream channels in most river networks and cumulatively supply most of the water in rivers.

Streams are functionally connected to rivers by the movement of water and other materials through this network of channels (Table 3–1). The longitudinal, vertical, and lateral connections within river networks are inextricably tied. Even losing-stream reaches that at times lack sufficient flow for hydrologic connection can still influence downstream waters by functioning as sinks for water and materials carried by water. The river network and its flow of materials represent the integration of its streams' cumulative contributions to downstream waters. Existing evidence indicates that headwater streams (including intermittent and ephemeral streams) transform, store, and export significant amounts of material (e.g., water, organic matter, organisms) to downstream waters. The most compelling evidence linking headwater streams to downstream habitats supports source, sink (or lag), and transformation functions (Section 2.3.1; Table 2-1). For example, studies that involved sampling throughout river networks have documented headwater streams as sources of water (via floods and baseflow) to rivers (Section 3.3.1). Nitrogen and carbon transported from headwater streams cumulatively contribute to nitrogen and carbon levels in downstream rivers, and headwater streams can function as nitrogen and carbon sinks for river networks (Sections 3.4.1 and 3.4.2). Studies documenting the fate and transport of contaminants through headwater streams to downstream waters also represent clear lines of evidence for headwater streams as sources and sinks (Section 3.4.4). Many organisms, such as anadromous salmon, have complex life cycles that involve migration through the river network, from headwater streams to downstream rivers and oceans, over the course of their lives (Section 3.5). In fact, the importance of headwater streams (including intermittent and ephemeral streams) in the life cycles of many organisms capable of moving throughout river networks provides strong evidence for connectivity among these systems.

Most of the evidence relevant to issues of connectivity between headwater streams and large rivers is based on data collected either in the upper (i.e., from headwater streams to intermediate tributaries) or lower (i.e., from large tributaries to mainstem rivers) portions of the river network. Although few studies have explicitly examined the movement of materials along entire river networks, the exchange of materials among closely located stream reaches—which numerous studies have documented, for a variety of materials—can be extended over large spatial scales.

Table 3-1. Examples of mechanisms by which streams are connected to and influence downstream waters, by functional type. See relevant section and appendix numbers in parentheses for greater detail. Note that the distinction between types of functions is not always clear. For example, denitrification can be considered a sink or transformation function. Bold letters represent the primary type of connection (B = biological; C = chemical; and P = physical).
Source Function
• Streams supply water downstream through baseflow and floods that influence discharge and habitat (3.3.1, B.4.2.5, B.4.3.1.1, B.5.3, B.5.4.2, B.5.5.1). **P** • Streams supply downstream waters with sediment (3.3.2, 3.4.4, B.4.3.1.3, B.5.3, B.5.4.2). **P** • Streams supply downstream waters with nutrients and other ions (3.4.1, 3.4.3, B. 4.3.2.1, B.5.4.2). **C** • Streams can transport to downstream waters contaminants and pathogens that adversely affect organisms and human health (3.4.4, B.4.3.1.3). **C** • Streams supply dissolved and particulate organic matter that can fuel heterotrophy in downstream waters and influence physicochemical conditions (3.3.3, 3.4.2, B.4.3.2.2, B.5.4.2). **C** • Organisms actively and passively move between streams and downstream waters, carrying with them nutrients, contaminants, pathogens, and other organisms (3.5, B.4.2.4, B.4.3.3). **B** • Organisms can enhance the supply of materials to downstream waters (3.5.1, 3.5.2). **B**
Sink Function
• Streams can divert surface flow from downstream waters via infiltration into underlying alluvium and evapotranspiration to the atmosphere (3.3.1, B.5.3, B.5.4.2, B.5.5.1). **P** • Streams can divert nitrate from downstream waters via denitrification (3.4.1, B.4.3.2.1). **C** • Streams can prevent sediment and associated contaminants from being transported to downstream waters through deposition on floodplains (3.3.2, 3.4.4, B.5.3). **C**
Refuge Function
• Streams can afford protection from temperature extremes, drying, predators, and competition with nonnative species for organisms that inhabit downstream waters (3.5, B.4.3.3). **B**
Transformation Function
• Streams can mediate the form and mobility of nutrients before they enter downstream waters via nutrient spiraling (3.4.1, B.4.3.2.1). **C** • Streams can mediate the form and mobility of organic matter before they enter downstream waters via carbon spiraling (3.4.2, B.4.3.2.2). **C** • Streams can mediate the form and mobility of contaminants before they enter downstream waters via hyporheic exchange or exposure to other physicochemical gradients that lead to biogeochemical transformations (3.4.4). **C** • Organisms can mediate the transformation of materials through their trophic and physical activities (3.4.1, 3.4.2, 3.5.1, 3.5.2, B.4.3.2.2). **B**
Lag Function
• Streams can delay water from arriving at downstream waters through local and network structures, thus reducing flood magnitudes, but increasing baseflows in downstream waters (3.3.1, 3.3.3, B.4.3.1.1, B.5.3, B.5.4.2). **P** • Streams can delay sediment from arriving at downstream waters through local and network structures (3.3.2, 3.3.3, 3.4.4, B.5.3). **P** • Streams can delay nutrients from arriving at downstream waters through local and network structures and biological uptake (3.4.1, B.4.2.4, B.4.3.2.1). **C** • Streams can delay organic matter from arriving at downstream waters through local and network structures and biological uptake (3.3.3, 3.4.2, B.4.3.2.2). **C** • Streams can delay contaminants from arriving at downstream waters through local and network structures and exchanges that enhance mineralization and precipitation or adsorption to sediment, or both (3.4.4). **C** • Organisms can delay nutrients, organic matter, and contaminants from arriving at downstream waters through consumption, assimilation, and bioconsolidation (3.4.1, 3.4.2, 3.5.1, 3.5.2, B.4.3.2.2). **B**



CHAPTER 4. WETLANDS: PHYSICAL, CHEMICAL, AND BIOLOGICAL CONNECTIONS TO RIVERS

4.1 Abstract

Wetlands are transitional ecosystems that occur between terrestrial and aquatic systems. They are inundated or saturated by water at a frequency and duration sufficient to support hydrophytic vegetation and development of hydric soils. The effects of wetlands on rivers and other downstream waters depend on functions within the wetlands and connectivity between wetlands and downstream waters. Riparian/floodplain wetlands can be hydrologically connected to streams and rivers through unidirectional flows (i.e., from wetlands to rivers and streams, but not vice versa) of surface water and ground water from upgradient areas (e.g., hillslopes and nearby uplands). In addition, riparian/floodplain wetlands have bidirectional connections to streams and rivers (i.e., from wetlands to streams and rivers and vice versa) through lateral movement of surface and ground water between the channel and riparian/floodplain areas. Connections between riparian/floodplain wetlands and streams or rivers occur over a gradient of connectivity, for example, they can be permanent, can occur frequently (e.g., if the wetland is located within the mean high-water mark), or can occur infrequently (e.g., if the wetland occurs near the edge of the floodplain; Sections 1.2.2 and 2.4.2). Even riparian/floodplain wetlands that rarely flood can have important, long-lasting effects on streams and rivers. Riparian/floodplain wetlands can reduce flood peaks by storing floodwaters, store large amounts of sediment and nutrients from upland areas, influence stream geomorphology by providing woody debris and sediment, and regulate stream temperature. Riparian/floodplain wetlands also are sources of food for stream and river invertebrates and serve as rearing habitat for fish.

Wetlands in non-floodplain landscape settings lack bidirectional hydrologic connections with channels (i.e., water flows from the wetland to the channel but not from the channel to the wetland). These settings, however, have the potential for unidirectional hydrologic flows from wetlands to the river

network through surface water or ground water. Non-floodplain wetlands can attenuate floods through depressional storage and can recharge ground water and thereby contribute to baseflow. These wetlands can affect nutrient delivery and improve water quality by functioning as sources (e.g., of dissolved organic carbon) and as sinks for nutrients (e.g., nitrogen), metals, and pesticides. Non-floodplain wetlands also can provide habitat or serve as sources of colonists for biological communities in downstream waters, through movement of amphibians, reptiles, birds, and mammals. The extent to which non-floodplain wetlands perform these functions depends on their hydrologic and biological connectivity with downstream waters. Non-floodplain wetlands also occur on a hydrologic gradient, from wetlands having permanent connections with perennial channels, to geographically isolated wetlands having ground-water or occasional surface-water connections, to highly isolated wetlands having minimal hydrologic connection to the river network (but which could include surface and subsurface connections to other wetlands; Section 4.4.2). Non-floodplain wetlands that are connected to the river network through a channel (i.e., wetlands that serve as stream origins) will have an effect on downstream waters, regardless of whether the outflow is permanent, intermittent, or ephemeral. For non-floodplain wetlands that do not connect to the river network through a stream channel (i.e., geographically isolated wetlands and wetlands that spill into losing streams that are completely disconnected from the river network), the type and degree of connectivity with downstream waters will vary with position in the watershed and over time.

This literature review is unable to provide evaluations of connectivity for specific groups or classes of wetlands (e.g., prairie potholes or vernal pools). Evaluations of individual wetlands or groups of wetlands, however, could be possible through case-by-case analysis. We can conclude the following:

1. A non-floodplain wetland having a surface-water outflow to a stream network (e.g., a wetland that serves as a stream origin) is connected to the stream network and has an influence on downstream waters.
2. Many non-floodplain wetlands interact with ground water, which can travel long distances and affect downstream waters.
3. Even when wetlands lack a hydrologic connection to other water bodies, they can influence downstream water through water and material storage and mitigation of peak flows (flood reduction and flood attenuation). Sink functions of non-floodplain wetlands will have effects on a downstream water when these wetlands are situated between the downstream water and known point or nonpoint sources of pollution, thereby intersecting the flowpath between pollutant source and downstream water. More generally, wetland sink functions are likely to be greatest when the wetland is located downgradient from pollutant sources and upgradient from a stream or river.
4. Within a watershed or wetland landscape setting, wetlands and open waters that are closer to rivers and streams will have a higher probability of being connected than more distant areas, assuming that conditions governing type and quantity of flows (e.g., slope, soil, and aquifer permeability) are similar.

5. Caution should be used in interpreting connectivity for wetlands that have been designated as "geographically isolated."

4.2 Introduction

This chapter provides detailed information, based on a review of the pertinent peer-reviewed literature, on how wetlands connect to and influence streams and rivers. In particular, we address two questions (Section 1.1): (1) What are the connections to and effects of riparian/floodplain wetlands and open waters (e.g., oxbow lakes) on downstream waters? (2) What are the connections to and effects of non-floodplain wetlands and open waters on downstream waters?

In Chapter 1, we provided the scientific context for concepts and gradients of connectivity in hydrology and ecology (Section 1.2). In Chapter 2, we provided definitions for wetlands, gave a rationale for distinguishing between wetlands in riparian/floodplain and non-floodplain settings, and discussed general hydrologic and biological mechanisms by which wetlands can connect to and affect streams and rivers. Given that streams and rivers are the endpoints of interest, we limit our discussion of riparian/floodplain wetlands to those occurring in riparian and floodplain settings. Below, we provide a detailed review of the contributions of riparian/floodplain wetlands (Section 4.3) and non-floodplain wetlands (Section 4.4) to rivers, followed by conclusions concerning these wetlands and their effects on rivers (Section 4.5). Examples of some of the functions discussed in these two sections are found in Table 4-1. In addition, four case studies on specific types of wetlands or lentic waters representing different landscape settings and geographic regions are in Appendix B: Carolina and Delmarva bays (Section B.1), oxbow lakes (Section B.2), prairie potholes (Section B.3), and vernal pools (Section B.6).

Much of the literature that we evaluate in this chapter does not specify the type or size of the stream or river (or other water body) to which the wetland(s) are connected or which they influence. If available, we note this information (e.g., whether riparian areas were located in floodplains or along portions of river networks without floodplains), but often we can discuss only generic connections to streams, rivers, or downstream waters. Given that rivers are connected to all upstream components of the river network, including streams (Chapter 2), and the functional relationships between streams and rivers (Chapter 3), however, we consider any evidence of connectivity with a stream (other than endorheic streams; Sections 3.2 and B.5.5.1) to be evidence of connectivity with the river and other downstream waters.

4.3 Riparian/Floodplain Wetlands

4.3.1 Introduction

This section focuses on the connections and influence of riparian/floodplain wetlands on downstream waters. As previously defined in Section 2.2.1, riparian/floodplain wetlands are locations within riparian areas and floodplains (Figures 1-1A, 2-2, and 2-3), respectively, that meet the Cowardin et al. (1979)

Table 4-1. Examples of mechanisms by which riparian/floodplain wetlands and wetlands in non-floodplain settings influence downstream waters, by functional type. See relevant section and appendix numbers in parentheses for more detail. Note that the distinction between types of functions is not always clear, for example, denitrification could be considered a sink or transformation function.
Source Function
• Riparian/floodplain wetlands and non-floodplain wetlands connected to the stream network by channelized flow—ranging from ephemeral to permanent—are sources of downstream water (4.3.2.1, 4.4.2.1, B.1.2.3, B.2.3.1, B.3.3.1, B.6.3.1). • Wetlands that serve as origins for streams (e.g., seeps) can be sources of ground-water discharge, contributing to stream baseflow (4.4.2.3). • Non-floodplain wetlands lacking a channel outlet can be sources of water via overland flow to the stream network if wetland storage capacity is exceeded (4.4.2.1, B.3.3.1, B.6.3.1.1). They can also provide water via subsurface drains (“tile drains”) or surface ditches (4.4.2.1, B.1.3.1, B.3.3.1). • Riparian/floodplain wetlands and non-floodplain wetlands can be sources of nutrients and sediments to downstream waters (4.3.2.2, 4.3.3, 4.4.3.1, B.1.3.2, B.3.3.2). • Riparian areas are a source of allochthonous inputs, the primary energy input into the food webs of small, forested streams (4.3.3.4). They also are sources of woody debris that can affect stream morphology and flow regime, and provide habitat for aquatic organisms (4.3.2.2). • Riparian areas and non-floodplain wetlands can be sources of dissolved organic matter that aquatic food webs use, with additional potential effects on pH and mercury concentrations of downstream waters (4.3.3.4, 4.3.3.6, 4.4.3.1). • Riparian/floodplain wetlands and non-floodplain wetlands can be sources of organisms, including plants, invertebrates, amphibians, reptiles, and fish, to downstream waters transported via passive or active dispersal (4.3.4, 4.4.4, B.2.3.3, B.3.3.3, B.6.3.2). • Riparian/floodplain wetlands can provide feeding habitat for riverine organisms, such as fish, during periods of overbank flow (4.3.4.2, B.2.3.3).
Sink Function
• Riparian/floodplain wetlands and non-floodplain wetlands can be sinks for water by intercepting overland or subsurface flow, if available water storage capacity of the wetlands is not exceeded, which can reduce or attenuate flow to downstream waters and flooding (4.3.2.1, 4.4.2.3, B.3.3.1). • Riparian areas and non-floodplain wetlands can be sinks for sediment and chemical contaminants, such as pesticides, metals, mercury, and excess nutrients carried by overland or subsurface flow, potentially reducing loading to downstream waters (4.3.2.2, 4.3.3, 4.4.3.2). • Riparian areas can be sinks for water, sediment, pesticides, and nutrients from overbank flow events, reducing or attenuating downstream peak flows and materials entrained in the water column (4.3.2.1, 4.3.2.2, 4.3.3, B.2.3.2). They can also be sinks for seeds and plant fragments deposited via overbank flow (4.3.4.1). • Riparian/floodplain wetlands and non-floodplain wetlands can be sinks for nitrogen by converting oxidized forms of nitrogen to molecular nitrogen through denitrification, which is then lost to the atmosphere (4.3.3.2, 4.4.3.2).
Refuge Function
• Riparian/floodplain wetlands and non-floodplain wetlands can provide refuge for fish, aquatic insects, or other lotic organisms from predators or other environmental stressors, facilitating individual or population survival (4.3.4, 4.4.4). • Riparian/floodplain wetlands and non-floodplain wetlands can provide refuge during certain life stages for lotic organisms. For example, they are breeding sites for frogs and other amphibians that reside in streams as adults (4.4.4, B.1.3.3, B.6.3.2; Table 4-2); non-floodplain wetlands are additionally nesting and nursery sites for American alligators that otherwise primarily reside in streams (4.4.4).

Table 4-1. Examples of mechanisms by which riparian/floodplain wetlands and wetlands in non-floodplain settings influence downstream waters, by functional type. See relevant section and appendix numbers in parentheses for greater detail. Note that the distinction between types of functions, is not always clear, for example, denitrification could be considered a sink or transformation function (continued).
Transformation Function
• Microbial communities in riparian/floodplain wetlands and non-floodplain wetlands can transform elemental mercury to methylmercury before it enters a stream. Methylmercury is a particularly toxic and mobile form that bioaccumulates in aquatic food webs (4.3.3.6, 4.4.3.1). • Riparian/floodplain wetlands and non-floodplain wetlands can transform nitrate to molecular nitrogen through denitrification (4.3.3.2, 4.4.3.2).
Lag Function
• Riparian/floodplain wetlands can temporarily store water following overbank flow, which then can move back to the stream over time as baseflow (4.3.2.1). • Non-floodplain wetlands can contribute to ground-water recharge under low water table conditions, which ultimately contributes to baseflow (4.4.2.3, B.3.3.1). • Non-floodplain wetlands can increase the time for stream discharge to rise and fall in response to a precipitation event due to wetland storage capacity (4.4.2.3).

definition of having wetland hydrology, hydrophytic vegetation, or hydric soils. The terms “riparian wetland” and “floodplain wetland” frequently describe the same geographic area. Because riparian areas and floodplains also contain upland areas, some riparian/floodplain wetlands are geographically isolated (i.e., completely surrounded by upland).

Although ample literature is available on riparian/floodplain wetlands—especially bottomland hardwood and swamp wetlands—most papers on riparian areas and floodplains do not specify whether the area is a wetland. This lack of specification occurs because riparian areas and floodplains also are studied by stream ecologists and hydrologists who might not focus on whether their study site meets the Cowardin et al. (1979) definition of a wetland. This situation creates a dilemma, because limiting our literature review to papers that explicitly describe the area as a wetland would exclude a major portion of this body of literature and greatly restrict our discussion of wetland science. Alternatively, if we include papers that do not explicitly classify the area as a wetland, we could mistakenly incorporate results that are relevant only to upland riparian areas. Our response to this dilemma was to survey the floodplain and riparian literature broadly and include any results and conclusions that we judged pertinent to riparian/floodplain wetlands. This judgment was based, in part, on: (1) the processes described in the integrated systems perspective on interactions of watersheds, streams, wetlands and downstream waters (Sections 2.2.2 and 2.2.3); (2) whether the information applies to all riparian areas, regardless of whether they are wetlands or uplands (e.g., all riparian areas are subject to periodic overbank flooding); and (3) an understanding of the specific processes. For example, riparian studies of denitrification are likely to be either in a wetland or applicable to riparian/floodplain wetlands, because the alternating oxidation/reduction conditions required for denitrification are present in wetlands. Therefore, in our assessment of evidence regarding the connectivity and effects of riparian areas and floodplains, we have concluded that the processes and functions discussed occur in water bodies within those areas.

As addressed in Chapter 2, much of the theory developed to explain how river systems function has focused on linkages between system components (Vannote et al., 1980; Newbold et al., 1982a; Newbold et al., 1982b; Junk et al., 1989; Ward, 1989; Power et al., 1995a; Power et al., 1995b; Huggenberger et al., 1998; Ward, 1998; Fausch et al., 2002; Ward et al., 2002b; Wiens, 2002; Benda et al., 2004; Thorp et al., 2006; Humphries et al., 2015). The integral connectivity between rivers and their floodplains and riparian areas is a central tenet of stream hydrology and ecology, as is the substantial influence that this bidirectional exchange has on the physical form, hydrology, chemistry, and biology of the river system (Junk et al., 1989; Abbott et al., 2000; Tockner et al., 2000; Woessner, 2000; Amoros and Bornette, 2002; Ward et al., 2002a; King et al., 2003; Naiman et al., 2005; Church, 2006; Kondolf et al., 2006; Poole et al., 2006; Poole, 2010; Tockner et al., 2010; Vidon et al., 2010; Helton et al., 2011; McLaughlin et al., 2011; Humphries et al., 2015). For example, the flood pulse concept, which Junk et al. (1989) first articulated and Tockner et al. (2000) extended, is a fundamental paradigm in river ecology, depicting the lateral expansion and contraction of the river in its floodplain and the resulting exchange of matter and organisms.

The influence of riparian/floodplain wetlands on downstream waters is especially notable because of the potential magnitude and spatial extent of their interactions with rivers and their locations within river networks. Although floodplains can form in modest size streams (Hughes and Lewin, 1982), they typically form in the lower portion of river networks (Montgomery, 1999; Church, 2002, 2006), where they can provide transient storage and subsequent release of river water and materials (Stanford and Ward, 1993; Squillace, 1996; Mertes, 1997; Winter et al., 1998; Tockner et al., 2000; Fernald et al., 2001; Amoros and Bornette, 2002; Malard et al., 2002; Claxton et al., 2003; Davis et al., 2011). Floodplain patterns and river channel complexity are determined by sediment supply and character, river valley slope, stream power, woody debris, and vegetation (Montgomery, 1999; Church, 2002; Coulthard, 2005; Church, 2006; Osterkamp and Hupp, 2010; Sear et al., 2010; Collins et al., 2012). Circumstances conducive to the formation of complex, rapidly changing channel forms (e.g., anastomosing, braided, meandering) and the deposition of coarse sediment create conditions optimal for river-floodplain interactions (Nanson and Croke, 1992; Mertes et al., 1995; Fernald et al., 2001; Fernald et al., 2006; Poole et al., 2006; Whited et al., 2007).

Wetlands that occur in floodplains are referred to as riverine wetlands within the hydrogeomorphic classification system (Smith et al., 1995). Although floodplain wetlands can occur as marshes (Villar et al., 2001; Lee et al., 2005) or scrub-shrub wetlands (Chipps et al., 2006), these areas are known for supporting forested wetlands. Mitsch and Gosselink (2007) classify floodplain forested wetlands as freshwater swamps—for example, cypress-tupelo swamps (*Taxodium distichum* and *Nyssa aquatica*, respectively) and white cedar swamps (*Chamaecyparis thyoides*)—if water is available throughout most of the growing season, or as riparian ecosystems if the floodplain receives seasonal pulses of flooding. Examples of the latter are bottomland hardwoods in the Southeast—for example, sycamore-sweetgum (*Platanus occidentalis* and *Liquidambar styraciflua*, respectively) and cypress-tupelo forests—or cottonwood-willow (*Populus* spp. and *Salix* spp., respectively) and alder (*Alnus* spp.) riparian communities in the Southwest (Mitsch and Gosselink, 2007).

This section provides further details on the connections between riparian/floodplain wetlands and streams and rivers, and the resulting effects. Below, we examine the physical (Section 4.3.2), chemical (Section 4.3.3), and biological (Section 4.3.4) effects of riparian/floodplain wetlands on rivers and other downstream waters.

4.3.2 The Physical Influence of Riparian Areas on Streams

4.3.2.1 Hydrology

Riparian areas within and outside of floodplains are an important part of the overall riverine landscape (Ward, 1998). Riparian areas are also connected to streams and rivers by a diverse set of hydrologic inputs and outputs (Figure 2-6A; Junk et al., 1989; Winter and Rosenberry, 1998; Benke et al., 2000; Tockner et al., 2000; Bunn et al., 2006). These inputs and outputs are described in Section 2.2 and have been reviewed by various authors (National Research Council, 2002; Naiman et al., 2005; Vidon et al., 2010).

Many studies document that riparian floodplains help attenuate flood pulses in streams and rivers by capturing water from overbank flow and by storing excess water from streams (Mertes et al., 1995; Poole et al., 2006; Rassam et al., 2006). Bullock and Acreman (2003) reviewed the wetland literature and reported that floodplain wetlands reduced or delayed floods in 23 of 28 studies. Walton et al. (1996) found that peak discharges between upstream and downstream water gages on the Cache River in Arkansas were reduced 10–20%, primarily due to floodplain water storage. Gamble et al. (2007) reported that 12 floodplain wetlands in Ohio stored an average of 3,654 m^3 ha^{-1} of water. The authors developed equations relating volume to area and depth for more than 650 regional wetlands and reported that these systems could store approximately 1–2% of the daily flow of larger streams and approximately 40% of the daily flow of small streams. As streamflow decreases after hydrologic events, the water temporarily stored in riparian/floodplain areas can flow back into the channel, supporting stream baseflow (Whiting and Pomeranets, 1997; Chen and Chen, 2003). Although not all riparian/floodplain wetlands store the same amount of water, nearly all of them have the potential to perform this function.

The potential for hydrologic connectivity between riparian/floodplain wetlands and rivers and streams is high during periods of overbank flow and during periods of lower streamflow. Hyporheic exchange occurs when water moves from river or stream channels into riparian or floodplain alluvial deposits and back to the channels, and it occurs during flooded and non-flooded conditions (Sjodin et al., 2001; Gooseff et al., 2008; Bencala, 2011) and on scales ranging from meters to kilometers (Stanford and Ward, 1988; Bencala, 1993, 2005). Complex floodplains typically are environments with high levels of hyporheic exchange (Woessner, 2000; Poole et al., 2006; Poole, 2010).

Vegetation in riparian/floodplain wetlands can influence hyporheic and river water through transpiration. Phreatophytes (plants that obtain their water from the saturated zone) can intercept ground-water and overland flow before it enters a stream and decrease streamflow by directly taking up stream water through their roots. For example, Meyboom (1964) studied two streams in the prairie region of the United States to understand the effect of floodplain vegetation on streamflow fluctuations. When the two streams decreased in flow, the floodplain vegetation accounted for 20% and 100% of this reduction (Meyboom, 1964).

4.3.2.2 Geomorphology (Sediment-vegetation Interactions)

A bidirectional relationship exists between fluvial geomorphology and riparian and floodplain vegetation (Corenblit et al., 2007). Distributions of vegetation communities often are shaped by river flow dynamics and associated erosional and deposition processes, but the communities also exert controls on geomorphic processes and riverine landforms.

Riparian/floodplain wetlands are key depositional environments for sediment that overland flow carries from erosion of nearby uplands (Boto and Patrick, 1979; Whigham et al., 1988). Riparian areas retain portions of this sediment before it enters the stream, especially if the overland flow enters the riparian area as sheetflow runoff rather than as channelized flow, due to the greater volume of water exposed to riparian-wetland soils and vegetation surfaces (Dabney et al., 1995; Meyer et al., 1995; Naiman and Decamps, 1997; National Research Council, 2002; Naiman et al., 2005). Riparian open waters (e.g., oxbow lakes; Section B.2) and wetlands are effective at retaining eroded clays, silts, and sands that otherwise would enter stream channels (Cooper et al., 1987; Heimann and Roell, 2000). Riparian areas were shown to remove 80–90% of sediments leaving agricultural fields in North Carolina (Cooper et al., 1987; Daniels and Gilliam, 1996; Naiman and Decamps, 1997). Grassy riparian areas alone can trap more than 50% of sediments from uplands when overland water flows are less than 5 cm deep (Dillaha et al., 1989; Magette et al., 1989; Naiman and Decamps, 1997). Thus, riparian areas can buffer stream channels against excessive sediment input.

Riparian areas and floodplains can be both sinks and sources for sediments in streams. When streams flood their banks, increased surface contact and friction decrease the flow velocity. The slower moving water has a diminished capacity for keeping material in the water column in suspension, which causes the sediments to deposit (Church, 2002, 2006). Heavy particles such as sand are the first to be removed, whereas finer, lighter particles such as clays and silts take longer to deposit. In southeastern Coastal Plain systems, sediment deposition rates from the stream to the floodplain are high because of frequent overbank flow and relatively high sediment loads of the rivers (Hupp, 2000).

Conversely, riparian areas and floodplains can also be a source of sediment to the stream, particularly through streambank erosion. Although streambank erosion is a natural process, it can be accelerated through vegetational changes because root tensile strength of riparian vegetation reinforces the soil (Naiman and Decamps, 1997; Burt et al., 2002). Streambanks that are devoid of vegetation are often highly susceptible to channel widening (Hupp et al., 1995; Naiman and Decamps, 1997). In a study of 748 bends in four southern British Columbia streams, for example, Beeson and Doyle (1995) reported that bank erosion was 30 times more prevalent on nonvegetated versus vegetated banks. In a comparison of row-crop agricultural, grazing, and forested riparian areas in central Iowa, the forested areas exhibited significantly reduced streambank erosion rates (Zaimes et al., 2004). Certain riparian wetland vegetation types, such as black willow (*Salix nigra*), maintain bank integrity and decrease erosion so well that they are used in river restoration and bank stabilization projects (Pezeshki et al., 2007).

Riparian vegetation also influences stream and river geomorphology through inputs of woody debris or logs, which in turn shape stream channels (Brummer et al., 2006; Sear et al., 2010; Collins et al., 2012). Woody debris can enter streams through tree mortality, bank undercutting, windthrow, wildfire, floods, landslides, and debris flows (Gurnell et al., 2002; Reeves et al., 2003). Gurnell et al. (2002) reported that the amount of woody debris deposited into streams can range from 12 to 40 t km^{-1} yr^{-1}, depending on the type of stream and nearby vegetation. As discussed in Section 3.3.3, woody debris can alter stream channels, trap sediments, and form new aquatic habitat (Anderson and Sedell, 1979; Harmon et al., 1986; Nakamura and Swanson, 1993; Abbe and Montgomery, 1996; Naiman and Decamps, 1997; Gurnell et al., 2002).

4.3.2.3 Temperature and Sunlight

Riparian areas can modify stream temperatures and the amount of light available for photosynthesis in stream and river environments through stream shading, particularly in forested settings (Barton et al., 1985; Gregory et al., 1991; Blann et al., 2002). Dense, overhanging vegetation greatly reduces the intensity of light, whereas open canopies allow light to penetrate (Gregory et al., 1991). This radiant energy, or lack thereof, strongly influences stream temperature (Barton et al., 1985; Gregory et al., 1991; Blann et al., 2002). The maximum temperature of a stream in Oregon, for example, was 7 °C higher in a reach where the riparian vegetation was removed compared to its temperature when it was forested. Fifteen years of regrowth in the harvested area was required for the stream temperature to return to preharvest levels (Johnson and Jones, 2000).

By affecting stream temperatures, shading by riparian vegetation can alter fish growth, activity, and mortality, while also influencing their prey species (Beschta et al., 1987). Higher temperatures, for example, can lead to greater stream invertebrate biomass (Beschta et al., 1987). The net temperature effect on fish growth, however, depends on the balance between food availability and higher metabolic rates (Beschta et al., 1987). Riparian vegetation enhancement can be used by managers to promote fish habitat for certain desired species. Blann et al. (2002) investigated the degree to which different types of riparian vegetation could increase shade, reduce stream temperatures, and promote habitat for brook trout (*Salvelinus fontinalis*) in Minnesota. The researchers concluded that both forested and herbaceous riparian vegetation shaded the stream and buffered stream temperature, and could aid in creating appropriate coldwater trout habitat (Blann et al., 2002).

Shading of the stream by riparian vegetation also directly influences the instream net primary productivity of aquatic plants and other photosynthetic organisms, such as algae, by altering light availability (Gregory et al., 1991). Net primary production is greatest in open reaches and is significantly less in reaches that are forested and shaded (Gregory et al., 1991). For example, Gregory et al. (1991) reported that net primary productivity in open streams in Oregon averaged 210 mg carbon (C) m^{-2} d^{-1}, whereas forested reaches of streams with deciduous vegetation averaged 58 mg C m^{-2} d^{-1}. Reduced net primary production leads to lower densities of herbivores in streams (Hawkins and Sedell, 1981; Gregory et al., 1991). Shading can limit stream productivity (Hill and Knight, 1988; Gregory et al., 1991), but it can also be beneficial by reducing excessive algal production in nutrient-enriched waters. Algae can lead to excessive biological oxygen demand and turbidity and can decrease water quality in downstream systems (Volkmar and Dahlgren, 2006).

In addition to shading by riparian vegetation, riparian areas and floodplains can influence stream and river water temperature through hyporheic exchange (Brosofske et al., 1997; Naiman and Decamps, 1997; Poole and Berman, 2001; Naiman et al., 2005). Hyporheic cooling of stream and river water during warm summer periods has been observed in a wide range of settings, including large gravel bed rivers in Oregon (Fernald et al., 2006; Burkholder et al., 2008; Seedang et al., 2008), an alpine stream in the mountains of Colorado (Constantz, 1998), a boreal river in Sweden (Nyberg et al., 2008), and small streams in Illinois (Peterson and Sickbert, 2006) and northern California (Loheide and Gorelick, 2006). Important to note, however, is that hyporheic exchange can warm streams (Valett et al., 1990). Arscott et al. (2001) found that hyporheic and other thermal regulating processes can lead to large thermal heterogeneity of water bodies associated with complex floodplains. Hester and Gooseff (2010) argue that, for streams impacted by human activities, restoration of hyporheic zones is essential for the recovery of stream functions and ecosystem services.

4.3.3 The Chemical-nutrient Influence of Riparian Areas on Streams

Riparian areas in and outside of floodplains are instrumental in controlling the biogeochemistry of riverine systems through (1) overbank flooding (flood pulse); (2) internal biogeochemical processes; and (3) hyporheic exchange (Junk et al., 1989; Thurman et al., 1991; Heiler et al., 1995; Tockner et al., 2000; Adair et al., 2004; Noe and Hupp, 2005; Valett et al., 2005; Noe and Hupp, 2007; Helton et al., 2011; Powers et al., 2012; Bennett et al., 2015). All three mechanisms help shape nitrogen, carbon, phosphorus, and pesticide cycling with the riverine environment.

Wetlands have been described as depositional areas in an eroding landscape (Brittain and Eikeland, 1988). Pollutants and materials relevant to discussions on water quality—such as nutrients, pesticides, and metals—enter wetlands (e.g., Tiner, 2003c; Comer et al., 2005) through flowpaths that include dry and wet (e.g., rain, snow) atmospheric deposition; point sources such as outfalls, pipes, and ditches; and nonpoint sources, such as runoff from agricultural and urban fields and lawns, drift spray, and diffuse near-surface water inputs (Nixon and Lee, 1986; Whigham and Jordan, 2003; Whitmire and Hamilton, 2008). For riparian/floodplain wetlands, transport from upstream reaches or through the hyporheic zone (Figure 2-6) is another important source of these substances. Such materials can then be sequestered via sorption (adsorption and absorption) or sedimentation processes, assimilated into the flora and fauna, transformed into other compounds, or lost to the atmosphere through transformational processes (Nixon and Lee, 1986; Johnston, 1991; Mitsch and Gosselink, 2007). These processes include conversion between particulate and dissolved forms of compounds via biologically mediated degradation (e.g., Bärlocher et al., 1978) and reduction-oxidation (redox) reactions (Nixon and Lee, 1986; Reddy and DeLaune, 2008). Redox reactions are essential to microbial respiration and are critical to both defining wetland systems and understanding transformational processes that microbes mediate (Boon, 2006; Reddy and DeLaune, 2008).

4.3.3.1 Hyporheic/Soil Processing of Nutrients

Riparian areas connect upland and aquatic environments through both surface and subsurface hydrologic flowpaths (Figure 2-6; Naiman et al., 2005). Riparian areas act as buffers that are among the most effective tools for mitigating nonpoint source pollution (Knight et al., 2010). These areas are uniquely situated in watersheds to receive and process waters that pass through the root zone before reaching streams (Gregory et al., 1991). These processes do not affect deep ground-water hydrologic flowpaths (Figure 2-5) that enter a river or stream below the active riparian root zone. The focus of this section, however, is on surface and shallow subsurface flows; we do not address deep ground-water flowpaths here.

Riparian areas can significantly influence nutrients and other exports from watersheds (Gregory et al., 1991) and can be considered areas of major nutrient transformation as subsurface waters move through them (Dahm et al., 1998). Riparian areas remove nutrients such as nitrogen and phosphorus from water as it flows from uplands to streams (Lowrance et al., 1997; Dosskey, 2001; Mayer et al., 2007). For instance, Johnston (1993) reported that a floodplain wetland retained, 15.2, 13.7, and 14.2% of the solids, total nitrogen, and total phosphorus fluxes, respectively, from the watershed. The degree to which a riparian area serves as either a source or a sink for nitrogen, phosphorus, organic matter, pesticides, and mercury is controlled largely by the substance's concentration in riparian soils (Gregory et al., 1991), soil redox conditions, and hydrology (Vidon et al., 2010). For example, riparian plant communities can release seasonal pulses of dissolved leachates derived from stream litter (Fisher and Likens, 1973). Riparian areas are therefore central to watershed water quality management (Burt, 1997; Lowrance et al., 1997).

4.3.3.2 Nitrogen

Riparian areas can remove dissolved nitrogen (N) in subsurface flowpaths that would otherwise flow into streams (Vidon et al., 2010). Removal occurs via plant uptake and microbial transformations (i.e., assimilative uptake, assimilatory nitrate reduction to ammonium, and dissimilatory nitrate reduction to ammonium or nitrogen gases such as dinitrogen, nitric oxide, and nitrous oxide via denitrification). One study demonstrated that intact riparian and hyporheic zones are critical in decreasing the amount of dissolved inorganic nitrogen that moves from headwaters to larger, downstream waters (Triska et al., 2007). Vidon et al. (2010) showed that riparian areas remove more than half the nitrogen from surface and shallow subsurface water transporting ammonium and nitrate through the rhizosphere (Vidon et al., 2010). Leaching from nitrogen-fixing plants (e.g., red alder, *Alnus rubra*) in riparian systems, however, also can be a major source of nitrogen to stream systems (Compton et al., 2003).

Denitrification potential in surface and shallow subsurface flows is not homogeneous across the riparian area, increasing markedly in the presence of organic carbon or anoxic conditions that create denitrification “hot spots” (McClain et al., 2003; Orr et al., 2014). Therefore, for riparian areas to appreciably increase nitrogen removal, flowpaths that convey nitrate-rich water into such denitrification “hot spots” must be present (Vidon et al., 2010).

The highest denitrification potentials occur in floodplain systems where high organic matter levels, denitrifying microbes, and saturated soil conditions are present (Vidon et al., 2010). Rates of denitrification are greater in riparian soils nearer to streams (Gregory et al., 1991). Johnston (1993) reported nitrate removal along a floodplain gradient of 6.6 g per 100-m distance from the stream. High soil moisture and deposited organic matter enhance microbial activity, thereby tending to increase denitrification (Reddy and DeLaune, 2008).

As subsurface flow passes through riparian areas, vegetative demand for dissolved nutrients also can reduce nutrient loads (Vidon et al., 2010). More than three-quarters of the dissolved nitrate (NO_3^-) transported from agricultural fields to a Maryland river (Vidon et al., 2010) was removed by riparian forests. Nitrogen was removed at a rate of 45 kg N ha^{-1} yr^{-1} as subsurface flow moved from agricultural fields through riparian zones to nearby streams (Peterjohn and Correll, 1984). In the coastal plains of Georgia, riparian forests retained more than 65% of the nitrogen and 30% of the phosphorus contributed from nearby agriculture (Vidon et al., 2010). In southern Pennsylvania, a forested riparian area had a subsurface nitrate budget with an average removal of 90 kg NO_3^- ha^{-1} yr^{-1}, which was 26% of the total nitrate input (Newbold et al., 2010).

4.3.3.3 Phosphorus

The movement and uptake of phosphorus in riparian areas are a function of phosphorus sources, hydrology, and biogeochemistry (Vidon et al., 2010), with interactions between ground water and surface waters driving the biogeochemical processes (Hoffmann et al., 2009). Phosphorus loss and retention in riparian areas are related to the flowpath of the water through the riparian area to the stream (e.g., overland flow of water from nearby agricultural fields, river-water inundation of floodplain riparian areas). Flowpath dictates the confluence and interaction of phosphorus with minerals that drive biogeochemical cycling of phosphorus in riparian areas (Hoffmann et al., 2009). The physical processes of sedimentation and plant uptake are active in these flowpaths and can account for particulate phosphorus retention rates as high as 128 kg P ha^{-1} yr^{-1} and 15 kg P ha^{-1} yr^{-1}, respectively (Hoffmann et al., 2009). Retention of dissolved phosphorus in riparian areas is more modest, with values less than 0.5 kg P ha^{-1} yr^{-1} often reported. Studies show, however, significantly higher numbers for the release of dissolved phosphorus: up to 8 kg P ha^{-1} yr^{-1} (Hoffmann et al., 2009).

Although riparian soils generally serve as sources of phosphorus when soils are anoxic or when mineral dissolution releases phosphorus (Baldwin and Mitchell, 2000; Chacon et al., 2008), riparian areas are phosphorus sinks in oxic soils (Carlyle and Hill, 2001). Portions of riparian areas where agricultural sediments are deposited are phosphorus sources to streams if the phosphorus is desorbed and leached but can be sinks by adsorbing dissolved phosphorus if sediment phosphorus concentrations are low

(Dillaha and Inamdar, 1997; Sharpley and Rekolainen, 1997). Riparian areas also serve as phosphorus sinks when upland surface runoff travels through the riparian area or when fine-grained sediment containing phosphorus is deposited overbank onto the riparian area (Dillaha and Inamdar, 1997). These sediments, however, can become sources of phosphorus if they are later saturated with water and iron and manganese are reductively dissolved during anoxic conditions, thus causing them to desorb phosphorus (Reddy and DeLaune, 2008).

4.3.3.4 Carbon and Allochthonous Inputs

Both production and consumption of organic and inorganic carbon occur in riparian areas. In areas with reducing conditions, microbes generally oxidize organic carbon and reduce available electron acceptors, releasing carbon dioxide gas and making the soils more alkaline (Vidon et al., 2010). This process can result in chemical gradients in which electron acceptor concentrations decrease and alkalinity increases along subsurface flowpaths (Burns, 1996; Cirmo et al., 2000; Bailey Boomer and Bedford, 2008). Riparian areas, especially those in low-lying flatlands, tend to have low subsurface flow velocities resulting in anoxic conditions, shallow water tables, and slow organic matter decomposition, as is often seen in riparian wetlands. This is why riparian areas are active areas for biogeochemical transformations (Vidon et al., 2010).

Allochthonous inputs from riparian areas to streams are critical to aquatic food webs, particularly in headwater catchments (reviewed in Tank et al., 2010). Allochthonous inputs are terrestrial organic materials that enter the stream through vegetation litter (i.e., woody debris, leaves, and partially decomposed plant parts), erosion, and hydrologic flows (Wetzel, 1992). In small forested watersheds, overhanging trees provide organic matter inputs, while simultaneously reducing photosynthesis by autotrophic organisms (Vannote et al., 1980). This dual effect makes allochthonous inputs the primary source of energy flow into the food webs of these streams. For example, in a New Hampshire stream the surrounding forest supplied more than 98% of the organic matter (Gregory et al., 1991). Organic matter inputs are important because they affect food availability to aquatic organisms by releasing organic carbon and nitrogen into streams (Wetzel and Manny, 1972; Mulholland and Hill, 1997). For example, in a small headwater stream near Louisville, KY, macroinvertebrate communities, which are critical food sources for fish (Wallace and Webster, 1996), relied almost exclusively on leaf inputs (Minshall, 1967). Excluding litter from the riparian area changed the food web structure of a North Carolina stream (Wallace et al., 1997) and decreased its dissolved organic carbon concentrations and loadings (Meyer et al., 1998). In addition to the impacts of total inputs, the composition and timing of allochthonous inputs, largely determined by riparian plant species composition, also can influence instream decomposition and aquatic invertebrates (Cummins et al., 1989; Swan and Palmer, 2006).

Downstream, much less of the stream is directly influenced by streamside vegetation, due to larger stream widths and consequently greater distances from the banks. This decreases the relative importance of allochthonous inputs while concomitantly increasing the importance of instream photosynthesis (Vannote et al., 1980). The macroinvertebrate community responds to this shift in input types. For example, macroinvertebrate shredders that use large inputs, such as leaves, become less prevalent as streams increase in size. Besides changing longitudinally with stream size, riparian allochthonous inputs also can vary seasonally, with a large pulse occurring in deciduous forests during autumn leaf fall.

4.3.3.5 Pesticides

The roots in riparian areas can be important in removing pesticides from shallow subsurface flow, because the labile organic matter and organic residues that accumulate near roots can increase microbial biomass and activity (Vidon et al., 2010). Pesticides and their metabolites can be mineralized and adsorbed where surface area contact is high and contact time with roots is sufficient (Krutz et al., 2006). A study of the pesticides alachlor and atrazine in a riparian area notes the importance of plant uptake in the fate of these pesticides, and suggests that vegetated buffer zones help protect water supplies (Paterson and Schnoor, 1992). Studies examining specific pesticides—for example, isoproturon (Benoit et al., 1999), metolachlor (Staddon et al., 2001), and atrazine (Mudd et al., 1995)—found that the presence of vegetation, associated root zones, and accumulated organic matter increased the removal of those pesticides (Vidon et al., 2010). Pesticide-degrading microbial populations increase after repeated chemical applications (Gonod et al., 2006), suggesting that riparian areas can become better at degrading pesticides that enter these zones (Vidon et al., 2010). In addition, microbial biomass has been shown to be positively correlated with the loss of the herbicides 2,4-D (2,4-dichlorophenoxyacetic acid) and dicamba, suggesting a relationship between the amount of microbial biomass in the soil and the capacity of an ecosystem to degrade pesticides (Voos and Groffman, 1996).

4.3.3.6 Mercury

Mercury enters the global atmosphere primarily through waste incineration and coal combustion. It can directly enter wetland systems or can be deposited on terrestrial areas and then transported into riparian areas and wetlands via rainfall and runoff (St. Louis et al., 1994). Riparian soils and wetlands are important both for mercury mobilization (Mierle and Ingram, 1991; Driscoll et al., 1995) and the production of methylmercury, a particularly toxic and mobile form of the element. Mercury methylation occurs in the presence of anoxic, saturated soils high in organic matter, mercury-methylating microbes, and mercury from either atmospheric deposition or soils (St. Louis et al., 1996). The redox conditions found in the presence of a fluctuating water table are thought to be a strong driver of mercury methylation (Heyes et al., 2000; Branfireun and Roulet, 2002; Branfireun, 2004). Export of mercury and methylmercury can expose organisms in downstream aquatic ecosystems to potential toxicity (Thurman, 1985; Driscoll et al., 1995). Mercury bioaccumulates in fish, and consumption of fish is the main human pathway for exposure to mercury (Rypel et al., 2008).

The source-sink dynamics of riparian areas with respect to mercury are complex. Because soils accumulate mercury, they buffer aquatic ecosystems against the full impact of this pollutant (Aastrup et al., 1991). Because some of this mercury and methylmercury moves from soils to surface waters, however, riparian areas might also be a source of the mercury that ends up in the aquatic food web.

4.3.4 Biological Connections Between Riparian Areas and Streams

The dynamic nature of river systems is most apparent in riparian areas and floodplains, where a shifting landscape mosaic supports diverse communities of aquatic, amphibious, and terrestrial plant and animal species adapted to periodic or episodic inundation of riparian areas and floodplains (Power et al., 1995a; Power et al., 1995b; Galat et al., 1998; Robinson et al., 2002; Toth and van der Valk, 2012; Rooney et al., 2013; Granado and Henry, 2014). In unregulated rivers, floodplain inundation greatly increases the area and diversity of aquatic habitats (Junk et al., 1989; Tockner et al., 2000; Brooks and Serfass, 2013). It also enables rapid cycling of nutrients imported from river channels (Section 4.3.3.2), resulting in high primary productivity of plants and algae (Junk et al., 1989; Tockner et al., 1999). The combination of diverse habitat types and abundant food resources makes floodplains important foraging, hunting, and breeding sites for fish (Copp, 1989; Bestgen et al., 2000; Schramm and Eggleton, 2006; Sullivan and Watzin, 2009; Alford and Walker, 2013; Magana, 2013), aquatic life stages of amphibians (Richardson et al., 2005), and aquatic invertebrates (Smock et al., 1992; Smock, 1994). Many of these organisms have growth stages or reproductive cycles timed to coincide with seasonal hydrologic connectivity between rivers and floodplains. Thus, lateral fluctuations in hydrologic connectivity can increase overall levels of species productivity and biodiversity in river systems (Junk et al., 1989) and can be integral to the viability of many riverine species (Bunn and Arthington, 2002). Here, we review examples of adaptation to and exploitation of riparian habitats by aquatic species of plants, fish, mammals, and invertebrates.

4.3.4.1 Vascular Plants and Phytoplankton

Channels and riparian/floodplain wetlands provide habitat for aquatic vegetation, emergent vegetation, and phytoplankton. When seeds, plant fragments, or whole organisms move back and forth between riparian/floodplain wetlands and the river network (via water, wind, or animal dispersal), these areas become biologically connected. Species can disperse via overbank flow between channels and riparian/floodplain wetlands (e.g., Schneider and Sharitz, 1988; Middleton, 2000; Nilsson et al., 2010). Seeds from vegetation within the channel or that have been mobilized from upstream riparian/floodplain wetlands can be deposited on bordering or downstream riparian areas and floodplains (Nilsson et al., 2010), much like sediment and in many cases with sediment (Gurnell, 2007; Gurnell et al., 2008). For example, in the southwestern United States, soil seed banks of wetland plants can be established or replenished in floodplains when those areas are connected to a stream channel by overbank flow (Boudell and Stromberg, 2008). In another example, 41% of plant species for which the seeds were deposited on riparian areas during winter flood flow in two United Kingdom rivers were wetland or aquatic plants (Gurnell et al., 2008). Overland flow or flooding also can dislodge viable plant fragments in riparian/floodplain wetlands, which then are transported down the river network. Fragments of seep monkeyflower (*Mimulus guttatus*) are easily dislodged by the relatively high flow velocities along the riparian-channel interface, and fragments can survive and reestablish downstream at rates exceeding 90% (Truscott et al., 2006).

Floodplains can function as sinks for seeds and plant fragments. For example, in a forested floodplain wetland in Illinois, many bald cypress (*Taxodium distichum*) seeds dispersed by the river network were deposited but did not germinate (Middleton, 2000). Alternatively, establishment and reproduction of refuge floodplain populations can become important wetland seed sources for the river network, especially if catastrophic flooding scours vegetation and seed banks that can exist on streambeds (Gurnell et al., 2008).

Hydrologic connectivity between channels and riparian/floodplain wetlands can significantly enhance riparian vegetation diversity (Jansson et al., 2005) and determine floodplain wetland community structure (Boschilia et al., 2008). For nonnative species, however, connectivity can facilitate invasion, resulting in changes in riparian vegetation community structure. In an intermittent stream in Illinois, tubers of the nonnative Chinese yam (*Dioscorea oppositifolia*) were dispersed via stormflow and overbank flow and became established along a narrow upstream riparian area and wider channel and floodplain more than 1 km downstream; the presence of the nonnative plant significantly reduced native plant cover (Thomas et al., 2006). Vegetation community composition, in turn, can affect the function of riparian areas as nutrient sources or sinks to the river network (Sections 4.3.3.2 and 4.3.3.3). Invasion by nonnative riparian plants also can result in altered stream invertebrate diversity, among other effects (Lecerf et al., 2007).

Seeds of aquatic and riparian plants also can be actively dispersed by animals that consume them. For example, seeds of the aquatic emergent bur-reed (*Sparganium emersum*) were ingested and viably excreted by common carp (*Cyprinus carpio*) (Pollux et al., 2007), which elsewhere have been observed using channel and floodplain wetland habitat (King et al., 2003). Riparian floodplain and wetland vegetation can also disperse and exchange seeds via terrestrial animal vectors and the wind. Animals that travel overland can also disperse ingested seeds or seeds adhering to fur, feathers, or limbs between riparian/floodplain wetlands and the river network (see Sections 4.3.4.2, 4.4.4, and B.3.3.3 for discussions of animal movement). Many macrophyte species have evolved for dispersal by wind, including some of the most invasive in North America, cattail and reed canary grass (Barrat-Segretain, 1996; Soons, 2006 and references therein). Given the proximity of riparian/floodplain wetlands and the river network itself, dispersal of pollen and seeds between these habitats could be quite frequent. For example, seeds of some 20 species found in floodplain wetlands in bald cypress swamps in Illinois were caught in aerial seed traps, and dispersal of three species averaged more than 100 seeds m^{-2} yr^{-1} (Middleton, 2000).

Phytoplankton also move via water between floodplain wetlands and the river network. A river with overbank flow can homogenize the phytoplankton communities in floodplain wetlands separated by more than 5 km (Angeler et al., 2010), and phytoplankton communities in river networks can be bolstered by high-productivity conditions in temporarily connected floodplain wetlands. For example, a portion of flow from California's Sacramento River is seasonally diverted from the main channel into the Yolo Bypass, a nearby 240 km^2 floodplain. From January to June 2003, 14 and 31% of total diatom and total green algae biomass, respectively, was produced in the floodplain (Lehman et al., 2008). This considerable contribution of carbon to the aquatic food web, which ultimately supports downstream fisheries, resulted from the high net primary productivity of the floodplain. This observation is particularly noteworthy because the median flow through the floodplain during the period of measurement (23 m s^{-1}) was just 3% of the median flow through the main channel. Considered collectively, these studies indicate riparian/floodplain wetlands can be both sources and sinks for phytoplankton and water-, animal-, and wind-dispersed vascular plants with respect to the river network.

4.3.4.2 Vertebrates

Animals, including many fish and mammals, move between riparian/floodplain wetlands and the river network. The evidence is strong and abundant that fish can move between the main river channel and riparian/floodplain wetlands when the channel and wetlands are hydrologically connected, even when, in some cases, the connection is seasonal or temporary. Such wetlands provide refuge, feeding, and rearing habitat for many fish species and augment recruitment to the river network (Boltz and Stauffer, 1989); examples include fish taxa in forested floodplain wetlands of the southeastern and southwestern United States and salmonids of the northwestern United States such as coho salmon (*Oncorhynchus kisutch*) and Chinook salmon (*Oncorhynchus tshawytscha*) (e.g., Wharton et al., 1982; Matheney and Rabeni, 1995; Pease et al., 2006; Henning et al., 2007; Jeffres et al., 2008). In one section of the mainstem Rio Grande in New Mexico, more than 90% of the larval and juvenile fish of six captured species were from riparian areas with zero water velocity (backwaters, former side channels, and isolated pools; Pease et al., 2006). Oxbow lakes are also important habitats for fish feeding and rearing. Based on a 5-year study of fish in oxbow lakes, Shoup and Wahl (2009) concluded that the entire floodplain should be considered a single functioning unit that supports the overall biological integrity of a river (Section B.2). The use of riparian/floodplain wetlands by fish depends on many factors intrinsic to the particular river system (e.g., periodicity and duration of floodplain inundation) and the characteristics of the resident or migratory fish community (King et al., 2003).

Fish also move between lacustrine wetlands (wetlands associated with lakes) and large lakes when hydrologic connections exist. Fish communities in the Great Lakes and their surrounding wetlands become more homogeneous when surface connections between the wetlands and lake are present. Fish use these wetlands for refuge from predators and as rearing habitat (Jude and Pappas, 1992). Miyazono et al. (2010), studying floodplain lakes in the Yazoo River Basin, found that conditions that included decreases in habitat connectivity, wetland buffers, and certain water quality parameters led to the increased dominance of environmentally tolerant fish in those lakes. Fish assemblages in riparian wetlands along the semiarid region of the Murray River, Australia showed a large decline in diversity when those wetlands were disconnected from the river through hydrologic modifications. This trend was reversed after a managed inundation treatment restored connections between the wetlands and the river (Vilizzi et al., 2013). River-dwelling mammals also move between rivers and riparian/floodplain wetlands, including river otters, which have been observed using wetlands extensively as latrines (Newman and Griffin, 1994). In addition, both river otters and beavers have a strong preference for riparian areas that are pond- and lake-dominated (Swimley et al., 1999). Thus, movement of animals, especially fish, connects riparian/floodplain wetlands to the river network and supplies streams and rivers with a source of biological materials.

In addition to acting as sources, sinks, and refuges for individual species of organisms, riparian/floodplain wetlands can improve the overall health of biological communities. For example, a positive relationship between wetland cover and an index of biological integrity for fish communities in rivers was observed in 23 sites in several small catchments of the River Raisin in Michigan (Roth et al., 1996).

Besides providing a form of biological connectivity that can link riparian/floodplain wetlands and downstream waters, vertebrates in riparian areas can affect stream characteristics and influence various forms of connectivity. Perhaps the most familiar example of this is the beaver (*Castor canadensis*). Although beaver damming would be expected to reduce hydrologic connectivity through impoundment, their influence can be more complex. For example, Westbrook et al. (2006) found that beaver dams in the Colorado River affected depth, extent, and duration of inundation resulting from a 10-year flood event. In addition, beaver dams attenuated declines in water tables during drier summer periods in 25% of their 58 ha study area. They concluded that the main hydrologic effects occurred downstream, however, rather than near the dam (Westbrook et al., 2006). The hydraulic head generated by the dam raised the water level above the banks, resulting in lateral and downstream spreading of flows during high- and low-flow periods; these effects extended over hundreds of meters. For example, mottled soils occurred throughout the study area, suggesting that the dams caused waterlogged soils for extended periods. Increased overbank flooding increases hydrologic connectivity between riparian areas and streams. In contrast, when no dams were present, flooding was limited to the area immediately near the stream channel. Beaver dams also can affect stream biogeochemistry. For example, beaver dams modify nutrient cycling and decomposition dynamics and can affect downstream transport of materials (Naiman et al., 1988; Naiman et al., 1994). For example, beaver-dam wetlands can serve as a source of methylmercury (Roy et al., 2009). Beaver dams also can affect fish species, such as coho salmon (Pollock et al., 2004).

Vertebrates also can indirectly affect hydrologic connectivity through cascading effects on riparian plant communities. Beschta and Ripple (2012) provide evidence from analyses at three western National Parks for a trophic cascade model where large predators can affect the morphology of river channels through intermediate effects on ungulate browsers and riparian plant community structure. For example, extirpation of wolves (*Canis lupus)* at Yellowstone National Park by the mid-1920s led to an increase in elk (*Cervus canadensis*) numbers. This increase caused suppression and mortality of riparian willow (*Salix* spp.) communities, ultimately resulting in changes to stream morphology such as bank erosion, decreased sinuosity, increased active channel width, and increased amount of unvegetated alluvium (Beschta and Ripple, 2012). Based on results from the three National Parks and other sites, Beschta and Ripple (2012) concluded that the removal of apex predators due to extirpation increased ungulate herbivory, which altered riparian plant communities, thereby increasing bank erosion that led to either widening of the active channel or channel incision. These channel alterations, in turn, reduced the frequency of overbank flows, which decreases hydrologic connectivity between the riparian area and downstream waters.

4.3.4.3 Invertebrates

Stream macroinvertebrates (e.g., insects, crayfish, mollusks) and microinvertebrates (e.g., cladocerans, copepods, rotifers, gastropods) colonize nutrient-rich riparian areas and floodplains in large numbers during seasonal or episodic immersion by rivers and streams (Junk et al., 1989; Ilg et al., 2008). Macroinvertebrates and microinvertebrates (also called zooplankton) are the intermediate link between primary producers (e.g., algae), detrital pools (e.g., leaf litter), and predators (e.g., fish, amphibians) in river food webs (Malmqvist, 2002; Woodward and Hildrew, 2002; Stead et al., 2005; Woodford and McIntosh, 2010). The distribution of invertebrate populations in dynamic river systems is governed by the location of resources required for different needs and life stages, and invertebrates actively dispersing to find and exploit resources wherever they become available (Malmqvist, 2002). As with vascular plants, hydrologic connectivity between channels and riparian/floodplain wetlands can significantly influence macroinvertebrate community structure in riparian areas (Paillex et al., 2009; Yetter, 2013). For example, the species diversity and abundance of macroinvertebrates in the wetlands of a river delta have been found to be positively correlated with a gradient of connectivity (Dou et al., 2015).

Invertebrates have evolved two basic strategies to exploit habitats near streams and rivers: (1) rapid colonization of flooded areas and short life cycles that complete before floodplains dry again, or (2) use of aquatic refuges or dormant life stages to persist in permanent waters, the hyporheic zone, or floodplain soils between inundations (Tronstad et al., 2007). To evaluate the relative importance of each strategy in the same river system, Jenkins and Boulton (2003) compared the abundance and species composition of microinvertebrates emerging from floodplain sediments to those transported by floodwater from instream habitats at reach and watershed scales. Initially, most colonizers of newly flooded riparian habitats came from distant upstream reaches of the river network, washed downstream by floodwaters. After a few days, however, species hatching from eggs diapausing in soils greatly increased the diversity and size of the river/floodplain community. This study illustrates two important points about biological connectivity of river/riparian habitats:

1. Stream invertebrate communities comprise species adapted to different stresses in their environment (in this case, resilient species adapted to high flows and resistant species adapted to desiccation).
2. Floods that periodically connect different parts of the river network generate potential for gene flow across time and space by mixing individuals from different locations (e.g., upstream/downstream, channel/floodplain) and different years (e.g., eggs that might have diapaused for tens or even hundreds of years).

The findings by Jenkins and Boulton (2003), that resting egg banks in riparian soils are important to the persistence of aquatic species and the composition of river communities, were validated in a separate study by Frisch and Threlkeld (2005), who compared flood-pulse colonization in a field study with laboratory hatching of copepod microcrustaceans from egg banks of inundated soils in Mississippi. The laboratory samples showed that, in the absence of hydrologic connections, egg banks were sufficient for persistence of copepod populations; the field samples showed that when hydrologic connections were present, water dispersal and hatching from dormant stages were both important colonization pathways for copepods. In a perched floodplain in Missouri, Fisher and Willis (2000) showed that flood-pulsed movement of water and organisms between river channels and floodplains was bidirectional. Adaptations by stream-dwelling invertebrates to variable moisture conditions, and rapid two-way dispersal to exploit temporary or seasonal hydrologic connections, are strong evidence of long-term biological connectivity between rivers and riparian areas.

Invertebrates that disperse by aerial means also take advantage of flooded riparian habitats. Tronstad et al. (2007) investigated aerial colonization of floodplains by insects during multiple flood pulses having different inundation periods in an unregulated river in Alabama's Coastal Plain. At least 41 genera in 21 families across 7 orders of flight-capable insects colonized floating trays placed in floodplain waters in June, August, November, and April. Insect densities varied across the period and reached a maximum in August of about 80,000 individuals m^{-2}, most of which were seeking mates or oviposition sites rather than foraging or hunting. High densities (21,291 individuals m^{-2}) of passively dispersing (e.g., via wind or animal vectors) microcrustaceans also were observed. Vanschoenwinkel et al. (2009) erected 9 windsocks (sampling devices for aerially dispersing organisms) near temporary rock pools for 1 month, during which 850 viable dormant eggs, larvae, and adults from 17 invertebrate taxa were collected. Results from these studies illustrate that aerial dispersal of multiple taxonomic orders and phyla is a significant source of stream invertebrate colonists in newly inundated floodplain habitats.

4.4 Non-floodplain Wetlands

4.4.1 Introduction

This section focuses on the connections and influence of non-floodplain wetlands (defined in Section 2.2.1) on downstream waters. Brinson (1993), in his hydrogeomorphic classification system, categorized wetlands according to four geomorphic settings. This system subsequently was expanded to the following seven classes by Smith et al. (1995): riverine, depressional, slope, mineral soil flats, organic soil flats, estuarine fringe, and lacustrine fringe. Non-floodplain wetlands consist of certain depressional, slope, and flats wetlands (although some of these wetlands can occur in riparian and floodplain wetland settings; Section 2.2.1). Depressional wetlands, as their name suggests, occur in topographic depressions and might or might not have a surface water inlet or outlet. Common types of depressional wetlands include kettles, potholes, vernal pools, playa lakes, and Carolina bays (Brinson, 1993). Slope wetlands (also known as seeps) are located in breaks of slopes and are sites of ground-water discharge (Hall et al., 2001a; O'Driscoll and DeWalle, 2010). Slope wetlands include fens, which typically are ground-water driven and have diffuse outputs (Brinson, 1993; Bedford and Godwin, 2003). Mineral soil flats commonly occur on interfluves, relic lake bottoms, or large floodplain terraces.

Precipitation dominates the water sources in mineral soil flats, with little ground-water input. Wet pine flatwoods and large playas are examples of this wetland type. Non-floodplain wetlands also include organic soil flats. These contain extensive peatlands, or peat bogs, where the accumulation of partially decayed organic matter dominates (Mitsch and Gosselink, 2007). Precipitation also generally dominates the water inputs to bogs, which can connect to downstream waters via a channel outlet or diffuse overland flow (Brinson, 1993). Bogs are generally more acidic than fens (Bedford and Godwin, 2003). Depressional, slope, or flats wetlands also can serve as stream origins (Figure 2-18A).

Below, we examine the physical (Section 4.4.2), water quality (Section 4.4.3), and biological (Section 4.4.4) effects of non-floodplain wetlands on rivers and other downstream waters. We then briefly consider the issue of geographic isolation in non-floodplain wetlands (Section 4.4.5).

4.4.2 The Physical Influence of Non-floodplain Wetlands on Streams

Section 2.4.1 provided a general description of how non-floodplain wetlands can connect to downstream waters via surface and ground-water flow (Figure 2-18). In this section, we provide further details on these connections and discuss how such connections affect streamflow.

4.4.2.1 Surface-water Connections

Non-floodplain wetlands can be connected by perennial surface flows to river networks. For example, seeps are likely to have perennial connections to streams that provide important sources of baseflow, particularly during summer (Morley et al., 2011). In a study in Maine, seeps were found to provide 40–80% of stream water during baseflow periods (Morley et al., 2011). In other cases, surface connections between non-floodplain wetlands and streams can be intermittent or ephemeral. Rains et al. (2008) and Rains et al. (2006) showed that California vernal pools, situated on both clay and hardpan soils, connected with streams through channels containing transient water flow (Section B.6). The series of vernal pools on the clay soils were filled with water for 200 days of the year, and water spilled from these wetlands through swales and channels for 60% of those days (Rains et al., 2008). McDonough et al. (2015) found that forested Delmarva bays had seasonally intermittent surface water connections to streams; these connections occurred during periods of low evapotranspiration and high water tables, that is, from mid-fall to late-spring. In contrast, surface-water connectivity of restored and prior converted (wetlands converted to agriculture before 1985) bays was ephemeral, that is, it occurred in response to rainfall. The cumulative duration of connections to perennial streams was greater and had fewer transitions between connected and disconnected states for forested bays than for restored and prior converted bays (McDonough et al., 2015). Drainage of wetlands via ditching also can produce surface water outflows from depressional wetlands directly to streams (Section 2.4.4); ditches, however, also can introduce nutrients and ions into downstream waters (Brunet and Westbrook, 2012).

Even non-floodplain wetlands that are considered to be geographically isolated (i.e., completely surrounded by uplands), can have surface-water outflows that connect them to other water bodies (Figure 2-18B). Tiner (2003b) identifies vernal pools as 1 of 10 types of geographically isolated wetlands. Yet, as just discussed, the studies by Rains et al. (2008) and Rains et al. (2006) indicate that vernal pools can be connected to stream networks by channels. As another example, a recent study of depressional wetlands in the Texas Gulf Coast area showed that, although classified as geographically isolated, these wetlands are actually connected to nearby waterways via intermittent streams (Wilcox et al., 2011). During a study period of almost 4 years, nearly 20% of the precipitation that fell on a wetland complex flowed as surface runoff through the stream to a nearby water body, the Armand Bayou (Wilcox et al., 2011). Non-floodplain wetlands also can have temporary hydrologic connections to each other. Such connections can occur through the expansion and contraction of surface water that occur between wet and dry periods (e.g., Figure 2 in Niemuth et al., 2010) and through fill and spill of surface waters. One consequence of fill-and-spill behavior is that the contributing area of such a wetland is dynamic and has a nonlinear relationship to potential storage area (Shaw et al., 2012; Shaw et al., 2013). In the intermontane West, evidence suggests that depressional wetlands can connect to one another via temporary overland or shallow ground-water flows (Cook and Hauer, 2007). In the prairie pothole region, temporary overland connectivity between potholes has been observed in wet years. In 1996, during heavy spring rains, an estimated 28% of the wetlands in the study area had surface-water connections to at least one other wetland (Leibowitz and Vining, 2003). Le and Kumar (2014) analyzed topographic depressions in five study areas across the United States and found that hydrologic connectivity—as determined by nearest neighbor distances—followed a universal power law distribution. One implication of this distribution is that, although most depressions are connected over short distances, a few are connected by long distances, which could cause rapid increases in hydrologic connectivity as the system wets up (Le and Kumar, 2014). However, the distribution can be altered through wetland drainage (Van Meter and Basu, In press). Although some of these studies focused on wetland-to-wetland connections, the findings illustrate (1) the potential for geographically isolated wetlands to exhibit temporary surface water connections with other water bodies, and (2) that interacting wetland complexes might best be understood as a functional unit (Section 4.4.5).

4.4.2.2 Ground-water Connections

In addition to surface-water connections, ground-water flow can connect non-floodplain wetlands with other water bodies, potentially over great distances (Figures 2-5 and 2-18C). Many studies have shown that non-floodplain wetlands can connect to ground water, either receiving ground-water discharge (flow of ground water to the wetland), contributing to ground-water recharge (flow of water from the wetland to the ground water), or both (e.g., Lide et al., 1995; Devito et al., 1996; Matheney and Gerla, 1996; Rosenberry and Winter, 1997; Pyzoha et al., 2008). For example, a 1989 study of four North Dakota prairie pothole wetlands by Arndt and Richardson (1989) clearly demonstrated ground-water connections as one wetland recharged ground water, one was a flow-through wetland, and one was a discharge system. Hunt et al. (2006) found that benthic invertebrate communities were correlated with amounts of ground-water discharge to stream-wetland complexes in northern Wisconsin. Using stable hydrogen and oxygen isotopes in water, Matheney and Gerla (1996) concluded that, although most of the water in a depressional prairie wetland came from precipitation, ground-water connections accounted for the high salinity of the wetland soil. The high salinity is indicative of net ground-water discharge to the wetland (Brinson, 1993). Min et al. (2010) reported that 38% of rainfall that entered four historically geographically isolated wetlands in Florida was recharged to ground water. A literature survey by Bullock and Acreman (2003) found 69 studies making reference to ground-water recharge from wetlands; of these, 32 studies observed ground-water recharge from a wetland, whereas 18 studies did not.

Ground-water flow-through wetlands are sites of both ground-water discharge and recharge, in essence a surface expression of the ground-water system (Richardson et al., 1992; Kehew et al., 1998; Ferone and Devito, 2004). In these wetlands, ground-water discharge generally flows into the wetland on one side or area, and flows back into the ground water on the other side or area of the wetland. This dynamic has been shown in many locations, including prairie potholes (Richardson et al., 1992), wetlands in glacially formed landscapes in southwest Michigan (Kehew et al., 1998), Alaskan ponds (Rains, 2011), Florida cypress dome systems (Sun et al., 1995), and small Wisconsin lakes (Born et al., 1979). The lakes and wetlands of the Nebraska Sand Hills are also predominantly flow-through and an expression of a large regional ground-water system (Winter, 1999). The flow-through wetland influences the chemistry of the transiting, shallow ground water. Kehew et al. (1998) found a wetland of this type diluted nitrogen concentrations in the ground water of an agricultural watershed.

Whether a wetland recharges ground water, is a site of ground-water discharge, or both, is determined by topography, geology, soil features, and seasonal position of the water table relative to the wetland. Shedlock et al. (1993), for example, concluded that ground water discharged into a bog along Lake Michigan through a breach in the sediments underlying the wetland. In dry periods when water tables are low, water tends to move from wetlands into the ground water, while in wetter periods with higher water tables, water can flow in the opposite direction from shallow ground water into the wetlands (Phillips and Shedlock, 1993; Pyzoha et al., 2008; McLaughlin et al., 2014). Lide et al. (1995) observed both ground-water flow into and from a Carolina bay wetland, with discharge to the wetland when the water table was high and recharge to the ground water when the water table was low. Sun et al. (1995) observed similar phenomena in a Florida cypress dome. This exchange and temporary storage of water represents a lag function that can make wetlands particularly important for ground-water recharge during dry periods. Rosenberry and Winter (1997) indicated that ground-water discharge to a wetland often alternates with flow from the wetland to ground water, and the direction of flow is controlled by the balance of recent precipitation with current evapotranspiration demands.

The magnitude and transit time of ground-water flow from a wetland to other surface waters depends on the intervening distance and the properties of the rock or unconsolidated sediments between the water bodies (i.e., the hydraulic conductivity of the material). In some carbonate or volcanic rocks, for example, ground water can flow relatively freely through large openings; while in unconsolidated material—such as gravel, sand, silt, or clay—the spaces between particles determine the time required for water to flow a given distance (Winter et al., 2003). In porous material, such as gravel, water can travel a distance of a kilometer in a few days; in fine-textured materials, such as silt or clay, hundreds to thousands of years might be required for a single parcel of water to travel the same distance (Winter and LaBaugh, 2003).

In agricultural regions, the transit time of subsurface flows can be decreased substantially by artificial subsurface drainage pipes, known as tile drains (Section 2.4.4; Schiller et al., 2012). Wetlands in these areas are sometimes fitted with inlets that connect directly to tile drains, quickly moving temporarily ponded water through the subsurface and to outlets that discharge directly to ditches or streams (Tomer et al., 2010).

In summary, non-floodplain wetlands can have a range of hydrologic connectivity with other waters (Figure 2-18). Non-floodplain wetlands can be connected by permanent, intermittent, or ephemeral surface flows through swales or channels, or be connected to other water bodies via shallow or deep ground-water flows. Conversely, a wetland can be isolated hydrologically if it lacks surface water and ground-water connections entirely and evapotranspiration is the dominant form of water loss. A wetland also can be hydrologically isolated from streams and rivers if it recharges a ground-water aquifer that does not feed surface waters. Wetlands that lack surface connectivity in a particular season or year can be connected, nevertheless, in wetter seasons or years. A wetland that serves as the origin of a stream will have a permanent or temporary surface water connection with a stream network through a stream channel, unless the wetland feeds an endorheic stream (Sections 3.2 and B.5.5.1).

4.4.2.3 Effects of Non-floodplain Wetlands on Streamflow

Non-floodplain wetlands can affect streamflow by altering baseflow or stormflow (Section 2.2.2; Figure 2-8) through several mechanisms, including surface storage and ground-water recharge. Depressional wetlands effectively store water because the aboveground portion of the wetland contains a largely empty volume for water storage, in contrast to belowground water storage where only part of the volume is available for water storage, for example, due to soil particles (i.e., the specific yield; Johnson, 1967; McLaughlin et al., 2014). Large-scale studies have shown that wetlands, by storing water, reduce peak streamflows, and thus, downstream flooding. Hubbard and Linder (1986), for example, calculated the water retention capacity of more than 200 closed depressional prairie potholes in northeastern South Dakota. They observed that a large amount of snowmelt and precipitation could be cumulatively held by many small wetlands, reducing the potential for flooding at downstream locations. Similarly, a USGS study in the prairie pothole region found that wetlands—including both depressional and nondepressional types—stored about 11−20% of the precipitation that fell in a given watershed, and that storage could be increased by wetland restoration (Gleason et al., 2007). Vining (2002) concluded that wetland storage in the Starkweather Coulee subbasin of North Dakota likely resulted in decreased streamflow. Rovansek et al. (1996) found snowmelt to be the most important source of water for wetlands and ponds in the Alaskan Arctic Coastal Plain, and that these wetlands and ponds functioned as surface storage, thereby removing water from the snowmelt floods. However, Ford and Bedford (1987) note that in permafrost-dominated areas of Alaska, wetland soils tend to be frozen during snowmelt events, resulting in a significant proportion of these floodwaters running directly to streams, thus rendering these wetlands unimportant in streamflow regulation. Likewise, Roulet and Woo (1986) found that wetlands in the Continuous Permafrost Region of Canada tended to be unimportant for either long-term water storage or streamflow regulation.

Regression equations developed to predict peak flows during flooding events generally use lake and wetland storage areas as variables. Using this approach for Wisconsin watersheds, Novitzki (1979) estimated that peak flood flows were only 20% as large in watersheds with 40% lake and wetland area relative to watersheds without lakes or wetlands. Johnston et al. (1990) found that small losses of wetlands in watersheds with <10% wetlands could have major effects on flood flow in basins around Minneapolis, Minnesota. Wang et al. (2010) modeled the influence of wetlands on hydrologic processes in Manitoba and Minnesota and found that the loss of 10-20% of the wetlands in the study basins would increase peak discharge by 40%. Similarly, Yang et al. (2010) calculated restoration of 600 ha of wetlands in a 25,139 ha watershed would decrease peak stream discharge by 23%. Peak streamflows were shown to be negatively correlated with lake and wetland storage in Minnesota (Jacques and Lorenz, 1988), although a later study found peak flows to be correlated with lake storage only and not wetland storage (Lorenz et al., 2010).

The ability of wetlands to reduce flooding via storage varies with topography, wetland type, antecedent moisture conditions, and available water storage capacity. Using stable hydrogen and oxygen isotopes of water, McEachern et al. (2006) found that snowmelt in boreal forests was discharged rapidly in a sloped watershed. In contrast, in a lowland watershed, much of the snowmelt was stored by wetlands, particularly by bogs with stream channel outlets. In northern Canada, stream runoff was positively correlated with slope and the presence of channel fens, but negatively correlated with lowland depressional bogs (Quinton et al., 2003). In a Light Detection and Ranging (LiDAR)-based assessment of depressional wetlands in Florida, Lane and D'Amico (2010) found an average potential wetland water storage capacity of 1,619 m^3 ha^{-1}, with values ranging from 1,283 m^3 ha^{-1} for palustrine scrub-shrub wetlands to 2,906 m^3 ha^{-1} for palustrine aquatic-bed wetlands. A literature review found that four out of four studies that examined surface water depressions having no direct connectivity to a river system concluded that those wetlands reduced or delayed flooding (Bullock and Acreman, 2003). Findings were more varied for slope wetlands with direct connectivity to a river: 26 of 62 studies found reduced flooding, while 27 of the 62 studies concluded that those wetlands increased flooding.

In addition to wetland type, antecedent moisture conditions and available storage capacity also influence wetland water retention. The wetlands noted above, that serve as stream origins, likely increased flood peaks under saturated conditions, with low additional wetland water storage capacity (due to spring rains or snowmelt, for example), and thus conveyed any additional precipitation rapidly downstream (Bullock and Acreman, 2003). Similarly, Branfireun and Roulet (1998) concluded that prior saturation of upland areas immediately surrounding a wetland produced increased stormflows. This might mean that wetlands have less attenuating effect on larger floods because floods commonly occur during saturated conditions.

