4. More complicated for localities to maintain a large number of small facilities.

5. Access may be more difficult.

6. Do not typically have maintenance features such as forebays, access roads, and sediment disposal areas. Difficulty in access and maintenance often results in maintenance responsibility being shifted to homeowner's associations, which experience has shown, are not generally capable of coordinating the public works function required to effectively maintain stormwater management facilities. Uncertainty of maintenance puts long- term reliability of the facility in question.

7. Pose a greater public safety hazard.

8. Have more potential to become "eyesores."

9. Can only be sited to address stormwater discharges from future development since they are implemented for individual development projects only.

10. More expensive.

11. May result in a haphazard siting pattern for stormwater management facilities; with only limited control of down stream erosion and flooding.

Asserted benefits of regional facilities:

1. More efficient and ensure the highest possible efficiencies for the entire watershed, rather than one small site.

2. Offer the ability to control temperature of outflow which is not possible with small facilities.

3. Can be strategically located within a watershed and designed for coincident stormwater releases,

resulting in a coordinated system of controls.[1]

4. Can be located to control some existing, as well as future, development and can compensate for pre-existing development that does not have adequate (or any) stormwater control to help reduce stream bank erosion and negative impacts to downstream floodplains and wetlands.

5. More likely to be adequately maintained.

6. Lower lifetime maintenance cost; more easily accessed and maintained.

7. Provide a recreational amenity.

Asserted adverse consequences that may result from regional facilities:

1. Reaches of a stream above an instream facility receive untreated stormwater containing a variety of pollutants that adversely impact water quality and stream habitat.

2. Upstream inundation from the pond's impounded water destroys floodplains, wetlands and stream habitats.

3. Changes in water depth and frequency and duration of flooding can change the plant communities above and below the pond.

4. Wet ponds block the passage of fish and other aquatic life that normally move up and down the stream and disrupt the downstream movement of food particles, which are the base of the food chain for stream ecosystems.

5. The hydrologic change caused by the impoundment will eliminate species that thrive on flowing stream conditions, but cannot tolerate ponded conditions.

6. Water temperature increases in the pond, as well as downstream, due to incoming runoff can eliminate certain species of fish and aquatic insects.

7. Are more likely to be located in and adversely impact wetlands.

8. Large regional facilities are more difficult to administer because the locality must (1) prepare

[1] Peak flow reductions are only localized in nature because of several factors: The small drainage area controlled by each facility; the extended duration over which the facility releases stormwater flows; the relatively high peak release rates from the on-site facilities (compared to regional facilities which can be sized to achieve release rates that are much less than pre-development conditions); and interactions among releases from on-site facilities which are not coordinated.

a master plan specifying the sites and design criteria, (2) implement a phased construction program so that facilities are in place when new development occurs, and (3) recover pro-rata charges from new development or establish a stormwater utility with which to offset the costs for the regional facilities.

2-5 COMPREHENSIVE WATERSHED MANAGEMENT

The 1994 General Assembly passed Senate Joint Resolution (SJR) No. 44 which allowed for the continued study of the efficiency and consistency of the stormwater management and permitting policies of the Commonwealth. The resolution included, among other elements, the study of approaches to watershed management of stormwater. The following incorporates the findings of the Technical Task Force of the SJR 44 Joint Study Committee.

A comprehensive watershed management plan is the result of studying the environmental and land use features of a watershed to identify those areas that should be protected and preserved and stormwater management measures and design criteria to be utilized to protect such areas so that development, when it does occur, will not negatively impact water resources. In so doing, watershed planning uses and protects ecological processes to lessen the need for structural control methods that require capital costs and maintenance. By including consideration of the watershed and its characteristics, cumulative impacts and inter-jurisdictional issues are more effectively managed than when solely relying on a single site permit approach. Watershed planning can be an important tool for maintaining environmental integrity and economic development.

The Stormwater Management Act (§10.1 - 603.1 et. seq. of the Code of Virginia) enables localities to adopt more stringent stormwater management criteria than those promulgated in the Stormwater Management Regulations (4VAC3-20), provided that the more stringent regulations are based upon the findings of local comprehensive watershed management studies.

Historically, a watershed or regional plan simply focused on the implementation of regional stormwater management facilities within a designated watershed. As our understanding of the dynamic relationship between development and water resources grows, so should the goals of a watershed plan. A watershed plan should provide:

- guidance as to the areas and resources to avoid and protect,
- development guidelines to minimize the impacts of new development on water resources,
- identification of retrofit opportunities such as BMP retrofits, stream restoration, etc. to mitigate impacts resulting from existing development, and
- appropriate stormwater management options (structural and non-structural) including design criteria and locations.

To accomplish these goals, a watershed plan should consist of three components: **Inventory, Planning, and Implementation.**

These three components include the following:

A. Inventory

1. **Define the watershed boundary.**
2. **Conduct a watershed inventory of natural resource features** (wetlands, floodplains, stream corridors, greenways, rare and endangered species, steep slopes, erodible soils, karst bedrock areas, sensitive habitats, fish and wildlife resources, recreational areas, sources of water supply).
3. **Conduct a stream inventory** (size, order, water and habitat quality, flow regime).
4. **Identify significant environmental features in neighboring watersheds** (large pollution sources, wildlife refuges, sources of water supply).
5. **Identify and quantify existing sources of point and nonpoint source pollution.**
6. **Model the existing hydrology and hydraulics of the watershed** (understand the impact of land use, conveyances, land cover, stormwater management facilities, stream cross sections, roadway crossings, flooding and drainage problems).

B. Planning

1. **Define the goals of the watershed management plan** (what is envisioned for the watershed and who is going to lead the implementation efforts).
2. **Identify and quantify future sources of point and nonpoint source pollution.**
3. **Model the future hydrology and hydraulics of the watershed.**
4. **Develop and evaluate alternatives to meet the goals and manage water quality** (point and nonpoint source pollution) **and quantity** (hydrology and hydraulics).
5. **Identify opportunities to restore natural resources.**
6. **Develop the watershed management plan** (include specific recommendations on development and land use evaluation, selection of structural and non-structural BMPs, public education needs, regulatory requirements, and funding).

C. Implementation

1. **Identify the stakeholders responsible for developing, implementing and updating the plan to ensure long-term accountability.**
2. **Define the implementation costs** (capital costs and annual administrative, operations and maintenance costs) **and who will pay for the implementation of the watershed management plan** (provide incentives and secure commitments).
3. **Develop a watershed monitoring program.**
4. **Develop an evaluation and revision process for the watershed management plan.**
5. **Establish and implementation schedule.**

The process described in the following sections is based on the above mentioned steps and can be used to develop a watershed management plan for any watershed. The amount of effort expended on each step depends on the specific goals of the project, the data available, and the people involved in preparing and implementing the plan. Some of the steps need to be conducted concurrently to facilitate a successful implementation of the plan.

2-5.1 Inventory of Watershed Characteristics

The inventory of the watershed characteristics will serve as the basis for the design and location of BMPs at the regional (watershed) level and flood/erosion controls. The inventory data will be integrated with information from the planning and implementation components to develop the watershed management plan.

1. Define the Watershed Boundary

In order to develop a meaningful and implementable watershed management plan, an appropriate watershed or subwatershed needs to be selected. Watershed plans often end up on the shelf because the size of the watershed was too large (greater than 60 square miles) and the focus of the plans became too fuzzy (Center for Watershed Protection, 1996). In addition, the impacts of different land uses on the watershed hydrology, stream health and water quality is difficult to evaluate, unless very detailed models are developed.

Municipalities can be subdivided into watersheds or subwatersheds ranging from 2 to 20 square miles in drainage area. When these watershed or subwatersheds extend beyond the municipality's corporate limits, efforts should be made to develop memoranda of understanding with adjacent jurisdictions to facilitate and promote implementation of watershed management plans. Once the watershed or subwatersheds are delineated, the municipality can prioritize the development of watershed management plans based on local needs and water quality and quantity criteria.

2. Conduct a Watershed Inventory of Natural Resource Features

Successful implementation of a watershed management plan will also depend on the ability to obtain the appropriate permits from state and federal agencies. An inventory of natural resource features in the watershed will promote the development of a BMP siting approach that minimizes or avoids impacts on environmental resources to the maximum extent practicable. This BMP siting approach will facilitate permitting.

The natural resource features to be inventoried would depend on the characteristics of the watershed being studied and could include:

- Wetlands
- Floodplains
- Stream corridors and greenways
- Steep slopes
- Erodible soils
- Karst bedrock areas
- Rare and endangered species
- Sensitive habitats
- Cultural resources
- Fish and wildlife resources
- Recreational areas
- Sources of water supply

Wetlands

Wetlands provide unique habitats for both plants and wildlife, including many threatened and endangered species. As a consequence, wetlands are valued for aesthetic and recreational reasons. Wetlands also provide valuable flood storage, groundwater recharge, and pollutant-filtering functions.

Wetlands are widely scattered throughout Virginia and commonly are encountered on development sites and throughout watersheds. Protecting the natural functions of wetlands is a critical element of the site development process and watershed management planning. For moderate- to high-quality wetlands, which are very difficult to replace, avoidance is recommended. If the watershed contains scattered, small, low-quality wetlands, which are more readily replaced, mitigating the wetlands at a central location may be more appropriate, thereby enhancing wetland functions and reducing a potential constraint to development. Early coordination with resource agencies is recommended.

Floodplains and Stream Corridors

Floodplains and stream corridors include waterways and adjacent riparian lands that may be subject to flooding. Natural waterways provide habitat for fish, aquatic plants, and benthic (bottom dwelling) organisms. Development in waterways may destroy aquatic organisms and introduce large loads of sediment and pollutants into the waterways. Modifying waterways to accommodate development also may destroy the physical features essential to a good habitat, including: stable stream banks and bottom substrates, pools and riffles, meanders, and spawning areas.

Vegetated riparian land adjacent to streams stabilizes the stream bank, filters pollutants from storms and floods, and provides habitats for a variety of amphibians, aquatic birds, and mammals that depend on the proximity to water for their life functions. Development in floodplains and riparian corridors can impair the functions and subject structures to damage from flooding and the meandering of natural streams.

A filter strip or riparian-forested buffer should be preserved or created along the banks of streams, where possible. Furthermore, consideration should be given to establishing setbacks for intensive development (e.g., buildings, parking lots, roadways). This will minimize the potential for sediment releases to the streams, as well as maintain the corridor to achieve flood control, water quality, and habitat enhancement objectives. If a development site contains a highly channelized stream, the best interest of both the developer and the aquatic resource may be served by restoring the stream corridor.

Shorelines of ponds, lakes, and wetlands provide many of the same functions as riparian stream corridors provide for streams. Stable vegetated shorelines are particularly valuable in preventing erosion caused by wave action. Protection of shorelines should be considered when developing water dependent development, such as piers and marinas (CH2M HILL, 1998).

Steep Slopes and Highly Erodible Soils

From an erodibility standpoint, the definition of steep can vary depending on surface soil type and underlying geology. In general, extra caution is warranted on a slope exceeding 10 percent (1 foot of vertical drop per 10 feet of horizontal distance). However, even flatter slopes that have soil classified as highly erodible should be identified as steep.

Disturbing steep slopes with development causes instability of the soil on the slopes. Inappropriate development destroys vegetation, root systems, and soil structures. High runoff velocities from exposed steep slopes result in destructive and unsightly erosion, denuded slopes that may be difficult to revegetate, and sediment deposition in sensitive areas both on and off the site.

A general rule to be followed in site development is to minimize the area and time of disturbance and to fit the development to the natural terrain. Stabilizing vegetation should be protected to the maximum extent practicable and disturbed areas should be immediately revegetated. Extending this general rule to the entire watershed will promote preservation of natural resource features.

Karst Bedrock Areas

Karst bedrock areas are underlain by bedrock containing soluble minerals. Karst areas develop voids and solution channels as groundwater gradually dissolves the bedrock. In these terrains groundwater flow can be extremely rapid and unpredictable. Furthermore, the concentration of runoff may stimulate the formation of sinkholes. Sinkholes can develop as flowing water exposes and then washes into the mouths of the near surface openings of subterrain channels and caverns. Rapid degradation of groundwater resources can result when sediment or pollutant laden runoff percolates into karst bedrock aquifers.

Several areas of Virginia are underlain by limestone, dolomite, or marl carbonate rocks which are potentially susceptible to the development of karst conditions. Before introducing site alterations that could concentrate or pond runoff, the presence or absence of carbonate bedrock should be established. If carbonate rocks do occur a professional geologist or civil engineer should be consulted to determine whether sink hole activity is likely. The United States Geological Survey is a good source of information on karst bedrock in Virginia. If an area is prone to sink hole development, site drainage should be planned to minimize the concentration of runoff. This can be accomplished by reducing the hydraulic connectivity of impervious surfaces and by the use of filter strips. Where they are required, channels or ponds should be lined.

Certain BMPs can be used in karst areas to provide infiltration opportunities over a very large area. Examples are filter strips, large bioretention facilities, and permeable pavement. These practices mimic the natural process by which rainfall enters the subsurface. Point sources of infiltration, such infiltration trenches or dry wells should be avoided (CH2M HILL, 1998).

Threatened and Endangered Species

Existing information can be obtained from surveys conducted by the Division of Natural Heritage (DNH) of the Virginia Department of Conservation and Recreation. For portions of the watershed that have not been previously surveyed, DNH's Element List can be compared to plant community information derived from previous investigations in the watershed, as well as from wetlands identification efforts. The inventory should include a list of potential threatened or endangered species.

Cultural Resources

Existing information can be obtained from the Virginia Department of Historic Resources. For potential regional (watershed) BMP sites, background research to characterize the cultural resource potential of the project area can be conducted. This research will provide a historic context for evaluating any cultural resources that might be located in the project area.

Fish and Wildlife Resources

Existing information can be obtained from the Virginia Department of Game and Inland Fisheries. This information will be useful when defining watershed goals and selecting BMPs to protect sensitive areas. In addition, fish can be a good indicator of stream health and can be used during the evaluation of effectiveness of the watershed management plan, as part of a watershed monitoring program.

Recreational Areas and Sources of Water Supply

An inventory of recreational areas and sources of water supply will also facilitate, and in some cases mandate, the goals of the watershed. This information will also be important in the selection of models that will be needed to identify sources of pollution, understand the hydrologic and hydraulic characteristics of the watershed, and evaluate alternatives to meet the watershed goals and manage water quality.

3. Conduct a Stream Inventory

Classifying the stream system within a watershed will further the understanding of its characteristics and will provide a framework for evaluating alternatives. Streams within a watershed can be inventoried based on size, order, water and habitat quality, or flow regime.

4. Identify significant environmental features in neighboring watersheds

Each subwatershed is nested within many larger watersheds. Therefore, watershed management plans for smaller watershed have to be developed within the context of the larger watershed in which they are located. Once the larger and neighboring watersheds are identified, the goals of those watersheds can be incorporated in the watershed management plan. Some of the goals that typically are incorporated in local watershed management plans include nutrient and toxic targets, such as the Tributary Strategy targets, water supply, flood protection, and waste water requirements or effluent limits (Center for Watershed Protection, 1996). In addition, large pollution sources, wildlife refuges, and sources of water supply in neighboring watersheds may also provide additional goals for the watershed management plan.

5. Identify and Quantify Existing Sources of Point and Nonpoint Source Pollution

Existing information on point sources of pollution can be obtained from the Virginia Department of Environmental Quality (DEQ). Typically, the NPDES permits for point sources will also include some monitoring requirements that can provide additional information for the watershed management efforts. Nonpoint source data can be obtained from DCR and from the local Soil and Water Conservation Districts. The local public works or engineering office can also be good sources of information on previous studies and monitoring efforts.

Watershed models are tools used to understand the cause-and-effect relationships within a watershed. Specifically, water quality models provide information on pollutant loads (from point and nonpoint sources) and their movement throughout the watershed.

Model selection is a function of the following variables:

- The goals and objectives of the watershed management plan
- The data available to describe the hydrologic and hydraulic characteristics and water quality problems in the watershed
- The regulatory requirements and other watershed specific environmental and water quality issues (including time and space scales of the issues or problems)
- The resources (cost, time, hardware and software, modeling expertise, funds) available for applying the model and implementing the recommendations developed with the model

The objectives of the model application for a watershed management plan may range from simple screening of environmental problems that require minimum data input to detailed analysis of water quantity and quality in the watershed. Detailed analysis requires more input data and usually provides information needed for the design of a specific project or for the analysis and solution of specific environmental problems. Detailed analyses are used to represent the watershed processes that affect pollution generation. However, it is not always true that detailed analyses, based on sophisticated models, provide the most accurate representation of the watershed and its environmental problems; it is best to use the least complicated model that will produce the results for appropriate decision making.

Model selection also depends significantly on the data available in the watershed. The precision of the model predictions is affected by dynamic and transient conditions, high spatial variability (mainly related to rainfall variability and land use), and differences in event conditions (such as antecedent moisture conditions, infiltration potential, local pipe or stream conditions, etc.). The data availability and the simulation complexities affect model selection by tempering the decision towards acceptance of a model that is accurate but not as precise as other more sophisticated models.
In addition to data availability issues, monitoring data and watershed responses can be highly variable. Selecting a simpler model, and accepting results that are not as precise as desired but remain accurate, is an appropriate strategy.

6. Model the Existing Hydrology and Hydraulics of the Watershed

The model selection strategy presented in the previous section also applies to hydrologic and hydraulic models.

Hydrologic models provide information on the amount of runoff that will reach the outlet of the watershed and any receiving waters. Hydraulic models estimate water surface elevations and velocities of surface water. These models are also used to characterize the drainage system in the watershed. Groundwater models represent the movement of groundwater.

The focus of the modeling of the existing characteristics of the watershed is to develop baseline information that will be used to evaluate BMP siting and sizing alternatives for meeting the watershed goals and solving drainage and flooding problems. The hydrologic and hydraulic models will also facilitate the understanding of the impact of land use, conveyances, land cover, stormwater management facilities, stream cross sections, roadway crossings, and flooding and drainage problems.

Accurate land use data will ensure accurate modeling results. Developing an updating land use and impervious cover information will facilitate the implementation of the watershed plan.

2-5.2 Planning and Developing the Watershed Management Plan

This second component will define the goals for the watershed management plan; will model future characteristics of the watershed; will develop alternatives to restore resources and meet the goals, including BMPs at the regional (watershed) level; and will produce the watershed management plan. The inventory data developed in the first component will be used as part of the decision-making process illustrated in this component.

1. Define the Goals of the Watershed Management Plan

The first step of the planning component is to define the goals that are most important to the watershed to be protected and to the stakeholder group that will be defined as part of the third component, implementation. As previously mentioned, some of the steps of the three components (inventory, planning, and implementation) need to be conducted concurrently.

A stakeholder group beginning a watershed effort needs to determine what it wants to accomplish and how it wants to use the water body being protected (water quality enhancements and quantity control). The clearer the goals, the easier it is to track progress towards meeting those goals. The goals tend to become clearer as the stakeholders proceed in their efforts. Therefore, the planning process should allow for a systematic re-evaluation of the goals at least every 3 to 5 years.

If possible, express the goals of the watershed management plan in terms of the condition of the waterbody relative to its beneficial uses, not in terms of achieving a certain level of pollutant reduction or applying a certain technology.

2. Identify and Quantify Future Sources of Point and Nonpoint Source Pollution

This step involves using the water quality models developed in the inventory component (**Section 2-5.1, step 5**) and modifying them to include future development conditions in the watershed. It is important to use future land-use information from the comprehensive plan of the municipality and any amendments or recent rezoning cases.

3. Model the Future Hydrology and Hydraulics of the Watershed

This step involves using the hydrologic and hydraulic models described in the inventory component (**Section 2-5.1, step 5**) and modifying them to include future development conditions in the watershed. It is important to use future-land use information from the comprehensive plan of the municipality and any amendments or recent rezoning cases.

4. Develop and Evaluate Alternatives to Meet the Goals and Manage Water Quality and Quantity

In order to meet the watershed goals and to solve the watershed's problems effectively, the watershed master plan should consider all feasible alternatives. These alternatives will manage water quantity and quality in the watershed. Therefore, the alternatives will address flooding, drainage, erosion, and stormwater pollution problems.

Generally, alternative solutions mitigate **flooding and drainage damages** by providing additional storage of flows, by increasing the conveyance capacity of the drainage and stream system, or by floodproofing structures at risk of flooding. Alternative solutions mitigate **erosion damages** by stabilizing stream banks using non-erosive materials and/or by redefining the meandering pattern and using the channel and floodplain to dissipate the flow energy. Alternative solutions mitigate **stormwater pollution** problems by providing structural and non-structural BMPs.

Alternatives should be evaluated by using the existing and future condition models and the information from the inventory component described in **Section 2-5.1**. A map of the watershed showing the recommended alternatives should be prepared and distributed to all stakeholders.

Each alternative, or combination of alternatives, also could be evaluated according to screening criteria that address technical, practical, environmental, economic, and political feasibility. Alternatives can be investigated in detail when they appeared to have potential to be cost-effective and satisfy all project criteria.

Selecting sites for regional (watershed-level) BMPs or flood/erosion controls involves balancing pollutant removal, runoff attenuation, environmental permitting constraints, and cost issues. The following is a typical sequence of the iterative process to be completed for each of the potential sites:

A. Identify potential regional BMP sites and sites for flood/erosion controls.

B. Field screen the sites taking into account the following:
   - drainage area
   - topography
   - existing development and projected future development
   - access and construction issues
   - wetlands constraints
   - other regulatory constraints
   - land ownership/value issues

C. Use the previously described watershed models to analyze pollutant reduction (phosphorous and total suspended solids management), flood/erosion control, and resource protection.

D. Use the inventory and models to identify performance standards for the selection, design, and location of BMPs and for the establishment of erosion, sedimentation, and flood control requirements.

5. Identify Opportunities to Restore Natural Resources

Protecting natural resources and drainage features, particularly vegetated drainage swales and channels, is desirable because of their ability to infiltrate and attenuate flows and to filter pollutants. However, this goal is often not accomplished in most developments. In fact, commonly held drainage philosophy encourages just the opposite pattern. Streets and adjacent storm sewers typically are located in the natural headwater valleys and swales, thereby replacing natural drainage functions with a completely impervious system. Runoff and pollutants generated from impervious surfaces flow directly into storm sewers with no opportunity for attenuation, infiltration, or filtration.
One method of preserving natural drainage features is to use *cluster development* to avoid disturbing major swales. Another recommended approach is to develop site plans that keep roads and parking areas higher in the landscape and *locate existing swales along back lot lines* within drainage easements.

6. Develop the Watershed Management Plan

The watershed management plan will integrate and summarize the different steps described in **Sections 2.5.1** and **2-5.2**. The plan needs to be succinct and simple to ensure that people read it. The plan needs to address the goals and problems of the watershed and should provide recommendations that are specific and implementable. Finally, the plan should include a budget and an implementation schedule, as described in **Section 2-5.3**, below.

2-5.3 Implementation of the Watershed Management Plan

A watershed management plan is effective if it is implemented. Implementation depends on the level of buy-in of the plan from the stakeholders. Stakeholders will remain interested if they are involved from the beginning and they have ways of monitoring the success of the plan.

1. Identify the stakeholders responsible for developing, implementing and updating the plan

Assemble stakeholders who are most affected early in the process. Specifically include those who use, impact and regulate the affected waterbody, and allow them to shape key decisions. Early and effective stakeholder involvement will ensure long-term accountability.

2. **Define the implementation costs and who will pay for the implementation of the watershed management plan**

Use uniform and consistent procedures to estimate project costs for the alternatives developed to solve the problems in each watershed. The cost should include capital costs and annual administrative, operations and maintenance costs for all the elements of the plan.

Identify the funding sources for implementation of the watershed management plan. Below is a summary of the possible funding sources:

- General obligation and revenue bonds
- Stormwater utility fees
- Land development fees
- Pro-rata share contributions
- General fund resources
- Loans and grant programs
- Special service districts and watershed improvement districts

3. **Develop a watershed monitoring program**

Develop a monitoring program that enables the stakeholders to objectively measure and track indicators of the watershed management plan's success. The indicators should focus on water quantity and quality issues, programmatic and socioeconomic needs, and physical and hydrologic measures.

Stormwater chemistry is fairly well understood. Therefore, chemical monitoring of stormwater outfalls will not necessarily provide valuable data. On the other hand, physical and biological monitoring and selected long-term stream monitoring stations will provide valuable information to "measure" the successful implementation of the watershed plan. If success is not achieved, the monitoring program will provide the data to make revisions to the plan. The monitoring program also will provide information to re-evaluate the watershed goals and the implementation schedule.

4. **Develop an evaluation and revision process for the watershed management plan**

During the implementation of the watershed management plan, it is likely that at least one of the following problems will occur:

- Monitoring indicates that the wrong problem is being solved.
- Solving one problem unmasks another problem that is more difficult to control.
- The program reaches some program or activity goals but may not be effective enough to reach the water

quality goals.

- Quantifiable objectives (e.g., pollutant load reduction or flood protection for specific storms) were set too low to solve the problem.

These unpleasant realizations typically occur because of data gaps during the development of the plan. Therefore, the watershed plan needs to include evaluation periods where aspects of the program can be revised if necessary. Watershed plan evaluations can take place every 3 to 5 years.

5. Establish and implementation schedule

Each of the steps presented in the previous sections represent groups of specific activities that make up the watershed plan. Because of the complex and developing nature of the plan, the implementation of the individual steps will occur over differing time frames and will not necessarily follow in a linear sequence but rather be in a parallel sequence.

Some activities need to be implemented quickly to ensure protection of the watershed others will take more time. Therefore, an implementation schedule typically includes a combination of immediate, short-term, and longer-term actions.

Implementation schedules need to be updated and distributed to all stakeholders regularly.

MINIMUM STANDARD 3.01

EARTHEN EMBANKMENT

Definition

An earthen embankment is a raised impounding structure made from compacted soil.

Purpose

The purpose of an earthen embankment is to impound stormwater runoff.

Conditions Where Practice Applies

An earthen embankment is appropriate for use with infiltration, detention, extended-detention or retention facilities.

The design procedures presented in this section **may not** apply to small embankments or to storm drainage outfall structures with less than 3 feet of embankment height. The review and approval of such structures should be based on sound engineering practices and supporting calculations that verify a stable outfall for the 10-year storm, at a minimum.

Similarly, this section **does not** apply to embankments with a height of 25 feet or more and a maximum storage capacity of 50 acre-feet or more, as measured from the top of the embankment. Such structures may be regulated under the Virginia Dam Safety Act and the Virginia Dam Safety Regulations (VR 625-01-00).

The *height of an earthen embankment* is the vertical distance from the natural bed of the stream or watercourse, measured at the downstream toe of the embankment, to the top of the embankment. If the embankment does not span a stream or watercourse, the height is the vertical distance between the lowest elevation, measured at the outside limit of the embankment, and the top of the embankment.

Planning Considerations

Earthen embankments are complex structures that must be designed and constructed with consideration given to the following: a) *specific site and foundation conditions*, b) *construction material characteristics*, c) *purpose of the impoundment*, and d) *hazard potential associated with the particular site and/or impoundment*.

The *hazard potential* associated with an impoundment is defined in the Virginia Dam Safety Regulations. It is based on the potential for loss of life and/or economic loss due to facility failure. While stormwater management embankments are typically much smaller than those regulated under the Virginia Dam Safety Program, the potential for significant property damage and loss of life may still be present. The engineer is responsible for analyzing potential downstream impacts and for determining if more stringent analyses are required. **Minimum** guidelines for those facilities **not covered** under Virginia's Dam Safety Regulations are provided in this handbook.

Embankment Types

The type of embankment selected will depend on the purpose of the stormwater facility (detention, extended-detention, retention, etc.) and the available soil material for construction. The two general types are listed below:

1. A *homogeneous embankment* is composed of one kind of material (excluding slope protection). The material used must be sufficiently impervious to provide an adequate water barrier, and the slopes must be moderately flat for stability and ease of maintenance (see **Figure 3.01-1a**).

2. A *zoned embankment* contains a central impervious core, flanked by zones of more pervious material, called shells. These pervious zones or shells enclose, support, and protect the impervious core. Typically, a zoned embankment requires an internal drain, or filter, between the impervious zone and the downstream shell and between the shell and the foundation (see **Figure 3.01-1b**.

Soils Investigation

A soils investigation, or geotechnical study, should be completed before designing any earthen embankment covered in this section. The scope of such a study will vary from site to site based upon the size of each project. Recommended minimum guidelines for a geotechnical study are provided below. Refer to U.S. Department of Interior (USDI), Design of Small Dams, latest edition, for additional information.

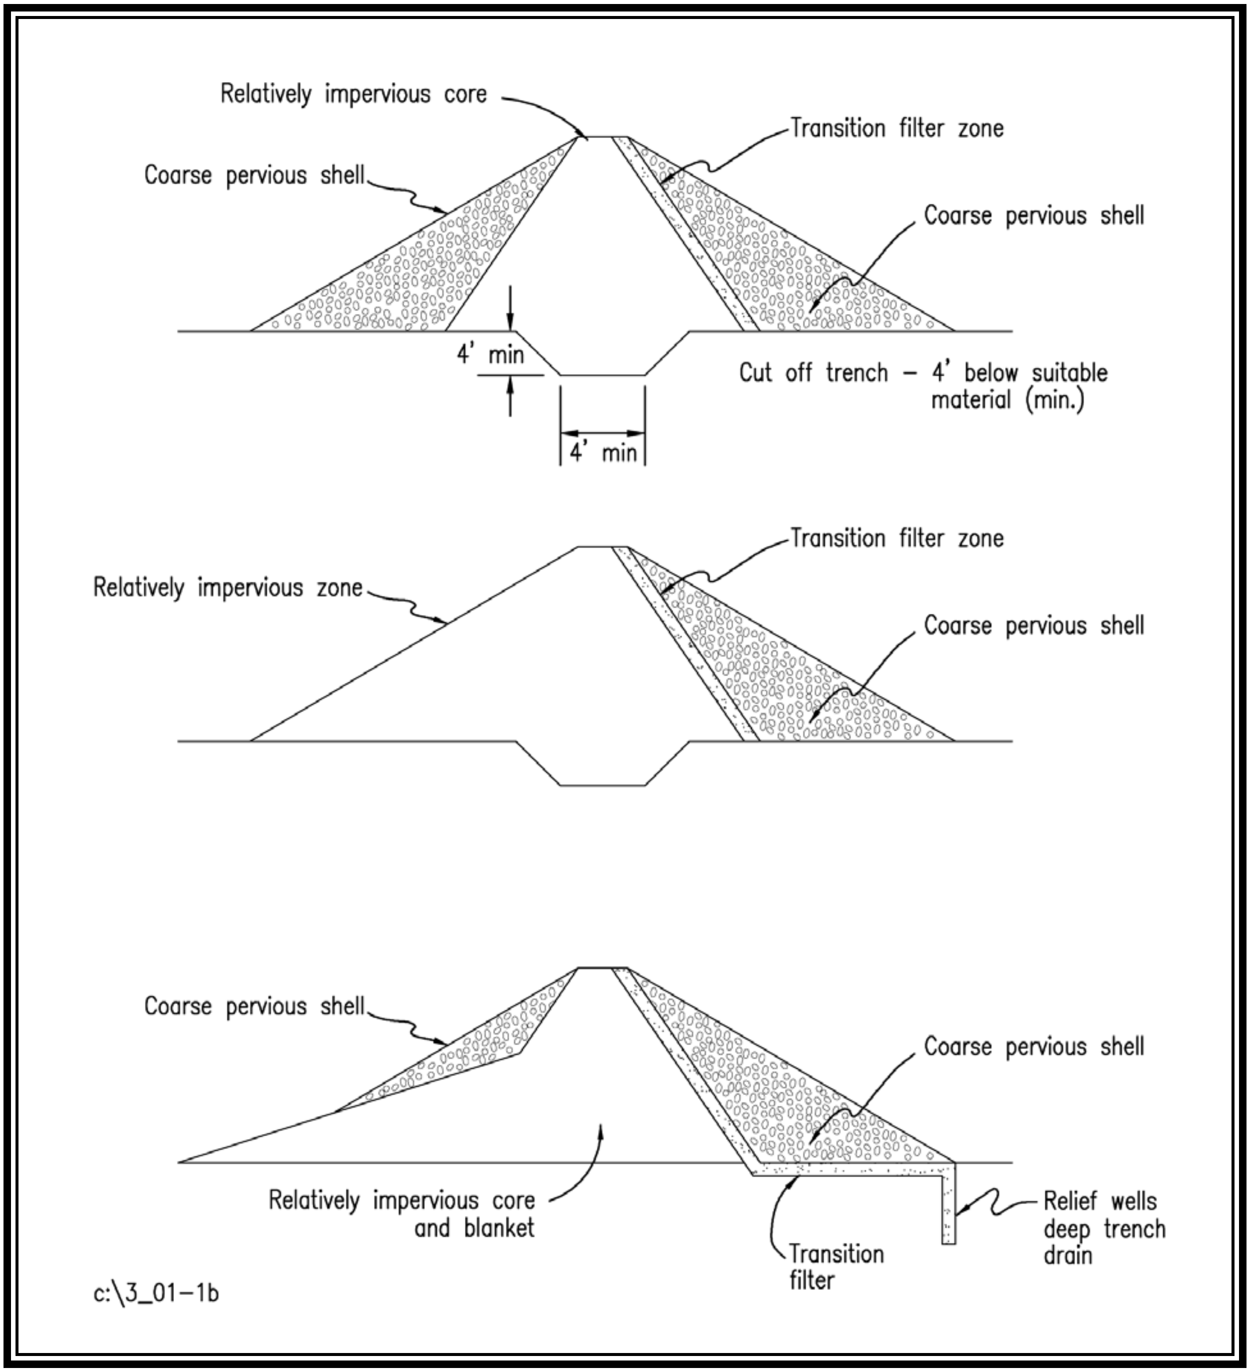
Zoned Embankment



Geotechnical Guidelines

The following discussion presents minimum recommended criteria for the planning and design of earthen embankments. The designer is responsible for determining which of the guidelines are applicable to the specific project and for determining if any additional investigations are required.

The validity of the design depends on the thoroughness of the site investigation, the adequacy of the testing program, and the soundness of the designer's judgment. Design components based on quantitative soil tests, such as analyses of slope stability, seepage, and settlement, are not discussed herein, but they are necessary to design large dams. Such analyses will logically follow the selection of a preliminary design. Even for small earth dams that have a low hazard potential, the following criteria should be considered in a geotechnical report.

A geotechnical engineering study should evaluate the stability of the proposed embankment.

A geotechnical engineering study should consist of 1) *a site investigation*, 2) *laboratory testing*, and 3) *an engineering analysis*.

1. A field investigation should include the review of available soils information and a subsurface exploration. Test borings, test pits, or both, should be used to evaluate the foundations, abutments, borrow materials, reservoir area, embankment design and any other pertinent geological considerations. In areas underlain by Karst limestone, a subsurface profile using seismic or sonar technology should be considered to verify that subsurface anomalies do not exist. This type of subsurface investigation may also be recommended in areas known to have been previously mined for mineral extractions.

2. Laboratory testing should be completed to evaluate the various soils. At a minimum, an *index property test* should be completed to classify the soils following the Unified Soil Classification System. Shear strength, compressibility, and permeability testing may be required depending upon the size and complexity of the embankment and the nature of the site's subsurface conditions.

3. A geotechnical engineer should do an engineering analysis and present his or her findings, recommendations and comments on items such as: foundation materials and preparation; design of interior drainage features and filters; and geotechnical design of conduits/structures through the embankment, including seepage and stability analyses. The engineer should also provide a summary describing the soil types and rock strata encountered and explaining the laboratory tests and their results.

Stream Diversions

The design of some earthen embankments will require provisions for stream diversions around or through the embankment site during construction. A stream diversion can be accomplished by a variety of acceptable means, including open channels, conduits, coffer dams, and pumping. Occasionally, stream diversions may be required to meet additional requirements and/or to be permitted by agencies such as the U.S. Army Corps of Engineers, the Virginia Department of Environmental Quality, and/or the Virginia Marine Resources Commission. Refer to the Virginia Erosion and Sediment Control Handbook (VESCH), 1992 edition, for additional guidance on stream diversions.

Design Criteria

To establish *design water surface elevations* and *spillway capacity* for earthen embankments, various hydrologic design methods and spillway storm frequencies may be used. Factors that affect their selection include: a) *the purpose of the stormwater facility: flood control, water quality enhancement, and/or channel erosion control,* b) *the contributing watershed size,* and c) *local regulations*. Despite the design method selected or the frequency storm is used, **the embankment should always be analyzed to ensure safe passage of the maximum spillway design storm while maintaining its structural integrity and stability**. Furthermore, the embankment height should be set such that runoff from the spillway design storm can safely pass through one of the following spillways without overtopping the embankment:

- a natural or constructed spillway,
- a principal spillway, or
- a combination of a principal spillway and an emergency spillway.

Hydrologic and hydraulic methods are described in **Chapters 4** and **5**, respectively.

Local ordinances or watershed conditions may require a more stringent analysis of the embankment concerning overtopping or spillway capacity. The Soil Conservation Service's (SCS) National Engineering Handbook and the Virginia Dam Safety Regulations provide a classification of dams based on the *potential hazard* from failure. A dam failure analysis, or *breach analysis*, may be required to learn the extent of the potential hazard. Any dam breach analysis should use a method similar to the Army Corps of Engineers, SCS (TR-60), National Weather Service, or that specified by the local authority.

Embankment Stability

An earthen embankment must be designed to be stable against any *force condition* or combination of *force conditions* that may develop during the life of the structure. Other than overtopping caused by inadequate spillway capacity, the three most critical conditions that may cause failure of the embankment are:

1. *Differential settlement* within the embankment or its foundation due to a variation in materials, a variation in embankment height, or compression of the foundation strata. Differential settlement may, subsequently, cause the formation of cracks through the embankment that are roughly parallel to the abutments. These cracks may concentrate seepage through the dam and lead to failure by internal erosion.

2. S*eepage* through the embankment and foundation. This condition may cause piping within the embankment or the foundation, or both.

3. S*hearing stresses* within the embankment and foundation due to the weight of the fill. If the shearing stress force exceeds the strength of the materials, sliding of the embankment or its foundation may occur, resulting in the displacement of large portions of the embankment.

The stability of an embankment and its side slopes is dependent on the following: 1) *construction materials*, 2) *foundation conditions*, 3) *embankment height and cross-section geometry*, 4) *normal and maximum pool levels*, and 5) *purpose of BMP: retention, detention, or extended-detention*. The embankment cross-section should be designed to provide an adequate factor of safety to protect against sliding, sloughing, or rotation in the embankment or foundation. SCS's TR-60 publication provides guidelines for slope stability analysis when required. The most important factors in determining the stability of an embankment are:

1. **Physical characteristics of the fill materials**. Soil classification for engineering uses can be found in the SCS Engineering Field Manual, Chapter 4, and other references listed at the end of this section.

2. **Configuration of the site**. The height of the embankment may vary considerably throughout its length, so the total settlement of any given section of the embankment may differ from that of adjacent sections. The length of the embankment and slope of the abutments profoundly influence the degree of differential settlement between adjacent sections of the embankment. As the length shortens and the abutments become more steep, differential settlement becomes more likely. (**Minimum Standard 3.02**, **Principal Spillway** discusses the use of a concrete cradle to protect the spillway barrel sections from separating due to the forces of differential settlement.)

3. **Foundation materials**. The character and distribution of the foundation material must be considered for its *shear strength*, *compressibility*, and *permeability*. Occasionally, the shear strength of the foundation may govern the choice of embankment slopes. Permeability and stratification of the foundation may dictate the need for a *zoned embankment*. Quite often, foundations contain compressible soils that settle under the weight of the embankment, although the shear strength of these soils is satisfactory. When such settlement occurs in the foundation, the embankment settles. This settlement is rarely uniform over the basal area of the embankment. Therefore, fill materials used on such sites must be sufficiently plastic to deform without cracking. (**Minimum Standard 3.02**, **Principal Spillway** discusses the use of a concrete cradle to protect the spillway barrel sections from separating due to the forces of differential settlement.)

A foundation composed of homogeneous soil is simple to evaluate; however, this condition rarely occurs in natural soil deposits. Most often, a stratified deposit composed of layers of several soil types is encountered. To determine the suitability of such a foundation, the following information becomes very important: 1) *the geologic history of the site*, 2) *the degree of stratification*, and 3) *the order in which materials occur within the stratification*. A complex, stratified foundation containing plastic or compressible soil should be investigated by an experienced engineer or geologist.

Foundation cutoff - A foundation cutoff trench of moderately impervious material should be provided under the embankment. The cutoff trench should be installed at or upstream of the dam's centerline, and should extend up the abutments to the 10-year water surface elevation.

The bottom of the cutoff trench should be wide enough to accommodate excavation, backfill and compaction equipment. The trench's minimum width and depth should be 4 feet and the side slopes should be no steeper than 1H:1V (refer to **Figures 3.01-1a,b** and **3.01-2**).

Rock foundations - The presence of rock in the embankment foundation area requires specific design and construction recommendations (provided in the geotechnical engineering analysis) to insure a proper bond between the foundation and the embankment.

Generally, no blasting should be permitted within 100 feet of the foundation and abutment area. If blasting is essential, it should be carried out under controlled conditions to reduce adverse effects on the rock foundation, such as over-blasting and opening fractures. This is especially critical in areas of Karst topography.

Embankment zoning and seepage - The stability of an embankment slope and the seepage pattern through it are greatly influenced by the *zoning of the embankment*. (Refer to **Embankment Types** in the **Planning Considerations** section of this standard.) The position of the saturation line within a homogeneous embankment is theoretically independent of the type of soil used in it. Although soils vary greatly in regard to permeability, even the tightest clays are porous and cannot prevent water from seeping through them. **The rate of seepage through an embankment is dependent on the consistency of the reservoir level and the permeability of the embankment or core material**.

The upper surface of seepage is called the *phreatic surface* (zero pressure). In a cross-section, it is called the *phreatic line*. The position of the phreatic line in a retention basin embankment can be assumed to begin at the normal pool elevation on the upstream slope and extend at a 4H:1V slope downward through the embankment. **This assumption is based on the presence of a permanent pool**. For detention and extended-detention facilities with no permanent pool, many designers assume that the embankment will not impound water long enough for a phreatic surface to occur. This assumption, however, is based on a properly designed, constructed, and maintained embankment. Many jurisdictions, therefore, have chosen a conservative design approach by requiring that the phreatic line start at the 10-year design storm water surface elevation, regardless of the presence of a permanent pool.

For most stormwater management facilities, determining the location of the phreatic surface will often suggest the need to install seepage collars on the barrel. (Refer to **Minimum Standard 3.02, Principal Spillway**, for a discussion on seepage control along conduits.) For larger stormwater facilities, especially those with a permanent pool, the location of the phreatic surface may require additional design considerations such as an internal drain.

If the saturation line intersects the downstream slope of the embankment at a point above the toe, then seepage will exit the embankment along the downstream face and toe. Typically, the quantity of seepage is so slight that it does not affect the slope's stability. However, sometimes the saturation of the toe will cause sloughing or serious reduction of the shear strength in the downstream section of the embankment. Seepage control should be included in the design if the following conditions exist:

- pervious layers in the foundation are not intercepted by the cutoff,
- possible seepage from the abutments may create a wet embankment,
- the phreatic line intersects the downstream slope, or
- special conditions exist which require drainage to insure a stable embankment.

For *seepage collar design*, it is recommended that the phreatic line start at the 10-year design storm water surface elevation and extend through the embankment at a 4H:1V slope. **If the phreatic line intersects the downstream slope, a qualified soil scientist should be consulted to decide if additional controls are needed**. The location of the phreatic surface, therefore, may have a significant impact on the design of the embankment.

Seepage may be controlled by:

- foundation, abutment or embankment drains,

- a downstream drainage blanket,
- a downstream toe drain, or
- a combination of these measures (see **Figure 3.01-1b**).

Seepage encountered in the cutoff trench during construction may be controlled by *foundation drains*. These drains must be downstream of the embankment centerline and outside the limits of the proposed cutoff trench.

Including a toe drain in the design of most homogeneous embankments may be desirable. Embankments built on pervious foundations or constructed of materials that exhibit susceptibility to piping and cracking should always be protected by adequate toe drainage. Toe drains may be constructed of sand, gravel, or rock, depending on the nature of the embankment fill material. Whenever a rock toe drain is installed, a graded filter should be placed between the fill and the drain. Often, a 12-inch layer of well-graded, stream-run, sandy gravel will satisfy this requirement. Filter and drainage diaphragm design criteria are presented in the references listed as USDA-SCS Soil Mechanics Notes No. 1 and No. 3 at the end of this section, and provided in **Chapter 5 Appendix 5B**.

<u>Piping</u>

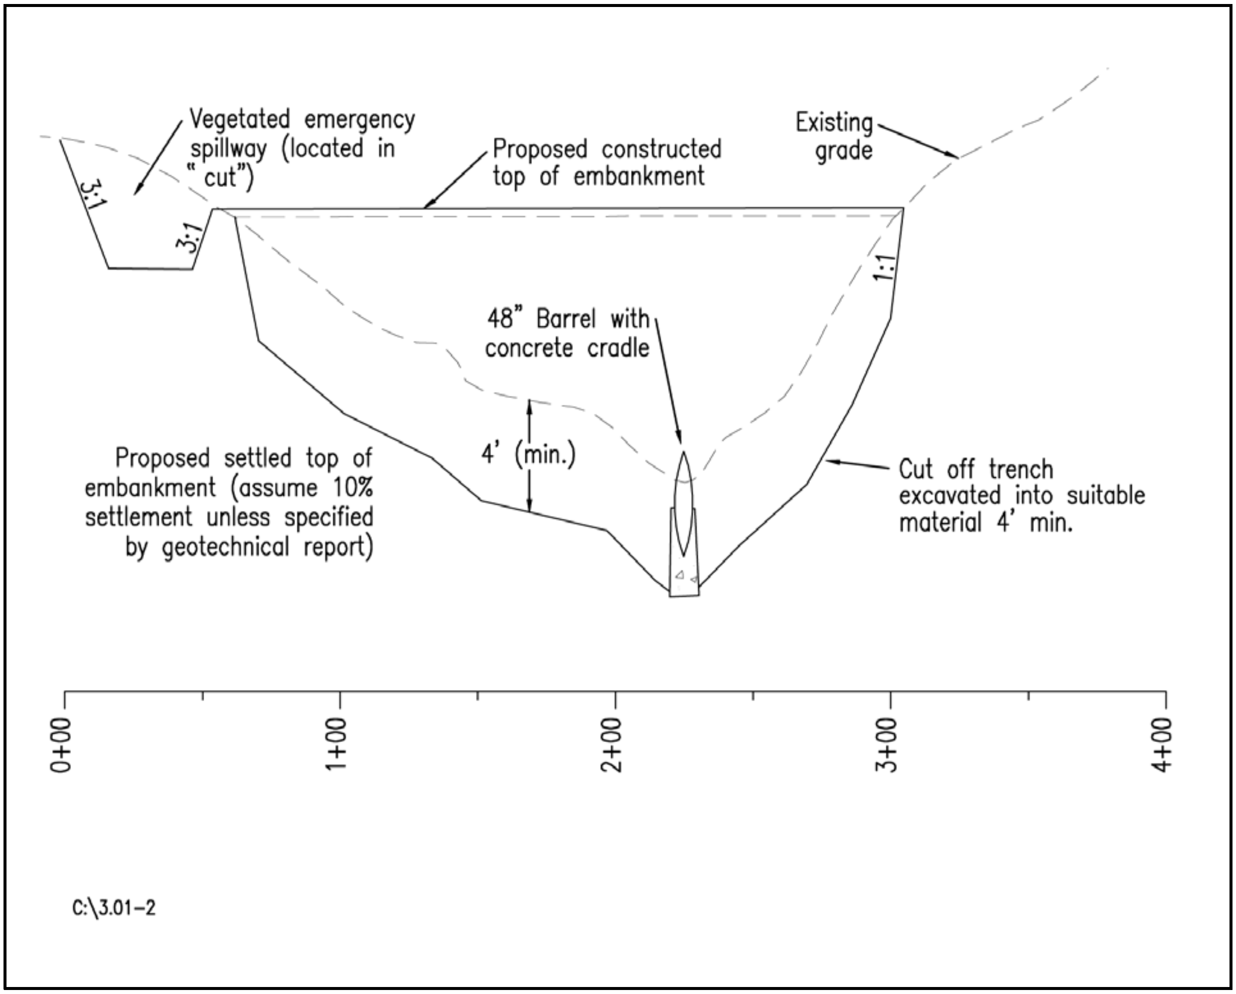
The contact areas between the embankment soils, foundation material, abutments, and conduits are the most susceptible locations for *piping failures.* Piping occurs due to the variation in materials at contact points and the difficulty in compacting the soil in these areas. Compaction is especially difficult next to and under conduits and seepage collars. Therefore, it is highly recommended that all utility conduits, except the principal spillway, be installed away from the embankment. When utility conduits through the embankment cannot be avoided, they should meet the requirements for spillways, i.e., water tight joints, no gravel bedding, restrained to prevent joint separation due to settlement, etc.

Seepage along pipe conduits that extend through an embankment should be controlled by use of the following:

- anti-seep collars, or
- filter and drainage diaphragms.

Refer to **Minimum Standard 3.02, Principal Spillway** for additional information on the use of anti-seep collars. Filter and drainage diaphragms are presented in USDA-SCS Soil Mechanics Notes No. 1 and No. 3, available upon request from DCR or USDA-SCS. When filter and drainage diaphragms are used, their design and construction should be supervised by a registered professional engineer.

FIGURE 3.01 - 2
Profile Along Centerline of Embankment



<u>Embankment Geometry</u>

1. **Height** - The height of an earthen embankment is based upon the freeboard requirements relative to the maximum water surface elevation during the 100-year frequency storm event. **An embankment <u>with</u> an emergency spillway must provide at least 1 foot of freeboard from the maximum 100-year storm water surface elevation (WSE) to the lowest point on the top of the embankment (excluding the emergency spillway)**. (Note that the *spillway design storm W.S.E*, if specified, may be used instead of the 100-year elevation.)

An embankment <u>without</u> an emergency spillway must provide at least 2 feet of freeboard from the maximum 100-year storm WSE to the lowest point on the top of the embankment. (Note that the *spillway design storm WSE*, if specified, may be used instead of the 100-year elevation.)

2. ***Top Width*** - The top of an earthen embankment should be shaped to provide positive drainage. The top width is based on the following table:

TABLE 3.01 - 1
Embankment Top Widths

Total Height of Embankment (*ft.*)	**Minimum Top Width (*ft.*)**
14 or less	8
15-19	10
20-24	12
25 or more	15

<u>Compacted Fill</u>

The soil types, as covered in the geotechnical analysis, should be specified by using the Unified Soil Classification System.

The compaction requirements should include the percent of maximum dry density for the specified density standard, allowable range of moisture content, and maximum loose lift thickness. Refer to **Construction Specifications for Earthen Embankments** later in this standard. In general, the design of an embankment should account for approximately 10% settlement unless otherwise specified by a geotechnical report based on the embankment foundation and fill material. The top of the embankment must be level in order to avoid possible overtopping in one location in cases of extreme storms or spillway failure.

Compaction tests should be performed regularly throughout the embankment construction; typically, one test per 5,000 square feet on each layer of fill or as directed by the geotechnical engineer. Generally, one of two compaction tests will be specified for embankment construction: the *Standard Proctor Test* (ASTM D698) or the *Modified Proctor Test* (ASTM D1557). For the construction of earth dams, the Modified Proctor Test is likely to be more appropriate (Terzaghi, Peck, 1948).This is due in part to the unconfined nature of the earth fill for dam construction. A new Proctor test is required if the material changes from that previously tested.

Embankment Construction

A geotechnical or construction inspector should be on site during embankment construction. Inspectors should be required to do more than just test fill compaction, i.e., observe foundation preparation, pipe installation, riser construction, filter installation, etc. (Refer to inspection checklist for impoundment structures, **Appendix 3**).

> *A vertical trench through the embankment material to place the spillway pipe should not be allowed under any circumstances. Trench side slopes should be laid back in steps at a 2:1 slope, minimum.*

Maintenance and Safety

Embankment slopes should be no steeper than 3H:1V if possible, with a maximum combined upstream and downstream slope of 5:1 (3:1 downstream face and 2:1 upstream face). For embankments exceeding 15 feet in height, a 6 to 10 foot wide bench should be provided at intervals of 10 to 15 feet of height, particularly if slopes are steeper than 3H:1V.

The following design considerations are provided to help reduce the long-term maintenance burden on the owner(s):

1. *Internal drainage systems in embankments (e.g., drainage blankets, toe drains)* should be designed such that the collection conduits discharge downstream of the embankment at a location where access for observation is possible by maintenance personnel.

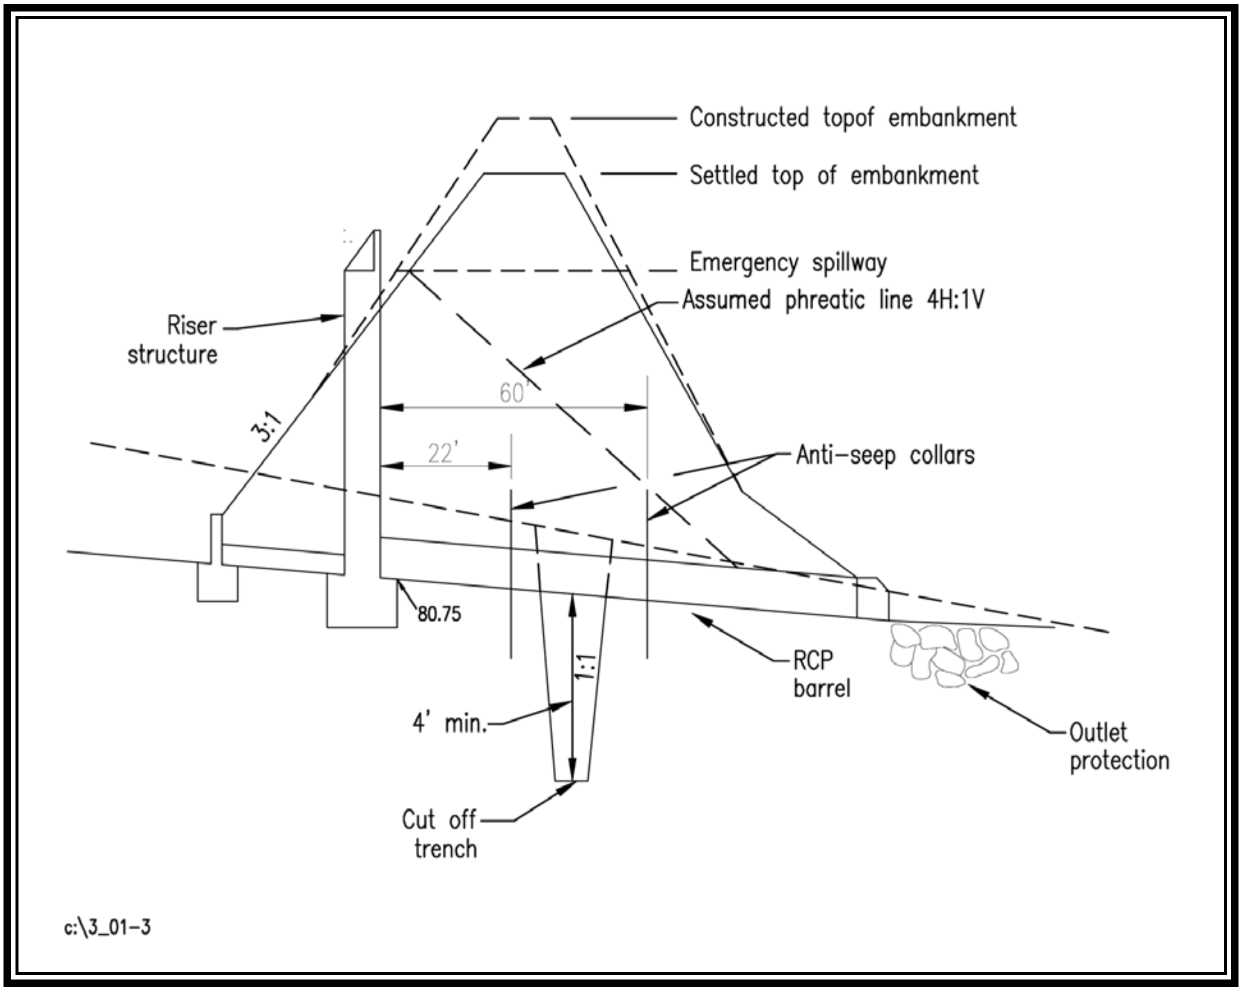
2. *Adequate erosion protection* is recommended along the contact point between the face of the embankment and the abutments. Runoff from rainfall concentrates in these areas and may reach erosive velocities depending on the gutter slope and embankment height. Although a sod gutter will be satisfactory for most small embankments, an evaluation should be made to decide if another type of gutter protection is required. For most embankments, a riprap gutter is preferred to a paved concrete gutter.

3. *Trees, shrubs, or any other woody plants should not be planted on the embankment* or adjacent areas extending at least 25 feet beyond the embankment toe and abutment contacts.

4. *Access should be provided to all areas of an impoundment that require observation or regular maintenance*. These areas include the embankment, emergency spillway, basin shoreline, principal spillway outlet, stilling basin, toe drains, riser structure, extended-drawdown device, and likely sediment accumulation areas.

FIGURE 3.01 - 3

Profile Along Centerline of Principal Spillway



Construction Specifications

The construction specifications for earthen embankments outlined below should be considered as minimum guidelines, with the understanding that more stringent specifications may be required depending upon individual site conditions, as evaluated by the geotechnical engineer. Final construction specifications should be included on the construction plans. In general, widely accepted construction standards and specifications for embankments, such as those developed by the USDA Soil Conservation Service or the U. S. Army Corps of Engineers, should be followed.

Further guidance can be found in the SCS Engineering Field Manual and National Engineering Handbook. Specifications for the embankment work should conform to the methods and procedures indicated for installing earthwork, concrete, reinforcing steel, pipe, water gates, metal work, woodwork and masonry, as they apply to the site and the purpose of the structure. The specifications should also satisfy all requirements of the local government.

Site Preparation

Areas designated for borrow sites, embankment construction, and structural work should be cleared, grubbed and stripped of topsoil. All trees, vegetation, roots and other objectional material should be removed.

All cleared and grubbed material should be disposed of outside and below the limits of the embankment and reservoir, as directed by the owner or his representative. When specified, a sufficient quantity of topsoil should be stockpiled in a suitable location for use on the embankment and other designated areas.

Earth Fill

1. **Material** - Fill material should be taken from an approved, designated borrow area. It should be free of roots, stumps, wood, rubbish, stones greater than 6 inches, and frozen or other objectionable materials. Fill material for the center of the embankment and the cutoff trench should conform to Unified Soil Classification GC, SC, or CL. Consideration may be given to the use of other materials in the embankment if the design and construction are supervised by a geotechnical engineer.

2. **Placement** - Areas on which fill is to be placed should be scarified before its placement. Fill material should be placed in layers a maximum of 8 inches thick (before compaction), which should be continuous over the entire length of the fill. The most permeable borrow material should be placed in the downstream portions of the embankment. The principal spillway must be installed concurrently with fill placement and **not excavated** into the embankment.

3. **Compaction** - Fill material should be compacted with appropriate compaction equipment such as a sheepsfoot, rubber-tired or vibratory roller. The number of required passes by the compaction equipment over the fill material may vary with soil conditions. Fill material should contain sufficient moisture such that the required degree of compaction will be obtained with the equipment used.

   The minimum required density is 95% of maximum dry density with a moisture content within ± 2% of the optimum, unless otherwise specified by the engineer. Each layer of the fill should be compacted as necessary to obtain minimum density and the engineer should certify, at the time of construction, that each fill layer meets the minimum density requirement. All compaction is to be determined by either Standard Proctor Test (ASTM D698) or the Modified Proctor Test (ASTM D1557) as directed by the geotechnical enginer based on site and soil conditions and the size and type of structure being built.

4. **Cutoff Trench** - The cutoff trench should be excavated into impervious material along or parallel to the centerline of the embankment as shown on the plans. The bottom width of the trench should be governed by the equipment used for excavation, with the minimum width being 4 feet. The depth should be at least 4 feet below existing grade or as shown on the plans. The side slopes of the trench should be 1H:1V or flatter. The backfill should be compacted with construction equipment, rollers, or hand tampers to assure maximum density and minimum permeability.

5. **Top Soil** - The surface layer of compacted fill should be scarified prior to placement of at least 6 inches of top soil. The top soil shall be stabilized with in accordance with the Virginia Erosion and Sediement Control Handbook, latest edition.

<u>Structure and Conduit Backfill</u>

Backfill that is beside pipes or structures should be of the same type and quality as specified for the adjoining fill material. The fill should be placed in horizontal layers not to exceed 4 inches in thickness and compacted by hand tampers or other manually directed compaction equipment. The material should completely fill all spaces under and beside the pipe. During the backfilling operation, equipment should not be driven closer than 4 feet, as measured horizontally, to any part of a structure. Also, equipment should **NEVER** be driven over any part of a structure or pipe, unless compacted fill has been placed to a depth specified by the structural live load capacity of the structure or pipe in order to adequately distribute the load.

<u>Filters and Drainage Layers</u>

In order to achieve maximum density of clean sands, filter layers should be flooded with clean water and vibrated just after the water drops below the sand surface. The filter material should be placed in lifts of no more than 12 inches.

Up to four feet of embankment material may be placed over a filter material layer before excavating back down to expose the previous layer. After removing any unsuitable materials, the trench may be filled with additional 12 inch lifts of filter material, flooded, and vibrated as described above, until the top of adjacent fill is reached.

Filter fabrics should not be used in lieu of sands and gravel layers within the embankment.

Maintenance and Inspection Guidelines

A thick, healthy grass cover, free of trees and brush, should be maintained on the embankment. Such a cover will help stabilize the surfaces of the embankment and will simplify inspections.

The maintenance and inspection guidelines presented below are **NOT** all-inclusive. Specific facilities may require other measures not discussed here. It is the designer's responsibility to decide if additional measures are necessary.

1. The embankment should be mowed periodically during the growing season, ensuring that the last cutting occurs at the end of the season. The grass should not be cut less than 6 to 8 inches in height.

2. If necessary, the embankment should be limed, fertilized and seeded in the fall, after the growing season. Lime and fertilizer application rates should be based on soil test results. The type of seed should be consistent with that originally specified on the construction plans.

3. All erosion gullies noted during the growing season should be backfilled with topsoil, reseeded and protected (mulched) until vegetation is established.

4. All bare areas and pathways on the embankment should be properly seeded and protected (mulched) or otherwise stabilized to eliminate the potential for erosion.

5. All animal burrows should be backfilled and compacted and burrowing animals should be removed from the area.

6. All trees, woody vegetation and other deep-rooted growth, including stumps and associated root systems, should be removed from the embankment and adjacent areas extending to at least 25 feet beyond the embankment toe and abutment contacts. The root systems should be extracted and the excavated volume replaced and compacted with material similar to the surrounding area. All seedlings should be removed at the first

opportunity. Similarly, any vine cover and brush should be removed from the embankment to allow for inspections.

7. Any repairs made to the princpal spillway (riser or barrel) should be reviewed by a professional engineer. Vertical trenching to expose the barrel should not be allowed under any circumstances. The trench side slopes should be stepped back at a 2:1 slope, minimum.

PRINCIPAL SPILLWAY

Definition

A principal spillway is the primary outlet device for a stormwater impoundment. It usually consists of either a *riser structure in combination with an outlet conduit*, which extends through the embankment, or *a weir control section* cut through the embankment.

Purpose

The purpose of a principal spillway is to provide a primary outlet for storm flows, usually up to the 10- or 25-year frequency storm event. The principal spillway is designed and sized to regulate the allowable discharge from the impoundment facility.

Conditions Where Practice Applies

A principal spillway is used on any impoundment BMP, including retention, extended-detention, and detention facilities. It may also be used with constructed wetlands and infiltration measures.

Planning Considerations

A principal spillway typically consists of a *multistage riser structure* and an outlet conduit or a *weir* that allows flow to pass over a *control section* of the embankment. The shape and geometry of the weir as well as that of the riser structure can be manipulated to meet the needs of the specific facility. The use of a weir as the principal spillway eliminates the barrel projecting through the embankment. The barrel through the embankment and the associated piping and seepage control represent not only significant material and construction costs, but also the potential trouble spots for long term maintenance and possible repair.

The most common type of riser structure is a *drop inlet spillway*. A drop inlet spillway usually consists of a rectangular or other shaped riser structure containing one or several openings sized to control one or more discharge rates. For aesthetic or safety concerns, the drop inlet riser structure may be installed in the embankment with only its top showing. The discharge openings may be extended to the design water surface elevations with pipe. See **Figures 3-02.1(a-f)** for typical riser structures and locations.

The barrel shape or geometry and size through the embankment is based upon the required flow capacities and availability of materials.

Design Criteria

The purpose of this section is to provide minimum design recommendations and guidelines for principal spillway systems (riser structure and barrel). The designer is responsible for determining those aspects that are applicable to the particular facility being designed, and for determining if any additional design elements are required to insure the long-term functioning of the system.

The crest elevation of the principal spillway must be at least 1.0 ft. below the crest of the emergency spillway.

Drop Inlet Spillways

Drop inlet spillways (riser and barrel system) should be designed such that a) *full flow is established in the outlet conduit and riser at the lowest head over the riser crest as is practical,* and b) *the facility operates without excessive surging, noise, vibration, or vortex action at any stage*. To meet these two requirements, the riser must have a larger cross-sectional area than the outlet conduit. **Chapter 5** provides the basic hydraulic calculation procedures needed to design the spillway riser and barrel system.

Headwall/Conduit Spillways

Headwall spillways consist of a pipe extending through an embankment with a headwall at the upstream end. The headwall is typically oversized to provide an adequate surface against which to compact the embankment fill.

Weir Spillways

A weir spillway, when used as a principal spillway, should be armored with concrete or other non-erosive material, since it usually carries water during every storm event. At the spillway, armoring should extend from the upstream face of the embankment to a point downstream of the spillway toe.

In general, all principal spillways should be constructed of a nonerosive material. The selected material should have an anticipated life expectancy similar to that of the stormwater management facility. Precast riser structures can not be substituted if plans call for a cast in place structure, unless approved by the design engineer and the plan approving authority. Sections of precast structures must be anchored together for stability and flotation requirements. A structural engineer should evaluate shop drawings for pipe, precast structures, or other fabricated appurtenances before fabrication or installation. **Cinder block and masonry block structures should not be used**.

Vegetated spillways designed to carry flow during the 100-year frequency storm or greater are discussed in **Minimum Standard 3.03**, **Vegetated Emergency Spillway**.

Combined Principal and Emergency Spillways

An *emergency spillway*, separated from the principal spillway, is generally recommended. However, using an overland emergency spillway at the embankment abutments may not be practical due to site limitations, such as the following:

- topographic conditions (e.g., abutments are too steep)
- land use conditions (e.g., existing or proposed development imposes constraints)
- other factors (e.g., roadway embankments are used as a dam, basins are excavated, etc.).

In these instances, a *combined principal/emergency spillway* may be considered. A combined principal/emergency spillway is simply a single spillway structure that conveys both low flows and extreme flows (such as the 100-year frequency flow). The combined spillway may take the form of a drop inlet spillway, a weir spillway, a headwall/conduit spillway or any other spillway type.

A primary design consideration for a combined principal/emergency spillway, particularly if it is a drop inlet spillway, is protection against clogging.

Typical Principal Spillway Structures

<u>Conduits/Structures through Embankments</u>

The *contact point* between the embankment soil, the foundation material, and the conduit is the most likely location for *piping* to occur due to the discontinuity in materials and the difficulty in compacting the soil around the pipe. Therefore, special attention must be given to the design of any conduit that penetrates an embankment.

It is highly recommended that the designer limit the number of conduits that penetrate through an embankment. Whenever possible, utility or other secondary conduits should be located outside of and away from the embankment. When additional conduits cannot be avoided, they should meet the requirements for spillways i.e., water tight joints, no gravel bedding, encasement in concrete or flowable fill, restrained to prevent joint separation due to settlement, etc.

Many embankment failures occur along the principal spillway because of the difficulty in compacting soil along a pipe. To help alleviate this concern, designers should consider the use of a weir as an control structure.

An additional cause of embankment failure is the separation of pipe joints due to differential settlement and pipe deflection. Corrugated metal pipe (CMP) must meet or exceed the minimum required thickness specified in **Table 3.02-1**. The contractor and project inspector should verify the metal thickness (compare manufacturer's certification which accompanies the pipe shipment with the plan specifications), corrugation size, proper connecting bands, and gasket type. Maximum allowable deflection of CMP conduits is 5% of the pipe diameter. However, with larger pipe sizes, it may be difficult to get water tight joints even if the deflection is less than that which is allowed. For increased design life, the engineer may choose to specify a heavier gage than indicated in **Table 3.02-1**.

Water tight joints are necessary to prevent infiltration of embankment soils into the conduit. All joints must be constructed as specified by the pipe manufacturer. "Field joints" where the ends of the pipes are cut off in the field should not be accepted. In addition, six inch hugger bands and "dimple bands" should not be accepted for CMP conduits. The construction specifications (found later in this Standard) specify 12-inch bands with 12-inch O-ring or flat neoprene gaskets for pipes 24 inches or less in diameter. Larger pipes require 24-inch wide bands with 24-inch wide flat gaskets and four "rod and lug" type connectors. Flanged pipe with gaskets is also permitted. Refer to the Construction Specifications in this standard for more information.

All pipe gaskets should be propely lubricated with the material provided by the pipe manufacturer.

Use of an incorrect lubricant may cause deterioration of gasket material.

Conduit Piping and Seepage Control – *Seepage* or *piping* along a pipe conduit, which extends through an embankment, should be controlled by use of one of the following: 1) *anti-seep collars*, as shown in **Figure 3.02-2**, or 2) *filter or drainage diaphragms* as shown in **Figure 3.02-3**. Concrete cradles, as discussed in item 3 below, may also be used.

***Seepage control will not be required on pipes less than 6 inches in diameter*.**

1. *Anti-Seep Collars* - These collars lengthen the percolation path along the conduit, subsequently reducing the *exit gradient*, which helps to reduce the potential for piping. While this works well in theory, the required quality of compaction around the collars is very difficult to achieve in the field.

The Bureau of Reclamation, the U.S. Army Corps of Engineers, and the Soil Conservation Service no longer recommend the use of anti-seep collars. The Bureau of Reclamation issued Technical Memorandum No. 9 in 1987 that states:

> *"When a conduit is selected for a waterway through an earth or rockfill embankment, cutoff collars will not be selected as the seepage control measure."*

Alternative measures have been developed and used in the designs of major structures. These measures include *graded filters* or *filter diaphragms*, and *drainage blankets*. These devices are not only less complicated and more cost-effective to construct than the cutoff collars, but also allow for easier placement of the embankment fill.

Designers and engineers, however, continue to use anti-seep collars as the sole method of seepage control for small dams. This may be due to the complexity of the design procedure for graded filters. It may also be due to the designer's concern that little engineering supervision and/or inspection will occur during construction, which is generally necessary for the successful installation of graded filters.

Anti-seep collars, when used, should be installed around all conduits through earth fills according to the following criteria:

a. Enough collars should be placed to increase the seepage length along the conduit by a minimum of 15%. This percentage is based on the length of pipe in the saturation zone.

b. The assumed normal saturation zone should be determined by projecting a line through the embankment, with a 4H:1V slope, from the point where the normal water elevation meets the upstream slope to a point where it intersects the invert of the conduit. This line, referred to as the *phreatic line*, represents the upper surface of the zone of saturation within the embankment. For stormwater management basins, the phreatic line starting elevation should be the 10-year storm pool elevation. (See **Minimum Standard 3.01**, **Earthen Embankment**.)

c. Maximum collar spacing should be 14 times the minimum projection above the pipe. The minimum collar spacing should be 5 times the minimum projection.

d. Anti-seep collars should be placed within the saturation zone. In cases where the spacing limit will not allow this, at least one collar should be in the saturation zone.

e. All anti-seep collars and their connections to the conduit should be watertight and made of material compatible with the conduit.

f. Collar dimensions should extend a minimum of 2 feet in all directions around the pipe.

g. Anti-seep collars should be placed a minimum of 2 feet from pipe joints unless flanged joints are used.

The calculation procedure for sizing anti-seep collars is presented in Chapter 5: Multi-Stage Riser Design, STEP 15.

FIGURE 3.02 - 2
Anti-Seep Collar

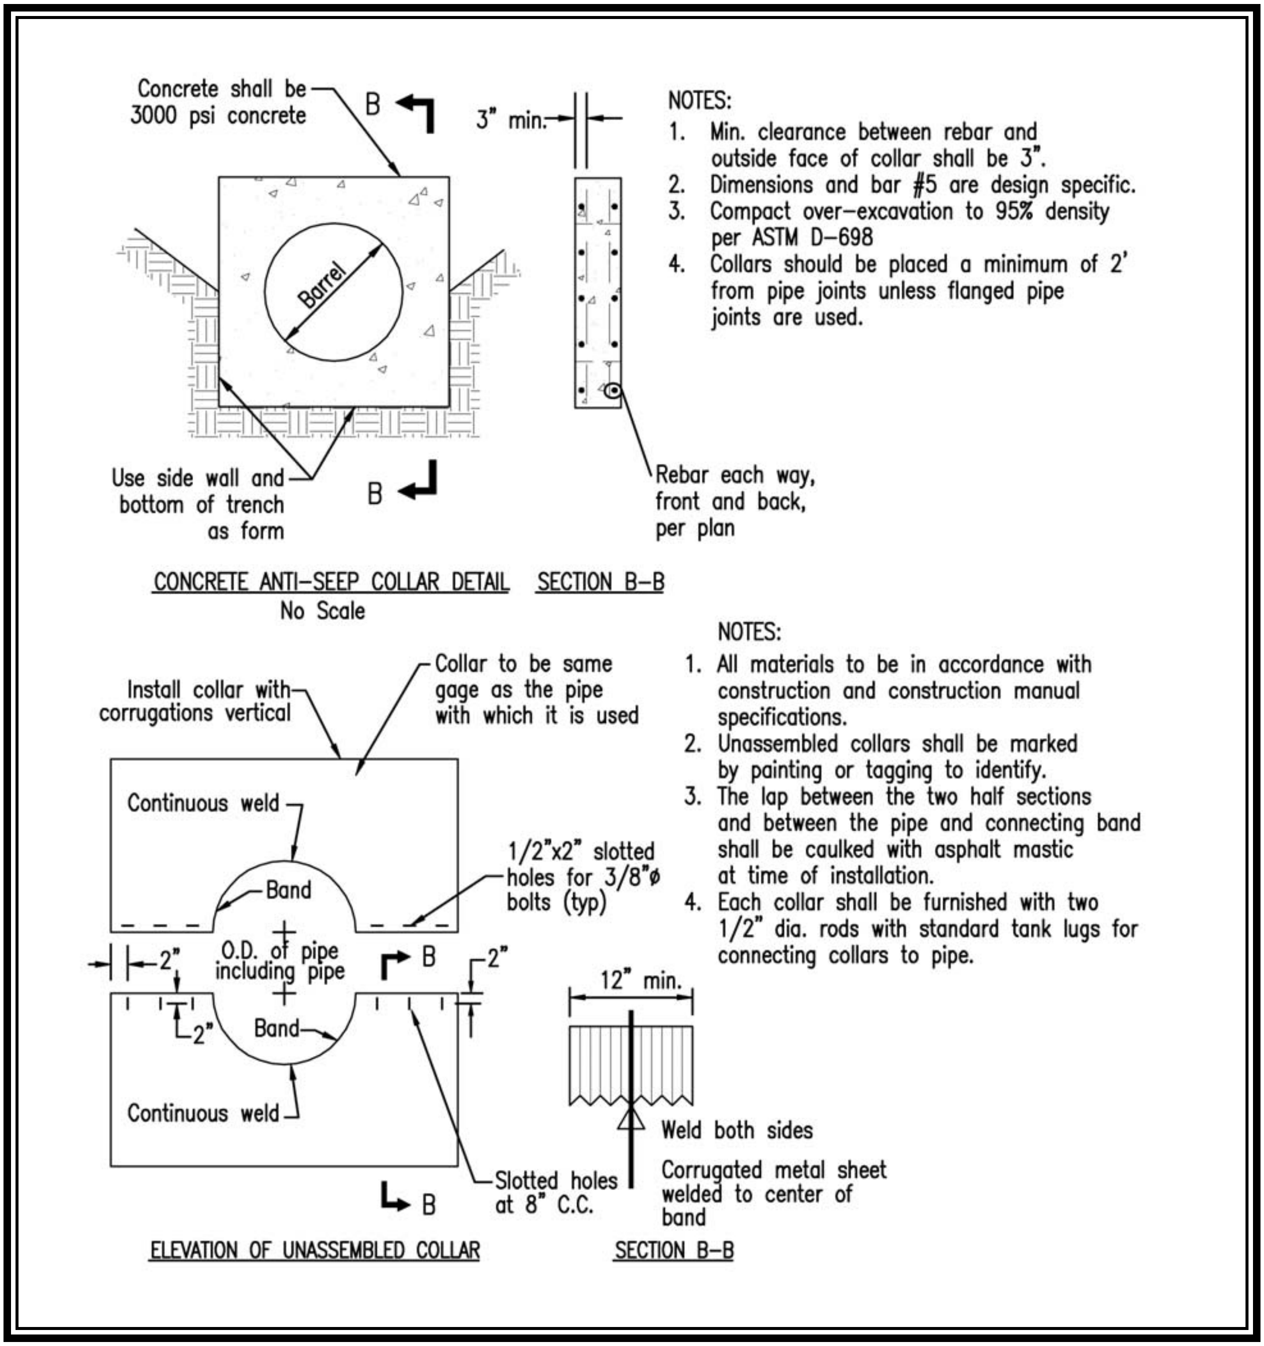

FIGURE 3.02 - 3
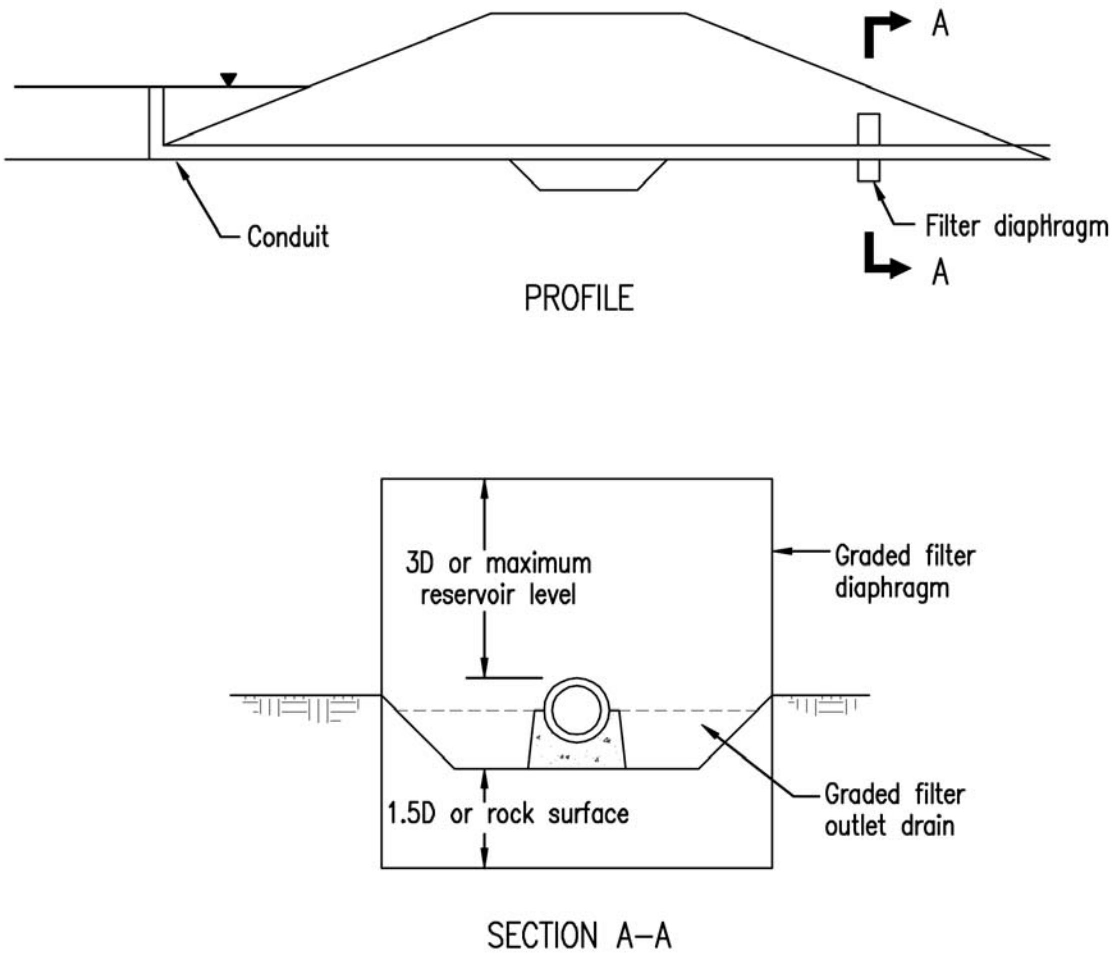
Graded Filter Diaphragm for Seepage Control Around Conduit



NOTES:
1. Delete filter diaphragm when conduit passes through chimney drain.
2. Delete outlet drain when filter diaphragm is connected to foundation drainage blanket.

c:\3_02–3

Source: Seepage Control Along Conduits Penetrating Embankment Dams, Ray E. Martin, Ph.D., P.E.

2. *Filter and Drainage Diaphragms* - Anti-seep collars extend the flow path along the conduit and, therefore, discourage piping. In contrast, filter and drainage diaphragms do not eliminate or discourage piping, rather they control the transport of embankment fines, which is the major concern in piping and seepage. Rather than trying to prevent seepage or increase its flow length, these devices channel the flow through a filter of fine graded material, such as sand, which traps any embankment material being transported. The flow is then conveyed out of the embankment through a perforated toe drain or other acceptable technique.

While filter and drainage diaphragms require careful design, the procedure is straightforward. The *grain size distribution* of the embankment fill and foundation material must be determined so that the filter material grain size distribution can be specified. If the specified filter material is not available on the site, it must be imported. The design procedure for filter and drainage diaphragms can be found in the following references:

Ë SCS TR-60
Ë SCS Technical Note No. 709
Ë SCS Soil Mechanics Notes 1 and 3 (Available upon request from DCR or NRCS)

There are some distinct advantages to using filter diaphragms over anti-seep collars:

¢ By eliminating the obstructions created by anti-seep collars, heavy compaction equipment can more thoroughly compact the embankment fill material adjacent to the conduit.

¢ The labor intensive formwork associated with anti-seep collar construction is eliminated.

¢ Cracks that form in the fill along the conduit will be terminated by the filter and will not propogate completely through the dam.

The design of filter and drainage diaphragms should be supervised by a geotechnical engineer. The critical design element is the grain size distribution of the filter material compared with that of the embankment fill and foundation material.

Overall, the following criteria apply to the use of filter and drainage diaphragms:

a. The diaphragm should consist of sand, meeting fine concrete aggregate requirements (at least 15% passing the No. 40 sieve but no more than 10% passing the No. 100 sieve). If unusual soil conditions exist, a special analysis should be completed.

b. The diaphragm should be a minimum of 3 feet thick and should extend vertically **upward** and **horizontally** at least 3 times the pipe diameter and vertically **downward** at least 24 inches beneath the barrel invert, or to rock, whichever is encountered first (SCS Tech. Note 709).

c. The diaphragm should be placed immediately downstream of the cutoff trench, approximately parallel to the centerline of the dam.

d. In order to achieve maximum density of clean sands, filter layers should be flooded with clean water and vibrated just after the water drops below the sand surface. The filter material should be placed in lifts of no more than 12 inches.

   Up to four feet of embankment material may be placed over a filter material layer before excavating back down to expose the previous layer. After removing any unsuitable materials, the trench may be filled with additional 12-inch lifts of filter material, flooded and vibrated as described above, until the top of adjacent fill is reached.

e. The diaphragm should be discharged at the downstream toe of the embankment. The opening sizes for slotted and perforated pipes in drains must be designed using the filter criteria. A second filter layer may be required around the drain pipe in order to alleviate the need for many very small openings. Fabric should not be used around the perforated pipe as it may clog rendering the perforations impenetrable by water.

The construction specifications for a filter diaphragm should include provisions to prevent settlement of the filter material upon saturation. This is usually accomplished by flooding the filter upon installation and compacting with vibratory equipment as soon as the water drops below the surface (Van Aller, 1990).

Whatever measures are taken to control seepage, proper construction techniques and inspection are critical to a successful project. The contractor should ensure that backfill material meets the specifications for *quality, lift thickness, placement, moisture content,* and *dry unit weight*. In addition, special care should be taken in the placement and compaction of the embankment material beside the barrel. Compaction along this conduit must extend away from the pipe enough to overlap with the compaction of the embankment. The use of filter and drainage diaphragms will ease this effort while providing greater protection against the damaging effects of piping and seepage.

During construction, it is recommended that filter and drainage diaphragms be inspected by a qualified professional. Inspection logs should be submitted along with any as-built plans.

3. *Concrete Pipe Bedding* - If the embankment fill material under the spring line of the conduit is **inadequately** compacted, *piping* may result. This problem is magnified if the conduit is not designed with flexible watertight joints; differential settlement of the embankment and foundation materials may pull the conduit joints apart, allowing the stormwater to escape into the surrounding soil, greatly adding to the piping condition. Installation of a concrete cradle will help to reduce the risk of piping under the barrel and the subsequent failure of the embankment, resulting from differential settlement.

Cradles not only provide conduit support, but also provide a better condition for the placement and compaction of backfill.

> Concrete cradles serve two distinctly different, yet related functions: 1) *they help to prevent piping along the conduit*, and 2) *they provide a 90E* ***bedding angle*** *for the loading support of the conduit. See* ***Figure 3.02 - 4****.*

The concrete cradle may not be necessary along the entire length of the conduit to prevent piping, but it is recommended. This will eliminate a sudden change in the support provided under the conduit. The load distribution of the conduit is assumed to be the same as the typical load distribution characteristics of reinforced concrete pipe (*RCP*). The external loading capacity of *RCP* depends upon a bedding condition that provides equal support around the base of the pipe. General pipe culvert installation specifications call for the placement of gravel under the pipe to distribute the load evenly. However, g**ravel bedding under an embankment conduit is <u>never</u> appropriate unless it is designed as a filter or drainage diaphragm.** Therefore, if the external load on the barrel is enough to warrant provision for its ***maximum supporting strength***, then a concrete cradle should be installed along the conduit's entire length. Note that external loads on the barrel may be due to the height of the embankment fill, the anticipated construction traffic, or the weight of the compaction equipment.

Single Conduits – All conduits penetrating dam embankments should be designed using the following criteria:

a. Conduits and structures penetrating an embankment should have a smooth surface without protrusions or indentations that will hinder compaction of embankment materials.

b. All conduits should be circular in cross-section except cast-in-place reinforced concrete box culverts.

c. Conduits should be designed to withstand the external loading from the proposed embankment without yielding, buckling or cracking, all of which will result in joint seperation.

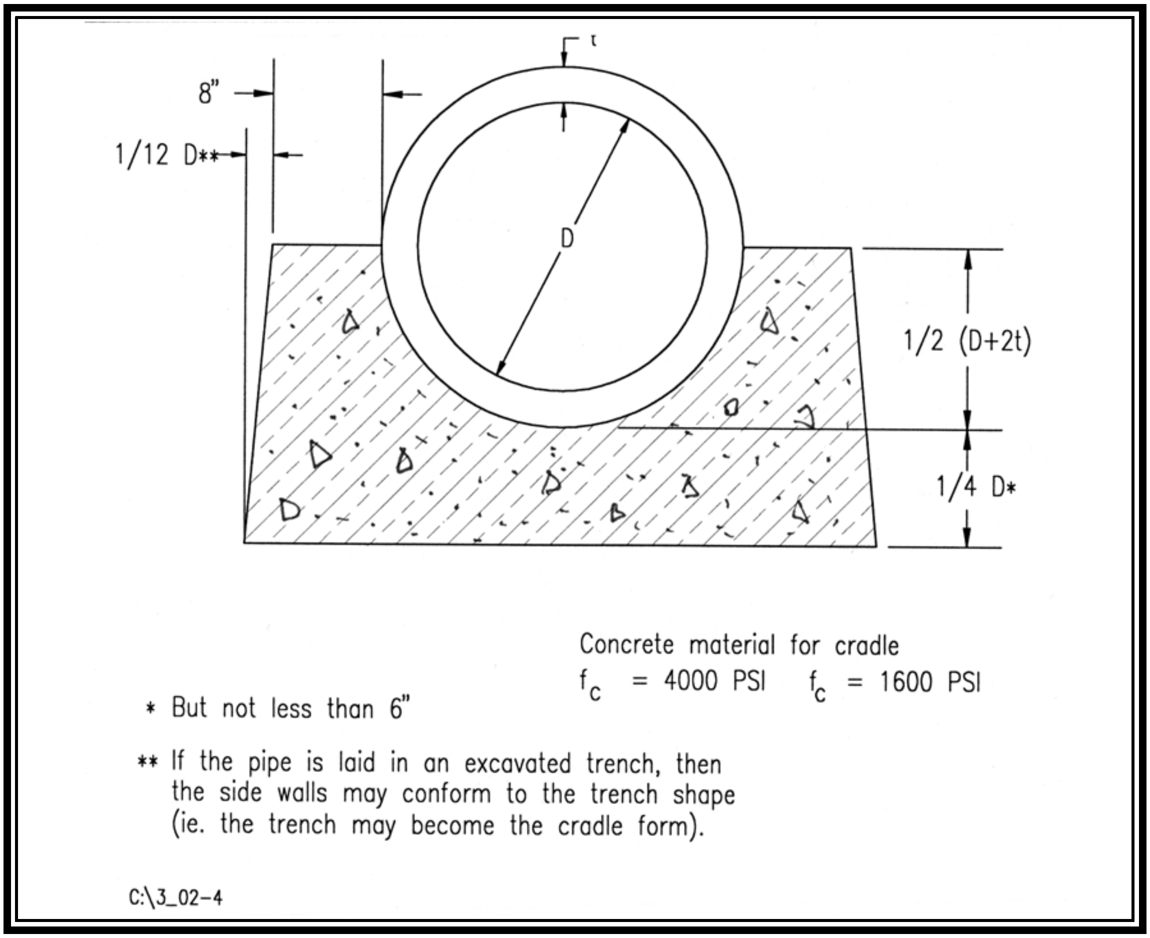
d. Conduit strength should not be less than the values shown in **Tables 3.02-1** and **3.02-2** for corrugated steel, aluminum, and PVC pipes, and the applicable ASTM standards for other materials. The manufacturer should submit certification that the pipe meets plan requirements for design load, pipe thickness, joint design, etc.

e. Inlet and outlet flared-end sections should be made from materials that are compatible with the pipe.

f. All pipe joints should be made watertight by using flanges with gaskets, coupling bands with gaskets, bell and spigot ends with gaskets, or by welding. See **Construction Specifications** later in this standard.

Multiple Conduits – Where multiple conduits are used, each conduit should conform to the requirements in item (b), above. In addition, sufficient space between the conduits and the installed anti-seep collars should be provided to allow for backfill material to be placed between the conduits with earth moving equipment and to allow for easy access by hand-operated compaction equipment. The distance between conduits should be equal to or greater than one-half of the pipe diameter, but not less than 2 feet.

FIGURE 3.02 - 4
Concrete Cradle



Cathodic Protection

In some areas of Virginia, sedimentary layers may be very acidic. This is particularly common in the coastal and piedmont regions east of the fall line, or roughly east of Interstate 95. Cathodic protection should be provided for *coated welded steel* and *galvanized corrugated metal* pipe when soil and resistivity studies indicate the need for a protective coating. Cathodic protection may also be provided when additional protection and longevity are warranted.

Outlet Protection

Outlet protection should be used on the downstream toe of a spillway structure to help dissipate the high energy flow through the spillway and to prevent excessive erosion in the receiving channel.

Various types of outlet protection can be used including: *riprap at the endwall or end-section of an outlet conduit* or a *designed hydraulic jump with impact blocks*. The type of outlet protection depends on the flow velocities associated with the spillway design flood and energy dissipation required. Riprap is the preferred form of outlet protection when designed according to **Chapter 5** of this handbook and the Virginia Erosion and Sediment Control Handbook (VESCH), 1992 edition. Gabion baskets are also an acceptable outlet protection material. Other references for designing outlet protection include publications by the Federal Highway Administration, the Soil Conservation Service, the Bureau of Reclamation and the U.S. Army Corps of Engineers.

The following general criteria are recommended for the placement of riprap at the outfall of a stormwater impoundment:

1. The bottom of the riprap apron should be constructed at 0% slope along its length. The end of the apron should match the grade and alignment of the receiving channel.

2. If the receiving channel is well-defined, the riprap should be placed on the channel bottom and side slopes (no steeper than 2:1) for the entire length, L_a, required per **Chapter 5** and the VESCH, 1992 edition. Riprap placement should not alter the channel's geometry. Excavation of the channel bed and banks may be required to construct the full thickness of the apron.

3. If the barrel discharges into the receiving channel at an angle, the opposite bank must be protected up to the 10-year storm elevation. In no instance should the total length of outlet protection be shortened. If a permit requires that no work may be performed in the stream or channel, then the outlet structure should be moved back to allow for adequate protection.

4. The horizontal alignment of the apron should have no bends within the design length, La. Additional rip rapshould be placed if a significant change in grade occurs at the downstream end of the outfall apron.

5. Filter fabric should be placed between the riprap and the underlying soil to prevent soil movement into and through the riprap.

Trash Racks and Debris Control Devices

Most basins will collect a certain amount of trash and debris from incoming flows. Floating debris such as grass clippings, tree limbs, leaves, trash, construction debris, and sediment bed load from upstream watersheds are common. Therefore, all control structures, including detention, extended-detention and retention basin low-flow weirs and orifices should have a trash rack or debris control device. The following are recommended design criteria for trash racks and debris control devices:

1. Openings for trash racks should be no larger than one-half of the minimum conduit dimension, and to discourage child access, bar spacing should be no greater than 1 foot apart. The clear distance between the bars on large storm discharge openings should generally be no less than 6 inches.

2. **Flat grates for trash racks are not acceptable**. Inlet structures that have flow over the top should have a non-clogging trash rack such as a hood-type inlet that allows passage of water from underneath the trash rack into the riser, or a vertical or sloped grate. The designer should verify that the surface area of the vertical perimeter of a raised grate equals the area of the horizontal top opening. This will allow adequate flow passage should the top horizontal surface become clogged. Examples are shown in **Figure 3.02-5**.

3. Metal trash racks and monitoring hardware should be constructed of galvanized or stainless steel metal.

4. Methods to prevent clogging of extended detention orifices in dry extended detention basins should be carefully designed since these orifices are usually very small and located at the invert or bottom of the basin (refer to **Minimum Standard 3:07, Extended Detention Basin**).

<u>Anti-vortex Device</u>

All drop inlet spillways designed for pressure flow should have adequate anti-vortex devices. An anti-vortex device is not required if weir control is maintained in the riser through all flow stages, including the maximum design storm or safety storm.

An anti-vortex device may be a baffle or plate installed on top of the riser, or a headwall set on one side of the riser. Examples of anti-vortex devices are shown in **Figure 3.02-6**.

<u>Drain Pipes and Valves</u>

Stormwater management facilities having permanent impoundments may be designed so that the permanent pool can be drained to simplify maintenance and sediment removal. The draining mechanism will usually consist of a valve or gate attached to the spillway structure and an inlet pipe projecting into the reservoir area with a trash rack or debris control device. The typical configuration of a drainpipe will place the valve inside the riser structure with the pipe extending out to the pool area. This configuration results in the drain pipe being pressurized by the hydraulic head associated with the permanent pool. Pressurized drain pipes should consist of mechanical joints in order to avoid possible leaks and seepage resulting from this condition. In all cases, valves should be secured to prevent unauthorized draining of the facility.

Basin drains should be designed with sufficient capacity to pass the 1-year frequency design storm with limited ponding in the reservoir area, such that sediment removal or other maintenance functions are not hampered.

An uncontrolled or rapid drawdown of a stormwater basin could cause a slide in the saturated upstream slope of the dam embankment or shoreline area. Therefore, the design of a basin drain system should include specific operating instructions for the owner. **Generally, drawdown rates should not exceed 6 inches per day**. For embankments or shoreline slopes of clay or silt, drawdown rates as low as *1 inch per week* may be required to ensure slope stability. (FPFM, 1994).

<u>Antiflotation</u>

The design of a principal spillway riser structure should include a *flotation* or *buoyancy* calculation.

When the ground around the riser is saturated and the water surface elevation in the basin is higher than the riser footing, then the riser structure behaves like a “vessel” floating in water. Such flotation forces on the riser can lead to failure of the connection between the riser and barrel, and any other rigid connections.

The downward force of the riser and footing (assuming the riser is attached firmly to the footing) is the *structure weight.* To maintain adequate stability, this weight must be at least 1.25 times greater than the upward force, or buoyant force, acting on the riser.

An *anti-flotation* calculation procedure is presented in Chapter 5.

<u>Maintenance and Safety</u>

As mentioned previously, trash racks and debris control structures should be sized to prevent entry by children. Fencing or other barriers should be considered around spillway structures having open or accessible drops more than 3 feet. A locking manhole cover on the riser may also be prudent to prevent unauthorized access.

FIGURE 3.02 - 5
Trash Rack

FIGURE 3.02 - 6
Anti-Vortex Device

Construction Specifications

The construction specifications for principal spillways outlined below should be considered as minimum guidelines. More stringent requirements may be needed depending upon individual site conditions. Overall, widely accepted construction standards and specifications, such as those developed by the USDA Soil Conservation Service or the U.S. Army Corps of Engineers, should be followed.

Further guidance can be found in the SCS Engineering Field Manual. Specifications for the work should conform to the methods and procedures specified for installing earthwork, concrete, reinforcing steel, pipe water gates, metal work, woodwork, and masonry, as they apply to the site and the purpose of the structure. The specifications should also satisfy all requirements of the local government. Final construction specifications should be included on the construction plans.

Corrugated Metal Pipe - The following criteria apply:

1. **Materials –** Corrugated metal pipe may be steel, aluminum coated steel or aluminum.

   a. *Steel Pipe* - This pipe and its appurtenances should be galvanized and fully bituminous coated and should conform to the requirements of AASHTO Specification M-190 Type A with watertight coupling bands. Any bituminous coating damaged or otherwise removed should be replaced with cold applied bituminous coating compound. Steel pipes with polymeric coatings should have a minimum coating thickness of 0.01 inches (10 *mils*) on both sides of the pipe. The following coatings or an approved equal may be used: Nexon, Plasti-Cote, Blac-Clad, and Beth-Cu-Loy. Coated corrugated steel pipe should meet the requirements of AASHTO M-245 and M-246.

   b. *Aluminum Coated Steel Pipe* - This pipe and its appurtenances should conform to the requirements of AASHTO Specification M-274 with watertight coupling bands or flanges. Any aluminum coating damaged or otherwise removed should be replaced with cold applied bituminous coating compound.

   c. *Aluminum Pipe* - This pipe and its appurtenances should conform to the requirements of AASHTO Specification M-196 or M-211 with watertight coupling bands or flanges. Aluminum surfaces that are to be in contact with concrete should be painted with one coat of zinc chromate primer. Hot dipped galvanized bolts may be used for connections. The pH of the surrounding soils should be between 4 and 9.

2. **Coupling bands, anti-seep collars, end-sections, etc.** - All connectors must be composed of the same material as the pipe. Metals must be shielded from dissimilar materials with rubber or plastic insulation at least 24 mils thick.

3. **Connections** - All connections to pipes must be completely watertight. The drain pipe (or barrel) connection to the riser should be welded all around when both are metal. Anti-seep collars should be connected to the pipe so that they are completely watertight. **Dimple bands are not considered watertight**.

   A rubber or neoprene gasket should be used when joining pipe sections. The end of each pipe should be re-rolled by enough corrugations to fit the band width. The following connection types are acceptable for pipes less than 24 inches in diameter: flanges with gaskets on both ends of the pipe, a 12-inch wide standard lap type band with a 12-inch wide by ½-inch thick closed cell circular neoprene gaskets, and a 12-inch wide hugger type band with 0-ring gaskets having a minimum diameter of 3/8 inches greater than the corrugation depth. Pipes 24 inches in diameter and larger should be connected by a 24-inch long annular corrugated band using rods and lugs and a 24 inch wide by 3/8 inch thick closed cell circular neoprene gasket. Helically corrugated pipe should have either continuous welded seams or lock seams with internal caulking or a neoprene bead.

   All pipe gaskets must be properly lubricated with the material provided by the pipe manufacturer, and tensioned. Flat gaskets must be factory welded or solvent glued into a circular ring, with no overlaps or gaps.

4. **Bedding** - The pipe should be firmly and uniformly bedded throughout its length. Where rock or soft, spongy or other unstable soil is encountered, it should be removed and replaced with suitable earth that is subsequently compacted to provide adequate support. Under no conditions should gravel bedding be placed under a conduit through the embankment.

5. **Backfill** - All backfill material and placement should conform to Structure Backfill specifications in **Minimum Standard 3.01, Earthen Embankment**.

Reinforced Concrete Pipe - The following criteria apply:

1. **Materials** - Reinforced concrete pipe should have bell and singular spigot joints with rubber gaskets and should equal or exceed ASTM Designation C-361.

2. **Bedding** - All reinforced concrete pipe conduits should be laid in a **concrete** bedding for their entire length. This bedding should consist of high slump concrete placed under the pipe and up the sides of the pipe at least 25% of its outside diameter, and preferrably to the spring line, with a minimum thickness of 3 inches, or as shown on the drawings.

3. **Laying pipe** - Bell and spigot pipe should be placed with the bell end upstream. Joints should be made per recommendations from the manufacturer. After the joints are sealed for the entire run of pipe, the bedding should be placed so that all spaces under the pipe are filled. Care should be taken to prevent any deviation from the original line and grade of the pipe.

4. **Backfill** - All backfill material and placement should conform to Structure Backfill specifications in **Minimum Standard 3.01, Earthen Embankment**.

Polyvinyl Chloride (PVC) Pipe - The following criteria apply:

1. **Materials** - PVC pipe should be PVC-1120 or PVC-1220 conforming to ASTM D-1785 or ASTM D-2241.

2. **Connections** - Joints and connections to anti-seep collars should be completely watertight.

3. **Bedding** - The pipe should be firmly and uniformly bedded throughout its length. Where rock or soft, spongy or other unstable soil is encountered, it should be removed and replaced with suitable earth that is subsequently compacted to provide adequate support.

4. **Backfill** - All backfill material and placement should conform to Structure Backfill specifications in **Minimum Standard 3.01, Earthen Embankment**.

Filters and Drainage Layers

In order to achieve maximum density of clean sands, filter layers should be flooded with clean water and vibrated just after the water drops below the sand surface. The filter material should be placed in lifts of no more than 12 inches.

Up to four feet of embankment material may placed over a filter material layer before excavating back down to expose the previous layer. After removing any unsuitable materials, the trench may be filled with additional 12-inch lifts of filter material, flooded, and vibrated as described above, until the top of adjacent fill is reached.

Filter fabrics should not be used in lieu of sands and gravel layers within the embankment.

Concrete

Concrete should meet the requirements of the Virginia Department of Transportation (VDOT) Road and Bridge Specifications, latest edition.

Outlet Protection

Outlet protection should meet the requirements and construction specifications of the VESCH, 1992 edition, Std. & Spec. 3.18, Outlet Protection, and 3.19, Riprap, latest edition. Materials should conform to the following:

1. Filter fabric should meet or exceed the requirements in Standard & Specification 3.18 and 3.19 in the VESCH, 1992 edition.

2. Riprap should meet or exceed the requirements in Standard & Specification 3.18 and 3.19 in the VESCH, 1992 edition.

3. Gabion baskets should be made of hexagonal triple-twist mesh, PVC coated, heavily galvanized steel wire. The maximum linear dimension of the mesh opening should not exceed 4 1/2 inches and the area of the mesh opening should not exceed 10 square inches.

Stone or riprap for the baskets should be sized according to the following criteria:

TABLE 3.02 - 3
Gabion Basket Criteria

BASKET THICKNESS		STONE SIZE
inches	*millimeters*	*inches*
6	150	3 - 5
9	225	4 - 7
12	300	4 - 7
18	460	4 - 7
36	910	4 - 12

The stone or riprap should consist of field stone or rough, unhewn quarry stone. The stone should be hard and angular and of a quality that will not disintegrate from exposure to water or weather. The specific gravity of the individual stones should be at least 2.5.

Recycled concrete may be used and will be considered equivalent if it has a density of at least 150 pounds per cubic foot and no exposed steel or reinforcing bars.

Trash Rack and Debris Control Devices

All trash rack and debris control components should be stainless steel or galvanized metal per the Virginia Department of Transportation (VDOT) specifications. Trash racks attached to a concrete spillway structure should be secured with stainless steel anchor bolts.

Maintenance and Inspection Guidelines

This section presents general operation, maintenance and inspection guidelines for principal spillways and components. However, these guidelines are not intended to be all-inclusive. Specific structures may require special measures not discussed here. The engineer is responsible for determining what, if any, additional items are necessary.

1. Spillway structures should be cleared of debris periodically and after any significant rainfall event where inspection reveals a significant blockage.

2. During low water conditions, concrete spillway structures should be inspected to decide if water is passing through any joints or other structure contacts and to identify any cracks, spalling, broken or loose sections. Any cracked, spalled, broken or loose sections should be cleaned and refilled with an appropriate concrete patching material. A professional engineer should be consulted to repair extensive leakage, spalls or fractures.

3. Outlet protection (stilling basins) and discharge channels should be cleared of brush at least once per year.

4. Trash racks and locking mechanisms should be inspected and tested periodically to make sure they are intact and operative.

5. All sluice gates (or other types of gates or valves used to drain an impoundment) should be operated periodically to insure proper function. The gate and stem should be periodically lubricated and all exposed metal should be painted to protect it from corrosion.

6. Any repairs made to the principal spillway (riser or barrel) should be reviewed by a professional engineer. Vertical trenching to expose the barrel should not be allowed under any circumstances. The trench side slopes should be stepped back at a 2:1 slope, minimum.

VEGETATED EMERGENCY SPILLWAY

Definition

A vegetated emergency spillway is an open channel, usually trapezoidal in cross-section, that is constructed beside an embankment. It consists of an *inlet channel*, a *control section*, and an *exit channel*, and is lined with erosion-resistant vegetation.

Purpose

The purpose of a vegetated emergency spillway is to convey flows that are greater than the principal spillway's design discharge at a *non-erosive velocity* to an *adequate channel*.

Conditions Where Practice

A vegetated emergency spillway is appropriate to use when the required maximum design flood volume exceeds the capacity of the principal spillway system. A vegetated emergency spillway may also be used as a safety feature to pass flood flows when or if the principal spillway becomes clogged.

Planning Considerations

The *adjacent topography* (steepness of the abutments), the *existing or proposed land* use, and *other factors* (such as a roadway over the embankment) influence the design and construction of a vegetated emergency spillway.

Vegetated emergency spillways must be built in existing ground or "cut." Therefore, additional land disturbance beside the embankment must be accounted for during the planning stages of a project. Sometimes, an emergency spillway may not be practical due to this or other considerations.

Remember, even though an emergency spillway helps to extend the life expectancy of an impoundment and lowers the associated downstream hazard conditions, it should not be located on any portion of the embankment fill.

If site topography or other constraints preclude the use of a vegetated emergency spillway in "cut," the principal spillway can be oversized to pass the additional flows or an *armored* emergency spillway may be provided. A cost analysis may be helpful to aid in the selection of the spillway type. If armoring is chosen, riprap, concrete or any other permanent, nonerodible surface may be used. Note, however, that **an armored emergency spillway over the top of an embankment should be designed by a qualified professional**.

Vegetated emergency spillways should be used only where the soils and topography will permit safe discharge of the peak flow at a point downstream from the embankment and at a velocity that will not cause appreciable erosion. Additional flood storage in the reservoir may be provided to reduce the design flow or the frequency with which the spillway is used.

Design Criteria

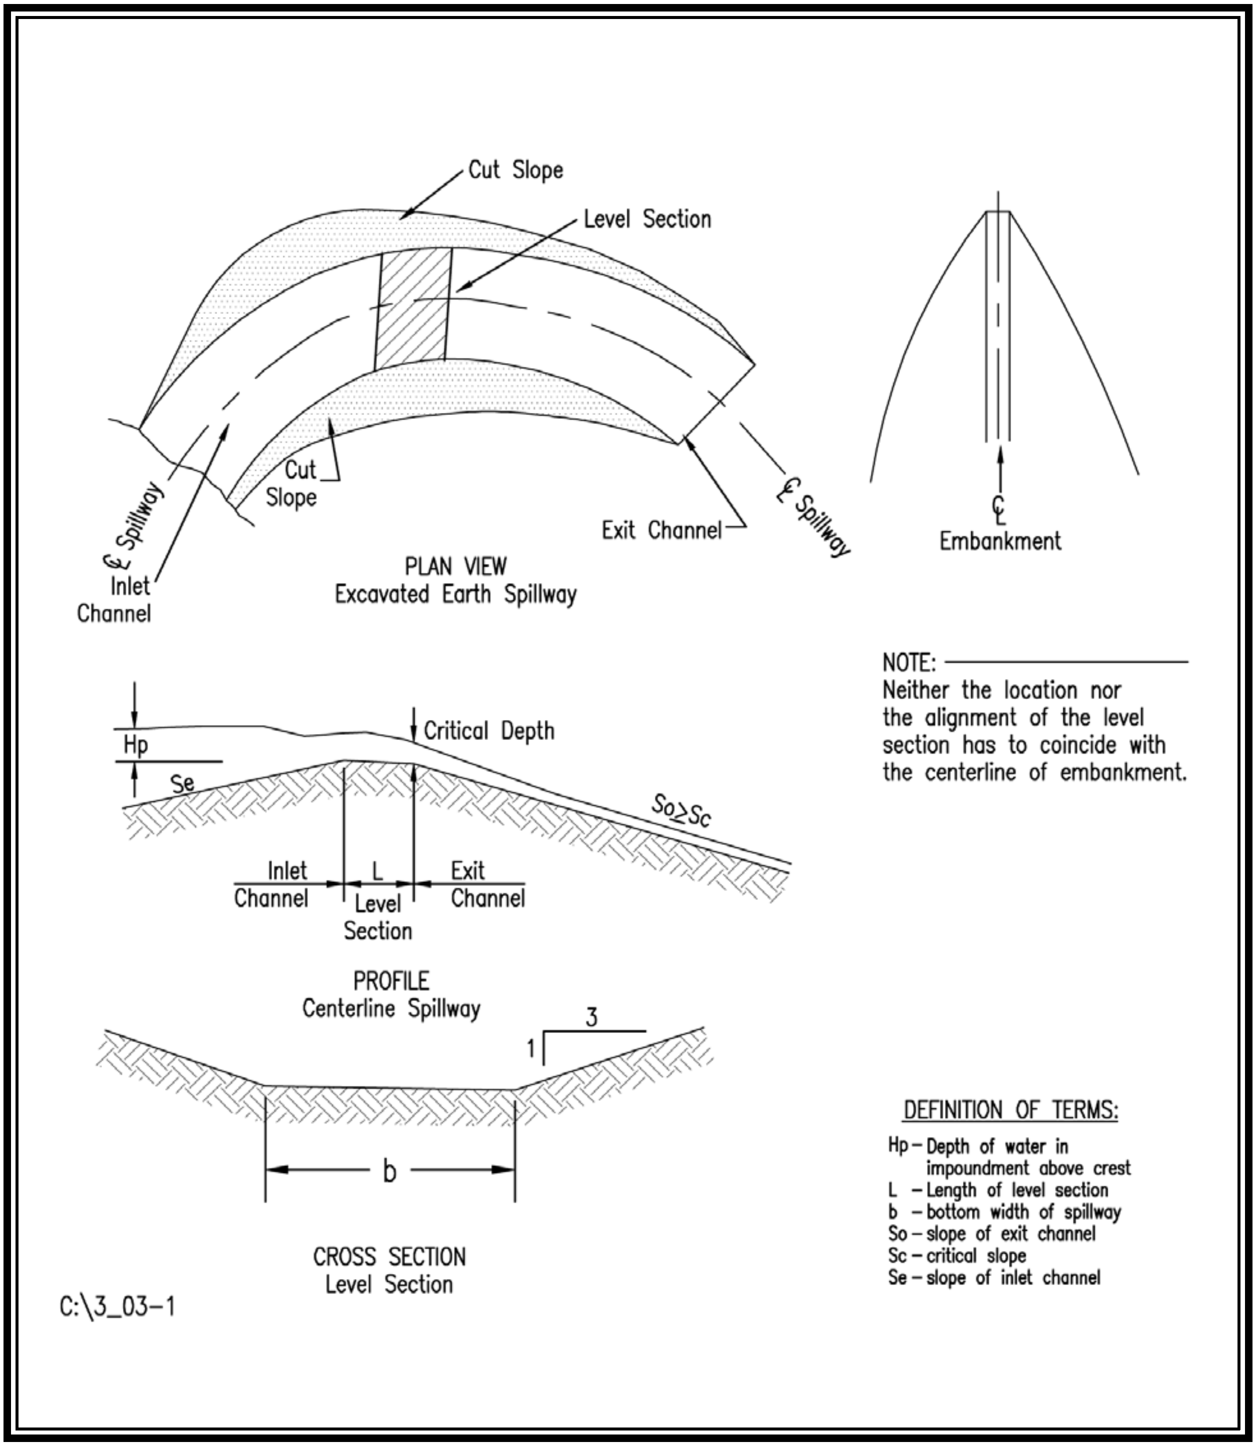
A vegetated emergency spillway is designed to convey a pre-determined design flood discharge without excessive velocities and without overtopping the embankment. **The maximum design water surface elevation through the emergency spillway should be at least 1 foot lower than the settled top of the embankment**.

Layout

Vegetated spillways should be constructed in undisturbed earth in the abutments at one or both ends of an earthen embankment or over a topographic saddle anywhere on the periphery of the basin. **The channel should be excavated into undisturbed earth or rock and the water surface, under maximum design flood discharge, should be confined by undisturbed earth or rock**.

Excavated spillways consist of three elements: 1) an *inlet channel*, 2) a *level section*, and 3) an *exit channel*. (See **Figure 3.03-1**.) Flow enters the spillway through the inlet channel. The depth of flow, H_p, located upstream from the level section, is controlled in the level section and then discharged through the exit channel. Flow in the inlet channel is *sub-critical*. Flow in the exit channel can be either *critical* or *supercritical*. **The control section is, therefore, the point on the spillway where the flow passes through critical depth**. It is recommended that the control section be installed close to the intersection of the earthen embankment and the emergency spillway centerlines.

FIGURE 3.03 - 1
Typical Plan and Profiles Along the Centerline of an Earth Spillway



The topography must be carefully considered when constructing an emergency spillway. The alignment of the exit channel must be straight to a point far enough below the embankment to insure that any flow escaping the exit channel cannot damage the embankment. This may result in additional clearing and/or grading requirements beside the abutments, property line, etc.

Figure 3.03-1 shows profiles along the centerline of a typical vegetated spillway. To reduce losses through the inlet channel, the cross-sectional area of flow in the inlet channel should be large in comparison to the flow area at the control section. Where the depth of the channel changes to provide for the increased flow area, the bottom width should be altered gradually to avoid abrupt changes in the shape of the sloping channel banks.

The exit channel must have an adequate slope to discharge the peak flow within the channel. However, the slope must be no greater than that which will produce maximum permissible velocities for the soil type or the planned grass cover.

Soil Types and Vegetative Cover

The type of soil and vegetative cover used in an emergency spillway can be used to establish the spillway design dimensions (Procedure 2 - **Chapter 5-8**). Soil types are classified as *erosion resistant* and *easily erodible*. ***Erosion resistant soils*** are those with a high clay content and high plasticity. Typical soil textures for erosion resistant soils are silty clay, sandy clay, and clay. ***Easily erodible soils*** are those with a high content of fine sand or silt, and a low plasticity or non-plastic. Typical soil textures for easily erodible soils are fine sand, silt, sandy loam, and silty loam. **Table 3.03-1** provides permissible velocities for a vegetated spillway based on its soil type, vegetated cover, and exit channel slope. The maximum permissible velocity may be increased by 25% when the anticipated average use is less than once in 10 years.

In general, it is recommended that a vegetated emergency spillway be designed to operate during the 100-year frequency storm or greater.

The *type* and *length of vegetative cover* affect the design of a vegetated spillway. Vegetation provides a *degree of retardance* to the flow through the spillway. **Table 3.03-2** gives retardance values for various heights of vegetative cover. Retardance for a given spillway will depend mostly upon the *height* and *density* of the cover chosen. Generally, after the cover is selected, “retardance with a good, uncut condition” should be used to find the capacity. Since a condition offering less protection and less retardance exists during the establishment period and after mowing, a lower degree of retardance should be used when designing for stability. Refer to the sample exercises for the design of vegetated spillways found in **Chapter 5**.

Hydraulic Design

The hydraulic design of earthen spillways can be simplified if the effects of *spillway storage* are ignored. Stormwater facilities designed for compliance with state or local stormwater management regulations are typically small, resulting in minimal storage effects on the flood routing.

Two design calculation procedures are presented in **Chapter 5-8**. The first (Procedure 1) is a conservative design procedure which is also found in the Virginia Erosion & Sediment Control Handbook (VESCH) 1992 edition, (Std., & Spec. 3.14). This procedure is typically acceptable for stormwater management basins. The second method (Procedure 2) utilizes the roughness, or retardance, and durability of the vegetation and soils within the vegetated spillway. This second design is appropriate for larger or regional stormwater facilities where the construction inspection and permanent maintenance are more readily enforced. These larger facilities typically control relatively large watersheds and are located such that the stability of the emergency spillway is essential to safeguard downstream features.

If the inflow is known (from the post-developed condition hydrology) and either the desired maximum water surface elevation, or the approximate width of the proposed emergency spillway (established by the embankment geometry and the adjacent topography), then the relationship between H_p, the depth of flow through the emergency spillway, and b, the emergency spillway bottom width, can be established using design Procedure 1 (**Chapter 5-8**) and **Table 5-12**.

If the required discharge capacity, *Q*, permissible velocity, *V* (see **Table 3.03-1**), degree of retardance, *C* (see **Table 3.03-2**), and the natural slope of the exit channel, s_o , are known, then the bottom width, *b*, of the level and exit sections and the depth of flow, H_p , may be computed using design Procedure 2 (**Chapter 5-8**) and **Table 5-13**.

Table 5-13(a-d) is not appropriate for bottom widths less than 8 feet.

The hydraulic design of a vegetated emergency spillway should comply with the following:

1. The maximum permissible velocity for vegetated spillways should be selected using **Table 3.03-1**.

2. The slope range of the exit channel provided in **Table 5-11**, **Chapter 5**, is a minimum slope range needed to insure ***supercritical*** flow in the exit channel.

3. Spillway side slopes should be no steeper than 3H:1V unless the spillway is excavated into rock.

4. For a given H_p , a decrease in the exit slope from s_o, as given in **Table 5-11** of **Chapter 5**, decreases the spillway discharge, but increasing the exit slope from s_o does not increase discharge.

5. The exit channel should have a straight alignment and grade and, at a minimum, the same cross-section as the control section.

6. The inlet channel should have a straight alignment and grade.

7. The selected bottom width of the spillway should not exceed 35 times the design depth of flow. Where this ratio of bottom width to depth is exceeded, the spillway is likely to be damaged by meandering flow and accumulated debris. Whenever the required bottom width of the spillway is excessive, consideration should be given to the use of a spillway at each end of the dam. The two spillways do not need to be of equal width if their total capacity meets design requirements. If the required discharge capacity exceeds the ranges shown in the referenced tables, or topographic conditions preclude the construction of the exit channel bottom using a slope that falls within the designated ranges, alternate design procedures should be used.

8. Vegetated emergency spillways should be designed for use with the 100-year frequency storm or greater.

Construction Specifications

Overall, widely acceptable construction standards and specifications for a vegetated emergency spillway on an embankment, such as those developed by the USDA Soil Conservation Service or the U. S. Army Corps of Engineers, should be followed. Further guidance can be found in the SCS Engineering Field Manual and the National Engineering Handbook. Specifications for all earthwork and any other related work should conform to the methods and procedures that apply to the site and the purpose of the structure. The specifications should also satisfy any requirements of the local government.

Installation of a vegetated emergency spillway consists of the following: a) *excavating the proper bottom width and side slopes according to the approved plan*, b) *backfilling with 12 inches of topsoil (minimum)*, and c) *stabilizing the area* following the VESCH, 1992 edition.

Maintenance and Inspection Guidelines

The following maintenance and inspection guidelines are recommendations. The engineer must decide if additional criteria are needed based upon the size and scope of the facility.

1. Vegetated emergency spillway channels should be mowed concurrently with the embankment and should not be cut to less than 6 to 8 inches in height.

2. The emergency spillway approach and discharge channels should be cleared of brush and other woody growth periodically.

3. After any flow has passed through the emergency spillway, the spillway crest (control section) and exit channel should be inspected for erosion. All eroded areas should be repaired and stabilized.

SEDIMENT FOREBAY

Definition

A sediment forebay is a settling basin or plunge pool constructed at the incoming discharge points of a stormwater BMP.

Purpose

The purpose of a sediment forebay is to allow sediment to settle from the incoming stormwater runoff before it is delivered to the balance of the BMP. A sediment forebay helps to isolate the sediment deposition in an accessible area, which facilitates BMP maintenance efforts.

Condition Where Practice Applies

A sediment forebay is an essential component of most impoundment and infiltration BMPs including retention, detention, extended-detention, constructed wetlands, and infiltration basins.

Planning Considerations

A sediment forebay should be located at each inflow point in the stormwater BMP. Storm drain piping or other conveyances may be aligned to discharge into one forebay or several, as appropriate for the particular site. Forebays should be installed in a location which is accessible by maintenance equipment.

Water Quality

A sediment forebay not only serves as a maintenance feature in a stormwater BMP, it also enhances the pollutant removal capabilities of the BMP. The volume and depth of the forebay work in concert with the outlet protection at the inflow points to dissipate the energy of incoming stormwater flows. This allows the heavier, course-grained sediments and particulate pollutants to settle out of the runoff. **Note that for the BMPs listed in this handbook, the target pollutant removal efficiencies have been established assuming sediment forebays are included in the design**. Therefore, no additional pollutant removal efficiency is warranted for using a sediment forebay.

Channel Erosion Control and Flood Control

An "on line" BMP designed for flood control and channel erosion control is subject to the natural bed material (sediment) load, plus any bed load increases due to higher velocities in the upstream channels. This is especially true for regional facilities where the upstream channel is used to convey the increased developed condition flows. In such cases, the sediment forebay becomes an essential facility maintenance component since it serves to simplify clean-out operations.

Studies indicate that a well-designed retention basin will function for 20 to 25 years before it needs dredging. This implies a gradual sediment accumulation process. A concern regarding stormwater basins is that the landowners will probably change at least once during that 20 to 25-year period. The new owners may not be aware of the maintenance requirements and, may therefore, neglect to maintain the facility. Sediment will then continue to accumulate and will eventually fill the BMP pool volume.

A sediment forebay, however, is designed to trap the sediments within a confined area. This causes a more rapid sediment accumulation. Studies indicate that for a typical mixed-use watershed, sediment removal from the forebay should occur every 3 to 5 years. Despite this frequency, removal of sediment from the forebay should be less costly over the same time period than a one time cleaning of the entire basin. This is due in part to the fact that removing sediment from the forebay is a much simpler operation than that of an entire stormwater basin or pond. The sediment is confined to strategic forebay locations with easy access. Furthermore, the more frequent and less expensive schedule will likely become a regular part of the operation and maintenance efforts of the owners.

Design Criteria

The most attractive aspect of a sediment forebay is its isolation from the rest of the facility. To create this separation, an earthen berm, or a gabion, concrete, or riprap wall can be constructed along the outlet side of the forebay. A designed overflow section should be constructed on the top of the separation to allow flow to exit the forebay at non-erosive velocities during the 2-year and 10-year frequency design storms. The overflow section may be set at the permanent pool elevation or the extended-detention volume elevation. It may also be designed to serve as a spillover for the forebay if the forebay is set at a higher elevation than the second or remaining cell.

The use of an aquatic bench with emergent vegetation around the perimeter will help with water quality as well as provide a safety feature for large forebays (used on large lake BMPs or retrofits).

Volume

The sediment forebay should be sized to hold 0.25 inches of runoff per impervious acre of contributing drainage area, with an absolute minimum of 0.1 inches per impervious acre. The volume of the sediment forebay is not in addition to the required volume of the retention basin permanent pool, but rather as part of the required pool volume. For dry facilities, the forebay does not represent available storage volume if it remains full of water. A dry forebay must be carefully designed to avoid the resuspension of previously deposited sediments. The 0.1 to 0.25 impervious watershed inches is guidance for ideal performance. For smaller stormwater facilities, a more appropriate sizing criteria of 10% of the total required pool or detention volume may be more practical. This volume should be 4 to 6 feet deep to adequately dissipate turbulent inflow without resuspending previously deposited sediment (Center for Watershed Protection, 1995).

Maintenance

Direct access to the forebay should be provided to simplify maintenance. Provision of a hardened access or staging pad adjacent to the forebay is also beneficial. Such an area helps protect the forebay and basin from excessive erosion resulting from operation of the heavy equipment used for maintenance. The pad area can be hardened by installing block pavers or similar material. Also, a hardened bottom to the forebay will help avoid over excavation during clean out operations.

In addition, a fixed, vertical, sediment depth marker should be installed in each sediment forebay to measure the sediment deposition. The sediment depth marker will allow the owner to monitor the accumulation and anticipate maintenance needs. Clean out frequency will vary depending on the conditions of the upstream watershed and the given site.

In general, sediment should be removed from the forebay every 3 to 5 years, or when 6 to 12 inches have accumulated, whichever comes first. To clean the forebay, draining or pumping and a possible temporary partial drawdown of the pool area may be required. Refer to the VESCH, 1992 edition for proper dewatering methods.

To reduce costs associated with hauling and disposing of dredged material, a designated spoil area should be approved and identified on the site during initial design and development of the project.

LANDSCAPING

Definition

Landscaping is the placement of vegetation in and around stormwater management BMPs.

Purpose

The purpose of landscaping is to help stabilize disturbed areas, enhance the pollutant removal capabilities of a stormwater BMP and improve the overall aesthetics of a stormwater BMP.

Conditions Where Practice Applies

A landscape plan is an integral part of any land development project. It provides guidance and specifications for the type, location, and number of planting units according to the various requirements of the development project. A landscape plan may need one or all of the following:

1. Minimum green space or other requirements per local zoning or stabilization ordinances.

2. Natural and manmade vegetative buffer requirements between differing land uses or between developed land and natural resources.

3. Landscaping and stabilization requirements for stormwater management BMPs.

This minimum standard focuses on landscaping and stabilization requirements for stormwater management BMPs and their associated buffer areas. This standard may also be appropriate for other landscaping applications used in plan and specification preparation.

Certain BMPs, such as constructed wetlands, retention basins with an aquatic bench, *enhanced* extended detention basins with a shallow marsh, bioretention facilities, etc., require very specific plant materials and handling specifications. Refer to the minimum standards found in this chapter for additional criteria applicable to specific BMP designs.

Landscaped areas can provide significant reductions in pollutant export from developed sites through biological uptake of nutrients, sediment trapping, filtering, and infiltration.

For stormwater management purposes, landscaping is considered an integral component of a structural BMP. While the benefit realized from landscaping may be difficult to measure, it is widely accepted that the biological processes occurring in detention and retention BMPs are greatly enhanced by using vegetation. **The target pollutant removal efficiencies assigned to the BMPs in this handbook are based on the use of vegetative practices within the BMP buffer areas and the various BMP planting zones**. The vegetative practices should be specified in a landscape plan as part of the overall BMP and site construction documents.

Planning Considerations

Plant selection should be based on the planting zones within the BMP. Various zones exist within a stormwater impoundment and each represents a different inundation frequency and soil moisture condition. The planting zones can be classified as follows:

Zone 1: Deep Water Areas: This zone is submerged beneath 18 inches to 6 feet of water. It supports submerged aquatic vegetation such as pondweed, coontail, wild celery, etc., and floating vegetation such as duckweed. Plants can actively remove metals from the water and provide food and habitat for invertebrates at the bottom of the food cycle. This zone may be present in retention basins, constructed wetlands, and in sediment forebays and micro-pools of extended-detention and *enhanced* extended-detention basins.

Zone 2: Shallow Water Area: This zone is 0 to 18 inches in normal depth and is the primary area for the establishment of emergent wetland plants. It may be present in retention basins, constructed wetlands, and *enhanced* extended-detention basins. This zone is divided into **low-marsh** and **high-marsh** sub-zones. The low-marsh extends from 6 to 18 inches in depth below the normal water surface. The high-marsh ranges from 6 inches below the normal water surface and up to the normal water surface. Vegetation in this zone can serve the following purposes:

- enhances nutrient uptake,
- reduces flow velocities to increase the rate of sediment deposition,
- reduces resuspension of bottom sediments,
- provides food and cover for wildlife,
- provides habitat for predatory insects and to serve as a check for mosquitoes,
- reduces shoreline erosion, and
- improves aesthetics

Suggested plants for this zone include common three-square, soft-stem bulrush, pickerelweed, arrow arrum, sedges, and others.

Zone 3: Shoreline Fringe: This zone is regularly inundated during runoff-producing storm events and may remain saturated due to the proximity of the permanent pool. However, plants must be tolerant of periodic drying, especially during the summer months. This zone extends from the normal water surface to about 1 foot above the normal water surface for retention basins and constructed wetlands. It also continues up to the maximum extended-detention volume elevation for extended-detention and *enhanced* extended-detention basins. The vegetation in this zone may serve the following purposes:

- stabilizes the shoreline,
- improves aesthetics,
- limits shoreline access by people and animals (geese),
- provides food, cover, and nesting for wildlife, and
- provides shade

Recommended species for this zone include herbaceous vegetation such as soft-stem bulrush, pickerelweed, rice cutgrass, sedges, and others. It also includes trees such as black willow and river birch and shrubs such as chokeberry.

Zone 4: Riparian Fringe Area: This zone is only briefly inundated during storms. It generally includes the upper storage areas of extended-detention basins (above the water quality or channel erosion control volume) and the lower basin areas of dry detention basins. It experiences both wet and dry soil conditions and periodic inundation. The vegetation in this zone may serve the following purposes:

- reduce resuspension of newly deposited sediments,
- prevent erosion, and
- provide habitat and food for wildlife,

A variety of trees, shrubs, and ground covers can be used in this zone, including black willow, river birch, red chokeberry, green ash, sweetgum and others.

Zone 5: Floodplain Terrace: This zone experiences inundation only during large storms. It is generally between the 2-year and 100-year water surface elevations. Plant species native to floodplains usually grow well in this zone. Plants selected for the floodplain terrace should have the following traits:

- ability to provide erosion control on steep slopes,
- ability to survive periodic mowing,
- ability to withstand exposure and compacted soil, and
- require minimal maintenance

Zone 6: Upland Areas: This zone seldom, if ever, experiences inundation and may include any buffer areas required for stormwater basins. Selection of plant species in this zone typically depends on local soil conditions and the intended secondary uses of the area. Refer to **Table 3.05-4** for a plant guide.

Figure 3.05-1 shows a schematic cross-section of the six planting zones. Designers should select appropriate plant and tree species based on the characteristics of each zone, local soil conditions, sun and wind exposure levels, and intended secondary uses of the buffer area.

Preservation of Existing Vegetation

Although there are many reasons to minimize land disturbance associated with development, one of the greatest benefits may be the reduced runoff associated with undisturbed ground. Existing vegetation helps prevent erosion, filters runoff, and allows stormwater to filter into the ground, which ultimately results in lower stormwater management costs. As for the economics of site development, planning for the selective preservation of vegetation on a site **before land disturbance** is much less costly than trying to reestablish it once it has been removed. This holds true for both labor and replacement costs. In addition, studies conducted by the U.S. Forest Service and others indicate that preserving mature vegetation on residential sites can increase property values by 30% (NVPDC, 1996).

For guidance on non-structural BMPs and vegetative practices in general, refer to the following references:

- *Piedmont Provinces Vegetative Practices Guide, NVPDC, 1996.*
- *Nonstructural BMP Handbook: A Guide to Nonpoint Source Pollution Prevention Measures, NVPDC, 1996.*
- *Vegetative Practices Guide for Nonpoint Source Pollution Management, HRPDC, 1992.*
- *Chesapeake Bay Local Assistance Manual, CBLAD, 1989.*
- *Virginia Erosion & Sediment Control Handbook (VESCH), DCR, 1992.**

* The VESCH, 1992 edition, also provides details for tree preservation during construction.

Design Criteria

The landscape plan for a stormwater BMP depends on the BMP being used. However, there are key components to any landscape plan which help assure its overall success. The following section describes these components.

A landscape plan for a stormwater management BMP should contain the following, at a minimum:

Plant Species Selection

Plants selected for a stormwater BMP must tolerate urban stresses such as pollutants, along with variable soil moisture and ponding fluctuations, climate, soils, and topography. Virginia has three distinct physiographic regions that reflect changes in soils and topography: Coastal Plain, Piedmont, and Appalachian and Blue Ridge regions. See **Figure 3.05-2**.

When selecting plants, native plant species should be used, if possible. Nonnative plants may require more care to adapt to the hydrology, climate, exposure, soil and other conditions. Also, some nonnative plants can become invasive, especially those used for stabilization, and may ultimately choke out the native plant population.

Newly constructed stormwater BMPs will be fully exposed for several years before the buffer vegetation becomes adequately established. Therefore, plants which require full shade, are susceptible to winter kill, or are prone to wind damage, should be avoided.

The plant material should conform to the American Standard for Nursery Stock, current issue, as published by the American Association of Nurserymen. The botanical (scientific) name of the plant species should be in accordance with the landscape industry's standard nomenclature. All plant material specified should be suited for USDA Plant Hardiness zones 6 or 7. See **Figure 3.05- 3**.

Transport and Storage of Plant Material

Specifications may be required for the handling and storage of certain plant materials. Aquatic or emergent plants, for example, require very precise instructions for the contractor. Depending on the time of year and the sequence of construction, it may not be prudent to deliver the plants to the site until the project is ready for landscaping.

Sequence of Construction

The *sequence of construction* describes the site preparation activities such as grading, addition of soil amendments, and any preplanting requirements. It also addresses the installation of erosion and sediment control measures, which should be in place until the entire landscape plan is implemented and the site is stabilized.

Installation of Plant Material

The success of any landscape plan depends on the selection of the proper specifications that are subsequently implemented by the contractor. The specifications should include procedures for installing the plants. They should also provide details for the steps to be taken before and after installation, such as any special instructions for the preparation of the planting pit and fertilization requirements. Any seasonal requirements for installation should also be specified. Typically, containerized or balled and burlapped trees or shrubs should be planted between March 15 and June 30, or between September 15 and November 15.

The placement of trees or shrubs on an embankment is prohibited. The root system of large trees and shrubs can threaten the structural integrity of the embankment and possibly cause its failure.

The side slopes of detention and retention BMPs are usually compacted during the construction process to ensure stability. The density of these compacted soils is often such that plant roots cannot penetrate to an adequate depth, leading to premature mortality or loss of vigor. Therefore, it is advisable to excavate oversized holes around the proposed planting sites and backfill with uncompacted topsoil. In general, planting holes should be 3 times deeper and wider than the diameter of the root ball (B&B stock) and 5 times deeper and wider for container-grown stock (MWCOG, 1992).

Contractor Responsibilities

The contractor should conform to any specifications that directly affect his aspect of the work. He should be aware that there may be penalties for unnecessarily delayed work, minimum success rate of plantings, etc.

For projects involving bio-retention basins or constructed wetlands, it may be advisable to utilize a subcontractor who specializes in aquatic landscaping. The plant specifications, handling, and installation procedures can be unusual compared to traditional landscaping requirements.

Maintenance

A maintenance schedule should be provided in the project plans and/or specifications. This is particularly important for BMPs that have a vegetative component that is integral to the pollutant removal efficiency. The schedule should include guidance regarding methods, frequency, and time of year for landscape maintenance and fertilization.

Specific plant communities may require different levels of maintenance. Upland and floodplain terrace areas, grown as meadows or forests, require very little maintenance, while aquatic or emergent vegetation may need periodic thinning or reinforcement plantings. Note that after the first growing season it should be obvious if reinforcement plantings are needed. If they are, they should be installed at the onset of the second growing season after construction.

Research indicates that for most aquatic plants the uptake of pollutants are stored in the roots, not the stems and leaves (Lepp 1981). Therefore, aquatic plants should not require harvesting before winter plant die-back. There are still many unanswered questions about the long term pollutant storage capacity of plants. It is possible that aquatic and emergent plant maintenance recommendations may be presented in the future.

Trees and Shrubs

Tree/Shrub	*Zone	Form	Available	Inundation Tolerance	Wildlife Value	Notes
American Beech *(Fagus grandifolia)*	5,6	Dec. Tree	no	no	High, mammals and birds.	Prefers shade and rich, well-drained soils.
American Holly *(Ilex opaca)*	5,6	Dec. Tree	yes	some	High,songbirds, food, cover, nesting.	Coastal plain only. Prefers shade and rich soils.
American Hornbeam *(Carpinus caroliniana)*	4,5	Dec. Tree	yes	yes	Moderate, food, browsing.	Most common in flood plains and bottom land of Piedmont and mountains.
Arrowwood Viburnum *(Viburnum dentatum)*	2,3,4	Dec. Shrub	yes	no	High, songbirds and mammals.	Grows best in sun to partial shade.
Bald Cypress *(Taxodium distichum)*	3,4	Dec. Tree	yes	yes	Little food value but good perching site for waterfowl.	Forested Coastal Plain wetlands. North of normal range. Tolerates drought.
Bayberry *(Myricia pensylvanica)*	4,5,6	Dec. Shrub	yes	no	High, nesting, food cover. Berries last into winter.	Coastal Plain only. Roots fix N. Tolerates slightly acidic soil.
Bitternut Hickory *(Carya cordiformis)*	3,4,5	Dec. Tree	no	yes	High, food.	Moist soils or wet bottom land areas.
Black Cherry *(Prunus serotina)*	5,6	Dec. Tree	yes	yes	High, fruit is eaten by many birds.	Temporarily flooded forested areas. Possible fungus infestation.
Black Walnut *(Juglans nigra)*	5,6	Dec. Tree	yes	yes	High, food.	Temporarily flooded wetlands along flood plains. Well drained, rich soils.
Blackgum or Sourgum *(Nyssa sylvatica)*	4,5,6	Dec. Tree	yes	yes	High, songbirds, egrets, herons, raccoons, owls.	Can be difficult to transplant. Prefers sun to partial shade.
Black Willow *(Salix nigra)*	3,4,5	Dec. Tree	yes	yes	High, browsing and cavity nesters.	Rapid growth, stabilizes stream banks. Full sun.
Buttonbush *(Cephalanthus occidentalis)*	2,3,4,5	Dec. Shrub	yes	yes	High, ducks and shorebirds. Seeds, nectar and nesting.	Full sun to partial shade. Will grow in dry areas.
Chestnut Oak *(Quercus prinus)*	5,6	Dec. Tree	no	no	High. Cover, browse and food.	Gypsy moth target. Dry soils.

FIGURE 3.05 - 4a (cont.)

Tree/Shrub	*Zone	Form	Available	Inundation Tolerance	Wildlife Value	Notes
Common Choke Cherry *(Prunus virginiana)*	5,6	Dec. Tree	no	some	High, birds, mammals. Fruit and cover.	Prefers drier conditions.
Common Spicebush *(Lindera benzoin)*	4,5	Dec. Shrub	yes	no	Very high, songbirds.	Shade and rich soils. Tolerates acidic soils. Good understory species.
Eastern Cottonwood *(Populus deltoides)*	4,5	Dec. Tree	yes	yes	Moderate, cover, food.	Shallow rooted, subject to windthrow. Invasive roots. Rapid growth.
Eastern Hemlock *(Tsuga conadensis)*	5,6	Conif. Tree	yes	yes	Moderate. Mostly cover and some food.	Tolerates all sun/shade conditions. Tolerates acidic soil.
Eastern Red Cedar *(Juniperus virginiana)*	4,5,6	Conif. Tree	yes	no	High. Fruit for birds. Some cover.	Full sun to partial shade. Common in wetlands, shrub bogs and edge of streams.
Elderberry *(Sambucus canadensis)*	4,5,6	Dec. Shrub	yes	yes	Extremely high for food and cover, for birds and mammals.	Full sun to partial shade.
Flowering Dogwood *(Cornus florida)*	4,5,6	Dec. Tree	no	yes	High, birds, food.	Prefers rich, moist soils. Dogwood anthracnose possible problem.
Fringe Tree *(Chionanthus viginicus)*	3,4,5	Dec. Shrub or small tree	yes	some	Moderate. Food and cover.	Full sun to partial shade. Tolerates acidic soil.
Green Ash, Red Ash *(Fraxinus pennysylvanica)*	4,5	Dec. Tree	yes	yes	Moderate, songbirds.	Rapid growing stream bank stabilizer. Full sun to partial shade.
Hackberry *(Celtis occidentalis)*	5,6	Dec. Tree	yes	yes	High, food and cover.	Full sun to partial shade.
Ironwood/ Hophornbeam *(Ostrya virginiana)*	5,6	Dec. Tree	yes	yes	Moderate, food and browse.	Tolerant of all sunlight conditions.
Larch, Tamarack *(Larix laricina)*	3,4	Conif. Tree	no	yes	Low, nest tree and seeds.	Rapid initial growth. Full sun, acidic boggy soils.
Loblolly Pine *(Pinus taeda)*	5,6	Conif. Tree	yes	yes	Moderate, food, nesting, squirrels.	Coastal Plain only. Tolerant of extreme soil conditions.

FIGURE 3.05 - 4a (cont.)

Tree/Shrub	*Zone	Form	Available	Inundation Tolerance	Wildlife Value	Notes
Mountain Laurel *(Kalmia latifolia)*	6	Evergreen	no	some	Low, cover, and nectar. Foliage is toxic to cattle and deer.	Partial shade, acidic soils.
Persimmon *(Diospyros virginiana)*	4,5,6	Dec. Tree	yes	no	Extremely high, birds, mammals.	Not shade tolerant. Well-drained soils.
Pin Oak *(Quercus palustris)*	4,5,6	Dec. Tree	yes	yes	High, mast. Tolerates acidic soil.	Gypsy moth target. Prefers sun to partial shade.
Red Chokeberry *(Pyrus arbutifolia)*	3,4,5	Dec. Shrub	no	yes	Moderate, songbirds.	Bank stabilizer. Partial sun.
Red Maple *(Acer rubrum)*	4,5,6	Dec. Tree	yes	yes	High, seeds and browse. Tolerates acidic soil.	Rapid growth.
Red Oak *(Quercus rubra)*	5,6	Dec. Tree	yes	no	High, food and cover.	Gypsy moth target. Prefers well drained, sandy soils.
River Birch *(Betula nigra)*	3,4	Dec. Tree	yes	yes	Low, but good for cavity nesters.	Bank erosion control. Full sun.
Scarlet Oak *(Quercus coccinea)*	3,4	Dec. Tree	no	no	High, food and cover.	Gypsy moth target. Difficult to transplant.
Shadbush, Serviceberry *(Amelanchier canadensis)*	5,6	Dec. Tree	yes	yes	High, nesting, cover and food. Birds and mammals.	Prefers partial shade. Common in forested wetlands and upland woods.
Silky Dogwood *(Cornus amomum)*	5,6	Dec. Shrub	yes	yes	High, songbirds, mammals.	Shade and drought tolerant. Good bank stabilizer.

Wetland Plants

Wetland Plants	*Zone	Form	Available	Inundation Tolerance	Wildlife Value	Notes
Arrow arum *(Peltandra virginica)*	2	Emergent	yes	up to 1 ft.	High, berries are eaten by wood ducks.	Full sun to partial shade.
Arrowhead/Duck potato *(Saggitaria latifolia)*	2	Emergent	yes	up to 1 ft.	Moderate, tubers and seeds eaten by ducks.	Aggressive colonizer.
Broomsedge *(Andropogon virginianus)*	2,3	Perimeter	yes	up to 3 in.	High, songbirds and browsers. Winter food and cover.	Tolerant of fluctuating water levels and partial shade.
Cattail *(Typha spp.)*	2,3	Emergent	yes	up to 1 ft.	Low, except as cover.	Aggressive. May eliminate other species. Volunteer. High pollutant treatment.
Coontail *(Ceratophyllum demersum)*	1	Submergent	no	yes	Low, food, good habitat and shelter for fish and invertebrates.	Free floating SAV. Shade tolerant. Rapid growth.
Common Three Square *(Scipus pungens)*	2	Emergent	yes	up to 6 in.	High, seeds, cover, waterfowl, songbirds.	Fast colonizer. Can tolerate periods of dryness. Full sun. High metal removal.
Duckweed *(Lemna sp.)*	1,2	Submergent /Emergent	yes	yes	High, food for waterfowl and fish.	May biomagnify metals beyond concentrations found in water.
Lizard's Tail *(Saururus cernuus)*	2	Emergent	yes	up to 1 ft.	Low, except wood ducks.	Rapid growth. Shade tolerant.
Marsh Hibiscus *(Hibiscus moscheutos)*	2,3	Emergent	yes	up to 3 in.	Low, nectar.	Full sun. Can tolerate periodic dryness.
Pickerelweed *(Pontederia cordata)*	2,3	Emergent	yes	up to 1 ft.	Moderate, ducks, nectar for butterflies.	Full sun to partial shade.
Pond Weed *(Potamogeton pectinatus)*	1	Submergent	yes	yes	Extremely high, waterfowl, marsh and shore-birds.	Removes heavy metals.
Rice Cutgrass *(Leersia oryzoides)*	2,3	Emergent	yes	up to 3 in.	High, food and cover.	Full sun, although tolerant of shade. Shoreline stabilization.

FIGURE 3.05 - 4b (cont.)

Wetland Plants	*Zone	Form	Available	Inundation Tolerance	Wildlife Value	Notes
Sedges *(Carex spp.)*	2,3	Emergent	yes	up to 3 in.	High, waterfowl, songbirds.	Many wetland and several upland species.
Soft-stem Bulrush *(Scipus validus)*	2,3	Emergent	yes	up to 1 ft.	Moderate, good cover and food.	Full sun. Aggressive colonizer. High pollutant removal.
Smartweed (Polygonum spp.)	2	Emergent	yes	up to 1 ft.	High, waterfowl, songbirds, seeds and cover.	Fast colonizer. Avoid weedy aliens such as P. Perfoliatum.
Spatterdock (Nuphar luteum)	2	Emergent	yes	up to 1.5 ft.	Moderate, for food but high for cover.	Fast colonizer. Tolerant of fluctuating water levels.
Switchgrass *(Panicum virgatum)*	2,3,4, 5,6	Perimeter	yes	up to 3 in.	High, seeds, cover. Waterfowl, songbirds.	Tolerates wet/dry conditions.
Sweet Flag *(Acorus calamus)*	2,3	Perimeter	yes	up to 3 in.	Low, tolerant of dry periods.	Tolerates acidic conditions. Not a rapid colonizer.
Waterweed *(Elodea canadensis)*	1	Submergent	yes	yes	Low.	Good water oxygenator. High nutrient, copper, manganese and chromium removal.
Wild Celery *(Valisneria americana)*	1	Submergent	yes	yes	High, food for waterfowl. Habitat for fish and invertebrates.	Tolerant of murkey water and high nutrient loads.
Wild Rice *(Zizania aquatica)*	2	Emergent	yes	up to 1 ft.	High, food. Birds.	Prefers full sun.

RETENTION BASIN

Definition

A retention basin is a stormwater facility which includes a permanent impoundment, or pool of water, and, therefore, is normally wet, even during non-rainfall periods. Inflows from stormwater runoff may be temporarily stored above this permanent pool.

Purpose

A retention basin provides for long-term water quality enhancement of stormwater runoff. Stormwater inflows may also be temporarily stored above the permanent pool for downstream flood control and channel erosion control. A retention basin is considered one of the most reliable and versatile BMPs available.

Water Quality Enhancement

High removal rates of particulate and soluble pollutants (nutrients) can be achieved in retention basins through *gravitational settling*, *biological uptake* and *decomposition*. When an even higher degree of pollutant removal efficiency is required, the basin can be ***enhanced*** by using various modifications relating to the size and design of the permanent pool.

Monitoring studies have shown sediment removal efficiencies to range from 50-90%, total phosphorus removal efficiencies to range from 30-90% and soluble nutrient removal efficiencies to range from 40-80%. (MWCOG, 1992). The design elements, physical characteristics, and monitoring techniques varied for each basin studied, which explains the wide range of efficiencies. The target pollutant removal efficiencies assigned to the different design options are presented in **Table 3.06-1**.

FIGURE 3.06 - 1
Retention Basin - Plan & Section

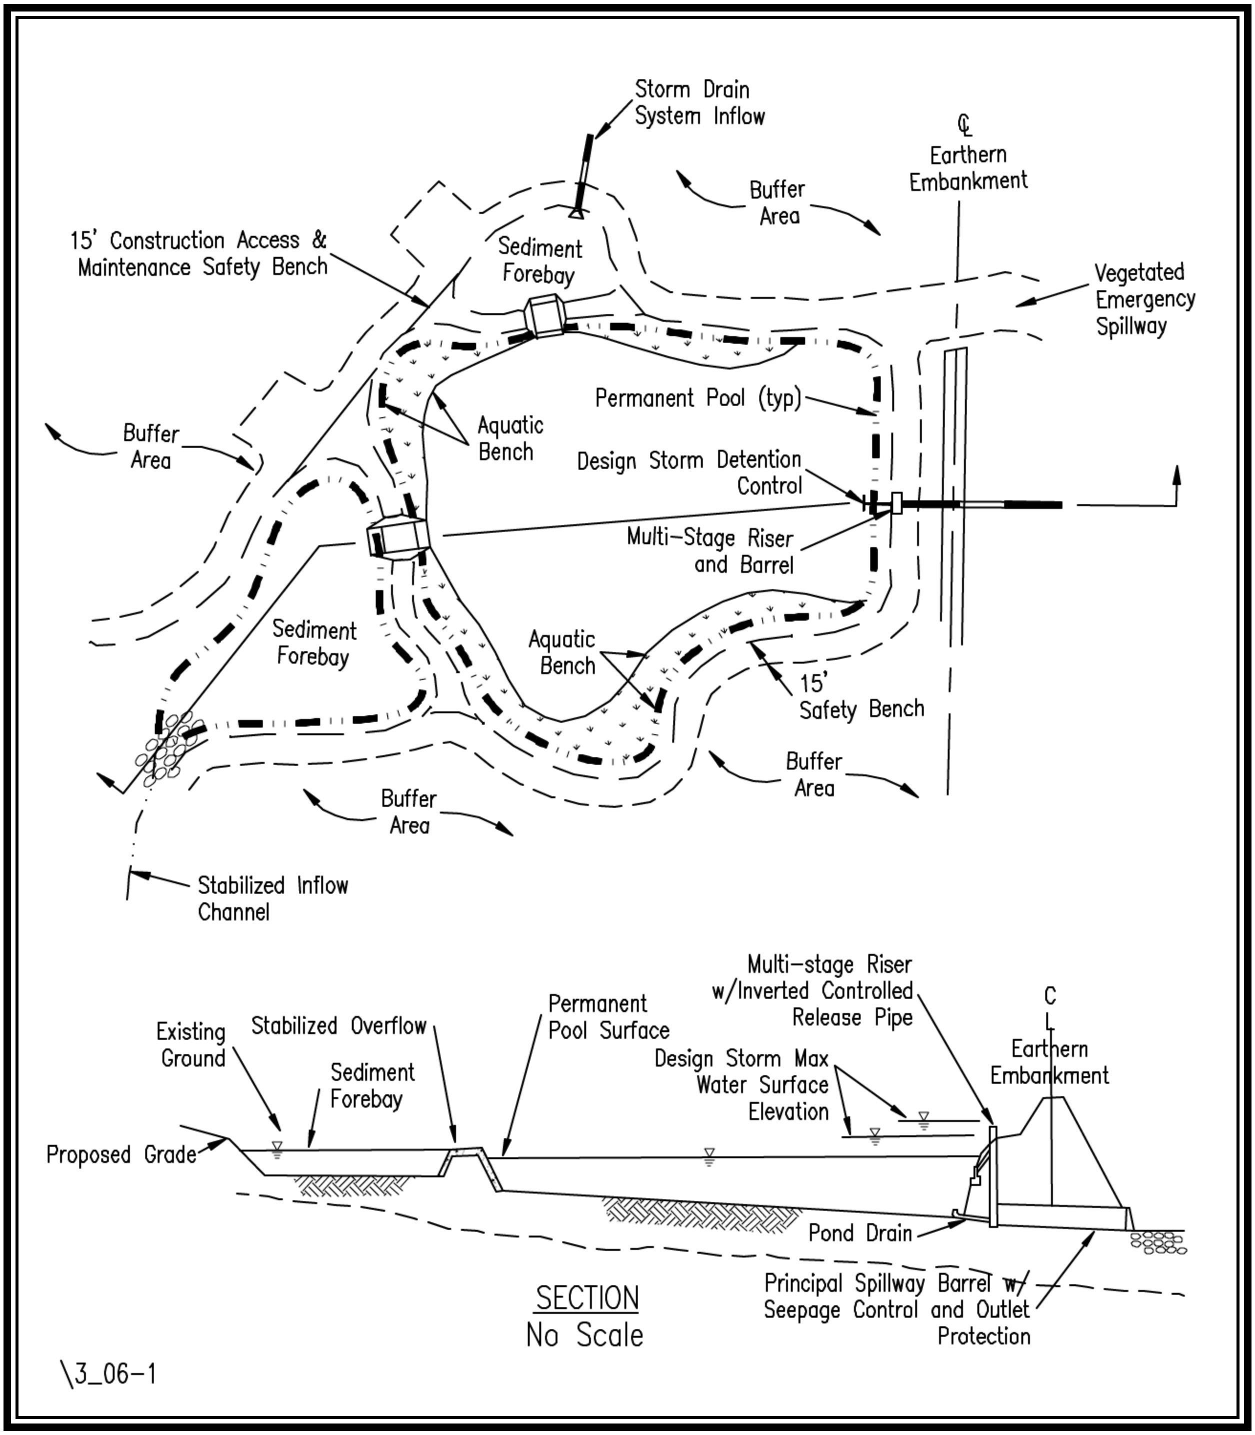

TABLE 3.06 - 1
Pollutant Removal Efficiencies for Retention Basins

Type	Sizing Rule	Target Phosphorus Removal Efficiency	Impervious Cover
Retention Basin I	3.0 x WQ Volume	40%	22-37%
Retention Basin II	4.0 x WQ Volume	50%	38-66%
Retention Basin III	4.0 x WQ Volume with Aquatic Bench	65%	67-100%

<u>Flood Control</u>

Retention basins which provide flood control are designed with "dry" storage above the permanent pool. This dry storage works in concert with a riser or control structure to reduce the peak rate of runoff from a drainage area. Typically, the design storms selected for flood control (i.e., 2-year, 10-year frequency, etc.) are specified by state and local ordinances, or are based on specific watershed conditions. In either case, the required volume to be stored above the permanent pool can be readily determined using the hydrologic methods discussed in **Chapter 4**. Similarly, a control or spillway structure can be designed using the engineering calculation procedures presented in **Chapter 5**.

<u>Channel Erosion Control</u>

The storage volume above the permanent pool can also be used to control or reduce channel erosion. Channel erosion protection can be accomplished by reducing the peak rate of discharge, similar to flood control, or by controlling the time over which the peak volume of discharge is released (extended detention), similar to water quality enhancement. **Chapter 5-11** provides a discussion on the design criteria for channel erosion control.

Conditions Where Practice Applies

<u>Drainage Area</u>

A contributing watershed of at least 10 acres and/or a good source of baseflow should be present for a retention basin to be feasible. Even with 10 acres of contributing watershed, the permanent pool may be susceptible to dry weather drawdowns due to infiltration and evaporation.

(Refer to **Chapter 5, Appendix 5C** for water balance calculation procedures.) Dry weather stagnation may result in aesthetic and odor problems for adjacent property owners. Therefore, for residential or high visibility applications, a minimum of 15 to 20 acres of contributing watershed may be more appropriate. Infiltration basins, trenches or extended-detention basins are more suitable for smaller sites.

A retention basin is recommended for use as a regional or watershed-wide stormwater management facility since its cost per acre treated is inversely proportional to the watershed size. Studies confirm that the most cost-effective application of a retention basin is on larger, more intensely developed sites (Schueler, et. al., 1985).

Note that excavated retention basins in areas of high groundwater, such as in Tidewater, Virginia, may be feasible with very small drainage areas. The groundwater elevation should be carefully monitored, however, to verify the design permanent pool elevation.

Development Conditions

Retention basins have the potential for removing high levels of soluble and particulate pollutants which makes them suitable for most types of development. They are appropriate for both high- and low- visibility sites. However, for high-visibility sites, care must be taken to avoid the aesthetic problems associated with stagnation or excessive infiltration of the permanent pool. Maintenance of the permanent pool is not necessarily critical to the retention basin's ability to remove pollutants, but maintenance **is critical** to ensure the BMP's acceptance by adjacent landowners. If adequate space is available, retention basins may also be used for both high and low density residential or commercial developments.

.

A minimum 20-foot wide vegetated buffer should be provided around a retention basin to help filter out pollutants before they enter the basin. This requirement results in the need for more land, especially for those basins that may already be oversized to enhance their pollutant removal capabilities. It is for this reason that the use of large retention basins may not be a feasible option in developing watersheds where land is at a premium. This strengthens the argument for a regional or watershed approach to stormwater management. A regional retention or extended-detention basin is not only more cost-effective, it is also more likely to be installed on land that is not suitable for development. (It should be noted, however, that the environmental impacts and appropriate permits must still be considered for such an application.)

Planning Considerations

The success of a retention basin is dependent on the designer's ability to identify any site or downstream conditions that may affect the design and function of the basin. Above all, the facility should be compatible with both upstream and downstream stormwater systems, thus promoting a *watershed approach* in providing stormwater management.

Site Conditions

Existing site conditions should be considered in the design and location of a retention basin. Features such as topography, wetlands, structures, utilities, property lines, easements, etc., may impose constraints on the location or construction of the basin. Local government land use and zoning ordinances may also designate certain requirements.

All retention basins should be a minimum of 20 feet from any structure or property line (as required by local ordinances), and 100 feet from any septic tank/drainfield. (The designer should be aware that an impoundment of water may elevate the local water table which could adversely effect drainfields and structures.) Retention basins should be a minimum of 50 feet from any steep slope (greater than 15%). Alternatively, a geotechnical report must address the potential impact of any retention basin that is to be constructed on or near such a slope.

Additional considerations are as follows:

1. **Soils –**

   In the past, many designs were accepted based upon soils information compiled from available data, such as SCS soil surveys. While such a source may be appropriate for a pre-engineering feasibility study, final design and acceptance **should be based on an actual subsurface analysis and a permeability test**, accompanied by appropriate engineering recommenda- tions. The references listed at the end of this standard and at the end of **Minimum Standard 3.10, Infiltration Practices** provide more detailed information regarding the feasibility analysis of subsurface conditions for various soil types. Due to its complexity, this topic is not covered here. Note that the geotechnical study required for the embankment design (reference **Minimum Standard 3.01, Earthen Embankment**) will often provide adequate data to verify the soil's suitability for a retention basin.

   The goal of a subsurface analysis is to determine if the soils are suitable for a retention basin. The textural character of the soil horizons and/or strata units within the subsoil profile should be identified to at least 3 feet below the facility bottom. This information is used to verify the infiltration rate or permeability of the soil. For a retention basin, water inflow (base flow and groundwater) must be greater than water losses (infiltration and evaporation). If the infiltration rate of the soil is too high, then a retention basin may not be an appropriate BMP.

   Permeable soils are not suited for retention basins. The depth of the permanent pool can influence the rate at which water will infiltrate through the existing soil. The soil permeability may be such that the basin can support a shallow marsh or constructed wetland. However, as the depth of the permanent pool increases, the increased head or pressure on the soil may increase the infiltration rate. If necessary, a liner of clay, geosynthetic fabric, or other suitable material may be used in the basin (as specified by a geotechnical engineer). Refer to the design criteria for basin liners.

2. **Rock –**

A subsurface investigation should also identify the presence of rock or bedrock. Excavation of rock may be too expensive or difficult with conventional earth moving equipment, precluding the use of a basin. Blasting the rock for removal may be possible, but blasting may open seams or create cracks in the underlying rock, resulting in an unwanted drawdown of the permanent pool. Blasting of rock is not recommended unless a liner, as described above, is installed.

3. **Karst –**

In regions where Karst topography is prevalent, projects may require thorough soils investigations and specialized design and construction techniques. The presence of karst should be determined **during the planning phase of the project** since it may affect BMP selection, design, and cost.

4. **Existing Utilities–**

Most utility companies will not allow a permanent or temporary pool to be installed over their underground utility lines or right-of-ways. However, if such a site must be used, the designer should obtain permission from the utility company **before designing** the basin. The relocation of any existing utilities should be researched and the costs included in the overall basin cost estimate.

Environmental Impacts

1. **Wetlands –**

Large facilities and/or regional facilities naturally lend themselves to being placed in low lying, and usually environmentally sensitive, areas. Such locations often contain wetlands, shallow marshes, perennial streams, wildlife habitat, etc., and may be protected by state or federal laws. The owner or designer should investigate regional wetland maps and contact appropriate local, state, and federal agencies to verify the presence of wetlands, their protected status, and suitability for a retention basin at the location in question.

With careful planning, it may be possible to incorporate wetland mitigation into a retention basin design. This assumes that the functional value of the existing or impacted wetland can be identified and included, reconstructed, or mitigated for, in the basin. The Virginia Department of Environmental Quality should be contacted for more information regarding wetland mitigation.

2. **Downstream Impacts –**

A retention basin may have an adverse impact on downstream water quality by altering the biological oxygen demand (BOD), dissolved oxygen (DO), temperature, etc., of the water body. This is of special concern in cold water trout streams. The release depth of the control structure, overall pond depth, hydraulic residence time, and other design features can be manipulated to help meet the site specific needs of the downstream channel.

Urban detention and retention basin design should be coordinated with a watershed or regional plan for managing stormwater runoff, if available. In a localized situation, an individual basin can provide effective stream protection for the downstream property if no other areas contribute runoff in a detrimental way to that property. However, an uncontrolled increase in the number of impoundments within a watershed can severely alter natural flow conditions, causing combined flow peaks or increased flow duration. This can ultimately lead to downstream flooding and degradation.

3. **Upstream Impacts –**

The upstream channel must also be considered, especially when the retention basin is to be used to control downstream channel erosion. Erosive upstream flows will not only degrade the upstream channel, but will also significantly increase the maintenance requirements in the basin by depositing large amounts of sediment eroded from the channel bottom.

<u>Water Quality Enhancement</u>

A retention basin is typically selected for its water quality enhancement abilities and/or aesthetic value. The flexibility of providing for additional control components (channel erosion control, flood control, habitat, etc.) increases their value. The permanent pool of a retention basin serves to enhance the quality of the stormwater within it. Studies show that providing a larger permanent pool, and/or adding modifications such as an aquatic bench, sediment forebay, etc., will provide greater and more consistent pollutant removal benefits (refer to the **Design Criteria** section in this standard). Currently, no credit is given for any additional pollutant removal efficiency that may occur with an extended-detention volume stacked on top of the permanent pool of a retention basin. However, significant improvements in channel erosion control have been reported using extended-detention for the 1-year frequency design storm (Galli, MWCOG, 1992). Refer to **Minimum Standard 3.07, Extended Detention Basins**.

A concern in specifying a retention basin is how much land it will occupy. The size of the permanent pool will be based on the desired pollutant removal efficiency. The "dry" storage volume above the permanent pool will be sized for downstream channel erosion and/or flood control. The size of these two components together will determine the size of the basin.

Preliminary sizing estimates for the permanent pool and "dry" storage volume are recommended during the planning stages to evaluate the feasibility of using a retention basin.

If a retention basin is used to remove pollutants, the water quality within the basin will be lowered, thus possibly reducing its desirability for water supply, recreation, and aesthetic purposes. Therefore, the engineer should be aware of the site's specific runoff components and understand their possible effects on the quality of the stored water. Runoff from highways and streets can be expected to carry significant concentrations of heavy metals such as lead, zinc, and copper. These and other heavy metals may accumulate in the bottom of a facility, creating a potential health and environmental hazard. If a basin is in a watershed where a significant portion of the runoff is from highways, streets or parking areas, then access to the facility should be limited and warning signs should be posted. Proper disposal of the bottom sediments from these basins may require that they be hauled to an approved facility.

Further, retention basins in residential areas are subject to nutrients from lawn fertilizers and other urban sources. Excess nutrients can lead to algae and other undesirable vegetation which can diminish the aesthetic and recreational value of the basin.

Flooding and Channel Erosion Control

Flood control and downstream channel erosion are managed by providing additional storage volume, referred to as dry storage, above the permanent pool, and properly sizing a discharge opening in the riser structure.

When a retention basin is designed for channel erosion control and/or flood control, but **not** water quality enhancement, the permanent pool volume should be sized to address maintenance, aesthetic, and feasibility concerns (adequate drainage area, etc.).

Sediment Control

A stormwater retention basin may initially serve as a sediment control basin during the project's construction. A sediment basin is designed for the maximum drainage area expected to contribute to the basin during the construction process, while a permanent stormwater basin is designed based on post-developed land use conditions. When designing a facility to do both, the basin should be sized using the most stringent criteria, sediment control or stormwater management, which will result in the largest storage volume. The design elevations should be set with final clean out and conversion in mind. The bottom elevation of the permanent SWM basin should be lower than the design bottom of the temporary E&S basin. This allows for the establishment of a solid permanent bottom after sediment is removed from the facility.

The riser and barrel hydraulics and materials should be designed as the permanent stormwater control structure. However, the permanent riser may be temporarily modified to provide a sediment basin with wet and dry storage as required by the Virginia Erosion and Sediment Control Handbook, (VESCH), 1992 edition.

Safety

Basins that are readily accessible to populated areas should include all possible safety precautions. Steep side slopes (steeper than 3H:1V) at the perimeter should be avoided and dangerous outlet structures should be protected by enclosures. Warning signs for deep water and potential health risks should be used wherever appropriate. Signs should be placed so that at least one is clearly visible and legible from all adjacent streets, sidewalks or paths. A notice should be posted warning residents of potential waterborne disease that may be contracted by swimming or diving in these facilities.

If the basin's surface area exceeds 20,000 square feet, an aquatic bench should be provided. (Refer to the **Design Criteria for Aquatic Bench**.)

A fence is **required** at or above the maximum water surface elevation **when a basin slope is a vertical wall**. Local governments and homeowner associations may also require appropriate fencing without regard for the steepness of the basin side slopes.

Maintenance

Retention basins have shown an ability to function as designed for long periods without routine maintenance. However, some maintenance is essential to protect the aesthetic and wildlife properties of these facilities.

Vehicular access to the permanent pool area and release structure must be provided to allow for long-term maintenance operations (such as sediment removal) and repairs, as needed. The incorporation of a *sediment forebay* at the inflow points into the basin will help to localize disturbance during sediment removal operations. An onsite area designated for sediment dewatering and disposal should also be included in the design. Care must be taken in the disposal of sediment that may contain an accumulation of heavy metals. **Sediment testing is recommended prior to sediment removal to assure proper disposal**.

A sign should be posted near the basin that clearly identifies the person or organization responsible for basin maintenance. Allowing participation by adjacent landowners or visitors is very helpful, especially if the facility serves as a recreational facility. Maintenance needs that are observed and addressed early will help to lower the overall maintenance costs. Routine maintenance inspections, however, should be conducted by authorized personnel. In all cases, access easements should be provided to facilitate inspection and maintenance operation.

Design Criteria

This section provides recommendations and minimum criteria for the design of stormwater retention basins intended to comply with the Virginia Stormwater Management program. It is the designer's responsibility to decide which aspects of the program apply to the particular facility being designed and if any additional design elements are required. The designer should also consider the long-term functioning of the facility in the selection of materials for the structural components.

Hydrology and Hydraulics

Chapter 4, **Hydrologic Methods** and **Chapter 5**, **Engineering Calculations** should be used to develop the pre- and post-developed hydrology for a basin's contributing watershed, to design and analyze the hydraulics of the riser and barrel system, and to design the emergency spillway.

The design of the riser and barrel system should take into account any additional storage provided above the permanent pool for peak discharge control. Generally, the 2-year storm should be used in *receiving channel adequacy* calculations and the 10-year storm should be used for *flood control* calculations. Alternative requirements such as 1-year extended detention for channel erosion control may be imposed by local ordinances.

The contributing drainage area should be a minimum of 10 acres with an adequate base flow. Fifteen to 20 acres is more appropriate to sustain a healthy permanent pool. Note that this requirement may preclude the use of the Modified Rational Method for the basin's design.

Embankment

The design of the earthen embankment for a retention basin should comply with **Minimum Standard 3.01, Earthen Embankment**. The requirements for geotechnical analysis, seepage control, maximum slopes and freeboard are particularly appropriate.

Principal Spillways

The design of the principal spillway and barrel system, anti-vortex device, and trash racks should comply with **Minimum Standard 3.02, Principal Spillway**.

Emergency Spillway

An emergency spillway that complies with **Minimum Standard 3.03, Vegetated Emergency Spillway** should be provided when possible, or appropriate.

Sediment Basin Conversion

When a proposed stormwater facility is used as a temporary sediment basin, the conversion to the permanent facility should be completed after final stabilization and approval from the appropriate erosion and sediment control authority.

In most cases the design criteria for the temporary sediment basin will require more storage volume (combined wet and dry) than that of a stormwater basin. In such cases, the extra volume should be allocated to the component of the facility that would derive the greatest benefit from the increased storage. This will depend on the primary function of the facility (i.e., water quality enhancement, flood control, or channel erosion control).

If modifications to the riser structure are required as part of the conversion to a permanent stormwater facility, they should be designed so that a) *the structural integrity of the riser is not threatened*, and b) *large construction equipment is not needed within the basin*. Any heavy construction work required on the riser should be completed during its initial installation. It is **NOT** recommended to install a temporary riser structure in the sediment basin and then replace it with a permanent riser after final stabilization. This may affect the structural integrity of the existing embankment and barrel.

The following additional criteria should be considered for a conversion:

1. Final elevations and a complete description of any modifications to the riser structure's geometry should be shown in the approved plans.

2. The wet storage area must be dewatered following the methods outlined in the VESCH, 1992 edition.

3. Sediment and other debris should be removed to a contained spoil area. Regrading of the basin may be necessary to achieve the final design grades and to provide an adequate topsoil layer to promote final stabilization.

4. Final modifications to the riser structure should be carefully inspected for watertight connections and compliance with the approved plans.

5. Final landscaping and stabilization should be per the VESCH, 1992 edition, and **Minimum Standard 3.05, Landscaping** in this handbook.

Permanent Pool

When designing a permanent pool for water quality benefits, certain physical and hydraulic factors can be manipulated to achieve a desired *pollutant removal efficiency*. These factors, which also influence the downstream water quality, include the permanent pool's *volume*, *depth*, *geometry*, *hydraulic residence time*, and *release depth*.

1. **Volume –**

Increasing the *volume* of the permanent pool increases the *residence time*, resulting in an increase in the pollutant removal efficiency of the permanent pool. **Table 3.06-1** provides the target pollutant removal efficiencies associated with different sizing rules.

2. **Depth –**

The *depth* of the permanent pool will affect several features of a retention basin including a) *aquatic plant selection*, b) *fish and wildlife habitat selection*, and c) *the rate at which nutrients are cycled*. Retention basins and artificial marshes built too shallow will not support fish populations year round. Basins built too deep may stratify, creating anaerobic conditions that may result in the resolubilizing of pollutants that are normally bound in the sediment. The release of such pollutants back into the water column can seriously reduce the effectivenes of the BMP and may cause nuisance conditions.

The depth of a stormwater management basin should vary to include as much diversity as possible, with an average depth of 3 to 6 feet. Approximately 15% of the basin area should be less than 18 inches deep. (Schueler, 1987). This can be accomplished by using an aquatic bench along the perimeter of the permanent pool as shown in **Figure 3.06-2**. **Table 3.06-2** below provides recommended surface area - pool depth relationships.

TABLE 3.06 - 2
Recommended Surface Area - Pool Depth Relationships for Retention Basins

BMP	**Pool Depth (*ft.*)**	**Surface Area (*as % of total BMP surface area*)**
Retention Basin	0 - 1.5 1.5 - 2 2 - 6	15% 15% 70%

Source: Washington State D.O.E.

3. **Geometry –**

The geometry of a stormwater basin and the associated drainage patterns are usually dictated by site topography and development conditions. However, the alignment of the incoming pipes should be manipulated relative to the release structure to the greatest extent possible to avoid *short-circuiting* of the incoming runoff. *Short-circuiting* is the condition where incoming runoff passes through the basin without displacing the old water. This can be avoided by maximizing the distance between the inlet and outlet structures. It can also be avoided by designing a *meandering* flow path through the basin, rather than a straight line flow path. In either case, a length-to-width ratio of 2:1 should be maintained. If site conditions prevent using the proper ratio, then baffles made from gabion baskets, earthen berms or other suitable materials may be used to lengthen the flow path (see **Figure 3.06-3**).

A retention basin should be multi-celled with at least two cells and preferably three. The first cell can be used as a sediment forebay to trap coarse sediments and reduce turbulence that may cause resuspension of sediments. This first cell should be easily accessible for maintenance purposes. The second (and third) cell provides for the further settling of pollutants and any biological processes.

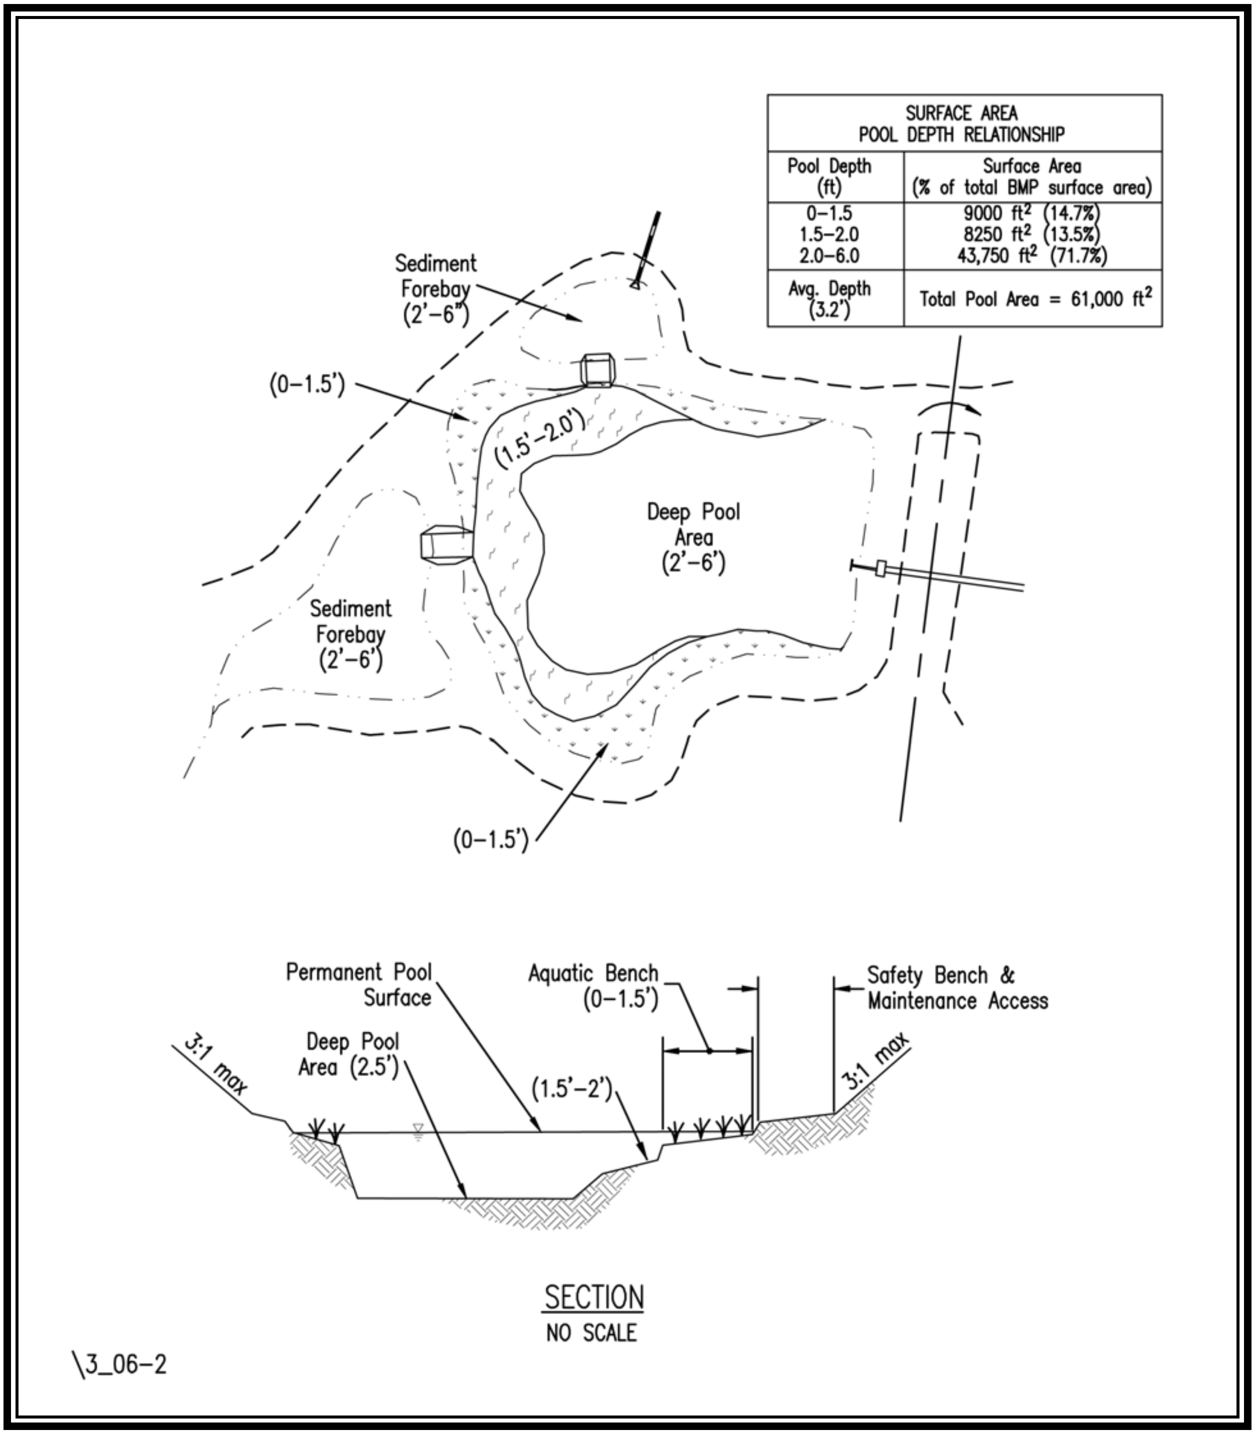
4. **Hydraulic Residence Time –**

Hydraulic residence time is the permanent pool volume divided by the average outflow discharge rate. The longer the residence time, the higher the pollutant removal efficiency (Driscoll, 1983, Kulzer, 1989). A retention basin used for channel erosion control and flood control will usually achieve higher pollutant removal rates. This is due to the increased residence time associated with the peak discharge control above the permanent pool. The hydraulic residence time would be a factor in the design of a retention basin with a permanent pool volume based on an impervious area which is relatively small when compared to the contributory drainage area. In this case, the total drainage area discharge will turn over, or replace, the volume of the "undersized" pool volume before it has achieved an adequate residence time. Optimal pollutant removal efficiency is generally associated with a *mean annual hydraulic residence* time of 14 to 30 days (Driscoll, 1988; Kulzer, 1989; Schueler, 1987).

5. **Release Depth –**

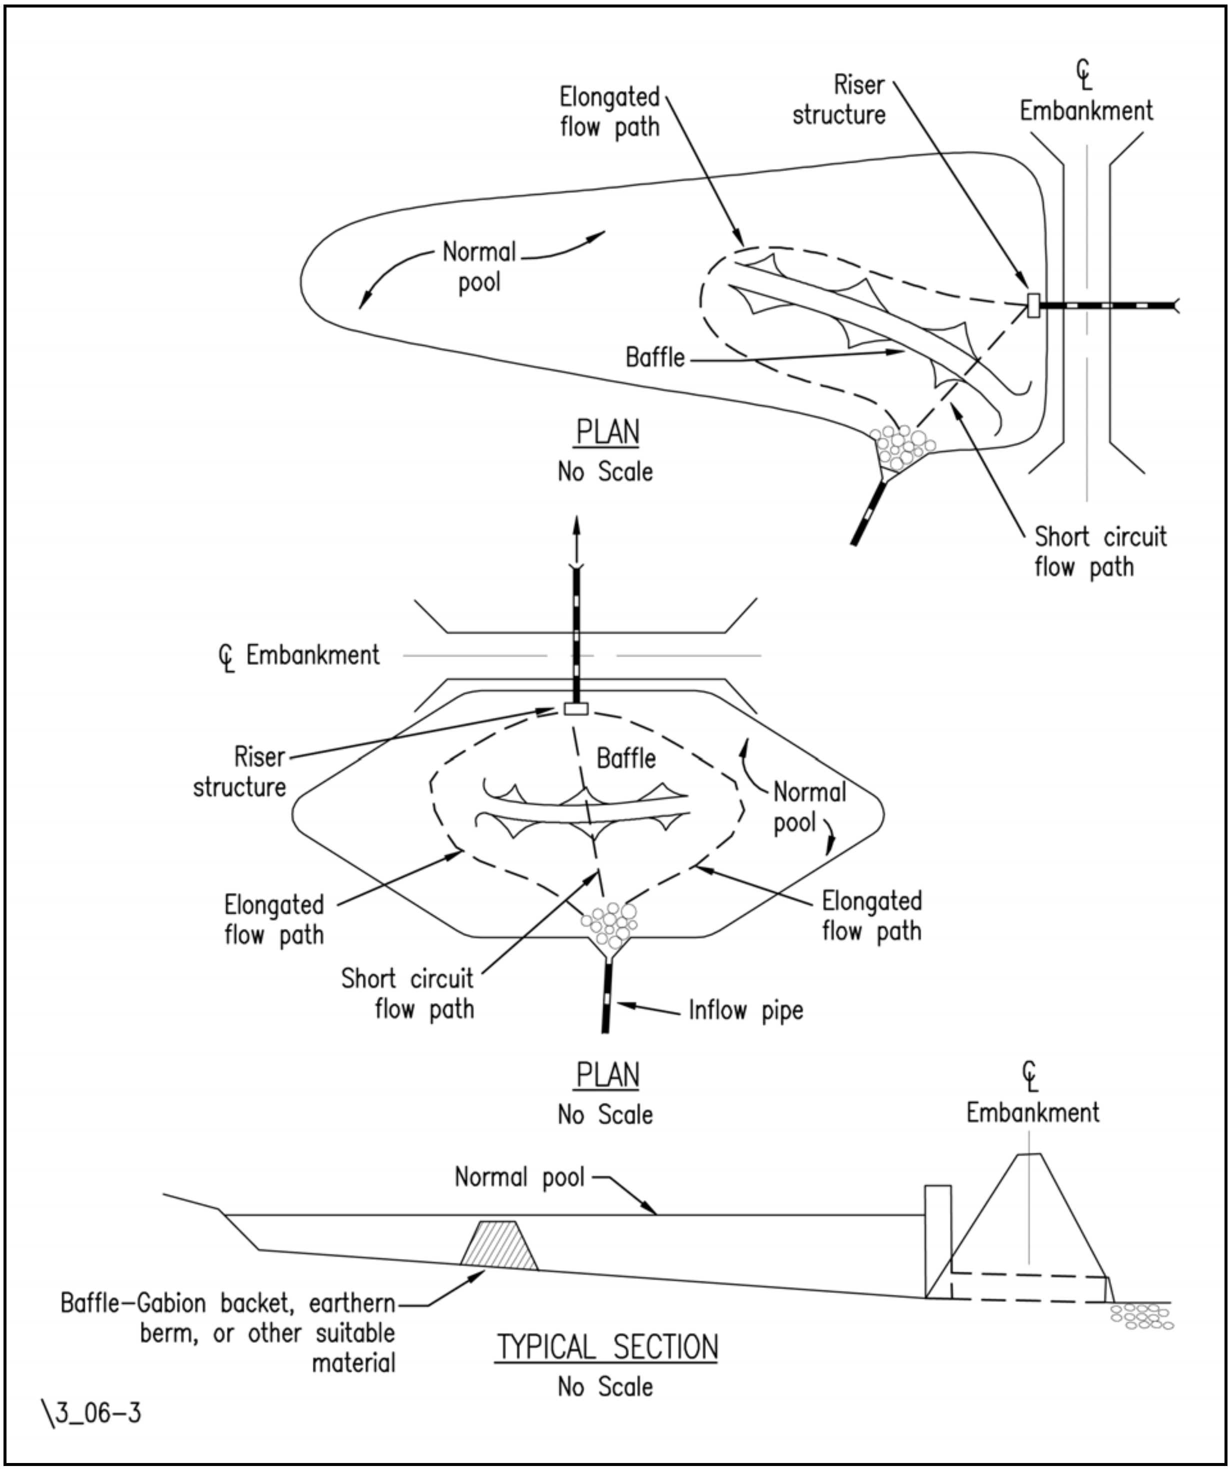
The best water quality in a retention basin's permanent pool is usually at or near the surface (Galli, 1988; Redfield, 1983). Under normal dry weather conditions, the concentrations of total dissolved solids, phosphorus, and nitrogen generally decrease in the upper portions of the water column due to physical settling and algal and biological assimilation (Galli, 1992). This suggests that <u>subsurface</u> releases have high levels of nutrients and suspended solids. In addition, deeper basins usually have very low levels of dissolved oxygen in the bottom portions of the water column.

FIGURE 3.06 - 2
Varying Depth of Permanent Pool



SURFACE AREA POOL DEPTH RELATIONSHIP	
Pool Depth (ft)	Surface Area (% of total BMP surface area)
0–1.5 1.5–2.0 2.0–6.0	9000 ft² (14.7%) 8250 ft² (13.5%) 43,750 ft² (71.7%)
Avg. Depth (3.2')	Total Pool Area = 61,000 ft²

FIGURE 3.06 - 3
Short-Circuiting

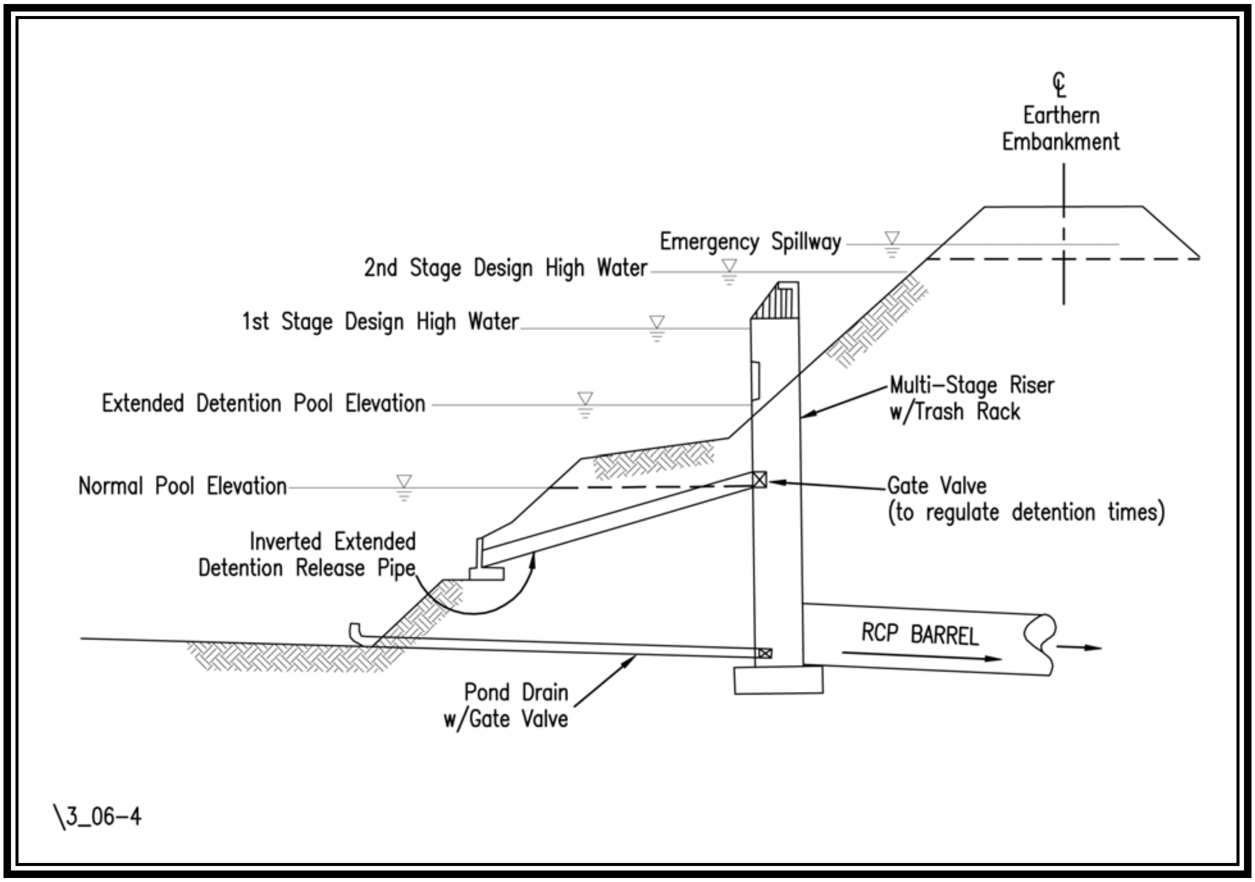


In contrast, the water at or near the surface of a retention basin is warmer because of solar heating of the basin and heated stormwater inflow. This resembles the cycling process of water in natural lakes and water bodies. However, the proximity of a retention basin to development (i.e., impervious surfaces) may lead to an excessive heat buildup from the incoming runoff during the warmer months. Therefore, a release depth of approximately 18 inches from the water surface is recommended (Galli, 1992) to avoid extremes in temperature, nutrient levels, and dissolved oxygen (see **Figure 3.06-4**).

It should be noted that inexpensive design modifications can be incorporated into the design of a retention facility to mitigate downstream impacts such as: a) *oversizing the barrel and adding surgestone or rip rap to the invert to help re-aerate the basin discharge* (Schueler, 1987), and b) *providing shade by planting (or saving) trees around the perimeter of the basin to help lower surface water temperature*.

If the receiving stream supports a trout population, the designer should contact the Department of Game and Inland Fisheries for additional measures to protect the downstream habitat.

FIGURE 3.06 - 4
Typical Retention Basin Control Structure



Aquatic Bench

The pollutant removal efficiency of a retention basin can be further enhanced by adding an *aquatic bench*. An aquatic bench is a 10 to 15 foot wide area that slopes from zero inches at the shoreline to between 12 and 18 inches deep in the basin (see **Figure 3.06-5**). This bench provides suitable conditions for a variety of aquatic plants and emergent vegetation. Specific landscaping requirements for an aquatic bench should be provided on the landscaping plan per **Minimum Standard 3.05, Landscaping**.

Most important, an aquatic bench augments the pollutant removal capabilities of a retention basin by providing an environment for aquatic vegetation and associated algae, bacteria and other microorganisms that reduce organic matter and nutrients (Schueler, 1987). In addition, aquatic bench vegetation provides an ideal habitat for wildlife, such as waterfowl and fish, and for predator insects that feed on mosquitoes and other nuisance insects.

An aquatic bench also serves to stabilize and protect the shoreline from erosion resulting from fluctuating water levels, and provides a safety feature by eliminating the presence of a steep submerged slope next to the shoreline.

The increase in pollutant removal efficiency associated with the establishment of an aquatic bench is **approximated** based on available information. Note that discharge monitoring may indicate much higher or lower values since many variables exist in any given stormwater basin design and the efficiencies are estimated.

Sediment Forebay

A *sediment forebay* will help to postpone overall basin maintenance by trapping incoming sediments at a specified location. The forebay should be situated and designed per **Minimum Standard 3.04, Sediment Forebays**. Usually, a sediment forebay is placed at the outfall of the incoming storm drain pipes or channels directed toward the basin and is situated to provide access for maintenance equipment.

A sediment forebay enhances the pollutant removal efficiency of a basin by trapping the incoming sediment load in one area, where it can be easily monitored and removed. The *target pollutant removal efficiency* of a retention basin, as listed in **Table 3.06-1**, is predicated on the use of sediment forebays at the inflow points to the basin.

Liner to Prevent Infiltration

A retention basin should have negligible infiltration through its bottom. Infiltration may impair the proper functioning of the basin and may contaminate groundwater. Where infiltration is anticipated, or in areas underlain by karst topography then a retention or detention facility should **not** be used unless an impervious liner is installed. When using a liner, the specifications provided in **Table**

3.06-3 for clay liners and the following recommendations apply:

1. A clay liner should have a minimum thickness of 12 inches.

2. A layer of compacted topsoil (minimum thickness 6 to 12 inches) should be placed over the liner before seeding with an appropriate seed mixture (refer to the VESCH, 1992 edition.)

3. Other liners may be used provided the engineer can supply supporting documentation that the material will achieve the required performance.

In many cases, the fine particulates and suspended solids in the water column of a new retention basin will settle out and quickly clog the the pores of the bottom soil. However, a geotechnical analysis should address the potential for infiltration and, if needed, specify liner materials.

Safety

The side slopes of a retention basin should be no steeper than 3H:1V and should be stabilized with permanent vegetation. If the basin surface exceeds 20,000 square feet, an aquatic bench should be provided to serve as a safety feature. Fencing may also be required by local ordinance.

Access

A 10 to 12-foot-wide access road with a maximum grade of 12% should be provided to allow vehicular access to both the outlet structure area and at least one side of the basin. The road's surface material should be selected to support the anticipated frequency of use and the anticipated vehicular load without excessive erosion or damage.

TABLE 3.06 - 3
Clay Liner Specifications

Property	Test Method (or equal)	Unit	Specification
Permeability	ASTM D-2434	*cm/sec*	1×10^{-6}
Plasticity Index of Clay	ASTM D-423 & D-424	%	Not less than 15
Liquid Limit of Clay	ASTM D-2216	%	Not less than 30
Clay Particles Passing	ASTM D-422	%	Not less than 30
Clay Compaction	ASTM D-2216	%	95% of Standard Proctor Density

Landscaping

A qualified individual should prepare the landscape plan for a retention basin. Appropriate *shoreline fringe*, *riparian fringe* and *floodplain terrace vegetation* must be selected to correspond with the expected frequency and duration of inundation. Selection and installation guidelines should be per **Minimum Standard 3.05, Landscaping**.

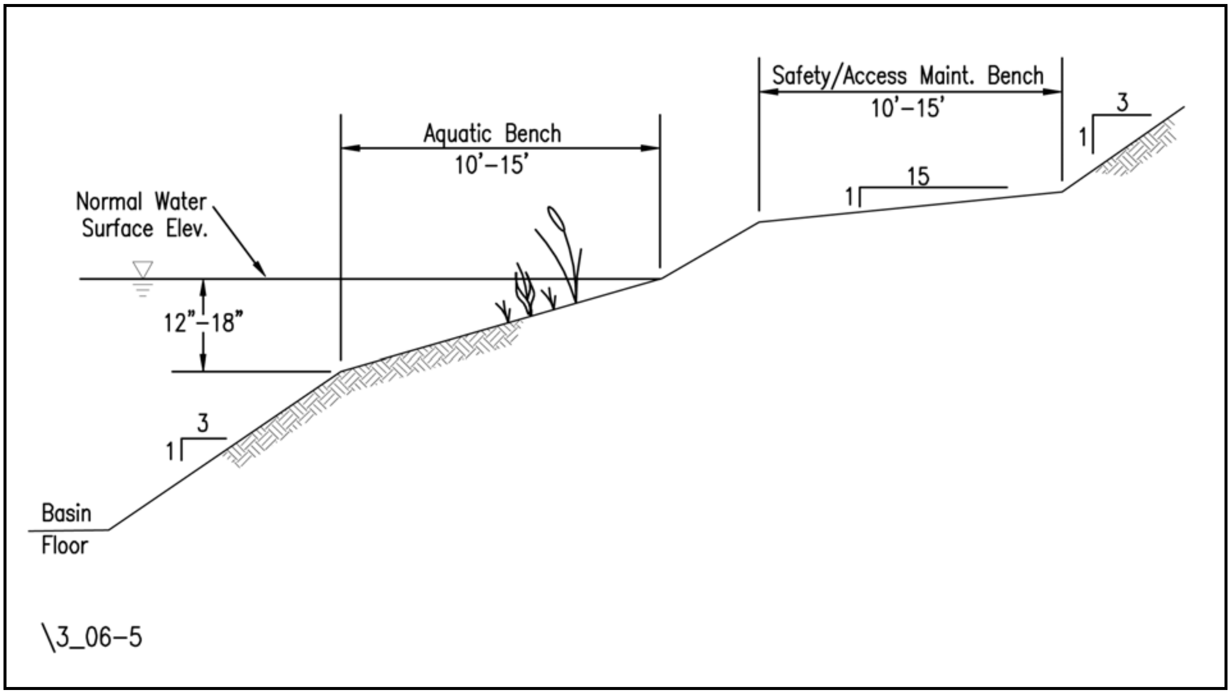
Vegetation should be planted in soil that is appropriate for the plants selected. Soil tests showing the adequacy of the soil or a soil enhancement plan should be submitted with the overall basin design.

The soil substrate must be soft enough to permit easy installation of the plants. If the basin soil has been compacted or vegetation has formed a dense root mat, the upper 6 inches of soil should be disked before planting. If soil is imported, it should be laid at least 6 inches deep to provide sufficient depth for plant rooting to occur.

Buffer Zones

A vegetated buffer strip should be maintained beside the basin. The strip should be a minimum of 20 feet wide, as measured from the maximum water surface elevation. Refer to **Minimum Standard 3.05, Landscaping**.

FIGURE 3.06 - 5
Typical Retention Basin Aquatic Bench - Section



Construction Specifications

The construction specifications for stormwater retention basins outlined below should be considered minimum guidelines. More stringent or additional specifications may be required based on individual site conditions.

Overall, widely accepted construction standards and specifications for embankment ponds and reservoirs, such as those developed by the USDA Soil Conservation Service or the U.S. Army Corps of Engineers, should be followed to build an impoundment.

Further guidance can be found in Chapter 17 of the Soil Conservation Service's Engineering Field Manual. Specifications for the work should conform to methods and procedures indicated for installing earthwork, concrete, reinforcing steel, pipe, water gates, metal work, woodwork and masonry and any other items that are apply to the site and the purpose of the structure. The specifications should also satisfy any requirements of the local plan approving authority.

The following minimum standards contain guidance and construction specifications for various components of retention basins: **3.01, Earthen Embankment**; **3.02, Principal Spillway**; **3.03, Vegetated Emergency Spillway**; **3.04, Sediment Forebay**; and **3.05, Landscaping**.

Maintenance and Inspections

The following maintenance and inspection guidelines are not intended to be all-inclusive. Specific facilities may require other measures not discussed here. The engineer is responsible for determining if any additional items are necessary.

Inspecting and maintaining the structures and the impoundment area should be the responsibility of either the local government, a designated group such as a homeowner's association or an individual. A specific maintenance plan should be formulated outlining the schedule and scope of maintenance operations.

Any standing water pumped during the maintenance operation must be disposed of per the VESCH, 1992 edition and any local requirements.

General Maintenance

Maintenance and inspection guidelines found in the following minimum standards apply: **3.01, Earthen Embankment**; **3.02, Principal Spillway**; **3.03, Vegetated Emergency Spillway**; **3.04, Sediment Forebay**; and **3.05: Landscaping**.

Vegetation

The basin's side slopes, embankment and emergency spillway should be mowed at least twice a year to discourage woody growth. For aesthetic purposes, more frequent mowing may be necessary in residential areas

Specific plant communities may require different levels of maintenance. Upland and floodplain terrace areas, grown as meadows or forests, require very little maintenance, while aquatic or emergent vegetation may need periodic thinning or reinforcement plantings. Note that after the first growing season, it should be obvious if reinforcement plantings are needed. If they are, they should be installed at the onset of the second growing season after construction.

Research indicates that for most aquatic plants the uptake of pollutants is stored in the roots, not the stems and leaves (Lepp 1981). Therefore, aquatic plants should not require harvesting before winter plant die-back. There are still many unanswered questions about the long term pollutant storage capacity of plants. It is possible that aquatic and emergent plant maintenance recommendations may be presented in the future.

Debris and Litter Removal

Debris and litter will accumulate near the inflow points and around the outlet control structure. Such material should be removed periodically. Also, as the water level rises during storm events, floatables accumulate around the grate or trash rack of the control structure. If a flat horizontal trash rack is used, floating debris will become lodged on the trash rack, which will remain clogged until it is manually cleaned. A significant accumulation can clog the riser structure. The use of an angled trash rack is recommended to allow any accumulated debris to slide off as the water level drops.

Sediment Removal

Sediment deposition should be continually monitored in the basin. Removal of any accumulated sediment, in the sediment forebay or elsewhere, is extremely important. A significant accumulation of sediment impairs the pollutant removal capabilities of the basin by reducing the permanent pool volume. The deposited sediment also becomes prone to resuspension during heavy flow periods. Unless unusual conditions exist, accumulated sediment should be removed from the sediment forebay and possibly other deep areas within the permanent pool every 5 to 10 years. The use of a sediment forebay with access for heavy equipment will greatly simplify the removal process. **During maintenance procedures, ensure that any pumping of standing water or dewatering of dredged sediments complies with the VESCH, 1992 edition, and any local requirements**.

Owners, operators, and maintenance authorities should be aware that significant concentrations of heavy metals (e.g., lead, zinc and cadmium) and some organics, such as pesticides, may be expected to accumulate at the bottom of a retention basin. Testing of sediment, especially near points of inflow, should be conducted regularly and **before disposal** to establish the leaching potential and level of accumulation of hazardous materials. Disposal methods must comply with applicable state and local regulations (e.g., for special waste).

<u>Inspections</u>

A retention basin and its components should be inspected annually, at a minimum, to ensure that they operate in the manner originally intended. Items in need of repair should be addressed promptly and as specified in the comprehensive maintenance program. Detailed inspections by qualified person(s) should address the following areas/concerns:

- Dam settling, woody growth, and signs of piping
- Signs of seepage on the downstream face of the embankment
- Condition of grass cover on the embankment, basin floor and perimeter
- Riprap displacement or failure
- Principal and emergency spillway meet design plans for operation
- Outlet controls, debris racks and mechanical and electrical equipment
- Outlet channel conditions
- Inlet pipe conditions
- Safety features of the facility
- Access for maintenance equipment
- Sediment accumulation
- Debris and trash accumulation
- Erosion of the embankment or side slopes

Design Procedures

1. Determine if the anticipated development conditions and drainage area are appropriate for a stormwater retention basin BMP.

   C Minimum drainage area of 10 acres and/or base flow

2. Determine if the soils (permeability, bedrock, Karst, embankment foundation, etc.) and topographic conditions (slopes, existing utilities, environmental restrictions) are appropriate for a stormwater retention basin BMP.

3. Determine any additional stormwater management requirements (channel erosion, flooding) for the project.

4. Locate the stormwater retention basin on the site.

5. Determine the hydrology and peak discharges of the contributory drainage area for each of the required design storms (**Chapter 4, Hydrologic Methods**).

6. Calculate the permanent pool volume and approximate storage volume requirements (**Chapter 5, Engineering Calculations**).

7. Design the embankment (**Min. Std. 3.01**), principal spillway (**Min. Std. 3.02**), emergency spillway (**Min. Std. 3.03**), sediment forebay (**Min. Std. 3.04**), landscaping plan (**Min. Std. 3.05**), and the permanent pool and other components of a stormwater retention basin BMP (**Min. Std. 3.06**) using **Chapter 5, Engineering Calculations**, and the Minimum Standards listed.

   - permanent pool depth
   - Permanent pool geometry
   - release depth
   - aquatic bench
   - pond drain

8. Design final grading of basin.

   - landscape plan
   - 20-foot buffer area
   - safety (3:1 slopes with bench)
   - access

9. Establish specifications for sediment control and sediment basin conversion (if required).

10. Establish construction sequence and construction specifications.

11. Establish maintenance and inspection requirements.

Checklists

Refer to **Appendix-3A** for **Design and Plan Review**, **Construction Inspection**, and **Operation and Maintenance** Checklists.

EXTENDED-DETENTION BASIN & *ENHANCED* EXTENDED-DETENTION BASIN

Definition

An extended-detention basin is an impoundment that temporarily stores runoff for a specified period and discharges it through a hydraulic outlet structure to a downstream conveyance system. An extended-detention basin is usually dry during non-rainfall periods.

Purpose

An extended-detention basin can be designed to provide for one, or all, of the following: a) *water quality enhancement*, b) *downstream flood control*, and c) *channel erosion control*.

Water Quality Enhancement

An **extended-detention basin** improves the quality of stormwater runoff through gravitational settling. However, due to frequent high inflow velocities, settled pollutants often get resuspended.

An ***enhanced*** **extended-detention basin** has a higher efficiency than an extended-detention basin because it incorporates a shallow marsh in its bottom. The shallow marsh provides additional pollutant removal through *wetland plant uptake*, *absorption*, *physical filtration*, and *decomposition*. The shallow marsh vegetation also helps to reduce the resuspension of settled pollutants by trapping them.

The target pollutant removal efficiencies for both extended-detention and *enhanced* extended-detention basins are presented in **Table 3.07-1**. The target pollutant removal efficiencies are based on certain design criteria associated with the physical characteristics of the basin, and shallow marsh, when used.

FIGURE 3.07 - 1a
Extended-Detention Basin - Plan

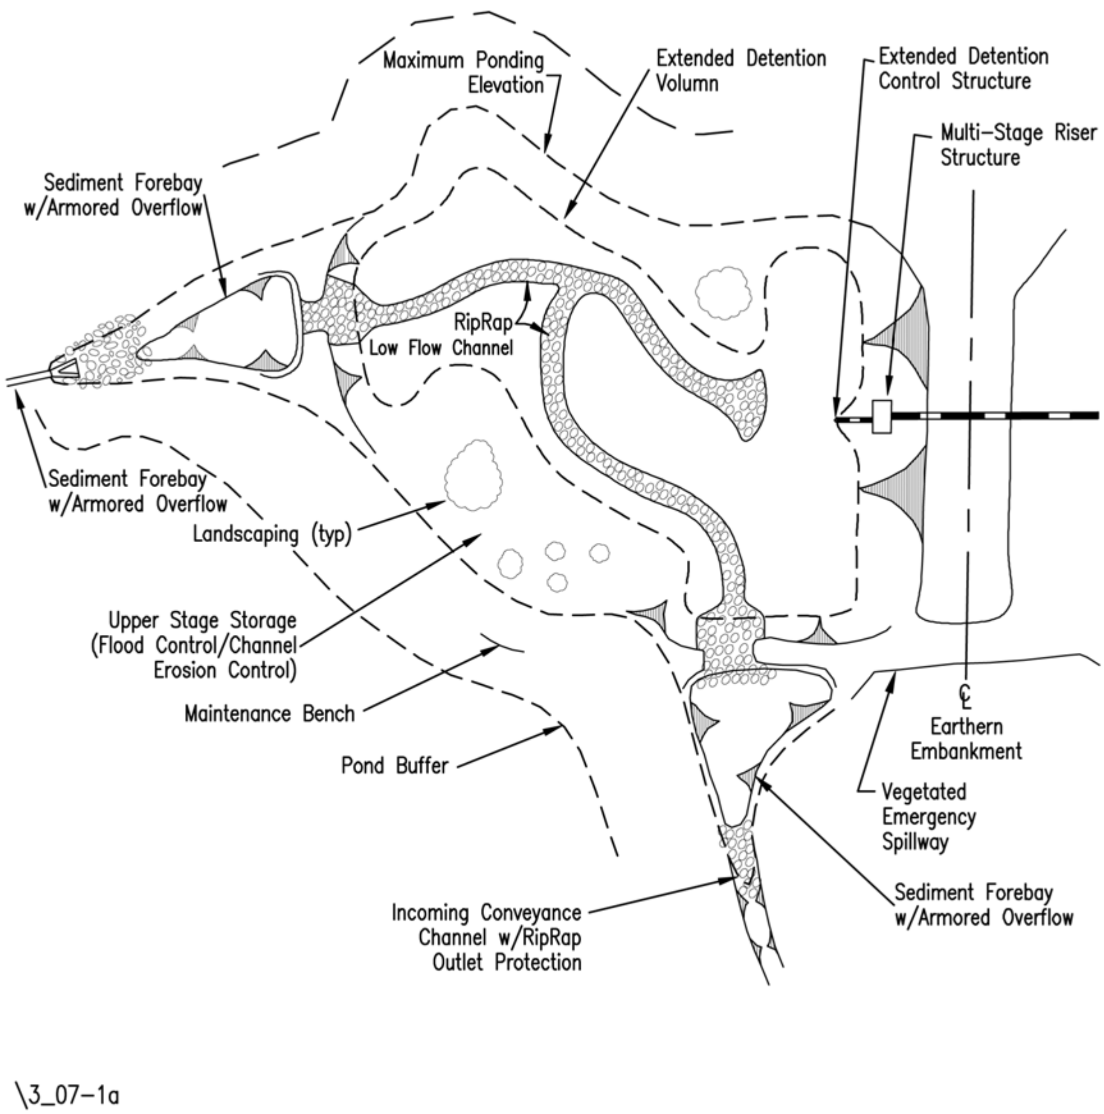

FIGURE 3.07-1b
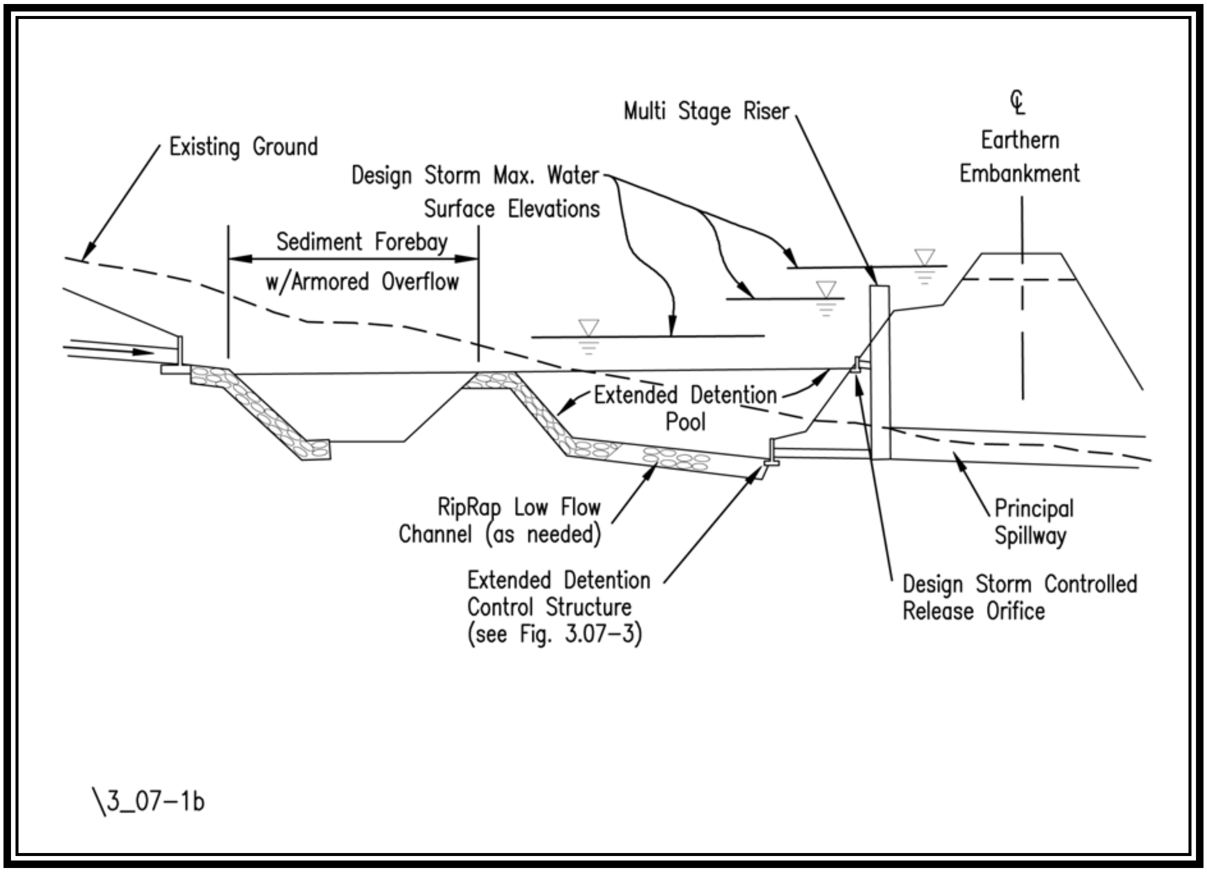
Extended-Detention Basin - Section



Flood Control

Extended-detention basins can be designed for flood control by providing additional storage above the extended-detention volume, and by reducing the peak rate of runoff from the drainage area. The design storms chosen for flood control are usually specified by ordinance, or are based on specific watershed conditions. By managing multiple storms, such as the 2- and 10-year storms, adequate flood control may be provided for a broad range of storm events.

The additional volume required for storage above the extended-detention volume can be readily determined using the hydrologic methods discussed in **Chapter 4, Hydrologic Methods**. Once this volume is known, a control or spillway structure can be designed and the reservoir routing and channel capacity design techniques discussed in **Chapter 5, Engineering Calculations**.

Extended-Detention & Enhanced Extended-Detention Basins

Type	Target Phosphorus Removal Efficiency	Impervious Cover
Extended-detention (30 *hr*. Drawdown of 2 × WQ Volume)	35%	22 - 37%
Enhanced extended-detention (30-*hr*. Drawdown of 1 × WQ Volume, and 1 × WQ Volume Shallow Marsh)	50%	38 - 66%

Channel Erosion Control

The objective in controlling channel erosion is to reduce the rate of discharge from a designated frequency storm to below the critical velocity of the downstream channel. The critical velocity of a channel is the velocity that, when exceeded, causes the channel bed or banks to erode. The Virginia Erosion and Sediment Control Handbook, 1992 edition, provides the theoretical critical velocities for various natural channel linings. This critical velocity approach, however, does not consider the frequency or the duration of the critical velocity flow. An increase in impervious cover will increase the frequency of occurance of the "pre-developed" design storm discharge by raising the rainfall to runoff response characteristics of the drainage area. A detention basin will increase the duration of the "pre-developed" design storm discharge by releasing the runoff over time. (A detention basin lowers the peak by spreading it out over a longer period of time.) An extended-detention basin, on the other hand, reduces the discharge based on an extended period of time rather than a peak rate of discharge. Extended-detention of a specific design storm will typically result in lower rates of discharge than the "pre-developed" rate (or critical velocity), thereby compensating for the effects of increased frequency and duration.

The selection of an design storm and a extended-detention period is not a scientific process and is currently determined to be the runoff from the 1-year frequency storm, detained and released over a 24 hour period. Studies show a significant reduction in stream channel erosion below extended-detention facilities designed to this criteria (Galli MWCOG, 1992). Extended-detention of the 1-year storm lowers the discharge velocities from a broad range of storm frequencies to non-erosive levels.

Conditions Where Practice Applies

Drainage Area

The **minimum** contributing drainage area for an extended-detention basin varies with the required extended-detention volume and draw down period and the resulting orifice size. The orifice configuration for small drainage areas should be selected carefully since small openings (less than 3 inches) are prone to clogging. Several different configurations for effective trash, debris, and sediment control are presented in **Figure 3.07-3**. The engineer is free to choose any of these, or to select from other innovative designs.

The **maximum** drainage area served by an extended-detention basin will vary from watershed to watershed. Drainage areas above 50 to 75 acres may require provisions for *base flow*. (Refer to **Design Criteria**). Care should be taken when sizing the water quality orifice if base flow is present.

An undersized orifice may create an undersized permanent pool within the extended-detention volume, leaving inadequate volume above it to provide the required extended-detention. An oversized orifice will result in little extended-detention of the water quality volume.

Development Conditions

Lacking a permanent pool of water, a detention facility is rarely considered aesthetically pleasing. It is, therefore, recommended for *low-visibility* sites. In certain situations, an extended-detention basin may be used on a *high-visibility* site, but the designer must be careful to avoid stagnation or excessive infiltration of the shallow marsh. Maintenance of the basin's shallow marsh is not necessarily critical to its ability to remove pollution, but maintenance **is critical** to ensure the BMP's acceptance by adjacent landowners.

Extended-detention basins can be used for low- to medium-density residential or commercial projects, as classified by their impervious cover. (see **Table 3.07-1**). Along with the storage and shallow marsh volumes required in the basin, a minimum 20-foot vegetated buffer should also be provided. This requirement results in the need for more land. It is for this reason that the use of extended-detention basins may not be the best choice of water quality BMP in developing watersheds where land is at a premium. This strengthens the argument for a regional or watershed approach to stormwater management. A regional extended-detention basin is not only more cost-effective, but is also more likely to be installed on land that is not suitable for development. (It should be noted, however,that the environmental impacts and appropriate permits must still be considered for such an application.)

Planning Considerations

The success of an extended-detention basin is dependent on the designer's ability to identify any site and downstream conditions that may affect the design and function of the basin. Above all, the facility should be compatible with both upstream and downstream stormwater systems to promote a *watershed approach* in providing stormwater management.

The planning considerations for designing the shallow marsh of an *enhanced* extended-detention basin are very similar to those of a constructed wetland (refer to **Minimum Standard 3.09, Constructed Stormwater Wetland; Planning Considerations**).

Site conditions

Existing site conditions should be considered in the design and location of an extended-detention basin. Features such as topography, wetlands, structures, utilities, property lines, easements, etc., may impose constraints on the development. Local government land use and zoning ordinances may also specify certain requirements.

All extended-detention basins should be a minimum of 20 feet from any structure or property line, and 100 feet from any septic tank/drainfield. Extended-detention basins should also be a minimum of 50 feet from any steep slope (greater than 15%). Otherwise, a geotechnical report will be required to address the potential impact of any basin that must be constructed on or near such a slope.

Additional considerations are as follows:

1. **Soils –**

   In the past, many designs were accepted based upon soils information compiled from available data, such as SCS soil surveys. While such a source may be appropriate for a pre-engineering feasibility study, final design and acceptance **should be based on an actual subsurface analysis and a permeability test**, accompanied by appropriate engineering recommendations. The references listed at the end of this standard and at the end of **Minimum Standard 3.10, Infiltration Practices** provide more detailed information regarding the feasibility analysis of subsurface conditions for various soil types. Due to its complexity, this topic is not covered here.

   Highly permeable soils are not suited for extended-detention basins. A basin with highly permeable soils will act as an infiltration facility until the soils become clogged. Although this phenomenon is not always considered a negative impact, it does change the function and design of the basin. For an *enhanced* extended-detention basin, the soils must support the shallow marsh **at the time of stabilization and planting**.

A thorough analysis of the soil strata should be conducted to verify its suitability for use with an extended-detention basin. The geotechnical study required for the embankment design (refer to **Minimum Standard 3.01, Earthen Embankment**) will often provide adequate data for this purpose. The soil permeability may be such that the basin can support a shallow marsh. However, as the depth of the temporary storage increases, the increased head or pressure on the soil may increase the rate of infiltration. If necessary, a liner of clay, geosynthetic fabric, or other suitable material may be used in the basin (as specified by a geotechnical engineer). Refer to the design criteria for basin liners.

2. **Rock –**

The subsurface investigation should also identify the presence of rock or bedrock. Excavation of rock may be too expensive or difficult with conventional earth moving equipment.Blasting the rock for removal may be possible, but it may also open seams or create cracks in the underlying rock, resulting in an unwanted drawdown of the shallow marsh. Blasting of rock is not recommended unless a liner, as described above, is used.

3. **Karst –**

In regions where Karst topography is prevalent, projects may require thorough soils investigation and specialized design and construction techniques. Since the presence of karst may affect BMP selection, design, and cost, a site should be evaluated **during the planning phase of the project**.

4. **Existing Utilities –**

Most utility companies will not allow a permanent or temporary pool to be installed over their underground lines or right-of-ways. If such a site must be used, the designer should obtain permission from the utility company **before designing the basin**. The relocation of any existing utilities should be researched and the costs included in the overall basin cost estimate.

Environmental Impacts

1. **Wetlands–**

Large facilities and/or regional facilities lend themselves to being placed in low lying, and usually environmentally sensitive, areas. Such locations often contain wetlands, shallow marshes, perennial streams, wildlife habitat, etc., and may be protected by state or federal laws. The owner or designer should investigate the regional wetland maps and contact appropriate local, state, and federal agencies to verify the presence of wetlands, their protected status, and the suitability for an extended-detention basin at the location in question.

With careful planning, it may be possible to incorporate wetland mitigation into an extended-detention basin design. This assumes that the functional value of the existing or impacted wetland can be identified and included, reconstructed, or mitigated for, in the basin. Contact the Virginia Department of Environmental Quality for more information regarding wetland mitigation.

2. **Downstream Impacts–**

Urban detention and retention basin design should be coordinated with a watershed or regional plan for managing stormwater runoff, if available. In a localized situation, an individual basin can provide effective protection for the downstream channel if no other areas contribute runoff in a detrimental way to the channel. However, an uncontrolled increase in the number of impoundments within a watershed can severely alter natural flow conditions, causing combined flow peaks or increased flow duration. This can ultimately lead to flooding downstream degradation.

3. **Upstream Impacts–**

The upstream channel must also be considered, especially when the extended-detention basin is used to control downstream channel erosion. Erosive upstream flows will not only degrade the upstream channel, but will also significantly increase the maintenance requirements in the basin by depositing large amounts of sediment eroded from the channel bottom.

Water Quality Enhancement

In an extended-detention basin, the quality of the incoming stormwater is improved through *gravitational settling* of pollutants from the water quality volume. The pollutant removal efficiency for *soluble* pollutants is usually much **lower** than for *particulate pollutants*. Therefore, the efficiency of an extended-detention basin can be **enhanced** by adding a *shallow marsh* to the lower stage of the basin. The shallow marsh creates physical and biological characteristics that are more conducive to the removal process for soluble pollutants.

Settling column studies suggest a maximum upper limit of approximately 40 to 50% removal for total phosphorous after 48 hours, with most of the removal occurring within the first 6 to 12 hours (MWCOG, 1987). However, field studies show a much broader range in removing phosphorous (15-70%) and in removing sediment (65%). Since the soluble form of phosphorous comprises nearly half the phosphorous found in urban runoff, the lower efficiency of 35% (**Table 3.07-1**) is deemed appropriate. The increase in efficiency of *enhanced* extended-detention is attributed to the ability of the shallow marsh to reduce the soluble pollutant levels.

Providing a larger extended-detention volume (similar to providing a larger permanent pool for a retention basin) may not increase the pollutant removal efficiency. **Increasing the volume without increasing the detention time results in a larger orifice size and, therefore, less control of the smaller "first flush" storms**. Simply increasing the detention time will not provide additional efficiency either, since the 30-hour drawdown period exceeds the *probable settling time* associated with most particulate pollutants.

The pollutant removal efficiency in an *enhanced* extended-detention basin **can** be increased, however, by enlarging the volume of the shallow marsh. As the volume of the marsh is increased, with respect to the contributing drainage area, the *hydraulic residence time* is increased. This longer residence time provides more opportunity for further biological uptake and decomposition of pollutants.

Flooding and Channel Erosion Control

Flood control and downstream channel erosion are managed by storing additional runoff above the extended-detention pool (and shallow marsh) and by properly sizing the discharge opening in the riser structure.

When selecting an extended-detention basin, the biggest concern is how much land it requires. The storage volume needed above the extended-detention pool (and shallow marsh) must be approximated and its availability verified on the preliminary site plan.

> *A preliminary sizing estimate is recommended* ***during the planning stage*** *to verify the feasibility of using an extended-detention basin. (See* ***Chapter 5, Engineering Calculations*** *for Storage Volume Requirement Estimates).*

Sediment Control

An extended-detention basin may be used as a *temporary sediment control basin* during construction. The design of a temporary sediment basin is based on the *maximum drainage area* and *rate of runoff* expected anytime during the site construction process. In contrast, the design of the permanent stormwater basin is based on *post-developed land use conditions*. When designing a basin to provide both temporary sediment control and permanent stormwater management, the criteria that produces the largest storage volume should be used to size the basin. The discharge structure should be designed as a permanent stormwater facility with respect to its riser and barrel hydraulics and materials. The riser's geometry may then be temporarily modified to provide the wet and dry storage for the temporary sediment basin, as required by VESCH, 1992 edition.

Safety

Basins that are readily accessible to populated areas should include all possible safety precautions. Steep side slopes (steeper than 3H:1V) at the perimeter should be avoided and dangerous outlet facilities should be protected by enclosures. Warning signs for temporary deep water conditions and potential health risks should be used wherever appropriate. Signs should be placed so that at least one is clearly visible and legible from all adjacent streets, sidewalks or paths. A dry basin may hold a significant amount of soft sediment in the bottom, posing a danger to small children.

A fence is required at or above the maximum water surface elevation when a basin slope is a vertical wall. Local governments and homeowners associations may also require appropriate fencing despite the steepness of the basin side slopes.

Maintenance

Extended-detention basins have shown an ability to function as designed for long periods without routine maintenance. However, some maintenance is essential to protect the aesthetic properties of these facilities.

Vehicular access to the sediment forebay and the release structure should be provided to allow for long-term maintenance (such as sediment removal) and repairs, as needed. The use of a sediment forebay at the upstream end of the basin will help to localize the disturbance during routine sediment removal operations. An onsite area designated for sediment dewatering and disposal should also be included in the design. Care must be taken in the disposal of sediment that may contain an accumulation of heavy metals. **Sediment testing is recommended prior to sediment removal to assure proper disposal**.

A sign should be posted near the basin that clearly identifies the person or organization responsible for basin maintenance. Allowing participation by adjacent landowners or visitors is very helpful, especially if the facility is used for recreation. Maintenance items observed and addressed early will

help to limit overall maintenance costs. Routine maintenance inspections, however, should be conducted by authorized personnel
.

Design Criteria

This section provides recommendations and minimum criteria for the design of extended-detention and *enhanced* extended-detention basins intended to comply with the Virginia Stormwater Management program. It is the designer's responsibility to decide which aspects of the program are applicable to the particular facility being designed and to decide if any additional design elements are required. The designer should also consider the long-term functioning of the facility when selecting materials for the structural components.

<u>Hydrology and Hydraulics</u>

The pre- and post-developed hydrology for a basin's contributing watershed, the hydraulic analysis of the riser and barrel system, and the emergency spillway design should be developed using **Chapter 4, Hydrologic Methods** and **Chapter 5, Engineering Calculations**.

Generally, the 2-year storm should be used in *receiving channel adequacy* calculations and the 10-year storm should be used for *flood control* calculations. Alternate requirements, such as 1-year extended detention for channel erosion control may be imposed by local ordinances.

<u>Embankment</u>

The design of the earthen embankment for an extended-detention and *enhanced* extended-detention basin should comply with **Minimum Standard 3.01, Earthen Embankment**. The requirements for geotechnical, seepage control, maximum slope, and freeboard are particularly appropriate.

<u>Principal Spillway</u>

The design of the principal spillway and barrel system, anti-vortex device, and trash racks should comply with **Minimum Standard 3.02, Principal Spillway**.

Emergency Spillway

An emergency spillway that complies with **Minimum Standard 3.03, Vegetated Emergency Spillway** should be provided when possible, or appropriate.

Sediment Basin Conversion

When a proposed stormwater facility is used initially as a temporary sediment basin, conversion to the permanent facility should be completed after final stabilization and approval from the appropriate erosion and sediment control authority.

Sometimes, the temporary sediment basin design criteria will require more storage volume than that of a stormwater basin. In such cases, the extra volume may be allocated to the component of the facility that would derive the greatest benefit from increased storage. This will depend on the primary function of the facility (i.e., water quality enhancement, flood control, or channel erosion control).

If modifications to the riser structure are required as part of the conversion to a permanent basin, they should be designed so that a) *the structural integrity of the riser is not threatened*, and b) *large construction equipment is not needed within the basin*. Any heavy construction work required on the riser should be completed during its initial installation. It is **NOT** recommended to install a temporary sediment basin riser structure in the basin and then replace it with a permanent riser after final stabilization. This may affect the structural integrity of the existing embankment and barrel.

The following additional criteria should be considered for a conversion:

1. Final elevations and a complete description of any modifications to the riser structure geometry should be shown on the approved plans.

2. The wet storage area must be dewatered following the approved methods in VESCH, 1992 edition.

3. Sediment and other debris should be removed to a contained spoil area. Regrading of the basin may be necessary to achieve the final design grades and to provide an adequate topsoil layer to promote final stabilization.

4. Final modifications to the riser structure should be carefully inspected for water tight connections and compliance with the approved plans.

5. Final landscaping and stabilization should be per VESCH, 1992 edition, and **Minimum Standard 3.05, Landscaping** in this manual. Establishing vegetation may prove difficult if flow is routed through the facility prior to germination. In such cases, specifying sod or other reinforcements for the basin bottom and low flow channels may be appropriate.

Extended-Detention Volume

Water quality extended-detention basins are designed to allow particulate pollutants to settle out of water quality volume. **Chapter 5, Engineering Calculations** provides calculation procedures for determining the *water quality volume* for a particular watershed, and for sizing the release orifice to provide the required 30-hour draw down. **The water quality volume is the first one-half inch of runoff from the impervious surfaces**.

Channel erosion control extended-detention basins are designed to reduce the rate of discharge such that the velocity is below the critical velocity for the downstream channel. **Chapter 5, Engineering Calculations** provides the calculation procedures for calculating the *channel erosion control volume* for a particular watershed, and for sizing the release structure to provide the required 24-hour draw down. **The channel erosion control volume is the runoff generated from the drainage area or watershed by the 1-year frequency design storm.**

The orifice sizing procedure for extended detention is based on a "*brim*" drawdown. The full design volume is assumed to be in the basin, and the drawdown period is the time it takes to drain that entire volume. In reality, this technique ignores the *routing effect* that occurs in the basin: as the runoff volume accumulates, stormwater is draining into the basin while simultaneously draining out of it. For small storms, the extended-detention volume will never fill to the "brim" and will, therefore, never achieve the maximum drawdown time.

The calculation procedure used to verify the draw down time is presented in **Chapter 5.** The extended-detention volume (in cubic feet) is divided by the <u>maximum</u> release rate (in cubic feet per second), which is based on the maximum hydraulic head associated with the water quality volume, to give the *detention time*, in seconds. Using the maximum release rate, rather than the average release rate, results in a smaller orifice, which helps to compensate for ignoring the routing effect, as discussed above.

Enhanced Extended-Detention Basin: Shallow Marsh

When a higher pollutant removal efficiency is needed, a water quality extended-detention basin can be enhanced by providing a *shallow marsh* in the bottom of the facility. The use of a shallow marsh limits the maximum range of vertical storage in the extended-detention pool to 3 feet above the marsh's water surface elevation. However, the surface area requirements for the shallow marsh will likely force the basin's geometry to broaden at the lower stages, which will compensate for the reduced vertical storage. Extended-detention water surface elevations greater than 3 feet, and the frequency at which those elevations can be expected, are not conducive to the growth of dense or diverse stands of emergent wetland plants.

Similar to the permanent pool of a constructed wetland, the shallow marsh in the bottom of an extended-detention basin should be designed to maximize pollutant removal efficiency. The physical and hydraulic factors that can influence the pollutant removal efficiency of a shallow marsh are: 1) *volume*, 2) *depth*, 3) *surface area*, 4) *geometry*, and 5) *hydraulic residence time*. In addition, careful attention should be given to the landscaping plan (refer to **Minimum Standard 3.09, Constructed Wetland** for design criteria regarding the establishment of vegetation in a shallow marsh.

The following criteria are general guidelines. The depth of the treatment volume and amount of surface area varies with each site and the intended secondary functions of the facility (i.e., providing habitat, aesthetics, etc.).

1. **Volume–**

The pool volume of an extended-detention shallow marsh varies with the water quality volume. The water quality volume (WQV), as defined by Virginia Stormwater Management regulations, is the **first one-half inch of runoff, multiplied by the area of impervious surface**. The target pollutant removal efficiency of an *enhanced* extended-detention basin, as presented in **Table 3.07-1**, is based on 2.0 times the WQV. The shallow marsh pool volume represents 1.0 × WQV and the extended-detention volume represents an additional 1.0 × WQV. The pollutant removal efficiency is directly related to the percentage of runoff available to be treated. If it is assumed that all of the rainfall that hits impervious surfaces turns into runoff (ignoring minor losses such as evaporation, depression storage, etc.), then a design volume of 2.0 × WQV represents a design storm of 1 inch of rainfall. Based upon available rainfall data from the Washington, D.C. area, 1 inch of rainfall represents approximately 85% of all runoff producing storm events (MWCOG, 1992). Therefore, 2.0 × WQV (or 1 inch of rainfall from impervious surfaces) represents a significant percentage of runoff producing events.

2. **Depth–**

The treatment volume of a shallow marsh should occupy different depth zones, as shown in **Table 3.07-2**, to maximize the physical and biological processes that occur within the marsh. Three basic depth zones should be used: a) *deep pools*, b) *low-marsh*, and c) *high-marsh*.

a. Deep pool areas should be 1.5 to 4 feet deep and may consist of 1) *sediment forebays*, 2) *micro-pools*, and 3) *deep water channels*.

1. A sediment forebay is highly recommended in a shallow marsh. It should be constructed near incoming pipes or channels to reduce the velocity of incoming runoff, trap course sediments, and spread the runoff evenly over the marsh area. The forebay should be constructed as a separate cell from the rest of the marsh, with maintenance access provided to simplify cleaning with heavy equipment (refer to **Minimum Standard 3.04, Sediment Forebay**).

2. A micro-pool should be a standard component of the extended-detention shallow marsh. The purpose of a micro-pool is to create sufficient depth near

the outlet to help reduce clogging of the extended detention orifice. This will allow for a reverse-sloped pipe to extend into the marsh below the pool surface elevation but above the pool bottom which helps to prevent clogging, since a typical marsh environment consists of floating plant debris and possible sediment and organic accumulation on the bottom. Micro-pools also provide open water areas to attract plant and wildlife diversity (refer to the **Overflow** discussion later in this section).

3. Deep water channels provide an opportunity to lengthen the flow path to avoid seasonal short-circuiting (refer to the **Geometry** discussion later in this standard.)

b. Low-marsh zones range in depth from 6 to 18 inches.

c. High-marsh zones range in depth from 0 to 6 inches. The high-marsh zone will typically support the greatest density and diversity of emergent plant species.

3. **Surface Area–**

At a minimum, the surface area of an extended-detention shallow marsh should be sized to equal 1% of the contributing drainage area. The recommended surface area allocation for the different depth zones is presented in **Table 3.07-2** (MWCOG, 1992). Note that the surface area criteria may create a conflict with the volume allocations. If this happens, the designer is reminded that these are recommendations. **The criteria that establish the largest permanent pool should be used**.

4. **Geometry–**

The geometry of the shallow marsh must be carefully designed to avoid *short-circuiting*. Meandering, rather than straight line flow is desirable. Maximum pollutant removal efficiencies will be achieved due to the increased contact time associated with the longest possible flow path through the marsh. A length-to-width ratio of 2:1 through the marsh should be maintained (see **Figure 3.07-4**). The length-to-width ratio is calculated by dividing the straight line distance from the inlet to the outlet by the marsh's average width.

TABLE 3.07 - 2
Recommended Allocation of Surface Area and Treatment Volume for Depth Zones

Depth Zone	% of Surface Area	% of Treatment Volume
Deep Water 1.5 to 4 feet in depth (forebay and micro-pool)	20	40
Low Marsh 0.5 to 1.5 feet in depth	40	40
High Marsh 0 to 0.5 feet	40	20

(Adapted from MWCOG, 1992)

5. **Hydraulic Residence Time–**

The *hydraulic residence time* is the shallow marsh pool volume divided by the average outflow discharge rate. The longer the residence time, the higher the pollutant removal efficiency (Driscoll, 1983, Kulzer, 1989).

In theory, by using 1.0 x WQV in sizing the shallow marsh volume, the smaller storms (those producing ½ inch of runoff or less) will displace the pool volume of the marsh. However, larger treatment volumes (such as 2 or 3 x WQV), compared with the watershed size, will provide longer residence times and greater efficiencies. In certain situations, increasing the target pollutant removal efficiency by using a higher water quality volume multiplier to size the marsh volume may be acceptable. However, the challenge will be to provide the recommended depth zone allocations for the allocated percentages of surface area and treatment volumes, as previously discussed.

Base Flow

The presence of a *base flow* makes the design of an extended-detention control structure difficult. If the extended-detention orifice is sized for the *wet weather base flow*, then the dry weather control is compromised because the release rate is too high. If the orifice is undersized to maintain the *dry weather control*, then the extended-detention pool may remain full of water during the wet weather season; this essentially eliminates the extended-detention volume by creating an undersized permanent pool (1.0 x WQV). When seasonal base flow is present, an adjustable orifice should be provided in the control structure to maintain the marsh volume.

The presence of a base flow and the associated potential for erosion within the basin should be considered in the design. Ideally, base flow, or *low flows*, should be spread out so that they *sheet flow* across the bottom of the basin. Due to maintenance difficulties and undesirable insect breeding associated with standing water, some localities may have ordinances that require *low-flow channels* (or *trickle ditches*) to carry base flows. If an *impervious* ditch is used to convey base flows, it should be designed to overflow during storm events and spread the runoff across the basin floor. The use of gabion baskets or riprap, instead of concrete, may provide the advantage of slowing the flow, encouraging spillover onto the basin floor. **Generally, an impervious low-flow channel is <u>NOT</u> recommended in a stormwater management water quality basin, as its use is contrary to the basin's water quality function**.

Local ordinances should be reviewed for specific requirements relating to low-flow or base-flow channels in dry detention basins.

<u>Overflow</u>

Similar to a constructed stormwater wetland, an extended-detention overflow system should be designed to provide adequate overflow or bypass for a full range of design storms. For an *enhanced* extended-detention basin, the overflow system should pass the full range of design storms with no more than 3 feet of hydraulic head above the shallow marsh.

<u>Sediment Forebay</u>

A sediment forebay will help to postpone overall basin maintenance by trapping incoming sediments at a specified location. The forebay should be situated and designed per **Minimum Standard 3.04, Sediment Forebay**. Usually, a sediment forebay is placed at the outfall of the incoming storm drain pipes and positioned to ensure access for maintenance equipment.

A sediment forebay enhances the pollutant removal efficiency of a basin by trapping the incoming sediment load in one area where it can be easily monitored and removed. For an *enhanced* extended-detention basin, the sediment forebay is included in the deep pool allocations of the surface area and storage volume. The target pollutant removal efficiency of an extended-detention basin, as listed in **Table 3.07-1**, is predicated on using a sediment forebay at the inflow points of the basin.

<u>Liner to Prevent Infiltration</u>

Extended-detention basins should have negligible infiltration rates through the bottom of the basin. Infiltration will impair the proper functioning of the basin and may contaminate groundwater, and in areas of Karst, may cause collapse. For an *enhanced* extended-detention basin, excessive infiltration may prevent the shallow marsh from holding water. If infiltration is anticipated, and the area is not suspected to be underlain by Karst, than an infiltration facility, rather than a detention water quality BMP, should be used **<u>or</u>** a liner should be installed in the basin to prevent infiltration.

When using a liner, the following recommendations apply:

1. A clay liner should have a minimum thickness of 12 inches and should comply with the specifications provided in **Table 3.07-3**.

2. A layer of compacted topsoil (minimum 6 to 12 inches thick) should be placed over the liner before seeding with an appropriate seed mixture (refer to VESCH, 1992 edition)

3. Other liner types may be used if supporting documentation is provided verifying the liner material's performance.

TABLE 3.07 - 3
Clay Liner Specifications

Property	Test Method (or equal)	Unit	Specification
Permeability	ASTM D-2434	*cm/sec*	1×10^{-6}
Plasticity Index of Clay	ASTM D-423 & D-424	%	Not less than 15
Liquid Limit of Clay	ASTM D-2216	%	Not less than 30
Clay Particles Passing	ASTM D-422	%	Not less than 30
Clay Compaction	ASTM D-2216	%	95% of Standard Proctor Density

Source: City of Austin, 1988

Access

A 10 to 12 foot wide access road with a maximum grade of 12% should be provided to allow vehicular access to both the outlet structure area and at least one side of the basin. The road's surface material should be selected to support the anticipated frequency of use and vehicular load without excessive erosion or damage.

Landscaping

A qualified individual should prepare the landscape plan for an extended-detention basin. Appropriate shoreline fringe, riparian fringe and floodplain terrace vegetation must be selected to correspond with the expected frequency and duration of inundation. Additional criteria for landscaping may be found in **Minimum Standard 3.05, Landscaping**. For establishment of vegetation in the marsh area, refer to **Minimum Standard 3.09, Constructed Wetland**.

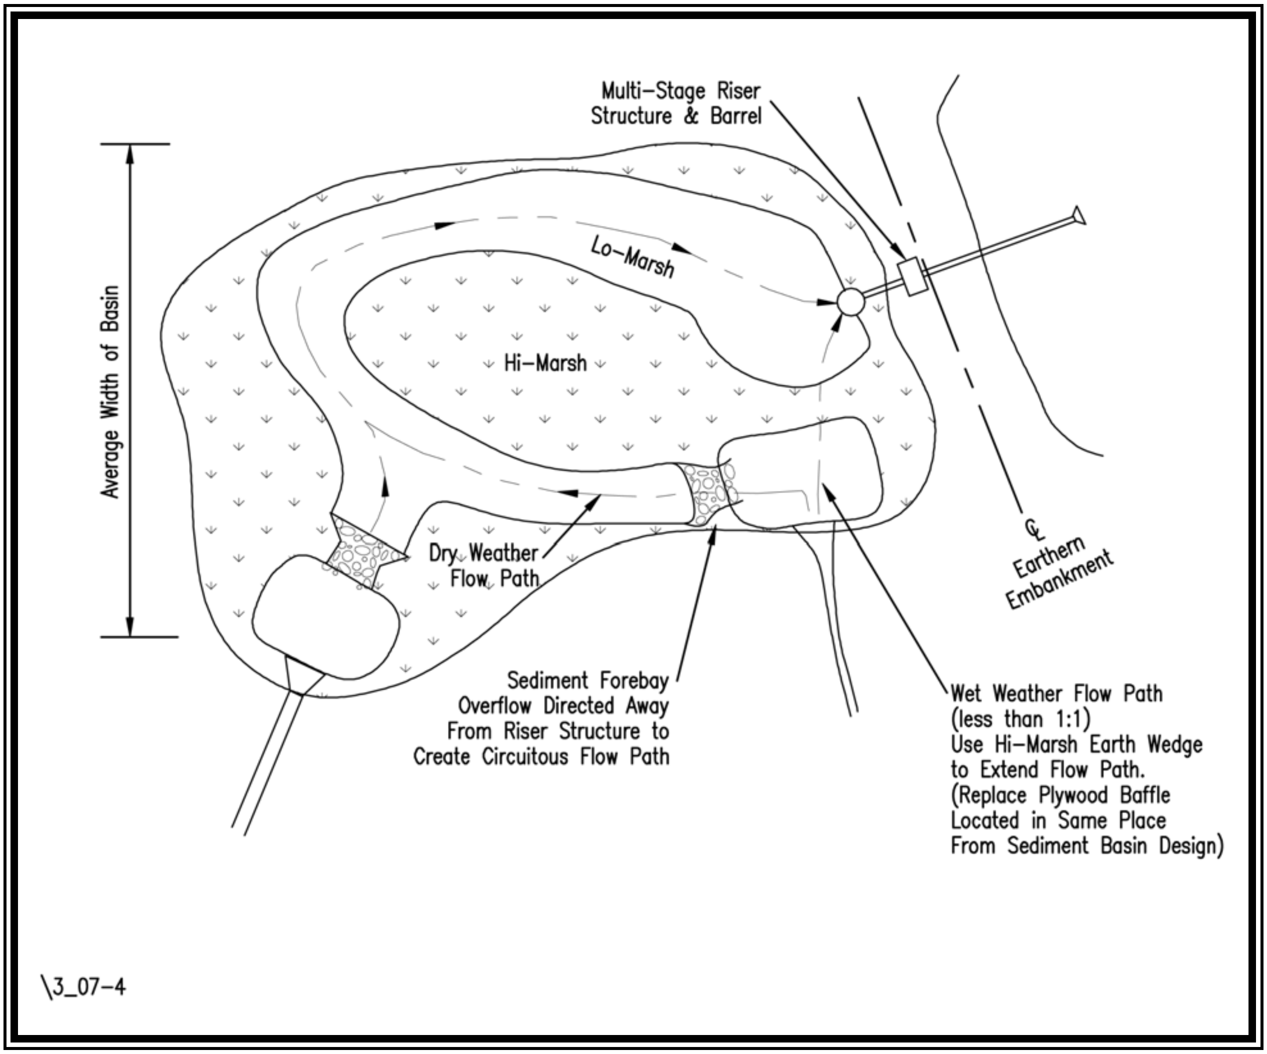
The vegetation should be planted in soil that is appropriate for the plants selected. Soil tests showing the adequacy of the soil or a soil enhancement plan should be submitted with the overall basin design.

The soil substrate must be soft enough to permit easy installation of the plants. If the basin soil has been compacted or vegetation has formed a dense root mat, the upper 6 inches of soil should be disked before planting. If soil is imported, it should be laid at least 6 inches deep to provide sufficient depth for plant rooting to occur.

<u>Buffer Zone</u>

A vegetated buffer strip should be maintained beside the basin. The strip should be a minimum of 20 feet wide, as measured from the maximum water surface elevation. Refer to **Minimum Standard 3.05, Landscaping**.

FIGURE 3.07 - 4
Flow Path/Short-Circuiting



Construction Specifications

The construction specifications for stormwater extended-detention and *enhanced* extended-detention basins outlined below should be considered minimum guidelines. More stringent or additional specifications may be required based on individual site conditions.

Overall, widely accepted construction standards and specifications for embankment ponds, such as those developed by the USDA Soil Conservation Service or the U.S. Army Corps of Engineers, should be followed to build an impoundment.

Further guidance can be found in Chapter 17 of the Soil Conservation Service's Engineering Field Manual. Specifications for the work should conform to methods and procedures specified for installing earthwork, concrete, reinforcing steel, pipe, water gates, metal work, woodwork and masonry and any other items that apply to the site and the purpose of the structure. The specifications should also satisfy any requirements of the local plan approving authority.

The following minimum standards contain guidance and construction specifications for various components of these facilities: **3.01, Earthen Embankment**; **3.02, Principal Spillway**; **3.03, Vegetated Emergency Spillway**; **3.04, Sediment Forebay**; **3.05, Landscaping**, and **3:09, Constructed Wetland**.

Maintenance and Inspections

The following maintenance and inspection guidelines are not intended to be all-inclusive. Specific facilities may require other measures not discussed here. The engineer is responsible for determining if any additional items are necessary.

Inspecting and maintaining the structures and the impoundment area should be the responsibility of the local government, a designated group such as a homeowner association, or an individual. A specific maintenance plan should be formulated outlining the schedule and scope of maintenance operations.

General Maintenance

Maintenance and inspection guidelines found in the following minimum standards also apply: **3.01, Earthen Embankment**; **3.02, Principal Spillway**; **3.03, Vegetated Emergency Spillway**; **3.04, Sediment Forebay**, and **3.05, Landscaping**.

Vegetation

The basin's side slopes, embankment and emergency spillway should be mowed at least twice a year to discourage woody growth. More frequent mowing may be necessary in residential areas for aesthetic purposes.

Dry extended-detention basins may have soggy bottoms, making mowing costly and difficult. The use of water-tolerant, hardy, and slow growing grass is recommended for the bottom of these basins. **Vegetation is preferred to an impervious low-flow channel since the channel may interfere with the pollution removal capabilities of the basin**. The designer should be aware of local program requirements, as some localities require low-flow channels.

Specific plant communities may require different levels of maintenance. Upland and floodplain terrace areas, grown as meadows or forests, require very little maintenance, while aquatic or emergent vegetation may need periodic thinning or reinforcement plantings. Note that after the first growing season it should be obvious if reinforcement plantings are needed. If they are, they should be installed at the onset of the second growing season after construction.

Research indicates that for most aquatic plants the uptake of pollutants is stored in the roots, not the stems and leaves (Lepp 1981). Therefore, aquatic plants should not require harvesting before winter plant die-back. There are still many unanswered questions about the long term pollutant storage capacity of plants. Possible aquatic and emergent plant maintenance recommendations may be presented in the future.

Debris and Litter Removal

Debris and litter will accumulate near the inflow points and around the outlet control structure. Such material should be removed periodically. Significant accumulation can clog the low-flow outlet and the upper control openings.

Sediment Removal

Sediment deposition should be continually monitored in the basin. Removal of accumulated sediment is extremely important. A significant accumulation of sediment impairs the pollutant removal capabilities of the basin by reducing the available storage for the water quality volume and/or reducing the available volume for the shallow marsh. In addition, accumulated sediment in the bottom of a basin creates unsightly conditions and chokes out established vegetation.

Unless unusual conditions exist, it is anticipated that accumulated sediment will need to be removed from the basin every 5 to 10 years (MWCOG, 1987). More frequent cleaning of the area around the low flow or extended-detention orifice may be required. The use of a sediment forebay with access for heavy equipment will greatly simplify the removal process. **During maintenance procedures,**

ensure that any pumping of standing water or dewatering of dredged sediments complies with the VESCH, 1992 edition, and any local requirements.

Owners, operators, and maintenance authorities should be aware that significant concentrations of heavy metals (e.g., lead, zinc and cadmium) and some organics, such as pesticides, may be expected to accumulate at the bottom of a basin. Testing of sediment, especially near points of inflow, should be conducted regularly and **before disposal** to find the leaching potential and level of accumulation of hazardous materials. Disposal methods must comply with the health department requirements of the local government.

Inspections

An extended-detention basin and its components should be inspected annually to ensure that they operate in the manner originally intended. If possible, inspections should be conducted during wet weather to determine if the extended-detention time is being achieved. Inspections should be conducted by a qualified individual following the checklist provided in **Chapter 3 Appendix**.

CONSTRUCTED STORMWATER WETLAND

Definition

Constructed stormwater wetlands are manmade shallow pools that create growing conditions suitable for both emergent and aquatic vegetation.

Purpose

Constructed wetlands are intentionally installed on non-wetland sites to enhance the quality of stormwater runoff.

In contrast, *created wetlands* are also intentionally installed on non-wetland sites, but are designed to produce or replace natural functional wetlands and wetland habitats (e.g., for compensatory mitigation projects).

This handbook deals primarily with *constructed wetlands*. Sometimes, a constructed wetland may provide some of the benefits of a created wetland. However, understanding the differences in these two manmade systems is important. For a *natural* or *created wetland*, pre-treatment BMPs, such as erosion controls, presettling basins, biofilters, etc., are used to reduce pollutants entering the wetland to prevent its degradation and clogging. The primary function of a *constructed wetland*, on the other hand, is to provide those same types of pre-treatment functions within the wetland itself. The constructed wetland, therefore, will require maintenance to assure long-term pollutant removal. **It should be noted that the pre-treatment BMPs mentioned above will often simplify or reduce maintenance requirements, as well as enhance and prolong the useful life of a constructed stormwater wetland.**

<u>Water Quality Enhancement</u>

A constructed stormwater wetland can achieve high removal rates of particulate and soluble pollutants (nutrients) through gravitational settling, wetland plant uptake, absorption, physical filtration, and biological decomposition. The pollutant removal efficiency of a constructed wetland is dependent on various design criteria relating to the size and design of the pool area. Other site-specific design features and variations in environmental conditions such as soils, climate, hydrology, etc. make it difficult to predict the actual pollutant removal efficiency. Monitoring of many stormwater wetland facilities has confirmed the wide range of pollutant removal efficiencies associated with such systems.

Constructed stormwater wetlands operate similar to retention basins, yet their overall performance is expected to be more variable. This may be due to any of the following:

1. The decrease in biological activity associated with seasonal cold weather.

2. The conversion of plant species and densities as the wetland matures and becomes acclimated to various environmental factors such as soils, hydrology, climate, and sediment and pollutant load.

3. The uncertainty of the biological cycling processes of phosphorous in the wetland environment.

The expected pollutant removal rate of constructed stormwater wetlands is provided in **Table 3.09-1**. While the rate may appear low, it reflects the uncertainty of their long-term viability.

TABLE 3.09 - 1
Pollutant Removal Efficiency for Constructed Stormwater Wetlands

Water Quality BMP	Target Phosphorus Removal Efficiency	Impervious Cover
Constructed Wetlands 2.0 x WQ Volume	30%	22 - 37%

Flood Control & Channel Erosion Control

Constructed stormwater wetlands should generally not be used for flood control or stream channel erosion control. This is due to the anticipated water level fluctuations associated with quantity controls. The clearing of vegetation and the addition of impervious surfaces may cause large and sudden surges of runoff during rain events, and may cause less than normal base flows due to lack of groundwater during dry periods. Large, sudden fluctuations in water levels can stress emergent wetland and upland edge vegetation. Most edge vegetation cannot survive drought or saturation extremes, leaving wetland banks exposed to potential erosion. It should be noted that the large surface area requirement for constructed stormwater wetlands will help to minimize the “extreme” water level fluctuations during all but the larger storm events. Also, certain plants can be specified for the upland banks which may be more tolerant to the wet and dry extremes. Therefore, preventing surges whenever possible and designing for gradual increases and decreases in water level is important for successful constructed wetland design. See **Design Criteria** for further discussion.

(Wetland vegetation can be used to enhance the pollutant removal efficiency of extended-detention flood control and stream channel erosion control facilities by constructing a shallow marsh in their bottoms. See **Minimum Standard 3.07, Extended-Detention and *Enhanced* Extended-Detention Basin**.)

Conditions Where Practice Applies

Drainage Area

The drainage area criteria for a constructed stormwater wetland is similar to that of a retention basin. However, because of their shallow depth, constructed stormwater wetlands may consume two to three times the site area compared with other stormwater quality BMPs (MWCOG, 1992). Vertical (depth) storage is usually not possible in constructed wetlands due to the needs of aquatic plants. Therefore, the maximum watershed size depends on the available area on the site that is suitable for a constructed wetland system.

The minimum watershed drainage area for constructed stormwater wetlands should be 10 acres. However, this minimum should be confirmed based on the watershed's hydrology and the presence of an adequate base flow to support the selected vegetation. Similar to retention basins, a drainage area of 15 to 20 acres or the presence of a dependable base flow is most desirable to maintain a healthy wetland. A clay liner may be necessary to prevent infiltration if losses are expected to be high.

Development Conditions

Constructed stormwater wetlands are suited for both low- and high-visibility sites. However, the aesthetic problems associated with having a natural and free growing landscape feature in an otherwise manicured development setting should be avoided for high-visibility sites. Additional concerns regarding stagnation or excessive infiltration during the dry summer months may also influence the choice of location. Proper planning, design, and maintenance are critical to ensure the pollutant removal capabilities of a constructed wetland and to insure its acceptance by adjacent landowners.

Like retention basins, constructed wetlands are also suited for low- and medium-density residential or commercial developments. However, the land area required for this BMP may limit its use.

Planning Considerations

Constructed stormwater wetlands should be designed to duplicate the functions of natural wetlands, while allowing for ongoing maintenance. The designer faces the difficult task of replicating natural wetland hydrology in a constructed setting, while ensuring easy access for maintenance.

Hydrology

The hydrology of a constructed stormwater wetland is largely influenced by surface runoff. The hydrology, in turn, affects several key characteristics of a stormwater wetland, such as:

1. *Water level fluctuations*. A *constructed stormwater* wetland will experience rapid inundation and drawdown periods with each runoff-producing event.

2. *Permanent pool*. A *natural* wetland may experience seasonal standing water and/or periodic drawdowns. However, a constructed stormwater wetland is engineered to permanently hold a specific volume of water, or at a minimum, maintain pools of water of varying depths. This stored water supports the aquatic and emergent plant regime and maintains the pollutant removal efficiency of the BMP.

3. *Vegetation*. The vegetation diversity in a constructed wetland is established by the landscape plan or volunteer vegetation. The selection of vegetation should be limited to native plant species suitable for the pool depths expected within the different depth zones. Care should be taken to avoid the introduction of exotic or invasive species. The use of appropriate donor soil and wetland mulch will help prevent this problem.

   In contrast, a natural wetland vegetates itself through natural selection based on the growing conditions within it. The existing source of seeds, which is usually enhanced by wildlife, allows for the constant renewal of plant life.

4. *Sediment and pollutant load*. A stormwater wetland is subject to sediment loads, especially from upland pervious areas during the first growing season. During this period, permanent vegetation in the developing watershed is still growing. Without a well-established ground cover, surface sediments can be easily transported by rainfall and resulting runoff. Accumulation of this sediment in the constructed stormwater wetland during the first growing season alone can dramatically alter the topography of the facility, affecting water levels and flow paths. Furthermore, the pollutant load (nutrients and organics) associated with urban runoff and sediments entering a constructed wetland is usually higher than that which enters a natural or undisturbed wetland in undeveloped watershed. Therefore, if the constructed wetland is used to remove pollutants, the water quality within the wetland itself will be decreased. During the planning stage of a facility, the designer should have a good understanding of site-specific runoff constituents and an understanding of their possible effects on the selected vegetation.

Site Conditions

Site conditions, such as property lines, easements, utilities, structures, etc., that may impose constraints on development should be considered when designing a constructed wetland. Local government land use and zoning ordinances may also specify certain requirements.

All facilities should be a minimum of 20 feet from any structure, property line, or vegetative buffer, and 100 feet from any septic tank/drainfield. Local landuse setbacks and other restrictions may apply.

All facilities should be a minimum of 50 feet from any steep slope (greater than 10%). Alternatively, a site-specific geotechnical report must address the potential impact of a constructed stormwater wetland that is to be installed on, or near, such a slope.

Additional considerations are as follows:

1. **Soils–**

   Permeable soils are not suited for constructed stormwater wetlands. A thorough analysis of the soil strata should be conducted to verify its suitability for holding water. In the past, many BMP designs were accepted based upon soils information compiled from available data, such as SCS soil surveys. While such a source may be appropriate for a pre-engineering feasibility study, final design and acceptance **should be based on an actual subsurface analysis and permeability tests**, accompanied by appropriate engineering recommendations. Refer to the references listed at the end of **Minimum Standard 3.10, Infiltration Practices** for additional information on soil analysis techniques.

   The goal of a subsurface analysis is to determine if the soils are suitable for a constructed stormwater wetland. The textural character of the soil horizons and/or strata units within the subsoil profile should be identified to at least 3 feet below the bottom of the facility. This information is used to verify the infiltration rate or permeability of the soil. For constructed stormwater wetlands, water inflow (base flow and groundwater) must be greater than water losses (infiltration and evaporation). If the infiltration rate of the soil is too great, then a constructed wetland may not be an appropriate BMP, or a liner may be required. The soil permeability may be such that the shallow depths of a constructed wetland can be maintained. However, as the depth of the permanent pool increases, the increased head or pressure on the soil may increase the infiltration rate.

   For discussions regarding the appropriate soils for landscaping, see the Landscape section in this standard and **Minimum Standard 3.05, Landscaping**.

2. **Rock–**

The subsurface investigation should also identify the presence of any rock or bedrock layers. The excavation of rock to achieve the proper wetland dimensions and hydrology may be too expensive or difficult with conventional earth moving equipment. However, blasting may open seams or create cracks in the underlying rock that may result in unwanted drawdown of the permanent pool. Blasting of rock is not recommended unless a liner is used.

3. **Karst–**

In regions where Karst topography is prevalent, projects may require a thorough soils investigation and specialized design and construction techniques. Since the presence of karst may affect BMP selection, design, and cost, a site should be evaluated **during the planning phase of the project**.

4. **Existing Utilities–**

Most utility companies will not allow their underground lines and right-of-ways to be submerged under a permanent pool. If such a site must be used, the designer should obtain permission **before designing the BMP**. Note that if the utilities ever require maintenance or repair, the characteristics of the constructed wetland may be irreparably changed or damaged. The cost to move any existing utilities during initial wetland construction should be determined and included in the project's overall construction costs.

Environmental Impacts

Constructed stormwater wetlands are generally located in areas with favorable hydrology. These locations are prone to being environmentally sensitive (low-lying) as well, and may contain existing wetlands, shallow marshes, perennial streams, wildlife habitat, etc., which may be protected by state or federal laws. The owner or designer should review local wetland maps and contact local, state, and federal permitting agencies to verify the presence of wetlands, their protected status, and the suitability of the location for a constructed wetland.

With careful planning, it may be possible to incorporate wetland mitigation into a constructed stormwater wetland. This assumes that the functional value of the existing or impacted wetland can be identified and included, reconstructed, or mitigated for, in the stormwater wetland. The Virginia Department of Environmental Quality should be contacted for more information regarding wetland mitigation.

Sediment Control

A constructed stormwater wetland should not be used as a sediment control facility during site construction. A presettling basin, or forebay, may be constructed above the proposed constructed wetland facility, however, any planting or preparation of the constructed wetland site should occur after the site construction has been completed. This will eliminate any forseeable impact from sediment loads that overwhelm temporary erosion and sediment control measures during storm events.

Maintenance

Constructed stormwater wetlands require periodic maintenance, as does any stormwater BMP. In addition, a constructed wetland will require active management of the hydrology and vegetation during the first few years or growing seasons in order for it to achieve the performance and functions for which it was designed.

Vehicular access and manuvering room in the vicinity of a constructed wetland (and sediment forebay) is necessary to allow for long-term maintenance. In addition, the establishment of an on-site sediment disposal area, properly located and contained, will significantly reduce the cost of routine maintenance and sediment removal. Care must be taken in the disposal of sediment that may contain an accumulation of heavy metals. **Sediment testing is recommended prior to sediment removal to assure proper disposal**.

Design Criteria

This section provides minimum criteria and recommendations for the design of a constructed stormwater wetland intended to comply with the runoff quality requirements of the Virginia Stormwater Management program. It is the designer's responsibility to decide which aspects of the program apply to the particular facility being designed and if any additional design elements are required to insure the long-term functioning of the wetland.

Hydrology and Hydraulics

Chapter 4, Hydrologic Methods and **Chapter 5, Engineering Calculations** should be used to develop the post-developed hydrology of the wetland's contributing watershed, to analyze the hydraulics of the riser and barrel system (if used) and to design the emergency spillway.

The contributing watershed's area should be a minimum of 10 acres and/or there should be an adequate base flow to support the hydrology.

Embankment

The design of the earthen embankment for any impoundmant BMP should comply with **Minimum Standard 3.01, Earthen Embankment**. Specific requirements for geotechnical analysis, seepage control, maximum slopes, and freeboard are particularly appropriate.

Principal Spillway

The design of the principal spillway and barrel system, or weir overflow system, anti-vortex device, and trash racks should comply with **Minimum Standard 3.02, Principal Spillway**. Weir spillways have a large cross-sectional area that can pass a considerable flow rate at low head conditions. Since reducing the depth of ponding in a constructed wetland helps to avoid stressing plant communities, an armored, weir-type spillway may be the most desirable overflow device for a constructed stormwater wetland. Further, the use of an adjustable weir will help maintain the proper water surface elevation during seasonal extremes.

Emergency Spillway

An emergency spillway that complies with **Minimum Standard 3.03, Vegetated Emergency Spillway** should be provided when possible.

Permanent Pool

Sizing a constructed stormwater wetland is based on maximizing its pollutant removal efficiency. The physical and hydraulic factors that influence the wetland's pollutant removal efficiency are the permanent pool *volume*, *depth*, *surface area*, *geometry*, and *hydraulic residence time*. Minimum design criteria are presented below for each of these factors:

1. **Volume –**

The required permanent pool volume of a constructed stormwater wetland is **2 times the water quality volume** (2 ×WQV). The target pollutant removal efficiency shown in **Table 3.09-1** is based on this sizing criteria.

2. **Depth –**

Four depth zones are needed within the permanent pool of a constructed stormwater wetland: a) *deep pool*, b) *low marsh*, c) *high marsh*, and d) *semi-wet* (see **Figure 3.09-2**).

a. The *deep pool* areas of a constructed wetland should be 18 *inches* to 6 *feet* in depth and may consist of 1) *sediment forebays*, 2) *micro-pools*, and/or 3) *deep-water channels*.

    1. *Sediment forebays* are highly recommended in constructed stormwater wetlands. They should be installed at stormwater inflow points to reduce the velocity of

incoming runoff and trap course sediments, and to spread the runoff evenly over the wetland area. The forebay should be constructed as a separate cell from the rest of the wetland and provide easy access for maintenance with heavy equipment. Refer to **Minimum Standard 3.04, Sediment Forebay** for further information.

2. *Micro-pools* offer open water areas to attract plant and wildlife diversity. If a low-flow discharge pipe is used, it should be constructed on a reverse slope and extended into the wetland below the pool surface elevation but above the bottom elevation. This helps to prevent clogging, since a typical wetland environment consists of floating plant debris and possible sediment and organic accumulation at the bottom. (Refer to the **Overflow** discussion later in this section.)

3. *Deep-water channels* provide an opportunity to lengthen the flow path to avoid seasonal short-circuiting (see pool geometry).

b. The *low-marsh zone* ranges in depth from 6 to 18 inches.

c. The *high-marsh zone* ranges in depth from 0 to 6 inches. Usually, this zone will support the greatest density and diversity of emergent plant species.

d. The *semi-wet zone* refers to the area that, during normal, non-rainfall periods, is above the pool, but is inundated during storm events for a period of time, depending on the amount of rainfall, and the hydraulics of the overflow device.

Note: The low-marsh, high-marsh, and semi-wet zones are useful as a perimeter shelf 10 to 15 feet wide. This shelf, or aquatic bench, can serve as a safety feature to keep children away from the open water deep pool areas. Also, as a secondary benefit, a heavily vegetated perimeter will help to discourage geese from using the facility as a permanent habitat.

The recommended surface area allocation for these depth zones is presented in **Table 3.09-2.**

3. **Surface Area–**

At a minimum, the pool surface area of a constructed stormwater wetland should equal 2% of the size of the contributing watershed. Recommended surface area allocations for different depth zones are shown in **Table 3.09-2** (MWCOG, 1992). Note that if the surface area criteria conflict with the volume allocations, the surface area allocations are more critical to an effective design.

4. **Geometry–**

The geometry of the constructed stormwater wetland must be designed to avoid short-circuiting. Maximum pollutant removal efficiency is achieved with the longest possible flow path, since this increases the contact time over the wetland area. The minimum length-to-width ratio of the pool should be 1:1 in wet weather and 2:1 during dry weather (see **Figure 3.09-3**).

TABLE 3.09-2
Recommended Allocation of Surface Area and Treatment Volume for Various Depth Zones

Depth Zone	% of Surface Area	% of Treatment Volume
Deep Water 1.5 to 6 feet deep	10	20
Low Marsh 0.5 to 1.5 feet deep	40	*
High Marsh 0 to 0.5 feet deep	50	*
		* combined marsh area = 80% of treatment volume

Adapted from MWCOG, 1992

The **wet weather** *length-to-width ratio* is calculated by dividing the straight line distance from the inlet to the outlet by the wetland's average width. The **dry weather** *length-to-width ratio* is calculated by dividing the dry weather flow path length by the wetland's average width. Note that the dry weather flow path is created by constructing high marsh areas perpendicular to the straight line flow path described above. These marsh areas act as submerged berms and lengthen the effective flow path.

5. **Hydraulic Residence Time–**

The hydraulic residence time is the permanent pool volume, divided by the average outflow discharge rate. The longer the residence time, the higher the pollutant removal efficiency (Driscoll, 1983, Kulzer, 1989).

Using *2 × WQV* to size the permanent pool means that smaller storms (*1 × WQV* or *½-in.*) will displace only half of the pool volume of the wetland, thus providing for extended residence times. Larger treatment volumes with respect to the watershed size (*3 × WQV*) will provide longer residence times and, therefore, greater efficiencies. In certain situations, using these larger volumes and efficiencies may be acceptable, but the decision should be made carefully. The associated challenge is to provide the recommended surface area allocations for the different depth zones as previously discussed.

<u>Overflow</u>

Providing flood control and/or channel erosion control within a constructed stormwater wetland creates a hydrologic regime that is very difficult to adapt to in the landscaping plan, due to extreme water depth fluctuations. If a constructed wetland is to serve as a quantity control BMP, it should be designed to provide adequate overflow or bypass for the full range of design storms with as little vertical ponding depth as possible. The hydraulic head needed to pass a design storm is a function of the relationship between the constructed wetland surface area, the geometry of the overflow structure, and the allowable discharge (refer to **Chapter 5, Engineering Calculations**). Outlet structures should be sized to pass the design storms (up to the 10-year storm) with a maximum of 2 feet of water ponded above the wetland pool.

In a stormwater wetland designed for water quality enhancement only, a bypass or diversion structure may be used to prevent sudden surges of runoff from flushing through the wetland (see **Figure 3.09-4**). This establishes the constructed wetland as an off-line facility. If site constraints prevent the use of an off-line facility, then the overflow should be designed to pass the full range of design storms with as little head as possible. An oversized riser and barrel system or a weir structure installed along the berm at the outlet may be used. Refer to **Minimum Standard 3.02, Principal Spillway** for outlet structure design criteria.

Sediment Forebay

Sediment forebays should be installed and designed per **Minimum Standard 3.04, Sediment Forebay**. Generally, they should be constructed at the outfall of incoming storm drain pipes or channels and should be made accessible for maintenance equipment. To lower maintenance costs, an on-site disposal area should be included in the design. Sediment forebays enhance the pollutant removal efficiency of BMPs by containing incoming sediment in one area, which also simplifies monitoring and removal. Therefore, the target pollutant removal efficiency of a constructed stormwater wetland, as presented in **Table 3.09-1**, is predicated on the use of sediment forebays at all inflow points.

Liner to Prevent Infiltration

Constructed stormwater wetlands should have negligible infiltration rates through their bottom. Infiltration impairs the proper functioning of any retention facility by lowering its pool elevation. If infiltration is expected, then a retention BMP must **not** be used, **or** a liner should be installed to prevent infiltration. If a clay liner is used, the specifications provided in **Table 3.09-3** apply and the following are recommended:

1. A clay liner should have a minimum thickness of 12 inches.

2. A layer of compacted topsoil (6 to 12 inches thick, minimum) should be placed over the liner.

3. Other liners may be used if adequate documentation exists to show that the material will provide the required performance.

Safety

The side slopes of a constructed stormwater wetland should be no steeper than 3H:1V. Also, local ordinances may require fencing of deep pool areas next to the shoreline as an additional safety measure. Dense plantings of shoreline fringe vegetation can serve as a safety feature by discouraging access to the pool areas.

TABLE 3.09 - 3
Clay Liner Specifications

Property	Test Method (or equal)	Unit	Specification
Permeability	ASTM D-2434	*cm/sec*	1 x 10^{-6}
Clay Plasticity Index	ASTM D-423 & D-424	%	Not less than 15
Liquid Limit of Clay	ASTM D-2216	%	Not less than 30
Clay Particles Passing	ASTM D-422	%	Not less than 30
Clay Compaction	ASTM D-2216	%	95% of Standard Proctor Density

Source: City of Austin, 1988

Access

A 10 to 12-foot wide access road with a maximum grade of 12% should be provided to allow vehicular access to the outlet structure area, at least one side of the basin, and the sediment forebay(s). The road’s surface should be selected to support the anticipated frequency of use and vehicular load without excessive erosion or damage.

Landscaping

A qualified individual should prepare the landscape plan for a constructed stormwater wetland. Appropriate aquatic, emergent, shoreline fringe, transitional, and floodplain terrace vegetation must be selected to correspond with the expected frequency, duration, and depth of inundation.

The landscaping plan for a constructed wetland is based on the projected depth zones and onsite soil analysis, and should contain the following:

1. **The location, quantity, and propagation methods of plant species and grasses for the stormwater wetland and its buffer.**

The location of plants is based on the depth zones in the wetland and the innundation tolerance of the plant species. Planting zones of uniform depth should be identified for each species selected.

Only one-half of the low- and-high marsh depth zones need to be planted. If the appropriate planting depths are achieved, the entire wetland should be colonized within three years. At least 5 to 7 emergent wetland species, including a minimum of two species for each of the marsh depth zones (high and low), should be used. Selections should be based on wildlife food value, depth tolerance, price, commercial availability and/or shade limitations. Certain species, such as cattails, should be selected with caution. Although they may provide excellent pollutant removal characteristics, they can be invasive and may eventually crowd out other species.

A constructed stormwater wetland does not contain a seed bank, nor does it have an existing natural seed transport cycle as found in native wetlands. While the use of donor soil from disturbed or dredged sites may provide a seed bank, these opportunities may not be readily available. Therefore, the most common and convenient technique for establishing wetland vegetation in a constructed system is to transplant nursery-grown stock. Other propagation techniques (which are outside the scope of this manual) may also prove successful, but special growing conditions must exist.

2. **Instructions for site preparation**.

The soil in which the vegetation is planted should be appropriate for the wetland plants selected. Soil tests showing the adequacy of the soil, or a soil enhancement plan should be submitted with the wetland design.

The soil substrate must be soft enough to permit easy insertion of the plants. If the basin soil is compacted or vegetation has formed a dense root mat, the upper 6 inches of soil should be disked before planting. If soil is imported, it should be laid at least 4 inches deep to provide sufficient depth for plant rooting.

3. **A schedule for transplanting emergent wetland stock**.

The window for transplanting emergent stock extends from early April to mid-June. Dormant rhizomes can be planted in fall or winter. To insure availability, ordering stock 3 to 6 months in advance may be necessary.

4. **Planting procedures**.

A landscape plan should describe any special procedures for planting nursery stock. Most emergent plants may be planted in flooded or dry conditions. If planting is done in dry conditions, then instructions should be included for flooding the wetland immediately following installation.

Proper handling of nursery stock is crucial. The roots must be kept moist to prevent damage. Plants received from the nursery will be in peat pots or bare-rooted. Bare-rooted plants will have some form of protection to keep the roots moist and may be kept for several days, but out of direct sunlight. For the maximum chance of success, all nursery stock should be planted as soon as possible. A minimum acceptable success rate of the plantings should be specified in the plan.

5. **A maintenance and vegetation reinforcement schedule for the first three years after construction**.