Besides affecting peak flows and downstream flooding, non-floodplain wetlands can alter baseflow or stormflows during dry periods. Ground-water discharge wetlands that are connected to streams, such as fens or seeps, are important sources of baseflow (Morley et al., 2011). Moreover, wetlands can be focal points for ground-water recharge and thus might contribute to baseflow. Rains (2011), for example, found that perched and flow-through ponds in southwestern Alaska were sites of net ground-water recharge. Given the high prevalence of ponds on the landscape (Rains, 2011), these wetland types cumulatively could substantially affect stream baseflow via ground-water inputs.

Other wetlands, however, might actually reduce flows during dry periods. Bullock and Acreman (2003) concluded that this was the case in two-thirds of the studies they surveyed. Antecedent moisture conditions and available wetland storage could partially explain this finding, in combination with relatively high evaporation rates from wetland-dominated landscapes (Bullock and Acreman, 2003). One study cited in their review (Boelter and Verry, 1977) noted that two storms of nearly equal volume and intensity produced different runoff responses from the same peatland. One storm occurring in the spring at a time of already high water tables led to runoff. The other, in midsummer at a time of low water tables, increased the water depth in the peatland but did not exceed the wetland's water storage capacity, precluding runoff. This mechanism has been observed in simulations of prairie pothole hydrology, in which wetlands reduced streamflow until storage capacity was exceeded (Haan and Johnson, 1968). Thus, wetlands can function as a sink in dry periods if storage capacity is not exceeded and evaporation rates surpass ground-water recharge. Where storage capacity is exceeded during storm events in otherwise dry periods, watersheds containing extensive wetlands can require more time for water discharge to rise and fall in response to storm events (Lindsay et al., 2004). This finding suggests that watersheds with wetlands take longer to fill and exceed water-holding capacity than watersheds without wetlands and so, in this case, they provide a lag function by releasing water downstream more slowly.

Non-floodplain wetlands also can reduce the variability of baseflow through landscape hydrologic capacitance (McLaughlin et al., 2014). McLaughlin et al. (2014) simulated the effects of geographically isolated wetlands on the variation in baseflow and found that the magnitude of this effect increased with total wetland area. Holding area constant and increasing the number of wetlands (while decreasing their size) also increased this capacitance. The effect of these wetlands on baseflow was the result of differences in specific yield (the change in output or input depth from evaporation or rain per change in water level) between wetlands and uplands, which causes flow reversals between them (McLaughlin and Cohen, 2013; McLaughlin et al., 2014). Specifically, water flows from upland areas to wetlands (wetland discharge) during wet periods and from wetlands to uplands (wetland recharge) during dry periods, thereby buffering water tables and baseflow.

4.4.3 Effects of Non-floodplain Wetlands on Water Quality

Non-floodplain wetlands can affect water quality of rivers and other aquatic systems through processes that can be generalized as source and sink functions, often mediated by transformational processes (see Section 4.3.3 for details on specific mechanisms). In some cases, non-floodplain wetlands directly modify the water quality in downstream waters through their relative lack of surface water connections; this modification is accomplished by removal, sequestration, or transformation of pollutants such as nitrogen, phosphorus, and metals through processes described by Ewel and Odum (1984), Mitsch et al. (1995), Reddy and DeLaune (2008), and Kadlec and Wallace (2009), among others. Although non-floodplain wetlands can lack surface water connections to downstream waters, surface and near-surface hydrologic connections to downstream waters do occur in many non-floodplain systems (Section 4.4.2; Figure 2-18; Sun et al., 1995; Whigham and Jordan, 2003; Wilcox et al., 2011), providing pathways for materials transformed in non-floodplain wetlands (such as methylmercury or degraded organic matter) to reach and affect other aquatic systems.

Below we show that non-floodplain wetlands are areas where extensive microbially mediated processes occur that can affect downstream waters. In Section 4.4.3.1, we describe how non-floodplain wetlands are sources for dissolved organic matter and entrained elements like carbon, nitrogen, and phosphorus, which are important components of food webs in downstream waters. Dissolved organic matter is also shown to be important in regulating whole-lake acidity and buffering capacity. Mercury is another material affected by microbial processing in non-floodplain wetlands; mercury can be transported along with dissolved organic matter to downstream waters, where it can become incorporated into the food web with potentially deleterious effects. In Section 4.4.3.2, we discuss how non-floodplain wetlands serve as sinks by sequestering or transforming materials, thereby affecting the chemical, physical, or biological condition of downstream waters. Nitrogen, nitrate, ammonium, and phosphorus compounds are shown to be removed or assimilated—often at high rates—in non-floodplain wetlands. Pesticides, metals, and other potential pollutants also can be sequestered or assimilated in non-floodplain wetlands.

4.4.3.1 Non-floodplain Wetlands as Sources for Downstream Waters

Like all wetlands, non-floodplain wetlands contain diverse microbial populations that have adapted to hydrologic, physical, and chemical extremes (Reddy and DeLaune, 2008). Microbial populations abound in wetland systems; for example, Boon (1991) reported that Australian wetlands contained 100 times more microbes in the water column than nearby rivers, with up to 157×10^9 cells L^{-1}. Functions that occur in non-floodplain wetlands can affect streams, rivers, and lakes when compounds that are transformed in wetland environments move to downstream waters through overland flow or shallow ground water (Section 4.4.2; Winter et al., 2003). Two processes that occur in non-floodplain wetlands (and in riparian/floodplain wetlands) are useful to illustrate the influence of non-floodplain wetlands on downstream waters: the methylation and transport of the bioaccumulating pollutant mercury, and the breakdown and transport of organic compounds to receiving waters.

Freshwater wetlands/peatlands are areas of active methylmercury (MeHg) production (Grigal, 2002). Ullrich et al. (2001) noted that methylmercury production was linked to low pH, low salinity, and presence of decomposable organic matter in reducing environments. Sulfate-reducing bacteria are primarily responsible for biological mercury methylation and thrive in the reduced conditions at wetland aerobic/anaerobic boundaries (Benoit et al., 1999); the addition of sulfate (e.g., through atmospheric acid deposition) increases the formation of methylmercury in peatlands (Branfireun et al., 1999). Once formed through microbial (or other) processes, mercury and methylmercury export is controlled by the export of organic matter, such as dissolved organic compounds and humic and fulvic acids (Linqvist et al., 1991; Mierle and Ingram, 1991; Driscoll et al., 1995). Methylmercury can be translocated in watersheds having non-floodplain wetlands by entrainment with organic matter exports. It also can move through near-surface and surface flows from non-floodplain peatlands to downstream waters. For example, Branfireun et al. (1996) reported 58% of MeHg-laden peat porewater leaving a headwater catchment study area occurred during stormflow, 41% during baseflow, and 1% transported via ground water. St. Louis et al. (1994) found that boreal forest catchments in Minnesota with non-floodplain wetlands reduced total mercury concentrations, but had yields of methylmercury from wetlands that were 26−79 times higher than upland areas. This yielded 1.84−5.55 mg MeHg ha^{-1} yr^{-1} to streams in the Great Lakes basin, where mercury could be incorporated into lake-wide food webs. Hurley et al. (1995) contrasted MeHg yields from different land use groups in Wisconsin and found that wetland/forest sites were higher than agricultural/forested and agricultural-only sites. Similarly, Porvari and Verta (2003) found that bioaccumulating methylmercury export from non-floodplain peatlands to downstream waters ranged from 0.03 to 3.8 ng MeHg L^{-1}, and that catchments with greater wetland abundances had greater methylmercury export.

Export of dissolved organic matter can have negative effects on downstream waters because contaminants, such as methylmercury and other trace metals, can be adsorbed to it (Thurman, 1985; Driscoll et al., 1995). Dissolved organic matter, however, is also an important source of energy for downstream aquatic communities (Hobbie and Wetzel, 1992; Reddy and DeLaune, 2008). Wetlands are the principal source of dissolved organic compounds to downstream waters in forested ecosystems (Mulholland and Kuenzler, 1979; Urban et al., 1989; Eckhardt and Moore, 1990; Koprivnjak and Moore, 1992; Kortelainen, 1993; Clair et al., 1994; Hope et al., 1994; Dillon and Molot, 1997; Gergel et al., 1999). Over prolonged periods, reductions in dissolved organic carbon (DOC) export (e.g., through wetland conversion or degradation or alterations in hydrology) decrease the ability of downstream waters to support primary productivity, due to reduced export of entrained carbon, nitrogen, sulfur, and phosphorus (Hedin et al., 1995; Nuff and Asner, 2001). Changes in DOC export also affect the pH and buffering capacity of downstream aquatic systems (Eshelman and Hemond, 1985) and their exposure to damaging UV-B rays (Schindler and Curtis, 1997). Boreal forest basins composed of non-floodplain wetlands in central Ontario were found to export between 11.4 and 31.5 kg C ha^{-1} yr^{-1} to downstream waters (Creed et al., 2003). Furthermore, near-surface lateral transport of DOC explained 88% of the variation in basin DOC export to lake systems where it directly affected pH and buffering capacity. Other studies have similarly shown a relationship between the proportion of wetlands in a watershed and the average annual concentration of DOC in the receiving streams of that area, and other areas of the boreal forest/Precambrian Shield (Urban et al., 1989; Eckhardt and Moore, 1990; Koprivnjak and Moore, 1992; Detenbeck et al., 1993; Clair et al., 1994; Hope et al., 1994; Dillon and Molot, 1997; Johnston et al., 2008).

The export of dissolved organic compounds from non-floodplain wetlands also can affect the acidity of downstream waters. Gorham et al. (1986) addressed watershed factors associated with lake and forest acidification in Nova Scotia, Canada. In addition to atmospheric deposition of acid precipitates, they found that the ratio of non-floodplain muskeg peatlands to lakes was significantly correlated with lake acidification, as muskeg wetland-dominated watersheds exported high-molecular-weight organic acids via either overland or shallow ground-water flow. Further linking non-floodplain wetlands to lakes, Gorham et al. (1986) reported that even small amounts of humic DOC can greatly affect lake water pH; the pH of waters with a dissolved organic carbon value of 4.5 mg DOC L^{-1} (the log-normal mean) was

100 times more acidic than waters with a dissolved organic carbon of <1 mg DOC L^{-1} (the minimum concentration).

4.4.3.2 Non-floodplain Wetlands as Sinks and Transformers for Downstream Waters

The wetland literature is replete with examples of wetlands improving water quality through assimilation, transformation, or sequestration of nutrients and other pollutants (e.g., Ewel and Odum, 1984; Nixon and Lee, 1986; Johnston, 1991; Detenbeck et al., 1993; Mitsch and Gosselink, 2007; Reddy and DeLaune, 2008; Kadlec and Wallace, 2009). These functions act on the large pool of pollutants that are available through nonpoint sources. Non-floodplain wetland processes that affect pollutant attenuation include denitrification, ammonia volatilization, and microbial and plant biomass assimilation (Reddy and DeLaune, 2008). Other pollutants in wetland systems can be retained through sedimentation, sorption and precipitation reactions, biological uptake, and long-term storage in plant detritus (Reddy et al., 1999; Reddy and DeLaune, 2008).

Non-floodplain wetlands act as sinks and transformers for various pollutants. For example, high levels of human sewage were applied to a forested non-floodplain wetland site for 4.5 years (Ewel and Odum, 1984 and chapters therein). More than 95% of the phosphorus (P), nitrate, ammonium, and total nitrogen (N) were removed by the wetland during the study period (Dierberg and Brezonik, 1984), and 66−86% of the nitrate removed was attributed to the process of denitrification. In another example, phosphorus retention in non-floodplain marshes of the lower Lake Okeechobee basin ranged from 0.3 to 8.0 mg soluble reactive P m^{-2} d^{-1} (Dunne et al., 2006). This retention represents a sizeable amount of phosphorus removal, because only about 7% of the watershed comprised non-floodplain marsh. Similarly, wetlands in the Lake Okeechobee, Florida basin were found to have greater storage of total phosphorus than the uplands in which they were bedded, 236 kg ha^{-1} vs. 114 kg ha^{-1} (Cheesman et al., 2010). These findings were echoed by Dunne et al. (2007), who reported that more phosphorus was stored in wetland plant biomass and soil than in corresponding upland compartments, with wetland surface soils (0−10 cm) representing the largest phosphorus reservoir (>87%) and soil organic matter accounting for >69% of the soil total phosphorus variability. They further suggest that restoring 5−20% of the geographical isolated wetland area in priority basins draining to Lake Okeechobee, Florida, could increase phosphorus storage in geographical isolated wetlands by up to 13 kg P ha^{-1}, mostly through increased soil organic matter with its concomitant phosphorus in wetland soils (Dunne et al., 2007). Marton et al. (2014) found that mean phosphorus sorption was approximately two to three times greater in natural depressional wetlands than in restored wetlands and agricultural fields (297, 114, and 86 mg P kg $soil^{-1}$, respectively). Marton et al. (2014) also found that depressional wetlands sorbed twice as much phosphorus as riparian systems. Craft and Casey (2000) reported similar accretion rates in depression and floodplain wetlands of Georgia for sediment, organic carbon, and nitrogen, and significantly highly floodplain storage of phosphorus. Cohen et al. (2007) found that riparian wetlands had higher phosphorus-sorption capacities than non-riverine wetlands. Non-floodplain wetland flats studied in Maryland and Delaware had microbially mediated denitrification enzyme activity (an indicator of potential denitrification) rates of 0.06−0.76 mg N kg^{-1} d^{-1} (Jordan et al., 2007). Because flats comprise greater than 70% of the wetland area in the basin, this value indicates a significant denitrification capacity. Marton et al. (2014) found that depressional wetlands denitrified at twice the rate upland systems did, 12.3 ± 4.5 ng N g^{-1} hr^{-1} versus 5.3 ± 1.7 ng N g^{-1} hr^{-1}. Craft and Chiang (2002) determined that wetland soils stored a disproportionately large share of nitrogen, compared with upland soils, in spite of uniform soil organic matter across the landscape. A non-floodplain bog in Massachusetts was reported to sequester nearly 80% of the system's various nitrogen inputs, including precipitation that had a range of 1.2−1.9 mg N L^{-1} (Hemond, 1983). Prairie pothole wetlands in the upper Midwest removed >80% of the nitrate load via denitrification (Moraghan, 1993). A large non-floodplain prairie marsh removed 86% of nitrate, 78% of ammonium, and 20% of phosphate through assimilation and sedimentation, sorption, and other mechanisms (Davis et al., 1981). Geographically isolated, non-floodplain wetland systems in Michigan were found to remove nitrate-nitrogen (NO_3-N) and sulfate (SO_4^{2-}) at rates of 0.04−0.55 mg NO_3-N L^{-1} ha^{-1} and 0.06−0.30 mg SO_4^{2-} L^{-1} ha^{-1}. These rates are significant, considering that nitrate-nitrogen pollution of ground water in Michigan was reported to average 0.50 mg NO_3-N L^{-1} (Whitmire and Hamilton, 2008). Bhadha et al. (2011) found that infiltration to the ground accounted for 14% of phosphorus loss from two historically isolated wetlands in a Florida study area, suggesting that near-surface flow gradients are important to landscape-level phosphorus dynamics. Together, these studies indicate that sink removal of nutrients by non-floodplain wetlands is significant and geographically widespread.

Other pollutants and compounds can be mitigated by non-floodplain wetland sink and transformation processes. For example, microbial methanogenesis completely removed the pesticide atrazine from a mountainous bog in North Carolina (Kao et al., 2002). The environmental contaminants cobalt (Co) and nickel (Ni) can be phytoremediated by wetland plants common in forested non-floodplain wetlands of the Southeast; plant concentrations were found to range from 1 to 530 mg Co kg^{-1} and up to 250 mg Ni kg^{-1} (Brooks et al., 1977). A bog in Massachusetts that Hemond (1980) extensively studied acted as a sink and annually stored 54 mg magnesium m^{-2}, 36 mg potassium m^{-2}, and 46 mg lead m^{-2}; the bog also provided acid-rain buffering for downstream waters. Based on the literature, Boon (2006) concluded that wetland microbial communities can mediate processes that degrade diesel fuel and other hydrocarbons, pesticides, heavy metals and metalloids, and chlorinated solvents that can pollute ground water.

4.4.4 Biological Connections Between Non-floodplain Wetlands and Streams

Many of the same factors that affect movement of organisms between riparian/floodplain wetlands and the river network (Section 4.3.4) govern movement of organisms between non-floodplain wetlands and the river network. Non-floodplain wetlands, however, are generally farther from stream channels than riparian/floodplain wetlands, which reduces hydrologic connectivity. The distance, number, and variety of heterogeneous landscape patches (including barriers) over which organisms must disperse also can be greater. Organisms have evolved numerous complex dispersal strategies to overcome non-floodplain flows, reduced hydrologic connectivity, and increased geographic distance between habitats and spatially subdivided populations. Passive transport (e.g., wind dispersal, "hitchhiking" on other animals) and active movement (e.g., walking, crawling, flying) are common modes of dispersal that can establish connectivity in the absence of hydrologic flows. Such dispersal events are often sporadic and asymmetric in non-floodplain wetland landscapes, making them more difficult to observe than surface water flows. Their effects on community structure and diversity—including metapopulation effects of wetland-to-wetland connectivity—have been well documented (e.g., Wellborn et al., 1996; Snodgrass et al., 2000; Julian et al., 2013), especially for amphibians. Other effects, such as water quality and population or species persistence, are not well understood. Below we review the various dispersal mechanisms that operate in non-floodplain wetland landscapes.

Despite being sessile, plants have evolved many adaptations that facilitate dispersal. Considerable attention has been given to waterborne dispersal of aquatic and emergent macrophytes (Nilsson et al., 2010), which can play a role in non-floodplain wetlands that are periodically connected hydrologically to river networks. In addition, significant numbers of such plants can be dispersed as seeds or pollen by wind (Soons, 2006). Wind dispersal enables colonization of geographically isolated non-floodplain wetlands such as prairie potholes (Galatowitsch and van der Valk, 1996). Given that geographically isolated wetlands are surrounded by uplands, using wind as a vector carries the relatively high risk that propagules of obligate wetland plants will land in unsuitable habitat. Plants have developed colonization strategies to compensate for such risks. For example, Soons and Heil (2002) showed that producing large numbers of seeds increased colonization success of short- and long-distance dispersing grassland forbs; results from this and other studies are being applied to models of wetland dispersal and colonization (e.g., Soons, 2006). Viable seeds or vegetative plant parts also can travel great distances within the guts of or externally attached to migratory birds (Murkin and Caldwell, 2000; Amezaga et al., 2002; Figuerola and Green, 2002), which move between non-floodplain wetlands and river networks, depending on temporally dynamic habitat availability (Murkin and Caldwell, 2000; Haukos et al., 2006 and references therein).

Identifying specific source and recipient populations for any organism over these distances can be challenging, but especially for plants having passively mobile life stages that cannot be precisely tracked. Determining whether wetlands function as sources to or recipients of plant propagules from river networks is especially difficult. Genetic similarity between populations can provide general evidence of connectivity between non-floodplain wetlands and the river network. Sawgrass (*Cladium jamaicense*) populations in Everglades wetlands showed low population genetic divergence at distances greater than 100 km; wind pollination and water dispersal of propagules through flooding likely keeps channel and wetland populations genetically similar (Ivey and Richards, 2001). Another approach that can provide evidence for dispersal is community-level surveying, which takes into account local determinants of community composition and structure. Controlling for local conditions like rainfall and soil type, a study in Connecticut (Capers et al., 2010) found that bodies of water—from small isolated wetlands to large lakes—that were located closer together had more similar plant communities. This finding suggests biological connectivity between proximal lakes and wetlands.

Recent evidence suggests that invertebrate hitchhiking on birds and mammals is more common than previously thought (Figuerola and Green, 2002; Figuerola et al., 2005). Allen (2007) trapped zooplankton dispersing from a pond in Illinois and found that animals wider than 3 cm were the primary vector of reproductive adult zooplankton forms. These results suggest that animals moving among water bodies can be an important factor in structuring non-floodplain wetland invertebrate metapopulations. Frisch et al. (2007) found that diapausing invertebrate eggs that dispersed by hitchhiking on birds had higher incidences of hatching in January (59.4%) than in November (11.5%). These invertebrates included nematodes, zooplankton (i.e., rotifers, ostracods, copepods), and insects (i.e., crane flies, nonbiting midges, hemipterans). This study indicates that winter migrations of aquatic birds can be an important mechanism for spring colonization of habitats separated by hundreds or even thousands of kilometers. Studies have thus shown that migratory birds can passively connect viable plant matter, macroinvertebrates, and zooplankton from disparate habitats across the landscape, with likely—although unresolved—impacts on food web dynamics (Polis et al., 1997).

The scientific literature has many examples of migratory birds—especially migratory waterfowl, including cranes, geese, ducks, and shorebirds—actively moving between and using the different available resources of estuarine, riverine, and riparian systems and non-floodplain wetlands. For example, wood ducks (*Aix sponsa*) are found throughout freshwater deciduous forests of North America. Preferred breeding sites include river floodplains, remote ponds, and woodland pools that receive snowmelt and spring rain, the latter particularly indicative of non-floodplain wetland use (Haramis, 1990). Below we provide several examples of this type of biological connectivity that can connect non-floodplain wetlands to each other and to other aquatic systems.

Approximately 80% of the entire North American population of redhead ducks (*Aythya americana*) winters along coastal Texas and northern Mexico (Weller, 1964). Woodin (1994) identified more than 20,000 redheads using both estuarine systems and freshwater wetlands, reporting that the estuarine systems were exclusively used for feeding, while freshwater coastal pond wetlands were used almost exclusively for drinking water and courting (Mitchell et al., 1992). The coastal ponds redheads used were seasonal basins, which frequently dried completely (Ballard et al., 2010). Ballard et al. (2010) further noted that although the ponds were densely distributed in coastal Texas (up to 4.8 coastal basins per km^2), water availability varied year-to-year. As a result, during dry years redheads would use available coastal ponds up to 8.1 km from the estuarine forging areas, while in wetter years closer ponds would be used (likely to minimize energy expended through flying). Similarly, Adair et al. (1996) reported that lesser scaup (*Aythya affinis*) and redheads avoided salt stress and metabolically expensive osmoregulation through salt-gland excretory functions by feeding in estuaries; drinking, preening, and resting in coastal basins; and then returning to estuaries. Grey teals (*Anas gibberifrons gracilis*) in Australia that feed in saline areas similarly required freshwater to osmoregulate (Lavery, 1972). Mallard ducks (*Anas platyrhynchos*) transiting Iowa during spring migration used seasonally flooded farmed basins in agricultural fields (also known as sheetwater wetlands; LaGrange and Dinsmore, 1989) for feeding and roosted in more permanent emergent wetlands at night. In the study, these shallow sheetwater wetlands provided 19,530 mallard use-days during the daytime compared with 103 use-days for the emergent wetlands.

Nebraska's Rainwater Basin historically had more than 11,000 playas, shallow wind-formed wetland depressions, although human activities over the past 100 years have resulted in the loss of 90% of the number and approximately 88% of the area (Webb et al., 2010; Uden et al., 2014). Nevertheless, the remaining basins are critical to dependent migratory waterfowl, with 7–10 million waterfowl using the approximately 16,000 km^2 area, including “virtually all of the 600,000 midcontinental greater white-fronted geese (*Anser albifrons*), 500,000 Canada geese (*Branta Canadensis)*, 50% of midcontinent mallards (*Anas platyrhynchos*), and 30% of continental northern pintails (*Anas acuta*)” (Webb et al., 2010, p. 109), 38 shorebird species, and the endangered whooping crane (*Grus americana*). In a 3-year spring migration study of 36–40 playas, Webb et al. (2010) identified 72 migratory species and more than 1.6 million birds actively using these playa basins. The abundance of all wetland bird taxa was related to wetland area within 5–10 km of the study playas, although diving duck abundance (e.g., redhead, canvasback, lesser scaup) was specifically related to riparian area within 5 km, likely due to the presence of open water within these systems (Webb et al., 2010; see their Table 1 for a complete list of taxa found).

Many additional studies have identified Nebraska as an important staging and stopover area for numerous species, perhaps due to its location on the Central Flyway. For example, almost the entire population of midcontinent sandhill cranes (*Grus canadensis*) uses the Central Platte River Valley. Avian researchers reported that cranes roost along both the current and former Platte River channel (Krapu et al., 1984) and forage in grasslands on semipermanent (unconsolidated mud bottom) and temporary palustrine wetlands (Folk and Tacha, 1990) and on frequently inundated soils—especially those within 4.8 km of roost sites (Anteau et al., 2011). Pearse et al. (2010) noted that after feeding in cornfields, sandhill cranes roosted along the Central Platte River Valley in pastures with ponds. These pond systems are likely either playas, as noted above, or palustrine wetlands often surrounded by croplands (Austin and Richert, 2005). Austin and Richert (2005) further stated that the endangered whooping crane was noted as roosting, feeding, and resting in both riverine and palustrine wetlands of the Great Plains. Vrtiska and S.Sullivan (2009) found that lesser snow geese (*Chen caerulescens*) and Ross’s geese (*Chen rossii*), which numbered up to 7.3 million in 2001 during peak migration, used wetland habitats in both the Rainwater Basin and Central Platte River Valley, depending on the availability of suitable (e.g., inundated) habitat.

Blanchong et al. (2006) found that this concentrated use of the Rainwater Basin by migratory lesser snow geese resulted in greater contact between individuals, contributing to the spread of *Pastruella multocida*, the bacterium that causes avian cholera. The loss of wetlands within the basin has resulted in higher concentrations of migratory birds within the remaining wetlands, which has led to higher risks of outbreaks of infectious diseases (Blanchong et al., 2006).

The U.S. Fish and Wildlife Service’s Subcommittee on Rocky Mountain Greater Sandhill Cranes (SRMGSC, 2007) reviewed the literature on habitat use for the migratory population of Rocky Mountain sandhill cranes. This population, one of five in North America, migrates from wintering areas in Arizona, New Mexico, and central Mexico to breeding areas in Canada, Montana, Idaho, Wyoming, Utah, and Colorado. SRMGSC (2007) reported that this population of sandhill cranes overwintered in multiple riverine, riparian, and non-floodplain habitats, including playas in New Mexico and southeastern Arizona. Areas used in the breeding range include non-floodplain wetlands, such as northern boreal forest bogs, and other habitat types (e.g., large marsh complexes, smaller, scattered marshes, intermittent streams, beaver ponds, subirrigated wet meadows along riparian zones; SRMGSC, 2007).

Shorebirds also use multiple habitat types during their North American migration. Skagen and Knopf (1993) concluded that dispersion and opportunism, rather than concentration and predictability, characterize movements of shorebirds in the Great Plains. For example, Haig et al. (1998) noted that large population declines of the endangered migratory piping plover (*Charadrius melodus*) along the Missouri River were not actually declines, but a result of the birds moving to the Missouri Coteau (a 7.3 million ha region of the Upper Midwest and Canada replete with closed-basin prairie potholes; Phillips et al., 2005), due to increased flooding along the Missouri. Farmer and Parent (1997) monitored pectoral sandpipers (*Calidris melanotus*) migrating through non-floodplain sheetwater wetlands in Missouri and small depressional wetlands of the Rainwater Basin in Nebraska and found that habitat connectivity affected shorebird movements. Habitat patch density affected movements such that pectoral sandpipers often perceived groups of wetlands as functionally connected and actively exploited the best feeding habitat within that wetland complex. As the landscape became disconnected, however, the monitored species altered their movement behavior, minimizing energy expenditure (Farmer and Parent, 1997).

Other taxa have been reported as linking downstream systems and non-floodplain wetlands. Fish tend to disperse between non-floodplain wetlands and the river network during periodic surficial hydrologic connections or when humans create surface-water connections via ditching (Snodgrass et al., 1996; Langston and Kent, 1997; Zimmer et al., 2001; Baber et al., 2002; Hanson et al., 2005; Herwig et al., 2010). Mammals that can disperse overland can also contribute to connectivity. Although muskrat territories are usually restricted (Shanks and Arthur, 1952), dispersal between suitable river and non-floodplain wetland habitat over longer distances that is seasonal, climate-induced, and density-dependent has been observed (Serfass et al., 1999; Clark, 2000 and references therein). Spinola et al. (2008) tracked translocated river otters (*Lontra canadensis*) in New York and found that, after release, most otters inhabited a mosaic of isolated aquatic habitats distributed throughout the agriculture-dominated landscape. As noted above for waterfowl, mammals (including muskrats) also can act as transport vectors for hitchhiking organisms like algae (Roscher, 1967).

Numerous flight-capable insects, including mayflies, caddisflies, diving beetles, backswimmers, whirligig beetles, water striders, water boatmen, scavenger beetles, crane flies, and nonbiting midges, use both streams and non-floodplain wetlands (Williams, 1996). Aerial dispersal enables such insects to move outside the stream network to seek suitable habitat for overwintering, refuge from adverse conditions, hunting, foraging, or breeding (Williams, 1996; Bohonak and Jenkins, 2003).

Amphibians and reptiles also move between streams or rivers and non-floodplain wetlands to satisfy part of their life-history requirements (Table 4-2). For example, Subalusky et al. (2009a) and Subalusky et al. (2009b) reported movement of adult female alligators (*Alligator mississippiensis*) from creeks to shallow, seasonal limesink wetlands for nesting and use of the wetlands as nurseries for juveniles. Subadults then shift to habitats within the river network by moving overland to the creek (Subalusky et al., 2009a; Subalusky et al., 2009b). Lamoureux and Madison (1999) used radio tracking to follow movements of green frogs (*Rana clamitans*) for 9 months in New York. Green frogs, which breed in wetlands and then move into terrestrial habitats, are susceptible to freezing temperatures. In late autumn, the frogs moved from upland habitats near breeding ponds to rapidly flowing streams and seeps to overwinter. Boreal toads (*Bufo boreas boreas*) disperse long distances (>1 km) in streams through home ranges (Adams et al., 2005). Knutson et al. (1999) found that the strongest land-use predictor of anuran richness was urban land use. They speculated that, in addition to urban landscapes being detrimental to anuran habitat quality, their tendency to fragment (i.e., disconnect) anuran habitats is also a factor in the decline of these assemblages. In northwestern Ohio and southern Michigan wetland complexes, the abundance of northern watersnakes (*Nerodia sipedon sipedon*) was positively correlated with wetland size and wetland connectivity, defined by the authors as a wetland's distance to other wetlands (Attum et al., 2007). The American toad (*Anaxyrus* [=*Bufo*] *americanus*) and eastern newt (*Notophthalmus viridescens*) are widespread habitat generalists that move among streams and wetlands to take advantage of both habitats, feed on aquatic invertebrate prey, and avoid predators (Table 4-2; Babbitt et al., 2003; Green, 2005; Hunsinger and Lannoo, 2005; Petranka and Holbrook, 2006).

4.4.5 Geographic Isolation of Non-floodplain Wetlands

In defining non-floodplain wetlands (Section 2.2.1), we noted that this category could include wetlands that are geographically isolated and those that are not. Further, we noted (Section 2.4.1) that certain types of wetlands can be found with or without an outlet and can occur along a gradient of hydrologic connectivity. This gradient can include non-floodplain wetlands that have permanent hydrologic connections to the river network through perennial channels; wetlands that have losing streams that are completely disconnected from the river network as output channels; geographically isolated wetlands that have ground-water or occasional surface-water connections; and geographically isolated wetlands that have minimal hydrologic connection to the river network (but which could include surface and subsurface connections to other wetlands). The existence of this gradient (Section 1.2.2) can make determining the degree to which particular non-floodplain wetlands are connected to or isolated from downstream waters difficult.

A related issue is that spatial scale must be considered when determining geographic isolation. Tiner (2003c) provided examples of how a wetland that was not isolated at a local scale could be geographically isolated at a larger scale. Conversely, individual wetlands that are geographically isolated could be connected to downstream waters when considered as a complex (a group of interacting wetlands). This concept is demonstrated by Wilcox et al. (2011), who examined a depressional wetland complex on the Texas Coastal Plain. Although the wetlands are hydrologically connected to each other by shallow swales, they might be geographically isolated, because swales often are considered upland. In fact, Tiner (2003c) classifies these Coastal Plain wetlands as geographically isolated. At the scale of the wetland complex, however, the wetlands are connected to a nearby waterway via an intermittent stream. During an almost 4-year study, nearly 20% of the precipitation that fell on the wetland complex flowed as surface runoff through the channel to a nearby waterway, the Armand Bayou (Wilcox et al., 2011). Although these wetlands might be geographically isolated at the local scale, the wetland

Table 4-2. Partial list of amphibian and reptile species known to use both streams and non-floodplain wetlands or other lentic waters.

Common Name	Scientific Name	Habitat Use
Green frog	*Rana clamitans*	Breeds in wetlands and pools; overwinters in streams (Lamoureux and Madison, 1999)
Leopard frog	*Rana pipiens*	Breeds in wetlands and pools; overwinters in streams (Rorabaugh, 2005)
Bullfrog	*Rana catesbeiana*	Uses seasonal pools as complementary nonbreeding habitat (Gahl et al., 2009)
Columbia spotted frog	*Rana luteventris*	Breeds in streams and wetlands; overwinters in streams (Pilliod et al., 2002)
Southern leopard frog	*Rana sphenocephala*	Breeds in shallow pools and wetlands; adults inhabit many shallow freshwater habitats, including temporary pools, cypress ponds, ponds, lakes, ditches, streams, river edges, floodplain pools, and slightly brackish coastal wetlands (Butterfield, 2005)
Pacific chorus frog	*Pseudacris regilla*	Breeds in wetlands, ponds, temporary pools, streams, lakes, rivers, and other aquatic habitats (Rorabaugh and Lannoo, 2005)
American toad	*Anaxyrus* [=*Bufo*] *americanus*	Breeds in lakes, ponds, streams, ephemeral wetlands, prairie potholes, ditches, and floodplain pools (Green, 2005)
Fowler's toad	*Anaxyrus* [=*Bufo*] *fowleri*	Breeds in ponds, temporary pools, streams, ditches, lake shores, and shallows of rivers (Green, 2005)
Two-toed amphiuma	*Amphiuma means*	Adults inhabit a wide variety of aquatic environments, including ponds, lakes, ephemeral wetlands, wet prairies, streams, and ditches (Gibbons and Semlitsch, 1991; Johnson and Owen, 2005)
Greater siren	*Siren lacertina*	Breeds in shallow pools and streams, adults live in lakes, streams, ponds, and wetlands (Gibbons and Semlitsch, 1991; Hendricks, 2005)
Eastern newt	*Notophthalmus viridescens*	Breeds in permanent and semipermanent pools, ponds, wetlands, and low-flow areas of streams; adults live in pools, ponds, streams, and wetlands (Hunsinger and Lannoo, 2005; Timm et al., 2007)

Table 4-2. Partial list of amphibian and reptile species known to use both streams and non-floodplain wetlands or other lentic waters (continued).

Common Name	Scientific Name	Habitat Use
Yellow-bellied watersnake	*Nerodia erythrogaster flavigaster*	Hunts in temporary pools and wetlands (Roe et al., 2004; Mitchell et al., 2007)
Copper-bellied watersnake	*Nerodia erythrogaster neglecta*	Hunts in temporary pools and wetlands (Roe et al., 2004; Mitchell et al., 2007)

complex serves as the source of water for a headwater stream, and therefore, the complex is not geographically isolated at a larger scale.

Besides the spatial scale of the wetland unit, assessments of non-floodplain wetland to stream connectivity can be affected by the resolution and source of the spatial data that are used. For example, higher connectivity was found in the Tuckahoe Creek watershed in Maryland, when wetland connectivity was evaluated for streams determined from LiDAR compared to streams from both the High Resolution National Hydrography Dataset (NHD) and NHD Plus (Lang et al., 2012). Yang and Chu (2013) found that Digital Elevation Model (DEM) resolution also affected connectivity assessments, with finer DEMs having a higher number of connected areas and less total connected area than coarser DEMs.

Given this discussion, caution should be used in interpreting connectivity for wetlands that have been designated as "geographically isolated," because (1) the term can be broadly applied to a heterogeneous group of wetlands that can include wetlands that are not actually geographically isolated, (2) wetlands with permanent channels could be miscategorized as geographically isolated if the designation is based on maps or imagery with inadequate spatial resolution (e.g., Lang et al., 2012), obscured views, etc., and (3) wetland complexes could have connections to downstream waters through stream channels even if individual wetlands within the complex are geographically isolated. The term "geographically isolated" should be applied only to groups of wetlands if all those wetlands are, in fact, known to be geographically isolated. Further, even geographically isolated wetlands can be connected to other wetlands and downstream waters through ground-water connections, occasional spillage, or biological connections. Thus, the term "geographically isolated" should not be used to infer lack of hydrologic, chemical, or biological connectivity.

Finally, precisely this isolation is responsible for many of the functions that geographically isolated wetlands provide to downstream waters. In particular, many of the sink and lag functions of these wetlands result from their relative isolation from the river network. This relative isolation, combined with the wetlands' storage capacity, enables them to store water and reduce peak streamflows and downstream flooding (Novitzki, 1979; Hubbard and Linder, 1986; Vining, 2002; Bullock and Acreman, 2003; McEachern et al., 2006; Gleason et al., 2007). For example, depressional wetlands in Florida had an average potential wetland water storage capacity of 1,619 m^3 ha^{-1} (Lane and D'Amico, 2010). These same sink and lag functions will also act on any materials associated with stored water, such as sediments and pollutants. Increased isolation also can decrease the spread of pathogens (e.g., Hess, 1996) and invasive species (e.g., Bodamer and Bossenbroek, 2008) and increase the rate of local adaptation (e.g., Fraser et al., 2011).

4.5 Wetlands: Synthesis and Implications

4.5.1 Riparian/Floodplain Wetlands

Based on our review of the literature, riparian/floodplain wetlands are highly connected to streams and rivers through surface water, shallow ground water, and biological connectivity. The effects of wetlands on streams and rivers are a function of the magnitude of floodwaters, the geomorphic structure of the floodplain, and the proximity of the channel. Although a gradient occurs in the frequency of connectivity within the floodplain (Section 1.2.2), even riparian/floodplain wetlands that rarely flood can be important because of long-lasting effects on streams and rivers. In fact, most of the major changes in sediment load and river-channel structure—for example, movement of rivers through meander belts and creation of oxbow lakes—that are critical to maintaining the health of the river result from large floods that provide infrequent connections with more distant riparian/floodplain wetlands. Areas that surface water infrequently floods also can be connected to the river more regularly through ground water and the organisms. Key conclusions from our literature review on riparian/floodplain wetlands are summarized in Table 4-3.

4.5.2 Non-floodplain Wetlands

Non-floodplain wetlands consist of depressional, slope, and flats wetlands that lack surface water inlets. Non-floodplain wetlands can include regional wetland types such as prairie potholes, playa lakes, vernal pools, and Carolina bays. Hydrologic flows through these wetlands are predominantly unidirectional, in contrast to bidirectional flows that occur in riparian/floodplain wetlands.

The literature we examined on non-floodplain wetlands indicates that these systems have important hydrologic, water-quality, and habitat functions that affect downstream waters and rivers provided a connection exists between the wetland and downstream water (Table 4-4). The challenge is to identify which non-floodplain wetlands have such a connection. Addressing this issue is difficult, because most wetland studies do not investigate wetland effects on downstream waters or, if they do, they rarely address connectivity explicitly.

Based on what is known about how water flows across the landscape (Chapter 2), hydrologists and ecologists would generally agree that all non-floodplain wetlands are interconnected to some degree and are connected with stream networks, which is why the water-cycle environment is referred to as the hydrosphere. Hydrologists and ecologists also generally agree that some areas are more connected or have a greater influence than others. The purpose of this review is to determine, based on the peer-reviewed literature, the degree of connectivity and associated effects between different non-floodplain wetlands and downstream waters.

Non-floodplain wetlands occur along the gradient discussed in Chapter 1, and can be described in terms of the frequency, duration, magnitude, timing, and rate of change of water, material, and biotic fluxes to downstream waters. With respect to hydrologic connectivity, this gradient includes wetlands that have permanent hydrologic connections to the river network through perennial channels; wetlands that have

Table 4-3. Key conclusions on the effects of riparian/floodplain wetlands on rivers.
Physical Connectivity and Function
• Riparian areas are highly connected to streams, so much so that considering the riparian influence on streams is essential to understanding their structure and function. • Riparian connectivity ranges from longitudinal flow and exchange in mountainous headwater streams to increasing lateral flow and exchange in river valleys and coastal terrain. • Water storage by riparian areas, especially wetlands and lentic water bodies (such as oxbow lakes) that lack surface channel connections to stream networks, attenuate downstream flood pulses. • Heterogeneous riparian areas that include wetlands and open waters remove large amounts of sediment and nutrients from upland areas before they can enter the stream network. • Riparian areas influence stream geomorphology during periodic flooding by releasing stored sediments. • Forested riparian areas provide woody debris that helps shape stream morphology. • Riparian vegetation shades the stream and influences and regulates stream temperature and stream net primary productivity. • Ground water that flows through riparian areas and into the stream helps moderate stream temperatures.
Chemical Connectivity and Function
• Riparian areas, acting as buffers, are critical to protecting stream-water quality. • The structure of the riparian area (e.g., vegetation, wetlands, redox potential) influences its ability to increase water quality before it reaches the stream. • The near-stream portion of a riparian area is often more important in protecting stream-water quality than is the near-field (near uplands) portion. • Allochthonous inputs generally are most important to food webs in small headwater streams, especially in forested areas. As rivers become larger, primary production becomes increasingly important. • Some of the best-documented functions of oxbow lakes are as sinks for nutrients from upland runoff that might otherwise flow into rivers.
Biological Connectivity and Function
• Many types of organisms move between riparian/floodplain wetlands and the river network; those transported by water often move in response to flooding and those transported by other mechanisms (e.g., wind) move in response to seasonal cues or life-history stage requirements. • Riparian/floodplain wetlands and oxbow lakes can be sources or sinks of organisms; one of the most important source functions is to provide rearing habitat for fish. • Riparian/floodplain wetlands provide food sources for stream and river invertebrates. • Many riparian/floodplain wetlands and open waters (e.g., oxbow lakes) are used by fish and other organisms from the stream or river during flooding.

output channels but are isolated from the river network; geographically isolated wetlands (i.e., wetlands completely surrounded by uplands) that have local or regional ground-water or occasional surface-water connections; and geographically isolated wetlands that have minimal hydrologic connection to the river network (but which could include surface and subsurface connections to other wetlands).

Based on our literature review and basic hydrologic principles, we conclude that non-floodplain wetlands that are connected to the river network through surface water will have an influence on downstream waters, regardless of whether the outflow is permanent, intermittent, or ephemeral. Such non-floodplain wetlands include wetlands that are the origins of streams or are connected downstream to the river network through ditches. They also would include geographically isolated wetlands that are connected downstream to the river network through upland swales. Further, although the literature review did not address other non-floodplain water bodies to the same extent as wetlands, our overall conclusions also apply to these water bodies (e.g., ponds and lakes that lack surface water inlets) because the same principles govern hydrologic connectivity between these water bodies and downstream waters (Chapter 2).

Non-floodplain wetlands that do not connect to the river network through surface water include wetlands that spill into losing streams that are completely disconnected from the river network; that is, the wetland exports water through an output channel but the water is completely lost before it reaches the river network due to evapotranspiration or loss to ground water. Also included are geographically isolated wetlands that either do not spill, or spill into an upland swale that does not enter the river network. Although such wetlands lack surface-water connections to streams and rivers, they can be connected through local, intermediate, or regional ground-water flows or through biological movement. Connectivity between these wetlands and downstream waters will vary within a watershed as a function of local factors (e.g., position, topography, and soil characteristics; Sections 2.4.1 and 2.4.2), some of which are identified and discussed in this section. Connectivity also will vary over time, as the river network and water table expand and contract in response to local climate.

It is difficult to generalize about the specific downstream effects of non-floodplain wetlands that lack surface water connections to downstream waters. In Chapter 2 we note that the influence of wetlands and streams on downstream waters depends on two factors: (1) functions that affect material fluxes and (2) connectivity (or isolation) that allows (or prevents) transport of materials between the systems (Section 2.3). The literature we reviewed and summarized provides ample evidence that non-floodplain wetlands provide hydrological, chemical, and biological functions that affect material fluxes. Thus, these wetlands could affect downstream waters if they are connected to (or isolated from) the river network in such a way that it allows (or prevents) transport of materials to downstream waters. However, the more than 200 peer-reviewed references on non-floodplain wetlands we reviewed infrequently evaluated connections between non-floodplain wetlands and river networks and rarely examined the frequency, duration, magnitude, timing, and rate of change of these connections. Even if it is known from an article that the study site is located near a downstream water, connectivity cannot be established without specific information on frequency and magnitude of precipitation events, soil infiltration rate, wetland storage capacity, hydraulic gradients, etc.—information that is only rarely available in publications. Thus, the literature provided no evaluations of connectivity for specific groups or classes of wetlands (e.g., prairie potholes or vernal pools). This lack of information applies to groups of these wetlands within a particular watershed and to comparisons between different types of regional wetlands. For example, our review did not reveal whether connectivity between vernal pools and downstream waters is greater than connectivity between prairie potholes and downstream waters. We emphasize that this does not mean these wetlands do or do not have connectivity with downstream waters: It simply means the literature we reviewed does not enable us to distinguish connectivity of these wetland types from each other. Literature that was not included in our review, such as reports

Table 4-4. Key conclusions on the effects of non-floodplain wetlands on rivers.
Physical Connectivity and Function
• The connections of non-floodplain wetlands with downstream waters exist along a spectrum from isolated depressional wetlands, to those connected through ground water, to those connected via intermittent or permanent surface flows. • The degree to which outputs (or connections) are dominated by surface water vs. ground water is controlled in part by soil permeability: Permeable soils favor ground-water outputs, while impermeable soils result in surface water outputs. Other factors, such as topographic setting, also can play a role. • Ground-water recharge is common in non-floodplain wetlands and can be a particularly important source of water to aquifers during dry periods. • Ground-water networks extend from the local to the intermediate and regional scales, and provide a mechanism by which non-floodplain wetlands can influence other water bodies over various periods. • Even when non-floodplain wetlands lack a connection to other water bodies, they can influence downstream water through water storage and mitigation of peak flows (flood reduction and attenuation).
Chemical Connectivity and Function
• Insofar as they often act as buffers between sources of pollution and riparian areas, non-floodplain wetlands are a "first line of defense" in protecting streams from polluted waters. • Non-floodplain wetlands affect nutrient delivery and water quality. • Non-floodplain wetlands are a principal source for dissolved organic carbon (which supports primary productivity) to some downstream waters; the area of a basin with non-floodplain wetlands is directly correlated to the contribution of that basin to dissolved organic carbon in downstream waters. • Non-floodplain wetlands are sources of mercury: Microbial processes in non-floodplain wetlands methylate mercury, which can be translocated through near-surface and surface flows to downstream waters where it can bioaccumulate. • Non-floodplain wetlands are sinks for sediment, nutrients (including phosphorus, nitrate, and ammonium), metals (e.g., nickel and cobalt), and pesticides (e.g., atrazine). • Non-floodplain wetlands can remove, retain, or transform many of the nutrient inputs to which they are exposed.
Biological Connectivity and Function
• Natural periodic and permanent human-engineered surface-water connections can connect biological communities in non-floodplain wetlands and the river network; in addition, wind dispersal and overland movement connect these types of water bodies with frequency decreasing as a function of distance, landscape barriers, or both. • Migratory birds are vectors of plants and invertebrates between non-floodplain wetlands and the river network, although their influence has not been quantified fully. • Non-floodplain wetlands promote biological interactions that can be critical to the life-history requirements of some stream species. • Overland ("fill-and-spill") hydrologic connections can support biological connections. For example, stream fish found in wetlands that periodically dry down indicate presence of surface flows sufficient for colonization.

from local resource agencies, could allow the connectivity of these wetlands to be evaluated further, as could analysis of existing or new data or field evaluation.

Further complicating our evaluation is that some of the effects that wetlands have on downstream waters are due to their isolation, rather than their connectivity. Wetland functions that trap materials and prevent their export to downstream waters (e.g., sediment and entrained pollutant removal, water storage) result because of the wetland's ability to isolate material fluxes. As above, to establish that a wetland influences a downstream water through its isolation, it would have to be known that the wetland intercepted materials that would otherwise reach the downstream water, and this information is typically not provided in publications. The literature we reviewed does provide limited examples of the direct effects of such isolation on downstream waters for some specific wetlands, but not for classes of wetlands (e.g., vernal pools). However, the literature we reviewed allows us to conclude that sink functions of non-floodplain wetlands, which result in part from their relative isolation, will have effects on a downstream water when these wetlands are situated between the downstream water and known point or nonpoint sources of pollution, and thus intersect the flowpath between pollutant source and downstream water. For example, in cases where agricultural land use is a known contributor of sediment to downstream waters, the presence of depressional wetlands along the flowpath between the agricultural land and downstream water will result in reduced sediment loading to the downstream water. These effects would also be realized from sink functions that do not result from the wetland's isolation *per se*, but are emergent wetland properties (e.g., biogeochemical reactivity based on anoxic conditions). Using the same example, if the agricultural land use is a known contributor of nitrogen to downstream waters, depressional wetlands occurring along the flowpath will result in reduced nitrogen loading to the downstream water. In such settings, wetland loss or increased connectivity (e.g., due to ditching or tiling) is likely to reduce the effects of such functions on downstream waters (although functions that depend on connectivity could be increased).

To provide more specific evaluations of the connectivity of non-floodplain wetlands to downstream waters, studies are needed that: (1) further develop and validate methods for assessing wetland and watershed connectivity; (2) apply such methods to different classes of non-floodplain wetlands, especially those that lack channelized surface-water or regular shallow subsurface-water connections; (3) evaluate the frequency, duration, magnitude, timing, and rate of change of water, material, and biotic fluxes to downstream waters; and (4) consider aggregate functions and connectivity of wetland complexes (groups of closely located and interacting wetlands). Such studies are needed throughout the country to cover the breadth of wetlands in non-floodplain settings satisfactorily (e.g., across areas with different climate, geology, and terrain).

Despite these limitations, we can make some conclusions:

1. A non-floodplain wetland having a surface-water outflow to a stream network (e.g., a wetland that serves as a stream origin) is connected to the stream network and has an influence on downstream waters.
2. Many non-floodplain wetlands interact with ground water, which can travel long distances and affect downstream waters.
3. Even when wetlands lack a hydrologic connection to other water bodies, they can influence downstream water through water and material storage and mitigation of peak flows (flood reduction and flood attenuation). Sink functions of non-floodplain wetlands will have effects on a downstream water when these wetlands are situated between the downstream water and known point or nonpoint sources of pollution, thereby intersecting the flowpath between

pollutant source and downstream water. More generally, wetland sink functions are likely to be greatest when the wetland is located downgradient from pollutant sources and upgradient from a stream or river.

4. Non-floodplain wetlands provide unique and important habitats for many species, both common and rare. Some of these species require multiple types of waters to complete their full life cycles, including downstream waters. Abundant or highly mobile species play important roles in transferring energy and materials between non-floodplain wetlands and downstream waters.
5. Biological connections are likely to occur between most non-floodplain wetlands and downstream waters through either direct or stepping stone movement of amphibians, invertebrates, reptiles, mammals, and seeds of aquatic plants, including colonization by invasive species. Many species in those groups that use both stream and wetland habitats are capable of dispersal distances equal to or greater than distances between many wetlands and river networks. Migratory birds can be an important vector of long-distance dispersal of plants and invertebrates between non-floodplain wetlands and the river network, although their influence has not been quantified. Whether those connections are of sufficient magnitude to impact downstream waters will either require estimation of the magnitude of material fluxes or evidence that these movements of organisms are required for the survival and persistence of biota that contribute to the integrity of downstream waters.
6. Spatial proximity is one important determinant of the magnitude, frequency and duration of connections between wetlands and streams that will ultimately influence the fluxes of water, materials and biota between wetlands and downstream waters. However, proximity alone is not sufficient to determine connectivity, due to local variation in factors such as slope and permeability.
7. The cumulative influence of many individual wetlands within watersheds can strongly affect the spatial scale, magnitude, frequency, and duration of hydrologic, biological and chemical fluxes or transfers of water and materials to downstream waters. Because of their aggregated influence, any evaluation of changes to individual wetlands should be considered in the context of past and predicted changes (e.g., from climate change) to other wetlands within the same watershed
8. Caution should be used in interpreting connectivity for wetlands that have been designated as "geographically isolated" because
   a. the term can be applied broadly to a heterogeneous group of wetlands, which can include wetlands that are not actually geographically isolated (e.g., some vernal pools are not geographically isolated because they have output channels;
   b. wetlands with permanent channels could be miscategorized as geographically isolated if the designation is based on maps or imagery with inadequate spatial resolution, obscured views, etc.; and

c. wetland complexes could have connections to downstream waters through stream channels even if individual wetlands within the complex are geographically isolated.

Thus, the term "geographically isolated" should be applied only to groups of wetlands if all those wetlands are, in fact, known to be geographically isolated, something that we cannot determine based on this literature review. As previously noted, additional information that was not included in our literature review (e.g., reports from local resource agencies, analysis of existing or new data, field evaluations) could allow some wetlands that are truly geographically isolated to be distinguished from some of those that are not. Further, even geographically isolated wetlands can be connected to other wetlands and downstream waters through ground-water connections, occasional spillage, or biological connections. Thus, the term "geographically isolated" should not be used to infer lack of hydrologic, chemical, or biological connectivity. Key conclusions from our literature review on non-floodplain wetlands are summarized in Table 4-4.

CHAPTER 5. APPLICATIONS AND DISCUSSION: CONNECTIVITY CASE STUDIES

5.1 Introduction

Chapters 3 and 4 of this report review evidence from the literature for the physical, chemical, and biological connections of three broad categories of waters—streams, riparian/floodplain wetlands, and non-floodplain wetlands—to, and their resulting effects on, downstream waters. In addition to the three questions in Table 1-1, the EPA's Office of Water asked us to provide detailed information on six specific water body types: Carolina and Delmarva bays, oxbow lakes, prairie potholes, prairie streams, southwestern streams, and vernal pools (Appendix B).

In this chapter, we summarize the results of the six case studies, applying the concepts in Chapters 1 and 2 to the detailed evidence in Appendix B, for each habitat. The full body of evidence and supporting citations, which we omitted here to improve readability, are provided in Appendix B. We summarize evidence from the individual case studies in terms of (1) the descriptors of connectivity (i.e., the frequency, duration, magnitude, timing, rate of change of fluxes to and biological exchanges with downstream waters; Section 1.2.2); (2) the consequences of different systems and degrees of connectivity on downstream waters (Sections 1.2.3 and 2.3); (3) and the effects of typical human alterations (Sections 1.2.4 and 2.4.4). We then use the information from these case studies and from Chapters 3 and 4 to illustrate, hypothetically, where streams, riparian/floodplain wetlands, and non-floodplain wetlands are positioned along a connectivity gradient, highlighting the primary lines of evidence that support that positioning.

5.2 Carolina and Delmarva Bays

Carolina bays are elliptical, ponded, depressional wetlands that occur along the Atlantic Coastal Plain from northern Florida to New Jersey, although they are most abundant in North Carolina and South Carolina (Section B.1). Carolina bays that are geographically specific to the Delmarva Peninsula are often referred to as Delmarva bays. Carolina and Delmarva bays range in size from less than 1 ha to greater than 3,600 ha and are densely concentrated in many areas. In the 1950s, roughly 500,000 bays existed, although the number today is markedly less due to human modification of the landscape. Bays primarily gain water from direct precipitation on their surfaces (with some water deriving from inlet channels, surface runoff, shallow ground water, and natural springs) and lose water through evapotranspiration. As a result, these relatively permanent bays experience fluctuating water levels. Their extensive distribution and wet-dry cycles promote and support a diverse biota.

5.2.1 Connectivity and Consequences on Downstream Waters

Some Carolina and Delmarva bays connect to each other and some connect to downstream waters. Delmarva bays inundate seasonally and connect hydrologically to other bays and to stream networks via intermittent stream channels. Studies also document shallow ground-water connections, via both nearly continuous shallow ground-water recharge and periodic shallow ground-water discharge.

When they occur, hydrologic connections are likely to result in effects on downstream waters. Carolina and Delmarva bays can reduce the amount of nitrate transported between surface-water systems and ground water via denitrification, which is promoted by the periodicity of wetting and drying that occurs in bays, and dilution. Seasonal connections of Delmarva bays to stream networks export accumulated organic matter from wetlands into tributaries of Chesapeake Bay. Hydrologic connections also export methylmercury from these systems (see below).

Although the current published evidence for biological connections is limited and primarily indirect, the potential for movement of organisms between bays and other water bodies is high. These bays provide valuable habitat and food web support for numerous plant and animal species. Fish presence in bays known to dry out periodically indirectly demonstrates that these bays must be connected to other waters. Amphibians and reptiles use bays extensively for breeding and for rearing young. In bays that lack fish, the absence of predators allows abundant amphibian populations to thrive, particularly those with aquatic larval stages. These animals can then disperse many meters across the landscape and colonize downstream waters. Bays also foster abundant aquatic insects, and their emergence can have consequences for nearby waters. Many species documented in Carolina and Delmarva bays are known to live in pond, wetland, and stream environments. As a result, species emerging from bays can become important food sources for organisms in nearby streams after aerial or terrestrial dispersal. Cumulative emergence from thousands of small bays across the landscape could create a significant food source for downstream waters.

5.2.2 Effects of Human Alteration

Human alteration of Carolina and Delmarva bays has affected their physical, chemical, and biological connections to, and effects on, downstream waters. Agriculture, logging, and other human activities have altered the vast majority of Carolina and Delmarva bays, affecting the frequency, duration, magnitude, and timing of hydrologic connections between bays and other waters. Agricultural practices have greatly reduced the number of bays over the past several decades. Channelization and ditching of bays for agriculture is common. Draining bays for agricultural use disrupts or alters numerous wetland functions: sediment and chemical storage and transformation, biological habitat and sources, and organic matter export. Because the ditches commonly connect the surface water of bays that drain agricultural fields to stream networks that drain into downstream water bodies, they serve as conveyances for nutrients, sediment, and contaminants—thereby increasing physical, chemical, and biological connections between bays and the downstream systems. The consequences of this increased connectivity for downstream waters can be especially important in terms of nutrient and contaminant transport. In addition to runoff from farmed fields, periodic drying and flooding of shallow Carolina and Delmarva bays promote the bacteria-mediated methylation of mercury. Subsequent transport of bioavailable methylmercury through ditches can pose a contamination risk to fish and piscivorous birds inhabiting downstream water bodies.

5.3 Oxbow Lakes

Oxbow lakes are natural features of floodplains, originating from curves (meanders) in the river that become cut off from the active river channel (Section B.2). They are located in flat, unconstrained floodplains of river systems.

5.3.1 Connectivity and Consequences on Downstream Waters

The evidence for physical, chemical, and biological connectivity of oxbow lakes to downstream waters is considerable. Because of their location within river floodplains, many oxbows are connected seasonally or episodically to downstream waters during natural flood events via surface and shallow subsurface flows. The frequency, duration, magnitude, and timing of these hydrologic connections depend on river stage, lake geomorphology, and relative position along and distance from the river network. Despite this spatial and temporal variability, oxbow lakes collectively are likely to influence downstream waters.

The frequency, magnitude, and duration of physical connection between oxbow lakes and the river channel have important consequences on the river network. Physical surface connections facilitate biological and chemical exchange between oxbow lakes and rivers. Oxbow lakes function as sinks, because they intercept and store nutrients and other materials from upland runoff that otherwise would flow directly into the river network. In these cases, the lack of a permanent connection between an oxbow lake and a river helps to preserve the chemical integrity of the river network.

When oxbow lakes are connected, the biological material produced within them can subsidize riverine food webs by passive or active transport from the lake to downstream waters. Oxbow lakes are important areas of biological productivity on floodplains. Periodic surface-water connections between rivers and oxbow lakes facilitate the movement of fish, allowing riverine fish to exploit these productive floodplain water bodies before they move back to the river. In this way, connectivity between oxbow lakes and rivers supports the biological integrity of the river network.

5.3.2 Effects of Human Alteration

Human alterations of the natural flow regime in rivers can influence connectivity between oxbow lakes and the active river channel. In some cases, permanent channels are constructed between oxbows and the river channel and connectivity is increased; in other cases, such as the creation of dikes or levees, connectivity is reduced between oxbows and the altered area of the river network. Practices that alter the natural flow regime of the river (e.g., dams) or inhibit periodic flooding of oxbow lakes (e.g., levees) affect movement of water and sediment and the use of oxbow lakes by riverine fish. When cut off from periodic inundation by the river channel, water in oxbow lakes can evaporate. Over time, these lakes can dry up, be colonized by terrestrial vegetation, and eventually become dry land.

5.4 Prairie Potholes

The prairie pothole region, located in northern-central North America, is named for the abundant, glacially formed wetlands that occur throughout the region, typically as depressions lacking natural outlets (Section B.3). The prairie pothole region covers approximately 777,000 km^2, a vast area that varies in climate, terrain, geology, land use, and human alteration. These variations result in a gradient of connectivity to and effects on downstream waters across the potholes themselves. For instance, the three major physiographic areas within the prairie pothole region (Red River Valley, Drift Prairie, and Missouri Coteau) vary in precipitation, distribution, and density of potholes and streams connecting potholes to downstream waters. Potholes exhibit a wide range of hydrologic permanence, from holding permanent standing water to wetting only in years with high precipitation. Differences in the frequency, duration, and timing of pothole inundation across the region influence wetland function and the diversity and structure of their biological communities.

5.4.1 Connectivity and Consequences on Downstream Waters

Individual prairie potholes span the continuum of isolation from and connection to the river network and other water bodies. In addition to differences among individual potholes, interactions between regional factors (e.g., precipitation) and local factors (e.g., landscape relief) can result in spatial patterns of connectivity across the landscape (Sections 2.4.5 and B.3.2.1) that have consequences for the downstream connectivity and effects of prairie potholes. Considered collectively, unaltered prairie pothole systems have infrequent direct surface-water connections to downstream waters. Evidence of the consequences of these connections on downstream waters is variable. Some studies document measurable effects of water storage capacity of potholes on flood attenuation and maintenance of stream baseflow, whereas other studies show no effect of pothole water storage on streamflows. These differences in observed effects might be explained, in part, by the spatial variation observed within the prairie pothole region. Potholes can connect to downstream waters via ground-water flows when both are within a continuous zone of a shallow local aquifer. In areas with restricted surface-water and ground-water interactions, the magnitude of effects from such connections will be small.

The chemical connectivity of prairie potholes is largely mediated by their hydrologic connectivity. As depressions on the landscape, potholes tend to accumulate nutrients, sediment, and pesticides that can be chemically transformed and decrease potential effects on downstream waters (e.g., denitrification frequently occurs in saturated pothole sediments). Although chemical sink (storage) functions and periodic source functions of potholes have been documented in the literature, their overall influence on lakes and river networks has been difficult to quantify. This difficulty exists in part because altered and unaltered potholes co-occur in watersheds with different land use and management practices, and many different parts of this complex landscape can affect the integrity of downstream waters. Thus, prairie potholes can have substantial hydrologic and chemical consequences on downstream water levels and flows, but this type of connectivity and its downstream effects are difficult to predict, demonstrate, and quantify.

Although direct evidence is sparse, indirect evidence suggests that prairie potholes are highly biologically connected. Prairie pothole systems have biological connections to downstream waters via annual bird migrations—especially for migratory waterfowl such as cranes, geese, ducks, and shorebirds, which actively move between and use multiple aquatic habitats, including prairie pothole systems. For instance, the prairie pothole region has been identified as an area of global and regional importance for migratory birds, and at least 15 duck species use prairie pothole wetlands. Mammals and many species of amphibians also use potholes. Plants and invertebrates disperse to and from prairie potholes via "hitchhiking" on waterfowl. That potholes lack an endemic aquatic and semiaquatic flora and fauna indicates that communities in potholes are biologically well connected with other aquatic ecosystems, but evidence for effects of biological connections on downstream waters is limited.

5.4.2 Effects of Human Alteration

Human alterations of the landscape affect the connectivity of prairie potholes. Land use in an upland that drains to a wetland can alter the amount of runoff that wetland receives. Much of Upper Midwest cropland is artificially drained to increase agricultural productivity. Filling potholes and lowering the regional water table through agriculture tile drainage have increased the isolation of remaining potholes by decreasing the density of depressions containing water. In some areas, extensive surface draining and ditching has directly and dramatically increased connectivity between pothole basins and the river network. Ditches create surface-water outlets from potholes, connecting potholes to streams and rivers; drains and underground pipes fitted at the bottoms of potholes often discharge to open ditches or streams. This increased hydrologic and chemical connectivity decreases water retention time, thereby reducing storage and biogeochemical processing of nutrients, sediments, and pesticides. The cumulative influence of human alterations on connectivity between potholes and downstream waters has not been systematically studied or reported across the entire prairie pothole region.

5.5 Prairie Streams

Prairie streams drain temperate grasslands in the Great Plains physiographic region of the central United States and Canada (Section B.4). Eventually, these streams drain into the Mississippi River or flow directly into the Gulf of Mexico or the Hudson Bay. Climate in the Great Plains region ranges from semiarid to moist subhumid and intra- and interannual variation in precipitation and evapotranspiration is high. This variation is reflected in the hydrology of prairie streams, which include ephemeral, intermittent, and perennial streamflows. Row cropping and livestock agriculture are the dominant land uses in the region, resulting in the withdrawal of water from stream channels and regional aquifers and its storage in reservoirs to support agriculture.

5.5.1 Connectivity and Consequences on Downstream Waters

Prairie streams typically are connected to downstream waters. Like other types of streams, prairie streams present strong fluvial geomorphic evidence for connectivity to downstream waters, in that they have continuous channels (bed and banks) that make them physically contiguous with downstream waters. Prairie river networks are dendritic and generally have a high drainage density, so they are particularly efficient at transferring water and materials to downstream waters. Their pool-riffle morphology, high sinuosity, and seasonal drying, however, also enhance material storage and transformation. The timing of connections between prairie streams and downstream waters is seasonal and therefore relatively predictable. For example, high-magnitude floods tend to occur in late fall into later spring, although they also occur at other times during the year (Section B.4.2.1); this observation indicates that the magnitude of connections to downstream also varies seasonally.

The frequent and predictable connections between prairie streams and downstream waters have multiple physical, chemical, and biological consequences for downstream waters. Dissolved solids, sediment, and nutrients are exported from the prairie river network to downstream waters. Ultimately, the expansion of the hypoxic zone in the Gulf of Mexico is a downstream consequence of cumulative nutrient loading to the Mississippi River network. Relative to small streams and large rivers draining the moist eastern parts of the Mississippi River basin, small to midsized prairie streams deliver less than 25–50% of their nutrient load to the Gulf of Mexico. Nonetheless, given the large number and spatial extent of headwater prairie streams connected to the Mississippi River, their cumulative effect likely contributes substantially to downstream nutrient loading.

Organisms inhabiting prairie streams have adapted to their variable hydrologic regimes and harsh physicochemical conditions via evolutionary strategies that include rapid growth, high dispersal ability, resistant life stages, fractional reproduction, and life cycles timed to avoid predictably harsh periods. Alterations in the frequency, duration, magnitude, and timing of flows—and thus hydrologic connectivity—are associated with the extinction or extirpation of species in downstream systems. Moreover, many fish species (e.g., Arkansas River shiner, speckled chub, flathead chub) in prairie river networks require sufficient unfragmented (i.e., connected) channel length with adequate discharge to keep their nonadhesive, semibuoyant eggs in suspension for incubation and early development. When these conditions are not met, the biological integrity of downstream waters is impaired.

5.5.2 Effects of Human Alteration

Human alteration of prairie river networks has affected the physical, chemical, and biological connectivity to and their consequences for downstream waters. Impoundments and water removal, through both surface flow diversions and pumping of ground-water aquifers, are common in this region. These activities have reduced flood magnitude and variability, altered timing, and increased predictability of flows to downstream waters. As a result, physical, chemical, and biological connections to downstream waters have been altered. In addition to the altered land uses and application of nutrients and pesticides for agriculture, human alteration of the river network itself, through channelization, levee construction, desnagging, dredging, and ditching, has enhanced longitudinal connectivity while reducing lateral and vertical connectivity with the floodplain and hyporheic zone, respectively. Pumping from streams and ground water has caused historically perennial river segments to regularly dry during summer months. Changes to the prairie's grazing (from bison to cattle) and burning regimes increase nutrient and suspended sediment loading to downstream waters. Introduced species have extirpated endemic species and altered food web structure and processes in prairie streams, thereby affecting the biological integrity of downstream waters.

5.6 Southwestern Intermittent and Ephemeral Streams

Southwestern streams are predominantly ephemeral and intermittent (nonperennial) systems located in the southwestern United States (Section B.5). Based on the National Hydrography Dataset, 94%, 89%, 88%, and 79% of the streams in Arizona, Nevada, New Mexico, and Utah, respectively, are nonperennial. Most of these streams connect to downstream waters, although 66% and 20% of the drainage basins in Nevada and New Mexico, respectively, are closed and drain into playas (dry lakes). Southwestern streams generally are steep and can be divided into two main types: (1) mountainous streams that drain higher portions of basins and receive higher rates of precipitation, often as snow, compared to lower elevations; and (2) streams located in valley or plateau regions that generally flow in response to high-intensity thunderstorms. Headwater streams are common in both types of southwestern streams.

5.6.1 Connectivity and Consequences on Downstream Waters

Nonperennial southwestern streams, excluding those that drain into playas, are periodically connected to downstream waters by low-duration, high-magnitude flows. In contrast to streams in humid regions where discharge is typically supplemented by ground water as drainage area increases, many southwestern streams lose streamflow to channel transmission losses as runoff travels downstream (Figure B-10). Connection of runoff and associated materials in ephemeral and intermittent streams to downstream waters is therefore a function of distance, the relative magnitude of the runoff event, and transmission losses.

Spatial and temporal variation in frequency, duration, and timing of southwestern stream runoff is largely explained by elevation, climate, channel substrate, geology, and the presence of shallow ground water. In nonconstraining substrate, southwestern rivers are dendritic and their watersheds tend to have a high drainage density. When high flows are present, southwestern streams are efficient at transferring water, sediment, and nutrients to downstream reaches. Due to the episodic nature of flow in ephemeral and intermittent channels, sediment and organic matter can be deposited some distance downstream, and then moved farther downstream by subsequent precipitation events. Over time, sediment and organic matter continue to move downstream and affect downstream waters.

The southwestern streams case study (Section B.5) describes the substantial connection and important consequences of runoff, nutrients, and particulate matter originating from ephemeral tributaries on the integrity and sustainability of downstream perennial streams. Channel transmission losses can be an important source of ground-water recharge that sustains downstream perennial stream and riparian systems. For example, isotopic studies indicate that runoff from ephemeral tributaries like Walnut Gulch, Arizona supplies roughly half the San Pedro River's baseflow through shallow alluvial aquifer recharge.

5.6.2 Effects of Human Alteration

Human alterations to southwestern river networks affect the physical, chemical, and biological connectivity to downstream waters. Impoundments trap water, sediment, and particulate nutrients and result in downstream impacts on channel morphology and aquatic function. Diversion of water for consumptive uses can decrease downstream baseflows but typically does not affect the magnitude of peak flows. Excessive ground-water pumping can lower ground-water tables, thereby diminishing or eliminating baseflows. Urbanization increases runoff volume and flow velocity, resulting in more erosive energy that can cause bank erosion, streambed downcutting, and reduced infiltration to ground water.

5.7 Vernal Pools

Vernal pools are shallow, rain-fed, fishless pools situated on bedrock or low-permeability soils (Section B.6). Vernal pools inundate seasonally and lack continuous surface-water connections to downstream water bodies. Although they can occur in other parts of the United States, this case study focuses on pools in the western states and the glaciated areas of northeastern states. Western vernal pools typically occur in open grasslands; most northern vernal pools are detrital and are fully contained within forest ecosystems. When inundation occurs, vernal pools can fill and overflow through swales or intermittent streams, which connect them to downstream waters.

5.7.1 Connectivity and Consequences on Downstream Waters

Direct surface connection of vernal pools to downstream waters is infrequent. The duration and magnitude of such connections are highly variable and depend on the climate, terrain, and geology of the region and on the location of the vernal pool in the watershed. Vernal pools generally are clustered, forming wetland complexes. Pools located at the downgradient end of a complex can receive surface water through stepping-stone spillage in addition to precipitation, and generally are inundated longer than upper pools. Because they experience greater inundation and are likely to be located nearer to streams, these downgradient pools are also more likely to be directly connected to streams. Temporary storage of heavy rainfall and snowmelt in individually small vernal pool systems (pools plus soils) can attenuate flooding, provide a reservoir for nearby vegetation during the spring growth period, and increase nutrient availability.

The timing of seasonal inundation and lack of permanent surface connections make vernal pools important biological refuges, which has consequences on the biological health of downstream waters. Vernal pools are highly productive ecosystems that have evolved in a “balance between isolation and connectedness” (Zedler, 2003; page 597). Because they are connected to other aquatic habitats through dispersal, they provide rich reservoirs of genetic and species diversity. Food webs in vernal pools include highly fecund amphibians and insects that convert detrital organic matter into biomass, which is then exported to aquatic ecosystems in other parts of the watershed. Northern vernal pools can provide alternative breeding habitat, refuge from predators or environmental stressors, hunting or foraging habitat, or stepping-stone corridors for dispersal and migration.

5.7.2 Effects of Human Alteration

Vernal pools have been drained and converted to other land uses (e.g., agriculture, logging, urban development). These activities have increased fragmentation of habitats for amphibians, plants, and invertebrates, and had similar effects on the frequency, duration, magnitude, and timing of inundations, surface-water outflows, and shallow subsurface-water connections to downstream waters as those described in Section 5.2.1 (Carolina and Delmarva bays).

5.8 Synthesis

These case study summaries highlight the key connections between specific water body types and downstream waters. The case study evidence provides further support that the structure and function of downstream waters highly depend on constituent materials and organisms contributed by and transported through water bodies located throughout the watershed. In addition, the studies support that variation in the types and degrees of connectivity determines the range of downstream effects.

These case study summaries illustrate two key points. First, each type of water body addressed here demonstrates variability in connectivity to and effects on downstream waters. Oxbow lakes, for example, are more or less connected to the main river channel based largely on their relative position in the landscape: Systems close to the river channel are highly connected and those farther away are connected less often or the impact on the river takes longer to be realized. Evidence presented in the prairie pothole case study also demonstrates variation in connectivity patterns across the region and shows the consequences of this variability on downstream rivers and lakes. The prairie streams case study discusses functions and varying degrees of connectivity of streams and their cumulative effects on downstream waters.

Second, the effects of human alteration on the connectivity to and effects on downstream waters depend on the type of water body. Human alteration of different types of streams and wetlands can be complex, either increasing or decreasing connectivity and subsequent effects on downstream waters. For example, evidence shows that ditches in the prairie pothole region increase hydrologic connectivity, and connectivity of oxbow lakes near active river channels can be reduced if that portion of the river is leveed. Coupled human-natural systems are an area of active research and new information about the effects of human activities on connectivity and water integrity is emerging in the peer-reviewed literature.

Positioning the specific water body types in the case studies (Appendix B) along a gradient of connectivity and effect proved to be premature for several reasons. First, the amount of documented evidence (i.e., number of published studies) varied among the water body types. In some instances, a large body of evidence exists and in others, only a few studies exist, limiting sound comparisons. Second, variation in connectivity consistently was reported to be high within some water body types, creating substantial overlap in ranges of connectivity among those water body types. In addition to a need for more studies documenting connectivity in less studied regions, a more refined classification using the descriptors of connectivity described in Chapter 1 (or others) and their controls (e.g., climate, geology, and terrain) within wetland landscape settings are required.

Based on the evidence presented in Chapters 3 and 4, ordering the three broad categories of water bodies considered in this report—streams, floodplain wetlands, and non-floodplain wetlands—along a connectivity gradient (Figure 5-1) is possible. Of these three water body types, streams are, in general, more connected to and have better-documented effects on downstream waters than either wetland category. Floodplain wetlands, in turn, tend to be more connected to downstream waters, and have better-documented downstream effects, than non-floodplain wetlands. This ordering must be recognized as a broad generalization, and considerable overlap can occur among the types, given the spatial and temporal variability in connectivity documented in these habitats (Figure 5-1). Nevertheless, several key lines of evidence support this hypothesized ordering of water body types along the gradient.

1. Streams are connected to rivers by a continuous channel, which is a physical reflection of surface connectivity. Formation of a channel indicates that connectivity, in terms of its combined descriptors (frequency, duration, magnitude, timing) is sufficiently strong (or "effective") and outweighs terrestrialization processes (e.g., revegetation, wind-mediated processes, soil formation processes).
2. Within-channel flows are more efficient for moving water, sediment, pollutants, and other materials than overland flow; for some aquatic organisms, channels are the only possible transport routes. Channels are places where excess water and materials from the landscape are concentrated as they are transmitted downstream. Recurrent flow of sufficient magnitude over a given area of landscape selects routes with least resistance, which develop into branched

channel networks with a repeating, cumulative pattern of smaller channels that join at confluences to form larger channels.

3. The continuous channels connecting streams to rivers also represent areas of relatively high shallow subsurface connectivity (shallow ground-water recharge and upwelling). Channels are typically more permeable than surrounding soils, lack dense terrestrial vegetation (and thus have lower uptake and evapotranspiration loss), and are topographic low points closer to concentrated shallow ground water.

4. Floodplain wetlands and open waters are connected to rivers by historical and recurrent surface connectivity. Riparian/floodplain wetlands are maintained by the recurrent inundation and deposition of materials from streams and rivers during the peak and recession of flood flows.

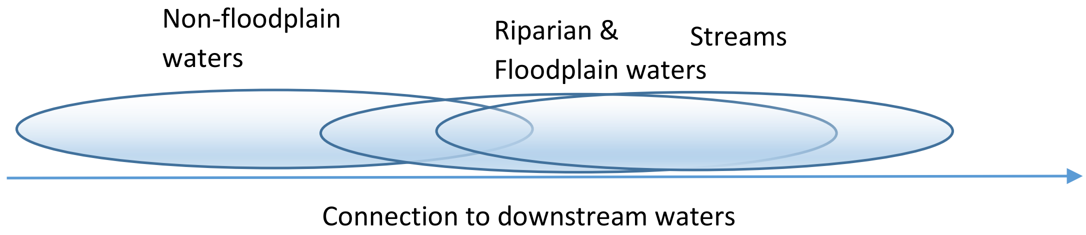
5. Riparian/floodplain wetlands and open waters are close to river networks and thus more likely to have strong connectivity with the downstream water than more distant wetlands, when all other conditions are similar.

6. Non-floodplain wetlands are positioned outside the floodplain, and so are not subject to direct flooding from the river or stream. Any hydrologic connections to the river system are therefore unidirectional (from wetland to downstream water and not vice-versa). They are also likely to be more distant from the network, increasing the flowpath lengths and travel time to the network.

7. Because of their large numbers, headwater streams and associated wetlands cumulatively represent a large portion of the landscape interface with a downstream water. These areas provide functions that enhance both exchanges with and buffering of the downstream water, making them critical to mediating the recognized relationship between the integrity of downstream waters and the land use and stressor loadings from the surrounding landscape.

8. Connectivity to downstream waters is reflected in the distribution of aquatic organisms and their dependence on particular aquatic habitats across different stages of their life cycles. For example, the recurrent presence of completely aquatic organisms (i.e., organisms that lack terrestrial life stages, overland dispersal, stages resistant to drying) in streams and wetlands that periodically dry provides indirect evidence for surface-water connections. Because many aquatic species can move and disperse overland, aquatic habitats can be highly connected biologically in the absence of hydrologic connectivity.

Figure 5-1. Relative positioning of streams, riparian and floodplain waters, and non-floodplain waters along a gradient of connectivity. Ellipses are used to illustrate the degree of expected overlap among water-body types based on the range of variation documented in the reviewed literature.



CHAPTER 6. CONCLUSIONS

This chapter presents the five major conclusions of this report, with a summary of key findings from the literature synthesized to develop these conclusions. It also discusses the relative abundance of literature on topics reviewed in this report. Finally, it briefly discusses emerging research that can close some current data gaps and help further clarify the role of connectivity in maintaining the integrity of downstream waters.

Citations have been omitted from the text of the conclusions and key findings to improve readability; please refer to individual chapters for supporting publications and additional information.

6.1 Major Conclusions and Key Findings

Based on our review and synthesis of the literature, we developed five major conclusions, which are presented in this section with a summary of key findings for each conclusion.

6.1.1 Conclusion 1: Streams

The scientific literature unequivocally demonstrates that streams, individually or cumulatively, exert a strong influence on the integrity of downstream waters. All tributary streams, including perennial, intermittent, and ephemeral streams, are physically, chemically, and biologically connected to downstream rivers via channels and associated alluvial deposits where water and other materials are concentrated, mixed, transformed, and transported. Streams are the dominant source of water in most rivers, and the majority of tributaries are perennial, intermittent, or ephemeral headwater streams. Headwater streams also convey water into local storage compartments such as ponds, shallow aquifers, or stream banks, and into regional and alluvial aquifers; these local storage compartments are important sources of water for maintaining baseflow in rivers. In addition to water, streams transport sediment, wood, organic matter, nutrients, chemical contaminants, and many of the organisms found in rivers. The literature provides robust evidence that streams are biologically connected to downstream waters by the dispersal and migration of aquatic and semiaquatic organisms, including fish, amphibians, plants, microorganisms, and invertebrates, that use both upstream and downstream habitats during one or more stages of their life cycles, or provide food resources to downstream communities. In addition to material transport and biological connectivity, ephemeral, intermittent, and perennial flows influence fundamental biogeochemical processes by connecting channels and shallow ground water with other landscape elements. Physical, chemical, and biological connections between streams and downstream waters interact via integrative processes such as nutrient spiraling, in which stream communities assimilate and chemically transform large quantities of nitrogen and other nutrients that otherwise would be transported directly downstream, increasing nutrient loads and associated impairments due to excess nutrients in downstream waters.

6.1.1.1 Conclusion 1, Key Findings

- Streams are hydrologically connected to downstream waters via channels that convey surface and subsurface water either year-round (i.e., perennial flow), weekly to seasonally (i.e., intermittent flow), or only in direct response to precipitation (i.e., ephemeral flow). Streams are the dominant source of water in most rivers, and the majority of tributaries are perennial, intermittent, or ephemeral headwater streams. For example, headwater streams, which are the smallest channels where streamflows begin, are the cumulative source of approximately 60% of the total mean annual flow to all northeastern U.S. streams and rivers.
- In addition to downstream transport, headwaters convey water into local storage compartments such as ponds, shallow aquifers, or stream banks, and into regional and alluvial aquifers. These local storage compartments are important sources of water for maintaining baseflow in rivers. Streamflow typically depends on the delayed (i.e., lagged) release of shallow ground water from local storage, especially during dry periods and in areas with shallow ground-water tables and pervious subsurfaces. For example, in the southwestern United States, short-term shallow ground-water storage in alluvial floodplain aquifers, with gradual release into stream channels, is a major source of annual flow in rivers.
- Infrequent, high-magnitude events are especially important for transmitting materials from headwater streams in most river networks. For example, headwater streams, including ephemeral and intermittent streams, shape river channels by accumulating and gradually or episodically releasing stored materials such as sediment and large woody debris. These materials help structure stream and river channels by slowing the flow of water through channels and providing substrate and habitat for aquatic organisms.
- There is strong evidence that headwater streams function as nitrogen sources (via export) and sinks (via uptake and transformation) for river networks. For example, one study estimated that rapid nutrient cycling in small streams with no agricultural or urban impacts removed 20−40% of the nitrogen that otherwise would be delivered to downstream waters. Nutrients are necessary to support aquatic life, but excess nutrients lead to eutrophication and hypoxia, in which over-enrichment causes dissolved oxygen concentrations to fall below the level necessary

to sustain most aquatic animal life in the stream and streambed. Thus, the influence of streams on nutrient loads can have significant repercussions for hypoxia in downstream waters.

- Headwaters provide habitat that is critical for completion of one or more life-cycle stages of many aquatic and semiaquatic species capable of moving throughout river networks. Evidence is strong that headwaters provide habitat for complex life-cycle completion; refuge from predators, competitors, parasites, or adverse physical conditions in rivers (e.g., temperature or flow extremes, low dissolved oxygen, high sediment); and reservoirs of genetic- and species-level diversity. Use of headwater streams as habitat is especially critical for the many species that migrate between small streams and marine environments during their life cycles (e.g., Pacific and Atlantic salmon, American eels, certain lamprey species). The presence of these species within river networks provides robust evidence of biological connections between headwaters and larger rivers; because these organisms also transport nutrients and other materials as they migrate, their presence also provides evidence of biologically mediated chemical connections. In prairie streams, many fishes swim upstream into tributaries to release eggs, which develop as they are transported downstream.
- Human alterations affect the frequency, duration, magnitude, timing, and rate of change of connections between headwater streams, including ephemeral and intermittent streams, and downstream waters. Human activities and built structures (e.g., channelization, dams, ground-water withdrawals) can either enhance or fragment longitudinal connections between headwater streams and downstream waters, while also constraining lateral and vertical exchanges and tightly controlling the temporal dimension of connectivity. In many cases, research on human alterations has enhanced our understanding of the headwater stream-downstream water connections and their consequences. Recognition of these connections and effects has encouraged the development of more sustainable practices and infrastructure to reestablish and manage connections, and ultimately to protect and restore the integrity of downstream waters.

6.1.2 Conclusion 2: Riparian/Floodplain Wetlands and Open Waters

The literature clearly shows that wetlands and open waters in riparian areas and floodplains are physically, chemically, and biologically integrated with rivers via functions that improve downstream water quality, including the temporary storage and deposition of channel-forming sediment and woody debris, temporary storage of local ground water that supports baseflow in rivers, and transformation and transport of stored organic matter. Riparian/floodplain wetlands and open waters improve water quality through the assimilation, transformation, or sequestration of pollutants, including excess nutrients and chemical contaminants such as pesticides and metals, that can degrade downstream water integrity. In addition to providing effective buffers to protect downstream waters from point source and nonpoint source pollution, these systems form integral components of river food webs, providing nursery habitat for breeding fish and amphibians, colonization opportunities for stream invertebrates, and maturation habitat for stream insects. Lateral expansion and contraction of the river in its floodplain result in an exchange of organic matter and organisms, including fish populations that are adapted to use floodplain habitats for feeding and spawning during high water, that are critical to river ecosystem function. Riparian/floodplain wetlands and open waters also affect the integrity of downstream waters by subsequently releasing (desynchronizing) floodwaters and retaining large volumes of stormwater, sediment, and contaminants in runoff that could otherwise negatively affect the condition or function of downstream waters.

6.1.2.1 Conclusion 2, Key Findings

- Riparian areas and floodplains connect upland and aquatic environments through both surface and subsurface hydrologic flowpaths. These areas are therefore uniquely situated in watersheds to receive and process waters that pass over densely vegetated areas and through subsurface zones before the waters reach streams and rivers. When pollutants reach a riparian or floodplain wetland, they can be sequestered in sediments, assimilated into wetland plants and animals, transformed into less harmful or mobile forms or compounds, or lost to the atmosphere. Wetland potential for biogeochemical transformations (e.g., denitrification) that can improve downstream water quality is influenced by local factors, including anoxic conditions and slow organic matter decomposition, shallow water tables, wetland plant communities, permeable soils, and complex topography.
- Riparian/floodplain wetlands can reduce flood peaks by storing and desynchronizing floodwaters. They can also maintain river baseflows by recharging alluvial aquifers. Many studies have documented the ability of riparian/floodplain wetlands to reduce flood pulses by storing excess water from streams and rivers. One review of wetland studies reported that riparian wetlands reduced or delayed floods in 23 of 28 studies. For example, peak discharges between upstream and downstream gaging stations on the Cache River in Arkansas were reduced 10−20% primarily due to floodplain water storage.
- Riparian areas and floodplains store large amounts of sediment and organic matter from upstream and from upland areas. For example, riparian areas have been shown to remove 80−90% of sediments leaving agricultural fields in North Carolina.
- Ecosystem function within a river system is driven in part by biological connectivity that links diverse biological communities with the river system. Movements of organisms that connect aquatic habitats and their populations, even across different watersheds, are important for the survival of individuals, populations, and species, and for the functioning of the river ecosystem. For example, lateral expansion and contraction of the river in its floodplain result in an exchange of matter and organisms, including fish populations that are adapted to use floodplain habitats for feeding and spawning during high water. Wetland and aquatic plants in floodplains can become important seed sources for the river network, especially if catastrophic flooding scours vegetation and seed banks in other parts of the channel. Many invertebrates exploit temporary hydrologic connections between rivers and floodplain wetland habitats, moving into these wetlands to feed, reproduce, or avoid harsh environmental conditions and then returning to the

river network. Amphibians and aquatic reptiles commonly use both streams and riparian/floodplain wetlands to hunt, forage, overwinter, rest, or hide from predators. Birds can spatially integrate the watershed landscape through biological connectivity.

6.1.3 Conclusion 3: Non-floodplain Wetlands and Open Waters

Wetlands and open waters in non-floodplain landscape settings (hereafter called "non-floodplain wetlands") provide numerous functions that benefit downstream water integrity. These functions include storage of floodwater; recharge of ground water that sustains river baseflow; retention and transformation of nutrients, metals, and pesticides; export of organisms or reproductive propagules to downstream waters; and habitats needed for stream species. This diverse group of wetlands (e.g., many prairie potholes, vernal pools, playa lakes) can be connected to downstream waters through surface-water, shallow subsurface-water, and ground-water flows and through biological and chemical connections.

In general, connectivity of non-floodplain wetlands occurs along a gradient (Conclusion 4), and can be described in terms of the frequency, duration, magnitude, timing, and rate of change of water, material, and biotic fluxes to downstream waters. These descriptors are influenced by climate, geology, and terrain, which interact with factors such as the magnitudes of the various functions within wetlands (e.g., amount of water storage or carbon export) and their proximity to downstream waters to determine where wetlands occur along the connectivity gradient. At one end of this gradient, the functions of non-floodplain wetlands clearly affect the condition of downstream waters if a visible (e.g., channelized) surface-water or a regular shallow subsurface-water connection to the river network is present. For non-floodplain wetlands lacking a channelized surface or regular shallow subsurface connection (i.e., those at intermediate points along the gradient of connectivity), generalizations about their specific effects on downstream waters from the available literature are difficult because information on both function and connectivity is needed. Although there is ample evidence that non-floodplain wetlands provide hydrologic, chemical, and biological functions that affect material fluxes, to date, few scientific studies explicitly addressing connections between non-floodplain wetlands and river networks have been published in the peer-reviewed literature. Even fewer publications specifically focus on the frequency, duration, magnitude, timing, or rate of change of these connections. In addition, although areas that are closer to rivers and streams have a higher probability of being connected than areas farther away when conditions governing the type and quantity of flows—including soil infiltration rate, wetland storage capacity, hydraulic gradient, etc.—are similar, information to determine if this similarity holds is generally not provided in the studies we reviewed. Thus, current science does not support evaluations of the degree of connectivity for specific groups or classes of wetlands (e.g., prairie potholes or vernal pools). Evaluations of individual wetlands or groups of wetlands, however, could be possible through case-by-case analysis.

Some effects of non-floodplain wetlands on downstream waters are due to their isolation, rather than their connectivity. Wetland sink functions that trap materials and prevent their export to downstream waters (e.g., sediment and entrained pollutant removal, water storage) result because of the wetland's ability to isolate material fluxes. To establish that such functions influence downstream waters, we also need to know that the wetland intercepts materials that otherwise would reach the downstream water. The literature we reviewed does provide limited examples of direct effects of wetland isolation on downstream waters, but not for classes of wetlands (e.g., vernal pools). Nevertheless, the literature we reviewed enables us to conclude that sink functions of non-floodplain wetlands, which result in part from their relative isolation, will affect a downstream water when these wetlands are situated between the downstream water and known point or nonpoint sources of pollution, and thus intersect flowpaths between the pollutant source and downstream waters.

6.1.3.1 Conclusion 3, Key Findings

- Water storage by wetlands well outside of riparian or floodplain areas can affect streamflow. Hydrologic models of prairie potholes in the Starkweather Coulee subbasin (North Dakota) that drains to Devils Lake indicate that increasing the volume of pothole storage across the subbasin by approximately 60% caused simulated total annual streamflow to decrease 50% during a series of dry years and 20% during wet years. Similar simulation studies of watersheds that feed the Red River of the North in North Dakota and Minnesota demonstrated qualitatively comparable results, suggesting that the ability of potholes to modulate streamflow could be widespread across eastern portions of the prairie pothole region. This work also indicates that reducing water storage capacity of wetlands by connecting formerly isolated potholes through ditching or drainage to the Devils Lake and Red River basins could increase stormflow and contribute to downstream flooding. In many agricultural areas already crisscrossed by extensive drainage systems, total streamflow and baseflow are increased by directly connecting potholes to stream networks. The impacts of changing streamflow are numerous, including altered flow regime, stream geomorphology, habitat, and ecology. The presence or absence of an effect of prairie pothole water storage on streamflow depends on many factors, including patterns of precipitation, topography, and degree of human alteration. For example, in parts of the prairie pothole region with low precipitation, low stream density, and little human alteration, hydrologic connectivity between prairie potholes and streams or rivers is likely to be low.
- Non-floodplain wetlands act as sinks and transformers for various pollutants, especially nutrients, which at excess levels can adversely impact human and ecosystem health and pose a serious pollution problem in the United States. In one study, sewage wastewaters were applied to forested wetlands in Florida for 4.5 years; more than 95% of the phosphorus, nitrate, ammonium, and total nitrogen were removed by the wetlands during the study period, and 66−86% of the nitrate removed was attributed to the process of denitrification. In another study, sizeable phosphorus retention (0.3 to 8.0 mg soluble reactive P m^{-2} d^{-1}) occurred in marshes that comprised only 7% of the lower Lake Okeechobee basin area in Florida. A non-floodplain bog in Massachusetts was reported to sequester nearly 80% of nitrogen inputs from various sources, including atmospheric deposition, and prairie pothole wetlands in the upper Midwest were found to remove >80% of the nitrate load via denitrification. A large prairie marsh was found to remove 86% of nitrate, 78% of ammonium, and 20% of phosphate through

assimilation and sedimentation, sorption, and other mechanisms. Together, these and other studies indicate that onsite nutrient removal by non-floodplain wetlands is substantial and geographically widespread. The effects of this removal on rivers are generally not reported in the literature.

- Non-floodplain wetlands provide unique and important habitats for many species, both common and rare. Some of these species require multiple types of waters to complete their full life cycles, including downstream waters. Abundant or highly mobile species play important roles in transferring energy and materials between non-floodplain wetlands and downstream waters.
- Biological connections are likely to occur between most non-floodplain wetlands and downstream waters through either direct or stepping stone movement of amphibians, invertebrates, reptiles, mammals, and seeds of aquatic plants, including colonization by invasive species. Many species in those groups that use both stream and wetland habitats are capable of dispersal distances equal to or greater than distances between many wetlands and river networks. Migratory birds can be an important vector of long-distance dispersal of plants and invertebrates between non-floodplain wetlands and the river network, although their influence has not been quantified. Whether those connections are of sufficient magnitude to impact downstream waters will either require estimation of the magnitude of material fluxes or evidence that these movements of organisms are required for the survival and persistence of biota that contribute to the integrity of downstream waters.
- Spatial proximity is one important determinant of the magnitude, frequency, and duration of connections between wetlands and streams that will ultimately influence the fluxes of water, materials, and biota between wetlands and downstream waters. However, proximity alone is not sufficient to determine connectivity, due to local variation in factors such as slope and permeability.
- The cumulative influence of many individual wetlands within watersheds can strongly affect the spatial scale, magnitude, frequency, and duration of hydrologic, biological, and chemical fluxes or transfers of water and materials to downstream waters. Because of their aggregated influence, any evaluation of changes to individual wetlands should be considered in the context of past and predicted changes (e.g., from climate change) to other wetlands within the same watershed.
- Non-floodplain wetlands can be hydrologically connected directly to river networks through natural or constructed channels, nonchannelized surface flows, or subsurface flows, the latter of which can travel long distances to affect downstream waters. A wetland surrounded by uplands is defined as "geographically isolated." Our review found that, in some cases, wetland types such as vernal pools and coastal depressional wetlands are collectively—and incorrectly—referred to as geographically isolated. Technically, the term "geographically isolated" should be applied only to the particular wetlands within a type or class that are completely surrounded by uplands. Furthermore, "geographic isolation" should not be confused with functional isolation, because

geographically isolated wetlands can still have hydrologic, chemical, and biological connections to downstream waters.

- Non-floodplain wetlands occur along a gradient of hydrologic connectivity-isolation with respect to river networks, lakes, or marine/estuarine water bodies. This gradient includes, for example, wetlands that serve as origins for stream channels that have permanent surface-water connections to the river network; wetlands with outlets to stream channels that discharge to deep ground-water aquifers; geographically isolated wetlands that have local ground-water or occasional surface-water connections to downstream waters; and geographically isolated wetlands that have minimal hydrologic connection to other water bodies (but which could include surface and subsurface connections to other wetlands). This gradient can exist among wetlands of the same type or in the same geographic region.
- Caution should be used in interpreting connectivity for wetlands that have been designated as "geographically isolated" because (1) the term can be applied broadly to a heterogeneous group of wetlands, which can include wetlands that are not actually geographically isolated; (2) wetlands with permanent channels could be miscategorized as geographically isolated if the designation is based on maps or imagery with inadequate spatial resolution, obscured views, etc.; and (3) wetland complexes could have connections to downstream waters through stream channels even if individual wetlands within the complex are geographically isolated. For example, a recent study examined hydrologic connectivity in a complex of wetlands on the Texas Coastal Plain. The wetlands in this complex have been considered to be a type of geographically isolated wetland. Collectively, however, they are connected both geographically and hydrologically to downstream waters in the area: During an almost 4-year study period, nearly 20% of the precipitation that fell on the wetland complex flowed out through an intermittent stream into downstream waters. Thus, wetland complexes could have connections to downstream waters through stream channels even when the individual wetland components are geographically isolated.

6.1.4 Conclusion 4: Degrees and Determinants of Connectivity

Watersheds are integrated at multiple spatial and temporal scales by flows of surface water and ground water, transport and transformation of physical and chemical materials, and movements of organisms. Although all parts of a watershed are connected to some degree—by the hydrologic cycle or dispersal of organisms, for example—the degree and downstream effects of those connections vary spatially and temporally, and are determined by characteristics of the physical, chemical, and biological environments and by human activities.

Stream and wetland connections have particularly important consequences for downstream water integrity. Most of the materials—broadly defined as any physical, chemical, or biological entity—in rivers, for example, originate from aquatic ecosystems located upstream or elsewhere in the watershed. Longitudinal flows through ephemeral, intermittent, and perennial stream channels are much more efficient for transport of water, materials, and organisms than diffuse overland flows, and areas that concentrate water provide mechanisms for the storage and transformation, as well as transport, of materials.

Connectivity of streams and wetlands to downstream waters occurs along a continuum that can be described in terms of the frequency, duration, magnitude, timing, and rate of change of water, material, and biotic fluxes to downstream waters. These terms, which we refer to collectively as connectivity descriptors, characterize the range over which streams and wetlands vary and shift along the connectivity gradient in response to changes in natural and anthropogenic factors and, when considered in a watershed context, can be used to predict probable effects of different degrees of connectivity over time. The evidence unequivocally demonstrates that the stream channels and riparian/floodplain wetlands or open waters that together form river networks are clearly connected to downstream waters in ways that profoundly influence downstream water integrity. The connectivity and effects of non-floodplain wetlands and open waters are more variable and thus more difficult to address solely from evidence available in peer-reviewed studies.

Variations in the degree of connectivity influence the range of functions provided by streams and wetlands, and are critical to the integrity and sustainability of downstream waters. Connections with low values of one or more descriptors (e.g., low-frequency, low-duration streamflows caused by flash floods) can have important downstream effects when considered in the context of other descriptors (e.g., large magnitude of water transfer). At the other end of the frequency range, high-frequency, low-magnitude vertical (surface-subsurface) and lateral flows contribute to aquatic biogeochemical processes, including nutrient and contaminant transformation and organic matter accumulation. The timing of an event can alter both connectivity and the magnitude of its downstream effect. For example, when soils become saturated by previous rainfall events, even low or moderate rainfall can cause streams or wetlands to overflow, transporting water and materials to downstream waters. Fish that use nonperennial or perennial headwater stream habitats to spawn or rear young, and invertebrates that move into seasonally inundated floodplain wetlands prior to emergence, have life cycles that are synchronized with the timing of flows, temperature thresholds, and food resource availability in those habitats.

6.1.4.1 Conclusion 4, Key Findings

- The surface-water and ground-water flowpaths (hereafter, hydrologic flowpaths), along which water and materials are transported and transformed, determine variations in the degree of physical and chemical connectivity. These flowpaths are controlled primarily by variations in climate, geology, and terrain within and among watersheds and over time. Climate, geology, and terrain are reflected locally in factors such as rainfall and snowfall intensity, soil infiltration rates, and the direction of ground-water flows. These local factors interact with the landscape positions of streams and wetlands relative to downstream waters, and with functions (such as the removal or transformation of pollutants) performed by those streams and wetlands to determine connectivity gradients.

- Gradients of biological connectivity (i.e., the active or passive movements of organisms through water or air and over land that connect populations) are determined primarily by species assemblages, and by features of the landscape (e.g., climate, geology, terrain) that facilitate or impede the movement of organisms. The temporal and spatial scales at which biological pathways connect aquatic habitats depend on characteristics of both the landscape and species, and overland transport or movement can occur across watershed boundaries. Dispersal is essential for population persistence, maintenance of genetic diversity, and evolution of aquatic species. Consequently, dispersal strategies reflect aquatic species' responses and adaptations to biotic and abiotic environments, including spatial and temporal variation in resource availability and quality. Species' traits and behaviors encompass species-environment relationships over time, and provide an ecological and evolutionary context for evaluating biological connectivity in a particular watershed or group of watersheds.
- Pathways for chemical transport and transformation largely follow hydrologic flowpaths, but sometimes follow biological pathways (e.g., nutrient transport from wetlands to coastal waters by migrating waterfowl, upstream transport of marine-derived nutrients by spawning of anadromous fish, uptake and removal of nutrients by emerging stream insects).
- Human activities alter naturally occurring gradients of physical, chemical, and biological connectivity by modifying the frequency, duration, magnitude, timing, and rate of change of fluxes, exchanges, and transformations. For example, connectivity can be reduced by dams, levees, culverts, water withdrawals, and habitat destruction, and can be increased by effluent discharges, channelization, drainage ditches and tiles, and impervious surfaces.

6.1.5 Conclusion 5: Cumulative Effects

The incremental effects of individual streams and wetlands are cumulative across entire watersheds and therefore must be evaluated in context with other streams and wetlands. Downstream waters are the time-integrated result of all waters contributing to them. For example, the amount of water or biomass contributed by a specific ephemeral stream in a given year might be small, but the aggregate contribution of that stream over multiple years, or by all ephemeral streams draining that watershed in a given year or over multiple years, can have substantial consequences on the integrity of the downstream waters. Similarly, the downstream effect of a single event, such as pollutant discharge into a single stream or wetland, might be negligible but the cumulative effect of multiple discharges could degrade the integrity of downstream waters.

In addition, when considering the effect of an individual stream or wetland, all contributions and functions of that stream or wetland should be evaluated cumulatively. For example, the same stream transports water, removes excess nutrients, mitigates flooding, and provides refuge for fish when conditions downstream are unfavorable; if any of these functions is ignored, the overall effect of that stream would be underestimated.

6.1.5.1 Conclusion 5, Key Findings

- Structurally and functionally, stream-channel networks and the watersheds they drain are fundamentally cumulative in how they are formed and maintained. Excess water from precipitation that is not evaporated, taken up by organisms, or stored in soils and geologic layers moves downgradient by gravity as overland flow or through channels carrying sediment, chemical constituents, and organisms. These channels concentrate surface-water flows and are more efficient than overland (i.e., diffuse) flows in transporting water and materials, and are reinforced over time by recurrent flows.
- Connectivity between streams and rivers provides opportunities for materials, including nutrients and chemical contaminants, to be transformed chemically as they are transported downstream. Although highly efficient at the transport of water and other physical materials, streams are dynamic ecosystems with permeable beds and banks that interact with other ecosystems above and below the surface. The exchange of materials between surface and subsurface areas involves a series of complex physical, chemical, and biological alterations that occur as materials move through different parts of the river system. The amount and quality of such materials that eventually reach a river are determined by the aggregate effect of these sequential alterations that begin at the source waters, which can be at some distance from the river. The opportunity for transformation of material (e.g., biological uptake, assimilation, or beneficial transformation) in intervening stream reaches increases with distance to the river. Nutrient spiraling, the process by which nutrients entering headwater streams are transformed by various aquatic organisms and chemical reactions as they are transported downstream, is one example of an instream alteration that exhibits significant beneficial effects on downstream waters. Nutrients (in their inorganic form) that enter a headwater stream (e.g., via overland flow) are first removed from the water column by streambed algal and microbial populations. Fish or insects feeding on algae and microbes take up some of those nutrients, which are subsequently released back into the stream via excretion and decomposition (i.e., in their organic form), and the cycle is repeated. In each phase of the cycling process—from dissolved inorganic nutrients in the water column, through microbial uptake, subsequent transformations through the food web, and back to dissolved nutrients in the water column—nutrients are subject to downstream transport. Stream and wetland capacities for nutrient cycling have important implications for the form and concentration of nutrients exported to downstream waters.
- Cumulative effects across a watershed must be considered when quantifying the frequency, duration, and magnitude of connectivity, to evaluate the downstream effects of streams and wetlands. For example, although the probability of a large-magnitude transfer of organisms from any given headwater stream in a given year might be low (i.e., a low-frequency connection when each stream is considered individually), headwater streams are the most abundant type of stream in most watersheds. Thus, the overall probability of a large-magnitude transfer of organisms is higher when considered for all headwater streams in a watershed—that is, a high-

frequency connection is present when headwaters are considered cumulatively at the watershed scale, compared with probabilities of transport for streams individually. Similarly, a single pollutant discharge might be negligible but the cumulative effect of multiple discharges could degrade the integrity of downstream waters. Riparian open waters (e.g., oxbow lakes), wetlands, and vegetated areas cumulatively can retain up to 90% of eroded clays, silts, and sands that otherwise would enter stream channels. The larger amounts of snowmelt and precipitation cumulatively held by many wetlands can reduce the potential for flooding at downstream locations. For example, wetlands in the prairie pothole region cumulatively stored about 11–20% of the precipitation in one watershed.

- The combination of diverse habitat types and abundant food resources cumulatively makes floodplains important foraging, hunting, and breeding sites for fish, aquatic life stages of amphibians, and aquatic invertebrates. The scale of these cumulative effects can be extensive; for example, coastal ibises travel up to 40 km to obtain food from freshwater floodplain wetlands for nesting chicks, which cannot tolerate salt levels in local food resources until they fledge.

6.2 Strength of Evidence for Conclusions and Data Gaps in the Available Literature

This report synthesizes a large body of scientific evidence to address the questions in Table 1-1 of this report. The major conclusions (Section 6.1) reflect the strength of evidence currently available in the peer-reviewed scientific literature for assessing the connectivity and downstream effects of water bodies identified in Table 1-1.

The conclusions of this report were corroborated by two independent peer reviews by scientists identified in the front matter of this report.

The term connectivity is defined in this report as the degree to which components of a watershed are joined and interact by transport mechanisms that function across multiple spatial and temporal scales (Sections 1.2.2 and 2.3.2.1). Our review found strong evidence supporting the central roles of the physical, chemical, and biological connectivity of streams, wetlands, and open waters—encompassing varying degrees of both connection and isolation—in maintaining the structure and function of downstream waters, including rivers, lakes, estuaries, and oceans. Our review also found strong evidence demonstrating the various mechanisms by which material and biological linkages from streams, wetlands, and open waters affect downstream waters, classified here into five functional categories (source, sink, refuge, lag, and transformation), modify the timing of transport and the quantity and quality of resources available to downstream ecosystems and communities. Thus, the currently available literature provided a large body of evidence for assessing the connections and functions by which streams and wetlands produce the range of observed effects on the integrity of downstream waters.

The body of literature on functions provided by streams and riparian/floodplain wetlands was abundant in all five categories (Table 6-1). The body of literature on functions of non-floodplain wetlands was abundant in two categories (sink and transformation) and moderate in the other three categories (source, refuge, and lag; Table 6-1). The evidence unequivocally demonstrates that the stream channels and wetlands or open waters that together form river networks are clearly connected to downstream waters in ways that profoundly influence downstream water integrity. The body of literature documenting connectivity and downstream effects was most abundant for perennial and intermittent streams, and for riparian/floodplain wetlands (Table 6-2). Although less abundant, the available evidence for connectivity and downstream effects of ephemeral streams was strong and compelling, particularly in context with the large body of evidence supporting the physical connectivity and cumulative effects of channelized flows that form and maintain stream networks.

As stated in Conclusion 3 (Section 6.1.3), the connectivity and effects of wetlands and open waters that are not structurally linked to other waters by stream channels and their lateral extensions into riparian areas and floodplains are more difficult to address solely from evidence available in peer-reviewed studies. One limitation was the relatively small number of published, peer-reviewed studies examining the relationships of non-floodplain wetlands to downstream waters (Table 6-2). The literature on non-floodplain wetlands that is available shows that these systems have important hydrologic, water-quality, and habitat functions that can affect downstream waters where connections to them exist; the literature also provides limited examples of direct effects of non-floodplain wetland isolation on downstream water integrity. Currently available peer-reviewed literature, however, does not identify which types of non-floodplain wetlands have or lack the types of connections needed to convey the effects on downstream waters of functions, materials, or biota provided by those wetlands. These limitations of the literature, considered in context with comments from the Science Advisory Board on an external review draft of this report (U.S. EPA, 2014), are reflected in the lower strength of evidence expressed in the conclusions (Section 6.1.3).

Additional information from other sources not included in this report (e.g., field assessments, analysis of existing or new data, reports from local resource agencies) could be used in case-by-case analysis of non-floodplain wetlands. Importantly, information from emerging research into the connectivity of non-floodplain wetlands, including studies of the types identified in Section 4.5.2 of this report, could close some of the current data gaps in the near future. Recent scientific advances in the fields of mapping (e.g., Heine et al., 2004; Tiner, 2011; Lang et al., 2012), assessment (e.g., McGlynn and McDonnell, 2003; Gergel, 2005; McGuire et al., 2005; Ver Hoef et al., 2006; Leibowitz et al., 2008; Moreno-Mateos et al., 2008; Lane and D'Amico, 2010; Ver Hoef and Peterson, 2010; Shook and Pomeroy, 2011; Powers et al., 2012; McDonough et al., 2015), modeling (e.g., Golden et al., 2013; McLaughlin et al., 2014), and landscape classification (e.g., Wigington et al., 2013) indicate that increasing availability of high-resolution data sets, promising new technologies for watershed-scale analyses, and methods for classifying landscape units by hydrologic behavior can facilitate and improve the accuracy of connectivity assessments. Emerging research that expands our ability to detect and monitor ecologically relevant connections at appropriate scales, metrics to accurately measure effects on downstream integrity, and management practices that apply what we already know about ecosystem function, will contribute to our ability to identify waters of national importance and maintain the long-term sustainability and resiliency of valued water resources.

Table 6-1. Relative abundance of literature by functional category. The table shows our confidence, which is based on the relative size of the body of literature documented in the report, in the evidence for source, sink, refuge, lag, and transformation functions of streams and wetlands and their associated effects on downstream waters. A small dot (•) indicates relatively lower confidence, a medium dot (●) indicates relatively intermediate confidence, and a large dot (⬤) indicates a relatively high level of confidence. The dot size does not necessarily correspond with the number of associated citations in this report because some citations are review articles or meta-analyses, which summarize information for many references. The dot size also does not correspond with the level of confidence in particular conclusions.

Type of water body	Function					Uncertainty discussion (Section)
	Source	Sink (Storage)	Refuge	Lag	Transformation	
Streams	Large dot	Large dot	Large dot	Large dot	Large dot	3.6
Riparian/floodplain wetlands	Large dot	Large dot	Large dot	Large dot	Large dot	4.5.1
Non-floodplain wetlands	Medium dot	Large dot	Medium dot	Medium dot	Large dot	4.5.2

Table 6-2. Relative abundance of literature by review topic area. The table shows the relative size of the body of literature documented in the report that addresses the physical, chemical, or biological connectivity to and effects on downstream waters. A small dot (•) indicates a relatively smaller body of literature, a medium dot (●) indicates a relatively intermediate body of literature, and a large dot (⬤) indicates a relatively large body of literature. The dot size does not necessarily correspond with the number of associated citations in this report because some citations are review articles or meta-analyses, which summarize information from many references. The dot size also does not correspond with level of confidence in particular conclusions.

Topic	Question		Biological		Chemical		Physical	
			Connection	Effect	Connection	Effect	Connection	Effect
Streams	What are the physical, chemical, and biological connections to and effects of ephemeral, intermittent, and perennial streams on downstream waters?	ephemeral	[medium dot]	[small dot]	[large dot]	[medium dot]	[large dot]	[medium dot]
		intermittent	[large dot]	[medium dot]	[large dot]	[medium dot]	[large dot]	[medium dot]
		perennial	[large dot]	[large dot]	[large dot]	[large dot]	[large dot]	[large dot]
Riparian/ Floodplain Wetlands	What are the physical, chemical, and biological connections to and effects of riparian or floodplain wetlands and open waters (e.g., riverine wetlands, oxbow lakes) on downstream waters?		[large dot]	[large dot]	[large dot]	[large dot]	[large dot]	[large dot]
Non-floodplain wetlands	What are the physical, chemical, and biological connections to and effects of wetlands and open waters in non-floodplain settings (e.g., most prairie potholes, vernal pools) on downstream waters?		[medium dot]	[small dot]	[medium dot]	[small dot]	[small dot]	[small dot]

APPENDIX A. GLOSSARY

Absorption—A reversible process that occurs when molecules in one state or phase penetrate those of another phase.

Adsorption—Adhesion of molecules to a surface, either physically or chemically. Physical adsorption occurs when the surface tension of a solid causes molecules to be held at its surface; this process can be reversible, depending on environmental conditions. Chemical adsorption occurs when chemicals bond at the surface of a solid, and is not readily reversible.

Allochthonous—Describing organic material that originates from outside of streams, rivers, wetlands, or lakes (e.g., terrestrial plant litter, soil).

Alluvial Aquifer—An aquifer with geologic materials deposited by a stream or river (alluvium) that retains a hydraulic connection with the depositing stream.

Alluvial Deposits—*See* Alluvium.

Alluvial Ground Water—Ground water occurring in an alluvial aquifer.

Alluvium—Deposits of clay, silt, sand, gravel, or other particulate materials that have been deposited by a stream or other body of running water in a streambed, on a flood plain, on a delta, or at the base of a mountain. *See* Colluvium.

Anastomosing Channel—A multithreaded stream or river channel in which the channels (distributaries) branch and rejoin farther downstream; distributary channels are separated by stable islands (usually vegetated) that are large relative to the size of the channels.

Anoxic Conditions—Without detectable dissolved oxygen; anaerobic. *See* Hypoxia.

Aquatic Ecosystem—Any aquatic environment, including all of the environment's living and nonliving constituents and the interactions among them.

Aquifer—A geologic formation (e.g., soil, rock, alluvium) with permeable materials partially or fully saturated with ground water that yields ground water to a well, spring, or stream.

Artificial Drainage—Use of constructed channels or subsurface structures to drain an area by increasing the rate of flow of water from the area.

Assimilatory Processes—The incorporation or transformation of simple compounds into more complex compounds.

Autochthonous—Describing organic matter that originates from production within streams, rivers, wetlands, or lakes (e.g., periphyton, macrophytes, phytoplankton).

Bank Storage—Storage of water that flows from a stream to an alluvial aquifer during a flood or period of high streamflow. The volume of water is stored and released after the high-water event over days to months. The volume of water stored and the timing of release depends on the hydraulic properties of the alluvial aquifer.

Baseflow—Sustained flow of a stream (or river) in the absence of stormflow (direct runoff). Natural baseflow is sustained by ground-water discharge in the stream network. Baseflow also can be sustained by human sources (e.g., irrigation recharges to ground water).

Basin—*See* Drainage Basin*.*

Bedrock—Solid rock underlying loose deposits such as soil or alluvium.

Bog—A peat-accumulating wetland that is generally nutrient poor.

Braided Channel—A multithreaded channel in which the channels (distributaries) branch and rejoin farther downstream and the channels are separated by mobile, transient bars (poorly vegetated) that are small relative to the size of the channels.

Carolina Bays—Elliptical, ponded, depressional wetlands that range along the Atlantic Coastal Plain from northern Florida to New Jersey. *See* Delmarva Bays.

Catchment—The area drained by a stream, river, or other water body; typically defined by the topographic divides between one water body and another. *Synonymous with* Watershed *and* Drainage Basin*.*

Channel—A natural or constructed passageway or depression of perceptible linear extent that conveys water and associated material downgradient.

Channelization—A type of artificial drainage in which complex channels are straightened to increase the rate of water flow from an area.

Channelized Flow—Flow that occurs in a natural or artificial channel.

Colluvium—A layer of unconsolidated soils, sediment and rock fragments deposited by surface runoff and gravitational processes; colluvium generally occurs as a blanket of poorly sorted sediment and rock fragments on the lower parts of hillslopes underlain by bedrock. *See* Alluvium.

Condition—General health or quality of an ecosystem, typically assessed using one or more indicators.

Confined Aquifer—An aquifer bounded above and below by confining units of distinctly lower permeability than that of the aquifer itself.

Confluence—The point at which two stream channels intersect to form a single channel.

Connectivity—The degree to which components of a river system are joined, or connected, by various transport mechanisms; connectivity is determined by the characteristics of both the physical landscape and the biota of the specific system.

Connectivity Descriptors (for streams and wetlands)—The frequency, duration, magnitude, timing, and rate of change of fluxes to and biological exchanges with downstream waters.

Contributing Area—Location within a watershed/river network that serves as a source of stream flow or material flux.

Contaminants—Any material that might be harmful to humans or other organisms when released to the environment.

Deep Ground Water—Ground-water flow systems having the deepest and longest flowpaths; also referred to as regional ground-water flow systems, they can occur beneath local and intermediate ground-water flow systems. *See* Local Ground Water, Regional Ground Water.

Delmarva Bays—Carolina bays that are geographically specific to the Delmarva Peninsula. These wetlands frequently have the same elliptical shape and orientation as Carolina bays. *See* Carolina Bays.

Dendritic Stream Network—A stream network pattern of branching tributaries (see Figure 2-19B).

Depressional Wetland—A wetland occupying a topographic low point that allows the accumulation of surface water. Depressional wetlands can have any combination of inlets and outlets or lack them completely. Examples include kettles, prairie potholes, and Carolina bays. This category also includes slope wetlands (wetlands associated with surface discharge of ground water or saturated overflow with no channel formation).

Diadromous—Migratory between fresh and salt waters.

Direct Runoff—Runoff that occurs in direct response to precipitation. *See* Stormflow.

Discharge—The volume of water (surface water or ground water) that passes a given location over a given period of time; the rate of runoff. Often expressed as $ft^3\ s^{-1}$ or $m^3\ s^{-1}$.

Discontinuous Flow—Refers to stream and river reaches that have flow in one part of the reach but not another part of the reach. *See* Reach.

Dispersal—Movement from natal breeding sites to new breeding sites.

Drainage Area—The spatial extent of a drainage basin. Typically expressed in mi^2 or km^2.

Drainage Basin—The area drained by a stream, river, or other water body; typically defined by the topographic divides between one water body and another. *Synonymous with* Catchment *and* Watershed.

Drainage Density—The total length of stream channels per unit drainage area (e.g., per mi^2 or km^2).

Drainage Network—*See* River Network.

Egg Bank—Viable dormant eggs that accumulate in soil or in sediments under water. *See* Seed bank.

Endorheic Basins—A closed drainage basin with no outflows to other water bodies.

Endorheic Stream—A stream or river reach that experiences a net loss of water to a ground-water system. *See* Losing Stream or Wetland.

Ephemeral Stream—A stream or river that flows briefly in direct response to precipitation; these channels are always above the water table.

Eutrophication—Natural or artificial enrichment of a water body by nutrients, typically phosphates and nitrates. If enrichment leads to impairment (e.g., toxic algal blooms), eutrophication is a form of pollution.

Evapotranspiration—The combined loss of water to the atmosphere due to evaporation and transpiration losses. Transpiration is the loss of water vapor to air by plants.

Fen—A peat-accumulating wetland characterized by mineral-rich water inputs.

Flood—The occurrence of stream or river flow of such magnitude that it overtops the natural or artificial banks in a reach of the stream or river; where a floodplain exists, a flood is any flow that spreads over or inundates the floodplain. Floods also can result from rising stages in lakes and other water bodies.

Flood (100-year)—Flood level (stage or discharge) with a 1% probability of being equaled or exceeded in a given year.

Flood Flows—Discharge or flow of sufficient (or greater) magnitude to cause a flood.

Flood Stage—The stage at which streams or rivers overtop their natural or artificial banks.

Floodwater—Water associated with a flood event.

Floodplain—A level area bordering a stream or river channel that was built by sediment deposition from the stream or river under present climatic conditions and is inundated during moderate to high flow events. Floodplains formed under historic or prehistoric climatic conditions can be abandoned by rivers and form terraces.

Floodplain Wetland—Portions of floodplains that meet the Cowardin et al. (1979) three-attribute definition of a wetland (i.e., having wetland hydrology, hydrophytic vegetation, or hydric soils). *See* Wetland.

Flow—Water movement above ground or below ground.

Flow Duration Class—A classification that assigns streamflow duration to ephemeral, intermittent, or perennial classes.

Flow Regime—Descriptor of flow types in a temporal or magnitude sense (i.e., slow-flow regime, low-flow regime)

Flowpath—*See* Hydrologic Flowpath*.*

Fluvial—Refers to or pertains to streams; e.g., stream processes (fluvial processes), fluvial landforms, such as fluvial islands and bars, and biota living in and near stream channels.

Flux—Flow of materials between system components per unit time.

Gaining Stream or Wetland—A wetland or a stream or river reach that experiences a net gain of water from ground water (see Figure 2-5). In this situation, the water table elevation near the stream or wetland is higher than the stream or wetland water surface. Conditions conducive to losing or gaining streams and wetlands can change over short distances within river networks and river basins. *See* Losing Stream or Wetland.

Geographically Isolated Wetland—A wetland that is completely surrounded by uplands; for example, hydrophytic plant communities surrounded by terrestrial plant communities or undrained hydric soils surrounded by nonhydric soils. This term often is mistakenly understood to mean hydrologically isolated. Geographically isolated wetlands vary in their degree of hydrologic and biotic connectivity.

Ground Water—Any water that occurs and flows in the saturated zone. *See* Saturated Zone.

Ground-water Discharge —The flow of ground water to surface waters; discharge areas occur where the water tables intersect land surfaces. *See* Seep*,* Spring*.*

Ground-water Discharge Wetland—A wetland that receives ground-water discharge.

Ground-water Flow—Flow of water in the subsurface saturated zone.

Ground-water Flow-through Wetland—A wetland that has both ground-water inputs and outputs. Ground water enters the wetland through the upgradient direction and exits the wetland downgradient.

Ground-water Recharge—The process by which ground water is replenished; a recharge area occurs where precipitation or surface water infiltrates and is transmitted downward to the saturated zone (aquifer). *See* Infiltration, Percolation, Transmission.

Ground-water Recharge Wetland—A wetland that recharges ground water.

Ground-water Reservoir—A saturated body of ground water having loosely definable spatial limits.

Ground-water System—Reference to the ground water and geologic materials comprising the saturated zone; the ground-water system, as a whole, is a three-dimensional flow field.

Ground water–Surface water Interactions—Movement of water between surface-water bodies and ground-water systems. Flows can occur in either direction.

Ground-water Withdrawal—Pumping of water from aquifers for human uses.

Habitat—Environment (place and conditions) in which organisms reside.

Headwater—Areas from which water originates within a river or stream network. This term typically refers to stream channels but can also describe wetlands or open waters, such as ponds.

Headwater Stream—Headwater streams are first- to third-order streams. Headwater streams can be ephemeral, intermittent, or perennial. *See* Stream Order, Flow Duration Class*.*

Hillslope—A sloping segment of land surface.

Hydraulic Conductivity—A measure of the permeability of a porous medium. For a given hydraulic gradient, water moves more rapidly through media with high hydraulic conductivity than low hydraulic conductivity.

Hydraulic Gradient—Slope of the water table. *See* Water Table.

Hydraulic Head—The height above a standard datum of the surface of a column of water that can be supported by the static pressure at a given point; for a well, the hydraulic head is the height of the water level in the well compared to a datum elevation.

Hydraulics—The physics of water in its liquid state.

Hydric—An area, environment, or habitat that is generally very wet with plenty of moisture. *See* Mesic, Xeric.

Hydrograph—A graph of stream or river discharge over time. Stage or water table elevation also can be plotted.

Hydrologic Event—An increase in streamflow resulting from precipitation or snowmelt.

Hydrologic Flowpath—The pathway that water follows as it moves over the watershed surface or through the subsurface environment.

Hydrology—The study of the properties, distribution, and effects of water as a liquid, solid, and gas on Earth's surface, in the soils and underlying rocks, and in the atmosphere.

Hydrologic Landscape—A landscape with a combination of geology, soils, topography, and climate that has characteristic influences on surface water and ground water.

Hydrologic Permanence—The frequency and duration of streamflow in channels or the frequency and duration of standing water in wetlands.

Hyporheic Flow—Water from a stream or river channel that enters subsurface materials of the streambed and bank and then returns to the stream or river.

Hyporheic Exchange—Water and solutes exchanged between a surface channel and the shallow subsurface. *See* Hyporheic Flow*.*

Hyporheic Zone—The area adjacent to and beneath a stream or river in which hyporheic flow occurs. The dimensions of the hyporheic zone are controlled by the distribution and characteristics of alluvium and hydraulic gradients between streams and local ground water.

Hypoxia—The condition in which dissolved oxygen is below the level necessary to sustain most animal life. *See* Anoxic Conditions.

Infiltration—The downward entry of water from the land surface into the subsurface.

Infiltration Capacity—The maximum rate at which infiltration can occur at a given location.

Interfluve—The area of higher terrain between adjacent stream valleys.

Intermediate Ground Water—Ground-water flow systems representative of the wide range of flowpath lengths and depths that occur between local and regional ground-water systems.

Intermittent—This term also can be applied to other surface-water bodies and ground-water flow or level*. See* Intermittent Stream.

Intermittent Stream—A stream or portion of a stream that flows continuously only at certain times of year; for example, when it receives water from a spring, ground-water source, or a surface source such as melting snow. At low flow, dry segments alternating with flowing segments can be present.

Inundation—To cover dry land with floodwaters.

Isolation—Condition defined by reduced or nonexistent transport mechanisms between system components.

Isotopic Tracer—*See* Stable Isotope Tracer.

Lag Function—Any function within a stream or wetland that provides temporary storage and subsequent release of materials without affecting cumulative flux (exports = imports); delivery is delayed and can be prolonged.

Lateral Source Stream—A first-order stream that flows into a higher order stream.

Lentic—Of, relating to, or living in still water. *See* Lotic.

Levee (Artificial)—An engineered structure built next to a stream or river from various materials to prevent flooding of surrounding areas. The levee raises the elevation of the channel height to convey greater discharge of water without flooding.

Levee (Natural)—A broad, low ridge or embankment of coarse silt and sand that is deposited by a stream on its floodplain and along either bank of its channel. Natural levees are formed by reduced velocity of flood flows as they spill onto floodplain surfaces and can no longer transport the coarse fraction of the suspended sediment load.

Local Ground Water—Ground water with a local flow system. Water that recharges at a high point in the water table that discharges to a nearby lowland. Local ground-water flow is the most dynamic and shallowest of ground-water flow systems. Therefore, it has the greatest interchange with surface water. Local flow systems can be underlain by intermediate and regional flow systems. Water in these deeper flow systems have longer flowpaths and longer contact time with subsurface materials. Deeper flow systems also eventually discharge to surface waters and influence their condition.

Losing Stream or Wetland—A stream, wetland, or river reach that experiences a net loss of water to a ground-water system (see Figure 2-5). In this situation, the water table elevation near the stream or wetland is lower than the stream or wetland water surface. Conditions conducive to losing or gaining streams and wetlands can change over short distances within river networks and river basins. *See* Gaining Stream or Wetland.

Lotic—Of, relating to, or living in moving water. *See* Lentic.

Mainstem—Term used to distinguish the larger (in terms of discharge) of two intersecting channels in a river network.

Materials—Any physical, chemical, or biological entity, including but not limited to water, heat energy, sediment, wood, organic matter, nutrients, chemical contaminants, and organisms.

Meltwater—Liquid water that results from the melting of snow, snowpacks, ice, or glaciers.

Mesic—An area, environment, or habitat with a moderate amount of moisture. *See* Hydric, Xeric.

Migration—Long-distance movements undertaken by organisms on a seasonal basis.

Non-floodplain Wetland—An area outside of the floodplain that meets the Cowardin et al. (1979) three-attribute definition of a wetland (i.e., having wetland hydrology, hydrophytic vegetation, or hydric soils). For the purposes of this report, riparian wetlands that occur outside of the floodplain are not included as non-floodplain wetlands, since these wetlands are subject to bidirectional, lateral hydrologic flows. *See* Floodplain, Wetland*.*

Nutrients (In Aquatic Systems)—Elemental forms of nitrogen, phosphorus, and trace elements, including sulfur, potassium, calcium, and magnesium, that are essential for the growth of organisms but can be contaminants when present in high concentrations.

Nutrient Spiraling—Longitudinal cycles ("spirals") of nutrient uptake and release along the stream or river continuum. The spirals are created as aquatic organisms consume, transform, and regenerate nutrients, altering the rates of nutrient transport to downstream waters.

Open-channel Flow—Water flowing within natural or artificial channels.

Open Waters—Nontidal lentic water bodies such as lakes and oxbow lakes that are frequently small or shallow.

Overbank Flow—Streamflow that overtops a stream or river channel.

Overland Flow—The portion of streamflow derived from net precipitation that fails to infiltrate the land surface at any point and runs over the surface to the nearest stream channel.

Oxbow Lakes—Water bodies that originate from the cutoff meanders of rivers; such lakes are common in floodplains of large rivers.

Peatland—A wetland that accumulates partially decayed organic matter. Fens and bogs are common examples.

Perched Ground Water—Unconfined ground water separated from an underlying body of ground water by an unsaturated zone; perched ground water is supported by a perching layer (bed) for which the permeability is so low that water percolating downward to the underlying unsaturated zone is restricted.

Perching Water Tables—*See* Perched Ground Water.

Percolation—The downward movement of water through soil or rock formations.

Perennial— *See* Perennial Stream. This term can be applied to other surface-water bodies and to ground-water flow or level.

Perennial Stream—A stream or portion of a stream that flows year-round and is maintained by local, intermediate, or regional ground-water discharge or flow from higher in the river network.

Permanent Waters—Water bodies that contain water year-round; perennial waters.

Permeability—Property of a porous medium that enables it to transmit fluids under a hydraulic gradient. For a given hydraulic gradient, water will move more rapidly through high permeability materials than low permeability materials.

Phreatophyte—Plants that use water from the saturated zone.

Potential Evapotranspiration—The amount of water that would be lost to the atmosphere over a given area through evaporation and transpiration, assuming no limits on the water supply. *See* Evapotranspiration.

Potentiometric Surface—The surface representing the level to which ground water will rise in a well penetrating a confined aquifer.

Prairie Potholes—Complex of glacially formed wetlands, usually lacking natural outlets, found in the central United States and Canada.

Precipitation—Water that condenses in the atmosphere and falls to a land surface. Common types include rain, snow, hail, and sleet.

Precipitation Intensity—The rate at which precipitation occurs; generally refers to rainfall intensity.

Primary Production—The fixation of inorganic carbon into organic carbon (e.g., plant and algae biomass) through the process of photosynthesis. Primary production is the first level of the food web, and provides most of the autochthonous carbon produced in ecosystems. The rate of fixation is referred to as gross primary productivity (GPP) or net primary productivity (NPP), where NPP is equal to GPP minus respiration. *See* Respiration, Secondary Production.

Propagule—Any part of an organism that can give rise to a new individual organism. Seeds, eggs, and spores are propagules.

Reach—A length of stream channel with relatively uniform discharge, depth, area, and slope.

Recession [of Flow)—Decrease in flow following a hydrologic event.

Recharge Area—An area in which water infiltrates the surface and reaches the zone of saturation.

Refuge Function—The protective function of a stream or wetland that allows an organism (or material) to avoid mortality (or loss) in a nearby sink area, thereby preventing the net decrease in material flux that otherwise would have occurred (exports = imports). This term typically refers to organisms but can be used for nonliving materials. *See* Sink Function.

Regional Ground Water—Ground water with a deep, regional-scale flow system; also referred to as deep ground water. These flow systems can occur beneath local and intermediate ground-water flow systems. *See* Local Ground Water, Deep Ground Water.

Respiration—The chemical process by which organisms break down organic matter and produce energy for growth, movement, and other biological processes. Aerobic respiration uses oxygen and produces carbon dioxide.

Return Flow—Water that infiltrates into a land surface and moves to the saturated zone and then returns to the land surface (or displaces water that returns to the soil surface).

Riparian Areas—Transition areas or zones between terrestrial and aquatic ecosystems that are distinguished by gradients in biophysical conditions, ecological processes, and organisms. They are areas through which surface hydrology and subsurface hydrology connect water bodies with their uplands. They include those portions of terrestrial ecosystems that significantly influence exchanges of energy and matter with aquatic ecosystems. Riparian areas are adjacent to perennial, intermittent, and ephemeral streams, lakes, and estuarine-marine shorelines. *See* Upland.

Riparian Wetland—Portions of riparian areas that meet the Cowardin et al. (1979) three-attribute definition of a wetland (i.e., having wetland hydrology, hydrophytic vegetation, hydric soils). *See* Wetland.

River—A relatively large volume of flowing water within a visible channel, including subsurface water moving in the same direction as the surface water, and lateral flows exchanged with associated floodplain and riparian areas. *See* Stream.

River Network—A hierarchical, interconnected population of channels or swales that drain water to a river. Flow through these channels can be perennial, intermittent, or ephemeral.

River Network Expansion/Contraction—The extent of flowing water in a river network increases during wet seasons and large precipitation events and decreases during dry periods. *See* Variable Source Area.

River System—A river and its entire drainage basin, including its river network, associated riparian areas, floodplains, alluvial aquifers, regional aquifers, connected water bodies, geographically isolated water, and terrestrial ecosystems.

Runoff—The part of precipitation, snowmelt, or other flow contributions (e.g., irrigation water) that appears in surface streams at the outlet of a drainage basin; it can originate from both above land surface (e.g., overland flow) and below land surface sources (e.g., ground water). Units of runoff are depth of water (similar to precipitation units, e.g., mm). This measurement is the depth of water if it were spread across the entire drainage basin. Can also be expressed as a volume of water (i.e., m^3, $feet^3$, acre-ft).

Saturated Zone—The zone below the land surface where the voids in soil and geologic material are completely filled with water. Water in the saturated zone is referred to as ground water. The upper surface of the saturated zone is referred to as the water table. *See* Ground Water, Unsaturated Zone, Water Table.

Saturation Overland Flow—Water that falls onto a saturated land surface and moves overland to the nearest stream or river.

Seasonality—Refers to the seasonal distribution of water surplus of a river system. *See* Water Surplus.

Secondary Production—The generation of biomass of consumer organisms that feed on organic material from primary producers (algae, microbes, aquatic and terrestrial plants), and biomass of predators that feed on consumer organisms. *See* Primary Production.

Seed Bank—Viable dormant seeds that accumulate in soil or in sediments under water. *See* Egg bank.

Seep—A small area where water slowly flows from the subsurface to the surface. A seep can also refer to a wetland formed by a seep; such a wetland is referred to as a ground-water slope wetland.

Seepage—Water that flows from a seep.

Shallow Ground Water—Ground water with shallow hydrologic flowpaths. *See* Local Ground Water.

Sink Function—Any function within a stream or wetland that causes a net decrease in material flux (imports exceed exports).

Snowpack—Accumulation of snow during the winter season; an important source of water for streams and rivers in the western United States.

Snowmelt—The complete or partial melting and release of liquid water from seasonal snowpacks.

Solute—A substance that is dissolved in water.

Source Area—The originating location of water or other materials that move through a river system.

Source Function—Any function within a stream or wetland that causes a net increase in material flux (exports exceed imports).

Spillage—Overflow of water from a depressional wetland to a swale or channel.

Spring—A surface-water body formed when the side of a hill, a valley bottom, or other excavation intersects a flowing body of ground water at or below the local water table.

Stable Isotope Tracer—Certain elements such as oxygen, hydrogen, carbon, and nitrogen have multiple isotopes that occur in nature that do not undergo radioactive decay. These isotopes can be used to track the source and movement of water and other substances.

Stage—The elevation of the top of a water surface.

Stream—A relatively small volume of flowing water within a visible channel, including subsurface water moving in the same direction as the surface water, and lateral flows exchanged with associated floodplain and riparian areas. *See* River.

Stream Burial—The process of incorporating streams—particularly headwaters—into storm sewer systems, usually by routing through underground pipes.

Stream Power—A measure of the erosive capacity of flowing water in stream channels or the rate of energy dissipation against the stream bed or banks per unit of channel length that has the mathematical form: $\omega_a = \rho gQS$ where ω_a is the stream power, ρ is the density of water (1000 kg/m^3), g is acceleration due to gravity (9.8 m/s^2), Q is discharge (m^3/s), and S is the channel slope.

Stream Network—*See* River Network. A stream network is the same as river network, but typically refers to a smaller spatial scale.

Stream Reach—*See* Reach.

Storm—A precipitation event that produces an increase in streamflow.

Stormflow—The part of flow through a channel that occurs in direct response to precipitation; it includes surface and subsurface sources of flow. *See* Direct Runoff.

Stream Order (Strahler)—A method for stream classification based on relative position within a river network, when streams lacking upstream tributaries (i.e., headwater streams) are first-order streams and the junction of two streams of the same order results in an increase in stream order (i.e., two first-order streams join to form a second-order stream, two second-order streams join to form a third-order stream, and so on). When streams of different order join, the order of the larger stream is retained. Stream-order classifications can differ, depending on the map scale used to determine order.

Streamflow—Flow of water through a stream or river channel. *See* Discharge.

Subsurface Water—All water that occurs below the land surface.

Surface Runoff—*See* Overland Flow.

Surface Water—Water that occurs on Earth's surface (e.g., springs, streams, rivers, lakes, wetlands, estuaries, oceans).

Surface-water Bodies—Types of water bodies that comprise surface water. *See* Surface Water.

Swale—A nonchannelized, shallow trough-like depression that carries water mainly during rainstorms or snowmelt. A swale might or might not be considered a wetland depending on whether it meets the Cowardin et al. (1979) three-attribute wetland criteria. *See* Wetland.

Symmetry Ratio—The size ratio of a minor tributary ($T2$) to a major tributary ($T1$) at a confluence. Discharge ($Q2/Q1$), drainage area ($A2/A1$), or channel width ($W2/W1$) can be used to characterize the ratio of tributary size.

Terminal Source Stream—A first-order stream that intersects another first-order stream.

Terrace—An historic or prehistoric floodplain that has been abandoned by its river and is not currently in the active floodplain. *See* Floodplain.

Terrene Wetlands—"Wetlands surrounded or nearly so by uplands and lacking a channelized outlet stream; a stream may enter or exit this type of wetland but it does not flow through it as a channel; includes a variety of wetlands and natural and human-made ponds" (Tiner, 2011).

Tracer—A substance that can be used to track the source and movement of water and other substances.

Transformation Function—Any function within a stream or wetland that converts a material into a different form; the amount of the base material is unchanged (base exports equal base imports), but the mass of the different forms can vary.

Transmission Loss—The loss of runoff water by infiltration into stream and river channel beds as water moves downstream; this process is common in arid and semiarid environments.

Transport Mechanism—Any physical mechanism, such as moving water, wind, or movement of organisms, which can transport materials or energy. As used in this report, the term specifically refers to physical mechanisms that move material or energy between streams or wetlands and downstream waters.

Tributary—A stream or river that flows into a higher order stream or river.

Turnover Length—The ratio of the downstream flux of organic carbon to ecosystem respiration per length of stream. It approximates the average distance that organic carbon is expected to travel before it is consumed and mineralized by aquatic organisms.

Unconfined Aquifer—An aquifer that has a water table; the aquifer is not bounded by lower permeability layers. *See* Confined Aquifer.

Unsaturated Zone— Also referred to as the vadose zone. The zone between land surface and the water table within which the moisture content is less than saturation and pressure is less than atmospheric. Soil pore spaces also typically contain air or other gases. *See* Saturated Zone.

Uplands—(1) Higher elevation lands surrounding streams and their floodplains. (2) Within the wetland literature, specifically refers to any area that is not a water body and does not meet the Cowardin et al. (1979)-attribute wetland definition. *See* Wetland.

Uptake Length (for dissolved nitrogen in streams)—The distance traveled in the water column before algal and microbial assimilation occurs.

Valley—A depression of the earth's surface that drains water between two upland areas.

Variable Source Area—Neither stormflow nor baseflow is uniformly produced from the entire surface or subsurface area of a basin. Instead, the flow of water in a stream at any given moment is influenced by dynamic, expanding or shrinking source areas, normally representing only a few percent of the total basin areas. The source area is highly variable during stormflow. During large rainfall or snowmelt events, the flowing portions of the river network, and associated source areas, expand. As the event ends, the network and source areas contract.

Vernal Pool—Shallow seasonal wetlands that generally accumulate water during colder, wetter months and gradually dry down during warmer, dryer months.

Water Balance—The accounting of the volume of water that enters, leaves, and is stored in a hydrologic unit, area, or arbitrarily defined control volume, typically a drainage basin or aquifer, during a specified period of time.

Water Body—Any sizable accumulation of water on the land surface, including streams, rivers, lakes, and wetlands.

Water Surplus—Water that is available for streamflow or recharge of ground water; precipitation minus evapotranspiration.

Water Table—The top of the zone of saturation of an unconfined aquifer.

Watershed—The area drained by a stream, river, or other water body; typically defined by the topographic divides between one water body and another. *Synonymous with* Catchment *and* Drainage Basin*.*

Wet Channel—Channel with flowing or standing water.

Wetland—An area that generally exhibits at least one of the following three attributes (Cowardin et al., 1979): (1) is inundated or saturated at a frequency sufficient to support, at least periodically, plants adapted to a wet environment; (2) contains undrained hydric soil; or (3) contains nonsoil saturated by shallow water for part of the growing season.

Wetland Storage—The capacity of a wetland to detain or retain water from various sources.

Xeric—An area, environment, or habitat that is generally dry with very little moisture. *See* Hydric, Mesic.

APPENDIX B. CASE STUDIES

B.1 Case Study: Carolina and Delmarva Bays

B.1.1 Abstract

Carolina and Delmarva bays are ponded depressional wetlands that occur along the Atlantic Coastal Plain from northern Florida to New Jersey. Most bays receive water through precipitation, lose water through evapotranspiration, and lack natural surface outlets. Both mineral-based and peat-based bays have shown connections to shallow ground water. Bays typically are near each other or near permanent waters, providing the potential for surface-water connections in large rain events via overland flow. Fish are reported in bays that are known to dry out, indirectly demonstrating surficial connections. Amphibians and reptiles use bays extensively for breeding and for rearing young. These animals can disperse many meters on the landscape and can colonize, or serve as a food source to, downstream waters. Similarly, bays foster abundant insects that can become part of the downstream food web. Humans have ditched and channelized a high percentage of bays, creating new surface connections to other waters and allowing transfer of nutrients, sediment, and methylmercury.

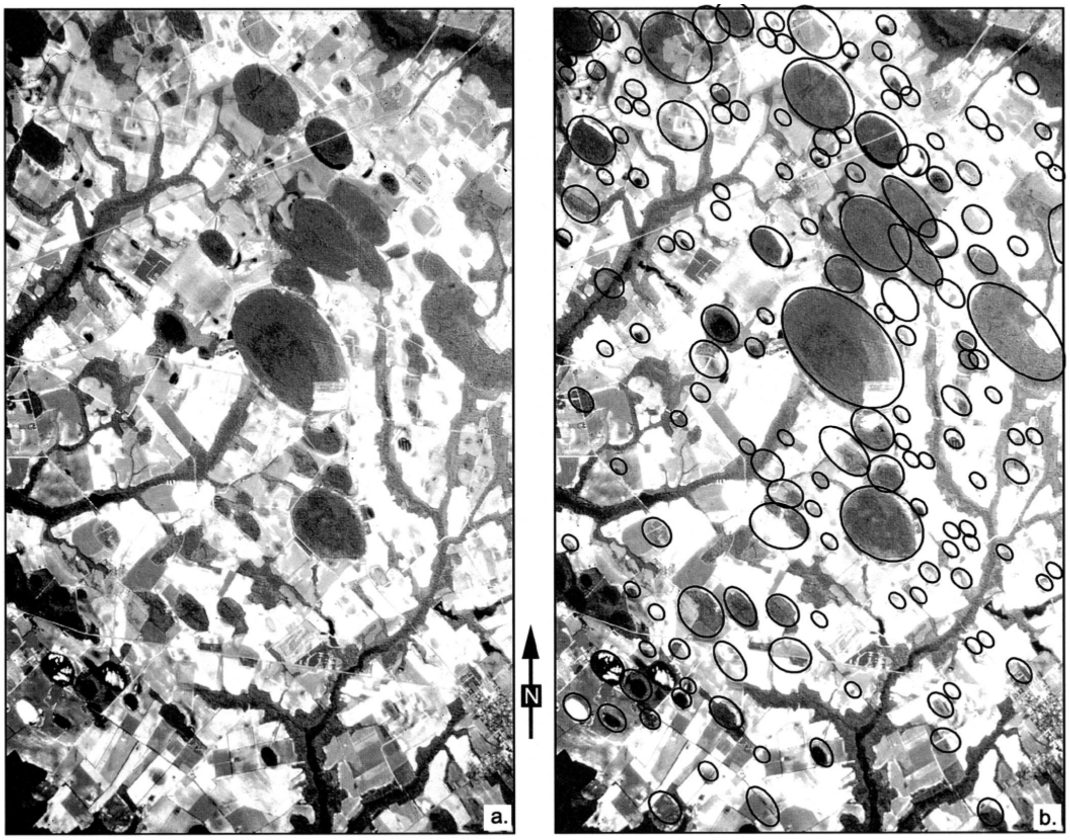
B.1.2 Introduction

B.1.2.1 Definition and Geographic Extent

Carolina bays are elliptical, ponded, depressional wetlands that occur along the Atlantic Coastal Plain from northern Florida to New Jersey (Prouty, 1952; Williams, 1996; Hunsinger and Lannoo, 2005). They have been called "geographically isolated" wetlands (i.e., wetlands surrounded by uplands; Tiner, 2003), and range from permanently inundated to frequently dry (Sharitz, 2003). Carolina bays range in size from greater than 3,600 ha to less than 1 ha and are most abundant in North Carolina and South Carolina (Sharitz and Gibbons, 1982; Sharitz, 2003). Carolina bays that are geographically specific to the Delmarva Peninsula are often referred to as Delmarva bays. Delmarva bays frequently have the same elliptical shape and orientation as other Carolina bays (Stolt and Rabenhorst, 1987a), yet some lack the shape or rim (Sharitz, 2003).

The number of Carolina bays was estimated at 500,000 in the 1950s (Prouty, 1952), but only 10,000–20,000 remained by the early 1990s (Richardson and Gibbons, 1993). Carolina and Delmarva bays have been ditched and drained for agricultural purposes (Figure B-1; Sharitz, 2003). A study of 2,651 Carolina bays in South Carolina found that 97% of bays larger than 0.8 ha had been disturbed by agriculture or logging (Bennett and Nelson, 1991). The northern Delmarva Peninsula has an estimated 1,500–2,500 Delmarva bays remaining (Stolt and Rabenhorst, 1987a). The number of Carolina and Delmarva bays is likely an underestimation, because many are too small to be readily mapped. The National Wetlands Inventory maps have mapping units of 0.4–1.2 ha, but the Department of Energy's

Figure B-1. Aerial photograph of Carolina bays within a region of the upper Coastal Plain of South Carolina. (A) Infrared image showing the pattern of intact and disturbed Carolina bays within a region of the upper Coastal Plain of South Carolina (scale: 1 cm = 1.5 km), and (B) the same image with bays (or former bays that have been disturbed by agriculture) outlined. Reprinted with permission from Sharitz (2003).



Savannah River Site on the upper Coastal Plain of South Carolina has 371 known Carolina bays with 46% having an area of 1.2 ha or less (Sharitz, 2003).

B.1.2.2 Geology

The origin of Carolina and Delmarva bays is unknown, but has been attributed to meteorite impacts, substrate dissolution, and historic modification of shallow ponds through the action of waves generated by winds (Johnson, 1942; Savage, 1982; Ross, 1987; Stolt and Rabenhorst, 1987a; Grant et al., 1998). The soils of Carolina and Delmarva bays range from mineral to organic depending on the position in the landscape, hydrologic conditions, vegetation, and disturbance (Stolt and Rabenhorst, 1987b; Sharitz, 2003). Most bays have alternating layers of sand or silt with impervious clay (Bliley and Pettry, 1979). The organic horizons in bays can range from 1 to 200 cm, with bays near the coast more likely to have the thicker peat deposits (Newman and Schalles, 1990). Despite variation in soil content, water often quickly infiltrates these soils before reaching an impervious clay layer (Sharitz, 2003).

B.1.2.3 Hydrology

Carolina and Delmarva bays gain water primarily from precipitation and lose water by evapotranspiration (Sharitz, 2003). Thus, these systems respond to seasonal rainfall, snowmelt, and temperature. The water levels of Carolina and Delmarva bays therefore fluctuate. The water level in a bay can change from 1−2 m above the soil surface to more than 1 m below the surface (Knight et al., 1989; Schalles and Shure, 1989; Lide et al., 1995; Sharitz, 2003). Bays often are wetter in winter and early spring, when evapotranspiration rates are low, and tend to dry down in summer when evapotranspiration rates are high. Recent work by Lang et al. (2012) using highly accurate LiDAR-derived stream maps has shown that the proportion of wetlands intersected by stream channels (and thus not geographically isolated) is higher than previously thought.

In an analysis of the Tuckahoe Creek watershed in the Delmarva Peninsula, the High Resolution NHD and NHD Plus were found to underestimate the number of wetlands intersected by natural stream channels by 13% and 27%, respectively (Lang et al., 2012). Other hydrologic inputs to bays include artesian wells (Wells and Boyce, 1953), shallow ground water (Phillips and Shedlock, 1993; Lide et al., 1995; Caldwell et al., 2007b), inlet channels (Sharitz, 2003), and some surface runoff during periods of high rainfall. Some bays, particularly those along the coast, can be flooded by high tides and thus are connected to coastal waters (Bliley and Pettry, 1979; Sharitz, 2003).

Despite the prevalence of clay substrates below many of these bays, some studies have found that bays exchange shallow ground water with the surroundings (Phillips et al., 1993; Lide et al., 1995; Sun et al., 2006; Caldwell et al., 2007a; Pyzoha et al., 2008). Some Carolina bays have natural outlet channels (Sharitz, 2003), and many have human-created outlet channels (i.e., ditches) typically resulting in connections to other bays or small streams (Sharitz, 2003).

B.1.2.4 Water Chemistry

Water chemistry of Carolina and Delmarva bays is affected by their position on the landscape, weathering of underlying mineral substrate, accrual and decomposition of organic matter, and the degree to which surface runoff, precipitation, and ground water influence their hydrology (Sharitz, 2003). In general, precipitation-fed wetlands are typically acidic and low in nutrients (Whigham and Jordan, 2003).

Newman and Schalles (1990) reported variable water chemistry in a study of 49 Carolina bays in North Carolina and South Carolina that spanned two transects from inland to the coast. All 49 bays were acidic (median pH = 4.6) and were classified as soft waters (median calcium = 1.69 mg Ca^{2+} L^{-1}). DOC represented 38% of the water anions (median DOC = 17.2 mg L^{-1}). Bays with thick peat layers tended to be low in nutrients, whereas bays with thin peat layers had water quality characteristics similar to local ground water (Newman and Schalles, 1990). Phillips and Shedlock (1993) also associated bay water chemistry with shallow ground water; their study found similarities in water chemistry between upland ground water and the margins of three Delmarva bays. The few studies of nutrient cycling within bays indicate some have the proper wetting and drying cycles to promote denitrification.

Several studies have shown that Carolina bays have the proper hydrology, organic matter content, and pH for the methylation of mercury (Snodgrass et al., 2000b; Brant et al., 2002). Mercury pollution enters water bodies from atmospheric deposition, typically in the ionic form of Hg^{2+}. Bacteria can convert Hg^{2+} to methylmercury, the bioavailable form of mercury that can accumulate in fish, birds, and other organisms. Periodic drying and flooding of Carolina bays, especially shallow ones, promotes mercury methylation and release (Snodgrass et al., 2000b). Mercury levels did not reach acute doses but posed a chronic risk to fish (Snodgrass et al., 2000b) and birds that feed on these fish (Brant et al., 2002).

B.1.2.5 Biological Communities

The wetting and drying cycles of Carolina and Delmarva bays promote a diverse biota, including the presence of numerous rare and endemic species (Sutter and Kral, 1994; Edwards and Weakley, 2001; Sharitz, 2003). Eleven types of vegetation communities have been described in regional surveys of Carolina bays, including species-rich herbaceous communities and cypress ponds (Bennett and Nelson, 1991; Weakley and Schafale, 1991). A seed bank study at the Savannah River Site in South Carolina reported higher diversity than any other reported freshwater wetland habitat (Kirkman and Sharitz, 1994). Researchers estimate that more than one-third of rare plant species in the Southeast occur in nonalluvial wetlands, including Carolina bays (Sutter and Kral, 1994; Sharitz, 2003).

Carolina and Delmarva bays are highly valuable for providing habitat and food web support for invertebrates and vertebrates (Sharitz, 2003). For example, a Savannah River Site study of zooplankton found 44 species of cladocerans and 7 species of copepods (Mahoney et al., 1990). Another invertebrate study showed that a 1.5-ha Carolina bay contained 115 taxa of aquatic and semiaquatic insects from 29 families and 7 orders; more than 11,600 and 8,400 insects emerged from the bay in 1992 and 1993, respectively (Leeper and Taylor, 1998).

Approximately 10−21% of sampled Carolina and Delmarva bays had fish populations (Gibbons and Semlitsch, 1991; Snodgrass et al., 2000a; Sharitz, 2003). The absence of predatory fish in many bays enables abundant amphibian populations to thrive, especially those that have aquatic larval stages (Sharitz and Gibbons, 1982; Sharitz, 2003). For example, one study sampled two 1-ha bays over the course of a year and captured more than 72,000 amphibians, including 9 salamander and 16 frog species (Sharitz and Gibbons, 1982). The Savannah River Site supports 34 species of amphibians, 16 of which depend entirely on seasonal wetlands for breeding (Gibbons and Semlitsch, 1991). Several of these amphibians are endangered or threatened, including the flatwoods salamander (*Ambystoma cingulatum*) and the gopher frog (*Rana capito*) (Sharitz, 2003).

Sharitz and Gibbons (1982) reported 6 turtle species, 9 lizard species, 19 snake species, and 13 small mammal species in bays. American alligators (*Alligator mississippiensis*) are indigenous to southern Carolina bays (Sharitz and Gibbons, 1982). Endangered wood storks (*Mycteria americana*) nest in Carolina bays, and birds such as egrets, coots, wood ducks, and other migratory waterfowl also use Carolina and Delmarva bays (Sharitz and Gibbons, 1982).

B.1.3 Evidence of Connectivity

B.1.3.1 Physical Connections

Research is ongoing on the hydrologic connectivity of Carolina and Delmarva bays to surrounding areas via ground-water flows and intermittent surface flows. A few studies have found ground-water connections or indirect evidence of surface-water connections.

A study by Lide et al. (1995) found a ground-water connection to a Carolina bay. The study examined a 7-ha Carolina bay on the Savannah River Site typical of other bays in western South Carolina with loamy-sand substrate and an underlying clay layer (Lide et al., 1995). The 2-year study examined data from 38 piezometers, borehole logs, pond-stage records, and weather data. They concluded that the Carolina bay was not a perched wetland, but a surface expression of the water table. Although fluctuation of pond stage was largely controlled by precipitation and evapotranspiration, nearly continuous shallow ground-water recharge was present and shallow ground-water discharge occurred periodically.