Sometimes additional stabilization of the basin area may be necessary to ensure that the vegetation becomes established and mature prior to the erosion of the planting soil. Annual grasses may be used for this purpose. However, the specified application rates in the Virginia Erosion and Sediment Control Handbook (VESCH), 1992 edition: Temporary Seeding Spec. 3.31 should be reduced to help prevent these grasses from competing with other plants, particularly those emerging from bulbs and rhizomes. Overall, permanent seeding (VESCH Spec. 3.32) should be prohibited in zones 1 through 4, as the grasses will indefinitely compete with the wetland plants. Refer to the Maintenance and Inspection section in this standard for more information.

Additional considerations and criteria for developing a landscape plan can be found in **Minimum Standard 3.05, Landscaping**.

Buffer Zones

A minimum 20-foot wide vegetated buffer, measured from the maximum water surface elevation, should be maintained beside the wetland. Refer to **Minimum Standard 3.05, Landscaping**.

Construction Specifications

Overall, widely accepted construction standards and specifications, such as those developed by the USDA Soil Conservation Service or the U.S. Army Corps of Engineers for embankment ponds and reservoirs, should be followed to build the impoundment.

Further guidance can be found in Chapter 17 of the Soil Conservation Service's Engineering Field Manual. Specifications for the work should conform to methods and procedures specified for earthwork, concrete, reinforcing steel, pipe water gates, metal work, woodwork and masonry and any other items that apply to the site and the purpose of the structure. The specifications should also satisfy any requirements of the local government.

Guidance and construction specifications in the following minimum standards also apply for various components of the facility: **3.01, Earthen Embankment**; **3.02, Principal Spillway**; **3.03, Vegetated Emergency Spillway**; **3.04, Sediment Forebay**; and **3.05, Landscaping**.

Maintenance and Inspections

A constructed stormwater wetland may be maintained without a permit from the U. S. Army Corps of Engineers or the Virginia Department of Environmental Quality (Va. DEQ).

Any pre-treatment facility or diversion structure should be inspected and maintained regularly to remove floatables and any large debris. Sediment should be removed from the forebay every 3 to 5 years, or when 6 to 12 inches have accumulated, whichever comes first. To clean the forebay, draining or pumping and a possible temporary partial drawdown of the pool area may be required. Refer to the VESCH, 1992 edition for proper dewatering methods. A predesignated spoil area, away from the wetlands, should be used.

The constructed stormwater wetland should be inspected at least twice a year in the first three years after construction, during both the growing and non-growing seasons,for vegetative establishment. Inspectors should document plant species distribution and fatality rates and verify compliance with the landscaping specifications. Also, sediment accumulation, water elevations, and the condition of the outlet should be documented. Records should be kept to track the wetland's health over time.

Management of Wetland Vegetation

The constructed wetland and its buffer may need a *reinforcement planting* at the onset of the second growing season after construction. The size and species of plants to be used should be based on the growth and survival rate of the existing plants at the end of their first growing season. Controlling the growth of certain invasive species, such as cattail and phragmites, may also be necessary. These plants can be very hard to contain if they are allowed to spread unchecked. The best strategy may be to design for a wide range of distinct depth zones.

Research shows that for most aquatic plants the bulk of the pollutants is stored in the roots, not the stems and leaves (Lepp 1981). Therefore, harvesting before winter dieback is unnecessary. Many unanswered questions remain concerning the long-term pollutant storage capacity of plants. Additional plant maintenance recommendations may be presented in the future, as such information becomes available.

The embankment and BMP access road should be mowed biannually, at a maximum, to prevent the growth of trees. Otherwise, the buffer and upland areas should be allowed to grow in meadow conditions.

GENERAL INFILTRATION PRACTICES

Definition

Infiltration facilities temporarily impound stormwater runoff and discharge it via infiltration into the surrounding soil.

Purpose

Infiltration facilities are primarily used for water quality enhancement. Their use to control large volumes of runoff for flooding and channel erosion control is often impractical. Therefore, the infiltration facilities presented in this handbook should generally be used to control the water quality volume and up to the 2-year design storm only. Infiltration practices that capture all of the runoff from the "first flush" (i.e., the water quality volume) may utilize dry storage above the water quality volume to provide sufficient reductions in the 1- or 2-year peak discharge as required. The 10-year and 100-year flows will usually exceed the capacity of an infiltration facility. **Table 3.10-1** contains the target pollutant removal efficiencies based on the runoff volume to be controlled.

Infiltration practices are appealing in that they help to reverse the hydrologic consequences of urban development by reducing peak discharge and providing groundwater recharge.

TABLE 3.10 - 1
Pollutant Removal Efficiency for Infiltration Facilities

BMP Description	Target Phosphorus Removal Efficiency
Infiltration facility with storage volume equivalent to 0.5 inches of runoff from the impervious Area.	50%
Infiltration facility with storage volume equivalent to 1.0 inch of runoff from the impervious area.	65%

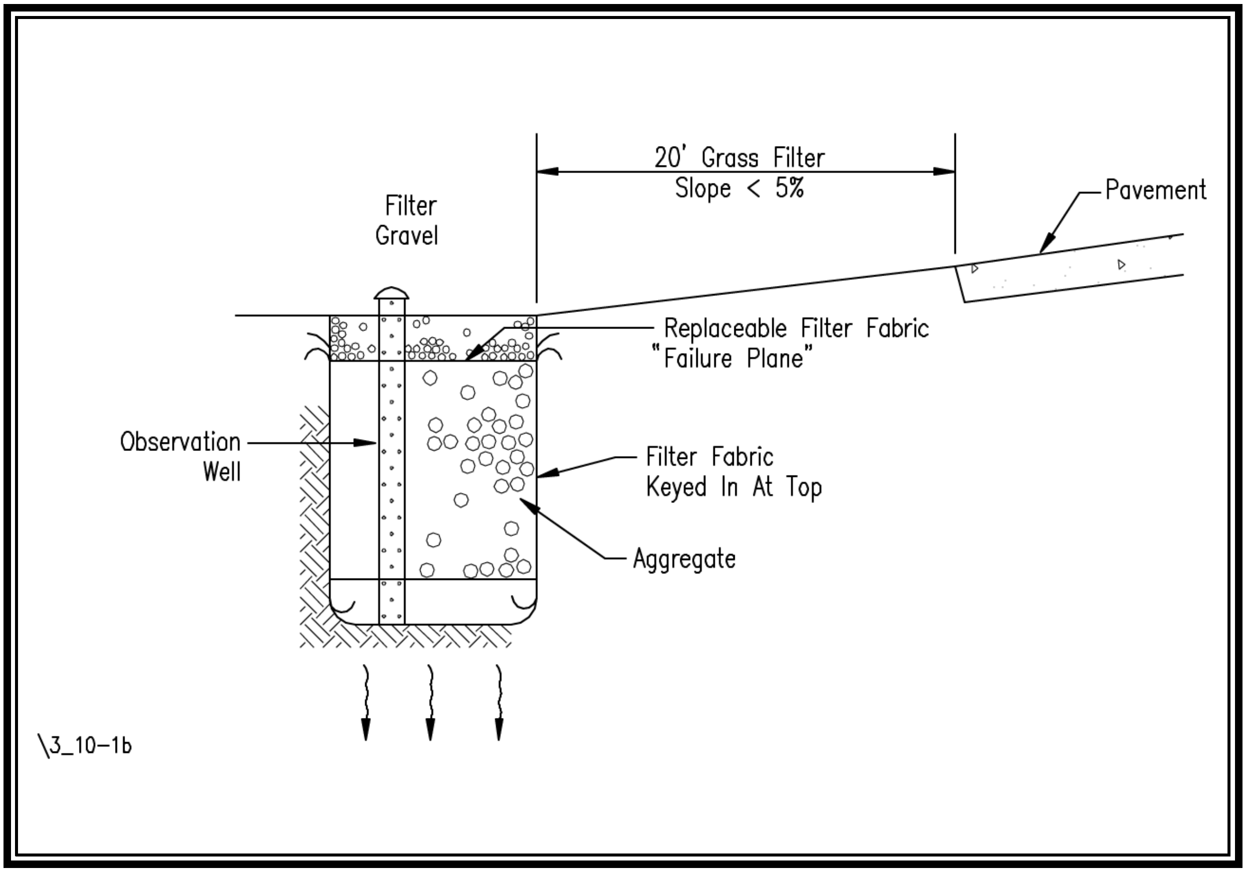
Infiltration Trench - Section



Conditions Where Practice Applies

Infiltration facilities are suitable for use where the subsoil is sufficiently permeable to provide a reasonable rate of infiltration. They are also practical where the water table is sufficiently lower than the design depth of the facility to prevent pollution of the groundwater. Infiltration is not recomended for areas underlain by karst topography. Concentrating runoff into an infiltration facility may cause solution channels to develop or cause karst collapse.

Infiltration practices are generally suited for low- to medium-density development (38% to 66% impervious cover). Specific conditions such as drainage area size and development conditions for each infiltration practice are discussed in the appropriate section of this Standard.

Infiltration facilities are subject to clogging and, therefore, are not recommended for areas where sediment, grease, or oil loadings may be high. Such areas include roadways, parking lots, car service facilities, etc. To increase the life expectancy of an infiltration facility, a pretreatment facility such as a settling basin or "cell", or additional BMP in series should be used to remove sediments or other substances from the stormwater runoff **before** it enters the infiltration facility. Refer to **Minimum Standard 3.15, Manufactured BMP Systems** for additional pretreatment BMPs.

Planning Considerations

The following planning considerations are provided for infiltration practices overall. More specific considerations that may be applicable are presented with each infiltration practice.

Site Conditions

In the past, many designs were accepted based on soils information compiled from available data, such as SCS soil surveys. While these sources may be appropriate for a pre-engineering feasibility study, final design and acceptance should be based on an actual subsurface analysis and permeability tests.

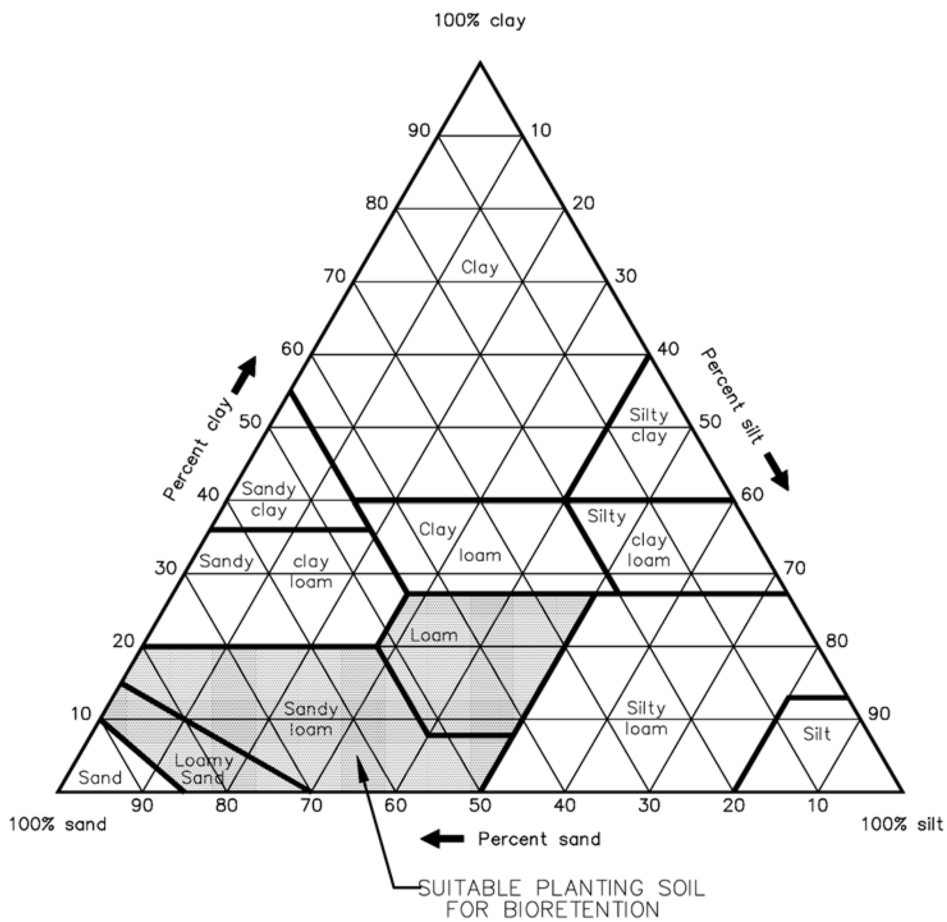
The high failure rates of infiltration facilities, as presented in recent studies (MWCOG), suggest that site-specific soil borings should be required to support the use of infiltration practices. The suitability of the soil for use with the desired infiltration practice can be determined from the soil boring analysis. Details for appropriate geotechnical techniques can be found in the references listed at the end of this section (MD WRA). In general, the following information should be included in a site-specific subsurface or geotechnical study:

1. **Soil permeability**

   The soil types within the subsoil profile, extending a minimum of 3 feet below the bottom of the facility, should be identified to verify the ***infiltration rate*** or ***permeability*** of the soil. The infiltration rate, or permeability, measured in inches per hour, is the rate at which water passes through the soil profile during saturated conditions. Minimum and maximum infiltration rates establish the suitability of various soil textural classes for infiltration. Each soil texture and corresponding hydrologic properties within the soil profile are identified through analysis of a gradation test of the soil boring material. **Soil textures acceptable for use with infiltration systems include those with infiltration rates between 0.52 inches per hour and 8.27inches per hour, and include loam, sandy loam, and loamy sand**.

Soil textures with infiltration rates ***less than 0.52 inches per hour*** *or greater than* ***8.27 inches per hour*** *are* ***<u>not</u> <u>suitable</u>*** *for infiltration practices.*

FIGURE 3.10 - 2
USDA Textural Triangle



SOURCE: U.S. SOIL CONSERVATION SERVICE, 1967.

Soils that have a 30% clay content are unacceptable for use with infiltration facilities since they are structurally unstable and susceptible to frost heaving. Similarly, soils that have poor percolation capabilities or excessively drained soils, such as sand, should not be used for infiltration purposes. The soil textures presented in **Table 3.10-2** correspond to the soil textures of the U.S. Department of Agriculture (USDA) Textural Triangle presented in **Figure 3.10-2**. It should be noted that the difference in soil textures of sand and loamy sand are the percentages of clay found in the soil. While the actual percent of difference is small, a significant difference in infiltration rates can be expected. Note that actual permeability tests may indicate infiltration rates different from those in **Table 3.10-2**.

Predicting the exfiltration of water from an infiltration facility is difficult, especially over an extended period, such as the desired life expectancy of the facility. A factor of safety should be applied in the design to ensure that the facility is sized to function even when partially clogged. (This is discussed further in the **General Design Criteria** presented later in this section.)

TABLE 3.10 - 2
Hydrologic Soil Properties Classified by Soil Texture

Texture Class	Effective Water Capacity (C_w) (inch per inch)	Minimum Infiltration Rate (*f*) (inch per hour)	Hydrologic Soil Grouping
Sand	0.35	8.27	A
Loamy Sand	0.31	2.41	A
Sandy Loam	0.25	1.02	B
Loam	0.19	0.52	B
Silt Loam	0.17	0.27	C
Sandy Clay Loam	0.14	0.17	C
Clay Loam	0.14	0.09	D
Silty Clay Loam	0.11	0.06	D
Sandy Clay	0.09	0.05	D
Silty Clay	0.09	0.04	D
Clay	0.08	0.02	D

2. **Depth to the seasonal high groundwater table and bedrock**.

Typically, infiltration facilities are not recommended in areas with a high groundwater table due to the inability of the soil to adequately filter out pollutants before the stormwater enters the water table. A distance of **2** to **4** feet is required between the bottom of an infiltration facility and the existing water table or bedrock. Similarly, infiltration facilities are not recommended for areas where karst topography is present (in Virginia, west of the Blue Ridge Mountains) due to the possibility of causing subsurface collapse and sink hole formation.

Determination of the seasonal high groundwater table elevation should be given a high priority because flooding of an infiltration facility will render it inoperable during periods of high precipitation. Occasionally, based on the hydraulic conductivity of the soil and the physical dimensions of the trench, a greater separation than 2 to 4 feet may be necessary. Since some soils do not always contain the low chroma (gray) mottles indicative of seasonal saturation, an observation well may be used to locate the seasonal high groundwater table to verify the soil analysis.

Subsurface analysis techniques and related engineering recommendations are too broad and complex for the scope of this handbook. The references listed at the end of this section are recommended for further reading if more detailed information regarding the feasibility analysis of subsurface conditions is needed.

Selecting the optimum depth of an infiltration facility is a process of analyzing constraints. It includes seeking those soil horizons which have a permeability rate that will allow the structure to empty within 48 hours after a design storm event. The design elements of this process are covered in **General Design Criteria**, presented later in this section.

3. **Topographic conditions**

The topographic conditions of a development site represent feasibility factors that should be examined before designing an infiltration system. These factors include the slope of the land, the nature of the soil (natural or fill), and the proximity of building foundations and water supply wells.

The use of a particular BMP is restricted by the allowable slope for that practice. Porous asphalt pavement, for example, requires a relatively level or gently sloping area less than or equal to 3% (20H:1V). All other infiltration practices should be located in areas in which the slope does not exceed 20% (5H:1V). Using infiltration practices on a steep grade increases the chance of water seepage from the subgrade to the lower areas of the site and reduces the amount which infiltrates.

Developments occurring on sloping and rolling sites often require extensive cut and fill operations. The use of stormwater management infiltration systems on fill material is not recommended due to the possibility of creating an unstable subgrade. Fill areas can be very susceptible to slope failure due to slippage along the interface of the in-situ and fill material. This condition could be aggravated if the fill material is allowed to become saturated by using infiltration practices.

Nearby building foundations should be at least 10 feet up-gradient of the infiltration system to prevent the possibility of flooding basements. Proximity to septic systems is also a concern and local health officials should be consulted for guidance on minimum setbacks. Additionally, the location of infiltration practices should be a minimum of 100 feet from any water supply well where the runoff is from commercial or industrial impervious parking areas.

Sediment Control

It has been reported that many infiltration BMPs have failed because adequate precautions to prevent sediment contamination were not implemented (NVPDC, MWCOG). Provisions for long-term sediment control, or pretreatment of the stormwater runoff, must be incorporated into the design, along with precautions taken during onsite construction activities. Advance consideration should be given to the potential impacts that construction techniques, work sequence, and equipment could have on the future maintenance requirements of the BMP. Serious maintenance problems can be averted, or reduced, by the adoption of relatively simple measures during construction.

1. **Construction Runoff**

> ***Infiltration BMPs should be constructed AFTER the site work is completed and stabilization measures have been implemented.***

Infiltration facilities built prior to the completion of site construction activities often become choked with sediment, rendering them inoperable from the outset. Simply providing inlet protection or some other filtering mechanism during site construction may not adequately control the sediment. One large storm can overload protection devices and completely clog the infiltration facility.

To protect an infiltration facility **during** construction, provisions for sediment control should be included in the design. The following references provide technical guidance on sediment control designs:

¢ Virginia Erosion and Sediment Control Handbook (VESCH), DCR, 1992,
¢ Standards and Specifications for Infiltration Practices, Md. DNR, 1984, and
¢ Controlling Urban Runoff (MWCOG, 1987).

> ***Experience with infiltration practices in other states has shown that stormwater management infiltration facilities must be protected until their contributing drainage areas have been adequately stabilized*** *(Maryland,1987).*

The definition of the term "adequately stabilized" when describing the contributing drainage area of an infiltration BMP is critical to the success of the facility. An approved erosion and sediment control plan will specify various devices for trapping sediment during construction, such as silt fences, diversions, sediment traps, etc. It will also specify measures and provide specifications for site stabilization. Following construction activities, the temporary sediment control measures should be removed at the direction of the erosion control inspector when, at a minimum, stabilization measures, such as seed and mulch, are in place. This does not mean, however, that stabilization has occurred. Often, it may take one or more full growing seasons before the pervious areas are fully stabilized, and the construction-related sediment load is controlled. **Therefore, provisions to bypass the stormwater around, or away from, the infiltration facility during the stabilization period should be implemented.**

2. **Urban Runoff**

A fully stabilized site will generate a particulate pollutant load resulting from natural erosion, lawn and garden debris such as leaves, grass clippings, mulch, roadway sand, etc. Various measures can be incorporated into the design to protect the facility and facilitate regular maintenance. The following discussion on pretreatment systems for infiltration facilities is adapted from the Northern Virginia BMP Handbook (NVPDC 1992) and Standards and Specifications for Infiltration Practices (Md. DNR, 1984).

Urban and ultra-urban development projects are usually limited to the use of infiltration trenches, which include ***dry wells***, ***porous pavement***, and ***roof downspout systems***. Runoff to any infiltration trench must be filtered to remove sediment prior to entering the structure.

Runoff to an infiltration trench is usually ***concentrated input***, which is conveyed by gutters, inlets, or pipes, and enters the facility at one or more points. Sediment control devices for *concentrated input* include in-line structures such as water quality inlets (Refer to **Minimum Standard 3.15, Manufactured BMP Systems**), sediment collection sumps or similar structures, provided there is an assured means of regular inspection and maintenance. Any pretreatment BMP which allows sediment- laden water to enter the infiltration facility upon failure of the pretreatment BMP should be avoided. Ideally, a clogged or failed pretreatment BMP should create a noticeable amount of overland flow bypassing the infiltration facility, which indicates that it is time to maintain the pretreatment decvice. Prompt maintenance of the pretreatment BMP will ensure that the infiltration facility remains intact.

The design of sediment control systems for concentrated input facilities invites innovation. Redundant controls or backup systems should be employed wherever there is an opportunity. One type of backup sediment control measure used for trenches with large diameter CMP pipe storage consists of lining the interior surface of the pipe with a geotextile fabric as shown in **Figure 3.10-3**. This continuous liner is held against the interior metal surface of the pipe by expandable rings. If routine monitoring reveals that the water is not being released from the pipe, the filter should be inspected and replaced as necessary. Note that the diameter of the pipe must be such that access for maintenance is possible.

Any sediment collection structure must be adequate to handle the expected flows. Therefore, filter systems should be designed with an additional capacity to account for eventual, partial clogging.

Runoff to an infiltration BMP may also be in the form of ***sheet flow***, entering the top of the storage reservoir over a wide area. **Figure 3.10-1b** portrays one such infiltration trench where overland sheet flow is directed across a gently sloping grassed filter strip to the surface of the infiltration trench. The grassed filter strip is the primary pretreatment control and must be at least **20 feet wide** and have a **5% slope or less** to be effective. The entry berm must be parallel to the contour to maintain uniform flow to the trench.

The choice of vegetative cover should be made with respect to its tolerance to water, growth rate, climatic preference, stabilization capacity, and maintenance considerations. Refer to the VESCH DCR, 1992, and any local ordinances for specific vegetative recommendations. It is essential that a complete cover of dense turf be established **BEFORE** stormwater flows are allowed to enter the facility.

The trench itself is protected from sediment entry by a layer of geotextile filter fabric (called a *sediment barrier*). The sediment barrier is separate from the filter fabric which lines the trench sides so it can be replaced as part of routine maintenance. It is installed over the top of the crushed stone storage chamber and covered with one-half to one foot of 3/4-inch crushed stone. The edges of the filter fabric must be placed so that runoff cannot bypass the sediment barrier. All input water must flow over the grassed filter strip and enter the trench through the sediment barrier at the top.

Unlike the other trench types, porous pavement may be difficult to maintain because the pollutant load is carried by other means, such as vehicle traffic, rather than runoff. Porous pavement, therefore, requires a strict maintenance program to ensure that the design flow can pass through the pavement. Specific maintenance requirements, along with construction methods and specifications for porous pavement and various other infiltration BMPs, are provided later in this chapter.

FIGURE 3.10 - 3
Concentrated Input Pretreatment

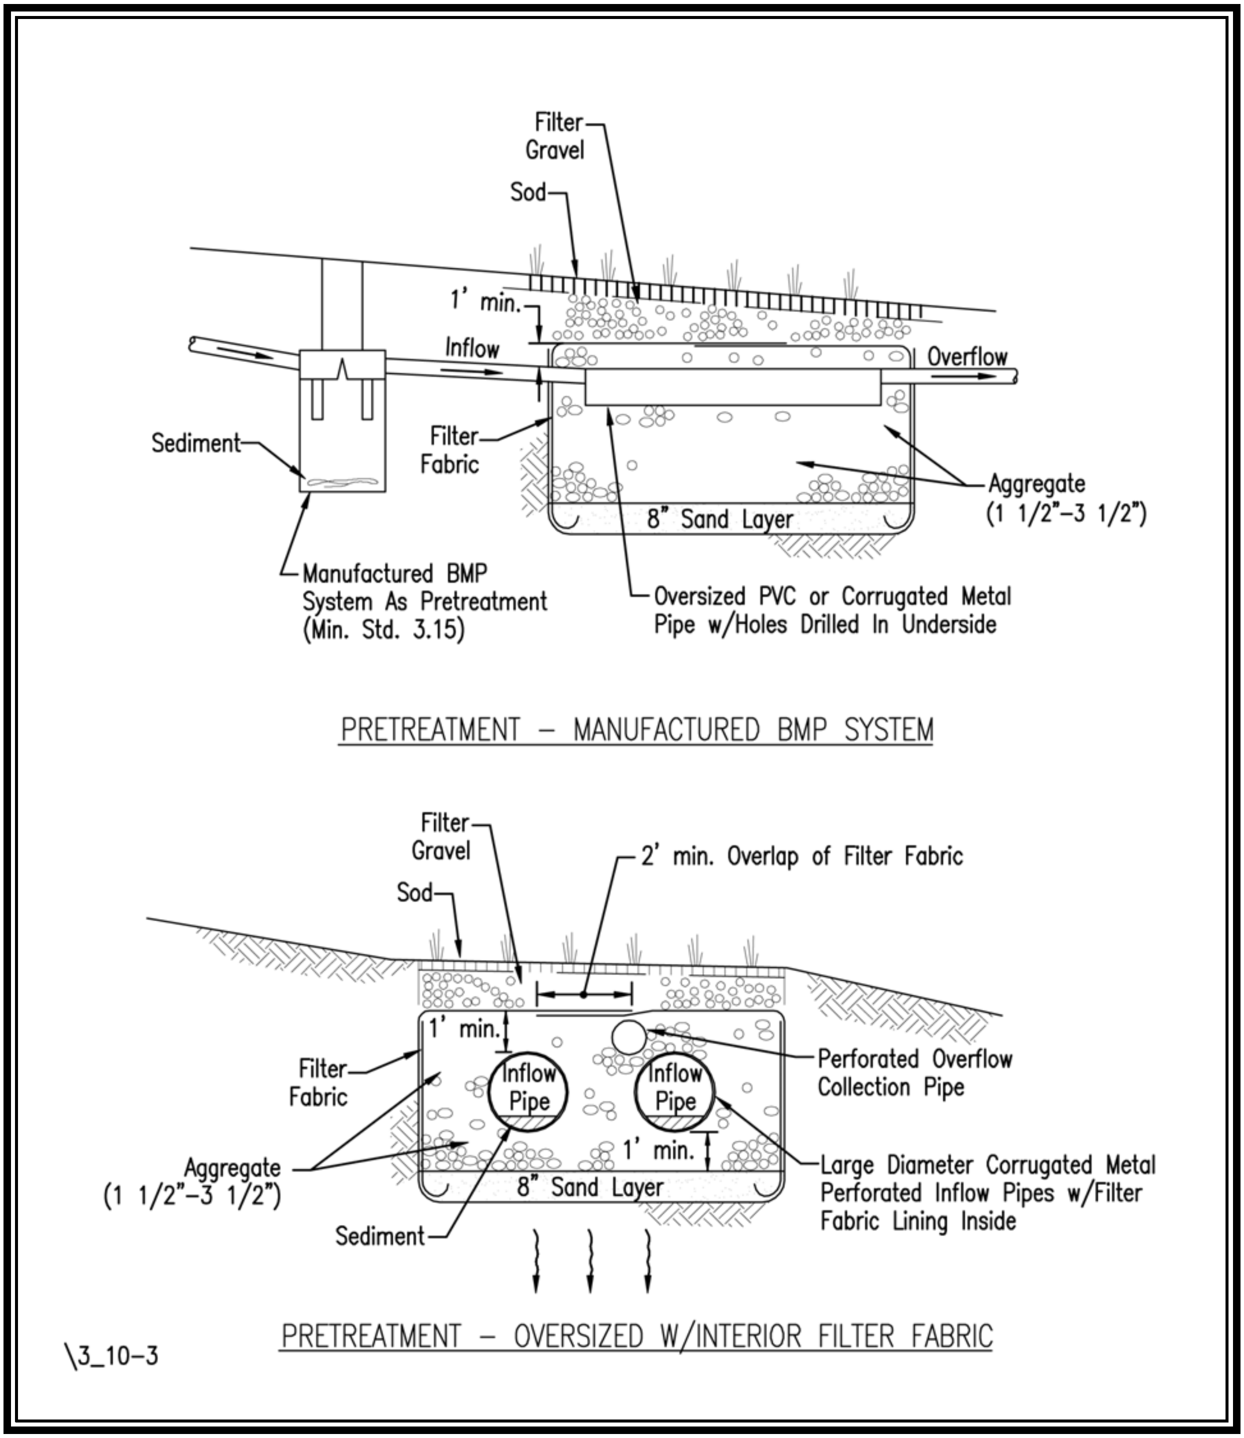


FIGURE 3.10 - 4
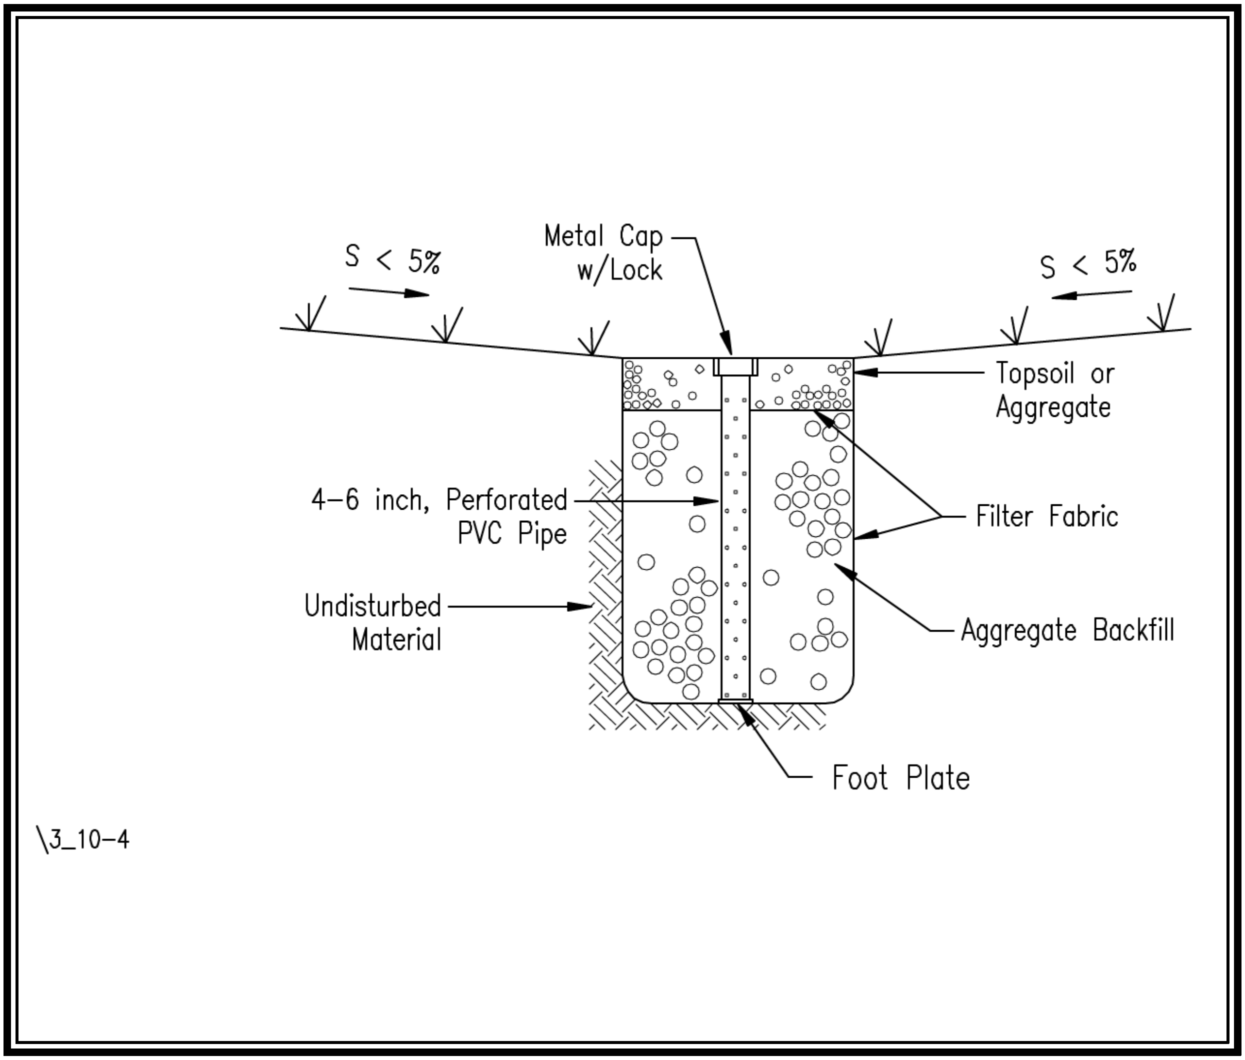
Observation Well



Maintenance

The maintenance requirements for a selected infiltration practice must be considered during the planning and design of the facility. Surface facilities such as basins and swales can be visually inspected and easily maintained. The surface of an infiltration trench or dry well can also be visually inspected and maintained if they are constructed at grade. Since their subsurface storage areas cannot be inspected above ground, **observation wells must be required** (refer to **Figure 3.10-4**). Maintenance of the subsurface storage area, however, short of excavating the facility, is very difficult. Therefore, many landowners, developers and local program administrators have been discouraged from using infiltration facilities.

Recent studies indicated that slightly more than half of the surveyed infiltration facilities had failed within the first five years of operation (MWCOG, 1992; Md. DOE, 1987). Often, failure was due to poor subsurface investigations and/or sediment control. Since repair or rehabilitation of underground facilities (infiltration trenches) is limited, design criteria, subsurface exploration, and maintenance requirements should be strictly enforced. In addition, pretreatment of the stormwater runoff will likely extend the life of an infiltration facility by trapping sediments and debris before they enter, and by allowing for the removal of the accumulated material without excavating the structure. To reduce the potential for costly maintenance and/or system reconstruction, it is strongly recommended that the stone reservoir portion of infiltration trenches be located in a lawn area and as close to the ground surface as possible.

Infiltration trenches should not be located beneath paved surfaces, such as parking lots.

General Design

The purpose of this section is to provide recommendations and minimum criteria for the design of infiltration practices intended to comply with the runoff quality requirements of the Virginia Stormwater Management program.

The types of infiltration facilities which are recognized for stormwater management purposes are ***infiltration basins*** and ***infiltration trenches***. The design, construction, and maintenance criteria for infiltration trenches is also applied to the design of the storage volume for ***porous pavement*** and ***roof downspout systems*** (or *dry wells*).

The criteria presented below apply to the design of infiltration basins and trenches for ***water quality enhancement***. This means that the runoff volume to be treated is determined by the water quality volume and the desired pollutant removal efficiency.

Hydrology and Hydraulics

The procedures outlined in **Chapter 4, Hydrologic Methods**, should be used to determine the post-developed hydrology of the drainage area being served by the infiltration BMP. Provisions for large storm bypass must be provided, even when a stormwater BMP is being utilized for water quality enhancement only and not peak discharge control. Ideally, large storms should be diverted around infiltration facilities, or through the facility with a minimum of disruption and/or turbulence

<u>Sizing Procedure</u>

The storage volume required for infiltration facilities designed for water quality enhancement is determined by the water quality volume - ½ to 1 inch of runoff, determined by the desired pollutant removal efficiency (refer to **Table 3.10-1**).

A Darcy's Law approach is recommended for sizing water quality infiltration BMPs. This will assume that the drain time of the facility is controlled by one-dimensional flow through the bottom surface.

$$Q = f\ I\ SA$$

Equation 3.10-1
Darcy's Law

where:
- Q = rate of exfiltration into soil, cfs
- f = infiltration rate of the soil in ft/hr
- I = hydraulic gradient
- SA = bottom surface area of facility in ft^2

1. **Infiltration Rate –**

Over the life of an infiltration facility, the rate of infiltration into the soil, *f*, may gradually decrease due to clogging of the surface layer of soil. The documented high failure rate of infiltration facilities (MWCOG) suggests that a safety factor be built into the design of the facility to allow for future clogging. Therefore, ***a safety factor of 2*** should be applied to the infiltration rate determined from the soil analysis. The design soil infiltration rate, f_d , therefore, is equal to one-half of the actual rate:

$$f_d = 0.5f$$

2. **Hydraulic Gradient –**

In areas with a shallow water table or impermeable layer, the hydraulic gradient may have an impact on the allowable design depth. The hydraulic gradient is given by the equation:

$$I = \frac{h + L}{L}$$

Equation 3.10-2
Hydraulic Gradient

where: I = hydraulic gradient

h = height of the water column over the infiltrating surface, ft.
L = distance from the top surface of the BMP to the water table, bedrock, impermeable layer, or other soil layer of a different infiltration rate, ft.

The hydraulic gradient will be asummed to be equal to one in all infiltration designs since the gradient approaches unity as the facility drains. Therefore,

$$I=1$$

3. **Maximum Ponding or Storage Time, T_{max} –**

A water quality infiltration facility should be designed with a maximum drain time, T_{max}, of 48 hours for the total volume.

The maximum drain time, along with the minimum design soil infiltration rate, f_d, as verified through a subsurface investigation and analysis, will dictate the maximum allowable design depth, d_{max}, of the structure. The maximum depth for an infiltration basin and trench is covered in the following minimum standards.

MINIMUM STANDARD 3.10A

INFILTRATION BASIN

Definition

An infiltration basin is a vegetated, open impoundment where incoming stormwater runoff is stored until it gradually infiltrates into the soil strata.

Purpose

Infiltration basins are used primarily for water quality enhancement. However, flooding and channel erosion control may also be achieved within an infiltration basin by utilizing a multi-stage riser and barrel spillway to provide controlled release of the required design storms above the water quality (infiltration) volume (refer to **Figure 3.10-1**).

Conditions Where Practice Applies

Infiltration basins may be used where the subsoil is sufficiently permeable to provide a reasonable infiltration rate and where the water table is low enough to prevent pollution of groundwater.

Drainage Area

Drainage areas served by infiltration basins should be limited to less than 50 acres. Drainage areas which are greater than 50 acres typically generate such large volumes of runoff that other detention or retention BMPs are more practical and cost-effective.

Development Conditions

Infiltration basins are generally suitable BMPs in low- to medium-density residential and commercial developments (38% to 66% impervious cover).

Planning Considerations

Appropriate soil conditions and protection of the groundwater are among the important considerations when planning an infiltration basin. Refer to the **Planning Considerations** for **General Infiltration Practices** previously discussed in this standard.

An infiltration basin has relatively large surface area requirements, when compared with an infiltration trench or dry well, and ranges from 3 to 12 feet in depth. The seasonal high groundwater table or bedrock should be located at least 2 to 4 feet below the bottom of the basin. Infiltration facilities are not recommended for areas where karst topography is present (in Virginia, west of the Blue Ridge Mountains) due to the possibility of causing subsurface collapse and sink hole formation.

Maintenance

Like all stormwater BMPs, access to an infiltration basin should be considered in the planning stage. Access (as well as maneuvering room) should be provided to at least one side of the facility and the control structure or spillway. In addition, identifying a location and designing for on-site sediment disposal will greatly reduce long-term maintenance costs.

Design Criteria

The purpose of this section is to provide recommendations and minimum criteria for the design of infiltration basins intended to comply with the runoff quality requirements of the Virginia Stormwater Management program.

General

The design of infiltration basins should be according to the following Minimum Standards where applicable: **3.01, Earthen Embankment**; **3.02, Principal Spillway**; **3.03, Vegetated Emergency Spillway**; **3.04, Sediment Forebay**; **3.05, Landscaping**, and **3.10, General Infiltration Practices**, along with additional criteria set forth below. The designer is not only responsible for selecting the appropriate components for his or her particular design but also for ensuring their long-term operation by specifying appropriate structural materials.

The design of the overflow vegetated spillway must consider the frequency of flow. The spillway may require an armored bottom if it is to function during every storm which exceeds the water quality volume (refer to **Minimum Standard 3.03**).

Hydrology and Hydraulics

Chapter 4, **Hydrologic Methods** should be used to develop the pre- and post-developed hydrology for a basin's contributing watershed. An infiltration basin designed for water quality enhancement still must provide an overflow or spillway for the bypass of large storms. **Chapter 5**, **Engineering Calculations** provides the procedures for the design of the riser and barrel system and the emergency spillway design procedures.

Soils Investigation

A minimum of one soil boring log should be required for each 5,000 square feet of infiltration basin area (plan view area) and under no circumstances should there be less than three soil boring logs per basin (Washington State DOE, 1992). Refer also to the **Planning Considerations** and **Design Criteria** of **General Infiltration Practices**, discussed at the beginning of this standard.

Topographic Conditions

Infiltration basins should be a minimum of 50 feet from any slope greater than 15%. If unavoidable, a geotechnical report should address the potential impact of infiltration on or near the steep slope. Developments on sloping sites often require extensive cut and fill operations. **The use of infiltration basins on fill sites is not permitted**. Also, infiltration basins should be a minimum of 100 feet up-slope and 20 feet down-slope from any buildings.

Design Infiltration Rate

The design infiltration rate, f_d, should be set to equal one-half the infiltration rate, f, determined from the soil analysis. Therefore:

$$f_d = 0.5\,f$$

Maximum Ponding Time and Depth

All infiltration basins should be designed to completely drain stored runoff within 2 days following the occurrence of a storm event. Thus, an allowable maximum ponding time, T_{max} , of 48 hours should be used.The maximum ponding depth for an infiltration **basin** is:

$$d_{max} = f_d T_{max}$$

Equation 3.10-3
Maximum Ponding Depth for Infiltration Basin

where: d_{max} = maximum depth of the facility, in ft.
f_d = design infiltration rate of the basin area soils, in ft/hr (f_d = ½ f)
T_{max} = maximum allowable drain time = 48 hrs.

The ponding depth should not be so great as to contribute to the compaction of the soil surface. Depending on the specific soil characteristics, a maximum ponding depth of 2 feet is generally recommended (MWCOG, 1992).

The minimum surface area of the facility bottom is:

$$SA_{min} = \frac{Vol_{wq}}{f_d T_{max}}$$

Equation 3.10-4
Minimum Bottom Surface Area for infiltration Basin

where:
SA_{min} = minimum basin bottom surface area, in ft^2;
Vol_{wq} = water quality volume requirements, in ft^3;
f_d = design infiltration rate of the basin area soils, in ft/hr;
T_{max} = maximum allowable drain time, in hours

Runoff Pretreatment

Infiltration basins should always be preceded by a pretreatment facility. Grease, oil, floatable organic materials, and settleable solids should be removed from the runoff before it enters the infiltration basin. Vegetated filters, sediment traps and/or forebays, water quality inlets (refer to **Minimum Standard 3.15, Manufactured BMP Systems**) are just a few of the available pretreatment strategies. Refer to the discussion on **Sediment Control** in the **General Infiltration Practices** portion of this section.

At a minimum, the layout and design of the basin should include a sediment forebay or pretreatment cell, as shown in **Figure 3.10-1**, to enhance and prolong the infiltration capacity. Any pretreatment facility should be included in the design of the basin and should include maintenance and inspection requirements. It is recommended that a grass strip or other vegetated buffer at least 20 feet wide be maintained around the basin to filter surface runoff.

Principal and Emergency Spillways

A diversion structure upstream of an ***off-line*** basin will regulate the rate of flow into the basin, but not the volume. Therefore, infiltration basins should have a spillway to convey flows from storm events which are larger than the design capacity. The primary outlet should be located above the required infiltration volume. Additionally, a riser and barrel system is advantageous for future conversion to an extended-detention or retention facility if the infiltration capacity of the soil becomes impaired. All design elements of a principal spillway should be per **Minimum Standard 3.02, Principal Spillways**.

An emergency spillway is recommended for all impounding structures, including infiltration basins. If a vegetated spillway is to be used as the primary outlet above the water quality volume, care should be taken to design for the increased frequency of use. This is especially critical between maintenance operations when the infiltration capacity is decreased due to sediment loads. If a spillway is to be used for all storms which generate more runoff than the water quality volume, then a nonerodible surface should be provided. All design elements of a *vegetated* emergency spillway should be per **Minimum Standard 3.03, Vegetated Emergency Spillways**.

Stabilization

As with all stormwater structures, all disturbed areas associated with the construction of the facility, including spoil and borrow areas, should be stabilized immediately according to the VESCH 1992 edition. The basin floor area, emergency spillway, and any vegetative buffer around the facility are critical areas and should be addressed with a specific stabilization measure.

The choice of vegetative cover should be made with respect to its tolerance to water, growth rate, climatic preference, stabilization capacity, and maintenance requirtements. Refer to the VESCH 1992 edition and any local ordinances for specific vegetative recommendations. It is essential that a complete cover of dense turf be established **BEFORE** stormwater flows are allowed to enter the facility.

Fencing

Fencing may be provided where deemed necessary by the developer, land owner, or locality for the purposes of public safety or protection of vegetation.

Construction Specifications

In general, widely accepted construction standards and specifications, such as those developed by the USDA Soil Conservation Service or the U.S. Army Corps of Engineers, should be followed where applicable. Further guidance can be found in the Soil Conservation Service's Engineering Field Manual. Specifications for the work should conform to the methods and procedures indicated for installing earthwork, concrete, reinforcing steel, pipe, water gates, metal work, woodwork and masonry as they apply to the site and the purpose of the structure. The specifications should also satisfy all requirements of the local government.

The construction of infiltration basins should also be in accordance with the following Minimum Standards and Specifications where applicable: **3.01, Earthen Embankment**; **3.02, Principal Spillway**; **3.03, Vegetated Emergency Spillway**; **3.04, Sediment Forebays**; **3.05, Landscaping**; along with the criteria set forth below. These specifications have been adapted from Standards & Specifications for Infiltration Practices (Md. DNR, 1984 and Washington State DOE, 1992).

Sequence of Construction

The sequence of various phases of basin construction should be coordinated with the overall project construction schedule. Rough excavation of the basin may be scheduled with the rough grading phase of the project to permit use of the material as fill in earthwork areas. Otherwise, **infiltration measures should not be constructed or placed into service until the entire contributing drainage area has been stabilized**. Runoff from untreated, recently constructed areas within the drainage area may load the newly formed basin with a large volume of fine sediment. This could seriously impair the natural infiltration ability of the basin floor.

The specifications for construction of a basin should state the following: 1) *the earliest point at which storm drainage may be directed to the basin*, and 2) *the means by which this delay in basin use is to be accomplished*. Due to the wide variety of conditions encountered among projects, each project should be evaluated separately to postpone basin use for as long as possible.

Excavation

Initially, the basin floor should be excavated to within one foot of its final elevation. Excavation to the finished grade should be delayed until all disturbed areas in the watershed have been stabilized or protected. The final phase of excavation should remove all accumulated sediment. Relatively light, tracked-equipment is recommended for this operation to avoid compaction of the basin floor. After the final grading is completed, the basin floor should be deeply tilled by means of rotary tillers or disc harrows to provide a well-aerated, highly porous surface texture.

Lining Material

Establishing dense vegetation on the basin side slopes and floor is recommended. A dense vegetative cover will not only prevent erosion and sloughing, but will also provide a natural means to maintain relatively high infiltration rates. Inflow points to the basin should also be protected with erosion controls (e.g., riprap, flow spreaders, energy dissipators, etc.), as well as a sediment forebay.

Selection of suitable vegetative materials and application of required fertilizer and mulch should be per the VESCH 1992 edition.

Maintenance / Inspection Guidelines

The following maintenance and inspection guidelines are not intended to be all-inclusive. Specific facilities may require other measures not discussed here.

Inspection Schedule

When infiltration basins are first made functional they should be inspected monthly and after any large storm event. Thereafter, once the basin is functioning satisfactorily and without potential sediment problems, inspections may be made semi-annually and after any large storm events. All inspections should include investigation for potential sources of contamination.

Sediment Control

The basin should be designed to allow for maintenance. Access should be provided for vehicles to easily maintain the forebay (pre-settling basin) without disturbing vegetation or sediment any more than what is absolutely necessary.

Grass bottoms in infiltration basins seldom need replacement since grass serves as a good filter material. If silty water is allowed to trickle through the turf, most of the suspended material is strained out within a few yards of surface travel. Well-established turf on a basin floor will grow up through sediment deposits forming a porous turf and preventing the formation of an impenetrable layer. Grass planted on basin side slopes should also prevent erosion.

Vegetation Maintenance

Maintenance of the vegetation on the basin floor and side slopes is necessary to promote a dense turf with extensive root growth, which subsequently enhances infiltration, prevents erosion and sedimentation, and deters invasive weed growth. Bare spots should be immediately stabilized and revegetated.

The use of low-growing, stoloniferous grasses will permit long intervals between mowings. Mowing twice a year is generally satisfactory. Fertilizers should be applied only as necessary and in limited amounts to avoid contributing to pollution problems, including groundwater pollution, for which the infiltration basin helps mitigate. Consult the VESCH, 1992 edition for appropriate fertilizer types and application rates.

Design Procedures

The following design procedure represents a generic list of the steps typically required for the design of an infiltration basin.

1. Determine if the anticipated development conditions and drainage area are appropriate for an infiltration basin application.

2. Determine if the soils (permeability, bedrock, water table, Karst, embankment foundation, etc.) and topographic conditions (slopes, building foundations, etc.) are appropriate for an infiltration basin application.

3. Locate the infiltration basin on the site within topographic constraints.

4. Determine the drainage area to the infiltration basin and calculate the required water quality volume.

5. Evaluate the hydrology of the contributing drainage area to determine peak rates of runoff.

6. Design the infiltration basin:
    - Design infiltration rate, $f_d = 0.5\, f$.
    - Max. Storage time T_{max} = 48 hours
    - Max. Storage depth, d_{max}
    - Runoff pretreatment - concentrated input, sheet flow input, sediment forebay
    - Vegetated buffer around basin to filter surface runoff
    - Vegetated emergency spillway and/or riser and barrel design
    - Earthen Embankment design

7. Provide material specifications.

8. Provide sequence of construction.

9. Provide maintenance and inspection requirements.

MINIMUM STANDARD 3.10B

INFILTRATION TRENCH

Definition

An infiltration trench is a shallow, excavated trench backfilled with a coarse stone aggregate to create an underground reservoir. Stormwater runoff diverted into the trench gradually infiltrates into the surrounding soils from the bottom and sides of the trench. The trench can be either an open surface trench or an underground facility.

Purpose

Infiltration trenches are used primarily as water quality BMPs. Trenches are generally 2 to 10 feet deep and are backfilled with a coarse stone aggregate, allowing for temporary storage of storm runoff in the voids between the aggregate material. Stored runoff gradually infiltrates into the surrounding soil. The surface of the trench can be covered with grating and/or consist of stone, gabion, sand, or a grassed area with a surface inlet. Utilizing underground pipes within the trench can increase the temporary storage capacity of the trench and can sometimes provide enough storage for flooding and/or stream channel erosion control (see **Figure 3.10-3**).

Conditions Where Practice Applies

An infiltration trench may be used where the subsoil is sufficiently permeable to provide a reasonable infiltration rate and where the water table is low enough to prevent pollution of groundwater.
Infiltration facilities are not recommended for areas where karst topography is present (in Virginia, west of the Blue Ridge Mountains) due to the possibility of causing subsurface collapse and sink hole formation.

<u>Drainage Area</u>

Infiltration trenches are not practical for large drainage areas. Generally, the drainage area for infiltration trenches should be limited to 5 acres. Multiple trenches may be considered to control the runoff from a large site, but this also increases the associated maintenance responsibilities.

Development Conditions

Infiltration trenches are generally suited for low- to medium-density residential and commercial developments. They can be installed in multi-use areas, such as along parking lot perimeters, or in small areas that cannot readily support retention basins or similar structures. Infiltration trenches can be used in residential areas, commercial areas, parking lots and open space areas. Unlike most BMPs, trenches can easily fit into the margin, perimeter, or other unused areas of developed sites, making them particularly suitable for retrofitting in existing developments or in conjunction with other BMPs. A trench may also be installed under a swale to increase the storage of the related infiltration system. In all cases, pretreatment of the stormwater runoff to remove course sediment and particulate pollutants prior to entering the infiltration trench should be provided.

Planning Considerations

Appropriate soil conditions and protection of groundwater are two important considerations when planning for an infiltration trench. For further discussion, refer to the **Planning Considerations** previously discussed in **General Infiltration Practices, Minimum Standard 3.10**.

Design Criteria

The purpose of this section is to provide recommendations and minimum criteria for the design of infiltration trenches intended to comply with the runoff quality requirements of the Virginia Stormwater Management program.

General

Infiltration trenches are assumed to have rectangular cross-sections. Thus, the infiltration surface area (trench bottom) can be readily calculated from the trench geometry. The storage volume of the trench must be calculated using the void ratio of the backfill material that will be placed in it.

The same general criteria presented for the design of infiltration basins apply to trenches; the following information is provided for additional guidance.

Soils Investigation

A minimum of one soil boring log should be required for every 50 feet of trench length. A minimum of two soil boring logs should be required for each proposed trench location (Washington State DOE, 1992).

Topographic Conditions

Infiltration trenches should be located 20 feet down-slope and 100 feet up-slope from building foundations. An analysis should be completed to identify any possible adverse effects of seepage zones if there are nearby building foundations, basements, roads, parking lots or sloping sites. Developments on sloping sites often require the use of extensive cut and fill operations. **The use of infiltration trenches on fill sites is not permitted**.

Design Infiltration Rate

The design infiltration rate, f_d, should be set to equal one-half the infiltration rate obtained from the soil analysis. Therefore,

$$f_d = 0.5\,f$$

Maximum Storage Time and Trench Depth

All infiltration trenches should be designed to empty within 2 days following the occurrence of a storm event. Thus, a maximum allowable storage time, T_{max}, of 48 hours should be used.

The maximum depth for an infiltration **trench** may be defined as:

$$d_{max} = \frac{f_d T_{max}}{V_r}$$

Equation 3.10-5
Maximum Depth for Infiltration Trench

where: d_{max} = maximum allowable depth of the facility, in ft;
f_d = design infiltration rate of the trench area soils, in ft/hr ($f_d = 0.5f$);
T_{max} = maximum allowable drain time = 48 hrs.;
V_r = void ratio of the stone reservoir expressed in terms of the percentage of porosity divided by 100 (0.4 typ.).

Refer to the Virginia Department of Transportation's Road and Bridge Specifications, latest edition, for information and specifications for coarse aggregates. A void ratio of 0.40 is assumed for stone reservoirs using 1.5 to 3.5 inch stone - VDOT No. 1 Coarse-graded Aggregate.

The minimum surface area of the facility bottom may be defined as:

$$SA_{min} = \frac{Vol_{wq}}{f_d T_{max}}$$

Equation 3.10-6
Infiltration Trench Minimum Bottom Surface Area

where: SA_{min} = minimum trench bottom surface area, in ft^2;
Vol_{wq} = water quality volume requirements, in ft^3;
f_d = design infiltration rate of the trench area soils, in ft/hr ($f_d = 0.5f$);
T_{max} = maximum allowable drain time = 48 hrs.

Runoff Pretreatment

Infiltration trenches should always be preceded by a pretreatment facility. Grease, oil, floatable organic materials, and settleable solids should be removed from the runoff before it enters the trench. Vegetated filters, sediment traps or forbays, water quality inlets (refer to **Minimum Standard 3.15, Manufactured BMP Systems**) are just a few of the available pretreatment strategies. To reduce both the frequency of turbulent flow-through and the associated scour and/or resuspension of residual material, infiltration trenches and associated pretreatment facilities should be installed off-line (MWCOG, 1992). Additional pretreatment arrangements are illustrated in **Figure 3.10-3**. Refer to the discussion on **Sediment Control** in **General Infiltration Practices**, **Minimum Standard - 3.10**.

A grass strip or other type of vegetated buffer at least 20 feet wide should be maintained around trenches that accept surface runoff as sheet flow. The slope of the filter strip should be approximately 1% along its entire length and 0% across its width. A recent study by MWCOG (Galli, 1992) concluded that for areas receiving high suspended solid loads, a minimum filter length of 50 feet is desirable.

All trenches with surface inlets should be engineered to capture sediment from the runoff before it enters the stone reservoir. Any pretreatment facility design should be included in the design of the trench, complete with maintenance and inspection requirements.

Backfill Material

Backfill material for the infiltration trench should be clean aggregate with a maximum diameter of 3.5 inches and a minimum diameter of 1.5 inches (i.e., VDOT No. 1 Open-graded Coarse Aggregate or equivalent). The aggregate should contain few aggregates smaller than the selected size. Void spaces for VDOT No. 1 aggregate is assumed to be 40 percent.

An 8 inch deep bottom sand layer (VDOT Fine Aggregate, Grading A or B) is required for all trenches to promote better drainage and reduce the risk of soil compaction when the trench is backfilled with stone (MWCOG, 1992).

Filter Fabric

The aggregate fill material should be surrounded with an engineering filter fabric as shown in **Figure 3.10-5**. For an aggregate surface trench, filter fabric should surround all of the aggregate fill material except the top one foot. A separate piece of fabric should be used for the top layer to act as a failure plane. This top piece can then be removed and replaced upon clogging. Note, however, that filter fabric should **not** be placed on the trench bottom. Refer to the VESCH 1992 edition, for filter fabric specifications.

Overflow Channel

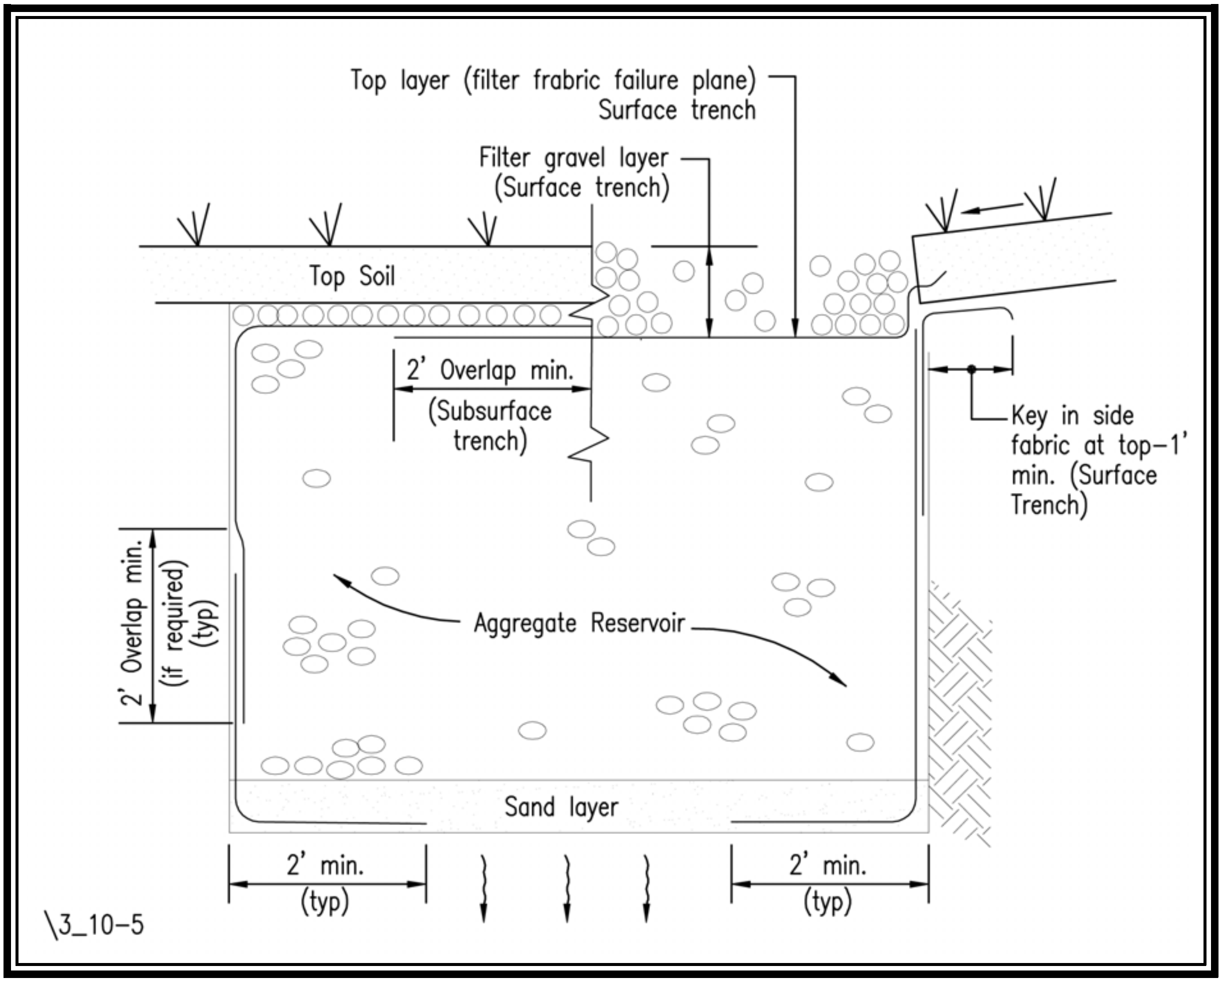
Usually, because of the small drainage areas controlled by an infiltration trench, an emergency spillway is not necessary. However, the overland flow path taken by the surface runoff, when the capacity of the trench is exceeded, should always be evaluated. A nonerosive overflow channel leading to a stabilized watercourse should be provided, as necessary, to insure that uncontrolled, erosive, concentrated flow does not develop.

Observation Well

An observation well should be installed for every 50 feet of infiltration trench length. The observation well will show how quickly the trench dewaters following a storm, as well as providing a means of determining when the filter fabric is clogged and maintenance is needed (refer to **Figure 3.10-4**).

The observation well should consist of perforated PVC pipe, 4 to 6 inches in diameter. It should be installed in the center of the structure, flush with the ground elevation of the trench. Putting the observation well in a non-parking or traffic area to simplify inspections is best. The top of the well should be capped to discourage vandalism and tampering.

FIGURE 3.10 - 5
Filter Fabric Placement



Construction Specifications

Overall, widely accepted construction standards and specifications, such as those developed by the USDA Soil Conservation Service or the U.S. Army Corps of Engineers, should be followed where applicable. Further guidance can be found in the Soil Conservation Service's Engineering Field Manual. Specifications for the work should conform to the methods and procedures indicated for installing earthwork, concrete, reinforcing steel, pipe, water gates, metal work, woodwork and masonry, as they apply to the site and the purpose of the structure. The specifications should also satisfy any requirements of the local government.

Construction of an infiltration trench should also be in conformance with the following:

Sequence of Construction

An infiltration trench should not be constructed or placed into service until all of the contributing drainage area has been stabilized. Runoff from untreated, recently constructed areas within the drainage area may load the newly formed trench and/or pretreatment facility with a large volume of fine sediment.

The specifications for the construction of an infiltration trench should state the following: 1) *the earliest point at which storm drainage may be directed to the trench*, and 2) *the means by which this delay in use is to be accomplished*. Due to the wide variety of conditions encountered among development projects, each project should be evaluated separately to postpone trench use for as long as possible.

Trench Preparation

Trench excavation should be limited to the specific trench dimensions. Excavated materials should be placed away from the trench sides to avoid impacting the trench wall stability.

The trench should be excavated with a backhoe or similar device that allows the equipment to stand away from the trench bottom. This bottom surface should be scarified with the excavator bucket teeth on the final pass to eliminate any smearing or shearing of the soil surface. Similarly, the sand filter material should be placed on the trench bottom so that it does not compact or smear the soil surface. The sand must be deposited ahead of the loader so the equipment is always supported by a minimum of 8 inches of sand.

Large tree roots must be trimmed flush with the trench sides to prevent the fabric from puncturing or tearing during subsequent installation procedures. No voids between the filter fabric and the excavation walls should be present. If boulders or similar obstacles are removed from the excavated walls, natural soils should be placed in these voids before the filter fabric is installed. The side walls of the trench should be roughened where sheared and sealed by heavy equipment.

Vertically excavated walls may be difficult to maintain in areas where the soil moisture is high or where soft cohesive or cohesionless soils predominate. These conditions may require that the side slopes be laid back to maintain stability; trapezoidal rather than rectangular cross sections may result.

Fabric Laydown

The roll of filter fabric should be cut to the proper width before installation. The width should allow for perimeter irregularities plus a minimum 12-inch overlap at the top. When a fabric overlap is required elsewhere, the upstream section should overlap the downstream section by a minimum of 2 feet to ensure that the fabric conforms to the excavation surface during aggregate placement. Note that filter fabric should **not** be placed on the trench bottom.

Stone Aggregate Placement Compaction

The crushed stone aggregate should be placed in the trench in loose lifts of about 12 inches using a backhoe or front-end loader with a drop height near the bottom of the trench, and should be lightly compacted with plate compactors. Aggregate should not be dumped into the trench by a truck.

Backfill material for the infiltration trench should be clean, washed aggregate *1.5* to *3.5* inches in diameter (VDOT No. 1 Open-graded Coarse Aggregate or equivalent). The aggregate should contain few aggregates smaller than the selected size.

The 8 inch deep bottom sand layer should consist of VDOT Fine Aggregate, Grading A or B.

Overlapping and Covering

Following the stone aggregate placement, the filter fabric should be folded over the stone aggregate to form a 12-inch minimum longitudinal overlap. The desired fill soil or stone aggregate should be placed over the lap at sufficient intervals to maintain the lap during subsequent backfilling.

Potential Contamination

Clean aggregate **should not** be mixed with natural or fill soils. All contaminated aggregate should be removed and replaced with clean aggregate.

Traffic Control

To prevent or reduce compaction of the soil, heavy equipment and traffic should not travel over the infiltration trench.

Observation Well

Observation wells should be provided as specified in the design criteria. The depth of the well at the time of installation should be clearly marked on the well cap.

Maintenance / Inspection Guidelines

The following maintenance and inspection guidelines are not intended to be all-inclusive. Specific facilities may require other measures not discussed here.

Inspection Schedule

The observation well and pretreatment facility should be monitored quarterly and after every large storm event. It is recommended that a log book be maintained showing the depth of water in the well at each observation in order to determine the rate at which the facility dewaters after runoff producing storm events. Once the performance characteristics of the structure have been verified, the monitoring schedule can be reduced to an annual basis, unless the performance data suggest that a more frequent schedule is required.

Sediment Control

Sediment buildup in the top foot of stone aggregate or the surface inlet should be monitored on the same schedule as the observation well. A monitoring well in the top foot of stone aggregate should be provided when the trench has a stone surface. Sediment deposited should not be allowed to build up to the point where it will reduce the infiltration rate into the trench.

It is recognized that infiltration facilities are subject to clogging. Once a trench facility has clogged, very little can be done to correct it, short of excavating the facility. Maintenance efforts, therefore, should focus on the measures used for pretreatment of runoff, in addition to the facility itself.

Vegetation Maintenance

Any vegetated buffers associated with an infiltration trench should be inspected regularly and maintained as needed. Regular maintenance of the buffer is necessary to promote dense turf with extensive root growth, which subsequently enhances runoff filtering, prevents erosion and sedimentation, and deters invasive weed growth. Bare spots should be immediately stabilized and revegetated. Fertilizers should be applied only as necessary and in limited amounts to avoid contributing to pollution problems which the infiltration basin helps to mitigate. Consult the VESCH 1992 edition for appropriate fertilizer types and application rates.

Design Procedures

The following design procedure represents a generic list of the steps typically required for the design of an infiltration trench.

1. Determine if the anticipated development conditions and drainage area are appropriate for an infiltration trench application.

2. Determine if the soils (permeability, bedrock, water table, Karst, etc.) and topographic conditions (slopes, building foundations, etc.) are appropriate for an infiltration trench application.

3. Locate the infiltration trench on the site within topographic constraints.

4. Determine the drainage area for each infiltration trench and calculate the required water quality volume.

5. Evaluate the hydrology of the contributing drainage area to determine peak rates of runoff.

6. Design the infiltration trench:
   - design infiltration rate, $f_d = 0.5\ f$
   - max. storage time T_{max} = 48 hours
   - max. storage depth, d_{max}
   - stone backfill of clean aggregate (1.5" to 3.5") VDOT No. 1 Open-Graded Course Aggregate
   - sand layer on trench bottom (8 inches)
   - runoff pretreatment - concentrated input, sheet flow input
   - vegetated buffer around trench to filter surface runoff
   - filter fabric on trench sides and top (not on trench bottom) keyed into trench
   - overflow channel or large storm bypass
   - observation well

7. Provide material specifications.

8. Provide sequence of construction.

9. Provide maintenance and inspection requirements.

MINIMUM STANDARD 3.10C

ROOF DOWNSPOUT SYSTEM

Definition

A roof downspout system is an infiltration trench practice intended only for infiltrating rooftop runoff transported to the trench via roof downspout drains.

Purpose

The purpose of a roof downspout system is to provide water quality enhancement of rooftop runoff via infiltration of the water quality volume into the surrounding soils. This facility is not designed to infiltrate other surface water that could transport sediment or pollutants, such as from paved areas.

Conditions Where Practice Applies

Roof downspout systems may be used in any situation where disposing of rooftop runoff without direct connections to existing drainage systems or BMPs is acceptable and advantageous. Because of their small size, they are well suited for retrofitting in areas where runoff control of existing or new rooftop areas associated with building additions becomes necessary. As part of a low impact development strategy, roof downspout systems effectively disconnect the rooftop imperviousness from the drainage system which helps reduce the stormwater impact of the development. Use of roof downspout systems (or infiltration trenches in general) in residential areas should be used with caution due to concern for the potential lack of inspections and maintenance, and ultimate failure and abandonment of the facility.

Planning Considerations

The planning considerations for roof downspout systems are the same as those for infiltration trenches (**Minimum Standard 3.10B**). The drainage area is limited to the rooftop areas of residential and/or commercial structures.

Design Criteria

This section provides recommendations and minimum criteria for the design of roof downspout systems intended to comply with the runoff quality requirements of the Virginia Stormwater Management program.

The design criteria for roof downspout systems are the same as those for infiltration trenches with the following exceptions and/or additions:

Distance from Structures

Roof downspout systems should be a minimum of 10 feet down-slope from any structure or property line, and 30 feet from any septic tank or drain field.

Runoff Pre-Treatment

Gutters should be fitted with mesh screens to prevent leaf litter and other debris from entering the system in areas where there is tree cover. The expected growth of newly planted trees should be considered.

A pretreatment settling basin as shown in **Figure 3.10-6** should be provided on all roof downspout systems.

Overflow

An overflow outlet should be provided on the downspout at the surface elevation to allow flow to bypass the infiltration facility when it is full or clogged. (See **Figure 3.10-6**.)

Adequate surface drainage away from the structure should be provided according to appropriate building codes.

Construction Specifications

The construction specifications for roof downspout systems are the same as those for infiltration trenches.

Maintenance and Inspection Guidelines

Maintenance procedures are identical for those of an infiltration trench. Since these facilities are installed on individual buildings and other structures, provisions need to be made for their maintenance, especially when they are installed on single family dwellings. When flow is observed to be bypassing the facility, the system has clogged and should be evaluated for rehabilitation.

Design Procedures

The following design procedure represents a generic list of the steps typically required for the design of a roof downspout system.

1. Determine if the anticipated development conditions and rooftop areas are appropriate for a roof downspout system.

2. Determine if the soils (permeability, bedrock, water table, Karst, etc.) and topographic conditions (slopes, building foundations, etc.) are appropriate for a roof downspout system.

3. Locate the roof downspout system on the site within site topographic constraints.

4. Determine the roof area for each roof downspout system and calculate the required water quality volume.

5. Design the roof downspout system:
    - design infiltration rate, $f_d = 0.5\, f$
    - max. Storage time $T_{max} = 48$ hours
    - max. Storage depth, d_{max}
    - stone backfill of clean aggregate (*1.5*" to *3.5*" diameter) - VDOT No. 1 Open-graded Course Aggregate
    - sand layer on trench bottom (*8* inches
    - runoff pretreatment - concentrated input: gutter screens, settling basin
    - filter fabric on trench sides and top (not on trench bottom) keyed into trench
    - overflow channel or large storm bypass
    - observation well

6. Provide material specifications.

7. Provide sequence of construction.

8. Provide maintenance and inspection requirements.

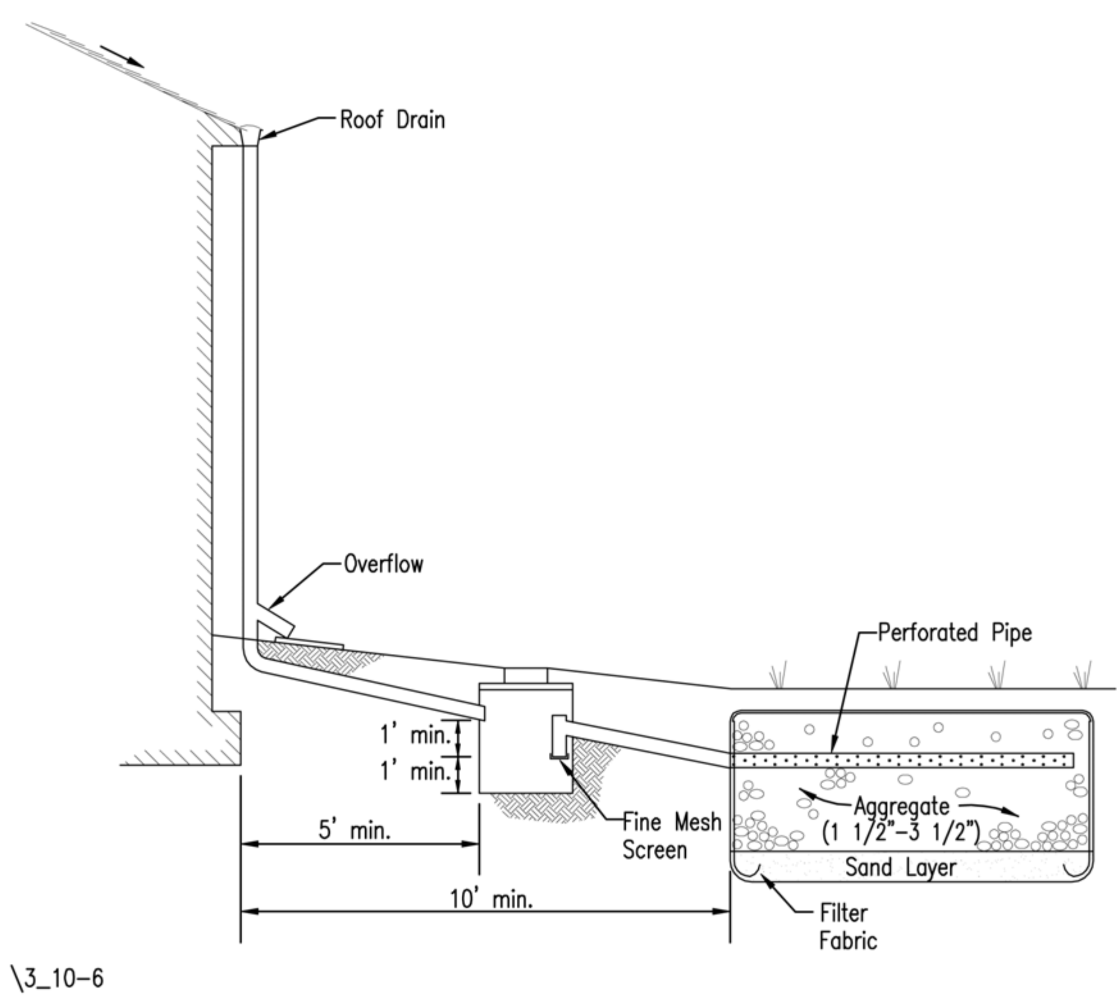
Roof Downspout System with a Pretreatment Sump Basin



MINIMUM STANDARD 3.10D

POROUS PAVEMENT

Definition

Porous pavement is a pervious pavement placed over a stone reservoir that is installed above a permeable soil.

The two pavements discussed in this section are ***porous asphalt pavement*** and ***porous concrete pavement***. *Porous asphalt pavement* is an open-graded coarse aggregate, bound together by asphalt cement into a coherent mass, with sufficient interconnected voids to provide a high rate of permeability to water. A typical porous asphalt pavement cross-section is presented in **Figure 3.10-11**. *Pourous concrete pavement* consists of specially formulated mixtures of Portland Cement, uniform, open-graded coarse aggregate and potable water.

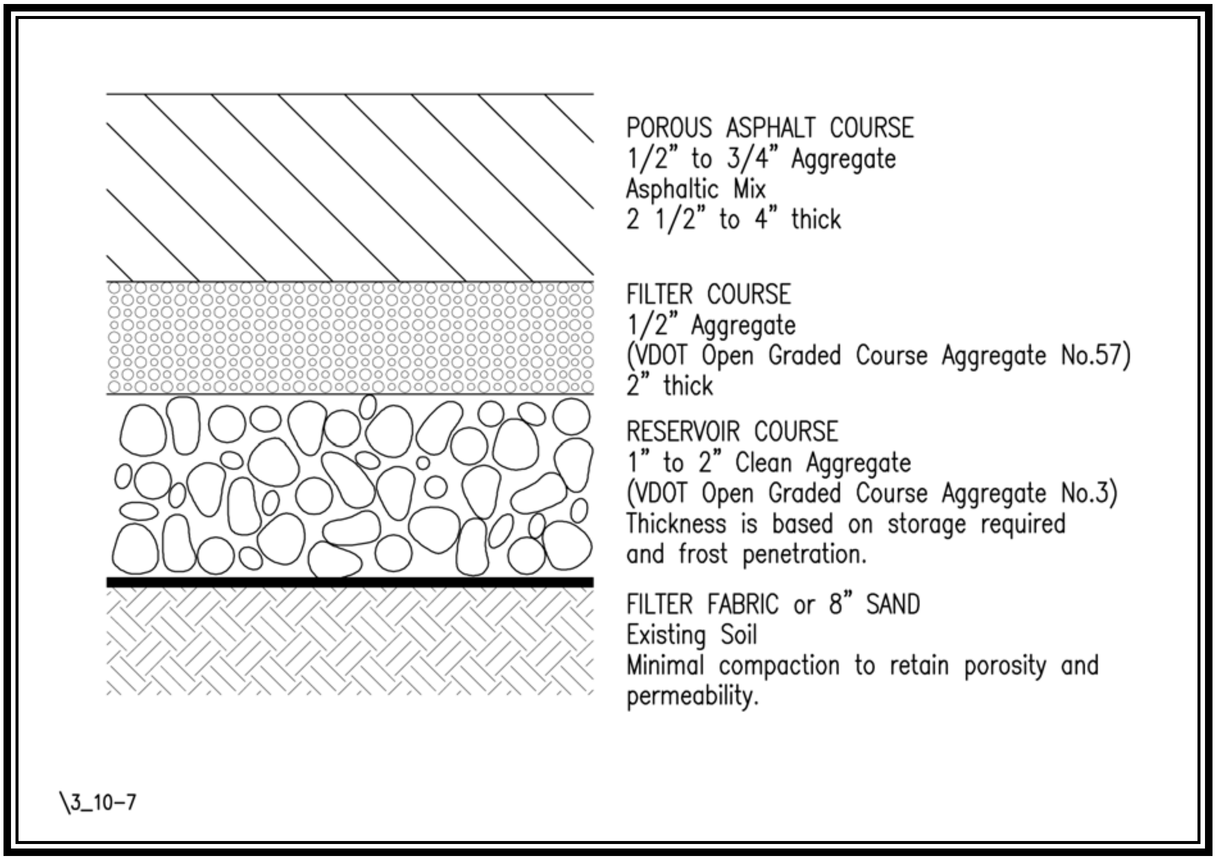
Purpose

The purpose of porous pavement is to provide water quality enhancement by infiltrating water through the paved surface and stone reservoir and into the underlying soils.

Conditions Where Practice Applies

Porous pavement is applicable as a substitute for conventional asphalt pavement on parking areas and low-traffic roadways if the grades, subsoil drainage characteristics and groundwater table conditions are suitable. Usually, the grades should be very gentle to flat, subsoil should have moderately rapid permeability ($f > 0.52$ *in/hr*) and the depth to the water table or bedrock should be at least 3 feet below the bottom of the stone reservoir. Parking lots, especially fringe or overflow parking areas, are suited for use with this paving material. Porous pavement should generally be installed on sites from 1/4 to 10 acres.

FIGURE 3.10 - 7
Porous Pavement Section



Planning Considerations

Porous pavement functions similar to infiltration trenches and, therefore, has similar planning considerations. Appropriate soil conditions and the protection of groundwater are among the important considerations which may limit its use. Refer to the **Planning Considerations** in **General Infiltration Practices**, **Minimum Standard 3.10** for additional discussion.

Generally, groundwater recharge rates are slightly higher under a porous pavement than under natural conditions, as vegetation is absent and water is not transpired during the summer months. Between 60% and 90% of the annual rainfall volume deposited on a porous pavement percolates into the ground (Washington DOE, 1992.)

It has been shown that porous pavement is more skid-resistant than conventional pavement in rainy weather and that the markings on a porous pavement are easier to see on rainy nights. In addition, studies have suggested that porous asphalt pavement is sufficiently strong and able to withstand freeze-thaw cycles and will last as long, structurally, as conventional pavement.

Typically, porous pavement is slightly more expensive than regular pavement. Additional costs associated with critical installation procedures and the availability of the asphalt mix may be offset by eliminating the need for curb and gutter, inlets, and conveyance systems. Availability is a consideration, since asphalt producers may not be willing to provide porous asphalt for small projects due to the demand for conventional asphalt mixes. For the production of a porous pavement mixture, the asphalt plant must be cleaned out to remove the fines not wanted in the porous mix. The cost of the stone reservoir and filter fabric associated with porous pavement is offset by the amount that would be spent on a stormwater facility elsewhere on the site.

Installation requires a very high level of workmanship throughout the construction process; porous pavement must be handled with great care in order for it to retain its porous qualities. Many pavement contractors and pavement engineers have limited experience in designing and constructing porous pavement. Improper installation can render a porous pavement design inoperative from the outset.

The biggest drawback to porous pavement is its tendency to clog if improperly maintained. Once it is clogged, it may have to be completely replaced since rehabilitating it is difficult and costly. On going maintenance of the pavement surface and specific limitations on the methods of snow and ice removal are often ignored and/or forgotten over time and with transfers of ownership. Clogging of the pavement surface from construction-related erosion can be prevented by waiting until all other phases of construction are complete and vegetation is stabilized before installing the pavement. Clogging of the pavement surface from natural circumstances is best prevented by installing it in areas that do not have highly erodible soils or steep slopes adjacent to the paved area.

Certain features can be incorporated into the design of porous pavement facilities to prolong the effective life of the system. One such feature is to “daylight” the aggregate base along the downslope edge of the pavement, forming a chimney drain into the stone storage under the pavement. The runoff can flow into the stone storage through the chimney drain if the pavement clogs.

If slow infiltration rates in the subgrade exist, porous pavement systems can be designed with an underdrain or collector system. When the collector system has a restriction plate on the outlet that controls the discharge, the stone reservoir can be designed as an underground stone-storage detention facility.

Evidence suggests that pollutants adsorb to the aggregate material, while particulates settle to the bottom of the aggregate layer. However, the target removal efficiency of 50% to 65%, as presented in **Table 3.10-1** for infiltration facilities, is too high for a stone-storage facility. **Therefore, a**

porous pavement facility with a stone storage underdrain system that provides positive drainage will be considered an extended-detention or detention facility. Its target pollutant removal efficiency will be based on the storage and release rate characteristics of these facilities as presented in **Minimum Standards 3.07, Extended-Detention**; and **3.08, Detention Basins**, until more information is collected to support the use of a higher pollutant removal efficiency.

Design Criteria

The purpose of this section is to provide recommendations and minimum criteria for the design of porous pavement intended to comply with the runoff quality requirements of theVirginia Stormwater Management programs.

The general design criteria for the porous pavement stone reservoir area and the underlying soils are the same as for infiltration trenches. Additional design is required for determining the porous pavement thickness. The design of the pavement is dependent on the strength of the sub-base soil, the projected traffic intensities, and the storage capacity of the reservoir and base.

A thorough examination of the site is of primary importance to the proper design and functioning of porous pavement. Soil and climate conditions, expected surface wear, and the use objectives of the porous surface should all be considered before designing the pavement.

The following represents a general list of design elements that should be considered in any porous pavement design:

1. Anticipated traffic intensities, defined by the ***average daily equivalent axle load*** (*EAL*).
2. ***California Bearing Ratio*** (CBR) of the soils.
3. Susceptibility of the soils to frost heave.

Due to the complexity of its design, a step-by-step procedure to engineer a porous pavement section will not be presented in this manual. **A professional engineer, with training and experience in porous pavement design and construction, should design the pavement section and supervise during the paving operation**.

Specific design requirements for a satisfactory ***porous asphalt pavement*** section equivalent to a conventional pavement design are available through the U. S. Department of Transportation's Federal Highway Administration and through other references listed at the end of this standard.

Specific design requirements for a satisfactory ***porous concrete pavement*** section are available through the Florida Concrete and Products Association, 649 Vassar Street, Orlando, Florida 32804. Other references are also listed at the end of this standard.

Porous Concrete Pavement Construction Specifications

The design criteria and material specifications for ***porous concrete pavement*** are **NOT INCLUDED** in this manual due their extreme complexity. Note that the methods of handling and placing porous concrete are different from other types of concrete. **Only concrete firms and contractors familiar with the intricacies of porous concrete should be used**. For further discussion, refer to **General Pavement Design Criteria** above.

Porous Asphalt Pavement Construction Specifications

The following construction specifications are general and typically represent aspects of design that require fine-tuning based on site conditions. A professional with experience in porous asphalt design should supervise construction to insure proper methods are used.

Overall, widely accepted construction standards and specifications, such as those developed by the USDA Soil Conservation Service or the U.S. Army Corps of Engineers, should be followed where applicable. Further guidance can be found in the Soil Conservation Service's Engineering Field Manual. Specifications for the work should conform to the methods and procedures specified for installing earthwork, concrete, reinforcing steel, pipe, water gates, metal work, woodwork and masonry, as they apply to the site and the purpose of the structure. The specifications should also satisfy any requirements of the local government.

The specifications for the asphalt mix should include:

1. Calculation of void space in the asphalt section.
2. Aggregate type, quality and gradation.
3. Asphalt cement grade in mix.
4. Asphalt content in mix.
5. Mixing temperature.

Construction of a porous asphalt pavement should also be in conformance with the following (adapted from Construction Sspecifications for the City of Rockville, Maryland:

Stabilization

To preclude premature clogging and/or failure, porous asphalt pavement should not be placed into service until all of the surface drainage areas contributing to the paved area have been effectively stabilized. Refer to the VESCH 1992 edition, for stabilization requirements.

Subgrade Preparation

1. Alter and refine the grades as needed to bring subgrade to required grades and sections as shown in the drawings.

2. The type of equipment used in subgrade preparation should not cause undue subgrade compaction. (Use tracked-equipment or equipment with oversized rubber tires **Do Not use standard rubber tire equipment**.) Traffic over the subgrade should be kept to a minimum. Where fill material is required, it should be compacted to a density equal to the undisturbed subgrade. Inherent soft spots should be corrected.

Trench Bottom

The trench bottom may be lined with filter fabric or an *8* inch layer of sand (VDOT Fine Aggregate, Grading A or B), based on the geotechnical and pavement design recomendations.

Reservoir course

1. The stone reservoir course aggregate should be 1 to 2 inch diameter clean, washed, crushed stone meeting VDOT specifications (Open Graded Course Aggregate No. 3).

2. The stone reservoir thickness (depth) is dependent on the storage volume requirements (water quality volume, quantity control volumes, etc.).

Filter Course

1. The filter course aggregate should be 1/2-inch diameter clean, washed, crushed stone, meeting VDOT specifications (Open-graded Course Aggregate No. 57).

2. The filter course thickness should be 2 inchs.

Porous Asphalt Surface Course

1. The surface course should be laid directly over the aggregate base course and should be laid in one lift.

2. The laying temperature should be between 230EF and 260EF, with a minimum air

temperature of 50EF, to make sure that the surface does not stiffen before compaction.

3. Compaction of the surface course should be completed while the surface is cool enough to resist a 10-ton roller. One or two passes of the roller are required for proper compaction. More rolling could cause a reduction in the surface course porosity.

4. The mixing plant should certify to the aggregate mix, the abrasion loss factor, and the asphalt content in the mix. The asphalt mix should be tested for its resistance to stripping by water using ASTD 1664. If the estimated coating area is not above 95%, antistripping agents should be added to the asphalt.

5. The mix should be transported to the site in a clean vehicle with smooth dump beds sprayed with a non-petroleum release agent. The mix should be covered during transportation to control cooling.

6. The asphalt mix should be 5.5 to 6% of dry aggregate by7 weight.

7. The asphalt's grade should meet AASHTO Specification M-20; 85 to 100% penetration road asphalt as a binder in the western part of the state, 65 to 80% in the piedmont area, and 50 to 65% in southeastern Virginia.

8. The aggregate grading should be as specified in **Table 3.10-3**.

<u>Protection</u>

After final rolling, no vehicular traffic of any kind should be permitted on the pavement until cooling and hardening has taken place, and never less than 6 hours (preferably 24 to 48 hours). All construction related traffic should be routed around or away from the porous pavement.

<u>Workmanship</u>

1. Work should be completed with expertise throughout the process and without staining or damage to other permanent work.

2. The transition between existing and new paving work should be neat and flush.

3. Finished paving should be even, without pockets, and graded to elevations shown.

4. All minor surface projections and edges adjoining other materials should be ironed smoothly to grade.

Certification

An appropriate professional should certify that these specifications were followed.

Maintenance and Inspections

The following maintenance and inspection guidelines are not intended to be all-inclusive. Specific applications may require other measures not discussed here.

Inspection Schedule

The observation well should be checked quarterly and after every large storm event. It is recommended that a log book be maintained showing the depth of water in the well during each inspection in order to determine the rate at which the facility dewaters after runoff producing storms events. Once the performance characteristics of the structure have been verified, the monitoring schedule can be reduced to an annual basis, unless the performance data suggest that a more frequent schedule is required.

Maintenance

The surface of porous asphalt pavement must be cleaned regularly to prevent it from becoming clogged by fine material. This cleaning is best accomplished through the use of a vacuum cleaning street sweeper, followed by high pressure water washing. Outside of regular cleaning, porous pavement requires maintenance similar to that of regular pavement. In times of heavy snowfall, however, application of abrasive material should be closely monitored to avoid clogging problems once the snow and ice has melted. There are no maintenance measures designed to repair fully clogged porous pavement, other than replacement.

Design Procedures

The following design procedure represents a generic list of the steps typically required for the design of an infiltration trench.

1. Determine if the anticipated development conditions and drainage area are appropriate for a porous pavement application.

2. Determine if the soils (permeability, bedrock, water table, Karst, etc.) and site topographic conditions (slopes, etc.) are appropriate for a porous pavement application.

3. Locate the porous pavement section on the site within the topographic constraints.

4. Determine the drainage area for the porous pavement and calculate the required water quality volume.

5. Evaluate the hydrology of the contributing drainage area to determine peak rates of runoff.

6. Design the porous pavement stone reservoir:
   - C design infiltration rate, $f_d = 0.5 f$
   - C max. storage time T_{max} = 48 hours
   - C max. storage depth, d_{max}
   - C stone backfill of clean aggregate (1.5" to 3.5") VDOT No. 1 Open-graded Course Aggregate
   - C filter gravel layer - two inches of clean aggregate (1/2") VDOT No. 57 Open-graded Course Aggregate
   - C sand layer on trench bottom (8 inche), or filter fabric, per geotechnical and pavement design recommendations
   - C Filter fabric on trench sides and top (not on trench bottom) keyed into trench
   - C Overflow channel or large storm bypass
   - C Observation well

7. Provide pavement section design and material specifications.

8. Provide sequence of construction.

9. Provide maintenance and inspection requirements.

BIORETENTION BASINS

Definition

Bioretention is an innovative BMP developed by the Prince George's County, Maryland Department of Environmental protection. The following information is drawn from their ***Design Manual for Use of Bioretention in Stormwater Management*** (P.G. County, 1993) unless otherwise noted. This technology is also referred to as "Rain Gardens."

Figure 3.11-1 illustrates the Maryland bioretention (Rain Garden) concept as adapted for use in Virginia. There are seven major components to the bioretention area (Rain Garden): 1) the grass buffer strip; 2) the ponding area; 3) the surface mulch and planting soil; 4) the sand bed (optional); 5) the organic layer; 6) the plant material, and 7) the infiltration chambers. Each component is critical to sustaining a properly functioning BMP.

Purpose

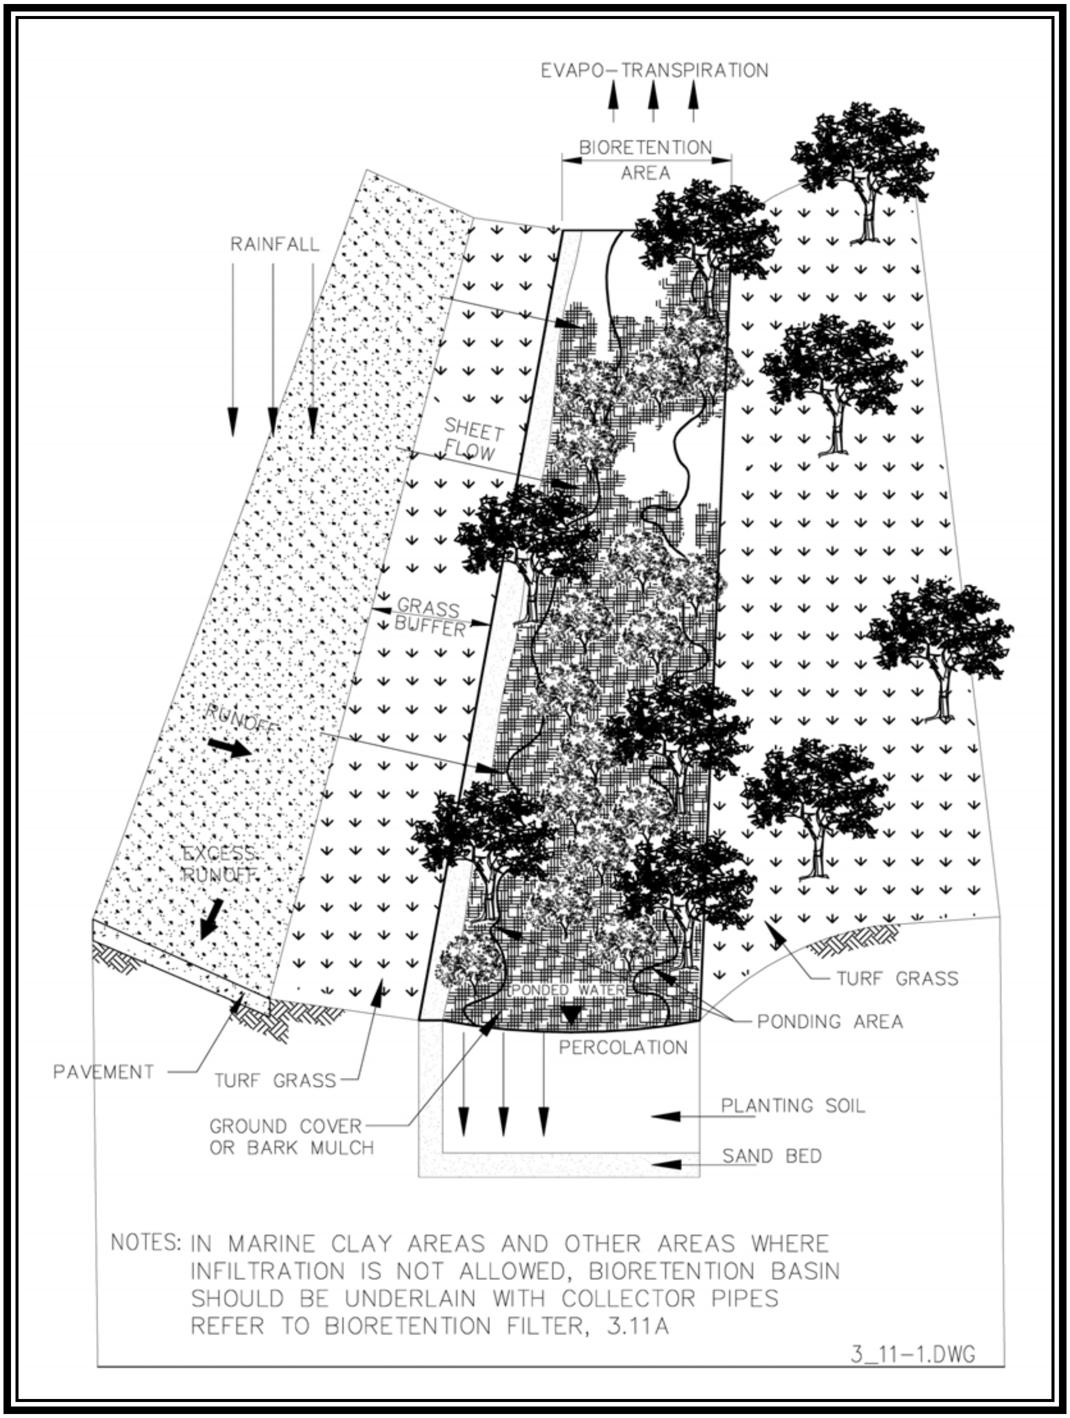
Bioretention basins are used primarily for water quality control. However, since they capture and infilter part of the stormwater from the drainage shed, they may provide partial or complete control of streambank erosion and partial protection from flooding (depending on the volume of water being captured and infiltered).

Bioretention facilities (Rain Gardens) are planting areas installed in shallow basins in which the stormwater runoff is treated by filtering through the bed components, biological and biochemical reactions within the soil matrix and around the root zones of the plants, and infiltration into the underlying soil strata. Properly constructed bioretention areas replicate the ecosystem of an upland forest floor through the use of specific shrubs, trees, ground covers, mulches and deep, rich soils. Since almost all bioretention basins are intended to be visual landscape amenities as well as stormwater BMPs, aesthetic considerations may be equally as important in their use as proper engineering. Bioretention design requires participation by a person with appropriate design skills and a working knowledge of indigenous horticultural practices, preferably a Landscape Architect.

Water Quality Enhancement

Bioretention basins enhance the quality of stormwater runoff through the processes of adsorption, filtration, volitization, ion exchange, microbial and decomposition prior to exfiltration into the surrounding soil mass. Microbial soil processes, evapotranspiration, and nutrient uptake in plants also come into play (Bitter and Bowers, 1995).

FIGURE 3.11 - 1
Bioretention Basin



The **grass buffer strip** filters particles from the runoff and reduces its velocity. The **sand bed** further slows the velocity of the runoff, spreads the runoff over the basin, filters part of the water, provides for positive drainage to prevent anaerobic conditions in the planting soil and enhances exfiltration from the basin. The **ponding area** functions as storage of runoff awaiting treatment and as a presettling basin for particulates that have not been filtered out by the grass buffer. The **organic or mulch layer** acts as a filter for pollutants in the runoff, protects the soil from eroding , and provides an environment for microorganisms to degrade petroleum-based solvents and other pollutants. The **planting soil layer** nurtures the plants with stored water and nutrients. Clay particles in the soil adsorb heavy metals, nutrients, hydrocarbons, and other pollutants. The **plant species** are selected based on their documented ability to cycle and assimilate nutrients, pollutants, and metals through the interactions among plants, soil, and the organic layer (*ibid*). By providing a variety of plants, monoculture susceptibilities to insect and disease infestation are avoided, and evapotranspiration is enhanced. The **vented infiltration chambers** provide unobstructed exfiltration through the open-bottomed cavities, decrease the ponding time above the basin, and aerate the filter media between storms through the open chamber cavities and vents to grade, preventing the development of anaerobic conditions. By providing a valve equipped drawdown drain to daylight, the basin can be converted into a soil media filter should exfiltration surface failures occur.

Perforated underdrain systems are recommended for facilities placed in residential areas and in all areas where the in-situ soils are questionable. Refer to **3.11A - Bioretention Filter**.

The minimum width for a bioretention area is usually 10 feet, although widths as narrow as 4 feet may be used if the runoff arrives as dispersed sheet flow along the length of the facility from a properly sized vegetated strip. The minimum length should be 15 feet (for lengths greater than 20 feet, the length should be at least twice the width to allow dispersed sheet flow). As an infiltration BMP, the maximum ponding depth is restricted to six inches to restrict maximum ponding time to preclude development of anaerobic conditions in the planting soil (which will kill the plants) and to prevent the breeding of mosquitoes and other undesirable insects in the ponded water. The planting soil must have sufficient depth to provide appropriate moisture capacity, create space for the root systems, and provide resistance from windthrow (Minimum depth equal to the diameter of the largest plant root ball plus 4 inches).

Table 3.11-1 contains the target removal efficiencies once a **mature** plant community is created in the bioretention areas based on the volume of runoff to be captured and infiltered.

Flood Control and Channel Erosion

The amount of flood and channel erosion control provided by bioretention basins depends on the local rainfall frequency spectrum, the amount of pre-development (or pre-redevelopment) impervious cover, the amount of post-development impervious cover, and the volume of runoff captured and infiltered by the basin(s). The effect of the BMPs on peak flow rates from the drainage shed must be examined. As with other infiltration practices, bioretention basins tend to reverse the consequences of urban development by reducing peak flow rates and providing groundwater discharge.

TABLE 3.11-1
Pollutant Removal Efficiencies for Bioretention Basins

BMP Description	Target Phosphorus Removal Efficiency
Bioretention basin with capture and treatment volume equal to 0.5 inches of runoff from the impervious area.	50%
Bioretention basin with capture and treatment volume equal to 1.0 inches of runoff from the impervious area.	65%

Conditions Where Practice Applies

Bioretention basins are suitable for use on any project where the subsoil is sufficiently permeable to provide a reasonable rate of infiltration and where the water table is sufficiently lower than the design depth of the facility to prevent pollution of the groundwater. Bioretention basins are generally suited for almost all types of development, from single-family residential to fairly high density commercial projects. They are attractive for higher density projects because of their relatively high removal efficiency. **Figures 3.11-2** through **3.11- 5** illustrate several applications. Bioretention basins may also be installed in off-line pockets along the drainage swales adjacent to highways or other linear projects, as illustrated in **Figure 3.11-6**. For large applications, several bioretention basins connected by an underground infiltration trench (“Green Alleys”) are preferable to a single, massive basin. Such a system is especially desirable along the landward boundary of reduced Chesapeake Bay Resource Protection Areas. **Minimum Standard 3.11B** discusses this system. Considering the character of bioretention basins, some jurisdictions may qualify them as buffer restoration.

Planning Considerations

Site Conditions

All of the Site Conditions considerations for general infiltration practices contained in **MINIMUM STANDARD 3.10** also apply to bioretention basins. Designers should also be mindful of local requirements for soil studies for infiltration practices such as those in the ***Northern Virginia BMP Handbook***. In addition to site conditions affecting infiltration practices in general, the following apply specifically to bioretention basins. The application of individual bioretention basins will usually be limited to drainage areas from 0.25 to 1 acre. Generally, commercial or residential drainage areas exceeding 1 acre in size will discharge sheet flows greater than 5 cfs.

1. Location Guidelines

Preferable locations for bioretention basins include 1) areas upland from inlets or outfalls that receive sheet flow from graded areas, and 2) areas of the site that will be excavated or cut. When available, areas of loamy sand soils should be used since these types of soils comprise the planting soils for bioretention basins. Locating the BMP in such natural locations would eliminate the cost of importing planting soils (see soil and organic specification under **Design Considerations**). BMP location should be integral with preliminary planning studies.

The following areas would be **undesirable** for bioretention basins: 1) areas that have mature trees which would have to be removed for construction of the bioretention basin, 2) areas that have existing slopes of 20% or greater, and 3) areas above or inclose proximity to an unstable soil strata such as marine clay.

2. Sizing Guidelines

For planning purposes, assume that the floor area of the bioretention basin will be a minimum of 2.5% of the impervious area draining to the basin if the first 0.5 inches of runoff is to be treated and a minimum of 4.0% of the impervious area on the drainage shed if the first 1.0 inches of runoff is to be treated. Derivation of these values is discussed below under **Design Considerations**. Note that small projects such as single family residences will likely default to the minimum 150 square foot area (10' X 15').

3. Aesthetic Considerations

Aesthetic considerations of the bioretention basin must be considered early in the site planning process. While topography and hydraulic considerations may dictate the general placement of such facilities, overall aesthetics of the site and the bioretention basins must be integrated into the site plan and stormwater concept plan from their inception. Both the stormwater engineer and the Landscape Architect must participate during the layout of facilities and infrastructure to be placed on the site. Bioretention design must be an integral part of the site planning process.

Sediment Control

Like other infiltration practices, provisions for long-term sediment control must be incorporated into the design, **as well as precautions during on-site construction activities.** Careful consideration must be given **in advance of construction** to the effects of work sequencing, techniques, and equipment employed on the future maintenance of the practice. Serious maintenance problems can be averted, or in large part, mitigated, by the adoption of relatively simple measures during construction.

1. Construction Runoff

Bioretention basin BMPs should be constructed AFTER the site work is complete and stabilization measures have been implemented. If this is not possible, strict implementation of E&S protective measures must be installed and maintained in order to protect the bioretention facility from premature clogging and failure.

Like other infiltration BMPs, bioretention basins constructed prior to full site stabilization will become choked with sediment from upland construction operations, rendering them inoperable from the outset. Simply providing inlet protection or some other filtering mechanism during construction will not adequately control the sediment. One large storm may completely clog the bioretention basin, requiring complete **reconstruction**.

Experience with infiltration practices has also demonstrated that the bioretention basin site should **NOT** be used as the site of sedimentation basins during construction. Such use tends to clog the underlying strata and diminish their capacity to accept infiltration below that indicated in preconstruction soil studies.

Bioretention basins are landscape amenities and should be installed with other landscaping as the last stage of project construction.

A detailed sediment control design to protect the bioretention basin **during** its construction should be included with the facility design. The ***Virginia Erosion and Control Handbook*** (VDCR, 1992), ***Standards and Specifications for infiltration Practices*** (Md. DNR, 1984), and ***Controlling Urban Runoff*** (MWCOG, 1987) provide technical guidance on sediment control designs.

Experience with bioretention basins in Maryland has demonstrated that they must be protected until the drainage areas contributing to the practice have been adequately stabilized (P.G. Co., 1993).

The definition of the term "adequately stabilized" is critical to the success of the facility. At the conclusion of construction activity, the temporary erosion and sediment control measures are usually removed at the direction of the erosion and sediment control inspector when, at a minimum, stabilization measures such as seed and mulch are in place. This does not mean, however, that stabilization has actually occurred. Bioretention basins must be protected until stabilization of the upland site is functioning to control the sediment load from denuded areas. Provisions to bypass the stormwater away from the bioretention basin during the stabilization period should be implemented.

2. Urban Runoff

A fully stabilized site will generate particulate pollutant load resulting from natural erosion, lawn and garden debris such as leaves, grass clippings, mulch, roadway sand, etc. Pretreatment of runoff to remove sediments prior to entering the bioretention basin is usually provided by a grass filter strip or grass channel. When runoff from sheet flow from such areas as parking lots, residential yards, etc., is involved, a grass filter strip, often enhanced with a pea gravel diaphragm, is usually employed. **Table 3.11-2** provides sizing guidelines as a function of inflow approach length, land use, and slope. The minimum filter strip length (flow path) should be 10 feet.

TABLE 3.11-2
Pretreatment Filter Strip Sizing Guidance
(Source: Claytor and Schueler, 1996)

Parameter	Impervious Parking Lots				Residential Lawns				Notes
Maximum Inflow Approach Length (feet)	35		75		75		150		
Filter Strip Slope	≤ 2%	≥2%	≤2%	≥2%	≤2%	≥2%	≤2%	≥2%	Maximum = 6%
Filter Strip Minimum Length	10'	15'	20'	25'	10'	12'	15'	18'	

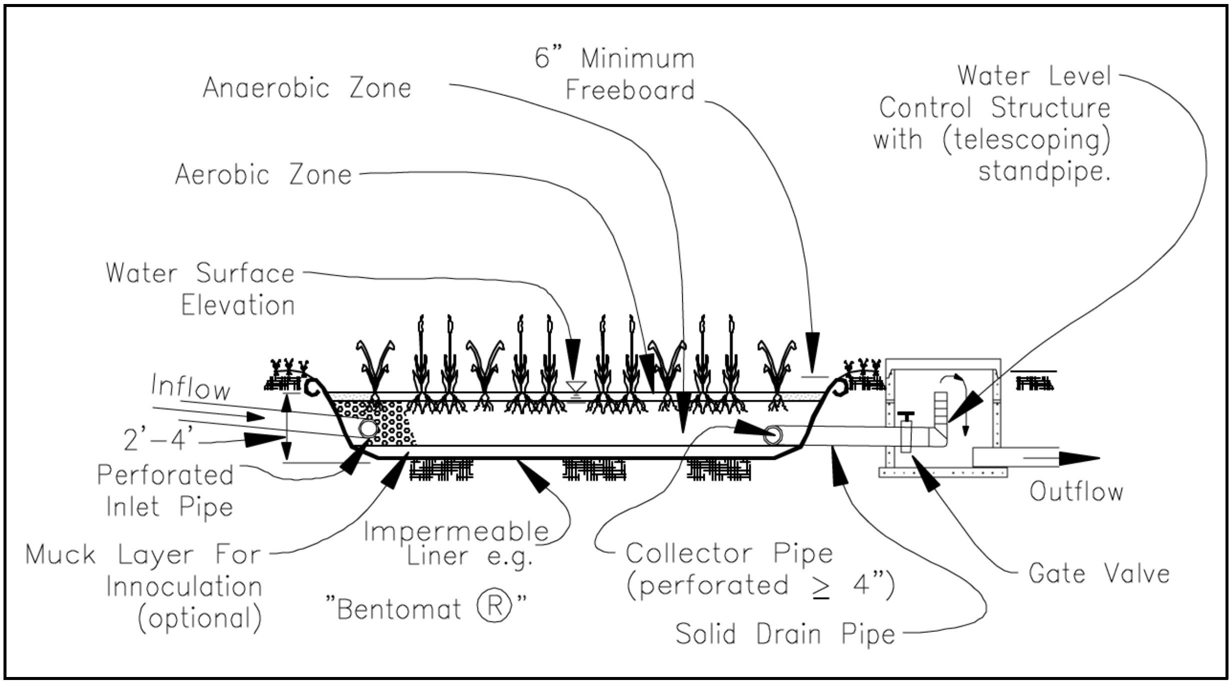
For applications where concentrated runoff enters the bioretention basin by surface flow, such as through a slotted curb opening, a grassed channel, often equipped with a pea gravel diaphragm to slow the velocity and spread out the flow entering the basin, is the usual pretreatment method. The length of the grassed channel depends on the drainage area, land use, and channel slope. **Table 3.11-3** provides recommendations on sizing for grass channels leading into a bioretention basin for a one acre drainage area. The minimum grassed channel length should be 20 feet.

"Grassed filter strips, grassed channels, and side-slopes of the basin should be **sodded with mature sod** prior to placement of the bioretention basin into operation. Simply seeding these areas will likely result in conveyance of sediments into the basin and premature failure. Wrapping of the planting soil mixture up the side slopes beneath the sod is also recommended."

TABLE 3.11-3
Pretreatment Grass Channel Sizing Guidance for a 1.0-Acre Drainage Area
(Source: Claytor and Schueler, 1996)

Parameter	**≤ 33% Impervious**		**Between 34% and 66% Impervious**		**≥ 67% Impervious**		**Notes**
Slope	≤2%	≥2%	≤2%	≥2%	≤2%	≥2%	Maximum slope = 4%
Grassed channel minimum length (feet)	25	40	30	45	35	50	Assumes a 2' wide bottom width

FIGURE 3.11-6
Upflow Inlet for Bioretention Basin
(Source: City of Alexandria)



When concentrated piped flow from impervious areas such as parking lots is routed to a bioretention basin, an energy absorbing and sedimentation structure in which the flow rises into the basin like a tide is usually advisable. Since sediments must usually be removed from such structures on a regular basis, they must be placed in locations where the extension booms on vacuum trucks may easily reach them. **Figure 3.11-6** illustrates an upflow inlet structure for a bioretention basin. Maintenance requirements for pretreatment measures are discussed **Maintenance/Inspection Guidelines**.

General Design Criteria

The purpose of this section is to provide minimum criteria for the design of bioretention basin BMPs intended to comply with the Virginia Stormwater Management program's runoff quality requirements. Bioretention basins which capture and infilter the first 1 inch of runoff from impervious surfaces may also provide streambank erosion protection.

General

The design of bioretention basins should be in accordance with the following Minimum Standards where applicable: **3.1: Earthen Embankments, 3.2: Principal Spillways, 3.3: Vegetated Emergency Spillways, 3.4: Sediment Forebay, 3.10: General Infiltration Practices, and 3.10A: Infiltration Basin,** as well as the additional criteria set forth below. The designer is not only responsible for selecting the appropriate components for the particular design but also for ensuring long-term operation.

Soils Investigation

Refer to the **Planning Considerations** and **Design Criteria** of **General Infiltration Practices, MS-3.10**, and to local jurisdiction soil study requirements such as Chapter 5, Section V. of the ***Northern Virginia BMP Handbook***. As with infiltration basins (**MS3.10A**), a minimum of one soil boring log should be required for each 5,000 square feet of bioretention basin area (plan view area) and in no case less than three soil boring logs per basin.

Topographic Conditions

Like other infiltration facilities, bioretention basins should be a minimum of 50 feet from any slope greater than 15 percent. A geotechnical report should address the impact of the basin upon the steep slope (especially in marine clay areas). Also, bioretention basins should be a minimum of 100 feet up-slope and 20 feet downslope from any buildings.

Basin Sizing Methodology

In Virginia, bioretention basins are designed to exfilter the treatment quantity into the underlying soil strata, or into an underlying perforated underdrain system connected to a storm drain system or other outfall when the underlying soils, proximity to building foundation, or other such restrictions preclude the use of infiltration. When such an underdrain system is used, the facility is referred to as a **Bioretention Filter - Minimum Standard 3.11A**.

Recent research at the University of Maryland has supported a reduction in overall depth of the planting soil to 2.5 feet. Generally, the soil depth can be designed to a minimum depth equal to the diameter of the largest plant root ball plus 4 inches. The recommended soil composition was revised to reduce the clay and increase the sand content (Refer to Soil Texture and Structure later in this standard). This revised soil composition also eliminated the 12" sand layer at the bottom of the facility. The researchers concluded that significant pollutant reductions are achieved in the mulch layer and the first 2 to 2.5 feet of soil.

The elevation of the overflow structure should be 0.5 feet above the mulch layer of the bioretention bed. When an underdrain system is used (Min. Std. 3.11A), the overflow can be as much as 1.0 feet above the mulch layer.

The size of the bioretention facility is dictated by the amount of impervious surface in the contributing drainage area. For facilities capturing the first 0.5 inches of runoff from the impervious areas in the drainage shed, the surface area of the bioretention bed should be a minimum of 2.5% of the impervious area, or 1,090 square feet per impervious acre. For facilities capturing the first 1.0 inch of runoff, the bioretention bed should be a minimum of 5.0% of the impervious area, or 2,180 square feet per impervious acre.

The minimum width and length is recommended at 10 feet and 15 feet respectively. (Widths as narrow as 4 feet may be used if the runoff arrives as dispersed sheet flow along the length of the facility from a properly sized vegetated strip).

The elevation of the overflow structure should be 0.5 feet above the mulch elevation of the bioretention bed.

Note that small projects such as single family residences may default to the minimum (10' X 15') **150 square foot area.**

TABLE 3.11-4
Basin Sizing Summary

Treatment Volume	**Basin Surface Area** (Expressed as percentage of impervious area)
0.5" per impervious acre	2.5%
1.0" per impervious acre	5.0%

Runoff Pretreatment

Like other infiltration basins, bioretention basins must always be preceded by a pretreatment facility to remove grease, oil, floatable organic material, and settleable solids (see Urban Runoff section of **Sediment Control** under **Planning Considerations** above). Where space constraints allow, runoff should be filtered by a grass buffer strip and sand bed. The buffer strip and sand bed will reduce the amount of fine material entering the bioretention area and minimize the potential for clogging of the planting soil. The sand bed also increases the infiltration capacity and provides aeration for the plant roots in the bioretention area. For basins for which high sediment loadings are expected (treating largely pervious areas, etc.), the design can be modified to include a sediment forebay (see **MS 3.04**). Any pretreatment facility should be included in the design of the basin and should include maintenance and inspection requirements.

Drainage Considerations

The grading design must shape the site so that all runoff from impervious areas is routed through the bioretention basins. The basins must be sited so as to accept the design runoff quantity before bypassing any excess flow to the storm drainage system. Bioretention basin locations must therefore be integrated into the basic site design from its inception. Most of the **Planning Considerations** delineated above must come into play at this early stage in the design process. The overall site and impervious surfaces must be contoured to direct the runoff to the basins. **Bioretention basins cannot usually be successfully integrated into a site design that does not take stormwater management into account from its inception.** Elevations must be carefully worked out to assure that the desired amount runoff will flow into the basins and pool at no more that the maximum design depth. This requires a much higher degree of vertical control during construction that is normal with most landscaping work.

Preferably, bioretention basins should be placed “off-line,” i.e. the design should provide for runoff to be diverted into the basin until it fills with the treatment volume and then bypass the remaining flow around the BMP to the storm drainage system. The drainage system is normally designed to handle a specific storm event (the 10-year storm in most of Virginia). To prevent flood damage , however, the bioretention basin design must take into account how the runoff will be processed when larger events occur. This may require, at a minimum, that a vegetated emergency spillway be provided (see **MS-3.03**), and that a path for overland flow to an acceptable channel be incorporated into the design. The designer should provide for relief from the storm event specified by local development approval authority or for the 25-year storm event, whichever is the most stringent.

Figure 3.11-2 illustrates an “off-line” application at the edge of a parking lot with curb and gutter. The inlet deflectors divert runoff into the bioretention basin until the basin fills and backs up. Subsequent runoff then bypasses to the adjacent, down gradient storm inlet. **Figure 3.11-3** illustrates an “off-line” application in a planting island in a parking lot, while **Figure 3.11-4** illustrates an “off-line application adjacent to a drainage swale (such highway drainage). Again, runoff flows into the bioretention basin until it fills, then bypasses down the swale. Placement of a flow diversion check dam in the swale will facilitate filling the basin. In some situations, an “off-line” configuration may not be practical or economical. Figure **3.11-1** and **3.11-5** illustrate applications where sheet flow enters the bioretention basin.

Figure 3.11-7 illustrates a grading plan for a bioretention basin. The grading plan was created for a double-cell bioretention area. There is a seven-foot buffer between cells which allow for the planting of upland trees. As indicated in the grading plan, sheet and gutter flow is diverted into the bioretention areas through openings in the curb. The elevation of the invert of the bioretention area is set by the curb opening elevation. The curb opening elevation is 0.5 ft. higher than the invert of the bioretention area, so water is allowed to pond to a maximum depth of one-half foot before runoff bypasses the bioretention area and flows into the storm drain system.

Precise grading of the basin is critical to capturing the water quality volume and operation of the facility. The plan should have a contour interval of no more than one-foot, and spot elevations should be shown throughout the basin. The perimeter contour elevation should contain the design storm without over topping anywhere except at the outflow structure.

Exclusion of Continuous Flows and Chlorinated Flows

Bioretention and bioretention filter BMPs will **NOT** function properly if subjected to continuous or frequent flows. The basic principles upon which they operate assume that the sand filter will dry out and reaerate between storms. If the sand is kept continually wet by such flows as basement sump pumps, anaerobic conditions will develop, creating a situation under which previously captured iron phosphates degrade, leading to **export** of phosphates rather than the intended high phosphorous removal (Bell, Stokes, Gavan, and Nguyen, 1995). Anaerobic conditions will also kill most of the plants in the basin, stopping the biochemical pollutant removal processes and negating the aesthetic landscaping amenity aspects. It is also essential to **exclude flows containing chlorine and other swimming pool and sauna chemicals** since these will kill the bacteria upon which the principle nitrogen removal mechanisms depend.

Continuous or frequent flows (such as basement sump pump discharges, cooling water, condensate water, artesian wells, etc.) and flows containing swimming pool and sauna chemicals MUST BE EXCLUDED from routing through bioretention or bioretention filter BMPs since such flows will cause the BMP to MALFUNCTION!

Planting Plan

Selection of plantings must include coordination with overall site planning and aesthetic considerations for designing the bioretention plant community. Tables listing suitable species of trees, shrubs, and ground cover are provided at the end of this section. This listing is not intended to be all-inclusive due to the continual introduction of new horticultural varieties ans species in the nursery industry.

1. Planting Concept

The use of plantings in bioretention areas is modeled from the properties of a terrestrial forest community ecosystem. The terrestrial forest community ecosystem is an upland community dominated by trees, typically with a mature canopy, having a distinct sub-canopy of understory trees, a shrub layer, and herbaceous layer. In addition, the terrestrial forest ecosystem typically has a well-developed soil horizon with an organic layer and a mesic moisture regime. A terrestrial forest community model for stormwater management was selected based upon a forest's documented ability to cycle and assimilate nutrients, pollutants, and metals through the interactions among plants, soil, and the organic layer. These three elements are the major elements of the bioretention concept.

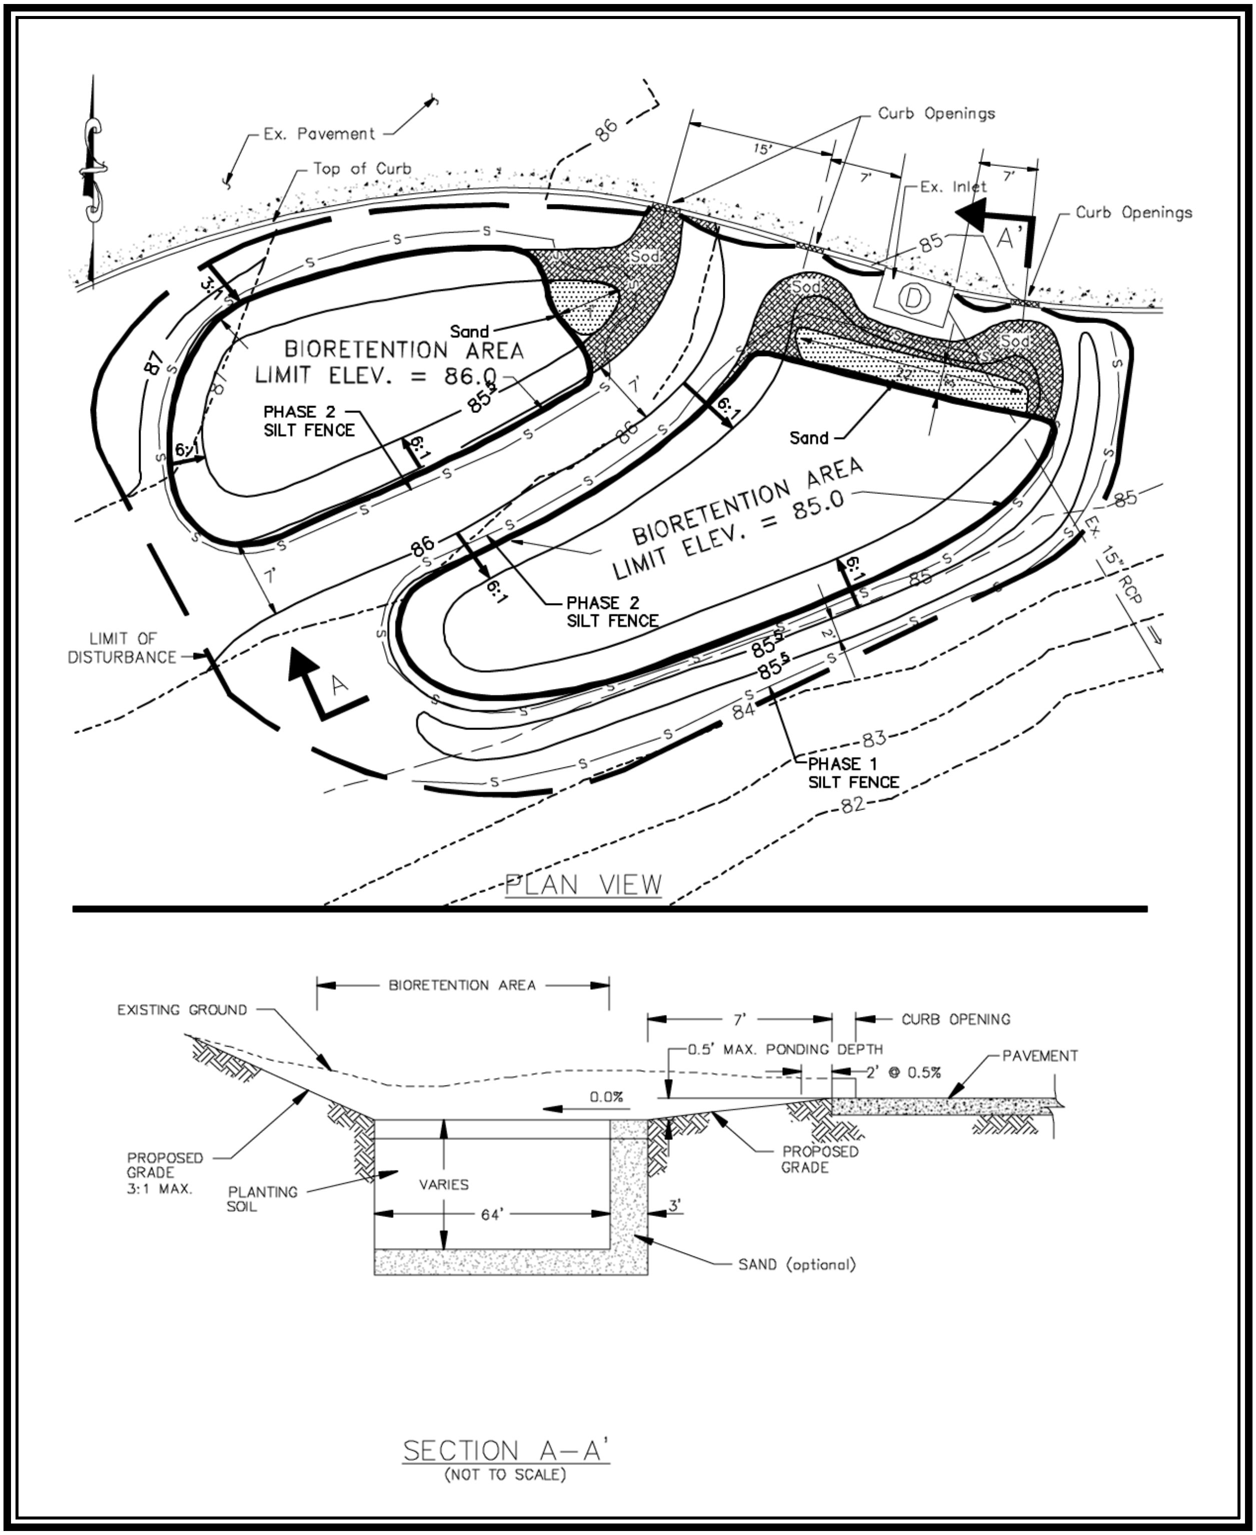
Key elements of the terrestrial forest ecosystem that have been incorporated into bioretention design include species diversity, density, and morphology, and use of native plant species. Species diversity protects the system against collapse from insect and disease infestations and other urban stresses such as temperature and exposure. Typically, indigenous plant species demonstrate a greater ability of adapting and tolerating physical, climatic, and biological stresses.

2. Plant Species Selection

Plant species appropriate for use in bioretention areas are presented in **Tables 3.11-7A** through **3.11-7C** , provided at the end of this section. These species have been selected based on the ability to tolerate urban stresses such as pollutants, variable soil moisture and ponding fluctuations. Important design considerations such as form, character, massing, texture, culture, growth habits/rates, maintenance requirements, hardiness, size, and type of root system are also included. A key factor in designating a species as suitable is its ability to tolerate the soil moisture regime and ponding fluctuations associated with bioretention. The plant indicator status (Reed, 1988) of listed species are predominantly facultative (i.e., they are adapted to stresses associated with both wet and dry conditions); however, facultative upland and wetland species have also been included. This is important because plants in bioretention areas will be exposed to varying levels of soil moisture and ponding throughout the year, ranging from high levels in the spring to potential drought conditions in the summer. All of the species listed in **Tables 3.11-7A - 3.11-7C** are commonly found growing in the Piedmont or Coastal Plain regions of Virginia as either native or ornamental species.

Recent research suggests an increase in the importance of the mulch layer and groundcover plant species in pollutant removal. The plant list in this standard will be expanded to include perennial flowering plants. A robust groundcover species with a thick mulch layer is recommended.

FIGURE 3.11 - 7
Grading Plan for Bioretention Basin



Designers considering species other than ones listed in **Tables 3.11-7A - 3.11-7C** should consult the following reference material on plant habitat requirements, and consider site conditions to ensure that alternative plant material will survive.

American Association of Nurserymen, Latest Edition. American Standard for Nursery Stock ASNI Z60, Washington, D.C.

Dirr, Michael A., 1975. Manual of Woody Landscape Plants, Stripes Publishing Company, Champagne, Illinois.

Hightshoe, G.L., 1988. Native Trees, Shrubs, and Vines for Urban and Rural America. Van Nostrand Reinhold, New York, New York.

Reed, P.B.Jr., 1988. National List of Species That Occur in Wetlands: Northeast. United States Fish and Wildlife Service, St. Petersburg Florida.

Reasons for exclusion of certain plants from bioretention areas include inability to meet the criteria outlined in **Tables 3.11-7A - 3.11-7C** (pollutant and metals tolerance, soil moisture and structure, ponding fluctuations, morphology, etc.). In addition, species that are considered invasive or not recommended by the Urban Design Section of the Maryland-National Capital Park and Planning Commission are not recommended (Prince George's County, 1989).

3. Site and Ecological Considerations

Each site is unique and may contain factors that should be considered before selecting plant species. An example **Plant Material Checklist** is provided in **Appendix 3E**. The checklist has been developed to assist the designer in identifying critical factors about a site that may affect both the plant material layout and the species selection.

Selection of plant species should also be based on site conditions and ecological factors. Site considerations include microclimate (light, temperature, wind), the importance of aesthetics, overall site development design and the extent of maintenance requirements, and proposed or existing buildings . Of particular concern is the increase in reflection of solar radiation from buildings upon bioretention areas. Aesthetics are critical in projects of high visibility. Species that require regular maintenance (shed fruit or are prone to storm damage) should be restricted to areas of limited visibility and pedestrian and vehicular traffic.

Interactions with adjacent plant communities are also critical. Nearby existing vegetated areas dominated by non-native invasive species pose a threat to adjacent bioretention areas. Proposed bioretention area species should be evaluated for compatibility with adjacent plant communities. Invasive species typically develop into monocultures by out competing other species . Mechanisms to avoid encroachment of undesirable species include increased maintenance, providing a soil breach between the invasive community for those species that spread through rhizomes, and providing annual removal of seedlings from wind borne seed dispersal. Existing disease or insect infestations associated with existing site conditions or in the general area that may effect the bioretention plantings.

4. Number of Species

A minimum of three species of trees and three species of shrubs should be selected to insure diversity. In addition to reducing the potential for monoculture mortality concerns, a diversity of trees and shrubs with differing rates of transpiration may ensure a more constant rate of evapotranspiration and nutrient and pollutant uptake throughout the growing season.

Herbaceous ground covers are important to prevent erosion of the mulch and the soil layers. Suitable herbaceous ground covers are identified in **Table 3.11-7C**.

5. Number and Size of Plants

The requisite number of plantings varies, and should be determined on an individual site basis. On average, 1000 trees and shrubs should be planted per acre. For example, a bioretention area measuring 15' x 40' would contain a combination of trees and shrubs totaling 14 individuals. The Prince Georges County recommended minimum and maximum number of individual plants and spacing are given in **Table 3.11-4.** Virginia jurisdictions with significant experience with bioretention prefer the simpler specification of 10 trees and shrubs per 1,000 square feet of basin area, with placement specified by a landscape professional to simulate natural conditions. Two to three shrubs should be specified for each tree (2:1 to 3:1 ratio of shrubs to trees).

At installation, trees should be 1.0 inches minimum in caliper, and shrubs 3 to 4 feet in height or 18 to 24 inches in spread per ASNI Z60. Ground cover may be as seed or, preferably, plugs. The relatively mature size requirements for trees and shrubs are important to ensure that the installation of plants are readily contributing to the bioretention process (i.e., evapotranspiration, pollutant uptake).

TABLE 3.11-5
Recommended Tree and Shrub Spacing

	Tree Spacing (feet)	Shrub Spacing (feet)	Total Density (stems/acre)
Maximum	19	12	400
Average	12	8	1000
Minimum	11	7	1250

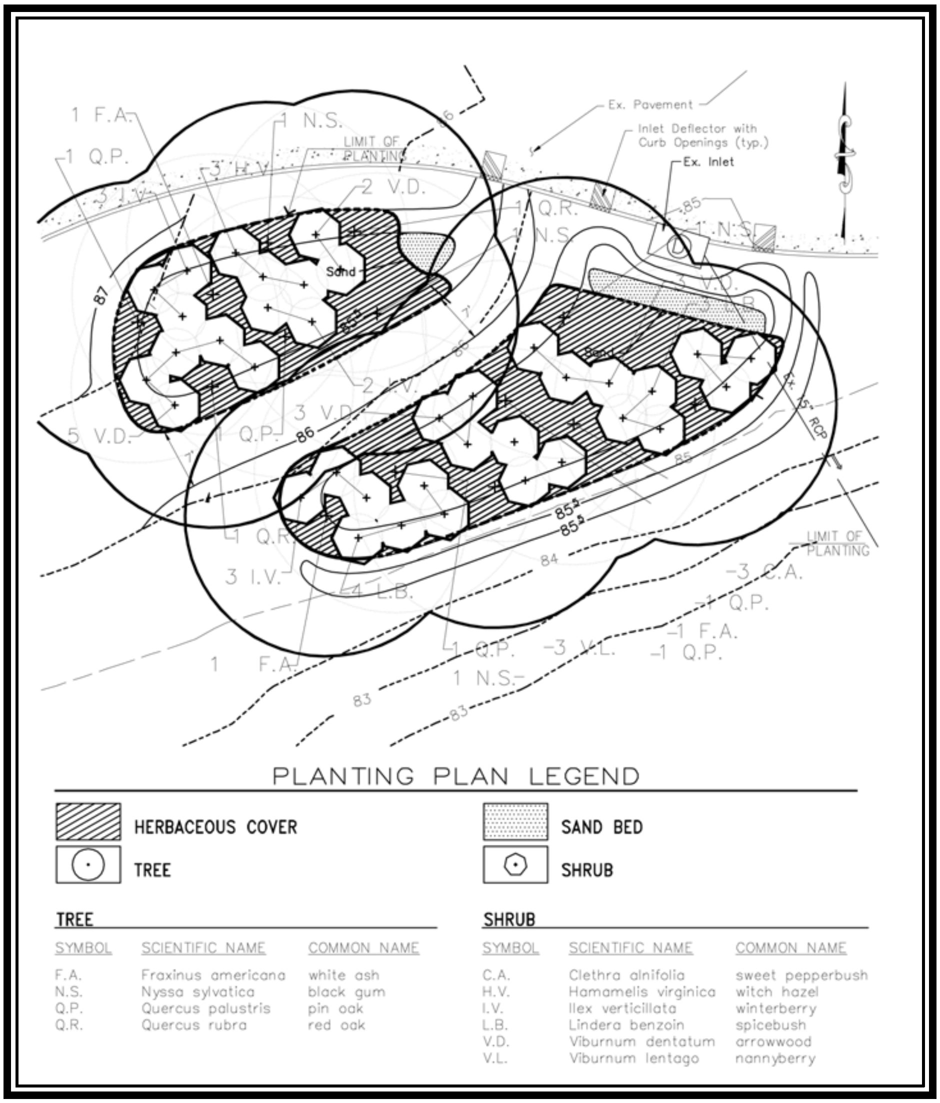
6. Plant Layout

The layout of plant material can be a flexible process; however, the designer should follow some basic guidelines. As discussed above, the designer should first review the Plant Checklist (Appendix D). The checklist table can help expose any constraints that may limit the use of a particular species and/or where a species can be installed.

There are two guidelines that should apply to all bioretention areas. First, woody plant material should not be placed within the immediate areas of where flow will be entering the bioretention area.

Besides possibly concentrating flows, trees and shrubs can be damaged as a result of the flow. Secondly, it is recommended that trees be planted primarily on the perimeter of bioretention areas, to maximize the shading and sheltering of bioretention areas to create a microclimate which will limit the extreme exposure from summer solar radiation and winter freezes and winds. An example planting plan is shown in **Figure 3.11-8**.

FIGURE 3.11 - 8
Sample Planting Plan



Planting Soil Guidelines

The characteristics of the soil play an important role in the improvement of water quality through the use of bioretention systems. The soil is a three-phase system composed of gas, liquid, and solid, each of which in the proper balance is essential to the pollutant removal achieved through bioretention. The soil anchors the plants and provides nutrients and moisture for plant growth. Microorganisms inhabit and proliferate within the soil solution, and the unsaturated pore space provides plant roots with the oxygen necessary for metabolism and growth.

A desirable planting soil would 1) be permeable to allow infiltration of runoff and 2) provide adsorption of organic nitrogen and phosphorus.

The recommended planting soil for bioretention would have the following properties:

1. Soil Texture and Structure

It is recommended that the planting soils for bioretention have a sandy loam, loamy sand, or loam texture. Experience in both Maryland and Virginia has indicated that the original soil specification contained in the Prince Georges County manual must be modified to decrease the clay content to **no more than five percent** to preclude premature failure of the basins due to clogging. Prince Georges County issued a design update in June 1998 in which the total depth of the facility is reduced to 2.5 feet by the elimination of the sand bed and the use of a soil media consisting of 50 percent sand, 20 percent leaf compost, and 30 percent topsoil. Virginia engineers with bioretention experience recommend using either the new Maryland media specification or a media of 50 percent sand and 50 percent hemic or fibric peat, using the Virginia topsoil thickness criteria in both cases, while retaining the sand bed. This could result in an overall thickness somewhat comparable to that specified in Maryland.

2. Soil Acidity

In a bioretention scheme, the desired soil pH would lie between 5.5 and 6.5 (Tisdale and Nelson, 1975). The soil acidity affects the ability of the soil to adsorb and desorb nutrients, and also affects the microbiological activity in the soil.

3. Soil Testing

The planting soil for bioretention areas must be tested prior to installation for pH, organic matter, and other chemical constituents. The soil should meet the following criteria (Landscape Contractors Association, 4th Addition, 1993):

pH range:	5.0 - 7.0
Organic matter:	Greater than 1.5
Magnesium (Mg):	100+ Units
Phosphorus (P_2O_5):	150+ Units
Potassium (K_2O):	120+ Units
Soluble salts:	not to exceed 900 ppm/.9 MMHOS/cm (soil)
	not to exceed 3,000 ppm/2.5 MMHOS/cm (organic mix)

It is recommended that one test for magnesium, phosphorus, potassium, and soluble salts be performed per borrow source or for every 500 cubic yards of soil material. It is recommended that a sieve analysis, pH, and organic matter test be performed per bioretention area.

4. Soil Placement

Placement of the planting soil in the bioretention area should be in lifts of 18 inches or less and lightly compacted. Minimal compaction effort can be applied to the soil by tamping.

Specifications for the planting soil are outlined below under **Construction Specifications**.

Mulch Layer Guidelines

Recent results of bioretention monitoring in Maryland has confirmed that the mulch layer plays a crucial role in the pollutant removal capabilities of the facility. This layer serves to prevent erosion and to protect the soil from excessive drying. Soil biota existing within the organic and soil layer are important in the filtering of nutrients and pollutants and assisting in maintaining soil fertility. Bioretention areas can be designed either with or without a mulch layer. If a herbaceous layer or ground cover (70 to 80% coverage) is provided, a mulch layer is not necessary. Areas should be mulched once trees and shrubs have been planted. Any ground cover specified as plugs may be installed once mulch has been applied.

The mulch layer recommended for bioretention may consist of either a standard landscape fine shredded hardwood mulch or shredded hardwood chips. Both types of mulch are commercially available and provide excellent protection from erosion.

Mulch shall be free of weed seeds, soil, roots, or any other substance not consisting of either bole or branch wood and bark. The mulch shall be uniformly applied approximately 2 to 3 inches in depth. Mulch applied any deeper than three inches reduces proper oxygen and carbon dioxide cycling between the soil and the atmosphere.

Grass clippings are unsuitable for mulch, primarily due to the excessive quantities of nitrogen built up in the material. Adding large sources of nitrogen would limit the capability of bioretention areas to filter the nitrogen associated with runoff.

Plant Material Guidelines

1. Plant Material Source

The plant material should conform to the current issue of the American Standard for Nursery Stock published by the American Association of Nurserymen. Plant material should be selected from certified nurseries that have been inspected by state or federal agencies. The botanical (scientific) name of the plant species should be in accordance with a standard nomenclature source such as Birr, 1975.

Some of the plant species listed in **Tables 3.11-7A - 3.11-7C**, Recommended Plant Species For Use in Bioretention may be unavailable from standard nursery sources. These are typically species native to Virginia and may not be commonly used in standard practices. Designers may need to contact nurseries specializing in native plants propagation.

2. Installation

The success of bioretention areas is dependent on the proper installation specifications that are developed by the designer and subsequently followed by the contractor. The specifications include the procedures for installing the plants and the necessary steps taken before and after installation. Specifications designed for bioretention should include the following considerations:

- Sequence of Construction
- Contractors Responsibilities
- Planting Schedule and Specifications
- Maintenance
- Warranty

The sequence of construction describes site preparation activities such as grading, soil amendments, and any pre-planting structure installation. It also should address erosion and sediment control procedures. Erosion and sediment control practices should be in place until the entire bioretention area is completed. The contractors responsibilities should include all the specifications that directly effect the contractor in the performance of his or her work. The responsibilities include any penalties for unnecessarily delayed work, requests for changes to the design or contract, and exclusions from the contract specifications such as vandalism to the site, etc.

The planting schedule and specifications include type of material to be installed (e.g., ball and burlap, bare root, or containerized material), timing of installation, and post installation procedures. Balled and burlapped and containerized trees and shrubs should be planted during the following periods: March 15 through June 30 and September 15 through November 15. Ground cover excluding grasses and legumes can follow tree and shrub planting dates. Grasses and legumes typically should be planted in the spring of the year. The planting of trees and shrubs should be performed by following the planting specifications set forth in **MS 3.05, Landscaping. MS 3.05** specifications provide guidelines that insure the proper placement and installation of plant material. Designers may choose to use other specifications or to modify the jurisdiction specifications. However, any deviations from the jurisdiction specifications need to address the following:

- transport of plant material
- preparation of the planting pit
- installation of plant material
- stabilization seeding (if applicable)
- maintenance

An example of general planting specification for trees and shrubs and ground cover is given under **Construction Specifications** below.

3. Warranties

Typically, a warranty is established as a part of any plant installation project. The warranty covers all components of the installation that the contractor is responsible for. The plant and mulch installation for bioretention should be performed by a professional landscape contractor. An example of standard guidelines for landscape contract work is provided below:

- The contractor shall maintain a one (1) calendar year 80% care and replacement warranty for all planting.
- The period of care and replacement shall begin after inspection and approval of the complete installation of all plants and continue for one calendar year.
- Plant replacements shall be in accordance with the maintenance schedule.

Plant Growth and Soil Fertility

A discussion of plant growth and soil fertility development over time is important to for estimating the success and lifespan of bioretention areas. The physical, chemical, and biological factors influencing plant growth and development will vary over time as well as for each bioretention area. However, there are certain plant and soil processes that will be the same for all bioretention areas.

1. Plant Growth

The role of plants in bioretention includes uptake of nutrients and pollutants and evapotranspiration of stormwater runoff. The plant material, especially ground covers, are expected to contribute to the evapotranspiration process within the first year of planting. However, trees and shrubs that have been recently planted demonstrate slower rates of growth for the first season due to the initial shock of transplanting. The relative rate of growth is expected to increase to normal rates after the second growth season.

The growth rate for plants in bioretention areas will follow a similar pattern to that of other tree and shrub plantings (reforestation projects, landscaping). For the first two years, the majority of tree and shrub growth occurs with the expansion of the plant root system. By the third or fourth year the growth of the stem and branch system dominates increasing the height and width of the plant. The comparative rate of growth between the root and stem and branch system remains relatively the same throughout the lifespan of the plant. The reproductive system (flowers, fruit) of the plants is initiated last.

The growth rates and time for ground covers to become acclimated to bioretention conditions is much faster than for trees and shrubs. The rate of growth of a typical ground cover can often exceed 100 percent in the first year. Ground covers are considered essentially mature after the first year of growth. The longevity of ground covers will be influenced by the soil fertility and chemistry as well as physical factors, such as shading and overcrowding from trees and shrubs and other ecological and physical factors.

Plants are expected to increase their contribution to the bioretention concept over time, assuming that growing conditions are suitable. The rate of plant growth is directly proportional to the environment in which the plant is established. Plants grown in optimal environments experience greater rates of growth. One of the primary factors determining this is soil fertility.

2. Soil Fertility

Initially, soil in bioretention areas will lack a mature soil profile. It is expected that over time discrete soil zones referred to as horizons will develop. The development of a soil profile and the individual horizons is determined by the influence of the surrounding environment including physical, chemical, and biological processes. Two primary processes important to horizon development is microbial action and the percolation of runoff in the soil.

Horizons expected to develop in bioretention areas include an organic layer, followed by two horizons where active leaching (eluviation) and accumulation (illuvation) of minerals and other substances occur. The time frame for the development of soil horizons will vary greatly. As an average, soil horizons may develop within three to ten years. The exception to this is the formation of the organic layer often within the first or second year (Brady, 1984).

The evaluation of soil fertility in bioretention may be more dependent on the soil interactions relative to plant growth than horizon development. The soil specified for bioretention is important in filtering pollutants and nutrients as well as supply plants with water, nutrients, and support. Unlike plants that will become increasingly beneficial over time, the soil will begin to filter the storm water runoff immediately. It is expected that the ability to filter pollutants and nutrients may decrease over time, reducing the soil fertility accordingly. Substances from runoff such as salt and heavy metals eventually disrupt normal soil functions by lowering the cation exchange capacity (CEC). The CEC, the ability to allow for binding of particles by ion attraction, decreases to the point that the transfer of nutrients for plant uptake can not occur. However, the environmental factors influencing each bioretention area will vary enough that it is difficult to predict for the lifespan of soils. Findings from other stormwater management systems suggest an accumulation of substances eliminating soil fertility within five years. The monitoring of soil development in bioretention areas will help develop better predictions on soil fertility and development.

Construction Specifications

The construction of bioretention basins should be in accordance with the following Minimum Specifications and Standards where applicable: **3.1: Earthen Embankments; 3.2: Principal Spillways; 3.3: Vegetated Emergency Spillways; 3.4: Sediment Forebays; 3.5: Landscaping; 3.10: General Infiltration Practices**, as well as the additional criteria set forth below. These specifications have been adapted from the Prince George's County, Maryland publication, ***Design Manual for Use of Bioretention in Stormwater Management***.

Sequence of Construction

The sequence of various phases of basin construction must be coordinated with the overall project construction. As with other infiltration practices, rough excavation of the basin may be scheduled with the rough grading of the project to permit use of the excavated material as fill elsewhere on the site. However, the bioretention basin must not be constructed or placed in service until the entire contributing drainage area has been stabilized. Runoff from untreated, recently constructed areas within the drainage area may otherwise load the newly formed basin with a large load of fine sediment, seriously impairing the natural infiltration ability of the basin floor. For these reasons, **the locations of infiltration bioretention basins must NOT be used for sediment basins for erosion and sediment protection during site construction.** The sequence of construction shall be as follows:

1. Install Phase I erosion and sediment control measures for the site.

2. Grade each site to elevations shown on plan. Initially, the basin floor may be excavated to within one foot of its final elevation. Excavation to finished grade shall be deferred until all disturbed areas within the watershed have been stabilized and protected. Construct curb openings, and/or remove and replace existing concrete as specified on the plan. Curb openings shall be blocked or other measures taken to prohibit drainage from entering construction area.

3. Complete construction on the watershed and stabilize all areas draining to the Bioretention basin.

4. Remove Phase I sediment control devices at direction of designated inspector.

5. Install Phase II erosion and sediment control measures for bioretention area.

6. Remove all accumulated sediment and excavate Bioretention Area to proposed depth. Use relatively light, tracked equipment to avoid compaction of the basin floor. After final grading is completed, deeply till the basin floor with rotary tillers or disc harrows to provide a well-aerated, highly porous surface texture.

7. Install the infiltration chambers, piping, manifolds, drains, vents, and infiltration stone in accordance in with the specifications and directions of the chamber manufacturer. Install a six-inch layer of washed, 1/4-inch pea gravel above the stone. Install a 1-foot layer of ASTM C-33 concrete sand on top of the pea gravel. Lightly compact with a landscaping roller.

8. After confirmation that soil meets specs by performing the requisite gradation and chemical tests (see below), fill Bioretention Area with planting soil and sand, as shown in the plans and detailed in the specifications.

9. Install vegetation and ground cover specified in the planting plan for Bioretention Area.

Install mulch layer if called for in the design.

10. Place sod, EC fabric, or non erosive lining (depending on inflow velocities) in the inlet channel and/or filter strips.

11. Upon authorization from designated inspector, remove all sediment controls and stabilize all disturbed areas. Unblock curb openings, and provide drainage to the Bioretention Areas.

Bioretention Area Soil Specifications

1. Planting Soil

The bioretention areas shall contain a planting soil mixture of 50% sand, 30% leaf compost (fully composted, NOT partially rotted leaves), and 20% topsoil. Topsoil shall be sandy loam or loamy sand of uniform composition, containing no more than 5% clay, free of stones, stumps, roots, or similar objects greater than one inch, brush, or any other material or substance which may be harmful to plant growth, or a hindrance to plant growth or maintenance.

The top soil shall be free of plants or plant parts of Bermuda grass, Quack grass, Johnson grass, Mugwort, Nutsedge, Poison Ivy, Canadian Thistle or others as specified. It shall not contain toxic substances harmful to plant growth.

The top soil shall be tested and meet the following criteria:

pH range:	5.0 - 7.0
Organic matter:	Greater than 1.5
Magnesium (Mg):	100+ Units
Phosphorus (P_2O_5):	150+ Units
Potassium (K_2O):	120+ Units
Soluble salts:	not to exceed 900 ppm/.9 MMHOS/cm (soil) not to exceed 3,000 ppm/2.5 MMHOS/cm (organic mix)

The following testing frequencies shall apply to the above soil constituents:

pH, Organic Matter: 1 test per 90 cubic yards, but no more than 1 test per Bioretention Area

Magnesium, Phosphorus, Potassium, Soluble Salts:

1 test per 500 cubic yards, but no less than 1 test per borrow source

One grain size analysis shall per performed per 90 cubic yards of planting soil, but no less than 1 test per Bioretention Area. Soil tests must be verified by a qualified professional.

2. Mulch

A mulch layer shall be provided on top of the planting soil. An acceptable mulch layer shall include shredded hardwood or shredded wood chips or other similar product.

Of the approved mulch products all must be well aged, uniform in color, and free of foreign material including plant material.

3. Sand

The sand for bioretention basins when utilized, shall be ASTM C-33 Concrete Sand and free of deleterious material.

4. Compaction

Soil shall be placed in lifts less than 18 inches and lightly compacted (minimal compactive effort) by tamping or rolled with a hand-operated landscape roller.

Bioretention Area Planting Specifications

1. Root stock of the plant material shall be kept moist during transport from the source to the job site and until planted.

2. Walls of planting pit shall be dug so that they are vertical.

3. The diameter of the planting pit must be a minimum of six inches (6") larger than the diameter of the ball of the tree.

4. The planting pit shall be deep enough to allow 1/8 of the overall dimension of the root ball to be above grade. Loose soil at the bottom of the pit shall be tamped by hand.

5. The appropriate amount of fertilizer is to be placed at the bottom of the pit (see below for fertilization rates).

6. The plant shall be removed from the container and placed in the planting pit by lifting and carrying the plant by its' ball (never lift by branches or trunk).

7. Set the plant straight and in the center of the pit so that approximately 1/8 of the diameter of the root ball is above the final grade.

8. Backfill planting pit with existing soil.

9. Make sure plant remains straight during backfilling procedure.

10. Never cover the top of the ball with soil. Mound soil around the exposed ball.

11. Trees shall be braced by using 2" by 2" white oak stakes. Stakes shall be placed parallel to walkways and buildings. Stakes are to be equally spaced on the outside of the tree ball. Utilizing hose and wire the tree is braced to the stakes.

12. Because of the high levels of nutrients in stormwater runoff to be treated, bioretention basin plants should not require chemical fertilization.

Maintenance/Inspection Guidelines

The following maintenance and inspection guidelines are not intended to be all inclusive. Specific Facilities may require additional measures not discussed here.

A schedule of recommended maintenance for bioretention areas is given in **Table 3.11-5**. The table gives general guidance regarding methods, frequency, and time of year for maintenance.

Planting Soil

Urban plant communities tend to become very acidic due to precipitation as well as the influences of storm water runoff. For this reason, it is recommended that the application of alkaline, such as limestone, be considered once to twice a year. Testing of the pH of the organic layer and soil, should precede the limestone application to determine the amount of limestone required.

Soil testing should be conducted annually so that the accumulation of toxins and heavy metals can be detected or prevented. Over a period of time, heavy metals and other toxic substances will tend to accumulate in the soil and the plants. Data from other environs such as forest buffers and grass swales suggest accumulation of toxins and heavy metals within five years of installation. However, there is no methodology to estimate the level of toxic materials in the bioretention areas since runoff, soil, and plant characteristics will vary from site to site.

As the toxic substances accumulate, the plant biologic functions may become impaired, and the plant may experience dwarfed growth followed by mortality. The biota within the soil can also become void and the natural soil chemistry may be altered. The preventative measures would include the removal of the contaminated soil. In some cases, removal and disposal of the entire soil base as well as the plant material may be required.

Mulch

Bioretention areas should be mulched once the planting of trees and shrubs has occurred. Any ground cover specified as plugs may be installed once the area has been mulched. Ground cover established by seeding and\or consisting of grass should not be covered with mulch.

Plant Materials

An important aspect of landscape architecture is to design areas that require little maintenance. Certain plant species involve maintenance problems due to dropping of fruit or other portions of the plant. Another problem includes plants, primarily trees, that are susceptible to windthrow, which creates a potential hazard to people and property (parked cars). As a result, some plant species will be limited to use in low-traffic areas.

Ongoing monitoring and maintenance is vital to the overall success of bioretention areas. Annual maintenance will be required for plant material, mulch layer, and soil layer. A maintenance schedule should include all of the main considerations discussed below. The maintenance schedule usually includes maintenance as part of the construction phase of the project and for life of the design. A example maintenance schedule is shown in **Table 3.11-6**.

Maintenance requirements will vary depending on the importance of aesthetics. Soil and mulch layer maintenance will be most likely limited to correcting areas of erosion. Replacement of mulch layers may be necessary every two to three years. Mulch should be replaced in the spring. When the mulch layer is replaced, the previous layer should be removed first. Plant material upkeep will include addressing problems associated with disease or insect infestations, replacing dead plant material, and any necessary pruning.

Control of Sediments on the Drainage Shed

Care must be taken to protect the bioretention basin from excessive sediments from the drainage shed. Whenever additional land disturbing activity takes place in the area draining to the basin, effective erosion and sediment control measures must first be put in place to exclude sediments from the basin. Performance based special measures over and above those specified in the ***Virginia Erosion and Sediment Control Handbook***, latest edition, may be required to assure that the bioretention basin is not damaged by such land disturbance. When sand or other street abrasives are used during the snow or icing conditions to provide traction on roadways or parking lots draining to bioretention basins, the pavement should be power/vacuum swept as soon as freezing weather abates to prevent damage to the basins.

Checklists

The Construction Inspection and As-Built Checklist provided in **Appendix 3E** is for use in inspecting bioretention basins during construction, and where required by local jurisdiction, engineering certification of the basin construction. The Operation and Maintenance Inspection Checklist, also found in **Appendix 3E**, is for use in conducting maintenance inspections of bioretention basins.

TABLE 3.11 - 6
Example Maintenance Schedule for Bioretention Basin

Description	**Method**	**Frequency**	**Time of the year**
SOIL			
Inspect and Repair Erosion	Visual	Monthly	Monthly
ORGANIC LAYER			
Remulch any void areas	By hand	Whenever needed	Whenever needed
Remove previous mulch layer before applying new layer (optional)	By hand	Once every two to three years	Spring
Any additional mulch added (optional)	By hand	Once a year	Spring
PLANTS			
Removal and replacement of all dead and diseased vegetation considered beyond treatment	See planting specifications	Twice a year	3/15 to 4/30 and 10/1 to 11/30
Treat all diseased trees and shrubs	Mechanical or by hand	N/A	Varies, depends on insect or disease infestation
Watering of plant material shall take place at the end of each day for fourteen consecutive days after planting has been completed	By hand	Immediately after completion of project	N/A
Replace stakes after one year	By hand	Once a year	Only remove stakes In the spring
Replace any deficient stakes or wires	By hand	N/A	Whenever needed
Check for accumulated sediments	Visual	Monthly	Monthly

MINIMUM STANDARD 3.11A

BIORETENTION FILTERS

Definition

Bioretention basins that rely on infiltration (**MINIMUM STANDARD 3.11: BIORETENTION BASINS**) may not be feasible in many ultra-urban settings because of the proximity of building foundations or because soils are not conducive to exfiltration from the basin. **Bioretention Filters** were developed for use in such circumstances.

Bioretention soil media filters are essentially bioretention basins with the infiltration chamber gallery equipped with a permanent and continuous connection to the storm sewer system. The bioretention basin shown in **Figure 3.11A-1** illustrates a bioretention basin equipped to function as a filter.

When used in areas underlain by marine clays or in proximity to building foundations, the entire basin must be provided with a dense clay or geomembrane liner. When the filter concept must be used simply because of low percolation rates of the soil, the liner may be omitted. The vertical sand column is also optional on a bioretention filter.

Purpose

Water Quality Enhancement

Like bioretention basins, bioretention filters are used primarily for water quality control. Bioretention filters enhance the quality of stormwater runoff through the processes of adsorption, filtration, volitization, ion exchange, microbial and decomposition prior to collection of the treated effluent in the collector pipe system. Microbial soil processes, evapotranspiration, and nutrient uptake in plants also come into play (Bitter and Bowers, 1995). The manner in which these processes work is discussed under **MINIMUM STANDARD 3.11, BIORETENTION BASINS**. The minimum widths and lengths for bioretention basins (10' and 15', respectively) also apply to bioretention filters. However, since runoff will be treated faster in a bioretention filter, it may be pooled to a maximum depth of 1 foot above the basin floor rather than the 0.5 feet allowed in a bioretention basin. **Table 3.11A-1** contains the target removal efficiencies for bioretention filters in which a **mature** forest community has been created, based on the volume of runoff to be filtered.

FIGURE 3.11A-1
Bioretention Filter

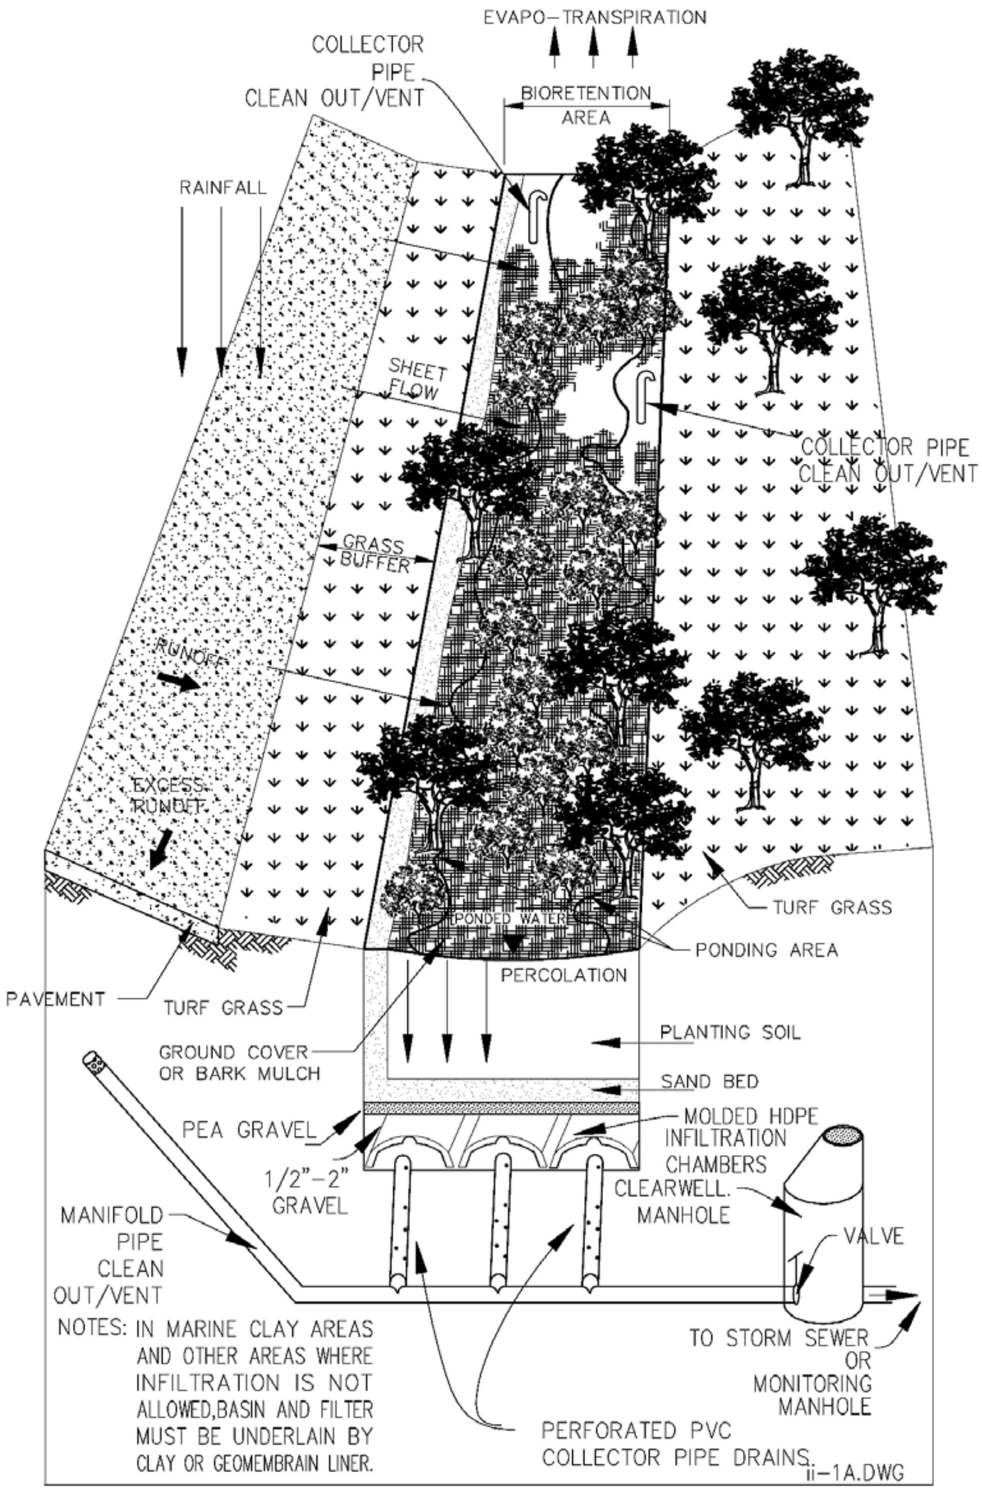

TABLE 3.11A - 1
Pollutant Removal Efficiencies for Bioretention Filters

BMP Description	Target Pollutant Removal Efficiency (Phosphorous)
Bioretention filter with capture and treatment volume equal to 0.5 inches of runoff from the impervious area.	50%
Bioretention filter with capture and treatment volume equal to 1.0 inches of runoff from the impervious area.	65%

Flood Control and Channel Erosion Control

The amount of flood and channel erosion control protection provided by bioretention basins depends on the local rainfall frequency spectrum, the amount of pre-development (or pre-redevelopment) impervious cover, the amount of post-development impervious cover, and the volume of runoff captured and infiltered by the basin(s). The effect of the BMPs on peak flow rates from the drainage shed must be examined As with other infiltration practices, bioretention basins tend to reverse the consequences of urban development by reducing peak flow rates and providing groundwater discharge.

Conditions Where Practice Applies

Bioretention Filters are generally suited for almost all types of development, from single-family residential to fairly high density commercial projects. They are attractive for higher density projects because of their relatively high removal efficiency. The critical prerequisite is the existence of a deep enough storm sewer to accept drainage from the collector pipe system by gravity flow. All of the applications shown in **Figures 3.11-2** through **3.11-6** under **MS 3.11** may be built as bioretention filters. As with bioretention basins, for large applications, several connected bioretention filters (another type of "Green Alleys") are preferable to a single, massive filter. Such systems are especially desirable along the landward boundary of reduced Chesapeake Bay Resource Protection Areas. **MS 3.11B** discusses this system. Considering the character of bioretention basins, some jurisdictions may qualify them as buffer restoration.

Planning Considerations

Site Conditions

Except for those dealing with proper soils to accept infiltration and sizing of the filters, all of the **Site Conditions** considerations for bioretention basins contained in **MINIMUM STANDARD 3.11: BIORETENTION BASINS** also apply to bioretention filters. The same drainage area range applies, as do the same **Location Considerations.** In addition to site conditions, the following apply specifically to bioretention filters.

1. Sizing Guidelines

For planning purposes, assume that the floor area of a bioretention filter will be 2.5% of the impervious area draining to the filter if 0.5 inches of runoff are to be treated and 5.0% of the impervious area on the drainage shed if the first 1.0 inches of runoff are to be treated.

2. Aesthetic Considerations

All of the discussion of aesthetics under **MINIMUM STANDARD 3.11: BIORETENTION BASINS** apply equally to bioretention filters. Overall aesthetics of the bioretention filters must be integrated into the site plan and stormwater concept plan from their inception. Biomorphic shapes which follow the ground contours should be used rather than angular shapes. The bioretention filter should be essentially almost invisible upon completion, blending in with the other landscaping of the site. Both the stormwater engineer and the landscaping planner must participate in the layout of the facilities and infrastructure to be placed on the site.

Sediment Control

All of the **Sediment Control** considerations for bioretention basins under **MS 3.11: Bioretention Basins** also apply to bioretention filters.

Like bioretention basins, bioretention filters should be constructed only AFTER the site work is complete and stabilization measures have been implemented. Experience with bioretention basins and soil media filters has demonstrated that bioretention filters must be protected from all sediment loads.

Bioretention filters must retain sediment control protection until stabilization of the upland site is functional to control the sediment load from denuded areas. Provisions to bypass the stormwater away from the bioretention filter during the stabilization period must be implemented.

General Design Criteria

The purpose of this section is to provide minimum criteria for the design of bioretention filter BMPs intended to comply with the Virginia Stormwater Management program's runoff quality requirements. Bioretention filters which capture and treat the first one inch of runoff from impervious surfaces may also provide streambank erosion protection.

General

The design of bioretention filters should be in accordance with the following Minimum Standards where applicable: **3.1: Earthen Embankments, 3.2: Principal Spillways, 3.3: Vegetated Emergency Spillways, 3.4: Sediment Forebay,** as well as the additional criteria set forth below. The designer is not only responsible for selecting the appropriate components for the particular design but also for ensuring long-term operation.

Integration of the bioretention filters into the general landscaping scheme of the project must be coordinated with the landscaping professional at the inception of the design process. Use of such techniques as biomorphic shapes to present a pleasing aesthetic appearance is of equal importance with hydrological and hydraulic functioning of the basins. Properly designed bioretention filters should not be readily identifiable as stormwater BMPs by the lay observer.

Basin Sizing Methodology

In Virginia, bioretention filters are designed to filter the treatment quantity into the underlying gravel bed and collector pipe system. **Bioretention filters are sized using the same sizing methodology as that of bioretention basins**.

The elevation of the overflow structure should be 1.0 feet above the elevation of the bioretention bed.

The **Runoff Pretreatment, Drainage Considerations**, and **Exclusion of Continuous Flows and Chlorinated Flows** considerations of **MINIMUM STANDARD 3.11: BIORETENTION BASINS**, are also applicable to bioretention filters. If the filter soil remains constantly wet, anaerobic conditions will develop, which will kill the plants and cause iron phosphates which have been previously captured to break down and escape into the effluent.

Continuous or frequent flows (such as basement sump pump discharges, cooling water, condensate water, artesian wells, etc.) and flows containing swimming pool and sauna chemicals must be EXCLUDED from routing through bioretention or bioretention filter BMPs since such flows will cause the BMP to MALFUNCTION!

The **Planting Plan, Planting Soil Guidelines, Mulch Layer Guidelines, Plant Material Guidelines, Plant Growth and Soil Fertility** criteria of **MINIMUM STANDARD 3.11: BIORETENTION BASINS**, also apply to bioretention filters.

Basin Liners

Impermeable liners may be either clay, concrete or geomembrane. If geomembrane is used, suitable geotextile fabric shall be placed below and on the top of the membrane for puncture protection. Clay liners shall meet the specifications in **Table 3.11A-2**.

The clay liner shall have a minimum thickness of 12 inches.

If a geomembrane liner is used it shall have a minimum thickness of 30 mils and be ultraviolet resistant.

The geotextile fabric (for protection of geomembrane) shall meet the specifications in **Table 3.11A-3**.

TABLE 3.11A - 2
Clay Liner Specifications (Source: City of Austin)

Property	Test Method	Unit	Specification
Permeability	ASTM D-2434	Cm/Sec	1 x 10^{-6}
Plasticity Index of Clay	ASTM D-423 & D-424	%	Not less than 15
Liquid Limits of Clay	ASTM D-2216	%	Not less than 30
Clay Compaction	ASTM-2216	%	95% of Standard Proctor Density
Clay Particles Passing	ASTM D-422	%	Not less than 30

TABLE 3.11A - 3
Geotextile Specification for Basin Liner "Sandwich"

Property	Test Method	Unit	Specification
Unit Weight		Oz./Sq.Yd.	8 (minimum)
Filtration Rate		In./Sec.	0.08 (minimum)
Puncture Strength	ASTM D-751 (Modified)	Lb.	125 (minimum)
Mullen Burst Strength	ASTM D-751	Psi.	400 (minimum)
Tensile Strength	ASTM D-1682	Lb.	300
Equiv. Opening Size	U.S. Standard Sieve	No.	80 (minimum)

Source: City of Austin

Equivalent methods for protection of the geomembrane liner will be considered on a case by case basis. Equivalency will be judged on the basis of ability to protect the geomembrane from puncture, tearing and abrasion.

When molded chambers are incorporated into the design, a minimum of four inches of gravel or crushed stone should be added beneath the molded chambers or other conveyance system to allow settling of filter fines into the voids. As with bioretention basins, filter strips, grassed channels, and side slopes should be sodded with mature sod, and planting soil should be wrapped up the side slopes under the sod.

All other factors dealing with bioretention filters are identical to those for bioretention basins in general, **M.S.3.11.**

MINIMUM STANDARD 3.11B

GREEN ALLEYS

Definition

Green Alleys consist of a network of bioretention basins/infiltration trenches or bioretention filters that provide both redundant water quality management and stormwater conveyance to stormwater management facilities. They create a carefully landscaped green border along, or a dividing corridor through, a development site. Unless otherwise noted, the information on Green Alleys in this section was provided by Keith Bowers of Biohabitats, Inc.

Green Alleys combine the redundancy of multiple stormwater quality BMPs and stormwater conveyance with urban and suburban site design features. Using bioretention, infiltration, and filtration as a foundation, Green Alleys consist of an above ground and below ground green ribbon of interconnecting BMPs that treat the first flush of stormwater while conveying excess runoff to management facilities. While Green Alleys provide an ecosystem based stormwater management technique, they also connect and facilitate the awareness of natural ecologic and hydrologic cycles.

Above ground, Green Alleys consist of a strip (greenway) consisting of native trees, schrubs, and groundcover that replicates native forest ecosystems and landscape processes to enhance sormwater quality. Green Alleys can also consist of a mixture of hardscape and landscape incorporating such features as walkways, urban plazas, open spaces, and streetscapes. Below ground, Green Alleys consist of sand filters and infiltration trenches that are connected by a series of perforated and solid pipes or molded plastic infiltration galleries that convey excess stormwater to quantity management facilities.

Purpose

Like bioretention basins and bioretention filters, green alleys are used primarily for water quality control. A number of other benefits may also accrue from green alleys. They provide redundancy in the number of treatment techniques and, except where precluded by soil conditions, some opportunity for infiltration even where filters are used; they may reinforce the visual and physical connection between the urban environment and the surrounding natural features; they may provide a greenway corridor (hedgerow) for wildlife habitat and/or pedestrian circulation; they may provide a green buffer between different land uses; and the system continues to function even if individual parts fail.

Water Quality Enhancement

As with other bioretention facilities, the treatment volume is managed and treated through microbial action and soil chemestry (nutrient cycling), evaportransporation, adsorption, and, where applicable, soîl infiltration. The manner in which these processes work is discussed under **MINIMUM STANDARD 3.11, BIOTETENTION BASINS.** **Table 3.11B-1** provides pollutant removal efficiencies for Green Alleys based on the volume of water to be treated.

TABLE 3.11B - 1
Pollutant Removal Efficiencies for Green Alleys

BMP Description	Target Pollutant Removal Efficiency (Phosphorous)
Green Alleys with capture and treatment volume equal to 0.5 inches of runoff from the impervious area.	50%
Green Alleys with capture and treatment volume equal to 1.0 inches of runoff from the impervious area.	65%

Flood Control and Channel Erosion Control

The amount of flood and channel erosion control provided by Green Alleys depends on the local rainfall frequency spectrum, the amount of pre-development (or pre-redevelopment) impervious cover, the amount of post-development impervious cover, and the volume of runoff captured and infiltered by the basin(s). The effect of the BMPs on peak flow rates from the drainage shed must be examined. As with other infiltration practices, bioretention basins tend to reverse the consequences of urban development by reducing peak flow rates and providing groundwater discharge.

Conditions Where Practice Applies

Green Alleys are generally suited for almost all types of development, from single-family residential to fairly high density commercial projects. They are attractive for higher density projects because of their relatively high removal eccifiency. The critical prerequisite is the existence of a deep enough storm sewer to accept drainage from the collector pipe system by gravity flow. All of the applications shown in **Figures 3.11-2** through **3.11-6** under **MS 3.11** may be built as bioretention filters.

Planning Considerations

Stormwater Management Concept Plan

Like all bioretention facilities, Green Alleys must be planned within the context of an overall stormwater management concept plan which addresses potential flooding and streambank erosion protection as well as water quality. This concept plan must be developed very early in the planning process to assure that sufficient space in the proper hydrological and hydraulic locations is reserved for stormwater management facilities. Minimum information necessary to develop a stormwater concept plan includes: existing and proposed drainage areas, size and capacity of downstream drainage conveyances, soils stidies, existing vegetation, and hydrographic features such as streams, floodplains, and wetlands, boundaries of Chesapeake Bay Preservation Resource Protection Areas. The plan must address the proposed location of areas of impervious cover on the site, the methods for collection and conveyance of runoff to an adequate channel or conduit, proposed detention facilities to address streambank erosion and potential flooding, and the proposed methods of providing quality treatment of the runoff.

Site Conditions

The **Site Conditions** considerations for for bioretention basins contained in **MINIMUM STANDARD 3.11: BIORETENTION BASINS** and **MS 3.11A: Bioretention Filters**, apply to Green Alleys which employ these BMPs. The same drainage area range applies, as do the same **Location Considerations.** In addition to site conditions, the following apply specifically to bioretention basins.

All other considerations for **M.S. 3.11, Bioretention Basins**, apply to Green Allies.

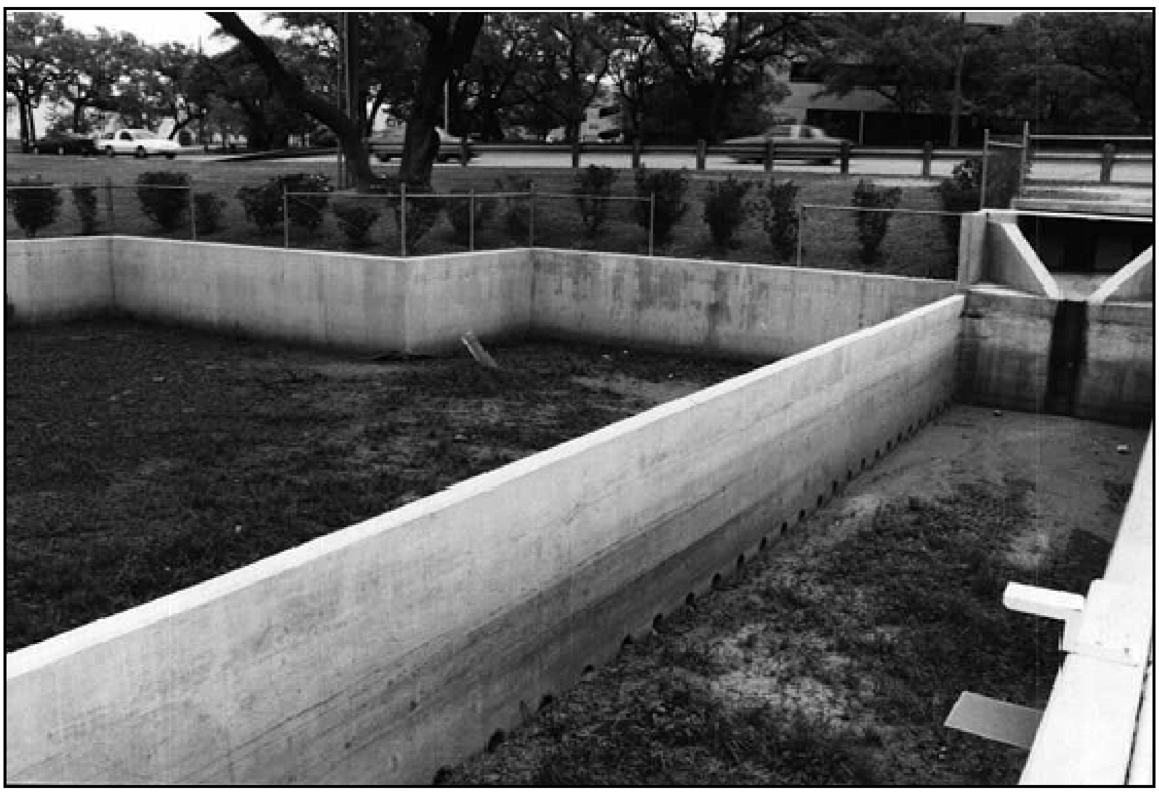
GENERAL INTERMITTENT SAND FILTER PRACTICES

Definition

Intermittent sand filter facilities capture, pretreat to remove sediments, store while awaiting treatment, and treat to remove pollutants (by percolation through sand media) the most polluted stormwater (the water quality volume) from a site. Intermittent sand filter BMPs may be constructed in underground vaults, in paved trenches within or at the perimeter of impervious surfaces, or in either earthen or concrete open basins. They have been successfully used in Austin Texas, the District of Columbia, The State of Delaware, and in Alexandria, Virginia over the last two decades. **Figure 3.12-1** is a photograph of a sand filter BMP in Austin.

FIGURE 3.12 - 1
Austin Partial Sedimentation Surface Sand Filter



(Photo Courtesy of City of Austin, Texas)

Purpose

Intermittent sand filter facilities are primarily used for water quality control. However, they do provide detention and slow release of the water quality volume from the site being treated. Whether this amount will be sufficient to provide the necessary peak flow rate reductions required for channel erosion control is dependent upon site conditions (hydrology) and required discharge reductions. The 10-year and 100-year flows will usually exceed the detention capacity of a sand media filter. When this occurs, separate quantity facilities must be provided. Table 3.12-1 contains the target removal efficiencies of sand and other soil media filter BMPs. Table 3.12-2 contains the results of an extensive sand filter monitoring study in Alexandria conducted for the Chesapeake Bay Local Assistance Department (Bell, Stokes, Gavan, and Nguyen, 1995).

Pollutant Removal Mechanisms at Work in Intermittent Sand Filter BMPs

Pollutant removal processes at work in intermittent sand filters are complex and involve physical, chemical, and biological transformations (Tchobanoglous and Burton, 1991; Anderson, Siegrist, and Otis, Undated). The most obvious mechanism is physical straining of suspended solids and particulate nutrients.

Suspended Solids

Mechanical straining, straining due to chance contact, and sedimentation are the principal mechanisms by which suspended solids are removed, although the growth of bacterial colonies within the sand grains may also cause autofiltration (Tchobanoglous and Burton, 1991).

Table 3.12-2

<u>Phosphorous</u>

Phosphorous removal is performed by physiochemical processes such as mechanical and chance contact straining, precipitation, and adsorption (Piluk and Hao, 1989; Laak, 1986).

There are three general types of adsorption (the condensation and concentration of ions or molecules of one material [the adsorbate] on the surface of another [the adsorbent]): physical, chemical, and exchange. Physical adsorption results from the weak forces of attraction between molecules and is generally quite reversible. Chemical adsorption results from much stronger forces comparable to those leading to the formation of chemical compounds, with the adsorbed material forming a one molecule thick layer over the surface of the absorbent until the capacity of the absorbent is exhausted. Chemical adsorption is seldom reversible. Exchange adsorption, on the other hand, results from electrical attraction between the adsorbate and the surface, such as occurs with ion exchange. Ions of the adsorbate concentrate on the surface of the adsorbent as a result of electrical attraction to opposite charges on the surface. It is sometimes difficult to assign a given adsorption to a specific type (Sawyer, Mcarty, and Parkin, 1994).

Although exchange adsorption may also be involved, most adsorption in intermittent sand filters appears to be chemical adsorption (Piluk and Hao, 1989; Otis, Undated; Anderson, Siegrist, and Otis, Undated).

In addition to the **filter mass available**, the adsorption of phosphorous in sand filters is also affected by the pH of the material being filtered (with higher removal rates occurring with the reduction of pH), temperature, contact time, and the character of the filter media (Laak, 1986). Sands containing iron, aluminum, or calcium have a higher phosphorous removal potential because phosphorous will combine with these elements through chemical precipitation and become relatively insoluble (Laak, 1986, Tchobanoglous and Burton, 1991). If the filter becomes anaerobic, the bonding with iron may break down, releasing orthophosphates (Harper and Herr, 1993). However, aerobic filters enriched with iron may attain almost complete phosphorous removal until the filter capacity is exhausted, and properly sized filters may have a life of up to 20 years (Laak, 1986). Sand particles with sufficient iron content may become positively charged, leading to more favorable medium-particle interactions and increased removal rates (Stenkamp and Benjamin, 1994). Entrapment in the filter of a high percentage of the iron in the runoff being treated may provide a source to replenish used up phosphorous adsorption capacity.

<u>Nitrogen and Biochemical Oxygen Demand</u>

Mineralization of organic nitrogen into ammonium (NH^{+}_{4}) may occur under either aerobic or anaerobic conditions if the required naturally occurring chemoautotrophic bacteria (organisms which obtain energy by oxidizing simple chemical compounds) are present (*Nitrosomonas, Nitrosococcus, Nitrospira, Nitrosolobus, Nitrososovibrio*) ((Laak, 1986; The Cadmus Group, 1991).

Organic N 6 Bacterial enzymes 6 NH_4^+ + other products

Positively charged ammonium ions are then adsorbed to negatively charged sand filter particles through exchange adsorption (The Cadmus Group, 1991).

The transformation of ammonia (NH_3) and ammonium into nitrite and nitrate (NO_2^- and NO_3^-) and the removal of BOD_5 occur under aerobic conditions by microorganisms (such as *Nitrosomonas* and *Nitrobacter*) present in the sand bed (Tchobanoglous and Burton, 1991;, Laak, 1991; The Cadmus Group, 1991).

$NH_4^+ + 1.5O_2$ 6 *Nitrosomonas*, etc 6 $NO_2^- + 2H + H_2O$ + Energy

$NO_2^- + 0.5O_2$ 6 *Nitrobacter* 6 NO_3^- + Energy

Since nitrite and nitrate are soluble anions, they are not affected by the cation exchange complex of the filter, but rather tend to leach readily to the filter effluent (Gold, Lamb, Loomis, and McKiel, Undated). However, anaerobic microenvironments (sometimes called "microsites") routinely coexist in principally aerobic intermittent sand filters (Tchobanoglous and Burton,1991; Gold, Lamb, Loomis, and McKiel, Undated). Naturally occurring anaerobic bacteria (*Pseudomonas, Micrococcus*, *Achromobacter*, *Bacilluss*) in these pockets may convert much of the nitrite into nitrate and the nitrate to nitrogen gas, resulting in total nitrogen removal in intermittent sand filters ranging up to 45-50 percent (Tchobanoglous and Burton, 1991; Laak, 1986; Ronayne, Paeth, and Osborne, Undated).

NO_3^- + Organic Carbon 6 Denitrifying bacteria 6 $N_2 + H_2O + CO_2$ + Cells

Organic carbon must be present for denitrification to occur, but low organic carbon/nitrogen rations will suffice (1:2 or less) (Laak, 1986, p.62). Some studies indicate that optimal denitrification occurs at ratios of 1:1-3:1 (Gold, et al, p.298). The maximum rate of denitrification occurs at temperatures above 10 degrees C and at a pH above 5.5, with the optimum pH range falling between 7.0 and 8.0. (The Cadmus Group, 1991, p.11). However, home wastewater systems have demonstrated excellent denitrification performance when the wastewater temperature was as low as 4 degrees C (Piluk and Hoa, 1989).

Heavy Metals

More than 70 percent of heavy metals in stormwater runoff is in particulate form (Harper and Herr, 1993). Over 70 percent of particulate heavy metals are of greater than 104 microns in size (Shaver and Baldwin, 1990). Particle settling in presettling basins and mechanical straining appear to be the principal mechanism for removing heavy metals in stormwater intermittent sand filter systems. Some iron may be removed by reacting with phosphorous in the runoff being treated.

Hydrocarbons

Mechanical straining and physical adsorption appear to be the mechanisms removing hydrocarbons which reach the sand filter.

Conditions Where Practice Applies

Intermittent sand filters are suitable for use in ultra-urban settings with a high degree of imperviousness where the land cost or loss of economic return on real estate required to construct retention basins may be prohibitive. They are generally suited for high pollutant removal on medium to high density development (65 to 100% impervious cover). Specific conditions such as drainage area size and development conditions are discussed with each type of intermittent sand filter. Because they are subject to failure by clogging, intermittent sand filters are not recommended for use on watersheds where sediment loadings can be significant. Wherever possible, their use should be limited to treating runoff from impervious surfaces. Most of the practices discussed below are designed to treat runoff from watersheds with at least 65% impervious cover. Where other runoff must be treated, sediment protection must be increased to severely curtail the sediment load reaching the filter media.

Planning Considerations

Site Conditions

1. ***Size and Topography of the Site***

Some types of intermittent sand filter BMPs are especially suited to larger drainage sheds, while others have upper size limits on their effective use. **Table 3.12-3** outlines drainage shed size applications of various types of intermittent sand filter facilities. On larger sites with multiple drainage sheds, a variety of BMPs might prove to be most cost effective.

TABLE 3.12 - 3
Appropriate Intermittent Sand Filter Applications to Various Site Areas

Type of Intermittent Sand Filter	Appropriate Drainage Shed to filter
District of Columbia Underground Vault Sand Filters	Medium (0.25-1.25 impervious acres)
Delaware Sand Filters	Small-Medium (≤ 1.25 impervious acres)
Austin Full Sedimentation Sand Filters (Surface or Vault)	Large (≥ 1.25 impervious acres)
Austin Partial Sedimentation Sand Filters (Surface)	Medium-Large
Austin Partial Sedimentation Sand Filters (Underground)	Medium

2. *Stormwater Infrastructure Serving Site*

Both the size and the elevations of stormwater infrastructure serving the site as a whole are important considerations. A critically important design parameter is the potential difference in elevation of the receiving manhole in the stormwater infrastructure and the elevation of the closest manhole in the new storm sewer system draining the site to be served. This will determine the depth of water than can be pooled above the filter media with the system operating on gravity flow. Almost all intermittent sand filter BMPs are designed to flow by gravity. However, in commercial and industrial applications where dedicated maintenance crews with familiarity with mechanical equipment will be available, pumped flow should be considered a viable alternative.

3. *Depth to Seasonally High Groundwater Table*

The liner or concrete shell of intermittent sand filter BMPs is usually placed at least 2 to 4 feet above the seasonally high water table or bedrock in order to assure dry conditions for construction and to minimize infiltration of groundwater into the filter structure. However, in some cases, it may be economical and practical to place filter shells below the seasonally high water table. In such cases, floatation effects must be countered by providing extra weight or hold down components in the filter shell.

4. *Value of the Real Estate and Expected Income from Development*

The value of real estate in highly urbanized areas may drive the overall cost of traditional structural BMPs too high for serious consideration. In Alexandria, for example, the cost of real estate alone to construct retention ponds averages $60,000 per impervious acre treated, while the cost of real estate for extended detention basins averages $40,000 per impervious acre treated. The overall costs of underground vault sand filters, which may be placed under parking lots and private streets or even within building structures and therefore have no real estate cost, can become quite competitive under such circumstances. The income stream from increased development allowed by underground BMPs should also be considered in such analyses.

5. *Aesthetic and Land Use Considerations*

Most traditional stormwater BMPs may be severely lacking in visual attractiveness. This may be especially true with some extended detention basins and retention basins lacking a base flow to prevent eutrophication during hot, dry weather. Questions also often arise about the use of valuable open space on projects for BMPs instead of alternative uses such as recreation. Most sand filter BMPs are visually unobtrusive and may be used in situations where aesthetic considerations or open space use are important.

Sediment Control

Intermittent sand filter BMPs which have been subjected to heavy sediment loadings have historically failed very quickly (LaRock, 1988; Harper and Herr, 1993). In a study in Denver, Colorado, Urbonis, Doerfer, and Tucket found that the hydraulic conductivity of a sand filter serving an equipment parking lot dropped rapidly as sediment accumulated on the surface of the filter (Urbonis, Doerfer, and Tucker, 1996). A layer of sediment approximately 1/16 inch (1.6 millimeters) thick was found to limit hydraulic conductivity to 0.05 feet per hour (1.6 ft/day), considerably less than the design coefficient of permeability used by Northern Virginia jurisdictions in the design of sand filters (*ibid.;* Bell, Stokes, Gavan, and Nguyen, 1995). The filter media of intermittent sand filter BMPs must therefore be protected from excessive sediment loads. This requires isolation during construction of the development, site design to restrict the amount of runoff from pervious areas reaching the filter after construction, and proper sizing of sediment removing features of the BMP to match final site conditions.

1. *Construction Runoff*

Sand filter BMPS must ***never*** *be placed in service until all site work has been completed and stabilization measures have been installed and are functioning properly.*

When this precaution has not been taken in the past, the sand filter BMPs have become clogged with sediment from upland construction operations almost immediately, requiring complete reconstruction of the sand filter and sometimes the collector pipe system. This can prove very expensive. However, since most sand filter BMPs are constructed off-line with a flow splitting device employed to divert only the Water Quality Volume to the filter, the BMP may usually be completely constructed but isolated from runoff by blocking the inflow pipe until the site is fully stabilized.

2. *Urban Runoff*

While experience indicates that intermittent sand filters fail very quickly when directly exposed to runoff from watersheds with low imperviousness and poor vegetated cover (LaRock, 1988; Harper and Herr, 1993), filters which treat runoff from almost exclusively impervious areas, such as highway surfaces, may perform satisfactorily for several years with very little maintenance (Shaver and Baldwin, 1991).

An 18-month, comprehensive study of runoff from street surfaces in 12 cities throughout the U.S. determined that, while most particulate matter is in the fractions equating to sand and gravel, the approximately 6 percent of particles in the silt and clay soil size contain over half the phosphorous and some 25 percent of other pollutants (Sartor, Boyd, and Agardy, 1974). **Table 3.12-4** illustrates this finding.

In planning the layout for a site on which sand filter BMPs are to be employed, care should be taken to direct only runoff from impervious surfaces to the filter insofar as possible. The drainage sheds feeding sand filter BMPs with only partial sediment protection (as delineated in the individual BMP discussions which follow) should ***never*** contain less than 65% impervious cover. Even when full sediment protection is provided in the form of a carefully sized presettlement basin, the amount of runoff from pervious areas directed to the filter must be minimized. The Denver study also indicates that full sediment protection may be required in areas subject to heavy atmospheric deposition of suspended solids even when only runoff from impervious surfaces is being treated.

The presettling basin or sedimentation chamber of an intermittent sand filter BMP is expected to remove all but the very fine particles of sediment, while most of the other pollutant removal is expected to occur in the sand filter, where the very fine particles will be trapped.

TABLE 3.12-4
Percent of Street Pollutants in Various Particle Size Ranges

	Particle Size (Microns)					
Pollutant	**>2000**	**840-2000**	**246-840**	**104-246**	**43-104**	**<43**

(Source: Shaver and Baldwin, 1990; adapted from Sartor, Boyd, and Agardy, 1974)

<u>Trash Exclusion</u>

Underground vault BMPs are confined space under Occupational Safety and Health Regulations and are therefore more expensive to enter and maintain than open facilities. Future operations and maintenance costs can substantially reduced by assuring that trash is, insofar as possible, excluded from entering the vault. Grated storm inlets and trash racks in flow splitters are two ready solutions to this problem.

<u>Projected Hydrocarbon Loadings</u>

Sand filters will quickly clog when subjected to direct heavy hydrocarbon loadings. Where such loadings are expected, a design which removes unemulsified hydrocarbons in a separate chamber or structure in the treatment train ahead of the filter should be selected.

Maintenance

The maintenance requirements for intermittent sand filters must be considered during the planning and design of the facility. All chambers of underground sand filters must have personnel access manholes and built-in access ladders . Access roads or streets must be of sufficient width and bearing capacity to support dump trucks loaded with accumulated sediments or heavy vacuum (e.g.”VACTOR”) trucks for removing accumulated sediments and hydrocarbons from sediment chambers and traps on a regular basis. Approximately every 3-5 years, the filter can be expected to clog to the point that replacement of the top few inches of sand or, where employed, the layer of washed gravel and the top layer of filter cloth will be required. **A minimum maintenance headspace of 60 inches above the filter is required in underground vault filters BMPs.** A 36-38-inch diameter maintenance manhole with a small, concentric personnel access lid or a rectangular load bearing access door (minimum 4 ft. x 4 ft.) should be positioned directly over the center of the filter. Large sedimentation basins and open filters must be equipped with access ramps to allow small earthmoving equipment such as “Bobcats” and light trash raking equipment to go into the basins. Finally, before finalizing the BMP design, follow the advice of Joseph J. Skupien, Principal Hydraulic Engineer of Somerset County, New Jersey, and “close your eyes, kick back, and think your BMP through a full year of operations, visualizing how it will perform under the conditions of all four seasons.”

General Design Criteria

The purpose of this section is to provide recommendations and minimum criteria for the design of intermittent sand filter practices intended to comply with the Virginia Stormwater Management program’s runoff quality requirements.

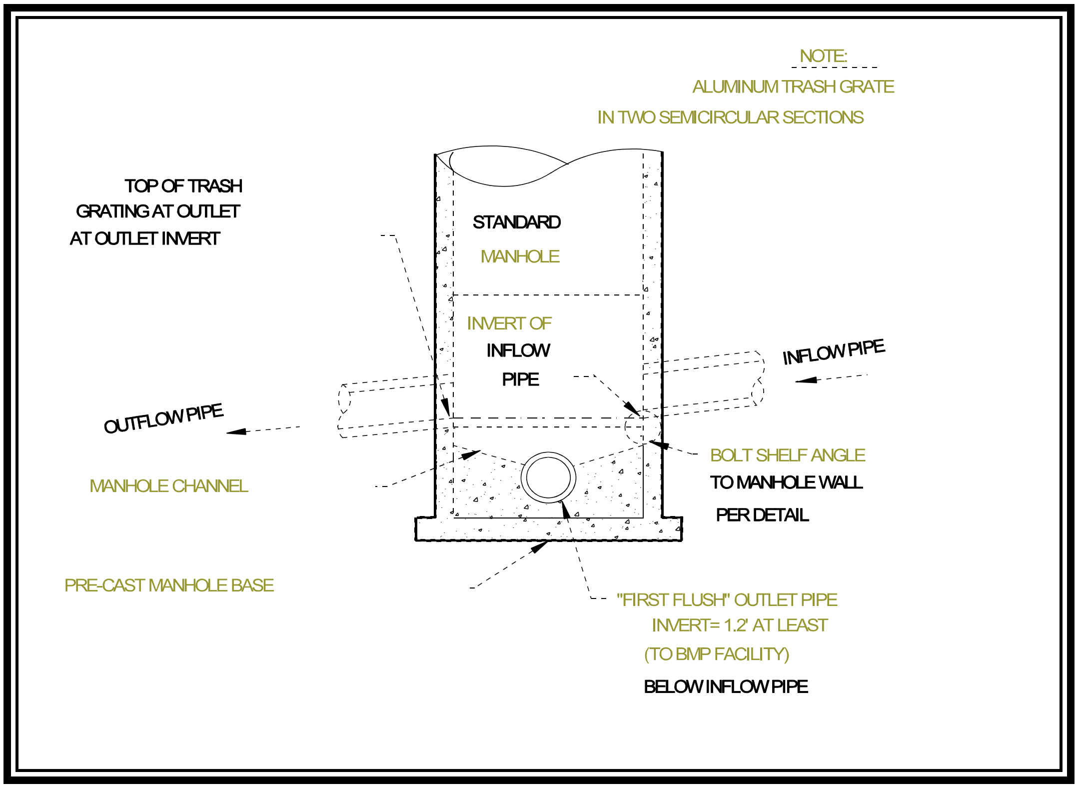
Several types of intermittent sand filter facilities are recognized for stormwater quality management purposes, including ***District of Columbia Underground Vault Filters***, ***Delaware Sand Filters, Austin Full Sedimentation Sand Filters,*** and ***Austin Partial Sedimentation Sand Filters***.

The general design criteria presented below apply to the design of intermittent sand filter facilities for ***water quality control***. This implies that the volume of runoff to be treated is determined by the **water quality volume** (the first 0.5 inches of runoff from the impervious surfaces on the site or drainage shed) and the desired pollutant removal efficiency.

Isolating the Water Quality Volume

The usual method for isolating the WQV is to construct an isolation/diversion weir in the stormwater channel or pipe, with the elevation of the weir set to allow overflow when the BMP is completely full. Additional runoff greater than the WQV spills over the weir to enter a peak flow rate reducer or exit directly to the storm sewer, minimizing mixing with the water in the BMP. Another approach is to provide a lower pipe to feed the filter until it fills, after which water rises in the slitter manhole and continues down a higher pipe. **Figure 3.12 - 2** illustrates this approach (source: Montgomery County, Maryland).

FIGURE 3.12 - 2
Flow Splitting Manhole Structure



Sizing Procedure

The majority of jurisdictions which are employing sand filter BMPs use hydraulic calculations based on Darcy's Law to establish the filter area that will allow flow-through of the treatment volume within the desired time frame, typically 40-48 hours (Austin, 1988, Shaver and Baldwin, 1991, Truong, 1989). Florida uses more complex falling-head computations and allows a drawdown time of up to 72 hours (Livingston, McCarron, Cox, and Sanzone, 1988). However, creating storage for the full WQV in shallow configuration systems may result in a larger filter than the hydraulic calculations would indicate (Alexandria, 1992).

Virginia uses the Austin Sand Filter Formula derived from Darcy's Law by the Austin Environmental and Conservation Services Department to size sand filters (Austin, 1988):

$A_f = I_a H d_f / k(h+d_f)t_f$ where,

A_f = surface area of sand bed (acres or sq. ft.)
I_a = impervious drainage area contributing runoff to the basin (acres or sq. ft.)
H = runoff depth to be treated (ft.)
d_f = sand bed depth (ft.)
k = coefficient of permeability for sand filter (ft/hr)

h = average depth (ft.) of water above surface of sand media between full and empty basin conditions (½ max. depth)
t_f = time required for runoff volume to pass through filter media (hrs.)

1. Coefficient of Permeability

When first installed, the coefficient of permeability of sand filters may be as high as 3.0 ft/hour, but these will typically decrease dramatically after the first few storms. Actual observations of filters in Austin, Texas, established that "ripe" filters stabilized in the range of 0.5-2.7 ft/day for filters with partial sedimentation control (Austin, 1988). This is probably caused by a combination of clogging of some filter pores from sediment loads and initial consolidation of the filter sand. **Figure 3.12 - 3** illustrates the similar rapid decrease in coefficient of permeability as sediment loads accumulated on a sand filter in Denver, Colorado (Urbonas, Doerfer, and Tucker, 1996). Falling head tests on a one year old Delaware Sand Filter in Alexandria, Virginia, resulted in an average coefficient of permeability of 8.5 ft/day (Bell, Stokes, Gavan, and Nguyen, 1995). The Alexandria filter was treating only runoff from pavement surfaces, and the mean input concentration of total suspended solids was only in the range of 75 milligrams/liter (75ppm)(*ibid)*. The Denver runoff, by contrast, had a mean concentration of 400 ppm (Urbonas, Doerfer, and Tucker, 1996), while the filters observed by Austin lacked full sedimentation protection. Use of conservative values for the coefficient of permeability is clearly indicated.

Based on long term observation of existing sand filter basins, Austin uses k values of 3.5 feet per day for systems with full sedimentation pretreatment and 2.0 feet per day for systems with only partial sedimentation pretreatment (full sedimentation pretreatment is defined as complete removal of particles with a diameter equal to or greater than 20 microns). Virginia jurisdictions utilizing intermittent sand filter BMPs have also adopted these values. Full sedimentation may usually be accomplished by capturing the WQV and releasing it to the filter over 24 hours. **Figure 3.12-4** illistrates a full sedimentation basin in Austin. Partial sedmientation basins, such as the one shown on **Figure 3.12-1**, should hold at least 20 percent of the WQV.

2. Drawdown time

Both Austin and the Virginia jurisdictions employ a BMP drawdown time (t_f) of 40 hours. This allows the filter to fully drain down and dry out to maintain an aerobic environment between storms (filters which remain continually wet may develop anaerobic conditions, under which previously captured iron phosphates may break down and wash out).

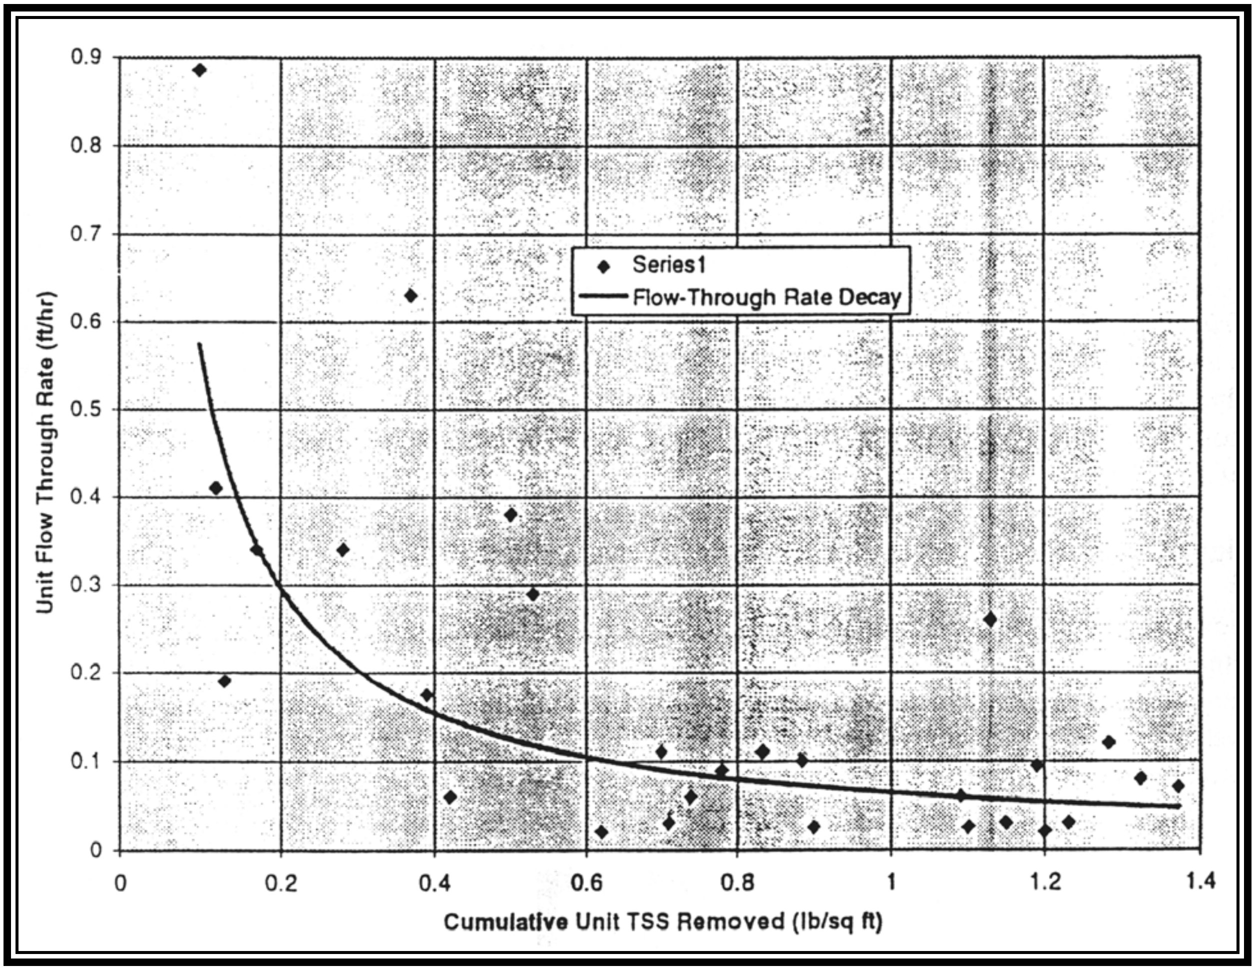
3. Simplified Filter Formula for Filters with Full Sedimentation Protection
(Sedimentation Basin containing full WQV with 24-hour drawdown to filter)

With k = 3.5 ft/day (0.146 ft/hour) and t_f = 40 hours, the sand filter formula reduces to:

$$A_{f(FS)} = 310 I_a d_f / (h + d_f)$$

where A_f is in ft^2 and I_a is in acres.

FIGURE 3.12-3
Degradation of Hydraulic Conductivity of Denver Sand Filter



(Source: Urbonas, Doeffler, and Tucker, 1996)

4. Simplified Filter Formula for Filters with Partial Sedimentation Protection
(Sediment Chamber containing 20% of WQV with free hydraulic flow to filter)

With k = 2.0 ft/day (.0833 ft/hour) and t_f = 40 hours, the formula reduces to:

$$A_{f(PS)} = 545 I_a d_f / (h + d_f)$$

where A_f is in ft^2 and I_a is in acres.

FIGURE 3.12-4

Full Sedimentation Basin on Austin Sand Filter

Exclusion of Continuous Flows and Chloronated Flows

Intermittent sand filter BMPs will **NOT** function properly if subjected to continuous or frequent flows. The basic principles upon which they operate assume that the sand filter will dry out and reaerate between storms. If the sand is kept continually wet by such flows as basement sump pumps, anaerobic conditions will develop, creating a situation under which previously captured iron phosphates degrade, leading to **export** of phosphates rather than the intended high phosphorous removal (Bell, Stokes, Gavan, and Nguyen, 1995). It is also essential to **exclude flows containing chlorine and other swimming pool and sauna chemicals** since these will kill the bacteria upon which the principle nitrogen removal mechanisms depend.

Continuous or frequent flows (such as basement sump pump discharges, cooling water,condensate water, ariesian wells, etc.) and flows containing swimming pool and sauna chemiclals *must be* ***EXCLUDED*** *from routing through intermittent sand filter BMPs since such flows will cause the BMP to* ***MALFUNCTION!***

Checklists

The **Construction Inspection and As-Built Survey Checklist** found in **Appendix 3D** is for use in inspecting intermittent sand filter facilities during construction and, where required by the local jurisdiction, engineering certification of the filter construction. The **Operation and Maintenance Checklist**, also found in **Appendix 3D**, is for use in conducting maintenance inspections of intermittent sand filter facilities.

MINIMUM STANDARD 3.12A

WASHINGTON D.C. UNDERGROUND VAULT SAND FILTER
(WET SEDIMENTATION CHAMBER)

Definition

A Washington D.C. vault sand filter is an underground stormwater sand filter contained in a structural shell with three chambers. The shell may be either precast or cast-in-place concrete, corrugated metal pipe, or fiberglass tanks. This BMP was developed by Mr. Hung V. Truong of the D.C. Environmental Regulation Administration. **Figure 3.12A-1** depicts Mr. Truong's system.

The three feet deep plunge pool in the first chamber and the throat of the second chamber, which are hydraulically connected by an underwater rectangular opening, absorbs energy and provides pretreatment, trapping grit and floating organic material such as oil, grease, and tree leaves.

The second chamber also contains a typical intermittent sand filter. The filter material consists of gravel, sand, and filter fabric. At the bottom is a subsurface drainage system of pierced PVC pipe in a gravel bed. The primary filter media is 18-24 inches of sand. A layer of plastic reinforced geotextile filter cloth secured by gravel ballast is placed on top of the sand. The top filter cloth is a pre-planned failure plane which can readily be replaced when the filter surface becomes clogged. A dewatering drain controlled by a gate valve must be installed to facilitate maintenance.

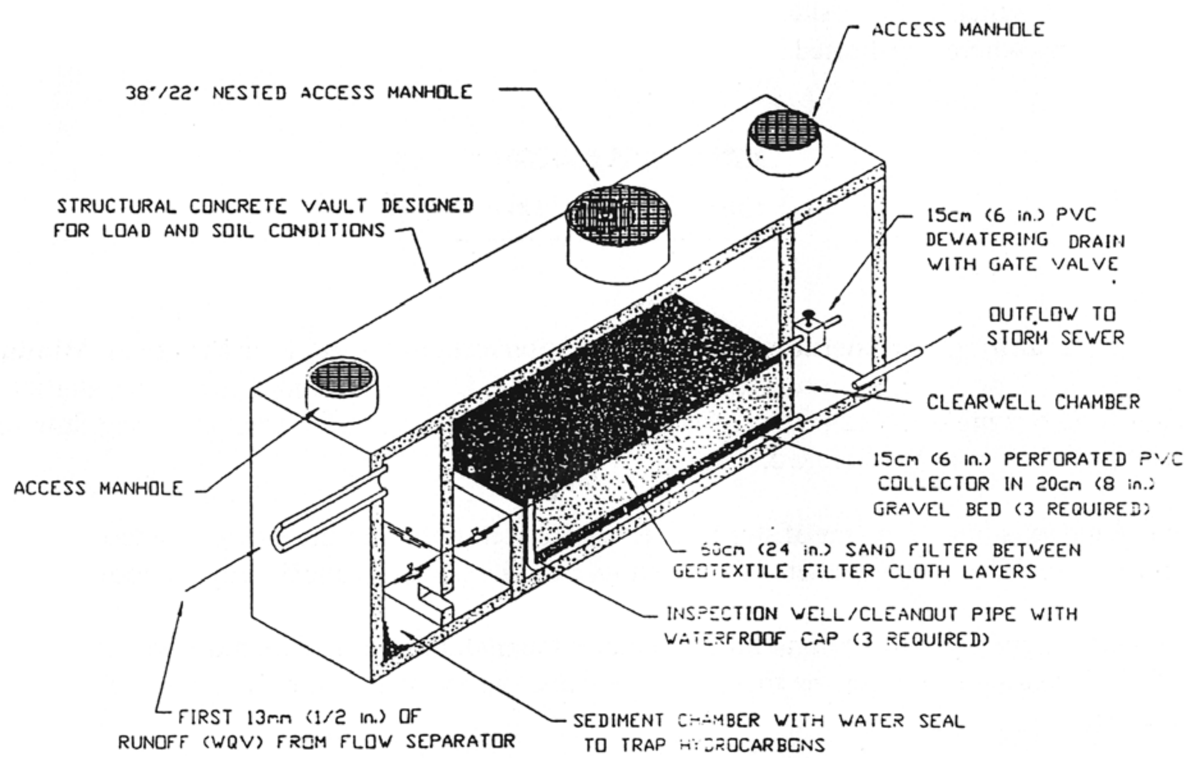
The third chamber, or clearwell, collects the flow from the underdrain pipes and directs it to the storm sewer.

In Virginia, D.C. Sand Filters will normally be placed off-line and be sized to treat the WQV.

Purpose

D.C. Sand Filters are primarily used for water quality control. However, they do provide detention and slow release of the water quality volume from the site being treated. Whether this amount will be sufficient to provide the necessary peak flow rate reductions required for channel erosion control is dependent upon site conditions (hydrology) and required discharge reductions. The 10-year and 100-year flows will usually exceed the detention capacity of a sand media filter. When this occurs, separate quantity must be provided.

FIGURE 3.12A - 1
Washington D.C. Underground Vault Sand Filter



Conditions Where Practice Applies

D.C. Sand Filters are ultra-urban BMPs best suited for use in situations where space is too constrained and/or real estate values are too high to allow the use of conventional retention ponds. Where possible, runoff treated should come only from impervious surfaces.

Drainage Area

Drainage areas served by one vault filter should be limited to 1.25 acres. For larger drainage sheds, either multiple vault filters or Austin Full Sedimentation Filters (surface or vault) should be utilized.

Development Conditions

D.C. Sand Filters are generally suitable BMPs for medium to high density commercial or industrial development. Because of confined space entry restrictions and maintenance requirements, they are not generally suitable for residential applications except for apartment complexes or large condominiums where a dedicated maintenance force will be present.

Planning Considerations

Refer to the **Planning Considerations** for **General Intermittent Sand Filter Practices, Minimum Standard 3.12,** previously discussed in this section. Of special concern are the stormwater infrastructure serving the site and the requirement to isolate the sand filter from receiving flows until the drainage shed is fully stabilized.

Potential and existing elevations of stormwater infrastructure serving the site will determine one of the most critical design parameters: the maximum depth to which runoff may be pooled over the filter and preserve a gravity flow configuration (whatever the pooling depth, there must be a minimum of five feet of clearance between the top of the filter and the top slab of the filter shell to allow filter maintenance).

*Sand filter BMPS must **never** be placed in service until all site work has been completed and stabilization measures have been installed and are functioning properly.*

Design Criteria

The purpose of this section is to provide recommendations and minimum criteria for the design of D.C. Sand Filter BMPs intended to comply with the Virginia Stormwater Management program's runoff quality requirements.

Refer to the **General Design Criteria** previously discussed under **General Intermittent Sand Filter Practices, Minimum Standard 3.12**

Filter Sizing Criteria

The D.C. Sand Filter is a partial sedimentation protection intermittent sand filter BMP. To compute the minimum area of filter required, utilize the Austin Filter Formula for partial sedimentation treatment:

$$A_{fm(PS)} = \frac{545 I_a d_f}{(h + d_f)}$$

where,

A_{fm} = minimum surface area of sand bed (square feet)
I_a = impervious cover on the watershed in acres
d_f = sand bed depth (normally 1.5 to 2ft)
h = average depth of water above surface of sand media between full and empty basin conditions (ft.)

Structural Requirements

The load-carrying capacity of the filter structure must be considered when it is located under parking lots, driveways, roadways, and, certain sidewalks (such as those adjacent to State highways). Traffic intensity may also be a factor. The structure must be designed by a licensed structural engineer and the structural plans require approval by the plan approving jurisdiction.

Design Storm

The inlet design or integral large storm bypass must be adequate for isolating the WQV from the design storm for the receiving storm sewer system (usually the 10 year storm) and for conveying the peak flow of that storm past the filter system. Since D.C. Sand Filters will be used only as off-line facilities in Virginia, the interior hydraulics of the filter are not as critical as when used as an on-line facility. The system should draw down in approximately 40 hours.

Infrastructure Elevations

For cost considerations, it is preferable that D.C. Sand Filters work by gravity flow. This requires sufficient vertical clearance between the invert of the prospective inflow storm piping and the invert of the storm sewer which will receive the outflow. In cases where gravity flow is not possible, a clearwell sump and pump are required to discharge the effluent into storm sewer. Such an application would be appropriate in commercial or industrial situations where a dedicated maintenance force will be available (shopping malls, apartment houses, factories of other industrial complexes, etc.).

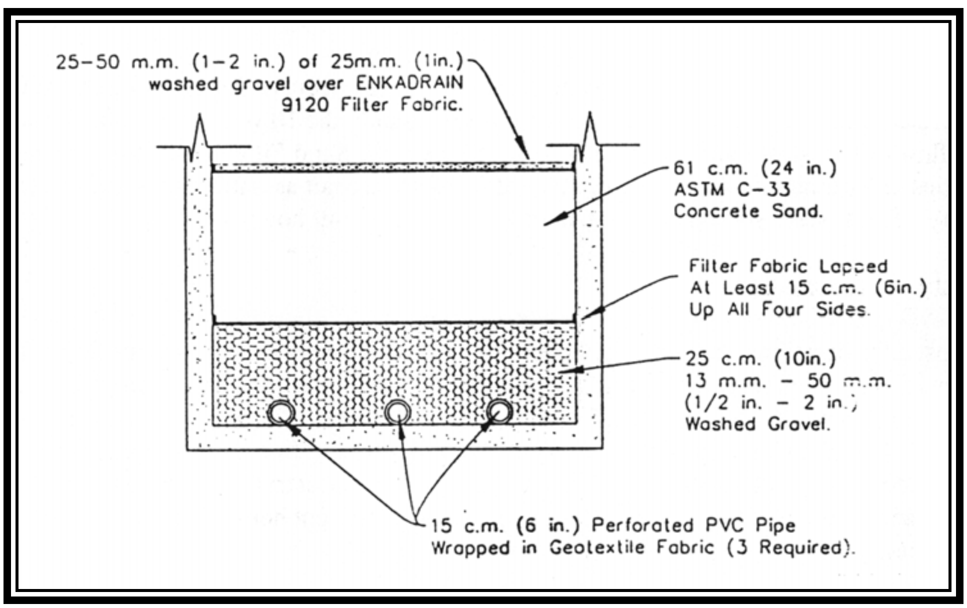
Accessibility and Headroom for Maintenance

Both the sedimentation basin and the filter must be accessible to approriate equipment and vacuum trucks for removing accumulated sediments and trash. The sedimentation basin must be cleaned approximately once per year, and the filter will likely need raking on that frequency to remove trash and restore permeability. When filters are placed in underground vaults, all three chambers must have personnel access manholes and built-in access ladders. **A minimum headspace of 60 inches above the filter is required to allow such maintenance and repair.** A 38-inch diameter maintenance manhole with eccentric nested covers (a 22-inch personnel access lid inside the 38-inch diameter lid) or a rectangular load bearing access door (minimum 4 ft. x 4 ft.) should be positioned directly over the center of the filter.

Construction Specifications

Figure 3.12A-2 is a cross-section of the filter chamber.

FIGURE 3.12A - 2
D.C. Sand Filter Cross-Section



Depth of Sedimantation Pool

The sedimentation "plunge pool" must be at least 36 inches deep to properly remove sediment and absorb energy from the incoming flow.

Depth of the Underwater Opening Between Chambers

To preserve an effective hydrocarbon trap, the top of the underwater opening between chambers must be at least 18 inches below the depth of the weir which divides the filter from the pool. To retain sediment in the first chamber, the bottom of the opening should be at least six inches above the floor. The area of the opening should be at least 1.5 times the cross-sectional area of the inflow pipe(s) to assure that the water level remains equal between the first and second chambers.

Total Depth of Filter Cross-Section

The total depth of the filter cross-section must match the height of the weir dividing the sedimentation pool from the filter. Otherwise, a "waterfall" effect will develop which will gouge out the front of the filter media. If a sand filter less than 24 inches is used, the gravel layer must be increased accordingly to preserve the overall filter depth.

Upper Aggregate Layer

The washed aggregate or gravel layer at the top of the filter shall be at least one inch thick and meet ASTM standard specifications (1-inch maximum diameter).

Geotextile Fabrics

The filter cloth layer beneath the upper aggregate layer shall be reinforced by an HDPE or PVC geomatrix (such as ENKADRAIN 9120) and meet the specifications shown in **Table 3.12C-1**. The filter fabric between the sand layer and the collector gravel shall conform to the specifications in **Table 3.12A-2**. The fabric rolls must be cut with sufficient dimensions to cover the entire wetted perimeter of the filtering area and lap up the filter walls at least six-inches.

Sand Filter Layer

For applications in Virginia, use **ASTM C33 Concrete Sand** or sand meeting the Grade A fine aggregate gradation standards of Section 202 of the VDOT ***Road and Bridge Specifications.*** The top of the sand filter must be completely level.

TABLE 3.12A - 1
Specifications for Nonwoven Geotextile Fabric on Top of D.C. Sand Filter

Property	Test Method	Unit	Specification
Unit Weight	ASTM D-1777	Oz./Sq.yd.	4.3 (minimum)

Thickness	--	In.	0.08 (minimum)

Table 3.12A - 2
Specifications for Nonwoven Geotextile Fabric Beneath Sand in D.C. Filter

Property	Test Method	Unit	Specification
Unit Weight	--	Oz./sq.yd.	8.0 (min.)
Filtration Rate	--	In/sec	0.08 (min.)
Puncture Strength	ASTM D-751 (Modified)	Lb.	125 (min.)
Mullen Burst Strength	ASTM D-751	Psi	400 (min.)
Equiv. Opening Size	U.S. Standard Sieve	No.	80 (min.)
Tensile Strength	ASTM D-1682	Lb.	300 (min.)

Gravel Bed Around Collector Pipes

The gravel layer surrounding the collector pipes shall be ½ to two (2) inch diameter gravel and provide at least two (2) inches of cover over the tops of the drainage pipes.

Underdrain Piping

The underdrain piping consists of three 6-inch schedule 40 or better polyvinyl perforated pipes reinforced to withstand the weight of the overburden. Perforations should be 3/8 inch, and each row of perforations shall contain at least six (6) holes. Maximum spacing between rows of perforations shall be six (6) inches.

The minimum grade of piping shall be 1/8 inch per foot (one [1] percent slope). Access for cleaning all underdrain piping is needed. Clean-outs for each pipe shall extend at least six (6) inches above the top of the upper filter surface, e.g. the top layer of gravel.

Each pipe shall be thoroughly wrapped with 8 oz./sq.yd. geotextile fabric meeting the specification in **Table 3.12A-2** above.

Dewatering Drain

When the filter is placed in an underground vault, A 6-inch dewatering drain controlled by a gate valve shall be installed between the filter chamber and the clearwell chamber with its invert at the elevation of the top of the filter. The dewatering drain penetration in the chamber dividing wall shall be sealed with a flexible strip joint sealant which swells in contact with water to form a tight pressure seal.

Access Manholes

When the filter is installed in an underground vault, access to the headbox (sediment chamber) and the clearwell shall be provided through at least 22-inch manholes. Access to the filter chamber shall be provided by a rectangular dood (minimum size: 4 feet by four feet) of sufficient strength to carry prospective imposed loads or by a manhole of at least 3- inch diameter with an offset concentric 22-inch lid (Neenah R-1741-D or equivalent).

Protection from Construction Sediments

The site erosion and sediment control plan must be configured to permit construction of the filter system while maintaining erosion and sediment control.

No runoff is to enter the sand filtration system prior to completion of all construction and site revegitation. Construction runoff shall be treated in separate sedimentation basins and routed to by-pass the filter system. Should construction runoff enter the filter system prior to site revegitation, all contaminated materials must be removed and replaced with new clean materials.

Watertight Integrity Test

After completion of the filter shell but before placement of the filter layers, entrances to the structure shall be plugged and the shell completely filled with water to demonstrate water tightness. Maximum allowable leakage is 5 percent of the filter shell volume in 24 hours. Should the structure fail this test, it shall be made watertight and successfully retested prior to placement of the filter layers.

Hydraulic Compaction of Filter Components

After placement of the collector pipes, gravel, and lower geotextile layer, fill the shell with filter sand to the level of the top of the sediment pool weir. Direct clean water into the sediment chamber until both the sediment chamber and filter chamber are completely full. Allow the water to draw down until flow from the collector pipes ceases, hydraulically compacting the filter sand. After allowing the sand to dry out for a minimum of 48 hours, refill the shell with sand to a level one inch beneath the top of the weir and place the upper geotextile layer and gravel ballast.

Portland Cement Concrete

Concrete liners may be used for sedimentation chambers and for sedimentation and filtration basins. Concrete shall be at least five (5) inch thick Class A3 defined in the Virginia Department of Transportation *Road and Bridge Specifications.*

Maintenance/Inspection Guidelines

The following maintenance and inspection guidelines are not intended to be all inclusive. Specific facilities may require other measures not discussed here.

Inspection Schedule

The water level in the filter chamber shall be monitored by the owner on a quarterly basis and after every large storm for the first year after completion of construction and a log shall be maintained of the results indicating the rate of dewatering after each storm and the water depth for each observation. Once the governing jurisdiction staff indicates that satisfactory performance of the structure has been demonstrated, the monitoring schedule can be reduced to an semiannual basis.

The BMP shall be inspected annually by representatives of the owner and the governing jurisdiction to assure continued proper functioning.

Sediment Chamber Pumpout

The sediment chamber must be pumped out halfway through the inspection cycle (e.g. after six months) and after each joint owner-governing jurisdiction annual inspection. If the chamber contains an oil skim, it should be removed by a firm specializing in oil recovery and recycling. The remaining material may then be removed by vacuum pump and disposed of in an appropriate landfill. **After each cleaning, refill the first chamber to a depth of three feet with clean water to reestablish the water seals**.

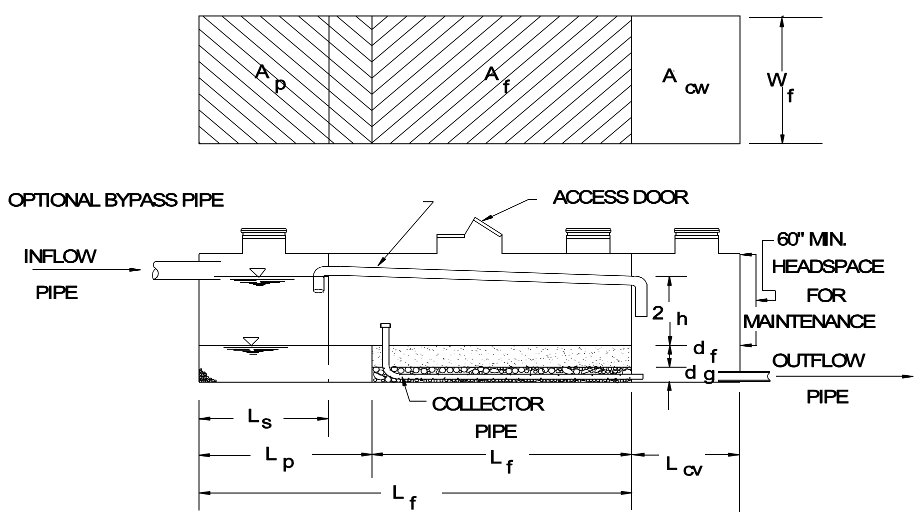
When the filter will no longer draw down within the required 40-hour period, the top layer of filter cloth and ballast gravel must be removed and replaced with new materials conforming to the original specifications. Any discolored or sediment contaminated sand shall also be removed and replaced.

Design Procedures

The following design procedure is structured to assure that the desired water quality volume is captured and treated by the D.C.Sand Filter. The procedure assumes that a filter shell with a rectangular cross-section is to be used.

Figure 3.12A-3 shows the dimensional relationships for a D.C. Sand Filter.

FIGURE 3.12A - 3
Dimensional Relationships for a D.C. Sand Filter



Standard Design Logic

Employ the following design logic to design D.C. Sand Filters for use in Virginia:

1. Determine Governing Site Parameters

Determine the Impervious area on the site (I_a in acres), the water quality volume to be treated (WQV in $ft.^3 = 1816\ I_a$), and the site parameters necessary to establish 2h, the maximum ponding depth over the filter (storm sewer invert at proposed connection point, elevation to inflow invert to BMP, etc).

2. Select Filter Depth and Determine Maximum Ponding Depth

Considering the data from Step 1) above, select the Filter Depth ((d_f) and determine the maximum achievable ponding depth over the filter (2h).

3. Compute the Minimum Area of the Sand Filter (A_{fm})

To compute the area of the filter, use the formula:

$$A_{fmPS} = \frac{545 I_a d_f}{(h + d_f)}$$

A_{fm} = minimum surface area of sand bed (square feet)
I_a = impervious cover on the watershed in acres
d_f = sand bed depth (normally 1.5 to 2ft)
h = average depth of water above surface of sand media between full and empty basin conditions (ft.)

4. Select Filter Width and Compute Filter Length and Adjusted Filter Area

Considering site constraints, select the Filter Width (W_f). Then compute the Filter Length (L_f) and the Adjusted Filter Area (A_f)

$$L_f = A_{fm}/W_f$$

$$A_f = W_f \times L_f$$

Note: From this point forward, computations assume a rectangular filter.

5. Compute the Storage Volume on Top of the Filter (V_{Tf})

$$V_{Tf} = A_f \times 2h$$

6. Compute the Storage in the Filter Voids (V_v)
(Assume 40% voids in filter media)

$$V_v = 0.4 \times A_f \times (d_f + d_g)$$

7. Compute Flow Through Filter During Filling (V_Q)
(Assume 1-hour to fill per D.C. practice)

$$V_Q = \frac{kA_f(d_f + h)}{d_f} \text{ ; use } k = 2 \text{ ft./day} = 0.0833\text{/hr.}$$

8. Compute Net Volume to be Stored Awaiting Filtration (V_{st})

$$V_{st} = WQV - V_{Tf} - V_v - V_Q$$

9. Compute Length of the Permanent Pool (Lpm)

$$Lpm \quad \frac{V_{st}}{(2h \times W_f)}$$

10. Compute Minimum Length of the Sediment Chamber (Lsc)
(to contain 20% of WQV per Austin practice)

$$L_{sm} = \frac{0.2WQV}{(2h \times W_f)}$$

11. Set Final Length of the Permanent Pool (L_p)

If $L_{pm} \geq L_{sm} + 2$ ft., make $L_p = L_{pm}$

If $L_{pm} < L_{sm} + 2$ ft., make $L_p = L_{sm + 2 \text{ ft.}}$

It may be economical to adjust final dimensions to correspond with standard precast structures or to round off to simplify measurements during construction.

Set the length of the clearwell (L_{cw}) for adequate maintenance and/or access for monitoring flow rate and chemical composition of the effluent (minimum = 3 ft.)

Minimizing Filter Shell Costs

Underground vault sand filter costs have been widely varying because many developers have simply had their foundation contractors cast the vault in place. Each installation therefore became a prototype with associated costs and overhead. Precast manufacturers currently offer precasting services for D.C. and other types of sand filter vaults, which should stabilize underground vault costs. **Figure 3.12A-4** is a photograph of a segmented precast filter shell installation in Alexandria.

MINIMUM STANDARD 3.12B

DELAWARE SAND FILTER (DSF) SYSTEMS

Definition

Mr. Earl Shaver of the Delaware Department of Natural Resources and Environmental Control has developed a surface sand filter system for use in Delaware (Shaver and Baldwin, 1991)

As originally conceived, the Delaware Sand Filter is an **on-line** facility processing all stormwater exiting the treated site up to the point that its overflow limit is reached (Delaware provides for treating the first one inch of runoff). However, when employed in Virginia, it will usually be provided with an integral flow-splitter to isolate and treat the Water Quality Volume.

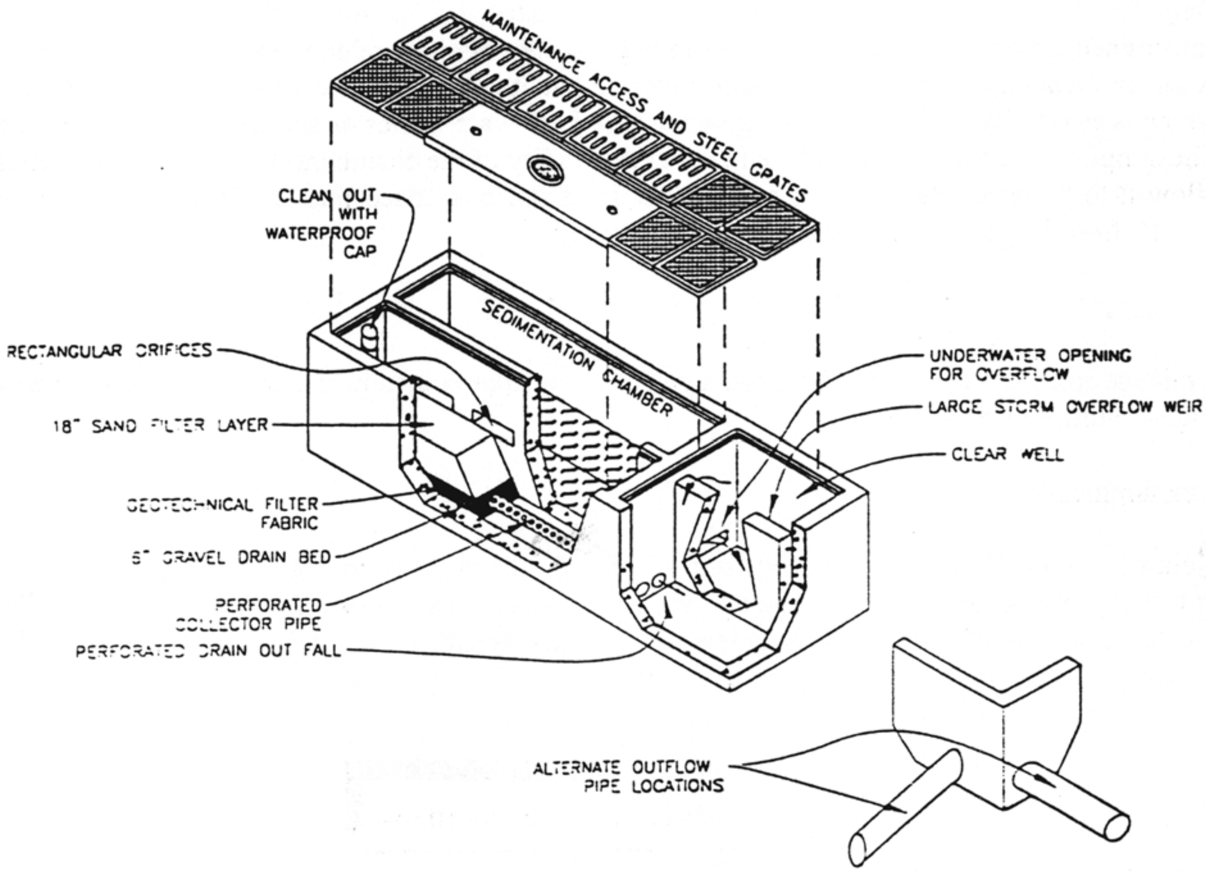
Figure 3.12B-1 shows a schematic drawing of the Delaware Sand Filter as used in Virginia. The system consists of two parallel concrete trenches connected by close-spaced wide notches in the wall dividing the trenches. The trench adjacent to the site being served is the sedimentation chamber. When accepting sheet flow, it is fitted with a grated cover. Concentrated stormwater may also be conveyed to the chamber in enclosed storm drain pipes. The second chamber, which contains the sand filter, is always fitted with a solid cover.

Storm flows enter the sedimentation chamber through the grates, causing the sedimentation pool to rise and overflow into the filter chamber through the weir notches in the dividing wall, assuring that the water to be treated **arrives at the filter as sheet flow**. This is essential to prevent scouring out the sand. The permanent pool in the sedimentation chamber is dead storage, which inhibits resuspension of particles that were deposited in earlier storms and prevents the heavier sediments from being washed into the filter chamber. Floatable materials and hydrocarbon films, however, may reach the filter media through the surface outflow.

The second trench contains at least 18 inches of ASTM C-33 Concrete Sand . When used in Virginia, an underdrain capability must be provided. Runoff percolates through the sand to the underdrain (s) and exits into the flow splitter/clearwell.

A transverse flow-splitter/clearwell at the lower end of the structure collects treated effluent and overflow and conveys the water to the storm sewer. When the filter shell fills with the Water Quality Volume, excess flow is forced through the underwater opening from the sedimentation chamber to the “wet” section of the clearwell to overflow the weir to the outflow pipe chamber. Floating trash and hydrocarbons are retained in the sedimentation chamber by this “trap.”

FIGURE 3.12B - 1
Precast Delaware Sand Filter as Used in Virginia



Purpose

Delaware Sand Filters primarily used for water quality control. However, they do provide detention and slow release of the water quality volume from the site being treated. Whether this amount will be sufficient to provide the necessary peak flow rate reductions required for channel erosion control is dependent upon site conditions (hydrology) and required discharge reductions. The 10-year and 100-year flows will usually exceed the detention capacity of a sand media filter. When this occurs, separate quantity must be provided.

Conditions Where Practice Applies

Delaware Sand Filters are ultra-urban BMPs best suited for use in situations where space is too constrained and/or real estate values are too high to allow the use of conventional retention ponds. A major advantage of the Delaware Sand Filter is that it can be installed in shallow configurations, which is especially critical in flatter regions where high water tables or shallow storm sewers exist. The simplicity of the system and the ready accessibility of the chambers for periodic maintenance allow it to be used where a filter built in confined space is unacceptable. Where possible, only runoff from impervious surfaces should be treated.

Drainage Area

Drainage areas served by one filter should be limited to approximately one acre. For larger drainage sheds, multiple DSFs may be used.

Development Conditions

Delaware Sand Filters are generally suitable BMPs for medium to high density commercial or industrial development. Because of confined space entry restrictions and maintenance requirements, they are not generally suitable for residential applications except for apartment complexes or large condominiums where a dedicated maintenance force will be present.

Planning Considerations

Refer to the **Planning Considerations** for **General Intermittent Sand Filter Practices, Minimum Standard 3.12,** previously discussed in this section. Of special concern are the stormwater infrastructure serving the site and the requirement to isolate the sand filter from receiving flows until the drainage shed is fully stabilized.

Potential and existing elevations of stormwater infrastructure serving the site will determine one of the most critical design parameters: the maximum depth to which runoff may be pooled over the filter and preserve a gravity flow configuration.

Sand filter BMPS must ***never*** *be placed in service until all site work has been completed and stabilization measures have been installed and are functioning properly.*

Design Criteria

The purpose of this section is to provide recommendations and minimum criteria for the design of Delaware Sand Filter BMPs intended to comply with the Virginia Stormwater Management program's runoff quality requirements.

Refer to the **General Design Criteria** previously discussed under **General Intermittent Sand Filter Practices, Minimum Standard 3.12**

Filter Sizing Criteria

Because of the shallow configuration of this BMP, resulting in low levels of hydraulic head above the filter, application of the usual partial sedimentation filter formula may not create enough storage volume to contain the WQV. With the dimensional relationships shown in **Figure 3.12B-2** and k = 2.0 ft/day, the required DSF filter area to contain the WQV may be written as follows:

$$A_f = \frac{1816 I_a}{(4.1h + 0.9)} = \frac{WQV}{(4.1h + 0.9)}$$

where:

A_f = the **area of the filter** in sq.ft.
I_a = the impervious area on the watershed in acres
h = 1/2 the maximum ponding depth over the filter (ft.)

If the maximum ponding depth above the filter (2h) is less than 2.67 feet (2'-8"), the WQV storage requirement governs and the above foumula must be used to size the filter (Alexandria, 1992). If the the maximum ponding depth above the filter (2h) is 2.67 feet or greater, use the partial sedimentation filter formula:

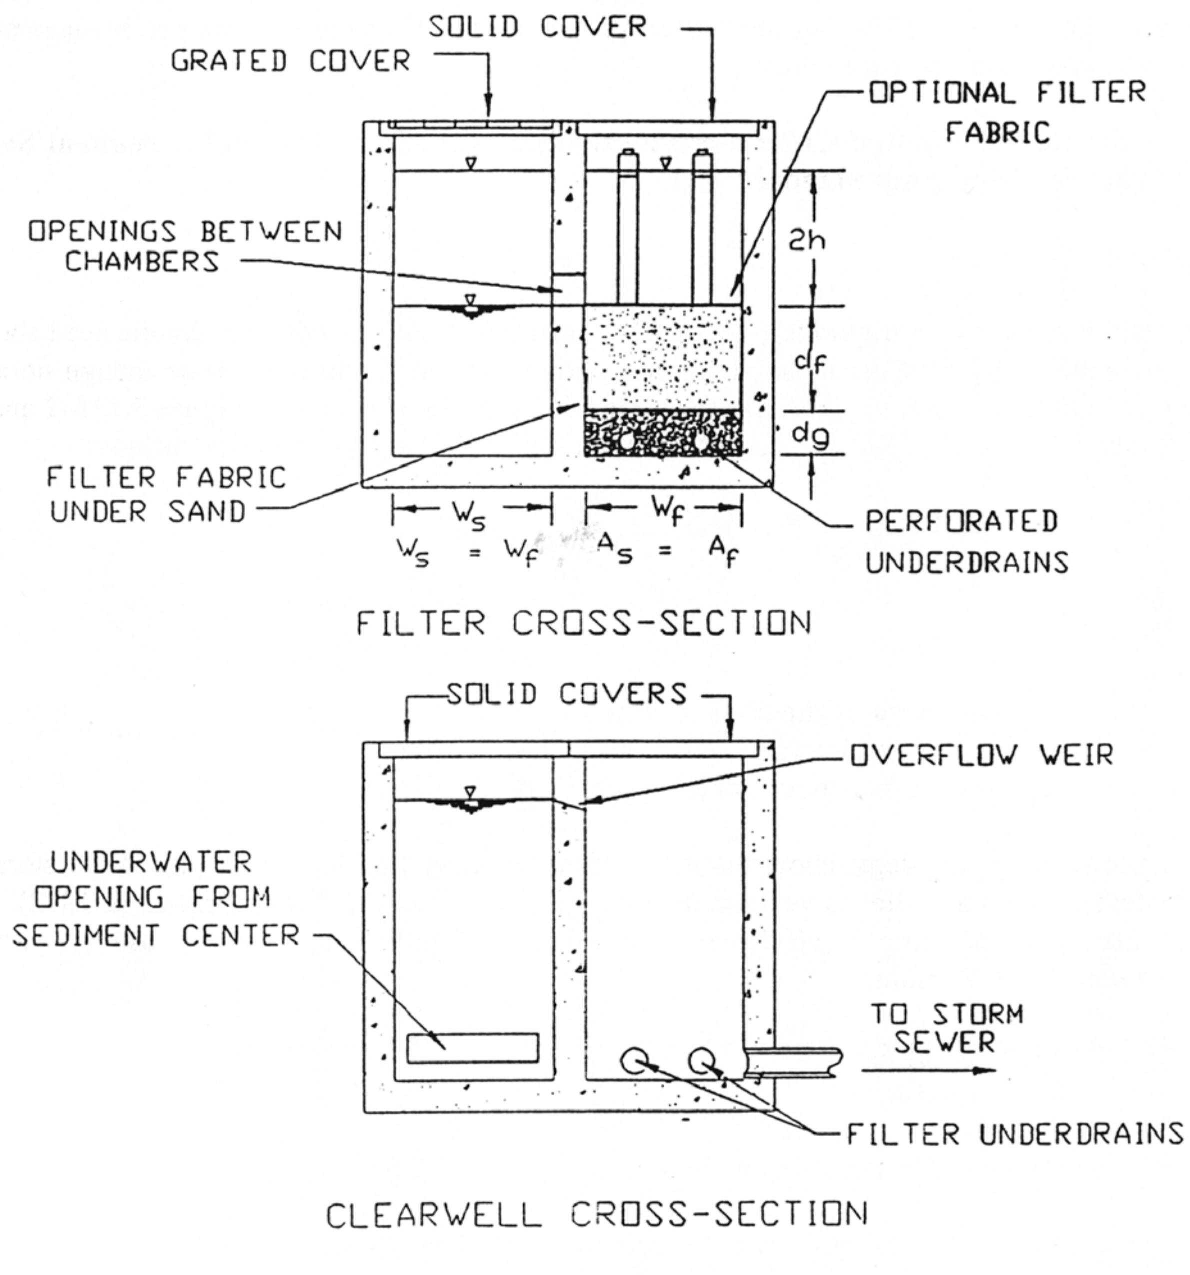
$$A_f = \frac{545 I_a d_f}{(h + d_f)}$$

Where d_f = depth of the filter media in ft. (1.5-2.0)

Delaware and Virginia make the area of the sediment chamber(A_s) equal the area of the filter:

$$A_f = A_s$$

FIGURE 3.12B- 2
Dimensional Relationships for Delaware Sand Filter



Structural Requirements

When the system is placed in a street or parking lot, it must be designed to support traffic wheel loads. When placed completely off the pavement, lower structural loads will be involved. The structure must be designed by a licensed professional engineer, and the design must be approved by the governing jurisdiction.

Design Storm

The inlet integral large storm bypass must be adequate for isolating the WQV from the design storm for the receiving storm sewer system (usually the 10 year storm) and for conveying the peak flow of that storm past the filter system. The system should draw down in approximately 40 hours.

Infrastructure Elevations

For cost considerations, it is preferable that Delaware Sand Filters work by gravity flow. This requires sufficient vertical clearance between the invert of the prospective inflow storm piping and the invert of the storm sewer which will receive the outflow. In cases where gravity flow is not possible, a clearwell sump and pump are required to discharge the effluent into storm sewer. Such an application would be appropriate in commercial or industrial situations where a dedicated maintenance force will be available (shopping malls, apartment houses, factories of other industrial complexes, etc.).

Construction Specifications

Upper Aggregate Layer

Some jurisdictions require a layer of filter cloth and gravel on top of the filter. When used, the washed aggregate or gravel layer at the top of the filter shall be one inch thick and meet ASTM standard specifications (1 inch maximum diameter.)

Geotextile Fabrics

When used, the filter fabric beneath the one-inch layer of gravel on top of the filter shall be Enkadrain 9120 filter fabric or equivalent with the specifications shown in **Table 3.12B - 1**.

Table 3.12B - 1
Specifications for Nonwoven Geotextile Fabric on Top of Delaware Sand Filter

Property	Test Method	Unit	Specification
Unit Weight	ASTM D-1777	Oz./sq.yd.	4.3 (min.)
Flow Rate	Falling Head Test	Gpm/sq.ft.	120 (min.)
Puncture Strength	ASTM D-751 (Modified)	Lb.	60 (min.)
Thickness	--	In.	0.8 (min.)

In instances where heavy hydrocarbon loadings are expected, a layer of activated carbon impregnated filter fabric such as Enkadrain PF-3 may be advantageous. When used, a plan to dispose of the hydrocarbon laden used filter fabric must be approved by the applicable jurisdiction prior to placing the sand filter in service.

The filter cloth layer beneath the sand shall conform to the specifications shown in **Table 3.12B-2**.

Table 3.12B - 2
Specifications for Nonwoven Geotextile Fabric Beneath Sand in Delaware Sand Filter

Property	Test Method	Unit	Specification
Unit Weight	--	Oz./sq.yd.	8.0 (min.)
Filtration Rate	--	In/sec	0.08 (min.)
Puncture Strength	ASTM D-751 (Modified)	Lb.	125 (min.)
Mullen Burst Strength	ASTM D-751	Psi	400 (min.)
Equiv. Opening Size	U.S. Standard Sieve	No.	80 (min.)
Tensile Strength	ASTM D-1682	Lb.	300 (min.)

The fabric rolls must be cut with sufficient dimensions to cover the entire wetted perimeter of the filtering area and lap up the filter walls at least six-inches.

Sand Filter Layer

For applications in Virginia, use **ASTM C33 Concrete Sand.** The top of the sand filter must be completely level. No grade is allowable.

Gravel Bed Around Collector Pipes

The gravel layer surrounding the collector pipes shall be ½ to two (2) inch diameter gravel and provide at least two (2) inches of cover over the tops of the drainage pipes. The gravel and the sand layer above must be separated by a layer of geotextile fabric meeting the specification listed above.

Underdrain Piping

When round perforated pipes are used, the underdrain piping shall consist of a minimum of two (2) schedule 40 or better four (4) inch polyvinyl perforated pipes reinforced to withstand the weight of the overburden. Perforations shall be 3/8 inch, and each row of perforations shall contain at least four (4) holes. Maximum spacing between rows of perforations shall be six (6) inches.

The minimum grade of piping shall be 1/8 inch per foot (one [1] percent slope). Access for cleaning all underdrain piping is needed. Clean-outs for each pipe shall extend at least six (6) inches above the top of the upper filter surface.

Each pipe shall be thoroughly wrapped with 8 oz./sq.yd. geotextile fabric meeting the specification in **Table 3.12B - 2** above.

Alternative Underdrains

Shallow rectangular drain tiles may be fabricated from such materials as fiberglass structural channels, saving several inches of filter depth. Drain tiles shall normally be in two-foot lengths and spaced to provide gaps 1/8-inch less than the smallest gravel sizes on all four sides. Sections of tile may be cast in the dividing wall between the filter and the clearwell to provide shallow outflow oricices. Flat perforated drainage piping such as AdvantEdge® may also be used to reduce the depth of filter. Another approach is to raise a grate on small masonary units above the floor of the shell, lay a layer of PVC or polyethelene geomatrix on the grate to spread the load, and install the filter cloth and sand above this matting; molded HDPE infiltration chambers may also be used as shown in **Figure 3.12A-5.** The entire bottom of the filter shell thus becomes a collector channel. When the shell bottom is so used, it shall have a minimum slope of 1/8 inch per foot (1%).

Weepholes

In addition to the underdrain pipes, weepholes may be installed between the filter chamber and the clearwell to provide relief in case of pipe clogging. The weepholes shall be three (3) inches in diameter. Minimum spacing shall be nine (9) inches center to center. The openings on the filter side of the dividing wall shall be covered to the width of the trench with 12 inch high plastic hardware cloth of 1/4 inch mesh or galvanized steel wire, minimum wire diameter 0.03-inch, number 4 mesh hardware cloth anchored firmly to the dividing wall structure and folded a minimum of 6 inches back under the bottom stone.

Protection from Construction Sediments

The site erosion and sediment control plan must be configured to permit construction of the filter system while maintaining erosion and sediment control.

No runoff is to enter the sand filtration system prior to completion of all construction and site revegitation. Construction runoff shall be treated in separate sedimentation basins and routed to by-pass the filter system. Should construction runoff enter the filter system prior to site revegitation, all contaminated materials must be removed and replaced with new clean materials.

Watertight Integrity Test

After completion of the filter shell but before placement of the filter layers, entrances to the structure shall be plugged and the shell completely filled with water to demonstrate water tightness. Maximum allowable leakage is 5 percent of the filter shell volume in 24 hours. Should the structure fail this test, it shall be made watertight and successfully retested prior to placement of the filter layers.

Hydraulic Compaction of Filter Components

After placement of the collector pipes, gravel, and lower geotextile layer, fill the shell with filter sand to the level of the top of the sediment pool weir. Direct clean water into the sediment chamber until both the sediment chamber and filter chamber are completely full. Allow the water to draw down until flow from the collector pipes ceases, hydraulically compacting the filter sand. After allowing the sand to dry out for a minimum of 48 hours, refill the shell with sand to a level one inch beneath the top of the weir and place the upper geotextile layer and gravel ballast.

Grates and Covers

When placed in traffic lanes, grates and covers must withstand H-20 wheelloadings. Use of standard Virginia Department of Transportation (VDOT) grates (Grate D1-1) will often be most cost-effective. Where allowed by local jurisdictions, galvanized steel bar grates are economical.

Portland Cement Concrete

Portland Cement concrete used for the trench structure shall conform to the A3 specification of the Virginia Department of Transportation ***Road and Bridge Specifications***, latest edition.

Maintenance/Inspection Guidelines

The following maintenance and inspection guidelines are not intended to be all inclusive. Specific facilities may require other measures not discussed here.

Inspection Schedule

During the first year of operation, the cover grates or precast lids on the chambers must be removed quarterly and a joint owner-jurisdiction inspection made to assure that the system is functioning. Once the jurisdiction inspectors are satisfied that the system is functioning properly, this inspection may be made on an annual basis for other than auto-related activities.

Sediment Chamber Pumpout

The sediment chamber must be pumped out when the joint owner-jurisdiction determines that . If the chamber contains an oil skim, it should be removed by a firm specializing in oil recovery and recycling. The remaining material may then be removed by vacuum pump and disposed of in an appropriate landfill. **After each cleaning, refill the first chamber with clean water to reestablish the water seals to the clearwell.**

Sand Filter

When deposition of sediments in the filtration chamber indicate that the filter media is clogging and not performing properly, sediments must be removed (a small shovel may be all that is necessary) along with the top two to three inches of sand. The coloration of the sand will provide a good indication of what depth of removal is required. Clean sand must then be placed in the filter to restore the design depth. Where a layer of geotechnical fabric overlays the filter, the fabric shall be rolled up and removed and a similar layer of clean fabric installed. Any discolored sand shall also be removed and replaced. Disposal of petroleum hydrocarbon contaminated sand or filter cloth should be coordinated with the appropriate environmental official of the local jurisdiction. On filters which employ an upper geotextile layer and ballast, the top layer of filter cloth and ballast gravel must be removed and replaced with new materials conforming to the original specifications when the filter will no longer draw down within the required 40-hour period. Any discolored or sediment contaminated sand shall also be removed and replaced with sand meeting the original specifications (ASTM C-33 Concrete Sand).

Concrete Shell Inspection

Concrete will deteriorate over time, especially if subjected to live loads. The concrete shell, risers, etc., must be examined during each annual inspection to identify areas that are in need of repair, and such repairs must be promptly effected.

Grass Clippings

Grass clippings from landscape areas on the drainage watershed flowing into the DSF must be bagged and removed from the site to prevent them washing into and contaminating the sediment chamber and filter.

Trash Collection

Trash collected on the grates protecting the inlets shall be removed no less frequently than weekly to assure preserving the inflow capacity of the BMP.

Design Procedures

The following design procedure is structured to assure that the desired water quality volume is captured and treated by the Delaware Sand Filter. The procedure assumes that a filter shell with a rectangular cross-section is to be used. **Figure 3.12B-2** shows the dimensional relationships required to compute the design.

Standard Design Logic

Employ the following design logic to design Delaware Sand Filters for use in Virginia:

1. Determine Governing Site Parameters

Determine the Impervious area on the site (I_a in acres), the water quality volume to be treated (WQV in $ft.^3 = 1816\ I_a$), and the site parameters necessary to establish 2h, the maximum ponding depth over the filter (storm sewer invert at proposed connection point, elevation to inflow invert to BMP, etc).

2. Select Filter Depth and Determine Maximum Ponding Depth

Considering the data from Step 1) above, select the Filter Depth ((d_f) and determine the maximum achievable ponding depth over the filter (2h).

3. Calculate the Required Surface Areas of the Chambers

If the maximum ponding depth above the filter (2h) is less than 2.67 feet (2'-8"), the WQV storage requirement governs and the above foumula must be used:

$$A_f = \frac{1816 I_a}{(4.1h + 0.9)} = \frac{WQV}{(4.1h + 0.9)}$$

where:

A_f = the **area of the filter** in sq.ft.

I_a = the impervious area on the watershed in acres

h = 1/2 the maximum ponding depth over the filter (ft.)

If the the maximum ponding depth above the filter (2h) is 2.67 feet or greater, use the partial sedimentation filter formula:

$$A_f = \frac{545 I_a d_f}{(h + d_f)}$$

where:

d_f = depth of the filter media in ft. (1.5-2.0)

Delaware and Virginia make the area of the filter equal the area of the sediment chamber:

$A_f = A_s$

4. Establish Dimensions of the Facility

Site considerations usually dictate the final dimensions of the facility. Sediment trenches and filter trenches normally be 18-30 inches wide. Use of standard VDOT D1-1 grates requires a trench width of 26". Some jurisdictions restrict the maximum allowable trench width to 36 inches.

Minimizing Filter Shell Costs

Underground vault sand filter costs have been widely varying because many developers have simply had their foundation contractors cast the vault in place. Each installation therefore became a prototype with associated costs and overhead. Precast manufacturers currently offer precasting services for D.C. and other types of sand filter vaults, which should stabilize underground vault costs. **Figure 3.12B3** is a photograph of a segmented precast shell installation in Alexandria.

Checklists

Worksheet 3.12B is for use in sizing calculations for Delaware Sand Filters. The **Construction Inspection and As-Built Survey Checklist** found in **Appendix 3D** is for use in inspecting intermittent sand filter facilities during construction and, where required by the local jurisdiction, engineering certification of the filter construction. The **Operation and Maintenance Checklist**, also found in **Appendix 3D**, is for use in conducting maintenance inspections of intermittent sand filter facilities.

= [ ] ft^3/hr ; /3600 [ ] = cfs;

x 448 = [ ] gpm

MINIMUM STANDARD 3.12C

AUSTIN SURFACE SAND FILTER SYSTEMS

Definition

The City of Austin, Texas, hase been using open basin intermittent sand filtration BMPs for treating stormwater runoff since the early 1980's. The Austin program is managed by the Environmental and Conservation Services Department, which has published design criteria in their *Environmental Criteria Manual* (Austin, 1988). Austin places heavy emphasis on pretreating the stormwater runoff in a sediment trapping presettling basin to protect the filter media from excessive sediment loading. The particles selected by Austin for complete removal in the full sedimentation protection basins are those which are greater than or equal in size to silt with a particle diameter of 0.00007 foot (20 microns) and a specific gravity of 2.65.

Figure 3.12C-1 illustrates an Austin Full Sedimantation Sand Filter application at a shopping center. In this system the sedimentation structure is a concrete basin designed to hold the entire WQV and then release it to the filtration basin over a 24-hour draw-down period. **Figure 3.12C-2** shows an alternative design which allows a smaller sedimentation chamber (20 percent of the WQV) while increasing the filter size to compensate for increased clogging of the filter media. Although the systems shown utilize concrete basins, a sediment pond and a geomembrane-lined filter built directly into he ground may be used where terrain and soil conditions allow.

.

Purpose

Austin Sand Filters are used primarily for water quality control. However, they do provide detention and slow release over time of the WQV. Whether this amount will be sufficient to provide the necessary peak flow rate reductions required for channel erosion control is dependent upon the site conditions. However, in cases where quantity detention beyond the volume of the WQV is required, an attractive alternative may well be to utilize a combined detention basin/pre-settling basin configuration, with the controlled release of the entire stored volume to the sand filter facility.

FIGURE 3.12C - 1
Austin Full Sedimentation Sand Filter System at Barton Ridge Plaza

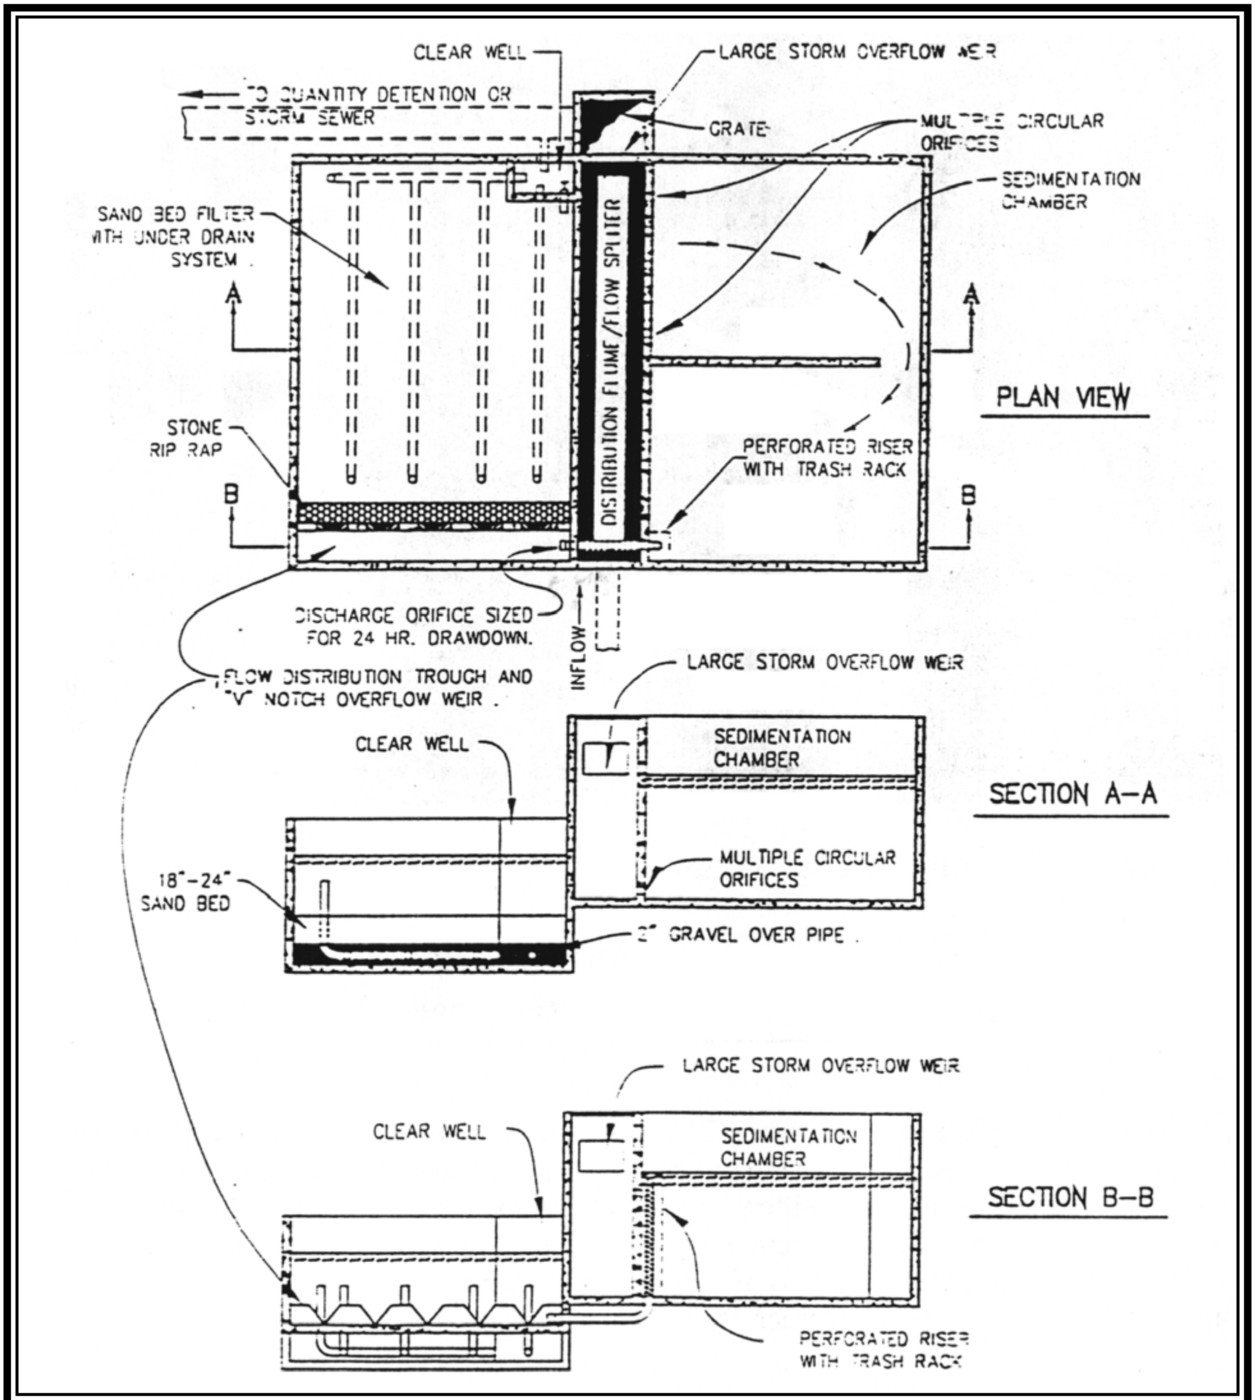

FIGURE 3.12C - 2
Sedimentation Basin of Jolleyville Partial Sedimentation System

(Poto Courtesy of the City of Austin, Texas)

Conditions Where Practice Applies

Austin Sand Filters Filters are ultra-urban BMPs best suited for use in situations where space is too constrained and/or real estate values are too high to allow the use of conventional retention ponds. Unlike D.C. and Delaware Sand Filters, when full sedimentation protection is provided, Austin filters may be used in situations where a higher amount of pervious surfaces are present or where higher sediment loads from deposition of wind-blown sediments are encountered. Because of their design, they may also be used on much larger drainage sheds.

<u>Drainage Area</u>

Austin full sedimentation and partial sedimentation basin sand filters have been used on drainage sheds up to 30 acres, and with great economy of scale. **Table 3.12-1** illustrates the relative costs of varying sized systems in Austin in mid-1990.

TABLE 3.12C - 1
Cost of Austin Sand Filtration Systems *(June 1990)*

Drainage Area (Acres)	**Water Quality Volume (ft^3)**	**Cost/Acre ($/acre)**	**Cost/ft^3 ($/$ft^3$)**	**Total Cost ($)**
1.0	1815	13,613* 19,058#	7.50* 10.50#	13,613* 19,058#
2.0	3,630	8,440* 9,801#	4.65* 5.40#	16,880* 19,602#
5.0	9,075	5,136	2.83	25,682
10.0	18,150	3,812	2.10	38,115
15.0	27,225	3,086	1.70	46,283
20.0	36,300	2,723	1.50	54,450
30.0	54,450	2.360	1.30	70,785

Footnotes:
* Calculated from data provided by Murfee Engineers
# Calculated from data provided by Austin Stormwater Management staff
All other values derived from combined data

While Austin has traditionally built these systems in open basins, there appears no reason why the basic designs cannot be adapted to underground vault construction where real estate values are high enough to justify their use. Austin Partial Sedimentation Sand Filters have been built in underground vaults in Alexandria on sheds of three-four acres of impervious cover. Precast segmented underground vaults are now available in very large configurations. Besides the modified precast box culvert technology illustrated under **MS 3.12A: D.C. Sand Filters**, precast arch technology has also been adapted to the construction of underground vaults. **Figure 3.12C-3** shows such a system. It appears that approximately five acres of impervious cover is the uper limit of the area that should be treated by a single underground vault system.

FIGURE 3.12C - 3
Underground Vault Fabricated From Precast Bridge Arch Components

(Photo Courtesy of BridgeTek Bridge Technologies, LLC., Fredericksburg, Virginia)

Development Conditions

Austin Sand Filters are generally suitable BMPs for medium to high density commercial or industrial development. Because of confined space entry restrictions when constructed in underground vaults and maintenance requirements, they are not generally suitable for residential applications except for apartment complexes or large condominiums where a dedicated maintenance force will be present.

Planning Considerations

Refer to the **Planning Considerations** for **Minimum Standard 3.12: General Intermittent Sand Filter Practices**. Of special concern are the stormwater infrastructure serving the site and the requirement to isolate the sand filter from receiving flows until the drainage shed is fully stabilized.

Potential and existing elevations of stormwater infrastructure serving the site will determine one of the most critical design parameters: the maximum depth to which runoff may be pooled over the filter and preserve a gravity flow configuration (whatever the pooling depth, there must be a minimum of five feet of clearance between the top of the filter and the top slab of the filter shell to allow filter maintenance).

Sand filter BMPS must ***never*** *be placed in service until all site work has been completed and stabilization measures have been installed and are functioning properly.*

Design Criteria

The purpose of this section is to provide recommendations and minimum criteria for the design of Austin Sand Filter BMPs intended to comply with the Virginia Stormwater Management program's runoff quality requirements.

Refer to the **General Design Criteria** previously discussed under **General Intermittent Sand Filter Practices, Minimum Standard 3.12**

Filter Sizing Criteria

1. ***Full Sedimentation with Filtration***

In this configuration, the sedimentation basin receives the WQV and detains it for a minimum draw-down time (time required to empty the basin from a full WQV condition) of 24 hours. The effluent from the sedimentation basin is discharged into the filtration basin..

Austin conducted a literature review of sedimentation basins and slow rate filters to establish design criteria.

For filtration basins, surface area is the primary design parameter. The required surface area is a function of sand permeability, bed depth, hydraulic head and sediment loading. A filtration rate of 0.0545 gallons per minute per square foot has been selected for design criteria (10.5 feet per day or 3.4 million gallons per acre per day). This filtration rate is based on a Darcy's Law coefficient of permeability k =3.5 feet per day, an average hydraulic head (h) of three (3) feet and a sand bed depth (d_f) of 18 inches, and a filter drawdown time, t_f of 40 hours.

Substituting these values in the basic Austin Filter Formula shown in **General Intermittent Sand Filter Practices, Minimum Standard 3.12** yields:

$A_f = I_aH/18$

where “A_f” is the minimum surface area of the filtration media in acres, “I_a” is the contributing impervious runoff area in acres and “H” is the runoff depth in feet (0.5 inch = 0.0417 feet when treating the WQV).

When treating the first 1/2-inch of runoff, this formula reduces to

$A_f = 0.0023I_a = 100\ Ft^2$ of filter per impervious acre.

This formula is obviously based on a number of simplifying assumptions. Determining the actual average depth of ponding over the filter is an extremely complex proposition considering thet the runoff is being released from the sedimentation chamber to the filter at first a rising and then a falling head and then percolating through the sand filter at first a rising and then a falling head. However, this design procedure has worked well for austin for over a decade and may be therefore be considered to be vaild.

When treating a volume greater than the WQV (as when a combined quantity detention/presettling basin is utilized) use the following formula:

$A_f = 0.0023I_a \times (TV / WQV)$

Where TV = the full retention volume of the detention basin/presettling basin.

2. Partial Sedimentation with Filtration

In this configuration, the sedimentation basin or chamber holds a minimum of 20 percent of the WQV and is hydraulically connected to the filter basin with orifices or slots which allow the water level to equalize between the two chambers.

For Austin Sand Filters with partial sedimentation protection, utilize the following formula:

$$A_{fm(PS)} = \frac{545I_ad_f}{(h + d_f)}$$

where,

I_a = impervious cover on the watershed in acres
d_f = sand bed depth (normally 1.5 to 2ft)
h = average depth of water above surface of sand media between full and empty basin conditions (ft.)

Sedimentation Basin Sizing

1. ***Full Sedimentation with Filtration***

The sedimentation basin must hold the entire WQV (or larger treatment volume) and release it to the filter over 24 hours. The volume of the basin is thus set by the amount of area to be treated. For sedimentation basins, the removal of discrete particles by gravity settling is primarily a function of surface loading, "Q_o/A_s ", where "Q_o " is the rate of outflow from the basin and "A_s" is the basin surface area. Basin depth is of secondary importance as settling is inhibited only when basin depths are too shallow (particle resuspension and turbulence effects). For sedimentation, surface area is the primary design parameter for a fixed minimum draw-down time, t_d, of 24 hours. Removal efficiency, E, is also a function of particle size distribution. For design purposes, the particles selected for complete removal in the sedimentation basin are those which are greater than or equal in size to silt with the following characteristics: particle diameter 0.00007 foot (20 microns) and specific gravity of 2.65. These are typical values for urban runoff .

Presettling basins are usually sized using the Camp-Hazen equation (Claytor and Schueler, 1996):

$$A_S = - (Q_O / w) \times \text{Ln } (1 - E)$$

Where,

A_S = Surface area (ft^2) of the sedimentation basin
E = Trap efficiency, which is the target removal efficiency of suspended solids (use 90%)
w = Particle settling velocity; for silt, use 0.0004 ft/sec
Q_O = rate of outflow from the basin = WQV (or treatment volume) divided by the detention time (24 hours)

Substituting the values recommended above yields the simplified formula:

$$A_S = 0.066 \times WQV \quad (ft^2)$$

For 1816 ft^3, this yields an area of 120 ft^2. However, Austin recommends that the sedimentation basin be no more that 10 feet deep, which yields a surface area approximately 115% of the basin Camp-Hazen area. The Austin formula for minimum surface area is:

$$A_S = 0.0042\ I_a$$

Where I_a is the contributing impervious runoff area in acres

2. Partial Sedimentation with Filtration

The minimum area of the sediment chamber may be computed by the formula:

$$A_S = WQV / 2h$$

Where 2h = the maximum depth of ponding over the filter and the sediment chamber.

Additional Full Sedimentation Basin Considerations

1. *Inlet Structure*

The inlet structure design must be adequate for isolating the water quality volume from the design storm and to convey the peak flow for the design storm past the basin. The water quality volume should be discharged uniformly and at low velocity into the sedimentation basin in order to maintain near quiescent conditions which are necessary for effective treatment. It is desirable for the heavier suspended material to drop out near the front of the basin; thus a drop inIet structure is recommended in order to facilitate sediment removal and maintenance. Energy dissipation devices may be necessary in order to reduce inlet velocities which exceed three (3) feet per second.

2. *Outlet Structure*

The outlet structure conveys the water quality volume from the sedimentation basin to the filtration basin. The outlet structure shall be designed to provide for a minimum draw-down time of 24 hours. A perforated pipe or equivalent is the recommended outlet structure. The 24 hour draw-down time should be achieved by installing a throttle plate or other flow control device at the end of the riser pipe (the discharges through the perforations should not be used for draw-down time design purposes)

3. *Basin Geometry*

The shape of the sedimentation basin and the flow regime within this basin will influence how effectively the basin volume is utilized in the sedimentation process. The length to width ratio of the basin should be 2:1 or greater. Inlet and outlet structures should be located at extreme ends of the basin in order to maximize particle settling opportunities.

Short-circuiting (i.e., flow reaching the outlet structure before it passes through the sedimentation basin volume) flow should be avoided. Dead storage areas (areas within the basin which are by-passed by the flow regime and are, therefore, ineffective in the settling process) should be minimized. Baffles may be used to mitigate short circuiting and/or dead storage problems. The sedimentation illustrated in **Figure 3.12C-1** (photo in **Figure 3.12-4**) illustrates the use of baffles to improve sedimentation basin performance.

4. *Sediment Trap (Optional)*

A sediment trap is a storage area which captures sediment and removes it from the basin flow regime. In so doing the sediment trap inhibits resuspension of solids during subsequent runoff events, improving long-term removal efficiency. The trap also maintains adequate volume to hold the water quality volume which would otherwise be partially lost due to sediment storage. Sediment traps may reduce maintenance requirements by reducing the frequency of sediment removal. It is recommended that the sediment trap volume be equal to ten (10) percent of the sedimentation basin volume. Water collected in the sediment trap shall be conveyed to the filtration basin in order to prevent standing water conditions from occurring. All water collected in the sediment trap shall drain out within 60 hours. The invert of the drain pipe should be above the surface of the sand bed filtration basin. The minimum grading of the piping to the filtration basin should be 1/4 inch per foot (two (2) percent slope). Access for cleaning the sediment trap drain system is necessary.