Phillips and Shedlock (1993) studied three Delmarva bays and also concluded that the bays were connected to local ground water. They studied water table levels and chemistry in transects that ran from uplands through the Delmarva bays. Local ground water strongly influenced the height of the water table in the Delmarva bays. The ground water also was attributed to maintaining a low pH, contributing dissolved aluminum and lowering bicarbonate in the Delmarva bay (Phillips et al., 1993).

Another Carolina bay study in western South Carolina also found evidence for ground-water connectivity (Pyzoha et al., 2008). The more than 13-year study examined piezometer and bay water levels monthly in an 8-ha bay with sandy-loam substrate and an underlying clay layer. Researchers concluded that surface-water and ground-water connections were important to bay hydrology and the bay was not an isolated system. Sun et al. (2006) incorporated climate, vegetation, and soil information to model the hydrology of this bay, which confirmed that the bay was receiving ground-water discharge and recharging ground water to lower topographic areas.

Caldwell et al. (2007b) also used a model to understand the hydrology of three Carolina bays in North Carolina and inferred ground-water connections. All three bays were larger than 100 ha, and their hydrology had not been altered by artificial drainage. Soil types were mineral on the perimeter to mostly organic in the center. The team modeled bay hydrology using climate, vegetation, soils, and hydrology data. They estimated that 10% of water inputs to the bays were surface runoff. Ground-water inflow was the source of 3−26% of water volume into the perimeter of the bays, and ground-water outflow volume (2−21%) was frequent in the center of the bays (Caldwell et al., 2007b).

In addition to ground water, several studies infer Carolina and Delmarva bays are connected to other water bodies through surface-water connections. For example, a study of Carolina bays in Virginia revealed that several of the largest bays were at sea level and bordered the Chesapeake Bay (Bliley and Pettry, 1979). Tidal marshes have encroached and entered these Carolina bays, reflecting a direct link between the Carolina bays and the estuarine environment.

Researchers have used geographic information system methods to determine the nearest river or tributary to Carolina bays (Sharitz, 2003). A geographic information system analysis at the Savannah River Site of 371 Carolina bays showed that 8% were within 50 m of a stream or tributary and 12% were within 100 m (mapping units with a minimum resolution of 0.22 ha; Sharitz, 2003). The same methods showed that 12% of the 2,170 Delmarva bays in Maryland were within 50 m and 19% were within 100 m of streams (mapping units with a minimum resolution of 0.40 ha; Sharitz, 2003). During large storms, the bays located closest to the river network can exhibit hydrologic connections via overland flow or shallow ground-water flow.

Perhaps the strongest evidence that Carolina bays are connected hydrologically to streams or estuaries is that many of these bays are ditched, creating a conveyance for surface water. These ditches commonly connect the surface water of bays to other bays that are lower on the landscape, and ultimately, to streams (Sharitz, 2003).

B.1.3.2 Chemical Connections

Few peer-reviewed papers examine chemical connections between Carolina and Delmarva bays and other waters. One, by Phillips et al. (1993), examined ground water in the Delmarva Peninsula and found that the amount of nitrate in ground water decreased with the presence of forested depressional bays. The authors speculated that the nitrate reduction was due to denitrification in the wetlands. These systems do have the appropriate wetting and drying hydrology to promote denitrification, which could reduce the amount of nitrate in both ground water and surface waters (Groffman et al., 1992).

Carolina and Delmarva bays are frequently connected chemically to downstream waters through ditches. If the bays are sediment and nutrient sinks due to their surficial isolation, ditch connections would make them sources for these materials. For example, Bennett and Nelson (1991) reported that 71% of 2,600 bays were disturbed by agriculture. Whereas the bays might have been a nutrient sink for excess fertilizer that was in surface runoff, these nutrients now could pass through the bays and into the ditches, reaching downstream locations. Additionally, the conditions in Carolina bays have been shown to promote mercury methylation (Snodgrass et al., 2000b). If these bays connect to downstream waters via ditches, some bioavailable mercury would be expected to move to other waters.

B.1.3.3 Biological Connections

Carolina and Delmarva bays are "hotspots" for regional biological diversity and animal use (Sharitz, 2003), which indicates a high potential for movement between bays and other water bodies. The current published evidence for biological connections between bays and other waters is, however, limited or indirect.

The presence of fish in Carolina and Delmarva bays indirectly demonstrates that these bays are connected to other waters. For example, fish were found in 21% of 63 Carolina bays on the Savannah River Site, many of which dry out during parts of the year; fish likely colonized these bays through intermittent or permanent surface hydrologic connections (Snodgrass et al., 1996). One Carolina bay in

North Carolina, Mattamuskeet Bay, has been colonized by both freshwater and estuarine fishes through four canals connecting the bay to Pamlico Sound (Rulifson and Wall, 2006).

Insect emergence from bays can affect nearby waters. Leeper and Taylor (1998) studied insects in a 1.5-ha Carolina bay and recorded 115 taxa representing 29 families. Of the 39 genera of the family Chironomidae represented, 16 are known to live in both pond and stream environments (Hudson et al., 1990; Leeper and Taylor, 1998). Although Leeper and Taylor (1998) did not directly document movement, these species can hatch in Carolina bays and then become important food sources for fish in nearby streams after adult emergence and aerial dispersal. The total number of chironomids emerging from the aforementioned Carolina bay was moderate compared to other wetlands, but cumulative emergence from thousands of bays across the landscape would create a significant food source for organisms, including fishes, in other nearby waters.

Carolina and Delmarva bays are immensely productive amphibian breeding habitats, and are critical for persistence of pond-breeding amphibian populations that can move to other water bodies (Sharitz and Gibbons, 1982). Gibbons et al. (2006) documented more than 360,000 juvenile amphibians from 24 species, emigrating from one Carolina bay during a single breeding season. More than 95% of the biomass (about 1,330 kg) came from juveniles of the southern leopard frog (*Rana sphenocephala*), which is known to use both stream and wetland habitats (Table 4-2). Given the finding that 12−19% of Carolina and Delmarva bays were within 100 m of a tributary (Sharitz, 2003), amphibians emigrating from these bays could transfer extremely high levels of energy and organic matter into rivers and streams. About 90% of Carolina bays located in the Savannah River Site have a tributary or river within 1,600 m (Sharitz, 2003).

B.1.4 Carolina and Delmarva Bays: Synthesis and Implications

The key findings of this case study are as follows:

- Both peat-based and mineral-based bays have been shown to have shallow ground-water inputs and outputs.
- Some Delmarva bays have surface-water connections to the Chesapeake Bay, and the many bays near each other and near permanent waters can be connected during high-precipitation events.
- Human channeling and ditching of the bays are widespread and create surface connections to other waters.
- Fish are found in bays that periodically dry out, indirectly showing that a hydrologic connection occurred at some time.
- Dispersive amphibians and reptiles use bays for breeding or rearing young.
- The abundant insects in bays could become part of the food web for downstream fish.

Although generally supporting the existence of or potential for connectivity between Carolina and Delmarva bays and regional rivers or estuaries, the preponderance of evidence found in the literature we reviewed for this case study is indirect. Furthermore, evidence from this literature review that these connections influence the physical, chemical, and biological conditions and functions of rivers or estuaries is circumstantial. Therefore, the literature that we reviewed does not provide sufficient information to evaluate fully the influence of Carolina and Delmarva bays on rivers and estuaries at this time.

B.2 Case Study: Oxbow Lakes

B.2.1 Abstract

Oxbow lakes are water bodies that originate from the meanders of rivers that become cut off. They are common in the floodplains of large rivers around the world. In the following case study, we provide evidence from the peer-reviewed literature to support two conclusions: (1) oxbow lakes periodically connect to the active river channel, and (2) the connection between oxbow lakes and the active river channel provides for several ecological effects on the river ecosystem.

B.2.2 Introduction

B.2.2.1 Origin and Description

Oxbow lakes and ponds (hereafter referred to as oxbow lakes) originate from river meanders that are cut off from the active river channel. In floodplain rivers, natural erosion of the outer banks of curves in the active river channel leads to increased meandering over time. As these meanders grow, the active channel can come into contact with itself and cut off the curved segment of the river; this cutoff channel becomes an oxbow lake within the floodplain.

Oxbow lakes are dynamic ecosystems. Young oxbow lakes are located near the active river channel and tend to have steep banks. As oxbow lakes are subjected to flooding over time and begin to fill with sediment, they can become shallower and eventually develop terrestrial characteristics. Continued movement and meandering of unconstrained, shallow river channels can leave some oxbow lakes at considerable distances from the active river channel (Winemiller et al., 2000). Owing to the dynamic physical processes that create and promote succession in oxbow lakes, among-lake variation in the character and connectivity of individual oxbow lakes within a floodplain often is large.

Oxbow lakes are an integral element in alluvial floodplain valleys of meandering rivers around the world (Winemiller et al., 2000; Glinska-Lewczuk, 2009). Studies of these ecosystems have been conducted in river floodplains in Australia (Crook and Gillanders, 2006), Europe (Hein et al., 2003), North America (Winemiller et al., 2000; Zeug et al., 2005), and South America (da Silva et al., 2010). Due to the common origin, characteristics of, and interactions between oxbow lakes and rivers, evidence from around the world is presented here.

B.2.3 Evidence

Oxbow lakes commonly connect with the active river channel. The most evident connections are direct physical linkages, in which water movement between the active river channel and oxbow lakes is traceable. Although these physical connections are intrinsically important, they also facilitate the movement and exchange of chemical and biological material between the river and lake ecosystems.

B.2.3.1 Physical Connections

Physical connections between the active river channel and oxbow lakes can be through water movement as overland surface flow, subsurface flow from river infiltration, and subsurface flow from hillslope aquifers (Amoros and Bornette, 2002). In some cases, natural or constructed stream channels are present between the river and the oxbow lake. For the purpose of this report, oxbow lakes with this type of permanent physical connection are a priori considered an integrated part of the river network. Evidence presented here is largely for oxbow lakes that lack permanent physical connections to the river network; therefore, we focus on overland flow events (i.e., temporary connections occurring during high river stages and floods) and shallow ground-water flow as the dominant surface connections between ecosystems.

Regional- and local-scale climate and hydrogeologic patterns are important for understanding the dynamics of physical connectivity between oxbow lakes and active river channels. Regional differences influence the predictability of hydrologic connectivity between rivers and oxbow lakes. In temperate rivers (e.g., Brazos River, TX), surface flow connections between the river channel and oxbow lakes are likely to occur at irregular intervals, in response to flow magnitude and lake geomorphology (Humphries et al., 1999; Zeug and Winemiller, 2008). Tropical rivers, in contrast, are likely to have more regular inundation patterns associated with seasonal flooding (Junk et al., 1989; da Silva et al., 2010). The predictability of subsurface connections also can vary regionally. An isotope tracer analysis of lakes in the Old Crow Flats, Yukon Territory, Canada, indicated that oxbow lakes receive much of their water input from shallow ground-water flow during the relatively short thaw season (Turner et al., 2010). The regularity of connectivity has important implications for the exchange of chemical and biological material between oxbow lakes and the river (Junk et al., 1989; Humphries et al., 1999).

Local landscape characteristics and position of water bodies in the floodplain influence the relative contribution of surface-water and subsurface-water movement between individual lakes and the active river channel, as a study of oxbow lakes on the Loire and Allier Rivers, France, demonstrates. Water in two oxbow lakes had different geochemical signatures, suggesting a difference between when river water was introduced to the lakes (Negrel et al., 2003). The younger oxbow lake was more connected to the surface network due to its closer proximity to the river channel and a small stream connection, while an older oxbow lake, which was more distant from the river channel, was more dependent on subsurface flow (Negrel et al., 2003).

In addition to these spatial differences, temporal differences can occur in the short-term dynamics of hydrologic connectivity. Amoros and Bornette (2002) describe a system of pulsing connectivity, where the direction of water exchange between floodplain water bodies, including oxbow lakes, and a river is related to river stage. At low water stage, floodplain water bodies might receive water from a hillslope aquifer, and water from the oxbow lake likely drains through the alluvium toward the river. In contrast, when a river has a high water stage, water is more likely to seep through the alluvium from the river to the oxbow lake. Finally, inundation would result in surface-water connectivity, where river water moves overland to the oxbow lake. This pattern of pulsing connectivity is influenced by the local topography and the characteristics of the floodplain alluvium (Amoros and Bornette, 2002) and is an illustration of the expansion and contraction concepts described in the framework (Section 2.2.3; Figure 1-2).

Physical connectivity between oxbow lakes and the river network has direct consequences on the hydrologic dynamics of that river network. Oxbow lakes provide flood protection. Like other floodplain water bodies, they retain water. This retention lowers water velocity and can reduce the height of floodwater over nearby terrestrial landscapes (Winemiller et al., 2000). In addition to storing floodwaters, oxbows trap sediment as the velocity of floodwaters declines during the process of retention, allowing sediment to settle out of suspension.

Human alterations of natural flow patterns in rivers can influence connectivity between oxbow lakes and the active river channel. On one hand, connectivity can be enhanced. Channels between oxbow lakes and the river channel often are constructed for their benefits to biological productivity (Glinska-Lewczuk, 2009). On the other hand, isolation might be enhanced. An analysis of sediment cores in two small oxbow lakes in the Vistula River valley, Poland, showed changes in sedimentation rate and grain size following flood dike construction along the river (Galbarczyk-Gasiorowska et al., 2009). These changes in sedimentation can alter the balance of subsurface connections. The absence of channel migration since the 1980s has restricted flooding to areas close to the main channel of the Ebro River, Spain. The effects of this diminished river-floodplain interaction (e.g., erosive floods) left two of three oxbow lakes examined relatively isolated from the river channel, with a thick layer of fine sediment and thus little connection to subsurface flows (Cabezas et al., 2009).

B.2.3.2 Chemical Connections

The dynamics of hydrologic connectivity are important for understanding the chemical character of oxbow lakes. Flooding of the river facilitates exchange of chemicals between the river water and the water in oxbow lakes. In some cases, these surface-water exchanges reset the chemical environment in oxbow lakes (e.g., periodic floods introducing well-aerated water to oxbow lakes in Poland; Obolewski et al., 2009). The chemical effects of flooding are not limited to changes in the water column. For example, the isolation of oxbow lakes from the active river channel corresponded with changes in sediment chemistry, and ultimately, an acceleration of eutrophication (Galbarczyk-Gasiorowska et al., 2009).

Subsurface connections also influence oxbow lake chemistry in important ways. For example, an assessment of oxbow lakes on the River Lyna, Poland indicated that nutrient concentrations in oxbow lakes likely were influenced by a combination of river water from surface connections, ground-water seepage from the alluvial aquifer, infiltration from hillslope runoff, and inlake nutrient processing (Glinska-Lewczuk, 2009). In some cases, these other connection types can play a more important role in oxbow lake chemistry than periodic surface connections created during flood events. An examination of sediment chemistry in floodplain water bodies on the River Havel, Germany showed little effect of flooding on sediment chemistry (particulate organic matter, carbon, nitrogen, phosphorus, and iron) in oxbow lakes (Knosche, 2006). As is the case with physical connectivity, the relative importance of surface and subsurface connectivity depends on local characteristics of the floodplain ecosystem.

Alterations of natural flood dynamics affect the exchange of chemical materials between the river and oxbow lakes. Total organic carbon accretion and total nitrogen accretion in river floodplains are important ecosystem functions of floodplain water bodies, like oxbow lakes, that might improve water quality in rivers (Mitsch, 1992). An analysis of sediment, carbon, and nitrogen accretion in oxbow lakes on the River Ebro, Spain showed lower recent accumulation (1963−2007) compared to the past (1927−1963; Cabezas et al., 2009). In this example, the reduced accumulation of carbon and nitrogen concentrations in oxbow lake sediment was related to reduced size and frequency of flood events in this floodplain ecosystem (Cabezas et al., 2009).

Importantly, oxbow lakes reduce pollution loading to the river network. Oxbow lakes can intercept nutrients from upland runoff, leaving them in the oxbow lake rather than in the river (Glinska-Lewczuk, 2009). A similar process of physical interception is observed in riparian wetlands, where wetland ecosystems have been considered habitats that might control nonpoint-source pollution of nutrients (Mitsch, 1992), sediment (Brix, 1994), or pesticides (Gregoire et al., 2009) to rivers. In addition to being areas of deposition, high mineralization rates in oxbow lakes suggest that these lakes can process and remove some nutrients in terrestrial runoff before the runoff reaches the river channel (Winemiller et al., 2000).

B.2.3.3 Biological Connections

Hydrologic connectivity influences the biological character of oxbow lakes and facilitates exchange of biological material between oxbow lakes and the active river channel. Evidence also suggests a temporally dynamic relationship between biological assemblages of river and oxbow lake ecosystems.

Oxbow lakes represent important areas of relatively high biological productivity in the floodplain landscape. Oxbow lakes can be a source of plankton to the active river channel (Hein et al., 2003). In contrast to terrestrial sources of carbon that often dominate the water column of rivers, plankton is more labile and easier to assimilate into aquatic food webs (Thorp and Delong, 2002; Bunn et al., 2003).

The connectivity relationship has added complexity for plankton, because oxbow lakes need to be periodically isolated from the river to establish populations of these organisms. Intermediate residence times (i.e., the amount of time a water molecule spends in a lake) of between 10 and 27 days in oxbow lakes along the River Danube resulted in the highest carbon flow between phytoplankton and zooplankton (Keckeis et al., 2003). Likewise, the time since inundation is an important factor influencing the composition of zooplankton communities. Recently inundated floodplain water bodies are dominated by rapid-colonizing rotifers, and then become dominated by cladocerans as the time since inundation increases (Baranyi et al., 2002). In this study, total zooplankton biomass, crustacean biomass, and the number of crustacean species were positively related to time since inundation. These results indicate a relationship between the time since inundation and plankton assemblages, and suggest that this relationship exists because colonization and reproduction within an oxbow lake requires time without disturbance.

Although short periods of isolation are necessary for the development of within-oxbow productivity, periodic connections are important for plankton exchange between oxbow lakes and the active river channel. Exchange can occur from the river to the oxbow lake (e.g., juvenile riverine fish might feed in floodplain water bodies; Baranyi et al., 2002) or from the oxbow lake to the river (e.g., phytoplankton; Hein et al., 2003). These periodic connections between floodplain water bodies and the corresponding export of labile phytoplankton from floodplain water bodies to rivers contribute to the food sources of biological assemblages in nearby rivers (Thorp and Delong, 2002; Bunn et al., 2003; Keckeis et al., 2003).

Connectivity between oxbow lakes in the floodplain and the active river channel is important for maintaining mollusk populations in oxbow lakes. A comparison of three oxbow lakes with different levels of connectivity (lotic, semilotic, and isolated) showed the highest level of mollusk diversity in the semilotic lake (eight vs. four taxa in each of the other lakes) on the Lyna River, Poland (Obolewski et al., 2009). In this example, the occurrence of taxa was associated with physiochemical characteristics (oxygen, temperature, and phosphorus) of oxbow lakes. These findings support the idea that the degree of oxbow lake-river connectivity influences the abundance and composition of mollusk communities in floodplain water bodies, and these communities support the diversity of mollusk taxa throughout the river system (Reckendorfer et al., 2006).

Physical connectivity between oxbow lakes and the active river channel influences the composition of benthic macroinvertebrate communities in oxbow lakes. For example, hydrologic connection explained 28% of the variability in benthic invertebrate communities among sites in the active river channel, constructed oxbow lakes, and natural oxbow lakes of the Middle Ebro River, Spain (Gallardo et al., 2008). Macroinvertebrate richness and abundance increased with hydrologic connectivity (i.e., floods and flow pulses) between oxbow lakes and the river channel, and a diversity metric (Shannon index) peaked at intermediate levels of connectivity (Gallardo et al., 2008).

Oxbow lakes have food resources and habitat that often support abundant fish populations (Winemiller et al., 2000; Zeug et al., 2005; Zeug and Winemiller, 2008; Zeug et al., 2009). A comparison of fish biomass in oxbow lakes and a river channel showed that fish biomass in oxbow lakes was three times the biomass caught in rivers. Average catch per unit effort in oxbow lakes was 364.3 g per 10-m seine haul and 5,318 g m^{-1} ha^{-1} of gillnet sampling, versus 138.1 g per 10-m seine haul and 495 g m^{-1} ha^{-1} of gillnet sampling in the river (Winemiller et al., 2000). Additional studies by this research group have found similar patterns for juvenile fish (Zeug and Winemiller, 2008).

Periodic surface-water connections between the river and oxbow lakes facilitate the movement of fish from the river to oxbow lakes, where riverine fish can exploit these relatively productive floodplain water bodies before moving back to the river. Dietary data provide evidence that oxbow lakes are important spawning and nursery habitats for gizzard shad in the Brazos River, TX (Zeug et al., 2009).

Isotope analysis showed that gizzard shad in oxbow lakes had different isotopic signatures based on habitat type: oxbow, river, and an oxbow-river mix (Zeug et al., 2009). Although oxbow lakes clearly provided habitat for both juvenile and adult shad, the authors did not observe oxbow-specific isotopic signatures in shad in the river channel (Zeug et al., 2009). In addition, an analysis of otolith chemical signatures by Crook and Gillanders (2006) indicates that floodplain lakes were an important source of carp recruitment to the Murray-Darling River, where floodplain lakes were estimated to be the source of 98% of the young-of-year carp for areas 140 km downstream of the floodplain lakes. In a third example, floodplain water bodies, with their diverse and productive habitats, were considered nurseries for drifting larvae of migratory fish (Meschiatti et al., 2000). Half the migratory fish species from the Mogi-Guaçu River, Brazil also were observed as juveniles in oxbow lakes along the river (24 of the 46 migratory riverine species were observed in 2 oxbow lakes), and most of the migratory fish observed in oxbow lakes were juveniles, rather than larvae or reproductively mature age classes (Meschiatti et al., 2000). This age structure suggests that the oxbow lakes were not the site of reproduction, but were important habitats for juvenile fish.

Individual fish species have specific habitat and reproductive requirements and use floodplain habitats in different ways, giving the dynamic hydrologic connectivity of oxbow lakes and the river network added significance. For example, owing to variable flow in the Rio Grande, NM, recruitment success varies between years of high (Junk et al., 1989) and low flow (Humphries et al., 1999), which contributes to overall fish diversity in the Rio Grande (Pease et al., 2006). Likewise, in a 5-year study of fish in floodplain lakes, Shoup and Wahl (2009) discuss how individual oxbow lakes had different conditions and thus varied in suitability for different fish species. In their study, interannual variability was present in oxbow lake hydrology (lake-river connectivity ranged from 0 to more than 21 weeks per year) and water chemistry, and in associated differences in fish assemblages (Shoup and Wahl, 2009). Because of the complex relationships observed in their study, Shoup and Wahl (2009) concluded that the entire floodplain should be considered a single functioning unit that supports the overall biological integrity of a river.

B.2.4 Oxbow Lakes: Synthesis and Implications

The key findings of this case study are as follows:

- Evidence indicates the presence of physical, chemical, and biological connections between oxbow lakes and the river channel. The specific local and regional characteristics of both the oxbow lakes and the river influence these connections.
- Some of the best-documented observed functions of oxbow lakes are as sources or sinks for water, sinks for nutrients from upland runoff that might otherwise flow into rivers, and sources of food and refuges for riverine organisms.
- Human alteration of these connections can be detrimental to the dynamics that balance connectivity and exchange between oxbow lakes and the active river channel. Practices that alter the natural flow regime of the river (e.g., river regulation) or inhibit periodic flooding of

oxbow lakes (e.g., levees) affect movement of water and sediment, the use of oxbow lakes by riverine fish, and the regional biological diversity of floodplain water bodies.

- Interannual variability in oxbow lake hydrology, water chemistry, and fish assemblages demonstrate complex relationships between rivers and floodplain open waters and river systems, in which the water bodies in floodplains function as single unit supporting the overall biological integrity of the river.

Although the incidence of observed connectivity between oxbow lakes and river networks varies according to spatial, temporal, physical, and biological factors, most of the evidence examined indicates that oxbow lakes are important determinants of the physical, chemical, and biological condition and function of rivers.

B.3 Case Study: Prairie Potholes

B.3.1 Abstract

Prairie potholes are a complex of glacially formed wetlands, usually occurring in depressions that lack permanent natural outlets, that are found in the central United States and Canada. The vast area they occupy is variable in many aspects, including climatically, topographically, geologically, and in terms of land use and alteration, which imparts variation on the potholes themselves. Potholes demonstrate a wide range of hydrologic permanence, from holding permanent standing water to wetting only in years with high precipitation, which in turn influences the diversity and structure of their biological communities. Owing in large part to their spatial and temporal variability, individual prairie potholes span the entire continuum of connectivity to and isolation from the river network and other bodies of water. Potholes generally accumulate and retain water effectively due to the low permeability of their underlying soil, which can modulate flow characteristics of nearby streams and rivers. Potholes also can accumulate chemicals in overland flow, thereby reducing chemical loading to other bodies of water. When potholes are artificially connected to streams and lakes through drainage, isolation is eliminated and they become sources of water and chemicals. Potholes also support a community of highly mobile organisms, from plants to invertebrates to birds, that travel among potholes and that can biologically connect the entire complex to the river network.

B.3.2 Introduction

Prairie potholes are a complex of wetlands and water bodies that cover more than 700,000 km^2 of the north-central United States and southern Canada, in an area referred to as the prairie pothole region (PPR; Kantrud et al., 1989). Formed by the retreat of Pleistocene glaciers, potholes are shallow depressions underlain by low-permeability, clay-rich glacial tills that allow for the collection and temporary retention of water. Prairie potholes range widely from more than 200 ha to less than 0.5 ha in surface area with an average of 1 ha or less (Cowardin et al., 1981; Kahara et al., 2009). Their density across the landscape varies from region to region, from roughly 5 potholes km^{-2} in the eastern part of the region to up to 90 km^{-2} in the western part as a result of several factors, including patterns of glacial movement, topography, and climate (van der Valk and Pederson, 2003; Kahara et al., 2009).

By the 1980s, more than 50% of potholes in the region were filled, drained, or ditched, with much higher percentages lost in agriculturally intensive regions like Iowa (Figure 2-21; Dahl, 1990). Conservation of remaining potholes and restoration of others have been prompted by various means, including the "Swampbuster" provision of the 1985 Food Security Act and the Wetland Reserve Program (administered by the U.S. Department of Agriculture National Resource Conservation Service since 1990).

B.3.2.1 Hydrologic Dynamics

Prairie potholes are hydrologically dynamic and heterogeneous, varying both spatially and temporally (Euliss et al., 2004). Water inflows consist largely of precipitation in the form of spring snowmelt runoff or summer rain falling directly into the depressions (Carroll et al., 2005). Some potholes also receive ground-water discharge (Winter and Rosenberry, 1998). Evapotranspiration accounts for most of the water outflow in most potholes (Carroll et al., 2005; van der Kamp and Hayashi, 2009). In some situations, water can leave the basin as overland flow (known as "fill-and-spill") and shallow or regional ground-water recharge. Potholes with ground-water flow-through or with directional reversal of ground-water flow (discharge under some conditions and recharge under others) also have been identified (Rosenberry and Winter, 1997).

Prairie potholes experience seasonal cycles in water level. Potholes fill in the spring, typically reaching maximum water volume as melting snow, unable to infiltrate frozen upland soils, runs overland into topographically low places on the landscape. Water levels decline through the summer, although they can be maintained or increase due to summer rains (Winter and Rosenberry, 1995). Hydrologic permanence of these systems varies among prairie potholes in response to precipitation, pothole depth, underlying soil permeability, and position in relation to the water table. Temporary potholes have intermittent standing water only in periods of high precipitation. Seasonal potholes collect water in spring, but typically dry by mid-summer each year. Semipermanent potholes usually maintain standing water throughout the year and occasionally dry in years with low precipitation. Permanent potholes have standing water year-round and maintain standing water from year to year. Importantly, loss of temporary and seasonal potholes has occurred at higher rates than loss of permanent pothole wetlands, because shallower, less permanent basins are easier to drain (Miller et al., 2009).

Spatial variation in precipitation affects interannual variation in water level and hydrologic permanence. The east-west gradient across much of the PPR delivers more than 800 mm of average precipitation to northwestern Iowa each year and less than 500 mm of average precipitation to most of North Dakota. These dynamics also depend on 20- to 200-year, large-scale climate cycles, including periodic flood and drought conditions (Ashworth, 1999; Leibowitz and Vining, 2003). Annual average climate and longer climate cycles profoundly affect individual pothole dynamics and the interactions both among potholes and between potholes and broader landscape features (Winter and Rosenberry, 1998; Johnson et al., 2004). Hydrologic dynamics can have major effects on the diversity and abundance of organisms (Euliss and Mushet, 2004).

In addition, topography at multiple scales, soil characteristics, and underlying geology influence pothole dynamics and interactions. Three major physiographic regions comprise the PPR from east to west: the Red River Valley, Drift Prairie, and Missouri Coteau. The Red River Valley was formerly a vast lake filled with glacial melt, and today consists of the relatively topographically flat, clay-rich till surrounding the Red River of the North. The Drift Prairie is higher in elevation than the Red River Valley, and consists of rolling, hummocky terrain formed by glacial deposits. The Missouri Coteau has the highest elevation of the region and relatively steep relief due to thick glacial debris deposits (Kantrud et al., 1989). More restricted local landform zones, various till plains in the Des Moines Lobe in Iowa and the Prairie Coteau in eastern South Dakota for example, also influence hydrologic characteristics of potholes (Miller et al., 2009).

B.3.2.2 Chemical Functions

The chemical composition of prairie potholes is determined largely by the degree of connectivity with ground water and the position of the wetland with respect to local and regional ground-water systems. Seasonal wetlands located high in the landscape tend to be less saline than the wetlands situated low in the landscape. This simplistic view is made more complex, however, by watershed characteristics, concentration of solutes by evapotranspiration, variability in ground-water and surface-water residence times, changing wetland volumes, and climatic variability. For example, LaBaugh et al. (1996) documented substantial interannual changes in dominant ionic species in response to climatic variability. These changes persisted beyond the climatic inputs, indicating that antecedent moisture conditions also influence wetland response to a changing climate.

Nutrient (including carbon, nitrogen, and phosphorus) cycling in prairie potholes likely depends on fluctuating water levels, wet-dry cycles, and resulting effects of vegetation cycling. Potholes tend to be nitrogen-limited environments, with the notable exception of potholes located on agricultural land that tend to receive runoff high in nitrate (Crumpton and Goldsborough, 1998). Denitrification that takes place in the anaerobic zone of these and other wetlands can make them effective nitrogen sinks (van der Valk, 2006).

B.3.2.3 Ecological Characteristics

The high spatial and temporal abiotic heterogeneity, both within an individual pothole and between potholes across the region, creates a variety of ecological niches and contributes to high biodiversity in these habitats. In response to hydrologic cycles, a semipermanent pothole can have up to four distinct, concentric zones of vegetation, ranging from floating aquatic plants to upland plants. Depending on the timing within annual or between interannual wet-dry cycles, a given pothole can have all zones or just one zone. A pothole also could be in the process of developing zones (regenerative phase) or losing zones (degenerative phase). Invasive species like reed canarygrass (*Phalaris arundinacea*) and cattail

(*Typha angustifolia* and *T. x glauca*) have established in streams and wetlands across the region, disrupting natural pothole vegetation communities.

Perhaps the best-known and most well-studied attribute of prairie potholes is their role as productive feeding and nesting habitat for waterfowl. Of the 34 species of duck that breed in North America, 12 are common in the region, which contributes up to 80% of the continent's waterfowl game (Batt et al., 1989). In addition, a diverse assemblage of microorganisms, invertebrates, amphibians, reptiles, and sometimes fish, obligately or facultatively use potholes to feed or reproduce. For example, 44 different invertebrate taxa, including nematodes, mollusks, and arthropods, were collected in Iowa potholes (Hentges and Stewart, 2010).

B.3.3 Evidence

B.3.3.1 Physical Connections

Because prairie potholes are small wetlands that form in depressions often lacking permanent outlets, they have been described as hydrologically isolated from each other and from other waters. In some instances, this generalization has proved true but in others, it is false.

One of the most noted hydrologic functions of potholes is water storage. Because most of the water outflow in potholes is via evapotranspiration, potholes can become water sinks, preventing flow to other waters in their river or terminal lake basins. Several studies have quantified the large water storage capacity of prairie pothole complexes. A conservative estimate puts the amount of precipitation that can be retained in prairie potholes on land enrolled in the federal Conservation Reserve Program and Wetland Reserve Program at more than 555 million m^3 (Gleason et al., 2008). In various subbasins across the PPR, including those that feed Devils Lake and the Red River of the North, both of which have a long history of flooding, potholes have consistently been estimated to hold tens of millions of cubic meters of water (Hubbard and Linder, 1986; Vining, 2002; Gleason et al., 2007).

Water storage by prairie potholes can affect streamflow. Simulations of the Starkweather Coulee subbasin that drains to Devils Lake indicate that streamflow declines substantially with increased wetland storage capacity. Increasing the volume of pothole storage across the subbasin by approximately 60% caused simulated total annual streamflow to decrease by 50% during a series of dry years and by 20% during wet years. The weaker effect of potholes on streamflow during wet years is likely due to high soil moisture conditions and maintenance of high water levels within potholes across years, which causes a greater proportion of runoff to reach streams relative to dry years (Vining, 2002). Similar simulation studies of watersheds in the Red River basin (one in North Dakota and one in Minnesota) produced qualitatively comparable results, suggesting that the ability of potholes to modulate streamflow can be widespread across the PPR (Vining, 2004). This work also indicates that reducing water storage capacity of wetlands by connecting formerly isolated potholes through ditching or drainage to the Devils Lake and Red River basins could increase stormflow and contribute to downstream flooding. In many agricultural areas already crisscrossed by extensive surface and subsurface drainage systems (Figure 2-21), total streamflow and baseflow are increased by directly connecting potholes to stream networks (Blann et al., 2009). The ensuing impacts of changing streamflow are numerous, including effects on stream geomorphology, habitat alteration, and ecological effects (reviewed in Blann et al., 2009).

Studies in some regions show a lack of association between pothole water storage and aspects of streamflow. For instance, modeling of an Iowa watershed indicated that total pothole outflow and total maximum pothole volume do not affect streamflow characteristics (Du et al., 2005). At the Minnesota watershed within the Red River basin discussed previously, simulated annual and daily streamflow decreased with increased pothole water storage capacity but peak streamflow was not reduced during a simulated flooding event, possibly due to an overwhelmed capacity of wetlands and upland soils to retain additional water (Vining, 2004). In yet another Minnesota watershed, wetland water storage provided no explanatory power in estimating peak streamflows for small streams (Lorenz et al., 2010).

The presence or absence of an effect of pothole water storage on streamflow depends on many factors, including patterns of precipitation, topography, and degree of human alteration. For instance, in parts of the PPR with low precipitation, low stream density, and little human alteration, the extreme hydrologic isolation of potholes likely results in few effects on larger waters. Neither a comprehensive examination of the downstream effects nor a systematic characterization of potholes for the factors that determine those effects has been conducted.

Surface-water isolation is common for many prairie potholes under average precipitation conditions, but intense precipitation events or high cumulative precipitation over one or more seasons can result in temporary hydrologic connectivity via overland flow. These "fill-and-spill" events between potholes have been witnessed and measured in the Missouri Coteau and in the Drift Prairie zones of the PPR in North Dakota (Winter and Rosenberry, 1998; Leibowitz and Vining, 2003), and inferred using digital aerial photography (Kahara et al., 2009). All else being equal, a wetter climate such as that experienced in the southeastern part of the PPR should promote hydrologic connectivity (Johnson et al., 2005). Local topography can enhance or diminish the likelihood and frequency of temporary surface-water connections. Authors have reasoned that the relatively wet and topographically low Red River Valley zone of the PPR should display greater surface-water connectivity of potholes than either the Drift Prairie or Missouri Coteau zones. Furthermore, they suggest that stream density will influence the chance that pothole spillage connects to the larger river network. Thus, potholes in the Missouri Coteau, with its limited network of streams, should be more hydrologically isolated than potholes in the Red River Valley or Drift Prairie (Leibowitz and Vining, 2003).

Individual potholes range from isolated to highly connected to other potholes via shallow local and deeper regional ground-water flows. A high water table and soil pocketed with root pores or fractures from wet-dry cycles promote water movement between wetlands via shallow ground-water aquifers. In these cases, water moves most often from topographically high, recharge wetlands to low, discharge wetlands (van der Kamp and Hayashi, 2009), although a single wetland can shift from recharge to discharge in years where the water table is high (Carroll et al., 2005). Other wetlands shift multiple times from recharge to discharge conditions during a single year, which can either facilitate or prevent ground-water connections to nearby wetlands (Rosenberry and Winter, 1997). Potholes can connect to the river network via ground water if both are located within the zone of shallow local aquifer flows. One study in North Dakota described prairie wetlands and lakes as water sources to the topographically low James River via shallow ground-water flow (Swanson et al., 1988). Broader, regional movement of ground water is restricted by very low permeability clay-rich tills that can keep deep ground-water recharge to only millimeters per year on average over a drainage basin (van der Kamp and Hayashi, 1998).

Human alterations of the landscape have had an impact on the connectivity of prairie potholes. Presence or absence of a crop on the upland near a wetland can alter the degree to which the wetland receives overland flow from the upland and the removal of water via transpiration that otherwise would recharge ground water (Hayashi et al., 1998). Up to 30% of cropland in the Upper Midwest is artificially drained to increase agricultural productivity (Pavelis, 1987). Filling potholes and lowering the water table through use of field tiling for agriculture has likely increased isolation of remaining potholes by decreasing the density of depressions containing water. Extensive surface draining and ditching, however, have directly and dramatically increased connectivity between pothole basins and surface waters of the river network, converting these systems from precipitation sinks to water sources (Blann et al., 2009). Ditches create new surface-water outlets from potholes, allowing collected water to flow into streams and rivers; drains fitted at the bottom of potholes connected to shallow subsurface pipes often discharge to open ditches or streams (Ginting et al., 2000).

B.3.3.2 Chemical Connections

The chemical connectivity of prairie potholes is largely mediated by their hydrologic connectivity. Hydrologically isolated potholes tend also to be isolated chemically. Unaltered potholes with no outlet can accumulate nutrients, sediment, and other chemical compounds as they collect runoff (Crumpton and Goldsborough, 1998; Donald et al., 1999). Such accumulations have measurable effects on the water quality of potholes and the resident organisms (Gleason et al., 2003). Presence of these materials in potholes is influenced by inflow, itself a function of precipitation and surrounding land use. Potholes surrounded by tilled fields with higher precipitation, for example, tend to accumulate nutrients, sediment, and pesticides (Gleason et al., 2008). Additionally, potholes within agricultural areas that have not been drained or ditched are hypothesized to be nitrogen sinks, transforming nitrate in the agricultural runoff they receive to nitrous oxide or nitrogen gas. Denitrification can transform up to 80% of nitrate that runs off into potholes (Crumpton and Goldsborough, 1998 and references therein).

On the other hand, potholes that periodically are connected hydrologically to other bodies of water via overland flow can transfer chemicals, such as dissolved ions (Leibowitz and Vining, 2003). Potholes modified by ditching or drainage also have increased hydrologic connectivity and, therefore, chemical connectivity to other water bodies (Whigham and Jordan, 2003). Wetlands drained for agriculture can contribute nitrogen, phosphorus, sediment, pesticides, and herbicides to the waters into which they drain (reviewed in Blann et al., 2009). For example, two wetlands in southwestern Minnesota fitted with surface drains that connected to subsurface tiles emptying into the Watonwan River (a tributary of the

Minnesota River) were found to be sources of total solids and total phosphorus to the river during periods of high runoff (Ginting et al., 2000).

Although the chemical sink and periodic chemical source functions of potholes have been documented in the literature, the overall influence of these functions on larger waters and river networks have been difficult to quantify. This inability is partly because altered and unaltered potholes are embedded in a matrix of land use and land management types, and many different parts of this complex landscape affect downstream water quality and ecological communities (Blann et al., 2009). The most fruitful future approach might be to model drainage basin sediment, nutrient, and pesticide transport under various climatic conditions, using pothole characteristics and functions as independent, explanatory variables (Gleason et al., 2008).

B.3.3.3 Biological Connections

Dispersal capabilities of organisms residing in potholes and features of the landscapes they must traverse help determine the strength of biological connectivity. Although some research has focused on internal seed and egg bank dynamics (van der Valk and Davis, 1978; Gleason et al., 2004), increasing evidence suggests that potholes are not biologically isolated. In fact, the observation that potholes lack an endemic aquatic and semiaquatic flora or fauna suggests that, at least over evolutionary time, potholes have been well connected biologically to communities in other ecosystems (van der Valk and Pederson, 2003).

Organisms can move into and out of potholes via wind, water, or land, by either self-propelling or hitchhiking on other mobile organisms. Many species of wetland plants and insects are dispersed on the wind (Keiper et al., 2002; Soons, 2006), including cattail (*Typha* spp.) seeds, which can disperse over huge areas (more than 80 ha; van Digglen, 2006) and have been found to colonize, quickly and passively, previously drained, restored potholes (Galatowitsch and van der Valk, 1996). Plants and invertebrates also can travel by becoming attached to or consumed and excreted by waterfowl (Amezaga et al., 2002). Seeds of up to half a dozen common pothole plants can be consumed and excreted by ducks in a viable state; because migrating waterfowl fly such long distances, the maximum dispersal distance of these hitchhiking plants is estimated to be 1,400 km (Mueller and van der Valk, 2002). Additionally, fast and efficient recolonization of species in restored potholes, including floating aquatics and emergent perennials, is likely facilitated by waterfowl movement (Aronson and Galatowitsch, 2008). Waterfowl often move between wetlands during the breeding season in search of food and cover, and some species also use habitats within the river network as wetlands dry or freeze (Pattenden and Boag, 1989; Murkin and Caldwell, 2000). Water also can provide a means for biologically connecting potholes. Fish and other organisms or parts of organisms that can be suspended in water (e.g., floating insect larvae or seeds) have been hypothesized to move between potholes during spillage events (Zimmer et al., 2001; van der Valk and Pederson, 2003; Herwig et al., 2010). Dispersal of waterborne organisms also can occur through manmade waterways (i.e., ditches) that connect potholes to stream networks (Hanson et al., 2005; Hentges and Stewart, 2010; Herwig et al., 2010). Most of these studies cite only anecdotal evidence for dispersal through ditches. Populations of aquatic plants in agricultural ditches in Europe, however, are genetically highly structured along these man-made waterways, suggesting that these watercourses determine dispersal pathways (Gornall et al., 1998).

Finally, overland dispersal of amphibians and mammals can connect potholes. Eight of twelve amphibian species were able to quickly recolonize restored potholes near source populations (Lehtinen and Galatowitsch, 2001). Although muskrat territories in the PPR are usually restricted (less than 100 m from the home stream or wetland), they can disperse longer distances to feed and breed in prairie wetland habitat under certain conditions (Clark, 2000 and references therein). In North Dakota, muskrats have been observed taking up residence in potholes for a series of years, provided suitable water levels and vegetation existed, and then emigrating, presumably to more permanent and larger lakes and streams (Winter and LaBaugh, 2003). Not all wetland animals disperse widely, however. Populations of the pothole-dwelling salamander *Ambystoma tigrinum* (studied in small, non-pothole wetlands, in this case) can be genetically differentiated from each other down to 1.5 km, indicating low dispersal (Routman, 1993).

Landscape features, including distance, relief, and human alterations, can promote or restrict biological connections between wetlands and larger bodies of water. Spatial distance is one important factor to consider. For a given species, wetlands located closer together will exchange more organisms than wetlands that are farther apart. Therefore, landscapes in which potholes are located in relative proximity to each other and to the river network are likely to be connected more frequently and by more species. For example, restored potholes in pothole-dense areas tend to be recolonized by plants more efficiently (Mulhouse and Galatowitsch, 2003), and high pothole density promotes greater movement of waterfowl (Krapu et al., 1997). Unfortunately, quantification of biological effects of potholes on larger waters is severely limited. In most cases, studies involving biological isolation or connectivity in the PPR have focused on the potholes themselves as sources and recipients of organisms.

B.3.4 Prairie Potholes: Synthesis and Implications

The key findings for this case study are as follows:

- The degree to which prairie potholes are connected or could connect to river networks depends on many factors. These factors include distance to rivers or streams, topography, precipitation, climate cycles (seasonal and on longer time scales), biotic community composition, and artificial drainage. Within the PPR, distance to rivers and streams is strongly influenced by the three major physiographic regions (Red River Valley, Drift Prairie, and Missouri Coteau), which vary in the number of potholes and stream density (e.g., Figures 2-20A and 2-20B).
- On a watershed scale, unaltered potholes often function as hydrologic sinks, sequestering water and reducing annual streamflow, but can become sources as they spill overland under high precipitation or low relief, or both. When artificially drained or ditched, potholes can become sources of water, nutrients, sediment, and pesticides. Their roles as sinks and sources affect river geomorphology and biological communities.

- Potholes also might have direct biological effects on river networks via connectivity of resident populations, although these effects are less well known and studied.

Because of wide variation in the conditions that determine the incidence or magnitude of connections between prairie potholes and river networks, pothole complexes in some watersheds are more likely to have important effects on associated rivers and lakes than others are. Given evidence in the current literature, however, when proper climatic or topographic conditions occur, or biotic communities are present that promote potential or observed connections, measurable influence on the physical, chemical, and biological condition and function of downstream waters is highly likely.

B.4 Case Study: Prairie Streams

B.4.1 Abstract

Prairie streams drain temperate grasslands in the central United States. Periods of flooding and drying characterize their hydrology, with spring-fed, perennial pools and reaches embedded within more intermittently flowing reaches; thus, water flow along prairie stream networks exhibits high temporal and spatial variability. Existing evidence indicates that small prairie streams are connected to downstream reaches, most notably via flood propagation and the extensive transport and movement of fish species throughout these networks. Nutrient retention in small prairie streams also significantly influences nutrient loading in downstream rivers.

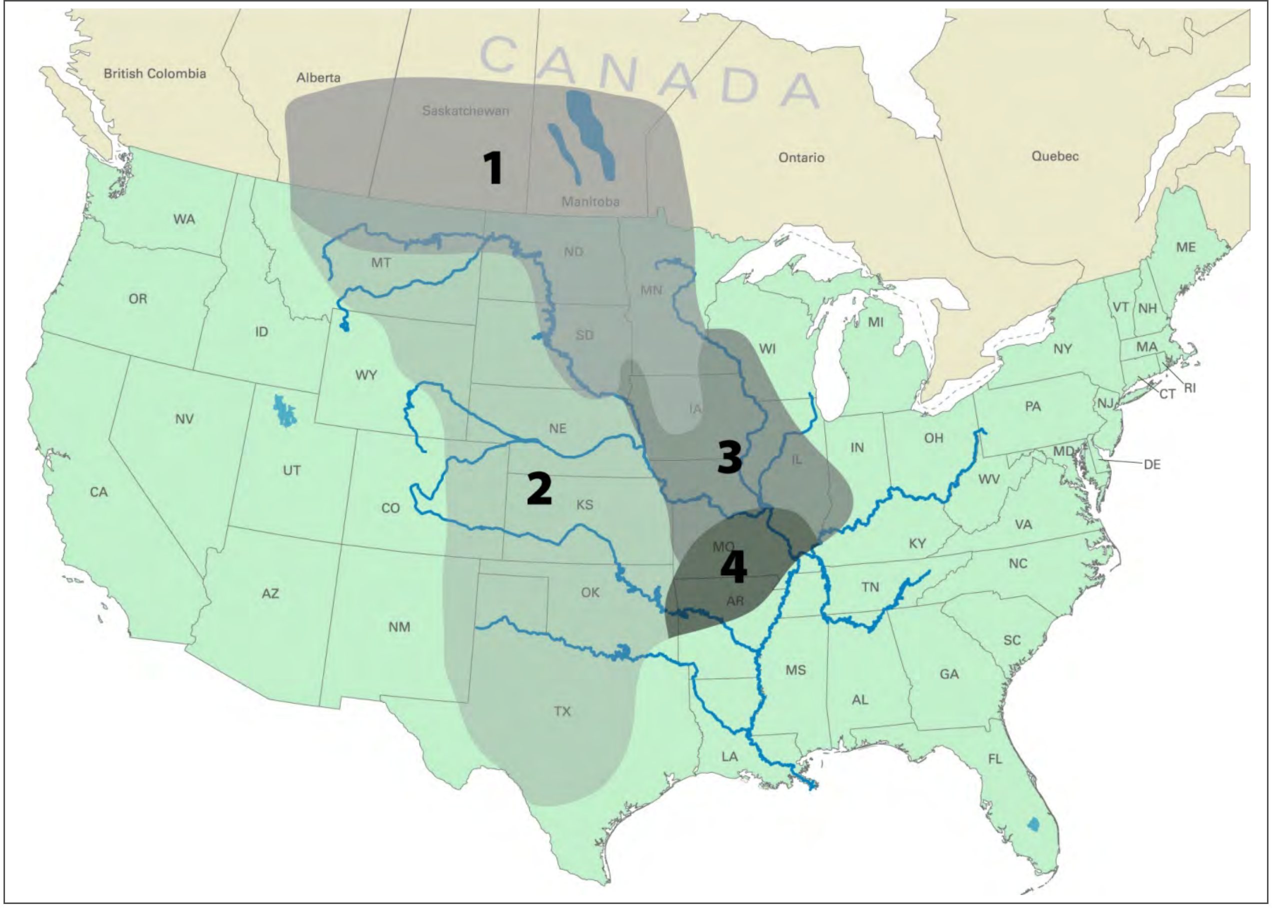
B.4.2 Introduction

B.4.2.1 Geography and Climate

Prairies are temperate grasslands located in the Great Plains physiographic region of the central United States and Canada (Figure B-2). Grasses and forbs (broad-leaf plants other than grasses) dominate the region, particularly in upland areas. Shrubs and trees can be found in lowlands, and are commonly called gallery forests. Native prairie ecosystems once covered approximately 1.62 million km^2 in North America but have been lost almost completely since European settlement, mainly replaced by row-crop agriculture (Samson and Knopf, 1994). Because of drastic alterations to much of the historical eastern plains (Iowa, Illinois, Missouri, Indiana, Minnesota), our discussion centers principally on river networks in the high plains subregion of the Great Plains (Subregion 2 in Figure B-2), where drier climate and thin, rocky soil have limited row-crop agriculture.

Prairies generally can be characterized by their relatively low topographic relief, although areas such as the Flint Hills in eastern Kansas, the Arikaree Breaks in northwestern Kansas, and the Arbuckle Mountains in south-central Oklahoma have relatively steep terrain compared to that of western Kansas or the Oklahoma panhandle (Osterkamp and Costa, 1987; Matthews, 1988). The underlying geology consists of extensive limestone deposits, but sandstone and shale deposits or unconsolidated sands, silts, and clays characterize other areas (Brown and Matthews, 1995). Soils in the Great Plains are predominantly loess, but some areas such as Nebraska's Sand Hills have high percentages of sand (Wolock et al., 2004). Although prairie soils tend to be less permeable than more humic forest soils,

Figure B-2. Map of the United States showing physiographic subregions and major rivers of the Great Plains: (1) glaciated prairie; (2) high plains; (3) eastern plains; and (4) Ozark Plateau. Modified from Covich et al. (1997).



fractures and macropores of the limestone geology in some prairie areas, such as the Flint Hills, allow for relatively rapid percolation and recharge of local ground water (Macpherson and Sophocleous, 2004).

Most of the large rivers draining the high plains subregion (e.g., the Missouri, Yellowstone, Milk, Cheyenne, White, Niobrara, Platte, Kansas-Republican, Arkansas, Cimarron, Canadian, Red, and Washita Rivers) are major tributaries to the Mississippi River. The southern portions of the subregion contain the headwaters of the Rio Grande River (Pecos River) or rivers that flow directly into the Gulf of Mexico (the Guadalupe, San Antonio, Colorado of Texas, Brazos, and Nueces Rivers). Some rivers in the northern portions of the glaciated prairie flow north, eventually into the Hudson Bay (notably the Red River of the North).

The climate in this region ranges from semiarid in the western portions to moist subhumid in the eastern portions. Mean annual precipitation ranges from 200 to 1,000 mm y^{-1} from west to east across the Great Plains (Lauenroth et al., 1999). Potential evaporation typically exceeds precipitation (Transeau, 1905, 1935). Mean annual temperatures increase from north (4–8 °C) to south (16–20 °C;

Lauenroth et al., 1999). Winters tend to be dry, with less than 20% of the annual precipitation (Borchert, 1950; Lauenroth et al., 1999; Boughton et al., 2010). Most precipitation falls in late spring and early summer (Borchert, 1950; Lauenroth et al., 1999), and much of the summer precipitation results from localized convective thunderstorms. Because of the region's geographic location relative to the Gulf of Mexico and the Rocky Mountains, however, substantial interannual variation exists, particularly in terms of summer rainfall deficit (Borchert, 1950).

B.4.2.2 Hydrology and Geomorphology

The hydrology of most prairie river networks is highly variable (Matthews, 1988; Brown and Matthews, 1995; Dodds et al., 2004). These systems are frequently subjected to the extremes of drying and flooding, and intermittent or flashy hydrology is prevalent in river networks throughout most of the Great Plains (Matthews, 1988; Zale et al., 1989; Poff, 1996; Dodds et al., 2004). The topology of most prairie river networks is dendritic due to the relatively flat landscape and uniform geology (Brown and Matthews, 1995). Prairie river networks tend to have high drainage density (Section 2.4.2), and are therefore efficient at transferring rainfall from uplands to downstream reaches (Gregory, 1976; Osterkamp and Friedman, 2000). Flood magnitudes tend to be higher in the semiarid Great Plains than in other regions, despite comparable rainfall intensities, due to low infiltration and vegetation interception (Osterkamp and Friedman, 2000). Although floods tend to occur in late fall through late spring, they can occur any time during the year (Brown and Matthews, 1995; Poff, 1996). Like most river networks, those draining prairie landscapes often contain ephemeral, intermittent, and perennial streams. Although many headwater prairie streams are ephemeral or intermittent (Matthews, 1988; Brown and Matthews, 1995; Dodds et al., 2004), some have perennial spring-fed reaches located at the network origins or distributed between intermittent reaches along headwater streams (Matthews et al., 1985; Sawin et al., 1999; Dodds et al., 2004; Bergey et al., 2008).

The flow regimes of streams draining the Rocky Mountains, Black Hills, and northern prairies are largely tied to snowmelt. Most systems originating in the mountains quickly transition in flow and morphology as they cross the Great Plains, becoming intermittent and then slowly gaining flow from large streams before joining the Mississippi River (Brown and Matthews, 1995). Some areas, however, have stable streamflow with few intermittent streams because flow is derived from large, permeable ground-water sources (e.g., Sand Hills in Nebraska; Winter, 2007).

The High Plains (Ogallala) aquifer system and other aquifers (e.g., Edwards-Trinity) are important hydrologic features interconnected with Great Plains river networks. The High Plains aquifer system is the largest (450,658 km^2) and most intensively pumped U.S. aquifer, underlying much of the Great Plains from southern South Dakota and southeastern Wyoming to central Texas (Sophocleous, 2005; Ashworth, 2006; Sophocleous, 2010). The High Plains aquifer is composed of blanket sand and gravel derived mainly from alluvial deposits and ancient marine sands. It is unconfined regionally, but locally can be confined where beds of silt, clay, or marl are present. Regional movement of water through the aquifer is from west to east, but locally the water moves toward major tributaries. Northern areas of the Great Plain are underlain by glacial deposit aquifers that can be a mixture of till (unsorted material ranging from clay to boulders) and outwash (stratified sand and gravel) that was deposited by glacial meltwater.

Most headwater streams originating in the prairie have riffle-pool morphology with alluvial gravel; only headwater streams originating in the western mountains have high gradient, cobble-boulder channels (Brown and Matthews, 1995). Southern prairie headwater streams tend to have finer substrate than those in the northern and central Great Plains (Brown and Matthews, 1995). Larger streams tend to have broad sand beds that are frequently braided (Section B.4.2.5). In contrast to headwater streams in forested regions, the riparian areas of prairie headwater streams typically lack overhanging trees. Grasses and shrubs are the dominant riparian vegetation, so channels lack woody debris and generally receive direct sunlight. Because of intense flooding, prairie streams tend to form wide, deep channels relative to their drainage areas, regardless of flow permanence (Hedman and Osterkamp, 1982; Brown and Matthews, 1995). Because of similarity in topography, climate, geology, and soils, stream geomorphology across the Great Plains is largely comparable (Miller and Onesti, 1988). High plains channels, however, tend to be slightly steeper in gradient and more sinuous than wider and deeper channels of the eastern plains (Miller and Onesti, 1988). During floods, the relatively incised channels and lack of woody debris in prairie headwater streams make them less retentive of organic matter and other materials than those of high-gradient forested channels; their pool-riffle morphology, high sinuosity, and seasonal drying, however, can enhance retention (Brown and Matthews, 1995).

B.4.2.3 Physicochemistry

The factors discussed above are strong drivers of prairie stream physicochemistry (Matthews, 1988; Brown and Matthews, 1995). Hot summers and cold winters in this region cause substantial direct and indirect changes in water temperature, dissolved oxygen, and nutrient concentrations. Isolation of surface water into pools during summer drying exacerbates these changes (Zale et al., 1989; Ostrand and Marks, 2000; Ostrand and Wilde, 2004). For example, water surfaces can be covered with ice in winter, whereas summer water temperatures can reach 35−40 °C with 9−10 °C diel (i.e., daily) fluctuations (Matthews, 1988; Matthews and Zimmerman, 1990). Concomitant fluctuations in dissolved oxygen occur, which when combined with stream respiration, contribute to dissolved oxygen values approaching anoxic conditions.

Prairie rivers and streams naturally have higher concentrations of dissolved solids (e.g., calcium, carbonate, bicarbonate, sodium, chloride, magnesium, sulfate) due to dissolution of the underlying geologic layers (Huntzinger, 1995). Associated with these high levels of dissolved ions are elevated alkalinity and pH. Mean total dissolved solids concentrations for many Great Plains rivers are among the highest in the United States, exceeding 500 mg L^{-1}; many Great Plains rivers, however, also receive anthropogenic total dissolved solid inputs from wastewater treatment effluents, agricultural runoff, irrigation contributions to baseflow, and disposal of produced water associated with fossil fuel production (Mathis and Dorris, 1968; Huntzinger, 1995; Farag et al., 2010). Some river networks, such as the headwaters of the Red River in Texas and Oklahoma, are saline because they derive from brine springs (Taylor et al., 1993).

Streams and rivers of the central United States are often cited as having elevated nutrient (i.e., nitrogen and phosphorus) loads. These loads are primarily attributable to nonpoint source runoff from fertilizer application and livestock waste, especially during higher flows in winter and spring (Huntzinger, 1995; Royer et al., 2006; Alexander et al., 2008). Data from streams draining native prairie indicate that nitrogen and phosphorus concentrations and fluxes are lower or comparable to other intact ecosystems (McArthur et al., 1985a; Dodds et al., 1996a; Kemp and Dodds, 2001).

B.4.2.4 Ecology

The low diversity of aquatic flora and fauna of prairie river networks, especially compared to assemblages in the eastern and southeastern United States (Jewell, 1927; Fausch and Bestgen, 1997), is likely due to the environmental instability of these river networks, their evolutionary history, and the magnitude and extent of human alterations. Most organisms have adapted to erratic hydrologic regimes and harsh physiochemical conditions in prairie streams by having rapid growth, high dispersal ability, resistant life stages, fractional or extended reproduction (i.e., spawn multiple times during a reproductive season), broad physiological tolerances, and life cycles timed to avoid predictably harsh periods (Matthews, 1988; Dodds et al., 1996b; Fausch and Bestgen, 1997).

Algae are foundational components of prairie streams, acting to retain nutrients and provide an important energy source to consumers (Gelwick and Matthews, 1997; Dodds et al., 2000; Evans-White et al., 2001; Evans-White et al., 2003). Flooding and drying in prairie streams reset algal assemblages, spur successional sequences, and maintain high levels of primary production (Power and Stewart, 1987; Dodds et al., 1996b; Murdock et al., 2010). Algal assemblages are composed primarily of diatoms (e.g., *Cymbella*, *Cocconeis*, *Pinnularia*, *Achnanthes*, *Navicula*, and *Gomphonema*), filamentous green algae (e.g., *Cladophora*, *Spirogyra*, *Rhizoclonium*, *Stigeoclonium*, *Zygnema*, and *Oedogonium*), and cyanobacteria (e.g., *Oscillatoria*, *Nostoc*).

Because of high light availability, algal primary production in prairie streams occasionally can be substantially higher than in forested headwaters (Hill and Gardner, 1987a; Dodds et al., 1996b; Mulholland et al., 2001; Bernot et al., 2010). Gallery forests farther downstream provide shade and contribute organic matter. Shade from the gallery forests lowers light transmission to algae, resulting in lower algal primary production in these reaches than in unshaded prairie headwater reaches. Thus, in contrast to conventional longitudinal paradigms like the River Continuum Concept, the organic matter driving prairie headwater streams derives mainly from within the channel (autochthonous production), whereas leaf litter and other detritus from nearby gallery forests (allochthonous production) dominate in intermediate-sized streams (Gurtz et al., 1982; Gurtz et al., 1988; Wiley et al., 1990). Despite having greater primary production than forested headwaters, prairie streams—like forested ones—tend to be net heterotrophic systems (Mulholland et al., 2001), but those that agricultural activities (e.g., elevated nutrients, channelization) influence can at times be net autotrophic (Prophet and Ransom, 1974; Gelroth and Marzolf, 1978; Wiley et al., 1990).

Invertebrates in prairie streams are represented by various aquatic insect groups (e.g., Diptera, Coleoptera, Plecoptera, Ephemeroptera, Trichoptera), crustaceans (crayfish, isopods, amphipods), mollusks, and oligochaetes. Consumers of fine benthic organic matter, epilithic algae, and other invertebrates tend to dominate invertebrate communities (Gray and Johnson, 1988; Harris et al., 1999; Stagliano and Whiles, 2002). Diversity and abundance of invertebrates tend to increase with flow permanence, but species composition generally highly overlaps, with intermittent stream assemblages representing a nested subset of those from perennial streams (McCoy and Hales, 1974; Miller and Golladay, 1996; Fritz and Dodds, 2002).

As with algae, flooding and drying are important drivers of invertebrate assemblages in prairie streams. Distinct successional transitions are apparent following these disturbances (Chou et al., 1999; Fritz and Dodds, 2002), and recovery to predisturbance levels can be rapid (Miller and Golladay, 1996; Miller and Nudds, 1996; Fritz and Dodds, 2004). Woody debris is often rare in prairie streams, but where it is present, invertebrates tend to be more abundant and more resistant to flooding, relative to those associated with less stable sand and gravel substrates (Golladay and Hax, 1995; Hax and Golladay, 1998; Johnson and Kennedy, 2003).

Fish are a well-studied component of river networks in the Great Plains, and are among the most threatened (Rabeni, 1996; Fausch and Bestgen, 1997; Hubert and Gordon, 2007; Hoagstrom et al., 2010). Approximately 200 fish species are found across prairie river networks, about 50 of which are endemic to these streams. The most common taxa are minnows (Cyprinidae), suckers (Catastomidae), darters (Percidae), sunfishes (Centrarchidae), and catfishes (Ictaluridae).

Longitudinal organization of fish assemblages has been recognized widely in Great Plains river networks (Harrell et al., 1967; Smith and Powell, 1971; Schlosser, 1987), and like macroinvertebrates these assemblages often are nested such that intermittent headwater communities are subsets of those in downstream perennial segments. Unlike algae and macroinvertebrates, fish inhabiting intermittent headwater streams have no terrestrial or drying-resistant life stages. Fish, however, are highly mobile and avoid desiccation by moving into downstream perennial reaches or perennial spring-fed pools in upstream segments (Deacon, 1961; Fausch and Bramblett, 1991). Periodic floods are important for creating perennial refuges and providing connectivity between habitats for the dispersal of fish and their eggs in prairie stream networks (Section B.4.3.3; Labbe and Fausch, 2000; Franssen et al., 2006).

B.4.2.5 Human Alterations

Human alterations to prairie river networks have affected physical, chemical, and biological connectivity in these systems both directly and indirectly. Crop and livestock agriculture are predominant land uses in the Great Plains (Galat et al., 2005; Matthews et al., 2005) and represent major nonpoint sources of nutrients, sediment, and pesticides (Battaglin et al., 2003; U.S. EPA, 2006; Alexander et al., 2008). Livestock concentrate in and near streams for shade, food, and water, leading to bank erosion, increased soil bulk density, sedimentation, and elevated fecal bacteria concentrations (Armour et al., 1991; Strand and Merritt, 1999).

To support these agricultural enterprises, water has been diverted from channels, withdrawn from regional aquifers, and stored in reservoirs. Ground-water withdrawals in the Great Plains are the highest in the United States (Sophocleous, 2010), causing many once perennial river segments to regularly dry up completely during summer months, particularly in the drier western portions of the Great Plains (Cross and Moss, 1987; Ferrington, 1993; Falke et al., 2011). Nearly all river networks in prairie regions have been altered by impoundments for irrigation storage and flood control, from small farm ponds in headwaters to large reservoirs on river mainstems (Smith et al., 2002; Galat et al., 2005; Matthews et al., 2005). Decline in flood magnitude, altered flow timing, and reduced flow variability and turbidity are evident in many prairie rivers compared to historically documented conditions (Cross and Moss, 1987; Hadley et al., 1987; Galat and Lipkin, 2000). Reductions in peak discharge derived from prairie streams have contributed to the narrowing of the region's once broad and shallow river channels (Friedman et al., 1998; Wohl et al., 2009). Dynamic mosaics of sand bars common in most prairie rivers have become stabilized and coalesced islands. The establishment of trees along prairie river riparian zones was limited by floods prior to settlement, but now dense zones of native and invasive trees and shrubs further reduce flows through high evapotranspiration (Johnson, 1994; Dahm et al., 2002).

B.4.3 Evidence

B.4.3.1 Physical Connections

B.4.3.1.1 Water

As in other river systems, water is the primary medium by which materials are transported from streams to rivers in prairie networks. Floods are common in Great Plains streams (Fausch and Bramblett, 1991; Hill et al., 1992; Fritz and Dodds, 2005), and propagation of these floods from streams to downstream rivers demonstrates hydrologic connectivity. Fritz and Dodds (2004, 2005) characterized the hydrology of intermittent streams draining native tallgrass prairie in a study that coincided with the highest flow on record (on May 13, 1995, with a return interval of at least 50 years). Kings Creek and one of its headwater streams (N01B) are both headwater streams draining into the Kansas River, downstream of the USGS gaging station at Fort Riley and upstream from the confluence of the Big Blue and Kansas Rivers and the USGS gaging station at Wamego (Figure B-3). The peak-flow rising and descending limbs were very rapid at Kings Creek and N01B compared to those recorded for the Kansas River at Wamego, where the peak arrived approximately 12 hours later (Figure B-4). Hydrographs for the upstream Fort Riley gage on the Kansas River and the Big Blue River indicate that the May 13, 1995 peak at the downstream Wamego gage was associated with floods propagating from Kings Creek and other small streams (Figure B-4). The subsequent peak at the Wamego gage that occurred 5 days later was associated with a storm mainly affecting portions of the Kansas River basin upstream of the Fort Riley gage, which elicited only a slight increase in discharge at Kings Creek and N01B (Figure B-4).

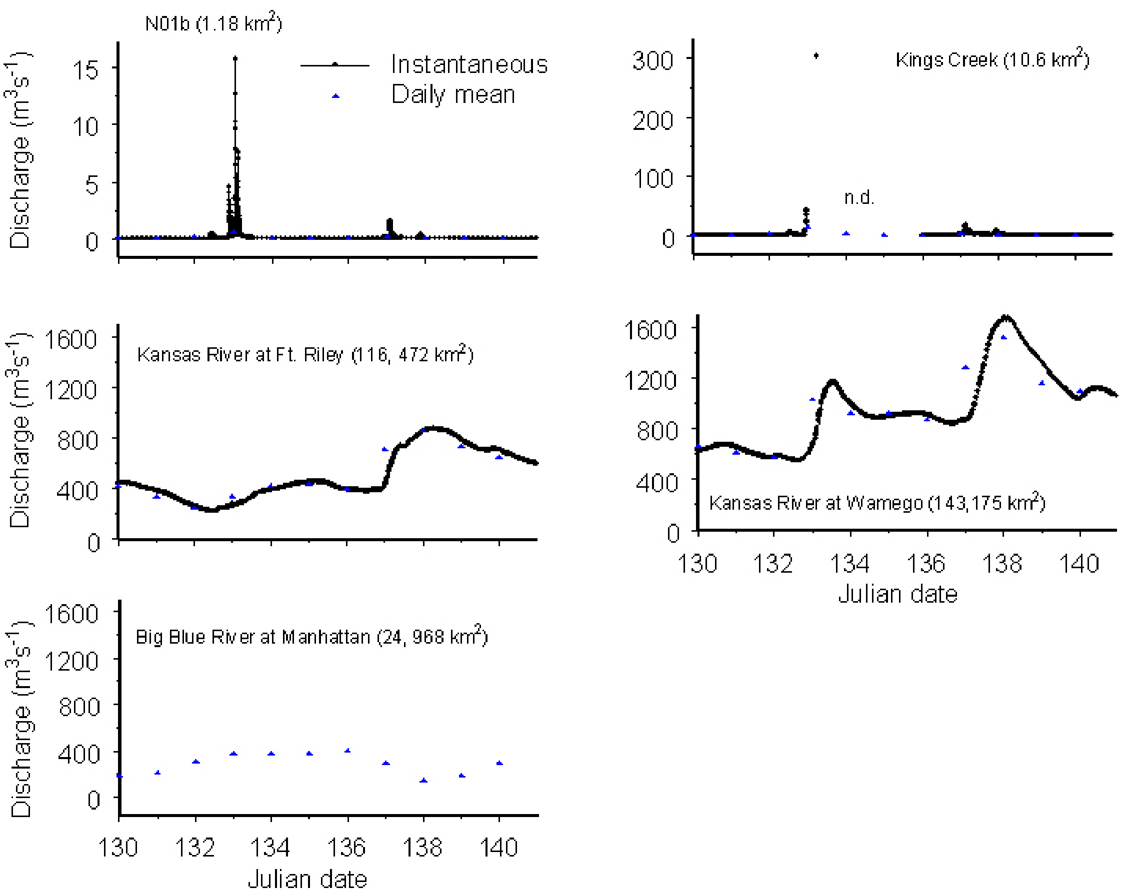
A flood occurring June 14–20, 1965 on the Platte River (Colorado and Nebraska) is among the largest U.S. floods in recorded history, with a recurrence interval of 900 to 1,600 years (Matthai, 1969). This flood originated from runoff of intense rainfall (360 mm in 4 hours) over headwater portions of the drainage south of Denver, CO. Normal annual precipitation for this area is approximately 400 mm. Flows in Plum Creek, one of the intermittent headwater streams to the Platte River that received the heaviest

Figure B-3. Map showing the location of Kings Creek and N01B, intermittent tributaries to the Kansas River.

rains, rose from <5 $m^3 s^{-1}$ to 4,360 $m^3 s^{-1}$ in only 40 minutes. Under the Federal Flood Control Act of 1944, detention impoundments were extensively constructed on headwater streams in the Great Plains to retard flooding in downstream rivers (Schoof et al., 1978; Van Haveren, 1986). Headwater impoundments reduced runoff to the Washita River in Oklahoma by 36%, but channel dredging of streams offset these reductions by increasing flow from ground water and reducing transmission loss (Schoof et al., 1978).

Machavaram et al. (2006) examined hydrologic connectivity between intermittent prairie streams, a headwater pond, and a perennial stream reach approximately 10 km downstream using chemical and isotopic tracers in a southeastern Kansas system. They found that, following precipitation, 20% of downstream water originated from the upstream pond, fed by ephemeral and intermittent streams; elevated oxygen stable isotope tracer associated with the pond water took 26–31 hours to reach the downstream site (Machavaram et al., 2006). Streams connected to lakes and wetlands contributed proportionally more flow to a southeastern Minnesota river in summer, when other water sources were minimal, than in spring (Lenhart et al., 2010). Flow from these streams has a delayed or lagged release because of storage in lakes and wetlands, and stream flow backed up because of high mainstem flows (Lenhart et al., 2010).

Figure B-4. Hydrographs (instantaneous and daily mean) showing propagation of the 13 May 1995 (Julian date 133) flood downstream from headwater sites (N01B and Kings Creek) to the Kansas River at Wamego. Also shown are hydrographs from upstream gages on the Kansas River at Fort Riley and the Big Blue River (see Figure B-3 for all site locations). Instantaneous data were not available at Kings Creek immediately following the flood because of damage to the USGS gage and were not available from Big Blue River. The peak instantaneous discharge for Kings Creek was estimated by USGS.



B.4.3.1.2 Temperature (heat energy)

Water temperatures represent a substantial stress to biotic communities in Great Plains rivers (Section B.4.3.3). Rivers to the north experience cold winters, and those to the south and west experience hot summers. Streams, particularly those strongly connected to more stable ground water, can provide thermal refuges for avoiding temporary hypothermic and hyperthermic stress (Section B.4.3.3.2). Wide, shallow channels with little overhead canopy can result in high water temperatures under summer low flows. Over a 1-km reach of the South Canadian River in Oklahoma, summer (August 18–19, 1976) maximum mainstem water temperatures were 36–37 °C, with cooler water (32–35 °C) in backwater pools and a tributary stream (Matthews and Zimmerman, 1990). Mean water temperatures of seven streams immediately upstream from confluences with the Missouri River (at the Kansas-Missouri border) did not differ from water temperatures in the mainstem river, 200–300 m downstream of the confluences, except during March when streams were warmer than the river (Braaten and Guy, 1999). Mean water temperature was determined to be homogeneous with no relationship between drainage area and water temperature across two agriculturally dominated drainages in Illinois, where most flow was derived from surface and shallow subsurface runoff (agricultural tiles) rather than deeper ground water (Wiley et al., 1990).

B.4.3.1.3 Sediment

Great Plains rivers are naturally turbid (Jewell, 1927; Cross and Moss, 1987; Huntzinger, 1995), with suspended sediment derived from the fine soils through which these river networks flow. Turbidity and suspended sediment concentration increase in prairie networks with increasing discharge and drainage area (Hill and Gardner, 1987b; Wiley et al., 1990; Lenhart et al., 2010), and can vary seasonally (Lenhart et al., 2010). Seasonal turbidity levels at tributary outlets and nearby mainstem reaches, however, were not related across seven Missouri River confluences in Kansas and Missouri (Braaten and Guy, 1999), suggesting that these streams did not influence river turbidity at baseflow conditions. In contrast to other studies in the prairie region, no relationship was found between suspended particle concentration and stream size among 22 sites ranging in land use and network position (second- to eighth-order) in the Kansas River basin (Whiles and Dodds, 2002). A significant positive relationship did exist when the authors excluded suburban sites and sites influenced by impoundments. Concentrations of suspended fine inorganic and organic matter were highest in the smallest stream draining suburban land use, whereas a comparably small stream draining native tallgrass prairie had among the lowest concentrations (Whiles and Dodds, 2002).

The downstream transport of metal-contaminated sediment was documented from mine tailings near a South Dakota headwater stream down through the river network to a reservoir approximately 200 km downstream, at the confluence of the Cheyenne and Missouri Rivers (Horowitz et al., 1988; Marron, 1989). The total amount of mine tailings transported from the headwater stream to downstream waters and floodplains over a 100-year span was estimated to be approximately 100 million metric tons (Marron, 1989). Contributions from streams to large rivers can therefore depend on the quantities available for transport from headwater streams from surrounding land uses.

B.4.3.2 Chemical Connections

B.4.3.2.1 Nutrients and other chemicals

Studies show that chemical constituents are exported from small prairie streams (Dodds et al., 1996a) and these chemical connections, or the downstream, flow-associated transport of nutrients, ions, dissolved and particulate organic matter, and other substances along prairie stream drainage networks, can significantly influence downstream water quality (Kemp and Dodds, 2002; Dodds et al., 2004; Dodds and Oakes, 2006).

Small prairie streams also can be important in preventing downstream nutrient transport. Studies conducted in Kings Creek, a stream draining a 1,060-ha tallgrass prairie catchment in Kansas, indicate that small prairie streams are highly nitrogen retentive (Tate, 1990; Dodds et al., 1996a; Dodds et al., 2000). For example, Dodds et al. (1996a) found that nitrogen transport through four second- and third-order streams in the Kings Creek watershed ranged from 0.01 to 6.0% of the total nitrogen supplied by precipitation, the balance being retained by the stream system. Similar patterns of nutrient retention have been demonstrated at larger spatial scales, as well. Alexander et al. (2000; 2008) modeled the contribution of different-sized streams and rivers (including prairie streams) to nutrient loading in the Gulf of Mexico. They found that large rivers deliver more of their nitrogen and phosphorus loads to the Gulf of Mexico than small streams, largely due to increased instream nutrient uptake and removal by small streams (Alexander et al., 2000). Despite their relative retentiveness, however, small streams do make substantial contributions to downstream nutrient loading due to their large numbers, with small to mid-sized streams in the western regions of the Mississippi River basin (which includes the Great Plains) delivering approximately 25−50% of their nitrogen loads to the Gulf (Alexander et al., 2008).

Correlations between water quality and upstream land use also indicate that prairie stream headwaters affect downstream reaches. Dodds and Oakes (2006, 2008) examined relationships between water quality and watershed land use at different spatial scales, along one fifth-order prairie stream network (Dodds and Oakes, 2006) and across 68 small prairie streams (Dodds and Oakes, 2008) in eastern Kansas. In the single drainage study, they found that concentrations of total nitrogen and nitrate were significantly related to riparian cover in the 2 km upstream of sampling sites, even when controlled for catchment land cover at each site (Dodds and Oakes, 2006). In the cross-drainage study, riparian cover along first-order streams was more closely correlated with total nitrogen, nitrate, ammonium, total phosphorus, atrazine, dissolved oxygen, and fecal coliform concentrations than riparian cover 2 or 4 km immediately upstream of sites across the 68 drainages (Dodds and Oakes, 2008). Nutrients are elevated in most prairie streams and rivers and nutrient concentrations in these systems are related to nonpoint land uses (Dodds and Oakes, 2004). These, along with widespread nature of headwater streams in river networks, are highly indicative that streams have strong chemical connection, functioning as important links between the surrounding lands to downstream waters.