Design Storm

The inlet design or integral large storm bypass must be adequate for isolating the WQV from the design storm for the receiving storm sewer system (usually the 10 year storm) and for conveying the peak flow of that storm past the filter system. Since D.C. Sand Filters will be used only as off-line facilities in Virginia, the interior hydraulics of the filter are not as critical as when used as an on-line facility. The system should draw down in approximately 40 hours.

Infrastructure Elevations

For cost considerations, it is preferable thatAustin Sand Filters work by gravity flow. This requires sufficient vertical clearance between the invert of the prospective inflow storm piping and the invert of the storm sewer which will receive the outflow. In cases where gravity flow is not possible, a clearwell sump and pump are required to discharge the effluent into storm sewer. Such an application would be appropriate in commercial or industrial situations where a dedicated maintenance force will be available (shopping malls, apartment houses, factories of other industrial complexes, etc.).

Special Considerations for Underground Filter Systems

When Austin Sand Filters are placed underground, a number of special considerations pertain. The restrictive orifice or gate valve for controlling the release of water from a separate sedimentation vault should be placed in a manhole located between the sedimentation vault and the filter vault. The sedimentation vault should contain a sediment sump into which accumulated sediments may be flushed with a high pressure hose for removal by vacuum trucks. Water should enter the filter vault in a separate headbox with a permanent pool for energy absorbtion and a hydrocarbon trap like that of a D.C. Sand Filter. The filter vault should also contain a separate clearwell.

Structural Requirements

The load-carrying capacity of the filter structure must be considered when it is located under parking lots, driveways, roadways, and, certain sidewalks (such as those adjacent to State highways). Traffic intensity may also be a factor. The structure must be designed by a licensed structural engineer and the structural plans require approval by the plan approving jurisdiction.

Accessibility and Headroom for Maintenance

Both the sedimentation basin and the filter must be accessible to appropriate equipment and vacuum trucks for removing accumulated sediments and trash. The sedimentation basin must be cleaned approximately once per year, and the filter will likely need raking on that frequency to remove trash and restore permeability. When filters are placed in underground vaults, all chambers must have personnel access manholes and built-in access ladders. **A minimum headspace of 60 inches above the filter is required to allow such maintenance and repair.** A 38-inch diameter maintenance manhole with eccentric nested covers (a 22-inch personnel access lid inside the 38-inch diameter lid) or a rectangular load bearing access door (minimum 4 ft. x 4 ft.) should be positioned directly over the center of the filter. A 30-inch manhole should also be placed directly over the sediment sump in an underground sedimentation vault. Similar manholes must be positioned to provide access for a high-pressure hose to reach all points in the sediment vault.

Construction Specifications

<u>Sedimentation Basin Liners</u>

Impermeable liners may be either clay, concrete or geomembrane. If geomembrane is used, suitable geotextile fabric shall be placed below and on the top of the membrane for puncture protection. Clay liners shall meet the specifications in **Table 3.12C-2**:

The clay liner shall have a minimum thickness of 12 inches.

If a geomembrane liner is used it shall have a minimum thickness of 30 mils and be ultraviolet resistant.

The geotextile fabric (for protection of geomembrane) shall meet the specifications in **Table 3.12C-3**.

TABLE 3.12C - 2
Clay Liner Specifications

Property	Test Method	Unit	Specification
Permeability	ASTM D-2434	Cm/Sec	1×10^{-6}
Plasticity Index of Clay	ASTM D-423 & D-424	%	Not less than 15
Liquid Limits of Clay	ASTM D-2216	%	Not less than 30
Clay Compaction	ASTM-2216	%	95% of Standard Proctor Density
Clay Particles Passing	ASTM D-422	%	Not less than 30

TABLE 3.12C - 3
Geotextile Specification for Basin Liner "Sandwich"

Property	Test Method	Unit	Specification
Unit Weight		Oz./Sq.Yd.	8 (minimum)
Filtration Rate		In./Sec.	0.08 (minimum)
Puncture Strength	ASTM D-751 (Modified)	Lb.	125 (minimum)
Mullen Burst Strength	ASTM D-751	Psi.	400 (minimum)
Tensile Strength	ASTM D-1682	Lb.	300
Equiv. Opening Size	U.S. Standard Sieve	No.	80 (minimum)

Source: City of Austin

Equivalent methods for protection of the geomembrane liner will be considered on a case by case basis. Equivalency will be judged on the basis of ability to protect the geomembrane from puncture, tearing and abrasion.

<u>Portland Cement Concrete</u>

Concrete liners may be used for sedimentation chambers and for sedimentation and filtration basins. Concrete shall be at least five (5) inch thick Class A3 defined in the Virginia Department of Transportation *Road and Bridge Specifications.*

<u>Outlet Structure for Full Sedimentation Basin</u>

A perforated pipe or equivalent is the recommended outlet structure. The 24-hour draw-down should be achieved by installing a throttle plate or other control device at the end of the riser pipe (the discharges through the perforations should not be used for draw-down time design purposes). The perforated riser pipe should be selected from **Table 3.12-4.**

TABLE 3.12C - 4
Perforated Riser Pipes

Riser Pipe Nominal Diameter (inches)	Vertical Spacing Between Rows (Center to Center in Inches)	Number of Perforations Per Row	Diameter of Perforations (inches)
6	2.5	9	1
8	2.5	12	1
10	2.5	16	1

Source: City of Austin

A trash rack shall be provided for the outlet. Openings in the rack should not exceed 1/3 the diameter of the vertical riser pipe. The rack should be made of durable material, resistant to rust and ultraviolet rays. The bottom rows of perforations of the riser pipe should be protected from clogging. To prevent clogging of the bottom perforations it is recommended that geotextile fabric be wrapped over the pipe's bottom rows and that a cone of one (1) to three (3) inch diameter gravel be placed around the pipe. If a geotextile fabric wrap is not used then the gravel cone must not include any gravel small enough to enter the riser pipe perforations. **Figure 3.12C-4** illustrates these considerations.

<u>Outlet Structure for Partial Sedimentation Basin</u>

The outlet structure should be a berm or wall with multiple outlet ports or a gabion so as to discharge the flow evenly to the filtration basin. Rock gabions should be constructed using 6-8 inch diameter rocks. The berm/wall/gabion height should not exceed six (6) feet and high flows should be allowed to overtop the structure (weir flow). Outlet ports should not be located along the vertical center axis of the berm/wall so as to induce flow-spreading. The outflow side should incorporate features to prevent gouging of the sand media (e.g., concrete splash pad or riprap)

<u>Sand Filter Layer</u>

For applications in Virginia, use **ASTM C33 Concrete Sand** or sand meeting the Grade A fine aggregate gradation standards of Section 202 of the VDOT ***Road and Bridge Specifications.*** The top of the sand filter must be completely level.

<u>Geotextile Fabrics</u>

The filter cloth layer beneath the sand shall conform to the specifications shown in **Table 3.12C-5**: The fabric rolls must be cut with sufficient dimensions to cover the entire wetted perimeter of the filtering area and lap up the filter walls at least six-inches.

FIGURE 3.12C - 4
Riser Pipe Detail for Full Sedimentation Basin

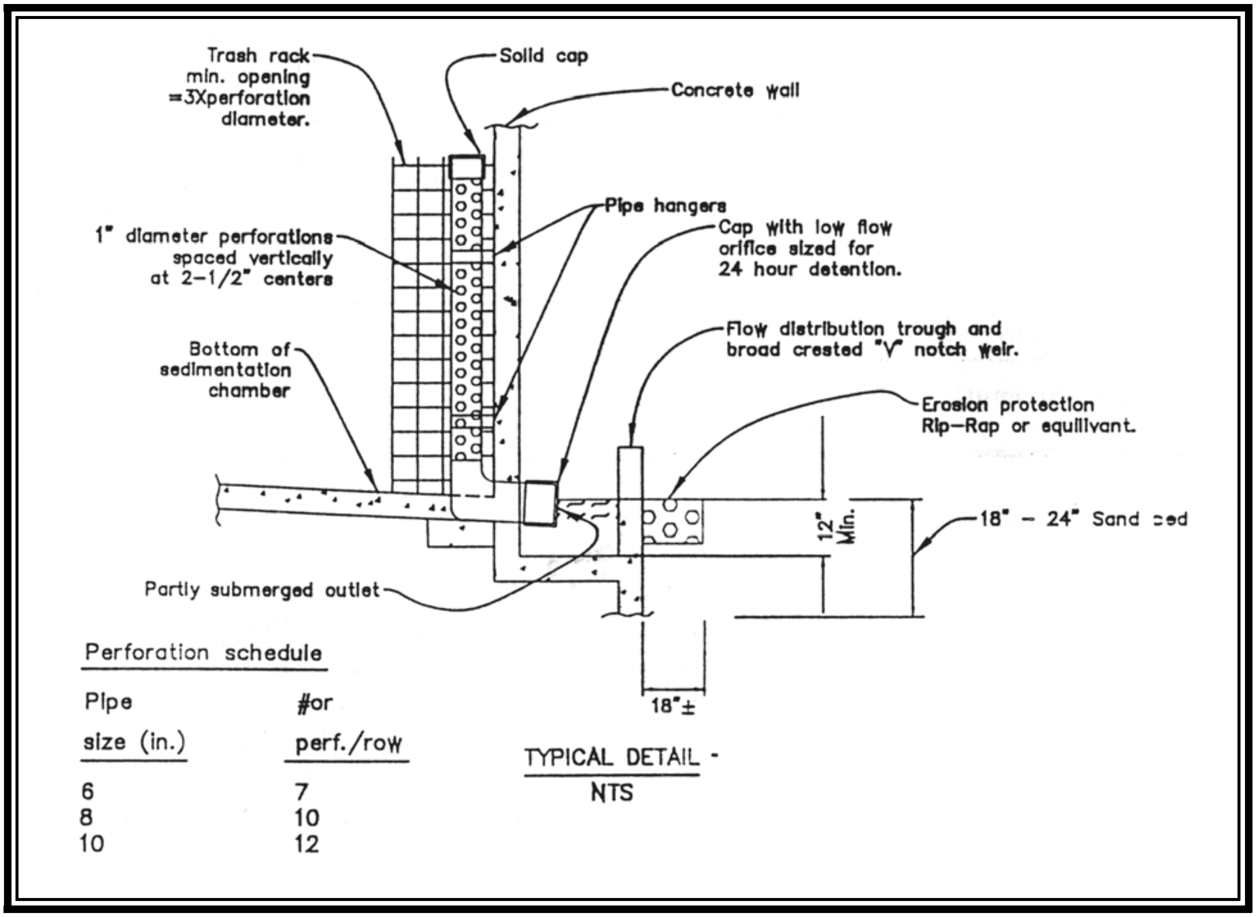

Table 3.12C - 5
Specifications for Nonwoven Geotextile Fabric Beneath Sand in Austin Sand Filter

Mullen Burst Strength	ASTM D-751	Psi	400 (min.)
Equiv. Opening Size	U.S. Standard Sieve	No.	80 (min.)
Tensile Strength	ASTM D-1682	Lb.	300 (min.)

Gravel Bed Around Collector Pipes

The gravel layer surrounding the collector pipes shall be ½ to two (2) inch diameter gravel and provide at least two (2) inches of cover over the tops of the drainage pipes. The gravel and the sand layer are usually separated by a layer of geotextile fabric meeting the specification listedabove. However, on small underground vault partial sedimentation systems, some jurisdictions allow the substitution for an additional six-inch layer of 1/4-inch washed pea gravel in lieu of the filter fabric. In such cases, hydraulic compaction and refilling of the filter is especially important. **FIGURE 3.12C-5** shows a cross-section of a filter with the usual configuration. **FIGURE 3.12C-6** shows an underground vault filter with a six-inch pea gravel layer.

Underdrain Piping

The underdrain piping consists of 4-inch or 6-inch schedule 40 or better polyvinyl perforated pipes reinforced to withstand the weight of the overburden. Perforations should be 3/8 inch, and each row of perforations shall contain at least four holes for four-inch pipe and six holes for six-inch pipe. Maximum spacing between rows of perforations shall be six (6) inches. Maximum spacing between pipes shall be 10 feet.

The minimum grade of piping shall be 1/8 inch per foot (one [1] percent slope). Access for cleaning all underdrain piping is needed. Clean-outs for each pipe shall extend at least six (6) inches above the top of the upper filter surface, e.g. the top layer of gravel.

Each pipe shall be thoroughly wrapped with 8 oz./sq.yd. geotextile fabric meeting the specification in **Table 3.12C-1** above.

FIGURE 3.12C - 5
Austin Sand Filter Cross-Section With Filter Fabric Layer

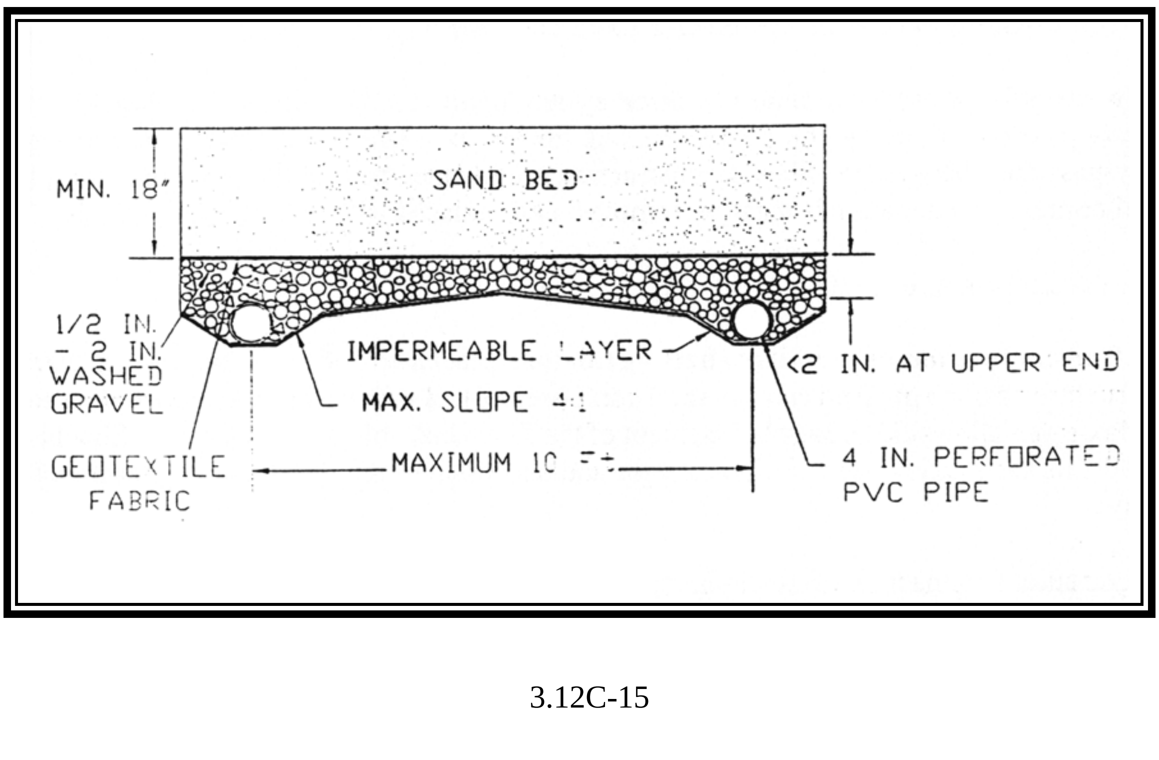

FIGURE 3.12C - 6
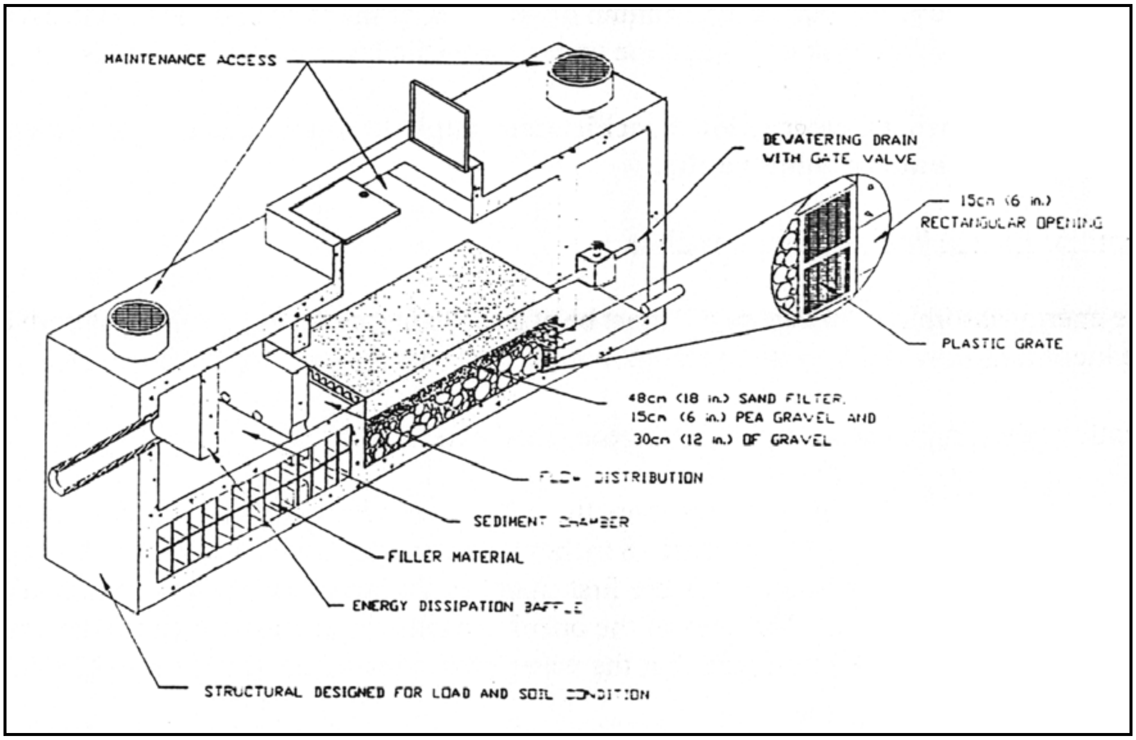
Partial Sedimentation Vault Filter With Pea Gravel Layer



<u>Protection from Construction Sediments</u>

The site erosion and sediment control plan must be configured to permit construction of the filter system while maintaining erosion and sediment control.

No runoff is to enter the sand filtration system prior to completion of all construction and site revegetation. Construction runoff shall be treated in separate sedimentation basins and routed to by-pass the filter system. Should construction runoff enter the filter system prior to site revegetation, all contaminated materials must be removed and replaced with new clean materials.

<u>Watertight Integrity Test</u>

After completion of the filter shell but before placement of the filter layers, entrances to the structure shall be plugged and the shell completely filled with water to demonstrate water tightness. Maximum allowable leakage is 5 percent of the filter shell volume in 24 hours. Should the structure fail this test, it shall be made watertight and successfully retested prior to placement of the filter layers.

Hydraulic Compaction of Filter Components

After placement of the collector pipes, gravel, and lower geotextile layer, fill the shell with filter sand to the level of the top of the sediment pool weir. Direct clean water into the sediment chamber until both the sediment chamber and filter chamber are completely full. Allow the water to draw down until flow from the collector pipes ceases, hydraulically compacting the filter sand. After allowing the sand to dry out for a minimum of 48 hours, refill the shell with sand to a level one inch beneath the top of the weir and place the upper geotextile layer and gravel ballast.

Note: The following Construction Specifications apply to Austin Sand Filters which are to be constructed in underground vaults.

Depth of Plunge Pool in Filter Headbox

The energy absorbing "plunge pool" must be at least 36 inches deep to properly absorb energy from the incoming flow and trap any hydrocarbons which pass through the sedimentation vault.

Depth of the Underwater Opening Between Chambers

To preserve an effective hydrocarbon trap, the top of the underwater opening between the headbox and the filter chamber must be at least 18 inches below the depth of the weir which divides the filter from the pool. To retain sediment in the first chamber, the bottom of the opening should be at least six inches above the floor. The area of the opening should be at least 1.5 times the cross-sectional area of the inflow pipe(s) to assure that the water level remains equal between the first and second chambers.

Total Depth of Filter Cross-Section

The total depth of the filter cross-section must match the height of the weir dividing the sedimentation pool from the filter. Otherwise, a "waterfall" effect will develop which will gouge out the front of the filter media. If a sand filter less than 24 inches is used, the gravel layer must be increased accordingly to preserve the overall filter depth.

Dewatering Drain

When the filter is placed in an underground vault, A 6-inch dewatering drain controlled by a gate valve shall be installed between the filter chamber and the clearwell chamber with its invert at the elevation of the top of the filter. The dewatering drain penetration in the chamber dividing wall shall be sealed with a flexible strip joint sealant which swells in contact with water to form a tight pressure seal.

Access Manholes

When the filter is installed in an underground vault, access to the headbox (sediment chamber) and the clearwell shall be provided through at least 22-inch manholes. Access to the filter chamber shall be provided by a rectangular door (minimum size: 4 feet by four feet) of sufficient strength to carry prospective imposed loads or by a manhole of at least 3- inch diameter with an offset concentric 22-inch lid (Neenah R-1741-D or equivalent).

Restrictive Orifice Manhole Between Vaults

The restrictive orifice or gate valve on the outlet pipe from the sedimentation vault should be placed in a manhole between the sedimentation and filter vaults with ready personnel access. **Figure 3.12C-7** illustrates this principle.

Maintenance/Inspection Guidelines

The following maintenance and inspection guidelines are not intended to be all inclusive. Specific facilities may require other measures not discussed here.

Major Maintenance Requirements for Sedimentation Basins

1. Removal of silt when accumulation exceeds six (6) inches in sediment basins without sediment traps. In basins with sediment traps, removal of silt shall occur when the accumulation exceeds four (4) inches in the basins, and sediment traps shall be cleaned when full.

2. Removal of accumulated paper, trash and debris every six (6) months or as necessary.

3. Vegetation growing within the basin is not allowed to exceed 18 inches in height at any time.

4. Corrective maintenance is required any time a sedimentation basin does not drain the equivalent of the Water Quality Volume within 40 hours (i.e., no standing water is allowed).

5. Corrective maintenance is required any time the sediment trap (optional) does not drain down completely within 96 hours (i.e., no standing water allowed).

Major Maintenance Requirements for Filtration Components

1. Removal of silt when accumulation exceeds 1/2 inch. - Removal of accumulated paper, trash and debris every six (6) months or as necessary.

2. Vegetation growing within the basin is not allowed to exceed 18 inches in height.

3. Corrective maintenance is required any time draw-down does not occur within 36 hours after the sedimentation basin has emptied.

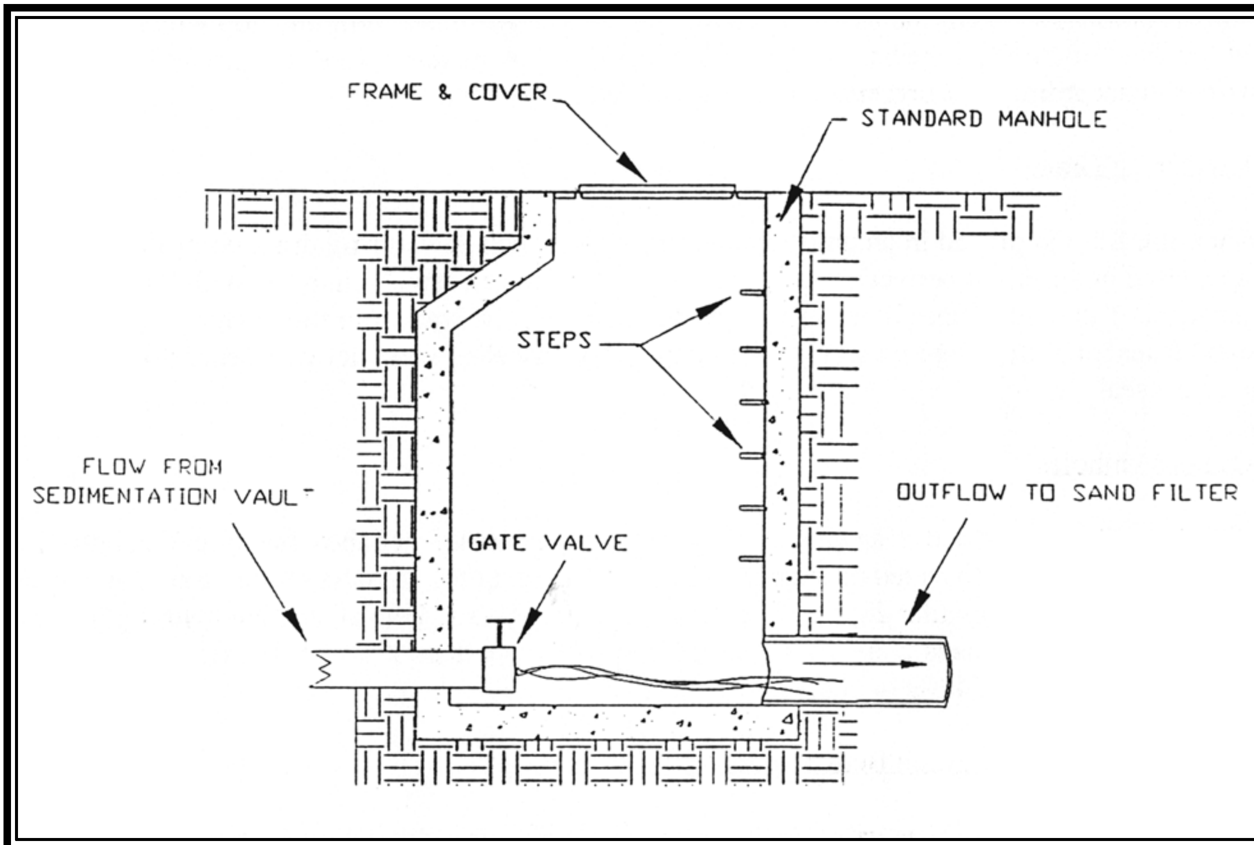
4. When an underground vault filter will no longer draw down within the required 36-hour period because of clogging with silt (approximately every 3-5 years), the upper layer of gravel and

geotechnical cloth must be replaced with new clean materials meeting the original specifications.

5. Monitoring manholes, flumes, and other facilities shall be kept clean and ready for use.

The BMP shall be inspected annually by representatives of the owner and the governing jurisdiction staff to assure continued proper functioning.

FIGURE 3.12C - 7
Restrictive Orifice Access Manhole



Sediment Chamber Pumpout

Full sedimentation chambers or basins require flushing and pumpout with a vacuum truck approximately once per year.

Concrete Shell Inspection

Concrete will deteriorate over time, especially if subjected to live loads. The concrete shell, risers, etc., must be examined during each annual inspection to identify areas that are in need of repair, and such repairs must be promptly effected.

Design Procedures

The following design procedure is structured to assure that the desired water quality volume is captured and treated by theAustin Filter. The procedure assumes that a filter shell with a rectangular cross-section is to be used.

Standard Design Logic

Employ the following design logic to design Austin Sand Filters for use in Virginia:

1. Determine Governing Site Parameters

Determine the Impervious area on the site (I_a in acres), the water quality volume to be treated (WQV in $ft.^3 = 1816\ I_a$), and the site parameters necessary to establish 2h, the maximum ponding depth over the filter (storm sewer invert at proposed connection point, elevation to inflow invert to BMP, etc).

2. Select Filter Depth and Determine Maximum Ponding Depth

Considering the data from Step 1) above, select the Filter Depth ((d_f) and determine the maximum achievable ponding depth over the filter (2h).

3. For Full Sedimantation Systems, size the sedimentation basin (vault) to hold the WQV with a minimum depth of 10 feet.

4. Compute the Minimum Area of the Sand Filter (A_{fm})

For systems with full sediment protection, provide a dediment chamber of sufficient volume to hold the WQV. Make the depth $\leq$ ten feet. To compute the area of the filter, use the formula:

$$A_f = 100I_a$$

Where I_a = the impervious acreage on the drainage shed.

For systems with only partial sediment protection, utilize the formula:

$$A_{fm(PS)} = \frac{545 I_a d_f}{(h + d_f)}$$

A_{fm} = minimum surface area of sand bed (square feet)
I_a = impervious cover on the watershed in acres
d_f = sand bed depth (normally 1.5 to 2ft)
h = average depth of water above surface of sand media between full and empty basin conditions (ft.)

5. Select Filter Width and Compute Filter Length and Adjusted Filter Area

Considering site constraints, select the Filter Width (W_f). Then compute the Filter Length (L_f) and the Adjusted Filter Area (A_f)

$$L_f = A_{fm}/W_f$$

$$A_f = W_f \times L_f$$

Sizing computations are completed at this point for the full sediment protection system. The only remaining task is to assure that the filter chamber is sized to contain a minimum of 20 % of the WQV. The logic continues for the partial sedimentation system.

6. Compute the Storage Volume on Top of the Filter (V_{Tf})

$$V_{Tf} = A_f \times 2h$$

7. Compute the Storage in the Filter Voids (V_v)
(Assume 40% voids in filter media)

$$V_v = 0.4 \times A_f \times (d_f + d_g)$$

8. Compute Flow Through Filter During Filling (V_Q)
(Assume 1-hour to fill per D.C. practice)

$$V_Q = \frac{kA_f(d_f + h)}{d_f} \text{ ; use } k = 2 \text{ ft./day} = 0.0833\text{/hr.}$$

9. Compute Net Volume to be Stored Awaiting Filtration (V_{st})

$$V_{st} = WQV - V_{Tf} - V_v - V_Q$$

10. Compute Length of Sediment chamber (L_{SC})

$$L_{SC} = \frac{V_{st}}{(2h \times W_f)}$$

11. Compute Minimum Length of Sediment Chamber (L_s)
(to contain 20% of WQV per Austin practice)

$$L_{sm} = \frac{0.2WQV}{(2h \times W_f)}$$

12. Set Final Length of the Sediment Chamber (L_{SCF})

If $L_{SC} \geq L_s$, make $L_{SCF} = L_{SC}$

If $L_{SC} < L_{sm}$, make $L_{SCF} = L_{sm}$

It may be economical to adjust final dimensions to correspond with standard precast structures or to round off to simplify measurements during construction.

Checklists

The **Construction Inspection and As-Built Survey Checklist** found in **Appendix 3D** is for use in inspecting intermittent sand filter facilities during construction and, where required by the local jurisdiction, engineering certification of the filter construction. The **Operation and Maintenance Checklist**, also found in **Appendix 3D**, is for use in conducting maintenance inspections of intermittent sand filter facilities.

GRASSED SWALE

Definition

A grassed swale is a broad and shallow earthen channel vegetated with erosion resistant and flood-tolerant grasses. Check dams are strategically placed in the swale to encourage ponding behind them.

A water quality swale is a broad and shallow earthen channel vegetated with erosion resistant and flood tolerant grasses, and underlain by an engineered soil mixture.

Purpose

The purpose of grassed swales and water quality swales is to convey stormwater runoff at a non-erosive velocity in order to enhance its water quality through infiltration, sedimentation, and filtration. Check dams are used within the swale to slow the flow rate and create small, temporary ponding areas. A water quality swale is appropriate where greater pollutant removal efficiency is desired.

Water Quality Enhancement

Grassed swalesand water quality swales remove pollution through *sedimentation*, *infiltration*, and *filtration*. Water quality swales are specifically engineered to filter stormwater through an underlying soil mixture while grasses swales are designed to slow the velocity of flow to encourage settling and filtering through the grass lining. Vegetation filters out the sediments and other particulate pollutants from the runoff and increases the opportunity for infiltration and adsorption of soluble pollutants. The flow rate becomes a critical design element, since runoff must pass through the vegetation slowly for pollutant removal to occur. Monitoring of grassed swales has indicated low to moderate removal of soluble pollutants (phosphorous and nitrogen) and moderate to high removal of particulate pollutants.

Flood Control

Grassed swales and water quality swales will usually provide some peak attenuation depending on the storage volume created by the check dams. However, flood control should be considered a secondary function of grassed swales since the required storage volume for flood control is usually more than they can provide.

FIGURE 3.13 - 1
Typical Grassed Swale Configuration

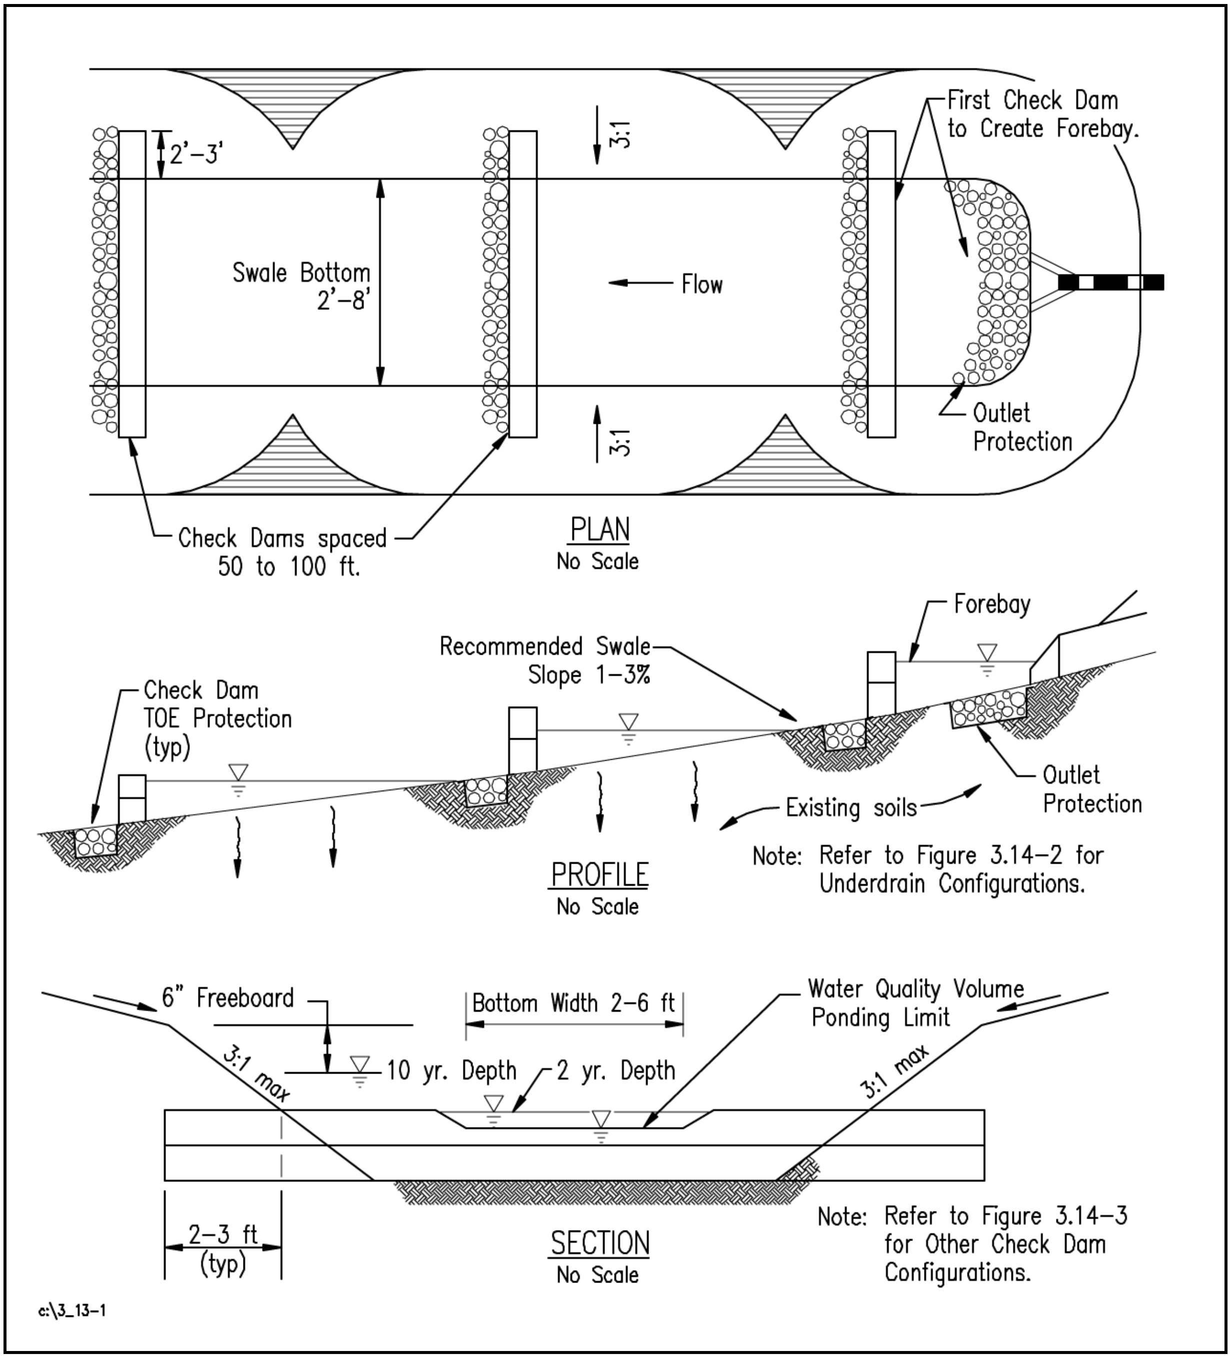

FIGURE 3.13 - 2
Typical Water Quality Swale Configuration

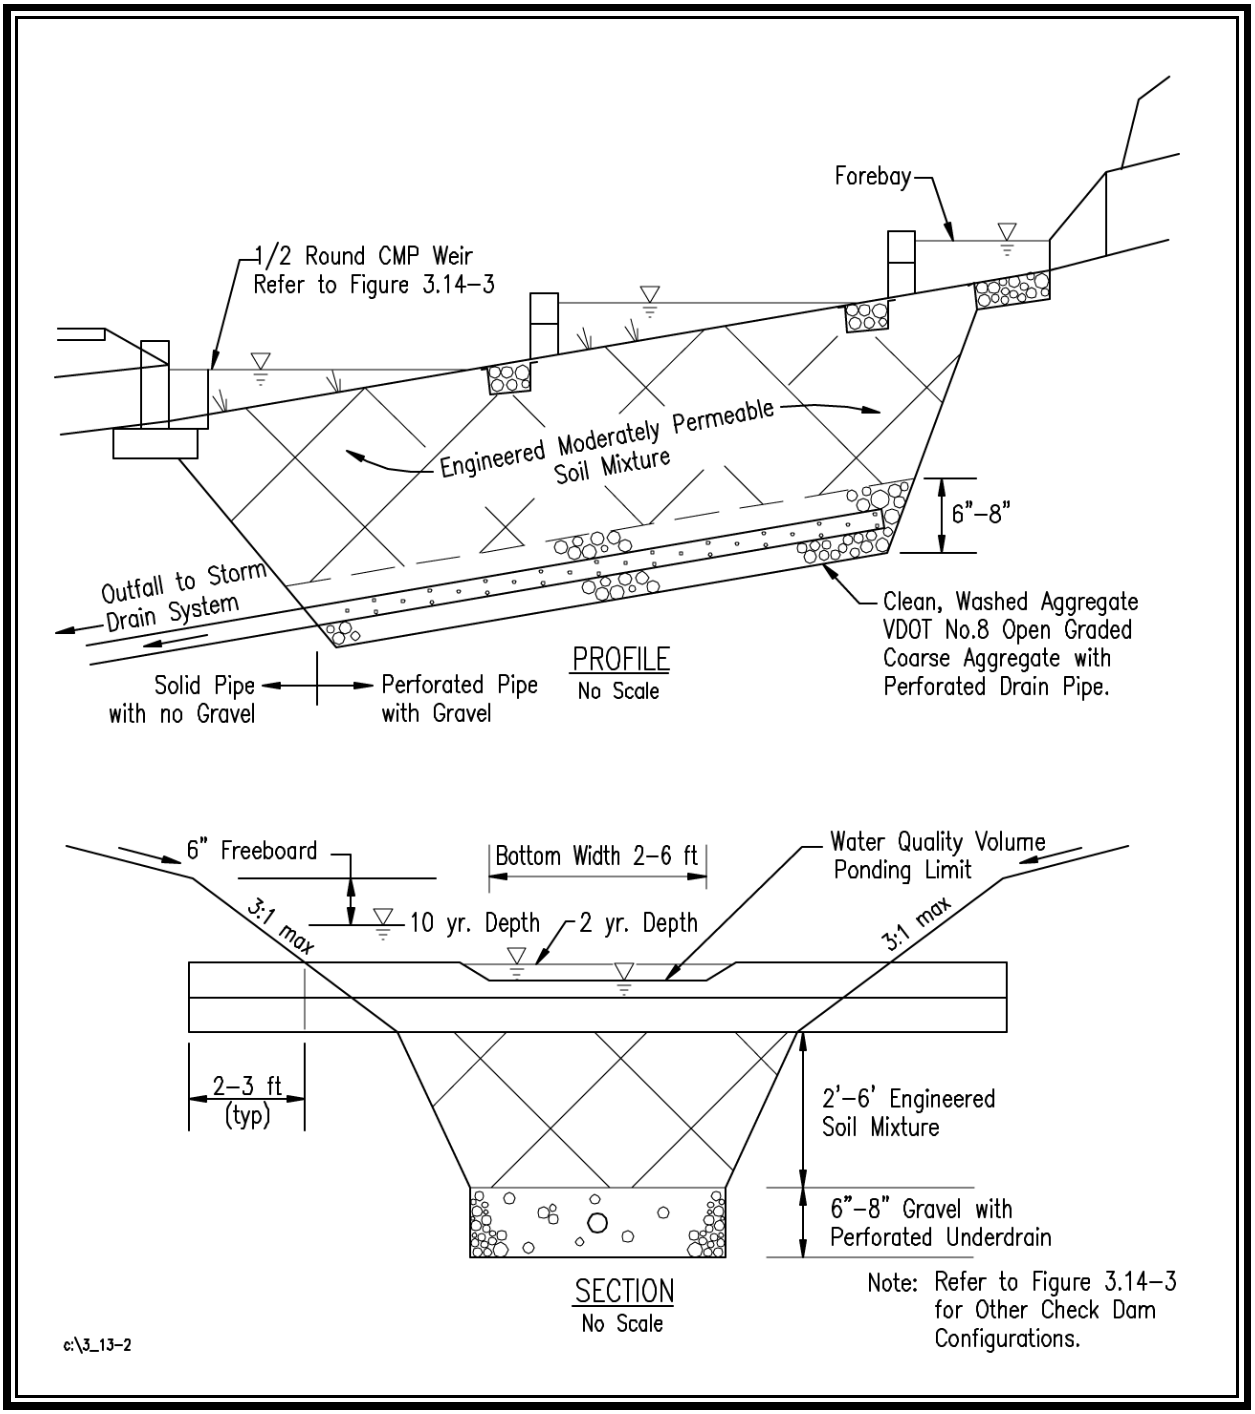

TABLE 3.13 - 1
Pollutant Removal Efficiency for Grassed Swales

Water Quality BMP	Target Phosphorus Removal Efficiency	Impervious Cover
Grassed Swale	15%	16 - 21%
Water Quality Swale	35%	16 - 37%

Channel Erosion Control

Grassed swales and water quality swales may also provide some benefits relative to channel erosion by reducing the peak rate of discharge from a drainage area. However, the holding capacity of a grassed swale designed for water quality purposes is limited.

Condition Where Practice Applies

Drainage Area

Grassed swales and water quality swales engineered for enhancing water quality cannot effectively convey large flows. Therefore, their contributing drainage areas must be kept small. The dimensions (length, width, and overall geometry) and slope of the swale, and its ability to convey the 10-year storm at a non-erosive velocity will set the size of the contributing drainage area.

Development Conditions

Grassed swales are commonly used instead of curb and gutter drainage systems in low- to moderate-density (16 to 21% impervious) single-family residential developments. Since grassed swales do not function well with high volumes or velocities of stormwater, they have limited application in highly urbanized or other highly impervious areas. However, swales may be appropriate for use in these areas if they are constructed in series or as pretreatment facilities for other BMPs.

Grassed swales are usually located within the right-of-way when used to receive runoff from subdivision or rural roadways. They may also be installed within drainage easements along the side or rear of residential lots. Grassed swales can be strategically located within the landscape to intercept runoff from small impervious surfaces (small parking lots, rooftops, etc.) as a component of a subdivision-wide or development-wide BMP strategy.

Water quality swales are appropriate for the same development conditions as those listed for grassed swales with the addition of higher densities of development (16 - 37% impervious) due to the increased pollutant removal capability.

Planning Considerations

Figure 3.13-1 pesents a grassed swale designed to hold small pockets of water behind each check dam. The water slowly drains through small openings in the chack dam and/or infiltrates into the ground. Slow channel velocities allow the vegetation to filter out sediments and other particulate pollutants from the runoff and increases the opportunity for infiltration and adsorption of soluble pollutants.

Figure 3.13-2 presents a water quality swale with an engineered soils media directly under the swale, with an underdrain. This design may be used in areas where the soils are not conducive to infiltration, or in developments where the swale is constructed beside a roadway using fill or compacted soils.

Site Conditions

The following items should be considered when selecting a grassed swale as a water quality BMP:

1. **Soils –** Grassed swales can be used with soils having moderate infiltration rates of 0.27 inches per hour (silt loam) or greater. Besides permeability, soils should support a good stand of vegetative cover with minimal fertilization.

   Water quality swales can be used in areas of unsuitable soil conditions for infiltration since the engineered soil mixture and underdrain system is used in place of the insitu soils.

2. **Topography –** The topography of the site should be relatively flat so that the swale can be constructed with a slope and cross-section that maintains low velocities and creates adequate storage behind the check dams.

3. **Depth to water table –** A shallow or seasonally-high groundwater table will inhibit the opportunity for infiltration. Therefore, the bottom of the swale should be at least 2 feet above the water table.

Sediment Control

Grassed swales may be used for conveyance of stormwater runoff during the construction phase of development. However, the swales should be maintained as required by the Virginia Erosion and Sediment Control Regulations and local program requirements. Before final stabilization, sediment must be removed from the swales and the soil surface prepared for final stabilization. Tilling of the swale bottom may be needed to open the surface pores and re-establish the soil's permeability.

Water quality swales should be constructed after a majority of the drainage area has been stabilized.

(Refer to **Min. Std. 3.11: Bioretention Facilities**).
This section presents minimum criteria and recommendations for the design of grassed swales used to enhance water quality. It is the designer's responsibility to decide which criteria are applicable to the particular swale being designed and to decide if any additional design elements are required. The designer must also provide for the long-term functioning of the facility by choosing appropriate structural materials.

Design Criteria

The design of a water quality grassed swale includes calculations for traditional swale parameters (flow rate, maximum permissible velocities, etc.) along with storage volume calculations for the water quality volume.

Hydrology

The hydrology of a grassed swale's contributing drainage area should be developed per **Chapter 4, Hydrologic Methods**.

Swale Geometry

A grassed swale should have a trapezoidal cross-section to spread flows across its flat bottom. Triangular or parabolic shaped sections will concentrate the runoff and should be avoided. The side slopes of the swale should be no steeper than 3H:1V to simplify maintenance and to help prevent erosion.

Bottom Width

The bottom width of the swale should be 2 feet minimum and 6 feet maximum in order to maintain sheet flow across the bottom and to avoid concentration of low flows. The actual design width of the swale is determined by the maximum desirable flow depth, as discussed below.

Flow Depth

The flow depth for a water quality grassed swale should be approximately the same as the height of the grass. An average grass height for most conditions is 4 inches. Therefore, the maximum flow depth for the water quality volume should be 4 inches (Center for Watershed Protection, 1996).

Flow Velocity

The maximum velocity of the water quality volume through the grassed swale should be no greater than 1.5 feet per second. The maximum design velocity of the larger storms should be kept low enough so as to avoid resuspension of deposited sediments. The 2-year storm recommended maximum design velocity is 4 feet per second and the 10-year storm recommended maximum design velocity is 7 feet per second.

Longitudinal Slope

The slope of the grassed swale should be as flat as possible, while maintaining positive drainage and uniform flow. The minimum constructable slope is between 0.75 and 1.0%. The maximum slope depends upon what is needed to maintain the desired flow velocities and to provide adequate storage for the water quality volume, while avoiding excessively deep water at the downstream end. Generally, a slope of between 1 and 3% is recommended. The slope should never exceed 5%.

Swale length

Swale length is dependent on the swale's geometry and the ability to provide the required storage for the water quality volume.

Swale Capacity

The capacity of the grassed swale is a combined function of the flow volume (the water quality volume) and the physical properties of the swale such as longitudinal slope and bottom width. By using the Manning equation or channel flow nomographs, the depth of flow and velocity for any given set of values can be obtained. The Manning's '*n*' value, or roughness coefficient, varies with the depth of flow and vegetative cover. An '*n*' value of 0.15 is appropriate for flow depths of up to 4 inches (equal to the grass height). The *n* value decreases to a minimum of 0.03 for grass swales at a depth of approximately 12 inches.

A grassed swale should have the capacity to convey the peak flows from the 10-year design storm without exceeding the maximum permissible velocities. (Note that a maximum velocity is specified for the 2-year and 10-year design storms to avoid resuspension of deposited sediments and other pollutants and to prevent scour of the channel bottom and side slopes.) The swale should pass the 10-year flow over the top of the check dams with 6 inches, minimum, of freeboard. As an alternative, a bypass structure may be engineered to divert flows from the larger storm events (runoff greater than the water quality volume) around the grassed swale. However, when the additional area and associated costs for a bypass structure and conveyance system are considered, it may be more economical to simply increase the bottom width of the grassed swale. It should then be designed to carry runoff from the 10-year frequency design storm at the required permissible velocity.

The longitudinal slope and the bottom width may be adjusted to achieve the maximum allowable velocity according to the Manning equation:

$$Q = \left[\frac{1.49}{n} r^{2/3} s^{1/2}\right] A$$

Equation 3.13-1
Manning Equation

Where:
- Q = peak flow rate, cfs
- n = Manning's roughness coefficient
- r = hydraulic radius, ft. = A / wp
- s = longitudinal slope of the channel
- A = cross-sectional area of the channel, ft^2

The portion of the equation within the brackets represents the velocity of flow. **Equation 3.13-1** can be rewritten as:

$$Q = VA$$

Equation 3.13-2
Continuity Equation

Where:
- Q = peak flow rate, cfs
- V = flow velocity, ft/s = $\frac{1.49}{n} r^{2/3} s^{1/2}$
- A = *cross-sectional area of the channel,* ft^2.

Additional guidance on the use of the Manning equation for the design of grassed swales is provided in the Virginia Erosion and Sediment Control Handbook (VESCH), 1992 edition.

Water Quality Volume

If a grassed swale is used as a conveyance channel, its purpose is to transport stormwater to the discharge point. However, the purpose of a water quality grassed swale is to slow the water as much as possible to encourage pollutant removal.

The use of check dams will create segments of the swale which will be inundated for a period of time. The required total storage volume behind the check dams is equal to the water quality volume for the contributing drainage area to that point. However, the maximum ponding depth behind the check dams should not exceed 18 inches. To insure that this practice does not create nuisance conditions, an analysis of the subsoil should be conducted to verify its permeability.

Underlying Soil Bed - Water Quality Swales

An underlying engineered soil bed and underdrain system may be utilized in areas where the soils are not permeable and the swale would remain full of water for extended periods of time (creating nuisance conditions). This soil bed should consist of a moderately permeable soil material with a high level of organic matter: 50% sand, 20% leaf mulch, 30% top soil. The soil bed should be 30 inches deep and should be accompanied by a perforated pipe and gravel underdrain system.

In residential developments with marginal soils, it may be appropriate to provide a soil bed and underdrain system in all grassed swales to avoid possible safety and nuisance concerns.

Check Dams

The use of check dams in a grassed swale should be per the following criteria:

1. **Height –** A maximum height of 18 inches is recommended, and the dam height should not exceed one-half the height of the swale bank.

2. **Spacing –** Spacing should be such that the slope of the swale and the height of the check dams combine to provide the required water quality volume behind the dams.

3. **Abutments –** Check dams should be anchored into the swale wall a minimum of 2 to 3 feet on each side.

4. **Toe Protection –** The check dam toe should be protected with riprap placed over a suitable geotextile fabric. The size (D_{50}) of the riprap should be based on the design flow in the swale. Class A1 Riprap is recommended.

5. **Overflow –** A notch should be placed in the top of the check dam to allow the 2-year peak discharge to pass without coming into contact with the check dam abutments, or the abutments may be protected with a non-erodible material. Six inches of freeboard should be provided between the 10-year overflow and the top of the swale.

6. **Riprap check dams –** Rip rap check dams should consist of a VDOT No. 1 Open-graded Coarse Aggregate core keyed into the ground a minimum of 6 inches, with a Class A1 riprap shell.

7. **Filter fabric –** Filter fabric is required under riprap and gabion check dams.

8. **Driveway culvert weirs –** Where a driveway culvert is encountered, a ½ round corrugated metal pipe weir bolted to the concrete driveway headwall may be utilized as a check dam, or a timber check dam placed at least one foot upstream of the culvert opening.

Outlets

Discharges from grassed swales must be conveyed at non-erosive velocities to either a stream or a stabilized channel to prevent scour at the outlet of the swale. Refer to VESCH, 1992 edition for design procedures and specifications regarding outlet stabilization.

Inflow Points

Swale inflow points should be protected with erosion controls as needed (e.g., riprap, flow spreaders, energy dissipators, sediment forebays, etc.).

Vegetation

A dense cover of water-tolerant, erosion-resistant grass or other vegetation must be established. Grasses used in swales should have the following characteristics:

- a deep root system to resist scouring,
- a high stem density, with well-branched top growth,
- tolerance to flooding,
- resistance to being flattened by runoff, and
- an ability to recover growth following inundation.

Recommended grasses include, but are not limited to, the following: Kentucky-31 tall fescue, reed canary grass, redtop, and rough-stalked blue grass. Note that these grasses can be mixed.

The selection of an appropriate vegetative lining for a grassed swale is based on several factors including climate, soils, and topography. For additional information, refer to STD. & SPEC. 3.32: Permanent Seeding in VESCH, 1992 edition.

Erosion control matting should be used to stabilize the soil before seed germination. This protects the swale from erosion during the germination process. In most cases, the use of sod is warranted to provide immediate stabilization on the swale bottom and/or side slopes. Refer to STD. & SPEC. 3.33: Sodding in VESCH, 1992 edition for additional information.

Construction Specifications

Overall, widely accepted construction standards and specifications, such as those developed by the USDA Soil Conservation Service or the U. S. Army Corps of Engineers, should be followed where applicable. Further guidance can be found in the SCS Engineering Field Manual. Specifications for the work should conform to the methods and procedures specified for earthwork, concrete, reinforcing steel, woodwork and masonry, as they apply to the site and the purpose of the structure. The specifications should also satisfy any requirements of the local government.

Sequence of Construction

The construction of grassed swales should be coordinated with the overall project construction schedule. The swale may be excavated during the rough grading phase of the project to permit use of the excavated material as fill in earthwork areas. Otherwise, grassed swales should not be constructed or placed into service until the entire contributing drainage area has been stabilized. Runoff from untreated, recently constructed areas may load the newly formed swale with a large volume of fine sediment. This could seriously impair the swale's natural infiltration ability.

The specifications for construction of a grassed swale should state the following:

- the earliest point in progress when storm drainage may be directed to the swale, and
- the means by which this delay in use will be accomplished.

Due to the wide variety of conditions encountered among projects, each project should be evaluated separately evaluated to decide how long to delay use of the swale.

Excavation

Initially, the swale should be excavated to within one foot of its final elevation. Excavation to the finished grade should be deferred until all disturbed areas in the watershed have been stabilized or protected. The final phase of excavation should remove all accumulated sediment. When final grading is completed, the swale bottom should be tilled with rotary tillers or disc harrows to provide a well-aerated, highly porous surface texture.

Vegetation

Establishing dense vegetative cover on the swale side slopes and floor is required. This cover will not only prevent erosion and sloughing, but will also provide a natural means to maintain relatively high infiltration rates.

Selection of suitable vegetative materials and application of required fertilizer and mulch should be per VESCH, 1992 edition.

Materials

1. **Check dams –** Check dams shall be constructed of a non-erosive material such as wood, gabions, riprap, or concrete. All check dams shall be underlaid by filter fabric per Std. & Spec 3.19: Rip Rap of VESCH, 1992 edition.

    a. *Wood* - pressure treated logs or timbers, or water-resistant tree species such as cedar, hemlock, swamp oak or locust.

    b. *Gabions* - hexagonal triple twist mesh with PVC coated galvanized steel wire. The maximum linear dimension of the mesh opening shall not exceed 4.5 inches. The area of the mesh opening shall not exceed 10 square inches.

    Stone or riprap for gabions shall be sized according to **Table 3.13-2**. It shall consist of field stone or rough unhewn quarry stone. The stone shall be hard and angular and of a quality that will not disintegrate with exposure to water or weathering. The specific gravity of the individual stones shall be at least 2.5.

    Recycled concrete may be used if it has a density of at least 150 pounds per cubic foot and does not have any exposed steel or reinforcing bars.

    c. *Riprap* - all riprap shall conform with VESCH Std. & Spec 3.19: Riprap, and VDOT Standards for open graded course aggregate.

    d. *Concrete* - All concrete shall conform with VDOT or SCS specifications.

2. **Underlying soil medium –** The underlying soils should consist of the following:

    a. *Soil* - USDA *ML, SM,* or *SC.*

    b. *Sand* - ASTM C-33 fine aggregate concrete sand; VDOT fine aggreagate, grading A or B.

3. **Pea Gravel –** Pea gravel should consist of washed ASTM M-43; VDOT No. 8 Open-graded Course Aggregate.

4. **Underdrain** – An underdrain system below the swale bottom shall consist of the following:

a. *Gravel* - AASHTO #7, ASTM M-43, VDOT No. 3 Open-graded Course Aggregate.

b. *PVC Pipe* - AASHTO M-278, 4-inch rigid schedule 40, perforations of 3/8-inch diameter at 6-inch centers, 4 holes per row.

c. *Filter fabric* - shall be per specifications found in VESCH, 1992 edition.

Maintenance and Inspection Guidelines

Maintenance of grassed swales includes upkeep of the vegetative cover and preservation of the swale's hydraulic properties. Individual land owners can usually carry out the suggested maintenance procedures for the swale or the portion of the swale on their property. To ensure continued long term maintenance, all affected landowners should be made aware of their maintenance responsibilities, and maintenance agreements should be included in land titles.

The following maintenance and inspection guidelines are not intended to be all-inclusive. Specific swales may require other measures not discussed here. It is the engineer's responsibility for determining if any additional items are necessary.

Vegetation

A dense and vigorous grass cover should be maintained in a grassed swale. This will be simplified if the proper grass type is selected in the design. Periodic mowing is required to keep the swale operating properly. Grass should never be cut to a height less than 3 inches. Ideally, a grass stand of 6 inches is most effective. Stabilization and reseeding of bare spots should be performed, as needed.

Check Dams

Properly constructed check dams should require very little maintenance since they are made of non-erodible materials. Periodic removal of sediment accumulated behind the check dams should be performed, as needed.

Debris and Litter Removal

The accumulation of debris (including trash, grass clippings, etc.) in the swale can alter the hydraulics of the design and lead to additional maintenance costs. Debris can also alter the flow path along the swale bottom causing low flows to concentrate and result in erosion of the swale bottom. As with any BMP, frequent inspections by the land owner will help prevent small problems from becoming larger.

Sediment Removal

The sediment that accumulates within the swale should be manually removed and the vegetation reestablished. If accumulated sediment has clogged the surface pores of the swale, reducing or eliminating the infiltration capacity, then the surface should be tilled and restabilized. Drilling or punching small holes into the surface layer can be used instead of tilling, if desired.

FIGURE 3.13 - 3
Typical Check Dam Configurations

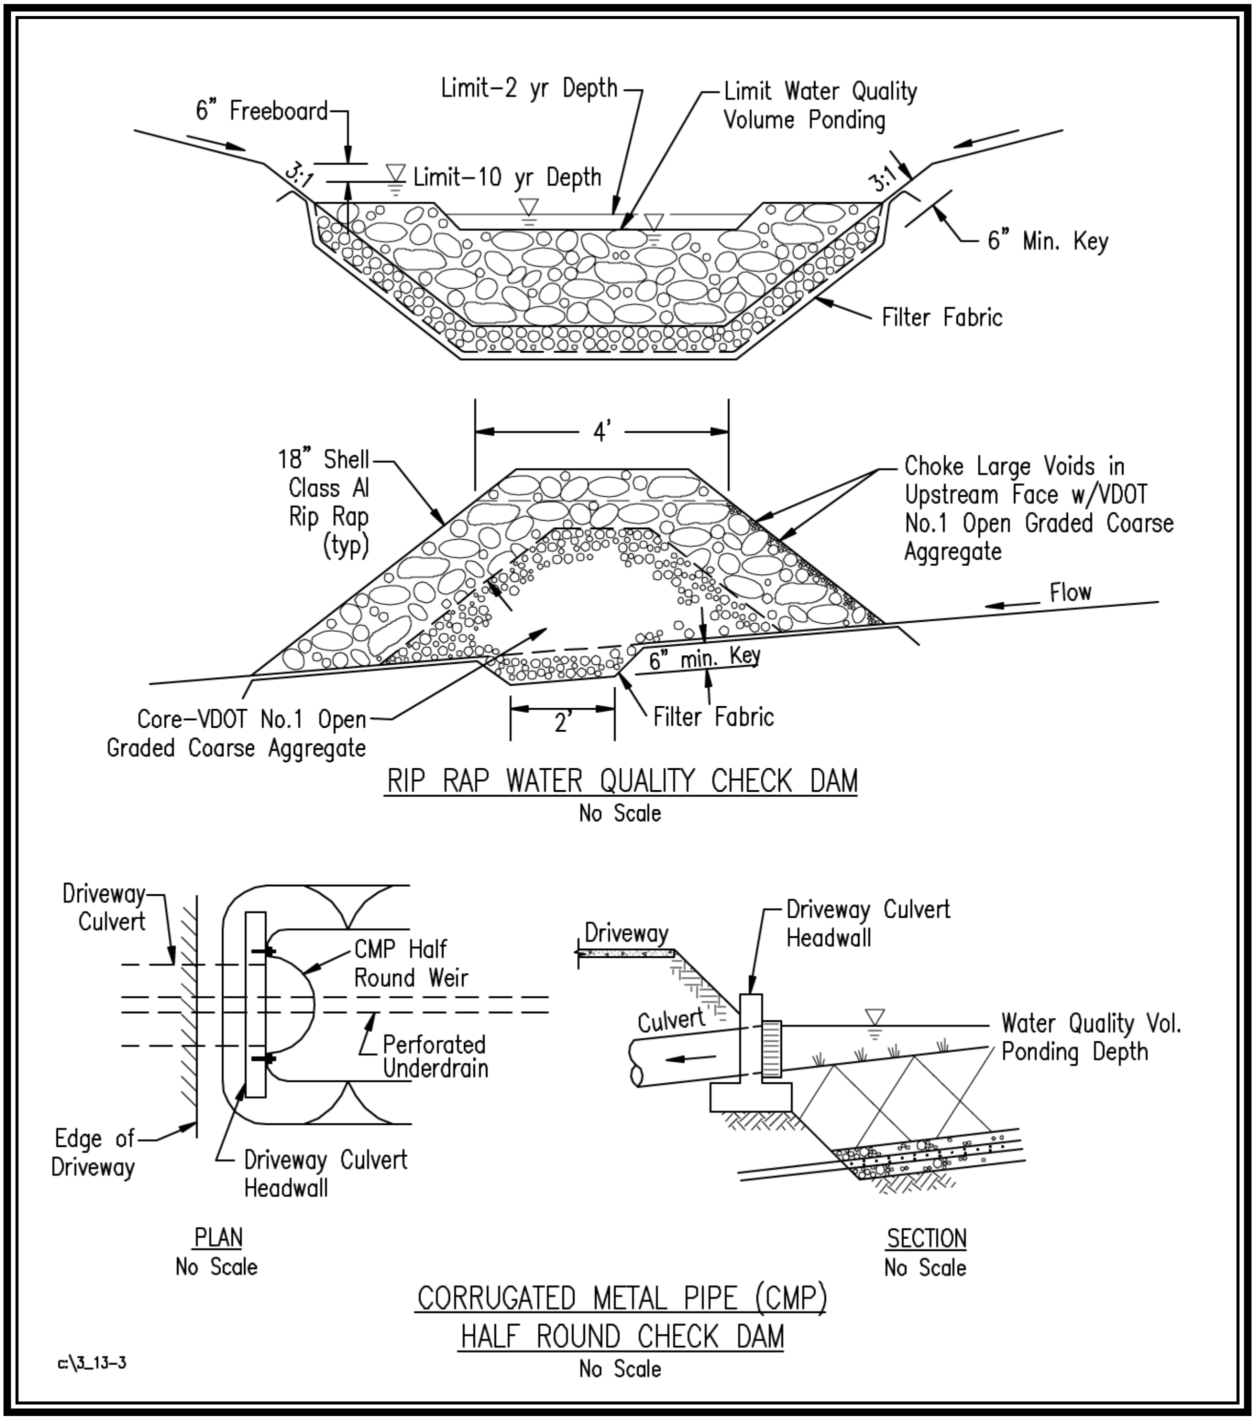

FIGURE 3.13 - 4
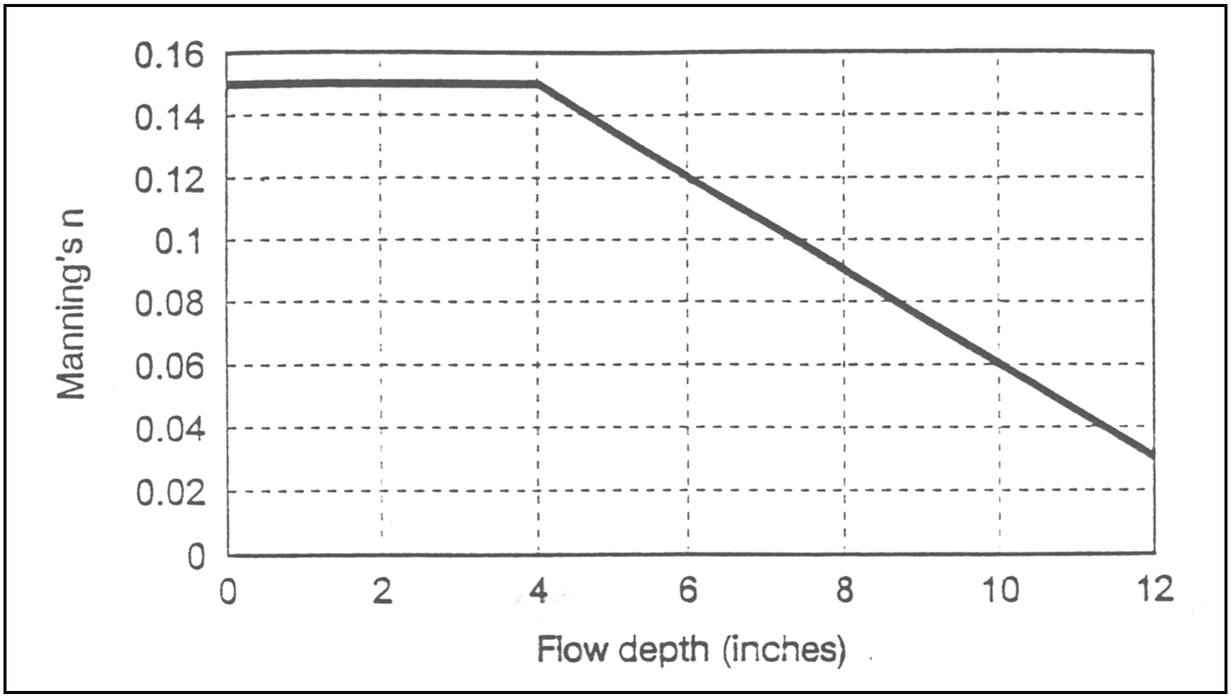
Manning's 'n' Values for Varying Depths of Flow



Design Procedures

The following design procedure represents a generic list of the steps typically required for the design of a *water quality grassed swale*.

1. Determine if the anticipated development conditions and drainage area are appropriate for a water quality grassed swale BMP.

2. Determine if the soils (permeability, bedrock, Karst, etc.) and topographic conditions (slopes, existing utilities, environmental restrictions) are appropriate for a grassed swale BMP.

3. Determine any additional stormwater management requirements (channel erosion, flooding) for the project.

4. Locate the grassed swale BMP(s) on the site.

5. Determine the hydrology and calculate the 2-year and 10-year peak discharges (**Chapter 4, Hydrologic Methods**), and the water quality volume for the contributing drainage area.

6. Approximate the geometry of the grassed swale and evaluate water quality parameters: water quality depth of flow (recommended maximum of 4 inches), and storage volume behind check dams (water quality volume). Adjust swale geometry and re-evaluate as needed.

7. Evaluate the grassed swale geometry for the the 2-year design storm peak discharge velocity (4 feet per second), and capacity (check dam overflow), and the 10-year design storm peak discharge velocity (7 feet per second) and capacity (6 inches of freeboard). (**Chapter 5, Engineering Calculations**). Adjust swale geometry and re-evaluate as needed.

8. Establish specifications for appropriate permenant vegetation on the bottom and side slopes of the grassed swale.

9. Establish specifications for sediment control.

10. Establish construction sequence and construction specifications.

11. Establish maintenance and inspection requirements.

VEGETATED FILTER STRIP

Definition

A vegetated filter strip is a densely vegetated strip of land engineered to accept runoff from upstream development as *overland sheet flow*. It may adopt any naturally vegetated form, from grassy meadow to small forest.

Purpose

The purpose of a vegetated filter strip is to enhance the quality of stormwater runoff through filtration, sediment deposition, infiltration and absorption.

A vegetated filter strip may be used as a pretreatment BMP in conjunction with a primary BMP. This reduces the sediment and particulate pollutant load that could reaching the primary BMP, which, in turn, reduces the BMP's maintenance costs and enhances its pollutant removal capabilities.

TABLE 3.14 - 1
Pollutant Removal Efficiency for Vegetated Filter Strips

BMP	Target Phosphorus Removal Efficiency	Impervious Cover
Vegetated Filter Strip	10%	16 - 21%

Vegetated filter strips rely on their flat cross-slope and dense vegetation to enhance water quality. Their flat cross-slope assures that runoff remains as sheet flow while filtering through the vegetation. There is limited ponding or storage associated with these BMPs, so they are ineffective for reducing peak discharges. Vegetated filter strips may lower runoff velocities and, sometimes, runoff volume. Typically, however, the volume reduction is not adequate for controlling stream channel erosion or flooding.

Conditions Where Practice Applies

Drainage Area

A vegetated filter strip should not receive large volumes of runoff since such flows tend to concentrate and form channels. Channels within a filter strip allow runoff to short-circuit the BMP, rendering it ineffective. Therefore, the contributing drainage area for a vegetated filter strip is based on the linear distance behind it that is maintained as sheet flow. Runoff is assumed to change from sheet flow to shallow concentrated flow after traveling 150 feet over **pervious** surfaces and 75 feet over **impervious** surfaces (Center for Watershed Protection, 1996). A level spreader may be used to convert shallow concentrated flow from larger areas back to sheet flow before it enters the filter strip. In any event, the contributing drainage area should never exceed five acres.

Development Conditions

Vegetated filter strips have historically been used and proven successful on agricultural lands, primarily due to their low runoff volumes. In urban settings, filter strips are most effective in treating runoff from isolated impervious areas such as rooftops, small parking areas, and other small impervious areas. Filter strips should not be used to control large impervious areas.

Since vegetated filter strips should not be used to treat concentrated flows, they are suitable only for low- to medium-density development (16-21% impervious), or as a pretreatment component for structural BMPs in higher density developments.

Planning Considerations

Site Conditions

The following site conditions should be considered when selecting a vegetated filter strip as a water quality BMP:

1. **Soils –** Vegetated filter strips should be used with soils having an infiltration rate of 0.52 inches/hour; (sandy loam, loamy sand). Soils should be capable of sustaining adequate stands of vegetation with minimal fertilization.

2. **Topography –** Topography should be relatively flat to maintain sheet flow conditions. Filter strips function best on 5 percent or less (NVPDC).

3. **Depth of Water Table –** A shallow or seasonally high groundwater table will inhibit the opportunity for infiltration. Therefore, the lowest elevation in the filter strip should be at least 2 feet above the water table.

If the soil's permeability and/or depth to water table are unsuitable for infiltration, the filter strip's primary function becomes the filtering and settling of pollutants. A modified design may be provided to allow ponding of the water quality volume at the filter's downstream end. The ponding area may be created by constructing a small permeable berm using a select soil mixture. (For berm details, see the Pervious Berm section in this standard.) The maximum ponding depth behind the berm should be 1foot.

Water Quality Enhancement

Vegetated filter strips are occasionally installed as a standard feature in residential developments. To be used as a water quality BMP, however, filter strips must comply with certain design criteria. Vegetated filter strip designs should include specific construction, stabilization, and maintenance specifications. The most significant requirement is for runoff to be received as sheet flow. Certain enhancements may be necessary, such as added vegetation and grading specifications, or the use of level spreaders, to ensure that runoff enters the filter strip as sheet flow.

Sediment Control

A natural area that is designed to serve as a vegetated filter strip should not be used for temporary sediment control. Sediment deposition may have significant impacts on the existing vegetation. If a vegetated filter strip is proposed in a natural area marginally acceptable for use, due to topography or existing vegetation, then it may be appropriate to use the filter strip for temporary sediment control. However, when the project is completed, the sediment accumulation should be removed, the area should be regraded to create the proper design conditions (sheet flow), and the strip should be re-stabilized per the landscaping plan.

Design Criteria

This section provides recommendations and minimum design criteria for vegetated filter strips intended to enhance water quality. It is the designer's responsibility to decide which criteria are applicable to the each facility and to decide if any additional design elements are required. The designer must also provide for the long-term functioning of the BMP.

Hydrology

The hydrology of a filter strip's contributing drainage area should be developed per **Chapter 4, Hydrologic Methods**.

Filter Strip Geometry

Compliance with the following parameters will result in optimal filter strip performance (NVPDC):

1. **Length** – The minimum length of a filter strip should be 25 feet, at a maximum slope of 2 percent. The length should increase by 4 feet for any 1 percent increase in slope. **The optimum filter strip length is 80 to 100 feet**.

2. **Width –** The width of the filter strip (perpendicular to the slope) should be equal to the width of the contributing drainage area. When this is not practical, a level spreader should be used to reduce the flow width to that of the filter strip. The level spreader's width will determine the depth of flow and runoff velocity of the stormwater as it passes over the spreader lip and into the filter strip. A wide lip will distribute the flow over a longer level section, which reduces the potential for concentrated flow across the filter.

3. Slope – The slope of the filter strip should be as flat as possible while allowing for drainage. Saturation may occur when extremely flat slopes are used.

Level Spreader

A level spreader should be provided at the upper edge of a vegetated filter strip when the width of the contributing drainage area is greater than that of the filter (see Figure **3.14-2**.) Runoff may be directed to the level spreader as sheet flow or concentrated flow. However, the design must ensure that runoff fills the spreader evenly and flows over the level lip as uniformly as possible. The level spreader should extend across the width of the filter, leaving only 10 feet open on each end.

Pervious Berm

To force ponding in a vegetated filter strip, a pervious berm may be installed. It should be constructed using a moderately permeable soil such as ASTM *ML*, *SM*, or *SC*. Soils meeting USDA sandy loam or loamy sand texture, with a minimum of 10 to 25% clay, may also be used. Additional loam should be used on the berm (± 25%) to help support vegetation. An armored overflow should be provided to allow larger storms to pass without overtopping the berm. **Maximum ponding depth behind a pervious berm is 1 foot**.

Vegetation

A filter strip should be densely vegetated with a mix of erosion resistant plant species that effectively bind the soil. Certain plant types are more suitable than others for urban stormwater control. The selection of plants should be based on their compatibility with climate conditions, soils, and topography and the their ability to tolerate urban stresses from pollutants, variable soil moisture conditions and ponding fluctuations. Virginia has three major physiographic regions that reflect changes in soils and topography: Coastal Plain, Piedmont, and Appalachian and Blue Ridge regions (see **Figure 3.14- 3**).

A filter strip should have at least two of the following vegetation types:

- *deep-rooted grasses, ground covers, or vines*
- *deciduous and evergreen shrubs*
- *under- and over-story trees*

Native plant species should be used if possible. Non-native plants may require more care to adapt to local hydrology, climate, exposure, soil and other conditions. Also, some non-native plants may become invasive, ultimately choking out the native plant population. This is especially true for non-native plants used for stabilization.

Newly constructed stormwater BMPs will be fully exposed for several years before the buffer vegetation becomes adequately established. Therefore, plants which require full shade, are susceptible to winter kill or are prone to wind damage should be avoided.

Plant materials should conform to the American Standard for Nursery Stock, current issue, as published by the American Association of Nurserymen. The botanical (scientific) name of the plant species should be according to the landscape industry standard nomenclature. All plant material specified should be suited for USDA Plant Hardiness Zones 6 or 7 (see **Figure 3.14- 4**).

Construction Specifications

Overall, widely accepted construction standards and specifications, such as those developed by the USDA Soil Conservation Service or the U.S. Army Corps of Engineers, should be followed where applicable to construct a vegetated filter strip. The specifications should also satisfy all requirements of the local government.

Sequence of Construction

Vegetated filter strip construction should be coordinated with the overall project construction schedule. Rough grading of the filter strip should not be initiated until adequate erosion controls are in place.

Soil Preparation

Topsoil should be 8 inches thick, minimum. If grading is necessary, the topsoil should be removed and stockpiled. If the subsoil is either highly acidic or composed of heavy clays, ground dolomite limestone should be applied at an appropriate rate based on soil and slope conditions.

Subsoil should be tilled to a depth of at least 3 inches to adequately mix in soil additives and to permit bonding of the topsoil to the subsoil. If the existing topsoil is inadequate to support a densely vegetated filter strip, then suitable material should be imported. Proper specifications for imported topsoil should include the following:

1. *The USDA textural triangle classification.*

2. *Requirements for organic matter content (not less than 1.5% by weight), pH (6 to 7.5), and soluble salt (not greater than 500 parts per million).*

3. *Placement thickness and compaction. Topsoil should be uniformly distributed and compacted, and should have a minimum compacted depth of 6 to 8 inches.*

All seeding, fertilization, and mulching should be per the Virginia Erosion and Sediment Control Handbook (VESCH), 1992 edition, or as specified by a qualified agronomist.

Maintenance/Inspection Guidelines

Vegetated filter strips require regular maintenance. Field studies indicate that these BMPs usually have short life spans because of lack of maintenance, improper location, and poor vegetative cover.

The following maintenance and inspection guidelines are **NOT** all-inclusive. Specific facilities may require other measures not discussed here. It is the designer's responsibility to decide if additional measures are necessary.

Filter strips should be inspected regularly for gully erosion, density of vegetation, damage from foot or vehicular traffic, and evidence of concentrated flows circumventing the strip. The level spreader should also be inspected to verify that it is functioning as intended.

Inspections are critical during the first few years to ensure that the strip becomes adequately established. Maintenance is especially important during this time and should include watering, fertilizing, re-seeding or planting as needed.

Once a filter strip is well established and functioning properly, periodic maintenance, such as watering, fertilizing and spot repair, may still be necessary. However, fertilization efforts should be minimized. Natural selection allows certain species (usually native plants) to thrive while others decline. Excessive fertilization and watering to maintain individual plantings may prove costly, especially in abnormally dry or hot seasons. Overseeding and replanting should be limited to those species which have exhibited the ability to thrive.

To increase the functional longevity of a vegetated filter strip, the following practices are recommended:

- *Regular removal of accumulated sediment,*
- *periodic reestablishment of vegetation in eroded areas or areas covered by accumulated sediment,*
- *periodic weeding of invasive species or weeds, and*
- *periodic pruning of woody vegetation to stimulate growth.*

MINIMUM STANDARD 3.15

MANUFACTURED BMP SYSTEMS

The Manufactured BMP Systems presented in this standard have been presented to the Virginia Department of Conservation and Recreation (DCR) by industry manufacturers. DCR acknowledges that there may be additional Manufactured BMP Systems available at this time that are not presented in this handbook. Presentation of the following products does not preclude the use of other available systems, nor does it constitute endorsement of any one system. Additional BMP systems will be presented in Technical Bulletins as they become available.

Definition

A Manufactured BMP system is a structural measure which is specifically designed and sized by the manufacturer to intercept stormwater runoff and prevent the transfer of pollutants downstream.

Purpose

Manufactured BMP systems are used solely for water quality enhancement in urban and ultra-urban areas where surface BMPs are not feasible. These are flow-through structures in that the design rate of flow into the structure is regulated by the inflow pipe or structure hydraulics as opposed to traditional BMPs designed to store the entire water quality volume. When the maximum design inflow is exceeded, the excess flow bypasses the structure or flows through the structure and bypasses the treatment with minimal turbulence and resuspension of previously trapped pollutants. Structures that rely on the inflow pipe to regulate the rate of flow into the treatment chamber typically cause stormwater to back up into the upstream conveyance system or associated storage facility. Depending on the type of structure and the configuration of the conveyance system, this excess flow will either bypass the treatment chamber or be attenuated and allowed to flow through the treatment chamber at the regulated rate.

Pollutant removal efficiencies presented in this standard are based upon currently available studies. Removal efficiencies are very variable, however, and highly dependant on storm size, influent pollutant concentrations, and rainfall intensity. Several monitoring studies are ongoing and many products may be modified to improve pollutant removal performance. Therefore, the removal efficiencies presented may be subject to change. As more of these products are built and additional monitoring studies track their performance over a wide range of rainfall events, the anticipated performance of these systems as water quality BMPs will become better established.

The discussion of each of the manufactured BMP systems presented in this standard includes the target pollutants for which the BMP was designed. Many of these systems were developed to remove a specific range of particulate pollutants, or total suspended solids (TSS), from stormwater runoff. Others, such as the filtering structures discussed below, were developed to capture a broad range of pollutants. The use of phosphorus as the target or "keystone" pollutant is recommended when using the *performance-based* water quality criteria to select a BMP. However, for stormwater "hot-spots", or areas from which a high concentration of urban pollutants can be expected, the primary pollutant of concern may be hydrocarbons (oil and grease), metals, or other compounds besides nutrients. Manufactured BMPs generally provide effective spill containment for material handling and transfer areas such as automobile fuel and service areas, and other urban hot-spots. Careful analysis of the proposed development project and intended uses help in selecting and appropriate BMP.

The manufactured BMP systems which have been evaluated at this time can be categorized as either:

- **Hydrodynamic Structures** - (*Stormceptor, Vortechs Stormwater Treatment System, Downstream defender, BaySaver Separation System*)

- **Filtering Structures** - (*StormFilter, StormTreat System*)

Hydrodynamic Structures

Hydrodynamic structures are those which rely on settling or separation of pollutants from the runoff. The hydrodynamic structures can be generally categorized as Chambered Separation Structures or Swirl Concentration Structures.

<u>Chambered Separation Structures</u> rely on settling of particles and, to a lesser degree, centrifugal forces to remove pollutants from stormwater. These structures contain an upper bypass chamber and a lower storage/separation chamber. Flow enters the structure in the upper bypass chamber and is channeled through a downpipe into the lower storage/separation, or treatment, chamber. The downpipe is configured such that when the rate of inflow into the structure exceeds its operating capacity, the flow simply "jumps" over the downpipe, bypassing the lower treatment chamber.

The outlet configuration of the downpipe forces the water to enter the lower treatment chamber in one direction, which encourages circular flow. This circular flow, as well as gravitational settling, traps the sediments and other particulate pollutants (as well as any pollutants which adsorb to the particulates) at the bottom of the chamber. The water leaves the treatment chamber through a return or riser pipe. The return or riser pipe extends below the water surface within the lower treatment chamber in order to prevent trapped floatables from exiting the structure. The hydraulic gradient of the structure prevents the inflow and the discharge from creating turbulent conditions within the lower treatment chamber. This feature helps prevent the resuspension of previously trapped particulate pollutants during high flow, or "bypass", storm events.

Swirl Separation Structures are characterized by an internal component that creates a swirling motion. This is typically accomplished by a tangential inflow location within a cylindrical chamber. The "swirl" technology is similar, if not identical to, the technology used in treating combined sewer overflows. The solids settle to the bottom and are trapped by the swirling flow path. Additional compartments or chambers act to trap oil and other floatables.

There is no bypass for larger flows prior to the treatment or swirl chamber. The larger flows simply pass through the structure untreated. However, due to the swirling motion within the structure, larger flows do not resuspend previously trapped particulates.

Filtering Structures

Filtering structures are characterized by a sedimentation chamber and a filtering chamber. The manufactured systems presented in this standard, the *StormFilter* and the *StormTreat System*, use very different configurations and filtering media. Both contain a primary settling chamber to remove heavy solids, floatables, oil, etc. The *StormTreat System* then directs the water through a series of screens and geotextile filters and into a containerized wetland system with soil and aquatic plants. The *StormFilter*, on the other hand, uses any one or combination of filter media cartridges. The filter media selected is typically based on the target pollutants to be removed or the desired efficiency. The number of cartridges is dependent on the project size, desired removal efficiency, and peak flow rates.

These categories represent the general groupings of manufactured systems that have been presented to DCR to date. More systems may be added in the future as they become available.

TABLE 3.15-1
Pollutant Removal Efficiencies for Manufactured BMPs

Type	Target Phosphorus Removal Efficiency*
Hydrodynamic Structures (*Stormceptor, Vortechs, Downstream Defender, BaySaver*)	15% - 20%
Filtering Structures (*StormFilter, StormTreat System*)	50%

*Pollutant removal efficiencies are subject to change pending monitoring results.

Conditions Where Practice Applies

Drainage Area

The sizing criteria for each manufactured BMP system should be obtained from the manufacturer to insure that the latest design and sizing criteria is used. In general, the flow-through configuration and treatment limitations will force drainage areas to remain relatively small.

Development Conditions

Manufactured BMP systems are ideal for use in ultra-urban areas since they are space efficient. Most of these systems can be placed under parking lots, or simply installed as a manhole junction box or inlet structure. Since other BMPs, such as sand filters and bioretention structures, are also suited for urban development, the designer must consider the type of pollutant load anticipated from the site, as well as other site factors, such as maintenance, aesthetics, etc., and select an appropriate BMP. In general, hydrodynamic are recommended for the following:

- Pretreatment for other BMPs;
- Retrofit of existing development or Redevelopment; and
- Ultra-urban development areas.

Filtering structures are generally recommended for use in applications similar to General Intermittent Sand Filters (**Minimum Standard 3.12**) and Bioretention Filters (**Minimum Standard 3.11**).

In all cases, Manufactured BMP systems must be designed in accordance with the manufacturers specifications.

Planning Considerations

The most significant feature of manufactured BMP systems is their small size and the ability to use them as retrofits underneath improved areas. (It should be noted that other BMPs, such as sand filters, can also be placed under improved areas.) The fact these BMPs are underground requires the designer to locate an acceptable outfall or improved drainage system for discharging runoff. The vertical elevation of the inflow and outflow pipe connections may be critical to the choice, or design, of the BMP.

Overflow

All of the manufactured BMP systems presented in this standard are flow-through structures that can be located on storm drainage systems that drain improved areas. Most manufactured systems, however, are designed to treat the first flush, or the water quality volume, of runoff. Therefore, an overflow, or bypass, is needed to divert flow that exceeds the design rate, or a storage facility is needed to store the appropriate volume of runoff for treatment. The discussion of each manufactured system will include the overflow or bypass provisions provided, or required.

Design Criteria

The design criteria for manufactured BMP systems should be obtained from the manufacturer. All designs should be reviewed by the manufacturer to insure that the system is appropriately designed and sized.

Maintenance and Inspections

All manufactured BMP systems require regular inspection and maintenance to maximize their effectiveness. The specific maintenance requirements and schedule should be prepared by the manufacturer and signed by the owner/operator. It should be noted that the frequency of maintenance is not only dependent on the type of manufactured system chosen, but also the pollutant load from the contributing drainage area. The frequency of maintenance required may vary from after any major storm, to once a month, to up to twice a year.

A maintenance log should be required to keep track of routine inspections and maintenance. A maintenance log can also help facility owners establish the effectiveness of certain "housekeeping" practices, such as street sweeping. Failure to maintain any stormwater BMP may result in reduced efficiency, resuspension or mixing of previously trapped pollutants, or clogging of the system.

Many suppliers of manufactured BMP systems recommend service contracts to ensure that maintenance occurs on a regular basis. Lack of maintenance is widely acknowledged to be the most prevalent cause of failure of both structural and non-structural BMPs.

Another consideration with manufactured BMP systems is the possible contamination and toxicity of trapped sediments, especially in areas considered to be stormwater hot-spots. Care must be taken in the disposal of sediment that may contain accumulations of heavy metals. Sediment testing is recommended prior to sediment removal to assure proper disposal. Experience in other jurisdictions has indicated a reluctance to on the part of waste water utility operators to accept the pump-out material from these structures. Landowners are encouraged to research the disposal options as part of the planning process prior to selecting the BMP.

MINIMUM STANDARD 3.15A

STORMCEPTOR

Description

Stormceptor is a precast, modular, vertical cylindrical tank, which is divided into an upper bypass chamber and a lower storage/separation chamber. Under normal design flow operating conditions flow enters the structure through the upper chamber and is diverted by a U-shaped weir through a downpipe and into the lower separation/holding, or treatment, chamber. The downward flow is redirected horizontally around the circular walls of the separation chamber by a tee-fitting on the downpipe outlet. This circular flow, as well as gravitational settling, traps sediments and other particulate pollutants (as well as any pollutants which adsorb to the particulates) at the bottom of the chamber.

Water exits the lower chamber through a submerged outlet riser pipe. The bottoms of the inlet downpipe and the outlet riser pipe are submerged and set at the same elevation (the elevation that provides the oil/floatable storage above the pipes, and the solids/sediment storage below the pipes). The submerged outlet riser pipe prevents trapped floatables from exiting the structure. This configuration prevents the inflow and discharge from creating turbulent flow conditions within the lower treatment chamber, thus avoiding resuspension and export of previously trapped pollutants during high flow, or “bypass,” storm events.

There are no moving parts and no external power requirements for the *Stormceptor*.

Overflow – During-high flow periods, stormwater floods over the diversion weir and continues through the upper bypass chamber into the downstream sewer. This rapid activity creates pressure equalization across the bypass chamber, thus decreasing the flow through the lower treatment chamber, and preventing scour and resuspension of previously trapped materials.

Hydraulics – The overflow of the system is controlled by the incoming velocity and the hydraulics of the diversion weir. This system will cause a slight backwater condition in the upstream conveyance system.

Planning Considerations

Stormceptor is precast and comes in various sizes and is designed for all types of land uses. The system is engineered for traffic loading and can be installed as a manhole structure on an existing system (as a retrofit) or on a new system where water quality enhancement is required.

Target Pollutants – *Stormceptor* is designed to capture sediment, total suspended solids (TSS), trash, organic material, and floatable oil and grease. In addition, many other urban pollutants which adsorb to sediments and particulates can also be trapped by the structure.

Design Criteria

The design criteria for the *Stormceptor* should be obtained from the manufacturer. All designs should be reviewed by the manufacturer to insure that the system is appropriately designed and sized.

Maintenance and Construction

It is generally recommended that the system be maintained (full pump-out) once per year. This frequency may have to be adjusted to a shorter interval once loading rates are determined. Regular inspections will help determine the required frequency of cleaning. More frequent inspections are appropriate where oil spills occur regularly. Maintenance is completed using a conventional vacuum truck.

MINIMUM STANDARD 3.15B

VORTECHS STORMWATER TREATMENT SYSTEM

Description

The *Vortechs Stormwater Treatment System* is a precast rectangular unit with three chambers. The first chamber is referred to as the grit chamber and consists of a 1/4-inch thick aluminum cylinder with openings to release water at a controlled rate. The flow enters this chamber at a tangent to create a swirling motion that directs settlable solids towards the center. The flow is slowly released from the swirl concentrator into the oil chamber. The oil chamber has a barrier which traps oil and grease and other floatables. The final chamber is the flow control chamber, which forces water to back up in the structure, this reducing the inflow velocities and turbulence.

There are no moving parts and no external power requirements for the *Vortechs System.*

Overflow - As the rate of runoff increases, the flow control chamber forces the runoff to fill the *Vortechs* structure. As this occurs, the swirling action in the grit chamber increases, keeping sediments and other material concentrated at the center of the chamber. The flow will back up to a level established by the elevation of the release openings within the overflow chamber. This provides the ability to achieve flow attenuation within the storage capacity of the upstream storm drainage system. If additional flow attenuation or quantity controls are needed, the elevation of the *Vortechs System* can be manipulated to back up water into a detention facility. Because the swirling action increases as the inflow velocity increases, resuspension of previously deposited material during high flows is eliminated.

Hydraulics - The hydraulics of the *Vortechs System* allow for the treatment of runoff from frequent storms as well as the flow from larger, less frequent storms. Larger storms will cause runoff to back up in the drainage system as the storage volume within the structure is above the inflow pipes.

Planning Considerations

The *Vortechs Stormwater Treatment System* is precast and comes in various sizes and is designed for all types of land uses. The system can be engineered for traffic loading, and depending on the invert elevations can be installed on an existing pipe system (as a retrofit) or on a new system where water quality enhancement is required.

Target Pollutants – The *Vortechs System* is designed to capture sediment as fine as clay sized particles, and the nutrients and metals that adhere to sediments. Also targeted are floating materials, including petroleum products.

Design Criteria

The design criteria for the *Vortechs System* should be obtained from the manufacturer. All designs should be reviewed by the manufacturer to insure that the system is correctly designed and sized.

Maintenance and Inspections

The *Vortechs System* has no ongoing maintenance requirements, although routine inspections are necessary to schedule cleaning. To insure proper performance and treatment efficiency, the system must be cleaned out when it is full. The rate at which the system accumulates contaminants is largely dependent upon site activities.

The first year of operation, Vortechnics recommends monthly inspections during periods of heavy contaminant loadings (e.g., winter sanding, soil disturbances, etc.). The inspection schedule can then be modified in subsequent years according to experience.

Clean-out of the *Vortechs System* with a vacuum truck is generally the best and most convenient method. <u>Only the manhole cover above the grit chamber</u> (the one farthest from the system outlet) needs to be opened to remove water and contaminants. As the grit chamber is pumped out, the oil and water drain back into it, so that oil scum, particulates and floatables are removed along with accumulated sediments. A pocket of water between the grit chamber and the flow control chamber seals the bottom of the oil barrier and prevents the loss of floatables to the outlet during cleaning.

MINIMUM STANDARD 3.15C

DOWNSTREAM DEFENDER

Description

The *Downstream Defender* consists of a concrete cylindrical structure with stainless steel internal components and a internal sloping base. Stormwater runoff enter the structure through a tangential inlet pipe which creates a swirling motion within the structure. The flow spirals down the perimeter of the structure, allowing heavier particles to settle out by gravity and drag forces exerted on the wall and base of the structure.

The base of the *Downstream Defender* is formed at a 30 degree angle. As the flow rotates about the vertical axis, solids are directed towards the base of the structure where they are stored in the collection facility. The steel internal components direct the main flow away from the perimeter and back up the middle of the vessel as a narrower spiraling column rotating at a slower velocity than the outer downward flow.

A dip plate is suspended from the underside of the component support frame. This dip plate serves two purposes: 1) it locates the shear zone, (the interface between the outer downward circulation and the inner upward circulation where a marked difference in velocity encourages solid separation), and 2) it establishes a zone between it and the outer wall where floatables, oil and grease are captured and retained after a storm. When the flow reaches the top of the structure, it is virtually free of solids and is discharged through the outlet pipe.

There are no moving parts and no external power requirements for the *Downstream Defender*.

Overflow - There is no overflow or bypass of larger storms. As the rate of runoff increases, the swirling motion keeps the sediments trapped in the collection facility, thus allowing the full range of storms to pass through the facility with minimum resuspension.

Hydraulics - The outlet flow from the *Downstream Defender* can be regulated with its associated valve, the *Reg-U-Flow Vortex Valve*. The valve can be adjusted to maximize the available storage in the upstream drainage system or upstream detention facility (if additional flow attenuation is required) by reducing the flow and backing the water up in the upstream system.

Planning Considerations

A drop structure upstream of the *Downstream Defender* may be required to ensure that the flow enters into the structure at the appropriate elevation. The *Downstream Defender* comes in various sizes and is designed for all types of land uses. Depending on existing pipe invert elevations it can be installed on an existing pipe system (as a retrofit) or in a new system where water quality enhancement is required.

Target Pollutants – The *Downstream Defender* is designed to capture sediments, and grit (TSS), as well as floatable materials, including petroleum products. In addition, pollutant which adsorb to the particulates can also be trapped.

Design Criteria

The design criteria for the *Downstream Defender* should be obtained from the manufacturer. All designs should be reviewed by the manufacture to insure that the system is correctly designed and sized.

Maintenance and Inspections

A simple sump-vac procedure is periodically required to remove floatables and solids from the *Downstream Defender* collection facility. Regular inspections should be carried out over the first 12 months of operation to determine the rate of sediment and floatables accumulation. A probe may be used after storm events to determine the sediment depth in the collection facility. This information can then be used to establish a maintenance schedule. H.I.L. Technology, Inc. recommends inspection and clean-out at least twice a year.

A standard septic tank hose is not appropriate for the clean-out procedure. A *Vacall* with a 6-inch, or larger, hydraulic hose is required. The *Vacall* is capable of loosening compacted solids by reversing the vacuum pump prior to the sump- vac procedure.

Floatables should be removed prior to emptying the collection facility. The floatables access port is located between the concrete vessel wall and the dip plate. The collection facility access port is located directly over the center shaft.

MINIMUM STANDARD 3.15D

STORMTREAT SYSTEM

Description

The *StormTreat System* captures and treats the first flush of runoff. An optional infiltration feature provides for the treatment of larger quantities of stormwater (beyond the first flush).

The system consists of a series of six sedimentation chambers and a constructed wetland which are contained within a modular 9.5-foot diameter tank. It is constructed of recycled polyethylene, which connects directly to existing drainage structures.

As stormwater enters the system, it is piped into sedimentation chambers where larger-diameter solids are removed. The internal sedimentation chambers contain a series of skimmers which selectively decant the upper portions of the stormwater in the sedimentation basins, leaving behind the more turbid lower waters. The skimmers significantly increase the separation of solids, as compared to conventional settling/detention basins. An inverted elbow trap serves to collect floatables, such as oils, within the inner tank. After moving through the internal chambers, the partially treated stormwater passes into the surrounding constructed wetland through a series of slotted PVC pipes.

The wetland is comprised of a gravel substrate planted with the bulrushes and other wetland plants. Unlike most wetlands constructed for stormwater treatment, the *StormTreat System* conveys stormwater into the subsurface of the wetland and through the root zone, where greater pollutant attenuation occurs through such processes as filtration, absorption, and biochemical reactions.

Precipitation of metals and phosphorus occurs within the wetland substrate, while biochemical reactions, including microbial decomposition, provide treatment of the stormwater prior to discharge through the outlet valve. An outlet control valve provides a variable holding time within the system and can be closed to contain a hazardous waste spill.

There are no moving parts and no external power requirements for the *StormTreat System*.

Overflow - There is no internal, large storm bypass within the *StormTreat System*. An overflow of the treated water is provided and is conveyed to a receiving channel or pipe system, or as option, the overflow can be directed into he surrounding soils for infiltration (if the soils meet the criteria for infiltration facilities - **Minimum Standard 3.10**). This feature can be enhanced by backfilling the excavation around the StormTreat System with 3/4" stone, similar to an infiltration trench with the StormTreat system providing pretreatment.

The flow into the *StormTreat System* is be regulated by the inflow pipe. A storage structure or basin may be used to temporarily hold the runoff until it can drain into the *StormTreat System.*

Hydraulics – The flow through the various filtering mediums is slow and, therefore, the backwater effects are high for this system. Flow through the system is gravity dependent such that a 4-foot difference in elevation is needed from the pavement surface to the discharge point. This may prove difficult on relatively flat sites.

Planning Considerations

The *StormTreat System* can be configured in clusters of tanks to fit within limited areas and is designed for all types of land uses. The manufacturer recommends that a sump catch basin be placed prior to the StormTreat System in order to trap larger diameter sediments.

Target Pollutants – The *StormTreat System* is designed to capture sediment (TSS), fecal coliform bacteria, total petroleum hydrocarbons, total dissolved nitrogen, total phosphorus, lead, chromium, and zinc.

Design Criteria

The design criteria for the *StormTreat System* should be obtained from the manufacturer. All designs should be reviewed by the manufacturer to insure that the system is designed and sized correctly.

Maintenance and Inspections

The *StormTreat System* requires minimal maintenance. Annual inspection is recommended to insure the system is operating effectively. During inspection the manhole should be opened, the burlap grit screening bag covering the influent line should be removed and replaced, and filters should be removed, cleaned, and reinstalled. Sediment should be removed from the system via suction pump once every 3 to 5 years, depending on local soil characteristics and catch basin maintenance practices.

MINIMUM STANDARD 3.15E

STORMFILTER

Description

The *StormFilter* uses cylindrical rechargeable filter cartridges which hold a variety of filter media and can be customized by using different filter media to remove desired levels of sediments, phosphorus, nitrates, soluble metals, and oil & grease. Housed in standard size pre-cast or cast-in-place concrete vaults, the filter systems can be installed in-line, allowing stormwater to percolate through the cylindrical cartridges before discharging to an open channel drainage way. The *StormFilter* is equipped with scum baffles that trap floating debris and surface films, even during overflow conditions.

There are no external power requirements for the *CSF Stormwater Treatment System*. Moving parts are contained within the filter cartridges as part of the *priming system* discussed in the Hydraulics section.

Overflow – The *CSF system* is designed with an overflow that operates when the inflow rate exceeds the infiltration capacity of the filter media. The overflow consists of a weir wall inside the structure housing. Depending upon individual site characteristics, some filters are equipped with high- and/or low-flow bypasses. High-flow bypasses can be installed when the calculated peak storm event generates a flow which overcomes the overflow capacity of the filter.

Hydraulics – The hydraulics of the *StormFilter* are designed to maintain the design flow rate through the filter without pumps or other motorized devices. Each filter cartridge contains a float-actuated device called a *priming system* within the central drainage tube. This system primes the cartridges, which then develop a siphon inside the drainage tube. The siphon increases as the filter cartridges become progressively clogged to help maintain the design flow.

Planning Considerations

The *StormFilter* is a structural BMP which can be easily installed in a parking lot or in fully developed areas as it does not require additional development space. However, consideration should be given to long term maintenance costs.

Target Pollutants – The *StormFilter* is designed to capture sediment (TSS), soluble metals, and oil and grease, nitrogen, and phosphorus. The various filter media can be selected to target pollutants of primary concern. The following filter media are available:

- Pleated fabric
- CSF leaf media
- Perlite
- Zeolite
- Granular activated carbon

According to the manufacturer, a combination of the pleated fabric and the zeolite media provides the best removal efficiencies for phosphorus and TSS.

Design Criteria

The design criteria for the *CSF Stormwater Treatment System* should be obtained from the manufacturer. All designs should be reviewed by the manufacturer to insure that the system is correctly designed and sized.

Maintenance and Inspections

Maintenance requirements of the *CSF Stormwater Treatment System* are controlled by the amount of plugging of the filters caused by sediment accumulation. The filters are progressively loaded with sediment contained in runoff. At least one scheduled inspection of the filter must be undertaken to perform minor maintenance activities, which includes flow valve adjustment. The major maintenance activity is performed to rejuvenate the media and clean the system. Major maintenance activities may also be required in the event of a chemical spill or excessive sediment loading (due to site erosion or extreme storms). It is also good practice to inspect the system after severe storm events.

When the cartridges become too occluded with sediments, maintenance involves the removal of the exhausted cartridges and replacement with freshly charged cartridges. The time period between when the cartridges are initially installed and when they must be replaced is dependent upon site specific conditions and sediment loading.

As with other filtration systems, sediments will accumulate on the filter surface, eventually slowing the infiltration capacity. To reduce sediment loading to the surface of filters, it is recommended that the filters be used in conjunction with sediment reducing practices such as parking lot sweeping and catch basin sand traps.

BAYSAVER

Description

The Bay Saver system is comprised of three main components: the Primary Separation Manhole, the Secondary Storage Manhole, and the BaySaver Separator Unit. The primary and secondary manholes are both standard precast concrete drop structures. The BaySaver Separator Unit is constructed of high-density polyethylene (HDPE).

Stormwater runoff enters the BaySaver system through the primary separation manhole. As the water flows into the manhole, the larger sediments settle to the bottom of the tank. **Figure 3.15-10** shows a profile of the primary manhole. The structure has a minimum water level at the elevation of the BaySaver's surface skimming weir. This weir is a trapezoidal shaped weir with a bottom width ranging from 3" to 6", and a flow depth of 9" to 18", depending on the size unit as required by the contributing drainage area. As water flows into the manhole, the surface water flows over the weir and is diverted to the storage manhole. This water carries with it floating pollutants (oils, for example), debris, and fine sediment particles.

The BaySaver Separator Unit incorporates three flow paths that water can take through the system. The trapezoidal surface-skimming weir diverts first flush and low flows into the second manhole for the most efficient treatment. As the water level rises in the primary separation manhole, more water flows over the weir. The majority of oils and fine sediments are removed by this flow path.

During a more intense storm, the BaySaver unit will also allow water to flow through the inverted 90E elbow pipes. The elbow pipes draw water from the middle of the primary separation manhole, with the intakes approximately four feet below the surface, and discharge directly to the system outfall. The water pulled by the elbows is free of floating contaminants and has had time for suspended sediments to settle out. By discharging this water, the BaySaver can continue full treatment of the surface flow in the second manhole.

If the flow becomes too great for the system to effectively treat, the BaySaver bypasses the treatment stages, conveying water directly from inlet to outlet. Elongated openings in the crown of the elbow pipes serve as pressure equalizers, significantly reducing flow through the submerged inlets of the elbow pipes during bypass. This reduction minimizes the resuspension and discharge of trapped contaminants from the primary manhole. Bypass flows also prevent water from flushing through the storage manhole, providing more protection against the risk of resuspension of fines and oils.

There are no moving parts and no external power requirements for the BaySaver.

Overflow - Large storm bypass is accomplished first by the two 90E inverted elbow pipes, and second by overflowing the top plate over the weir (set approximately at ½ the diameter of the separator unit).

Hydraulics - The separator unit and associated overflow pipes are sized according to the drainage area being served. The system should operate without creating a back water condition in the upstream drainage system.

Planning Considerations

The BaySaver primary and secondary manholes are precast and come in three sizes depending on drainage area size. The system can be installed on an existing system (as a retro fit) or on a new system where water quality enhancement is required.

Target Pollutants - The BaySaver system is designed to capture sediment, total suspended solids (TSS) trash, organic material, and floatable oil and grease. In addition, many other urban pollutants which absorb to sediments and particles can also be trapped by the structure.

Design Criteria

The design criteria for the BaySaver should be obtained from the manufacturer. All designs should be reviewed by the manufacturer to insure that the system is appropriately designed and sized.

Maintenance and Construction

It is generally recommended that the system be maintained (full pump-out) once per year. This frequency may have to be adjusted to a shorter interval once loading rates are determined. Regular inspections will help determine the required frequency of cleaning. More frequent inspections are appropriate where oil spills occur regularly or a large volume of trash and debris are expected.

Introduction - Checklists

Design and Plan Review Checklists

Design and plan review checklists provide general guidance for both the designer and plan reviewer. Many items listed on the checklists may not apply to any given design and it is therefore up to the designer to indicate items as "*not applicable*" or "*NA*" as appropriate. Similarly, the reviewer must be able to distinguish which items are required based on the local conditions or requirements and verify the status of those items. These checklists serve as a tool for providing the designer with the necessary information needed to develop an approvable plan, as well as for providing the plan review authority with a consistent review procedure.

Construction Inspections and As-Built Survey Checklists

The purpose of construction inspections and an as-built survey is to verify that constructed SWM facilities and associated conveyance systems have been built in accordance with the approved plan and design specifications. An as-built survey, including construction inspection logs should be provided prior to final site approval and release of the performance guarantee. This is in the best interest of the owner as well as the local program, since long term maintenance costs can increase significantly, if the facility is not built correctly. Also, there could be a problem that the system may not provide the quantitative and/or qualitative control, as prescribed by the approved plan. Liability issues arise if a downstream property owner is adversely affected and can prove that the facility is not per the approved plan.

A. Construction Inspections

Adequate construction inspection of stormwater BMPs will usually require an on-site inspector to verify that the materials, methods, and placement, are in accordance with the approved plans and specifications. Critical components of the design; such as the anti-seep collar or filter and drainage diaphragm on the outlet conduit, the embankment foundation, riser footing, and other sub-surface components, must be examined for compliance to the design prior to being backfilled with the earthen embankment. The use of an on-site inspector will help to avoid delays by allowing the contractor to proceed with the earthwork rather than waiting for a scheduled (or non scheduled) inspection of a critical component.

Localities will usually provide regular inspections of SWM facilities under construction. The frequency of these inspections will vary based on the workload represented by active projects and the number of inspectors on staff. These inspections should verify that the contractor and on-site inspector are documenting the construction inspections in order to adequately substantiate the as-built certification. In the case of a local program requirement of inspections during critical portions of the construction, a signed inspection log by a qualified individual (other than the contractor) should be acceptable. Otherwise, the locality should establish a construction inspection schedule with the contractor prior to construction.

All inspection logs and other related information should be incorporated into a file for each individual project.

B. As-Built Survey

Some as-built documentation must be obtained *during* the construction process, since some vital components are hidden in the final product. Therefore, construction inspections and inspection records are included in the as-built survey. For purposes of discussion, an as-built survey may be broken down into three components. These components are earthwork specifications, material specifications (other than earthwork) and a dimensions and elevations survey. The items noted within these components should be checked, and documentation be retained as needed to substantiate that the SWM BMP has been constructed in accordance with the approved plan and specifications. The following provides a discussion of the components of an as-built survey.

1. Earthwork Specifications

The acceptable completion of earthwork in the construction of a SWM facility is crucial in assuring that a facility is structurally sound. This category covers all aspects pertaining to the completion of earthwork for a facility. It is essential that specific elements of the construction inspection, as well as the pre-construction feasibility analysis of the soils, be documented. This may include compaction tests, inspections of the removal of unsuitable materials under and adjacent to the embankment foundation, construction of the cut off trench and other seepage control measures, compaction around the barrel, riser structure footing, and any other element that is hidden in the final condition. All work should be completed under supervision of a licensed geotechnical engineer. The inspection logs and test results should be included in the final as-built survey.

a. Geotechnical/Geophysical Testing

The examination of existing underlying strata indicates the composition of that strata and if that strata will support a SWM facility. For example, the presence of bedrock at the natural ground surface or in “cut” provides a plane of weakness that water may follow or exfiltrate to. This is especially critical in areas of karst. Also, the presence of organics or other unsuitable materials under the embankment and embankment footing may require additional excavation. This must be documented as having been completed.

Normally, in non-karst terrain (east of the Blue Ridge), simple geotechnical logs taken at the SWM site will provide adequate interpretative results. In karst west of the Blue Ridge, however, it is extremely useful that the testing be expanded to geophysical (seismic) evaluation. These tests provide images of underlying strata and indicate the presence of anomalies. This is critical since limestone geology exhibits extensive caves and cavities where ponding of runoff may exacerbate collapse of underlying cavities, which ultimately results in extremely expensive repairs.

b. Fill Classification

The geotechnical portion of the approved plan should provide a listing of soil classification types that are suitable for use at the project infill. Specialized criteria may also specify the classification of impermeable soil to be used for clay liners in areas of sandy soils or karst. Fill soils containing such materials as excessive or large rock, organic material or "fatty clay" (CH) classification are not acceptable due to the inability to achieve proper compaction or because of their shrink-swell properties. Verification must also be provided that the specifications for materials to be used in the construction of drainage and filter diaphragms have been complied with.

c. Compaction

The application of "lifts" in proper thickness and density is essential in attaining a stable SWM structure. The compaction of dam embankment to a percentage at or above the percent compaction specified in the approved plan and within the optimal range of moisture content assures that there will not be adverse settlement of the embankment. Careful compaction in areas adjacent to the barrel and seepage control measures is critical to eliminate excessive "void space" along the outlet barrel where the potential for embankment failure is high. Sufficient test results should be retained to document uniform compaction of the dam embankment and density/permeability of **existing soil formation and/or soils to be** used for liners (where applicable), in accordance with the approved plan.

2. Material Specifications

Construction materials may be classified as those items other than earthwork. A large number of component items needed for the construction of SWM facilities are grouped into this category. Some of these components must be inspected during installation. Materials would include, but not be limited to, concrete, reinforcing steel, concrete pipe, metal pipe, woodwork, masonry, and any other items that are applicable to the facility and satisfy all the requirements of the local program. The following provides a general discussion of some of the components of a SWM facility:

a. Riprap and Aggregate

The size distribution (diameter of aggregate), the amount of "fines" and integrity of rock may be factors, since aggregate sizing should be in accordance to the plan.

(1) Aggregate sizing plays a role in two distinct areas. In underground reservoir use, the size of aggregate dictates the amount of void space available for infiltration or retention/detention of runoff. In riprap use, the minimum size is critical in maintaining stability during high velocity flow, while a size in great excess of the stone specified may be as equally detrimental in regards to aesthetics and/or proper placement.

(2) The amount of fines contained within aggregate is generally a visual observation, although quarry delivery tags should bear out the specifications per VDOT specs. The percentage of fines generally is important where washed stone is to be utilized for an underground aggregate reservoir, or where the outlet protection of a facility is discharging into a stream or other sensitive area that is susceptible to turbidity.

(3) Rock integrity and shape is generally the visual observation that the aggregate used will meet specifications without long term decay. For example, sandstone does not make good riprap since it may be expected to disintegrate over time. Slate usually exhibits cleavage planes and therefore lays flat. When used for outlet protection, insufficient surface roughness of the slate may not dissipate concentrated flow energy.

b. Control Structure

There are an infinite number of design configurations for a control structure. Whatever the design, there should be project specifications for dimensions, strength and specific materials in accordance with the specifications found in Chapter 3, and any other local requirements. Appropriate documentation from the manufacturer should be retained (as applicable) to document each component. For example, pre-cast concrete risers normally arrive with as-built shop drawings that indicate specifications of the item furnished. Where components are constructed at the site, such as a cast in-place riser footing, test information and/or delivery tags from the concrete plant should be retained, while rebar reinforcement and dimensional information is documented in the construction log. Other items normally applicable to the control structure include:

(1) An outlet barrel, normally affixed to the control structure, is used to convey flow to an accepted discharge point. Items related to proper conduit installation include the procedure used in sealing joints of conduit together, the method of attachment to the control structure and the use of inlet and floor shaping (as applicable) within

the control structure.

There is also a need to inspect and document the existence, location and spacing of anti-seep collars, concrete cradle or other seepage control measures (at the outlet barrel) as specified in the approved plan. Documentation should include verification of critical dimensions, existence of reinforcement and indication of concrete mix strength. In the case of filter diaphragms, both earthwork and materials need to be **considered in installation.**

(2) Trash racks of varying design and construction are normally affixed to a control structure and in some cases inlets which "feed" the SWM facility. Visual observation (with inspection log entry) should indicate bar size, spacing grate configuration, and proper attachment to the control structure, or inlet and the application of rust resistant coating to the same where applicable.

c. Geotextiles

Synthetic fabrics are frequently specified for application beneath various components, under riprap or individually in spillways or for low flow channels. Proper selection of a manufacturer's product along with installation per the plan and/or manufactures directives is necessary to assure the performance intended. Method of installation should be observed and tag be provided from the product that verify compliance to the product specification given in the approved plan.

d. Conveyance System Components

One frequently overlooked portion of a SWM design is the components comprising the drainage system for the site. It is obvious that if the system is not built as intended by the approved plan, then the facility may not function accordingly. Critical items such as conveyance conduit diameter, slope, inlet and grate length/configuration are essential to insure that the required design storm (generated by contributory area) is adequately conveyed to the SWM facility for control and/or that non-contributory area is diverted away from SWM facilities.

3. Dimensions and Elevations Survey

The approved plan provides detailed information for specific elevations such as the inverts of the outlet conduits, control orifice and weir invert elevations, invert of emergency spillway, top of the dam, as well as pond bottom and slope of the same. Additional dimensional information exclusive of the control structure should also be provided. This could include the dimensions of the impoundment area at specific elevations and the top width and side slope of a dam embankment. The purpose of the as-built survey is to substantiate elevations and dimensions per the plan.

G. As-Built Submittal Requirements

As-built information should be documented and submitted in three forms: 1) a copy of the applicant's inspection log book. 2) a red-line revision of the approved SWM plan sheets and 3) a certification statement from a qualified individual regarding the conformance of the as-built to the approved plan.

1. A copy of the inspection log book should be kept at the project site. The log should document all aspects of the construction of the facility (with copies of applicable test results) to insure compliance with the approved plan. Any significant inconsistencies should immediately be reported to the engineer for evaluation and possible modification.

2. Red-line revision plans should be submitted upon completion of the facility. The plans should indicate any changes to the approved plan. Items that differ from the original approved plans and computations should be shown in red on both the plans and computations as follows:

   a. A red check mark must be made beside design values where they agree with actual constructed values.

   b. For changed values "line out" the design value and enter the actual value in red.

   c. Elevations to the nearest 0.1' are sufficient.

   d. A stage-storage summary table comparing the design values and the as-built values should be provided for facilities with storage volume.

3. The project owner should have those persons responsible for the inspection and implementation of the plan submit written certification that the SWM facility(s) and conveyance system have been built in accordance to the approved plan since this will cover underground facilities as well. Survey work during stake out and construction should be documented to verify underground volumes, elevations, pipe sizes, etc.

<u>Operation and Maintenance Inspection Checklists</u>

Once construction is completed, the SWM BMP takes on the role for which it was intended. Periodic site inspections are essential in order to monitor the effectiveness and to anticipate the maintenance needs of the BMP. It should be pointed out that not only the facility or BMP measure installed for stormwater control is important, but also the conveyance system to the BMP and the receiving channel immediately downstream of the BMP. The conveyance channel, curbing and/or storm sewer that convey flow to the facility or intentionally divert flows around it (as a part of the design) are all considered components and must function as intended.

The necessary frequency of inspections will vary with each facility based on the type of facility, size of the contributory drainage area, and development or land use conditions within the contributory drainage area. At a minimum, a full inspection should be performed at least once a year. Periodic inspections for trash and debris accumulation and general aesthetics should be performed after significant storm events.

The following checklists provide a guide for regular inspections of the various types of urban BMPs covered in this manual. The checklists are detailed enough for an inexperienced inspector or homeowner not familiar with the specific components of the facility. Checking the column provided under the *Investigate* heading for any given item indicates a potential problem that requires attention by a qualified individual to interpret the visual indicators for possible maintenance. The checklists should be signed, dated, and maintained at an accessible location such as with an official representative of the homeowners association, the individual or company contracted for maintenance, owner, etc.

Applicant:____________________________________ Phone No.:____________________
Designer:_____________________________________ Phone No.:____________________
Project Name: ____
Location:____
Type of Facility and Identification No.:______________________________

Plan status:
____ approved
____ not approved

Legend:
T - Complete
Inc. - Incomplete/Incorrect
N/A - Not Applicable

I. SUPPORTING DATA

_____ Narrative describing stormwater management strategy including all assumptions made in the design.

A. Drainage Area Map

_____ Site and drainage area boundaries
_____ Off-site drainage areas
_____ Pre- and post-developed land uses with corresponding acreage
_____ Pre- and post-developed time of concentration flow paths
_____ Existing and proposed topographic features
_____ Drainage area appropriate for BMP

B. Soils Investigation

_____ Soils map with site and drainage area outlined
_____ Geotechnical report with recommendations and earthwork specifications
_____ Boring locations
  _____ Borrow area
  _____ Basin pool area
  _____ Embankment area: centerline principal spillway, emergency spillway , abutments
_____ Boring logs with Unified Soils Classifications, soil descriptions, depth to seasonal high groundwater table, depth to bedrock, etc.
_____ Compaction requirements specified
_____ Additional geophysical investigation and recommendations in Karst environment

Design and Plan Review Checklist

II. COMPUTATIONS

A. Hydrology

_____ Runoff curve number determinations: pre- and post-developed conditions, with worksheets.

_____ Time of concentration: pre- and post-developed conditions, with worksheets.

_____ Hydrograph generation: pre- and post-developed condition for appropriate design and safety storms (SCS methods or modified rational-critical storm duration method)

B. Hydraulics

_____ Specify assumptions and coefficients used.

_____ Stage-storage table and curve

_____ Riser structure and barrel

- _____ Weir/orifice control analysis for riser structure discharge openings
- _____ Weir/orifice control analysis for riser crest
- _____ Barrel: inlet/outlet control analysis
- _____ Riser/Outlet Structure flotation analysis (factor of safety = 1.25 min.).
- _____ Anti-seep collar or filter diaphragm design.
- _____ Outlet protection per VE&SCH Std.. & Spec. 3.18.
- _____ Provisions for use as a temporary sediment basin riser with clean out schedule & instructions for conversion to a permanent facility.

_____ Emergency spillway adequacy/capacity analysis with required embankment freeboard.

_____ Stage - discharge table and curve (provide equations & cite references).

_____ Storm drainage & hydraulic grade line calculations.

_____ Reservoir routing of post-development hydrographs for appropriate design storms (2-yr., 10-yr., or as required by watershed conditions) & safety storms (100-yr. or as required).

C. Downstream impacts

_____ Danger reach study.

_____ 100 year floodplain impacts.

_____ "Adequate channel" calculations for receiving channel

_____ Provide downstream hydrographs at critical study points.

_____ Storm drainage plans for site areas not draining to BMP

- _____ Safe conveyance - MS-19
- _____ Areas compensated for in water quality performance-based criteria calculations

Design and Plan Review Checklist
Page 3 of 7

D. Water Quality

_____ Impervious cover tabulation
_____ Technology-based criteria: proper selection of BMP based on impervious cover
_____ Performance-based criteria: pre- and post-developed pollutant load and pollutant removal requirement calculations (provide worksheets)
_____ Water quality volume for retention basin I, II, or III permanent pool
_____ Water quality volume for ext. detention and ext. detention enhanced with drawdown calculations
_____ Proper surface area/depth allocations for permanent pool/shallow marsh/constructed wetland
_____ Constructed stormwater wetland / shallow marsh
- _____ Adequate drainage area and/or base flow
- _____ Adequate pool volume
- _____ Adequate surface area
- _____ Allocation of surface area to depth zones
- _____ Maximum ponding depth over pool surface specified

III. PLAN REQUIREMENTS

A. General Items

_____ Plan view drawn at 1"=50' or less (40', 30', etc.)
_____ North arrow
_____ Legend
_____ Location plan and vicinity map
_____ Property lines
_____ Existing & proposed contours (2' contour interval min.)
_____ Existing features & proposed improvements (including utilities and protective measures)
_____ Locations of test borings
_____ Earthwork specifications
_____ Construction sequence for SWM basin and E&S controls
_____ Temporary erosion & sediment control measures
_____ Conveyance of base flow during construction
_____ Temporary and permanent stabilization requirements
- _____ Emergency spillway
- _____ Basin side slopes

Design and Plan Review Checklist

    _____ Basin bottom

_____ Delineation of FEMA 100 year floodplain

_____ Plans sealed by a qualified licensed professional

B. BMP Plan Views

_____ Dimensions of basin features: perm. Pool, sediment forebay, embankment, etc.

_____ Location of all conveyance system outfalls into basin

    _____ Proper orientation to avoid short circuiting

    _____ Outlet protection per VE&SCH

_____ Top of bank & basin bottom elevations

_____ Elevations of permanent pool, water quality volume and max. design water surface elevations for all appropriate design storms and safety storms

_____ Side slope (H:V) of basin storage area and embankment (upstream and downstream slopes)

_____ Proper length-to-width ratio as specified in BMP design criteria

_____ **Pervious** low flow channel

_____ Sediment forebay

_____ Basin bottom slope

_____ Maintenance access to sediment forebay, riser structure, and one side of the basin ponding area

_____ Peripheral ledge for safety

_____ Aquatic Bench

_____ Shoreline protection

_____ Safety fence

_____ Riser and barrel materials and dimensions labeled

_____ Constructed stormwater wetland / shallow marsh

    _____ Basin liner specifications

    _____ Pool depth zones identified on plan

    _____ Pool geometry - wet/dry weather flow path

Design and Plan Review Checklist

Page 5 of 7

C. BMP - Section Views & Related Details

1. Embankment (or dam) and Ponding Areas

_____ Elevations of permanent pool, water quality volume and max. design water surface elevations for all appropriate design storms and safety storms
_____ Top of dam elevations- constructed height and settled height (10% settlement).
_____ Adequate freeboard
_____ Top width labeled
_____ Elevation of crest of emergency spillway
_____ Emergency spillway w/ side slopes labeled.
_____ Emergency spillway inlet, level, and outlet sections labeled
_____ Existing ground and proposed improvements profile along center line of embankment
_____ Existing ground and proposed improvements profile along center line of principal spillway
_____ Typical grading section through pond including typical side slopes with aquatic bench, safety ledge, shoreline protection, etc.
_____ Existing ground and proposed improvements along center line of emergency spillway
_____ Dimensions of zones for zoned embankment

2. Seepage Control

_____ Impervious lining
_____ Phreatic line (4:1 slope measured from the principal spillway design high water).

a. Anti-seep Collar

_____ Anti-seep collar (detail reqd..).
_____ Size (based upon 15% increase in seepage length).
_____ Spacing & location on barrel (at least 2' from pipe joint).

b. Filter Diaphragm

_____ Design certified by a professional geotechnical engineer.

3. Foundation Cut Off Trench or Key Trench

_____ Materials labeled
_____ Bottom width (4' min. or greater per geotech. report).
_____ Side slopes labeled (1:1 max. steepness).
_____ Depth (4' min. or as specified in geotechnical report)

Design and Plan Review Checklist

Page 6 of 7

4. Multi Stage Riser and Barrel System

_____ Materials labeled
_____ Bedding or cradle details provided
_____ Gauge & corrugation size for metal pipes specified
_____ Barrel diameter, inverts, and slope (%) labeled
_____ Outlet protection per VESCH, Std. & Spec. 3.18, 3.19 w/ filter cloth underlayment
_____ Crest elevation of riser structure shown
_____ Inverts and dimensions of control release orifices/weirs shown
_____ Structure dimensions shown
_____ Control orifice/weir dimensions shown
_____ Extended detention orifice protection (detail required for construction)
_____ Riser trash rack or screen (detail reqd.. for construction).
_____ Riser anti-vortex device (detail reqd.. for construction).
_____ Proper riser structure footing.
_____ Access to riser structure interior for maintenance.
_____ Basin drain pipe

D. Landscape Plan

_____ Planting schedule and specifications (transport / storage / installation / maintenance)
_____ Plant selection for planting zones 1thru 6
_____ Preservation measures for existing vegetation
_____ Top soil / planting soil included in final grading

E. Maintenance Items

_____ Person or organization responsible for maintenance.
_____ Maintenance narrative which describes the long-term maintenance requirements of the facility and all components.
_____ Facility access from public R/W or roadway.
_____ Maintenance easement.

Project Name: ____
Location:____
Type of Facility and Identification No.:_____________________________

Plan status:
____ approved
____ not approved

Legend:
T - Complete
Inc. - Incomplete/Incorrect
N/A - Not Applicable

I. SUPPORTING DATA

_____ Narrative describing stormwater management strategy including all assumptions made in the design.
(Infiltration basin, infiltration trench, roof downsput system, porous pavement)

A. Drainage Area Map

_____ Site and drainage area boundaries
_____ Off-site drainage areas
_____ Pre- and post-developed land uses with corresponding acreage
_____ Pre- and post-developed time of concentration flow paths
_____ Existing and proposed topographic features
_____ Drainage area appropriate for BMP

B. Soils Investigation

_____ Soils map with site and drainage area outlined
_____ Geotechnical report verifying suitability for infiltration (0.52"/hr $\leq f <$ 8.27"/hr)
_____ Boring locations
_____ Boring logs with Unified Soils Classifications
  _____ Soil descriptions
  _____ Depth to seasonal high groundwater (2' to 4' below design bottom of facility, min.)
  _____ Depth to bedrock (2' to 4' below design bottom of facility, min.)
  _____ Verification of absence of karst topography

Design and Plan Review Checklist

Page 2 of 5

C. Topographic Conditions

_____ Meets minimum slope requirements

- _____ Porous pavement: s < 3% (20H:1V)
- _____ All other infiltration facilities: s < 20% (5H:1V)

II. COMPUTATIONS

A. Hydrology

_____ Runoff curve number determinations: pre- and post-developed conditions, with worksheets.

_____ Time of concentration: pre- and post-developed conditions, with worksheets.

_____ Hydrograph generation: pre- and post-developed condition for appropriate design and safety storms (SCS methods or modified rational-critical storm duration method)

B. Hydraulics

_____ 48 hour drain time provided

_____ Specify assumptions and coefficients used.

_____ Stage-storage table and curve (void ratio of 0.4 for stane storage)

_____ Riser structure and barrel for large storm overflow or bypass

_____ Emergency spillway adequacy/capacity analysis with required embankment freeboard for infiltration basins

_____ Storm drainage & hydraulic grade line calculations.

D. Water Quality

_____ Impervious cover tabulation

_____ Technology-based criteria: proper selection of BMP based on impervious cover

_____ Performance-based criteria: pre- and post-developed pollutant load and pollutant removal requirement calculations (provide worksheets)

_____ Water quality volume for desired target phosphorus removal efficiency.

Design and Plan Review Checklist

Page 3 of 5

III. PLAN REQUIREMENTS

A. General Items

_____ Plan view drawn at 1"=50' or less (40', 30', etc.)
_____ North arrow
_____ Legend
_____ Location plan and vicinity map
_____ Property lines
_____ Existing & proposed contours (2' contour interval min.)
_____ Existing features & proposed improvements (including utilities and protective measures)
_____ Locations of test borings
_____ Construction sequence
    _____ Infiltration BMP to be constructed after site work is completed and stabilization measures have been implemented
    _____ traffic control
_____ Temporary erosion & sediment control measures
_____ Temporary and permanent stabilization requirements
    _____ Infiltration basin emergency spillway
    _____ Infiltration basin side slopes
_____ Construction specifications
    _____ Infiltration basin bottom surface preparation
    _____ Infiltration trench bottom surface preparation
    _____ Infiltration trench filter fabric laydown
    _____ Infiltration trench aggregate placement
_____ Plans sealed by a qualified licensed professional

B. BMP Plan Views

_____ Dimensions of infiltration facility
_____ Location of all conveyance system outfalls into basin with pretreatment and outlet protection per VE&SCH

Design and Plan Review Checklist

_____ Infiltration basin
- _____ Top of bank & basin bottom elevations
- _____ Elevations of water quality volume and max. design water surface elevations for all appropriate design storms and safety storms
- _____ Side slope (H:V) of basin storage area and embankment (upstream and downstream slopes)
- _____ Sediment forebay
- _____ Maintenance access to sediment forebay and riser structure

_____ Safety fence

_____ Observation well

C. <u>BMP - Section Views & Related Details</u>

1. <u>Infiltration Basin</u>

_____ Elevations of water quality volume and max. design water surface elevations for all appropriate design storms and safety storms

_____ Top of dam elevations- constructed height and settled height (10% settlement).

_____ Adequate freeboard

_____ Top width labeled

_____ Elevation of crest of emergency spillway

_____ Principal/emergency spillway w/ side slopes labeled.

_____ Principal/emergency spillway inlet, level, and outlet sections labeled

_____ Existing ground and proposed improvements profile along center line of embankment

_____ Existing ground and proposed improvements profile along center line of principal spillway

_____ Typical grading section through basin

_____ Existing ground and proposed improvements along center line of emergency spillway

_____ Dimensions of zones for zoned embankment

_____ Foundation Cut Off Trench or Key Trench
- _____ Materials labeled
- _____ Bottom width (4' min. or greater per geotech. report).
- _____ Side slopes labeled (1:1 max. steepness).
- _____ Depth (4' min. or as specified in geotechnical report)

Design and Plan Review Checklist

Page 5 of 5

2. Infiltration Trench

_____ Dimensions provided

_____ Backfll material specified

- _____ Stone storage: clean VDOT No. 1 Open Graded Course Aggregate or equal
- _____ Bottom sand layer: VDOT Fine Aggregate, Grading A or B

_____ Filter Fabric

_____ Observation well

3. Porous Pavement

_____ Subgrade preparation

_____ Aggregate

- _____ Filter course: clean VDOT No. 57 Open Graded Course Aggregate or equal
- _____ Reservoir course: clean VDOT No. 3 Open Graded Course Aggregate or equal
- _____ Sand layer: VDOT Fine Aggregate, Grading A or B

_____ Porous asphalt surface course

E. Maintenance Items

_____ Person or organization responsible for maintenance.

_____ Maintenance narrative which describes the long-term maintenance requirements of the facility and all components.

_____ Facility access from public R/W or roadway.

_____ Maintenance easement.

A separate checklist is to be completed for each BMP, should more than one be used at a given project.

* Key - (T) If acceptable

(Inc.) If not adequate, explanation at the end of a section is required

(NA) If not applicable

I. INSPECTION LOGS and TEST DOCUMENTATION

A. Flow splitter / Overflow

_____ Overflow invert at correct elevation
_____ Inflow pipe plugged prior to full site stabilization

B. Earthwork

_____ The results and interpretation of geo-physical testing in areas of karst formation (west of the Blue Ridge) or geo-technical analysis (boring log data) of underlying strata elsewhere in the state
    _____ Infiltration rate of soils
    _____ Depth to seasonal watertable
    _____ Depth to bedrock
_____ Verification of removal of all unsuitable material beneath dam embankment and footing
_____ Verification of fill classification/suitability for use in the embankment
_____ Verification of proper installation of cut-off trench
_____ Multiple compaction test results indicating adequacy throughout the embankment section including areas adjacent to the outlet conduit and any seepage control measures.
_____ Verification that underlying bedrock and/or the water table does not interfere with the impoundment
_____ Verification of dimensions of sub surface features such as the riser structure footing, anti seep collars, filter and drainage diaphragm, etc.

B. Materials

_____ Stone aggregate size, composition, and placement
_____ Filter fabric placement

CHAPTER 4

Stormwater Runoff

INDEX

STORMWATER RUNOFF

Criteria Development Reasoning IV-1

Statewide Stormwater Runoff Standard IV-2

Applying the Criteria IV-3

Criteria Development Reasoning

The problems associated with stormwater runoff in rapidly urbanizing watersheds have become well-known. These problems relate to both the quantity and quality of stormwater runoff. Major problems include increased flooding magnitude and frequency, accelerated stream channel erosion, and water quality degradation.

The basic underlying cause of these problems is not difficult to understand. The hydrologic systems which have reached a natural equilibrium over centuries simply cannot adjust gracefully to the sudden impact of urban development. Flooding occurs because the increased volume and peak rate of runoff exceeds the natural carrying capacity of the streams more often. Stream channel erosion accelerates due to suddenly increased flow velocities and flooding frequency. The water quality itself is degraded by sedimentation and because numerous other pollutants become available to be washed off the land surface and into the streams, rivers and lakes.

Studies have shown that most natural stream channels are formed with a bankfull capacity to pass runoff from a storm with a 1.5- to 2-year recurrence interval. As upstream development occurs, the volume and velocity of flow from these relatively frequent storms increase. Consequently, even smaller storms with less than 1-year recurrence intervals begin to cause streams to flow full or flood.

According to Leopold (76), stream channels are subject to a 3- to 5-fold increase in the frequency of bankfull flows in a typical urbanizing watershed. This increase in the flooding frequency places a stress on the channel to adjust its shape and alignment to accommodate the increased flow. Unfortunately, this adjustment takes place in a very short time period (in geologic terms), and the transition is usually not a smooth one. Meandering stream channels which were once parabolic in shape and covered with vegetation, typically become straight, wide rectangular channels with barren vertical banks. This process of channel erosion often causes significant property damage, and the resulting sediment which is generated is transported downstream, further contributing to channel degradation.

One strategy for dealing with this problem is to increase the carrying capacity and stability of affected streams through channel modifications (e.g., straightening, widening, lining with non-erodible material, etc.). This strategy may be employed most effectively on man-made channels or small, intermittent streams. Significant modifications to natural, continuous flowing steams, however, can be the subject of intense local controversy.

Wherever modification to natural flowing streams are being considered, extreme care must be taken to weigh the benefits of such modifications against the cost and the concerns of the local citizens. Where channel modifications are necessary, an attempt should be made to incorporate conservation practices which will minimize adverse impacts to fish, wildlife, and the aesthetic quality of the stream.

The following stormwater runoff requirements were developed to provide localities with maximum flexibility to deal with their stormwater runoff problems according to local needs and priorities. The only condition which is imposed statewide is that all local stormwater runoff criteria must contain provisions for the control of off-site erosion and sedimentation.

Statewide Stormwater Runoff Standard

The Erosion and Sediment Control Regulations (Minimum Standard #19) require that properties and waterways downstream from new development sites shall be protected from erosion due to increases in the volume, velocity, and peak flow rate of stormwater runoff. (See Chapter 8 for the text of the law and regulations.) In the absence of a local stormwater management program, the following criteria shall apply:

A. Increased volumes of sheet flow that may cause erosion or sedimentation on adjacent property must be diverted to a stable outlet, adequate channel or detention facility.

B. Concentrated stormwater runoff leaving a development site must be discharged directly into an adequate natural or manmade receiving channel, pipe or storm sewer system.

   An adequate channel is defined as "a watercourse that will convey a chosen frequency storm event without overtopping its banks or causing erosive damage to the bed, banks and overbank sections of the watercourse."

   A receiving channel may be considered adequate if the total drainage area to the point of analysis in the channel is 100 times greater than the contributing drainage area of the project site.

   For natural channels, the two-year frequency storm is used to verify that stormwater will not overtop the channel banks nor cause erosion of the channel bed or banks.

   For manmade channels, the ten-year frequency storm is used to verify that stormwater will not overtop the channel banks and the two-year storm is used to demonstrate that stormwater will not cause erosion of the channel bed or banks.

   For pipes and storm sewer systems, the ten-year frequency storm is used to verify that stormwater will be contained within the pipe or storm sewer.

C. If existing natural receiving channels or previously constructed manmade channels or pipes are not adequate, the applicant must choose one of the following options.

   1. Improve the channels to a condition where the ten-year frequency storm will not overtop the channel banks and the two-year frequency storm will not cause erosion to the channel bed or banks. The applicant must provide evidence of permission to make the improvements.

2. Improve the pipe or storm sewer system to a condition where the ten-year frequency storm is contained within the appurtenances. The applicant must provide evidence of permission to make the improvements.

3. Develop a site design that will not cause the pre-development peak runoff rate from a two-year frequency storm to increase when runoff discharges into a natural channel or will not cause the pre-development peak runoff rate from a ten-year storm to increase when runoff discharges into a manmade channel.

4. Provide a combination of channel improvements, stormwater detention or other measures which is satisfactory to the plan-approving authority to prevent downstream erosion.

D. If the applicant chooses an option that includes stormwater detention, the applicant must obtain approval from the locality of a plan for maintenance of the detention facility. The plan must establish the maintenance requirements of the facility and identify the person responsible for performing the maintenance.

E. All hydrologic analyses must be based on the existing watershed characteristics and the ultimate development condition of the project site.

F. In applying these stormwater runoff criteria, individual lots in a residential subdivision development are not considered separate development projects. Instead, the residential subdivision development, as a whole, is considered to be a single development project. Hydrologic parameters that reflect the ultimate subdivision development must be used in all engineering calculations.

G. Proposed commercial or industrial subdivisions must apply these stormwater runoff criteria to the development as a whole. Hydrologic parameters that reflect the ultimate subdivision development must be used in all engineering calculations.

Applying the Criteria

The following commentary is intended to aid the handbook user in understanding and applying the stormwater runoff criteria in the Erosion and Sediment Control Regulations (Minimum Standard #19) for localities which have not adopted comprehensive stormwater management programs.

The basic concept of the state criteria is simple. An applicant must show that the runoff from the development project, (from a 2-year frequency storm) will not damage adjacent properties, or exceed the capacity or cause erosion of receiving streams. This must be proven by engineering calculations in the erosion and sediment control plan. The following items should be considered when determining compliance:

1. The stormwater runoff requirements apply to all land development projects which require an erosion and sediment control plan under state law. With regard to residential subdivision projects, the criteria should be applied to the entire subdivision development, not to the individual lots.

2. The stormwater runoff criteria apply primarily at points of concentrated discharge along the perimeter of the development site. However, the project must also be designed so that increased sheet runoff (e.g., runoff from newly paved areas) will not cause damage to adjacent properties. Such increased sheet flows should be diverted to an outlet where the stormwater runoff criteria can be applied.

3. The applicant must show that, wherever concentrated stormwater will be discharged from the site (e.g., pipe or channel outlets), there is an adequate channel or pipe to receive the flow and carry it into the natural drainage system.

4. Each receiving channel must be tested for adequacy. A channel is considered adequate if any of the following conditions can be met:

   a. The bankfull capacity of the natural receiving channel is sufficient to pass the post development peak flow from the 2-year frequency storm and the channel velocity (2-year frequency storm) does not exceed the permissible (non-erodible) velocity of the channel lining.

   b. The bankfull capacity of the manmade receiving channel is sufficient to pass the post development peak flow from the 10-year frequency storm and the channel velocity (2-year frequency storm) does not exceed the permissible (non-erodible velocity of the channel lining.)

      [Engineering procedures for determining channel adequacy are contained in Chapter 5.]

   c. The 10-year frequency storm is contained within the pipe or storm sewer system.

   d. The contributing drainage area of the development site is less than 1% of the total drainage area to the point of consideration in the channel.

   e. There is no increase in the peak runoff rate for the 2-year frequency storm (for natural receiving channels) or the 10-year frequency storm (for manmade receiving channels) at the point of discharge after development

5. If the receiving channel is found to be inadequate, the applicant must incorporate measures to either improve the receiving channel to an adequate

condition, or detain runoff on his site so that the post-development peak runoff rate for the 2-year storm will not exceed the pre-development peak rate. The plan-approving authority may also approve a combination of channel improvements and detention or other measures deemed satisfactory to protect the channel.

6. If a channel-improvement option is chosen, the applicant must obtain necessary easements and comply with applicable regulations regarding channel modifications. Channel improvements must extend downstream until an adequate channel section is reached or until a point is reached where the total drainage area is at least 100-times greater than the drainage area of the development site.

7. If a stormwater detention option is chosen, the applicant must submit a plan for the continued maintenance requirements of the structure and designate someone who has consented to be responsible to carry out the maintenance. The local government may choose to accept the maintenance responsibility for detention structures. However, where this is not done, the responsibility must be borne by the landowner, a homeowners association, or other legal entity. In this case, a maintenance agreement should be executed between the responsible entity and the local government.

CHAPTER 1

INTRODUCTION

CHAPTER 1

INTRODUCTION

Erosion is a natural force without which life could not be supported. Erosion forms the landscape and helps produce the soils that grow our crops. However, major problems can occur when large amounts of sediment enter our waterways. Accelerated erosion comes from man's land-altering activities such as mining, agriculture, construction, urban/suburban stream banks, logging, and oil and gas exploration.

The West Virginia Department of Environmental Protection (WVDEP) Erosion and Sediment Control Best Management Practice Manual addresses erosion and sediment control for earth disturbing activities associated with construction. The manual is designed to assist construction site developers, engineers, designers, and contractors to identify and implement the most appropriate best management practices (BMPs) for construction activities.

The purpose of this manual is to provide standardized and comprehensive erosion and sediment control management practices that can be implemented on construction projects throughout West Virginia. This manual should be used as guidance for developing sediment control plans for the General West Virginia/National Pollution Discharge Elimination System Water Pollution Control Permit for Stormwater Associated with Construction Activities. However, the use of other best management practices manuals may also be acceptable. The goal is to reduce the water quality impacts of land-disturbing activities through design and implementation of effective erosion prevention and sediment control.

West Virginia's original manual was created in 1982. While the principles of erosion prevention and sediment control have changed little, a new manual was needed to cover the advancements of the last 24 years. This manual provides updated information on erosion prevention and sediment control measures, engineering methods, and changes in the law and regulations. It should be used by the regulated community, citizens and municipalities developing their own erosion and sediment control rules and regulations.

REGULATORY REQUIREMENTS

Erosion and sediment control requirements exist at the federal, state and local levels of government. Some city and county governments have adopted site development or sediment control ordinances or regulations, usually through subdivision regulations. Developers and contractors should check with local governments to determine whether ordinances may affect their proposed activities. Over the next several years, many municipalities will be developing their own sediment control requirements to meet the provisions of the Municipal Separate Storm Sewer System (MS4) General Permit.

Federal and State Sediment Control Requirements

Congress amended the Clean Water Act (CWA) in 1987, requiring a two-phase program be implemented to regulate stormwater discharges. The U.S. Environmental Protection Agency (EPA) promulgated the Phase I regulations in 1990, which, among other things, required National Pollutant Discharge Elimination System (NPDES) permit coverage for most stormwater discharges from construction activities. EPA authorized WVDEP to administer the NPDES program in West Virginia. WV DEP issued the first NPDES General Permit for stormwater discharges from construction activities in 1992 and has issued follow up General Permits every five years since that time. In 1999, EPA issued the Phase II regulations requiring NPDES permit coverage for sites with one acre or more of land disturbance. West Virginia's current General WV/NPDES Water Pollution Control Permit for stormwater associated with construction activities covers projects with one acre or more of earth disturbance.

Construction Projects that Need a Permit for Stormwater Discharge

Any land-disturbing activity that will disturb an area of one acre or more is required to be covered under an NPDES permit for its stormwater discharge. In addition, sites that disturb less than one acre that are part of a "common plan of development or sale" may also need to be covered by this permit. A common plan of development is a contiguous construction project where multiple separate and distinct construction activities may be taking place at different times and on different schedules, but under one plan. The "plan" is broadly defined as any announcement, piece of documentation or physical demarcation indicating construction activities may occur on a specific plot; most subdivisions are included in this definition.

Construction of single family residences by the homeowner or homeowner's contractor requiring land disturbances less than three acres in size are provided coverage under the General WV/NPDES Water Pollution Control Permit and do not require application for registration. All other terms and conditions of the General Permit, except for the Notice of Termination requirement, still apply.

State Water Quality Standards

West Virginia has several water quality standards that can address runoff from earth disturbing activities. The first are numerical water quality criteria. These are numerical values set forth in the state of West Virginia's Water Quality Standards [47 CSR 2]. They specify the levels of pollutants allowed in receiving waters that are protective of the stream's designated use. Designated uses can be to protect public water supply, for protection of fish, shellfish, and wildlife, and for recreational, agricultural, industrial, and navigational purposes.

Waste assimilation and transport are not designated uses. Therefore sediment traps and basins cannot be installed in waters of the State. Also, streams cannot be used to transport sediment from a construction site to a sediment trap or basin.

The primary numeric water quality standard addressing earth disturbing activities is turbidity. Other criteria that could be violated by runoff from a construction project include pH and iron.

Turbidity is defined as an expression of the optical property that causes light to be scattered and absorbed rather than transmitted in straight lines through the sample. It is an indirect measurement of how much suspended material is in a sample of water.

In West Virginia, turbidity in the receiving stream shall not exceed 10 nephlometric turbidity units (NTU) over background turbidity when the background turbidity is 50 NTU or less, or have more than a 10 percent increase plus 10 NTU in turbidity when the background turbidity is more than 50 NTU. The points of measurement are directly above and below the point of discharge [47 CSR 2-8.32].

There are also narrative water quality criteria, listed as "Conditions Not Allowable in State Waters" [47 CSR 2-3]. Several of these are applicable to earth disturbing activities including the prohibition against the following conditions: distinctly visible floating or settleable solids, suspended solids, scum, foam or oily slicks, deposits or sludge banks. Also the discharge must not contain materials that have taste or color or have materials in concentrations that are harmful, hazardous or toxic to man, animal or aquatic life.

Compliance with Standards

Surface water discharges associated with construction activity are subject to applicable state water quality standards. The Construction Stormwater General Permit does not authorize the violation of those standards. WVDEP expects that the selection and implementation of appropriate BMPs will result in compliance with standards for surface water discharges from construction sites. Proper implementation and maintenance of these controls is critical to adequately control any adverse water quality impacts from construction activity.

Total Maximum Daily Loads (TMDLs)

If construction activities will contribute pollutants for which a specific receiving water is listed as impaired, permittees must comply with Total Maximum Daily Loads (TMDLs) set for the receiving stream. Construction sites may be designated as contributors to the impairment if a stream is listed as impaired because of sediment or iron. Section 303(d) of the CWA established the TMDL process to guide the application of state water quality standards to individual water bodies and watersheds. A TMDL defines the amount of a particular pollutant that a water body can absorb daily without violating applicable water quality standards. Once this load is established, the WVDEP allocates a portion to each source of that pollutant within a particular watershed. In the case of construction activities within an impaired watershed, the WVDEP may require the permittee to implement more stringent BMPs, apply for an individual NPDES permit, or take other necessary actions to ensure compliance with TMDL discharge requirements. To find out if there are additional TMDL-related requirements for your project, please contact the WVDEP Stormwater Program.

Local Ordinances

Local regulations, such as zoning and subdivision ordinances, may also regulate construction activities in West Virginia. Numerous cities have subdivision requirements. Some counties and most larger cities have some sort of zoning regulations. Check the phone book under county and city for "Planning Commission". If there is no Planning Commission, contact the city government and county commissions.

Each county and city in the state is required to have a floodplain ordinance in order for residents to qualify for flood insurance. The local governmental authority in charge of the program regulates projects that physically alter land within the 100-year flood zone. When there is a Planning Commission in a county, it is usually their responsibility to manage and enforce the regulations. In other counties the applicant should contact the County Commission.

Endangered Species Act

If a construction project discharges to a receiving water where a federally endangered or threatened species or its habitat is present, potential impacts to that species need to be considered. For information on Endangered Species Act implementation in West Virginia and developing project-specific compliance strategies contact the U. S Fish and Wildlife Service in Elkins at:

U.S. Fish and Wildlife Service
West Virginia Field Office
P.O. Box 1278
Elkins, WV 26241
304-636-6586

Appendix B lists water bodies where Endangered Species may be found.

Permits for In-Stream Construction and Wetland Filling

Developers proposing to conduct construction activities in waterways, including jurisdictional wetlands, may be required to obtain permits from the US Army Corps of Engineers (USACE) and/or the West Virginia Division of Natural Resources (DNR) Office of Land and Streams, as well as WVDEP depending on the project scope and location.

DNR Stream Activity Application

The Office of Land and Streams holds the title to the "waters of the state". Waters of the state "… means any and all water on or beneath the surface of the ground, whether percolating, standing, diffused or flowing, wholly or partially within this state, or bordering this state and within its jurisdiction, and includes without limiting the generality of the foregoing, natural or artificial lakes, rivers, streams, creeks, branches, brooks, ponds (except farm ponds, industrial settling basins and ponds and water treatment facilities), impounding reservoirs, springs, wells, watercourses and wetlands" [22 CSR 12-3].

A DNR Stream Activity Application is required for construction activities that occur within the normal high water mark of a stream in West Virginia. Information on this program and application forms made be obtained at:

Office of Land and Streams
Building 3, Room 643
1900 Kanawha E
Charleston, WV 25305
304-558-3225
http://www.wvdnr.gov/REM/PLC.shtm

Federal Permits

The USACE administers Section 404 of the Clean Water Act (CWA) and Section 10 of the Rivers and Harbors Act of 1899. Under these jurisdictions, the USACE have issued a number of general Nationwide Permits for certain activities or similar types of activities that have a minimal impact on navigable waters (Section 10 permits) or waters of the U.S. (Section 404 permits). For activities not covered under a Nationwide Permit, the developer will need to apply for an Individual Permit.

Section 404 of the CWA establishes a program to regulate the discharge of dredged or fill material into waters of the U.S, including jurisdictional wetlands. Construction activities covered under this program include fill for commercial site development, subdivisions and infrastructure development (such as highways, airports and utility lines).

The USACE conducts and verifies wetland determinations and has the final say on jurisdiction. The USACE also develops policy and guidance on stream and wetland issues and enforces Section 404 permits and provisions.

The ACE District offices are located in Pittsburgh and Huntington.

401 Water Quality Certification

Section 401 Water Quality Certification is required for each permit or license issued by a federal agency to ensure that proposed projects will not violate the state's water quality standards or stream designated uses. States are authorized to issue Certification under Section 401 of the CWA.

The majority of certification requests are for dredge and fill operations regulated by the US Army Corps of Engineers. The US Coast Guard issues permits for bridge construction on navigable waterways. The Federal Energy Regulatory Commission is responsible for licenses related to hydropower facilities. Applicants must receive State 401 Water Quality Certification before they can receive a permit from the federal agency.

The DWWM may grant, grant with conditions, waive, or deny 401 Water Quality Certification. The decision to issue certification is based on project compliance with West Virginia Water Quality Standards. Field support for the 401 program is provided by the DNR’s Wildlife Resources Section.

Information on this program and application forms made be obtained at:

401 Certification Program

ACKNOWLEDGEMENTS

Development of this manual was begun in the mid-1990s and the current document has survived numerous staffing changes, agency and program reorganizations, and multiple edits and revisions. As such, it has become almost impossible to identify all who may have contributed to the manual and the exact sources of some of the information. We have attempted in the final edit to eliminate any information that could not be properly documented. The State Conservation Agency coordinated a multi-agency committee that established much of the early work on this manual. Several WVDEP staff contributed to the manual. The draft document was completed under a contract with Parsons Brinckerhoff Quade & Douglas, funded by a federal Clean Water Act grant from the US Environmental Protection Agency to the WV DEP DWWM. Final editing was completed by WVDEP Stormwater Program staff.

Technical sources:

Technical sources are noted in the document.

Corrections

Any errors or omissions are the responsibility of the WVDEP. Please report any errors or omissions to the WVDEP DWWM for correction.

Future updates

Modifications to the handbook will be necessary from time to time. The handbook has been designed to be a living document and will be updated as new information or revisions are obtained.

CHAPTER 2

HOW TO PREPARE A SEDIMENT CONTROL PLAN

How to Prepare a Sediment Control Plan

This chapter provides an overview of the important components of, and the process for, developing and implementing the sediment control plan (SCP) component of the construction stormwater pollution prevention plan (SWPPP).

> **Section 1** contains general guidelines with which site planners should become familiar. It describes criteria for plan format and content and ideas for improved plan effectiveness.
>
> **Section 2** outlines and describes a recommended step-by-step procedure for developing a SCP from data collection to finished product. This procedure is written in general terms to be applicable to all types of projects.
>
> **Section 3** includes a checklist for developing a SCP.

Design standards and specifications for best management practices (BMPs) referred to in this chapter are found in Chapter 3.

The SCP and SWPPP are separate stand-alone documents but should be integrated into the overall construction plan set.

Section 1

General Guidelines

What is a construction stormwater pollution prevention plan and how is it different from a sediment control plan?

The **construction stormwater pollution prevention plan** (SWPPP) is the overall document that describes the potential for pollution problems on a construction project and explains and illustrates the measures to be taken to control those problems.

A **sediment control plan** (SCP) is the document that deals exclusively with controlling erosion and sediment during the construction phase.

The SWPPP consists of several components including: the SCP, one or two groundwater protection plans, a stormwater management plan (if necessary) and a plan to control other pollutants. This manual provides practices and procedures necessary to develop a SCP.

The DEP reviews the Construction SWPPPs for compliance and adequacy in controlling erosion and sediment and other pollutants during construction. Single-family home construction projects may use the generic individual house sediment control plan.

The construction SWPPP is a separate and complete document. However, the appropriate sections (SCP in particular) should be incorporated into the contract drawings and documents. The construction SWPPP and site registration application must be located on the construction site for examination by DEP inspection personnel. As site work progresses, the plan must be modified to reflect changing site conditions that affect sediment and erosion control practices. These changes are subject to the permit modification procedures for the state.

What is in a sediment control plan?

The SCP for projects that disturb more than one acre must contain sufficient information to satisfy the state that the pollution problems have been adequately addressed for the proposed project. An adequate SCP includes both a narrative and drawings. The narrative is a written statement to explain the pollution prevention decisions made for a particular project. The narrative contains information about existing site conditions, proposed site conditions, construction schedules and sequence of events, design and calculations and other pertinent items. The drawings and notes describe where and when the various BMPs should be installed and the construction drawings and details of each practice mentioned in the narrative.

On construction sites the primary concern in the preparation of the SCP is impacts to surface water and groundwater. Each of the 12 elements found in the following section should be included in the SCP unless an element is determined not to be applicable to the project.

Best management practice guidelines and specifications

Chapter 3 contains guidelines and specifications for the BMPs referred to in this chapter.

The guidelines and specifications in Chapter 3 of this volume are not intended to limit any innovative or creative effort to effectively control erosion and sedimentation. In those instances where appropriate BMPs are not in this chapter, experimental practices can be considered. Some modifications to guideline practices may also be employed. However, the DEP must approve such practices before they may be used. All experimental practices and modified guideline practices are required to achieve the same or better performance of the BMPs listed in Chapter 3.

General principles

The following general principles should be applied to the development of the SCP:

• The duff layer, native topsoil, and natural vegetation should be retained in an undisturbed state to the maximum extent practicable.

• Prevent pollutant release. Select source control BMPs as a first line of defense. Erosion prevention can be easier than treating turbid runoff.

• Select BMPs depending on site characteristics (topography, drainage, soil type, ground cover, and critical areas) and the construction plan.

• Divert runoff away from exposed areas wherever possible. Keep clean water clean.

• Limit the extent of clearing operations and phase construction operations.

• If topsoil is not available, amend all soils with appropriate lime and fertilizer prior to seeding.

• Maintain and protect natural drainage features whenever possible.

• Minimize slope length and steepness.

• Control water through the use of diversions and slope drains.

• Reduce runoff velocities to prevent channel erosion.

• Prevent the tracking of sediment offsite.

• Control pollutants other than sediment.

• Anticipate rain. View the project controls as if there will be a significant rain event at some point during construction. Determine where runoff will drain to at each stage of the project and make sure there will be an appropriate sediment control device there to intercept it.

• Remember that the ground won't dry out as fast during the winter as it does in the summer.

• Be realistic about the limitations of controls that you specify and the operation and maintenance of those controls. Anticipate what can go wrong, how you can prevent it from happening, and what will need to be done to fix it.

Section 2
Step-By-Step Procedures

There are three basic steps in producing a sediment control plan:

Step 1 - Data collection

Step 2 - Data analysis

Step 3 - SCP development and implementation

Steps 1 and 2 described below are intended for projects that disturb one acre or more. Single-family home construction projects that are part of common plan of development or sale may use the simpler generic individual house sediment control plan.

Step 1 - Data collection

Evaluate existing site conditions and gather information that will help develop the most effective SCP. The information gathered should be explained in the narrative and shown on the drawings.

• Topography - Prepare a topographic drawing of the site to show the existing contour elevations at intervals of at most five feet depending upon the slope of the terrain.

• Drainage - Locate and clearly mark existing drainage swales and patterns on the drawing, including existing storm drainpipe systems.

• Soils - Identify and label soil type(s) and erodibility (low, medium, high, or an index value from the NRCS manual) on the drawing. Soils information can be obtained from a soil survey if one has been published for the county. If a soil survey is not available, a request can be made to a local Natural Resource Conservation Service office.

Soils must be characterized for permeability, percent organic matter, and effective depth by a qualified soil professional or engineer. These qualities should be expressed in averaged or nominal terms for the subject site or project.

• Ground cover - Label existing vegetation on the drawing. Such features as tree clusters, grassy areas, and unique or sensitive vegetation should be shown. Unique vegetation may include existing trees above a given diameter. Local requirements regarding tree preservation should be investigated. In addition, existing denuded or exposed soil areas should be indicated.

• Critical areas - Delineate critical areas adjacent to or within the site on the drawing. Such features as steep slopes, streams, floodplains, lakes, and wetlands should be shown. Delineate setbacks and buffer limits for these features on the drawings. Other related jurisdictional boundaries such as the Federal Emergency Management Agency (FEMA) base floodplain should also be shown on the drawings.

• Adjacent areas - Identify existing buildings, roads, and facilities adjacent to or within the project site on the drawings. Identify existing and proposed utility locations, construction clearing limits, and erosion and sediment control BMPs on the drawings.

• Existing encumbrances - Identify wells, existing and abandoned septic drain fields, utilities, easements, and site constraints.

• Precipitation records - Determine the average monthly rainfall and rainfall intensity for the required design storm events.

Step 2 - Data analysis

Consider the data collected in Step 1 to visualize potential problems and limitations of the site. Determine those areas that have critical erosion hazards. The following are some important factors to consider in data analysis:

• Topography - The primary topographic considerations are slope steepness and slope length. The longer and steeper the slope, the greater the erosion potential.

• Drainage - Natural drainage patterns should be maintained as much as possible in the developed site. Care should also be taken to ensure that increased runoff from the site will not erode or flood the existing natural drainage system. Possible sites for temporary surface water retention and detention should be considered at this point.

Direct construction away from areas of saturated soil - areas where ground water may be encountered - and critical areas where drainage will concentrate. Preserve natural drainage patterns on the site.

• Soils - Evaluate soil properties such as surface and subsurface runoff characteristics, depth to impermeable layer, depth to seasonal ground water table, permeability, shrink-swell potential, texture, settleability, and erodibility. Develop the SCP based on known soil characteristics.

• Ground cover – Preserving ground cover is the most important factor in terms of preventing erosion. Existing vegetation that can be saved will prevent erosion better than constructed BMPs. Trees and other vegetation protect the soil structure. If the existing vegetation cannot be saved, consider such practices as phasing construction, temporary seeding, and mulching. Phasing of construction involves stabilizing one part of the site before disturbing another. In this way, the entire site is not disturbed at once.

• Critical areas - Critical areas may include flood hazard areas, mine hazard areas, slide prone areas, sole source aquifers, wetlands, stream banks, streams, and other water bodies. Any critical areas within or adjacent to the development should exert a strong influence on land development decisions. Critical areas and their buffers shall be delineated on the drawings and clearly flagged in the field. Orange plastic fencing may be more useful than flagging to assure that equipment operators stay out of critical areas. Only unavoidable work should take place within critical areas and their buffers. Such unavoidable work may require special BMPs, permit restrictions, and mitigation plans.

• Adjacent areas - An analysis of adjacent properties should focus on areas upslope and down slope from the construction project. Waterbodies that will receive direct runoff from the site are a major concern. The types, values, and sensitivities of and risks to downstream resources, such as private property, surface water facilities, public infrastructure, or aquatic systems, should be evaluated. Care must be taken where upslope diversions will exit the property.

Erosion and sediment controls should be selected accordingly.

• Timing of the project - An important consideration in selecting BMPs is the timing and duration of the project. Projects that will proceed during the winter or that will last through several seasons must take precautions to remain in compliance with the SWPPP and General Permit. Requirements for some practices, especially seeding and mulching, can change according to the season they are implemented.

Step 3 - SCP development and implementation

After collecting and analyzing the data to determine the site limitations, the planner can then develop a SCP. Each of the 12 elements below must be considered and included in the SCP unless site conditions render the element unnecessary.

12 Basic Sediment Control Plan Elements

Element #1: Mark clearing limits

• Prior to beginning land disturbing activities, clearly mark all clearing limits, sensitive areas and their buffers, and trees that are to be preserved within the construction area. These shall be clearly marked, both in the field and on the plans, to prevent damage and offsite impacts.

• Plastic, metal, or stake wire fence may be used to mark the clearing limits.

• Suggested BMPs:

− Preserving natural vegetation
− Buffer zones
− Safety fence

Element #2: Establish construction access

• Construction vehicle access and exit should be limited to one route if possible.

• Access points shall be stabilized with crushed aggregate to minimize the tracking of sediment onto public and private roads.

• Wheel wash or tire baths should be located on site, if applicable.

• No sediment tracking on the roadway is allowed. In the event that sediment is inadvertently tracked onto the road, the road shall be cleaned thoroughly by the end of each day. Sediment shall be removed from roads by shoveling or pickup sweeping and shall be transported to a controlled sediment disposal area. Street washing of sediments to the storm drain system is not allowed. If street wash wastewater can be controlled from entering the storm drainage system, then it shall be pumped back onto the site, contained, and disposed of properly.

• Construction access restoration shall be equal to or better than the pre-construction condition.

• Suggested BMPs:

− Stabilized construction entrance

− Construction road/parking area stabilization

Element #3: Install sediment controls

• The duff layer, native topsoil, and natural vegetation shall be retained in an undisturbed state to the maximum extent practicable.

• Prior to leaving a construction site, surface water runoff from disturbed areas shall pass through a sediment basin/trap or other appropriate and approved sediment removal BMP.

• BMPs intended to trap sediment on site shall be constructed as one of the first steps in grading. These BMPs shall be functional before other land disturbing activities take place.

• Earthen structures such as dams, dikes, and diversions shall be seeded and mulched according to the timing indicated in Element #5.

• Suggested BMPs:

− Sediment trap
− Temporary sediment basin
− Silt fence
− Super silt fence

− Drop inlet protection
− Vegetated strip
− Wattles

Element #4: Stabilize soils

• Exposed and unworked soils shall be stabilized by application of effective BMPs that protect the soil from the erosive forces of raindrops, flowing water, and wind. The General Permit requires that all graded areas that are at final grade must be seeded and mulched within 7 days and areas that will not be worked again for 21 days or more must be seeded and mulched within 7 days.

• Applicable practices include, but are not limited to, temporary and permanent seeding, sodding, mulching, erosion control fabrics and matting, soil application of polyacrylamide (PAM), the early application of gravel base on areas to be paved, and dust control.

• Selected soil stabilization measures shall be appropriate for the time of year, site conditions, and estimated duration of use.

• Soil stockpiles must be stabilized and protected with sediment trapping measures.

• Linear construction activities such as right-of-way and easement clearing, roadway development, pipelines, and trenching for utilities, shall be conducted to meet the soil stabilization timeframe requirements. Contractors shall install the bedding materials, roadbeds, structures, pipelines, or utilities and re-stabilize the disturbed soils so that the 7-day requirements are met:

• Suggested BMPs:

_Temporary seeding
_Permanent seeding
_Mulching
_Rolled erosion control products
_Sodding
_Topsoiling
_Polyacrylamide for soil erosion protection
_Surface roughening
_Surface water control
_Dust control

Element #5: Protect slopes

• The General Permit prohibits upslope runoff from flowing down fill slopes. Contain fill runoff with temporary berms and in pipes, slope drains, or stabilized channels.

• Design, construct, and phase cut and fill slopes in a manner that will minimize erosion.

• Consider soil type and its potential for erosion.

• Reduce slope runoff velocities by reducing continuous length of slope with benches and diversions, reduce slope steepness, and roughen slope surface.

• Divert upslope drainage and run-on waters with interceptors at top of slope. Surface water from offsite should be handled separately from surface water generated on the site. Diversion of offsite surface water around the site may be a viable option. Diverted flows must be redirected to the natural drainage location at or before the property boundary.

• Provide drainage to remove ground water intersecting the slope surface of exposed soil areas.

• Excavated material shall be placed on the uphill side of trenches, consistent with safety and space considerations.

• Stabilize soils on slopes, as specified in Element #4.

• Suggested BMPs:

_Temporary seeding
_Permanent seeding
_Surface roughening
_Temporary diversions
_Temporary berms
_Pipe slope drains
_Level lip spreader
_Rock check dams
_Commercial check dams

Element #6: Protect drain inlets

• Storm drain inlets operable during construction shall be protected so that surface water runoff does not enter the conveyance system without first being filtered or treated to remove sediment.

• Approach roads shall be kept clean.

• Inlets should be inspected weekly at a minimum and daily during storm events. Inlet protection devices should be cleaned or removed and replaced before six inches of sediment can accumulate.

• Suggested BMPs:

_Drop inlet protection

Element #7: Convey stormwater in a non-erosive manner

• Points of discharge and receiving streams shall be protected from erosion due to increases in the volume, velocity, and peak flow rate of surface water runoff from the project site.

• Design and stabilize any stormwater conveyance for expected flows.

• Consider any local government requirements for stormwater management.

• Suggested BMPs:

− Outlet protection

_Level lip spreader

_Riprap

_Rock check dams

_Surface water controls

_Rolled erosion control products

Element #8: Control other pollutants

• All pollutants, including waste materials and demolition debris, that occur on site during construction shall be handled and disposed of in a manner that does not cause contamination of surface water. Woody debris may be chopped and spread on site.

• Cover, containment, and protection from vandalism shall be provided for all chemicals, liquid products, petroleum products, and non-inert wastes present on the site.

• Maintenance and repair of heavy equipment and vehicles involving oil changes, hydraulic system drain down, solvent and de-greasing cleaning operations, fuel tank drain down and removal, and other activities which may result in discharge or spillage of pollutants to the ground or into surface water runoff must be conducted using spill prevention measures, such as drip pans. Contaminated surfaces shall be cleaned immediately following any discharge or spill incident. Emergency repairs may be performed on-site using temporary plastic placed beneath and, if raining, over the vehicle.

• Wheel wash or tire bath wastewater shall be discharged to a separate on-site treatment system or to the sanitary sewer.

• Application of agricultural chemicals including fertilizers and pesticides shall be conducted in a manner and at application rates that will not result in loss of chemical to surface water runoff. Manufacturers' recommendations for application rates and procedures shall be followed.

• BMPs shall be used to prevent or treat contamination of surface water runoff by pH modifying sources. These sources include bulk cement, cement kiln dust, fly ash, new concrete washing and curing waters, waste streams generated from concrete grinding and sawing, exposed aggregate processes, and concrete pumping and mixer washout waters.

Element #9: Control dewatering

• Foundation, vault, and trench dewatering water shall be discharged into a controlled conveyance system prior to discharge to a sediment pond. Channels must be stabilized, as specified in Element #8.

• Clean, non-turbid dewatering water, such as well-point ground water, can be discharged to systems tributary to state surface waters, as specified in Element #7, provided the dewatering flow does not cause erosion or flooding of receiving waters. These clean waters should not be routed through surface water sediment ponds.

• Highly turbid or contaminated dewatering water from construction equipment operation, work inside a cofferdam shall be handled separately from surface water.

• Other disposal options, depending on site constraints, may include:

1. Infiltration;
2. Transport off-site in vehicle, such as a vacuum flush truck, for legal disposal in a manner that does not pollute state waters;
3. On-site treatment using chemical treatment or other suitable treatment technologies;
4. Sanitary sewer discharge with local sewer utility approval; or
5. Use of a dewatering bag with outfall to a ditch or swale for small volumes of localized dewatering.

Element #10: Maintain BMPs

• Temporary and permanent erosion and sediment control BMPs shall be maintained and repaired as needed to assure continued performance of their intended function. Maintenance and repair shall be conducted in accordance with BMPs.

• Sediment control BMPs shall be inspected weekly or after each storm of 0.5 inches or more.

• Temporary erosion and sediment control BMPs should be removed within 30 days after final site stabilization is achieved or after the temporary BMPs are no longer needed. Trapped sediment shall be removed or stabilized on site. Disturbed soil resulting from removal of BMPs or vegetation shall be permanently stabilized.

• Maintenance should be included as a separate bid item for each BMP, where applicable.

Element #11: Manage the project

• Phasing of Construction - Development projects shall be phased in order to prevent the transport of sediment from the development site during construction, unless the project engineer can demonstrate that construction phasing is infeasible. Revegetation of exposed areas and maintenance of that vegetation shall be an integral part of the clearing activities for any phase.

Clearing and grading activities for developments shall be permitted only if conducted pursuant to an approved site development plan (e.g., subdivision approval) that establishes areas of clearing, grading, cutting, and filling. When establishing clearing and grading areas, consideration should be given to minimizing removal of existing trees and disturbance and compaction of native soils. Any areas required to preserve critical or sensitive areas, and buffers, shall be delineated on both the plans and the site.

• Coordination with Utilities and Other Contractors - The primary project manager shall evaluate, with input from utilities and other contractors, the surface water management requirements for the entire project, including the utilities, when preparing the SCP.

• Inspection and Monitoring - All BMPs shall be inspected, maintained, and repaired as needed to assure continued performance of their intended function.

Whenever inspection and/or monitoring reveals that the BMPs identified in the SCP are inadequate, the SCP shall be modified, as appropriate, in a timely manner.

• Reporting - Report spillage or discharge of pollutants within 24-hours.

• Equipment Maintenance - Maintenance and repair of heavy equipment and vehicles involving oil changes, hydraulic system drain down, solvent and de-greasing cleaning operations, fuel tank drain down and removal, and other activities which may result in discharge or spillage of pollutants to the ground or into surface water runoff must be conducted using spill prevention measures, such as drip pans. Contaminated surfaces shall be cleaned immediately following any discharge or spill incident. Contaminated soil must be disposed of properly. Emergency repairs may be performed on-site using temporary plastic placed beneath and, if raining, over the vehicle.

• Maintenance of the SCP - The SCP shall be retained on-site. The SCP shall be modified whenever there is a significant change in the design, construction, operation, or maintenance of any BMP. The DEP must be notified of any changes to the Construction SWPP. Depending on the significance of the revision, a permit modification may need to be submitted to the DEP.

Element #12: Stabilization

The construction site should be stabilized as soon as possible after completion. Establishment of final cover must be initiated no later than 7 days after reaching final grade. A Notice of Termination must be filed with the DEP when the site reaches final stabilization. Final stabilization means that all soil-disturbing activities are completed, and that either a permanent vegetative cover with a density of 70% or greater has been established or that the surface has been stabilized by hard cover such as pavement or buildings... It should be noted that the 70% requirement refers to the total area vegetated and not just a percent of the site.

Section 3
Checklists for Sediment Control Plans

The SCP typically consists of two parts: a narrative and the drawings. The following two sections describe in general terms the contents of the narrative and the drawings. For more specific information to comply with the General Permit see the instructions to complete a site Registration application form following this section.

Several checklists are included in this manual that can be used as a quick reference to determine if all the major items are included in the SCP.

Narrative

The following topic headings are guideline to be used when preparing the SCP narrative.

• Project description – Describe the nature and purpose of the construction project. Include the size of the project area, any increase in existing impervious area, the area disturbed, and the volumes of grading cut and fill that are proposed.

• Existing site conditions – Describe the existing topography, vegetation, and drainage. Include a description of any structures or development on the parcel including the area of existing impervious surfaces.

• Adjacent areas – Describe adjacent areas, including streams, lakes, wetlands, residential areas, and roads that might be affected by the construction project. Provide a description of the downstream drainage leading from the site to the receiving body of water.

• Critical areas – Describe areas on or adjacent to the site that are classified as critical areas. Describe special requirements for working near or within these areas.

• Soil – Describe the soils on the site, giving such information as soil names, mapping unit, erodibility, settleability, permeability, depth, texture, and soil structure.

• Potential erosion problem areas – Describe areas on the site that have potential erosion problems.

• Twelve (12) elements – Describe how the SCP addresses each of the 12 required elements. Include the type and location of BMPs used to satisfy the each element. If a sediment basin or trap of the required volume cannot be constructed provide a written justification and explain in detail what other sediment and erosion controls will be used in its place.

• Construction phasing – Describe the construction sequence of events and proposed construction phasing.

• Construction schedule – Provide a relative construction schedule. It is not necessary to provide exact dates but rather describe in relative terms when each construction phase will take place and how and where each planned sediment and erosion control device or practice will be installed.

• Engineering calculations – Attach any calculations made for the design of such items as sediment ponds, diversions, and waterways, as well as calculations for runoff and surface water detention design (if applicable). Engineering calculations for permanent structures must bear the signature and stamp of an Engineer licensed in the State of West Virginia. References shall be provided for all variables used.

Drawings

Because contractors seldom will see the SWPPP, the Contract Drawings should include all of the critical provisions of the SWPPP.

Each set of Contract Drawings should have at a minimum the following information.

- Name of the project and owner, address; Parcel Number or other identifying mark; and scale.
- Vicinity Map – Provide a map locating the site in relation to the surrounding area and roads.
- Number of sheets with index.

• **Site map** – Provide a site map(s) showing the following features. The site map requirements may be met using multiple plan sheets for ease of legibility.

1. Standard notes that summarize the critical portions of the SCP. Notes addressing construction sequencing and scheduling must be included on the drawings.
2. Show project limits.
3. The direction of north in relation to the site.
4. Existing structures and roads, if present.
5. The boundaries of and label the different soil types.
6. Areas of potential erosion problems.
7. Any on-site and adjacent critical areas, their buffers, and FEMA base flood boundaries.
8. Existing contours and drainage basins and the direction of flow for the different drainage areas.
9. Final grade contours and developed condition flow paths and drainage basins.
10. Areas that are to be cleared and graded.
11. Existing unique or valuable vegetation and the vegetation that is to be preserved.
12. Cut and fill slopes indicating top and bottom of slope.
13. Stockpile, waste storage, and vehicle storage/maintenance areas.
14. Total cut and fill quantities and the disposal method and location of excess material. All existing and proposed utilities and any associated easements.
15. Proposed permanent structures including roads and parking areas.

• Conveyance systems – Show on the site map(s) the following temporary and permanent onsite and offsite conveyance features:

1. Locations for existing and permanent swales, diversions, or ditches.
2. Drainage pipes, berms, ditches, or diversions associated with erosion and sediment control and surface water management.
3. Temporary and permanent pipe inverts and minimum slopes.
4. Grades, dimensions, and direction of flow in all ditches and swales, culverts, and pipes.
5. Details for bypassing offsite runoff around disturbed areas.
6. Locations and outlets of any dewatering systems.

• **Location of stormwater management structures** – Show on the site map the locations of any stormwater management structures.

• Erosion and sediment control practices – Show on the site map the following erosion and sediment control practices:

1. The location of sediment basins/trap(s), pipes and structures.

2. Dimension basin berm widths and inside and outside pond slopes.
3. The trap/pond storage required and the depth, length, and width dimensions.
4. Typical section views through pond and outlet structure.
5. Typical details of riser and other outlet devices.
6. Stabilization technique details for basin inlets and outlets.
7. Temporary and permanent seeding and mulching specifications. Seeding timeframes.
8. Temporary stabilization methods and timeframe for berms, diversions and slopes.
9. Rock specifications and detail for outlet protection, rock check dam, and any other device used.
10. Construction drawings for each sediment and erosion control device used on the project. Include construction specifications for each device used.
11. The construction entrance location and a stabilization detail.

• Other non-traditional practices--Any structural practices used that are not referenced in this manual should be explained and illustrated with detailed drawings.

• Other pollutant BMPs--Indicate on the site map the location of BMPs to be used for the control of pollutants other than sediment.

Construction Sediment Control Plan Checklist

Project Name:____

Address:____

Section I – SCP Narrative

1. Project Description

___ A. Total Project Area
___ B. Total proposed impervious area.
___ C. Total proposed area to be disturbed.
___ D. Total volumes of proposed cuts/fill.

2. Existing Site Conditions

___ A. Description of the existing topography.
___ B. Description of the existing vegetation.
___ C. Description of the existing drainage.

3. Adjacent Areas

___ A. Description of adjacent areas which may be affected by site disturbance
    ___ 1. Streams
    ___ 2. Lakes
    ___ 3. Wetlands
    ___ 4. Residential areas
    ___ 5. Roads
    ___ 6. Ditches, pipes, culverts
    ___ 7. Other

___ B. Description of the downstream drainage path leading from the site to the receiving body of water. (Minimum distance of 1/4 mile.)

4. Critical Areas

___ A. Description of critical areas that are on or adjacent to the site.
___ B. Description of special requirements for working in or near critical areas.

5. Soils

___ A. Description of on-site soils.
    ___ 1. Soil name(s)
    ___ 2. Soil mapping unit
    ___ 3. Erodibility
    ___ 4. Settleability
    ___ 5. Permeability
    ___ 6. Depth
    ___ 7. Texture

___ 8. Soil structure

6. Erosion Problem Areas

___ A. Description of potential erosion problems on site.

7. Construction Stormwater Pollution Prevention Elements

___ A. Describe how each of the Construction Stormwater Pollution Prevention Elements has been addressed though the SCP.
___ B. Identify the type and location of BMPs used to satisfy the required element.
___ C. Written justification identifying the reason an element is not applicable to the proposal.

12 Required Elements - Construction Stormwater Pollution Prevention Plan:
___ 1. Mark Clearing Limits
___ 2. Establish Construction Access
___ 3. Install Sediment Controls
___ 4. Stabilize Soils
___ 5. Protect Slopes
___ 6. Protect Drain Inlets
___ 7. Convey stormwater in a non-erosive manner
___ 8. Control Other Pollutants
___ 9. Control Dewatering
___ 10. Maintain BMPs
___ 11. Manage the Project
___12. Stabilization

8. Construction Phasing

___ A. Construction sequence
___ B. Construction phasing (if proposed)

9. Construction Schedule

___ A. Provide a proposed construction schedule.

___ B. Wet Season Construction Activities

___ 1. Proposed wet season construction activities.
___ 2. Proposed wet season construction restraints for environmentally sensitive/critical areas.

11. Engineering Calculations

___ A. Provide Design Calculations.

___ 1. Sediment ponds/traps
___ 2. Diversions
___ 3. Waterways
___ 4. Runoff/stormwater calculations

Section II - Erosion and Sediment Control Plans

1. General

___ A. Vicinity Map
___ B. Address, Parcel # and Street names labels
___ C. Erosion and Sediment Control Notes

2. Site Plan

___ A. Legal description of subject property.
___ B. North Arrow
___ C. Indicate boundaries of existing vegetation, e.g. tree lines, pasture areas, etc.
___ D. Identify and label areas of potential erosion problems.
___ E. Identify any on-site or adjacent critical areas and associated buffers.
___ F. Identify FEMA base flood boundaries
___ G. Show existing and proposed contours.
___ H. Indicate drainage basins and direction of flow for individual drainage areas.
___ I. Label final grade contours and identify developed condition drainage basins.
___ J. Delineate areas that are to be cleared and graded.
___ K. Show all cut and fill slopes indicating top and bottom .

3. Conveyance Systems

___ A. Designate locations for swales, interceptor trenches, or ditches.
___ B. Show all temporary and permanent drainage pipes, ditches, or cut-off trenches required for erosion and sediment control.
___ C. Provide minimum slope and cover for all temporary pipes or call out pipe inverts.
___ D. Show grades, dimensions, and direction of flow in all ditches, swales, culverts and pipes.
___ E. Provide details for bypassing offsite runoff around disturbed areas.
___ F. Indicate locations and outlets of any dewatering systems.

4. Location of Stormwater Management Structures

___ A. Identify location of any stormwater management structures.

5. Erosion and Sediment Control Measures

___ A. Show the locations of sediment trap(s), pond(s), pipes and structures.
___ B. Dimension pond berm widths and inside and outside pond slopes.
___ C. Indicate the trap/pond storage required and the depth, length, and width dimensions.
___ D. Provide typical section views through pond and outlet structure.
___ E. Provide typical details of gravel cone and standpipe, and/or other filtering devices.
___ F. Detail stabilization techniques for outlet/inlet.
___ G. Detail control/restrictor device location and details.
___ H. Specify mulch and/or recommended cover of berms and slopes.
___ I. Provide rock specifications and detail for rock check dam(s), if applicable.
___ J. Specify spacing for rock check dams as required.

___ K. Provide front and side sections of typical rock check dams.
___ L. Indicate the locations and provide details and specifications for silt fabric.
___ M. Locate the construction entrance and provide a detail.

6. Detailed Drawings

___ A. Any structural practices used that are not referenced in the Manual should be explained and illustrated with detailed drawings.

7. Other Pollutant BMPs

___ A. Indicate on the site plan the location of BMPs to be used for the control of pollutants other than sediment, e.g. concrete wash water.

8. Monitoring

___ A. Describe inspection reporting responsibility, documentation, and filing.

CHAPTER 3

STANDARD GUIDELINES AND SPECIFICATIONS

3.01 - PRESERVING EXISTING VEGETATION

Introduction

This practice is to preserve the existing natural vegetation thereby reducing erosion wherever practicable. Limiting the amount of disturbance on a construction site is the single most effective method for reducing erosion. For example, trees can hold up to about 50 percent of all rain that falls during a storm. Up to 20-30 percent of this rain may never reach the ground but is taken up by the tree or evaporates. Raindrop erosion is also prevented. Vegetation cools the ground and reduces soil evaporation. Removing natural vegetation and destroying the existing soil profile is one of the greatest causes of increased runoff and subsequent flooding. In urbanizing areas such as the Eastern Panhandle, preserving existing vegetation can be one the most important practice contributing to clean water.

Natural vegetation should be preserved as much as possible but especially on critical areas such as: steep slopes, areas adjacent to perennial and intermittent watercourses or swales or wetlands, and on building sites in wooded areas.

It doesn't make sense to destroy all the trees in a subdivision and then name one of the new streets Shady Oak Lane.

Design and Installation Specifications

Natural vegetation can be preserved in natural clumps or as individual trees, shrubs and vines.

The preservation of individual plants is more difficult because heavy equipment is generally used to remove unwanted vegetation. The points to remember when attempting to save individual plants are:

- Is the plant worth saving? Consider the location, species, size, age, vigor, and the work involved. Check you're your local government. They may have ordinances to save natural vegetation and trees.

- Fence or clearly mark areas around trees that are to be saved. It is preferable to keep all disturbances away from the trees at least as far out as the drip line. (see drawing)

Plants need protection from three kinds of injuries:

Construction Equipment - This injury can be above or below the ground level. Damage results from scarring, cutting of roots, and compaction of the soil. Placing a fenced buffer zone around plants to be saved prior to construction can prevent construction equipment injuries.

Grade Changes - Changing the natural ground level will alter grades, which affects the plant's ability to obtain the necessary air, water, and minerals. Minor fills usually do not cause problems although sensitivity between species does vary and should be checked. Trees can tolerate fill of 6 inches or less. For shrubs and other plants, the fill should be less.

When there are major changes in grade, it may become necessary to supply air to the roots of plants. If fill has to be placed over the root system, place a layer of gravel and a tile system over the roots before the fill is made. The tile system should be laid out on the original grade leading from a dry well around the tree trunk. The system should then be covered with small stones to allow air to circulate over the root area.

Lowering the natural ground level can also seriously damage trees and shrubs. The highest percentage of the plant roots are in the upper 12 inches of the soil and cuts of only 2-3 inches can cause serious injury. To protect the roots it may be necessary to terrace the immediate area around the plants to be saved. If roots are exposed, construction of retaining walls may be needed to keep the soil in place. Plants can also be preserved by leaving them on an undisturbed, gently sloping mound. To increase the chances for survival, it is best to limit grade changes and other soil disturbances to areas outside the drip line of the plant.

Excavations - Protect trees and other plants when excavating for drainfields, power, water, and sewer lines. Where possible, the trenches should be routed around trees and large shrubs. When this is not possible, it is best to tunnel under them. This can be done with hand tools or with power augers. If it is not possible to route the trench around plants to be saved, then the following should be observed:

- Cut as few roots as possible. When you have to cut, cut clean. Paint cut root ends with a wood dressing like asphalt base paint.

- Backfill the trench as soon as possible.

- Tunnel beneath root systems as close to the center of the main trunk to preserve the important feeder roots.

Trees damaged or stressed by construction my die slowly or become more susceptible to attack from disease or insects. Failure to properly protect trees may result in expensive removal costs post construction.

Problem trees: The following trees are more susceptible to damage than others: beech, yellow poplar, Dogwood, hickory, birch, some oaks, most maples, and all conifers. These trees do not readily adjust to changes in the immediate environment and special care should be taken to protect these trees.

Maples and willows have water-seeking roots. These can cause trouble in sewer lines and infiltration fields. On the other hand, they thrive in high moisture conditions that other trees would not.

Minimum Tree Protection Measures

Active tree protection shall consist of, at a minimum, establishing a tree protection zone around each tree or grouping of trees by the installation of fencing at the outer edges of the critical root zone. Protecting the roots of a tree is the most important aspect of tree preservation on a construction project. This root zone can extend two to three times the radius of the drip line.

Despite this the tree protection zone is usually placed along the drip line. Some experts recommend a tree protection root zone calculated as one foot to one and half feet of radius for each inch of tree diameter at breast height. While this is a significant amount of space, if the tree is valuable, the root protection zone should extend to the edge all of the roots. If you want to protect the lower branches, the barrier must be just outside the drip line.

Tree protection fencing and tree protection area signs shall be installed prior to any land disturbance activity or building activity. Tree protection fencing should be at least four feet high and should be installed with either sturdy wooden or metal fence posts around the tree protection zone. Tree protection fencing must remain in good condition throughout the development and construction processes and should only be removed after construction has ceased.

Tree roots need oxygen so it is important to limit compaction around trees. If there is ANY disturbance with the root zone, the tree protection area should be mulched with a minimum of three inches and not more than eight inches of organic mulch such as pine straw, wood chips, tree leaves, or compost.

Allow NO storage, NO heavy equipment, NO machinery, NO trenching, NO digging, NO driving, NO lounging of workers in this area. The area within the protection zone must be off limits to ALL activity.

The Engineer or owner may require the installation of additional tree protection measures to insure survivability of conserved trees.

Materials

1. Protective fencing should be installed anytime existing natural vegetation is to be preserved.
2. Protective fencing is designated as the materials used to protect the root zones of trees. Three basic types of protective fencing materials can be used. Type A and Type B are typical applications and shall be installed where damage potential to a tree root system is high, while Type C shall be installed where damage potential is minimal.

3. The specific type of protective fencing for the work shall be as indicated on the Drawings.
4. Type C fencing shall be replaced by Type A or Type B fencing as directed by the Engineer or designated representative if it fails to perform the necessary function.

   a. Type A Chain Link fence (Typical Application-high potential damage)

      Type A protective fencing shall be installed in accordance with the Division of Highways Standard for Chain Link Fence and shall consist of a minimum five-foot high chain link fencing with tubular steel support poles or "T" posts.

   b. Type B Wood Fence (Typical Application-high potential damage)

      Type B protective fencing shall consist of any vertical planking attached to 2x4-inch horizontal stringers that are supported by 2x4-inch intermediate vertical supports and a 4x4-inch at every fourth vertical support.

   c. Type C Other Materials (Minimal potential damage)

      The following materials may be permitted as alternates for limited or temporary applications and where tree damage potential is minimal:

      (1) High visibility plastic construction fencing. The Standard for SAFETY FENCE in this manual can be used for this specification.
      (2) Other approved equivalent restraining material.

      The fencing materials, identified in (1) and (2) above, shall be supported by steel pipe, tee posts, U posts or 2" x 4" timber posts that are a minimum of 5-1/2 feet in height and spaced no more than 8 feet on centers. The fabric shall be secured to post by bands or wire ties.

Maintenance

Inspect flagged and/or fenced areas regularly to make sure flagging or fencing has not been removed or damaged. If the flagging or fencing has been damaged or visibility reduced, it shall be repaired or replaced immediately and visibility restored.

If tree roots have been exposed or injured, “prune” cleanly with an appropriate pruning saw or loppers directly above the damaged roots and recover with native soils. Treatment of sap flowing trees (pine, soft maples) is not advised as sap forms a natural healing barrier.

3.02 - STABILIZED CONSTRUCTION ENTRANCE

Introduction

Large quantities of mud can be tracked onto public and private roads causing dangerous driving conditions and muddy runoff when it rains. Construction entrances are stabilized to reduce the amount of sediment transported onto paved roads by vehicles or equipment by constructing a stabilized pad of stone at entrances to construction sites.

Conditions Where Practice Applies

Stabilized Construction Entrances shall be installed wherever construction traffic enters and leaves a site.

Design Criteria

1. Use 2-4 inch stone for low volume entrances, larger stone (4-6 inch) for heavy use or material delivery entrances.
2. Length is as required, but not less than 70 feet (except on a single residence lot where a 30 foot minimum length would apply).
3. Thickness should be not less than 6 inches.
4. The width shall be a minimum of 10 feet, but not less than the full width at points where ingress or egress occurs.
5. Geotextile fabric shall be placed over the entire area prior to the placing of stone.
6. All surface water flowing or diverted toward construction entrances shall be piped across the entrance. If a culvert is impractical, a mountable berm with 5:1 slopes shall be used.
7. If necessary, divert any water running down access road to a sediment trap located on either side of the Stabilized Construction Entrance.

Maintenance

The entrance shall be maintained in a condition that will prevent tracking or flowing of sediment onto public rights-of-way. This may require periodic top dressing with additional stone as conditions demand and repair and/or cleanout of any measures used to trap sediment. All sediment spilled, dropped, washed or tracked onto public rights-of-way must be removed immediately.

Wheels on all vehicles shall be cleaned to remove sediment prior to entrance onto public rights-of-way. If washing is required, it shall be done on an area stabilized with stone and which drains into approved sediment trapping device. If the street is washed precautions must be taken to prevent muddy water from running into waterways or storm sewers.

Inspection and needed maintenance should be provided daily but at a minimum every seven days and after every rain of 0.5 inch or greater.

3.03 - TEMPORARY CONSTRUCTION ROAD, WORK AND PARKING AREA STABILIZATION

Introduction

The temporary stabilization of access roads, haul roads, parking areas, laydown, material storage and other onsite vehicle transportation routes with stone immediately after grading. This practice is used to reduce the erosion and subsequent regrading of temporary and permanent roadbeds, work areas and parking areas rutted by construction traffic during wet weather. Provides easier access in all weather and reduces tracking mud onto public roads.

Conditions Where Practice Applies

All temporary work areas on a construction site where vehicular traffic will occur.

Construction Specifications

1. Temporary roads shall follow the contour of the natural terrain to the extent possible. Slopes should not exceed 15 percent.
2. Temporary parking areas should be located on naturally flat areas to minimize grading. Grades should be sufficient to provide drainage but should not exceed 4 percent.
3. Roadbeds should be at least 14 feet wide for one-way traffic and 20 feet wide for two-way traffic. Haul roads should be a least 30 feet wide.
4. All cuts and fills should be 2:1 or flatter.
5. Drainage ditches and culverts shall be provided as needed.
6. The roadbed or parking surface shall be cleared of all vegetation, roots and other objectionable material.
7. A 6-inch course of crushed aggregate shall be applied immediately after grading. Geotextile fabric should be applied to the roadbed for additional stability. In heavy duty traffic situations, stone should be placed at an 8 to10 inch depth to avoid excessive maintenance.
8. Stabilize disturbed areas not covered with stone immediately after installation with appropriate temporary or permanent vegetation according to the applicable standards and specifications contained in this manual.
9. Also see, access road section, for water control practices.

Maintenance

Inspect and perform needed maintenance at a minimum once every seven calendar days and within 24 hours after any storm event greater than 0.5 inches of rain per 24 hour period.

Both temporary and permanent roads, laydown and work areas and parking areas may require periodic top dressing with new gravel.

Seeded areas adjacent to the roads and parking areas should be checked periodically to ensure that a vigorous stand of vegetation is maintained.

Roadside ditches and other drainage structures should be checked regularly to ensure that they do not become clogged with silt or other debris.

3.04 - SAFETY FENCE

Introduction

Protective fencing should be installed to prevent access to potentially hazardous areas of a construction site.

Conditions Where Practice Applies

Applicable to any control measure or series of measures, which can be considered unsafe by virtue of potential for access by the public. The designer, developer, and contractor should always be sure that the most appropriate type of fence is utilized for a particular need.

Construction Specifications

1. Safety fences should be located so as to create a formidable barrier to undesired access, while allowing for the continuation of necessary construction operations.
2. Safety fences are most applicable to the construction of traps and dams. In use with those structures, safety fences should be located far enough beyond the outer toe of the embankment to allow for the passage of maintenance vehicles. Fences should not be installed across the slope of a dam or dike.
3. Signs noting potential hazards such as "DANGER" or "HAZARDOUS AREA --KEEP OUT" should be posted and easily seen by anyone approaching the protected area.
4. Plastic (polyethylene) fence may be used as safety fencing, primarily in situations where the need is for a temporary barrier. The fence should meet the physical requirements noted in Table 3.04.1.

Table 3.04.1 Physical properties of plastic safety fence

Physical property	Test	Requirements
Recommended color	N/A	International Orange
Tensile yield	ASTM D638	Average 2,000 lbs.
Ultimate tensile strength	ASTM D638	Average 2,900 lbs. per 4 ft. width
Elongation at break(%)	ASTM D638	Greater than 1000%
Chemical resistance	N/A	Inert to most chemicals/acids

5. Safety fences should be installed prior to the sediment control measure becoming accessible.
6. Applicable warning signs noting hazardous conditions must be installed immediately upon installation of safety fence.

7. Chain link fence should be used for permanent structures (greater than one year).

Maintenance

Safety fence shall be checked regularly for weather-related or other damage. Any necessary repairs must be made immediately.

Care should be taken to secure all access points (gates) at the end of each working day. All locking devices must be repaired or replaced as necessary.

3.05 - ROCK CHECK DAMS

Introduction

Small temporary stone dams can be constructed across a waterway to reduce the velocity of stormwater flows, thereby reducing erosion of the channel and trapping sediment. This practice is the replacement for the traditionally misused hay/straw bales and silt fence ditch checks. Constructing a small dugout trap upstream of the structure can enhance the sediment trapping efficiency.

Conditions Where Practice Applies

This practice, utilizing a combination of stone sizes, is limited to use in small open channels that drain 5 acres or less. It is never used in live streams. Check dams can be useful in the following instances:

1. Temporary ditches or swales
2. Temporary or permanent ditches and swales which need protection during the establishment of grass linings.
3. This practice is not a substitute for major perimeter trapping measures such as a sediment trap or a sediment basin.

Construction Specifications

No formal design is required for a check dam, however, the following conditions should be adhered to:

1. The drainage area of the ditch or swale being protected shall not exceed 2 acres when 2 to 4 inch aggregate is used alone; and shall not exceed 5 acres when a combination of 4 to 8 inch aggregate (added for stability) and the smaller aggregate is used. Refer to Figure 3.05.1 for orientation of stone and a cross-sectional view of the measure. An effort should be made to extend the stone to the top of channel banks.
2. The maximum height of the dam should be 3 feet.
3. The center of the check dam must be at least 6 inches lower than the outer edges. This is the single most important aspect in the proper installation of the rock check dam. High flows must go over the center of the dam, not around the edges where severe erosion can occur.
4. The maximum spacing between the dams should be such that the toe of the upstream dam is at the same elevation as the top of the downstream dam. The maximum distance between rock check dams is 300 feet.
5. When using a small trap in front of the check dam, ensure the minimum transition from the ditch into the trap is at least 5:1.

Commercial Products

There are several commercially available products on the market now that are viable alternatives to the rock check dam. See commercial silt dike section

Maintenance

1. Inspect each check dam at a minimum once every seven calendar days and within 24 hours after any storm event greater than 0.5 inches of rain per 24 hour period. Check to see if water has flowed around the edges of the structure.
2. Replace stone and repair dams as necessary to maintain the correct height and configuration.

3. Sediment should be removed from behind the check dams when it has accumulated to one half of the original height of the dam. Dispose of the sediment in an appropriate place.

3.06 - WATTLES

Introduction

Wattles are erosion and sediment control barriers consisting of straw or other organic materials wrapped in biodegradable tubular plastic or similar encasing material. Sometimes called Fiber Rolls. Wattles may reduce the velocity and theoretically spread the flow of rill and sheet runoff, and can capture and retain sediment. Wattles are typically 8 to 20 inches in diameter and 10 to 30 feet in length. The wattles are placed in shallow trenches and staked along the contour of disturbed or newly constructed slopes or in low flow ditches where they can function as check dams.

Wattles reduce slope length, and are intended to capture and keep sediment on the slopes. Wattles are useful to temporarily stabilize slopes by reducing soil creep, and sheet and rill erosion until permanent vegetation can be established. Wattles can catch soil that is moved down the slope by the freeze/thaw processes. Organic matter and seeds are trapped behind the rolls, which provide a stable medium for germination. Rolls trap topsoil and retain moisture from rainfall, which aids in growth of seedlings planted upslope of the rolls.

Conditions Where Practice Applies

1. Install on disturbed areas that require immediate erosion protection.
2. Use on slopes requiring stabilization until permanent vegetation can be established.
3. Can be used along the perimeter of a project, as a check dam in unlined ditches and around temporary stockpiles
4. Wattles can be staked to the ground using willow cuttings for added revegetation
5. Erosion can occur beneath and between wattles if not properly entrenched, allowing water to pass below and between wattles. It is therefore very important to install wattles correctly.
6. They can replace sediment fence on steep slopes.
7. Rolls are a short-term solution to help establish native vegetation
8. Rolls store moisture for vegetation planted immediately upslope.
9. Plastic netting will eventually photo-degrade, eliminating the need for retrieval of materials after the fiber or straw has broken down.

Construction Specifications

1. It is critical that wattles are installed perpendicular to the flow direction and parallel to the slope contour.
2. Narrow trenches should be dug across the slope, on contour, to a depth of 3 to 5 inches on clay soils and soils with gradual slopes. On loose soils, steep slopes, and during high rainfall events, the trenches should be dug to a depth of 5 to 7 inches, or ½ to 2/3 of the thickness of the wattle.

3. Start construction of trenches and installing wattles from the base of the slope and work uphill. Excavated material should be spread evenly along the uphill slope and compacted using hand tamping or other method. Construct trenches at contour intervals of 3 to 30 feet apart depending on the steepness of the slope, soil type, and rainfall. The steeper the slope the closer together the trenches should be constructed.
4. Install the wattles snugly into the trenches and abut tightly end to end. Do not overlap the ends.
5. Install stakes at each end of the wattle, and at 4-foot centers along the entire length of the wattle.
6. If required, install pilot holes for the stakes using a straight bar to drive holes through the wattle and into the soil.
7. At a minimum, wooden stakes should be approximately ¾ x ¾ x 24 inches. Willow cuttings or 3/8-inch rebar can also be used for stakes.
8. Stakes should be driven through the middle of the wattle, leaving 2 to 3 inches of the stake protruding above the wattle.

Maintenance

Inspect wattles at least once a week and after each rain event greater than 0.5 inch.

Repair or replace split, torn, raveling, or slumping wattles.

Remove sediment accumulations when exceeding ½ the height between the top of the wattle and the ground surface.

Repair any rills or gullies promptly.

Reseed or replant vegetation if necessary until the slope is stabilized

3.07 - COMMERCIAL SILT DIKES

Introduction

Rock check dams are the most commonly used practice to protect ditchlines from erosion and to trap small amounts of sediment. There are now several commercially available replacements for rock check dams. These new check dams are made from a variety of lightweight materials. One of these is made from foam rubber surrounded by a geotextile filter fabric. Others are made from plastic or a combination of synthetics and natural materials. They can be used as check dams, perimeter protection, drop inlet protection, or as a temporary interceptor dike.

Commercial silt dikes work on the same principle as rock check dams; they intercept and pond sediment-laden runoff. Ponding the water reduces the velocity of any incoming flow and allows some of the suspended sediment to settle. Water exits some commercial silt dikes by flowing over the top and others by flowing through with higher flows going over the top. The apron on the downstream side of the dike helps prevent scour caused by this flowing water.

Conditions Where Practice Applies

1. In place of rock check dams in ditches, especially in locations where hauling the rock would be difficult or in ditches with shallow soils underlain by rock.
2. May be used on soil with staples or on pavement with adhesive.
3. Commercial silt dikes can be used creatively to build temporary sediment traps, diversion ditches, concrete washout facilities, curbing, water bars, level spreaders, and berms.

Construction Specifications

1. Commercial silt dikes are made of urethane foam sewn into a woven geosynthetic fabric, permeable plastic or wattles.
2. Commercial silt dikes come in various shapes, sizes and materials and must be used as detailed in this practice and as the manufacturer states. The connection between individual pieces must be continuous.
3. Install commercial silt dikes perpendicular to the flow of the water except when used as diversions.
4. The commercial silt dikes should extend far enough so that the bottoms of the end dikes are higher than the top of the lowest center dike. This prevents water from flowing around the commercial silt dikes.
5. Attach the commercial silt dikes and their flaps to the ground with wire staples. Wire staples must be No. 11 gauge wire or stronger and shall be 6 to 12 inches in length. Follow the manufacturer's recommendation for installation.
6. When multiple units are installed, the sleeve of fabric at the end of the unit shall overlap the abutting unit and be stapled.

7. Commercial silt dikes must be located and installed as soon as construction will allow.
8. When used as check dams, the leading edge must be secured with rocks, sandbags, or a small key slot and staples.
9. Space dikes apart as shown for rock check dams.
10. Commercial silt dikes can be removed when the grass channel lining has matured sufficiently to protect the ditch or the ditch is stabilized with some sort of permanent lining such as riprap. The soil beneath the commercial silt dikes check dams shall be seeded and mulched immediately after dam removal.

Maintenance

Inspect at a minimum once every seven calendar days and within 24 hours after any storm event greater than 0.5 inches of rain per 24 hour period. Sediment shall be removed when it reaches one half the height of the silt dike.

Anticipate submergence and deposition above the dike and erosion from high flows around the edges of the dike/dam. Immediately repair any damage or any undercutting of the dike/dam.

3.08 - SURFACE ROUGHENING

Introduction

Surface roughening means providing a rough soil surface with horizontal depressions created by operating a tillage or other suitable implement on the contour, or by leaving slopes in a roughened condition by not fine-grading them. This will aid in establishment of vegetative cover with seed, reduce runoff velocity, and increase infiltration, and reduce erosion and provide for sediment trapping. Surface roughening is also a way to prepare the seedbed.

Conditions Where Practice Applies

1. All slopes steeper than 3:1 require surface roughening, either stair-step grading, grooving, furrowing, or tracking if they are to be stabilized with vegetation.
2. Areas with grades less steep than 3:1 should have the soil surface lightly roughened and loose to a depth of 2 to 4 inches prior to seeding.
3. Slopes with a stable rock face do not require roughening or stabilization.

Planning Considerations

It is difficult to establish vegetation on graded areas with smooth, hard surfaces due to reduced water infiltration and the potential for erosion. Rough slope surfaces with uneven soil and rocks left in place may appear unattractive or unfinished at first, but encourage water infiltration, speed the establishment of vegetation, and decrease runoff velocity.

Rough loose soil surfaces give lime, fertilizer and seed some natural coverage. Niches in the surface provide microclimates that generally provide a cooler and more favorable moisture level than hard flat surfaces; this aids seed germination.

There are different methods for achieving a roughened soil surface on a slope, and the selection of an appropriate method depends upon the type of slope. Roughening methods include stair-step grading, grooving, and tracking. Factors to be considered in choosing a method are slope steepness, mowing requirements, and whether the slope is formed by cutting or filling.

Cut Slope Applications For Areas Which Will Not Be Mowed

Cut slopes with a gradient steeper than 3:1 should be stair-step graded or grooved.

1. Stair-step grading may be carried out on any material soft enough to be ripped with a bulldozer. Slopes consisting of soft rock with some subsoil are particularly suited to stair-step grading.

   The ratio of the vertical cut distance to the horizontal distance shall be less than 1:1 and the horizontal portion of the "step" shall slope toward the vertical wall.

   Individual vertical cuts shall not be more than 30 inches on soft soil materials and not more than 40 inches in rocky materials.

2. Grooving consists of using machinery to create a series of ridges and depressions that run perpendicular to the slope (on the contour). Grooves may be made with any appropriate implement which can be safely operated on the slope and which will not cause undue compaction. Suggested implements include disks, tillers, spring harrows, and the teeth on a front-end loader bucket. These grooves should not be less than 3 inches deep nor further than 15 inches apart.

Fill Slope Applications For Areas Which Will Not Be Mowed

Fill slopes with a gradient steeper than 3:1 shall be grooved or allowed to remain rough as they are constructed. The methods below may be used:

1. Groove according to #2 above.
2. As lifts of the fill are constructed, soil and rock materials may be allowed to fall naturally onto the slope surface.

At no time shall slopes be bladed or scraped to produce a smooth, shiny, hard surface.

Cuts, Fills, and Graded Areas Which Will Be Mowed

Mowed slopes should not be steeper than 3:1. Excessive roughness is undesirable where mowing is planned. These areas may be roughened with shallow grooves such as remain after tilling, disking, harrowing, raking, or use of a cultipacker-seeder. The final pass of any such tillage implement shall be on the contour (perpendicular to the slope).

Grooves formed by such implements shall be not less than 1-inch deep and not further than 12-inches apart. Fill slopes that are left rough as constructed may be smoothed with a dragline or pick chain to facilitate mowing.

Roughening With Tracked Machinery

Roughening with tracked machinery on clayey soils is not recommended unless no alternatives are available. Undue compaction of surface soil results from this practice. Sandy and rocky soils do not compact severely, and may be tracked. In no case is tracking as effective as the other roughening methods described.

When tracking is the chosen surface roughening technique, it shall be done by operating tracked machinery up and down the slope to leave horizontal depressions in the soil. As few passes of the machinery should be made as possible to minimize compaction.

Seeding

Roughened areas shall be seeded and mulched as soon as possible to obtain optimum seed germination and seedling growth but at a minimum within seven days of reaching final grade or within seven days if no additional activity is anticipated for 21 days or more.

3.09 - TOPSOILING

Introduction

Topsoiling is the spreading of topsoil of a suitable quality over an area to be stabilized by establishing vegetation. Topsoil is the surface layer of the soil profile, generally characterized as darker than the subsoil due to the enrichment with organic matter. It is the major zone of root development and biological activity. Microorganisms that enhance plant growth thrive in this layer. Topsoil can usually be differentiated from subsoil by texture as well as color. Clay content usually increases in the subsoil. Where subsoils are high in clay, the topsoil layer may be significantly coarser in texture. The depth of natural topsoil may be quite variable. On severely eroded sites it may be gone entirely.

Advantages of topsoil include its higher organic matter content, friable consistence (soil aggregates can be easily crushed with only moderate pressure), its available water holding capacity, and its nutrient content. Most often it is superior to subsoil in these characteristics. The texture and friability of topsoil are usually much more conducive to seed germination, emergence, and root growth.

In addition to being a better growth medium, topsoil is often less erodible than subsoil, and the coarser texture of topsoil increases infiltration capacity and reduces runoff.

Vegetative growth is more rapid on sites with at least 4 inches of topsoil, and the health and quality of the vegetation is better than on sites with little or no topsoil.

Conditions Where Practice Applies

Where the preservation or importation of topsoil is determined to be the most effective method of providing a suitable growth medium.

Where the subsoil or existing soil present any or all of the following problems:

1. The texture, bulk density, pH, or nutrient balance of the available soil cannot be modified by a reasonable means to provide an adequate growth medium for the desired vegetation.
2. The soil is too shallow to provide adequate rooting depth or will not supply necessary moisture and nutrients for growth of desired vegetation.
3. The soil contains substances toxic or potentially toxic to the desired vegetation.
4. Where high-quality turf or ornamental plants are desired.

Design Considerations

Determine if sufficient quantities of suitable topsoil is available at the site or nearby. Topsoil shall be spread at a lightly compacted depth of 2 to 4 inches. Depths of 4 inches or greater are recommended where fine-textured (clayey) subsoil or other root limiting factors are present.

If topsoil is to be stockpiled at the site, select a location so that it will not erode, block drainage, or interfere with work on the site.

During construction of the project, soil stockpiles shall be stabilized by temporary seeding and mulching and protected with sediment trapping measures such as silt fence. Perimeter controls shall be placed around the stockpile immediately; seeding and mulching of stockpiles shall be completed within seven days of formation of the stockpile if it is to remain in place for longer than 21 days.

If the topsoil is not properly bonded to the existing soil, water will not infiltrate evenly, and it will be difficult to establish vegetation.

Care must be taken not to apply topsoil to an existing soil surface if the two have contrasting textures. Clayey topsoil over sandy subsoil is a particularly poor combination, as water creeps along the junction between the two soil layers and may cause the topsoil to slough.

Do not apply topsoil to slopes greater than 2:1 to avoid slippage. Topsoiling of steep slopes should be discouraged unless good bonding of the soils can be achieved.

Construction Specifications

The plans and specifications for installing topsoil shall be in keeping with this standard and shall describe the requirements for applying the practice to achieve its intended purpose. At a minimum include the following items:

1. Topsoil source.
2. Stockpile location and method of stabilization prior to its use.
3. Topsoil/subsoil bonding procedures.
4. Site preparation plans and method of application, distribution and compaction.

Site preparation- Before spreading topsoil, assure that all necessary erosion and sediment control practices such as diversions, berms, dikes, waterways, and sediment basins are in place and functioning properly. These practices must be maintained until the site is permanently stabilized.

Grading- Maintain grades on the areas to be topsoiled according to the approved plan and do not alter them by adding topsoil.

Liming of subsoil- Where the pH of the existing subsoil is 6.0 or less, or the soil is composed of heavy clays, incorporate agricultural limestone in amounts recommended by soil tests or specified for the seeding mixture to be used. Incorporate lime to a depth of at least 2 inches by disking.

Roughening- Immediately prior to spreading the topsoil, loosen the subgrade by disking or scarifying to a depth of at least 4 inches, to ensure bonding of the topsoil and subsoil. If no amendments have been incorporated, loosen the soil to a depth of at least 6 inches before spreading the topsoil.

Spreading topsoil- Uniformly distribute topsoil to a minimum compacted depth of 2 inches on 3:1 slopes and 4 inches on flatter slopes.

Topsoil shall not be spread while it is frozen or saturated or when the subsoil is frozen or saturated.

Irregularities in the surface that result from topsoiling or other operations shall be corrected to prevent the formation of depressions or ponding of water.

Compact the topsoil enough to ensure good contact with the underlying soil, but avoid excessive compaction, as it increases runoff and inhibits seed germination and seedling growth. Light packing with a roller is recommended where high-maintenance turf is to be established.

In areas that are not going to be mowed, the surface can be left rough.

Maintenance

After topsoil application, follow procedures for seedbed preparation. Take care to avoid excessive mixing of topsoil into the subsoil. Permanently stabilize the site following appropriate practice standards as quickly as practicable. Periodically inspect the site until permanent stabilization is achieved. Make necessary repairs to eroded areas or areas of light vegetative cover.

3.10 - TEMPORARY SEEDING

Introduction

Temporary erosion control measures consist of seeding and mulching, or matting used to produce a quick ground cover to reduce erosion on exposed soils that may be redisturbed or permanently stabilized at a later date.

Conditions Where Practice Applies

Use this method where exposed soil surfaces are not to be fine-graded for periods longer than 21 days. Such areas include denuded areas, soil stockpiles, dikes, dams, sides of sediment basins, temporary road banks, etc. A permanent vegetative cover shall be applied to areas that will be left unworked for a period of more than six months.

Planning Considerations

Sheet erosion, caused by the impact of rain on bare soil, is the source of most fine particles in sediment. To reduce this sediment load in runoff, the soil surface itself should be protected. The most efficient and economical means of controlling sheet and rill erosion is to establish vegetative cover. Annual plants that sprout rapidly and survive for only one growing season are suitable for establishing temporary vegetative cover. Temporary seeding is encouraged whenever possible to aid in controlling erosion on construction sites.

Temporary seeding also reduces costly maintenance operations on sediment control systems. For example, sediment basin/trap clean-outs can be reduced if its drainage area is vegetated when grading is not taking place. Perimeter dikes are more effective if not choked with sediment. Silt fence does not need to be cleaned as often.

Temporary seeding is essential to preserve the integrity of earthen structures used to control erosion and sediment, such as dikes, diversions, and the banks and dams of sediment basins/traps. If the design life of the basin or trap is more than one year, permanent seeding should be used.

Proper seedbed preparation and the use of quality seed are important in this practice just as in permanent seeding. Failure to carefully follow sound agronomic recommendations will often result in an inadequate stand of vegetation that provides little or no erosion control.

Construction Specifications

Prior to seeding, install necessary erosion control practices such as dikes, waterways, and basins.

Plant Selection

Select plants appropriate to the season and site conditions.

Seedbed Preparation

To control erosion on bare soil surfaces, plants must be able to germinate and grow. Seedbed preparation is essential. If the area has been recently loosened or disturbed, no further roughening is required. When the area is compacted, crusted, or hardened, the soil surface must be loosened by disking, raking, harrowing, or other acceptable means (see surface roughening section).

Seeding

Seed shall be evenly applied with a broadcast seeder, drill, cultipacker seeder or hydroseeder. Small grains shall be planted no more than 1.5 inches deep. Small seeds, such as annual rye, shall be planted no more than quarter inch deep. Other grasses and legumes shall be planted no more than half inch deep.

Mulching

Temporary seeding conducted in fall for winter cover and during hot and dry summer months shall be mulched with straw or hay according to the standard for mulching. Hydromulches (fiber mulch) may not provide adequate temperature and moisture control.

Maintenance

Areas that fail to establish a vegetative cover adequate to prevent rill erosion should be re-seeded as soon as such areas are identified.

Table 3.10.1 Temporary seed chart

PLANT NAMES		PLANTING DATES	APPLICATION RATE LBS/ACRE
COMMON	SCIENTIFIC		
Annual Ryegrass	*Lolium multiflorum*	2/16 – 5/15 8/1 – 11/1	40
Field Bromegrass	*Bromus ciliatus*	3/1 – 6/15 8/1 – 9/15	40
Spring Oats	*Avena sativa*	3/1 –6/15	100
Winter Rye	*Secale cereale*	8/15 –2/28	170
Winter Wheat	*Triticum aestivum*	8/15 – 2/28	180
Japanese Millet	*Echinochloa crusgalli*	5/15 – 8/15	30
Redtop	*Agrostis alba*	3/1 – 6/15	10
Annual Ryegrass and Spring Oats	*Lolium multiflorum* *Avena sativa*	3/1 – 6/15	30 70
German/Foxtail Millet	*Setaria italica*	5/1 – 8/1	40
Hairy Vetch	*Vicia villosa*	8/15 – 4/1	60

*Inoculation is required. If a hydroseeder is utilized,
the application rate is 5 times the recommended rate.

3.11 - PERMANENT SEEDING

Introduction

Permanent seeding is the establishment of perennial vegetative cover on disturbed areas by planting seed.

Purpose

1. To reduce erosion and decrease sediment yield from disturbed areas.
2. To permanently stabilize disturbed areas in a manner that is economical, adaptable to site conditions and allows selection of the most appropriate plant materials.

Conditions Where Practice Applies

1. Disturbed areas where permanent, long-lived vegetative cover is needed to stabilize the soil.
2. Rough-graded areas that will not be brought to final grade for six months or more.

Planning Considerations

Vegetation controls erosion by reducing the velocity and the volume (by increasing infiltration) of overland flows, protecting the bare soil surface from raindrop impact and binding the soil particles together by the roots and rhizomes.

Advantages of seeding over other means of establishing plants include the small initial establishment cost, the wide variety of grasses and legumes available, low labor requirement and ease of establishment in difficult areas.

Disadvantages include the potential for erosion during the establishment stage, a need to reseed areas that fail to establish, limited periods during the year suitable for seeding, the potential need for weed control during the establishment phase, and a need for water and appropriate micro-climatic conditions during germination.

There are so many variables in plant growth that an end product cannot be guaranteed. Much can be done in the planning stages to increase the chances for successful seeding. Selection of the right plants for the site, good seedbed preparation, proper timing and conscientious maintenance are important. By meeting the requirement to seed and mulch your site within seven days, the seedbed preparation and timing components are easily met.

Selecting Plants

The factors affecting plant growth are climate, soils and topography. In West Virginia, there are three major physiographic regions that reflect changes in soil and topography. In selecting appropriate plant materials, one should take into account the characteristics of the physiographic region in which the project is located.

Physiographic Regions

Western Plateau- Characterized by steep slopes and narrow valleys drained by dendritic low gradient streams. Soils are highly variable and on the acidic side. Erosion can be catastrophic and almost impossible to control, especially in the western sections of the state. Clays and silty-clays predominate with rich well-drained soils in the major river valleys. Rainfall averages 40 inches a year and is spread evenly throughout the year. Rain events average every four days. Soil moisture is optimal in the spring and fall. Droughts of short duration can occur every summer. Both cool and warm season grasses will grow.

Ridge and Valley Region- This region is divided into plateaus, mountains, narrow valleys and wide fertile valleys near the major stems of the Potomac River. Streams have medium gradient. Soils tend to be shallow and acid, and may erode rapidly on steep slopes. The significant shalely slopes are often unstable and droughty. This area is significantly drier than the rest of the state; however, storm events are significantly greater. The rugged topography makes plant establishment difficult. Cool season grasses are normally specified in this region.

Mountains-This region consists of high mountains (up to 4,860 feet) and plateaus, deep, steep valleys, short summers and cold snowy winters, and fast flowing, steep gradient streams. Rainfall averages 50 to 60 inches with up to 240 inches of snow each winter in the highest elevations. Soil depths range from bedrock along areas of the Allegheny Front, to thin to moderate. The range of soil fertility is large and many are acidic. Erodibility ranges from low in the shalely soils common to the Ridge and Valley, to very high in the soils formed from the Mauch Chunk sandstones. Erosion can be a problem because of the extreme steepness of the slopes. Because of the shortness of the growing season, the timeliness of seeding is of utmost importance. However, summer drought is unusual.

Soils

Soils in West Virginia usually require some nitrogen fertilization along with phosphorus and potassium to establish plants. Except for shallow limestone soils in Greenbrier, Pocahontas, Jefferson and Berkeley counties, and some small pockets elsewhere, lime is universally needed.

Microclimates, or localized climate conditions, affect plant growth. A south-facing slope is drier and hotter than a north-facing slope, and may require drought-tolerant plants. Shaded areas require shade-tolerant plants; the windward side of a ridge will be drier than the leeward, etc. Shaley soils are droughty.

The addition of lime is equally as important as applying fertilizer. Lime is best known as a pH or acidity modifier, but it also supplies calcium and magnesium, which are plant nutrients. More importantly, the correct pH frees up nutrients to the plant. Soils with a pH that is too low will not allow a plant to utilize nitrogen and phosphorus properly. Raising the pH can also prevent aluminum toxicity by making aluminum less soluble in the soil. Many soils in West Virginia are high in aluminum, which can stunt the growth of plant roots. Also remember that rainfall is acidic, compounding the low pH problem in the soil.

Once the soil temperature is correct, the two key limiting factors of seed germination are pH and moisture. If you control these two factors, your chances of success are greatly enhanced.

Seed Mixtures

As previously noted, the establishment of high quality turf frequently involves planting one single species. However, in seedings for erosion control purposes, the inclusion of more than one species should always be considered. Mixtures need not be excessive in poundage or seed count. The addition of a quick-growing annual provides early protection and facilitates establishment of one or two perennials in a mix. More complex mixtures might include a quick-growing annual, one or two legumes and more than one perennial grass. The addition of a nurse crop (quick-growing annuals added to permanent mixtures) is a sound practice for soil stabilization, particularly on difficult sites - those with steep slopes, poor, rocky, erosive soils, those seeded outside of the optimum seeding periods or in any situation where the permanent cover development is likely to be slow. The nurse crop germinates and grows rapidly, holding the soil until the slower-growing perennial (permanent) seedlings become established.

Maintenance

Even with careful, well-planned seeding operations, failures occur. When it is clear that plants have not germinated on an area or have died, these areas must be prepared and reseeded immediately to prevent erosion damage. It is extremely important to determine why germination did not take place and make any necessary corrective actions. **Healthy vegetation is the most effective erosion control available**. Some highly acidic soils (especially around various coal seams in the coalfields) will resist the best efforts to revegetate them. In these cases, topsoling will be the only way to establish vegetation.

Table 3.11.1 Permanent seeding

SEED MIX	PLANT NAMES		APPLICATION RATE LBS/ACRE

♦ Nurse crop required – See Table B
1 Urban areas only

Seedbed Requirements

Vegetation should not be established on slopes that are unsuitable due to inappropriate soil texture, poor internal structure or internal drainage, volume of overland flow, or excessive steepness until measures have been taken to correct these problems.

To maintain a good stand of vegetation, the soil must meet certain minimum requirements as a growth medium.

The soil should have these characteristics:

1. Enough fine-grained material to maintain adequate moisture and nutrient supply.
2. Sufficient pore space to permit root penetration. A fine granular or crumb-like structure is favorable.
3. Sufficient depth of soil to provide an adequate root zone. The depth to rock or impermeable layers such as hardpans should be 12 inches or more, except on slopes steeper than 2:1 where the addition of soil is not feasible.
4. A favorable pH range for plant growth.
5. Freedom from toxic amounts of materials harmful to plant growth.
6. Freedom from excessive quantities of roots, branches, large stones, large clods of earth or trash of any kind.

Appropriate structural erosion control practices, such as berms, waterways, diversions, pipe slope drains, water bars or right of way diversions, needed to control overland flow to protect the seedbed should be installed prior to seeding.

Surfaces will be roughened in accordance with surface roughening section contained within this manual.

Soil Conditioners

In order to modify the texture, structure, or drainage characteristics of a soil, the following materials may be added to the soil:

1. Peat is a very costly conditioner, but works well. If added, it shall be sphagnum moss peat, hypnum moss peat, reed-sedge peat or peat humus, from freshwater sources.
2. Sand shall be clean and free of toxic materials. If this practice is considered, consult a professional authority to ensure that it is done properly.
3. Vermiculite shall be horticultural grade and free of toxic substances.
4. Manure, including poultry litter, in its composted form, is a viable soil conditioner. The use of manure should be based on site-specific recommendations offered by a professional in this field such as an agriculture extension agent or USDA employee.
5. Thoroughly rotted sawdust shall have six pounds of nitrogen added to each cubic yard and shall be free of stones, sticks, and toxic substances.
6. When composted, treated sewage sludge offers an alternative soil amendment. This practice should be thoroughly evaluated by a professional and used in accordance with any local, state, and federal regulations.

Lime and Fertilizer

Lime and fertilizer needs should be determined by soil tests. Soil tests may be performed by the WVU Extension Service soil testing laboratory or by a reputable commercial laboratory. Information concerning the WVU soil testing laboratory is available from county extension agents.

Under unusual conditions where it is not possible to obtain a soil test, the following soil amendments will be applied:

Lime

Two tons/acre (90 lbs./1,000 ft.^{2}) pulverized agricultural grade limestone.

Note: An agricultural grade of limestone should always be used except in inaccessible areas; lime may have to be applied separately in pelletized or liquid form.

Fertilizer

Mixed grasses and legumes: 1,000 lbs./acre nutrients (23 lbs./1,000 ft.^{2}) 10-20-10 or equivalent.

Legume stands only: 1,000 lbs./acre (23 lbs./ 1,000 ft.^{2}) 5-20-10 is preferred; however, 1,000 lbs./acre of 10-20-10 or equivalent may be used.

Grass stands only: 1,000 lbs./acre (23 lbs./1,000 ft.^{2})10-20-10 or equivalent nutrients.

Other fertilizer formulations, including slow-release sources of nitrogen (preferred from a water quality standpoint), may be used provided they can supply the same amounts and proportions of plant nutrients.

Lime and fertilizer shall be incorporated into the top 4 to 6 inches of the soil by disking or other means whenever possible. When applying lime and fertilizer with a hydroseeder, apply to a rough, loose surface.

Seeding

1. Appropriately labeled seed will be used for all permanent seeding whenever possible. Labeled seed is inspected by the West Virginia Department of Agriculture. The seed must be appropriately labeled or tagged as defined in the West Virginia Seed Law, Chapter 19 Article 16.
2. Legume seed should be inoculated appropriate to the species. Seed of the lespedezas, the clovers and crownvetch should be scarified to promote uniform germination.
3. Apply seed uniformly with a broadcast seeder, drill, culti-packer seeder or hydroseeder. See Seedbed Requirement above for seedbed preparation. Seeding depth should be a quarter to half inch.
4. To avoid poor germination rates as a result of seed damage during hydroseeding, it is recommended that if a machinery breakdown of 30

minutes to two hours occurs, 50 percent more seed be added to the tank, based on the proportion of the slurry remaining in the tank. Beyond two hours, a full rate of new seed may be necessary.

5. Surface roughening is particularly important when hydroseeding, as a roughened slope will provide some natural coverage for lime, fertilizer and seed.

Legume inoculants should be applied at five times the recommended rate when the inoculant is included in the hydroseeder slurry.

Mulching

All permanent seeding must be mulched immediately upon completion of seed application. Refer to the mulching section contained within this manual.

Irrigation

The newly seeded area should be supplied with adequate moisture. Supply water as needed, especially late in the season, in abnormally hot or dry weather, or on adverse sites. Water application rates should be controlled to prevent excessive runoff. Inadequate amounts of water may be more harmful than no water by causing the seedlings roots to curve towards the surface of the ground looking for moisture.

Reseeding

Inspect seeded areas for failure (less than 70 percent coverage) and make necessary repairs and reseeding within the same growing season, if possible.

a. If vegetative cover is inadequate to prevent rill erosion, overseed and fertilize in accordance with soil test results. If rills are large enough it may be necessary to regrade the rills out and reestablish a seedbed.

b. If a stand has less than 70 percent coverage, reevaluate choice of plant materials and quantities of lime and fertilizer. The soil must be tested to determine if acidity or nutrient imbalances are responsible. Reestablish the stand following seedbed preparation and seeding recommendations.

Fertilization

Cool season grasses should be fertilized 90 days after planting to ensure proper stand and density. Warm season grasses should be fertilized 30 days after planting.

Apply maintenance levels of fertilizer as determined by soil test. In the absence of a soil test, fertilization should be as follows:

Cool Season Grasses

Apply 4 lbs. nitrogen, 1 lb. phosphorus, 2 lbs. potassium per 1,000 $ft.^2$ per year. Seventy-five percent of the total requirements should be applied between September 1 and December 31. The balance should be applied prior to May 1 the following year. More than 1 lb. of soluble nitrogen per 1,000 $ft.^2$ should not be applied at any one time.

Warm Season Grasses

Apply 4 to 5 lbs. nitrogen between May 1 and August 15 per 1,000 $ft.^2$ per year. Phosphorus and Potassium should only be applied according to soil test.

Note: The use of slow-release fertilizer formulations for maintenance of turf is encouraged to reduce the number of applications and the impact on groundwater.

Note: The permanent seeding section is not meant to be an all-inclusive list of possible seeding mixtures. There may be other purposes such as wildlife habitat or natural beauty that would require alternative mixtures. The DEP encourages the submission of enhanced vegetation plans for other purposes with your NPDES permit application.

3.12 – MULCHING INCLUDING FLEXIBLE GROWTH MEDIUM AND BONDED FIBER MATRIX

Introduction

The application of straw, hay or other suitable materials to the soil surface used to:

1. Prevent erosion by protecting the soil surface from raindrop impact and reducing the velocity of overland flow.
2. Foster the growth of vegetation by increasing available moisture and providing insulation against extreme heat and cold. Mulching increases the window of opportunity for seeding by moderating temperature and moisture extremes. This is important because the general permit does not define specific seeding dates and requires only that areas be seeded within seven days of reaching final grade.

Conditions Where Practice Applies

1. Areas that have been temporarily or permanently seeded should be mulched immediately following seeding.
2. Areas that cannot be seeded because of the season should be mulched to provide some protection to the soil surface. An organic mulch should be used, and the area then seeded as soon as weather or seasonal conditions permit. Do not use fiber mulch (cellulose-hydroseed) alone for this practice; at normal application rates it will not give the protection that is achieved by using other types of mulch.
3. Mulch may be used together with plantings of trees, shrubs, or other ground covers that do not provide adequate soil stabilization by themselves.

Planning Considerations

Mulches are applied to the soil surface to conserve desirable soil properties or to promote plant growth. Mulching can be an effective means of controlling runoff and erosion on disturbed land.

Mulches increase the infiltration rate of the soil, reduce soil moisture loss by evaporation, prevent crusting and sealing of the soil surface, modify soil temperatures and provide a suitable microclimate for seed germination.

Organic mulch materials such as straw and hay are the most effective, followed by wood chips, bark and fiber.

At this time chemical soil stabilizers or soil binders should not be used alone for mulch. These materials are useful to bind organic mulches together to prevent displacement.

A variety of manufactured rolled erosion control products have been developed for erosion control in recent years. See standard for erosion control matting for alternatives to mulching. Some of these products can be used as mulches, particularly in critical areas such as waterways, steep slopes and windy ridges. They also may be used to hold other mulches to the soil surface.

The choice of materials for mulching will be based on the type of soil to be protected, site conditions, season and economics. It is especially important to mulch liberally in mid-summer and prior to winter, and on cut slopes and southern slope exposures.

Organic mulches

Straw- The mulch most commonly used in conjunction with seeding. The straw should come from wheat or oats (free of troublesome weed seeds) and may be spread by hand or machine. Straw can be windblown and should be anchored down by an acceptable method. Straw's attributes such as its hollow core (provides insulation), rigidity (does not easily compress) and general lack of weeds makes it the best mulch available

Hay- May be used in lieu of straw where incompatible vegetation will not present a problem, and may be spread by hand or machine. Hay can be windblown and should be anchored or tacked down.

Additionally, when hay or straw mulch decomposes it adds valuable organic material to the soil.

Wood cellulose fiber mulch- Used in hydroseeding operations and applied as part of the slurry. It creates the best seed-soil contact when applied over top of (as a separate operation) newly seeded areas. These mulches do not require tacking, although tacking agents or binders are sometimes used in conjunction with the application of fiber mulch. Fiber mulch does not provide sufficient protection on highly erodible soils or during less favorable growing conditions. **Fiber mulch should not be used alone during the dry summer months or for late fall mulch cover**. Use straw/hay mulch during these periods. Fiber mulch may be used to tack (anchor) straw/hay mulch. Fiber mulch is well suited for steep slopes, critical areas, and areas susceptible to wind.

Chemical mulches, soil binders and tackifiers

A wide range of synthetic spray-on materials is marketed to stabilize and protect the soil surface. These are emulsions or dispersions of petroleum distillates, emulsions of copolymer acrylates, latexes, and polyvinyl acetates, clay colloids, and dry powered vegetable gums derived from guar, psyllium, and sodium alginase, which are mixed with water and sprayed over the mulch and to the soil. They may be used alone in some cases as temporary stabilizers, or in conjunction with fiber mulch, hay or straw. The DEP does not recommend the use of asphalt emulsion as a binder.

Unlike organic mulches, most chemical mulches do not insulate the soil or retain soil moisture when used alone. They may also be easily damaged by traffic. Application of these mulches is usually more expensive than organic mulching, and the mulches decompose quickly.

The industry is continually improving alternative soil binders/mulches and the permittee is encouraged to investigate these new products for use on the site.

Always follow the manufacturer's recommendations when applying any of the above products.

Construction Specifications

Organic mulches

Organic mulches may be used in any area where mulch is required, subject to the restrictions noted in Table 3.12.1.

Select mulch material based on site requirements, availability of materials and availability of labor and equipment. Table 3.12.1 lists the most commonly used organic mulches.

Prior to mulching, complete the required grading and install needed sediment control practices.

Lime and fertilizer should be incorporated and surface roughening accomplished as needed. Seed should be applied prior to mulching except in the following cases:

1. Where seed is to be applied as part of a hydroseeder slurry containing wood cellulose fiber mulch (DEP recommends that the seed be spread prior to the spraying of the fiber mulch if at all possible).
2. Where seed is to be applied following a temporary mulch spread during winter months.

Mulch materials shall be spread uniformly, by hand or machine. When spreading straw mulch by hand, divide the area to be mulched into approximately 1,000 sq. ft. sections and place 70-90 lbs. (1½ to 2 bales) of straw in each section to facilitate uniform distribution.

Straw and hay mulch should be anchored immediately after spreading to prevent displacement. Other organic mulches listed in Table 3.12.1 should not require anchoring. The following methods of anchoring straw and hay may be used:

1. **Mulch anchoring tool (often referred to as a krimper or krimper tool) -** A tractor-drawn implement designed to punch mulch into the soil surface. This method provides good erosion control with straw. It is limited to use on slopes where the equipment can operate safely. Machinery shall be operated on the contour.
2. **Wood cellulose fiber mulch-** Apply fiber mulch by means of a hydroseeder at a rate of 500-750 lbs./acre over top of straw mulch or hay. It has an added benefit of providing additional mulch to the newly seeded area.
3. **Liquid mulch binders-** Application of liquid mulch binders and tackifiers should be heaviest at edges of areas and at crests of ridges and banks, to prevent displacement. The remainder of the area should have binder applied uniformly. Binders may be applied after mulch is spread or may be sprayed into the mulch as it is being blown onto the soil.
4. **Synthetic binders-** Formulated binders or organically formulated products may be used as recommended by the manufacturer to anchor mulch.
5. **Mulch netting-** Lightweight plastic, cotton and coir nets may be stapled over the mulch according to manufacturer's recommendations (See rolled erosion control products section).

Chemical mulches

Chemical mulches* may be used alone only in the following situations:

1. Where no other mulching material is available.
2. From March 15 to May 1 and August 15 to September 30, provided that they are used on areas with slopes no steeper than 4:1, which have been roughened in accordance with surface roughing standards. If rill erosion occurs, another mulch material shall be applied immediately.

* Note: Some chemical mulches may be used to bind other mulches or with fiber mulch in a hydroseeded slurry. Manufacturer's recommendations for application of chemical mulches shall be followed.

Maintenance

All mulches and soil coverings should be inspected periodically (particularly after rainstorms and high winds) to check for erosion and displacement. Where erosion is observed in mulched areas, additional mulch should be applied and erosion repaired if necessary. Nets and mats should be inspected after rainstorms for dislocation or failure. If washouts or breakage occur, reinstall netting or matting as necessary after regrading to repair damage to the slope or ditch. Inspections should take place up until grasses are firmly established or the area is redisturbed.

Table 3.12.1 Organic mulch materials and application rates			
Mulches:	Rates:		Notes:
	Per acre	Per 1,000 ft^2.	
Straw or hay	1½ - 2 tons (minimum 2 tons for winter cover)	70 - 90 lbs.	Free from weeds and coarse matter. Must be anchored. Spread with mulch blower or by hand.
Fiber mulch	Minimum 1,500 lbs.	35 lbs.	Do not use as mulch for winter cover or during hot, dry periods.* Apply as slurry.
Cornstalks	4 - 6 tons	185 - 275 lbs.	Cut or shredded in 4-6" lengths. Air-dried. Do not use in fine turf areas. Apply with mulch blower or by hand.
Wood chips	4 - 6 tons	185 - 275 lbs.	Free of coarse matter. Air-dried. Treat with 12 lbs. nitrogen per ton. Do not use in fine turf areas. Apply with mulch blower, chip handler, or by hand.
Bark chips or Shredded bark	50 - 70 cu. yds.	1-2 cu. yds.	Free of coarse matter. Air-dried. Do not use in fine turf areas. Apply with mulch blower, chip handler, or by hand.

* When fiber mulch is the only available mulch during periods when straw should be used, apply at a minimum rate of 2,000 lbs./ac. or 45 lbs./1,000 sq. ft.

From VA DSWC

3.13 - ROLLED EROSION CONTROL PRODUCTS

Introduction

Rolled Erosion Control Products (RECPs) are temporary or permanent erosion control nets, blankets and three-dimensional matrixes made from a wide variety of natural (such as jute, coir and straw) and manmade materials alone or in combination. There are numerous commercially available products so great care must be used to choose the correct product for the application.

RECPs help prevent erosion in several ways. They can be a direct replacement for straw or hay mulch and provide uniform protection from raindrop erosion, moderating temperature and moisture extremes and preventing detachment of the soil by sheet flow. They can hold seed and mulch in place on slopes and in channels so that vegetation can become established. And they can be used to permanently reinforce turf to protect channels and stream banks in high flows conditions.

Conditions Where Practice Applies

Temporary Rolled Erosion Control Products

Temporary rolled erosion control products (RECPs) consist of prefabricated blankets or netting that are formed from both natural and synthetic materials. Temporary RECPs are used as a temporary surface stabilizing measure and to aid in the establishment of vegetation. They are typically used on steep slopes and to help establish grass in low velocity vegetated channels.

Temporary RECPs consist of netting or blanket materials that are used to stabilize disturbed surfaces and promote the establishment of vegetation. RECPs may also be used to stabilize the surface of channels where the flows are low to moderate until vegetation can be established.

They are manufactured from a wide variety of different materials including coconut fiber (coir), jute, nylon, polypropylene, PVC, straw, hay, or wood excelsior. These materials may be used individually, or in combination to form nets or blankets.

The products function by protecting the ground surface from the impact of raindrops and stabilize the surface until vegetation can be established. RECPs also promote the growth of vegetation by helping to keep seed in place, and by maintaining a consistent temperature and moisture content in the soil.

RECPs are not intended to provide long-term or permanent stabilization of slopes or channels. Their role is to protect the surface until the vegetation can establish itself and become the permanent stabilizing feature. In fact, most RECPs are either biodegradable or photodegradable and will decompose over a period of time.

Jute matting must be used in conjunction with mulch. Excelsior, woven straw blankets and coir (coconut fiber) blankets may be installed without mulch. There are many other types of erosion control nets and blankets on the market that may be appropriate in certain circumstances.

In general, most nets (e.g., jute matting) require mulch in order to prevent erosion because they have a fairly open structure. Blankets typically do not require mulch because they usually provide complete protection of the surface.

The temporary rolled erosion control product shall conform to one of the following specifications and corresponding properties found in Table 3.13.1

Permanent Rolled Erosion Control Products

Permanent RECPs or Turf Reinforcement Mats (TRMs) are similar to the Temporary RECPs but they usually are intended for reinforcing grass-lined channels and stream banks and can be useful when underlying soil boundaries may subside or shift slightly after installation They are composed of ultraviolet (UV) stabilized polymeric fibers, filaments, nettings and/or wire mesh, integrating together to form a three-dimensional matrix. The types of polymer include polypropylene, polyethylene, polyamides, and polyvinyl chloride. Often TRMs are combined with organic material such as coir to aide vegetation establishment and provide the initial temporary erosion control necessary to resist the forces of running water until the vegetation can become established. Typical vegetation includes grasses that can withstand inundation.

TRMs can be installed after applying seed to the prepared soil surface or deployed first, and then seeded following infilling with soil. The former method allows the roots and shoots to grow through and interlock with the geosynthetic matrix.

For applications where natural vegetation alone will not sustain expected flow conditions and/or provide sufficient long-term erosion protection a permanent rolled erosion control product will be required The permanent RECP must have the necessary performance properties to effectively control erosion and reinforce vegetation under the expected long-term site conditions.

The permanent erosion control product shall conform to one of the specifications and corresponding properties found in Table 3.13.2.

Rolled erosion control products are designated as follows:

1. Mulch control netting. (MCN) A planar woven natural fiber or extruded geosynthetic mesh used as a temporary degradable rolled erosion control product to anchor loose fiber mulches.
2. Open weave textile. (OWT) A temporary degradable rolled erosion control product composed of processed natural or polymer yarns woven into a matrix, used to provide erosion control and facilitate vegetation establishment. Can replace straw or hay mulch.
3. Erosion control blanket. (ECP) A temporary degradable rolled erosion control product composed of processed natural or polymer fibers mechanically, structurally or chemically bound together to form a continuous matrix to provide erosion control and facilitate vegetation establishment. Can replace straw or hay mulch.
4. Turf reinforcement mat. (TRM) A rolled erosion control product composed of non-degradable synthetic fibers, filaments, nets, wire mesh and/or other elements, processed into a permanent, three-dimensional matrix of sufficient thickness. TRMs, which may be supplemented with degradable components, are designed to impart immediate erosion protection, enhance vegetation establishment and provide long-term functionality by permanently reinforcing vegetation during and after maturation. Note: TRMs are typically used in hydraulic applications, such as high flow ditches and channels, steep slopes, stream banks, and shorelines, where erosive forces may exceed the limits of natural, un-reinforced vegetation or in areas where limited vegetation establishment is anticipated.

Design Considerations for degradable RECPs

Given the wide variety of RECPs available, it is impossible to cover the design considerations for each type of product herein. Therefore, it is recommended that the designer contact a manufacturer to obtain the appropriate information. Many manufacturers provide design software and/or a RECP product selection guide through their company website. Also, the Erosion Control Technology Council (ECTC) is an organization representing suppliers and manufacturers of rolled erosion control products. (www.ectc.org) The construction specifications that follow are from that organization.

Tables 1 and 2 provide guidance on the selection of appropriate RECPs for various situations.

For channel applications, the final permanent grass lining planned for the channel should be analyzed for the 10-year storm in the permanent vegetated state. The RECP should also be analyzed for shear stress. This analysis should be for the unvegetated state, representing the situation immediately after installation. Since it is considered a temporary measure, stabilizing the channel only until vegetation is established, the RECP does not need to be analyzed for a 10-year event as the vegetation does. Analyses of the RECP's shear strength for a 2-year event is adequate.

Design Considerations for TRMs

There is also a wide variety of TRMs available so it is impossible to cover the specific design considerations of each product. However, most TRM products are designed, tested, and rated for resistance to shear stress. As with all permanent channels use the peak flows from a 10-year/24-hour storm event.

Shear stress in channels lined with TRMs is calculated in the same manner as for grass channels. If the channel is to be vegetated, a variable Manning coefficient will need to be calculated. If the channel is being analyzed for performance with the TRM alone, a constant Manning coefficient, provided by the manufacturer, may be used..

After calculating the shear stress in the channel, an appropriate TRM able to withstand the anticipated shear stress can be selected. Most TRM manufacturers have software available to aid in the calculation of shear stress and the selection of an appropriate TRM. This software may be available through the manufacturer's website or local product representative.

TRMs should always be installed in accordance with the manufacturer's recommendations.

Construction Specifications

This specification is intended to provide general guidelines for the installation of RECPs and does not supersede manufacture's guidelines. The following sections summarize the general, accepted procedures for installation of RECPs and provide basic guidance for slope and channel installations. Detailed design/installation information should be obtained from the manufacturer.

General Procedure. Prepare a stable and firm soil surface free of rocks and other obstructions. Apply soil amendments as necessary to prepare seedbed. Apply seed and fertilizer in accordance with the Permanent Seeding Specification. Typically, RECPs are unrolled parallel to the primary direction of flow. Ensure the product maintains intimate contact with the soil surface over the entirety of the installation. Do not stretch or allow material to bridge over surface inconsistencies. Staple/stake RECPs to soil such that each staple/stake is flush with underlying soil. Install anchor trenches, seams and terminal ends as specified.

Install RECPs after application of seed, fertilizer, mulches (if necessary) and other necessary soil amendments, unless soil in-filling of the TRM is required. For TRMs if soil in-filling, install TRM, apply seed, and other soil amendments lightly brush or rake 0.3 to 0.7 in. of topsoil into TRM matrix to fill the product thickness. If in-filling with a hydraulically-applied matrix or medium is required; install TRM, then install hydraulically-applied matrix or medium at the manufacturer's suggested application rate.

Apply MCNs (Materials Type 1.A., 2.A., 3.A.) immediately after dry mulch application.

Anchor Trenches, Seams and Terminal Ends

(A) **Anchor Trenches** – Utilize one of the methods detailed below for initial anchoring of RECPs:

1. Staples. Install the RECPs 3 ft. beyond the shoulder of the slope onto flat final grade. Secure roll end with a single row of stakes/staples on 1 ft. centers.
2. Anchor trench. Excavate a 6 in. by 6 in. (150 mm by 150 mm) anchor trench. Extend the upslope terminal end of the RECPs 3 ft. past the anchor trench. Use stakes or staples to fasten the product into the bottom of the anchor trench on 1 ft. centers. Backfill the trench and compact the soil into the anchor trench. Apply seed and any necessary soil amendments to the compacted soil and cover with remaining 1 ft. terminal end of the RECPs. Secure terminal end of RECPs with a single row of stakes or staples on 1 ft. centers.
3. Check slot. Construct a stake/staple check slot along the top edge of the RECPs by installing two rows of staggered stakes/staples 4 in. apart on 4 in. centers.

(B) **Seams** – Utilize one of the methods detailed below for seaming of RECPs:

1. Adjacent seams. Overlap edges of adjacent RECPs by 6 in. or by abutting products as defined by manufacturer. Use a sufficient number of stakes or staples to prevent seam or abutted rolls from separating.
2. Consecutive rolls. Shingle and overlap consecutive rolls 6 in. in the direction of flow. IE Cover the downslope roll with the next upslope roll.
3. Check seam. Construct a stake/staple check seam along the top edge of RECPs for slope application and at specified intervals in a channel by installing two staggered rows of stakes/staples 4 in. apart on 4 in. centers.

(C) **Terminal Ends** – Utilize one of the methods detailed below for all terminal ends of RECPs:

1. Staples. Install the RECPs 3 ft. beyond the end of the channel and secure end with a single row of stakes/staples on 1 ft. centers. Stakes/staples for securing

RECPS to the soil are typically 6 in. long. Use longer staples in sandy soils.

2. Anchor trench. Excavate a 6 in. by 6 in. anchor trench. Extend the terminal end of the RECPs 3 ft. past the anchor trench. Use stakes or staples to fasten the product into the bottom of the anchor trench on 1 ft. centers. Backfill the trench and compact the soil into the anchor trench. Apply seed and any necessary soil amendments to the compacted soil and cover with remaining 1 ft. terminal end of the RECPs. Secure terminal end of RECPs with a single row of stakes or staples on 1 ft. centers.

3. Check slot. Construct a stake/staple check slot along the terminal end of the RECPs by installing two rows of staggered stakes/staples 4 in. apart on 4 in. centers.

Slope Installations. At the top of slope, anchor the RECPs according to one of the method detailed in Section (A) above. Securely fasten all RECPs to the soil by installing stakes/staples at a minimum rate of 1.5/yd2. For the most effective RECP installation use stake/staple patterns and densities as recommended by the manufacturer. For adjacent and consecutive rolls of RECPs follow seaming instructions detailed in Section (B) above. The terminal end of the RECPs installation must be anchored using one of the methods detailed in Section (C) above.

Channel Installations. Construct an anchor trench at the beginning of the channel across its entire width according to Section (A) (2) above. Follow the manufacturer's installation guidelines in constructing additional anchor trenches or stake/staple check slots at intervals along the channel reach and at the terminal end of the channel, according to paragraph (A) above respectively. Unroll RECPs down the center of the channel in the primary water flow direction. Securely fasten all RECPs to the soil by installing stakes/staples at a minimum rate of 2/yd2. Significantly higher anchor rates and longer stakes/staples may be necessary in sandy, loose, or wet soils and in severe applications. For adjacent and consecutive rolls of RECPs follow seaming instructions detailed in Section (B) above. All terminal ends of the RECPs must be anchored using one of the methods detailed in Section (C) above.

With any RECP installation, ensure sufficient staples to resist uplift from hydraulics, wind, mowers, and foot traffic. For the most effective installation of RECPs, it is recommended to use stake/staple patterns and densities as recommended by the manufacturer.

Maintenance

During the initial period after installation inspect once at week or after every rain of 0.5" or more. Basic monitoring should consist of visual inspections to determine mat integrity and attachment performance. Rill development beneath the mat or edge lifting is evidence of inadequate attachment.

Until the vegetation is fully established, the ground surface should be inspected for signs of rill or gully erosion below the matting. Any signs of erosion, tearing of the matting, or areas where the matting is no longer anchored firmly to the ground should be repaired. Repair any damaged areas immediately by restoring soil to finished grade, re-applying soil amendments and seed, and replacing the RECPs. Additional staking and trenching can be employed to correct defects. Recently placed mats may be replaced, but once vegetation becomes established, replacement is not a reasonable option unless large failures have occurred. If the RECPs are vegetated, the vegetation should be watered as needed. Getting grass established as quickly as possible is very important.

Table 3.13.1 ECTC STANDARD SPECIFICATION FOR TEMPORARY ROLLED EROSION CONTROL PRODUCTS

For use where natural vegetation alone will provide permanent erosion protection.

ULTRA SHORT-TERM - Typical 3 month functional longevity.

Type	Product Description	*Material Composition*	Slope Applications* Maximum Gradient	Slope Applications* C Factor[2, 5]	Channel Applications* Max. Shear Stress[3, 4, 6]	Minimum Tensile Strength[1]
1.A	Mulch Control Nets	A photodegradable synthetic mesh or woven biodegradable natural fiber netting.	5:1 (H:V)	≤ 0.10 @ 5:1	0.25 lbs/ft² (12 Pa)	5 lbs/ft (0.073 kN/m)
1.B	Netless Rolled Erosion Control Blankets	Natural and/or polymer fibers mechanically interlocked and/or chemically adhered together to form a RECP.	4:1 (H:V)	≤ 0.10 @ 4:1	0.5 lbs/ft² (24 Pa)	5 lbs/ft (0.073 kN/m)
1.C	Single-net Erosion Control Blankets & Open Weave Textiles	Processed degradable natural and/or polymer fibers mechanically bound together by a single rapidly degrading, synthetic or natural fiber netting or an open weave textile of processed rapidly degrading natural or polymer yarns or twines woven into a continuous matrix.	3:1 (H:V)	≤ 0.15 @ 3:1	1.5 lbs/ft² (72 Pa)	50 lbs/ft (0.73 kN/m)
1.D	Double-net Erosion Control Blankets	Processed degradable natural and/or polymer fibers mechanically bound together between two rapidly degrading, synthetic or natural fiber nettings.	2:1 (H:V)	≤ 0.20 @ 2:1	1.75 lbs/ft² (84 Pa)	75 lbs/ft (1.09 kN/m)

SHORT-TERM - Typical 12 month functional longevity.

Type	Product Description	Material Composition	Slope Applications* Maximum Gradient	Slope Applications* C Factor[2, 5]	Channel Applications* Max. Shear Stress[3, 4, 6]	Minimum Tensile Strength[1]
2.A	Mulch Control Nets	A photodegradable synthetic mesh or woven biodegradable natural fiber netting.	5:1 (H:V)	≤ 0.10 @ 5:1	0.25 lbs/ft² (12 Pa)	5 lbs/ft (0.073 kN/m)

** "C" factor and shear stress for Types 1.A., 2.A. and 3.A mulch control nettings must be obtained with netting used in conjunction with pre-applied mulch material.*

[1] Minimum Average Roll Values, Machine direction using ECTC Mod. ASTM D 5035.

[2] "C" Factor calculated as ratio of soil loss from RECP protected slope (tested at specified or greater gradient, h:v) to ratio of soil loss from unprotected (control) plot in large-scale testing.These performance test values should be supported by periodic bench scale testing under similar test conditions using Erosion Control Technology Council (ECTC) Test Method # 2.

[3] Required minimum shear stress RECP (unvegetated) can sustain without physical damage or excess erosion (> 12.7 mm (0.5 in) soil loss) during a 30-minute flow event in large-scale testing. These performance test values should be supported by periodic bench scale testing under similar test conditions and failure criteria using Erosion Control Technology Council (ECTC) Test Method #3.

[4] The permissible shear stress levels established for each performance category are based on historical experience with products characterized by Manning's roughness coeffecients in the range of 0.01 - 0.05.

[5] Acceptable large-scale test methods may include ASTM D6459, Erosion Control Technology Council (ECTC) Test Method # 2, or other independent testing deemed acceptable by the engineer.

[6] Per the engineers discretion. Recommended acceptable large-scale testing protocol may include ASTM D6460, Erosion Control Technology Council (ECTC) Test Method #3 or other independent testing deemed acceptable by the engineer.

Table 3.13.2 ECTC STANDARD SPECIFICATION FOR PERMANENT ROLLED EROSION CONTROL PRODUCTS

For applications where vegetation alone will not sustain expected flow conditions and/or provide sufficient long-term erosion protection.

Permanent[1] - All categories of TRMs must have a minimum thickness of 0.25 inches (6.35 mm) per ASTM D 6525 and U.V. stability of 80% per ASTM D 4355 (500 hours exposure).

Type	Product Description	Material Composition	Slope Applications Maximum Gradient	Channel Applications Maximum Shear Stress[4, 5]	Minimum Tensile Strength[2,3]
5.A	Turf Reinforcement Mat	Turf Reinforcement Mat (TRM) – A rolled erosion control product composed of non-degradable synthetic fibers, filaments, nets, wire mesh and/or other elements, processed into a permanent, three-dimensional matrix of sufficient thickness. TRMs, which may be supplemented with degradable components, are designed to impart immediate erosion protection, enhance vegetation establishment and provide long-term functionality by permanently reinforcing vegetation during and after maturation. Note: TRMs are typically used in hydraulic applications, such as high flow ditches and channels, steep slopes, stream banks, and shorelines, where erosive forces may exceed the limits of natural, unreinforced vegetation or in areas where limited vegetation establishment is anticipated.	0.5:1 (H:V)	6.0 lbs/ft^2 (288 Pa)	125 lbs/ft (1.82 kN/m)
5.B	Turf Reinforcement Mat		0.5:1 (H:V)	8.0 lbs/ft^2 (384 Pa)	150 lbs/ft (2.19 kN/m)
5.C	Turf Reinforcement Mat		0.5:1 (H:V)	10.0 lbs/ft^2 (480 Pa)	175 lbs/ft (2.55 kN/m)

[1] For TRMs containing degradable components, all property values must be obtained on the non-degradable portion of the matting alone.

[2] Minimum Average Roll Values, machine direction only for tensile strength determination using ASTM D6818 (Supercedes Mod. ASTM D5035 for RECPs)

[3]Field conditions with high loading and/or high survivability requirements may warrant the use of a TRM with a tensile strength of 44 kN/m (3,000 lb/ft) or greater.

[4] Required minimum shear stress TRM (fully vegetated) can sustain without physical damage or excess erosion (> 12.7 mm (0.5 in.) soil loss) during a 30-minute flow event in large scale testing. These performance test values should be supported by periodic bench scale testing under similar test conditions and failure criteria using Erosion Control Technology Council (ECTC) Test Method #3.

[5] Acceptable large-scale testing protocol may include ASTM D6460, Erosion Control Technology Council (ECTC) Test Method #3, or other independent testing deemed acceptable by the engineer

3.14 - SODDING

Introduction

The purpose of sodding is to establish permanent turf for immediate erosion protection and to stabilize drainage ways where concentrated overland flow will occur.

Conditions Where Practice Applies

Sodding may be used in the following areas:

1. Disturbed areas that require short-term or long-term cover
2. Disturbed areas that require immediate vegetative cover
3. All waterways that require vegetative lining. Waterways may also be seeded rather than sodded and protected with a RECP.

Design Consideration

Sod shall be free of weeds, of uniform thickness (approximately 1-inch thick), and shall have a dense root mat for mechanical strength.

Construction Specifications

The following steps are recommended for sod installation:

1. Shape and smooth the surface to final grade in accordance with the approved grading plan.
2. Amend two inches (minimum) of well-rotted compost into the top six inches of the soil if the organic content of the soil is less than 10 percent.
3. Fertilize according to the supplier's recommendations. Disturbed areas within 200 feet of waterbodies and wetlands must use non-phosphorus fertilizer.
4. Work lime and fertilizer one to two inches into the soil, and smooth the surface.
5. Lay strips of sod beginning at the lowest area to be sodded and perpendicular to the direction of water flow. Wedge strips securely into place. Square the ends of each strip to provide for a close, tight fit.
6. Stagger joints at least 12 inches. Staple on slopes steeper than 3:1. Roll the sodded area and irrigate.
7. When sodding is carried out in alternating strips or other patterns, seed the areas between the sod immediately after sodding.

Maintenance

If the grass is unhealthy, the cause shall be determined and appropriate action taken to reestablish a healthy groundcover. If it is impossible to establish a healthy groundcover due to frequent saturation, instability or some other cause, the sod shall be removed, the area seeded with an appropriate mix, and protected with a net or blanket.

3.15 - TEMPORARY DIVERSION

Introduction

A temporary berm or excavated channel or combination berm and channel constructed across sloping land on a predetermined grade. This variable practice is used to protect work areas from upslope runoff and reduce the size of the drainage are going to sediment trapping structures, transport runoff across a project to minimize erosion and to divert sediment-laden water to an appropriate sediment trapping facility.

Conditions Where Practice Applies

This practice applies to construction areas where runoff can be diverted and disposed of properly to control erosion, sedimentation, or flood damage. Specific locations and conditions can include the following:

1. To divert upslope clean water around a construction site to reduce the quantity of water within the sediment control system. Also called a clean water ditch or upslope diversion.
2 To shorten or reduce the length of the slope that runoff will cross. (see also RIGHT OF WAY DIVERSION and the WATER CONTROL sections)
3. To divert upslope water from disturbed areas such as cut or fill slopes to a stabilized outlet or if sediment laden, to a sediment trapping device. Similar in concept to upslope diversion.
5. To divert sediment laden water at or near the perimeter of the construction area to either a sediment basin or a sediment trap. Also called a dirty water ditch or perimeter ditch.
6. To divert internal sediment laden water to a sediment-trapping structure or a stabile internal waterway.
7. Above critical disturbed areas before stabilization to prevent erosion and maintain acceptable working conditions
8. To divert water away from footers, walls, and other structures.

Design Considerations

It is important that diversions are properly designed, constructed and maintained since they concentrate water flow and increase erosion potential. Temporary diversions must be designed and installed so they stable throughout their useful life and to meet the criteria given in this section. Particular care must be taken in planning diversion grades. Too much slope can result in erosion in the diversion channel. This is especially true at the entrance to a sediment trapping structure. Conversely, a reduction in grade will cause sediment to be deposited, plugging the channel. The blockage may cause failure by overtopping and the discharge of sediment-laden runoff off site.

Frequent inspection and timely maintenance are essential to the proper functioning of diversions. Sufficient area should be available to construct and properly maintain diversions.

It is usually less costly to excavate a channel and form a ridge or dike on the downhill side with the spoil than to build diversions by other methods. Where space is limited, it may be necessary to build the ridge by hauling in the berm material. If the diversion is located where construction traffic will cross, stabilize the channel and berm with stone. If there will be extensive traffic it will be necessary to install a temporary culvert.

Whenever possible, install dirty water diversions in conjunction with the construction of the sediment trapping structure prior clearing and grubbing. Install other types diversions as needed.

Because diversions collect overland flow, changing it into concentrated flows, they can create an additional erosion hazard. In areas of highly erodible soils it may be necessary to armor the channel with riprap. This will be necessary especially in the transition into a sediment trap or basin and on slopes over 10 percent.

For longer slopes, several dikes or swales are placed across the slope at intervals. This practice reduces the amount of runoff that accumulates on the face of the slope and carries the runoff safely down the slope.

Diversion may create difficulties in establishing vegetation if water flow is too fast or ponds.

Poorly laid out and constructed diversion require unnecessary additional maintenance, inspections, and repairs.

Interceptor dikes and swales can be permanent controls. However, permanent controls: must be designed to handle runoff after construction is complete, must be permanently stabilized, and should be inspected and maintained on a regular basis.

If the watershed drained by the diversion is unstabilized at any time, the diversion must lead to a sediment-trapping device.

General design criteria:

1. Drainage area should not exceed five acres.
2. The minimum cross section should be adequate for the anticipated flows but at a minimum must handle the peak discharge from a 2-year/24-hour storm.
3. The grade may be variable depending upon the topography and must have a positive grade along its entire length. The maximum channel grade should be limited to 5.0 percent.

5 Diverted runoff must outlet onto a stabilized area, into a properly designed waterway, grade stabilization structure or sediment trapping facility.

6. Diversions that are to serve longer than 14 working days shall be stabilized immediately with seed and mulch with or without a

RECP meeting the requirements found in this manual to preserve dike height, prevent erosion and reduce maintenance.

7. The channel cross section may be parabolic, v-shaped or trapezoidal.

Specific Design Criteria

1. Temporary (less than 6 months) diversions must be designed to handle the peak discharge from a 2-year/24-hour storm with 0.3 ft. of freeboard.
2. A long term (more than 6 months) or permanent diversion must have a minimum capacity to carry the runoff expected from a 10-year/24-hour frequency storm with a freeboard of at least 0.3 foot (see drawing)
3. Diversions designed to protect homes, schools, industrial buildings, roads, parking lots, and comparable high-risk areas, and those designed to function in connection with other structures, shall have sufficient capacity to carry peak runoff expected from a storm frequency consistent with the hazard involved.

Channel The diversion channel may be parabolic, trapezoidal or vee-shaped.

Berm/dike Design The supporting ridge cross section shall meet the following criteria (also see drawings):

1. The side slopes shall be no steeper than 2:1.
2. The width at the design water elevation should be a minimum of 4 feet.
3. The minimum freeboard shall be 0.3 foot.
4. The design of the berm/dike shall include a 10 percent settlement factor.

Outlet: Diversions shall have stabilized outlets that release the concentrated runoff without causing erosion. Acceptable outlets for sediment free runoff include a permanently stabilized stormwater conveyance channel, Level Lip Spreader, drop inlet structure, underground stormwater system, Outlet Protection or natural waterway.

All except the most short-lived diversions, all diversions must be stabilized according to the anticipated velocity and erodibilty of the soil and the ablity of the lining to protect the channel from eroding. Stabilization measures include, grass, grass with a RECP, RECP alone if designed for this purpose, and riprap. The following charts give basic minimum design for the dimensions and the maximum permissible velocities for various linings and soil types. See the section on RECPs for additional information on how to select the appropriate material and the correct installation techniques. If conditions exceed the requirements noted above and in the charts, the channel and lining must be professionally designed.

Table 3.15.1 CHANNEL CROSS SECTION REQUIREMENTS		
	A	**B**
Drainage area	< 5 acres	5 – 10 acres
Bottom width flow channel	4 feet	6 feet
Depth of flow channel	1 foot	1 foot
Side slopes	2:1 or flatter	2:1 or flatter
Grade	0.5% minimum	0.5% minimum

Table 3.15.2 CHANNEL STABILIZATION REQUIREMENTS		
Channel Grade (%)	**A < 5 acres**	**B 5 – 10 acres**
0.5 – 3.0	Seed & straw mulch	Seed & straw mulch
3.1 – 5.0	Seed & straw mulch	Seed & cover /RECP; sod; or line with riprap
5.1 – 8.0	Seed & cover w/ RECP; sod;or line with riprpa	Line with riprap
8.1 – 20.0	Line with riprap	Engineering design

Table 3.15.3
PERMISSIBLE VELOCITIES FOR GRASS-LINED CHANNELS

Channel Slope	Grass Species	Velocity* (ft./sec.)
0 - 0.5%	Bermudagrass	6
	Reed canarygrass Tall fescue Kentucky bluegrass	5
	Grass-legume mixture	4
	Red fescue Redtop Sericea lespedeza Annual lespedeza Small grains Temporary vegetation	2.5
5 - 10%	Bermudagrass	5
	Reed canarygrass Tall fescue Kentucky bluegrass	4
	Grass-legume mixture	3
Greater than 10%	Bermudagrass	4
	Reed canarygrass Tall fescue Kentucky bluegrass	3

* For highly erodible soils, decrease permissible velocities by 25%.

For vegetated earth channels having permanent turf reinforcement matting, the permissible flow velocity shall not exceed 8 ft/sec. Turf reinforcement matting shall meet the requirements in the Section on RECPs.
An erodibility factor (K) greater than 0.35 would indicate a highly erodible soil. Erodibility factors (K-factors) can be obtained from local NRCS offices.

Table 3.15.4 MAXIMUM PERMISSIBLE DESIGN VELOCITIES		
Soil Texture	**Channel Vegetation Retardance and Cover**	**Permissible Velocities (ft./sec.)**
Sand, silt, sandy loam, silt loam, loamy sand	Tall fescue, smooth bromegrass	3.5
	Kentucky bluegrass, redtop, red fescue	3.0
	Annuals 2/, small grain (rye, oats, wheat, ryegrass)	2.5
	Bare channel	1.5
Silty clay loam, sandy clay loam	Tall fescue, smooth bromegrass	4.5
	Kentucky bluegrass, redtop, red fescue	4.0
	Annuals 2/, small grain (rye, oats, wheat, ryegrass)	3.5
	Bare channel	2.0
Clay	Tall fescue, smooth bromegrass	5.5
	Kentucky bluegrass, redtop, red fescue	5.0
	Annuals 2/, small grain (rye, oats, wheat, ryegrass)	4.0
	Bare channel	2.0

1/ To be used only in stabilized protected areas.
2/ Annuals – use only as temporary protection until permanent vegetation is established.

These charts are guidelines only. If conditions on the site do not reflect the parameters in the chart it is recommended to provide a full design using HEC-15 or other similar standard. During plan development label all diversions. Example: Two diversions will direct sediment laden water to a sediment trap. Label the sediment trap as trap I and each ditch respectively Ia and Ib. If the diversions are engineered then use these labels on any charts and design sheets.

Construction Specifications

1. Clear the area of all trees, brush, stumps or other obstructions.
2. Diversions (upslope and perimeter) must be installed as a first step in the land-disturbing activity and must be functional prior to land disturbance. Diversions may be removed when stabilization of the drainage area and outlet are complete.

3. Runoff from undisturbed areas can be channeled to an existing waterway or to a level lip spreader.
4. Stabilization for the dike and flow channel of the swale should be completed immediately after construction.
5. Stabilization materials can include vegetation, RECP or stone/riprap.
6. When the drainage area to the diversion is greater than 10 acres, standard engineering practices shall be used to properly size the channel.
7. Intercepted sediment laden water must always be diverted to a sediment trap or sediment basin, never silt fence
8. Grades over 10% may require engineering design.
9. Construct the diversions to the designed cross-section, line and grade making sure that there are no irregularities or bank projections to impede the flow.
10. The dike shall be compacted using earth-moving equipment to prevent failure of the dike.
11. Attempt to construct the dike where it will not interfere with major areas of construction traffic so that vehicle damage to the dike will be kept to the minimum. Install culvert crossings anywhere regular construction traffic will cross the channel.
12. The swale must have a positive grade for its entire length. There should be no dips or low points in the swale where storm water will collect and pond.
13. If diversions remain in place longer than 14 days, they are to be properly stabilized.
14. Rock check dams can be installed in the diversion if erosion of the channel appears to be a problem and the channel is deep enough.

Maintenance

The measure shall be inspected after every storm of more than 0.5 inch and repairs made as necessary. At least once week, the measure shall be inspected and repairs made immediately. Inspect the dike, flow channel and outlet for deficiencies or signs of erosion. Reseed or otherwise stabilize the dike as needed to maintain its stability. Inspect for sediment deposits, constrictions and blockages. Remove any blockage immediately.

Damages caused by construction activities or traffic must be repaired immediately

During repairs, properly compacted any material added to the dike.

Vegetated swale channels should be inspected regularly to check for points of scour, bank failure or inadequate vegetative cover; rubbish or channel obstruction; rodent holes or excessive wear from pedestrian or construction traffic. Lined swale channels should be checked regularly for deterioration from freezing, salt or chemicals; scour or undermining at the inlet and outlet; or points of sediment deposition.

Any needed repairs shall be made promptly.

3.16 - PIPE SLOPE DRAIN

Introduction

A flexible tubing or conduit extending from the top to the bottom of a cut or fill slope to temporarily conduct concentrated stormwater runoff down the face of the cut or fill in a non-erosive manner.

Conditions Where Practice Applies

There is often a significant lag between the time a cut or fill slope is completed and the time a permanent drainage system can be installed. During this period, the slope is usually not stabilized and is particularly vulnerable to erosion. This situation also occurs on slope construction that is temporarily delayed before final grade is reached. Temporary slope drains can provide valuable protection of exposed slopes until permanent drainage structures can be installed or vegetation can be established.

Table 3.16.1 PIPE SIZES FOR PIPE SLOPE DRAIN

Size Diameter (D)	12	18	21	24
Maximum Drainage in Area (Acres)	0.5	1.5	2.5	5.0

Pipe slope drains are used in conjunction with diversions and berms. The diversion/berm direct surface runoff to the slope drain, which conveys concentrated flow down the face of a slope or across a disturbed area. The drainage to a pipe slope drain should be limited to 5 acres.

Because of the height limitation of the berms or diversions, the maximum pipe diameter will be 24".

Construction Specifications

1. The Pipe Slope Drain shall have a slope of 3 percent or steeper.
2. The top of the dike over the inlet pipe shall be at least 8" above the top of the Pipe.
3. Flexible corrugated plastic tubing is preferred. However, corrugated metal pipe or equivalent PVC pipe can be used. All connections shall be watertight.
4. A flared end section can be attached to the inlet end of pipe with a watertight connection. Filter cloth can be placed under the inlet of the pipe slope drain and shall extend out 5 feet from the inlet. The filter cloth shall be entrenched on all sides.
5. The entrance section shall pitch toward the slope at the minimum rate of 1/2 inch per foot.
6. The Pipe Slope Drain shall be securely anchored to the slope by staking at the grommets provided or with straps made specifically for this

purpose. Spacing for anchors shall be as provided by the manufacturer's specification, but no less than 10 feet. In no case shall less than two (2) anchors be provided equally spaced along the length of pipe.

7. The soil around and under the pipe and end section shall be hand tamped in 4-inch lifts to the top of the earth dike.
8. All pipe connections shall be watertight.
9. Where a Pipe Slope Drain drains an unstabilized area, it shall outlet into a SEDIMENT TRAP OR BASIN. If this is not possible then the pipe slope drain will discharge into a stable conveyance that leads to a sediment trap or basin. When discharging into a trap or basin the Pipe Slope Drain shall discharge at the same elevation as the wet pool elevation. The discharge area must be protected from erosion. The discharge from the Pipe Slope Drain must be located at the most distant point from the sediment control device's outlet as possible.
10. When the drainage area is stabilized or undisturbed, the Pipe Slope Drain shall discharge onto a stabilized area at a non-erosive velocity.
11. The Pipe Slope Drain should be placed on undisturbed soil or well-compacted fill.
12. Do not space more than 250 feet apart.
13. A small sediment trap can be installed at the entrance to the pipe if saturation of the fill will not be a problem.

Maintenance

Inspect and perform any required maintenance once a week and after each 0.5-inch rain event.

The inlet must be kept open at all times. It is very important that these temporary structures be installed properly, since their failure will often result in severe gully erosion on the site and sedimentation below the slope.

The contractor should avoid the placement of any material on and prevent construction traffic across the pipe slope drain.

The diversion and berm must be kept clear to keep water flowing to the inlet. Correct any erosion of the berm and remove sediment deposits along the berm.

It cannot be overstated that maintenance is extremely important with this device. Occasionally this device will be left in place over the winter. A written maintenance schedule, using the above requirements, should be established and rigorously followed.

While this structure prevents erosion of the fill slope, failure to properly maintain this structure can cause **catastrophic** erosion over the dike and on the face of the fill slope.

FIGURE 3.16.1

PIPE SLOPE DRAIN

3.17 - OUTLET PROTECTION

Introduction

A section of rock protection placed at the outlet end of the culverts and channels.

Pipe outlets are points of critical erosion potential. Stormwater exiting from a closed conveyance system generally reaches a velocity that exceeds the permissible or erosion resistant velocity of the receiving channel or overland area. To prevent scour at stormwater system outlets, a flow transition structure is needed which will absorb the initial impact of the flow and reduce the flow velocity to a level which will not erode the receiving channel or overland area.

Outlet protection consists of the construction of an erosion resistant section between a conduit outlet and a stable downstream channel. Erosion at an outlet is chiefly a function of soil type and the velocity of the conduit discharge. Therefore, in order to mitigate erosion, an adequate design must stabilize the area at the conduit outlet and reduce the outlet velocity to a velocity consistent with a stable condition in the downstream channel.

The design of riprap outlet protection applies to the immediate area or reach downstream of the pipe outlet and does not apply to continuous rock linings of channels or streams. For pipe outlets at the top of exit slopes or on slopes greater than 10%, the designer should assure that suitable safeguards are provided beyond the limits of the localized outlet protection to counter the highly erosive velocities caused by the re-concentration of flow beyond the initial riprap apron. Every effort should be made to protect the receiving channel from erosion down to a location in a natural waterway that can resist the forces of the water.