Because prairie streams frequently experience intermittent flow, their influence on downstream waters is often discharge-dependent and temporally variable. For example, nitrate concentrations tend to be higher in intermittent prairie streams immediately after flows resume, versus when flow recedes (Tate, 1990). In addition, nitrogen uptake lengths (Dodds et al., 2000) and total phosphorus loads (Banner et al., 2009) increase with discharge. The effect of precipitation-driven flows on downstream water quality can depend on the relative contributions of surface water delivered from upstream channels and ground water. Prairie streams typically are tied closely to ground-water sources (Section B.4.2.2), so the influence of headwaters can be especially pronounced during periods of high precipitation. Kemp and Dodds (2001) found that nitrate concentrations in fourth- and fifth-order lowland prairie reaches were lowest during periods of high precipitation, when more low-nitrate water was delivered downstream from second- and third-order reaches and high-nitrate ground-water influences were minimized.

B.4.3.2.2 Dissolved and particulate organic matter

Differences in DOC inputs along the prairie stream longitudinal gradient provide further indirect evidence of chemical connections between prairie stream headwaters and downstream reaches. McArthur et al. (1985b) isolated bacteria from stream sediments of grassland reaches and gallery forest reaches of a prairie stream and exposed them to leachates derived from grasses and bur oak (a common gallery forest species). Grassland bacteria only grew when provided with grass leachates as a carbon source, whereas gallery forest bacteria grew when provided with either grass or bur oak leachates. This finding suggests that either (1) grass-derived DOC-consuming bacteria are transported downstream and then coexist with bacteria consuming forest-derived DOC, or (2) grass-derived DOC is transported downstream, and local bacterial communities have adapted to use more refractory DOC exported from upstream reaches (McArthur et al., 1985b).

Studies measuring POM exported from low-order prairie stream reaches show significant temporal and spatial variability. For example, Golladay (1997) documented little POM export from a third-order prairie stream in Kansas, whereas two prairie streams in Texas had much higher rates of POM transport (Hill and Gardner, 1987b). In part, these differences might reflect variability between stormflow and baseflow sampling, as organic matter concentrations can be positively correlated with stream discharge (Hill and Gardner, 1987b; Golladay, 1997). Whiles and Dodds (2002) examined seston (suspended fine particles) dynamics along the Kansas River drainage network (second- to eighth-order), and found that seston concentrations showed a significant positive relationship with stream size, increasing approximately 17-fold along the longitudinal gradient. This increase in seston was correlated with an increase in the taxa richness of filter-feeding invertebrates (Whiles and Dodds, 2002), illustrating that detrital transport along the stream gradient can influence invertebrate assemblages, which is a basic tenet of the River Continuum Concept (Vannote et al., 1980).

Stagliano and Whiles (2002) found that the standing stock of fine particulate organic matter FPOM in a perennial reach of a tallgrass prairie stream was insufficient to support the annual secondary production (i.e., the rate of heterotrophic biomass formation) of collector-gatherers (Cummins and Klug, 1979), the dominant group of macroinvertebrates feeding on deposited FPOM. The replenishment of FPOM standing stocks, at least in part from upstream sources via algal senescence, the transport and settlement of suspended POM, and the breakdown and transport of coarse POM, likely accounted for this apparent imbalance: Turnover of FPOM standing stocks was estimated to occur every 20 days (Stagliano and Whiles, 2002). Whiting et al. (2011) examined organic matter dynamics and trophic structure along a tallgrass prairie stream network (first- to fifth-order). They found that collector-filterers (macroinvertebrates that feed on suspended POM; Cummins and Klug, 1979) in upstream reaches consumed <1% of suspended POM flux; gatherers that feed on fine and very fine POM dominated secondary production in downstream reaches; and predators in downstream forested reaches consumed 107% of locally derived macroinvertebrate production. Predators in the upstream and middle reaches consumed 65% and 74% of available macroinvertebrate production, respectively. These findings support the idea that downstream secondary production depends in part on the export of energy sources (i.e., POM and invertebrates) from upstream reaches (in order for downstream predators to consume >100% of locally derived macroinvertebrate production).

As discussed earlier (Section B.4.2.4), prairie stream headwaters typically are open-canopied systems that receive little organic matter from terrestrial inputs, relative to forested headwaters (Jewell, 1927). Given the importance of autochthonous production in these systems, that algal-based contributions to prairie stream seston can be significant (Swanson and Bachmann, 1976; Hill and Gardner, 1987b; Lenhart et al., 2010) is not surprising. In four Iowa streams, export of chlorophyll *a* (a measure of algal biomass) was positively correlated with upstream channel bottom area, suggesting that downstream suspended algae originated as benthic algae in upstream portions of the network (Swanson and Bachmann, 1976). This downstream transport of algae also can provide colonists for downstream reaches after flooding or drying of stream channels. For example, Dodds et al. (1996b) examined the recovery of periphyton biomass upon channel rewetting in an intermittent prairie stream. Within 2 weeks, chlorophyll had returned to maximum levels on rocks placed in the stream, even when the rocks had been treated and scrubbed to remove desiccation-resistant propagules; this finding suggests that algal colonists in this stream were transported downstream from permanent upstream pools (Dodds et al., 1996b).

Coarse POM can connect prairie stream headwaters to downstream reaches. Johnson and Covich (1997) examined detrital inputs along a second- to fifth-order prairie stream network in Oklahoma. They found that leaves in the stream originated from farther upstream than expected, with the percentage of whole leaves at a site best explained by riparian forest cover in reaches 500 and 1,000 m upstream. The percentage of leaf fragments >1 mm was best explained by downstream distance along the stream network (Johnson and Covich, 1997), suggesting increased processing and fragmentation of leaves as they move down the longitudinal gradient.

B.4.3.3 Biological Connections

B.4.3.3.1 Invertebrates

Existing evidence for invertebrate-mediated biological connectivity along prairie stream networks mainly comes from studies of invertebrate assemblage recovery following flooding and drying in small prairie streams. Recovery from these disturbances tends to be relatively rapid, with substantial gains in invertebrate taxa richness and density observed within days to weeks (Miller and Golladay, 1996; Hax and Golladay, 1998; Fritz and Dodds, 2004), suggesting that these reaches are quickly repopulated by invertebrate drift from upstream sources, aerially dispersing adults, or disturbance-resistant survivors.

Fritz and Dodds (2002, 2004, 2005) examined postflooding and postdrying recovery of invertebrates in small intermittent and perennial prairie streams along an approximately 5-km stretch of Kings Creek in Kansas. They found that initial recovery of invertebrate taxa richness in intermittent reaches, and taxa richness of invertebrate drift and aerially colonizing insects, were negatively related to distance from upstream perennial water (Fritz and Dodds, 2002, 2004). Distance from upstream refuges, however, was not a significant predictor of invertebrate diversity measures across annual time scales (Fritz and

Dodds, 2005); they speculated that movement of water along the entire stream network (i.e., maintenance of hydrologic connectivity) makes proximity to colonists less important over longer time scales. These findings suggest that recovery from disturbance in these systems depends on biological connectivity via both downstream drift of colonizers and downstream (and potentially upstream) movement of aerially dispersing, egg-depositing adults (Miller and Golladay, 1996; Dodds et al., 2004).

B.4.3.3.2 Fishes

Research on fish assemblages in prairie streams provides perhaps the strongest and most well-studied evidence of biological connections throughout these networks. Much of this evidence focuses on two related aspects of the ecology of prairie stream fish: the dispersal and recruitment of pelagic-spawning prairie stream fish and the recovery of fish assemblages after disturbance, especially flooding and drying.

Many prairie stream fish broadcast spawn nonadhesive, semibuoyant eggs, which develop (typically hatching within 1 to 2 days) as they are transported downstream with water flow (Cross and Moss, 1987; Fausch and Bestgen, 1997; Platania and Altenbach, 1998; Durham and Wilde, 2006). The distance these eggs travel downstream depends on discharge and several other factors (e.g., development time); Platania and Altenbach (1998) estimated, however, that unimpeded eggs could travel as far as 144 km before hatching, and another 216 km as developing protolarvae (i.e., the swim-up stage), illustrating that downstream transport of these drifting organisms can be extensive. Without adequate water flow along sufficient lengths of the stream network, eggs can drop out of suspension before hatching (Platania and Altenbach, 1998; Durham and Wilde, 2006). Based on historical and contemporary fish surveys, eight species of pelagic-spawning cyprinids require a minimum length of greater than approximately 100 km (ranging from 103 to 297 km, depending on the species) of undisrupted stream channel (e.g., channels with no impoundments and no drying associated with human withdrawal) to support persistent populations (Perkin and Gido, 2011).

This pelagic-spawning reproductive strategy also necessitates upstream movement by adult fish, if populations are to be maintained in small prairie streams (Fausch and Bestgen, 1997; Durham and Wilde, 2008). Prairie stream fishes generally are highly vagile, with adults capable of long-distance migrations. For example, individuals of one species of prairie fish (*Hybognathus placitus*) in the South Canadian River, NM were observed to move approximately 250 m upstream over a 15-minute period, illustrating that prairie fishes can move substantial distances over relatively short periods (Fausch and Bestgen, 1997).

The effect that impoundment of prairie streams and rivers has had on the region's native fish assemblages highlights the importance of hydrologic connectivity in these systems. Many studies have documented statistically significant associations between impoundment of prairie streams and loss of native fishes (Winston et al., 1991; Luttrell et al., 1999; Schrank et al., 2001; Falke and Gido, 2006; Matthews and Marsh-Matthews, 2007). For example, Schrank et al. (2001) found that, across 26 streams in the Flint Hills region of Kansas, sites from which Topeka shiners (*Notropis topeka*) had been extirpated had significantly more small impoundments on them and higher largemouth bass

(*Micropterus salmoides*) catch-per-unit-effort than sites at which the shiners were extant. Fewer studies have specifically examined the mechanisms by which impoundments affect these changes, although impoundments likely disrupt both the downstream transport of developing eggs and larvae (Platania and Altenbach, 1998) and the upstream and downstream movement of adult fish.

Because many small prairie streams have intermittent flow, maintenance of fish populations often depends on dispersal out of intermittent reaches before drying occurs and recolonization of these habitats once water flow resumes—both of which require hydrologic connectivity along the stream network. Many fishes also require different habitats during different life stages, further necessitating hydrologic connectivity across these areas (Labbe and Fausch, 2000; Falke et al., 2010).

For dispersal and recolonization to occur, fishes must be able to access refuge habitats under adverse conditions, and then expand into newly habitable areas once adverse conditions abate. Small, spring-fed prairie streams serve as key refuges for endemic prairie fishes (Hoagstrom et al., 2010), because they are ground water fed and maintain permanent pools that can provide habitat during periods of channel drying (Wohl et al., 2009). This ground-water influence also allows these spring-fed streams to provide refuge from adverse temperatures. For example, a spring-fed stream in Missouri had more stable temperatures than the mainstem river, with cooler summer and warmer winter temperatures; in winter, fish from the mainstem river moved into this habitat, where their food availability, growth, and average egg size were greater than those of fish that stayed in the mainstem (Peterson and Rabeni, 1996).

During and after floods, juvenile and adult fishes can move upstream or downstream (or get displaced downstream) into newly available habitat (Fritz et al., 2002; Franssen et al., 2006). Once channels are rewetted, prairie stream fishes can move quickly into these previously unoccupied habitats (Harrell et al., 1967; Fritz et al., 2002; Franssen et al., 2006). For example, Harrell et al. (1967) examined fish response to channel drying in third- to sixth-order reaches of Otter Creek, an intermittent prairie stream in north-central Oklahoma, and found that most fish species collected after 8 months of flow prior to channel drying were already present 3 days after channel rewetting (Harrell et al., 1967). After a flood in an intermittent prairie stream in Kansas, fish dispersed into the headwaters from a perennial reach approximately 5 km downstream (Franssen et al., 2006).

B.4.4 Prairie Streams: Synthesis and Implications

Prairie streams typically represent a collection of spring-fed, perennial pools and reaches, embedded within larger, intermittently flowing segments (Labbe and Fausch, 2000). Due to the region's geographic location, substantial interannual variation in rainfall exists. Expansion (flooding) and contraction (drying) of these systems, particularly in terms of summer rainfall deficit (Borchert, 1950), determine the timing of hydrologic connectivity at any given time. Because of this temporal variability, connectivity in prairie river networks must be considered over relatively long time scales (multiple years).

- Studies have demonstrated significant physical, chemical, and biological connections from prairie headwater streams to larger rivers, despite extensive alteration of historical prairie regions by agriculture, water impoundment, water withdrawals, and other human activities

(Matthews and Robinson, 1998; Dodds et al., 2004), and the challenges these alterations create for assessing connectivity.

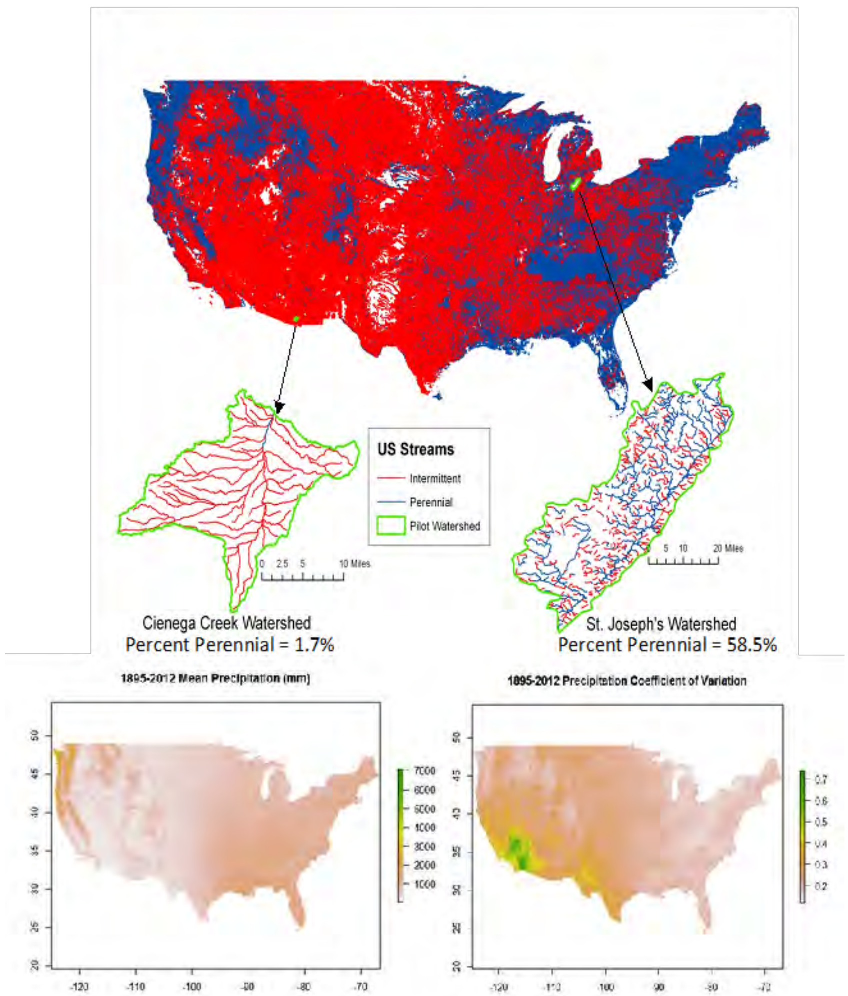
- The most compelling evidence for connectivity along prairie river networks comes from examples of streams as sources of water via flood propagation (Matthai, 1969; Fritz and Dodds, 2004, 2005), sources of contaminated sediment transport (Horowitz et al., 1988; Marron, 1989), sites of nutrient lags and transformation (Dodds et al., 1996a; Alexander et al., 2008), the downstream transport of prairie fish eggs and larvae (Platania and Altenbach, 1998; Perkin and Gido, 2011), and refuges for prairie fishes (Fausch and Bestgen, 1997; Franssen et al., 2006).
- Impoundments for irrigation storage and flood control have altered flood magnitude, altered flow timing, and reduced flow variability and turbidity across the prairie regions (Cross and Moss, 1987; Hadley et al., 1987; Galat and Lipkin, 2000). The effect that impoundment of prairie streams and rivers has had on the regions' native fish assemblages highlights the importance of hydrologic connectivity in these systems. Maintenance of fish populations often depends on dispersal out of intermittent reaches before drying occurs and recolonization of these habitats once water flow resumes—both of which require hydrologic connectivity along the stream network—and many fishes also require different habitats during different life stages (Labbe and Fausch, 2000; Falke et al., 2010).

B.5 Case Study: Southwestern Intermittent and Ephemeral Streams

B.5.1 Abstract

Ephemeral and intermittent streams are abundant in the arid and semiarid landscapes of the West and particularly the Southwest (Figure B-5.). These areas are characterized by low and highly variable precipitation where potential evapotranspiration exceeds precipitation. Based on the National Hydrography Dataset; 94%, 89%, 88%, and 79% of the streams in Arizona, Nevada, New Mexico, and Utah are intermittent or ephemeral (NHD, 2008). The heavily studied Upper San Pedro Basin in southeastern Arizona is discussed in detail because it is a well-understood example of the hydrologic behavior and connectivity of rivers common to the southwestern United States where ephemeral and intermittent tributaries comprise the majority of the basin's stream reaches. Flows and floods from ephemeral and intermittent streams are also major drivers of the dynamic hydrology of the relatively few perennial reaches in the Southwest. These streams also supply water to mainstem alluvial aquifers and regional ground-water aquifers. Both alluvial and regional aquifers, in turn, supply baseflow to perennial mainstem stream reaches over extended periods (sometimes months) when little or no precipitation occurs. It is this baseflow and shallow ground water that supports the limited naturally occurring, vibrant riparian communities in the region. In addition, ephemeral streams export sediment, which contributes to shaping the fluvial geomorphology and alluvial aquifers of streams in the regions (Shaw and Cooper, 2008), and nutrients, which contribute to river productivity. Several studies found

Figure B-5. Upper: Geographic distribution of intermittent and ephemeral (red) and perennial (blue) streams in the Continental United States and two example watersheds in Arizona and Michigan/Ohio/Indiana from the National Hydrography Dataset (NHD) stream map (http://nhd.usgs.gov/). Lower: maps of mean precipitation and the precipitation coefficient of variation (equal to the standard deviation divided by the mean) of annual precipitation from 1895 to 2012. Note that the NHD might not accurately reflect the total extent of ephemeral or intermittent streams, as it does not include stream segments less than 1.6 km (1 mile) long, combines intermittent and ephemeral streams, and is based on 1:100,000-scale topographic maps.



that native fishes and invertebrates are well adapted to the variable flow regimes common in rivers of the Southwest and are heavily influenced by ephemeral tributary streams (Turner and List, 2007).

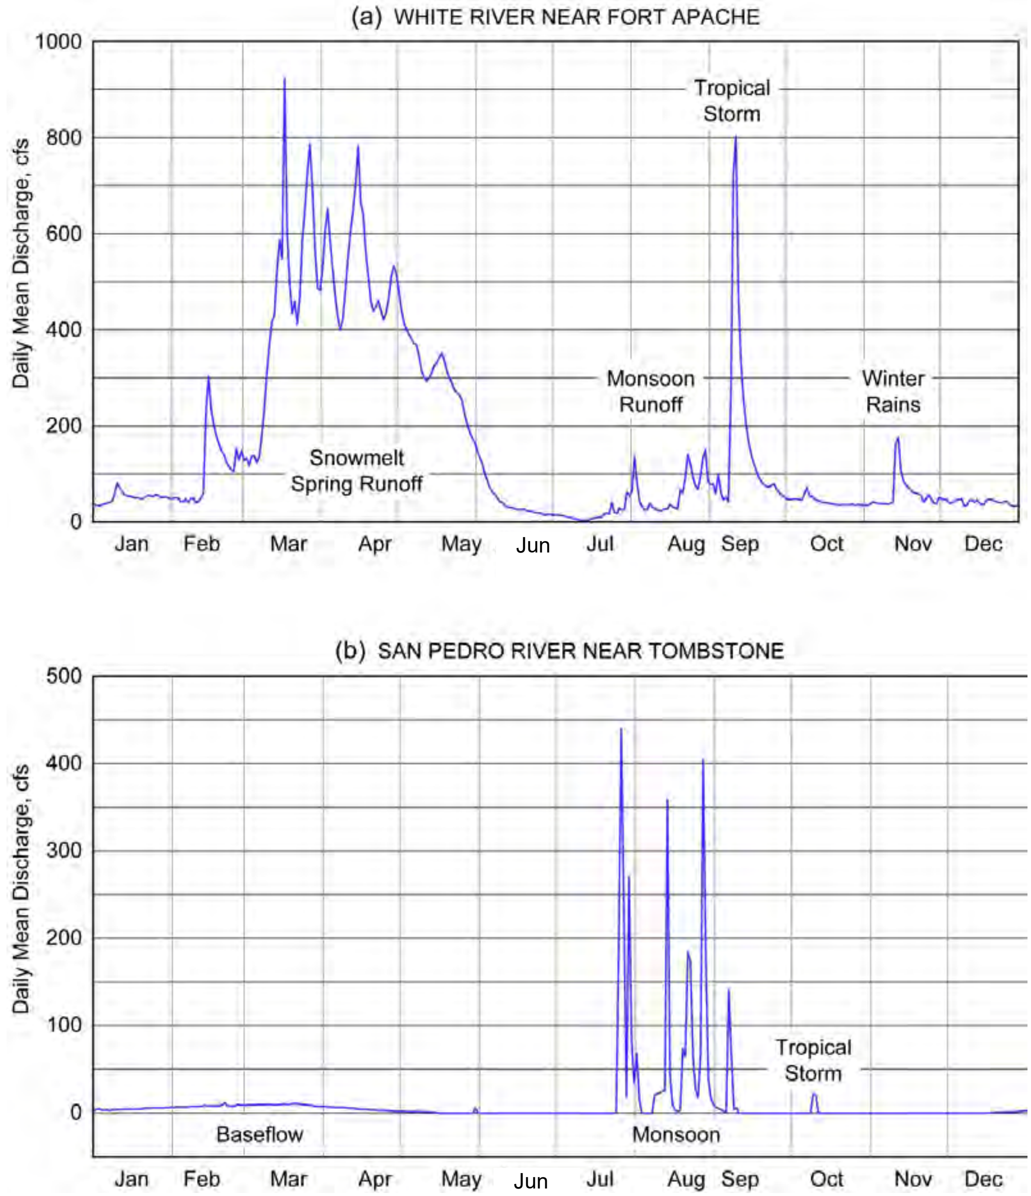
B.5.2 Introduction

This case study addresses the hydrologic and ecological influence of ephemeral and intermittent streams on perennial or intermittent rivers in the arid and semiarid southwestern United States with particular emphasis on Arizona and New Mexico. The structure of this case study differs slightly from the other case studies because of the uniquely thorough understanding of one particular southwestern river system, the San Pedro River, which has been the subject of a long-term research program (Goodrich et al., 2000; Stromberg and Tellman, 2009). Hence, evidence for the function and connectivity of ephemeral and intermittent tributaries to the San Pedro River is described in detail, and its application to other river systems in the Southwest is subsequently explored.

B.5.3 Southwestern Rivers

Understanding the unique characteristics of southwestern American rivers is necessary to evaluate the connectivity and influence of ephemeral and intermittent streams on these rivers (Levick et al., 2008). Southwestern rivers differ in many ways from rivers in the humid eastern United States or in the Midwest and West. Southwestern rivers typically can be divided into two main types, particularly in the Basin and Range geologic province. The first type comprises rivers in the mountainous upper basins that receive more precipitation, often as snow, and the second type comprises those rivers located in the arid or semiarid plateau regions and valley plains dominated by ephemeral streams (Blinn and Poff, 2005). For example, more than 80% of the Gila River corridor in New Mexico and Arizona meanders through desert scrublands. Precipitation is seasonal. In summer, precipitation is strongly influenced by atmospheric moisture flowing from the Gulf of Mexico and the Gulf of California (Mexican monsoon), where local heating triggers high-intensity air-mass thunderstorms. In fall, tropical depressions, often remnants of hurricanes, can bring infrequent but long-duration rainfall events; such storms are responsible for many of the larger floods in the region (Webb and Betancourt, 1992). Cyclonic storms from the Pacific Ocean, resulting in large frontal systems, dominate winter precipitation in the form of snow in higher elevations and typically as low-intensity rainfall in lower elevations (Blinn and Poff, 2005). Figure B-6 illustrates the 2003 calendar year hydrograph from the White River near the Fort Apache USGS gaging station (upper) in east-central Arizona, and the San Pedro River near Tombstone, in southeastern Arizona (lower). Although the two gaging stations differ in elevation by less than 200 m, the watershed contributing to the White River is substantially larger and is higher in elevation than the San Pedro watershed, resulting in long-duration spring runoff from snowmelt. Monsoon-generated, short-duration runoff dominates the San Pedro watershed but monsoonal influence also is apparent in the White River hydrograph. Runoff generated from late monsoon precipitation in September caused a major increase in discharge in the White River and a minor increase in the San Pedro. Most perennial and intermittent rivers in the Southwest are ground water dependent, flowing primarily in a baseflow regime and supported by discharge from a connected regional or alluvial aquifer or both. As discussed in more detail below, part of the baseflow is often sustained or augmented by slow drainage of a shallow alluvial aquifer from past flooding. In arid and semiarid regions, the riparian areas that perennial and intermittent streams support occupy a small percentage of the overall landscape but they host a disproportionately greater percentage of the biodiversity than the areas surrounding them (Goodrich et al., 2000; Stromberg et al., 2005). Reservoir construction, irrigation withdrawals, and the cumulative impacts of ground-water pumping have converted many historical, perennially flowing reaches into intermittently flowing reaches (Blinn and Poff, 2005).

Figure B-6. 2003 calendar year hydrographs from (a) the White River near Fort Apache, AZ and (b) the San Pedro River near Tombstone, AZ.



Abrupt changes in streamflow regimes (i.e., a change from perennial to intermittent or ephemeral and back again) can also result from underlying geology. Streams with abrupt changes are often referred to as interrupted streams (Meinzer, 1923; Hall and Steidl, 2007). A constriction and rise in bedrock geology can force regional ground water to the surface resulting in perennial flow while streamflow encountering highly fractured bedrock or a highly porous karst system can virtually disappear over very short distances. Another relatively abrupt transition in arid and semiarid stream hydrology and morphology occurs where steep mountain slopes transition into lower valley slopes. At this transition, watersheds with high sediment transport out of the mountainous portion often form alluvial fans. The stream channel system above the transition is typically dendritic and below the transition, the channel system often becomes a diffusive set of shallow braided channels. Runoff over alluvial fans typically becomes less concentrated or confined to a single large channel but more diffuse and shallower turning into broad sections of sheet flow (Parker et al., 1998). The diffuse runoff is more likely to infiltrate into the alluvial fan. Very large flows may be required for runoff to cross the alluvial fan and connect to downstream waters.

Dominant hydrologic flowpaths vary with location within southwestern river basins. After climate and weather, recharge and infiltration mechanisms are the next most important factors determining the occurrence of ephemeral, intermittent, and perennial streams. Recharge over longer time scales (months to centuries) is essential to replenishing regional ground water and near-stream alluvial aquifers, which in turn are essential to maintaining baseflow in perennial streams. Primary recharge mechanisms include mountain block recharge, mountain front recharge, diffuse hillslope or interchannel recharge, and ephemeral channel recharge. Key advances brought forth in a recent synthesis of research on ground-water recharge in the southwestern and western United States include (1) desert vegetation effectively eliminates diffuse recharge in most areas of the basin floor; (2) ephemeral channel recharge can be very important in wet years and greatly dominates recharge in basin-floor environments; and (3) environmental tracers are now available to "fingerprint the sources and amounts of ground-water recharge at the basin scale" (Phillips et al., 2004).

Mountains with deeper soils or those consisting of fractured rock will have higher infiltration capacities, less frequent occurrences of overland flow, and serve as recharge areas for regional ground water (Wilson and Guan, 2004; Blasch and Bryson, 2007; Wahi et al., 2008). Mountains with shallow soils and more consolidated rock will shed stormflow and shallow ground water off the mountain block onto the valley, which often consists of deep alluvium, particularly in the basin and range geologic province. This area is where mountain-front recharge occurs. High-elevation perennial streams often become intermittent or ephemeral at this transition, with their downstream disappearance of surface flow dependent on the flow rates coming off the mountain block and the permeability of the valley alluvium into which they enter. During periods of high flow, they can reconnect with other perennial stream reaches maintained by ground-water flow (Blinn and Poff, 2005; Blasch and Bryson, 2007; Yuan and Miyamoto, 2008).

Runoff generation in arid and semiarid valley floors and lowlands where basin alluvium is relatively porous and deep is dominated by the infiltration-excess mechanism in which precipitation rates exceed infiltration rates. In the arid and semiarid Southwest, high-intensity convective thunderstorms typically trigger this situation. Generally, such storms are relatively short in duration, resulting in ephemeral flows with short runoff duration (Goodrich et al., 1997). As water flows down dry ephemeral channels, it infiltrates the channel bottom and sides (i.e., channel transmission losses occur) where channel substrate is porous. If restricting soil or geologic layers underlying the channel do not substantially inhibit downward motion, channel transmission losses will recharge either the regional or alluvial ground water (Tang et al., 2001; Constantz et al., 2002; Harrington et al., 2002; Goodrich et al., 2004; Coes and Pool, 2005; Vivoni et al., 2006; Blasch and Bryson, 2007). In this influent stream environment typical of many southwestern streams, the volume of transmission water losses in ephemeral channels increases as watershed size increases, resulting in a losing stream environment as opposed to a gaining stream environment encountered in wetter hydroclimatic regimes (Goodrich et al., 1997). As noted above and discussed in Phillips et al. (2004), these ephemeral tributary channels are the dominant source of recharge in valley floors, and at the basin scale they can provide substantial recharge during wet years. Typically, as stream drainage area increases, the alluviums under and next to streams begin to serve as important shallow aquifers that receive and store streamflow infiltration during hydrologic events and sustain baseflow and riparian communities between storms (Stromberg et al., 2005; Baillie et al., 2007; Dickinson et al., 2010).

The magnitude of aquifer recharge is highly temporally variable in the Southwest. Winter precipitation, which has a predominant effect on mountain-block and mountain-front recharge in the Arizona-New Mexico portion of the Southwest, is correlated with the El Niño/Southern Oscillation (Woolhiser et al., 1993) at interannual time scales. Over decadal climate cycles, winter precipitation also is related to the Pacific Decadal Oscillation (Pool, 2005). The magnitude of ephemeral channel recharge varies widely from year to year, depending on the strength of the monsoon season (Goodrich et al., 2004) and the occurrence of relatively infrequent and prolonged precipitation events resulting from tropical depressions. Floods and large runoff events caused by any of these mechanisms can have a long-lasting influence (6 to 10 months) on baseflow of southwestern rivers by recharging near-stream alluvial aquifers and thereby sustaining streamflow as they drain (Brooks and Lemon, 2007).

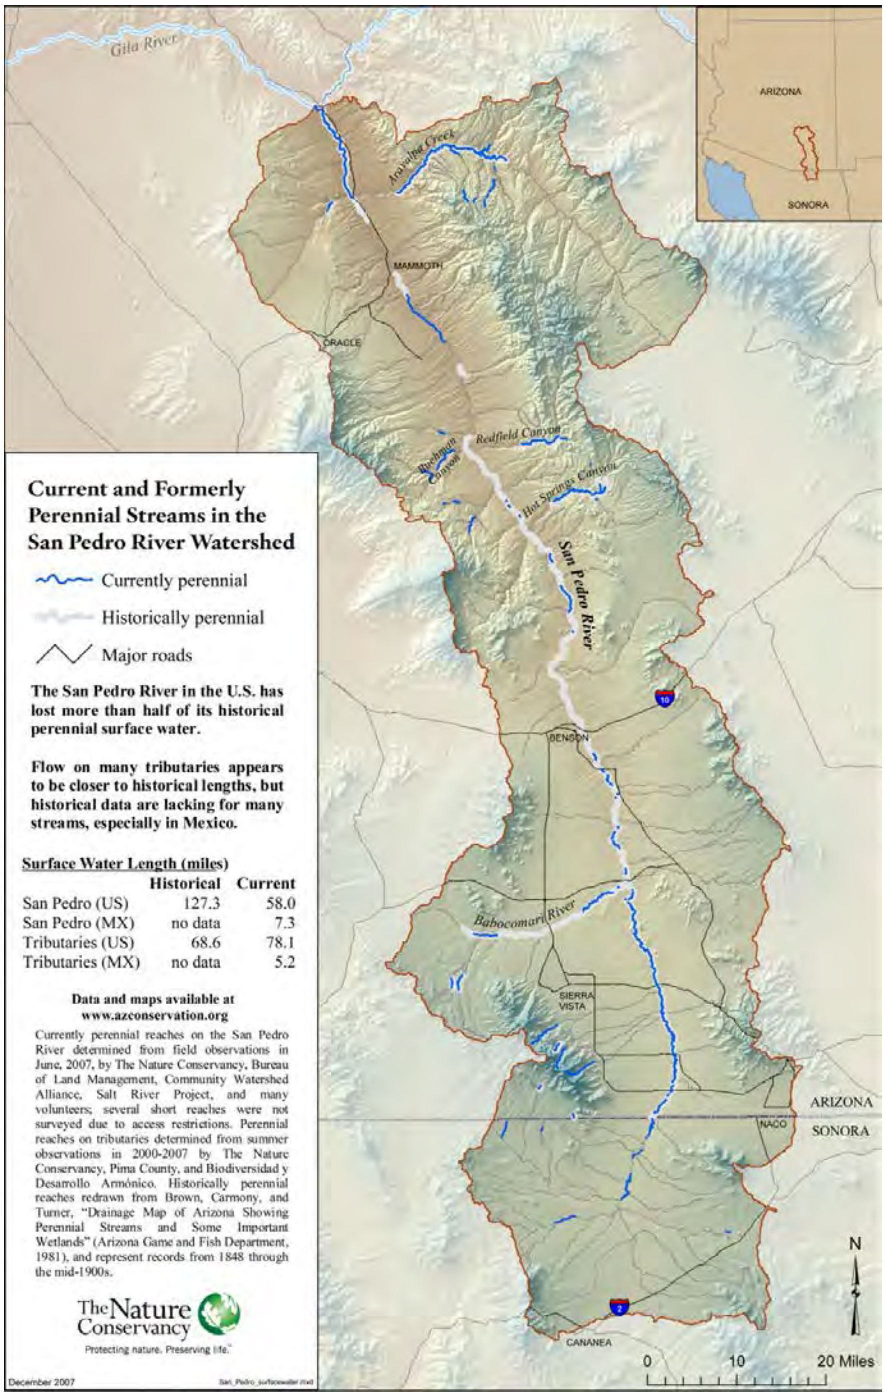
B.5.4 San Pedro River

B.5.4.1 Basin Characteristics

Because of a rich research and long-term monitoring history, the San Pedro Basin and River in southeastern Arizona represents an excellent case study of the hydrologic behavior and connectivity of southwestern rivers (Goodrich et al., 2000; Stromberg and Tellman, 2009; Brookshire et al., 2010). The San Pedro River originates in Mexico, flowing undammed north to its confluence with the Gila River. The San Pedro is the only significant un-impounded river in Arizona and the last remaining stream in southern Arizona with long perennial reaches (Figure B-7; Kennedy and Gungle, 2010). Most tributaries to the river are ephemeral at their confluence with the mainstem. The river basin, located in the Basin and Range Province, has a valley that is generally 30−50 km wide, comprising sedimentary fill deposits, and slopes upward from the river to mountains with elevation ranging from 2,000 to 2,900 m. The San Pedro Basin consists of 93% nonperennial reaches (including ephemeral and intermittent), 6.3% artificial path (canals, diversions, pipeline, connectors), and 0.7% perennial reaches in the U.S. portion of the basin as derived from the USGS NHD[1] (Figure B-8). The percentage of streams types is not static but varies from year-to-year. The Nature Conservancy and its partners annually map the wet and dry reaches along the San Pedro mainstem and several large tributary streams since 2007

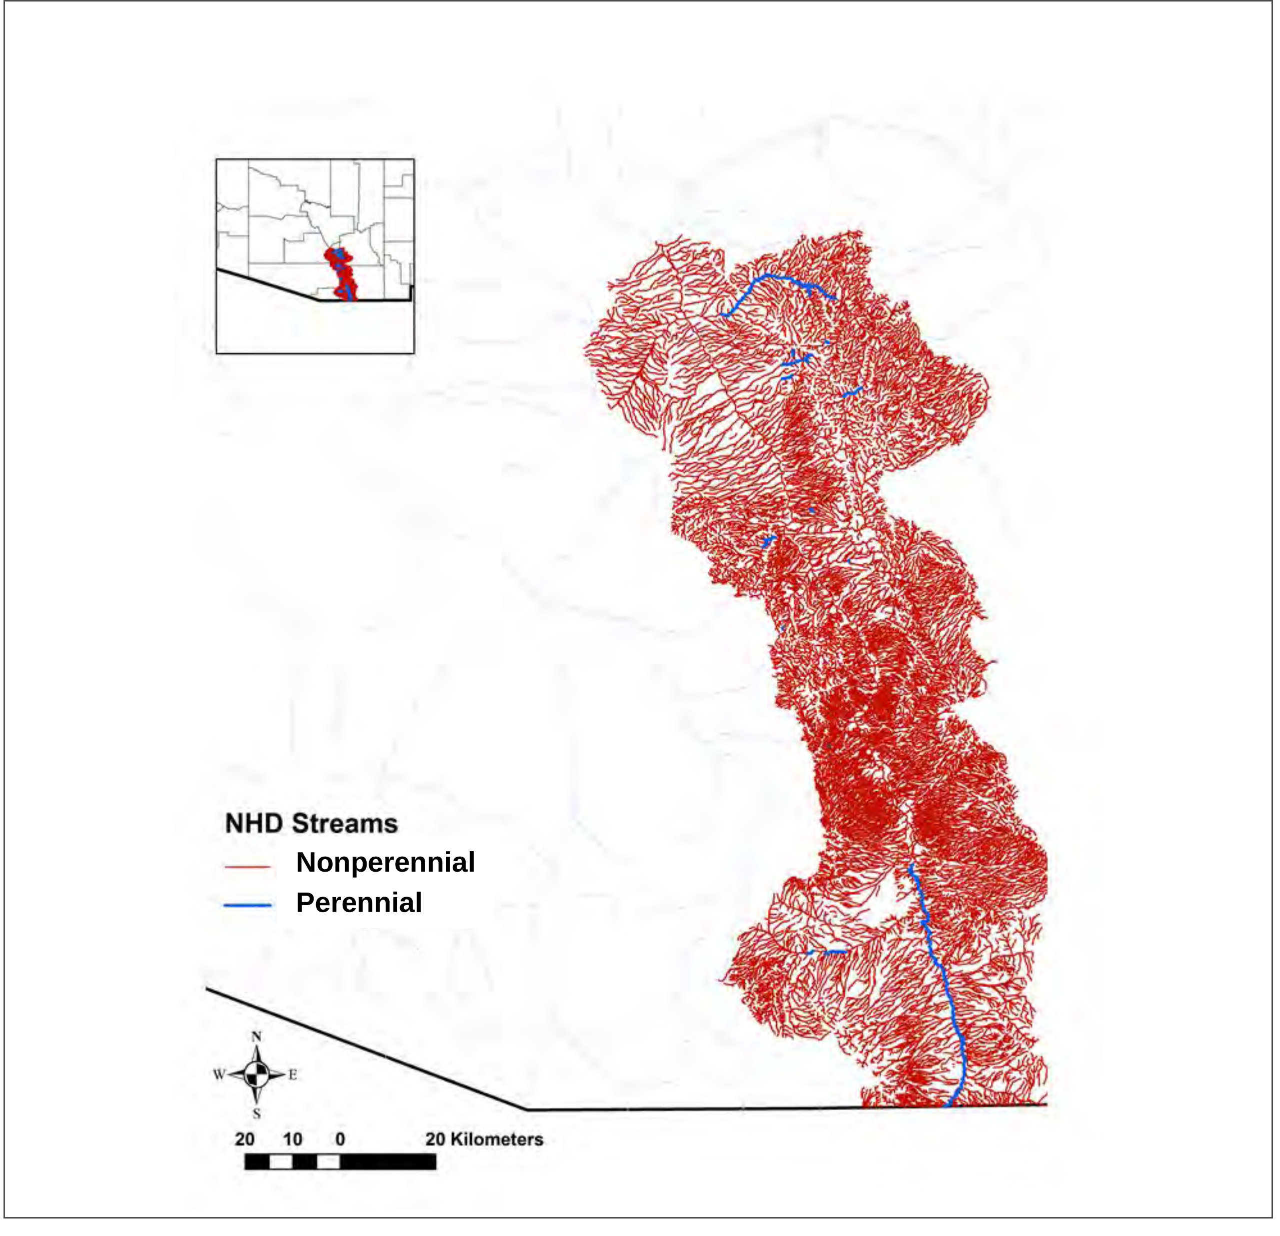
[1]Based on USGS National Hydrography Dataset (NHD) stream map (http://nhd.usgs.gov/). Note that the NHD might not reflect the total extent of ephemeral or intermittent streams accurately, as it does not include stream segments less than 1.6 km (1 mile) long, combines intermittent and ephemeral streams, and is based on 1:100,000-scale topographic maps.

Figure B-7. San Pedro River basin map showing major physiographic features and current and historical perennial reaches. From Levick et al. (2008), courtesy of The Nature Conservancy, Arizona. Available online at http://azconservation.org/map_gallery/current_and_formerly_perennial_san_pedro_river_surface_water.



(Turner and Richter, 2011). The wet-dry mapping is conducted roughly in the middle June, historically the time of lowest streamflow, prior to the onset of the monsoon. For 2014, about 25% (54.1 km) of the 214 km surveyed were found to be wet (214 km is ~1.1% of the stream length plotted in Figure B-8).

Figure B-8. Perennial (blue) and nonperennial (red) streams in the San Pedro Basin from the U.S.-Mexico border to its confluence with the Gila River based on USGS National Hydrography Dataset (NHD) stream map (http://nhd.usgs.gov/).



The wet-dry survey data is accessible at:
(http://azconservation.org/downloads/category/san_pedro_river).

Annual precipitation within the basin ranges from 300 to 750 mm with highest amounts occurring in the mountains. Vegetation includes desert scrub, grasslands, oak woodland savannah, mesquite woodland, riparian forest, coniferous forest, and agriculture (Kepner et al., 2000; Kepner et al., 2004). Brush and grasses typical of southwestern semiarid landscapes (Goodrich et al., 1997) dominate the valley floor vegetation.

At the Walnut Gulch Experimental Watershed (WGEW—a subwatershed of the San Pedro watershed near Tombstone, Arizona), operated by U.S. Department of Agriculture, Agricultural Research Service (USDA-ARS), approximately two-thirds of the annual precipitation on the watershed occurs as high-intensity, convective thunderstorms of limited aerial extent (Goodrich et al., 1997). Winter rains (and occasional snows) are generally low-intensity events associated with slow-moving cold fronts and are typically of greater aerial extent than summer rains. Runoff on the lower elevations of the WGEW is generated almost exclusively from convective storms during the summer monsoon season via infiltration excess that produces overland flow. The hydrogeology of the San Pedro River basin is typical of many alluvial basins in the Southwest (Dickinson et al., 2010). Ground water flows through the basin-fill aquifer (regional aquifer) from recharge areas near the mountains and beneath ephemeral tributaries to perennial reaches of the San Pedro River (Wahi et al., 2008; Dickinson et al., 2010). A narrow band of highly permeable stream alluvium is incised into the basin-fill along the major stream channels (Figure B-9). The stream and floodplain alluvium is an important alluvial aquifer that receives discharge from the basin-fill aquifer and streamflow via streambank infiltration occurring during high stream stages.

This bank and alluvial aquifer storage supports riparian vegetation during periods lacking runoff (Dickinson et al., 2010). The San Pedro River network with associated shallow alluvial aquifers (mainstem and portions of some tributaries) supports extensive riparian vegetation communities (Stromberg et al., 2005) that provide habitat for more than 350 species of birds, 80 species of mammals, and 40 species of reptiles and amphibians (Kennedy and Gungle, 2010). Alluvial aquifers also are zones of extensive hyporheic exchange (Stanford and Ward, 1988; Fernald et al., 2001).

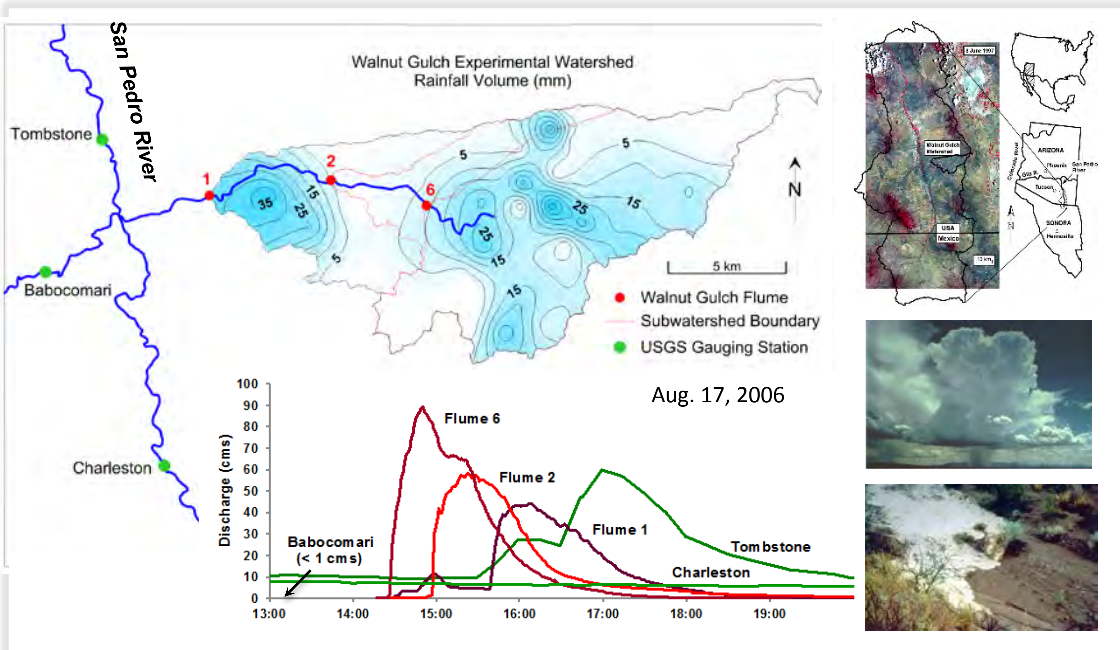
B.5.4.2 Ephemeral Stream Connections and Their Influence on the San Pedro River

Overland runoff generation and associated ephemeral streamflow is common in San Pedro tributary streams. Goodrich et al. (1997) examined hundreds of hydrologic events in different-sized catchments at the USDA-ARS WGEW and found that the relationship between watershed area and runoff volume was increasingly nonlinear as drainage area increased. The authors found a critical threshold watershed area of approximately 36−60 ha, at which runoff responses became much less linear and channel transmission losses increased more rapidly with increasing watershed area. This relationship is very different from commonly observed relationships in humid streams of the East, where runoff generally is proportional to watershed area (Section 3.3.1). Two reasons for this variability in runoff produced per unit watershed area are: (1) the spatial variability and limited spatial extent of runoff producing precipitation, and (2) the loss of runoff by infiltration into the bed of ephemeral channels (transmission losses). Figure B-10 illustrates this process. During a major rainstorm on 17 August 2006, most of the precipitation from multiple air-mass thunderstorm cells occurred over relatively localized areas in the upper and lower portions of the USDA WGEW. As overland flow occurred and became concentrated in the ephemeral tributary network, streamflow dramatically diminished as the runoff hydrograph traveled downstream through the channel network. However, a substantial amount of runoff from this storm traversed the ephemeral Walnut Gulch tributary and reached the mainstem of the San Pedro River, augmenting the flow as measured at the USGS Tombstone stream gage. Runoff in Walnut Gulch (149 km^2 drainage area) and many arid and semiarid streams is characterized by short duration, highly episodic flows. The longitudinal extent of the effects of these flows on downstream waters is a function of the flow magnitude, its duration, the depth, conductivity and antecedent moisture conditions of the ephemeral channel substrate that the runoff flows across, and the depth to ground water. For example, in 2006 there were 23 runoff flows measured at Walnut Gulch flume 1 (the outlet of the WGEW). The average volume, peak runoff rate, and duration of these runoff events was 31,460 m^3, 7.23 m^3/s, and 239 minutes, respectively. Four (4) of the 23 runoff events recorded at Flume 1 were estimated to have measureable impacts on flows measured at the downstream USGS Tombstone stream gage (4510 km^2) on the San Pedro River (including the event shown in Figure B-10).

Evidence is strong that transmission losses in ephemeral tributary streams recharge alluvial and regional aquifers (Goodrich et al., 1997; Callegary et al., 2007). Using three fundamental approaches to estimate ephemeral channel recharge (1—closing the water balance for the channel reach, 2—measuring changes in ground-water volume directly [well levels] or indirectly [microgravity], and 3—using geochemical tracers), Goodrich et al. (2004) estimated that during the relatively wet 1999 and 2000 monsoon seasons, regional aquifer ground-water recharge from ephemeral streams ranged from approximately 15 to 40% of total average annual recharge as estimated from a calibrated regional ground-water model (Pool and Dickinson, 2007). During the dry monsoon seasons of 2001 and 2002, limited ephemeral runoff and stream channel infiltration occurred, but no discernible deep aquifer recharge was detected.

The influence of stormflows from ephemeral tributary streams extends to the San Pedro River mainstem. As stormflow is exported from the tributaries to the mainstem and water moves downstream, transmission losses and bank recharge occur within the mainstem river itself and supply water to the alluvial aquifer of the mainstem (Kennedy and Gungle, 2010). Using geochemical tracers (chloride, sulfate, and stable isotopes of hydrogen and oxygen in water), Baillie et al. (2007) found two main sources of water in the alluvial aquifer for the upper San Pedro River: (1) regional ground water

Figure B-10. Storm rainfall and downstream hydrographs with decreasing runoff volume and peak rate due to channel transmission losses as measured by in the USDA-ARS Walnut Gulch Experimental Watershed (WGEW) and the impact of this storm runoff on the San Pedro River in SE Arizona. Inset photos show a typical air-mass thunderstorm and the front of surface flow progressing down an ephemeral channel. Photo of ephemeral stream from Levick et al. (2008).



recharged along the Huachuca Mountains (mountain block, mountain front) to the west, and (2) local recharge from monsoon floodwaters. Alluvial ground-water composition varied between gaining and losing reaches. Locally recharged floodwater comprised 60 to 85% of the alluvial ground water in losing reaches but only 10 to 40% in gaining reaches. Baseflow also contained a significant component of monsoon floodwater throughout the year, from 80% in upstream reaches to 55% after passing through several gaining reaches.

Ephemeral tributary stormflows are also sources of sediment and alluvium for the main San Pedro River. Only the largest, less frequent events can flush sediment completely through ephemeral tributaries (Lane et al., 1997). For example, a reach-scale study in the WGEW estimated sand transport distances of only 401 and 734 m in nine floods over two consecutive years (Powell et al., 2007). In another study, Lekach et al. (1992) found that more than 90% of the bedload yield originated from the mid-watershed channels during larger runoff events from an arid watershed in Israel. Ephemeral tributary stormflows and their associated sediment loads influence the character of river floodplains and alluvial aquifers (Nanson and Croke, 1992; Shaw and Cooper, 2008).

Extensive riparian plant communities along the mainstem San Pedro River depend on the availability of water in the alluvial aquifer along the river, including water derived from ephemeral stream stormflows (Stromberg et al., 2005; Baillie et al., 2007). These riparian areas, in turn, strongly influence river attributes through stream shading, channel stabilization, nutrient cycling, inputs of invertebrates and other organisms, and inputs of detritus, wood, and other materials (Gregory et al., 1991; National Research Council, 2002; Naiman et al., 2005).

Ephemeral tributary stormflow inputs heavily influence the nutrient and biogeochemical status of the San Pedro River. Brooks and Lemon (2007) performed synoptic sampling on a 95-km reach of the San Pedro River to identify the effects of regional hydrology and land use on dissolved carbon and nitrogen concentrations. They found that, during the summer monsoon season, baseflow increased 5- to 10-fold, and dissolved organic matter and inorganic nitrogen increased 2- to 10-fold. The fluorescence index of water samples indicated a large input of terrestrial solutes with the onset of monsoon runoff inflows, and values of both chloride and oxygen isotope tracers indicated that stream water and alluvial ground water were well mixed along the entire 95-km reach. Meixner et al. (2007) used chloride tracer samples and mixing analyses to examine sources of San Pedro River water during six summer floods in 2001 (wet year) and 2002 (dry year). Results of mixing models indicated that both a ground water-soil water end-member and a precipitation end-member (indicative of overland flow) contributed to the floods. The highest percentage of ground water-soil water in the flood flow (46%) occurred during an early 2001 flood and the lowest during large monsoonal floods of 2002. They noted that ground water probably made lower contributions than soil water to streamflow, because high river stage during flood events created hydraulic gradients from the river to alluvial ground water in the riparian area (water moved from the river to alluvial ground water via bank storage, Figure 2-13B). During the first floods of each year, nitrate and dissolved organic carbon increased dramatically in the river, whereas dissolved organic nitrogen did not exhibit increases in 2001 but did in 2002. During floods, nitrate-nitrogen (NO_3-N) concentrations in river water were 0.2–0.5 mg NO_3-N L^{-1} higher in 2002 than during 2001. This result was consistent with higher observed nitrate-nitrogen concentrations in soil water of the riparian zone (alluvial aquifer) in 2002 than in 2001.

In summary, ephemeral tributary streams have strong physical and chemical connections to the San Pedro River. The river ecosystem, including its abiotic and biotic components, depends on the influences exerted by the ephemeral tributary streams on the river environment.

B.5.5 Other Southwestern Rivers

B.5.5.1 Physical Connections

Hydrologic behavior and river-system connectivity similar to the San Pedro River have been observed in other southwestern rivers, increasing confidence that the observations made within the San Pedro are applicable to other southwestern river systems.

Plummer et al. (2004) found that the Rio Grande in New Mexico has two primary sources of regional ground water: (1) recharge from mountains and (2) seepage from the Rio Grande and Rio Puerco, and from Abo and Tijera Arroyos (arroyos are ephemeral streams). Vivoni et al. (2006) observed ground-water recharge processes in the Rio Puerco, a tributary river to the Rio Grande, and in the Rio Grande itself. They note that a summer monsoonal rainstorm produced a flood event on the Rio Puerco that, in turn, generated a pulse of floodwaters along a losing reach of the Rio Grande (Figure 3-2). Forty-nine percent (49%) of flood volume was lost to the shallow alluvial aquifer of the Rio Grande. Loss of river water to the alluvial aquifer was observed to decrease with distance down the river reach.

Another important drainage basin type in the western and southwestern United States is endorheic or closed drainage basins draining to lakes and playas having no outlet to the ocean. The largest of these western basins is the Great Basin, which is approximately 490,000 km^2 (~5% of the area of the United States) and covers most of Nevada and parts of Oregon, Utah, and California (Atwood, 1994). Closed basins can contain ephemeral, intermittent, and perennial stream reaches. Although endorheic streams do not drain into oceans, many support downstream waters and habitat and numerous large perennial lakes such as Lake Tahoe in California and Nevada and the Great Salt Lake in Utah.

The Pecos River basin in eastern New Mexico and western Texas comprises part of southern Rocky Mountains in the north and grasslands, irrigated farmlands, deserts, and deep canyons in the southern lower reaches of the river (Yuan and Miyamoto, 2008). Precipitation occurs as snow in the mountains and summer monsoonal rainfall in the lower river valley. Based on hydrogen and oxygen isotope composition of river water, Yuan and Miyamoto (2008) separated the river basin into three subbasins: (1) the upper basin, (2) the middle basin, and (3) the lower basin. Snowmelt dominates the mountainous upper basin. The river in the topographically gentle middle basin had mixed sources of water. Thirty-three percent (33%) of river water was lost through evaporation occurring in the streams channels and irrigated fields of the middle basin. Similar to the San Pedro River, up to 85% of streamflow in the lower basin was estimated to derive from local freshwater sources, mainly monsoonal rainfall. This finding is consistent with significant contributions of flow from ephemeral tributary streams.

Shaw and Cooper (2008) studied the 14 ephemeral stream reaches in the Little Colorado River Basin in northeastern Arizona. As derived from the USGS National Hydrography Dataset, this basin contains a lower percentage of ephemeral and intermittent stream reaches (70%) as compared to the ~93% of such reaches in the Upper San Pedro. Shaw and Cooper (2008) related watershed characteristics of the Little Colorado to downstream reaches and the riparian plant communities of those reaches. They found that, as the watershed area draining to the studied reaches increased, the overall basin channel slope deceased, which resulted in less erosive capacity due to channel transmission losses and a decrease in the variability of alluvial ground water in these channels. This resulted in "decreased disturbance potential and increased moisture availability in the downstream direction," and these reaches had a greater abundance of obligate riparian vegetation. Shaw and Cooper (2008) went on to develop a stream classification system that related the functional linkages between contributing upstream watersheds, stream reaches, and riparian plant ecology. Type I stream reaches have relatively small drainage areas (less than 10 km^2), which have the greatest disturbance potential with in-channel and near-channel plants resembling those of surrounding upland species. Between 10 and 100 km^2, Type II streams exhibit "more moderate shear stresses and more persistent alluvial groundwater" with riparian vegetation that is a mixture of upland and riparian species. Having larger areas (greater than 100 km^2), Type III reaches are "controlled mainly by upstream hydro-climatic conditions" with wetland tree and shrub communities. Shaw and Cooper (2008) concluded that the connection of streamflow and ground-water regimes to riparian vegetation in the larger Type III watersheds, draining greater than 100 km^2, to upstream reaches far removed from larger regional floodplain rivers "… were driven by climatic patterns from distant portions of the upper watershed and were relatively insensitive to local rainfall." This finding reinforces the fact that stream-reach characteristics are influenced and connected, often episodically, to distant portions of the contributing watershed.

B.5.5.2 Human Alterations

Anthropogenic uses and activities on arid and semiarid landscapes can have significant effects—both good and bad—on downstream waters and overall health of watersheds. Human alteration to arid and semiarid watersheds occurs in many forms and includes livestock grazing, land clearing, mining, timber harvesting, ground-water withdrawal, streamflow diversion for water supply and irrigation, channelization, urbanization, agriculture, roads and road construction, off-road vehicle use, camping, hiking, and vegetation conversion (Levick et al., 2008). Climate change likely will have increasing influence on streams and their connectivity in the Southwest. Most climate models predict important changes for the southwestern United States, including increased warming and drying, intensification of droughts, and increased variability of precipitation (Seager et al., 2007). These changes will result in less runoff, reduced snowpack, and changes in streamflow patterns. Reduced snowpack will result in shorter periods of longitudinal stream connectivity in intermittent streams, as snowmelt will occur more rapidly in a warmer climate.

Streamflow augmentation can occur in human-dominated watersheds in the form of treated municipal and industrial wastewater effluent discharges. Streams that would dry without these discharges are effluent-dependent streams, whereas those that receive most, but not all, of their flow from effluent are effluent-dominated streams (Brooks et al., 2006). Streams draining human-dominated areas also can acquire baseflow from ground water recharged by over-irrigation and leaky infrastructure (Lerner, 1986; Roach et al., 2008; Townsend-Small et al., 2013).

Riparian areas near mainly perennial streams, but also in many cases intermittent streams, historically have been attractive for human development, leading to their alteration on a scale similar to that of wetlands degradation nationally (National Research Council, 2002). This situation is especially true in arid and semiarid regions because riparian areas typically are indicative of water availability either as surface water or as shallow ground water. Riparian areas in arid and semiarid regions are also greener and cooler than most upland areas. Riparian areas are more sensitive to development impacts than wetter areas, however, because of their limited geographical extent, drier hydrologic characteristics, and fragile nature (e.g., erodible soils). Historically, riparian habitats represented about 1% of the landscape in the West, and within the past 100 years, an estimated 95% of this habitat has been lost due to a wide variety of land-use practices such as river channelization, unmanaged livestock grazing, agricultural clearing, water impoundments, and urbanization. The following subsections present some of the types of human-caused impacts on ephemeral and intermittent streams and their associated riparian areas.

B.5.5.2.1 Land development

Land development includes urban, suburban, and exurban development but is referred to here collectively as urban development. Before the 2008 recession, the Southwest was one of the fastest growing regions of the United States, having an increase in population of approximately 1,500% over the previous 90 years. In contrast, the population of the country as a whole grew by just 225% over that time. Arizona and Nevada have grown the most, with population increases of 2,880% and 2,840%, respectively. Typical urban development significantly changes the hydrologic characteristics of a watershed by covering uplands with impervious surfaces, and removal, channelization, or armoring of headwater streams (Box 3-1; Kennedy et al., 2013). Alteration of the natural stream network disrupts natural flow patterns and sediment transport and storage, resulting in downstream flooding and changes to the clarity and quality of the downstream flows and receiving waters. These effects can damage downstream water supplies and habitat. The aerial photograph presented in Figure B-11 shows a network of ephemeral streams that flows through a small community southeast of Tucson, AZ, to Cienega Creek, a protected perennial stream.

Figure B-11. Aerial photograph showing ephemeral tributaries to Cienega Creek, a perennial stream, flowing through the small community of Vail, southeast of Tucson, AZ. Photograph: Lainie Levick/Aerial flight courtesy of Lighthawk, www.lighthawk.org.

The impact of urbanization increases as the percentage of impermeable surface increases. Various studies have shown that semiarid stream systems become irreparably impaired once the impervious surfaces within the watershed exceed about 10% and experience dramatic morphological changes once those surfaces exceed about 20% (Schueler, 1994; Miltner et al., 2004).

As the amount of impervious surface increases, runoff increases and infiltration decreases (Kennedy et al., 2013), starting a chain of events that includes flooding, erosion, stream-channel alteration, increases in human-caused pollutants, and ecological damage. Floods become more severe and more frequent, and peak flows and runoff volumes will be many times greater than in natural basins. The greater volume and intensity of flooding causes increased erosion and sediment transport downstream. To accommodate the increased flow and sediment load, streams in urbanized areas tend to become deeper and straighter over time. The resulting bank erosion can destroy established streamside habitat and tree cover, leading to higher temperatures, sedimentation, and disruption of wildlife corridors.

Storm sewers and lined drainages increase the rate of water delivery to the downstream channel network. Erosion and sedimentation increases during construction and road building for new urban areas. Improperly constructed and maintained roads, especially unpaved roads, can alter hillslope drainage, and change baseflow and precipitation-runoff relationships, causing erosion and sedimentation in streams (USDA, 2002). The primary geomorphic consequence of these hydrologic changes is the erosional entrenchment of nearby channels and associated transportation of the excavated sediment downstream, causing a significant increase in sediment load. Sediment is of particular concern in arid and semiarid regions because many other pollutants tend to adhere to eroded soil particles. Additional pollutants from urban runoff can include pathogens, nutrients, toxic contaminants, sediment, and debris. Consequently, urban areas require stormwater management plans both during and after construction to control runoff and offsite pollution.

Streams are channelized in urbanizing areas to protect private property and control streambank erosion. Channelization typically straightens and steepens the stream, however, resulting in increased flow velocity and sediment movement. These changes transfer flooding and bank erosion downstream of the protected area. In the channelized reaches, the greatly reduced out-of-bank flow disrupts water, sediment, organic matter, and nutrient enrichment of the flood plain (National Research Council, 2002). In addition, removal of vegetation as part of the channelization process degrades wildlife habitat.

Habitat fragmentation is a common consequence of urbanization (Hilty et al., 2006). New developments can alter large areas of land, removing natural drainage systems and wildlife habitat, and replacing them with houses and roads. Altering, bisecting, or channelizing streams effectively can eliminate the main biological functions of the stream channel by disrupting vegetation communities and hydrologic function. Habitat fragmentation reduces wildlife diversity and abundance and might cause sensitive species to disappear (England and Laudenslayer, 1995).

B.5.5.2.2 Land use

In addition to urbanization, agriculture (livestock and crops) and mining, including sand and gravel operations, are major land uses in the desert Southwest. Livestock grazing is one of the more common uses of rural land in the Southwest. Late 1800s estimates of cattle numbers in Arizona and New Mexico exceeded 1.5 million and 2 million, respectively. During this period, the region experienced both significant droughts and floods. During drought, the resulting desiccation of the uplands drove cattle to the riparian areas, which were heavily damaged as a result. When the rains returned to the denuded landscape, erosive processes were greatly enhanced. The overgrazing that occurred during this time is one of the factors attributed to a relatively widespread period of channel downcutting, forming deep arroyos and lowering ground-water levels (Schumm and Hadley, 1957; Hastings, 1959; Graf, 1988).

In modern grazing-land management, livestock are provided with watering sources away from streams when possible, but frequently they must depend on the streams for water. Livestock management efforts attempt to avoid overuse of an area, but because water is scarce in arid environments, cattle and wildlife tend to linger near water sources. Where not properly managed, cattle can remain too long in a riparian area and trample streambanks, eat the riparian vegetation to the ground, contaminate the water with wastes, and compact the soil (Levick et al., 2008). Several literature sources have stressed that the cumulative impacts of unmanaged livestock in southwestern riparian ecosystems for the past several hundred years probably have been the single most important factor in riparian ecosystem degradation (Wagner, 1978; Ohmart, 1995).

Mining is another activity that historically has played a large role in the economy and land use in the Southwest. Some of the largest copper and gold mines in the world are found in this region, and some cover many thousands of hectares. Mining can cause major impacts on riparian areas along tributaries and downstream waters by altering the local hydrology. Mining not only dewaters the area, it removes vegetation and soil and changes the topography, severely affecting the watershed. Instream and floodplain gravel mining can alter channel dimensions, increase sediment yield, and increase fine sediment loading and deposition that can reduce infiltration into ephemeral channels (Bull and Scott, 1974).

Cultivated agriculture has had a long history in the southwestern deserts, and areas such as the Central Valley in California provide much of the country's food supply. Most crops, however, must be irrigated due to the low annual rainfall. Impacts to local hydrology from agricultural activities include (Levick et al., 2008):

- Increased salinity caused by clearing of native vegetation that raises the ground-water reservoir;
- Reduced flows from ground-water pumping or stream diversions for irrigation;
- Increased nutrients and turbidity from the use of fertilizers that run off into the streams across the land surface or through the soil, causing excessive algal growth; and
- Fish, aquatic invertebrate, and bird kills from pesticides that run off into the streams or leach into the ground water.

Due to the abundant solar resources in the arid and semiarid Southwest, numerous, large-scale solar energy projects are envisioned or already under development. O'Connor et al. (2014) note that development of solar energy zones will significantly affect ephemeral channel systems; the authors have developed a scoring system to conduct ephemeral stream assessments using publicly available geospatial data and high-resolution aerial imagery.

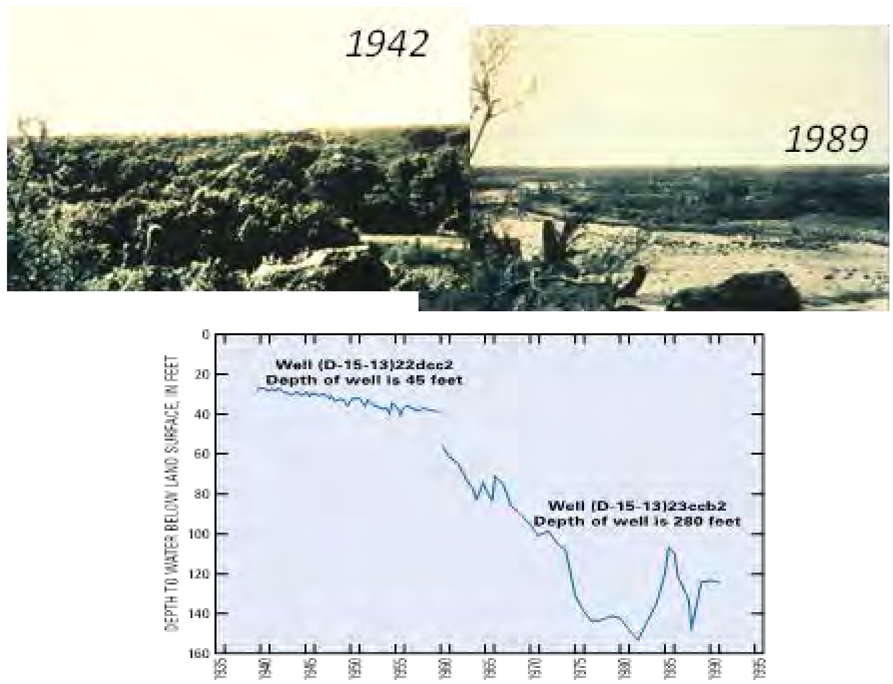
B.5.5.2.3 Water resources impacts

The Southwest has experienced rapid growth over the past several decades. This growth can be sustained only with reliable water supplies. Lack of surface-water flows has placed increased reliance on ground water for human and agricultural uses. The percentage of population dependent on ground water for domestic water needs in New Mexico, Arizona, and California is 90%, 60%, and 45% respectively (Anderson and Woosley, 2005). When ground-water pumping is sufficiently large or prolonged, it can result in lower water-table levels in regional and alluvial aquifers. If these aquifers are a primary source of water for sustaining surface-water flow in perennial or intermittent streams and if the drop in aquifer water levels is large enough, the pumping can effectively dewater these stream reaches, severing longitudinal and vertical connectivity (Winter et al., 1998; Scanlon et al., 2012). The perennial and intermittent streams effectively become ephemeral streams, and the habitat supported by reliable surface flow or shallow ground water is lost (Stromberg et al., 1996).

The impact of aquifer water-level declines is illustrated in Figure B-12 with repeat photography of the Santa Cruz River south of Tucson from 1942 and 1989 showing changes in riparian vegetation. Tucson's population in 1940 was roughly 36,000 and increased to approximately 405,000 by 1990. Until the Central Arizona Project brought Colorado River water to Tucson in the early 1990s, Tucson's domestic water supply was solely provided by ground water. As ground-water pumping increased to supply the growing population, the aquifer water level dropped by more than 25 meters and the riparian habitat was completely altered, as all phreatophytic vegetation died out. The growing population of Tucson also resulted in proportional increases in discharge of treated effluent. Portions of the Santa Cruz River downstream of the reach photographed in Figure B-12 near treatment plant outfalls are now effluent-dependent perennial stream reaches. Depending on the level of treatment, effluent can have various effects on the stream ecosystem (Brooks et al., 2006). Without careful water management and reuse (Bischel et al., 2013), the benefits of baseflow augmentation can be overshadowed by potential risks, such as increased contaminant and pathogen exposures (Jackson and Pringle, 2010).

Dams and retention or detention basins frequently are used to store water or as flood-control devices in the Southwest. They disrupt natural surface flow and sediment transport, interfere with natural geomorphic processes, alter water temperatures, and fragment the natural stream systems both upstream and downstream of the structure (Williams and Wolman, 1984). Upstream locations can experience flooding, whereas downstream locations can be dewatered and become starved of sediment (Sections 2.4.4 and 3.3.2).

Figure B-12. Change in riparian vegetation along the Santa Cruz River, Tucson, AZ, as the result of water-level declines in the regional aquifer. Photographs of the Santa Cruz River looking south from Tucson, AZ, provided by Robert H. Webb, U.S. Geological Survey Anderson and Woosley (2005).



B.5.5.3 Biological Connections

Much of the material in this section, as in Section B.5.5.2, is derived from the material presented in Levick et al. (2008). As noted in Chapter 3, ephemeral and intermittent streams perform many of the same functions in a watershed as perennial streams. In particular, in arid and semiarid regions, riparian areas, including those near ephemeral and intermittent streams, support the vast majority of wildlife species, are the predominant sites of woody vegetation including trees, and surround what are often the only available surface-water sources, even if they are available only for limited periods. Desert washes are easily recognizable by their dense corridors of vegetation that strongly contrast with the more sparsely vegetated uplands (Figure B-13). In contrast to the nearby uplands, these stream corridors and their associated vegetation communities provide structural elements of food, cover, nesting, and breeding habitat, and movement/migration corridors for organisms. These corridor vegetation communities moderate soil and air temperatures, stabilize channel banks, provide seed banking and trap silt and fine sediment that favor the establishment of diverse floral and faunal species, and dissipate stream energy (Levick et al., 2008). The resulting microclimates in and around ephemeral and intermittent stream vegetation corridors are used extensively by fauna. In arid climates, such conditions often benefit less mobile species that cannot avoid the harsh desert environment by moving to microclimates that are more favorable. These stream corridors provide primary habitat, predator protection, breeding and nesting sites, shade, travel corridors, migration stopover sites, and food sources.

Figure B-13. Aerial photograph showing dense corridor of vegetation lining ephemeral washes in southeastern Arizona. Image accessed from Google Earth from May 2005 imagery date.

Both passive and active biological connections exist in the intermittent and ephemeral streams network. Passive connections involve the transport of organisms and organic matter driven by water flow; these connections thus depend on hydrologic connectivity. Active connections do not depend on flowing water; instead, dispersal of organisms and organic matter occurs throughout the stream network through walking, flying, or hitchhiking on mobile organisms. All these organism-mediated connections form the basis of biological connectivity between headwater streams and downstream waters. Movement can be both longitudinal along the stream network and lateral, and can occur over the life cycles of numerous organisms (Schlosser, 1991; Fausch et al., 2002).

Meyer et al. (2007) noted the importance of headwater streams, including ephemeral and intermittent streams, as vital parts of the biological integrity of U.S. waterways. Ephemeral and intermittent stream channels are bordered by a zone of continuous or near-continuous vegetation, and thus they provide important wildlife movement corridors as they afford both cover and food. Summer monsoons in the Southwest coincide with periods when herptofauna such as snakes and amphibians are most active; the episodic flows provide a generally continuous aquatic corridor for their dispersal. The translocation and dispersal of species enables genetic interchange between subpopulations that are often isolated for most of the year. In addition, recolonization of sites can occur when subpopulations are lost due to drought or disturbance. Degradation of these habitats and loss of their connections to larger streams can have negative consequences for the diversity of downstream and riparian ecosystems and for the biological integrity of the entire river network. Nearly 81% of all streams are ephemeral or intermittent in the six Southwestern states (USGS, 2006). From a strictly numerical viewpoint, therefore, degradation of these ephemeral streams diminishes ecosystem functions in most southwestern watersheds.

B.5.5.3.1 Physical features important to biological connectivity and integrity

Ephemeral and intermittent riverbanks in the arid Southwest provide shelter for numerous species of wildlife, including reptiles, amphibians, birds, mammals, and invertebrates. These shelters typically are independent of whether the streams contain water year-round. Shelters are created through the action of water, wind, and gravity. Ephemeral dry-wash embankments notoriously are full of small caves and crevices critical in the life of desert animals such as the desert tortoise (*Gopherus agassizii*) (Van Devender, 2002). The alluvium in ephemeral and intermittent streams is often looser than the soils or colluvium of surrounding uplands. These conditions provide enhanced habitat by specialized sand-burrowing species of wildlife. High-value shelters also are created when woody debris is swept in from the watershed and collects in the floodplain and stream channel. In cases of deep ephemeral stream incision, cooler canyon-type environments might be created in which moisture loss is retarded.

B.5.5.3.2 Vegetation habitat features important to biological connectivity and integrity

Large ephemeral washes with shallow ground-water zones often are colonized with a variety of phreatophytic trees, such as Fremont cottonwood (*Populus fremontii*), Arizona sycamore (*Platanus wrightii*), and Arizona ash (*Fraxinus velutina*). These washes also include distinctive shrubs, such as willow (*Salix* spp.), seepwillow (*Baccharis* spp.), burrobrush (*Ambrosia monogyra*), and saltcedar (*Tamarix ramosissima*), and dense grass stands of sacaton (*Sporobolus* spp.). Those washes that lack a shallow ground-water system or water augmentation by effluent discharge nonetheless give rise to a distinctive vegetative habitat from the surrounding uplands. These environments often are referred to as xeroriparian habitat.

The floral species in these habitats is moderated by the frequency and magnitude of runoff events. Common tree species in xeroriparian habitat include subtropical legumes such as mesquite (*Prosopis* spp.), catclaw acacia (*Acacia greggii*), ironwood (*Olneya tesota*), and blue palo verde (*Cercidium floridum*). Mesquite has been identified as the key provider of food for numerous migrating birds (Van Riper and Cole, 2004). Netleaf hackberry (*Celtis reticulatata*) and Arizona sycamore (*Platanus wrightii*) have been identified as providing exceptional cover for nesting birds on intermittent streams (Powell and Steidl, 2002).

B.5.5.3.3 Hydrologic habitat features important to biological connectivity and integrity

Stanley et al. (1997) provide an excellent overview of the expansion and contraction of flowing waters within southwestern streams in response to variable precipitation events. This phenomenon commonly results in reaches of streams or rivers that have flow or residual pools with water surrounded by reaches without water. This phenomenon is common in dryland rivers across the globe (Arthington et al., 2005; Bunn et al., 2006). The isolated pools often serve as refuges for fish to survive in intermittent streams during dry periods (Labbe and Fausch, 2000).

Episodic stream flow might be the most visually prominent hydrologic aspect of a stream but is seldom the only hydrologic habitat feature of biological significance. An arid stream wash with a shallow ground-water system also might have moist banks fed by capillary flow that provide sites for turtle or insect reproduction. Distinct invertebrate fauna can inhabit the hyporheic (subsurface) zone of flow beneath a dry streambed. Episodic flooding, human excavations, and channel scour can produce in-channel or off-channel pools where amphibians breed. Within-channel or floodplain springs can provide distinct chemical compositions or thermal refuges from the main ephemeral or intermittent stream.

The natural episodic and intermittent flow regime in the arid Southwest is a competitive factor of native species over exotics adapted to lake and pond conditions (Minckley and Meffre, 1987; Poff et al., 1997). Louw and Seely (1982) and Williams (2005) concluded most desert species have developed adaptations to the water-limited conditions of these regions that enable them to survive under harsh environmental conditions. Fauna using ephemeral or intermittent waters include fish, mammals, amphibians, reptiles, birds, and invertebrates. The variability of climate and flow regime, which influences species abundance and diversity, however, makes evaluation difficult unless surveys are conducted over years in different community types (Boulton and Lake, 1992).