This standard applies to the planning, design, and construction of rock riprap and gabions for protection of downstream areas. It does not apply to rock lining of channels or streams. However, the riprap apron can be extended downstream for reasonable distances until stable conditions are reached even though this may exceed the length calculated for design velocity control.

Conditions Where Practice Applies

This practice applies where discharge velocities and energies at the outlets of culverts, conduits, or channels are sufficient to erode the next downstream reach. This applies to:

1. Culvert outlets of all types.
2. Pipe conduits from all sediment basins, dry storm water ponds, and permanent type ponds.
3. New channels constructed as outlets for culverts and conduits.

4. Velocity at outlet should be below 15 fps. If velocities exceed 15 fps a specifically designed outfall structure such as plunge pool or stilling basin should be used.

Design Criteria

The most commonly used device for outlet protection is a riprap-lined apron. Where practical, they are constructed at a zero grade or a minimum slope to slow the outlet velocity. The type and length of the riprap-lined apron is related to the outlet flow rate, the tailwater level and whether there is a defined channel downstream.

If the tailwater depth is less than half the outlet pipe rise, it shall be classified as a Minimum Tailwater Condition. If the tailwater depth is greater than or equal to half the outlet pipe rise, it shall be classified as a Maximum Tailwater Condition.

The design of rock outlet protection depends entirely on the location. Pipe outlets at the top of cuts or on slopes steeper than 10 percent, cannot be protected by rock aprons or riprap sections due to re-concentration of flows and high velocities encountered after the flow leaves the apron. Several counties in West Virginia have regulations and design procedures that may establish the dimensions, type and size of materials, and locations where outlet protection is required. Where these requirements exist, they shall be followed.

Tailwater Depth--The depth of tailwater immediately below the pipe outlet must be determined for the design capacity of the pipe. If the tailwater depth is less than half the diameter of the outlet pipe, and the receiving stream is wide enough to accept divergence of the flow, it shall be classified as a Minimum Tailwater Condition; see Figure 3.17.2 on page 3.17-11 as an example. If the tailwater depth is greater than half the pipe diameter and the receiving stream will continue to confine the flow, it shall be classified as a Maximum Tailwater Condition; see Figure 3.17.1 on page 3.17-10 as an example. Pipes which outlet onto flat areas with no defined channel may be assumed to have a Minimum Tailwater Condition; see Figure 3.17.2 on page 3.17-11 as an example.

Apron Length--The apron length shall be determined from the curves solely according to the tailwater conditions.

Minimum Tailwater – Use Figure 3.17.2 on page 3.17-11
Maximum Tailwater – Use Figure 3.17.1 on page 3.17-10

Apron Width--Where there is no defined channel immediately downstream of the apron, the width of the apron at the pipe outlet should be three times the maximum inside pipe span and the width at the end of the apron should be as follows:

For Minimum Tailwater Conditions:

Width at end of apron should equal the pipe diameter plus the calculated length of apron.

For Maximum Tailwater Conditions:

Width at end of apron should equal the diameter of the pipe plus 0.4 times the length of the outlet.

If the pipe discharges directly into a well defined channel, the apron shall extend across the channel bottom and up the channel banks to an elevation one foot above the maximum tailwater depth or to the top of the bank, whichever is less. The upstream end of the apron, adjacent to the pipe, shall have a width three (3) times the diameter of the outlet pipe, or conform to pipe end section if used. The bottom width of the apron should be at least equal to the bottom width of the existing channel.

Bottom Grade--The outlet protection apron shall be constructed with no slope along its length. There shall be no overfall at the end of the apron. The elevation of the downstream end of the apron shall be equal to the elevation of the receiving channel or adjacent ground.

Alignment--The outlet protection apron shall be located so that there are no bends in the horizontal alignment.

Materials--The outlet protection may be done using rock riprap, grouted riprap, or gabions. Riprap shall be composed of a well-graded mixture of stone size so that 50 percent of the pieces, by weight, shall be larger than the d_{50} size determined by using the charts. A well-graded mixture, as used herein, is defined as a mixture composed primarily of larger stone sizes, but with a sufficient mixture of other sizes to fill the smaller voids between the stones. The diameter of the largest stone size in such a mixture shall be 1.5 times the d_{50} size.

Thickness--The minimum thickness of the riprap layer shall be 1.5 times the maximum stone diameter. The following chart lists some examples:

D_{50} (inches)	d_{max} (inches)	blanket thickness (inches)
4	6	9
6	9	14
9	14	21
12	18	27
15	22	33
18	27	41
21	32	48
24	36	54

Stone Quality--Stone for riprap shall consist of fieldstone or rough unhewn quarry stone. The stone shall be hard, angular and of a quality that will not disintegrate on exposure to water or weathering. The specific gravity of the individual stones shall be at least 2.5. Recycled concrete equivalent may be used provided it has a density of at least 150 pounds per cubic foot, and does not have any exposed steel or reinforcing bars.

Separation Fabric--In all cases, filter fabric shall be placed between the riprap and the underlying soil to protect soil movement into, through, and underneath the riprap. The material must meet or exceed these requirements: The plastic filter cloth can be woven or non-woven monofilament yarns, and shall meet these base requirements: thickness 20-60 mils, grab strength 90-120 lbs; and shall conform to ASTM D-1777 and ASTM D- 1682.

Gabions--Gabions shall be made of hexagonal triple twist mesh with heavily galvanized steel wire. The maximum linear dimension of the mesh opening shall not exceed 4 ½ inches and the area of the mesh opening shall not exceed 10 square inches.

Gabions shall be fabricated in such a manner that the sides, ends, and lid can be assembled at the construction site into a rectangular basket of the specified sizes. Gabions shall be of single unit construction and shall be installed according to manufacturer's recommendations.

The area on which the gabion is to be installed shall be graded as shown on the drawings. Foundation conditions shall be the same as for placing rock riprap, and filter cloth shall be placed under all gabions. Where necessary, key, or tie, the structure into the bank to prevent undermining of the main gabion structure.

For submittal to DEP, include the following in the SWPPP:

- Location where the practice will be installed.
- Dimensions of the practice.
- Plan view, profile and cross section of each channel reach between the storm drain outlet under consideration and the existing publicly maintained system or the natural stream channel receiving the discharge flow.
- Rock size.
- Rock thickness.
- Fabric specifications.

Construction Specifications

1. The subgrade for the filter, riprap, or gabion shall be prepared to the required lines and grades. Any fill required in the subgrade shall be compacted to a density of approximately that of the surrounding undisturbed material.

2. The rock or gravel shall conform to the specified grading limits when installed respectively in the riprap or filter.

3. Filter cloth shall be protected from punching, cutting, or tearing. Any damage other than an occasional small hole shall be repaired by placing another piece of cloth over the damaged part or by completely replacing the cloth. All overlaps, whether for repairs or for joining two pieces of cloth shall be a minimum of one foot.

4. Stone for the riprap or gabion outlets may be placed by equipment. Both shall be constructed to the full course thickness in one operation and in such a manner as to avoid displacement of underlying materials. The stone for riprap or gabion outlets shall be delivered and placed in a manner that will ensure that it is reasonably homogenous with the smaller stones and spalls filling the voids between the larger stones. Riprap shall be placed in a manner to prevent damage to the filter blanket or filter cloth. Hand placement will be required to the extent necessary to prevent damage to the permanent works.

Maintenance

Once a riprap outlet has been installed, the maintenance needs are very low. It should be inspected after high flows for evidence of scour beneath the riprap or for dislodged stones. If a significant number of stones have been dislodged it will be necessary to recalculate stone size and replace the existing stone with properly sized stone. Any repairs must be made immediately.

Design Procedure

1. Investigate the downstream channel to assure that non-erosive velocities can be maintained.

2. Determine the tailwater condition at the outlet to establish which curve to use.

3. Enter the appropriate chart with the design discharge to determine the riprap size and apron length required. It is noted that references to pipe diameters in the charts are based on full flow. For other than full pipe flow, the parameters of depth of flow and velocity must be used to adjust the design discharges.

4. Calculate apron width at the downstream end if a flare section is to be employed.

Examples

Example 1: Pipe Flow (full) with discharge to unconfined section.

Given: A circular conduit flowing full.

> Q = 280 cfs, diameter = 66 in., tailwater (surface) is 2 ft. above pipe invert (Minimum Tailwater Condition).

Find: Read d_{50} = 1.2 ft and apron length (L_a) = 38 ft.

Apron width = diam. + L_a = 5.5’ + 38’ = 43.5 ft.

Use: d_{50} = 15”, d_{max} = 22”, blanket thickness = 32”

Example 2: Box Flow (partial) with high tailwater

Given: A box conduit discharging under partial flow conditions. A concrete box 5.5 ft. x 10 ft. flowing 5.0 ft. deep,

Q = 600 cfs and tailwater surface is 5 ft. above invert (max. tailwater condition).

Since this is not full pipe and does not directly fit the nomograph assumptions substitute depth as the diameter, to find a discharge equal to full pipe flow for that diameter, in this case 60 inches.

$$\text{Since, } Q = AV \text{ and } A = \frac{\pi D^2}{4}$$

First, compute velocity:

V = (Q/A) = (600/(5) (10)) = 12 fps

Then substituting:

$$Q = \frac{\pi D^2}{4} \text{ x } V = \frac{3.14\,(5\text{ ft})^2}{4} \text{ x } 12 \text{ fps} = 236 \text{ cfs}$$

At the intersection of the curve, d = 60 in. and Q = 236 cfs, read d_{50} = 0.4 ft.

Then reading the d = 60 in. curve, read apron length (L_a) = 40 ft.

Apron width, W = conduit width + (6.4)(L_a) = 10 + (0.4) (40) = 26 ft.

Example 3: Open Channel Flow with Discharge to Unconfined Section

Given: A trapezoidal concrete channel 5 ft. wide with 2:1 side slopes is flowing 2 ft. deep, Q = 180 cfs (velocity = 10 fps) and the tailwater surface downstream is 0.8 ft. (minimum tailwater condition).

Find: Using similar principles as Example 2, compute equivalent discharge for a 2 foot, using depth as a diameter, circular pipe flowing full at 10 feet per second.

Velocity:

$$Q = \frac{\pi\,(2\text{ft})^2}{4} \text{ x } 10 \text{ fps} = 31.4 \text{ cfs}$$

At intersection of the curve, d = 24 in. and Q = 32 cfs, read d_{50} = 0.6 ft.

Then reading the d = 24 in. curve, read apron length (L_a) = 20 ft.

Apron width, W = bottom width of channel + L_a = 5 + 20 = 25 ft.

Example 4: Pipe flow (partial) with discharge to a confined section

Given: A 48 in. pipe is discharging with a depth of 3 ft. Q = 100 cfs, and discharge velocity of 10 fps (established from partial flow analysis) to a confined trapezoidal channel with a 2 ft. bottom, 2:1 side slopes, n = .04, and grade of 0.6%.

Calculation of the downstream channel (by Manning's Equation) indicates a normal depth of 3.1 ft. and normal velocity of 3.9 fps.

Since the receiving channel is confined, the Maximum Tailwater Condition controls.

Find: discharge using previous principles:

$$Q = \frac{\pi\,(3ft)^2}{4} \times 10 \text{ fps} = 71 \text{ cfs}$$

At the intersection of d = 36 in. and Q = 71 cfs, read d_{50} = 0.3 ft.

Reading the d = 36" curve, read apron length (L_a) = 30 ft.

Since the maximum flow depth in this reach is 3.1 ft. that is the minimum depth of riprap to be maintained for the entire length of the apron.

3.18 - RIGHT OF WAY DIVERSION

Introduction

Right-of-way Interceptor Diversion is a ridge of dirt or a ridge and a channel combination constructed on an angle across a utility right-of-way used to shorten flow paths and flatten slopes to reduce the erosive force of water or to direct water away from critical resources. It can be both a temporary and permanent structure.

Conditions Where Practice Applies

This practice is applicable on all utility construction that occurs on sloping ground. In fact, it is probably the most common sediment control practice used in pipeline construction.

Design Criteria

No formal design is required. The spacing between diversions shall not exceed the requirements below.

Construction Specifications

1. Drainage Area: The maximum allowable drainage area is 1 acre.
2. Spacing: Use the following table when choosing the placement of the diversion. Use this chart for both permanent and temporary diversions.

Table 3.18.1 Right-of-way Diversion Spacing

Percent Slope	Spacing in Feet
[5	300
10	175
15	125
20	100
〈25	75

* It is difficult to install diversions on slopes steeper than 35%, the Division of Water and Waste Management will allow greater distances between diversions on extreme slopes.

3. Height: The minimum allowable height measured from the upslope side of the dike is 12 inches.
4. Grade: The channel behind the dike shall have a positive grade to a stabilized outlet. The diversion must be angled at least 3 or 4 degrees relative to the fall line of the slope and should not exceed 8 degrees.
5. Outlet: Each diversion should exit onto stabilized ground. It should never exit onto the right-of-way where it can run down to the next diversion.

6. Temporary diversion dikes must be installed as a first step after clearing and grubbing, or grading on a replacement project.
7. The diversions must be in place and functional at the end of each workday, especially when work will be discontinued for several days as on a weekend. Keep an eye on the weather forecast.
8. The berm shall be compacted by running a tracked piece of equipment across the length of the berm at least once.
9. Where the required spacing cannot be met due to excessive slope, a diversion will be installed at the nearest convenient point above and below the step section.

Maintenance

The measure shall be inspected after every rain event of .5 inch or more and repairs made as necessary. Once every week, whether a storm event has occurred or not, the measure shall be inspected and repairs made if needed. In areas where construction is actively occurring, diversions should be inspected daily, and damage caused by construction traffic or other activity repaired before the end of each working day.

3.19 - LEVEL LIP SPREADER

Introduction

An outlet for dikes and diversions consisting of an excavated depression constructed at zero grade across a slope used to convert concentrated runoff to sheet flow and release it uniformly onto areas stabilized by existing vegetation.

Conditions Where Practice Applies

Where there is a need to divert **small** amounts of clean stormwater away from disturbed areas to avoid overwhelming erosion control measures; where sediment-free storm runoff can be released in sheet flow down a well-vegetated, stabilized slope without causing erosion.

This practice applies only in those situations where the spreader can be constructed on undisturbed soil and the area below the level lip is uniform with a slope of 10% or less and is stabilized by natural vegetation or other non-erosive materials. The runoff water should not be allowed to re-concentrate after release unless it occurs during interception by another measure (such as a permanent pond or detention basin) located below the level spreader.

Caution should be used in using this device. Sheet flow easily changes to concentrated flow and consequently can cause downslope erosion if the specifications in this section are not followed closely.

Planning Considerations

The Temporary Diversion Dike, permanent stormwater conveyances and other waterways call for a stable outlet for concentrated stormwater flows. The level spreader is a relatively low-cost structure to release small volumes of concentrated flow but only when site conditions are suitable.

The outlet area must be uniform and well vegetated with slopes 10% or less. Particular care must be taken to construct the outlet lip completely level in a stable, undisturbed soil. Any depressions in the lip will concentrate the flow, resulting in erosion. Under higher design flow conditions, a rigid outlet lip design should be used to create the desired sheet flow conditions. Runoff water containing high sediment loads must be treated in a sediment-trapping device before being released to a level spreader.

This practice is difficult to install correctly. It is critical to install the lip perfectly level; failure to do so will cause a concentration of flows and erosion.

Design Criteria

No formal design is required except in the case of a permanent application the spreader should be designed to handle the peak discharge expected from a 10-year/24-hour storm.

Construction Specifications

1. Level spreaders must be constructed on undisturbed soil (not fill material).
2. The entrance to the spreader must be shaped in such a manner as to insure that runoff enters directly onto the 0% channel.
3. Construct a 20-ft. transition section from the diversion channel to blend smoothly to the width and depth of the spreader.
4. The level lip shall be constructed at 0% grade to insure uniform spreading of stormwater runoff.
5. Protective covering (blankets) for vegetated lip should be a minimum of 4 feet wide extending 6 inches over the lip and buried 6 inches deep in a vertical trench on the lower edge. The upper edge should butt against smoothly cut sod and be securely held in place with closely spaced heavy-duty wire staples.
6. Rigid level lip should be entrenched at least 2 inches below existing ground and securely anchored to prevent displacement. An apron of AASHTO #1, #2 or #3 Coarse Aggregate should be placed to top of level lip and extended downslope at least 3 feet. Place filter fabric under stone and use galvanized wire mesh to hold stone securely in place.
7. The released runoff must outlet onto undisturbed stabilized areas with slope not exceeding 10%. Slope must be sufficiently smooth to preserve sheet flow and prevent flow from concentrating.
8. The level spreader should be sized to transfer 0.25 cfs per linear foot of spreader for the peak discharge from a ten-year/24-hour storm.
9. Immediately after its construction, appropriately seed and mulch the entire disturbed area of the spreader.

Maintenance

The measure shall be inspected after every rainfall of .5" or more and repairs made, if required. After construction and until fully revegetated, the level spreaders need to be carefully inspected for any signs of channelization and immediately repaired.

Level spreader lip must remain at 0% slope to allow proper function of measure.

The contractor should avoid the placement of any material on and prevent construction traffic across the structure.

If the measure is damaged by construction traffic, it shall be repaired immediately.

Repeated failure of the structure will require the developer to replace the Level Lip Spreader with a properly designed stormwater conveyance channel from the diversion to the nearest natural waterway or stormwater basin.

3.20 - SURFACE WATER CONTROL

Introduction

One of the most important (but often overlooked) techniques of sediment and erosion control is the proactive management of surface water runoff. By anticipating where runoff will occur and directing water to go where it will do the least damage, erosion can be, in some cases, almost eliminated. By directing runoff to stabilized conveyances such as pipe slope drains, riprap channels and rock underdrains, slopes, fills and haul roads can be protected from excessive erosion. Work areas dry quicker after rainfall events, and the contractor saves time and money by not having to regrade areas damaged by erosion. The use of some of these techniques can reduce the size requirements of sediment basins and traps, but only if approved by DWWM during the SWPPP review.

Except for areas that can be treated by silt fence or super silt fence, all runoff from disturbed areas must be intercepted and conveyed to a sediment pond or trap.

At a minimum, temporary storm water conveyances should have the capacity to pass the peak flow from 2-year/24-hour storm. Significant sources of clean upslope surface water that drain onto disturbed areas shall be intercepted and conveyed to a stabilized discharge point where the water will not drain back onto the disturbed area. Upslope diversions must discharge where there can be no damage to adjacent land. Surface water controls shall be installed concurrently with rough grading.

Conditions Where Practice Applies:

The purpose of surface water control is to collect and convey surface water so that erosion is minimized and contaminated runoff from disturbed areas is treated by a sediment pond or trap. Upslope diversions reduce the volume of runoff to the disturbed area on a construction project and allows for the design of a smaller sediment trapping structure.

Surface water control consists of several practices alone or in combination:

1. Interception of runoff above cut slopes to a stable outlet.
2. Conveyance of the contaminated runoff to a sediment pond or trap.
3. Internal control of runoff across roadways and fills.
4. Control runoff from fill areas via pipe slope drains, rip-rap channels, or rock wick underdrains.
5. Control of water on the cut slope.
6. Conveyance of the treated runoff from the trap or basin to a stable waterway.

However, “controlling runoff” is not easily defined and there will be numerous conditions during the construction phase that this specification will not cover. Contractors are encouraged to incorporate these techniques and guidelines into their typical construction methods. However, the most important concept is to plan construction as if it will rain, not that it won't rain.

Timing of Installation

Surface water controls such as upslope clean water diversions and dirty water diversions to sediment basins and traps are to be constructed during the initial clearing and grubbing of an area and must be functional prior to the start of major grading operations.

The rock underdrain must be started prior to initial fill placement.

The rest of the water runoff control practices are installed as needed as grading operations proceed. Diversion berms at the top of slopes and either pipe slope drains or rip rap channels are installed as the fill progresses.

When using the riprap channel conveyance the installation of the channel must coincide with filling operations. There should be little or no delay in installing the channel and connecting it to the top of the fill.

Positive drainage and/or diversions must be maintained at all times to direct runoff towards the pipe slope drain, rock underdrain or rip rap channel.

Individual BMPs used in this practice:

1. Interceptor dikes/swales,
2. Rock wick or underdrain.
3. Rip rap ditches
4. Pipe slope drains,
5. Outlet protection

See the following drawings for schematic representation on the use of these measures.

Materials

The Surface Water Control Best Management Practice utilizes a number of other individual Best Management Practices from this Manual. Except for the rock underdrain, the material requirements can be found under each individual practice.

The Rock Underdrain is constructed like a huge French Drain. Rock for the underdrain or wick shall consist of durable Shot Rock, Select Embankment or large Riprap with little or no fine material. The rock core must be wrapped in a suitable filter fabric geotextile to prevent soil fines from clogging the voids.

Maintenance

Maintenance requirements are listed in each separate practice. But in general, this practice is to be inspected once a week or immediately after each 0.5-inch or greater rain event.

Positive drainage towards the conveyance(s) must be maintained at all times.

NOTE **The use of the Fill with Rock Underdrain may not be appropriate in all cases and should be reviewed by a geotechnical engineer.**

3.21 - INSTREAM BMPs

Introduction

Many times construction activities have to take place within the streambed. Utility construction in particular, by virtue of its linear nature, frequently crosses and negatively impacts streams. Large amounts of sediment can be generated when equipment is working in a stream. The only way that sediment be reduced during instream construction is by isolating the work or "working in the dry". By isolating the work area from the stream flow much of this sediment can be eliminated. There are several techniques that can be used to dewater and isolate the work area.

While this practice emphasizes utility construction each of these techniques can be used for any type of instream construction activity.

When the project will last more than 72 hours and the work area has to be completely dewatered such as when culverts are being installed, the temporary stream diversion can be used.

Runoff from the shore and approaches can also produce sediment, as can improperly stabilized streambanks.

Conditions Where Practice Applies

These practices are applicable to all instream construction activities such as utility lines, bridge piers and abutments, retaining walls and/or bank stabilization, culverts, water intakes and pipe outfalls. Temporary isolation techniques are used when construction within a full flowing stream will create severe environmental impacts due the resulting sedimentation.

Under most circumstances the pump around technique will be sufficient to dewater the work site. However, a full stream diversion is required when the construction of an instream structure will take place across the entire channel width and the pump around or flume would not be sufficient to handle the anticipated stream flows. It is also applicable when the construction timeframe is longer than 72 hours and there is sufficient lead-time to construct the new channel and stabilize it.

The stream diversion technique only works if there is sufficient room to install the diversion and construct the structure.

These practices are not permanent. A full engineering design is required if a stream channel has to be relocated into new permanent channel. There are numerous requirements, including natural stream design, in the Army Corps of Engineers' Section 404 Permit, WV DEP Section 401 Certification and the Public Lands Corporation Right-to-Enter.

Planning Considerations

The production of significant amounts of sediment is inevitable when conducting construction activities in a stream. There is also a potential for excessive sediment loss into a stream by runoff from the adjoining streamside and approach areas.

It is often a difficult task to decide what type of control to use when working in a stream. The ONLY way to limit sediment is to work “in the dry”. Any attempt to trap sediment in the stream below the construction site is pointless. There are several very effective methods that can be used to work in the dry and prevent the creation of sediment One, “boring and jacking” or horizontal directional drilling of pipe under the streambed, which prevents any disturbance within the watercourse, is the least destructive and preferred method. However, boring is expensive and sometimes impractical. But when working in very high quality steams such as Tier 2.5 or 3 it may be the only method allowed. In others it may be convenient as a continuation of an ongoing project, such as extending a Division of Highways’ road bore underneath an adjacent stream.

However, when instream work is unavoidable, consideration must be given to providing adequate mitigation of sediment loss while minimizing the amount of encroachment and time spent working in the channel. There are several methods available that completely isolate the work area from the stream flow. These “dry ditch” measures include pumping around, flume pipes, cofferdams and stream diversions. Each of these techniques work in smaller streams and during periods of low flows.

In larger streams where isolation techniques become difficult or impossible to install, there can be some “give and take”. Sometimes there can be less damage to the environment if minimal instream sediment control takes place. When using these “wet ditch” methods it is necessary to minimize the amount of time spent working in the stream, quickly stabilize the work area and provide substantial controls on the approach areas. However, when the construction within streambed and banks will take an extended period of time, consideration should be given to substantial in-stream controls or to construct a stream diversion.

As a result of the difficulty in choosing the right method for a utility stream crossing, designers should always make a site visit of proposed crossing to ensure that the most appropriate method is chosen. The designer should also be aware that most instream construction projects are subject to federal section 404 Army Corps of Engineers, NPDES Construction Permit and Public Lands Corporation’s Right of Entry.

Included in this BMP are several methods (with varying construction time and stream size scenarios) which allow for “work in the dry” to prevent excessive sedimentation damage. By no means are these methods all-inclusive. As with other control measures, site-specific design and innovative variations are encouraged.

All planning should begin with an onsite evaluation. The following items should be considered when designing a stream crossing..

- Site Conditions
  - Channel Cross Section
  - Channel Bed (Solid Rock, Cobbles, Soil)
  - Bank Slopes
  - Bank Stability
  - Flow Characteristics of Stream
- Season
- Suitable Location
  - Avoid bends of the steams
  - Avoid Wetlands or other environmental sensitive areas
- Other Considerations
  - Applicability of other permitting regulations (See Permitting section of this manual)
  - Endangered Species
- Floodplain encroachment
- Determine the appropriate construction method

General Design Criteria

1. The drainage area should be no greater than one square mile (640 acres).
2. All filter cloth used in the construction of the utility crossing must conform to physical requirements noted in GEOTEXTILE.
3. Water diverting structures should be used at all trenching and/or construction road approaches (50 feet on either side of the crossing).
4. Design criteria more specific to each particular crossing can be found in the following drawings.
5. All construction activities must meet the applicable Minimum Standard for Instream Construction.
6. Bank stabilization should be based on soil erodibility and bank-full velocity. Restabilization shall consist of the installation of ungrouted riprap on all disturbed streambank areas (or on the area 6 feet on both sides of the centerline of its utility trench, whichever is greater) with slopes of 3:1 or greater. Refer to RIPRAP and the drawings in this section for installation requirements. For slopes of 3:1 or less, vegetative stabilization may be used, pending approval by the Division of Water and Waste Management. Stabilization of its streambed and banks and the approach areas should occur immediately following the attainment of final grade.
7. Provide sediment control such as SILT FENCE, SUPER SILT FENCE or DIVERSIONS and SEDIMENT TRAP on either side of the stream

Construction Criteria

The following specifications are for stream crossings such as would be needed for a utility line crossing. Each can be used for other instream activities with little or no modification. The stream diversion will typically be used for larger projects.

The least damaging and preferred method is “boring and jacking” or horizontal directional drilling..

Open cut dry ditch methods - In these methods the work area is isolated by diverting the stream around the pipeline crossing. The trench is then excavated, the pipe installed and backfilled and the stream and streambank stabilized, all “in the dry”.

The three main methods of dry ditch crossings are the pump around, cofferdam and the flume pipe methods. In the pump around, the stream is dammed and water is moved around the construction site with a pump. In the cofferdam method, impervious barriers are used to isolate part of the work area. Typically half the stream is dammed and the pipe is laid before moving to the other half. In the flume method, the stream is dammed and the stream is bypassed in a culvert that spans across the work area.

One negative to using these methods is the installation and removal of the dam can create a good bit of sediment. Other problems include: leakage around/underneath dam, dam and flume failures, insufficient pump capacity, flooding, and inadequate maintenance.

Pump-Around

The pump around method is the preferred technique to dewater a work site. It is the simplest method if the necessary equipment is available. This method requires damming the stream with a non-erodible material covered with an impervious membrane to create a pool upstream of the work area where a pump intake can be placed. Depending on the gradient of the stream another dam below the work area may be needed. In between the dams a dry work area is created. A pump moves the water around the construction area where the installation of the pipe can be done in the dry. It can be labor intensive when placing the sand or gravel bags. Obtaining sand bags in West Virginia can also be problematic.

Key issues:

1. Provide adequate sediment and erosion control on the approaches.
2. Construction should be preformed in low flow periods.
3. Use a pump or pumps sufficiently large to pump the entire stream flow around the site
4. Construct a dam impervious to water.
5. The inlet of the pump is to be suspended above the streambed in order to prevent sucking mud and sediment.
6. The discharge point must be stabilized with rock to disperse the energy and prevent erosion.

Cofferdam

Cofferdams have long been used to provide dry work areas. Their use is declining as other methods gain ground. However in the right circumstance they can still provide adequate performance. Cofferdams are labor intensive and costly and can be difficult to seal to prevent infiltration of water. To be used when stream diversion is not practical and stream is wide enough (10 feet or wider) to make cofferdam installation practical.

If the stream needs to be diverted more than 75% of its width, then Diversion Channel criteria should be followed.

a) Construction should be performed in low flow periods
b) Crossing shall be accomplished in a manner that will not inhibit the flow of the stream.
c) Dewatering to be accomplished in accordance with section for DEWATERING.
d) Cofferdams should not extend beyond 2/3 the width of the streambed to allow for stream flows.
e) As with all utility line crossings, approach areas should be controlled with perimeter measures (silt fence, diversions, etc.)
f) Remove large rocks, woody vegetation, or other material from the streambed and banks that may get in the way of placing the stone, sandbags, sheet metal, or wood planks or installing the utility pipe or line.
g) Form a cofferdam by placing stone or sandbags, jersey barriers (or other non-erodible materials), covered by an impervious material in a semicircle along the side of the stream in which the utility installation will begin. It must be surrounded and underlain with filter cloth as shown in the drawing. The height of and area within the dam will depend upon the size of the work area and the amount of stream flow. Stack materials as high as will be necessary to keep water from overtopping the dam and flooding the work area.
h) Cofferdams should be no more than one half the height of the stream bank plus one-foot.
i) When the stream flow is successfully diverted by the cofferdam, dewater the work area into a dewatering structure.
j) Stabilization of the crossing, streambanks, and approaches should occur immediately following completion of the crossing.

There are commercially available cofferdams now on the market. These water filled bladders or standing steel supports can be installed quickly and can provide cost savings over traditional hardened cofferdams. Their installation and removal can lessen the creation of sediment. Some of the products available are Portadam, Dam-it Dams, and Aqua-Barrier

Flume Pipe

A flume pipe crossing consists of two impervious dams across a stream with one or more culverts installed to pass the stream flow across the work area. A flume pipe crossing can be used when in-stream construction will last less than 72 hours and stream is narrow (less than 15 feet wide) or wider in low water conditions. Ideal for gas pipeline, sewerline and waterline construction especially when used in conjunction with and as an extension of a Vehicular Stream Crossing.

a) The flume pipe crossing must be made operational prior to the start of the instream construction.

b) A large flume pipe(s) or culvert(s) of an adequate size to support normal water channel flow (see Table 3.21.1) shall be installed in the streambed across the proposed pipeline trench centerline. Riprap, jersey barrier or sandbags shall be placed close to each end of the flume pipe so as to dam off the creek forcing the water to flow through the flume pipe (see drawing). Sandbags are the preferred method for diverting water into the flumes. The commercial cofferdams can be used if a tight seal can be created.

c) The entrapped water in the work area can then be pumped into an approved Dewatering Device. The trench can then be dug under the flume pipe. The pipe sections will then be installed to the proper depth under the flume pipe. After the pipe is installed, the ditch will be backfilled and restabilization shall be carried out.

d) Reclamation of the stream banks will occur the same day as the installation of he pipe is completed. Restabilization shall consist of the installation of ungrouted riprap on all disturbed streambank areas (or on the area 6 feet on both sides of the centerline of the utility trench, whichever is greater) with slopes of 3:1 or greater. Refer to the specification for Riprap, for installation requirements. For slopes of 3:1 or less, vegetative stabilization with or without Rolled Erosion Control Product may be used, pending approval by the Division of Water and Waste Management. Stabilization of its streambed and banks and the approach areas should occur immediately following the attainment of final grade.

e) After completion of backfilling operation and restoration of stream banks and leveling of streambed, the flume pipe can then be removed. The stone can be removed or spread as stabilization of the streambed depending on permit requirements. Sediment control in approach areas shall not be removed until all construction is completed in the stream crossing area and the contributing drainage area to the device is stabilized. All ground contours shall be returned to their original condition.

Drainage Area (Acres)	Table 3.21.1 Average Slope of Watershed			
	1%	4%	8%	16%
	Culvert Size			
1 – 25	24	24	30	30
26 - 50	24	30	36	36
51 – 100	30	36	42	48

Note: Table is based on USDA-SCS Graphical Peak Discharge Method for 2-year frequency storm event, CN = 65; Rainfall depth = 3.5 inches (average for Virginia). Source: Va. DSWC

Open cut wet ditch

This technique does not use any method to divert the stream around the work area. The utility line is installed and backfilled while the river/stream continues to run through the site. The benefits are low cost and a quick completion time. However, this type of crossing produces some very negative impacts. These include severe pollution from greatly increased total suspended sediment (TSS) concentrations, changes in channel morphology, and localized destruction of aquatic ecosystems. These impacts can be somewhat mitigated by a quick completion time.

DEP does not recommend this type of crossing unless a creating a dry ditch is impossible. There shouldn't be any significant rain forecast during the entire construction timeframe. This method may be used with prior approval when other preferred methods are proven to be unfeasible.

Stabilization of the crossing, streambanks, and approaches should occur immediately following completion of the crossing.

The wet ditch method may be used when the following conditions are met:

a.) When the distance across the flume pipes become too wide for a backhoe to dig from both sides and connect the trench underneath the pipes. This measurement would vary according to the number of flume pipes, the height of the stream banks, the size and digging angle of the backhoe, the depth to bed rock and ease of digging.

b.) When the crossing can be accomplished within 72 hours. However, the contractor should make every effort to complete the crossing in one working day. All disturbed streambanks must be stabilized the same day the construction is finished

c.) When the crossing is at right angles (± 5°) to the stream channel.

d.) If water is pumped during the installation of the pipe it must be treated as per the DEWATERING specification.

This method is also applicable to small intermittent and ephemeral streams that are completely dry and no rain is forecast for the entire installation timeframe.

Stream Diversion Bypass

Temporary stream diversions are used when construction within a full flowing stream will create severe environmental impacts due the resulting sedimentation. This technique also provides a safe and dry work area. Typically a stream diversion is required when the construction of an instream structure will take place in the entire channel and the pump around or flume dewatering techniques would not be sufficient to handle the anticipated stream flows. It is also applicable when there is a significant construction timeframe. A stream diversion is most commonly used when a large fill is placed across a valley and a culvert is installed to carry the stream such as when building a road or dam.

Once started, any work to relocate the stream and install the permanent structure shall not be discontinued until it is completed. The connection to the natural channel should be performed under dry conditions

Diversion channels only work if there is sufficient room to both install the diversion and construct the structure.

Construction Specifications

a) The diversion channel crossing must be operational before the construction activity starts so that construction can occur “in the dry").
b) Minimum width of bottom shall be four feet or equal to average width of existing streambed, whichever is greater.
c) Maximum steepness of side slopes shall be 2:1. Depth and grade may be variable, dependent on site conditions, but shall be sufficient to ensure continuous flow of water in the diversion.
d) There are three types of diversion channel linings that can be used, based upon expected velocity of bankfull flow. Refer to the drawing and the accompanying table.

e) The seed mix for the grass liner is to be in accordance with the Temporary Seeding" section. An average growth of two inches in height shall be achieved throughout the diversion with 70% cover before water is turned into it.

f) Stream diversion liners shall be entrenched at the upstream end as shown in the stream channel drawing for ROLLED EROSION CONTROL PRODUCTS. Fabric liners must be stapled every three feet. Polyethylene liners shall be weighted with rock along the base of the side slope.

Table 3.21.2
STREAM DIVERSION LININGS

Acceptable Lining Material	Classification	Maximum Velocity
Grass and Matting	TYPE A	5.0 f.p.s.
Geotextile Filter Cloth	TYPE B	8.0 f.p.s.
Class I Riprap and Filter Cloth	TYPE C	13.0 f.p.s.

g) Start installing stream diversion liners at the downstream end. Stream diversion liners should be overlapped 18 inches (upstream over downstream) when a continuous liner is not available or is impractical. Overlaps along the sides should be made such that a liner is placed in the steam diversion bottom first and additional pieces of liner on the slopes overlap the bottom piece by a minimum of 18 inches. See ROLLED EROSION CONTROL PRODUCTS for drawings.

h) Stream diversion liners shall be entrenched at the top of the diversion slopes (slopes breaks) along with a line of silt fence. Silt fence may be excluded if the diversion liner is extended to such a point that siltation of the stream will not occur. If silt fence is excluded, the diversion liner must be secured. Liners shall extend from slope break to slope break as shown in the drawing.

i) Non-erodible materials such as riprap, jersey barriers, sandbags, or sheet piling, shall be used as flow barriers to divert the stream away from its original channel and to prevent or reduce backup into the lower end of the construction area.

j) The downstream and upstream connection to the natural channel should be performed under dry conditions and may be so accomplished by use of sandbag cofferdams. The downstream flow barrier is to be removed prior to the upstream barrier when preparing a stream diversion for the transport of water.

k) The diversion should be sealed off at the down stream end and then backfilled once water is put back in its original channel.

l) Stream should be re-diverted only after restabilization of original streambed and banks is completed or the inlet and outlet of the culvert pipe is finished. Stabilization of the streambed and banks and the approach areas should occur immediately following the attainment of final grade.

m) Temporary bypass channels should be backfilled and properly stabilized by riprap or RECPs to prevent the stream from reestablishing the path.

n) Any water pumped from this operation shall be directed into an approved Dewatering Structure.

Alternative Technique

Designers need to know that another way of installing culverts is possible. Traditionally a new culvert was installed as close to the original alignment of the existing stream as possible. This entails the construction of a significant stream diversion. If the conditions are right there is another way.

An alternative to building a stream diversion is to design and install the new culvert outside the existing stream channel and use the existing natural channel as the bypass. With this method there is much less likelihood of erosion and sedimentation of a temporary channel. Time can also be saved by not having to construct a whole new channel. The only "instream" work will be the tying in the old channel into the inlet and outlet channels of the new culvert or spillway.

It is sometimes likely that a combination of existing and new channel will be needed.

Other Considerations

Stream crossings must be approached as a separate project. All materials necessary to construct the crossing must be on site and ready to use. If possible, pipe should be coupled on shore and then pulled across and placed in the trench in one operation.

During reclamation it is not necessary to create a perfectly smooth stream bottom. Elevated spots should be removed but in most cases the bed load and scour from next high water event will eliminate all signs of the crossing. On smaller crossings the bed load from one flood event can fill the entire trench. In these cases, anchoring the pipe with river weights or critically placed buckets of gravel may be all that is required to reclaim the creek bottom.

It is important to use machinery that is in good mechanical shape. Use newer pieces of equipment that are less likely to have fluid leaks. Maintain spill containment kits inside each piece of equipment working in moving water. Maintain hydraulic hoses on equipment that is used for work in or around streams.

Refuel and maintain vehicles a minimum of 100 feet from of the stream. A comprehensive spill containment and cleanup kit should be readily available on site.

Maintenance

Structures and erosion and sediment controls should be inspected after every rainfall of 0.5 inches or more and at least once a week and repair all damages immediately. Check for debris especially flotsam clogging the inlet to the culverts. All deposited materials and obstructions must be removed immediately.

In general inspect all active steam crossings at the end of each day to make sure that the construction materials are positioned securely. This will ensure that the work area stays dry and that no construction materials float downstream. The contractor should carefully watch the weather forecast and coordinate the installation based on the proper conditions.

Cleanup and stabilize the entire stream crossing site immediately upon completion of the installation of the pipe. One exception would be on a natural gas transmission lines where the attached vehicle crossing will be used for an extended time. Stabilize all other areas immediately.

Temporary Vehicular Stream Crossing

A temporary structural span (includes bridges, round pipes, pipe arches, or oval pipes) installed across a watercourse for use by construction traffic. These structures are used to provide a means for construction traffic to cross a stream without damaging the channel or banks and to keep sediment generated by construction traffic out of the stream.

A rule of thumb is that if there are more than two crossings a stabilized stream crossing must be installed. As an example, if during the clearing and grubbing a bulldozer has to cross a stream going out and coming back just once a culverted stream crossing is not necessary. However if the route the bulldozer takes becomes the access to the site and more than one other vehicle has to cross the stream then a crossing a specified here needs to be installed.

Generally applicable to streams with drainage areas less than 1 square mile (660 acres).

For streams larger than 1 square mile the structure should be designed by a registered professional engineer, using professionally recognized methods that will more accurately define the actual hydrologic and hydraulic parameters that will affect the functioning of the structure.

Design Criteria

Temporary Bridge Crossing

a. Bridges may be designed in various configurations. However, the materials used to construct the bridge must be able to withstand the anticipated loading of the construction traffic.

b. Crossing Alignment - The temporary waterway crossing shall be at right angles to the stream. Where the approach conditions dictate, the crossing may vary 15E from a line drawn perpendicular to the centerline of the stream at the intended crossing location.

c. The centerline of both roadway approaches shall coincide with the crossing alignment centerline for a minimum distance of 50 feet from each bank of the waterway being crossed. If physical or right-of-way restraints preclude the 50 feet minimum, a shorter distance may be provided. All fill materials associated with the roadway approach shall be limited to a maximum height of 2 feet above the existing flood plain elevation.

d. A water diverting structure such as a dike or swale shall be constructed (across the roadway on both roadway approaches) 50 feet (maximum) on either side of the waterway crossing. This will prevent roadway surface runoff from directly entering the waterway. The 50 feet is measured from the top of the waterway bank. If the roadway approach is constructed with a reverse grade away from the waterway, a separate diverting structure is not required.

e. Appropriate perimeter controls such as SILT FENCE, SUPER SILT FENCE and/or DIVERSION and SEDIMENT TRAP must be employed when necessary along banks of stream parallel to the same.

f. Clearing and excavation of the streambed and banks shall be kept to a minimum.

g. The temporary bridge structure shall be constructed at or above bank elevation to prevent the entrapment of floating materials and debris.

h. Any abutments shall be placed parallel to and on stable banks.

i. Bridges shall be constructed to span the entire channel. Instream piers should be kept to a minimum. Any work within the normal high water mark will require a Public Lands Corporation Right-of-Entry, a Army Corps of Engineers 404 Permit and WV DEP 401 Certification..

j. Stringers shall either be logs, sawn timber, pre-stressed concrete beams, metal beams, or other engineer-approved materials.

k. Curbs or fenders may be installed along the outer sides of the deck. Curbs or fenders are an option that will provide additional safety and keep mud from flowing over the edge into the stream.

l. Bridges should be securely anchored at only one end using steel cable or chain. Anchoring at only one end will prevent channel obstruction in the event that floodwaters float the bridge. Acceptable anchors are large trees, large boulders, or driven steel anchors. Anchoring shall be sufficient to prevent the bridge from floating downstream and possibly causing an obstruction to the flow.

m. All areas disturbed during installation shall be stabilized immediately.

n. When the temporary bridge is no longer needed, all structures including abutments and other bridging materials should be removed immediately.

o. Final clean up shall consist of removal of the temporary bridge from the waterway, protection of banks from erosion, and removal of all construction materials. All removed materials shall be stored outside flood plain of the stream. Removal of the bridge and clean up of the area shall be accomplished without construction equipment working in the waterway channel.

Temporary Culvert Crossing

a. 2” to 4” Coarse Aggregate or larger will be used to form the crossing. DO NOT USE ERODIBLE MATERIAL FOR CONSTRUCTION OF THE CROSSING. The depth of stone cover over the culvert shall be equal to one-half the diameter of the culvert or 12 inches, whichever is greater. If multiple culverts are used, they shall be separated by at least 12 inches of compacted aggregate fill. To protect the sides of the stone from erosion, riprap shall be used.

b. If the structure will remain in place for up to 6 months, the culvert shall be large enough to convey the bankfull flow without appreciably altering the stream flow characteristics. To insure the proper capacity the culvert(s) should have cross sectional area equal to the cross sectional area of the stream at bankfull.

Should the structure will remain in place 6 months or longer, the culvert shall be large enough to convey the flow from a 10-year frequency storm. In this case, the hydrologic calculations and subsequent culvert size must be done for the specific watershed characteristics. If the structure must remain in place over 1 year, a qualified registered Professional Engineer must design it as a permanent measure.

c. Multiple culverts may be used in place of one large culvert if they have the equivalent capacity of the larger one. The minimum sized culvert that may be used is 18 inches. Two 18-inch culverts do not replace a 36-inch culvert.

d. All culverts shall be strong enough to support their cross-sectioned area under maximum expected loads.

e. The culvert(s) shall extend a minimum of five foot beyond the upstream and downstream toe of the aggregate placed around the culvert.

f. The slope of the culvert shall be at least 0.25 inch per foot.

g. Crossing Alignment - The temporary waterway crossing shall be at right angles to the stream. Where approach conditions dictate, the crossing may vary 15 from a line drawn perpendicular to the centerline of the stream at the intended crossing location.

h. The centerline of both roadway approaches shall coincide with the crossing alignment centerline for a minimum distance of 50 feet from each bank of the waterway being crossed. If physical or right-of-way restraints preclude the 50 feet minimum, a shorter distance may be provided. All fill materials associated with the roadway approach shall be limited to a maximum height of 2 feet above the existing flood plain elevation.

i. The roadway approaches to the structure shall consist of stone pads meeting the following specifications:

1) Stone: 2”- 4”
2) Minimum thickness: 6 inches
3) Minimum width: equal to the width of the structure
4) Minimum length: 50 feet on either side of the crossing.

j. A water diverting structure such as a swale shall be constructed (across the roadway on both roadway approaches) 50 feet (maximum) on either side of the waterway crossing. This will prevent roadway surface runoff from directly entering the waterway. The 50 feet is measured from the top of the waterway bank. If the roadway approach is constructed with a reverse grade away from the waterway, a separate diverting structure is not required.

k. Appropriate perimeter controls such as SILT FENCE, SUPER SILT FENCE and/or DIVERSION and SEDIMENT TRAP must be employed when necessary along banks of stream parallel to the same.

l. Clearing and excavation of the streambed and banks shall be kept to a minimum.

m. The invert elevation of the culvert shall be installed on the natural streambed grade to minimize interference with fish migration.

n. Filter cloth shall be placed on the streambed and streambanks prior to placement of the pipe culvert(s) and aggregate. The filter cloth shall cover the streambed and extend a minimum of six inches and a maximum of one foot beyond the end of the culvert and bedding material. Filter cloth reduces settlement and improves crossing stability. The required physical qualities of the filter cloth should be sufficient for the anticipated loads.

o. When the crossing has served its purpose, all structures including culverts, bedding and filter cloth materials shall be removed. Removal of the structure and clean up of the area should be accomplished without construction equipment working in the waterway channel.

p. Upon removal of the structure, the stream bank shall immediately stabilized.

q. During routine road maintenance do not grade mud and debris over the sides of the crossing into the stream.

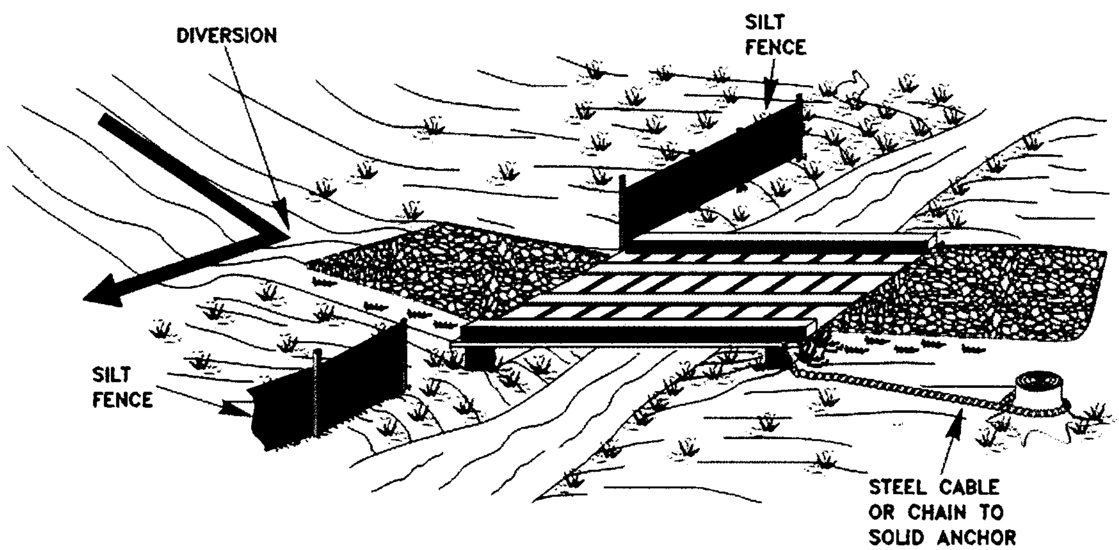
When the temporary structure has served its purpose, including bridge abutments or culverts and other bridging materials shall be removed and the disturbed area stabilized within 7 days. Care should be taken so that any aggregate left does not create an impediment to the flow or restrict fish passage.

All construction materials shall be stored outside the waterway flood plain. Clean up shall be accomplished without construction equipment working in the stream channel.

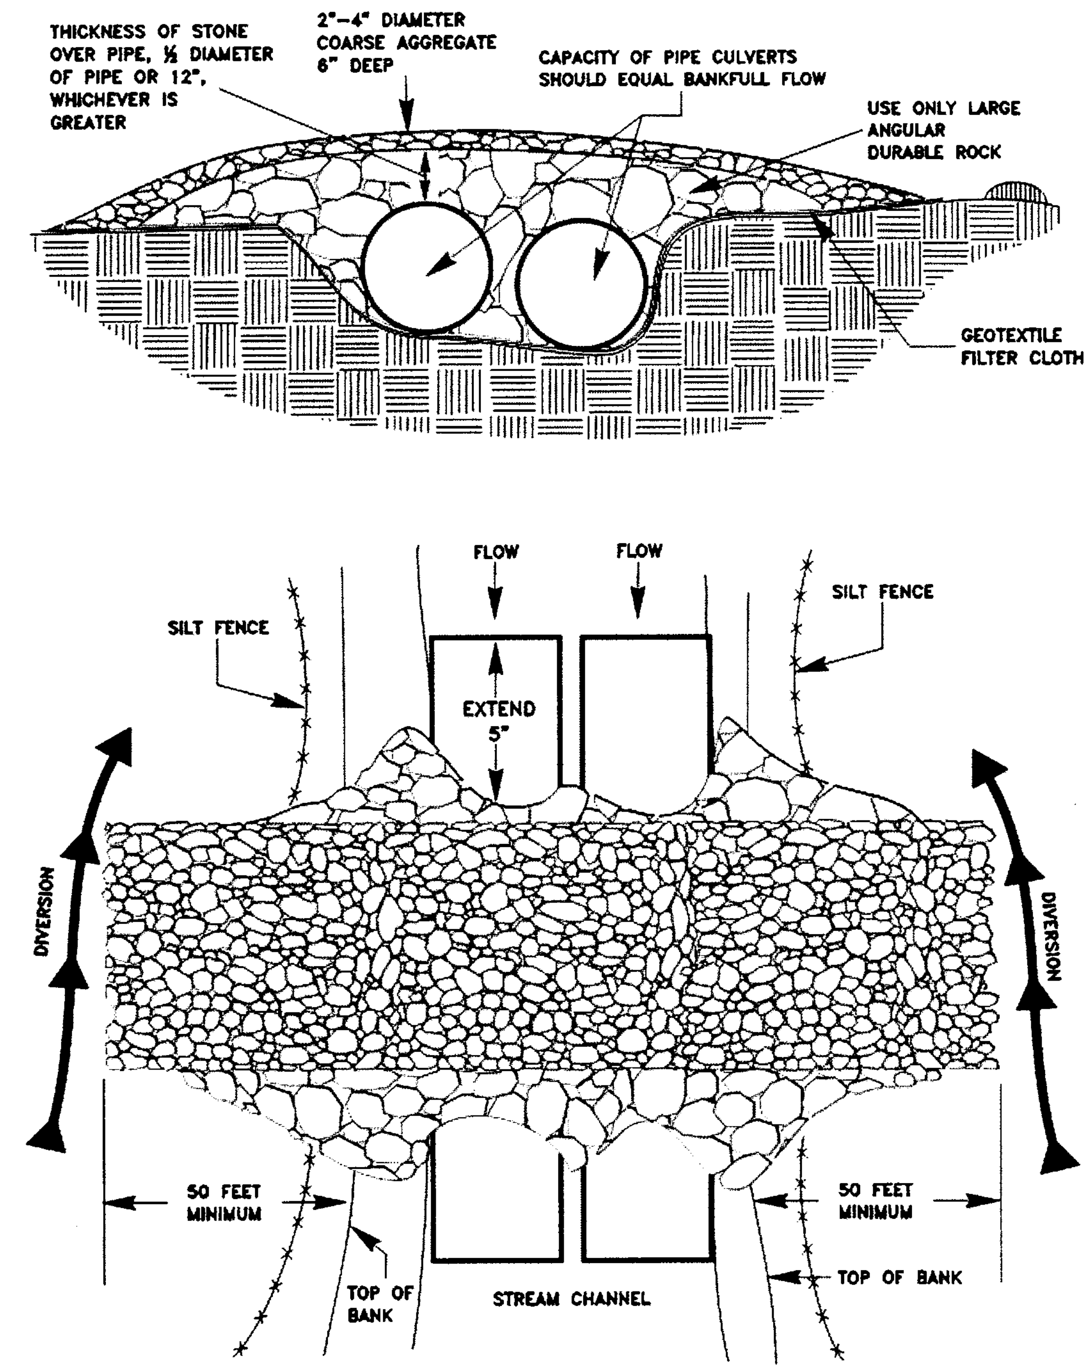
Maintenance Periodic inspection must be performed to ensure that the bridge, culverts, streambed and stream banks are maintained and not damaged, that sediment is not entering the stream. At a minimum each crossing must be inspected after every rain event of 0.5 inches or more and once a week. Never allow the culverts to become clogged with debris Remove any obstructions immediately.

Sediment and debris removed shall be disposed of outside of the flood plain and stabilized.

TEMPORARY BRIDGE CROSSING



CULVERT STREAM CROSSING



FROM: VA DSWC

MINIMUM STANDARDS FOR INSTREAM CONSTRUCTION ACTIVITIES

General Requirements for all instream activities

1. All appropriate permits should be obtained prior to beginning instream construction activities such as construction activities such as creating a restriction or impediment of flow. See the Regulatory Requirements section of this manual.
6. Isolating the work area and "working in the dry" is the only effective way of controlling sediment.
7. All instream construction should be scheduled to occur during low flow periods, typically during the summer and fall months. If construction must be accomplished during higher flows, the work area must be isolated from the stream by a structural measure such as a non-erodible cofferdam or sheet piling. Emergency repairs of public utilities or public roads are exempted.
8. All streambanks are to be stabilized with an appropriate protective material such as riprap, revegetation, geotextiles, revetments, etc. immediately upon completion of the final grading.
9. The choice of stabilization materials (vegetative or structural) should be based on sound engineering practices and will include investigations of the soil's erodibilty and the anticipated velocities of the stream.
10. Inlet and outlet protection is required for all culverts (both temporary and permanent). Outlet protection can consist of riprap, gabion baskets, or other approved materials. See Outlet Protection section of this manual.
11. Every effort, in both planning and construction, should be made to limit the amount of instream work. Utility lines should not be installed within the stream, with the exception of stream crossing, without irrefutable proof that alternate avenues of alignment are not available. Convenience is not a justifiable reason to install a utility line down a stream.
12. Utility lines and roadways should cross the stream at right angles (± 15°) to the flow of the water.
13. Each stream crossing should be treated as a separate project and work should progress until the approaches and stream banks are completely stabilized. In no case should stabilization of the stream bank exceed 24 hours from completion of the backfill.
14. Streamside vegetation should be left intact to the greatest extent possible. Riparian buffer zones are to be enhanced whenever possible.
15. The sequence of construction events for the each instream activity should be included in the sediment control plan.

16. When a stream crossing is being constructed for vehicles, the crossing should be constructed as detailed in vehicle stream crossing section of this manual.
17. When work is performed in a flowing stream, precautions should be taken to minimize encroachment, control sediment transport and stabilize the work area to the greatest extent possible during construction. Use only non-erodible material for the construction of causeways, stream diversions and berms and cofferdams. Earthen fill may be used for cofferdams if armored by non-erodible cover materials such as filter fabric and appropriately sized stone.
18. All water pumped from a work area along, in or near a stream must be treated in an approved settling structure located outside the waterway before being discharged into a waterway. See DEWATERING section of this manual.
19. Green concrete is toxic to aquatic life and must not be placed in contact with flowing water.
20. Streambed excavation should be undertaken from the top of stream banks whenever possible.
21. When instream work is required, the use of rubber-tired vehicles and excavators is recommended.
22. Excavated material to be reused for trench backfill should be stockpiled outside the stream channel. Surround the storage area by silt fence or similar barrier to prevent sediment and mud from running back into the stream. Material not used for backfill should be removed to an appropriate soil disposal area located outside the floodplain and properly stabilized.
23. Temporary access roads in close proximity to a stream should be stabilized using the same requirements for a Stabilized Construction Entrance.
24. Do not use the stream as a vehicular right-of-way. Do not use the stream to deliver materials or to move construction equipment from one section to another.
25. Spill containment kits should be readily available onsite.

3.22 - DEWATERING

Definition

Dewatering refers to the act of removing and discharging water from excavated areas on construction sites, utility line construction or from sediment traps or basins on construction sites.

Given the unique conditions at any particular construction site, any or all of the practices may apply. In all cases, every effort shall be made to eliminate sediment pollution associated with dewatering.

Practices for Dewatering Excavated Areas

1. Pumping of water to an existing sediment basin or trap in which the entire volume of water from the area to be dewatered can be contained without discharge to receiving waters.
2. Pumping of water to an existing sediment basin or trap such that the entire volume of water from the area to be dewatered can be managed without exceeding the design outflow from the sediment control structure.
3. Use of a straw bale/silt fence pit or trap as shown in the drawings.
4. Pumping water through a geotextile bag made specifically for this purpose.
5. A well-vegetative Filter Strip, capable of withstanding the velocity of discharged water without eroding. Install some sort of energy dissipation (haybales, riprap or sheet of plywood) at the pump discharge.
6. Use a sump pit as shown on drawings to reduce the pumping mud.

Dewatering of Sediment Traps and Basins

Designers shall specify on plans, in the sequences of events and in the the practices for dewatering of traps and basins. In all cases, water removed from traps and basins shall be discharged so that it passes through a sediment control device prior to entering receiving waters.

Practices for Dewatering of Traps and Basins

1. Use of a straw bale/silt fence pit or trap as shown in the drawings.
2. Pumping water through a geotextile bag made specifically for this purpose.
3. A well-vegetative Filter Strip, capable of withstanding the velocity of discharged water without eroding. Install some sort of energy dissipation (haybales, riprap or sheet of plywood) at the pump discharge.
4. Regardless of the type of treatment always use a floating suction hose to pump the cleaner water from the top of the pond. As the cleaner water is pumped, the suction hose will lower and

eventually encounter sediment-laden water. At this point cease pumping operations and remove the remainder of the trapped sediment with machinery. Even when pumping from the top of the water column, provisions must still be made to filter water as required in this section prior to discharging to a stream. During the dewatering, personnel should be assigned to monitor pumping operations at all times to ensure that sediment pollution is abated. Pumping sediment-laden water into the waters of the State without filtration is prohibited.

Design Criteria

1. The dewatering device must be sized (and operated) to allow pumped water to flow through the filtering apparatus without exceeding the capacity of the structure. The following formula can be used to determine the storage volume for dewatering structures:

   Pump discharge (g.p.m.) x 16 = cubic feet of storage required

2. Material from any required excavation shall be stored in an area and protected in a manner that will prevent sediments from eroding and moving off-site.
3. An excavated basin (applicable to "Straw Bale/Silt Fence Pit") may be lined with filter fabric to help reduce scour and to prevent erosion of soil from within the structure. It may also be helpful to direct the discharge onto a hay or straw bale or riprap.
4. Design criteria more specific to each particular dewatering device can be found in the drawings.

Construction Methods

Straw Bale/Silt Fence Pit

a. Measure shall consist of straw bales, silt fence, a stone outlet consisting of a combination of 4-8 inch riprap and ½ to 2 inch aggregate and a wet storage pit oriented as shown in drawing.
b. The excavated area should be a minimum of 3 feet below the base of the perimeter measures (straw bales or silt fence).
c. Once the water level nears the crest of the stone weir (emergency overflow), the pump must be shut off while the structure drains down to the elevation of the wet storage.
d. The wet storage pit may be dewatered only after a minimum of 6 hours of sediment settling time. This effluent should be pumped across a well-vegetated area or through a silt fence prior to entering a watercourse.
e. Once the device has been removed, ground contours will be returned to original condition.

Geotextile Filter Bag

a. The bag shall be installed on a very slight slope so incoming water flows downhill through the bag without creating more erosion.
b. The neck of the Filter Bag shall be tightly strapped (minimum two straps) to the discharge hose.
c. The bag should be placed on an aggregate or hay bale bed to maximize water flow through the entire surface area of the bag.
d. The Filter Bag is full when it no longer can efficiently filter sediment or pass water at a reasonable rate.
e. Flow rates vary depending on the size of the Dewatering Device, amount of sediment discharged into the Dewatering Device, the type of ground, rock, or other substance under the bag and the degree of the slope on which the bag lies. The Filter Bag should be sized to accommodate the anticipated flow rates from the type of pump used. Typically Filter Bags can handle flow rates of up to 1000 gallons per minute, but in all cases follow the manufacturers recommendations for flow rates.
f. Use of excessive flow rates or overfilling the Dewatering Device with sediment will cause ruptures of the bag or failure of the hose attachment straps.
g. The Filter Bag can be left in place after cutting the top off and seeding and mulching the accumulated sediment or removed and disposed of offsite in an approved landfill.
h. Each standard Dewatering Device shall have a fill spout large enough to accommodate the discharge hose. Use two stainless steel straps to secure the hose and prevent pumped water from escaping without being filtered.
i. The Dewatering Device shall be a nonwoven bag, which is sewn with a double needle stitching using a high strength thread.
j. The Dewatering Device seams shall have an average wide width strength per ASTM D 4884 of 100 LB/IN (1.15 kg/meter).
k. The geotextile fabric shall be a nonwoven fabric with the following properties:

Table 3.22.1 GEOTEXTILE FABRIC PROPERTIES

Properties	Test Method	English	Metric
Grab Tensile	ASTM D-4632	250 Lbs.	113 kg
Puncture	ASTM D-4833	165 Lbs.	75 kg
Flow Rate	ASTM D-4491	70 Gal/Min/ Square Foot	25 liters/Min/ Square Meter
Permitivity	ASTM D-4491	1.3 Sec.-1	1.3 Sec.-1
Mullen Burst	ASTM D-3786	550 Lbs./ Square inch	3.79 MPa
UV Resistant	ASTM D-4355	70%	70%
AOS % Retained	ASTM D-4751	100%	100%

*All properties are minimum average roll value.

Maintenance

The filtering devices must be inspected frequently during pumping operations and repaired or replaced once the sediment build-up prevents the structure from functioning as designed.

Once the wet storage area becomes filled with sediment to one-half of the excavated depth, accumulated sediment shall be removed and disposed of properly.

The accumulated sediment that is removed from a dewatering device must be spread on-site and stabilized or disposed of at an approved disposal site as per approved plan.

3.23 - RIPRAP

Introduction

A permanent, erosion-resistant ground cover of large, loose, angular stone with filter fabric or granular underlining used to protect the soil from:

1. The erosive forces of concentrated runoff.

2. To slow the velocity of concentrated runoff while enhancing the potential for infiltration.

3, To stabilize slopes with seepage problems and/or non-cohesive soils.

Conditions Where Practice Applies

Wherever soil and water interface and the soil conditions, water turbulence and velocity, expected vegetative cover, etc., are such that the soil may erode under the design flow conditions. Riprap may be used, as appropriate, at storm drain outlets, on channel banks and/or bottoms, roadside ditches, drop structures, at the toe of slopes, as transition from concrete channels to vegetated channels, etc.

Planning.

Riprap is classified as either graded or uniform. A sample of graded riprap would contain a mixture of stones that vary in size from small to large. A sample of uniform riprap would contain stones which are all fairly close in size. For most applications, graded riprap is preferred to uniform riprap. Graded riprap forms a flexible self-healing cover, while uniform riprap is more rigid and cannot withstand movement of the stones. Graded riprap is cheaper to install, requiring only that the stones be dumped so that they remain in a well-graded mass. Hand or mechanical placement of individual stones is limited to that necessary to achieve the proper thickness, line and grade. Uniform riprap requires placement in a more or less uniform pattern, requiring more hand or mechanical labor.

Riprap sizes can be designed by either the diameter or the weight of the stones. The weight of the stone is the more significant design parameter but it is simpler to specify the diameter of the stone. The correlation between stone size and weight is typically based upon an assumed specific weight of 165 lbs./ft3.

Since graded riprap consists of a variety of stone sizes, a method is needed to specify the size range of the mixture of stone. This is done by specifying a diameter of stone in the mixture for which some percentage, will be smaller. For example, d85 refers to a mixture of stones in which 85% of the stone would be smaller than the diameter specified. Most designs are based on d50. In other words, the design is based on the median size of stone in the mixture, where 50% will be larger than the d50 and 50% will be smaller. It is also necessary to give the upper and lower limits for the stone size too.

To ensure that stone of substantial weight is used when constructing riprap structures, specified weight and diameter ranges for individual stones and composition requirements should be followed. Such guidelines will help to prevent inadequate stone from being used in construction of the measures and will promote more consistent stone classification statewide. Table 3.23.1 notes these requirements.

Table 3.23.1 AASHTO RIPRAP GRADATION CLASSES

Riprap Class	Rock Size[1] feet (mm)		Rock Size[2] pounds (kg)		Percent of Riprap Smaller Than
A	1.30	(400)	200	(90)	100
	0.95	(290)	75	(35)	50
	0.40	(120)	5	(2)	10
B	1.80	(550)	500	(225)	100
	1.30	(400)	200	(90)	50
	0.40	(120)	5	(2)	10
C	2.25	(690)	1000	(455)	100
	1.80	(550)	500	(225)	50
	0.95	(290)	75	(35)	10
D	2.85	(870)	2000	(910)	100
	2.25	(690)	1000	(455)	50
	1.80	(550)	500	(225)	5
E	3.60	(1100)	4000	(1815)	100
	2.85	(870)	2000	(910)	50
	2.25	(690)	1000	(455)	5
F	4.50	(1370)	8000	(3630)	100
	3.60	(1100)	4000	(1815)	50
	2.85	(870)	2000	(910)	5

1 Assuming a specific gravity of 2.65.
2 Based on AASHTO gradations.

In practice though it is hard to acquire stones of the desired size. Quarries normally sell a narrower range of riprap sizes and in ranges incompatible with the above chart. The typical range of riprap available in West Virginia will be 4"-8" (gabion stone per DOH specifications), 6"-12", 10"-24", and 12"-36". Many times the contractor will crush their own stone on site.

If stone is crushed on site great care must be taken to produce stone sizes that mirror the requirements created by the designer and this specification. The most common problem is generating stone that is much too large and in a range of sizes that does not meet the gradation requirements.

Oversize stones, even in isolated spots, may cause riprap failure by precluding mutual support between individual stones, providing large voids that expose filter and bedding materials, and creating excessive local turbulence that removes smaller stones. Small amounts of oversize stone should be removed individually and replaced with proper size stones.

> When excessively large stone is used for channel lining there is an increased chance of erosion underneath the rock, which can cause a total failure of the channel. During higher flows the runoff must travel across the top of the riprap, not underneath. This point cannot be stressed enough. Bigger is not better when it comes to rock for channel lining.

Sequence of Construction

Since riprap is used where erosion potential is high, construction must be sequenced so that the riprap is put in place as quickly as possible.

Disturbance of areas where riprap is to be placed should be undertaken only when final preparation and placement of the riprap can follow immediately behind the initial disturbance. Where riprap is used for outlet protection, the riprap should be installed before the construction of the pipe or channel is competed

Design Criteria

Gradation-The riprap shall be composed of a well-graded mixture down to the l-inch size particle such that 50% of the mixture by weight shall be larger than the d50 size as determined from the design procedure. A well-graded mixture as used herein is defined as a mixture composed primarily of the larger stone sizes but with a sufficient mixture of other sizes to fill the progressively smaller voids between the stones. The diameter of the largest stone size in such a mixture shall be 1.5 times the d50 size.

The designer, after determining the riprap size that will be stable under the flow conditions, should consider that size to be a minimum size and then, based on riprap gradations actually available in the area, select the size or sizes that equal or exceed the minimum size. The possibility of damage by children shall be considered in selecting a riprap size, especially if there is nearby water or a gully in which to toss the stones.

Thickness-The minimum thickness of the riprap layer shall be 2 times the maximum stone diameter, but not less than 6 inches.

Quality of Stone-Stone for riprap shall consist of fieldstone or rough unhewn quarry stone of approximately rectangular shape. The stone shall be hard and angular and of such quality that it will not disintegrate on exposure to water or weathering and it shall be suitable in all respects for the purpose intended. The specific gravity of the individual stones shall be at least 2.5.

Rubble concrete may be used provided it has a density of at least 165 pounds per cubic foot, and other wise meets the requirements of this BMP. All rebar shall be removed flush with the surface of the concrete.

Filter Fabric Underlining--A lining of engineering filter fabric (geotextile) shall be placed between the riprap and the underlying soil surface to prevent soil movement into or through the riprap. GEOTEXTILE has the minimum physical properties of the filter fabric.

Filter fabric shall not be used on slopes greater than 1.5:1 as slippage may occur and should be used in conjunction with a layer of course aggregate (granular filter blanket is described below) when the riprap to be placed is Class C or larger.

Granular Filter--Although the filter cloth underlining or bedding is the preferred method of installation, a granular (stone) bedding is a viable option when the following relationship exists:

$$\frac{d_{15}\, filter}{d_{85} base} \langle\ 5 \ \langle\ \frac{d_{15}\, filter}{d_{15} base} \langle\ 40$$

and

$$\frac{d_{50}\, filter}{d_{50} base} \langle\ 40$$

In these relationships, filter refers to the overlying material and base refers to the underlying material. The relationships must hold between the filter material and the base material and between the riprap and the filter material. In some cases, more than one layer of filter material may be needed. Each layer of filter material should be approximately 6-inches thick.

Riprap at Outlets-

Design criteria for sizing the stone and determining the dimensions of riprap pads used at the outlet of drainage structure are contained in OUTLET PROTECTION. A filter fabric underlining is required for riprap used as outlet protection.

Riprap for Channel Stabilization

Riprap for channel stabilization shall be designed to be stable for the condition of bankfull flow in the reach of channel being stabilized. This method establishes the stability of the rock material relative to the forces exerted upon it. (see Figure 3.21.7)

Riprap shall extend up the banks of the channel to a height equal to the maximum depth of flow or to a point where vegetation can be established to adequately protect the channel.

The riprap size to be used in a channel bend shall extend upstream from the point of curvature and downstream from the bottom of the channel to a minimum depth equal to the thickness of the blanket and shall extend across the bottom of the channel the same distance.

Freeboard and Height of Bank

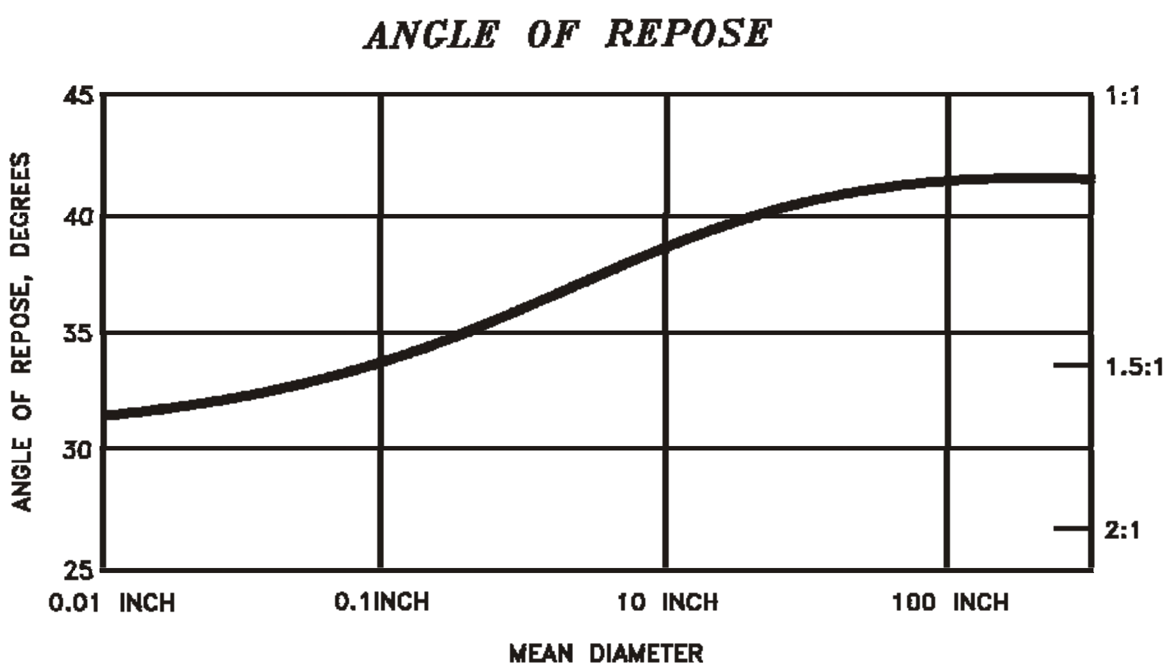
For riprapped and other lined channels, the height of channel lining above the water surface should be based on the size of the channel, the flow velocity, the curvature, inflows, wind action, flow regulation, etc. This manual does not provide the design for riprap revetment. The Federal Highway Administration in HEC-11 provides the necessary information to design riprap streambank protection.

The height of the bank above the water surface varies in a similar manner, depending on the above factors plus the type of soil.

Riprap for Slope Stabilization

Riprap for slope stabilization shall be designed so that the natural angle of repose of the stone mixture is greater than the gradient of the slope being stabilized (see Figure 3.23.1).

Figure 3.23.1 ANGLE OF REPOSE



Construction Specifications

Subgrade Preparation: The subgrade for the riprap or filter shall be prepared to the required lines and grades. Any fill required in the subgrade shall be compacted to a density approximately that of the surrounding undisturbed material. Brush, trees, stumps and other objectionable material shall be removed.

Filter Fabric or Granular Filter: Placement of the filter fabric should be done immediately after slope preparation. For granular filters, the stone should be spread in a uniform layer to the specified depth, normally 6 inches. Where more than one- layer of filter material is used, the layer should be spread so that there is minimal mixing of the layers.

When installing geotextile filter cloths, the cloth should be placed directly on the prepared slope. The edges of the sheets should overlap by at least 12 inches. Anchor pins, 15 inches long, should be spaced every 3 feet along the overlap. The upper and lower ends of the cloth should be buried at least 12 inches. Care should be taken not to damage the cloth when placing the riprap. If damage occurs, that sheet should be removed and replaced. For large stone (Class C or greater), a 6-inch layer of granular filter will be necessary to prevent damage to the cloth.

Stone Placement: Placement of riprap should follow immediately after placement of the filter. The riprap should be placed so that it produces a dense well-graded mass of stone with a minimum of voids. The desired distribution of stones throughout the mass may be obtained by selective loading at the quarry, controlled dumping of successive loads during final placing, or by a combination of these methods.

The riprap should be placed to its full thickness in one operation. The riprap should not be placed in layers. The riprap should not be placed by dumping into chutes or similar methods that are likely to cause segregation of the various stone sizes.

Blend the stone surface smoothly with the surrounding area, allowing no protrusions, overfall or in the case of channels so the stone does not form a dam to incoming runoff.

Care should also be taken not to dislodge the underlying material when placing the stones.

The finished slope must be free of pockets of small stone or clusters of large stones.

Hand placing may be necessary to achieve the required grades and a good distribution of stone sizes. Final thickness of the riprap blanket should be within plus or minus 1/4 of the specified thickness.

Common Installation Problems

- Channel not excavated deep enough to accept the design thickness of the stone. Riprap blocks channel, resulting in erosion along edges.
- Stone too large resulting in water eroding underneath and undermining the stone.
- Slope too steep: Results in stone displacement. Do not use riprap as a retaining wall.
- Foundation not properly smoothed for filter placement: Results in damage to filter.
- Filter omitted or damaged: Results in piping or slumping.
- Riprap not properly graded: Results in stone movement and undermining and erosion of foundation.
- Foundation toe not properly reinforced: Results in undercut riprap slope or slumping.
- Fill slopes not properly compacted before placing riprap: Results in stone displacement.

Maintenance

Once a riprap installation has been completed, it should require very little maintenance. It should, however, be inspected periodically to determine if high flows have caused scour beneath the riprap or filter fabric or dislodged any of the stone. Care must be taken to properly control sediment-laden construction runoff that may drain to the point of the new installation. If repairs are needed, they should be accomplished immediately.

3.24 - GEOTEXTILES

Introduction

Geotextiles are any permeable textile fabric used to increase soil stability, provide erosion control or aid in drainage. Geotextiles are usually made from a synthetic polymer such as polypropylene, polyester, polyethylenes and polyamides. Geotextiles can be woven, knitted or non-woven.

Conditions Where Practice Applies

Geotextiles come in a tremendous variety and are used in many situations on a construction site. Geotextiles usage falls into four broad categories, three of which are important to sediment and erosion control. These three categories are separation, reinforcement and filtration. The fourth type is as an impervious barrier. Each subcategory of geotextile is designed to perform a specific function. To select the right product, it is important to understand the product's functions and the physical characteristics needed to meet those functions.

Separation- It is sometimes necessary to maintain a physical separation between two dissimilar materials to maximize the physical attributes of each of those materials. For example, in drainage systems, it is necessary to prevent fine soils from filling the voids in a rock base; otherwise, the drainage system becomes clogged and ineffective over time. Yet, it is important to allow water to pass between the soil and the drainage system.

In other applications, it is desirable to prevent any water from coming into contact with the soil, so an impervious separation surface is required. The selection of an appropriate product to achieve a physical separation is determined, therefore, by the desired outcome.

Reinforcement- The physical characteristics of soils, especially on slopes resulting from cuts and fill activities, can create unstable conditions. Geotextiles can help strengthen the soil face and increase the soil's ability to remain in place. Slopes can be stabilized either temporarily or permanently, slowing or preventing creep or slips. Also, geotextiles can be used either to prevent water from permeating a slope or to control the amount of infiltration that occurs during rainfall.

Geotextiles are especially useful in reinforcing inadequate subsoil when building roads, parking areas and paths. When soil conditions are weak, adding an appropriate geotextile can create a three-dimensional surface that will withstand heavier vehicles.

Filtration- The filtration aspect of geotextiles was understood early on by the originator of silt fence as a sediment control device. Where the flows are minimal, a geotextile can be placed across the contour to create a dam and settle out the suspended solids contained in the runoff. While not technically a filter, the geotextile's openings serve as the outlet necessary to pass water through the dam and filter out soil particles that are in suspension. Finer particles can pass through the fabric, so the size of the particles, the flow rate of the water and the physical location of the filter will determine the type of fabric that is appropriate.

For most geotextile applications relating to the construction industry, the American Association of State Highway and Transportation Officials (AASHTO) has developed guidelines. These guidelines provide classifications that are primarily based on the mechanical stresses the geotextile would be subjected to during installation. Typically, the stresses borne by geotextiles are highest during the installation of the fabric and placement of the cover material. The charts in this section are based on these AASHTO guidelines but come from the city of Seattle.

Geotextiles are either woven or non-woven.

Woven- Typically, woven fabric provides higher strengths. Weaving two or more strands of synthetic yarn at right angles produces woven fabrics. The yarn typically comes in two shapes: round and flat. Flat, also called slit film, is used where high strength is required but filtration is not. Round, or monofilament fabric, provides both high strength and filtration.

Woven stabilization fabrics provide the strength and separation needed for paved or unpaved road applications. High tensile strength and low elongation reduces rutting in both paved and unpaved surfaces. The fabrics separate the base course while reinforcing the adjacent soft soil.

Woven fabric is also used for silt fence and super silt fence. Geotextiles used for these practices must have the porosity and strength to withstand and pass through water as well as ultraviolet light inhibitors to protect it from the sun.

Non-woven- Non-woven fabric resembles felt and can provide planar water flow when used in subsurface drains, asphalt pavement overlays and erosion control. Higher weight non-woven fabric can be also used for separation under aggregate.

Non-woven fabric, slit films and combination fabrics have little open area, and often trap soil particles with the thickness of the fabric, clogging the geotextile.

Care must be taken to choose the appropriate fabric for the existing conditions, and, as with all commercial products, follow the manufacturer's recommendations.

Other design considerations are the porosity of the fabric, permitivity, tensile strength, elongation, Mullen burst, puncture strength, AOS (average opening size), seam strength and resistance to ultraviolet radiation. Each use will have a unique set of requirements that need to be taken into consideration.

ASSHTO M288 Classifications

M288-96 is based on geotextile survivability from installation stresses. Selection of the geotextile is based on knowledge of the anticipated exposure to installation stresses. M288-96 covers six geotextile applications: subsurface drainage, separation, stabilization, permanent erosion control, temporary silt fences and paving fabrics.

In M288-92, geotextile survivability was divided into classes A and B. Class A was used where installation stresses determined by aggregate shape, trench depth, and the size and height of an armor stone drop were more severe than in Class B installations. There are no definitive measurements set for differentiating between severe and less severe installation stresses.

In M288-96, the general strength requirements for the subsurface drainage, separation, stabilization and permanent erosion control applications are broken into three classes of geotextiles. Class 1 represents the most robust and Class 3 the least. Within each survivability class, the strength requirements are established based on elongation at break in the grab strength test. The highest strength requirement is for materials that break at less than 50 percent elongation (typically woven) and the least for those that break at greater than 50 percent elongation (typically unwoven). The requirements for the silt-fence applications are based on supported or unsupported fences. Paving fabrics are limited to fabrics with elongation at break of greater than 50 percent.

AASHTO Specification M288-96 for geotextiles is published in the two volume Standard Specifications for Transportation Materials and Methods of Sampling and Testing, 18th Ed.

Design Considerations

In order to choose the appropriate geotextile, a proper evaluation of the proposed use, material specification and installation procedure is required. Since using geotextiles for stabilization of soils involves four basic functions, reinforcement, separation, filtration and drainage, it is important to be familiar with both the site conditions where the fabric will be installed and the various properties of geotextiles. The local soil characteristics and groundwater are two of the more important considerations to be considered. And since fabric strength calculations are based primarily on installation stresses, the type and size of the aggregate to be used is also important. Therefore there are a number of factors that will need to be considered when specifying fabrics.

Geotextile and thread for sewing

The material shall be a geotextile consisting only of long chain polymeric fibers or yarns formed into a stable network such that the fibers or yarns retain their position relative to each other during handling, placement and design service life. At least 95 percent by weight of the material shall be polyolefins or polyesters. The material shall be free from defects or tears. The geotextile shall also be free of any treatment or coating which might adversely alter its hydraulic or physical properties after installation. The geotextile shall conform to the properties as indicated in Tables 3.24.2 through 3.24.7 for each use specified.

Thread used for sewing shall consist of high strength polypropylene, polyester or polyamide. Nylon threads will not be allowed. The thread used to sew permanent erosion control geotextiles shall be resistant to ultraviolet radiation. The thread shall be of contrasting color to that of the geotextile itself.

The geotextile uses included in this section and their associated tables of properties are as follows:

Construction Specifications

Since the greatest stresses occur during installation of the geotextile and overlying material, the following conditions should be met:

1. Ensure the ground surface is clear of stones, roots, and debris.
2. Provide a surface to lay the fabric on that is as smooth as possible and free of humps or holes.
3. Ensure that the geotextile is in intimate contact with the soil.
4. Carefully place the stone on top of the fabric to prevent damage to the geotextile.

When the geotextile is used between two layers of aggregate, there is a greater chance of stress and damage, so it is recommended to use a higher strength fabric.

Maintenance

Once the installation of the filter fabric system has been completed, it should require very little maintenance. It should, however, be inspected periodically to determine if high flows have caused scour beneath the fabric or dislodged any of the stone. If repairs are needed, they should be completed immediately.

3.25 - VEGETATIVE BUFFER STRIP

Introduction

A vegetative buffer strip is the maintenance of existing or planted vegetation adjacent to streams, wetlands, or other areas of significant natural resource value for the purpose of stormwater pollutant removal. The term vegetative buffer is typically used to describe the preservation of existing vegetation without specific regard to pollutant removal efficiency, whereas the term filter strip is generally used when vegetation (usually grass) is specifically designed to achieve pollutant removal goals.

However, since the terms are often used interchangeably and provide essentially the same sediment removal function, both will be considered as one practice. However, developers should not destroy native vegetation to plant a grass strip for this practice. The protection of vegetation along streams also stabilizes stream banks, moderates water temperatures, and provides food sources and habitat for fish and wildlife.

Conditions Where Practice Applies

This practice may be utilized on construction sites with good existing vegetative cover or where good vegetative cover can be established prior to site disturbance. Vegetative buffers are most useful adjacent to streams, wetlands or other water bodies, although they may also be used as a non-structural practice on upland sites. To function effectively, runoff to and flow across the buffer area must not be concentrated or channelized. The use of level spreaders or other energy-dissipating devices may be utilized in some circumstances to promote overland (sheet) flow across the buffer. Buffers are probably more effective as filters during the growing season, when the density of vegetation is generally higher.

Approved Practices

1. Retaining existing native vegetation adjacent to the area to be protected. The width needed is dependent on site conditions (see design criteria).
2. Establishing vegetation by planting or natural regeneration adjacent to the area to be protected. The width and vegetation type is dependent on site conditions (see design criteria). Planting and/or natural regeneration can be used in conjunction with preserving existing vegetation if needed to achieve desired buffer width. All vegetation must be established prior to site disturbance.
3. Stormwater runoff to the buffer area must be in the form of overland (sheet) flow. If treatment occurs outside of the buffer, stabilized outlets may be located within the buffer area. The use of energy-dissipating devices may be used in some circumstances to promote overland flow within the buffer.
4. No disturbance is permitted within a vegetative buffer, except for necessary infrastructure improvements (utility lines, road crossings, etc.), or unless planting is required.

Design Criteria

It is recommended that designers use site-specific criteria to determine the appropriate buffer width, if possible. Factors to consider include soil type, slope, size distribution of the sediment, contributing drainage area, vegetation present and other natural resource considerations, such as fish and wildlife habitat value. Because vegetative buffers along streams provide many environmental benefits, designers are encouraged to provide as large a buffer area as practicable for the project. If there is insufficient buffer width, the buffer available may be used in conjunction with other BMPs such as silt fence or super silt fence.

1. The minimum vegetative buffer width shall be 100 feet, unless specific design information can be provided to justify a smaller buffer width. For slopes greater than 10 percent, the minimum distance is 250 feet. Smaller buffers may be used in conjunction with other BMPs.
2. The width of the contributing area to the vegetative buffer should not exceed 300 feet, unless energy-dissipating devices are provided. Buffers may be used as a supplement to other BMPs for larger drainage areas.
3. Good (minimum of 80 percent) vegetative cover must be present in the proposed buffer area.

Construction Specifications

1. The buffer boundary shall be clearly marked onsite prior to site clearing or grading.
2. No soil disturbances, equipment storage or construction traffic shall occur within the buffer area.

Maintenance

Inspect at a minimum once every seven calendar days and within 24 hours after any storm event greater than 0.5 inches per 24 hour period. Heavy deposits of sediment should be removed (with minimal disturbance to the buffer vegetation). If erosion gullies form, the use of an energy- dissipating device or an alternative BMP is needed.

3.27 - SILT FENCE

Introduction

A temporary sediment barrier consisting of a synthetic filter fabric stretched across and attached to supporting posts and entrenched. Used to intercept and detain small amounts of sediment from disturbed areas during construction operations in order to prevent sediment from leaving the site.

No sediment control device is misused more than silt fence (with the possible exception of hay bales). Much of the silt fence used in West Virginia is not installed properly. The device does not work if:

1. not entrenched a minimum of 4 inches.
2. not placed on the contour-perpendicular to the flow of the water.
3. installed in areas of concentrated flows.
4. installed to contain sediment from too large of an area.
5. little or no maintenance is performed on it.

Silt fence does not actually filter sediment from muddy water. In field conditions silt fence acts as a barrier to the flow of water, like a dam, reducing the energy of the water, which causes the suspended material to settle out. It is because of the low permeability of the fabric that silt fence is limited to small drainage areas

Installing silt fence is very labor intensive. It is usually installed by hand and accumulated sediment must be removed and disposed of by hand. In many scenarios, installing a diversion and sediment trap would be more effective and less expensive than using silt fence. In addition, the NPDES permit requires that a sediment trap or basin be installed whenever possible.

Conditions Where Practice Applies

1. Below disturbed areas where erosion would occur in the form of sheet and small rill erosion.
2. Where the size of the drainage area is no more than one-quarter acre per 100 feet of silt fence length; the maximum gradient above the barrier should be less than 2:1.
3. Silt fence will not be used in areas where rock or some other hard surface prevents the full and uniform anchoring of the barrier.
4. Silt fence should NEVER be installed in streams or swales or in any area where there is a reasonable chance of concentrated flow. In areas where concentrated flows can be expected, use diversions and sediment traps and /or sediment basins. In ditches or swales rock check dams should be used in place of silt fence.

Design Criteria

1. No formal design is required. An effort should be made to locate silt fence at least 5 feet to 10 feet beyond the toe of slope.

2. Silt fence should be limited to situations in which only sheet is expected.
3. Silt fence should be installed prior to major soil disturbance.
4. Silt fence should be placed across the bottom of a slope along a line of uniform elevation (ALWAYS perpendicular to the direction of flow).
5. Any time a section of silt fence is knocked down by concentrated flows the silt fence will be replaced with a diversion and sediment trap or super silt fence.

Construction Specifications

Materials

1. Synthetic filter fabric shall be a pervious sheet of propylene, nylon, polyester or ethylene yarn and shall be certified by the manufacturer or supplier as conforming to the requirements noted in WV DOT DOH Specifications or the GEOTEXTILE section.
2. Synthetic filter fabric shall contain ultraviolet ray inhibitors and stabilizers to provide a minimum of 6 months expected usable construction life at a temperature range of 0 to 120 degrees Fahrenheit.
3. If wooden stakes are utilized for silt fence construction, they must be a minimum of 2" x 2" when oak is used and 2" x 4" when pine is used. Wooden stakes should have a minimum length of 5 feet.
4. If steel posts (standard "U" or "T" section) are utilized for silt fence construction, they must have a minimum weight of 1.33 pounds per linear foot and should have a minimum length of 5 feet.

Installation

1. The height of a silt fence shall be a minimum of 16 inches above the original ground surface and shall not exceed 34 inches above ground elevation.
2. The filter fabric shall be purchased in a continuous roll cut to the length of the barrier to avoid the use of joints. When joints are unavoidable, the silt fence shall be spliced together only at a support post, by twisting the last post of each run around the other, and securely sealed. (see drawing)
3. A trench shall be excavated approximately 4 inches wide and 4 inches deep on the upslope side of the proposed location of the measure.
4. The filter fabric shall be fastened securely to the upslope side of the posts using one inch long (minimum) heavy-duty wire staples or tie wires and eight inches of the fabric shall be extended into the trench. The fabric shall not be stapled to existing trees. The most common type of silt fence has the stakes attached to the fabric at the factory.
5. The 4-inch by 4-inch trench shall be backfilled and the soil compacted over the filter fabric.

6. Silt fence shall be removed when it has served its useful purpose, but not before the upslope area has been permanently stabilized.
7. Turn the end of a run of Silt Fence slightly uphill to prevent runoff from going around the end.

Maintenance

1. Silt fences shall be inspected immediately after each rainfall of 0.5 inch or greater and at least daily during prolonged rainfall or once a week. Any required repairs or maintenance shall be made immediately.
2. Close attention shall be paid to the repair of damaged silt fence resulting from end runs and undercutting. If the fence is not installed on the contour (perpendicular to the flow of the water) both of these conditions can occur.
3. Should the fabric on a silt fence decompose or become ineffective prior to the end of the expected usable life and the barrier still is necessary, the fabric shall be replaced promptly.
4. Sediment deposits should be removed after each storm event. They must be removed when deposits reach approximately one-half the height of the barrier.
5. If any section of silt fence is knocked down during a rain event (because it was installed in an area of concentrated flow) then other measures such as a sediment trap and diversion or super silt fence must be installed.

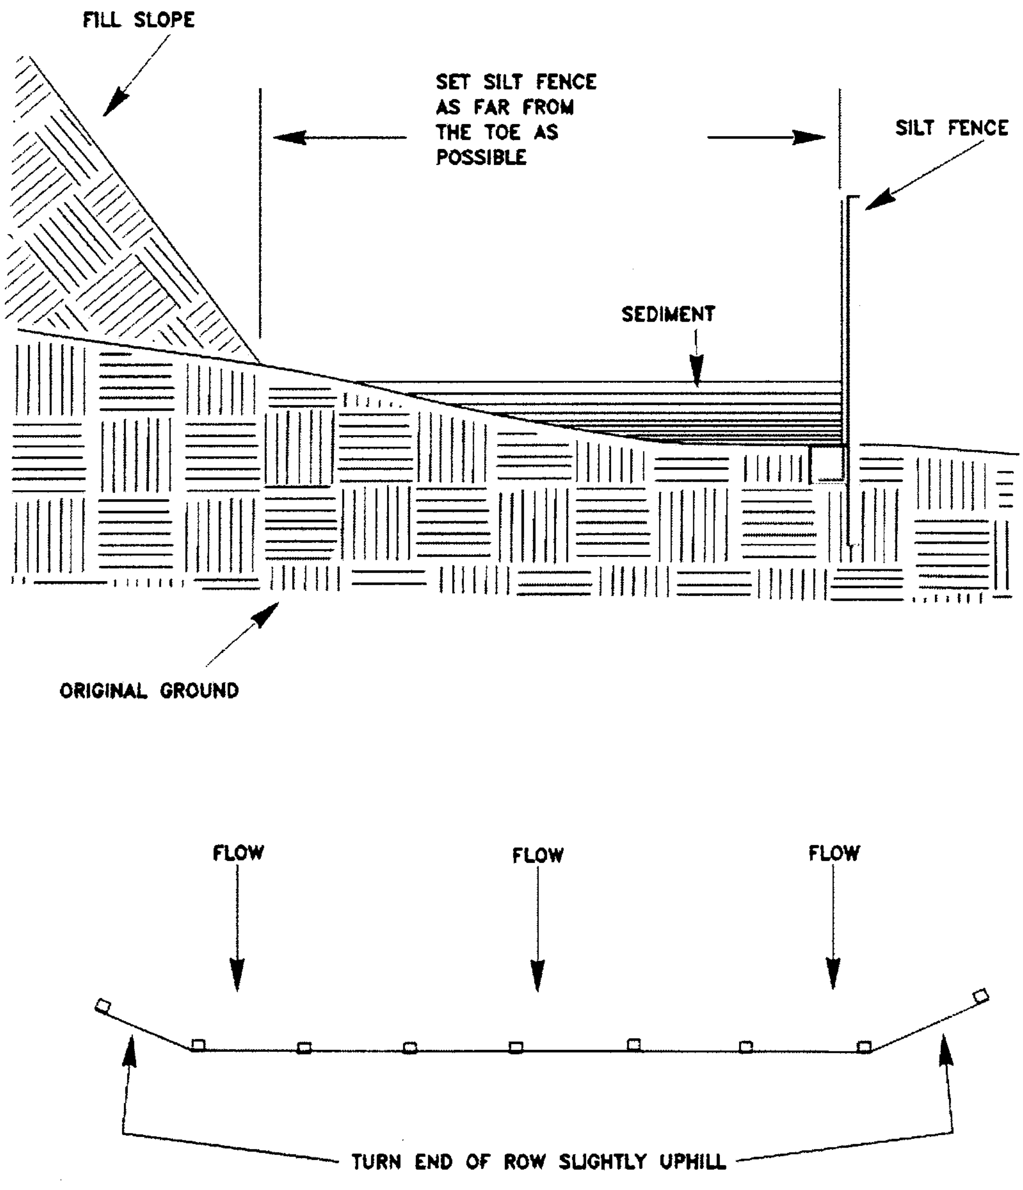
FIGURE 3.27.1

PLACEMENT OF SILT FENCE



3.28 - SUPER SILT FENCE

Definition

A super silt fence is a temporary barrier of geotextile fabric over chain link fence. It is used to intercept sediment-laden runoff from areas that are too large for regular silt fence. Super silt fence can be a replacement for sediment traps in certain instances.

Conditions Where Practice Applies

To reduce runoff velocity and allow sediment to become trapped behind or up slope of the super silt fence. Limits imposed by ultraviolet light stability of the fabric will dictate the maximum period that the silt fence may be used.

Super silt fence provides a barrier that can collect and hold debris and soil, preventing the material from entering critical areas, streams, streets, etc.

Super silt fence can be used where the installation of a DIVERSION and/or SEDIMENT TRAP would destroy sensitive areas, woods, wetlands, riparian zones, etc. This practice is very useful below bridge piers and abutments along streams and rivers.

Design Criteria

Design computations are not needed.

- Slope length above the fence should not exceed 400 ft in steep terrain. In flatter terrain the slope length can be extended with consultation with DWWM.
- Where ends of the geotextile fabric come together, the ends shall be overlapped, folded, and stapled to prevent sediment bypass.
- The backfilled trench shall be compacted.
- Only woven geotextile fabric will be used.
- Super silt fence should be placed as close to the contour as possible. No section of silt fence should exceed a grade of 5% for more than a distance of 20 feet.

Construction Specifications

Fencing shall be 48 inches in height and constructed in accordance with the WV DOT, Division of Highways specification for Chain Link Fencing. The DOT specification for a 6-foot fence shall be used, substituting 48-inch fabric and 6 foot length posts. The filter fabric shall meet the requirements of 715.11.5/AASHTO M 288, Section 7, Class 1.

1. The poles do not need to set in concrete.
2. Chain link fence shall be fastened securely to the fence posts with wire ties or staples.
3. Geotextile fabric shall be fastened securely to the chain link fence with ties spaced every 24” at the top and mid section.

4. Geotextile fabric shall be embedded a minimum of 12” into the ground.
5. When two sections of geotextile fabric adjoin each other, they shall be overlapped by 6” and folded.
6. Metal posts as specified by DOH can be replaced by pressure-treated 4” x 4” posts.

Maintenance

Silt fences shall be inspected immediately after each rainfall, daily during prolonged rainfall and once a week during dry periods. Any required repairs shall be made immediately.

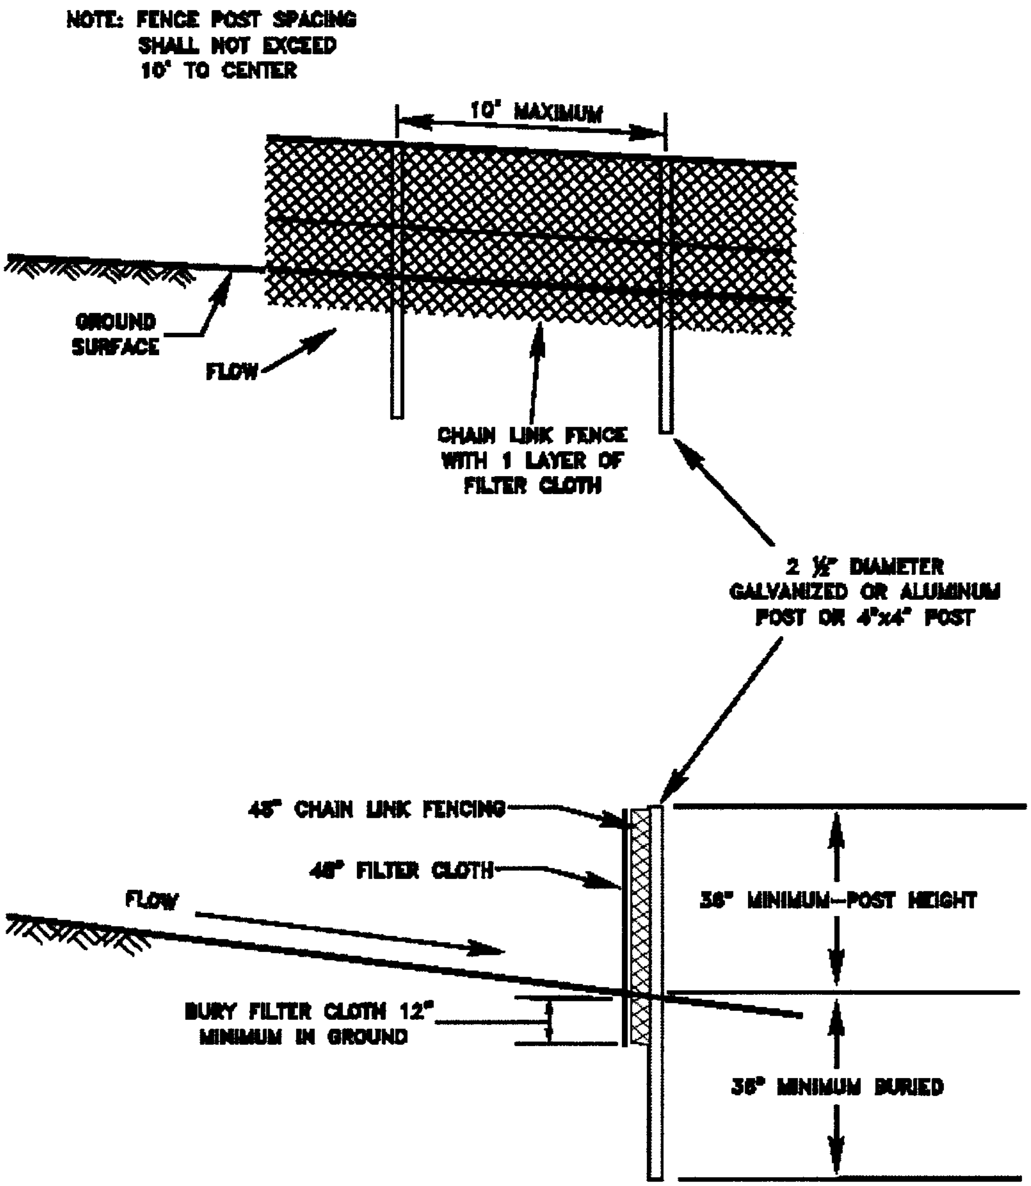
Close attention shall be paid to the repair of damaged silt fence resulting from end runs and undercutting. If the fence is not installed perpendicular to the flow of the water, these conditions will occur.

Should the fabric on a silt fence decompose or become ineffective, the fabric shall be promptly replaced.

Sediment deposits shall be removed when deposits reach approximately one-half the height of the barrier.

FIGURE 3.28.1

SUPER SILT FENCE



3.29 - SEDIMENT TRAP

Introduction

A temporary ponding area formed by constructing an embankment or excavation and embankment that will trap the flow of sediment-laden runoff. Sediment traps have a properly stabilized outlet/weir or riser and pipe to detain sediment-laden runoff from small disturbed areas of five acres or less. Outlets must be designed to extend the detention time and allow the majority of the sediment to settle out.

This practice is one of the most efficient and cost effective methods of sediment control. When possible, sediment traps should be constructed as a first step in any land-disturbing activity. As with any sediment control device the sediment trap should not be removed until the contributing drainage area is stabilized.

Sediment traps can be highly variable in design and configuration. Almost every site has someplace to install one or more sediment traps. However it may not be evident during the design stages exactly where a trap would fit best. Once clearing, grubbing and site excavation begins, logical locations usually appear. It may be necessary to state in the plan that a particular trap will be field located to fit the site conditions.

Conditions Where Practice Applies

1. Sediment traps are appropriate for drainage areas of 5 acre or less. For drainage areas greater than 5 acres use a Sediment Basin (See SEDIMENT BASIN)
2. At the outlet of ditches and other perimeter controls installed during the first stage of construction.
3. At the outlet of any structure which concentrates sediment-laden runoff i.e. at the discharge point of diversions, channels, slope drains, or other runoff conveyances.
4. At the inlet to culverts underneath roads
5. Above a storm water inlet that may receive sediment-laden runoff.

Design Considerations

The following items should be addressed where applicable when planning and designing a sediment trap.

1. The sediment trap should have a storage volume of 3600 cubic feet per acre of drainage area. Half of the volume must be in the form of a permanent pool or wet storage to provide a stable-settling medium. The remaining half must be in the form of a drawdown or dry storage, which provides extended settling time. The volume of the wet storage should be measured from the low point of the excavated area to the base of the outlet structure or the invert of the first perforation in the riser. The volume of the dry storage should be measured from the base of the outlet to the crest of the outlet (overflow mechanism) or from the lowest perforation in the riser to the top of riser.

2. The embankment should not exceed 5 feet in height. The recommended minimum width at the top of the embankment should be equal to the height of the embankment.
3. The recommended inside embankment should be a 2:1 slope or flatter. The recommended outside embankment should be a 3:1 slope or flatter.
4. The width of the outlet channel weir must not be less than 4 ft. wide or, 2 feet plus 2 feet for each acre of drainage i.e. 12 ft wide for 5 acres. The top of the outlet channel must be at least 1 ft. below the top of embankment to provide a minimum of 1 ft. of free board.
5. The trap should be accessible for ease of maintenance.
6. Sediment must be removed from the trap when the trap's wet storage volume is reduced by one-half. Designers should designate a clean-out elevation.
7. The trap should provide a storage area which is at least twice as long as it is wide; with the outlet position at the furthest possible point from the inlet (measured from point of maximum runoff introduction to the outlet). Baffling can be used if this 2 to 1 ratio cannot be met.
8. All earthen side slopes should be a minimum of 2:1.
9. Seed and mulch all disturbed areas associated with the installation of the sediment trap immediately.
10. The sediment trap must have a stabilized outlet, either a weir or pipe and riser. Outlet protection must be provided.
11. Fill material around the pipe spillway where it goes through the embankment shall be hand compacted in 4" to 6" layers. A minimum of 2' of hand compacted backfill should be placed over the barrel before construction traffic is allowed to cross.
12. The riser shall be anchored with either a concrete base or steel plate bases sufficient to prevent flotation. For concrete bases, the depth shall be 12" with the riser buried 9". A 1/4" minimum thickness steel plate shall be attached to the riser by a continuous weld around the bottom to form a watertight connection and then place 2" of stone, gravel or tamped earth on the plate.
13. Anti-seep collars are required. Install based on manufacturers' instructions.
14. It is recommended that a concentric trash rack and anti-vortex device be installed on all risers.
15. If a stone outlet is used for the sediment trap, it should consist of a stone section of the embankment located at the low point in the basin. The stone outlet should be a combination of coarse aggregate and rock riprap. The stone section of the embankment should be separated from the earthen embankment by a geotextile. Riprap should consist of well-graded stone 2 inches to 8 inches in diameter. Coarse aggregate is washed gravel ½ to 1½ inches in diameter. The course aggregate is placed 1 ft thick on the upstream face of he stone outlet. The crest of the stone outlet must be at least 1.0 foot below the top of the embankment to ensure that the flow will travel over the stone and not the embankment. The outlet should be configured as noted in the drawing.
16. The outlet pipe and riser should be sized as noted in the table below. The riser pipe should be weighted to prevent flotation. An anti-seep collar is

recommended around the outlet pipe as well as a concentric trash rack and anti-vortex device.

17. If there is any chance that a failure of the structure could damage any downstream property, the designer should look into creating a spillway or combination of spillways commensurate with the level risk should the structure fail.
18. The inlet to the sediment trap should be excavated to provide for a gentle transition from the diversion ditch to the bottom of the trap to protect from head cutting and scour.
19. The maximum depth of excavation within the wet storage area should be 4 feet to facilitate clean-out and for site safety considerations

Table 3.29.1 PIPE OUTLET DIAMETER SELECTION

Maximum Drainage Area (Acres)	Minimum Size Outlet Diameter (inches)	Minimum Size Riser Diameter (inches)
1	12	15
2	15	18
3	18	21
4	21	24
5	21	27

Volume calculation

For an embankment sediment trap, the **wet storage volume** may be approximated as follows:

$$V_1 = 0.85 \times A_1 \times D_1$$

where,

V_1 = the wet storage volume in cubic feet

A_1 = the surface area of the flooded area at the base of the stone outlet, in square feet

D_1 = the maximum depth in feet, measured from the low point in the trap to the base of the stone outlet

The **dry storage volume** may be approximated as follows:

$$V_2 = \frac{A_1 \times D_2}{2} \times D_2$$

where,

V_2 = the dry storage area of the flooded area at the base of the stone outlet in square feet

A_1 = the surface area of the flooded area at the base of the stone outlet, in square feet

A_2 = the surface area of the flooded area at the crest of the stone outlet (overflow mechanism), in square feet

D_2 = the depth in feet, measured from the base of the stone outlet to the crest of the stone outlet

Plan Preparation

During the preparation of the sediment control plan for the Construction Storm Water General Permit prepare a table detailing the key design aspects of each sediment trap planned and designed.

Construction Specifications

1. The area under the embankment should be cleared, grubbed, and stripped of any vegetation and root mat.
2. Fill material for the embankment should be free of roots or other woody vegetation, organic material, large stones, and other objectionable material. The embankment should be compacted in 6-inch layers by traversing with construction equipment.
3. The earthen embankment should be seeded and mulched to provide temporary or permanent vegetation immediately after installation.
4. Construction operations should be carried out in such a manner that erosion and water pollution are minimized.
5. Sediment Traps should not be removed until the contributing disturbed area has been stabilized.
6. Material removed from the excavated section of the sediment trap should be placed in an area and stored in a manner that will not create an erosion problem.

7. The outlet pipe and riser connections should be watertight.
8. Above the wet storage elevation, the riser should be perforated with 1-inch diameter holes spaced 8 inches vertically and 10 inches to 12 inches horizontally.

Maintenance

Sediment should be removed from the trap before the traps wet storage volume is reduced by one-half. Sediment removed from the trap should be stored or disposed in a manner in which will not create an erosion or sediment problem.

Filter stone should be regularly checked to ensure that filtration performance is maintained. Stone choked with sediment should be removed and cleaned or replaced

The structure shall be checked every 7 days and /or after 0.5 inch of rain to ensure that it is structurally sound and has not been damaged.

3.30 - SEDIMENT BASIN

Introduction

A temporary structure consisting of an earthen embankment, or embankment and excavated area, located in a suitable area to capture sediment laden runoff from a construction site. A sediment basin reduces the energy of the water through extended detention (48 to 72 hours) to settle out the majority of the suspended solids and sediment and prevent sedimentation in waterways, culverts, streams and rivers. Sediment basins have both wet and dry storage space to enhance the trapping efficiency and are appropriate in drainage areas of 5 acres and greater. For drainage areas of less than 5 acres see the standard for SEDIMENT TRAP.

Basins are dewatered through a riser and drainage hole(s) or a skimmer system. Because sediment basins are located in larger drainage areas and the failure of a structure could cause significant damage or death they need to be designed to safely pass the peak discharge from a 25-year/24-hour storm with one foot of freeboard.

They are temporary structures but are often modified to function as a permanent structure after construction is completed.

Properly designed and maintained sediment basins can be very effective in preventing sedimentation of downstream areas. Coarse and medium size particles and associated pollutants will settle out in the basin. Suspended solids and attached nutrients may break down before proceeding downstream.

The effectiveness of sediment trapping structures is greatly improved by use of aggressive erosion control (especially in diversions leading to the basin) in the contributing drainage.

Conditions Where Practice Applies

Sediment basins are needed where drainage areas exceed the design criteria of other measures. Sediment traps are allowed in watersheds of 5 acres and less. General criteria for installation of a sediment basin are as follows:

1. Keep the drainage area less than 100 acres;
2. Ensure that basin location provides a convenient concentration point for sediment-laden flows from the area served;
3. Ensure that basin location allows access for sediment removal and proper disposal under all weather conditions;
4. Keep the basin life limited to 1 year, unless it is designed as a permanent structure;
5. Should not locate sediment basins in intermittent or perennial streams;
6. Sediment basins must dewater in 2 to 3 days;

7. Skimmers can be used to enhance trapping efficiency, however perforated risers are also acceptable;
8. Install basins where they will not interfere with construction activities.

Planning Considerations

Select key locations for sediment basins during initial site evaluation. Install basins before any site grading takes place within the drainage area. Select basin sites to capture sediment from all areas that are not treated adequately by other sediment trapping devices. Always consider access for cleanout and disposal of the trapped sediment. Locations where a pond can be formed by constructing a low dam across a natural swale are generally preferred to sites that require excavation. If practical, divert sediment-free runoff away from the basin. This will help reduce the size of the structure and decrease the amount of erosion on the construction site.

Sediment trapping efficiency is primarily a function of sediment particle size, the ratio of basin surface area to inflow rate and the ability of the basin to reduce the energy of the water. Therefore, design the basin to have a large surface area for its volume and the maximum amount of detention time.

The performance of sediment trapping structure depends on several factors:

1. The size and shape of the basin
2. The soil properties
3. Runoff volume and flow rates
4. Water chemistry
5. Outlet type
6. Temperature

Structures larger than 25 feet in height from the downstream toe to highest point along the crest of the dam and have a maximum storage capacity of 15 acre-feet of water or more are subject to the West Virginia Dam Safety Act.

By virtue of their potential to impound and release large volumes of water, the design of sediment basins is required to be completed by professionals trained in the design of impounding structures, and in accordance with good engineering practices. Sediment basins with an expected life greater than 1 year should be designed as permanent structures. Permanent ponds must be designed and certified by a Professional Engineer. Permanent pond design is beyond the scope of this manual. For further information the USDA Soil Conservation Service Practice Standard Ponds Code No. 378 is an excellent source of information and provides criteria for design of permanent ponds.

In larger drainages or when the discharge is to a Tier 2.5 or 3 Stream, an alternative design procedure that more accurately defines the specific hydrology, sediment loading, hydraulics of the site, and the control measures in use be utilized to perform design calculations. The design criterion in this manual does not generate hydrographs, estimate erosion and delivery rates, provide hydraulic routing or predict sediment capture efficiency. More rigorous and accurate design considerations that are more site specific than those in this manual, are acceptable and encouraged with any size basin.

The design and construction of sediment basins shall comply with all state and local laws, ordinances, permit requirements, rules and regulations. Basins shall be constructed according to the approved Storm Water Pollution Prevention Plan (SWPPP) unless modified a engineering design professional.

Sediment basins must dewater in 2 to 3 days. Skimmers are the preferred dewatering device, however perforated risers are also acceptable.

Sediment basins should be provided with an emergency spillway constructed in original ground with a minimum bottom width of 8'. Energy dissipaters must be included at all inlet and outfalls to prevent scouring.

Sediment basins are attractive to children and can be very dangerous. Local ordinances regarding health and safety must be adhered to. If fencing of the basin is required, the type of fence and its location should be shown in the SWPPP and in the construction specifications.

Limit the contributing area to the sediment basin to only the runoff from the disturbed soil areas. Use temporary water controls to divert runoff from undisturbed areas away from the sediment basin.

The basin should be located: (1) by excavating a suitable area or where a low embankment can be constructed across a swale, (2) where post-construction (permanent) detention basins will be constructed, and (3) where the basins can be maintained during construction to provide access for maintenance, including sediment removal and sediment stockpiling in a protected area, and to maintain the basin to provide the required capacity.

As with all sediment control device it must be maintained until the drainage area is permanently stabilized.

Provide construction details for each proposed sediment basin on the erosion and sediment control plans. Show all significant features and elevations on those plans.

Design Criteria

Drainage areas—Limit drainage areas to 100 acres.

Design basin life—Ensure a design life of 1 year or more.

Dam height—Limit dam height to 15 feet if possible. Height of a dam is measured from the highest point of the dam to the lowest point at the downstream toe. According to the Dam Control Act the volume is measured to the highest point on the top of the dam.

Basin locations—Select areas that:

Provide capacity for storage from as much of the planned disturbed area as practical;

Exclude runoff from undisturbed areas, where practical;

Provide access for sediment removal throughout the life of the project and;

Interfere minimally with construction activities.

Basin shape—It is important that the designer of the sediment basin incorporate features to maximize detention time and reduce the energy of the inflow before water is discharged. Some of the methods to improve basin geometry:

1. Length to width ratio of at least 2:1, with 4:1 optimal. Try not to exceed 6:1 as basin velocities can increase and the basin starts to behave as a channel. Length is measured at the elevation of the principal spillway.
2. Wedge shape with the inlet at the narrow end. Line up the inlet, riser and center or the dam.
3. Installation of baffles
4. Maximize surface area to provide efficient settling.

Storage volume—Ensure that the sediment storage volume of the basin, measured at the elevation of the crest of the principal spillway, is at least 3,600 cubic feet per acre of the total area draining into the basin.

Unless using a skimming device, half of the volume shall be in wet storage and half of the storage shall be in dry storage. Use the maximum drainage area found at any point during construction. Since watersheds often change during grading operations, the largest drainage area is not necessarily the pre- or post-construction drainage area. The maximum watershed area used to size the basin should be delineated on the drawings.

Remove sediment from the basin when approximately one-half of the wet storage volume has been filled. Show this elevation in the plans and provide a method of determining it in the field.

When the construction of a single basin with storage volume of 3600 cubic feet per acre is not feasible due to site constraints it can be advantageous to install several smaller structures in series with a combined storage volume of 3600 cubic feet. Creating a fore bay can also improve the trapping efficiency.

The volume requirements of the General Permit and this standard should be regarded as the minimum necessary to protect water quality. The design professional is encouraged to increase these storage requirements to protect a critical aquatic resource such as Tier 2.5 or 3 streams or the safety/health of the public. The following conditions could require additional storage or increased spillways capacity:

1. Highly erodible soils
2. Steep upslope topography
3. Space limiting basin geometry (depth or shape)
4. Degree to which off-and/or on-site runoff is diverted from the contributing undisturbed areas
5. Sediment cleanout schedule
6. Ease of access to clean out basin
7. Flocculant use
8. Extent of upslope erosion and sediment control
9. Critical downstream conditions

Minimum depth The sediment basin should be at least two feet deep.

Spillway capacity—The combined spillway system must carry the peak runoff from the 25-year/24 hour storm with a minimum 1-foot of freeboard.

Base peak flow runoff computations on the largest disturbed area expected and the worst soil cover conditions during the effective life of the structure.

Sediment basin spillways must be able to discharge 2 cfs/acre from the entire contributing watershed. However, if this rule of thumb is used, a minimum of 24 inches of freeboard will be required above the elevation of the 2 cfs/acre. If the emergency spillway is being used to provide part of the 2 cfs/acre discharge, the freeboard must be provided above the design flow elevation in the emergency spillway.

Principal spillway—Construct the principal spillway with a vertical riser connected to a horizontal barrel that extends through the embankment and outlets beyond the downstream toe of the dam, or an equivalent design.

• Capacity—The primary spillway system should carry the peak runoff from the 2-year storm, with the water surface at the emergency spillway crest elevation.

Basin dewatering

A sediment basin must be able to dewater the dry storage volume in 48 to 72 hours. There are two traditional ways to accomplish this

The basin should be provided either with a perforated riser with a hole or series of holes at the wet storage elevation or to enhance the trapping efficiency a surface skimmer.

Dewatering orifice---In order to dewater the sediment basin in 48 to 72 a hole or several holes that add up to A_o should be cut into the riser.

$$A_o = A_s \times (2h)^{0.5} / (T \times C_d \times 20{,}428)$$

where

A_o = total area of dewatering holes, ft^2;
A_s = surface area of the basin, ft^2;
h = head of water above the hole, ft;
C_d = coefficient of contraction for an orifice, approximately 0.6;
T = detention time or time needed to dewater the basin, hours

• **Skimmer**—A floating skimmer may be attached to the base of the riser. The orifice in the skimmer will control the rate of dewatering. The skimmer should be sized to dewater the basin in 48-72 hours.

Use the manufacturers Installation Manual to size the skimmer orifice. See SKIMMER BASIN for details on the installation of skimmers.

Sediment cleanout elevation—The clean out elevation is 50 percent of the wet storage elevation. Indicate on the drawings this elevation and mark in the field with a permanent stake.

Crest elevation—Keep the crest elevation of the riser a minimum of 1 foot below the crest elevation of the emergency spillway.

Riser and Barrel—Keep the minimum barrel size at 15 inches for corrugated metal pipe or 12 inches for smooth wall pipe to facilitate installation and reduce potential for failure from blockage. Ensure that the pipe is capable of withstanding the maximum external loading without yielding, buckling or cracking. To improve the efficiency of the principal spillway system, make the cross-sectional area of the riser at least 1.5 times that of the barrel. The riser should be sized to minimize the range of stages when orifice flow will occur.

Pipe Connections—Ensure that all conduit connections are watertight.

Rod and lug type connector bands with gaskets are preferred for corrugated metal pipe to assure water tightness under maximum loading and internal pressure. Do not use dimple (universal) connectors under any circumstances.

It is important that a suitable trash guard be installed to prevent the dewatering holes from becoming clogged.

Trash rack—Install a trash rack on the top of the riser to prevent trash and other debris from clogging the conduit. A combination anti-vortex device and trash rack improves the efficiency of the principal spillway and protects against trash intake.

Protection against piping—Install at least one watertight anti-seep collar with a minimum projection of 1.5 feet around the barrel of principal spillway conduits, 8 inches or larger in diameter. Locate the anti-seep collar slightly downstream from the dam centerline. A properly designed drainage diaphragm installed around the barrel may be used instead of an anti-seep collar when it is appropriate.

Protection against flotation—Secure the riser by an anchor with buoyant weight at least 1.25 times greater than the water displaced by the riser.

Outlet—Protect the outlet for the barrel against erosion. Discharge velocities must be within allowable limits for the receiving stream. (See OUTLET PROTECTION)

Emergency spillway—Construct the entire flow area of the emergency spillway in undisturbed soil (not fill). Make the cross section trapezoidal at least 8 feet wide and with side slopes of 3:1 or flatter. Make the control section of the spillway straight and at least 20 feet long. The inlet portion of the spillway may be curved to improve alignment, but ensure that the outlet section is straight due to supercritical flow in this portion. The channel should be located so as to avoid sharp bends. The outlet of the spillway channel should be to a defined natural channel downstream of the toe of the embankment.

Capacity—The minimum design capacity of the emergency spillway must be the peak rate of runoff from the 25-year/24 hour storm, less any reduction due to flow in the principal spillway. In no case should freeboard of the emergency spillway be less than 1 foot above the design depth of flow.

Outlet Velocity—Ensure that the velocity of flow discharged from the basin is non-erosive for the existing conditions. When velocities exceed that allowable for the receiving areas, provide outlet protection (See OUTLET PROTECTION).

Embankment Design Standards

Cut-off trench Excavate a minimum of 2 feet wide trench with 1:1 side slopes at the centerline of the embankment. Ensure that the trench is in undisturbed soil and extends through the length of the embankment to the elevation of the riser crest at each end. A minimum of 2 feet depth is recommended.

Top width The minimum top width of the dam is as follows.

Acceptable Dimensions for Basin Embankment

Fill Height	minimum top Width
less than 10 ft	8.0 ft
10 ft to 15 ft	10.0 ft
16 ft to 25 ft	15.0 ft

Freeboard Ensure that the minimum difference between the design water elevation in the emergency spillway and the top of the settled embankment is 1 foot.

Side slopes Make the side slopes of the impoundment structure so that the total slope of both sides equals 5:1 or flatter. IE. If the upstream slope is 2:1 the downstream must be 3:1 but at no time shall an embankment slope exceed 2:1.

Allowance for settlement Increase the constructed height of the fill at least 10 percent above the design height to allow for settlement.

Erosion protection Stabilize all areas disturbed by construction (except the lower 1/2 of the wet storage pool) by suitable means immediately after completing the basin.

Trap efficiency Sediment basin trapping efficiency can be improved by using the following considerations in the basin design:

Surface area In the design of the settling pond, allow the largest surface area possible. Studies indicate that surface area (in acres) should be larger than 0.01 times the peak inflow rate in cfs.

$$A = 0.01q$$

where A is the basin surface area in acres and q is the peak inflow rate in cubic feet per second

Length The length to width ratio should be between 2:1 to 6:1.

Baffles Provides a minimum of two baffles to evenly distribute flow across the basin and reduces turbulence. See specification on BAFFLES.

Inlets Locate the sediment inlets to the basin the greatest distance from the principal spillway. Protect the inlet from scour and erosion with appropriate riprap protection. If there is room, provide a forebay to help slow the speed of the water down.

Inflow rate Reduce the inflow velocity and divert all sediment-free runoff away from the basin's watershed.

A summary table showing all critical dimensions and elevations for each basin should be prepared for the construction drawings and the NPDES application.

Construction Specifications

Site preparation—Install appropriate sediment and provide erosion controls as required. Clear, grub, and strip topsoil from areas under the embankment to remove trees, vegetation, roots, and other objectionable material. Delay clearing the pool area until the dam is complete and then remove brush, trees, and other objectionable materials to facilitate sediment cleanout and prevent floatables that can clog the outlets. Stockpile all topsoil or soil containing organic matter for use on the outer shell of the embankment to facilitate vegetative establishment.

Cut-off trench—Excavate a cut-off trench along the centerline of the earth fill embankment. Cut the trench to stable soil material, but in no case make it less than 2 feet deep. The cut-off trench must extend into both abutments to at least the elevation of the riser crest. Make the minimum bottom width wide enough to permit operation of excavation and compaction equipment, but in no case less than 2 feet. Make side slopes of the trench no steeper than 1:1. Compaction requirements are the same as those for the embankment. Keep the trench dry during backfilling and compaction operations.

Embankment Core - The core shall be parallel to the centerline of the embankment as shown on the plans. The top width of the core shall be a minimum of four feet. The height shall extend up to at least to the top of the riser or as shown on the plans. The side slopes shall be 1 to 1 or flatter. The core shall be compacted with construction equipment, rollers, or hand tampers to assure maximum density and minimum permeability. In addition, the core shall be placed concurrently with the outer shell of the embankment.

Embankment—Take fill material from the approved areas shown on the plans. It should be clean mineral soil, free of roots, woody vegetation, rocks, organic topsoil and other objectionable material. Scarify areas on which fill is to be placed before placing fill. Fill material for the center of the embankment, and cut off trench shall conform to Unified Soil Classification GC, SC, CH, or CL and must have at least 30% passing the #200 sieve. The fill material must contain sufficient moisture so it can be formed by hand into a ball without crumbling. If water can be squeezed out of the ball, it is too wet for proper compaction.

Place fill material in 8 inch continuous layers over the entire length of the fill area and compact it. Hand compact areas around the anti-seep collars. Compaction may be obtained by routing the construction hauling equipment over the fill so that the entire surface of each layer is traversed by at least one wheel or tread track of heavy equipment, or a compactor may be used. Construct the embankment to an elevation 10 percent higher than the design height to allow for settling.

As an alternate, the following can be used to specify embankment placement. The minimum required density shall not be less than 95% of maximum dry density with a moisture content within 2% of the optimum. Each layer of fill shall be compacted as necessary to obtain that density, and is to be certified by the Engineer at the time of construction. All compaction is to be determined by AASHTO Method T-99 (Standard Proctor).

Conduit spillways—Securely attach the riser to the barrel or barrel stub to make a watertight structural connection. Secure all connections between barrel sections by approved watertight assemblies. The backfill adjacent to pipes or structures shall be of the type and quality conforming to that specified for the adjoining fill material. Place the barrel and riser on a firm, smooth foundation of impervious soil. Do not use pervious material such as sand, gravel, or crushed stone as backfill around the pipe or antiseep collars. Place the fill material around the pipe spillway in 4-inch layers, and compact by hand tampers or other manually directed compaction equipment under and around the pipe to at least the same density as the adjacent embankment. The material needs to fill completely all spaces under and adjacent to the pipe. The pipe shall be firmly and uniformly bedded throughout its entire length. Where rock or soft, spongy or other unstable soil is encountered, all such material shall be removed and replaced with suitable earth compacted to provide adequate support. Care must be taken not to raise the pipe from firm contact with its foundation when compacting under the pipe haunches. At no time during the backfilling operation shall driven equipment be allowed to operate closer than four feet, measured horizontally, to any part of a structure. Place a minimum depth of 2 feet of compacted backfill over the pipe spillway before crossing it with construction equipment.

Anchor the riser in place by concrete or other satisfactory means to prevent flotation.

In no case should the pipe conduit be installed by cutting a trench through the dam after the embankment is complete.

Emergency spillway—Install the emergency spillway in undisturbed original ground. The achievement of planned elevations, grade, design width, and entrance and exit channel slopes are critical to the successful operation of the emergency spillway.

Inlets—Discharge water into the basin in a manner to prevent erosion. Use diversions with outlet protection to divert sediment-laden water to the upper end of the pool area to improve basin trap efficiency (See DIVERSIONS and OUTLET PROTECTION).

Erosion control— The installation of a sediment basin can in some instances be a significant construction project in its own right. The designer must create a comprehensive sediment control plan for each sediment basin installation.

Install appropriate sediment control prior to starting constructing. Minimize the disturbed area. Divert surface water away from bare areas and around the embankment footprint. Complete the embankment before the remaining construction site is cleared. Stabilize the emergency spillway embankment and all other disturbed areas above the wet storage elevation immediately after construction. Install Riprap channel protection in the emergency spillway if needed and at the outlet of the pipe.

Care of Water during Construction --All work on permanent structures shall be carried out in areas free from water. The contractor shall construct and maintain all temporary dikes, levees, cofferdams, drainage channels, and stream diversions necessary to protect the areas to be occupied by the permanent works. The contractor shall also furnish, install, operate, and maintain all necessary pumping and other equipment required for removal of water from various parts of the work and for maintaining the excavations, foundation, and other parts of the work free from water as required or directed by the engineer for constructing each part of the work.

After having served their purpose, all temporary protective works shall be removed or leveled and graded to the extent required to prevent obstruction in any degree whatsoever of the flow of water to the spillway or outlet works and so as not to interfere in any way with the operation or maintenance of the structure. Stream diversions shall be maintained until the full flow can be passed through the permanent works.

The removal of water from the required excavation and the foundation shall be accomplished in a manner and to the extent that will maintain stability of the excavated slopes and bottom required excavations and will allow satisfactory performance of all construction operations. During the placing and compacting of material in required excavations, the water level at the locations being refilled shall be maintained below the bottom of the excavation at such locations which may require draining the water sumps from which the water shall be pumped.

Baffles Install baffles as specified in Baffles section.

Safety—Sediment basins may attract children and can be dangerous. Avoid steep side slopes, and fence and mark basins with warning signs if trespassing is likely. Follow all state and local requirements.

Sediment Basin Removal and Cleanup

Final cleanup and disposition : The designer shall prepare a Sediment Control Plan for the removal of all sediment-trapping structures. Include in the Plan the method for dewatering the wet storage and removal of the trapped sediments.

Once the site is stabilized and the basin is no longer needed the structure shall be removed and the original contours reestablished. Sediment shall be removed so it cannot reenter a waterway.

Dewatering must not cause water quality violations. See the Basin or Sediment Trap Sediment Storage Dewatering Facility drawing for approved procedures to dewater a basin or trap.

All disturbed areas will be seeded and mulched immediately according to the specifications in this manual.

Maintenance

Inspect temporary sediment basins weekly and after each rainfall event 0.5 inch or greater and repair immediately.

Provide access for sediment removal and other required maintenance activities. Remove sediment and restore the basin to its original dimensions when it accumulates to one-half the wet storage depth. Place removed sediment where there is no possibility of its reentry into a waterway.

Check the embankment, spillways, and outlet for erosion damage, and inspect the embankment for piping and settlement. Make all necessary repairs immediately. Remove all trash and other debris from the riser and pool area.

3.33 - DROP INLET PROTECTION

Introduction

A sediment barrier and/or an excavated impounding area around a storm drain drop inlet or curb inlet used to trap sediment before contaminated runoff enters a storm drainage system.

Conditions Where Practice Applies

Where storm drain inlets are to be made operational before permanent stabilization of the corresponding disturbed drainage area.

Storm sewers that are made operational prior to stabilization of the associated drainage areas can convey large amounts of sediment to natural drainageways. In case of severe sediment loading, the storm sewer itself may clog and lose a major portion of its capacity. To avoid these problems, it is necessary to prevent sediment from entering the system at the inlets.

>>Storm sewers are installed to handle the runoff from their contributing drainage area and are sized to handle the flows from a particular size storm event. Installing any of these drop inlet protection practices reduces opening size of the inlet or severely restricts the hydraulic conditions entering the inlet, thereby reducing the capacity of the inlet to handle the excess flows from storm events. Design and install each of these practices with great care. It is highly recommended to use the 6" freeboard requirement whenever possible. Care must be taken not to create conditions where flooding will occur either when the inlet becomes clogged with sediment or debris and/or the top of the drop inlet protection is higher than the nearest low spot and storm flows bypass the inlet. This could lead to a cascading series of failures of other inlet protection, ending up with severe flooding to adjacent properties or severe erosion of fill slopes.

This practice contains several types of inlet barriers and traps that have different applications dependent upon site conditions and type of inlet. Plan developers are encouraged to investigate some of the commercially available products now on the market.

General Design Criteria

1. The drainage area should be no greater than 1 acre per inlet. The drainage area should be fairly flat with slopes of 5% or less and the area immediately around the inlet should not exceed a slope of 1%.
2. The inlet protection device shall be constructed in a manner that will facilitate clean out and disposal of trapped sediment and minimize interference with construction activities.
3. The inlet protection devices shall be constructed in such a manner that any resultant ponding of stormwater will not cause excessive inconvenience or damage to adjacent areas or structures.
4. For the inlet protection devices that utilize stone as the chief ponding/filtering medium, a range of stone sizes is offered The designer should attempt to get the greatest amount of "filtering" action possible

(by using smaller-sized stone), while not creating significant ponding problems.

5. In all designs that utilize stone with a wire-mesh support as a filtering mechanism, the stone can be completely wrapped with the wire mesh to improve stability and provide easier cleaning.
6. Filter Fabric may be added to any of the devices that utilize stone to significantly enhance sediment removal, but with a reduced flow capacity. The fabric, which must meet the physical requirements noted for "extra strength", should be secured between the stone and the inlet (on wire-mesh if it is present). As a result of the significant increase in filter efficiency provided by the fabric, a larger range of stone sizes (up to gabion size) may be utilized with such a configuration.
   Note: Significant ponding will occur at the inlet if filter cloth is utilized in this manner.
7. If there is a possibility that ponding will occur, the top of the inlet protection must be at least six inches below the nearest low spot to insure sufficient freeboard. See Figure 3.33.2.
8. Remove any obstructions to excavating and grading. Excavate any sump area, grade slopes and properly dispose of soil.
9. The inlet grate should be secured to prevent seepage of sediment-laden water.
10. Ensure that weep holes in the inlet structure are protected by filter fabric and gravel.
11. Hardware cloth or wire mesh with ½-inch inch openings.
12. Filter fabric
13. Washed gravel 3/4 inches to 4 inches in diameter. All cut slopes shall be 2:1 or flatter.

Construction Specifications

Silt Fence Drop Inlet Protection

a. Silt Fence shall conform to the specifications for "extra strength" and shall be cut from a continuous roll to avoid joints.
b. For stakes, use 2 x 4-inch wood (preferred) or equivalent metal with a minimum length of 3 feet.
c. Space stakes evenly around the perimeter of the inlet a maximum of 3-feet apart, and securely drive them into the ground, approximately 18 inches deep.
d. To provide needed stability to the installation, frame with 2 x 4-inch wood strips around the crest of the overflow area at a maximum of 1 foot above the drop inlet crest.
e. Place the bottom 12 inches of the fabric in a trench and backfill the trench with 12 inches of compacted soil. This limits this practice to unpaved areas.
f. Fasten fabric securely by staples or wire to the stakes and frame. Joints must be overlapped to the next stake.
g. It may be necessary to build a temporary dike on the downslope side of he structure to prevent bypass flow.
h. It is recommended that a sediment trapping sump of 1 to 2 feet in depth with side slopes of 2:1 by provided.
i. If the filter fabric becomes clogged it should be replaced immediately.

j. Make sure that the stakes are firmly in the ground and that the filter fabric continues to be securely anchored.

Gravel and Wire Mesh Drop Inlet Protection

a. Wire mesh shall be laid over the drop inlet so that the wire extends a minimum of 1 foot beyond each side of the inlet structure. Wire mesh with ½-inch openings shall be used. If more that one strip of mesh is necessary, the strips shall be overlapped.

b. Coarse aggregate shall be placed over the wire mesh as indicated in the drawing. The depth of stone shall be at least 12 inches over the entire inlet opening. The stone shall extend beyond the inlet opening at least 18 inches on all sides.

c. If the stone filter becomes clogged with sediment so that it no longer adequately performs its function, the stones must be pulled away from the inlet, cleaned and/or replaced.

Note: This filtering device has no overflow mechanism; therefore, ponding is likely especially if sediment is not removed regularly. This type of device must never be used where overflow may endanger an exposed fill slope or flooding of adjacent properties. Consideration should also be given to the possible effects of ponding on traffic movement, nearby structures, working areas, adjacent property, etc.

Block and Gravel Drop Inlet Protection

a. Place concrete blocks lengthwise on their sides in a single row around the perimeter of the inlet, with the ends of adjacent blocks abutting. The height of the barrier can be varied, depending on design needs, by stacking combinations of 4-inch, 8-inch and 12-inch wide blocks. The barrier of blocks shall be at least 7½-inches high but no greater than 24-inches high.

b. Wire mesh shall be placed over the outside vertical face (webbing) of the concrete blocks to prevent stone from being washed through the holes in the blocks. Wire mesh with ½-inch openings shall be used.

c. Stone shall be piled against the wire to the top of the block barrier, as shown in the drawing.

d. If the stone filter becomes clogged with sediment so that it not longer adequately performs its function, the stone must be pulled away from the blocks, cleaned and replaced.