B.5.5.3.4 Fish and aquatic insects

As discussed in the previous section, the interplay between stormflow from ephemeral tributary streams, water from alluvial aquifers, and water from regional ground water control the distribution and timing of flowing water in southwestern rivers. Native fish species of southwestern streams and rivers are adapted to these dynamic environments (John, 1964; Meffe, 1984). Rinne and Miller (2006) compared fish assemblage data in river networks for two southwestern rivers, the Gila River (New Mexico and Arizona) and the Verde River (Arizona) over 7 to 12 years. They included river hydrology and geomorphology data in their analysis and found that variable streamflows and higher flow volumes favor native fish species over nonnatives. They also noted that the presence of unconstrained alluvial valley river reaches with shallow pools favored native fish. Furthermore, when humans alter the hydrologic dynamics of ephemeral and intermittent tributaries such that flows connecting them to the river network are more frequent or more consistent, nonnative fish can invade (Turner and List, 2007). Recent nonnative invasion and a corresponding decline in native fish species diversity were observed in the lower reaches of Aravaipa Creek, a tributary of the San Pedro River, which historically was only rarely connected to the mainstem (Eby et al., 2003).

Lytle et al. (2008) found a similar adaptation strategy in populations of an aquatic insect (*Abedus herberti*) occupying sites along a natural gradient of disturbance predictability. In their study, predictability was defined as the ability of a signal or cue (rainfall) to cause a disturbance. In this case, the disturbance was a flash flood. Using signal detection theory, they found that for 13 of 15 insect populations, the observed insect response times "were an optimal compromise between the competing risks of abandoning versus remaining in the stream, mediated by the rainfall-flood correlation of the local environment." They concluded that these aquatic insect populations could evolve in their responses to changes in the flow disturbance regime, providing evidence that these aquatic populations can adapt to "among-stream differences in flow regime."

B.5.6 Southwestern Intermittent and Ephemeral Streams: Synthesis and Implications

Rivers of the arid and semiarid Southwest are products of a highly variable and dynamic environment. Ephemeral and intermittent streams and their tributaries in the American Southwest provide a wide range of functions that are critical to the health and stability of arid and semiarid watersheds and ecosystems. Most importantly, they provide hydrologic connectivity within a basin, linking ephemeral, intermittent, and perennial stream segments. This linkage and the corridor of connectivity facilitates the movement of water, sediment, nutrients, debris, fish, wildlife, and plant propagules throughout the watershed. The relatively more vegetated streams corridors connected to downstream perennial reaches provide wildlife habitat and more humid environment than do the surrounding uplands. During ephemeral and intermittent streamflow, energy dissipates as part of natural fluvial adjustment, and sediment, organic matter, and debris are transported. The variability of the hydrologic regime in these streams is the key determinant of spatial and temporal distribution of plant community structure and the types of plants and wildlife present. Some of the major ways in which ephemeral streams are connected with and influence rivers are as follows:

- Flows from ephemeral streams are a major driver of the dynamic hydrology of southwestern rivers. Ephemeral tributary streamflows are especially important drivers of downstream floods during monsoon seasons.
- Fishes and invertebrates native to mainstem rivers are adapted to the variable flow regimes that ephemeral tributary streams strongly influence. Ephemeral flows prevent or mitigate invasion by introduced species.
- Ephemeral tributary streams supply water to mainstem river alluvial aquifers; these alluvial aquifers help sustain river baseflows.
- Ephemeral streams export sediment to rivers during major hydrologic events; the sediment contributes to materials that comprise alluvial aquifers and shape the fluvial geomorphology of rivers.
- Ephemeral tributaries export nutrients to mainstream rivers during hydrologic flow events; nutrients occur in many forms and contribute to river productivity.
- Ephemeral and intermittent streams and their associated vegetation communities provide structural elements of food, cover, nesting and breeding habitat, and movement/migration corridors for organisms.
- Water, sediment, and nutrients exported to the river from ephemeral tributaries support riparian communities of mainstem rivers; the riparian communities profoundly influence river attributes through shading and allochthonous inputs of organic matter, detritus, wood, and invertebrates to the river.

- Regional ground-water aquifers are in part recharged through infiltration of water to the streambed of ephemeral stream channels during wet years; the regional aquifer supplies a varying but critical portion of baseflow for perennial river reaches.

B.6 Case Study: Vernal Pools

B.6.1 Abstract

Vernal pools are shallow, seasonal wetlands that accumulate water during colder, wetter months and gradually dry down during warmer, dryer months. Despite differences in geology, climate, and biological communities, some common findings about the hydrologic connectivity of vernal pools in different regions include evidence for temporary or permanent outlets, frequent filling and spilling of higher pools into lower elevation swales and stream channels, and conditions supporting subsurface flows through pools without perched aquifers to nearby streams. Insects and amphibians that can live in streams or permanent pools opportunistically use glaciated vernal pools as alternative breeding habitat, refuge from predators or environmental stressors, hunting or foraging habitat, or stepping-stone corridors for dispersal and migration. Nonglaciated vernal pools in western states are reservoirs of biodiversity and can be connected genetically to other locations and aquatic habitats through wind- and animal-mediated dispersal.

B.6.2 Introduction

The term “vernal pool” is broadly used to describe shallow, fishless pools situated on bedrock or low-permeability soils that lack continuous surface-water connection to permanent water bodies but have a seasonal period of inundation on which aquatic species depend for completion of their life cycles (Zedler, 2003). This case study reviews evidence for physical and biological relationships between vernal pools and downstream waters in the western United States (western vernal pools) and glaciated areas of northeastern and midwestern states (northern vernal pools), where vernal pools are particularly abundant (Zedler, 2003).

B.6.2.1 Geography and Geology

B.6.2.1.1 Western vernal pools

Zedler (1987) used the term vernal pool to describe basin/swale systems in California’s Mediterranean climate that flood in winter, host diverse communities of aquatic plants and animals in early spring, transition to terrestrial ecosystems in late spring, and desiccate during hot, dry summer months. Western vernal pools are seasonal wetlands associated with topographic depressions; soils with poor drainage; mild, wet winters; and hot, dry summers in western North America from southeastern Oregon to northern Baja California, Mexico (Bauder and McMillan, 1998). Locally, wetlands that fit this definition might be known by other names, such as the upland playas in Oregon (Clausnitzer and Huddleston, 2002).

Historically, vernal pools covered 518 km^2, or 5−6% of the total land surface in southern California and northern Baja, but losses in that area have been substantial (Bauder and McMillan, 1998). Pools occur on impermeable or slowly permeable soils or bedrock (Smith and Verrill, 1998) that limit percolation and thus produce surficial aquifers that perch above regional ground-water aquifers. Pool-forming soil layers in this region include clay-rich soils, silica-cemented hardpans (duripans), volcanic mudflows, or bedrock (Weitkamp et al., 1996; Hobson and Dahlgren, 1998; Smith and Verrill, 1998; Rains et al., 2006). Because their hydrology and ecology are so tightly coupled with the local and regional geologic processes that formed them, western vernal pools typically occur within "vernal pool landscapes" (Smith and Verrill, 1998), or complexes of pools in which swales connect pools to each other and to seasonal streams (Weitkamp et al., 1996; Rains et al., 2008).

B.6.2.1.2 Northern vernal pools

The geologic formations underlying northern vernal pool landscapes were formed by the movement of glaciers across the northeastern and north-central states approximately 12,000 years ago. Retreating glaciers scoured basins in rock ledges and mountaintops, or left behind large pieces of ice that later collapsed to form topographic depressions containing deposits of gravel, sand, or mud (Colburn, 2004). Although not all vernal pools in these areas were formed by glaciers, the soils, geology, and evolutionary history of plants and animals in northern vernal pools have been profoundly affected by glacial events. Like western vernal pools, northern vernal pools are significantly grouped or clustered (Brooks, 2005). Grant (2005) found that pools in Massachusetts are more likely to occur in more porous substrates (alluvial, fine grained, or sand/gravel soils) than glacial till or impermeable bedrock, increasing their hydrologic connection to shallow ground water.

Unlike western vernal pools, which typically occur in open grasslands, most northern vernal pools are detrital wetlands fully contained within forest ecosystems that depend on the pulse of organic matter from leaf fall that coincides with initial filling of temporary pools in these regions.

B.6.2.2 Temporal Dynamics

Zedler (1987) identified four distinct ecosystem phases in the annual hydrologic cycle of western vernal pools, which we have generalized here (with additional citations) to describe the temporal dynamics of northern vernal pools as well:

- Wetting or newly flooded phase: Rainwater, snow, runoff, or snowmelt infiltrate upper layers of permeable soil and, when topsoils are saturated, collect in pool basins formed by impervious rock, clay, or till layers (aquitards or aquicludes; Rains et al., 2008). In early spring, perennial plants sprout and stored seeds germinate in wet soils. Aquatic invertebrate communities develop from resting eggs and seed banks (Colburn, 2004).
- Aquatic phase: Soils are saturated and pools hold standing water, in many locations filled to capacity. In some western vernal pools, surface and subsurface flows from upland pools through swales feed downgradient pools, connecting pools at a site and extending the aquatic phase of

the pool complex (Weitkamp et al., 1996; Hanes and Stromberg, 1998). Pools are colonized by dispersing insects and breeding amphibians.

- Terrestrial phase: Evapotranspiration rates increase and pool water recedes, although soils remain saturated. In western pools, aquatic plants flower and seed. Aquatic animals disperse or become dormant. Terrestrial plant communities persist.
- Dry phase: Pools and soils dry to moisture levels similar to uplands, and many plants senesce or die. Summer rains produce no new ponding or plant growth.

In the western United States, vernal complexes saturate and begin to pool during winter rains, reach maximum depth by early spring, and lose all standing water by late spring (Zedler, 1987). The timing of filling and drying of northern vernal pools varies, depending on pool type. Colburn (2004) proposed five hydrologic classes for northern vernal pools, based on time of filling and average duration of flooding: (1) short-cycle, spring-filling pools that stay wet for 3–4 months; (2) long-cycle, spring-filling pools that stay wet for 5–8 months; (3) short-cycle, fall-filling pools that stay wet for 7–9 months; (4) long-cycle, fall-filling pools that stay wet for 9–11 months; and (5) semipermanent pools that stay wet for 36–120 months. Many northern vernal pools do not dry down completely, but retain areas of saturated sediment or standing water in part of the basin. Such pools are considered "incompletely dry," to differentiate them from pools that are "continuously flooded" or "dry."

B.6.2.3 Ecology

Vernal pool ecosystems support large breeding populations of amphibians, aquatic invertebrates, and aquatic or semiaquatic plants, including many rare or endemic taxa (King et al., 1996; Zedler, 2003; Colburn, 2004; Calhoun and DeMaynadier, 2007). The annual cycle of basin flooding and drying plays an important role in structuring biological communities in vernal pools. The wet phase prevents establishment of upland plant species in pool basins, while the dry phase limits colonization by aquatic and semiaquatic plant and animal species that occur in permanent wetlands, ponds, or streams (Keeley and Zedler, 1998; Bauder, 2000). Despite their cyclical nature, vernal pool habitats are species rich and highly productive, in part because they provide relatively predator-free breeding habitat for invertebrates and amphibians (Keeley and Zedler, 1998; Calhoun et al., 2003). Many resident species are locally adapted to the timing and duration of inundation, soil properties, and spatial distribution of vernal pools in a specific geographic subregion. Other species that are widespread across regions and aquatic habitat types (including streams or lakes) use inundated pools periodically for refuge, reproduction, or feeding (King et al., 1996; Williams, 1996; Colburn, 2004).

B.6.3 Evidence

B.6.3.1 Physical Connections

Vernal pools are primarily precipitation fed and typically lack permanent inflows from or outflows to streams or other water bodies. They can be connected temporarily, however, to permanent waters by surface or shallow subsurface flow (flow through) or ground-water exchange (recharge; Weitkamp et al., 1996; Brooks, 2005; Rains et al., 2008). Hydrologic connectivity is typically limited to flow through in vernal pools formed by perching layers; ground-water exchange can occur in vernal pool systems without perching layers (Brooks, 2005).

B.6.3.1.1 Western vernal pools

Rains et al. (2006; 2008) examined the hydrology and biogeochemistry of two vernal pool complexes in the northern end of California's Central Valley (Smith and Verrill, 1998). The 2006 study evaluates water balance and the relative importance of direct precipitation, evaporation, surface flow, and shallow subsurface flow in a hardpan vernal pool complex (Rains et al., 2006). The 2008 study contrasts the role of geology and soil type—specifically, clay-rich versus hardpan soils—in controlling vernal pool hydroperiod, hydrodynamics, and water chemistry (Rains et al., 2008). Clay-rich and hardpan complexes are common vernal pool types in California's Central Valley (Smith and Verrill, 1998). In both studies, study sites were pool complexes located in the upper portion of the watersheds. Within each complex, upland (feeder) pools were connected to lower (collector) pools by ephemeral swales, and the lowest pool was connected by swale to a seasonal stream.

Results showed that high and low pools were connected via surface flows 10−60% of the time; surface water flowed through swales connecting low-elevation pools to streams during 60% of the inundation period (Table B-1). Underlying geology and soil type influenced ponding rates and inundation periods: In water year 2003, pools in clay-rich soils accumulated water at the onset of rainfall and held water longer than pools in hardpan soils, which have higher soil infiltration rates (Table B-1; Rains et al., 2008). Horizontal subsurface flows reduced the number and volume of higher elevation surface flows into hardpan pools, relative to the clay-rich pools. Most water discharging from the swale to the seasonal stream at the hardpan site was perched ground water that had flowed around, rather than through, the pool basins. In both soil types, however, vernal pool basins, swales, and seasonal streams were shown to be part of a single surface-water and shallow ground-water system connected to the river network when precipitation exceeds storage capacity of the system (Rains et al., 2006; Rains et al., 2008). Pyke (2004) reported that a complex of 38 vernal pools north of Sacramento was filled to capacity in 10 of 11 years from November 1999 to June 2001. A direct precipitation-evaporation model for another hardpan complex near this Sacramento site showed that direct precipitation could fill pools beyond capacity in most years (Hanes and Stromberg, 1998). Pools located at the lower end of a complex (and thus more likely to be directly connected to streams) can receive surface water through stepping-stone spillage in addition to direct input from precipitation; thus, they can remain wetted longer than upper pools. For example, Bauder (2005) found that "collector" pools with no outlet held water longer than headwater pools with no inlet. Collectively, these findings suggest that filling and overflow of vernal pools are not rare phenomena. Filling and spilling also can occur in other vernal pool types because all vernal pools are underlain by aquitards (Rains et al., 2008).

B.6.3.1.2 Northern vernal pools

Northern vernal pools include both perched and ground water-connected aquifers (Brooks, 2004; Boone et al., 2006). As in western vernal pools, rainfall or snowmelt in excess of pool capacity is lost to surface

Table B-1. California vernal pool inundation and hydrologic connectivity. Summarized from Rains et al. (2008)				
Soil; hydrology	Inundation period (days/water year[a])	Flow-through paths (pool-pool and pool-stream)	Surface flows between high- and low-elevation pools[b]	Surface flows between lowest elevation pool and stream network[b]
Fine-grained, clay-rich soils; perched surface water	200−205	surface only	120 (60%)	120−123 (60%)
Coarse-grained, hardpan soils; perched surface water and ground water	150−154	surface and horizontal subsurface	15 (10%)	90−92 (60%)

[a]October 1 2002−September 30, 2003.
[b] Units = days/water year[a], % of inundation period.

runoff or subsurface flows into shallow, nearby ground water (Brooks, 2005). Studies of surface and subsurface inflows and outflows were not found in the literature. Brooks (2004) reports that precipitation and potential evapotranspiration alone could not account for large observed water losses in four vernal pools he studied for 10 years. These losses could have been due to inaccurate estimates of precipitation or evapotranspiration (both of which were significantly related to water depth) or to surface overflow and soil infiltration, which were not measured. In a separate study, Boone et al. (2006) used a classic water-budget model to predict vernal pool hydroperiods in Minnesota and found that, although precipitation and evapotranspiration were good predictors of pool inundation in most cases, errors in model estimates for a few pools suggested that surface outflows or infiltration might have been occurring at some sites.

Individually small, temporary storage of heavy rainfall and snowmelt in vernal pool systems (pools plus soils) can attenuate flooding, provide a reservoir for nearby vegetation during the spring growth period, and increase nutrient availability (Hobson and Dahlgren, 1998).

B.6.3.2 Biological Connections

Dispersal of vernal pool organisms can be active or passive and occurs at multiple scales: local scale (among nearby pools), neighborhood scale (among pools in a geographic cluster or complex), or regional (outside of the complex, to other ecosystem types; Compton et al., 2007). Examples of active regional dispersal include insect flight or juvenile dispersal by amphibians. Passive transport is of particular interest for regional-scale dispersal, as it enables plants and low-vagility animals such as microcrustaceans to move long distances. Examples of passive transport to and from unidirectional wetlands and pools include water-mediated dispersal of larvae (Hulsmans et al., 2007); transport of diapausing (dormant) eggs by waterbirds (Figuerola et al., 2005; Frisch et al., 2007) or flying insects (Van De Meutter et al., 2007); and wind-mediated dispersal of dormant eggs, larvae, and adult zooplankton from dry rock pools (Vanschoenwinkel et al., 2009).

Western vernal pools are highly productive ecosystems that have evolved in what Zedler (2003) describes as a "balance between isolation and connectedness." Pacific vernal pool landscapes are tightly coupled with variable climate, soils, and geologic formations in the western United States, producing diverse habitats for organisms with different life-history strategies (Bauder and McMillan, 1998). Seasonal wetlands in this region might have served as evolutionary refuges since Mesozoic times (King et al., 1996). As a result, present-day vernal pool communities have a large proportion of passively dispersing, endemic (i.e., restricted to small geographic area) species in genera that are widely distributed across continents and aquatic systems (King et al., 1996; Keeley and Zedler, 1998; Zedler, 2003). This apparent paradox is explained by the fact that individuals transported passively over long distances have colonized, and through time have become locally adapted to, different vernal pool landscapes, creating new endemic species from the rootstock of ancient lineages. As a result, Pacific vernal pools are now rich reservoirs of genetic and species diversity connected to other locations and aquatic habitats through continuing dispersal. The existence and connectivity of such reserves are especially important at a time when changing climatic conditions are likely to increase intermittency of stream flows and decrease duration of wetland inundations in other areas.

Western vernal pools also support generalist invertebrate communities, including crustaceans and insects that are widely distributed in permanent wetlands, ponds, lakes, and streams (Zedler, 1987; 2003). Invertebrates and zooplankton can be flushed from vernal pools into streams or other water bodies during periods of overflow, carried by animal vectors (including humans), or dispersed by wind. Wind-mediated dispersal can be of particular importance in seasonal wetlands: during the dry phase, dry soils containing large numbers of transportable seeds, resting eggs, cysts, diapausing larvae, and adults are picked up and blown away (Vanschoenwinkel et al., 2009). The maximum distance such propagules can travel is not known, but, from currently available literature, pool-pool or pool-stream transport is clearly possible, and the potential for long-distance transport also exists.

Food webs in northern vernal pools include highly fecund amphibians and insects that convert detrital organic matter inputs into biomass that subsidizes terrestrial and aquatic ecosystems in other parts of the watershed (Semlitsch and Bodie, 1998; Brooks, 2000; Gibbons et al., 2006). Northern vernal pools can provide alternative breeding habitat, refuge from predators or environmental stressors, hunting or foraging habitat, or stepping-stone corridors for dispersal and migration. For example, Gahl et al. (2009) reports that bullfrog (*Rana catesbeiana*) densities per unit wetland perimeter were greater in two small seasonal pools than in a larger, permanent breeding wetland. Regular use of seasonal pools by bullfrogs throughout this study offers compelling evidence for the role of seasonal pools as a component of their nonbreeding habitat. Spotted turtles (*Clemmys guttata*) used seasonal pools for foraging, basking, and mating at two sites in Massachusetts (Milam and Melvin, 2001). Many insects and amphibians found in streams, lakes, or riparian/floodplain wetlands are facultative users of vernal pool habitats (Table 4-2).

B.6.4 Vernal Pools: Synthesis and Implications

The key findings from this case study are as follows:

- In the aquatic phase, some western vernal pools are filled to capacity in most years, creating conditions under which water flows from pools into swales and stream channels.
- Documented evidence of surface flows connecting western vernal pool complexes to the river network via swales and seasonal streams is available in the literature.
- Indirect evidence indicates that surface and subsurface flows connect northern pools without perched aquifers to shallow ground water and thus to nearby streams.
- Many insects and amphibians that can live in streams or pools that are more permanent opportunistically use northern vernal pools as alternative breeding habitat, refuge from predators or environmental stressors, hunting or foraging habitat, or stepping-stone corridors for dispersal and migration.
- Nonglaciated vernal pools in western states have achieved a long-term "balance between isolation and connectedness" and have functioned as refuges for plant and animal diversity since the Mesozoic era. They are current reservoirs of biodiversity connected genetically to other locations and aquatic habitats through continuing dispersal.

Direct evidence supports the existence of seasonal hydrologic connections and indirect evidence supports the movement of organisms between western vernal pool complexes and streams. Indirect evidence supports the existence of hydrologic and biological connections between northern vernal pools and river networks, with potential for storing water during the wet season, and providing alternative breeding habitat or food resources for stream organisms.

Functional Assessment Approach for High Gradient Streams

West Virginia
June, 2007

INTRODUCTION

This document describes the components and application of a method for assessing the condition of headwater streams and riparian areas in the mountains of West Virginia. It is specifically designed to address the typical impacts and likely mitigation proposals considered in the context of processing Clean Water Act Section 404 permit applications. The focus of this assessment method is on high gradient, headwater streams in West Virginia. These streams can be characterized as first and second order ephemeral and intermittent stream with a channel slope that ranges from 4 percent to greater than 10 percent. The stream channel sinuosity is low, but has common to many step pools and would classify as A, Aa, or Aa+ (Rosgen 1998) with a gravel, cobble or bolder controlled channel within a Type I valley. Flow rates in these streams are typically less than 7 cubic feet per second (cfs). The surrounding watershed contributing to the channel is forested with hardwood trees and woody shrubs, on moderately steep to very steep slopes (USDA 2004).

This approach, like various similar assessment tools developed for other regions and ecosystems, is based on the proposition that the condition of aquatic and wetland systems depends on a suite of physical and biological processes. These processes generally reflect the position of the system in the landscape, which controls how it interacts with geology, hydrology, and soils. These in turn influence vegetation, which further interacts with physical processes such as sediment movement, provides many elements of on-site animal habitat, and contributes nutrients and organic materials to the aquatic system on-site and downstream. Therefore, rapid assessment systems such as this one are designed to evaluate the extent to which key processes are operating or have been disrupted.

The approach involves visual evaluation of the physical and biological structure of the assessment site, or rating of the site as to the extent that it is functionally compromised by various stressors. These evaluations or ratings are formulated as simple equations, or models, where the condition assessments of a set of indicators are combined into an overall index of functionality for each of four functional categories: hydrology, biogeochemistry, plant communities, and wildlife habitat.

A set of eleven indicators are used in the models, where they are variously combined to reflect key elements of the functional category being assessed. The indicators are scaled from zero to 1.0, where 1.0 represents the fully functional (or reference), condition. The specific reason for using each indicator and the structure of the rating scale are explained further in the following sections of this document. Generally, however, the indicators (also called variables) are scaled based on a combination of field observations within a range of sites in the region, professional judgment, published literature, and rating scales developed for the same types of indicators in other regions and ecosystems. No field studies have been conducted in the region specifically to calibrate the indicators used here, therefore all scaling is approximate.

The method presented here is intended to be applied to potential or actual impact and mitigation sites by one experienced person in half a day or less. It is designed to produce consistent results across the range of headwater stream conditions typically encountered in the region.

PROCEDURE

1. Identify the Assessment Site on a topographic map. The Assessment Site includes the affected stream reach, and the watershed that drains to that reach.

2. Assemble any required materials and information, such as a camera, slope measuring device, a distance measuring tape, a ruler, and similar equipment. Review the data forms in the context of the size and accessibility of the Assessment Area to determine if you will require aerial photos and a soil survey. Bring any pertinent descriptions and maps of proposed impacts or mitigation plans. Make sufficient copies of data sheets from this document.

3. At each assessment area, assign a site identifier, take photos and keep notes concerning the orientation and principal subject of each photo (e.g., "channel looking downstream from midpoint of impact reach"). Complete the data sheets, consulting the individual variable descriptions for specific directions regarding the assignment of scores. Note that each indicator is scored using a weighted approach, where the percent of the assessment area in each score range is estimated and recorded.

4. If the average percent cover of either trees or shrubs is more than 10 percent the cover of herbaceous vegetation does not need to be determined.

5. Copy the basic spreadsheet and name the copy with the same site identifier recorded on the datasheets. Transfer values from data sheets to the spreadsheet and calculate Function Scores. Save and label all digital photos. Save the spreadsheet and all digital photos in a folder labeled with the same site identifier as used on the datasheets. Print hard copies of the spreadsheet, photos, and photo descriptions, and any other pertinent materials, and attach original data sheets.

6. Summarize the assessment. Depending on the scenario being investigated, the calculated index scores can be used in various ways. Typically, they should be converted to Functional Units by multiplying the index for each function by the stream length. Decisions about how to use the numbers are a matter of policy, and are not specified here. Normally, subsequent analyses are done without combining the four functions (i.e., the total habitat functional units lost to an impact are compared to the total habitat functional units gained by a mitigation action). However, some users of assessment systems find it convenient and more understandable to add all functional units together, or to average them, despite the obvious logic problems with this approach. Others base decisions on the "most impacted function." Similarly, impacts and mitigation credits can be calculated based on some target year (i.e., 5 years after impact) or on a projected average condition over the life of the project, or on some other criterion.

Variables

Stream channel alterations (*CHANNELALT*). This variable reflects alterations to the natural hydrology of the stream due to activities within the channel itself. Both natural and man-induced alterations can affect the hydrology of high gradient, ephemeral and intermittent streams. Examples in West Virginia include ditches, dams, culverted and unculverted road crossings, and downcutting or entrenchment of the channel. The intent of this variable is to capture those impacts that alter the hydrograph of the headwater stream system. This variable differs from *SLOPE* and *LANDUSE* in that the impacts occur within the stream channel and not in the surrounding landscape.

CHANNELALT is used in calculating the hydrology, biogeochemical, plant community, and habitat functional indices.

This variable is quantified by the type of structure or alteration to the stream channel. Measure *CHANNELALT* using the following procedure:

1) If stream is unaltered or no obstructions to natural water flow, and there is no excessive ponding within the channel, the score for this variable is 1.0.

2) If hydrology has been altered, identify the percentage of the stream affected by any permanent obstructions to channel flow such as dams, roads or fill, or by any deepening or straightening intended to speed flows, or any deepening or sedimentation that apparently resulted from land uses in the watershed, such as timber harvests. Do not include such changes if they appear to be the result of natural phenomena, such as increased incision following a forest fire or ponding by beaver.

3) Use Table 1 to determine the variable score for each of the alterations identified to the natural hydrology. Determine the weighted average for the entire stream reach impacted.

Table 1
Stream channel alterations (*CHANNELALT*)

Type of alteration	Score
unaltered	1.0
restored	0.75
incised, or excess sediment in channel	0.5
dammed	0.1
channelized/straightened	0.1
channel >50% filled	0.0

Average percent slope of the watershed (*SLOPE*). This variable reflects anthropogenic alterations to the natural slope of the headwater watershed. Under natural conditions in West Virginia, headwater stream systems form within moderately steep to extremely steep mountain coves, where average slope exceeds 45 percent. Steep slopes facilitate movement of water downslope to the stream channel, and removal of detrital material downstream to perennial streams. The intent of this variable is to capture changes to the watershed slope that can alter the movement of water and nutrients downstream at a reduced rate. This variable differs from *CHANNELALT* in that the impacts occur within the surrounding watershed and not directly in the stream channel.

SLOPE is used in calculating the hydrology and biogeochemical functional indices.

This variable is quantified by measuring alterations to slopes draining to the stream reach being assessed. Measure *SLOPE* using the following procedure:

1) If the watershed slope is unaltered, regardless of slope, then the score for this variable is 1.0.

2) Using topographic maps, soil survey maps, digital elevation maps, clinometers, Abney hand level, or other appropriate tools for measuring slope, determine the average percent slope of the watershed surrounding the stream reach being assessed. If the watershed slope is extremely variable (contains 3 or more categories identified in Table 2) determine a weighted average using the percent of the watershed for each category.

3) Use Table 2 to determine the variable score for the watershed slope.

Table 2
Average percent slope of the watershed (*SLOPE*)

Percent slope	Score
30 to 45 or unaltered	1.0
(20 to 29) or (45 to 65)	0.75
10 to 19	0.5
(5 to 9) or (66 to 90)	0.25
less than 5	0.1

Stream Sediment Size (*SED*). Stream sediment size is the predominant particle size of materials comprising the surface of the streambed. Sediment size is based on USDA texture classes for coarse and fine soil particles (USDA 1993). The composition of the streambed has a direct impact on the dissipation of water energy in the stream channel and influences habitat for vertebrates and invertebrates.

SED is used in calculating habitat functional indices.

Using the following procedure, determine the score for *SED*:

(1) During field reconnaissance, visually estimate the size of the predominant bed material in the stream channel.

(2) Use Table 3 to determine the variable score for Stream Sediment Size.

(3) If Stream Sediment Size is extremely variable in the watershed being assessed, determine a weighted average for this variable.

In West Virginia minimally altered headwater stream systems stream sediment is dominated by cobbles, stones, and boulders.

Table 3
Stream Sediment Size (*SED*)

USDA Soil Texture	Score
boulders, stones, cobbles (>3 in.)	1.0
Gravel (3/4 to 3 in.)	0.75
sand	0.5
silt	0.1
clay/pavement/bedrock	0.1

Land Cover within the Watershed (*COVER*). This variable is defined as the surface water runoff potential from the watershed into the stream. With increased disturbance and increased impervious surface surrounding the stream, more surface water enters the channel and it enters more quickly than under undisturbed conditions.

For headwater stream assessments in West Virginia, this variable is scored based on land cover that can be observed on aerial photographs and verified during field reconnaissance. Under undisturbed conditions, the watershed surrounding headwater slope streams is dominated by hardwood forest. Aerial photographs depicting land cover are available from a number of internet sources including TerraServer (http://terraserver.homeadvisor.msn.com/), Google Maps (http://maps.google.com/), and Web Soil Survey (http://websoilsurvey.nrcs.usda.gov/). The score for *COVER* is based on the weighted average of scores for types of land cover identified in the upland and riparian areas within the catchment of the headwater stream being assessed. Areas affected by natural fire should be scored the same as undisturbed forest. Mined areas that have been reclaimed according to regulatory standards are considered to be highly, though not entirely, functional with respect to this variable.

COVER is used in calculating the hydrology, biogeochemistry, and habitat functional indices.

Using the following procedure, determine the score for *COVER*:

(1) Visually estimate the percent of the watershed and riparian zone covered by the cover types identified in Table 4.

(2) Calculate the weighted average for the watershed to determine the score for *COVER*.

Table 4
Land Cover Within the Watershed (*COVER*)

Land cover	Score
forest	1.0
shrub	0.75
orchards	0.5
pasture or hay	0.25
urban, roads	0.0

Average Percent Cover of Trees (*TREE*). This variable is defined as the average percent cover of trees in the watershed surrounding the headwater stream. Trees are defined as woody plants greater than or equal to 3 inches ($\geq$8 cm.) dbh. Percent cover of trees is only measured if percent tree cover is 10 percent or greater. Tree cover is a measure of the dominance and biomass of trees in a forest stand. Trees capture water in the canopy and reduce rainfall impact to the soil which reduces soil erosion and slows water runoff from the watershed to the stream. Trees are also the primary source for large woody debris and detritus in undisturbed high gradient, headwater riverine systems in West Virginia.

TREE is used in the assessment of all functions when tree or shrub cover is greater than 10 percent.

This variable is quantified by the average percent cover of trees. Measure *TREE* using the following procedure:

1) During a field reconnaissance of the watershed and riparian area, or using aerial photographs or other remote sensing data and verified during a field reconnaissance visually estimate the percent cover of trees. If the site is unaltered and the percent cover of trees is 90 percent or more the score for *TREE* would be 1.0.

2) If the site had been disturbed and percent cover of trees in some areas is less than 90 percent, estimate the percent cover of trees for each area.

3) Use Table 5 to determine the variable score for each area of the watershed or riparian area that differs in percent cover of trees. Determine the weighted average for *TREE*.

In reference standard sites, average percent cover of trees in the watershed and adjacent riparian area was greater than 90 percent.

Table 5
Average Percent Cover of Trees (*TREE*)

Percent	Score
greater than 90	1.0
70 to 90	0.75
50 to 69	0.5
20 to 49	0.25
10 to 19	0.1
less than 10	0.0

A score of 0.0 is assigned to severely altered sites that average less than 10 percent cover of trees.

Shrub cover (*SHRUB*). This variable is defined as the average percent cover of woody vegetation greater than 39 inches (>1 m) in height and less than 3 inches (8 cm) dbh (e.g., shrubs and small trees). Shrubs reduce erosion, slow runoff, take up nutrients, produce biomass, and provide cover and breeding sites for wildlife. Shrubs may dominate the community in headwater areas during early to mid-successional stages. In this context, *SHRUB* reflects the amount of woody vegetation in the understory and woody regeneration on the site that influences runoff directly to the headwater stream, affects nutrient cycling, and will eventually be the source of a mature forest canopy. Therefore, higher values of sapling/shrub cover are assumed to contribute more to these functions.

SHRUB is used in calculating the hydrology, biogeochemical, and plant community functional indices when tree or shrub cover is greater than 10 percent.

Use the following procedure to measure *SHRUB:*

1. During a field reconnaissance visually estimate the percent cover of shrubs within the watershed. If percent cover is extremely variable, develop a weighted average across the site.

2. Report the average shrub cover as a percent.

3. Use Table 6 to determine the variable score for *SHRUB*.

Table 6
Average Percent Cover of Shrubs (*SHRUB*)

Percent	Score
Greater than 50	1.0
20 to 50	0.5
10 to 19	0.25
Less than 10	0.0

A score of 0.0 is assigned to severely altered sites that average less than 10 percent cover of shrubs.

Average Percent Cover of Herbaceous Vegetation (*HERB*). This variable is defined as the average percent cover of ground vegetation. Ground vegetation is defined as all herbaceous vegetation, regardless of height, and woody vegetation less than 39 inches (1 m) in height. Ground vegetation cover is an index to the biomass of low vegetation in headwater areas, which affects the productivity and structure of these habitats.

HERB applies to the hydrology, biogeochemical, plant community, and habitat functions and only when canopy tree cover and shrub cover are each less than 10 percent.

If tree and shrub cover are each less than 10 percent, estimate average percent cover of herbaceous vegetation as follows:

1. During field reconnaissance visually estimate the percent cover of herbaceous vegetation in the watershed. If percent cover is extremely variable determine the weighted average of herbaceous vegetation by estimating the percentage of the Assessment Area in each cover class.

2. Use Table 7 to determine the score for *HERB*.

Table 7
Average Percent Cover of Herbaceous Vegetation (*HERB*)

Percent	Score
70 to 100	0.1
less than 70	0.0

Average percent cover of herbaceous vegetation is not used to evaluate headwater riverine systems in West Virginia that have a well-developed tree or shrub canopy. Instead, *HERB* is measured only in areas where tree and shrub cover are both less than 10 percent due to severe natural or anthropogenic disturbance. Even under these conditions, ground-layer vegetation contributes some reduction in erosion, organic material to the wetland's carbon cycle, provides some benefits for wildlife, and helps produce conditions favorable to the regeneration of a woody midstory and canopy. Because fully functional headwater areas typically are dominated by woody vegetation, even with 100 percent cover of herbaceous vegetation the maximum score that can be achieved is 0.1.

Vegetation composition and diversity (*COMP*). This variable reflects the "floristic quality" of the woody plant community based on concepts in Andreas and Lichvar (1995) and Smith and Klimas (2002). In undisturbed high gradient, headwater riverine systems in West Virginia, the tallest vegetation stratum is composed of native trees of a variety of species. In headwater riverine systems that have undergone recent and severe natural or anthropogenic disturbance, the tallest stratum may be dominated by shrubs or herbaceous species. Implicit in this approach is the assumption that the diversity of the tallest layer is a good indicator of overall community composition and successional patterns (i.e., appropriate shrub composition indicates appropriate future canopy composition). Note that the tree stratum includes all trees greater than 3 inches (8 cm) dbh, and the shrub layer includes all woody species at least 39 inches (1 m) tall but less than 3 inches (8 cm) dbh. There must be at least 10 percent tree cover to consider the tree stratum to be present and the focus of this evaluation. If tree cover is less than 10 percent, assess the composition of the sapling layer instead.

COMP applies to the plant community function and only when canopy tree or shrub cover is greater than 10 percent.

1. If tree cover is greater than 10 percent count the number of different species on the site being assessed during field reconnaissance.

2. If tree cover is less than 10 percent and shrub cover is greater than 10 percent, count the number of different woody species in the shrub stratum.

3. If both tree and shrub cover are each less than 10 percent then *COMP* would receive a score of zero.

4. Use Table 8 to determine the score for *COMP*.

In fully functional headwater areas in West Virginia, the number of native woody species present in the tallest stratum typically is 5 or more.

Table 8
Number of Native Species (*COMP*)

Number	Score
5 or more species	1.0
4 species	0.75
3 species	0.5
2 species	0.25
1 species	0.1
0 species	0.0

Soil Detritus (*DETRITUS*). The soil detrital layer is defined as the soil layer dominated by partially decomposed, but still recognizable organic material such as leaves, sticks (less than 3 inches in diameter), needles, flowers, fruits, dead moss, or detached lichens on the surface of the ground. Detritus is a direct indication of short term (one or two years) accumulation of organic matter primarily from vegetation within the watershed and the potential source for organic export to downstream systems.

DETRITUS is used in calculating the biogeochemical and habitat functional indices when tree or shrub cover is greater than 10 percent.

Using the following procedure to determine the score for *DETRITUS*:

(1) Visually estimate the percent of the ground surface covered by leaves, sticks (less than 3 inches in diameter or other organic material within the watershed.

(2) Use Table 9 to determine the subindex score for Soil Detritus

In West Virginia, minimally altered watersheds of headwater stream systems were observed to have soil detritus cover of greater than 75 percent.

Table 9
Soil Detritus (*DETRITUS*)

Percent cover	Score
greater than 75	1.0
50 to 75	0.75
25 to 49	0.5
10 to 24	0.25
less than 10	0.1

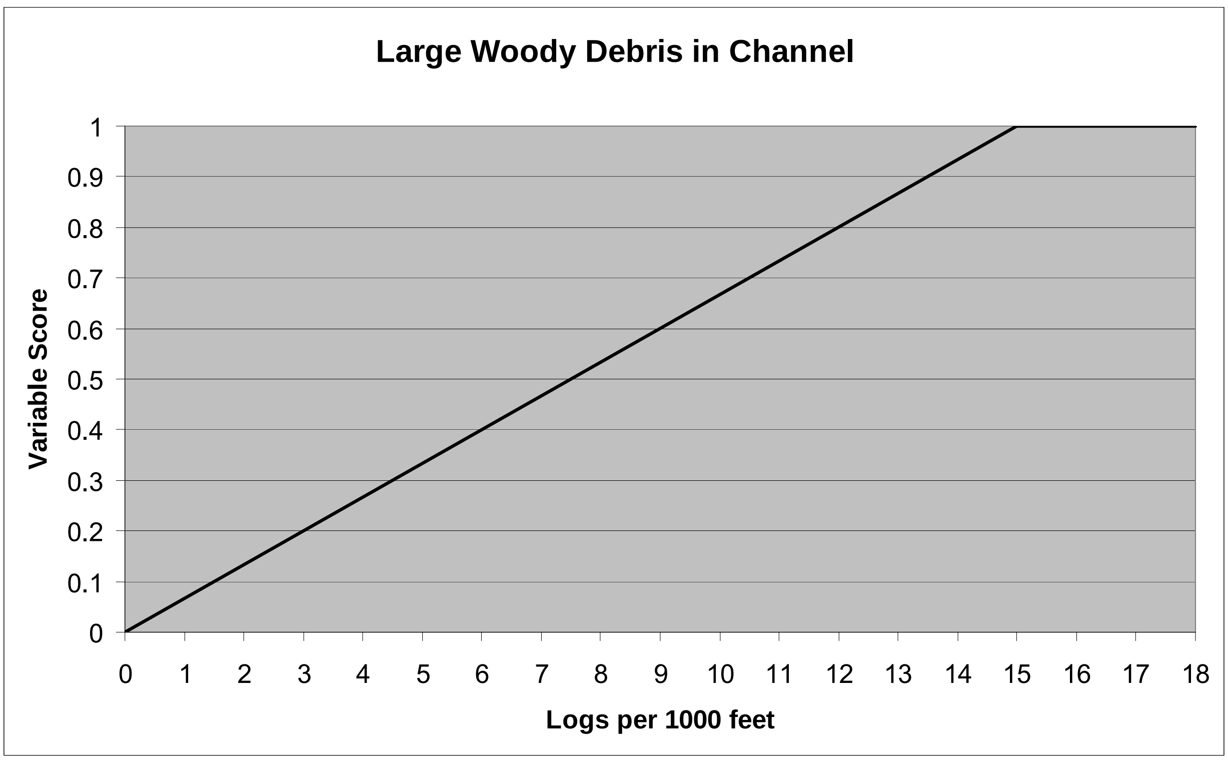
Large woody debris in channel (*LWDEBRIS*). This variable is defined as the number of down logs in the headwater stream channel per 1000 feet. Logs are defined as whole or partial dead tree stems. The portion of the log that is within the channel must be at least 39 inches (1 m) long, or if the channel is narrower than 39 inches (1 m), it must span the channel completely. The portion of the log that is within the channel must have a diameter greater than or equal to 3 inches (8 cm) at the widest point. Large woody debris is a measure of the dead biomass of trees within the high gradient, headwater stream ecosystem. Decomposing wood in the channel reduces channel erosion by dissipating stream energy, provides habitat for vertebrates and invertebrates, and contributes nutrients and organic matter to the downstream ecosystem.

LWDEBRIS is used in calculating the hydrology, biogeochemical, and habitat functional indices.

This variable is quantified by the number of logs in the stream channel per 1000 feet of channel length. Measure *LWDEBRIS* using the following procedure:

1) Measure the length of the stream channel being assessed and count the number of logs that are completely or partially lying in the channel.

2) Use Figure 1 to determine the variable score for the headwater stream. If the channel length is less than or greater than 1000 feet the number of logs needed to receive a variable score of 1.0 is proportional to the length.



In fully functional headwater stream systems in West Virginia the number of logs in the stream channel is 15 or more per 1000 feet of stream channel.

Stream channel geomorphology (*CHANNGEO*). This variable reflects direct alterations to the natural geomorphology of the stream channel. Examples in West Virginia include straightening, removal of the natural step-pool geomorphology, and reducing or increasing the slope or steepness of the stream channel. The intent of this variable is to capture those impacts that alter the slope and shape of natural headwater stream systems. This variable differs from *CHANNELALT* in that the impacts occur within the stream channel without affecting the amount of water in the channel, but do affect the energy of flows and how nutrients are retained within the headwater stream system.

This variable is quantified by the average channel slope and the frequency of step-pools within the stream channel. Measure *CHANNGEO* using the following procedure:

1) If stream is unaltered or the channel slope is greater than 4 percent and has many step-pools, then the subindex score for this variable is 1.0 and the following steps may be skipped.

2) If the channel has been altered or restored, use Table 10 to determine the variable score for stream channel geomorphology. Determine the weighted average for the entire stream reach impacted.

In reference standard sites, there were no alterations to the natural geomorphology of headwater stream channels.

Table 10
Stream channel geomorphology (*CHANNGEO*)

Slope and pools	Score
Greater than 4% slope with many step pools	1.0
2 to 4% slope with common step pools	0.5
1 to 1.9% slope with few step pools	0.1
Less than 1% slope with no step pools	0.0

Functions

Function 1: Hydrology

Definition

The Hydrology function is defined as the capacity of the high gradient, headwater riverine ecosystem to store water within the soil for a few days to several weeks and slowly release this water to streams down slope as well as to transport nutrients and organic matter through surface runoff. A potential independent, quantitative measure for validating the functional index is a direct measurement of the amount of surface water that runsoff as well as the water that is dynamically stored within the soil over a portion of the year.

Rationale for selecting the function

The annual water budget of high gradient headwater riverine streams in West Virginia is controlled mainly by precipitation and upland runoff and secondarily by interception of groundwater. Performance of the Hydrology function causes the ecosystem to retain water inputs for a sufficient period of time to develop other wetland characteristics (e.g., hydric soils, hydrophytic vegetation). Water storage also moderates the pulse of runoff that occurs following a storm event and prolongs the period of discharge into streams maintaining baseflow.

In addition to direct effects of water storage on the stream hydrograph, this function plays a role in all other wetland functions associated with headwater stream systems. Water storage has a significant effect on biogeochemical cycling in the stream. Prolonged saturation leads to anaerobic soil conditions and initiates chemical reactions that are highly dependent upon the redox capacity of the soil (Mausbach and Richardson 1994). The oxygen concentration in wetland soils greatly affects the redox potential and the chemical cycling properties of elements and compounds, particularly nutrients. This function also has important impacts on invertebrate and vertebrate populations. For example, some invertebrates, such as midges, have very short life cycles and are highly adapted to ephemeral systems.

Characteristics and processes that influence the function

The characteristics and processes that influence the capacity of a headwater ecosystem to store water have both natural and anthropogenic origins. Climate and landscape-scale geomorphic characteristics within and around the headwater system are factors largely established by natural processes. Anthropogenic alterations to these ecosystems (e.g., filling, logging) also influence the way the stream system stores and ultimately transports water. Such effects may occur due to changes in the dominant land cover in and near the watershed and stream and whether the stream channel has been hydrologically modified through filling or damming.

In West Virginia, rain is fairly evenly distributed throughout the year. Summer thunderstorms are common and tropical storms and hurricanes occasionally affect the area. Surface soil saturation and runoff can occur during any month and, in some sites, is evident all year. In others, saturation to the surface in the riparian zone is most evident in late winter and early spring before trees have completely leafed out.

In addition to geomorphic and climatic processes, human activities may also have a profound effect on the storage of water within a high gradient, headwater riverine ecosystem. Modifications to the uplands surrounding the stream or directly to the stream itself may affect the receipt and retention of water. Land-use changes, such as filling, soil compaction, road construction, urban development, and changes in evapotranspiration that result from logging are modifications that directly affect this function.

Filling for the purpose of mine spoil disposal and damming to provide stormwater retention have modified many headwater streams, converting them to depressions, lakes, or even uplands. Such modifications so significantly affect the natural short-term water storage of the headwater stream that they lose their natural characteristics and hydrologic functions.

Functional Capacity Index

The following variables are used in the assessment model for the Hydrology function:

- Channel Alterations (*CHANNELALT*)
- Channel Geomorphology (*CHANNELGEO*)
- Large Woody Debris (*LWDEBRIS*)
- Land Cover (*COVER*)
- Watershed Slope (*SLOPE*)
- Tree Cover (*TREE*)
- Shrub Cover (*SHRUB*)
- Herbaceous Cover (*HERB*)

The basic assessment model for calculating the functional capacity index (FCI) for the Hydrology function in forested or shrub-dominated headwater stream systems is as presented in equation 1, below. Equation 2 presents a modified version for application in systems dominated by herbaceous vegetation:

$$\left[\left(CHANNELALT \times \left\{\frac{CHANNELGEO + LWDEBRIS}{2}\right\}\right)^{1/2} \times \left(\frac{COVER + SLOPE + \left\{\frac{TREE + SHRUB}{2}\right\}}{3}\right)\right]^{1/2} \quad (1)$$

$$\left[\left(CHANNELALT \times \left\{\frac{CHANNELGEO + LWDEBRIS}{2}\right\}\right)^{1/2} \times \left(\frac{COVER + SLOPE + HERB}{3}\right)\right]^{1/2} \quad (2)$$

In this model (equation 1), the Hydrology function of high gradient, headwater streams depends on inputs of water from surface runoff from the surrounding upland. Water is removed from the system in surface outflow and evapotranspiration. The model assumes that, if natural hydrologic inputs from runoff from the surrounding uplands are unaltered, outflow is not reduced by filling or increased by downcutting or blocked by anthropogenic obstructions such as dams, and a mature forest is present to disperse runoff at characteristic rates, then the stream is functioning at reference standard condition.

This model addresses three main factors that influence water storage. The first part of the equation reflects natural or anthropogenic alterations to the stream channel (*CHANNELALT*) that affect its capacity move water to other channels downstream. However, storage of atypically large amounts of surface water due to damming the stream results in a decrease in function. The second part is a combination of physical features that slow water flow in the stream channel and relate to the stability of the channel (*CHANNELGEO* and *LWDEBRIS*). The third part of the equation is a combination of factors affecting the supply of water from the surrounding uplands (*COVER* and *SLOPE*) through runoff, and the effect of a mature forest (*TREE* and *SHRUB*) on surface water runoff and erosion of excessive fine sediment into the stream. The first two parts are combined using a geometric mean, the result being that if *CHANNELALT* equals zero the functional capacity index will equal zero for the hydrologic function. Variables in the third part of the equation are averaged using an arithmetic mean.

The three parts of the equation are combined using a geometric mean based on the assumption that *CHANNELALT* is as important as the combination of the other variables in relation to water storage. In other words, if the stream system is drained to the point that it no longer has riverine hydrology and has been changed from a headwater stream to a depressional, upland, or lacustrine system, then the subindex score for *CHANNELALT* would be 0.0 and the functional capacity for water storage would be zero as well. For herbaceous dominated ecosystems (equation 2), the maximum FCI is 0.67.

Function 2: Biogeochemical cycling

Definition

The biogeochemical function is defined as the ability of the high gradient, headwater ecosystem to retain and transform inorganic materials needed for biological processes into organic forms and to oxidize those organic molecules back into elemental forms through decomposition. Thus, biogeochemical cycling includes the biogeochemical processes of producers, consumers, and decomposers. Potential independent, quantitative measures that may be used in validating the functional index include direct measurements of net annual productivity (gm/m^2), annual accumulation of organic matter (gm/m^2), and annual decomposition of organic matter (gm/m^2).

Rationale for selecting the function

Biogeochemical cycling is a fundamental function performed by all ecosystems, but tends to be accomplished at particularly high rates in many wetland systems (Mitsch and Gosselink 2000). A sustained supply of organic carbon in the soil provides for maintenance of the characteristic plant community including annual primary productivity, composition, and diversity (Bormann and Likens 1970, Whittaker 1975, Perry 1994). The plant community (producers) provides the food and habitat structure (energy and materials) needed to maintain the characteristic animal community (consumers) (Crow and MacDonald 1978, Fredrickson 1978, Wharton et al. 1982). In time, the plant and animal communities serve as a source of detritus that is the source of energy and materials needed to maintain the characteristic community of decomposers. The decomposers break down these organic materials into simpler elements and compounds that can reenter the nutrient cycle (Reiners 1972, Dickinson and Pugh 1974, Pugh and Dickinson 1974, Schlesinger 1977, Singh and Gupta 1977, Hayes 1979, Harmon et al. 1986, Vogt et al. 1986).

Characteristics and processes that influence the function

Biogeochemical cycling is a function of biotic and abiotic processes that result from conditions within and around the headwater stream. In high gradient, headwater ecosystems carbon is stored within, and cycled among, four major compartments: (a) the soil, (b) primary producers such as vascular and nonvascular plants, (c) consumers such as animals, fungi, and bacteria, and (d) dead organic matter, such as leaf litter or woody debris, referred to as detritus. It is the maintenance of the characteristic primary productivity of the plant community that sets the stage for all subsequent transformations of energy and materials at each trophic level within the ecosystem. It follows that alterations to hydrologic inputs, outputs, or storage and/or changes to the characteristic plant community will directly affect the way in which the ecosystem can perform this function.

Abiotic processes affecting retention and cycling of carbon are dependent primarily on the adsorption of materials to soil particles, the amount of water that passes through the wetland carrying dissolved carbon, the hydroperiod or retention time of water, and the importation of materials from surrounding areas (Grubb and Ryder 1972, Federico 1977, Beaulac and Reckhow 1982, Ostry 1982, Shahan 1982, Strecker et al. 1992, Zarbock et al. 1994). Natural soils, hydrology, and vegetation are important factors in maintaining these characteristic processes.

The ability of a high gradient, headwater ecosystem to perform this function depends upon the transfer of carbon between trophic levels within the ecosystem, the rate of decomposition, and the flux of materials in and out of the wetland. A change in the ability of one trophic level to process carbon will result in changes in the processing of carbon in other trophic levels (Carpenter 1988).

The ideal approach for assessing biogeochemical cycling in a headwater riverine ecosystem would be to measure the rate at which carbon is transferred and transformed between and within trophic levels over several years. However, the time and effort required to make these measurements are well beyond a rapid assessment procedure, and instead we use plant community structure and detrital loading as indirect indicators. Reference data from other ecosystems suggest that land-use practices and forest management have great effect on plant community structure (species composition and coverage), diversity, and primary productivity. Changes in the vegetative cover directly affect the amount of organic carbon present in the ecosystem. Canopy removal in particular directly affects the amount and type of detritus present in the headwater stream system. Changes in hydrology or vegetation, deposition of fill material, excavation, or recent fire can alter the amount of soil detritus. Changes to the hydrology of headwater ecosystems through drainage, increased surface water flow, or ponding has a tremendous effect on biogeochemical cycling. Increased surface water flow can sweep nearly all detrital matter from the ecosystem and disrupt the biogeochemical cycle. Drainage, over time, changes the vegetative composition and, therefore, the type and amount of detrital matter. Ponding reduces the rate of decomposition and increases the accumulation of organic carbon, as well as changing the vegetative community. It is assumed that measurements of these characteristics reflect the level of biogeochemical cycling taking place within an ecosystem.

Functional capacity index

The following variables are used in the assessment model for the Biogeochemical function:

- Channel Alterations (*CHANNELALT*)
- Channel Geomorphology (*CHANNELGEO*)
- Soil Detritus (*DETRITUS*)
- Large Woody Debris (*LWDEBRIS*)
- Land Cover (*COVER*)
- Watershed Slope (*SLOPE*)
- Tree Cover (*TREE*)
- Shrub Cover (*SHRUB*)
- Herbaceous Cover (*HERB*)

The assessment models for calculating the FCI for the biogeochemical functions in high gradient, headwater riverine systems are given below. The models depend, in part, on the characteristics of the tree and shrub stratum of vegetation within the watershed, including the riparian area. If the site supports a tree or shrub layer ($\geq$10% total cover), then equation 3 is used. If the site is unvegetated or dominated by herbaceous vegetation (<10% canopy cover of trees or shrubs), then equation 4 is used.

$$\left[\left(CHANNELALT \times CHANNELGEO\right)^{1/2} \times \frac{\left(\frac{COVER + SLOPE}{2}\right) + \left(\frac{TREE + SHRUB}{2}\right) + \left(\frac{DETRITUS + LWDEBRIS}{2}\right)}{3}\right]^{1/2} \quad (3)$$

$$\left[\left(CHANNELALT \times CHANNELGEO\right)^{1/2} \times \left\{\frac{HERB + LWDEBRIS + \left(\frac{COVER + SLOPE}{2}\right)}{3}\right\}\right]^{1/2} \quad (4)$$

In these models, changes in the biogeochemical cycling capacity of high gradient, headwater riverine ecosystems relative to reference standard conditions depend on increased outflow of water, or on reductions in water inflows, organic matter, or quantity of vegetation. The models are based on the assumption that if organic matter and vegetation are in place, and anthropogenic hydrologic disturbance is not present in the stream channel or the surrounding watershed, then carbon cycling will occur at an appropriate rate. In the first part of each equation, removal or retention of surface water is represented by *CHANNELALT* and *CHANNGEO*. In the second part, *COVER* and *SLOPE* are averaged and represent inputs related to water quality and time that water and particulates are delivered to the stream system. *DETRITUS* is used as an indicator of recent organic input and accumulation. If vegetation has been removed from the watershed, including the riparian area during the previous year or two, then the amount of detritus will likely be reduced or absent. Also, if the hydrology of the wetland or adjacent watershed has been altered to the point that detritus is being flushed from the headwater ecosystem, then this alteration should be reflected in the amount of detrital cover. Large Woody Debris (*LWDEBRIS*) loading within the channel is an indicator of long-term organic matter accumulation within the watershed as a whole. If hydrology or vegetation has been altered for more than a few years, then the amount of Large Woody Debris should be reduced, reflecting a decrease in organic matter content in the stream system. Also, if fill material has been placed in the stream or adjacent watershed or soil excavation has taken place; the organic matter in the previous condition will have been buried by the fill or removed in excavation. These two variables, *DETRITUS* and *LWDEBRIS* are combined using an arithmetic mean. This is based on the assumption that detritus and large woody debris are of equal importance in biogeochemical cycling. Headwater riverine ecosystem vegetation is represented by the combination of *TREE* and *SHRUB*, or herbaceous vegetative cover (*HERB*). If the amount of vegetation, represented by percent cover, is reduced, then it is assumed that carbon cycling will be reduced.

In equation 3, the variables that directly relate to the channel and variables related to inputs to the stream are combined using a geometric mean. The implications are that if all of the variables in any part of the model equal zero, then the function would receive an FCI of zero. For watersheds where both tree and shrub strata have less than 10 percent cover the maximum FCI is 0.76 (equation 4).

Function 3: Plant Community functions

Definition

This function is defined as the degree to which a high gradient, headwater riverine ecosystem supports a plant community that is similar in structure and composition to that found on the least disturbed sites in West Virginia. Various approaches have been developed to describe and assess plant community characteristics that might be appropriately applied in developing independent measures of this function. However, none of these approaches alone can supply a "direct independent measure" of plant community function, because they are tools that are employed in more complex analyses that require familiarity with regional vegetation and collection of appropriate sample data.

Rationale for selecting the function

The ability to maintain a characteristic plant community is important in part because of the intrinsic value of the species found there. In the West Virginia landscape, the dominant community type is hardwood forest, and the high gradient, headwater riverine subclass constitutes a small percentage of the overall area. The presence of a characteristic plant community also is critical in maintaining various biotic and abiotic processes occurring in wetlands. For example, plant communities are the source of primary productivity, produce carbon and nutrients that may be exported to other ecosystems, and provide habitats and refugia necessary for various animal species (Harris and Gosselink 1990).

Overview of the plant community

The plant communities of headwater ecosystems are complex and vary across the State and even locally. Except immediately following severe disturbances, forest is the dominant community type in these ecosystems. Sites that have been relatively undisturbed for decades or hundreds of years support trees of various sizes and ages. Depending on the species that initially occupy a site after a major disturbance, succession can progress along different paths, but because of small-scale disturbances (e.g., individual trees dying and creating canopy gaps that may be colonized by different species), eventually an uneven-aged forest with well-developed stratification will be achieved (Hunter 1990). In general, older stands tend to be more stratified than younger ones and forests with several vertical strata have higher species diversity than young or middle-aged stands with few strata (Willson 1974, Hunter 1990). This is important in maintenance of the community over time given that species diversity has been found to be positively related to community stability (Bolen and Robinson 2003).

Factors that influence the plant community

Factors that influence the development and maintenance of a characteristic plant community in most wetlands including high gradient, headwater riverine systems in West Virginia include the physical site characteristics, the hydrologic regime, weather events, anthropogenic disturbances, and various ecological processes such as competition, disease, browsing pressure, shade tolerance, and community succession. Alterations to these factors or processes in the stream channel, adjacent riparian area, or to the surrounding watershed may directly affect the species composition and biodiversity of the site (Askins et al. 1987, Keller et al. 1993, Kilgo et al. 1997).

The moisture regime is one of the most important determinants of the structure and composition of plant communities. In high gradient, headwater riverine ecosystems, water delivery occurs as direct precipitation, overland flow, or groundwater discharge from the surroundings uplands. Overland flow is believed to be the most important of the three in the maintenance of hydrology in these riverine systems.

Activities that degrade the physical nature of a stream, especially its flow regime, have the potential to have deleterious effects on the plant community and, if significant enough, may alter the plant community for extended periods, and even permanently. For example, depositing fill in a stream channel fundamentally changes the substrate and hydrologic regime and, if amounts are substantial, can result in conversion of the area from riverine system to upland.

Some alterations that do not even occur in the stream channels themselves may have serious negative consequences for the plant community. For example, clearing the natural vegetation in the upland watershed and adding impervious surfaces (roads, parking lots, etc.) can result in significantly more water entering a stream and could alter community composition and structure. If mean water depths increase beyond the ability of even these species to survive, the area essentially would become an open water basin with vegetation existing only at the edges.

Except for anthropogenic impacts, high gradient, headwater riverine ecosystems in West Virginia are influenced primarily by small-scale frequent disturbances, especially individual tree mortality which leads to gap-phase regeneration. Forests that develop under such conditions generally are composed of shade-tolerant species of different age (and by inference size) classes (Hunter 1990).

Functional capacity index

The following variables are used in the assessment model for the Plant Community function:

- Channel Alterations (*CHANNELALT*)
- Vegetation composition and diversity (*COMP*)
- Tree Cover (*TREE*)
- Shrub Cover (*SHRUB*)
- Herbaceous Cover (*HERB*)

The assessment models for calculating the FCI for the maintenance of a characteristic plant community in high gradient, headwater riverine ecosystems are given below. The choice of models depends on the characteristics of the dominant vegetation present within the ecosystem. If the site contains a tree or shrub layer ($\geq$10% total tree or shrub cover), then equation 5 is used. If neither trees nor shrubs are common (<10% cover), then equation 6 is used.

$$\left[CHANNELALT \times \left(\frac{TREE + SHRUB + COMP}{3}\right)\right]^{1/2} \qquad (5)$$

$$\left(CHANNELALT \times HERB\right)^{1/2} \qquad (6)$$

These models represent the existing plant community in the wetland and include variables that provide insight into its serial stage, structure, species composition, diversity, and stability. The models assume that the physical environment necessary to maintain the community (e.g., hydrology) is also present. If not, any recent environmental changes that may affect the long-term persistence of the community should be reflected in reduced FCIs for Functions 1 and 2. In the context of this function, Average Percent Cover of Trees (*TREE*) and Average Percent Cover of Shrubs (*SHRUB*) are structural indicators of serial stage and of disturbance. The vegetation composition and diversity variable (*COMP*) reflects floristic quality and diversity, as well as seral stage and disturbance. In a forested system (equation 5), subindices for *TREE*, *SHRUB*, and *COMP* are averaged. In systems without trees or shrubs *HERB* is the only vegetation variable and equation 6 is used. In both equations the vegetative variables are combined with *CHANNELALT* using a geometric mean reflecting the importance of hydrology to the ecosystem. For herbaceous dominated ecosystems, the maximum FCI is 0.32.

Function 4: Wildlife Habitat

Definition

This function is defined as the capacity of a high gradient, headwater riverine ecosystem to provide critical life requisites to selected components of the vertebrate and invertebrate wildlife community. Ecosystems within the subclass provide habitat for numerous species of amphibians, reptiles, birds, and mammals. Birds and amphibians were selected as the focus of this function. Birds were chosen because they are of considerable public and agency interest, and they respond rapidly to changes in the quality and quantity of their habitats. In addition, birds are a diverse group and individual species have strong associations with the different strata of the multi-layered forests that characterize those sites that were considered to be functioning at the highest level (reference standard). Birds have been shown to be sensitive indicators and integrators of environmental change such as that brought about by human use and alteration of landscapes (Morrison 1986, Croonquist and Brooks 1991, O'Connell et al. 2000). Amphibians were chosen because of the importance of wetlands as breeding habitat. Various species of salamanders and frogs breed in shallow streams, temporary ponds, and moist leaf litter or duff. In the adult stages, they often disperse into suitable habitat in the adjacent uplands.

A potential independent, quantitative measure of this function that could be used to validate the assessment model (Wakeley and Smith 2001) is the combined species richness of birds and amphibians that use high gradient, headwater ecosystems in West Virginia throughout the annual cycle. Data requirements for model validation include direct monitoring of wildlife communities using appropriate techniques for each taxon. Ralph et al. (1993) described field methods for monitoring bird populations. Gibbons and Semlitsch (1981) described procedures for sampling small animals including reptiles and amphibians. Heyer et al. (1994) and Dodd (2003) described monitoring procedures for amphibians.

Rationale for selecting the function

Wetlands and the adjacent surrounding upland are recognized as valuable habitats for a diversity of animal species including both vertebrates and invertebrates. In the vicinity of headwater streams, birds and mammals are diverse and abundant. However, amphibians can be particularly important. Burton and Likens (1975) reported that amphibians constitute the single largest source of vertebrate biomass in some ecosystems. Because many amphibians require both wetland and adjacent upland habitats, they serve as a conduit for energy exchange between the two systems (Mitchell et al. 2004). Wharton et al. (1982), Johnson (1987), Whitlock et al. (1994), Crowley et al. (1996), Mitsch and Gosselink (2000), and Bailey et al. (2004) are all good sources of information regarding animal communities of wetlands.

Many wildlife species associated with wetlands have experienced serious population declines. Within the United States, approximately one third of the plant and animal species listed as threatened or endangered are associated with wetlands during some part of their life cycles (Dahl and Johnson 1991). In West Virginia, high gradient, riverine wetlands and the adjacent riparian areas constitute a relatively small percentage of the landscape within the state, therefore, these areas are likely are important for the maintenance of local populations of many species.

Characteristics and processes that influence the function

Hydrologic alteration of high gradient, riverine ecosystems has the potential to impact a number of wildlife species, but the most serious impacts would be to amphibians. Animals with direct dependence on water, such as amphibians that use seasonally ponded micro-depressions within high gradient, riverine ecosystems for reproduction, are highly vulnerable to drainage or filling. Even partial draining or filling could impact breeding activity because of the length of time needed for egg development and maturation of the young. There is considerable variability in development time among species. Most anurans require the presence of water for 2-3 months (Duellman and Trueb 1986). Some species, however, require substantially shorter periods of time. Conversely, artificially increasing the amount of time that surface water is present in a riverine ecosystem by excavating or by augmenting runoff into the wetland can potentially reduce the suitability for amphibians by allowing fish populations to become established. Bailey et al. (2004) noted that predatory fish prey on breeding amphibians, their eggs, and tadpoles. They recommended that wherever ecosystems free of fish exist, efforts should be made to avoid accidental or deliberate introductions.

Besides the direct effects of hydrologic change on animals, indirect effects can occur through changes in the plant community. Sites with unaltered hydrology that have not been subjected to significant disturbance for long periods support a characteristic vegetation composition and structure (i.e., tree size, density, stratification, etc.) as described in the plant community model discussion. Wildlife species have evolved with and adapted to these conditions. Thus, altering the hydroperiod has the potential to change the composition and structure of the wildlife community. Factors other than hydrology, including droughts and catastrophic storms, competition, disease, browsing pressure, shade tolerance, community succession, and natural and anthropogenic disturbances, also affect the plant community directly and wildlife community indirectly. Following is an overview of the relationships between specific characteristics of the plant community and wildlife utilization of forested ecosystems including wetlands. Wharton et al. (1982), Hunter (1990), and Morrison et al. (1992) are all good sources of information on this subject.

Habitat structure is probably the most important determinant of wildlife species composition and diversity (Wiens 1969, Anderson and Shugart 1974). Undisturbed high gradient, riverine ecosystems in West Virginia normally contain multiple strata. This structural complexity provides a myriad of habitat conditions for animals and allows numerous species to coexist in the same area (Schoener 1986). This is especially well documented with birds, which tend to show affinities for habitats based on physical characteristics, such as the size and density of overstory trees, density of shrub and ground cover, number of snags, and other factors. For example, some bird species utilize the forest canopy, whereas others are associated with the understory (Cody 1985, Wakeley and Roberts 1996).

While the structure of the forest in the immediate vicinity of a headwater stream is an important determinant of animal habitat availability, the characteristics of adjacent uplands are equally critical to many species. Although tied to wetlands and other aquatic habitats for breeding, many frogs and some salamanders spend the remainder of the year in terrestrial habitats, often in hardwood forests (Mitchell et al. 2004). Semlitsch and Jensen (2001) noted that suitable terrestrial habitat surrounding the breeding site is critical for feeding, growth, maturation, and maintenance of juvenile and adult populations of pond-breeding salamanders. Bailey et al. (2004) concurred, stating that "a seasonal wetland without appropriate surrounding upland habitat will lose its amphibian and reptile fauna." Semlitsch and Jensen (2001) suggested that the terrestrial habitat be referred to as part of the "core habitat" used by the animals, because it is as essential as the breeding site itself. This is different from the traditional concept of the "buffer zone" commonly recommended around wetlands to protect various wetland functions (Boyd 2001).

Semlitsch and Bodie (2003) reviewed the literature on terrestrial habitats used by amphibians. Habitat features such as leaf litter, coarse woody debris (i.e., logs), boulders, small mammal burrows, cracks in rocks, spring seeps, and rocky pools were important for foraging, refuge, or over-wintering. A well-developed canopy (for shade) and coarse woody debris and litter (for refuge and food) were considered to be essential habitat features. The abundance of litter is related to the age of forest stands. The litter layer in an older forest usually is much thicker than in a younger forest due to the differential amount of foliage produced. Young stands do not begin to contain significant amounts of litter and coarse woody debris until natural thinning begins. Coffey (1998) reported that minimal woody debris was found in bottomland hardwood stands younger than 6 years of age. Such a pattern probably also exists in upland forests. Shade, which is critical to some amphibian species in slowing or preventing dehydration (Spight 1968, Rothermel and Semlitsch 2002), is provided to some extent in all forest stands but likely is not effective until tree canopies begin to close (Rothermel and Semlitsch 2002). Thus total canopy cover is an important consideration in evaluating amphibian habitat in forest ecosystems.

Terrestrial areas immediately adjacent to wetlands also are important to the integrity of the wetland ecosystem itself. Such areas serve to reduce the amounts of silt, contaminants, and pathogens that enter the stream, and to moderate physical parameters such as temperature (Rhode et al. 1980, Young et al. 1980, Hupp et al. 1993, Snyder et al. 1995, Daniels and Gilliam 1996, Semlitsch and Jensen 2001, Semlitsch and Bodie 2003). These functions directly or indirectly affect amphibians through improved water quality and provide benefits to the entire wildlife community. Semlitsch and Bodie (2003) recommended a 30-60 m (100-200 ft) wide "buffer" around the wetland for this purpose alone.

Functional Capacity Index

The following variables are used in the assessment model for the function Provide Characteristic Wildlife Habitat:

- Channel Alterations (*CHANNELALT*)
- Channel Geomorphology (*CHANNELGEO*)
- Large Woody Debris (*LWDEBRIS*)
- Land Cover (*COVER*)
- Stream Sediment Size (*SED*)
- Soil Detritus (*DETRITUS*)
- Tree Cover (*TREE*)
- Herbaceous Cover (*HERB*)

The model used for deriving the functional capacity index for the wildlife habitat function in high gradient, riverine ecosystems depend on the characteristics of the uppermost stratum of vegetation within the wetland. If the site supports a tree layer (≥10% total tree or shrub cover), then equation 7 is used. If neither trees nor shrubs are common (<10% cover), then equation 8 is used.

$$\left[CHANNELALT \times \left(\frac{COVER + CHANNGEO + SED + TREE + DETRITUS + LWDEBRIS}{6}\right)\right]^{1/2} \quad (7)$$

$$\left[CHANNELALT \times \left(\frac{COVER + HERB + SED + CHANNGEO + LWDEBRIS}{5} \right) \right]^{\frac{1}{2}} \quad (8)$$

This model is assumed to reflect the ability of high gradient, riverine ecosystems to provide critical life requisites for wildlife, with an emphasis on amphibians and birds. If the components of this model are similar to those found under reference standard conditions, then it is likely that the entire complement of amphibians and birds characteristic of high gradient, riverine ecosystems within the reference domain will be present.

The first part of each equation is an expression of the hydrologic integrity of the stream channel and only involves the variable *CHANNELALT*. In the context of this function, a characteristic hydrologic regime is essential as a source of water for breeding amphibians and to support the plant community upon which the animal community depends. The second part of each equation contains variables that reflect seral stage, cover potential, food production potential, nest site potential, availability of dispersal habitat, and other factors that depend on stand structure, maturity, and connectivity. *TREE* is used when the ecosystem is dominated by trees and *HERB* is used in wetlands lacking sufficient trees. Other features of forested wetlands such as snags, are also are important habitat requirements for various members of the wildlife community, but are not explicitly included in the model. It was assumed that if the structure of the tree layer is appropriate, then these additional features will be present in the appropriate numbers or amounts. Channel integrity is assumed to be critical to the maintenance of wetland wildlife habitat; therefore, the hydrology component is used as a multiplier in each equation. The other terms in the model, which reflect onsite and offsite habitat conditions, are assumed to be partially compensatory (i.e., a low value for one term will be partially compensated by a high value for the other(s)). In high gradient, headwater riverine ecosystems dominated by trees, the maximum possible FCI is 1.0. In ecosystems containing few trees, the maximum FCI is 0.82.

Models

Hydrology Functions

$$\left[\left(CHANNELALT\times\left\{\frac{CHANNELGEO+LWDEBRIS}{2}\right\}\right)^{1/2}\times\left(\frac{COVER+SLOPE+\left\{\frac{TREE+SHRUB}{2}\right\}}{3}\right)\right]^{1/2} \quad (1)$$

$$\left[\left(CHANNELALT\times\left\{\frac{CHANNELGEO+LWDEBRIS}{2}\right\}\right)^{1/2}\times\left(\frac{COVER+SLOPE+HERB}{3}\right)\right]^{1/2} \quad (2)$$

Biogeochemical Functions

$$\left[\left(CHANNELALT\times CHANNELGEO\right)^{1/2}\times\frac{\left(\frac{COVER+SLOPE}{2}\right)+\left(\frac{TREE+SHRUB}{2}\right)+\left(\frac{DETRITUS+LWDEBRIS}{2}\right)}{3}\right]^{1/2} \quad (3)$$

$$\left[\left(CHANNELALT\times CHANNELGEO\right)^{1/2}\times\left\{\frac{HERB+LWDEBRIS+\left(\frac{COVER+SLOPE}{2}\right)}{3}\right\}\right]^{1/2} \quad (4)$$

Plant Community Functions

VANNOTE, R. L., G. W. MINSHALL, K. W. CUMMINS, J. R. SEDELL, AND C. E. CUSHING. 1980. The river continuum concept. Can. J. Fish. Aquat. Sci. 37: 130–137.

From headwaters to mouth, the physical variables within a river system present a continuous gradient of physical conditions. This gradient should elicit a series of responses within the constituent populations resulting in a continuum of biotic adjustments and consistent patterns of loading, transport, utilization, and storage of organic matter along the length of a river. Based on the energy equilibrium theory of fluvial geomorphologists, we hypothesize that the structural and functional characteristics of stream communities are adapted to conform to the most probable position or mean state of the physical system. We reason that producer and consumer communities characteristic of a given river reach become established in harmony with the dynamic physical conditions of the channel. In natural stream systems, biological communities can be characterized as forming a temporal continuum of synchronized species replacements. This continuous replacement functions to distribute the utilization of energy inputs over time. Thus, the biological system moves towards a balance between a tendency for efficient use of energy inputs through resource partitioning (food, substrate, etc.) and an opposing tendency for a uniform rate of energy processing throughout the year. We theorize that biological communities developed in natural streams assume processing strategies involving minimum energy loss. Downstream communities are fashioned to capitalize on upstream processing inefficiencies. Both the upstream inefficiency (leakage) and the downstream adjustments seem predictable. We propose that this River Continuum Concept provides a framework for integrating predictable and observable biological features of lotic systems. Implications of the concept in the areas of structure, function, and stability of riverine ecosystems are discussed.

Key words: river continuum; stream ecosystems; ecosystem structure, function; resource partitioning; ecosystem stability; community succession; river zonation; stream geomorphology

VANNOTE, R. L., G. W. MINSHALL, K. W. CUMMINS, J. R. SEDELL, AND C. E. CUSHING. 1980. The river continuum concept. Can. J. Fish. Aquat. Sci. 37: 130–137.

De la tête des eaux à l'embouchure, un réseau fluvial offre un gradient continu de conditions physiques. Ce gradient devrait susciter, chez les populations habitant dans le réseau, une série de réponses aboutissant à un continuum d'ajustements biotiques et à des schémas uniformes de charge, transport, utilisation et emmagasinage de la matière organique sur tout le

parcours d'une rivière. Faisant appel à la théorie de l'équilibre énergétique des spécialistes de la géomorphologie fluviale, nous avançons l'hypothèse que les caractéristiques structurales et fonctionnelles des communautés fluviatiles sont adaptées de façon à se conformer à la position ou condition moyenne la plus probable du système physique. Nous croyons que les communautés de producteurs et de consommateurs caractéristiques d'un segment donné de la rivière se mettent en harmonie avec les conditions physiques dynamiques du chenal. Dans des réseaux fluviaux naturels, on peut dire que les communautés biologiques forment un continuum temporel de remplacements synchronisés d'espèces. Grâce à ce remplacement continu, il y a répartition dans le temps de l'utilisation des apports énergétiques. Ainsi, le système biologique vise à un équilibre entre une tendance vers l'utilisation efficace des apports d'énergie en partageant les ressources (nourriture, substrat, etc.), d'une part, et une tendance opposée vers un taux uniforme de transformation de l'énergie durant l'année, d'autre part. A notre avis, les communautés biologiques habitant dans des cours d'eau naturels adoptent des stratégies de transformation comportant une perte minimale d'énergie. Les communautés d'aval sont organisées de façon à tirer profit de l'inefficacité de transformation des communautés d'amont. On semble pouvoir prédire à la fois l'inefficacité (fuite) d'amont et les ajustements d'aval. Nous suggérons ce concept d'un continuum fluvial comme cadre dans lequel intégrer les caractères biologiques prévisibles et observables des systèmes lotiques. Nous analysons les implications du concept quant à la structure, fonction et stabilité des écosystèmes fluviaux.

Statement of the Concept

Many communities can be thought of as continua consisting of mosaics of integrading population aggregates (McIntosh 1967; Mills 1969). Such a conceptualization is particularly appropriate to streams. Several workers have visualized streams as possessing assemblages of species which respond by their occurrences and relative abundances to the physical gradients present (Shelford 1911; Thompson and Hunt 1930; Ricker 1934; Ide 1935; Burton and Odum 1945; Van Deusen 1954; Huet 1954, 1959; Slack 1955; Minshall 1968; Ziemer 1973; Swanston et al. 1977; Platts 1979). Expansion of this idea to include functional relationships has allowed development of a framework, the "River Continuum Concept," describing the structure and function of communities along a river system. Basically, the concept proposes that understanding of the biological strategies and dynamics of river systems requires consideration of the gradient of physical factors formed by the drainage network. Thus energy input, and organic matter transport, storage, and use by macroinvertebrate functional feeding groups may be regulated largely by fluvial geomorphic processes. The patterns of organic matter use may be analogous to those of physical energy expenditure proposed by geomorphologists (Leopold and Maddock 1953; Leopold and Langbein 1962; Langbein and Leopold 1966; Curry 1972). Further, the physical structure coupled with the hydrologic cycle form a templet (Southwood 1977) for biological responses and result in consistent patterns of community structure and function and organic matter loading, transport, utilization, and storage along the length of a river.

Derivation of the Concept

As the cyclic theory for explaining the evolution of land forms and streams (young, mature, ancient) proved unsatisfactory, the concepts gradually were replaced by a principle of dynamic equilibrium (Curry 1972). The concept of the physical stream network system and the distribution of watersheds as open systems in dynamic ("quasi") equilibrium was first proposed by Leopold and Maddock (1953) to describe consistent patterns, or adjustments, in the relationships of stream width, depth, velocity, and sediment load. These "steady state" systems are only rarely characterized by exact equilibria and generally the river and its channel tend toward a mean form, definable only in terms of statistical means and extremes (Chorley 1962); hence, the idea of a "dynamic" equilibrium. The equilibrium concept was later expanded to include at least nine physical variables and was progressively developed in terms of energy inputs, efficiency in utilization, and rate of entropy gain (Leopold and Langbein 1962; Leopold et al. 1964; Langbein and Leopold 1966). In this view, equilibration of river morphology and hydraulics is achieved by adjustments between the tendency of the river to maximize the efficiency of energy utilization and the opposing tendency toward a uniform rate of energy use.

Based upon these geomorphological considerations, Vannote initially formulated the hypothesis that structural and functional characteristics of stream communities distributed along river gradients are selected to conform to the most probable position or mean state of the physical system. From our collective experience with a number of streams, we felt it was possible to translate the energy equilibrium theory from the physical system of geomorphologists into a biological analog. In this analysis, producer and consumer communities characteristic of a given reach of the river continuum conform to the manner in which the river system utilizes its kinetic energy in achieving a dynamic equilibrium. Therefore, over extended river reaches, biological communities should become established which approach equilibrium with the dynamic physical conditions of the channel.

Implications of the Concept

It is only possible at present to trace the broad outlines of the ways the concept should apply to stream ecosystems and to illustrate these with a few examples for which reasonably good information is available. From headwaters to downstream extent, the physical variables within a stream system present a continuous gradient of conditions including width, depth, velocity, flow volume, temperature, and entropy gain. In developing a biological analog to the physical system, we hypothesize that the biological organization in rivers conforms structurally and functionally to kinetic energy dissipation patterns of the physical system. Biotic communities rapidly adjust to any changes in the redistribution of use of kinetic energy by the physcial system.

Stream Size and Ecosystem Structure and Function

Based on considerations of stream size, we propose some broad characteristics of lotic communities which can be roughly grouped into headwaters (orders 1–3), medium-sized streams (4–6), and large rivers (>6) (Fig. 1). Many headwater streams are influenced strongly by the riparian vegetation which reduces autotrophic production by shading and contributes large amounts of allochthonous detritus. As stream size increases, the reduced importance of terrestrial organic input coincides with enhanced significance of autochthonous primary production and organic transport from upstream. This transition from headwaters, dependent on terrestrial inputs, to medium-sized rivers, relying on algal or rooted vascular plant production, is thought to be generally reflected by a change in the ratio of gross primary productivity to community respiration (P/R) (Fig. 2). The zone through which the stream shifts from heterotrophic to autotrophic is primarily dependent upon the degree of shading (Minshall 1978). In deciduous forests and some coniferous forests, the transition probably is approximately at order 3 (Fig. 1). At higher elevations and latitudes, and in xeric regions where riparian vegetation is restricted, the transition to autotrophy may be in order 1. Deeply incised streams, even with sparse riparian vegetation, may be heterotrophic due to side slope ("canyon") shading.

Large rivers receive quantities of fine particulate organic matter from upstream processing of dead leaves and woody debris. The effect of riparian vegetation is insignificant, but primary production may often be limited by depth and turbidity. Such light attenuated systems would be characterized by P/R < 1. Streams of lower order entering midsized or larger rivers (e.g. the 3rd order system shown entering the 6th order

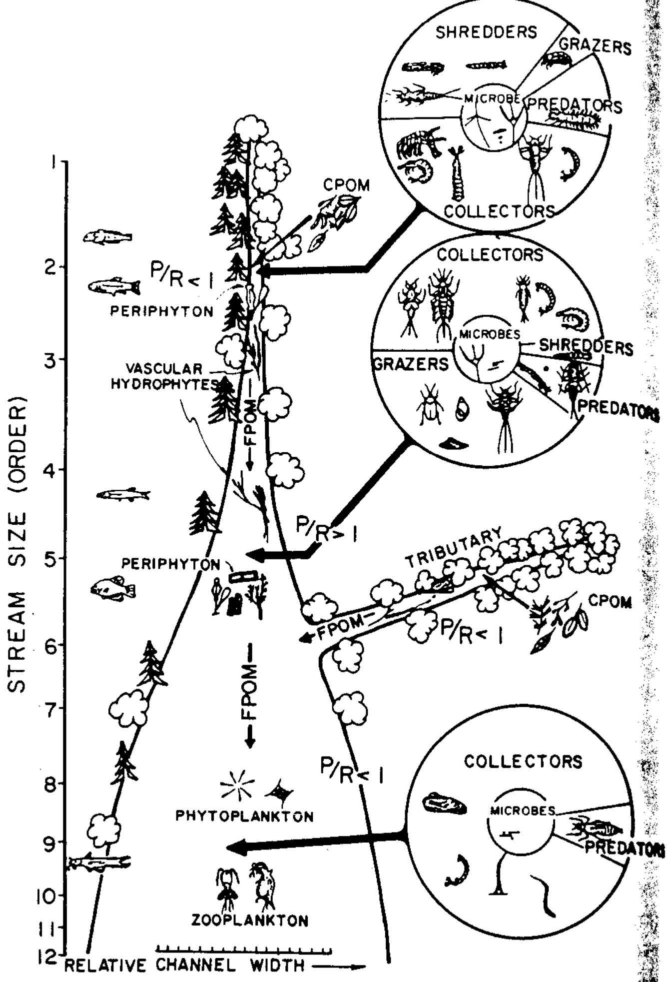

FIG. 1. A proposed relationship between stream size and the progressive shift in structural and functional attributes of lotic communities. See text for fuller explanation.

river in Fig. 1) have localized effects of varying magnitude depending upon the volume and nature of the inputs.

The morphological–behavioral adaptations of running water invertebrates reflect shifts in types and locations of food resources with stream size (Fig. 1). The relative dominance (as biomass) of the general functional groups — shredders, collectors, scrapers (grazers), and predators are depicted in Fig. 1. Shredders utilize coarse particulate organic matter (CPOM, >1 mm), such as leaf litter, with a significant dependence on the associated microbial biomass. Collectors filter from transport, or gather from the sediments, fine and ultrafine particulate organic matter (FPOM, 50 μm–1 mm; UPOM 0.5–50 μm). Like shredders, collectors depend on the microbial biomass associated with the particles (primarily on the surface) and products of microbial metabolism for their nutrition. Scrapers are adapted primarily for shearing attached algae from surfaces. The proposed dominance of scrapers follows shifts in primary production, being maximized in midsized rivers

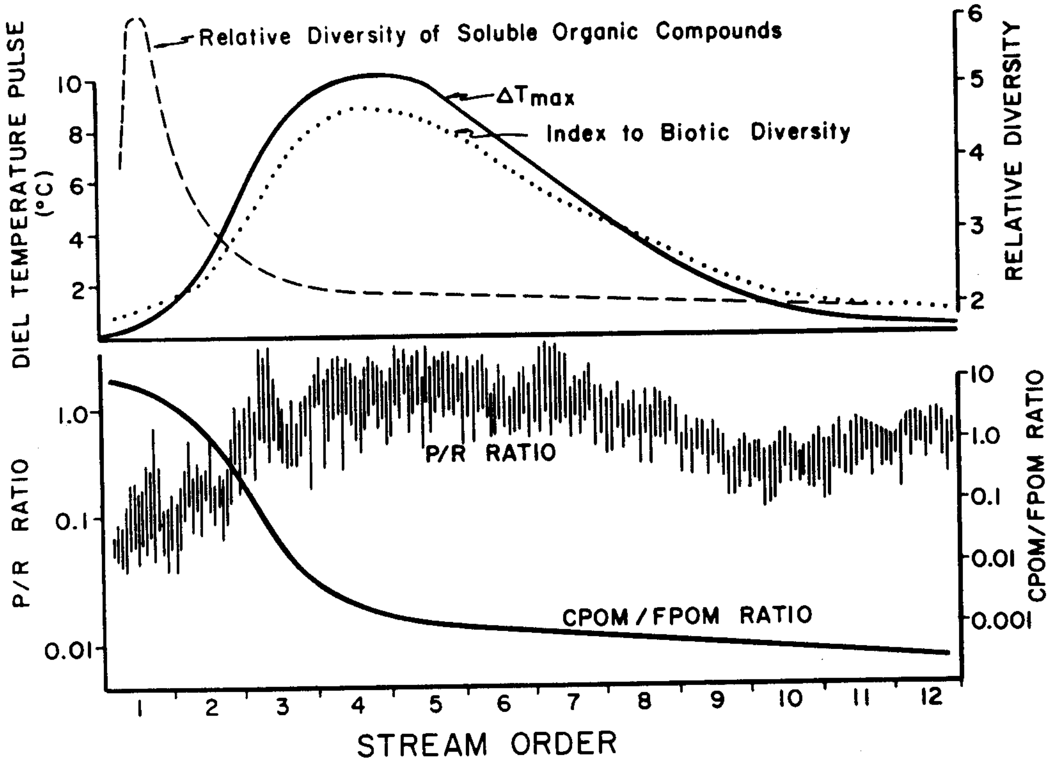

FIG. 2. Hypothetical distribution of selected parameters through the river continuum from headwater seeps to a twelfth order river. Parameters include heterogeneity of soluble organic matter, maximum diel temperature pulse, total biotic diversity within the river channel, coarse to fine particulate organic matter ratio, and the gross photosynthesis/respiration ratio.

with $P/R > 1$. Shredders are hypothesized to be codominant with collectors in the headwaters, reflecting the importance of riparian zone CPOM and FPOM–UPOM derived from it. With increasing stream size and a general reduction in detrital particle size, collectors should increase in importance and dominate the macroinvertebrate assemblages of large rivers (Fig. 1).

The predatory invertebrate component changes little in relative dominance with stream order. Fish populations (Fig. 1) show a shift from cool water species low in diversity to more diverse warm water communities (e.g. Huet 1954). Most headwater species are largely invertivores. Piscivorous and invertivorous species characterize the midsized rivers and in large rivers some planktivorous species are found — reflecting the semi-lentic nature of such waters.

The expected diversity of soluble organic compounds through the continuum is shown in Fig. 2 (dashed line). Headwater streams represent the maximum interface with the landscape and therefore are predominantly accumulators, processors, and transporters of materials from the terrestrial system. Among these inputs are heterogeneous assemblages of labile and refractory dissolved compounds, comprised of short- and long-chain organics. Heterotrophic use and physical absorption of labile organic compounds is rapid, leaving the more refractory and relatively high molecular weight compounds for export downstream. The relative importance of large particle detritus to energy flow in the system is expected to follow a curve similar to that of the diversity of soluble organic compounds; however, its importance may extend further downstream.

Thus the river system, from headwaters to mouth, can be considered as a gradient of conditions from a strongly heterotrophic headwater regime to a seasonal, and in many cases, an annual regime of autotrophy in midreaches, and then a gradual return to heterotrophic processes in downstream waters (Fisher 1977). Major bioenergetic influences along the stream continuum are local inputs (allochthonous litter and light) and transport from upstream reaches and tributaries (Fig. 1). As a consequence of physical and biological processes, the particle size of organic material in transport should become progressively smaller down the continuum (reflected by CPOM:FPOM ratio in Fig. 2, except for localized input of lower order tributaries) and the stream community response reflect progressively more efficient processing of smaller particles.

RIVER ECOSYSTEM STABILITY

Stability of the river ecosystem may be viewed as a tendency for reduced fluctuations in energy flow, while community structure and function are maintained, in the face of environmental variations. This implicitly couples community stability (sensu Ricklefs 1979) to the instability ("noise") of the physical system. In highly stable physical systems, biotic contribution to ecosystem stability may be less critical. However, in widely fluctuating environments (e.g. stream reaches with lage fluctuations in temperature), the biota may assume critical importance in stabilizing the entire system. In this interpretation, ecosystem stability is achieved by a dynamic balance between forces contributing to stabilization (e.g. debris dams, filter feeders, and other retention devices; nutrient cycling) and those contributing to its instability (e.g. floods, temperature fluctuations, microbial epidemics). In systems with a highly stable physical structure, biotic diversity may be low and yet total stability of the stream ecosystem still be maintained. In contrast, systems with a high degree of physical variation may have high species diversity or at least high complexity in species function which acts to maintain stability.

For example, in stream zones experiencing wide diel temperature changes, organisms may be exposed to suboptimum temperatures for significant portions of the day, but over some range in the diel cycle each organism encounters a favorable or optimum temperature range. Under these conditions an optimum temperature will occur for a larger number of species than if the thermal regime displayed minimum variance. Also, in the thermally fluctuating system, many populations have an opportunity to process energy, and as temperatures oscillate around a mean position, various populations may increase or decrease their processing rates. Thus, an important aspect of the predictably fluctuating physical system is that it encompasses optimum conditions for a large number of species. This interplay between physical and biological components can be seen in terms of ecosystem stability by considering the response of total biotic diversity in the river channel as balanced against the maximum diel temperature range (ΔT max) (Fig. 2). Headwater streams in proximity to groundwater supply or infiltration source areas exhibit little variation in ΔT max. With increased distance from subsurface sources and separation of the forest canopy, ΔT max will attain its widest variance because of increased solar input. The ΔT max amplitude is greatly diminished in high order streams due to the buffering effect of the large volume of water in the channel (Ross 1963). In headwater springs and brooks, diversity may be low because biological communities are assembled from those species which can function within a narrow temperature range on a restricted nutritional base; the stability of the system may be maintained by the low amplitude of diel and annual temperature regimes. Total community diversity is greatest in medium-sized (3rd to 5th order in Fig. 2) streams where temperature variations tend to be maximized. The tendency to stabilize energy flow in midsized streams may be aided by high biotic diversity which mitigates the influence of high variance in the physical system as characterized by ΔT max; i.e. variation due to fluctuating thermal regimes should be offset by a high diversity of biota. In large rivers, stability of the system should be correlated with reduction in variance of diel temperature. We wish to emphasize that temperature is not the only factor responsible for the change in community structure; it is simply one of the easiest to visualize. Other factors such as riparian influence, substrate, flow, and food also are important and change in predictable fashion downstream both absolutely and in terms of the relative heterogeneity of each.

Temporal Adjustments in Maintaining an Equilibrium of Energy Flow

Natural stream ecosystems should tend towards uniformity of energy flow on an annual basis. Although the processing rates and efficiencies of energy utilization by consumer organisms are believed to approach equilibrium for the year, the major organic substrates shift seasonally. In natural stream systems, both living and detrital food bases are processed continuously, but there is a seasonal shift in the relative importance of autotrophic production vs. detritus loading and processing. Several studies (Minshall 1967; Coffman et al. 1971; Kaushik and Hynes 1971; MacKay and Kalff 1973; Cummins 1974; Sedell et al. 1974) have shown the importance of detritus in supporting autumn-winter food chains and providing a fine particle base for consumer organisms during other seasons of the year. Autotrophic communities often form the major food base, especially in spring and summer months (Minshall 1978).

Studies on headwater (order 1–3) streams have shown that biological communities in most habitats can be characterized as forming a temporal sequence of synchronized species replacement. As a species completes its growth in a particular microhabitat, it is replaced by other species performing essentially the same function, differing principally by the season of growth (Minshall 1968; Sweeney and Vannote 1978; Vannote 1978; Vannote and Sweeney 1979). It is this continuous species replacement that functions to distribute the utilization of energy inputs over time (e.g. Wallace et al. 1977). Individuals within a species will tend to exploit their environment as efficiently as possible. This results in the biological system (composite species assemblage) tending to maximize energy consumption. Because some species persist through time and because new species become dominant, and these too are exploiting their environment as efficiently as possible, processing of energy by the changing biological system tends to result in uniform energy processing over time. Thus, the biological system moves towards equilibrium by a trade-off between a tendency to make most efficient use of energy inputs through resource partitioning of food, substrate, temperature, etc. and tendency toward a uniform rate of energy processing throughout the year. From strategies observed on small to medium-sized streams (orders 1–5), we propose that biological communities, developed in natural streams in dynamic equilibrium, assume processing strategies involving minimum energy loss (termed maximum "spiraling" by Webster 1975).

Ecosystem Processing Along the Continuum

The dynamic equilibrium resulting from maximization of energy utilization and minimization of variation in its use over the year determines storage or leakage of energy. Storage includes production of new tissue and physical retention of organic material for future processing. In stream ecosystems, unused or partially processed materials will tend to be transported downstream. This energy loss, however, is the energy income, together with local inputs, for communities in downstream reaches. We postulate that downstream communities are structured to capitalize on these inefficiencies of upstream processing. In every reach some material is processed, some stored, and some released. The amount released in this fashion has been used in calculating system efficiency (Fisher 1977). Both the upstream inefficiency (leakage) and the downstream adjustments seem predictable. Communities distributed along the river are structured to process materials (specific detrital sizes, algae, and vascular hydrophytes) thereby minimizing the variance in system structure and function. For example, materials prone to washout, such as flocculant fine-particle detritus, might be most efficiently processed either in transport or after deposition in downstream areas. The resistivity of fine particle detritus to periodic washout is increased by sedimentation in depositional zones or by combination in a matrix with the more cohesive silt and clay sediments. Thus, enhanced retention results in the formation of a distinct community adapted to utilize this material. The minimization of the variance of energy flow is the outcome of seasonal variations of energy input rates (detritus and autotrophic production), coupled with adjustments in species diversity, specialization for food processing, temporal expression of functional groups, and the erosional–depositional transport and storage characteristics of flowing waters.

Time Invariance and the Absence of Succession in Stream Communities

A corollary to the continuum hypothesis, also arising from the geomorphological literature (Langbein and Leopold 1966), is that studies of biological systems established in a dynamically balanced physical setting can be viewed in a time independent fashion. In the context of viewing adaptive strategies and processes as continua along a river system, temporal change becomes the slow process of evolutionary drift (physical and genetic). Incorporation of new functional components into the community over evolutionary time necessitates an efficiency adjustment towards reduced leakage. In natural river systems, community structure gains and loses species in response to low probability cataclysmic events and in response to slow processes of channel development.

The concept of time invariance allows integration of community structure and function along the river without the illusion that successional stages are being observed at a given location in a time-dependent series. The concept of biological succession (Margalef 1960) is of little use for river continua, because the communities in each reach have a continuous heritage rather than an isolated temporal composition within a sequence of discrete successional stages. In fact, the biological subsystems for each reach are in equilibrium with the physical system at that point in the continuum. The concept of heritage implies that in natural river systems total absence of a population is rare, and biological subsystems are simply shifting spatially (visualize a series of overlapping normal species-abundance curves in which all species are present at any point on the spatial axis but their abundance differs from one point to the next) and not in the temporal sense typical of plant succession.

On an evolutionary time scale, the spatial shift has two vectors: a donwstream one involving most of the aquatic insects and an upstream one involving molluscs and crustaceans. The insects are believed to have evolved terrestrially and to be secondarily aquatic. Since the maximum terrestrial–aquatic interface occurs in the headwaters, it is likely that the transition from land to water first occurred here with the aquatic forms then moving progressively downstream. The molluscs and crayfish are thought to have developed in a marine environment and to have moved through estuaries into rivers and thence upstream. The convergence of the two vectors may explain why maximum species diversity occurs in the midreaches.

Conclusion

We propose that the River Continuum Concept provides a framework for integrating predictable and observable biological features of flowing water systems with the physical–geomorphic environment. The model has been developed specifically in reference to natural, unperturbed stream ecosystems as they operate in the context of evolutionary and population time scales. However, the concept should accommodate many unnatural disturbances as well, particularly those which alter the relative degree of autotrophy:heterotrophy (e.g. nutrient enrichment, organic pollution, alteration of riparian vegetation through grazing, clear-cutting, etc.) or affect the quality and quantity of transport (e.g. impoundment, high sediment load). In many cases, these alterations can be thought of as reset mechanisms which cause the overall continuum response to be shifted toward the headwaters or seaward depending on the type of perturbation and its location on the river system.

A concept of dynamic equilibrium for biological communities, despite some difficulties in absolute definition, is useful because it suggests that community structure and function adjust to changes in certain geomorphic, physical, and biotic variables such as stream flow, channel morphology, detritus loading, size of particulate organic material, characteristics of autotrophic production, and thermal responses. In developing a theory of biological strategies along the river continuum, it also should be possible to observe a number of patterns that describe various processing rates, growth strategies, metabolic strategies, and community structures and functions. Collection of extensive data sets over the long profile of rivers are needed to further test and refine these ideas.

Acknowledgments

The ideas presented here have been refined through discussions with our associates in the River Continuum Project, especially T. L. Bott, J. D. Hall, R. C. Petersen, and F. J. Swanson; and other colleagues including S. A. Fisher, C. A. S. Hall, L. B. Leopold, F. J. Triska, and J. B. Webster. We are grateful to J. T. Brock, A. B. Hale, C. P. Hawkins, J. L. Meyers, and J. R. Moeller for their constructive criticism of a draft version of the manuscript. GLOSSARY

PREFACE

Welcome to the *Working Draft* of the Virginia Stormwater Management Handbook!! This document is in no way intended to be a trailblazer in the way of new technologies and design standards and methodologies. Rather, the focus was on collecting basic hydrologic, hydraulic, and BMP design principles, most of which have been previously documented in other manuals published within the Chesapeake Bay watershed, and through out the country, and publishing them under one cover. Our number one goal is to promote and develop consistent and effective implementation of stormwater management policies.

So here it is!! This Handbook is a dynamic and evolving resource. Four Technical Bulletins have been developed and are included in the back of the manual. You may wish to insert them in the appropriate chapters or keep them in one place. Additional Technical Bulletins will be developed to provide you with the latest technologies, policies, and guidance. These Technical Bulletins help the Department of Conservation and Recreation (DCR) serve as a clearing house of information on local program development, local program funding ideas and experiences, innovative BMP design, BMP pollutant removal efficiencies, BMP maintenance, ongoing studies, and any other information which would be helpful to Handbook users. Future Technical Bulletins, as well as edits and updates to the Manual, will be available on the DCR website. The best news is that the entire handbook will be available in PDF format on our website: www.dcr.state.va.us

The list of Technical Bulletin topics being requested by our clients is beginning to look like the makings of another Handbook. DCR, however, is committed to providing continual guidance on stormwater issues. We are also interested in your comments. If there are issues which have not been addressed, or issues which deserve more attention, please contact us in writing at:

Stormwater Management Handbook

Richmond, Virginia 23219

ACKNOWLEDGMENTS

We take our hats off to all those who have developed technical manuals and handbooks before us. There are as many different opinions regarding style and format as there are people who have an interest in hydrology and hydraulics. To quote a famous philosopher: "What a long strange trip its been".

Many people have played a part in the completion of this Handbook (whether they realize it or not!). Jimmy Edmonds provided great support by taking on the incredible workload of both the Stormwater and Erosion Control Programs during some lean times, always doing whatever was needed while supporting the staff. His efforts and commitment are greatly admired and appreciated. Many others also deserve thanks, however, this Handbook is already thicker than was ever intended. (We slowly bought into the engineering strategy of stormwater reports: thicker is better.) The following list of people hopefully includes everybody involved, both directly and indirectly. Many thanks go to:

Virginia Department of Conservation and Recreation (DCR): Jack Frye, Bill Browning, Matt Bley, John Baranowski, Regina Greene, Kathleen Carter, Wendy Mears, and Stu Wilson.

> DCR Stormwater Program Staff: Joseph Battiata, P.E., Robert Cooper, P.E., PK Das, James Lowery, John Mlinarcik, and George Williamson.
>
> Erosion and Sediment Control Program Staff: Jake Porter, Doug Carter, Robert Connelly, Laura Daniels, Al Gregg, Kenny Harper, Phyllis Hinch, Clarence Huff, Mike Lee, Lynn Snyder, and Janet Smith
>
> Floodplain Management Program Staff: Richard Dameron P.E., and Steve Billcheck.

Special thanks go to Warren Bell, Larry Gavin, and by reference Larry Coffman, for their help on Bioretention and Sand Filters, Clayton Hodges of Anderson & Associates and Dr. David Kibler of Virginia Tech for providing IDF curve data from Virginia Tech/Penn State Urban Hydrology Model, Rita Taylor for her expertise in generating CADD figures for the Handbook, Keith White P.E., Fernando Pasquel P.E., Mike Flagg P.E., Cindy Linkenhoker, David Bulova, Scott Crafton, Marlene Hale, Doug Beisch, and Leon App.

Additional thanks to Richard Claytor, Thomas Schueler, Jennifer Zielinski, and the rest of the staff at the Center for Watershed Protection for all of their trailblazing efforts over the years in documenting incredibly useful information on stormwater BMPs, watershed management, nonpoint source pollution, and the many other topics on which they have written and spoken. Also, thanks to Howard Boggess for agreeing to fix all of our "desktop publishing" mistakes.

Most importantly, thanks go to the members of the Virginia Board of Conservation and Recreation, and the Stormwater Management Subcommittee of the Board (Joseph Maroon, Franklin Hanks, and Susan Moseley) for their tireless efforts in educating themselves on all of the issues surrounding the Stormwater Management Regulations. Also, thanks go to the Stormwater Management Ad-Hoc Committee for their perseverance and commitment in amending the Stormwater Management Regulations.

We would also like to thank those who took time out of their schedules to review and comment on the draft sections: Ved Malhotra, P.E., Shaw L.Yu, Tony Esse, Adam L. Crist, Barry P. Fitz-James, P.E., David Hirschman, Bill Frost, Jeff Perry, Seshadri Suryanarayana, Ph.D., Dr. Osman Akan, Gary Szymanski, P.E., Otis Williams, Jr., Brian McReynolds, P.E., John J. Hagen, P.E., Hal Jones, Dan Rublee, P.E., Scott N. Wilson, P.E., George W. Simpson, III, P.E., Charles Van Allman, and Larry Ogle.

CHAPTER 1

VIRGINIA STORMWATER MANAGEMENT PROGRAM

TABLE OF CONTENTS

#	SECTIONS	PAGE
1-1	INTRODUCTION	1-1
1-2	VIRGINIA STORMWATER MANAGEMENT PROGRAM	1-3
1-3	VIRGINIA STORMWATER MANAGEMENT LAW	1-7
1-4	VIRGINIA STORMWATER MANAGEMENT REGULATIONS	1-15
1-5	VIRGINIA EROSION and SEDIMENT CONTROL REGULATIONS	1-33
1-6	RELATED WATER QUALITY REGULATIONS and INITIATIVES	

1-1 INTRODUCTION

This Handbook has been developed by the Virginia Department of Conservation and Recreation (DCR) to provide basic guidance for compliance with the Virginia Stormwater Management Regulations. (4VAC3-20 et seq.) The technical material provided within represents some of the more basic types of hydrologic and hydraulic analysis procedures, mostly derived from SCS sources such as the SCS National Engineering Handbook (NEH), and the SCS Engineering Field Manual (EFM), and others. The science of stormwater management analysis is very broad and in no way are the methods and procedures presented here intended to represent the only acceptable way of preparing a stormwater management plan.

Chapter 1: Virginia Stormwater Management Program, provides an overview of the various State regulations which address water quality and nonpoint source pollution, as well as the interrelationship among the agencies.

Chapter 2: Stormwater Management and Urban BMPs, presents the basic components of stormwater management, as found in the Virginia SWM Regulations, and follows them through the BMP sizing and selection criteria. Most importantly, this Chapter 2 presents the basics of Regional Stormwater Management and Comprehensive Watershed Management.

Chapter 3: Minimum Standards, provides the technical design requirements and specifications, and maintenance requirements for stormwater BMPs defined in the Regulations. These criterion were derived from available sources such as the Northern Virginia BMP Handbook, Hampton Roads BMP Handbook, and various other publications, including those from the Metropolitan Washington Council of Governments and the Center for Watershed Protection. These minimum standards represent current, and in some cases innovative, design information pulled together under one cover in order to promote consistency in the design and construction, and therefore the effectiveness, of stormwater BMPs. These BMPs include:

3.01 Earthen Embankments
3.02 Principal Spillways
3.03 Vegetated Emergency Spillway
3.04 Sediment Forebay
3.05 Landscaping
3.06 Retention Basins
3.07 Extended Detention Basin
3.08 Detention Basin
3.09 Constructed Wetlands
3.10 Infiltration Practices
3.11 Bio-Retention
3.12 Sand Filters
3.13 Grassed Swale
3.14 Vegetated Filter Strip
3.15 Manufactured BMP Systems

Chapter 4: Hydrologic Methods, presents four methods for conducting a hydrologic analysis and determining the peak discharge from a watershed or drainage area. These methods include the Rational Method, Modified Rational Method, SCS TR-55 Graphical Peak Discharge Method and Tabular Hydrograph Method. Also included is a basic overview of various types of design hydrographs used in stormwater modeling.

Chapter 5: Engineering Calculations, provides very detailed calculation procedures for designing an impoundment BMP using standard hydraulic equations. These procedures include storage volume requirements, water quality and channel erosion control volume calculations, extended detention calculations, principal spillway and emergency spillway design, anti-seep collar design, outlet protection, riser floatation calculations, and water quality calculation procedures.

Chapter 6: Example Problems, provides some design examples including hydrologic and hydraulic analyses.

1-2 VIRGINIA STORMWATER MANAGEMENT PROGRAM

The 1998 amendments to the Virginia Stormwater Management (SWM) Regulations (4 VAC 3-20-10 et. seq.) reflect an on-going evolution in the definition and role of stormwater management. The initial goal of the amendment was to develop a more "user friendly" regulation; one which allowed flexibility for local program adoption, while also maintaining a solid framework of technical criteria. During the amendment process, legislative studies on the efficiency and consistency of the stormwater management and permitting policies of the Commonwealth provided additional guidance in the area of regulatory consistency. Providing consistent technical criteria for the water quality related programs in Virginia soon became a goal as well. To satisfy the these two goals, the technical criteria within the amended SWM regulations is divided into components: *Water Quality*, *Stream Channel Erosion*, and *Flooding*.

Water Quality

The water quality component reflects consistency between the Virginia SWM Regulations (DCR), The Chesapeake Bay Preservation Act (CBPA) and regulations (CBLAD), and the Virginia Pollution Discharge Elimination System (VPDES) permit (DEQ).

The reader should note that the land disturbing thresholds for compliance with these other water quality programs are independent of the SWM regulations: A VPDES permit is required for various industrial activities (including construction activities of 5 acres or more) and CBPA local regulatory compliance is required for projects of a certain size and/or in certain locations (refer to the local ordinance). Once it is determined that compliance with one of these water quality related programs is required, then the stormwater management regulations technical criteria for water quality (4 VAC 3-20-11) provides the consistent criteria for compliance.

Stream Channel Erosion

The stream channel erosion component of the SWM Regulations (4 VAC 3-20-81) incorporates the technical provisions of stormwater runoff component of the Erosion and Sediment Control Regulations (Minimum Standard 19, 4 VAC 50-30-40.19) as required by law. This component will be the subject of significant scrutiny as we try to further develop an appropriate technical criteria for stream channel erosion control. The challenge is the variable nature of stream channel hydraulics and hydrologic modeling. As the technical criteria is expanded to define the analysis and required solutions, we lose the emphasis on the engineers' ability and responsibility to determine the appropriate level of design for stream channel protection. An alternative would be to simply require that "downstream channels and properties be protected from erosion and damage due to increase in volume, velocity, and peak flow rate". The engineer would then be responsible for determining what level of control is needed to satisfy the requirement. On the other hand, requiring a full analysis of the channel geomorphology in order to establish the protection criteria would probably be too complex of an analysis, with few people qualified to review it.

The amended SWM regulations provide an alternative design criteria that has been found to be more effective in preventing downstream channel erosion: extended detention of the runoff from the 1-year frequency 24-hour storm. This criteria effectively reduces the runoff flow rate and velocity from a wide range of storms to less than the critical velocity. Further updates and guidance on the channel erosion component will be provided.

Flexible Adoption

The most significant amendment to the regulations is the flexible adoption of the stormwater components. A locality may now adopt individual components for local implementation. During the development of these amendments, this flexible adoption was referred to as a *cafeteria style* approach: choose the desired components from the "menu" of options. **However, any local SWM program adopted pursuant to the Stormwater Management Law (Title 10.1, Chapter 6, Article 1.1) must, at a minimum, contain the Flooding component (4VAC3-20-85).**

Administrative Procedures and Reporting

Other elements within the Regulations which caused concern on the part of localities interested in adopting a program were the Administrative Procedures which address stormwater management plan submission and review, and local program reporting. DCR acknowledged that our intent is not to supersede any local program development review process. State law does mandate a maximum review time of 60 days, with communication of the review to the applicant in writing. A survey of local program administrative procedures indicated that the actual review times, whether as required by local ordinance or by the level of development, were actually much less than the required 60 day maximum.

The issue of local program reporting was evaluated in light of the General Assembly requirement of an annual report on the extent to which local stormwater management programs have reduced nonpoint source pollution and mitigated the effects of localized flooding. Local government officials were wary of a reporting burden draining available staff time. DCR reviewed the type of information which was needed to compile the annual report to the General Assembly and determined the level of reporting to be a simple accounting of stormwater BMPs approved through the development review process or otherwise implemented in the locality. Additional information, such as monitoring studies, regional watershed plan studies and implementation, are certainly considered helpful in compiling a report to the General Assembly, however, not every locality will have such information. Again, a local program survey indicated that most existing local review and approval procedures do contain a simple accounting of what has been approved. Therefore, DCR amended the Reporting section of the Regulations (4VAC3-20-251) to ask local programs to voluntarily submit an annual report to the Department, as well as indicate the type of information which would be appropriate. The basis for this was that if most local programs are already compiling the type of information needed for the annual report, as the local program survey indicated, than the reporting of that information should not be burden. For localities that are just starting a program, DCR will commit to providing a simple record keeping system to help document the stormwater management BMPs and associated information.

In summary, the amendments to the Stormwater Management Regulations have made the adoption of a local program extremely simple and unburdonsome. Consider a local government currently operating, as required by law, an Erosion and Sediment Control Program with MS-19 requirements, and a Chesapeake Bay Preservation Act (CBPA) ordinance. MS-19 requirements satisfy the Stream Channel Erosion component of the Stormwater Management Regulations, and the water quality provisions within the CBPA ordinance satisfy the water quality component of the Stormwater Regulations. If the locality also has a flood control requirement (10-year storm, 25-year storm, etc.), than that locality is in full compliance with the State minimum technical requirements for a local stormwater management program. Without changing any of the actual duties or requirements mandated by the local ordinance, the locality may simply reference the authority for their combined program as the Virginia Stormwater Management Law, and thereby operate under the simple umbrella of enabling authority offered by the Stormwater Management Law. (It may be advisable to consolidate the various components into one section or chapter of the local ordinance for simplicity.)

There are many variations of the above example where localities are currently operating under fragmented enabling authority, and can now amend their ordinance to reference the Stormwater Management Law. The Department will periodically review these programs to insure consistency in implementation. The purpose of the review is to help the Department promote consistency in stormwater management policies across the commonwealth, as directed by the General Assembly, as well as help the local program maintain effective implementation of the technical criteria.

State Agency Compliance with Local Programs

Another incentive for local programs to adopt a State Stormwater Management Program is the ability to require state agency projects to comply with the local requirements. This can be especially important if a regional (watershed-wide) plan has been adopted. The Regulations allow for a local program to request, in writing, that the Department consider the local program requirements when reviewing state agency plans. Further, the regulations require that state agencies, to the maximum extent practicable, comply with any local stormwater management program technical criteria adopted pursuant to the Act, and that it shall be the responsibility of the state agency to demonstrate that the local program requirements are not practical for the project under consideration. (4VAC3-20-210).
Experience has indicated that this cooperation between local programs and state agencies has resulted in a win-win deal for the locality and the state agency, and in most cases resulted in more effective BMP implementation. Localities must notify DCR of their desire to have state agency plans comply with the local program technical requirements or investigate participating in a local regional SWM program.

1-3 VIRGINIA STORMWATER MANAGEMENT LAW and REGULATIONS

The following is the complete, edited text of Title 10.1, Chapter 6, Article 1.1 of the Code of Virginia as amended through 1998. Please refer to the Code of Virginia for an official copy of the Law.

§ 10.1-603.1. Cooperative state-local program.

The General Assembly has determined that the lands and waters of the Commonwealth are great natural resources; that as a result of intensive land development and other land use conversions, degradation of these resources frequently occurs in the form of water pollution, stream channel erosion, depletion of groundwater resources, and more frequent localized flooding; that these impacts adversely affect fish, aquatic life, recreation, shipping, property values and other uses of lands and waters; that existing authorities under the Code of Virginia do not adequately address all of these impacts. Therefore the General Assembly finds it in the public interest to enable the establishment of stormwater management programs.

§ 10.1-603.2. Definitions.

As used in this article, unless the context requires a different meaning:

"Applicant" means any person submitting a stormwater management plan for approval.

"Board" means the Board of Conservation and Recreation.

"Department" means the Department of Conservation and Recreation.

"Flooding" means a volume of water which is too great to be confined within the banks or walls of the stream, water body or conveyance system and which overflows onto adjacent lands, causing or threatening damage.

"Land development" or *"land development project"* means a manmade change to the land surface that potentially changes its runoff characteristics.

"Linear development project" means a land development project that is linear in nature such as, but not limited to, (I) the construction of electric and telephone utility lines, and natural gas pipelines; (ii) construction of tracks, rights-of-way, bridges, communication facilities and other related structures of a railroad company; and (iii) highway construction projects.

"Local stormwater management program" or "local program" means a statement of the various methods employed by a locality to manage the runoff from land development projects and may include such items as local ordinances, policies and guidelines, technical materials, inspection, enforcement, and evaluation.

"Nonpoint source pollution" means pollution whose sources cannot be pinpointed but rather is washed from the land surface in a diffuse manner by stormwater runoff.

"Runoff" means that portion of precipitation that is discharged across the land surface or through conveyances to one or more waterways.

"Stormwater management plan" or *"plan"* means a document containing material for describing how existing runoff characteristics will be maintained by a land development project.

"Subdivision" means the same as defined in §15.1-465.

"Watershed" means a defined land area drained by a river or stream or system of connecting rivers or streams such that all surface water within the area flows through a single outlet.

§ 10.1-603.3. Counties, cities and towns may by ordinance establish stormwater management programs as a local option; effective date

Each locality may, by ordinance, to be effective on or after July 1, 1990, establish a local stormwater management program which shall include, but is not limited to, the following:

1. Consistency with regulations promulgated in accordance with provisions of this article;

2. Provisions for long-term responsibility for and maintenance of stormwater management control devices and other techniques specified to manage the quality and quantity of runoff; and

3. Provisions for the integration of locally adopted stormwater management programs with local erosion and sediment control, flood insurance, flood plain management and other programs requiring compliance prior to authorizing construction in order to make the submission and approval of plans, issuance of permits, payment of fees, and coordination of inspection and enforcement activities more convenient and efficient both for the local governments and those responsible for compliance with the programs.

§ 10.1-603.4. Development of regulations.

The Board is authorized to promulgate regulations which specify minimum technical criteria and administrative procedures for stormwater management programs in Virginia. In order to inhibit the deterioration of existing waters and waterways, the regulations shall:

1. Require that state and local programs maintain after-development runoff rate of flow, as nearly as practicable, as the pre-development runoff characteristics;

2. Establish minimum design criteria for measures to control nonpoint source pollution and

localized flooding, and incorporate the stormwater management regulations promulgated pursuant to the Virginia Erosion and Sediment Control Law, Article 4 (§10.1-560 et seq.) of Chapter 5 of this title, as they relate to the prevention of stream channel erosion. These criteria shall be periodically modified as required in order to reflect current engineering methods;

3. Require the provision of long-term responsibility for and maintenance of stormwater management control devices and other techniques specified to manage the quality and quantity of runoff; and

4. Require as a minimum the inclusion in local programs of certain administrative procedures which include, but are not limited to, specifying the time period within which a local government which has adopted a stormwater management program must grant written approval of a plan, the conditions under which approval shall be granted, the procedures for communicating disapproval, the conditions under which an approved plan may be changed and requirements for inspection of approved projects.

§ 10.1-603.5. State agency projects.

A. After January 1, 1991, a state agency may not undertake any land clearing, soil movement, or construction activity involving soil movement or land development unless the agency has submitted and obtained approval of a stormwater management plan from the Department. In lieu of such a plan, the agency may annually submit stormwater management standards and specifications.

B. Notwithstanding the provisions of this article, all state agencies shall comply with the stormwater management provisions of the Erosion and Sediment Control Law, Article 4 (§10.1-560 et seq.) of Chapter 5 of this title, and related regulations. The Department shall perform random site inspections to assure compliance with this article, the Erosion and Sediment Control Law and regulations promulgated thereunder.

C. The Department shall have thirty days in which to comment on the stormwater management plan, and its recommendations shall be binding on the state agency or the private business hired by the state agency. Individual approval of separate projects is not necessary when annually approved standards and specifications have been approved.

As on-site changes occur, the state agency shall submit changes in the stormwater management plan to the Department.

The state agency responsible for the land-disturbing activity shall ensure compliance with the approved plan or specifications.

§ 10.1-603.6. Involvement of the Department with local programs.

A. The Department shall provide technical assistance, training, research, and coordination in stormwater management technology to the local governments consistent with the purposes of this article.

B. The Department is authorized to review the plan for any project with real or potential interjurisdictional impacts upon the request of one of the involved localities to determine that the plan is consistent with the provisions of this article. Any such review shall be completed and a report submitted to each locality involved within ninety days of such request.

§ 10.1-603.7. Authorization for more stringent regulations.

Localities are authorized to adopt more stringent stormwater management regulations than those necessary to ensure compliance with the Board's minimum regulations, with the exception of regulations related to plan approval, provided that the more stringent regulations are based upon the findings of local comprehensive watershed management studies and that prior to adopting more stringent regulations a public hearing is held after giving due notice.

§ 10.1-603.8. Regulated activities; submission and approval of a control plan; security for performance; exemptions.

A. Except as provided in §10.1-603.5, after the adoption of a local ordinance, a person shall not develop any land for residential, commercial, industrial, or institutional use in that locality until he has submitted a stormwater management plan to the locality that has jurisdiction and has obtained approval of the plan from that locality. The plan may include appropriate maps, mathematical calculations, detail drawings and a listing of all major decisions to assure that the entire unit or units of land will be so treated to achieve the objectives of the local program. Prior to issuance of any permit, the locality may also require an applicant to submit a reasonable performance bond with surety, cash escrow, letter of credit, any combination thereof, or such other legal arrangement acceptable to the locality, to ensure that measures could be taken by the locality at the applicant's expense should he fail, after proper notice, within the time specified to initiate or maintain appropriate actions which may be required of him by the approved stormwater management plan as a result of his land-development project. If the locality takes such action upon such failure by the applicant, the agency may collect from the applicant for the difference should the amount of the reasonable cost of such action exceed the amount of the security held. Within sixty days of the completion of the requirements of the approved stormwater management plan, such bond, cash escrow, letter of credit or other legal arrangement, or the unexpended or unobligated portion thereof, shall be refunded to the applicant or terminated. These requirements are in addition to all other provisions of law relating to the issuance of such plans and are not intended to otherwise affect the requirements for such plans.

B. Notwithstanding any other provisions of this article, the following activities are exempt:

1. Permitted surface or deep mining operations and projects, or oil and gas operations and projects conducted under the provisions of Title 45.1;

2. Tilling, planting or harvesting of agricultural, horticultural, or forest crops;

3. Single-family residences separately built and not part of a subdivision, including additions or modifications to existing single-family detached residential structures;

4. Land development projects that disturb less than one acre of land area; however, the governing body of a locality which has adopted a stormwater management program may reduce this exception to a smaller area of disturbed land or qualify the conditions under which this exception shall apply; and

5. Linear development projects, provided that (I) less than one acre of land will be disturbed per outfall or watershed, (ii) there will be insignificant increases in peak flow rates, and (iii) there are no existing or anticipated flooding or erosion problems downstream of the discharge point.

§ 10.1-603.9. Approved plan required for issuance of grading, building, or other permits.

Upon the adoption of a local ordinance no grading, building or other permit shall be issued for a property unless a stormwater management plan has been approved that is consistent with the local program and this article and unless the applicant has certified that all land clearing, construction, land development and drainage will be done according to the approved plan.

§ 10.1-603.10. Recovery of administrative costs.

Any locality which administers a stormwater management program may charge applicants a reasonable fee to defray the cost of program administration, including costs associated with plan review, issuance of permits, periodic inspection for compliance with approved plans, and necessary enforcement, provided that charges for such costs are not made under any other law, ordinance or program. The fee shall not exceed an amount commensurate with the services rendered and expenses incurred or $1,000, whichever is less.

§ 10.1-603.11. Monitoring, reports and inspections.

A. The plan-approving authority or, if a permit is issued in connection with land-disturbing activities which involve the issuance of a grading, building, or other permit, the permit-issuing authority (I) shall provide for periodic inspections of the installation of stormwater management measures and (ii) may require monitoring and reports from the person responsible for carrying out the plan, to ensure compliance with the approved plan and to determine whether the measures required in the plan provide effective stormwater management. The owner, occupier or operator shall be given notice of the inspection and an opportunity to accompany the inspectors. If the permit-issuing authority or plan-approving authority determines that there is a failure to comply with the plan, notice shall be served upon the permittee or person responsible for carrying out the plan by registered or certified mail to the address specified in the permit application or in the plan certification, or by delivery at the site of the development activities to the agent or employee supervising such activities. Where the plan-approving authority serves notice, a copy of the notice shall also be sent to the issuer of the permit. The notice shall specify the measures needed to comply with the plan and shall specify the time within which such measures shall be completed. Upon failure to comply within the time specified, the permit may be revoked and the permittee or person responsible for carrying out the plan shall be deemed to be in violation of this article and upon conviction shall be subject to the penalties provided by §10.1-603.14.

B. Notwithstanding subsection A of this section, the following may be applied:

1. Where a county, city, or town administers the local control program and the permit-issuing authority and the plan-approving authority are not within the same local government department, the locality may designate one department to inspect, monitor, report and ensure compliance.

2. Where a permit-issuing authority has been established, and such authority is not vested in an employee or officer of local government but in the commissioner of revenue or some other person, the locality shall exercise the responsibilities of the permit-issuing authority with respect to monitoring, reports, inspections, and enforcement unless such responsibilities are transferred as provided for in this section.

§ 10.1-603.12. Department to review local and state agency programs.

A. The Department shall periodically conduct a comprehensive review and evaluation of the effectiveness of each local government's and state agency's stormwater management program. The review shall include an assessment of the extent to which the program has reduced nonpoint source pollution and mitigated the detrimental effects of localized flooding. A summary of these reviews and evaluations shall be submitted annually to the General Assembly.

B. If, after such a review and evaluation, a local government is found to have a program which does not comply with the provisions of this article or regulations promulgated thereunder, the Department may issue an order requiring that necessary corrective action be taken within a reasonably prescribed time.

§ 10.1-603.13. Appeals of decisions of counties, cities or towns.

A. An appeal from a decision of a locality concerning an application for approval or disapproval of a stormwater management plan may be taken by the applicant, or any aggrieved party authorized by law, within thirty days after the rendering of such a decision of the locality, to the circuit court of the jurisdiction in which the land development project is located.

B. Judicial review shall be on the record previously established and shall otherwise be in accordance with the provisions of the Administrative Process Act (§9-6.14:1 et seq.).

§ 10.1-603.14. Penalties, injunctions and other legal actions.

Any person who violates any provision of a local ordinance or program adopted pursuant to the authority of this article shall be guilty of a misdemeanor and shall be subject to a fine not exceeding $1,000 or up to thirty days imprisonment for each violation or both. Such a local ordinance may also include the following sanctions:

1. A locality operating its own program may apply to the circuit court in any jurisdiction wherein the land lies to enjoin a violation or a threatened violation of the provisions of this article or of the local ordinance without the necessity of showing that an adequate remedy at law does not exist.

2. Without limiting the remedies which may be obtained in this section, a locality operating its own program may bring a civil action against any person for violation of any ordinance or any condition of a permit, or any provision of a local program adopted pursuant to this article. The action may seek the imposition of a civil penalty of not more than $2,000 against the person for each violation.

3. With the consent of any person who has violated or failed, neglected or refused to obey any ordinance or any condition of a permit or any provision of a local program adopted pursuant to this article, the administrator of the local program may provide, in an order issued by the administrator against such person, for the payment of civil charges for violations in specific sums, not to exceed the limit specified in subdivision 2 of this section. Such civil charges shall be instead of any appropriate civil penalty which could be imposed under subdivision 2.

§ 10.1-603.15. Cooperation with federal and state agencies.

Localities operating their own programs and the Department are authorized to cooperate and enter into agreements with any federal or state agency in connection with plans for stormwater management.

1-4 VIRGINIA STORMWATER MANAGEMENT REGULATIONS

The following is a complete text of the Virginia Stormwater Management Regulations 4VAC3-20 amended by the Board of Conservation and Recreation, effective March 5, 1998

PART I.
GENERAL.

4 VAC 3-20-10. Definitions.

The following words and terms used in this chapter have the following meanings, unless the context clearly indicates otherwise.

"Act" means Article 1.1 (§ 10.1-603.1 et seq.) of Chapter 6 of Title 10.1 of the Code of Virginia.

"Adequate channel" means a channel that will convey the designated frequency storm event without overtopping the channel banks nor causing erosive damage to the channel bed or banks.

"Applicant" means any person submitting a stormwater management plan for approval.

"Aquatic bench" means a 10- to 15-foot wide bench around the inside perimeter of a permanent pool that ranges in depth from zero to 12 inches. Vegetated with emergent plants, the bench augments pollutant removal, provides habitats, conceals trash and water level fluctuations, and enhances safety.

"Average land cover condition" means a measure of the average amount of impervious surfaces within a watershed, assumed to be 16%. Note that a locality may opt to calculate actual watershed-specific values for the average land cover condition based upon 4 VAC 3-20-101.

"Best management practice (BMP)" means a structural or nonstructural practice which is designed to minimize the impacts of development on surface and groundwater systems.

"Bioretention basin" means a water quality BMP engineered to filter the water quality volume through an engineered planting bed, consisting of a vegetated surface layer (vegetation, mulch, ground cover), planting soil, and sand bed, and into the in-situ material.

"Bioretention filter" means a bioretention basin with the addition of a sand filter collector pipe system beneath the planting bed.

"Board" means the Board of Conservation and Recreation.

"Channel" means a natural or manmade waterway.

"Constructed wetlands" means areas intentionally designed and created to emulate the water quality improvement function of wetlands for the primary purpose of removing pollutants from stormwater.

"Department" means the Department of Conservation and Recreation.

"Development" means a tract of land developed or to be developed as a unit under single ownership or unified control which is to be used for any business or industrial purpose or is to contain three or more residential dwelling units.

"Director" means the Director of the Department of Conservation and Recreation.

"Flooding" means a volume of water that is too great to be confined within the banks or walls of the stream, water body or conveyance system and that overflows onto adjacent lands, causing or threatening damage.

"Grassed swale" means an earthen conveyance system which is broad and shallow with erosion resistant grasses and check dams, engineered to remove pollutants from stormwater runoff by filtration through grass and infiltration into the soil.

"Impervious cover" means a surface composed of any material that significantly impedes or prevents natural infiltration of water into soil. Impervious surfaces include, but are not limited to, roofs, buildings, streets, parking areas, and any concrete, asphalt, or compacted gravel surface.

"Infiltration facility" means a stormwater management facility which temporarily impounds runoff and discharges it via infiltration through the surrounding soil. While an infiltration facility may also be equipped with an outlet structure to discharge impounded runoff, such discharge is normally reserved for overflow and other emergency conditions. Since an infiltration facility impounds runoff only temporarily, it is normally dry during nonrainfall periods. Infiltration basin, infiltration trench, infiltration dry well, and porous pavement shall be considered infiltration facilities.

"Inspection" means an on-site review of the project's compliance with the approved plan, the local stormwater management program, and any applicable design criteria.

"Land development" or *"land development project"* means a manmade change to, or construction on, the land surface, except as exempted in the Stormwater Management Act, § 10.1-603.8 B of the Code of Virginia, that changes its runoff characteristics.

"Linear development project" means a land development project that is linear in nature such as, but not limited to, (i) the construction of electric and telephone utility lines, and natural gas pipelines; (ii) construction of tracks, rights-of-way, bridges, communication facilities and other related structures of a railroad company; and (iii) highway construction projects.

"Local stormwater management program" or *"local program"* means a statement of the various methods adopted pursuant to the Act and implemented by a locality to manage the runoff from land development projects and shall include an ordinance with provisions to require the control of after-development stormwater runoff rate of flow, the proper maintenance of stormwater management facilities, and minimum administrative procedures consistent with this chapter.

"Locality" means a county, city, or town.

"Nonpoint source pollution" means contaminants such as sediment, nitrogen and phosphorous, hydrocarbons, heavy metals, and toxics whose sources cannot be pinpointed but rather are washed from the land surface in a diffuse manner by stormwater runoff.

"Nonpoint source pollutant runoff load" or *"pollutant discharge"* means the average amount of a particular pollutant measured in pounds per year, delivered in a diffuse manner by stormwater runoff.

"Percent impervious" means the impervious area within the site divided by the area of the site multiplied by 100.

"Person" means any individual, partnership, firm, association, joint venture, public or private corporation, trust, estate, commission, board, public or private institution, utility, cooperative, county, city, town or other political subdivision of the Commonwealth, any interstate body or any other legal entity.

"Planning area" means a designated portion of the parcel on which the land development project is located. Planning areas shall be established by delineation on a master plan. Once established, planning areas shall be applied consistently for all future projects.

"Post-development" refers to conditions that reasonably may be expected or anticipated to exist after completion of the land development activity on a specific site or tract of land.

"Pre-development" refers to the conditions that exist at the time that plans for the land development of a tract of land are approved by the plan approval authority. Where phased development or plan approval occurs (preliminary grading, roads and utilities, etc.), the existing conditions at the time *prior to* the first item being approved or permitted shall establish pre-development conditions.

"Regional (watershed-wide) stormwater management facility" or *"regional facility"* means a facility or series of facilities designed to control stormwater runoff from a specific watershed, although only portions of the watershed may experience land development.

"Regional (watershed-wide) stormwater management plan" or *"regional plan"* means a document containing material describing how runoff from open space, existing development and future planned development areas within a watershed will be controlled by coordinated design and implementation of regional stormwater management facilities.

"Runoff" or *"stormwater runoff"* means that portion of precipitation that is discharged across the land surface or through conveyances to one or more waterways.

"Sand filter" means a contained bed of sand which acts to filter the first flush of runoff. The runoff is then collected beneath the sand bed and conveyed to an adequate discharge point or infiltrated into the in-situ soils.

"Shallow marsh" means a zone within a stormwater extended detention basin that exists from the surface of the normal pool to a depth of six to 18 inches, and has a large surface area and, therefore, requires a reliable source of baseflow, groundwater supply, or a sizeable drainage area,

to maintain the desired water surface elevations to support emergent vegetation.

"*Site*" means the parcel of land being developed, or a designated planning area in which the land development project is located.

"State project" means any land development project which is undertaken by any state agency, board, commission, authority or any branch of state government, including state supported institutions of higher learning.

"Stormwater detention basin" or *"detention basin"* means a stormwater management facility which temporarily impounds runoff and discharges it through a hydraulic outlet structure to a downstream conveyance system. While a certain amount of outflow may also occur via infiltration through the surrounding soil, such amounts are negligible when compared to the outlet structure discharge rates and are, therefore, not considered in the facility's design. Since a detention facility impounds runoff only temporarily, it is normally dry during nonrainfall periods.

"Stormwater extended detention basin" or *"extended detention basin"* means a stormwater management facility which temporarily impounds runoff and discharges it through a hydraulic outlet structure over a specified period of time to a downstream conveyance system for the purpose of water quality enhancement or stream channel erosion control. While a certain amount of outflow may also occur via infiltration through the surrounding soil, such amounts are negligible when compared to the outlet structure discharge rates and, therefore, are not considered in the facility's design. Since an extended detention basin impounds runoff only temporarily, it is normally dry during nonrainfall periods.

"*Stormwater extended detention basin-enhanced*" or *"extended detention basin-enhanced"* means an extended detention basin modified to increase pollutant removal by providing a shallow marsh in the lower stage of the basin.

"Stormwater management facility" means a device that controls stormwater runoff and changes the characteristics of that runoff including, but not limited to, the quantity and quality, the period of release or the velocity of flow.

"Stormwater management plan" or *"plan"* means a document containing material for describing how existing runoff characteristics will be affected by a land development project and methods for complying with the requirements of the local program or this chapter.

"Stormwater retention basin" or *"retention basin"* means a stormwater management facility which includes a permanent impoundment, or normal pool of water, for the purpose of enhancing water quality and, therefore, is normally wet, even during nonrainfall periods. Storm runoff inflows are may be temporarily stored above this permanent impoundment for the purpose of reducing flooding, or stream channel erosion.

"*Stormwater retention basin I*" or *"retention basin I"* means a retention basin with the volume of the permanent pool equal to three times the water quality volume.

"Stormwater retention basin II" or *"retention basin II"* means a retention basin with the volume of the permanent pool equal to four times the water quality volume.

"Stormwater retention basin III" or *"retention basin III"* means a retention basin with the volume of the permanent pool equal to four times the water quality volume with the addition of an aquatic bench.

"Subdivision" unless otherwise defined in a local ordinance adopted pursuant to § 15.1-465 of the Code of Virginia, means the division of a parcel of land into three or more lots or parcels of less than five acres each for the purpose of transfer of ownership or building development, or, if a new street is involved in such division, any division of a parcel of land. The term includes resubdivision and, when appropriate to the context, shall relate to the process of subdividing or to the land subdivided.

"Vegetated filter strip" means a densely vegetated section of land engineered to accept runoff as overland sheet flow from upstream development. It shall adopt any natural vegetated form, from grassy meadow to small forest. The vegetative cover facilitates pollutant removal through filtration, sediment deposition, infiltration and absorption, and is dedicated for that purpose.

"Water quality volume" means the volume equal to the first 1/2 inch of runoff multiplied by the impervious surface of the land development project.

"Watershed" means a defined land area drained by a river, stream or drainage ways or system of connecting rivers, streams, or drainage ways such that all surface water within the area flows through a single outlet.

4 VAC 3-20-30. Purposes.

The purposes of this chapter are to provide a framework for the administration, implementation and enforcement of the Act, while at the same time providing flexibility for innovative solutions to stormwater management issues.

4 VAC 3-20-40. Applicability.

This chapter is applicable to:

1. Every locality that establishes a local stormwater management program; and
2. Every state project.

PART II.
TECHNICAL CRITERIA.

4 VAC 3-20-50. Applicability.

This part specifies technical criteria for localities that establish a local stormwater management program and for state projects.

4 VAC 3-20-60. General.

A. Determination of flooding and channel erosion impacts to receiving streams due to land development projects shall be measured at each point of discharge from the development project and such determination shall include any runoff from the balance of the watershed which also contributes to that point of discharge.

B. The specified design storms shall be defined as either a 24-hour storm using the rainfall distribution recommended by the U.S. Soil Conservation Service when using U.S. Soil Conservation Service methods or as the storm of critical duration that produces the greatest required storage volume at the site when using a design method such as the Modified Rational Method.

C. For purposes of computing runoff, all pervious lands in the site shall be assumed prior to development to be in good condition (if the lands are pastures, lawns, or parks), with good cover (if the lands are woods), or with conservation treatment (if the lands are cultivated); regardless of conditions existing at the time of computation.

D. Construction of stormwater management facilities or modifications to channels shall comply with all applicable laws and regulations. Evidence of approval of all necessary permits shall be presented.

E. Impounding structures that are not covered by the Impounding Structure Regulations (4 VAC 50-20-10 et seq.) shall be engineered for structural integrity during the 100-year storm event.

F. Pre-development and post-development runoff rates shall be verified by calculations that are consistent with good engineering practices.

G. Outflows from a stormwater management facility shall be discharged to an adequate channel, and velocity dissipators shall be placed at the outfall of all stormwater management facilities and along the length of any outfall channel as necessary to provide a nonerosive velocity of flow from the basin to a channel.

H. Proposed residential, commercial, or industrial subdivisions shall apply these stormwater management criteria to the land development as a whole. Individual lots in new subdivisions shall not be considered separate land development projects, but rather the entire subdivision shall be considered a single land development project. Hydrologic parameters shall reflect the ultimate land development and shall be used in all engineering calculations.

I. All stormwater management facilities shall have a maintenance plan which identifies the owner and the responsible party for carrying out the maintenance plan.

J. Construction of stormwater management impoundment structures within a Federal Emergency Management Agency (FEMA) designated 100-year floodplain shall be avoided to the extent possible. When this is unavoidable, all stormwater management facility construction shall be in compliance with all applicable regulations under the National Flood Insurance Program, 44 CFR Part 59.

K. Natural channel characteristics shall be preserved to the maximum extent practicable.

L. Land development projects shall comply with the Virginia Erosion and Sediment Control Act and attendant regulations.

4 VAC 3-20-71. Water quality.

A. Compliance with the water quality criteria may be achieved by applying the performance-based criteria or the technology-based criteria to either the site or a planning area.

B. Performance-based criteria. For land development, the calculated post-development nonpoint source pollutant runoff load shall be compared to the calculated pre-development load based upon the average land cover condition or the existing site condition. A BMP shall be located, designed, and maintained to achieve the target pollutant removal efficiencies specified in Table 1 to effectively reduce the pollutant load to the required level based upon the following four applicable land development situations for which the performance criteria apply:

1. Situation 1 consists of land development where the existing percent impervious cover is less than or equal to the average land cover condition and the proposed improvements will create a total percent impervious cover which is less than the average land cover condition.

Requirement: No reduction in the after development pollutant discharge is required.

2. Situation 2 consists of land development where the existing percent impervious cover is less than or equal to the average land cover condition and the proposed improvements will create a total percent impervious cover which is greater than the average land cover condition.

Requirement: The pollutant discharge after development shall not exceed the existing pollutant discharge based on the average land cover condition.

3. Situation 3 consists of land development where the existing percent impervious cover is greater than the average land cover condition.

Requirement: The pollutant discharge after development shall not exceed (i) the pollutant discharge based on existing conditions less 10% or (ii) the pollutant discharge based on the average land cover condition, whichever is greater.

4. Situation 4 consists of land development where the existing percent impervious cover is served by an existing stormwater management BMP that addresses water quality.

Requirement: The pollutant discharge after development shall not exceed the existing pollutant discharge based on the existing percent impervious cover while served by the existing BMP. The existing BMP shall be shown to have been designed and constructed in accordance with proper design standards and specifications, and to be in proper functioning condition.

C. Technology-based criteria. For land development, the post-developed stormwater runoff from the impervious cover shall be treated by an appropriate BMP as required by the post-developed condition percent impervious cover as specified in Table 1. The selected BMP shall be located, designed, and maintained to perform at the target pollutant removal efficiency specified in Table 1. Design standards and specifications for the BMPs in Table 1 which meet the required target pollutant removal efficiencywill be available at the department.

Table 1*

Water Quality BMP	Target Phosphorus Removal Efficiency	Percent Impervious Cover
Vegetated filter strip	10%	16-21%
Grassed swale	15%	
Constructed wetlands	30%	22 -37%
Extended detention (2 x WQ Vol)	35%	
Retention basin I (3 x WQ Vol)	40%	
Bioretention basin	50%	38 -66%
Bioretention filter	50%	
Extended detention-enhanced	50%	
Retention basin II (4 x WQ Vol)	50%	
Infiltration (1 x WQ Vol)	50%	
Sand filter	65%	67 -100%
Infiltration (2 x WQ Vol)	65%	
Retention basin III (4 x WQ Vol with aquatic bench)	65%	

* Innovative or alternate BMPs not included in this table may be allowed at the discretion of the local program administrator or the Department. Innovative or alternate BMPs not included in this table which target appropriate nonpoint source pollution other than phosphorous may be allowed at the discretion of the local program administrator or the Department.

4 VAC 3-20-81. Stream channel erosion.

A. Properties and receiving waterways downstream of any land development project shall be protected from erosion and damage due to increases in volume, velocity and peak flow rate of stormwater runoff in accordance with the minimum design standards set out in this section.

B. The plan approving authority shall require compliance with subdivision 19 of 4 VAC 50-30-40 of the Erosion and Sediment Control Regulations, promulgated pursuant to Article 4 (§ 10.1-560 et seq.) of Chapter 5 of Title 10.1 of the Code of Virginia.

C. The plan approving authority may determine that some watersheds or receiving stream systems require enhanced criteria in order to address the increased frequency of bankfull flow conditions brought on by land development projects. Therefore, in lieu of the reduction of the 2-year post-developed peak rate of runoff as required in subsection B of this section, the land development project being considered shall provide 24-hour extended detention of the runoff generated by the 1-year, 24-hour duration storm.

D. In addition to subsections B and C of this section, localities may, by ordinance, adopt more stringent channel analysis criteria or design standards to ensure that the natural level of channel erosion, to the maximum extent practicable, will not increase due to the land development projects. These criteria may include, but are not limited to, the following:

1. Criteria and procedures for channel analysis and classification.
2. Procedures for channel data collection.
3. Criteria and procedures for the determination of the magnitude and frequency of natural sediment transport loads.
4. Criteria for the selection of proposed natural or man-made channel linings.

4 VAC 3-20-85. Flooding.

A. Downstream properties and waterways shall be protected from damages from localized flooding due to increases in volume, velocity and peak flow rate of stormwater runoff in accordance with the minimum design standards set out in this section

B. The 10-year post-developed peak rate of runoff from the development site shall not exceed the 10-year pre-developed peak rate of runoff.

C. In lieu of subsection B of this section, localities may, by ordinance, adopt alternate design criteria based upon geographic, land use, topographic, geologic factors or other downstream conveyance factors as appropriate.

D. Linear development projects shall not be required to control post-developed stormwater runoff for flooding, except in accordance with a watershed or regional stormwater management plan.

4 VAC 3-20-86. Regional (watershed-wide) stormwater management plans.

This section enables localities to develop regional stormwater management plans. State agencies intending to develop large tracts of land such as campuses or prison compounds are encouraged to develop regional plans where practical.

The objective of a regional stormwater management plan is to address the stormwater management concerns in a given watershed with greater economy and efficiency by installing regional stormwater management facilities versus individual, site-specific facilities. The result will be fewer stormwater management facilities to design, build and maintain in the affected watershed. It is also anticipated that regional stormwater management facilities will not only help mitigate the impacts of new development, but may also provide for the remediation of erosion, flooding or water quality problems caused by existing development within the given watershed.

If developed, a regional plan shall, at a minimum, address the following:

1. The specific stormwater management issues within the targeted watersheds.

2. The technical criteria in 4 VAC 3-20-50 through 4 VAC 3-20-85 as needed based on subdivision 1 of this section.

3. The implications of any local comprehensive plans, zoning requirements and other planning documents.

4. Opportunities for financing a watershed plan through cost sharing with neighboring agencies or localities, implementation of regional stormwater utility fees, etc.

5. Maintenance of the selected stormwater management facilities.

6. Future expansion of the selected stormwater management facilities in the event that development exceeds the anticipated level.

PART III.
LOCAL PROGRAMS.

4 VAC 3-20-90. Applicability.

This part specifies technical criteria, minimum ordinance requirements, and administrative procedures for all localities operating local stormwater management programs.

4 VAC 3-20-101. Technical criteria for local programs.

A. All local stormwater management programs shall comply with the general technical criteria as outlined in 4 VAC 3-20-60.

B. All local stormwater management programs which contain provisions for stormwater runoff quality shall comply with 4 VAC 3-20-71. A locality may establish criteria for selecting either the site or a planning area on which to apply the water quality criteria. A locality may opt to calculate actual watershed specific or locality wide values for the average land cover condition based upon:

1. Existing land use data at time of local Chesapeake Bay Preservation Act Program or Department storm water management program adoption, whichever was adopted first,

2. Watershed or locality size, and

3. Determination of equivalent values of impervious cover for nonurban land uses which contribute nonpoint source pollution, such as agriculture, forest, etc.

C. All local stormwater management programs which contain provisions for stream channel erosion shall comply with 4 VAC 3-20-81.

D. All local stormwater management programs must contain provisions for flooding and shall comply with 4 VAC 3-20-85.

E. All local stormwater management programs which contain provisions for watershed or regional stormwater management plans shall comply with 4 VAC 3-20-101.

F. A locality that has adopted more stringent requirements or implemented a regional (watershed-wide) stormwater management plan may request, in writing, that the department consider these requirements in its review of state projects within that locality.

G. Nothing in this part shall be construed as authorizing a locality to regulate, or to require prior approval by the locality for, a state project.

4 VAC 3-20-111. Requirements for local program and ordinance.

A. At a minimum, the local stormwater management program and implementing ordinance shall meet the following:

1. The ordinance shall identify the plan-approving authority and other positions of authority within the program, and shall include the regulations and technical criteria to be used in the program.

2. The ordinance shall include procedures for submission and approval of plans, issuance of permits, monitoring and inspections of land development projects. The party responsible for conducting inspections shall be identified. The local program authority shall maintain, either on-site or in local program files, a copy of the approved plan and a record of all inspections for each land development project.

B. The department shall periodically review each locality's stormwater management program, implementing ordinance, and amendments. Subsequent to this review, the department shall determine if the program and ordinance are consistent with the state stormwater management regulations and notify the locality of its findings. To the maximum extent practicable the department will coordinate the reviews with other local government program reviews to avoid redundancy. The review of a local program shall consist of the following:

1. A personal interview between department staff and the local program administrator or his designee;

2. A review of the local ordinance and other applicable documents;

3. A review of plans approved by the locality and consistency of application;

4. An inspection of regulated activities; and

5. A review of enforcement actions.

C. Nothing in this chapter shall be construed as limiting the rights of other federal and state agencies from imposing stricter technical criteria or other requirements as allowed by law.

4 VAC 3-20-121. Administrative procedures: stormwater management plans.

A. Localities shall approve or disapprove stormwater management plans according to the following:

1. A maximum of 60 calendar days from the day a complete stormwater management plan is accepted for review will be allowed for the review of the plan. During the 60-day review period, the locality shall either approve or disapprove the plan and communicate its decision to the applicant in writing. Approval or denial shall be based on the plan's compliance with the locality's stormwater management program.

2. A disapproval of a plan shall contain the reasons for disapproval.

B. Each plan approved by a locality shall be subject to the following conditions:

1. The applicant shall comply with all applicable requirements of the approved plan, the local program, this chapter and the Act, and shall certify that all land clearing, construction, land development and drainage will be done according to the approved plan.

2. The land development project shall be conducted only within the area specified in the approved plan.

3. The locality shall be allowed, after giving notice to the owner, occupier or operator of the land development project, to conduct periodic inspections of the project.

4. The person responsible for implementing the approved plan shall conduct monitoring and submit reports as the locality may require to ensure compliance with the approved plan and to determine whether the plan provides effective stormwater management.

5. No changes may be made to an approved plan without review and written approval by the locality.

4 VAC 3-20-131. Administrative procedures: exceptions.

A. A request for an exception shall be submitted, in writing, to the locality. An exception from the stormwater management regulations may be granted, provided that: (i) exceptions to the criteria are the minimum necessary to afford relief and (ii) reasonable and appropriate conditions shall be imposed as necessary upon any exception granted so that the intent of the Act and this chapter are preserved.

B. Economic hardship is not sufficient reason to grant an exception from the requirements of this chapter.

4 VAC 3-20-141. Administrative procedures: maintenance and inspections.

A. Responsibility for the operation and maintenance of stormwater management facilities, unless assumed by a governmental agency, shall remain with the property owner and shall pass to any successor or owner. If portions of the land are to be sold, legally binding arrangements shall be made to pass the basic responsibility to successors in title. These arrangements shall designate for each project the property owner, governmental agency, or other legally established entity to be permanently responsible for maintenance.

B. In the case of developments where lots are to be sold, permanent arrangements satisfactory to the locality shall be made to ensure continued performance of this chapter.

C. A schedule of maintenance inspections shall be incorporated into the local ordinance. Ordinances shall provide that in cases where maintenance or repair is neglected, or the stormwater management facility becomes a danger to public health or safety, the locality has the authority to perform the work and to recover the costs from the owner.

D. Localities may require right-of-entry agreements or easements from the applicant for purposes of inspection and maintenance.

E. Periodic inspections are required for all stormwater management facilities. Localities shall either:

1. Provide for inspection of stormwater management facilities on an annual basis; or

2. Establish an alternative inspection program which ensures that stormwater management facilities are functioning as intended. Any alternative inspection program shall be:

   a. Established in writing;

   b. Based on a system of priorities that, at a minimum, considers the purpose of the facility, the contributing drainage area, and downstream conditions; and

   c. Documented by inspection records.

F. During construction of the stormwater management facilities, localities shall make inspections on a regular basis.

G. Inspection reports shall be maintained as part of a land development project file.

PART IV.
STATE PROJECTS.

4 VAC 3-20-210. Technical criteria and plan requirements for state projects.

A. This part specifies technical criteria and administrative procedures for all state projects.

B. Stormwater management plans prepared for state projects shall comply with the technical criteria outlined in Part II (4 VAC 3-20-50 et seq.) of this chapter and, to the maximum extent practicable, any local stormwater management program technical requirements adopted pursuant to the Act. It shall be the responsibility of the state agency to demonstrate that the local program technical requirements are not practical for the project under consideration.

C. The department may establish criteria for selecting either the site or a planning area on which to apply the water quality criteria.

D. As a minimum, stormwater management plans and computations shall contain the following:

1. The location and the design of the proposed stormwater management facilities.

2. Overall site plan with pre-developed and post-developed condition drainage area maps.

3. Comprehensive hydrologic and hydraulic computations of the pre-development and post-development runoff conditions for the required design storms, considered individually.

4. Calculations verifying compliance with the water quality requirements.

5. A description of the requirements for maintenance of the stormwater management facilities and a recommended schedule of inspection and maintenance.

6. The identification of a person or persons who will be responsible for maintenance.

7. All stormwater management plans shall be appropriately sealed and signed by a professional in adherence to all minimum standards and requirements pertaining to the practice of that profession in accordance with Chapter 4 (§ 54.1-400 et seq.) of Title 54.1 of the Code of Virginia and attendant regulations.

4 VAC 3-20-220. Requirements for stormwater management annual standards and specifications.

A. A request for approval of stormwater management standards and specifications may be submitted to the department by a state agency on an annual basis. At a minimum, the following certifications shall accompany the request:

1. Individual stormwater management plans shall be prepared for each of the state projects.

2. The stormwater management plans shall comply with the technical criteria as outlined in Part II (4 VAC 3-20-50 et seq.) of this chapter and, to the maximum extent practicable, any local stormwater management program technical requirements adopted pursuant to the Stormwater Management Act. It shall be the responsibility of the state agency to demonstrate that the local program technical requirements are not practical for the project under consideration.

3. An inspection and maintenance schedule shall be developed and implemented.

B. Copies of such stormwater management specifications and standards including, but not limited to, design manuals, technical guides and handbooks, shall be submitted.

4 VAC 3-20-230. Administrative procedures: stormwater management plans.

A. Within 30 days after receipt of a complete stormwater management plan submitted by a state agency, the department shall approve or disapprove the plan.

1. The department shall transmit its decision in writing to the state agency which submitted the plan.

2. Disapproved plans shall be revised and resubmitted to the department.

B. Approval of a stormwater management plan for a state project shall be subject to the following conditions:

1. The state agency shall comply with all applicable requirements of the approved plan and this chapter, and shall certify that all land clearing, construction, land development, and drainage will be done according to the approved plan.

2. The land development shall be conducted only within the area specified in the approved plan.

3. No changes may be made to an approved plan without review and written approval by the department.

4. The department shall be notified one week prior to the pre-construction meeting and one week prior to the commencement of land disturbing activity.

5. The department shall conduct periodic inspections of the project to ensure compliance with the plan.

6. The department may require monitoring and reports from the state agency responsible for implementing the plan to ensure compliance with the plan and to determine if the measures required in the plan provide effective stormwater management.

C. Compliance with approved plans shall be subject to the following conditions:

1. Where inspections by department personnel reveal deficiencies in carrying out an approved plan, the responsible state agency shall be issued a notice to comply, with corrective actions specified and the deadline within which the work shall be performed.

2. Whenever the Commonwealth or any of its agencies fail to comply within the time provided in a notice to comply, the director may petition the secretary of a given secretariat or an agency head for a given state agency for compliance. Where the petition does not achieve timely compliance, the director shall bring the matter to the Governor for resolution.

3. Where compliance will require the appropriation of funds, the director shall cooperate with the appropriate agency head in seeking such an appropriation; where the director determines that an emergency exists, he shall petition the Governor for funds from the Civil Contingency Fund or other appropriate source.

4 VAC 3-20-241. Administrative procedures: exceptions.

A. A request for an exception shall be submitted, in writing, to the department. An exception from the stormwater management regulations may be granted, provided that: (i) exceptions to the criteria are the minimum necessary to afford relief and (ii) reasonable and appropriate conditions shall be imposed as necessary upon any exception granted so that the purpose and intent of the Act is preserved.

B. Economic hardship is not sufficient reason to grant an exception from the requirements of this chapter.

4 VAC 3-20-245. Administrative procedures: maintenance and inspections.

A. Responsibility for the operation and maintenance of stormwater management facilities shall remain with the state agency and shall pass to any successor or owner. If portions of the land are to be sold, legally binding arrangements shall be made to pass the basic responsibility to successors in title. These arrangements shall designate for each state project the property owner, governmental agency, or other legally established entity to be permanently responsible for maintenance.

B. At a minimum, a stormwater management facility shall be inspected on an annual basis and after any storm which causes the capacity of the facility principal spillway to be exceeded.

C. During construction of the stormwater management facilities, the department shall make inspections on a regular basis.

D. Inspection reports shall be maintained as part of the land development project file.

PART V.
REPORTING.

4 VAC 3-20-251. Reporting on stormwater management.

The department is required to report to the General Assembly on the extent to which stormwater management programs have reduced nonpoint source pollution to the Commonwealth's waters and mitigated the effects of localized flooding. In order to complete this report, localities with stormwater management programs and state agencies may be asked to voluntarily submit an annual report to the department. Such a request may suggest reporting of data on the number and types of stormwater management facilities installed in the preceding year, the drainage area or watershed size served, the receiving stream or hydrologic unit, a summary of monitoring data, if any, and other data useful in determining the effectiveness of the programs and BMP technologies in current use.

1-5 VIRGINIA EROSION AND SEDIMENT CONTROL REGULATIONS

The following is a complete text of the Virginia Erosion and Sediment Control Regulations 4VAC50-30 amended by the Virginia Soil and Water Conservation Board, Effective March 22, 1995

§4VAC50-30-10 Definitions.

The following words and terms, when used in these regulations, shall have the following meaning, unless the context clearly indicates otherwise. In addition, some terms not defined herein are defined in §10.1-560 of the Erosion and Sediment Control Law.

"Act" means the Erosion and Sediment Control Law, Article 4 (§10.1-560 et seq.) of Chapter 5 of Title 10.1 of the Code of Virginia.

"*Adequate channel*" means a watercourse that will convey the designated frequency storm event without overtopping its banks or causing erosive damage to the bed, banks and overbank sections of the same.

"*Agreement in lieu of a plan*" means a contract between the program authority and the owner which specifies conservation measures which must be implemented in the construction of a single-family residence; this contract may be executed by the program authority in lieu of an erosion and sediment control plan.

"*Applicant*" means any person submitting an erosion and sediment control plan or an agreement in lieu of a plan for approval or requesting the issuance of a permit, when required, authorizing land-disturbing activities to commence.

"*Board*" means the Virginia Soil and Water Conservation Board.

"*Causeway*" means a temporary structural span constructed across a flowing watercourse or wetland to allow construction traffic to access the area without causing erosion damage.

"*Channel*" means a natural stream or manmade waterway.

"*Cofferdam*" means a watertight temporary structure in a river, lake, etc., for keeping the water from an enclosed area that has been pumped dry so that bridge foundations, dams, etc., may be constructed.

"*Dam*" means a barrier to confine or raise water for storage or diversion, to create a hydraulic head, to prevent gully erosion, or to retain soil, rock or other debris.

"*Denuded*" means a term applied to land that has been physically disturbed and no longer supports vegetative cover.

"*Department*" means the Department of Conservation and Recreation.

"*Development*" means a tract or parcel of land developed or to be developed as a single unit under single ownership or unified control which is to be used for any business or industrial purpose or is to contain three or more residential dwelling units.

"*Dike*" means an earthen embankment constructed to confine or control water, especially one built along the banks of a river to prevent overflow of lowlands; levee.

"*Director*" means the Director of the Department of Conservation and Recreation.

"*District*" or "soil and water conservation district" means a political subdivision of the Commonwealth organized in accordance with the provisions of Article 3 (§10.1-506 et seq.) of Chapter 5 of Title 10.1 of the Code of Virginia.

"*Diversion*" means a channel with a supporting earthen ridge on the lower side constructed across or at the bottom of a slope for the purpose of intercepting surface runoff.

"*Dormant*" refers to denuded land that is not actively being brought to a desired grade or condition.

"*Energy dissipator*" means a non-erodible structure which reduces the velocity of concentrated flow to reduce its erosive effects.

"*Erosion and* sediment control plan, *conservation plan*" or "*plan*," means a document containing material for the conservation of soil and water resources of a unit or group of units of land. It may include appropriate maps, an appropriate soil and water plan inventory and management information with needed interpretations, and a record of decisions contributing to conservation treatment. The plan shall contain all major conservation decisions and all information deemed necessary by the plan-approving authority to assure that the entire unit or units of land will be so treated to achieve the conservation objectives.

"*Flume*" means a constructed device lined with erosion-resistant materials intended to convey water on steep grades.

"*Hydraulic outlet structure*" means a control section composed of orifice(s), weir(s) and/or conduit(s) which release impounded runoff at a prescribed flowrate.

"*Hydrologic unit*" means a defined land area drained by a river/stream or system of connecting rivers/streams such that all surface water within the area flows through a single outlet.

"*Live watercourse*" means a definite channel with bed and banks within which concentrated water flows continuously.

"*Locality*" means a county, city or town.

"*Natural stream*" means nontidal waterways that are part of the natural topography. They usually maintain a continuous or seasonal flow during the year and are characterized as being irregular in cross-section with a meandering course. Constructed channels such as drainage ditches or swales shall not be considered natural streams.

"*Nonerodible*" means a material, e.g., riprap, concrete, plastic, etc., that will not experience surface wear due to natural forces.

"*Person*" means any individual, partnership, firm, association, joint venture, public or private corporation, trust, estate, commission, board, public or private institution, utility, cooperative, county, city, town or other political subdivision of the Commonwealth, any interstate body, or any other legal entity.

"*Plan-approving authority*" means the Board, the program authority a department of a program authority, or an agent of the program authority responsible for determining the adequacy of a conservation plan submitted for land-disturbing activities on a unit or units of land and for approving plans.

"*Post-development*" refers to conditions that may be reasonably expected or anticipated to exist after completion of the land development activity on a specific site or tract of land.

"*Program administrator*" means the person or persons responsible for administering and enforcing the erosion and sediment control program of a program authority.

"Program authority" means a district, county, city, or town which has adopted a soil erosion and sediment control program which has been approved by the Board.

"*Pre-development*" refers to conditions at the time the erosion and sediment control plan is submitted to the plan-approving authority. Where phased development or plan approval occurs (preliminary grading, roads and utilities, etc.), the existing conditions at the time the erosion and sediment control plan for the initial phase is submitted for approval shall establish pre-development conditions.

"*Sediment basin*" means a temporary impoundment built to retain sediment and debris with a controlled stormwater release structure.

"*Sediment trap*" means a temporary impoundment built to retain sediment and debris which is formed by constructing an earthen embankment with a stone outlet.

"*Sheet flow*" (also called overland flow) means shallow, unconcentrated and irregular flow down a slope. The length of strip for overland flow usually does not exceed 200 feet under natural conditions.

Shore erosion control project" means an erosion control project approved by local wetlands boards, the Virginia Marine Resources Commission, the Virginia Department of Environmental Quality or the United States Army Corps of Engineers and located on tidal waters and within nonvegetated or vegetated wetlands as defined in Title 28.2 of the Code of Virginia.

"*Slope drain*" means tubing or conduit made of nonerosive material extending from the top to the bottom of a cut or fill slope with an energy dissipator at the outlet end.

"*Stabilized*" means land that has been treated to withstand normal exposure to natural forces without incurring erosion damage.

"*Storm sewer inlet*" means a structure through which stormwater is introduced into an underground conveyance system.

"*Stormwater detention*" means the process of temporarily impounding runoff and discharging it through a hydraulic outlet structure to a downstream conveyance system.

"*Temporary vehicular stream crossing*" means a temporary nonerodible structural span installed across a flowing watercourse for use by construction traffic. Structures may include bridges, round pipes or pipe arches constructed on or through nonerodible material.

"*Ten-year storm*" means a storm that is capable of producing rainfall expected to be equaled or exceeded on the average of once in 10 years. It may also be expressed as an exceedence probability with a 10% chance of being equaled or exceeded in any given year.

"Two-year storm" means a storm that is capable of producing rainfall expected to be equaled or exceeded on the average of once in two years. It may also be expressed as an exceedence probability with a 50% chance of being equaled or exceeded in any given year.

"Twenty-five-year storm" means a storm that is capable of producing rainfall expected to be equaled or exceeded on the average of once in twenty-five years. It may also be expressed as exceedence probability with a 4% chance of being equaled or exceeded in any given year.

§4VAC50-30-20 Purpose.

The purpose of these regulations is to form the basis for the administration, implementation and enforcement of the Act. The intent of these regulations is to establish the framework for compliance with the Act while at the same time providing flexibility for innovative solutions to erosion and sediment control concerns.

§4VAC50-30-30 Scope and Applicability.

A. These regulations set forth minimum standards for the effective control of soil erosion, sediment deposition and nonagricultural runoff that must be met:

   1. In erosion and sediment control programs adopted by districts and localities under §10.1-562 of the Act.

   2. In erosion and sediment control plans that may be submitted directly to the Board pursuant to §10.1-563 A of the Act;

3. In annual general erosion and sediment control specifications that electric and telephone utility companies and railroad companies are required to file with the Board pursuant to §10.1-563 D of the Act;

4. In conservation plans and annual specifications that state agencies are required to file with the Department pursuant to §10.1-564 of the Act; and

5. By federal agencies that enter into agreements with the Board.

B. The submission of annual specifications to the Board or the Department by any agency or company does not eliminate the need for a project specific erosion and sediment control plan.

C. These regulations must be incorporated into the local erosion and sediment control program within one year of their effective date.

§4VAC50-30-40 Minimum Standards.

An erosion and sediment control program adopted by a district or locality must be consistent with the following criteria, techniques and methods:

1. Permanent or temporary soil stabilization shall be applied to denuded areas within seven days after final grade is reached on any portion of the site. Temporary soil stabilization shall be applied within seven days to denuded areas that may not be at final grade but will remain dormant for longer than 30 days. Permanent stabilization shall be applied to areas that are to be left dormant for more than one year.

2. During construction of the project, soil stockpiles and borrow areas shall be stabilized or protected with sediment trapping measures. The applicant is responsible for the temporary protection and permanent stabilization of all soil stockpiles on site as well as borrow areas and soil intentionally transported from the project site.

3. A permanent vegetative cover shall be established on denuded areas not otherwise permanently stabilized. Permanent vegetation shall not be considered established until a ground cover is achieved that, is uniform, mature enough to survive and will inhibit erosion.

4. Sediment basins and traps, perimeter dikes, sediment barriers and other measures intended to trap sediment shall be constructed as a first step in any land-disturbing activity and shall be made functional before upslope land disturbance takes place.

5. Stabilization measures shall be applied to earthen structures such as dams, dikes and diversions immediately after installation.

6. Sediment traps and sediment basins shall be designed and constructed based upon the

total drainage area to be served by the trap or basin.

a. The minimum storage capacity of a sediment trap shall be 134 cubic yards per acre of drainage area and the trap shall only control drainage areas less than three acres.

b. Surface runoff from disturbed areas that is comprised of flow from drainage areas greater than or equal to three acres shall be controlled by a sediment basin. The minimum storage capacity of a sediment basin shall be 134 cubic yards per acre of drainage area. The outfall system shall, at a minimum, maintain the structural integrity of the basin during a twenty-five year storm of 24-hour duration. Runoff coefficients used in runoff calculations shall correspond to a bare earth condition or those conditions expected to exist while the sediment basin is utilized.

7. Cut and fill slopes shall be designed and constructed in a manner that will minimize erosion. Slopes that are found to be eroding excessively within one year of permanent stabilization shall be provided with additional slope stabilizing measures until the problem is corrected.

8. Concentrated runoff shall not flow down cut or fill slopes unless contained within an adequate temporary or permanent channel, flume or slope drain structure.

9. Whenever water seeps from a slope face, adequate drainage or other protection shall be provided.

10. All storm sewer inlets that are made operable during construction shall be protected so that sediment-laden water cannot enter the conveyance system without first being filtered or otherwise treated to remove sediment.

11. Before newly constructed stormwater conveyance channels or pipes are made operational, adequate outlet protection and any required temporary or permanent channel lining shall be installed in both the conveyance channel and receiving channel.

12. When work in a live watercourse is performed, precautions shall be taken to minimize encroachment, control sediment transport and stabilize the work area to the greatest extent possible during construction. Nonerodible material shall be used for the construction of causeways and cofferdams. Earthen fill may be used for these structures if armored by nonerodible cover materials.

13. When a live watercourse must be crossed by construction vehicles more than twice in any six-month period, a temporary vehicular stream crossing constructed of nonerodible material shall be provided.

14. All applicable federal, state and local regulations pertaining to working in or crossing live watercourses shall be met.

15. The bed and banks of a watercourse shall be stabilized immediately after work in the watercourse is completed.

16. Underground utility lines shall be installed in accordance with the following standards in addition to other applicable criteria:

    a. No more than 500 linear feet of trench may be opened at one time.

    b. Excavated material shall be placed on the uphill side of trenches.

    c. Effluent from dewatering operations shall be filtered or passed through an approved sediment trapping device, or both, and discharged in a manner that does not adversely affect flowing streams or off-site property.

    d. Material used for backfilling trenches shall be properly compacted in order to minimize erosion and promote stabilization.

    e. Restabilization shall be accomplished in accordance with these regulations.

    f. Applicable safety regulations shall be complied with.

17. Where construction vehicle access routes intersect paved or public roads, provisions shall be made to minimize the transport of sediment by vehicular tracking onto the paved surface. Where sediment is transported onto a paved or public road surface, the road surface shall be cleaned thoroughly at the end of each day. Sediment shall be removed from the roads by shoveling or sweeping and transported to a sediment control disposal area. Street washing shall be allowed only after sediment is removed in this manner. This provision shall apply to individual development lots as well as to larger land-disturbing activities.

18. All temporary erosion and sediment control measures shall be removed within 30 days after final site stabilization or after the temporary measures are no longer needed, unless otherwise authorized by the local program authority. Trapped sediment and the disturbed soil areas resulting from the disposition of temporary measures shall be permanently stabilized to prevent further erosion and sedimentation.

19. Properties and waterways downstream from development sites shall be protected from sediment deposition, erosion and damage due to increases in volume, velocity and peak flow rate of stormwater runoff for the stated frequency storm of 24-hour duration in accordance with the following standards and criteria:

    a. Concentrated stormwater runoff leaving a development site shall be discharged directly into an adequate natural or man-made receiving channel, pipe or storm sewer system. For those sites where runoff is discharged into a pipe or pipe system, downstream stability analyses at the outfall of the pipe or pipe system shall be performed.

b. Adequacy of all channels and pipes shall be verified in the following manner:

(1) The applicant shall demonstrate that the total drainage area to the point of analysis within the channel is one hundred times greater than the contributing drainage area of the project in question; or

(2) (a) Natural channels shall be analyzed by the use of a two-year storm to verify that stormwater will not overtop channel banks nor cause erosion of channel bed or banks; and

(b) All previously constructed man-made channels shall be analyzed by the use of a ten-year storm to verify that stormwater will not overtop its banks and by the use of a two-year storm to demonstrate that stormwater will not cause erosion of channel bed or banks; and

(c) Pipes and storm sewer systems shall be analyzed by the use of a ten-year storm to verify that stormwater will be contained within the pipe or system.

c. If existing natural receiving channels or previously constructed man-made channels or pipes are not adequate, the applicant shall:

(1) Improve the channel to a condition where a ten-year storm will not overtop the banks and a two-year storm will not cause erosion to the channel bed or banks; or

(2) Improve the pipe or pipe system to a condition where the ten-year storm is contained within the appurtenances; or

(3) Develop a site design that will not cause the pre-development peak runoff rate from a two-year storm to increase when runoff outfalls into a natural channel or will not cause the pre-development peak runoff rate from a ten-year storm to increase when runoff outfalls into a man-made channel; or

(4) Provide a combination of channel improvement, stormwater detention or other measures which is satisfactory to the plan-approving authority to prevent downstream erosion.

d. The applicant shall provide evidence of permission to make the improvements.

e. All hydrologic analyses shall be based on the existing watershed characteristics and the ultimate development of the subject project.

f. If the applicant chooses an option that includes stormwater detention he shall obtain approval from the locality of a plan for maintenance of the detention facilities. The plan shall set forth the maintenance requirements of the facility and the person responsible for performing the maintenance.

g. Outfall from a detention facility shall be discharged to a receiving channel, and energy dissipators shall be placed at the outfall of all detention facilities as necessary to provide a stabilized transition from the facility to the receiving channel.

h. All on-site channels must be verified to be adequate.

I. Increased volumes of sheet flows that may cause erosion or sedimentation on adjacent property shall be diverted to a stable outlet, adequate channel, pipe or pipe system, or to a detention facility.

j. In applying these stormwater runoff criteria, individual lots or parcels in a residential, commercial or industrial development shall not be considered to be separate development projects. Instead, the development, as a whole, shall be considered to be a single development project. Hydrologic parameters that reflect the ultimate development condition shall be used in all engineering calculations.

k. All measures used to protect properties and waterways shall be employed in a manner which minimizes impacts on the physical, chemical and biological integrity of rivers, streams and other waters of the state.

§4VAC50-30-50 Variances.

The plan-approving authority may waive or modify any of the regulations that are deemed inappropriate or too restrictive for site conditions, by granting a variance. A variance may be granted under these conditions:

1. At the time of plan submission, an applicant may request a variance to become part of the approved erosion and sediment control plan. The applicant shall explain the reasons for requesting variances in writing. Specific variances which are allowed by the plan-approving authority shall be documented in the plan.

2. During construction, the person responsible for implementing the approved plan may request a variance in writing from the plan-approving authority.
The plan-approving authority shall respond in writing either approving or disapproving such a request. If the plan-approving authority does not approve a variance within 10 days of receipt of the request, the request shall be considered to be disapproved. Following disapproval, the applicant may resubmit a variance request with additional documentation.

3. The plan-approving authority shall consider variance requests judiciously, keeping in

mind both the need of the applicant to maximize cost effectiveness and the need to protect off-site properties and resources from damage.

§4VAC50-30-60 Maintenance and Inspections.

A. All erosion and sediment control structures and systems shall be maintained, inspected and repaired as needed to insure continued performance of their intended function. A statement describing the maintenance responsibilities of the permittee shall be included in the approved erosion and sediment control plan.

B. Periodic inspections are required on all projects by the program authority. The program authority shall either:

a. provide for an inspection during or immediately following initial installation of erosion and sediment controls, at least once in every two-week period, within 48 hours following any runoff producing storm event, and at the completion of the project prior to the release of any performance bonds; or

b. Establish an alternative inspection program which ensures compliance with the approved erosion and sediment control plan. Any alternative inspection program shall be:

(1) Approved by the Board prior to implementation;

(2) Established in writing;

(3) Based upon a system of priorities that, at a minimum, address the amount of disturbed project area, site conditions and stage of construction; and
(4) Documented by inspection records.

§4VAC50-30-70 Developments.

A. An erosion and sediment control plan shall be filed for a development and the buildings constructed within, regardless of the phasing of construction.

B. If individual lots or sections in a residential development are being developed by different property owners, all land-disturbing activities related to the building construction shall be covered by an erosion and sediment control plan or an "Agreement in Lieu of a Plan" signed by the property owner.

C. Land-disturbing activity of less than 10,000 square feet on individual lots in a residential development shall not be considered exempt from the provisions of the act and these regulations if the total land-disturbing activity in the development is equal to or greater than 10,000 square feet.

§4VAC50-30-80 Criteria for Determining Status of Land-disturbing Activity.

A. The program administrator shall determine the validity of a claim of exempt status by a property owner who disturbs 10,000 square feet or more. As soon as a nonexempt status is determined, the requirements of the Act shall be immediately enforced.

B. Should a land-disturbing activity not begin during the 180-day period following plan approval or cease for more than 180 days, the plan-approval authority or the permit-issuing authority may evaluate the existing approved erosion and sediment control plan to determine whether the plan still satisfies local and state erosion and sediment control criteria and to verify that all design factors are still valid. If the authority finds the previously filed plan to be inadequate, a modified plan shall be submitted and approved prior to the resumption of land-disturbing activity.

C. Shore erosion control projects are not subject to these regulations. However, land-disturbing activity immediately outside the limits of the shore erosion project is subject to the Act and these regulations.

D. Whenever land-disturbing activity involves activity at a separate location (including but not limited to borrow and disposal areas), the program authority may either:

1. Consider the off-site activity as being part of the proposed land-disturbing activity; or,

2. If the off-site activity is already covered by an approved erosion and sediment control plan, the program authority may require the applicant to provide proof of the approval and to certify that the plan will be implemented in accordance with the Act and these regulations.

§4VAC50-30-90 Review and Evaluation of Local Programs: Minimum Program Standards

A. This section sets forth the criteria that will be used by the Department to determine whether a local program operating under authority of the Act, satisfies minimum standards of effectiveness, as follows.

Each local program must contain an ordinance or other appropriate document(s) adopted by the governing body. Such document(s) must be consistent with the Act and 4VAC50-30 and 4VAC50-50, including the following criteria:

1. The document(s) shall include or reference the definition of land-disturbing activity including exemptions, as well as any other significant terms, as necessary to produce an effective local program.

2. The document(s) shall identify the plan-approving authority and other positions of authority within the program, and must include the regulations and design standards to be used in the program.

3. The document(s) shall include procedures for submission and approval of plans, issuance of permits, monitoring and inspections of land-disturbing activities. The position, agency, department, or other party responsible for conducting inspections shall be identified. The local program authority shall maintain, either on-site or in local program files, a copy of the approved plan and a record of inspections for each active land-disturbing activity.

4. The local program authority must take appropriate enforcement actions to achieve compliance with the program and maintain a record of enforcement actions for all active land-disturbing activities.

B. The Department staff, under authority of the Board, shall periodically conduct a comprehensive review and evaluation of local programs. The review of a local program shall consist of the following: (1) personal interview between the Department staff and the local program administrator or designee(s); (2) review of the local ordinance and other applicable documents; (3) review of plans approved by the program; (4) inspection of regulated activities; (5) review of enforcement actions.

C. Local programs shall be reviewed and evaluated for effectiveness in carrying out the Act using the criteria in this section. However, the Director is not limited to the consideration of only these items when assessing the overall effectiveness of a local program.

D. If the Director determines that the deficiencies noted in the review will cause the local erosion and sediment control program to be inconsistent with the state program and regulations, the Director shall notify the local program authority concerning the deficiencies and provide a reasonable period of time for corrective action to be taken. If the program authority fails to take the corrective action within the specified time, the Director may formally request Board action pursuant to Code of Virginia §10.1-562.

E. Review and evaluation of local programs shall be conducted according to a schedule adopted by the Board.

§4VAC50-30-100 State Agency Projects

A. All state agency land-disturbing activities that are not exempt and that have commenced without an approved erosion and sediment control plan shall immediately cease until an erosion and sediment control plan has been submitted to and approved by the Department. A formal "Notice of Plan Requirement" will be sent to the state agency under whose purview the project lies since that agency is responsible for compliance with the Act.

B. Where inspections by Department personnel reveal deficiencies in carrying out an approved plan, the person responsible for carrying out the plan, as well as the state agency responsible, will be issued a notice to comply with specific actions and the deadlines that shall be met. Failure to meet the prescribed deadlines can result in the issuance of a stop work order for all land-disturbing activities on the project at the discretion of the Director of the Department or his designee who is authorized to sign such an order. The stop work order will be lifted once the required erosion and sediment control measures are in place and inspected by department staff.

C. Whenever the Commonwealth or any of its agencies fails to comply within the time provided in an appropriate final order, the Director of the Department may petition for compliance as follows: For violations in the Natural Resources Secretariat, to the Secretary of Natural Resources; for violations in other secretariats, to the appropriate secretary; for violations in other state agencies, to the head of such agency. Where the petition does not achieve timely compliance, the Director shall bring the matter to the Governor for resolution.

D. Where compliance will require the appropriation of funds, the Director shall cooperate with the appropriate agency head in seeking such an appropriation; where the Director determines that an emergency exists, he shall petition the Governor for funds from the Civil Contingency Fund or other appropriate source.

§4VAC50-30-110 Board Adopted Local Erosion and Sediment Control Programs

A. To carry out its duties under §10.1-562, the Board shall develop, adopt, and administer an appropriate local erosion and sediment control program for the locality under consideration. In fulfilling these duties, the Board shall assume the full powers of the local erosion and sediment control program granted by law.

B. The Board shall develop, adopt and administer a local erosion and sediment control program based on the minimum program standards established by these regulations and, as deemed appropriate by the Board, may include any or all of the provisions provided by law and regulations including administrative fees and performance securities.

C. Upon adoption of a local erosion and sediment control program by the Board, payment of monies including fees, securities, and penalties shall be made to the state treasury.

D. When administering a local erosion and sediment control program the Board may delegate to the Director such operational activities as necessary. Further, the Board may enter into agreements with other public or private entities to accomplish certain program responsibilities as it deems necessary to administer the local program.

2-1 COMPONENTS OF STORMWATER MANAGEMENT

The goal of storm water management is to mitigate the impact on the hydrologic cycle resulting from changes to the land surface. Urban development has been identified as having a direct impact on the hydrologic cycle by reducing or even eliminating the natural storage capacity of the land. This impact is the result of a decrease in tree cover, loose organic surface soils, and natural depressions, all of which provide natural storage capacity. These natural storage areas are then replaced with impervious and managed pervious surfaces. Impervious cover prevents the percolation of the runoff into the soil, which means that most, if not all of the rainfall is converted to runoff. In addition, managed pervious areas, such as courtyards and lawn areas typically do not provide opportunities for infiltration due to compaction of the surface soil profile and improved drainage conveyances. (The impact of development on the hydrologic cycle is discussed in detail in **Chapter 4; Hydrologic Methods**.) The results of increased stormwater runoff can be classified by its impact on *water quality*, *stream channel erosion*, and *localized flooding*. These components are identified in the Virginia Stormwater Management (SWM) Regulations.

2-1.1 Water Quality

One of the impacts of stormwater runoff is that of the quality of the runoff on the aquatic ecosystem. Various soluble and particulate pollutants are found in stormwater runoff. Studies have shown that the source of these pollutants are atmospheric deposition, urban and agricultural lands, and natural spaces. The focus of this document is on the urban land sources. The impervious surfaces, such as parking lots, roof tops, roads, etc., which are associated with land development serve to accumulate and transport these pollutants to receiving stream channels. It should be noted that pervious areas associated with development, such as golf courses, parks, open space, etc., also contribute pollutants.

The following presents a basic overview of the typical urban pollutants. Additional discussion of urban pollutants associated with certain ultra-urban development environments, referred to as *stormwater hotspots* (Claytor, 1996) is discussed in **Section 2-3: BMP Selection Criteria**.

Nutrients. Concentrations of nutrients, such as nitrogen and phosphorus, found in urban runoff can cause eutrophication of receiving streams, lakes, and rivers, and estuaries. As these nutrients collect in slower moving water bodies, they promote the growth of algae, which in turn blocks sunlight to bottom grasses, and eventually leads to a depletion of available dissolved oxygen (DO). Nutrients in urban runoff have been identified as being a significant contributor to the decline of the Chesapeake Bay. The Virginia Tributary Strategy initiative calls for a 40% reduction in nutrients reaching the Chesapeake Bay by the year 2000.

Suspended solids. All natural drainage channels have a natural sediment bed load which helps maintain a state of equilibrium within the channels of undeveloped watersheds. Increases in the peak rates of flow through the channel or stream system will disrupt the equilibrium by increasing the amount of sediment removed from the channel bed and banks. Suspended solids which result from excessive erosion and scour of the stream channel, the transport of sediments from impervious and managed pervious surfaces, and construction site runoff can have many adverse impacts on aquatic life throughout the water column. Further, these sediments will eventually settle in slower waters and smother the benthic habitat.

The "shock loading" which results from construction site runoff is most damaging to the aquatic habitat. The Virginia Erosion and Sediment Control Program addresses construction site runoff with the implementation of temporary erosion and sediment control measures specifically designed to inhibit sediment from leaving the site, as well as specifications for stabilization of the site once construction is complete. Even after final stabilization, however, loose soil or worn areas will continue to be a source of sediment to the receiving streams.

Bacteria. Varying levels of bacteria found in surface stormwater runoff can create public health concerns in receiving streams and lakes. The source of bacteria in stormwater runoff includes livestock operations, failing septic systems, unusually high concentrations of pet and wildlife droppings, leaking sewer lines, illicit connections between storm and sanitary lines, combined sewer overflows, etc. High concentrations of bacteria often result in the closure of public recreational uses of water resources, and may increase the cost of treatment for domestic water use.

Hydrocarbons. Hydrocarbon loading in urban runoff is often associated with automobile engine oil, lubricants, and other compounds. Hydrocarbon levels have been found to be highest in the runoff from parking lots, roads, and service stations.

Trace metals. Trace metals found in urban runoff, such as cadmium, copper, lead, and zinc, originate from a wide variety of sources such as roofing materials, down spouts, galvanized pipes, catalytic converters, brake linings, etc. Over time these surfaces wear down, enabling the metals to wash away in urban runoff.

Biological Oxygen Demand (BOD). Decomposition of organic matter in slow moving receiving water bodies such as lakes and estuaries increases the biological oxygen demand. High BOD depletes the available dissolved oxygen (DO) necessary to sustain aquatic life.

Thermal Impacts. Runoff from urban impervious surfaces can significantly increase ambient temperatures in receiving streams. Paved surfaces transfer significant amounts of thermal energy to runoff passing over it. When this warmed runoff reaches the receiving stream, a rise in temperature of just a few degrees can have a adverse impact on aquatic life.

2-1.2 Stream Channel Erosion

The impact of increased stormwater runoff can be easily observed in an urbanized stream system. Most of the drainage network is developed or improved to convey increased volumes and rates of runoff to the receiving stream channel. The stream channel then responds to the increase in flow by eroding to form a larger cross sectional flow area which, theoretically, should result in reduced flow velocities. An eroded channel, however, is quite often a very efficient conveyance system and promotes an even faster velocity of flow, which in turn, accelerates the channel erosion process. Once this process has begun, it is very difficult to stop because typical stream channel soils are highly erodible once the protective lining of cobble or vegetation is eroded away.

2-1.3 Flooding

When the rate of stormwater runoff exceeds the capacity of the various manmade or natural conveyance systems, the result is localized flooding. The conveyance system gradually catches up and drains the flood waters as the rainfall subsides. In some cases debris or other materials dislodged by the rising flood waters will clog the drainage system and cause longer periods of flooding. In either case, pockets of standing water which do not drain will remain for periods of time and eventually percolate into the ground or evaporate.

In the pre-developed condition, most stream channels have an adequate floodplain or flood fringe to convey and store the out of bank flows with minimal damage. With urbanization, however, these floodplain areas are often eliminated or developed with improvements. The periodic ponding of water in developed areas often results in damage. Pavement will fail or be undermined, structures will be water damaged, landscaping and other improvements not used to inundation will be damaged.

2-1.4 Regional (watershed-wide) Stormwater Plans

The cumulative effect of sedimentation, scouring, increased flooding, lower summer flows, higher water temperature, and pollution contribute to the overall degradation of the stream ecosystem. Many studies have documented the decline of fish diversity in urbanized watersheds. The aquatic insects which are a major food resource for fish are impacted by the increased sediment load, trace metals, nutrients, and flow velocities. Less noticeable impacts to the stream systems are changes in water temperature, oxygen levels, and substrate composition.

A regional or watershed-wide stormwater plan provides the framework needed to evaluate the impacts of changes to the land on water resources. A comprehensive watershed management plan considers all of the impacts of increased stormwater runoff: water quality, channel erosion, and flooding. The plan is the result of studying the environmental features of the watershed to identify those areas that should be protected and preserved. The plan identifies and strategically locates stormwater management measures and design criteria to be utilized to protect the watershed. The plan also aims to utilize and protect ecological processes to lessen the need for structural control methods that require capital costs and maintenance.

2-2 BMP SIZING CRITERIA

Stormwater management policies have been developed over the years in an attempt to mitigate the impact of land development on aquatic systems as discussed previously. Increased flash flooding and the associated flood damage in urbanizing areas gave rise to stormwater management policies based on controlling peak discharge. In addition to the structural damage, significant erosion of the channel bed and banks was considered to be a detriment to the value of property. Detention basins sized to reduce the post-development peak discharge to the pre-developed rates became an acceptable and commonly used method of mitigating these impacts of urbanization. As channels eroded, more and more localities developed peak rate control policies aimed at controlling channel erosion and localized flooding. These policies, however, were still based on a peak rate of discharge and did not address the increased *volume* and *frequency* of the peak discharge.

Both theory and experience indicates that, while detention basins designed to control peak discharge are effective in controlling peak rates, the basins are ineffective in controlling the degradation of erodible channels downstream of the basin. (McCuen, Moglen, 1988). Similarly, detention basin design must incorporate methods for improving water quality. The following discussion provides a discussion of various sizing criterion for stormwater quality, stream channel erosion, and flood control BMPs.

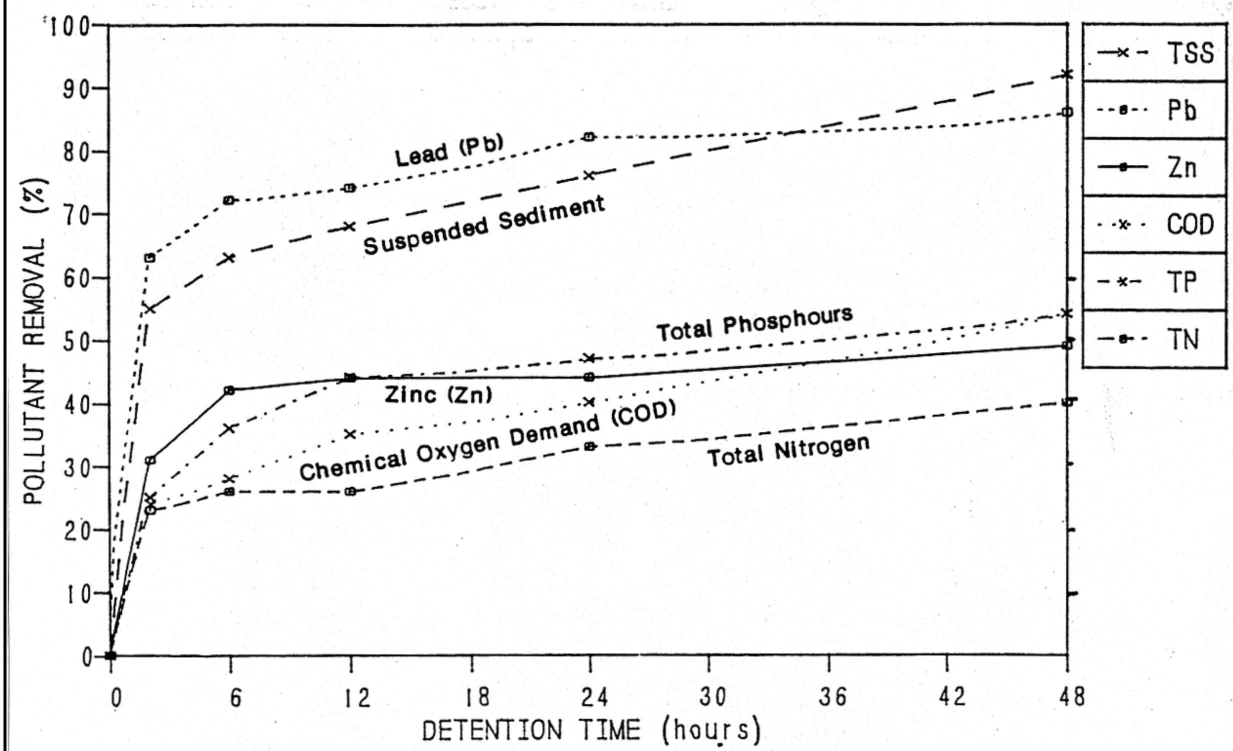
2-2.1 Water Quality

Pollutant Removal Mechanisms

Pollutant removal mechanisms employed by urban BMPs include *settling*, *filtering*, and *biological processes*.

Settling or *sedimentation* is limited to particulate pollutants which drop out of the water column by way of gravitational settling. In some cases, pollutants will attach themselves to heavier sediment particles or suspended solids and drop out of the water column. Laboratory and field studies indicated that significant settling of urban pollutants occurs in the first 6 to 12 hours of detention. **Figure 2-1** provides removal rate vs detention time for selected pollutants. The brim draw down requirement for water quality extended detention design is 30 hours, rather than the minimum of 6 to 12 hours. The additional time is required to allow for ideal settling conditions to develop within the stormwater facility. In addition, the added time will allow for settling of smaller particle sizes and nutrients, as well as increasing the opportunity for biological processes. Stormwater BMPs which utilize settling are usually suited for dual purposes, that is they can also provide storage volume for peak rate control, channel erosion, and/or flood control. These impoundment water quality BMPs are generally sized based on a volume of runoff, commonly referred to as the *water quality volume* (WQV), or “first flush” of runoff. The water quality volume is discussed in detail later in this section.

FIGURE 2-1
Removal Rate vs. Detention Time for Selected Pollutants



Source: Schueler, Controlling Urban Runoff, 1987

Stormwater filtering or *filtration* is typically limited to BMPs which address water quality. These facilities utilize a filter media, such as sand, peat, grass, compost, or various types of fabrics or other material to strain pollutants out of the stormwater. Since the stormwater must pass through the filter media in order to be treated, these structures are limited to small drainage areas (less than 5 acres) and low flow rates. A drawback to these structures is the overflow or bypass of large flows from high intensity storms. The current sizing criteria for these BMPs is the water quality volume. The Department is currently evaluating the option of designating a flow rate or return frequency intensity for design purposes. In most cases a bypass or diversion structure is needed to allow large flows to bypass the BMP without flushing previously deposited pollutants out of the BMP. Guidance on this issue will be provided in the future.

Biological processes are the most effective removal mechanisms for soluble pollutants, such as nutrients. A combination of shallow permanent pool depths and abundant vegetation help to create conditions which allow a natural food chain to develop. Marsh plants, algae and bacteria that grow on the shallow organic rich sediments can take up soluble forms of nutrients needed for their growth. BMPs suited for this pollutant removal mechanism include enhanced extended detention, retention, constructed stormwater wetlands, and in some cases bioretention. The sizing criteria for these BMPs is generally based on permanent pool volume defined as a multiple of the water quality volume, IE: 2.0 or 3.0 times the WQV. (Bioretention utilizes filtering as the primary pollutant removal mechanism.)

Table 2-1 identifies the pollutant removal mechanism utilized by each of the BMPs listed in Table 1 of the Virginia SWM Regulations. It should be noted that the Manufactured BMP Systems are not itemized in **Table 2-1**. For further discussion of Manufactured BMP Systems, refer to **Minimum Standard 3.15**.

TABLE 2-1
Pollutant Removal Mechanisms

Water Quality BMP	Settling	Filtering	Biological
Vegetated filter strip		U	
Grassed swale (w/ check dams)	U	U	
Constructed wetlands	U	U	U
Extended detention	U		
Extended detention enhanced	U	U	U
Bioretention		U	U
Retention basin I, II	U		U
Retention III	U		U
Sand filter		U	
Infiltration		U	

Many stormwater BMPs will utilize a combination of these pollutant removal mechanisms. In some cases, after a BMP has been in operation for a period of time, a layer of organic matter will develop within the BMP, thereby increasing the adsorption potential of the BMP. *Adsorption* is the chemical or molecular attraction which enhances the removal of soluble pollutants. BMPs which include plants and grasses also display increased pollutant removal efficiency over time as the biomass increases. As the vegetation thickens, it serves to slow the velocity of the runoff through the BMP. This allows for increased gravitational settling and filtering of pollutants, as well as decreased export of sediment and attached pollutants via erosion.

Water Quality Volume (WQV)

Ideally, the pollutant removal mechanism should dictate the treatment volume or frequency storm for water quality BMPs. The sizing of BMPs which utilize gravitational settling of pollutants as the removal mechanism can be based on a volume of runoff, while BMPs which utilize filtering should probably be based on a flow rate or frequency. Design criteria provided in **Chapter 3: BMP Minimum Standards**, specifies maximum flow velocities for grass swales and filter strips, as well as the need for a flow splitter or bypass structure for sand filters and other flow through structures.

The Virginia Stormwater Management Regulations require that the *first flush* of runoff be captured and "treated" to remove pollutants. The first flush, or water quality volume (WQV) is generally defined as the first ½" to 1" of runoff from impervious surfaces. Other methods of defining this first flush have been developed. One method in particular, developed by The Center for Watershed Protection, utilizes the Runoff Frequency Spectrum (RFS) for the Washington D.C. area and surrounding Chesapeake Bay watershed. The RFS is based on the fact that 90% of the annual runoff is generated by storms of 1" of rainfall or less. Therefore, the goal of treating at least 90% of the annual runoff results in a treatment volume based on a 1" rainfall. The volume of runoff is determined by multiplying a volumetric runoff coefficient (R_v), based on site imperviousness, by the 1" of rainfall. This method generates a water quality volume of close to 1" for highly impervious sites and gradually decreasing volumes for gradually decreasing levels of imperviousness.

As noted in the Virginia Stormwater Management Regulations, water quality BMPs which are dependent on volume, such as extended detention, constructed stormwater wetlands, and in some cases infiltration, have a required treatment volume of 2.0 x WQV (or 2.0 x 0.5" = 1.0" per impervious acre). This will result in a very similar volume as that based on the RFS method described above. As these methods are studied and BMPs are monitored, the design criteria for determining the WQV may be refined to achieve a greater overall level of treatment.

While the first flush from a storm event is considered to contain the highest concentration of pollutants, there is considerable debate over the intensity of rain needed to wash the pollutants from the urban landscape. Studies have shown that intensity is the critical wash off factor for most storm events, and many people can intuitively comprehend that higher intensity rains leave impervious surfaces cleaner than lower intensity rains. (Adams, 1997). The typical SCS rainfall hyetograph starts with a low rainfall intensity which gradually rises to a peak and then declines. This may indicate that in some cases the designated water quality volume provided in a stormwater basin may fill up with the relatively clean water at the onset of a rain event, consequently allowing the larger flows associated with the high intensity rain and pollutant wash off to pass through the facility.

A similar discussion on the design criteria for water quality structures focuses on the "volume" of runoff verses the "rate", or even the return frequency, of runoff. The water quality volume or first flush is detained in a basin or impoundment structure to allow the pollutants to settle out. Whether that specific volume of runoff enters the basin gradually, or as the result of a sudden high intensity rain, it is still detained for a period of time. Filtering structures, on the other hand, can handle only a certain design flow rate. Sudden high intensity rain will typically generate too much runoff too fast and therefore bypass the treatment facility.

A new category of water quality BMPs: Manufactured BMP Systems (**Minimum Standard 3.15**), utilizes combinations of settling, swirl concentration, and filtering to separate pollutants from the runoff. These structures vary in how they respond to high flows. Some will bypass large flows with little or no treatment, while others will continue to separate and treat the runoff at a reduced efficiency. Further study of these manufactured systems and the appropriate design criteria for flow through or hydro-dynamic structures is warranted and will be provided at a future time.

2-2.2 Stream Channel Erosion

Stream channel erosion results primarily from high scour velocities over extended durations of time. Studies show that natural channels are shaped by the 1½- to 2-year frequency storm event. (Leopold et al., 1964; Anderson, 1970). This frequency allows the channel to maintain a state of equilibrium with regard to the natural sediment load transport and natural vegetation which helps to stabilize channel banks. Therefore, local ordinances have traditionally regulated the 2-year storm, specifying that the post-developed peak rate of runoff may not exceed the pre-developed rate. Note, however, that this requirement does not address the increase in the *frequency* of that peak runoff rate. Urbanization usually increases the amount of impervious cover, resulting in less infiltration, less initial abstraction and less depression storage. Consequently, it takes less rainfall to produce the same *volume* of runoff. Therefore, the *peak rate of runoff* that normally occurs on a 2-year frequency before development, may occur several times a year following development.

To compound the problem, a detention basin stores the increased *volume* of runoff from a developed area and releases it at the pre-developed rate. The *duration* of this discharge is much longer than the pre-developed condition. The peak rate and velocity may be at pre-developed levels, but by receiving the pre-developed rate for a longer *duration*, coupled with the increase in *frequency*, a stable earth-lined channel can quickly degrade.

The increased frequency of a specific discharge can be illustrated by considering an undeveloped watershed which, during a 2-year frequency storm (3.2 inches of rain), generates a theoretical peak rate of runoff of 15 cfs, and a corresponding volume of runoff of 0.52 watershed inches. We will assume that this 2-year frequency flow represents the channel forming, bankfull discharge. After the watershed has experienced development (32% imperviousness) along with the associated improved drainage conveyance systems, the same watershed requires only 1.6 inches of rainfall to generate that same theoretical bankfull discharge of 15 cfs. This means that the channel will now experience bankfull flows at an approximate increased *frequency* of every three to six months rather than two years. In addition, for the 2-year storm, the *volume* of runoff has increased to 1.15 watershed inches, more than double the pre-developed volume, which means a significant increase in the *duration* of the peak flow can be expected. Under this scenario, the receiving stream will experience a significant increase in erosive flows.

The solution to designing for stream channel erosion is evolving into a study of stream channel geomorphology. Several studies have indicated that the level of erosion (or bed-material load) is a function of the difference between the flow velocity and the *critical* velocity.(McCuen, 1987). The critical velocity is a function of the type of soil of which the channel bed is composed. The studies indicate that the amount of bed sediment moved is a function of the time duration over which the velocity is greater than the critical velocity. According to McCuen, this explains from a conceptual standpoint why the duration of flow is just as important as the rate of flow. Further, it may explain why detention basins may actually increase the erosion compared to providing no control of the post-developed flows. When no control is provided, the flow tends to exceed the channel capacity and extend out into the floodplain; thus the velocity within the channel banks may not increase significantly even though the peak flow rate does increase significantly.

This should not be interpreted as justification for no control of stormwater runoff. Rather, it highlights the need for a design criteria that replicates the pre-development sediment load transport characteristics of the channel. Several methodologies have been recommended, some of which are very subjective as they are based upon the ability of the designer to analyze and interpret the stream sediment characteristics. This could easily become an expensive and cumbersome methodology, especially in localities that do not experience significant development pressure. The review and approval process could become bogged down in the analysis of field data and trying to verify the channel characteristics, especially when the requirements of the field work may be different for every project.

The Virginia Stormwater Management Regulations address stream channel erosion by requiring compliance with Minimum Standard 19 of the Virginia Erosion and Sediment Control Regulations (4VAC50-30-40.19). This standard requires that **properties downstream from development sites be protected from sediment deposition, erosion, damage due to increases in volume, velocity, and peak flow rate of stormwater runoff**. The specific design criteria specifies that downstream *natural channels* by analyzed for adequacy to convey the developed condition 2-year peak discharge within the channel banks and at a non-erosive velocity. In addition, *man made channels* are analyzed for adequacy to convey the 10-year peak discharge within the channel banks and the 2-year peak discharge at a non-erosive velocity.

When a channel is determined to be not adequate, the use of a stormwater detention BMP sized to discharge the 2-year and 10-year frequency developed-condition peak discharge at the respective pre-developed rates is one of the available options. (Refer to **Chapter 1** for the complete language of Minimum Standard 19.) As we discussed above, this criteria may not be adequate for natural channels due to the increase in the frequency, duration, and volume of the “pre-developed” discharge.

An alternative is to identify a design frequency storm and control the discharge such that it does not exceed that of the critical velocity for the channel. Recent studies have shown a significant reduction in stream channel erosion below facilities designed to provide 24-hour extended-detention of the runoff from the 1-year frequency storm. (Galli MWCOG, 1992). This criteria results in significantly lowered discharge rates and velocities considered to be non-erosive, despite the longer impact time and increased frequency. The Virginia SWM Regulations allow this criteria as an alternative to the 2-year peak discharge control requirement in cases where natural channels are experiencing erosion resulting from existing conditions, or where channels are considered to be sensitive to any increase in flow rate or duration.

Further guidance on the analysis of the adequacy of natural channels, consistent with the Erosion and Sediment Control Regulations will be provided by the DCR in the near future.

2-2.3 Flooding

Control of the 10-year frequency design storm to the pre-developed rate is considered to provide control over a wide range of storms for control of localized or out of bank flooding. This should not be confused with out of bank flooding as it pertains to the 100-year floodplain which is mapped by the Federal Emergency Management Agency (FEMA), and based on the 100-year frequency design storm. The mapped 100-year floodplain is important because it is used to designate and implement the National Flood Insurance Program. Most localities in Virginia have a Floodplain Management Ordinance which controls development within the 100-year floodplain.

2-2.4 More Stringent Criteria

Local programs are authorized under the Virginia Stormwater Management Act to require more stringent technical criteria than the state minimum criteria found in the regulations (4VAC3-20). The more stringent criteria must be based on a watershed plan or study which justifies the criteria, and must be passed into local ordinance through the local ordinance adoption process. The scope of an acceptable watershed plan or study is somewhat subjective and, at a minimum, must stand up to the scrutiny of the local adoption process. Some basic watershed plan concepts are provided in **Section 2-4**.

2-3 BMP SELECTION CRITERIA

The following discussion provides a general outline for choosing the appropriate BMPS for a development site. The order of presentation **does not** imply a decision making process that will systematically progress towards an acceptable BMP. On the contrary, any one of the criteria can render a preferred BMP unacceptable. **In some cases**, the designer may be able to accommodate certain limiting feasibility factors by providing an innovative design which addresses or remedies the constraint. **In all cases**, once a BMP is selected, we strongly recommend that the selection, along with the supporting criteria and any compromises or design features, be presented to the various review or permitting agencies to ensure proper evaluation and review. This will help avoid extensive changes to the stormwater management strategy during the review process.

One of the first considerations in selecting a stormwater BMP is the functional goal of the BMP. Previously, we discussed the components of SWM: *stormwater quality*, *stream channel erosion*, and *flooding*. Any one or combination of these components may be addressed by the local ordinance and will dictate the functional goal of the BMPs. (State agency projects, are required to comply with all three of these regulatory components). In general, stormwater BMPs can be categorized into water *quality* BMPs and water *quantity* (stream channel erosion and flooding) BMPs. **Table 2-2** provides a general categorization of BMPs by functional goal. Note, that some BMPS can be designed to satisfy both quality and quantity goals while others are specifically suited for only one.

The use of some BMPS are limited by site or watershed feasibility factors such as environmental impacts, drainage area or watershed size, and topographic constraints.

Finally, the BMPS designed for water quality control provide varying levels of pollutant removal and are suited for specific development densities. **Table 2-3** presents a generic list of water quality BMPS, their target phosphorus removal efficiency, and appropriate percent impervious cover.

The decision making process of choosing a stormwater BMP must weigh the goals of the proposed facility against the limiting site feasibility factors of the proposed site or BMP location. The limiting *site feasibility* factors include:

1. Topographic and geologic constraints,
2. Contributing drainage area size, and
3. Environmental impacts.
4. Access for maintenance

The possible stormwater management requirements or goals which influence BMP selection include:

1. Multiple Criterion: Stormwater quality, stream channel erosion, flooding, and environmental mitigation,
2. Multiple discharge points,

3. Pollutant removal capability, and
4. Performance-based vs technology-based water quality criteria.

2-3.1 Site Feasibility

1. Topographic and Geologic Constraints

The physical characteristics of the site must be compatible with the performance of the BMP. Reviewing the **Minimum Standards** found in **Chapter 3**, you will note that BMPs are restricted in certain areas based on the geologic or underlying conditions. This can be as simple as determining if the hydrologic soil group is appropriate for the BMP (such as infiltration in permeable soils) or may require a vigorous geotechnical investigation.

a. *Karst topography:* Karst topography consists of geologic formation underlain by carbonate rock and typified by the presence of limestone caverns and sink holes. These areas present very difficult challenges since any BMP which impounds water may cause underlying caverns or sink holes to expand and open at the surface. The use of liners may help the BMP hold the runoff as intended, however, the conveyance to the BMP, as well as the conveyance from the BMP to the receiving channel must also be considered since the overall volume of runoff is increasing and possibly being directed to areas previously not impacted by runoff.

   In addition, the presence of karst may allow a direct path for the stormwater runoff to enter the water table with little or no filtering of pollutants. Any design in regions suspected to include karst topography should be supported by a thorough subsurface geotechnical or geological investigation. Further guidance on geotechnical methods for karst topography will be provided by the Department in the near future.

b. *High water table*: A high water table can impact the proper functioning of a BMP. Infiltration BMPs are restricted since a high water table will prevent the percolation of the stormwater into the sub soils. A high water table may cause dry detention BMPs to evolve into wet facilities. While this may enhance pollutant removal by encouraging a marsh environment, it may not be the choice of design based on maintenance, aesthetics, etc. A high water table may also impact the construction of the embankment or impoundment facilities by making it difficult to achieve the proper compaction of the underlying foundation. Special geotechnical recommendations may be necessary to address impacts associated with a high water table.

c. *Bedrock:* The presence of bedrock close to the surface can have a significant impact on a development project. The cost of excavation increases considerably, especially if blasting is required. Blasting rock in the area of a proposed embankment is not acceptable unless a liner system is proposed for the basin. Blasting can open seams in the bedrock which may allow stormwater to drain out of (or under) the proposed facility.

A thorough geotechnical investigation and report should verify the subsurface conditions for the presence of any of the above features. The scope and requirements of a geotechnical investigation may vary from site to site. Refer to **Minimum Standard 3.10: General Infiltration Practices** for additional information on geotechnical investigations.

d. *Proximity to structures, steep slopes, and water supply wells.* One of the goals of stormwater facilities is to provide recharge of the groundwater. This tends to saturate the adjacent ground during, and for a period of time, after, a storm event. Building foundations, basements, and other structures may be impacted by the wet/dry cycle of the surrounding soils.

Saturating the soils on or adjacent to steep slopes (6 to 10 percent or greater) can cause a failure of the slope and adjacent structures.

The proximity to water supply wells raises concern over the introduction of pollutants into the water supply aquifer. Minimum distances from these features are presented in **Chapter 3: Minimum Standards**.

2. Contributing Drainage Area Size

Some BMPs are restricted based upon the size of the contributing drainage area. The recommended maximum and minimum sizes are considered guidelines and some flexibility should be allowed. The exceptions, however, are the Manufactured BMP Systems (**Minimum Standard 3.15**) The manufacturers design criteria should be adjusted or modified **by the manufacturer only**. The proper operation of these BMPs is dependent on the proper sizing of the structure.

3. Environmental Impacts

It is extremely important for the designer to asses the environmental impacts associated with the site development and the placement of the stormwater BMP. Local, State, and Federal regulations may restrict the disturbance, or encroachment upon any of the following: wetlands, Waters of the United States, stream or wetland buffers, floodplains, conservation easements, and other sensitive resources.

Virginia Water Protection Permit Program: The Virginia Department of Environmental Quality implements the Virginia Water Protection Permit (VWPP) Program. This program regulates all activities in Virginia which result in discharge or dredge or fill material into state waters. This can include wetlands, perennial streams, and other aquatic resources. The VWPP program is in conjunction with the U.S. Corps. of Engineers Federal Permit authorized by the Clear Water Act. Some projects may require one or both permits. The permit typically requires that the developer investigate alternatives to the proposed impacts. If no alternatives are viable, then possible design modifications may be needed, such as pre-treatment of stormwater prior to discharging into wetlands, thermal and dissolved oxygen impacts to the receiving stream be addressed, etc. The designer should contact the appropriate state or federal agencies prior to the design to identify such permit requirements.

Chesapeake Bay Preservation Act: The Chesapeake Bay Preservation Act (CBPA) and regulations, implemented by local governments, contain restrictions on development within certain buffer areas of wetlands, streams and other sensitive water resources. The designer should contact the Chesapeake Bay Local Assistance Department or the local government prior to the design to identify the restricted buffer areas and other requirements of the CBPA and regulations.

National Flood Insurance Program: The Department of Conservation and Recreation (DCR) coordinates the Federal Emergency Management Agency (FEMA) National Flood Insurance Program (NFIP) in Virginia. Local governments implement local floodplain management ordinances consistent with the state and federal statutes. The designer should contact DCR or the local government prior to design in order to identify any mapped 100-year foodplain located on the project.

2-3.2 Site or Watershed Stormwater Management Requirements

1. Multiple Criterion: Quality, Stream Channel Erosion, and Flooding

The functional goal of the stormwater BMP will be determined by the regulatory requirements imposed on the site. In some cases the downstream receiving waters will influence the regulatory requirements. Where multiple controls are required (quality and quantity), ideally these controls can be satisfied in one BMP strategically located on the site. This is usually accomplished with an impoundment BMP such as *extended detention* or *retention*.

On small sites, however, the use of impoundment facilities is limited by the available space, and their inability to adequately serve small areas for water quality. (The small orifice diameter required for adequate extended detention time can easily become a maintenance burden for a small site, and the contributing drainage area size should be at least 25 acres or contain a base flow when considering a retention basin.) Therefore, it may become necessary to utilize more than one BMP: one which addresses quantity and another which addresses quality. Reducing the stormwater quantity requirements through non-structural BMPs or innovating site design techniques will help to reduce the need for structural quantity control BMPs which typically are land intensive.

2. Multiple Discharge Points

The simplest site design includes a stormwater management strategy that consists of one discharge point from the site. Large developments, however, often contain multiple discharge locations as dictated by the topography. Traditionally, this situation has been addressed one of two ways: 1) Provide a Stormwater BMP at each location as required by the size of the contributing drainage area and associated increase in peak discharge, percent imperviousness, etc; or 2) overcompensate at one discharge point in order to allow the other discharge point(s) to go uncontrolled.

Overcompensation of Peak Discharge should be subject to the following conditions:

1. The drainage channels which leave the site must be part of the same stream or tributary network and the confluence should occur at some reasonable distance from the site.

2. The uncontrolled discharge is still subject to the requirements of MS-19, that is the receiving channel is adequate to convey the increased flow.

3. The overall peak rate of discharge leaving the site must not exceed that of the pre-developed condition.

Overcompensation of Water Quality is covered in more detail in the next section which discusses the use of the Performance-based Water Quality Criteria. However, as it applies to multiple discharge points, the following conditions should apply:

1. The drainage channels which leave the site must be part of the same stream or tributary network and the confluence should occur at some reasonable distance from the site.

2. Every effort should be made to provide water quality enhancement through the use of vegetated buffers, open grass/vegetated swales, bioretention, or other low maintenance water quality BMPs.

3. Every effort should be made to minimize the impacts in the uncontrolled drainage area through non-structural means as discussed previously.

4. The overall site water quality compliance must be determined using the performance-based water quality criteria.

Another alternative which may be considered is the control of existing development in lieu of the proposed development. This trade off should be considered only if specific site, watershed, or environmental considerations hinder the successful incorporation of on-site BMPs.

3. Pollutant Removal Efficiency

Years of pollutant removal monitoring of stormwater BMPs has provided us with a basic understanding of how efficient various BMPs are at removing urban pollutants. Most of this knowledge is limited to the older and more traditional impoundment BMP structures such as *retention* and *extended detention*. Recent regulatory requirements focused on reducing the export of nonpoint source pollution have given rise to new BMPs, some of which have had very limited monitoring with which to verify removal efficiencies. The pollutant removal efficiencies provided in the stormwater regulations and this handbook are derived from the best available information. We recognize that these values are subject to change as we learn more about the practical application and maintenance of these new BMPs.

Keystone Pollutant

The pollutant removal efficiencies presented in **Table 2-4** are removal efficiencies for phosphorus. This target or keystone pollutant was selected by the Chesapeake Bay Local Assistance Department in order to evaluate the performance of site design and BMPs at reducing pollutant export from a development site. The selection of one pollutant allows a consistent application of a performance based water quality criteria. Phosphorous was selected because it exhibits some of the characteristics of particulate pollutants, as well as those of soluble pollutants, making it a good indicator of urban pollutants in general. This is not meant to exclude other pollutants from being targeted. The performance-based water quality calculation procedure was originally adopted as guidance in the Chesapeake Bay Local Assistance Department's *Local Assistance Manual* for localities implementing Chesapeake Bay Preservation Act (CBPA) programs. In situations where other pollutants are identified as a problem, such as from "stormwater hotspots", those other pollutants should be addressed.

Stormwater Hotspots

Stormwater hotspots are defined as a land use or activity that generates higher concentrations of a particular pollutant or pollutants, such as sediment, hydro-carbons, trace metals, or toxicants, than are found in typical stormwater runoff, based on monitoring studies. (Center for Watershed Protection, 1997). The use of some BMPs are limited on sites considered to be stormwater hotspots. This is due to the potential for the contamination of groundwater. *Infiltration facilities* are not recomended for hotspots for this reason. Further, the use of impoundment type structures for hotspots should be qualified by an adequate separation from the seasonal groundwater table (four foot separation is desirable, and a two foot separation minimum), or an impermeable liner used to prevent leachate infiltration

TABLE 2-2
Functional Goal of Stormwater BMPs

Stormwater BMP	Quality	Stream Channel Erosion	Flooding
Vegetated filter strip	U++		
Grassed Swale (w/ check dams)	U++	U	
Constructed wetlands	U++	U	
Extended detention	U+	U++	U
Extended detention enhanced	U++	U+	U
Bioretention	U++		
Retention basin	U++	U+	U
Sand filter	U++		
Infiltration	U++		
Infiltration Basin	U+	U	U
Detention		U+	U++
Manufactured BMPs	U++		

Legend: U++ = Primary functional goal

U+ = Potential secondary functional goal

U = Potential secondary functional goal with design modifications or additional storage

NOTE: *Some BMPs, when properly designed, can provide secondary goals. Table 2-2 indicates several water quality BMPs with potential secondary goals. This is not meant to restrict the designer from incorporating design modifications or additional storage as appropriate for the particular site. Care must be taken to ensure that the the design modifications do not diminish the primary goal capabilities of the BMP.*

TABLE 2-3
Target Phosphorus Removal Efficiency*

Water Quality BMP	Target Phosphorus Removal Efficiency	Percent Impervious Cover
Vegetated filter strip Grassed swale	10% 15%	16-21%
Constructed wetlands Extended detention (2 x WQ Vol) Retention basin I (3 x WQ Vol)	30% 35% 40%	22 -37%
Bioretention basin Bioretention filter Extended detention-enhanced Retention basin II (4 x WQ Vol) Infiltration (1 x WQ Vol)	50% 50% 50% 50% 50%	38 -66%
Sand filter Infiltration (2 x WQ Vol) Retention basin III (4 x WQ Vol with aquatic bench)	65% 65% 65%	67 -100%

** Innovative or alternate BMPs not included in this table may be allowed at the discretion of the local program administrator or the Department. Innovative or alternate BMPs not included in this table which target appropriate nonpoint source pollution other than phosphorous may be allowed at the discretion of the local program administrator or the Department.*

TABLE 2-4
Classification of Stormwater Hotspots

The following land uses and activities are deemed *stormwater hotspots*

< vehicle salvage yards and recycling facilities #
< vehicle fueling stations
< vehicle service and maintenance facilities
< vehicle and equipment cleaning facilities #
< fleet storage areas (bus, truck, etc.) #
< industrial sites (for SIC codes contact Virginia Dept. Of Environmental Quality)
< marinas (service and maintenance) #
< outdoor liquid container storage
< outdoor loading/unloading facilities
< public works storage areas
< facilities that generate or store hazardous materials #
< commercial container nursery

# indicates that the land use or activity is required to prepare a stormwater pollution prevention plan in accordance with the Virginia Pollution Discharge Elimination System program permit as required by the Virginia Department of Environmental Quality.

2-3.3 *Technology-Based* and *Performance-Based* Water Quality Criteria

The *Technology-based* and *Performance-based* water quality criterion represent a consolidation of the water quality technical criteria of three state agencies charged with the responsibility of monitoring and improving the water resources of the Commonwealth: The Department of Conservation and Recreation (DCR), the Department of Environmental Quality (DEQ), and the Chesapeake Bay Local Assistance Department (CBLAD). The specific responsibilities of these agencies are presented in **Chapter 1**. The stormwater management water quality regulations require compliance by **either** a *performance-based water quality criteria* **or** a *technology-based water quality criteria*.

The *performance-based* water quality criteria states that for land development, the calculated post-development nonpoint source pollutant runoff load shall be compared to the calculated pre-development load based upon the average land cover condition or the existing site condition. This approach requires the designer to calculate the pollutant load to be removed, implement a BMP strategy, and then calculate the performance of that strategy, based on the effectiveness or pollutant removal efficiency of the selected BMP(s), (**Table 2-3**) .

The calculation procedure for verifying compliance with the performance-based water quality criteria is based on the Simple Method. The *Simple Method* is empirical in nature and utilizes the extensive data base obtained in the Washington D. C. National Urban Runoff Pollution (N.U.R.P.) study, as well as the national N.U.R.P. data analysis (MWCOG, 1983) to establish pollutant loading values for various land uses. The derivation of the Simple Method can be found in Appendix A of Controlling Urban Runoff: A Practical Manual for Planning and Designing Urban BMPs, published by The Metropolitan Washington Council of Governments.

The *technology-based* water quality criteria states that for land development, the post-developed stormwater runoff from the impervious cover shall be treated by an appropriate BMP as required by the post-developed condition percent impervious cover as specified in **Table 2-3**. The selected BMP shall be located, designed, and maintained to perform at the target pollutant removal efficiency specified in **Table 2-3**.

These two criterion are considered to be equivalent when implemented as described in this handbook. The design criteria found in **Chapter 3** establishes the minimum design elements which should result in the expected pollutant removal performance of the BMP.

1. Performance-Based Water Quality Criteria

The *performance-based water quality criteria* states that for land development, the calculated post-development nonpoint source pollutant runoff load shall be compared to the calculated pre-development load based upon the average land cover condition or the existing site condition. A BMP shall be located, designed, and maintained to achieve the target pollutant removal efficiencies specified in **Table 2-3** to effectively reduce the pollutant load to the required level based upon the following four applicable land development situations for which the performance criteria apply:

1. *Situation 1* consists of land development where the existing percent impervious cover is less than or equal to the average land cover condition and the proposed improvements will create a total percent impervious cover which is less than the average land cover condition.

    Requirement: No reduction in the after development pollutant discharge is required.

2. *Situation 2* consists of land development where the existing percent impervious cover is less than or equal to the average land cover condition and the proposed improvements will create a total percent impervious cover which is greater than the average land cover condition.

    Requirement: The pollutant discharge after development shall not exceed the existing pollutant discharge based on the average land cover condition.

3. *Situation 3* consists of land development where the existing percent impervious cover is greater than the average land cover condition.

> Requirement: The pollutant discharge after development shall not exceed (i) the pollutant discharge based on existing conditions less 10% or (ii) the pollutant discharge based on the average land cover condition, whichever is greater.

("...which ever is greater" refers to the calculated pollutant discharge to which the after development pollutant discharge is compared. Additional explanation is provided in the discussion following this section.)

4. *Situation 4* consists of land development where the existing percent impervious cover is served by an existing stormwater management BMP that addresses water quality.

> Requirement: The pollutant discharge after development shall not exceed the existing pollutant discharge based on the existing percent impervious cover while served by the existing BMP. The existing BMP shall be shown to have been designed and constructed in accordance with proper design standards and specifications, and to be in proper functioning condition.

The definition of the average land cover condition is important to the successful implementation of the performance-based water quality criteria. An analysis of the Chesapeake Bay watershed identified the average land cover condition using the following categories: urban land use, forest cover, pasture land, conservation till acreage, and conventional till acreage. Using the pollutant load values from the N.U.R.P. studies, the average land cover condition was then used to establish a baseline existing land use condition pollutant load value of 0.45 lb/ac/yr of phosphorous. Since the Simple Method is based on impervious cover, an equivalent percent impervious cover is needed. 16% impervious cover has been determined to be an equivalent pollutant load source for all of the urban and non-urban land uses which contribute nonpoint source pollution. These values (16% impervious cover and 0.45 lb/ac/yr of phosphorous) represent the average land cover conditions for the Chesapeake Bay watershed. (Keep in mind that these values may be adjusted based on actual land use conditions within the locality or individual watersheds within the locality at the time of DCR or CBLAD program adoption, whichever occurred first.) This allows the designer to calculate, using the Simple Method, the pre-developed pollutant load using average land cover conditions, and the post-developed pollutant load using the project post-developed impervious cover. The difference between the pre- and post-developed pollutant load represents the increase in pollutant load which must then be controlled by an appropriate BMP.

Since this methodology is based on impervious cover, there may be some developments such as golf courses, cemetaries, etc. which would be calculated as having no increase in pollutant load. Depending on the pre-developed land cover, this may or may not be the case. Unmanaged meadow which is graded into a golf course fairway will probably experience an increase in pollutant discharge. Since this is not accounted for in the calculation procedure, the designer and reviewer are encouraged to use sound engineering judgement in applying the water quality criteria. Site feasibility factors should be evaluated and an appropriate BMP selected in situations where the calculation procedures do not accurately reflect the post developed condition impact on water quality.

The designation of an average land cover condition helps to prevent extreme compliance situations. Without such a provision, a site in its natural state with very little runoff and NPS pollution, e.g. a forested site, might become impossible to develop simply because currently available BMPs may not be able to satisfy the pollutant removal requirement of *post* back to *pre*. Conversely, a development of open land with sparse vegetation may generate a significant pre-development load such that careful development of the site, without the use of BMPs, may satisfy the rpollutant removal standard. The concept of average land cover condition attempts to provide a balance in implementing the performance-based and technology-based water quality criteria regulations.

The following presents a brief discussion of the four development situations and the application of the performance based criteria:

Development Situation 1 describes new low density development with a percent imperious cover of less than the average land cover condition (16% Chesapeake Bay watershed default value or a watershed specific value pre-determined by the locality).

Note that the designation of the 16% impervious cover value is not intended to be a threshold for water quality compliance. Simply stated, a development with less than 16% impervious cover should be reviewed for the type and distribution of the impervious cover prior to determining that no water quality measures are required.

A low density development with scattered disconnected impervious cover (such as lots sized at 1 acre or more) can easily be considered to have negligible impacts on water quality if the clearing and grading is limited to the minimum needed to build the road and site the houses (other considerations such as maintaining the natural stream buffers, avoiding steep slopes, and minimizing wetland impacts and tree removal should also be evaluated).

Some low impact development (LID) strategies recommend the clustering of development and the associated impervious cover and preserving open space. This strategy allows the overall impervious cover to be kept low while allowing for the preservation of high priority open space such as stream buffers and unmanaged open space. However, the clustered development represents a significant source of increased runoff and pollutant load when directly connected to the drainage system. Guidance on mitigating these impacts within the LID strategy can be found in the references provided at the end of this chapter.

If, on the other hand, the development consists of commercial or industrial development and associated infrastructure (parking lots, roads, and other impervious surfaces), located on a sufficiently large parcel such that the total area of impervious cover is less than 16%, and the improvements include a directly connected drainage network, then water quality controls should be provided. This type of development poses a very difficult development situation to regulate using the performance-based water quality criteria since the overall percent impervious cover is low. Initial efforts to define the impervious cover as connected or disconnected led to very awkward and subjective regulatory language. Another option considered revising the definition of *percent impervious* to read "the impervious area divided by the drainage area within the site multiplied by 100." Again, various development situations were presented which led to subjective interpretations of these definitions. The preferred method of dealing with this issue was determined to be clear guidance on the intent of the 16% impervious cover "average land cover condition," and a case by case evaluation of the application of the performance-based water quality criteria.

When improvements on a site are concentrated such that the impervious area is collected and drained to a single receiving channel (connected impervious cover), it is reasonable to expect that the developed condition runoff will have an impact on the receiving system in terms of water quality impairments, regardless of the overall "site" percent imperviousness, and therefore should be considered in the water quality strategy. In such cases, DCR recommends that the percent impervious cover calculation be based on the drainage area being collected by the improved drainage system.

Development Situation 2 describes new development which results in impervious cover greater than the average land cover condition. The selection and location of a BMP to satisfy the pollutant removal requirement is verified using the Simple Method.

Development Situation 3 describes development of a site with existing development already present. This development situation is provided to help create an incentive for development, or "redevelopment" of existing infrastructure as opposed to developing a raw piece of land. Clearly redevelopment contains more challenges with regard to existing utilities, building locations, entrances, drainage systems, etc. The requirement of 10% reduction in calculated pollutant load from the site allows flexibility in siting a BMP at the most advantageous location with regard to existing site restrictions. If the amount of impervious surface does not change significantly, the designer has the choice of several BMPs to achieve the 10% reduction including the Manufactured BMP Systems (**Minimum Standard 3.15**) which can be easily located on an existing storm system.

Development situation 4 accounts for redevelopment where the existing development is served by an existing water quality BMP. This implies that the BMP was specifically designed to serve as a water quality BMP. In order for the existing BMP to satisfy the criteria it must be shown to have been designed and constructed properly and be in good working condition. New maintenance agreements may be necessary for continued operation of the BMP, as well as design enhancements, to ensure continued successful operation in the new development or redevelopment condition.

The performance-based water quality criteria allows the designer to locate the BMP at the most advantageous location on the site relative to the post-developed drainage divides, topography, etc, in order to meet the "pollutant removal" requirements of the four development situations. The pollutant removal requirements are based on the anticipated pollutant load from the site. Since a "site" may consist of several distinct drainage areas and discharge points, the designer must apply the removal efficiency of the BMP to the area draining to the BMP only. If this does not meet the removal requirement for the site, additional BMPs must be located in other drainage areas until the total pollutant removal satisfies the requirements, or a more efficient BMP should be selected. (All drainage discharges **are** subject to Erosion and Sediment Control Minimum Standard MS-19 - Channel Adequacy).

BMPs with the same pollutant removal mechanisms should not be located in series (runoff flowing from one BMP to the next) with removal efficiencies simply summed together. Consideration should be given to the form of pollutant which is targeted for removal. Sources cite that approximately 40% of phosphorus is bound to sediment or in particulate form. Thus BMPs added in series which serve to remove only particulates (settling) will not significantly increase the pollutant removal efficiency. While there may be some additional removal efficiency, the increase is certainly less than the algebraic sum of the two individual efficiencies.

The performance-based water quality criteria and calculation procedures should generally be applied to subdivision developments on a whole, and not to individual lots. This is not a contradiction to the previous discussion, however, there does appear to be a certain amount of judgement required to effectively comply with the intent of the water quality criteria. Many subdivision type developments can be effectively controlled with several BMPs serving individual lots or concentrated areas of impervious cover. The calculation procedure accounting for several BMPs may still be applied to the whole parcel or development in order to calculate the total pollutant removal achieved by the BMP strategy (the BMP strategy in this case includes multiple BMPs).

2. Technology-Based Water Quality Criteria

The selection of a BMP using the technology-based water quality criteria is based on the imperviousness and size of the drainage area. Review of **Table 2-3** reveals that each BMP is associated with a range of impervious cover. The development of a highly impervious land use such as an office park, in the range of 38 - 66% impervious cover, would indicate that an appropriate selection of BMP should be bio-retention basin or filter, extended detention-enhanced, retention basin II, or infiltration (or any of the BMPs listed for an imperviousness range of 67 - 100%).

Likewise the development of a low density subdivision in the range of 16 -21% imperviousness would indicate the selection of a vegetated filter strip or grassed swale (or any of the more efficient BMPs). The designer need only verify using the performance-based calculation procedure that the required removal efficiency would dictate a similar selection, thus indicating the equality of the two methodologies.

The difference in the two methodologies is the ability to incorporate a combination of BMPs using the performance-based criteria. Consider the just mentioned office park. If an extended detention-enhanced basin is selected, yet does not capture the runoff from the entire site to the effect that the calculated pollutant removal of the BMP does not satisfy the site or planning area pollutant removal requirement, then an additional BMP or a more efficient BMP must be designed.

Consider, as part of the office park, a two acre parking area along the edge of the office park which does not drain to the extended detention-enhanced facility. The designer may choose to incorporate a grassed swale with check dams to control the two acre drainage area. Since the two acre drainage area is almost entirely impervious, strict application of the technology-based criteria would preclude the use of anything but the most efficient BMPs (sand filter, infiltration, etc.) The performance-based criteria, on the other hand, allows for a total pollutant removal to be calculated to measure the combined effectiveness of the more efficient extended detention-enhanced facility on the majority of the site along with the lower efficiency grassed swale serving the small portion of the site.

The use of sound judgement in the application of multiple BMPs should dictate. If the designer is using the technology approach to control a majority of the site, and proposes a less efficient BMP to control the small area draining in the other direction, the requirement to calculate the total site pollutant removal using the performance-based calculation procedure is at the discretion of the plan approving authority. On the other hand, if a portion of the development site is being left uncontrolled, the plan approving authority may certainly require the performance-based calculation procedure to verify compliance.

Several examples will be provided by DCR as guidance in these types of review decisions.

2-4 REGIONAL STORMWATER MANAGEMENT PLANS

The development of a regional stormwater management plan allows a local government to strategically locate stormwater facilities to provide the most efficient control of localized flooding, stream channel erosion, and water quality. In addition, a regional plan provides the added benefit of mitigating the impacts of existing development to allow for restoration of urbanized stream systems.

The objective of a regional stormwater management plan is to address the stormwater management concerns in a given watershed with greater economy and efficiency by installing regional stormwater management facilities versus individual, site-specific facilities. The result will be fewer stormwater management facilities to design, build and maintain in the affected watershed. It is also anticipated that regional stormwater management facilities will not only help mitigate the impacts of new development, buy may also provide for the remediation of erosion, flooding or water quality problems caused by existing development within the given watershed.

If developed, a regional plan shall, at a minimum, address the following:

1. The specific stormwater management issues within the targeted watershed.
2. The technical criteria in 4VAC3-20-50 through 4 VAC 3-20-85 as needed based on number 1 above.
3. The implications of any local comprehensive plans, zoning requirements and other planning documents.
4. Opportunities for financing a watershed plan through cost sharing with neighboring agencies or localities, implementation of regional stormwater utility fees, etc.
5. Maintenance of the selected stormwater management facilities.
6. Future expansion of the selected stormwater management facilities in the event that development exceeds the anticipated level.

The benefits of regional stormwater management plans are well documented by those localities which have implemented them. Likewise, adverse impacts are also documented. The debate over the merits of regional facilities versus the impacts is different in each watershed. The following provides a list of some of the more common issues frequently surrounding the decision making process. Future guidance, in conjunction with the Corps of Engineers and the Department of Environmental Quality, will be provided by DCR.

Asserted problems with on-site facilities:

1. Not as efficient at pollutant removal as larger facilities.

2. More land is disturbed because of need for a number of smaller facilities; an additional 5 to 10 acres will not be available for development out of every 1, 000 acres served by stormwater management facilities.

3. Not well maintained, reducing pollutant removal efficiency.