Pipe Riser Drop Inlet Protection

a. Each pipe riser must be constructed from steel plate that is cut to the dimensions of the drop inlet grate with an inch over lap on each side and a length of 12 inch corrugated metal pipe. Use a minimum of 10 gauge steel plate with a 12 inch hole cut in the center. The corrugated pipe is welded to the plate.

b. Cut a series of one-inch holes in the corrugated pipe as shown on the drawings. Wire mesh with ½ inch openings can be wrapped around the outside of the pipe to prevent stone from being washed through the holes.

c. Place a square piece of geotextile filter fabric at least one foot larger than the inlet dimensions around the riser and over the metal plate.

d. Stone shall be piled to the top of the pipe, as shown in the drawing.

e. If the stone filter becomes clogged with sediment so that it not longer adequately performs its function, the stone must be pulled away from the blocks, cleaned and replaced.

f. This practice can be combined with the Excavated Drop Inlet Sediment Trap to increase the available storage.

Excavated Drop Inlet Sediment Trap

a. The excavated trap shall be sized to provide a minimum storage capacity calculated at the rate of 3600 cubic feet per acre of drainage area. (if attainable). The trap should be not less than 1-foot nor more than 2-feet deep measured from the top of the inlet structure. Side slopes shall not be steeper than 2:1.

b. The slope of the basin may vary to fit the drainage area and terrain. Observations must be made to check trap efficiency and modifications shall be made as necessary to ensure satisfactory trapping of sediment. Where an inlet is located so as to receive concentrated flows, such as in a highway median, it is recommended that the basin have a rectangular shape in a 2:1 (length/width) ratio, with the length oriented in the direction of the flow.

c. Sediment shall be removed and the trap restored to its original dimensions when the sediment has accumulated to one-half the design depth of the trap. Removed sediment shall be deposited in a suitable area and in a manner such that it will not erode.

d. If there is sufficient freeboard available this practice can be combined with other drop inlet protection devices such as Silt Fence or Pipe Riser.

Gravel Curb Inlet Protection

a. Wire mesh with ½-inch openings shall be placed over the curb inlet opening so that at least 12 inches of wire extends across the inlet cover and at least 12 inches of wire extends across the concrete gutter from the inlet opening, as depicted in drawing.

b. Stone shall be piled against the wire so as to anchor it against the gutter and inlet cover and to cover the inlet opening completely.

c. If the stone filter becomes clogged with sediment so that it no longer adequately performs its function, the stone must be pulled away from the block, cleaned and replaced.

Curb Inlet Protection with 2-inch x 4-inch Wooden Weir

a. Attach a continuous piece of wire mesh (30-inch minimum width x inlet throat length plus 4 feet) to the 2-inch x 4-inch wooden weir (with a total length of throat length plus 2 feet) as shown in the drawing. Wood should be "construction grade" lumber.

b. Place a piece of approved "extra-strength" filter cloth of the same dimensions as the wire mesh over the wire mesh and securely attach to the 2-inch x 4-inch weir.

c. Securely nail the 2-inch x 4-inch weir to the 9-inch long vertical spacers which are to be located between the weir and inlet face at a maximum 6-foot spacing.

d. Place the assembly against the inlet throat and nail 2-foot (minimum) lengths of 2-inch x 4-inch board to the top of the weir at spacer locations. These 2-inch x 4-inch anchors shall extend across the inlet tops and be held in place by sandbags or alternate weight.

e. The assembly shall be placed so that the end spacers are a minimum 1 foot beyond both ends of the throat opening.

f. Form the wire mesh and filter cloth to the concrete gutter and against the face of curb on both sides of the inlet. Place coarse aggregate over the wire mesh and filter fabric in such a manner as to prevent water from entering the inlet under or around the filter cloth.

g. This type of protection must be inspected frequently and the filter cloth and stone replaced when clogged with sediment.

h. Assure that storm flow does not bypass inlet by installing temporary earth or asphalt dikes directing flow into inlet.

Block and Gravel Curb Inlet Protection

a. Two concrete blocks shall be placed on their sides abutting the curb at either side of the inlet opening.

b. A 2-inch x 4-inch stud shall be cut and placed through the outer holes of each spacer block to help keep the front blocks in place.

c. Concrete blocks shall be placed on their sides across the front of the inlet and abutting the spacer blocks as depicted in the drawing.

d. Wire mesh with ½-inch opening shall be placed over the outside vertical face (webbing) of the concrete blocks to prevent stone from being washed through the holes in the blocks.

e. Coarse aggregate shall be piled against the wire to the top of the barrier as shown in the drawing.

f. If the stone filter becomes clogged with sediment so that it not longer adequately performs its function, the stone must be pulled away from the blocks, cleaned and/or replaced.

Gravel Bag Curb Inlet Protection

a. In general, gravel bags are used to create a small sediment trap upstream of inlets and are appropriate for gently sloping streets where ponded water will not endanger the public or cause property damage

b. Flow from a severe storm should not overtop the curb.

c. In areas of high clay and silts, use filter fabric and gravel as additional filter media.

d. Use sandbags made of geotextile fabric (not burlap) and fill with uniform coarse aggregate material such as ½” rock or ¼” pea gravel. Do not use sand, as the bag must be porous.

e. Place one or two layers of overlapping gravel bags, and pack them tightly together. A gap of one sandbag on the top row on either side of the inlet can serve as an overflow spillway for larger storms.

f. Leave room upstream of barrier for water to pond and sediment to settle.

g. Drape geotextile filter fabric over the barrier and place the aggregate to "filter" sediment from storm water. Small pipes (2" diameter or smaller) for additional safety can be placed through the gravel bag barrier if also covered by filter fabric.

h. If the stone filter becomes clogged with sediment so that it not longer adequately performs its function, the stone must be pulled away from the blocks, cleaned and/or replaced

Manufactured Drop Inlet Protection

There are a number of new commercially available products on the market now. Some show great promise in providing excellent sediment control. However, great care must be taken when choosing a product as some have significant problems with their design.

Do not install any practice that completely blocks the entrance of a drop inlet without some type of excess freeboard or adequate overflow. There are several curb inlet protections that block the inlet while providing several small holes for overflow. These holes are not large enough to pass larger storm events and can cause localized flooding. Some drop inlet protections cover the entire top of the inlet or are installed under the grate. These too have little overflow capacity and must be used judiciously. Practices that are placed inside inlets and out of sight are particularly easy to forget and become clogged and fail. In all cases the freeboard requirement must be met. While some of the products can work, great care must be taken to install correctly and to inure the design capacity of the inlet is not compromised.

Maintenance

1. The structure shall be inspected after each .5" of rain and at least once a week and repairs made as needed. Construction traffic has a tendency to destroy these practices so frequent inspections are necessary.
2. Sediment shall be removed and the trap restored to its original dimensions when the sediment has accumulated to one half the design depth of the trap. Removed sediment shall be deposited in a suitable area and in such a manner that it will not erode.
3. Inlet protection should remain in place and operational until the drainage area is completely stabilized. Immediately stabilize the area disturbed by the installation and removal of the practice.
4. It is essential that maintenance be done to insure that structures do not fail, especially to prevent clogging. Failure of one practice can create a domino effect of failures, with the potential of severe flooding of adjacent properties.

3.35 - ACCESS ROAD/ LOW VOLUME ROAD/DRIVEWAY

Introduction

Access roads and driveways are a major source of sediment in the State of West Virginia. Roads can dramatically change the hydrologic conditions of the immediate watershed. Roads that are improperly designed, constructed and stabilized can cause significant erosion and produce vast quantities of sediment. Common problems with roads are:

1. Inadequate number and size of culverts.
2. Road grade too steep.
3. Road surface not stabilized.
4. Poor soil conditions.
5. Poor drainage.
6. Poor stream crossings.
7. Cuts and fills too steep causing slips.

Since roads are typically long-term features, cutting costs during the construction phase almost always costs more in the long run as maintenance costs will be significantly higher on improperly designed and constructed roads.

To control sediment from roads it is necessary to practice aggressive erosion control. The single most important thing to do when designing and building a road is to control the water. Running water more than a few hundred feet down a road will cause long-term erosion and increase maintenance costs.

It is important that concentrated upslope water from streams or drainageways is directed immediately across the road with a culvert. Adequately sized and stabilized ditches to catch minor hillside runoff must also be constructed. The goal is to maintain the existing hydrologic conditions as much as possible by installing adequate numbers of cross culverts.

Conditions Where Practice Applies

Wherever low volume access roads are built. This practice can apply to any type of dirt or gravel road outside the Department of Transportation's road system.

Planning.

Planning and location are two of the more important aspects of road development and takes considerable time and effort. Good planning upfront can forestall problems later on.

1. You will need topographic maps, soil surveys and soil maps, and a device to determine grade. Roads should not be built on some soils. Check with the Natural Resources Conservation Service for information on soils. Review available information and

consult with professionals as necessary to help identify erodible soils and unstable areas, and to locate appropriate road surface materials.

2. Fit the road to the topography by locating roads on natural benches and following natural contours. Avoid long, steep road grades and narrow valleys.
3. If possible use switchbacks where it is impossible to construct a road below the maximum grade.
4. If it is necessary to construct in steep terrain break the road grade as much as possible by alternating steep section with flatter sections. Sometimes the road grade can be reversed which will shorten slope length and reduce the number of culverts, water bars and broad-based dips.
5. Locate roads on stable geology, including well-drained soils and rock formations that tend to dip into the slope. Avoid slumps and slide prone areas characterized by steep slopes, highly weathered bedrock, clay beds, concave slopes, hummocky topography, and rock layers that dip parallel to the slope.
6. Avoid wet areas, including moisture laden or unstable toe slopes, seeps, wetlands, and natural drainage channels. Ridge tops can be good places for a road as long as proper drainage can be constructed. Be aware that conditions may change when constructing in the dryer times of the year. Be prepared to add culverts after construction when hidden springs and streams start back up in the winter and spring.
7. Avoid crossing streams, if practical. If unavoidable, look for the best places to cross, considering the following.

    - Always cross at right angles.
    - Cross at points where the stream is narrow and the stream banks are stable.
    - Minimize the number of crossings.
    - Leave a buffer zone of undisturbed ground between the road and streambed, where the road runs parallel to the stream.
    - Divert water from road with a diversion or water bar to prevent water running directly into the stream.

8. If possible build roads on the drier south or west facing slopes. Clear trees to allow the sun to hit the road as much as possible.
9. Stabilization of all disturbed soil must take place as quickly as possible. Seed and mulch all cut and fill slopes and shoulders within seven days of reaching final grade. Stabilize the ditches as the line and grade is finalized.
10. Stabilization should occur as the road is constructed. Build the road in sections. Initiate stabilization on a finished section prior to moving to the next section. Finish road crossings and section nearest the creek immediately. Do not rough grade the entire road and then come back to the beginning to start restoration and stabilization. Quick stabilization of the disturbed area will greatly enhance any sediment control.

Mapping

Using the above information, locate control points (areas where you can and can't build a road) such as rock outcrops, extreme slopes, slip prone areas, poor soils, streams, ridges, saddles, hillside benches, property lines, access points and end point on a topo map. Lay the road out on a contour map with a pencil hitting or missing these control points. Calculated the grade of the road, attempting to keep it below 10 percent. This will show where sections are too steep and the road needs to be moved. Grades over 12 percent for more than a few hundred feet should be avoided if possible. Change the location of the road or break the grade to maintain the optimum grade. After all the changes are made it is time to go to the field to verify the site conditions.

Next mark on the map the tentative locations of the culverts using this formula:

400/% grade + 75' = culvert spacing

Do not space culverts more than 300' apart.

In field walk the centerline. Locate the control points and flag the centerline by tying plastic ribbon at eye level. Using an Abney Level or Clinometer, check the actual grades from ribbon to ribbon, back checking each run. Adjust the grade where the road exceeds 12 percent

Look for wet spots, springs and water features missed because of the topo map's scale. Move the centerline to miss any unmapped features or add culverts where needed. It may be necessary to move most of the culverts to make it easier to install them and to correctly locate where concentrated flows cross the road. If bedrock is found, the culvert can be moved down hill even if it exceeds the spacing requirement. Sometimes it is advantageous to add a culvert immediately above a steep section to keep upslope drainage from entering a high velocity section.

Approaches to public roads need an Entrance Permit from the Division of Highways. Do not allow water to run onto public roads, divert with berm or water bar. The BMP for STABILIZED CONSTRUCTION ENTRANCE can be used for permanent access roads.

Design and Construction Criteria

The are several critical design criteria that must be met if the long-term stability of an access road is to be maintained.

The key criteria are:

1. Cross-section
2. Road Grade
3. Ditch line protection
4. Water Control

5. Stream Crossing
6. Stabilization
7. Sediment Control

One of the most important design parameters is to keep the road grade as flat as possible. Any road grade over 10 percent can cause difficulties with surface stability, washing off of the gravel surface, and gully formation. If steeper sections (such as to get over a rocky section) are necessary install more culverts or break the grade, or add water bars.

Road Cross-Sections Five road cross-sections typically are used in road construction: crowned fill, crowned turnpike, outslope, inslope with ditch, and crowned and ditched (Figure 3.35.1).

The choice of which cross-section to use depends on the drainage needed, soil stability, slope, and the expected volume of traffic on the road. You can use these cross-sections in combination as the terrain changes or as drainage problems are encountered.

- Crowned fill section is for use on flat ground where water standing on a road surface may be a problem.
- Outslope section is for use on moderate slopes for low volume roads and stable soils. Outsloping can be more dangerous in wet and snowy weather. Broad-based dips and water bars can be used on this cross-section rather than culverts.
- Inslope with ditch section is for use on steep hills, areas with fine textured soils, winter logging, and areas where drainage is necessary.
- Crowned and ditched section is for high volume roads on steep side hills.

Road Grade: Road grade is the single most important factor in planning a low volume road. Road grades must be kept to a minimum. If possible do not exceed 10 percent. The maximum for short distances can be 12 percent but it will be harder to keep gravel in place, ditch lines are harder to stabilize and culverts, water bars and broad-based dips are harder to install. Ruts form easier and the higher runoff velocities will erode them faster.

Grade is expressed as a percent and can be determined as follows.

percent slope = rise in vertical feet divided by the horizontal run in feet.

Ditch line Protection: Recommended ditch line protection can be based on the grade as follows:

1. Less than 3 percent - grassed
2. 3 – 8 percent - grass with rolled erosion control products

3. Greater than 9 percent - riprap or equivalent geotextile (must submit manufacturers specifications and calculated velocities).

If the flows are significant the protection should based on an engineering study of the particular characteristics of the waterway and soils.

For more information see DIVERSIONS.

Water Control Structures: The construction of roads can radically alter the hydrologic regime of the local watershed. By installing structures, devices and measures to reestablish or approximate the original flow paths, erosion and road maintenance can be almost eliminated. Conversely, failure to provide adequate flow management can create very serious erosion. In most situations, providing appropriate measures is straightforward and simple. Proper planning and the flexibility to address onsite problems are necessary to control storm flows and will make it easier to protect the investment of building the road and improve water quality.

The single most common problem on low volume roads is the lack of culverts. Culverts allow the upslope water to cross the road at right angles and without coming into contact with the road surface. Maintaining the natural flow path is critical to reducing erosion on roads. Streams of any size should NEVER be allowed to run down a road. The road surface can wash away and ditch lines can be destroyed.

Culverts: There are two types of culverts on roads. One is used to pass upslope perennial and intermittent streams across the road. The other is sometimes called a cross-drainage culvert and is used to move lesser amounts of water from springs, seeps and upslope runoff across the road.

Culverts must be installed at each stream/waterway crossing and periodically along the roadway. Cross-drainage culverts are spaced apart at least 125’ and no more than 300’.

400/percent grade + 75’ = culvert spacing

Install OUTLET PROTECTION at each culvert. Install a headwall or similar device at each culvert.

The minimum size should be 12 inches. The culvert chart (Table 3.35.1) can be used to size culverts with a drainage area up to 600 acres.

The minimum grade should be 1 percent and culverts should be installed from 25 to 45 degrees to the centerline of the ditch to minimize turbulence at the inlet.

Culverts must extend at least one foot beyond the toe of the fill. Do not discharge onto the side of a road fill. If not possible, design OUTLET PROTECTION using grouted riprap .

Firmly backfill the trench and around culvert with fine-grained material, taking care to create good contact underneath the pipe. Cover the top of the culvert with at least 12 inches of fill, more if heavy loads are anticipated on the road.

Drainage Area (Acres)	**Table 3.35.1 Average Slope of Watershed**			
	1%	4%	8%	16%
	Culvert Size			
1 – 25	24	24	30	30
26 - 50	24	30	36	36
51 – 100	30	36	42	48
101- 150	30	42	48	48
151 - 200	36	42	48	54
200 - 250	42	48	60	60
251 - 300	42	48	60	60
301 - 350	42	48	60	60
351 - 400	42	54	60	60
401 - 450	42	54	60	72
451 - 500	42	54	60	72
501 - 550	48	60	60	72
551 - 600	48	60	60	72
601 - 640	48	60	72	72

Broad-based Dips: Broad-based dips (Figure 3.35.3) were developed at the Fernow Experimental Forest in West Virginia to control surface water on Forest Service roads. Under the right conditions and correctly constructed they are an excellent method of controlling runoff.

Regular traffic can easily traverse them and once installed require little maintenance. However, they are almost impossible to install on steep roads and difficult to maintain in poor soil conditions. They are easily installed on roads with less than 10 percent grade and where the subgrade material is suitable:

Broad-based dips cannot be used to pass continuous flowing water across the road or under extended damp conditions such as where springs are located. Culverts are required in these situations.

Spacing for Broad-based Dips is the same as culverts.

400/percent grade + 75 feet = dip spacing

Do not space broad-based dips more than 300 feet apart.

Water Bars: Water bars (Figure 3.35.4) are a small berm and swale construction across a road to direct surface water off the road and into a stabilized vegetated area. Water bars are useful on infrequently used or abandoned roads.

Water bars are installed similarly to TEMPORARY RIGHT-OF-WAY DIVERSIONS. They should be installed at an angle (30 to 45 degrees) across the road. The water bar must extend across the entire width of the road. They should never dam the water but should intercept and divert the water off the road. The discharge point should be fully open and protected from erosion and discharge to a stable vegetated area or undisturbed forest flow.

As with the broad-based dip it should not be used where there is a continuous flow of water such as a stream or spring or seep. It is very important the water bar not create erosion over the road fill. To prevent erosion use RIP RAP or a RECP.

The spacing for water bars is the same as for broad based dip.

Turnouts: Turnouts are extensions of the ditch line into a vegetated area or natural waterway. Sometimes the ground drops off either side of the road and a culvert can't be installed. A turnout can be constructed to transfer water away from the roadway into a natural water way or onto a flat well-vegetated area. Turnouts are similar to LEVEL LIP SPREADERs but for smaller quantities of flow. It is important that a dam isn't formed at the end that can erode and the turnout is PERMANENT SEEDED immediately upon completion.

It is possible to install a SEDIMENT TRAP at the end of many turnouts.

Stream Crossings: See the specification under INSTREAM CONSTRUCTION BMPS for more information. Bridges are always preferable to culverts when crossing a perennial stream.

Culverts installed for permanent applications must be designed at a minimum to pass the peak discharge from a ten-year/24-hour storm with out causing upstream backup and downstream scour.

Sediment Control: During construction sediment control will consist of installing appropriate sediment control devices such as BRUSH BARRIERS, SILT FENCE, SUPER SILT FENCE and SEDIMENT TRAPS. (Figure 3.35.2)

On extreme slopes it may be impossible to install anything other than a BRUSH BARRIER or SILT FENCE. Sediment control can be accomplished by following the recommendations in this BMP and by rapid restoration and stabilization according to the PERMANENT SEEDING specification. Recognizing these difficulties, DEP will allow lesser sediment control if offset by an aggressive stabilization schedule shown in the SWPPP.

Critical areas such as stream crossings will still require appropriate sediment control while in other areas smaller traps/sumps may be used. Alternative sediment controls can be pursued or modifying existing one may be necessary. One place is at the head of most of the side ditch culverts. A small sediment trap/sump can be installed here.

This BMP does not cover specifications for earth moving nor sets out standards other than the basics covered above.

For more information on construction see the following drawings.

Maintenance

Initially inspect the road after each rainfall of 0.5 inch or more. Initially it would be better to inspect during the first few rainstorms. Look for water running down the road and for scour in the ditch lines. Look for water coming out of cut slopes and for upslope concentrated flows not going to culverts. If water bars or broad based dips are used see if they are deep enough to capture road surface runoff. If runoff goes past either practice, repair immediately.

If ruts are found immediately regrade and direct runoff into ditch line or to outslope as necessary.

HYDROLOGY

URBAN HYDROLOGY FOR SMALL WATERSHEDS (TR-55)

URBAN HYDROLOGY FOR SMALL WATERSHEDS – TR-55

The following information was developed by the United States Department of Agriculture, Natural Resources Conservation Service, Conservation Engineering Division in Urban Hydrology for Small Watersheds TR-55, Technical Release 55 June 1986.

Preface

Technical Release 55 (TR-55) presents simplified procedures to calculate storm runoff volume, peak rate of discharge, hydrographs, and storage volumes required for floodwater reservoirs. These procedures are applicable in small watersheds, especially urbanizing watersheds, in the United States. First issued by the Soil Conservation Service (SCS) in January 1975, TR-55 incorporates current SCS procedures. This revision includes results of recent research and other changes based on experience with use of the original edition.

The major revisions and additions are:

- A flow chart for selecting the appropriate procedure;
- Three additional rain distributions;
- Expansion of the chapter on runoff curve numbers;
- A procedure for calculating travel times of sheet flow;
- Deletion of a chapter on peak discharges;
- Modifications to the Graphical Peak Discharge method and Tabular Hydrograph method;
- A new storage routing procedure;
- Features of the TR-55 computer program; and
- Worksheets.

This revision was prepared by Roger Cronshey, hydraulic engineer, Hydrology Unit, SCS, Washington, DC; Dr. Richard H. McCuen, professor of Civil Engineering, University of Maryland, College Park, MD; Norman Miller, head, Hydrology Unit, SCS, Washington, DC; Dr.Walter Rawls, hydrologist, Agricultural Research Service, Beltsville, MD; Sam Robbins (deceased), formerly hydraulic engineer, SCS, South National Technical Center (NTC), Fort Worth, TX; and Don Woodward, hydraulic engineer, SCS, Northeast NTC, Chester, PA. Valuable contributions were made by John Chenoweth, Stan Hamilton, William Merkel, Robert Rallison (ret.), Harvey Richardson, Wendell Styner, other SCS hydraulic engineers, and Teresa Seeman.

Revised June 1986
Update of Appendix A January 1999

CHAPTER 5

DESIGN EXAMPLES

Sediment Basin Design Example

Problem statement: Design a sediment basin that captures a drainage area of 25 acres during construction. The disturbed project area equals the drainage area to the basin.

When locating your basin, try to capture as much of the disturbed area from the construction site as necessary, while diverting as much undisturbed runoff coming to the site as possible.

Calculate the resultant total area draining to basin = 25 acres.
Calculate the total disturbed area draining to basin = 25 acres.
Required wet storage = 25 ac. x 1800 cf/ac = 45,000 cf
Required dry storage = 25 ac. x 1800 cf/ac = 45,000 cf
The clean-out volume corresponds to the volume equal to half the wet storage volume.
Clean-out volume = 25 x 900 cf/ac = 22,500 cf.

Stage-Storage Chart (determined from the basin/pond geometry, which is not given for this example). Assumes the following:

Elevation (ft.)	**Sum Volume** (ac-ft.)
151	0.00
152	0.15
153	0.33
154	0.55
155	0.81
156	1.10
157	1.44
158	1.82
159	2.25
160	2.73
161	3.26
162	3.84
163	4.48
164	5.18
165	5.93
166	6.75

With a pond bottom of elevation 151, the corresponding elevation for the wet storage volume = 45,000 cf (1.033 ac-ft) is approximately 155.8 feet.

The clean-out elevation is the elevation corresponding to the clean-out volume = 22,500 cf (0.52 ac-ft), which is equal to approximately 153.9 feet. Show this elevation on the plans and provide a means of determining it in the field.

With the wet storage volume elevation set at 155.8, the corresponding elevation for the dry storage volume (cumulative 90,000 cf or 2.066 ac-ft) is approximately 158.6 feet.

Set the top of the temporary riser above this elevation so top of riser = 159.0.

A perforated riser with a hole or series of holes should be provided at the wet storage elevation. In order to dewater the sediment basin in 48 to 72 hours, perforations should be sized in the riser according to the following equation:

Ao = As x (2h)^0.5/(T x Cd x 20,428)

Where

Ao = total area of dewatering holes, ft^2
As – surface are of the basin, sq.ft.
H = head of water above the hole, ft
Cd = coefficient of contraction for an orifice, ~ 0.6
T = detention time needed to dewater the basin, hours

Using the basin geometry gives:

Ao = 21,000 sq.ft. x (2 x 3.2 ft.)^0.5/(72 x 0.6 x 20428)
Ao = 0.06 sq.ft. which equals an orifice area with a diameter of 3.3 inches.
Use 3 – 1-inch holes

Compute the peak discharge from a 2-year and 25-year, 24-hour storm event.

Condition	Area	CN	Tc
	Acre		Hrs
Pre-developed	25	73	0.499
Post-developed	25	78	0.267

From TR-55 Worksheets 2 and 3

Perform Preliminary Hydrologic Calculations

The site is located in a county in West Virginia that has the following 24-hour rainfalls:

2-year, 24-hour rainfall = 2.75 inches
25-year, 24-hour rainfall = 4.78 inches

Condition	Q 2-yr	Q2-yr	Q 25-yr	Q 25-yr
Runoff	inches	cfs	inches	cfs
Post-developed	0.962	24.4	2.530	69.2

From TR-55 Worksheet 4 or 5b

Determine the maximum principal spillway capacity for a Q2 of 24.4 cfs

- Try a riser with a diameter of 36-inches and a barrel with a diameter of 24 inches, trying to keep the diameter of the riser = 1.5 x the diameter of the barrel to improve the efficiency of the principle spillway system.
- Solving the weir equation for the riser with a perimeter, L = 9.4248 feet and an area, A = 7.06858, gives an H = 0.88 feet feet. So the 2-year storm will pass through the temporary riser with an H of 0.88 feet.
- Check the pipe barrel performance for the 2-year event with an assumed size of 24-inches, a pipe length of 100 feet, a pipe slope of 10%, and a roughness coefficient of n=0.024.
- Solving the pipe equation for inlet control gives Q = 45.4 cfs (refer to Sediment Basin Outlet results).
- Solving the pipe equation for outlet control gives Q = 44.0 cfs (refer to Sediment Basin Outlet results).
-

For the 25-year design storm:

Condition	Q 25-yr	Q 25-yr
Runoff	inches	cfs
Post-developed	2.530	69.2

From TR-55 Worksheet 4 or 5b

- Knowing the Runoff Q (inches) from TR-55 Worksheet 2 and the Area (in square miles), compute the Runoff Volume Vr = Q (A) 53.33
  = 2.53 x 0.0.03906 x 53.33 = 5.27 ac. ft.

Stage-Storage Chart Using the stage-storage chart for a runoff volume of 5.27 ac-ft.-

Elevation	**Sum Volume**
(ft.)	(ac-ft.)
151	0.00
152	0.15
153	0.33
154	0.55
155	0.81
156	1.10
157	1.44
158	1.82
159	2.25
160	2.73
161	3.26
162	3.84
163	4.48
164	5.18
165	5.93
166	6.75

With a pond bottom of elevation 151, the corresponding elevation for the 25-year runoff volume = 5.27 ac-ft is approximately 164.1 feet. Set the emergency spillway at an elevation at least 1 foot minimum above the top of the temporary riser elevation of 159.0 feet, , while ensuring a minimum freeboard of 1' above the top of the basin elevation which is 164 feet. Try setting the emergency spillway at 161.00.

Use the Design Data for Earth Spillways (USDA-SCS) to determine the spillway width for the associated head. A width of 28 feet using the earth spillway design data allows for the passage of 56 cfs with 1 foot of head, and 179 cfs with 2 foot of head, assuming a z of 2 and an n value of 0.040. (See the Sediment Basin Outlet results).

Follow the recommendations for providing a core trench if necessary, anti-seep collars as needed, provide an allowance for settlement of the embankment, and provide baffles as needed.

Sediment Basin Outlet Results

Elevation	Orifice Outlet						36" Riser Outlet								24" Barrel Pipe				Emergency Spillway		Overtopping the Dam		Total Discharge	Storage

Stormwater Management Pond Design Example

Problem statement: Design a stormwater management extended detention pond that will provide control of the channel protection volume (1-yr) event with a 24-hour extended detention time, the overbank protection volume (10-year) event, and also safely pass the 100-year event.

Step 1 – Compute runoff control volumes from the SCS approach.

Be sure to check to see if there is a Water Quality Volume (WQv) requirement, and compute as required (for example, there is a WQv requirement in Berkeley County). The following example assumes there is no water quality volume requirement.

Develop Site Hydrologic and Hydrologic Input Parameters. Any hydrologic models using SCS procedures, such as TR-20, HEC-HMS, or HEC-1, can be used to perform preliminary hydrologic calculations. Chapter 4 of the manual contains TR-55 Urban Hydrology for Small Watersheds that gives instructions and examples in determining the Runoff Coefficient, and Time of Concentration. TR-55 methodology is used in this design example.

Condition	Area	CN	Tc
	Acre		Hrs
Pre-developed	38	73	0.499
Post-developed	38	78	0.267

From TR-55 Worksheets 2 and 3

Perform Preliminary Hydrologic Calculations

The site is located in a county in West Virginia that has the following 24-hour rainfalls:

1-year, 24-hour rainfall = 2.35 inches
10-year, 24-hour rainfall = 4.20 inches
100-year, 24-hour rainfall = 5.75 inches

Condition	Q 1-yr	Q1-yr	Q 10-yr	Q 100-yr
Runoff	inches	cfs	cfs	cfs
Pre-developed	0.49	29.2	115.3	210.7
Post-developed	0.69	62.8	197.2	335.3

From TR-55 Worksheet 4 or 5b

Compute Channel Protection Volume, (Cpv)

For stream channel protection, provide 24 hours of extended detention for the 1-year event.

Utilize SCS approach to compute channel protection storage volume

- Initial abstraction (Ia) for CN of 78 is 0.564 [Ia = (200/CN)-2]
- Ia/P – (0.564)/2.35 inches = 0.24
- Tc = 0.267 hours
- qu = 645 csm/in (Type II storm)

Knowing qo, qi, qu and T (extended detention time), find qo/qi for the 1-year design event. For a Type II rainfall distribution, and using TR-55 Worksheet 6a:

- Peak outflow discharge/peak inflow discharge (qo/qi) = 29.2/62.8 = 0.465
- Using qo/qi and TR-55 Figure 6-1, find Vs/Vr, where Vs equals channel protection storage (Cpv) and Vr equals the volume of runoff in inches.
- Vs/Vr = 0.295
- Knowing the Runoff Q (inches) from TR-55 Worksheet 2 and the Area (in square miles), compute the Runoff Volume Vr = Q (A) 53.33
  = 0.692 x 0.1406 x 53.33 = 5.19 ac. ft.
- Storage Volume Vs = Vr (Vs/Vr) = 5.19 x 0.295 = 1.53 ac.ft or 66,647 cf.

Compute Overbank Flood Protection Volume, (Q10-yr)

Knowing qo, qi, qu and T (extended detention time), find qo/qi for the 10-year design event. For a Type II rainfall distribution, and using TR-55 Worksheet 6a:

- Peak outflow discharge/peak inflow discharge (qo/qi) = 115.3/197.2 = 0.585
- Using qo/qi and TR-55 Figure 6-1, find Vs/Vr, where Vs equals overbank flood protection volume storage and Vr equals the volume of runoff in inches.
- Vs/Vr = 0.250
- Knowing the Runoff Q (inches) from TR-55 Worksheet 2 and the Area (in square miles), compute the Runoff Volume Vr = Q (A) 53.33
  = 2.048 x 0.1406 x 53.33 = 15.36 ac. ft.
- Storage Volume Vs = Vr (Vs/Vr) = 15.36 x 0.250 = 3.84 ac.ft or 167,270 cf.

Analyze Safe Passage of the 100-Year Design Storm (Q100)

Check to see if there are any local requirements or field observations that would advocate controlling the 100-year storm. If so, storage estimates would have been made similar to the volumes in the previous steps.

Step 2 – Determine pond location and preliminary geometry. Keep in mind the recommendations of keeping the length to width ratio greater than 2:1, making the distance between the inflows and outflow of the pond as maximum as possible, and providing sediment forebays, safety ledges and other features recommended in the local jurisdiction.

Step 3 – Set water surface elevation for Channel Protection Event.

Use TR-55 Worksheet 6A to develop a stage/storage chart for the pond based on the preliminary geometry.

Stage-Storage Chart (determined from the basin/pond geometry, which is not given for this example) Assumes the following:

Elevation (ft.)	**Sum Volume** (ac-ft.)
151	0.00
152	0.15
153	0.33
154	0.55
155	0.81
156	1.10
157	1.44
158	1.82
159	2.25
160	2.73
161	3.26
162	3.84
163	4.48
164	5.18
165	5.93
166	6.75

Determine the maximum storage elevation corresponding to the storage volume computed in Step 1 for the 1-year channel protection event. From the stage-storage chart, the corresponding water surface elevation for the 1-year channel protection design event = 157.3.

Next, determine the size of a low-flow orifice by defining the average release rate to empty 1.53 ac-ft in 24 hours.
Q = (1.53ac-ft x 43,560 ft^2/ac)/(24 hrs x 3600 sec/hr) = 0.771 cfs

With the pond bottom set at elevation 151.0 feet, that gives an average head of 3.15 ft, as the pond empties from 157.3 feet to 151.00 feet. Solve the orifice flow equation:
Q = C A ((2 g h) ^ (½))
where
Q = discharge, cfs
C = discharge coefficient, 0.62
A = cross sectional area of the orifice, ft^2
h = total head, using an average head of 3.15 ft to empty the volume.

Solving for the area, A, gives an orifice diameter of approximately 4 inches.

Step 4 – Set water surface elevation for Overbank Protection Volume.

From the stage/storage chart, determine the maximum storage elevation corresponding to the 10-year design event storage volume.
From the stage-storage chart, the corresponding water surface elevation for the 10-year design event = 162.0 feet.

Set the elevation of the riser above the 1-year water surface elevation but below the 10-year water surface elevation and then calculate the size of the riser by solving the weir and orifice equations.

- Set the crest elevation at 160.0 feet, which gives a head of 2.0 feet. At this elevation, the low flow orifice head is 10.833', measured to the centerline of the orifice. Solving the orifice equation, the low flow orifice Q = 1.4cfs.
- The maximum outflow Q = 115.3 – 1.4 cfs – 113.9 cfs (Pre-developed 10-year flow minus the orifice flow)
- Solving the weir equation for the riser gives an L=13.01 feet. In order to make sure that the barrel pipe controls the flow before the riser is submerged, choose a riser with a slightly larger L. Therefore, select a 60-inch riser with a perimeter, L = 15.7 ft and an area, A = 19.63 square feet.
- Design the pipe barrel based on the 10-year storm event.
- Corresponding 10-year water surface elevation from above = 162.0 feet.
- Invert elevation = 150.0 feet.
- Head = 12.0 feet
- Determine the slope of the outlet pipe; Slope = 10%.
- Maximum Q = 115.3 cfs
- Assuming CMP, with a Manning's roughness n = 0.024, determine the diameter barrel to pass 115.3 cfs.
- Try a diameter D = 36-inches.
- Solving the pipe equation for inlet control gives Q = 110.3 cfs (refer to Detention Basin Outlet results).
- Solving the pipe equation for outlet control gives Q = 121.6 cfs (refer to Detention Basin Outlet results).

Next, develop and complete the stage-discharge storage summary (see the Detention Basin Outlet result) up to the preliminary 10-year water surface elevation = 162.0 feet and route the 10-year post-developed condition inflow by hand or using computer software.

Step 5 - Design the emergency spillway based on safely passing the 100-year storm event with a minimum of 1 foot of freeboard.

Set the emergency spillway elevation above the 10-year water surface elevation, but at least a minimum of 2' below the top of the embankment. Setting the crest elevation at elevation 16 feet gives a head of 1.0 feet.
The maximum Q100 inflow = 210.7 cfs – 125 cfs (barrel outflow) = 85.7 cfs.

Use the Design Data for Earth Spillways (USDA-SCS) to determine the spillway width for the associated head. A width of 28 feet using the earth spillway design data allows for the passage of 56 cfs with 1 foot of head, and 179 cfs with 2 foot of head, assuming a z of 2 and an n value of 0.040. (See the Detention Basin Outlet results).

There are several excellent examples in various stormwater management manuals available on the internet for designing a stormwater management pond as well as other best management practices. This example only illustrates the preliminary, basic design for a stormwater management pond.

6.0 – Individual House
Sample Sediment and Erosion Control Plan

Primary Concerns Related to Erosion and Sedimentation

Water Quality

Sediment is the number one pollutant, by volume, of surface waters in the state of West Virginia. It impacts water quality by degrading the habitat of aquatic organisms and fish, by decreasing recreational value, and by promoting the growth of nuisance weeds and algae.

Flooding

Sediment accumulation in streams, lakes, and rivers reduces their capacity to contain stormwater, which can result in increased flooding.

Local Taxes

Sediment that finds its way into streets, storm sewers, and ditches results in additional maintenance costs for local, state, and federal governments.

Property Values

Sediment deposits not only impair water quality but also damage property, thus reducing its use and value.

Sample Erosion and Sediment Control Plan

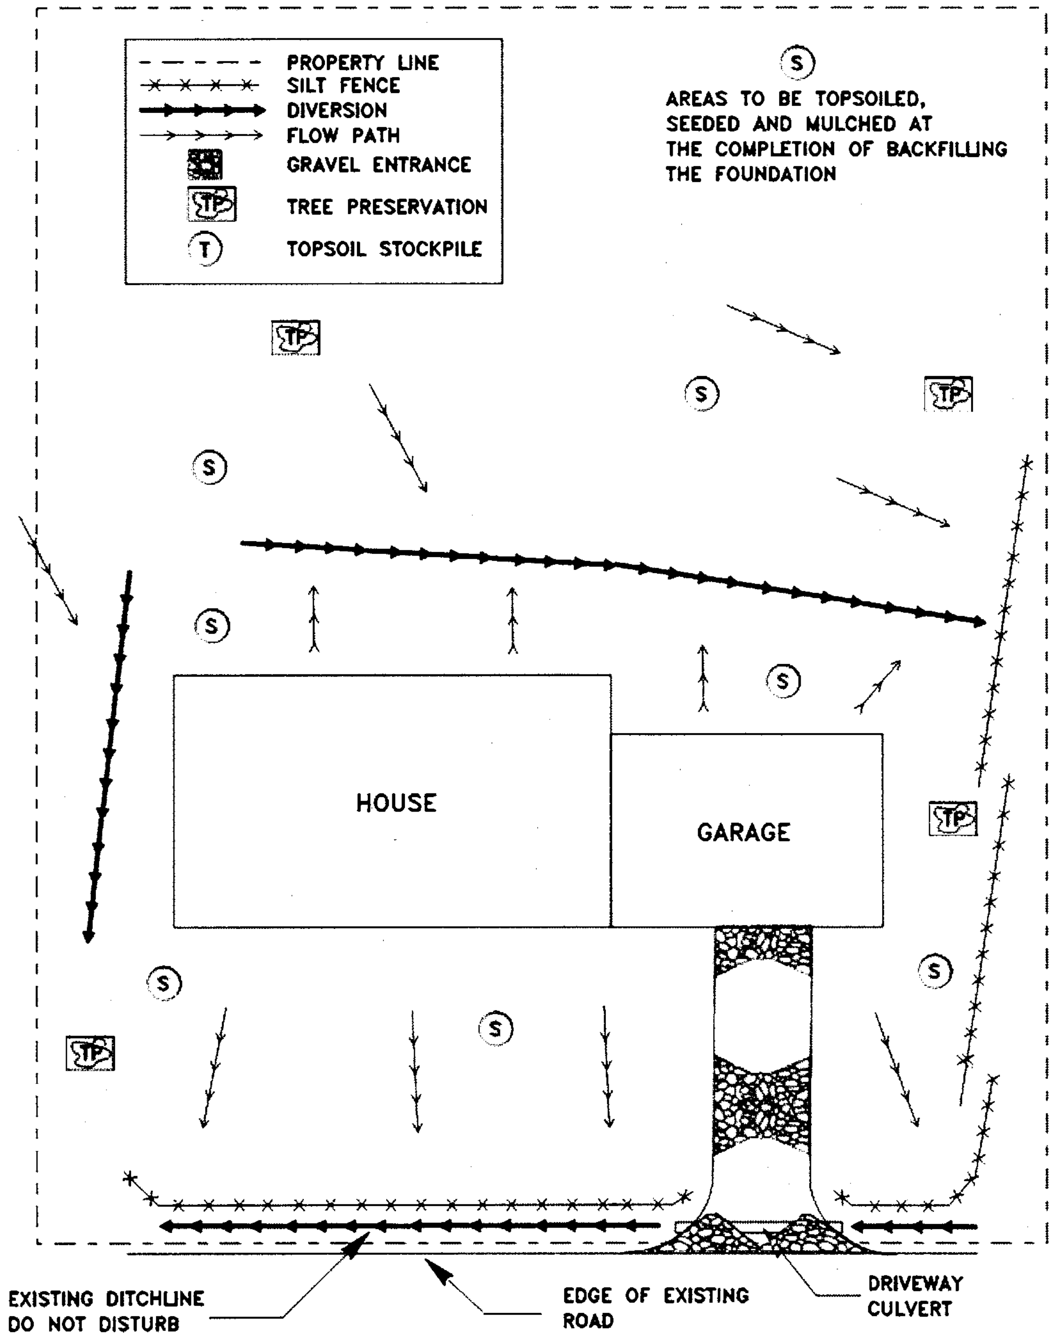
Every building site is unique and poses its own potential erosion hazards. In many instances, additional or alternative control methods are necessary if the lot is adjacent to a creek, lake, or wetland; slopes are greater than six percent; receives runoff from adjacent areas; and/or more than one acre of ground is disturbed.

NOTES:

1. It is the responsibility of the property owner and contractor to comply with State laws and local and county ordinances regarding construction site erosion and sediment control.
2. This plan is only a sample plan and is not intended to be all-inclusive or address every situation; additional or modified practices may be required on some sites.
3. Erosion or sediment control measures must be functional and maintained throughout construction.
4. Maintain positive drainage away from the structure(s).

FIGURE 6.1

INDIVIDUAL HOUSE LOT SEDIMENT CONTROL PLAN



Controlling Building Site Erosion & Sedimentation

Erosion control is important on any building site regardless of its size. Usually, principles and methods for controlling erosion and reducing offsite sedimentation are relatively simple and inexpensive. Here are four basic steps to follow when developing a building site.

Evaluate the Site

Inventory and evaluate the resources on the lot before building. Location of structures should be based on the lot's natural features. Identify trees that you want to save and vegetation that will remain during construction. Also identify areas where you want to limit construction traffic. Wherever possible, preserve existing vegetation to help control erosion and off-site sedimentation.

Select & Install Initial Erosion/ Sediment Control Practices

Determine the specific practices needed, and install them before clearing the site. Among the more commonly used practices are vegetative filter strips, silt fences, gravel drives, and inlet protection.

Develop a Maintenance Program

Maintenance of all practices is essential for them to function properly. Practices should be inspected twice a week and after each rainfall event. When a problem is identified, repair or replace the practice immediately. If frequent repairs are required (such as Silt Fence being knocked down), another more substantial practice may need to be selected. In addition, any sediment that is tracked onto the street should be scraped and deposited in a protected area. Do not flush sediment from the street with water.

Revegetate the Site

Providing a vegetative cover is the most important practice in preventing erosion and sediment. Therefore, establish vegetation as soon as possible. A well-maintained lot has a higher sale potential.

Building Lot Drainage

The best time to provide for adequate lot drainage is before construction begins. With proper planning, most drainage problems can be avoided. That's important because correcting a problem after it occurs is usually much more difficult and costly. Here's what it takes to ensure good lot surface and subsurface drainage.

Surface Drainage

- Position the structure a minimum of 18 inches above street level.

- Divert stormwater runoff away from the foundation by grading the lawn to provide at least six inches of vertical fall in the first ten feet of horizontal distance.

- Construct side and rear yard swales to take surface water away from the structure.

- Do not fill in existing drainage channels and roadside ditches, since that could result in wetness problems on someone else's property and/or damage to adjacent road surfaces.

Subsurface Drainage

- Provide an outlet for foundation or footer drains and for general lot drainage by using storm sewers (where allowed), or obtain drainage easements if you must cross adjoining properties.

Construction Sequence for Erosion & Sediment Control Practices

1. Evaluate the Site

Before construction, evaluate the site; mark vegetative areas and trees to be protected, unique areas to preserve, on-site septic system absorption fields, and vegetation suitable for filter strips, especially in perimeter areas.

Identify Vegetation to be Saved

Select and identify the trees, shrubs and other vegetation to be saved (see Step 2: "Vegetative Filter Strips").

Protect Trees & Sensitive Areas

- To prevent root damage, do not grade, burn, stock pile topsoil, or park vehicles near trees or in areas marked for preservation.
- Place plastic mesh or snow fence barriers around the trees' driplines to protect the area below their branches.
- Place a physical barrier, such as plastic fencing, around the area designated for a septic system absorption field (if applicable).

2. Install Perimeter Erosion and Sediment Controls

Identify the areas where sediment-laden runoff could leave the construction site, and install perimeter controls to minimize the potential for off-site sedimentation. It's important that perimeter controls are in place before any earthmoving activities begin.

Protect Down-Slope Areas with Vegetative Filter Strip

- On slopes of less than six percent, preserve a 20-to 30-foot wide (minimum) vegetative buffer strip around the perimeter of the property, and use it as a filter strip for trapping sediment.
- Do not mow filter strip vegetation shorter than four inches.

Protect Down-Slope Areas with Silt Fence and Other Appropriate Practices

- Use silt fencing along the perimeter of the lot's downslope side(s) to trap sediment. Refer to silt fence practices.

Install Stabilized Construction Entrance

- Restrict all lot access to this drive to prevent vehicles from tracking mud onto roadways or destroying perimeter controls. Refer to Stabilized Construction Entrances.

3. Prepare the site for construction

Prepare the site for construction and for installation of utilities. Make sure all contractors (especially the excavating contractor) are aware of areas to be protected.

Salvage and Stockpile Topsoil or Subsoil

- Remove topsoil (typically the upper four to six inches of the soil material) and stockpile.
- Remove subsoil, including any excavated material associated with basement construction, and stockpile separately from the topsoil.
- On small building sites, it may not be feasible to stockpile soil material on each individual lot due to space limitations. In these situations, soil material should be transported to protected areas designated on the overall construction plan or those areas designated by the developer.
- Locate the stockpiles away from any downslope street, driveway, stream, lake, wetland, ditch or drainageway.
- Immediately after stockpiling, temporary seed the stockpiles with annual rye or winter wheat and/or install sediment barriers around the perimeter of the piles.

4. Build Structure(s) and Install Utilities

Construct the home and install the utilities; also install the sewage disposal system and drill water well (if applicable); then consider the following:

Install Downspout Extenders

- Although not required, downspout extenders are highly recommended as a means of preventing lot erosion from roof runoff.
- Add the extenders as soon as the gutters and downspouts are installed.
- Be sure the extenders have a stable outlet, such as a paved area, or a well vegetated area. Do not route runoff directly to a street in winter due to the formation of ice.

Refer to temporary downspout extenders diagram.

5. Maintain Control Practices

Maintain all erosion and sediment control practices until construction is completed and the lot is stabilized.

- Inspect the control practices daily and after each storm event, making any needed repairs immediately.
- Toward the end of the each workday, sweep or scrape up any soil tracked onto roadway(s). Do not flush mud down the street with water.

6. Revegetate Building Site

Immediately after all outside construction activities are completed, stabilize the lot with sod, seed, and/ or mulch.

Redistribute the Stockpiled Subsoil and Topsoil

- Spread the stockpiled subsoil to rough grade.
- Spread the stockpiled topsoil to a depth of four to six inches over rough-graded areas.
- Fertilize and lime according to soil test results or recommendations of a seed supplier or a professional landscaping contractor. Fertilize and lime if needed according to soil test (or apply 10 lb./1000 sq. ft. of 10-10-10 fertilizer).

Seed or Sod Bare Areas

- Contact local seed suppliers or professional landscaping contractors for recommended seeding mixtures and rates.
- Follow recommendations of a professional landscaping contractor for installation of sod.
- Rake lightly to cover seed with ¼” of soil. Roll lightly.
- Water newly seeded or sodded areas every day or two to keep the soil moist. Less watering is needed once grass is two inches tall.

Mulch Newly Seeded Areas

- Spread straw mulch on newly seeded areas, using one and one half to two bales of straw per 1,000 square feet. The mulch should cover to where the ground is just visible.
- On flat or gently sloping land, anchor the mulch by crimping it two to four inches into the soil. On steep slopes, anchor the mulch with netting or tackifiers. An alternative to anchored mulch would be the use of erosion control blankets.

Temporary Seeding

If the site will not be permanently seeded anytime soon, sow 40 lbs of Annual Rye (year round) or 170 lbs. of Winter Wheat (fall and winter) per acre on all disturbed soils immediately upon backfilling the foundation.

7. Remove Remaining Temporary Control Measures

Once the sod and/or vegetation is well established, remove any remaining temporary erosion and sediment control practices, such as:

- Remove downspout extenders. Or, shorten to outlet on an established vegetated area, allowing for maximum filtration.
- Remove storm sewer inlet protection measures.

Individual Erosion & Sediment Control Practices for Homebuilders

Silt Fence

1. Install silt fence parallel to the contour of the land.
2. Extend ends upslope to allow water to pond behind fence.
3. Excavate a trench 4-inches wide, 8-inches deep.
4. Install fence with posts on the down slope side.
5. Place 12-inches of fabric in the trench, extending the bottom four inches toward the upslope side.
6. Join silt fence sections by using a wrap joint.
7. Backfill trench with soil materials and compact.
8. Inspect at least weekly and after each storm event, repairing as needed and removing sediment deposits when they reach one-half the fence height.

Note: Silt fence has a life expectancy of six months to one year, whereas straw bale barriers have a limited life of three months or less.

Stabilized Construction Entrance

1. Place six inches of 2” to 4”coarse aggregate over a stable subgrade.
2. Construct the drive at least 12-feet wide and 50-feet long or the distance to the foundation.
3. Add stone as needed to maintain six inches of clean depth.
4. To improve stability or if wet conditions are anticipated, place geotextile fabric on the graded foundation.

Temporary Downspout Extenders

1. Install extenders as soon as gutters and downspouts are installed to prevent erosion from roof runoff.
2. Use non-perforated (un-slotted) drainage tile.

3. Route water to a stable grassed or paved area or to the storm sewer. Do not route water directly to a street or sidewalk in the winter due to the formation of ice.
4. Remove downspout extenders after vegetation is established.

For more detailed information of these and other practices, the West Virginia Erosion and Sediment Control Manual is available to assist you in making informed decisions.

CHAPTER 7

STREAM RESTORATION STANDARD GUIDELINES AND SPECIFICATIONS

Chapter 7 – Stream Restoration BMPs

Introduction

The Natural Stream Design (NSD) approach to stream restoration uses the characteristics of a stable stream to design the restoration of an unstable one. Some of the stream characteristics that should be identified are the bed and bank materials (clay, sand, gravel, cobble and bedrock), stream pattern, channel gradient, dimension and size of the floodplain.

NSD projects require federal and state permits for in-stream construction. Therefore, NSD projects are thoroughly reviewed by the resource agencies to assure that the project will have a net positive benefit on the aquatic resource. The NPDES program was designed to eliminate and/or dramatically reduce stormwater and associated sediment from upland residential, commercial or industrial construction projects from entering the watercourse. NSD projects aim to enhance/restore stable dimensions, patterns, and profiles to stream channels as well as to enhance/restore floodplains and riparian zones. Methods commonly employed involve the construction of new channel reaches, installation of in-stream structures (rock vanes, log vanes, cross vanes, J-hooks) and construction of floodplain benches. These activities take place in or immediately adjacent to the active stream channel. Best Management Practices (BMPs) for upland construction or other in-stream construction projects are not always practical or appropriate for NSD projects. Therefore, a set of BMPs specifically for NSD projects that reduce turbidity to reasonable, practical and acceptable levels during construction of the stream restoration project have been developed. In addition to the BMPs developed for NSD projects, other appropriate BMPs as defined in Chapter Three may be utilized in developing the Storm Water Pollution Prevention Plan (SWPPP).

Conditions where Practice Applies

NSD is a broad term that encompasses a variety of projects that have the common goal of improving the quality of the stream ecosystem. Channelization and dredging to increase the flow capacity of the stream is not considered a NSD-type project. Impacts associated with channel construction such as increased turbidity, disturbance of channel substrates and floodplain alteration can be visually dramatic. However, these temporary impacts are mitigated by long-term restoration of the impaired channel to a more natural stable condition.

Planning Considerations

NSD projects may be relatively simple habitat improvement projects using structures such as cross vanes designed to improve pool habitat, or simple bank stabilization projects using rock/log vanes. Other NSD projects will be more complex and may physically alter the dimension, pattern, and/or profile of the stream.

Enhancement Projects – This category generally includes riparian buffer establishment; non-point source removal activities (livestock exclusion, removal of adjacent agriculture fields from further production, elimination of future timber harvest); bank revegetation; and/or removal or reduction of impervious surfaces in the watershed. The category also incorporates activities that augment channel stability, water quality and stream ecology in accordance with a reference condition where appropriate. These activities may include in-stream and/or streambank activities, but fall short of restoring one or more of the geomorphic variables, which include dimension, pattern and profile. Examples may include stabilization of streambanks using bioengineering techniques; creation of bankfull benches; and introduction of in-stream habitat.

Restoration Projects – These projects involve the conversion of an unstable, altered or degraded stream corridor, including adjacent riparian zones (buffers) and flood-prone areas, to a natural stable condition based on historical, recent and future watershed conditions. This process is typically based on a reference condition/reach for the stream valley type and includes restoration of the appropriate geomorphic dimension (cross-section), pattern (sinuosity), and profile (channel slope). This process supports reestablishing physical, biological and chemical integrity, including transport of the water and sediment produced by the stream's watershed in order to achieve dynamic equilibrium.

Construction Criteria

The following general practices are accepted methods to be used to reduce temporary impacts associated with construction of NSD type projects. These practices are general in nature and some may be included as special conditions in the 404/401 permit. Some general BMP's may have more detailed specifications listed in following sub-sections. Other practices may be approved on a case by case basis.

1. On-site pre-application and/or pre-construction meetings are strongly encouraged to review each project, permit application and the selected BMP(s). These meetings should include the project designer, project sponsor(s), construction contractor(s), USACE, DNR, and DEP permitting and/or enforcement personnel and other appropriate personnel.

2. Clean and inspect equipment prior to arriving on the construction site and before leaving the site to minimize transferring invasive species and contaminating the aquatic system with fluids.

3. If it's necessary for maneuvering equipment prune overhanging vegetation prior to construction. All pruned vegetation should be cut clean.

4. Minimize construction time, and maximize efficiency by:

   a. Utilizing the proper size, type and quantity of equipment
   b. Ensuring that the sufficient type, quality and quantity of materials are on-site during construction
   c. Ensuring sufficient personnel are on-site during construction
   d. Preparing and following an effective sequence of construction
   e. Minimizing down time. Once the project is under construction, it should be completed without undue delay.

5. Preserving riparian vegetation (including sod) is critical for minimizing site disturbance, reduction of upland sediment inputs, and post-construction project stability (see appropriate BMPs in Chapter Three).

6. Use upland transportation corridors to minimize impacts to the riparian zone.

7. Work in-the-dry or from the top of bank whenever feasible and practical. Minimize the amount of time and extent of disturbance in the channel as much as possible.

8. Pump-around may be used when feasible and practical.

9. Update field map with minor field modifications daily.

10. While the permit is in effect, project sites must be stabilized according to the approved Erosion and Sediment Control Plan for the 1-year, 24-hour rainfall event, ***or bankfull event for NSD projects***. If a storm event exceeds the 1-year, 24-hour rainfall limit ***or bankfull***, follow "upset procedures" in General Permit conditions.

11. Practice contemporaneous site reclamation to the extent feasible and practical during construction. Stabilize all

disturbed areas concurrently with restoration activities (see appropriate BMPs in Chapter Three).

12. Follow manufacturer specifications on equipment and materials, or provide the justification to vary from them in NPDES permit application.

7.01- IN-STREAM STRUCTURES, RIFFLES AND POOLS

Introduction

In-stream structures, and profile alterations such as riffles and pools, are constructed to provide bank stabilization, habitat enhancement, improved sediment transport and stream restoration. Types of structures may include cross vanes, rock vanes, j-hooks, and possibly log structures. In-stream structures and profile alterations are constructed to provide long -term stability to the stream reach.

Conditions Where Practice Applies

These techniques should be practiced, all or in part, during all phases of stream restoration projects. The practices that are determined most effective and feasible to sediment and erosion control for the specific site should be exercised.

Construction Specifications:

1. Where practical and feasible, in-stream work should be done on the side of the stream where the structure is being built.

2. Tracks of stationary equipment working in the stream should be parallel to stream flow when practical and feasible, to do so.

3. Minimize drop height when placing material in the channel.

4. Minimize use of temporary stream diversion/deflection structures (see drawings, attached) to reduce additional stream impacts. When used, deflection structures should:

   a. Deflect flow away from the side of stream where structures are being placed and/or profile is being altered.
   b. Be composed of native channel material if available adjacent to structure, and if channel material is to be removed anyway. This saves the impact of hauling in clean fill, while also hauling out channel material. If native channel material is not to be removed from an adjacent location, clean non-erodible rock with 15% or less of fines of like material should be imported to build deflection structures.
   c. Serve as a platform upon which equipment can be stationed to build in-stream structure.

6. Use appropriately-sized equipment to build structures, with hydraulic thumbs to place rock. Equipment that is smaller than necessary will take more time; equipment that is larger than necessary will have more impact on the site.

7. Construction should be sequenced and specified effectively and efficiently to complete the project.

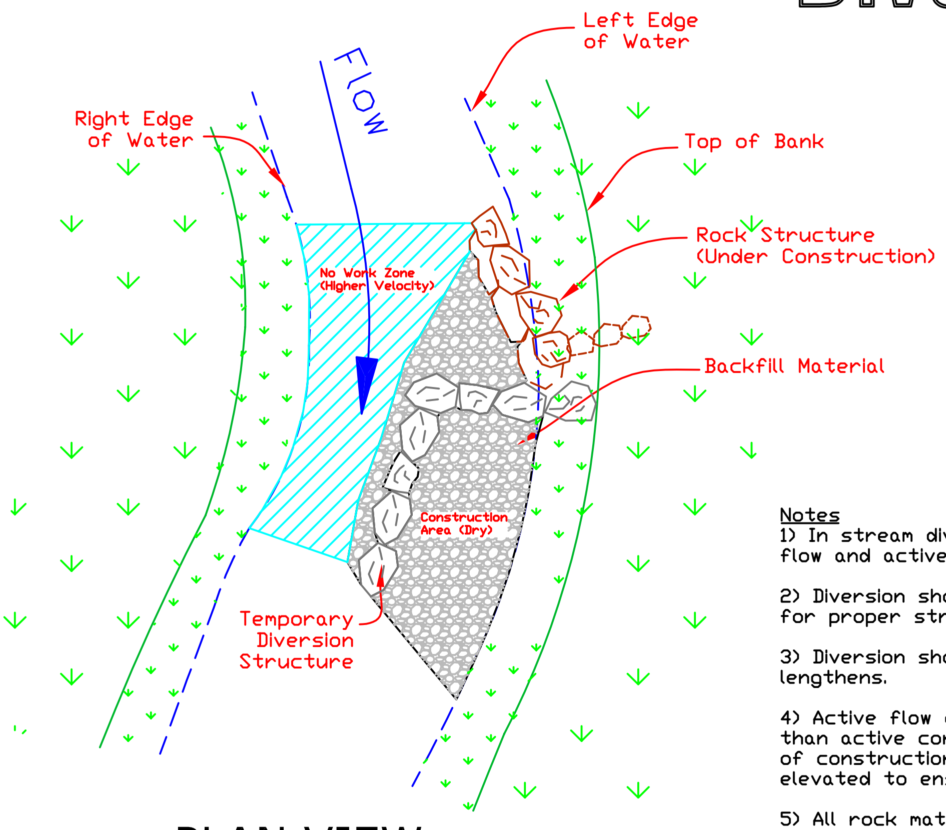
8. Where site conditions permit, turbidity curtains may be utilized per manufacturer's recommendations around structures under construction.

9. Geotextile (woven or non-woven) fabric should be placed behind structures and backfilled in channels with gravel beds (or finer particles).

10. Work in-the-dry or from the top of bank whenever feasible and practical. Minimize the amount and extent of disturbance in the channel as much as possible.

11. Pump-around may be used when feasible and practical.

In Stream Diversion (Dry)



PLAN VIEW

Notes

1) In stream diversion to act as barrier to the active flow and active construction area.

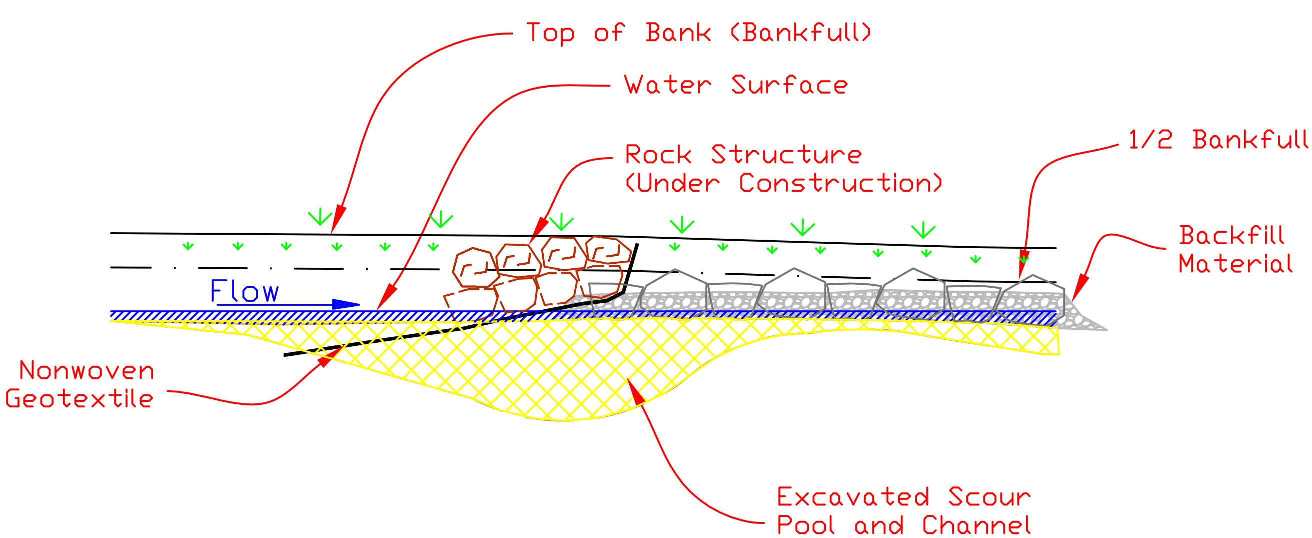
2) Diversion should be placed below structure and allow for proper structure placement.

3) Diversion shall expand up stream as structure lengthens.

4) Active flow area shall have a thalweg depth greater than active construction area to allow for dewatering of construction area. Active construction area will be elevated to ensure for a dry working area.

5) All rock materials shall be of proper size and quality, as stated in construction specifications.

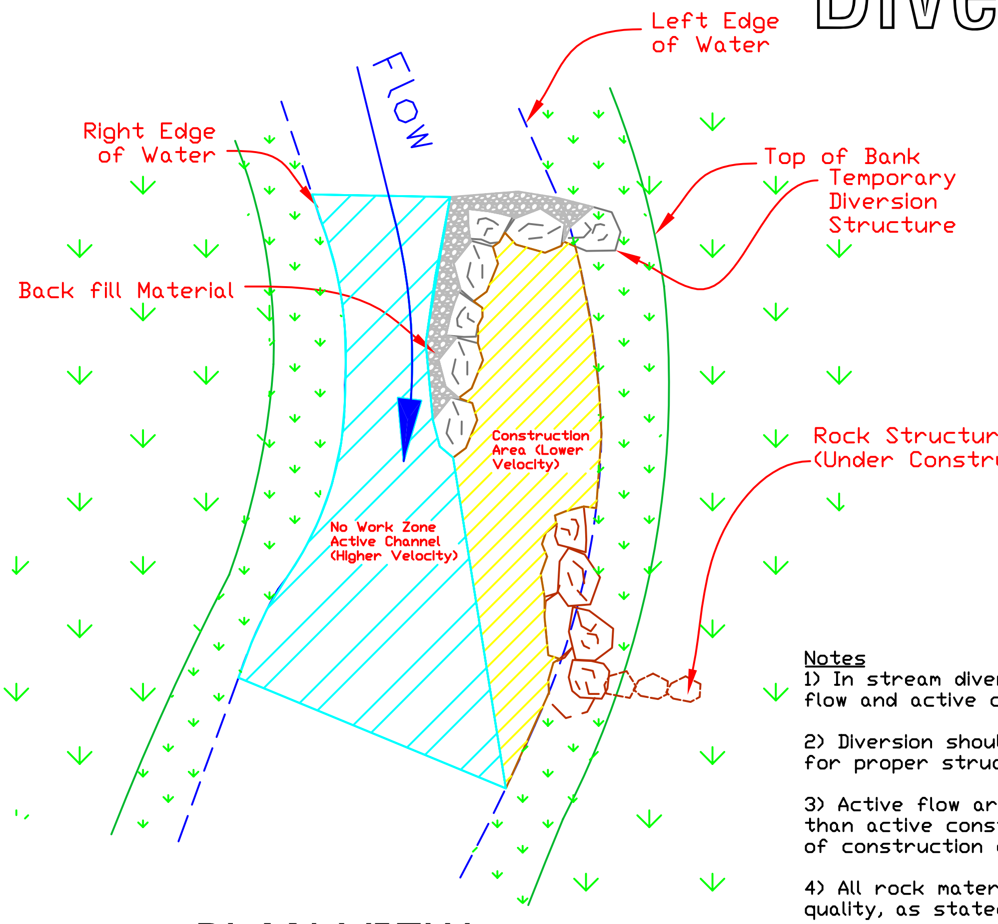
6) All rock and fabric material used in construction of diversion shall be removed immediately after completion of project.



PROFILE VIEW

Figure 7.01.2

In Stream Diversion (wet)



PLAN VIEW

<u>Notes</u>

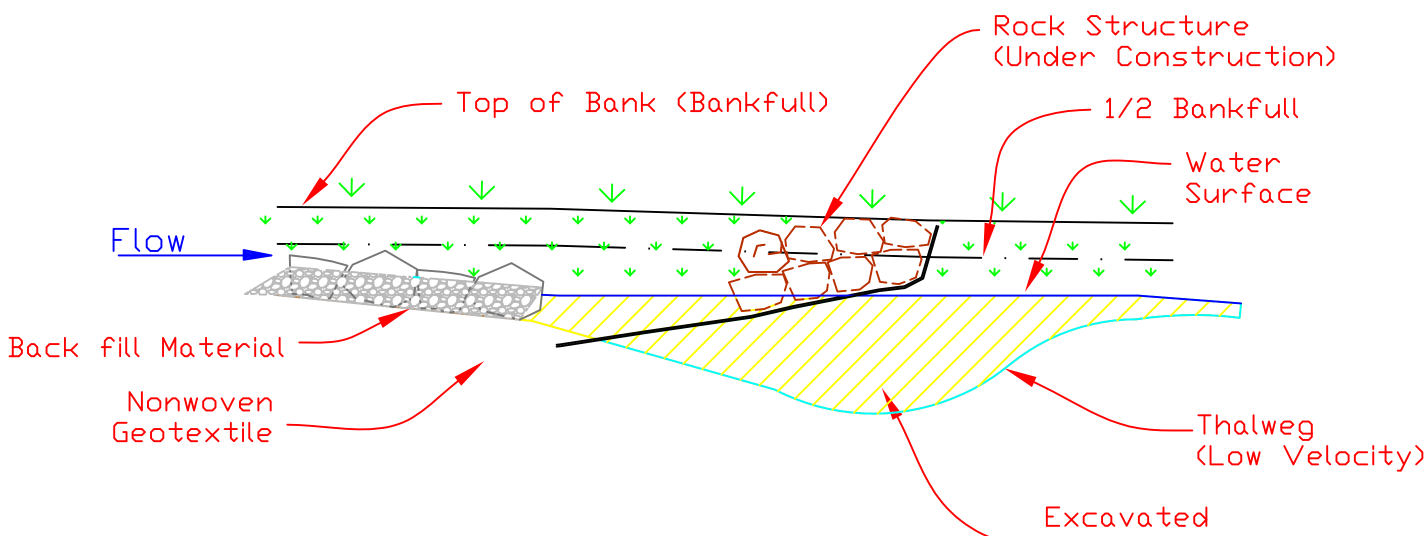
1) In stream diversion to act as barrier to the active flow and active construction area.

2) Diversion should be placed above structure and allow for proper structure placement.

3) Active flow area shall have a thalweg depth greater than active construction area to allow for dewatering of construction area.

4) All rock materials shall be of proper size and quality, as stated in construction specifications.

5) All rock and fabric material used in construction of diversion shall be removed immediately after completion of project.



PROFILE VIEW

7.02 - CONSTRUCTED BENCHES AND FLOODPLAINS

Introduction

Construction of new benches and floodplains improves both the lateral and vertical stability of the reach by allowing the stream to access the floodplain, and reduces the bank height ratio. Stabilizing banks also reduces turbidity from on-going bank erosion. BMPs exercised during construction should be site specific.

Conditions Where Practice Applies

Minimizing project area disturbance is critical to sediment and erosion control during stream restoration projects. Site specific factors influencing BMPs include quality of riparian buffer, bank material, bed material, bankfull width, bankfull depth, floodprone width, stream gradient, discharge and bank height.

Construction Specifications

1. New bankfull benches and floodplains should be seeded and mulched. Choose seed appropriate to season, region and site conditions (see appropriate BMPs in Chapter Three).

2. Install berms or silt fences along transportation routes on new benches or floodplains.

3. When constructed benches are composed of fine soils, they should be back-sloped away from the channel (using a slope of 20:1) until final grading and seeding. The back-sloped areas should be drained into ditches or sumps. Any dewatering must be through appropriate devices (see appropriate BMPs in Chapter Three).

4. Stabilize bench and floodplain slopes, and justify stabilization method according to slope material.

7.03 – NEW CHANNEL CONSTRUCTION

Introduction

Restoring natural pattern, dimension and profile may sometimes require the construction of an entirely new stream channel, or sections of new channel tied into the existing channel. Building new channel is often combined with creating suitable floodplain and establishing a riparian zone. The new stream channel will be constructed with a stable pattern and profile and appropriate dimensions based on reference conditions and design parameters. The new floodplain and riparian zone will also be established based on site and reference conditions, and will support the physical, biologic, and chemical restoration goals of the project. The construction of the new channel and floodplain must incorporate BMPs to control stormwater and associated sediment inputs.

Conditions Where Practice Applies

This restoration alternative should be applied to any new channel construction or relocation.

Construction Specifications

1. Construction should occur "in the dry", out of the existing flow, whenever possible.

2. Construction should be sequenced to effectively and efficiently complete the project.

3. When constructed benches are composed of fine soils, they should be back-sloped away from the channel (using a slope of 20:1) until final grading and seeding. The back-sloped areas should be drained into ditches or sumps to pump out, as necessary. Follow existing NPDES permit requirements about filtering all pumped discharge into streams.

4. Install sediment and erosion control at downstream end of active construction zone.

5. Stabilize new channel and bank slopes before releasing flow into the new channel, and justify stabilization method according to slope material.

6. Where feasible, release of the flow into the new channel should be a staged process. This can be accomplished by gradually removing the barrier between the old and the new channel, which allows more control of the stream flow.

7. If the abandoned channel will be backfilled, the process should proceed from upstream to downstream, and existing BMPs for seeding and mulching should be followed (Chapter Three). If the abandoned channel will not be backfilled, it must be stabilized.

8. Material excavated from the new channel should be placed in stockpile area(s) with appropriate sediment and erosion control, and utilized or disposed of in accordance with permittee's NPDES registration.

9. Disturbance to riparian vegetation adjacent to the new stream channel should be minimized when possible.

7.04 –TRANSPORTING MATERIALS ON THE STREAM BED

Introduction

Preserving riparian vegetation (including sod) is critical in minimizing site disturbance, upland sediment and turbidity inputs. Depending on local site conditions, constructing the access road along the riparian corridor may result in greater impacts than using sections of the stream bed to transport material. Examples of local site conditions where transporting material on the stream bed may be justified include but are not limited to infrastructure or other physical constraints that restrict transportation activities beyond the stream channel, critical and/or fragile riparian environments, and impact-resistant stream beds composed of bedrock or cobble. Any use of the stream bed as a route to transport materials must be clearly justified and explained in the NPDES permit application. If transporting materials on the stream bed would create considerable turbidity issues, the use of multiple stream access points may be a suitable alternative (see appropriate BMPs in Chapter Three).

Conditions Where Practice Applies

The use of the stream bed as a route for transportation of materials is limited to stream beds composed of bedrock, cobble, or large gravel, and where a transportation route on the stream bed will cause less impact than a transportation route in adjacent uplands.

Construction Specifications

When using the stream bed as a route to transport materials:

1. Use equipment of the appropriate type and size to transport material efficiently and effectively. Equipment must be no wider than the bottom width of the channel.

2. Equipment with low ground pressure is recommended to minimize stream impacts.

3. Inspect equipment daily. Low toxicity oil and coolant is recommended.

4. Limit transportation to low-flow periods (considering both daily and seasonal conditions).

5. Keep equipment out of the water where possible.

6. Limit transportation activities to one route in any single stream reach.

7. Minimize the number of turns and trips in the channel.

8. Minimize transportation activities in the rain.

9. Limit the number of stream access points and crossings to the fewest possible.

10. Locate, design and construct stream access points to minimize erosion and sedimentation into the stream. Provide adequate sediment and erosion control at stream access points.

11. Plan material storage areas and transportation routes to allow work to be done in an efficient and effective manner.

12. Stabilize all stream access and turn-around points immediately following the completion of the in-stream work.

CHAPTER 8

STEEP SLOPE CONSTRUCTION GUIDELINES IN AREAS OF HIGH SLIP POTENTIAL SOILS

Chapter 8 – Steep Slope Construction Guidelines in areas of High Slip Potential Soils

Introduction

Landslide issues at many construction sites in West Virginia illustrate the importance making some changes to the storm water permitting process in order to identify potential problems and incorporate additional requirements to reduce the number of future slips.

Conditions Where Practice Applies

High slip potential soils are a key factor with the majority of slips at construction projects in West Virginia (see **Appendix D** for table showing West Virginia High Slip Potential Soils by County).

Planning Considerations

Dewatering a critical slope is usually simple, cost efficient and will potentially provide an effective means to stabilize a slope and prevent slips.

The following provides a description of BMP's employed to protect slopes in high slip potential areas at or greater than 3:1 and to minimize soil erosion and/or slips due to seeps, springs and surface runoff that can percolate into soil strata during and after earth disturbance and trenching excavation. This moisture infiltration has the potential to cause slips by saturating the soils resulting in lower resistance to movement while decreasing the angle of repose. The methods proposed for water management is to direct flows away from potentially unstable areas by installing horizontal drains to passively drain water from the slope area and prevent saturation of slope materials. The following construction criteria is technical guidance on the design of bleeder drains however on a case by case basis, other techniques may be satisfactory.

Construction Criteria

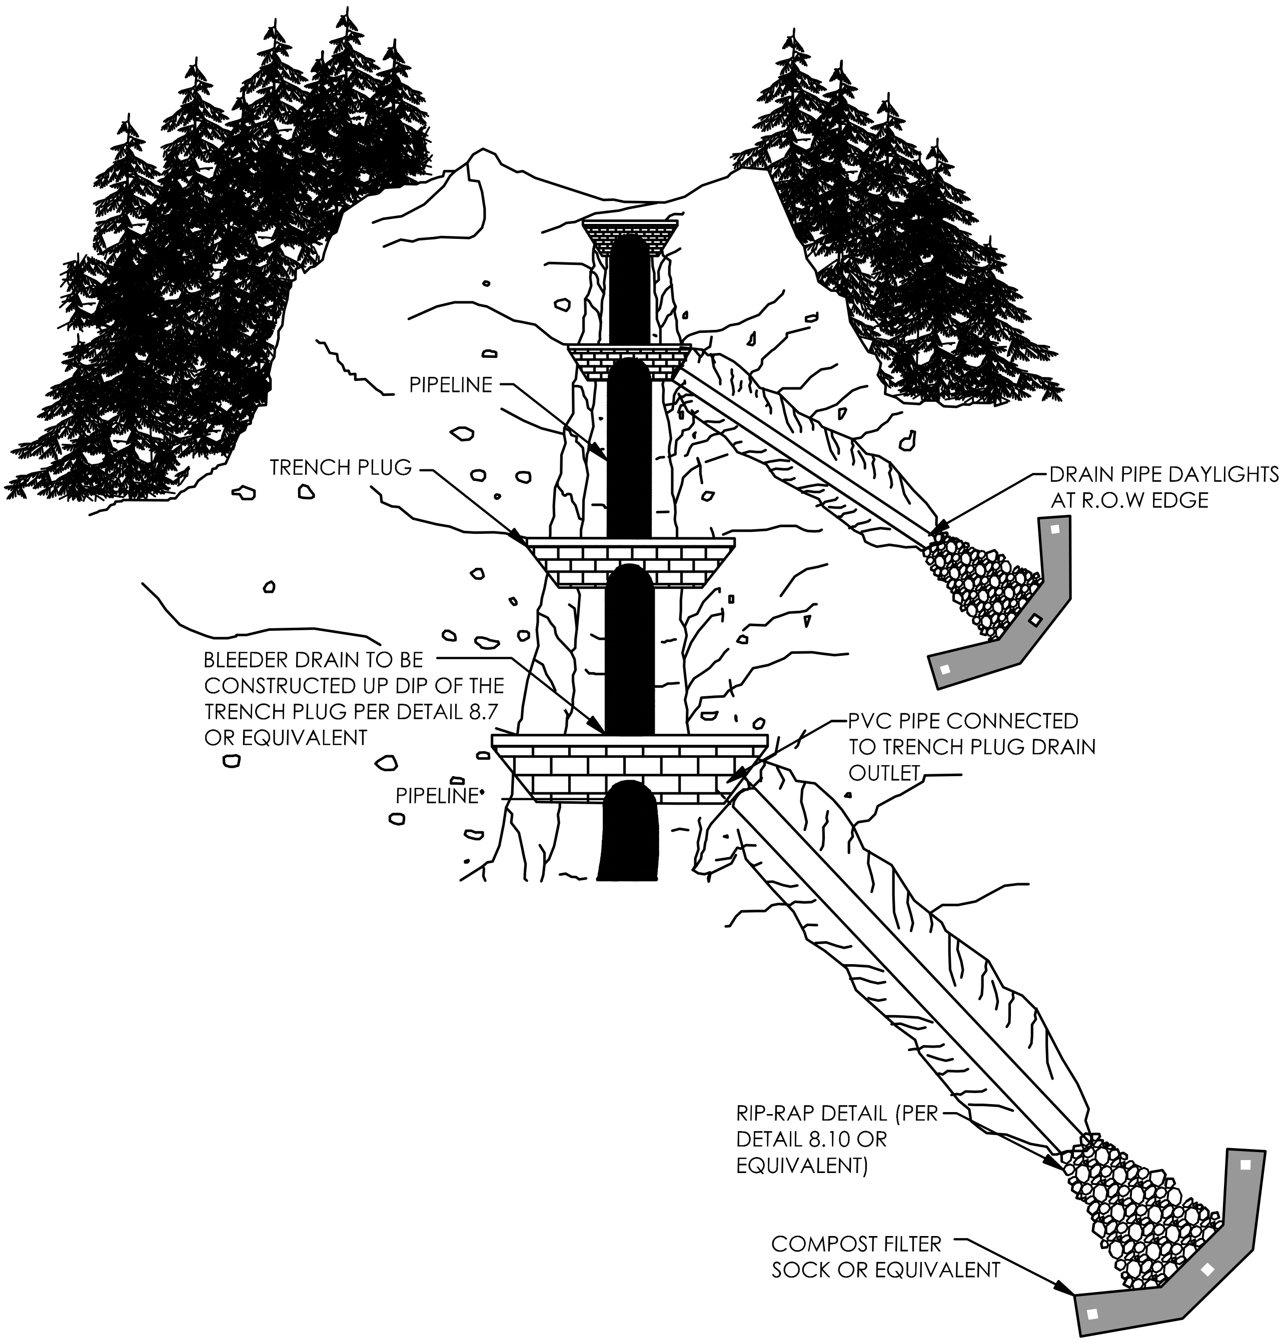
There are three (3) areas where these drains will be required:

1. In order to avoid the consequences of a “dam” behind trench plugs caused by ground water or surface water infiltrating the backfilled trench, water management is required to prevent soil saturation of the trench area by installing passive bleeder drains. (See Exhibits 8.4 thru 8.7 for bleeder drain illustrations).

2. A drain shall be installed at low topographical areas where the existing ground slopes perpendicular to the ROW are greater than 3:1 and with significant contributing drainage area Two (2) acres or more. (See Exhibits 8.8 and 8.9).

3. A drain shall be installed at seepage areas encountered during construction and positioned upslope from backfilled trench to intercept water before it seeps into the backfilled trench. (See Exhibits 8.11 and 8.12).

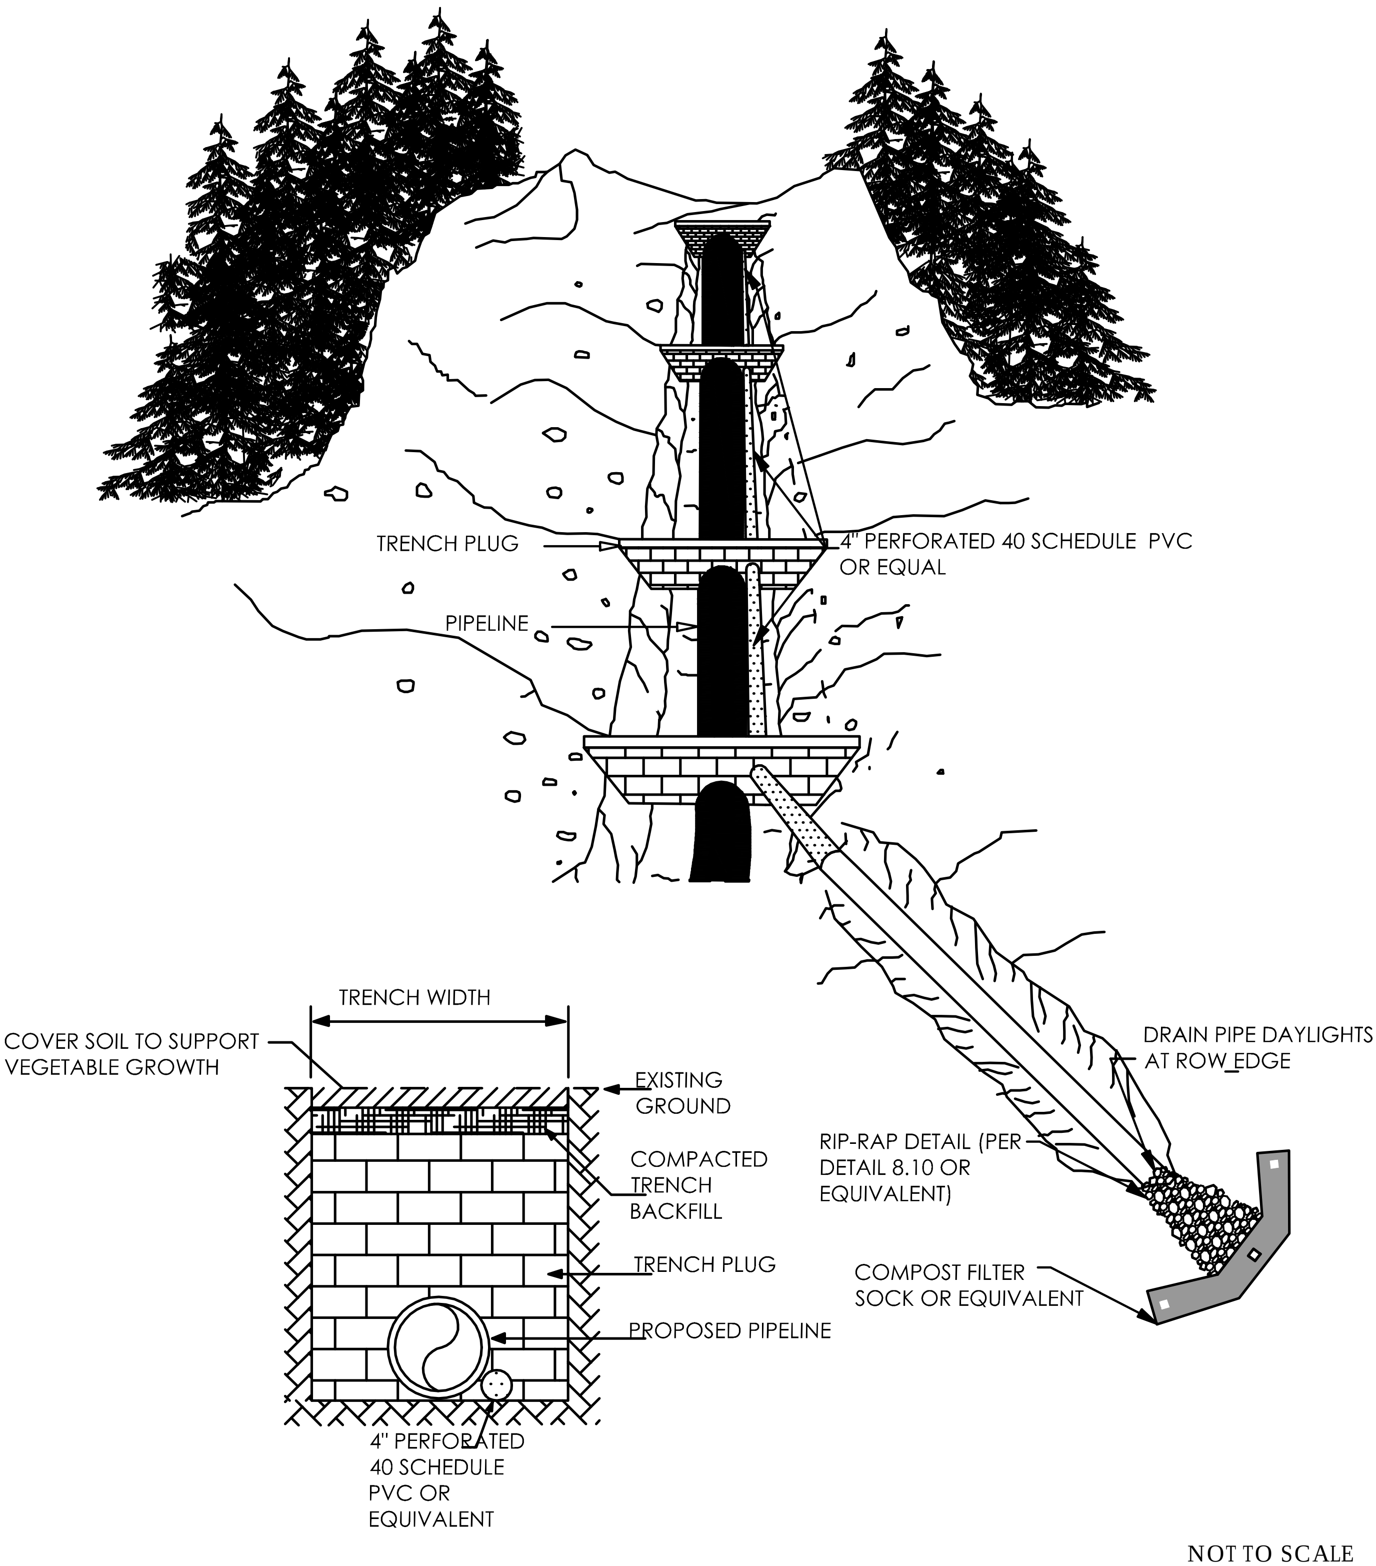
Where trenching activities are proposed in high slip potential soils and in areas where existing ground slopes are greater than 3:1, bleeder drains shall be installed to passively drain water from the trench area. The following illustration shows a drain placed at every second trench plug.



NOT TO SCALE

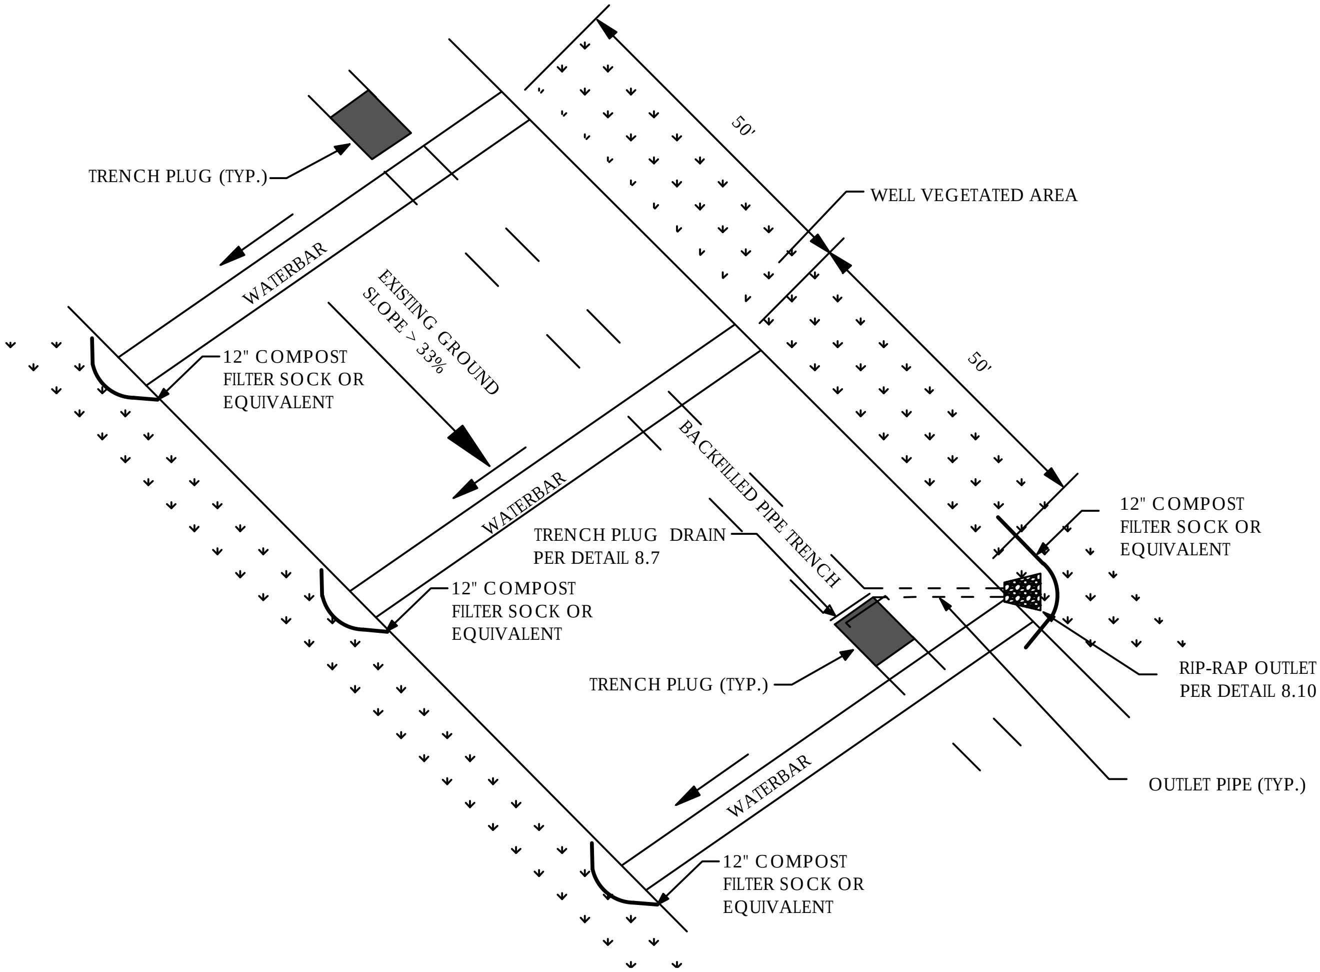
SLIP PREVENTION: BLEEDER DRAIN AND OUTLET DETAIL

A bleeder drain placed parallel along the pipeline is an effective way to passively drain water from the backfilled trench area. This technique will reduce the number of outlets and control the placement of outlets. The following illustration shows this method.



SLIP PREVENTION: BLEEDER DRAIN PARALLEL TO PIPELINE

The outlets associated with pipeline trench drains are typically used in conjunction with right-of-way diversions. Used in this manner, additional outlets and sediment filter controls will not be needed. Spacing for trench plugs in high slip potential soils is related to the severity of the ROW slopes. Trench plug drains shall be installed at every other trench plug on slopes that are 30% or greater.



<u>Spacing of Trench Plugs (Drains to be installed at every other Plug)</u>

Percent Slope	Spacing in Feet
<5	*
5 - 15	500
15 - 25	300
25 - 35	200
➢ 35	100

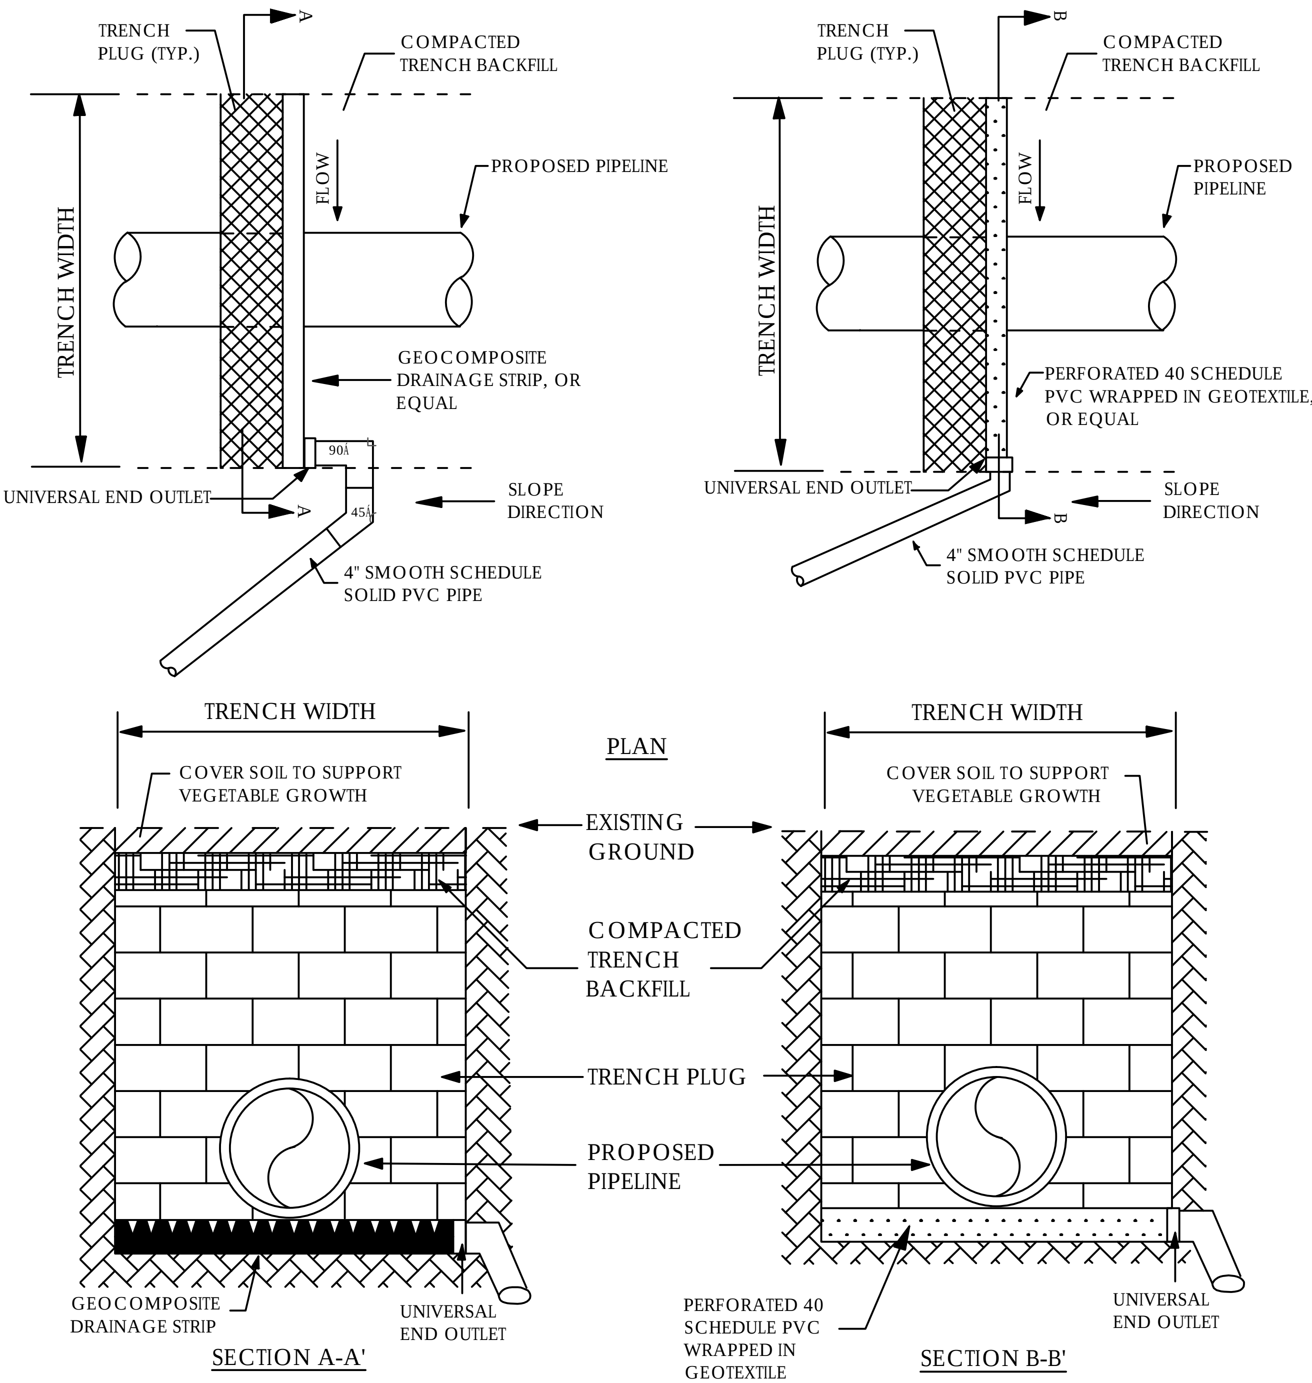
SLIP PREVENTION: TRENCH PLUG DRAIN OVERVIEW

Two (2) types of trench plug drains are illustrated below. Geocomposite Drainage Strips or Perforated Schedule 40 PVC placed behind the trench plug and below the pipeline are effective ways to passively drain water. Both methods show Schedule 40 PVC discharge pipe at a minimum of a 2% grade.



NOT TO SCALE

SLIP PREVENTION: TRENCH PLUG DRAIN DETAILS

Bleeder drains will sometimes be required at low points associated with side hill construction activities in high slip potential soils. Drainage from the undisturbed profile can infiltrate the backfilled soil within the trench and drain to a low point with the potential of saturating the soil. A drain shall be installed at low topographical areas where the existing ground slopes perpendicular to the ROW are greater than 3:1 and with significant contributing drainage area two (2) acres or more. Unusual conditions will be reviewed on a case by case basis.

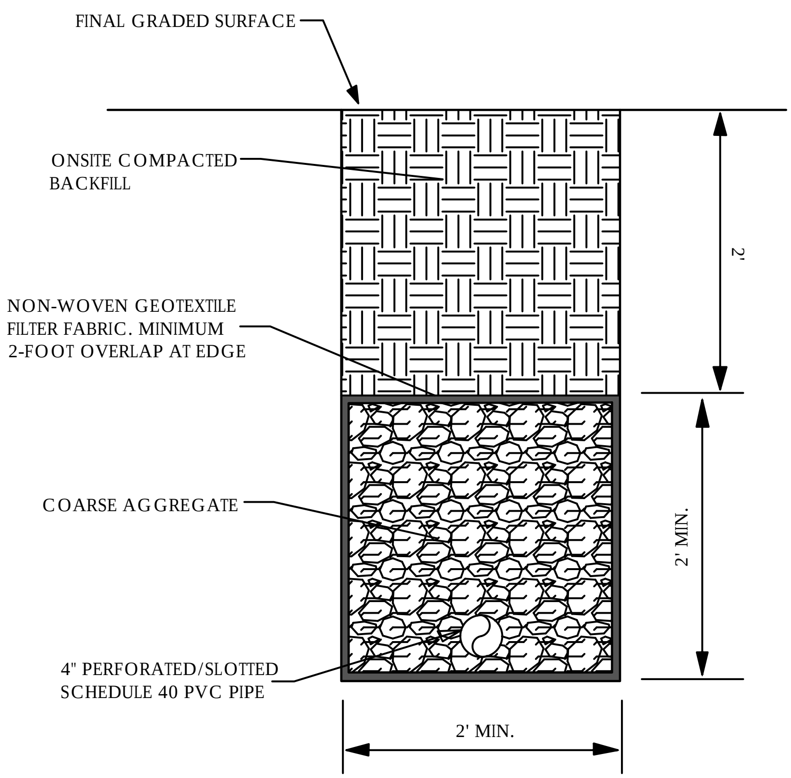
SLIP PREVENTION: DRAIN OUTLET RIP-RAP OUTLET

French drains can be constructed to passively drain water away from the trench area. These drains can be installed at seepage areas encountered during construction. These drains should be sloped at a minimum of 2% to the outlet locations



NOT TO SCALE

SLIP PREVENTION: SUBSURFACE DRAIN (FRENCH DRAIN)

Parallel drainage tiles can be installed at seepage areas encountered during construction. The drains may be perforated PVC or geocomposite drain strips placed between the seepage area and the pipeline to intercept soil-water before it seeps into the open or backfilled trenchline. These drains should be sloped at a minimum of 2% to the outlet locations.

APPENDIX A
GLOSSARY

GLOSSARY

AASHTO - American Association of State Highway & Transportation Officials (Formerly AASHO.)

ACCEPTABLE OUTLET - That point where storm water runoff can be released into a watercourse or drainage way of adequate capacity without causing scour or erosion.

ACID SOIL - A soil giving an acid reaction throughout most or all of the portion occupied by roots. (Precisely, below a pH of 7.0; practically, below a pH of 6.6.)

ALLUVIAL FAN - A sloping, fan shaped mass of sediment deposited by a stream where it emerges from an upland onto a plain.

ALLUVIUM - A general term for all detrital material deposited or in transit by streams, including gravel, sand silt, clay and all variations and mixtures of these. Unless otherwise noted, alluvium is unconsolidated.

ANGLE OF REPOSE - The stable angle between the horizontal and the maximum slope that a soil assumes through natural processes that will not slough.

ANTI-SEEP COLLAR - An impermeable diaphragm usually of sheet metal or concrete constructed at intervals within the zone of saturation along the conduit of a principal spillway to increase the seepage length along the conduit and thereby prevent piping or seepage along the conduit.

ANTI-VORTEX DEVICE - A device, usually a vertical or horizontal plate, carefully designed and placed at the entrance of a pipe to prevent the formation of a vortex in the water at the pipe entrance.

APRON - A floor or lining to protect a surface from erosion, for example, the pavement below chutes, spillways, or at the toes of dams.

ASPECT - The direction a slope faces - a physiographic feature of steep slopes which influences plant growth and adaptation.

ATTERBERG LIMITS - Atterberg limits are soil properties measured for soil materials passing the No. 40 sieve.

Liquid Limits (LL) - the liquid limit is the water content corresponding to the arbitrary limit between the liquid & plastic states of consistency of a soil.

Plastic Limits (PL) - The plastic limit is the water content corresponding to an arbitrary limit between the plastic andsemisolid states of consistency of a soil.

Plasticity Index (PI) - The plasticity index is the numerical difference between the liquid limit and plastic limit.

BAFFLES - Vanes, guides, grids, grating or similar devices placed in a conduit to deflect or regulate flow and effect a more uniform distribution of velocities.

BARREL - The usually mild sloping closed conduit used to convey water under or through a dam; part of a principal spillway.

BASE FLOW - The stream discharge from ground water accretion.

BEDLOAD - The sediment that moves by sliding, rolling or bounding on or very near the streambed; sediment moved mainly by tractive or gravitational forces or both but at velocities less than the surrounding flow.

BERM - A shelf that breaks the continuity of a slope.

BIODEGRADABLE - Capable of being broken down (degraded) by common soil organisms.

BLIND DRAIN - A type of drain consisting of an excavated trench refilled with pervious material, such as coarse sand, gravel or crushed stone, through whose voids water percolates and flows to an outlet. Often referred to as a French drain because of its initial development and widespread use in France.

BRACKISH (WATER) - Slightly to moderately salty water.

BULKHEAD - A wall made from wood, steel, concrete, etc. for protection of shoreline from waves or currents.

CALCIUM SULFATE - Gypsum. A hydrated form used to treat high sodium soils. CaS04

CHANNEL - A natural stream that conveys water; a ditch or channel excavated for the flow of water.

CHANNEL IMPROVEMENT - The improvement of the flow characteristics of a channel by clear
ing, excavation, realignment, lining, or other means in order to increase its water carrying capacity.

CHANNEL STABILIZATION - Erosion prevention and stabilization of velocity distribution in a channel using jetties, drops, revetments, structural linings, vegetation and other measures.

CHANNEL STORAGE - Water temporarily stored in channels while en route to an outlet.

CHECK DAM - A small dam construction in a gully or other small watercourse to decrease the stream flow velocity (by reducing the channel gradient), minimize channel scour, and promote deposition of sediment.

CHUTE - A high velocity, open channel for conveying water to a lower level without erosion.

CLAY (SOILS) - 1. A mineral soil separate consisting of particles less than 0.002 millimeter in equivalent diameter. 2. A soil texture class. 3. (Engineering) A fine grained soil (more than 50 percent passing the No. 200 sieve) that has a high plasticity index in relation to the liquid limit. (Unified Soil Classification System)

COMPACTION - To unite firmly. With respect to construction work with soils, engineering com tion is any process by which the soil grains are rearranged to decrease void space and bring them into closer contact with one another, thereby increasing the weight of solid material per unit of volume, increasing the shear and bearing strength and reducing permeability.

CONDUIT - Any channel intended for the conveyance of water, whether open or closed.

CONTOUR - 1. An imaginary line on the surface of the earth connecting points of the same el tion. 2. A line drawn on a map connecting points of the same elevation.

COOL (SLOPE EXPOSURE) - A slope facing north or east, or a slope shaded during the hot part of the day.

CORE TRENCH - A trench, filled with relatively impervious material intended to reduce seepage of water through porous strata.

CRADLE (ENGINEERING - A structure usually of concrete shaped to fit around the bottom and sides of a conduit to support the conduit, increase its strength and in dams, to fill all voids between the underside of the conduit and the soil.

CREST - 1. the top of a dam, dike, spillway or weir, frequently restricted to the overflow portion. 2. The summit of a wave or peak of a flood.

CRITICAL AREA OR SITE - Sediment producing, highly erodible or severely eroded areas.

CRITICAL DEPTH (HYDRAULICS) - Depth of flow in a channel of specified dimensions at which specific energy is a minimum for a given discharge.

CROWN (OF SLOPE) - Top of slope; apex.

CRUSHED STONE - Aggregate consisting of angular particles produced by mechanically crushing rock.

CULM - The stem of grasses, sedges and rushes which is jointed and usually hollow in grasses and usually solid in sedges and rushes.

CULTIPACKER SEEDER - A farm tool equipped with a seed box which drops the seed between cultipacker rollers to place the seed to firm soil where they will be pressed into soil by the second corrugated roller.

CUT - Portion of land surface or area from which earth has been removed or will be removed by excavation; the depth below original ground surface to excavated surface.

CUT-AND-FILL - Process of earth moving by excavating part of an area and using the excavated material for adjacent embankments or fill areas.

CUTOFF - A wall or other structure, such as a trench, filled with relatively impervious material intended to reduce seepage of water through porous strata.

CUTTINGS - A small shoot cut from a plant to start a new plant.

CYCLONE (SEEDER) - A hand turned or tractor drawn seeder that broadcasts seed onto the seed bed by a rotary motion that slings the seed outward from the seeder.

DAM - A barrier to confine or raise water for storage or diversion, to create a hydraulic head, to prevent gully erosion, or for retention of soil, sediment or other debris.

DEBRIS - Broken remains of plants, objects and rocks that form trash or remains.

DECIDUOUS - Plants that shed their leaves annually as opposed to evergreen.

DEPOSITION - The accumulation of material dropped because of a slackening movement of the transporting agent, water or wind.

DESICCATION - Drying out as of root systems of plants before they are planted.

DESILTING AREA - An area of grass, shrubs or other vegetation used for inducing deposition of silt and other debris from slowing water, located above a pond, field or other area needing protection from sediment accumulation. (See filter strip.)

DETENTION DAM - A dam constructed for the purpose of temporary storage of stream flow or surface runoff which releases the stored water at controlled rates.

DIKE (ENGINEERING) - An embankment to confine or control water, for example, one built along the banks of a river to prevent overflow or lowlands; a levee.

DISTURBED AREA - An area in which the natural vegetative soil cover has been removed or altered and, therefore, is susceptible to erosion.

DIVERSION - A channel with a supporting ridge on the lower side constructed across the slope to divert water from areas where it is in excess to sites where it can be used or disposed of safely. Diversions differ from terraces in that they are individually designed.

DOLOMITIC (LIMESTONE) - Liming materials that contain more than 6 percent magnesium (mg); high magnesium lime.

DRAIN (NOUN) - 1. A buried pipe or other conduit (subsurface drain). 2. A ditch or channel (open drain) for carrying off surplus surface water or groundwater.

DRAIN (VERB) - 1. To provide channels, such as open ditches or closed drains, so that excess water can be removed by surface flow or internal flow. 2. To lose water (from the soil) by pertion.

DRAINAGE - 1. The removal of excess surface water or ground water from land by means of surface or subsurface drains. 2. Soils characteristics that affect natural drainage.

DRAINAGE AREA (WATERSHED) - All land and water area from which runoff may run to a common (design) point.

DRAUGHTY (SOIL OR SLOPE) - Lacking moisture during part of the growing season during a typical year.

DROP INLET SPILLWAY - An out fall structure in which the water drops through a vertical riser connected to a discharge conduit.

DROP SPILLWAY - An out fall structure in which the water drops over a vertical wall onto an apron at a lower elevation.

DROP STRUCTURE - A structure for dropping water to a lower level and dissipating surplus energy; a fall. The drop may be vertical or inclined.

DRY STORAGE - The 1800 cubic feet of storage in a trap or basin that is dewatered after rain events.

EMERGENCY SPILLWAY - A dam spillway designed and constructed to discharge flow in excess of the principal spillway design discharge.

ENERGY DISSIPATOR - A designed device such as an apron of rip rap or a concrete structure placed at the end of a water transmitting apparatus such as pipe, paved ditch or paved chute for the purpose of reducing the velocity, energy and turbulence of the discharged water.

ENTRANCE HEAD - The head required to cause flow into a conduit or other structure, including both entrance loss and velocity head.

EROSION - 1. The wearing away of the land surface by running water, wind, ice, or other geo cal agents, including such processes as gravitational creep. 2. Detachment and movement of soil or rock fragments by water, wind, ice or gravity. The following terms are used to describe different types of water erosion:

Accelerated erosion - Erosion much more rapid than normal, natural or geological erosion, primarily as a result of the influence of the activities of man or, in some cases, of other animals or natural catastrophes that expose base surfaces, for example, fires.

Gully erosion - The erosion process whereby water accumulates in narrow channels and, over short periods, removes the soil from this narrow area to considerable depths, ranging from 1 or 2 feet to as much as 75 to 100 feet.

Rill erosion - An erosion process in which numerous small channels only several inches deep are formed. See rill.

Sheet erosion - The spattering of small soil particles caused by the impact of raindrops on wet soils. The loosened and spattered particles may or may not subsequently removed by surface runoff.

EROSIVE VELOCITIES - Velocities of water that are high enough to wear away the land surface. Exposed soil will generally erode faster than stabilized soils. Erosive velocities will vary according to the soil type, slope, structural or vegetative stabilization used to protect the soil.

ESTHETIC (AESTHETIC) - Pleasing in appearance; showing good taste.

EVERGREEN - Plants that have leaves or needles yearlong as opposed to those that lose their leaves during part of the year.

EXCELSIOR BLANKET - An erosion retardant material made from excelsior strands held together with net
like stands of plastic or other material.

EXPOSURE (SLOPE) -

North - Slopes facing in any compass direction clockwise between N45W and S45E.

South - Those slopes that face in any compass direction clockwise between S45E and N45W.

FILTER STRIP - A strip of permanent vegetation above ponds, diversions and other structures to retard flow of runoff water, causing deposition of transported material, thereby reducing sediment flow.

FINES (SOIL) - Generally refers to the silt and clay size particles in soil.

FREEBOARD (HYDRAULICS) - The distance between the maximum water surface elevation anticipated in design and the top of retaining banks or structures. Freeboard is provided to prevent overtopping due to unforeseen conditions.

GABION - A flexible woven-wire basket composed of two to six rectangular cells filled with small stones. Gabions may be assembled into many types of structures such as revetments, retaining walls, channel liners, drop structures and groins.

GABION MATTRESS - A thin gabion, usually six or nine inches thick, used to line channels for erosion control .

GRADE - 1. The slope of a road, channel or natural ground. 2. The finished surface of a canal bed, roadbed, top of embankment, or bottom of excavation; any surface prepared for the support of construction, like paving or laying a conduit. 3. To finish the surface of a canal bed, roadbed, top of embankment or bottom of excavation.

GRAFTING - A method of propagating plants by joining wood from one plant to another plant to get more desirable growth on the second plant.

GRASSED WATERWAY - A natural or constructed waterway, usually broad and shallow covered with erosion resistant grasses, to convey surface water down the slope.

GRAVEL - 1. Aggregate consisting of mixed sizes of 1/4 inch to 3 inch particles which normally occur in or near old streambeds and have been worn smooth by the action of water. 2. A soil having particle sizes, according to the Unified Soil Classification System, ranging from the No. 4 sieve size angular in shape as produced by mechanical crushing.

GRAVEL FILTER - Washed and graded sand and gravel aggregate placed around a drain or well screen to prevent the movement of fine materials from the aquifer into the drain or well.

GROIN - A shore protection structure built (usually perpendicular to the shoreline) to trap littoral drift or retard erosion of the shoreline.

GROUND COVER - Plants which are low-growing and provide a thick growth which protects the soil as well as providing some beautification of the area occupied.

GULLY - A channel or miniature valley cut by concentrated runoff through which water commonly flows only during and immediately after heavy rains or during the melting of snow. The distinction between gully and rill is one of depth. A gully is sufficiently deep that it would not be obliterated by normal tillage operations, whereas a rill is of lessor depth and would be smoothed by ordinary farm tillage.

HEAD (HYDRAULICS) - 1. The height of water above any plane of reference. 2. The energy, either kinetic or potential, possessed by each unit weight of a liquid expressed as the vertical height through which a unit weight would have to fall to release the average energy possessed. Used in various terms such as pressure head, velocity head, and head loss.

HERBACEOUS PERENNIAL (PLANTS) - A plant whose stems die back to the ground each year.

HERBICIDE - Chemical formulation used to control weeds or brush.

HULLED (SEED) - Hullless seed, such as sericea lespedeza. Seed are usually processed after threshing to take off outer hull to facilitate scarification and quicken germination.

HYDRAULIC GRADE LINE - In a closed conduit a line joining the elevations to which water could stand in risers or vertical pipes connected to the conduit at their lower end and open at their upper end. In open channel flow, the hydraulic grade line is the free water surface.

HYDRAULIC GRADIENT - The slope of the hydraulic grade line. The slope of the free surface of water flowing in an open channel.

HYDRAULIC JUMP - The sudden turbulent rise in water level from a flow stage below critical depth to flow stage above critical depth, during which the velocity passes from super critical to sub-critical.

HYDROGRAPH - A graph showing variation in stage (depth) or discharge of a stream of water over a period of time.

H-3 l -6

HYDROSEEDER - A machine designed to apply seed, fertilizer, lime and short fiber wood or paper mulch to the soil surface.

HYDRO-SEEDING - Seeding with a hydroseeder.

INFLOW PROTECTION - A water handling device used to protect the transition area between any water conveyance (dike, swale, or swale dike) and a sediment trapping device.

INTERCEPTOR DRAIN - A surface or subsurface drain, or a combination of both, designed and installed to intercept flowing water.

LIME - Basic calcareous materials used to raise pH of acid soils for benefit of plants being grown. May be either ground limestone or hydrated lime.

LITTORAL DRIFT - The sedimentary material moved in the littoral zone under the influence of waves and currents.

MANNING'S FORMULA (HYDRAULICS) - A formula used to predict the velocity of water flow in an open channel or pipeline:

MULCH - Covering on surface of soil to protect and enhance certain characteristics, such as water retention qualities.

MULCH ANCHORING TOOL - A tool that looks like a dull disk designed to press straw and similar mulches into the soil to prevent loss due to wind, water or gravity.

NETTING (MULCH) - Paper or cotton material used to hold mulch material on the soil surface.

NITROGEN - FIXING (BACTERIA) - Bacteria having the ability to fix atmospheric nitrogen, making it available for use by plants. Inoculation of legume seeds is one way to insure a source of these bacteria for specified legumes.

NON-EROSIVE VELOCITY - Controlling the velocity of water to prevent detachment and movement of soil or rock. Erosive velocity will vary according to the soil type, slope, structural or vegtive stabilization used to protect the soil.

NORMAL DEPTH - Depth of flow in an open conduit during uniform flow for the given con tions. (See uniform flow.)

NOXIOUS WEEDS - Harmful; undesirable; hard to control.

a. Restricted - May be sold in the trade but are limited to very small amounts as undesirable connates.

b. Prohibited - Prohibited from sale.

OUTFALL - The point where water flows from a conduit, stream or drain.

OUTLET - The point at which water discharges from such things as a stream, river, lake, tidal basin, pipe, channel or drainage area.

OUTLET CHANNEL - A waterway constructed or altered primarily to carry water form man-made structures such as terraces, subsurface drains, diversions and impoundments.

OVERFALL - Abrupt change in stream channel elevation; the part of a dam or weir notch over which the weir notch over which the water flows.

PAPER FIBER - A short fiber mulch material usually applied by hydroseeder along with fertilizer and seed.

PARENT MATERIAL - The unconsolidated rock material from which the soil profile develops.

PENDULOUS - More or less hanging or inclined downward.

PERMANENT SEEDING - Results in establishing perennial vegetation which may remain on the area for many years.

PERMISSIBLE VELOCITY (HYDRAULICS) - The highest average velocity at which water may be carried safely in a channel or other conduit. The highest velocity that can exist through a subtial length of a conduit and not cause scour of the channel. A safe, non-eroding or allowable vety.

pH - A number denoting the common logarithm of the reciprocal of the hydrogen ion concentration. A pH of 7.0 denotes neutrality, higher values indicate alkalinity, and lower values indicate acidity.

PHREATIC LINE - The upper surface of the zone of saturation in an embankment is the phreatic (zero pressure) surface; in cross-section, this is called the phreatic line.

PIPING - Removal of soil material through subsurface flow channels or pipes developed by seepage water.

PLUGS - Pieces of turf or sod, usually cut with a round tube, which can be used to propagate the turf or sod by vegetative means.

PROJECTION - In sediment basins or other dams the perpendicular distance that the anti-seep collar extends from the outside surface of the pipe or pipe cradle.

RECP – See Rolled Erosion Control Products

RETENTION - The amount of precipitation on a drainage area that does not escape as runoff. It is the difference between total precipitation and total runoff.

REVETMENT - Facing of stone or other material, either permanentor temporary, placed along the edge of a stream or shoreline to stabilize the bank and to protect it from the erosion action of water.

RHIZOME - Any prostrate, more or less elongated stem growing partly or completely beneath the surface of the ground; usually rooting at the nodes and becoming upcurved at the apex.

RIGHT-OF-WAY - Right of passage, as over another's property. A route that is lawful to use. A strip of land acquired for transport or utility construction.

RILL - A small channel cut by concentrated runoff but through which water commonly flows only during and immediately after rains or during the melting of snow. A rill is usually only a few inches deep (but no more than a foot) and, hence, no obstacle to tillage operations.

RIP RAP - Broken rock, cobbles, or boulders placed on earth surfaces, such as the face of a dam or the bank of a stream, for protection against the action of water (waves); also applies to brush or pole mattresses, or brush and stone, or similar materials used for soil erosion control.

ROLLED EROSION CONTROL PRODUCTS - Rolled Erosion Control Products (RECPs) are temporary or permanent erosion control nets, blankets and three-dimensional matrixes made from a wide variety of natural (such as jute, coir and straw) and manmade materials alone or in combination.

ROUGHNESS COEFFICIENT (HYDRAULICS) - A factor in velocity and discharge formulas representing the effect of channel roughness on energy losses in flowing water. Manning's is a commonly used roughness coefficient.

RUNOFF (HYDRAULICS) - That portion of the precipitation on a drainage area that is discharged from the area in the stream channels. Types include surface runoff, ground water runoff or seepage.

SALINE SOIL - A non-alkali soil containing sufficient soluble salts to impair plant growth.

SAND - 1. (Agronomy) A soil particle between 0.05 and 2.0 millimeters in diameter. 2. A soil textural class. 3. (Engineering) According to the Unified Soil Classification System, a soil particle larger than the No. 200 sieve (0.074mm) and passing the No. 4 sieve (approximately 1/4 inch).

SCD - Soil Conservation District.

SEDIMENT - Solid material, both mineral and organic, that is in suspension, is being transported, or has been moved from its site of origin by air, water, gravity, or ice and has come to rest on the earth's surface either above or below sea level.

SEDIMENTATION - Deposition of detached soil particles.

SEDIMENT DISCHARGE (SEDIMENT LOAD) - The quantity of sediment, measured in dry weight or by volume, transported through a streamcross-section in a given time. Sediment discharge consists of both suspended load and bedload.

SEEPAGE - 1. Water escaping through or emerging from the ground. 2. The process by which water percolates through the soil.

SEEPAGE LENGTH - In sediment basins or ponds, the length along the pipe and around the anti-seep collars that is within the seepage zone through an embankment. (See phreatic line.)

SHA - Maryland State Highway Administration.

SHEET FLOW - Water, usually storm runoff, flowing in a thin layer over the ground surface.

SIDE SLOPES (ENGINEERING) - The slope of the sides of a canal, dam or embankment. It is customary to name the horizontal distance first, as 1.5 to 1, or frequently, 1 1/2: 1, meaning a hortal distance of 1.5 feet to 1 foot vertical.

SILT - 1. (Agronomy) A soil separate consisting of particles between 0.05 and 0.002 millimeter in equivalent diameter. 2. A soil textural class. 3. (Engineering) According to the Unified Soil Clas
tion System a fine grained soil (more than 50 percent passing the No. 200 sieve) that has a low plasticity index in relation to the liquid limit.

SLURRY - A thickened, aqueous mixture of such things as seed, fertilizer, short fiber mulch or soil.

SMALL GRAIN MULCH MATERIAL - Straw material from oats, barley, wheat, or rye.

SOD - A piece of earth containing grass plants with their matted roots. Turf.

SOIL - 1. (Agronomy) the unconsolidated mineral and organic material on the immediate surface of the earth that serves as a natural medium for the growth of land plants. 2. (Engineering) Earth and rock particles resulting from the physical and chemical disintegration of rocks, which may or may not contain organic matter. It includes fine material (silts and clays), sand and gravel.

SOIL TEST - Chemical analysis of soil to determine needs for fertilizers or amendments for species of plant being grown.

SPECIFIC ENERGY - The average energy per unit weight of water at a channel section as ex pressed with respect to the channel bottom.

SPILLWAY - An open or closed channel, or both, used to convey excess water from a reservoir. It may contain gates, either manually or automatically controlled to regulate the discharge ofexcess water.

SPREADER (HYDRAULICS) - A device for distributing water uniformly in or from a channel.

STABILIZATION - Providing adequate measures, vegetative and/or structural that will prevent erosion from occurring.

STABILIZED AREA - An area sufficiently covered by erosion resistant material such as a good cover of grass, or paving by asphalt, concrete, or stone, in order that erosion of the underlying soil does not occur.

STABILIZED GRADE - The slope of a channel at which neither erosion nor deposition occurs.

STABLE (STREAM OR CHANNEL) - The condition of a stream, channel or other water course in which no erosion or deposition occurs; adequately protected from erosion.

STAGE (HYDRAULICS) - The variable water surface or the water surface elevation above any chosen datum.

STATIC HEAD - Head resulting from elevation differences, for example, the difference in elevation in headwater and tailwater in a hydroelectric plant.

STILLING BASIN - An open structure or excavation at the foot of an outfall, conduit, chute, drop, or spillway to reduce the energy of the descending stream of water.

STOLON - A trailing or reclining above ground stem capable of rooting and/or sending up new shoots from the nodes.

STRUCTURAL - Relating to something constructed or built by man.

STRUCTURAL (SOIL) - The combination or arrangement of primary soil particles into secondary particles, units or peds. (Dune sand is structureless)

SUBCRITICAL FLOW - Flow at velocities less than critical velocity.

SUBGRADE - The soil prepared and compacted to support a structure or a pavement system.

TAILWATER (HYDRAULICS) - Water, in a river or channel, immediately downstream from a structure.

TEMPORARY SEEDING - A seeding which is made to provide temporary cover for the soil while waiting for further construction or other activity to take place.

TERRACE - An embankment or combination of an embankment and channel constructed across a slope at a suitable spacing to control erosion by diverting or storing surface runoff instead of per ting it to flow uninterrupted down the slope. Normally used only on cropland.

TEXTURE (SOIL) - The relative proportions of various soil separates in a soil material.

THATCH - A tightly intermingled layer of living and dead stems, leaves and roots of grasses.

TIME OF CONCENTRATION - Time required for water to flow from the most remote point of a watershed, in a hydraulic sense, to the outlet.

TOE (OF SLOPE) - Where the slope stops or levels out. Bottom of the slope.

TOE WALL - Downstream wall of a structure, usually to prevent flowing water from eroding under the structure.

TOPSOIL - Fertile or desirable soil material used to top dress roadbanks, subsoils, parent material, etc.

TRAP EFFICIENCY - The capability of a reservoir to trap sediment. The ratio of sediment trapped to the sediment delivered, usually expressed in percent.

TRASH RACK - Grill, grate or other device at the intake of a channel, pipe, drain or spillway for the purpose of preventing oversize debris from entering the structure.

UNHULLED (SEED) - Seed still encased with a hull. Example: Sericea lespedeza before it is rendered hulless by mechanically removing the hull.

UNIFIED SOIL CLASSIFICATION SYSTEM (ENGINEERING) - A classification system based on the identification of soils according to their particle size, gradation, plasticity index and liquid limit.

UNIFORM FLOW - A state of steady flow when the mean velocity and cross-sectional area are equal at all sections of a reach.

UNIVERSAL SOIL LOSS EQUATION - An equation used for the design of water erosion control system: A=RKLSCP where A is average annual soil loss in tons per acre per year; R is rainfall factor; K is soil erodibility factor; L is length of slope; S is percent of slope; C is cropping and management factor; and P is conservation practice factor.

UPLIFT (HYDRAULICS) - The upward force of water on the base or underside of a structure.

VARIETY - A variant within a species which reproduces true by seed or vegetative propagation.

VELOCITY HEAD (HYDRAULICS) - Head due to the velocity of a moving fluid, equal to the square of the mean velocity divided by twice the acceleration due to gravity (32.16 feet per second per second).

WATER SURFACE PROFILE (HYDRAULICS) - The longitudinal profile assumed by the surface of a stream flowing in an open channel; the hydraulic grade line.

WEEP-HOLES (ENGINEERING) - Openings left in retaining walls, aprons, linings or foundations to permit drainage and reduce pressure.

WET STORAGE - The wet storage area is the 1800 cubic feet in the permanent pool of water in a sediment trap or basin.

WETTED PERIMETER (HYDRAULICS) - The length of the line of intersection of the plane or the hydraulic cross-section with the wetted surface of the channel

WING WALL - Side wall extensions of a structure used to prevent sloughing of banks or channels and to direct and confine overfill.

WOOD FIBER - A short fiber mulch material, usually applied with a hydro-seeder in an aqueous mixture.

From VA

APPENDIX B

MISCELLANEOUS

Appendix B

Endangered species by stream

Applicants should notify the US Fish & Wildlife Service due to the presence or possible presence of endangered/threatened species when projects will discharge to the stream segments shown below:

- Kanawha River (Kanawha Falls to river mile 89.0 near Boomer) – Fayette County (Tubercled-blossom pearlymussel, *Epioblasma torulosa torulosa*; Pink mucket pearlymussel, *Lampsilis abrupta*; and Fanshell, *Cuprogenia stegaria*)

- Potts Creek – Monroe County (James spinymussel, *Pleurobema collina*)

- South Fork Potts Creek – Monroe County (James spinymussel, *Pleurobema collina*)

- Elk River – Braxton, Clay and Kanawha Counties (Pink mucket pearlymussel; *Lampsilis abrupta;* Northern riffleshell, *Epioblasma torulosa rangiana;* and Clubshell, *Pleurobema clava*)

- Meathouse Fork Middle Creek – Doddridge County (Clubshell, *Pleurobema clava*)

- Middle Island Creek – Doddridge, Tyler and Pleasants Counties (Clubshell, *Pleurobema clava*)

- Ohio River – Cabell, Mason and Wood Counties (Pink mucket pearlymussel, *Lampsilis abrupta*; and Fanshell, Cyprogenia stegaria)

- Gauley River – Nicholas and Fayette Counties (Virginia spiraea, *Spiraea virginiana*)

- Bluestone River – Mercer and Summers Counties (Virginia spiraea, *Spiraea virginiana*)

- Greenbrier River – Pocahontas and Greenbrier Counties (Virginia spiraea, *Spiraea virginiana*)

- Meadow River – Greenbrier and Fayette Counties (Virginia spiraea, *Spiraea virginiana*)

- Dingess Branch of Marsh Fork and associated palustrine emergent and scrub-shrub wetlands – Raleigh County (Virginia spiraea, *Spiraea virginiana*)

- Millers Camp Branch of Marsh Fork and associated palustrine emergent scrub-Shrub wetlands – Raleigh County (Virginia spiraea, *Spiraea virginiana*)

- South Fork Hughes River – Ritchie County (Clubshell, *Pleurobema clava*)

- Sleepy Creek – Morgan County (Harperella, *Ptilimnium nodosum*)

- Cacapon River – Morgan County (Harperella, *Ptilimnium nodosum*)

- Back Creek – Morgan County (Harperella, *Ptilimnium nodosum*)

- Hackers Creek of West Fork River – Lewis County (Clubshell, *Pleurobema clava*)

- Wetlands – Berkeley County Northeastern bulrush, *Scirpus ancistrochaetu*

APPENDIX D

West Virginia High Slip Potential Soils by County

BARBOUR		
Name	**Symbol**	**Soil Slip Potential**
Belmont and Cateache gravelly silt loams, 20 to 35 percent slopes, very stony	BcE	HIGH
Belmont and Cateache gravelly silt loams, 35 to 65 percent slopes, very stony	BcF	HIGH
Bethesda channery silt loam, 15 to 35 percent slopes	BeE	HIGH
Bethesda-Rock outcrop complex, very steep, very stony	BoF	HIGH
Clarksburg silt loam, 15 to 25 percent slopes	ClD	HIGH
Dekalb channery loam, 25 to 35 percent slopes	DaE	HIGH
Dekalb channery loam, 35 to 65 percent slopes	DaF	HIGH
Dekalb channery loam, 15 to 35 percent slopes, very stony	DbE	HIGH
Dekalb channery loam, 35 to 65 percent slopes, very stony	DbF	HIGH
Ernest silt loam, 15 to 25 percent slopes	EnD	HIGH
Ernest silt loam, 3 to 20 percent slopes, extremely stony	ErC	HIGH
Gilpin channery silt loam, 25 to 35 percent slopes	GcE	HIGH
Gilpin channery silt loam, 25 to 35 percent slopes, severely eroded	GcE3	HIGH
Gilpin channery silt loam, 35 to 65 percent slopes	GcF	HIGH
Gilpin-Dekalb complex, 15 to 35 percent slopes, very stony	GdE	HIGH
Gilpin-Dekalb complex, 35 to 65 percent slopes, very stony	GdF	HIGH
Gilpin-Upshur complex, 15 to 25 percent slopes	GuD	HIGH
Gilpin-Upshur complex, 15 to 25 percent slopes, severely eroded	GuD3	HIGH
Gilpin-Upshur complex, 25 to 35 percent slopes	GuE	HIGH
Gilpin-Upshur complex, 25 to 35 percent slopes, severely eroded	GuE3	HIGH
Gilpin-Upshur complex, 35 to 70 percent slopes	GuF	HIGH
Itmann channery clay loam, very steep	ItF	HIGH
Janelew channery silt loam, 15 to 35 percent slopes	JnE	HIGH
Janelew-Rock outcrop complex, very steep, very stony	JoF	HIGH
Westmoreland silt loam, 25 to 35 percent slopes	WmE	HIGH
Westmoreland silt loam, 25 to 35 percent slopes, severely eroded	WmE3	HIGH
Westmoreland silt loam, 35 to 60 percent slopes	WmF	HIGH
Westmoreland silt loam, 35 to 60 percent slopes	WmF3	HIGH

BRAXTON		
Name	**Symbol**	**Soil Slip Potential**
Vandalia silt loam, 25 to 35 percent slopes	VaE	HIGH
Vandalia silt loam, 15 to 35 percent slopes, very stony	VxE	HIGH

BROOKE		
Name	**Symbol**	**Soil Slip Potential**
Berks channery silt loam, 25 to 35 percent slopes, severely eroded	BeE3	High
Berks soils, 35 to 65 percent slopes	BkF	High
Brooke silty clay loam, 15 to 25 percent slopes	BoD	High
Brookside silt loam, 15 to 25 percent slopes	BrD	High
Clarksburg silt loam, 15 to 25 percent slopes	CkD	High
Guernsey silt loam, 8 to 15 percent slopes	GuC	High
Guernsey silt loam, 15 to 25 percent slopes	GuD	High
Guernsey silt loam, 15 to 25 percent slopes, severely eroded	GuD3	High
Westmoreland silt loam, 25 to 35 percent slopes	WeE	High
Westmoreland silt loam, 35 to 60 percent slopes	WeF	High

CABELL		
Name	**Symbol**	**Soil Slip Potential**
Gilpin silt loam, 25 to 35 percent slopes	GlE	HIGH
Gilpin-Upshur complex, 15 to 25 percent slopes	GuD	HIGH
Gilpin-Upshur complex, 25 to 35 percent slopes	GuE	HIGH
Gilpin-Upshur complex, 35 to 70 percent slopes	GuF	HIGH
Vandalia silt loam, 15 to 25 percent slopes	VaD	HIGH

CALHOUN		
Name	**Symbol**	**Soil Slip Potential**
Vandalia silt loam, 15 to 25 percent slopes	VaD	HIGH

CLAY		
Name	Symbol	Soil Slip Potential
Cedarcreek very channery loam, very steep, very stony	CeF	HIGH
Fairpoint channery loam, very steep, very stony	FpF	HIGH
Gilpin-Upshur silt loams, 15 to 25 percent slopes	GuD	HIGH
Gilpin-Upshur silt loams, 25 to 35 percent slopes	GuE	HIGH
Gilpin-Upshur complex, 35 to 70 percent slopes, very stony	GxF	HIGH
Itmann channery clay loam, very steep	ItF	HIGH
Vandalia silt loam, 15 to 25 percent slopes	VaD	HIGH
Vandalia silt loam, 25 to 35 percent slopes	VaE	HIGH

DODDRIDGE		
Name	Symbol	Soil Slip Potential
Gilpin-Upshur silt loams, 15 to 25 percent slopes	GuD	HIGH
Gilpin-Peabody complex, 25 to 35 percent slopes	GpE	HIGH
Gilpin-Peabody complex, 15 to 35 percent slopes, very stony	GsE	HIGH
Gilpin-Peabody complex, 35 to 70 percent slopes, very stony	GsF	HIGH
Gilpin-Upshur-Urban land complex, 15 to 25 percent slopes	GyD	HIGH
Vandalia silt loam, 15 to 25 percent slopes	VaD	HIGH
Vandalia silt loam, 25 to 35 percent slopes	VaE	HIGH
Vandalia silt loam, 15 to 35 percent slopes, very stony	VsE	HIGH
Vandalia-Urban land complex, 15 to 25 percent slopes	VuD	HIGH

FAYETTE		
Name	Symbol	Soil Slip Potential
Berks-Highsplint-Sharondale complex, 35 to 80 percent slopes, very stony	BhG	High
Cateache-Pipestem complex, 35 to 80 percent slopes, very stony	CcG	High
Gilpin-Highsplint-Berks complex, 35 to 90 percent slopes, extremely stony	GhG	High
Layland-Clifftop complex, 35 to 70 percent slopes, very stony	LdF	High
Layland-Dekalb-Guyandotte complex, 35 to 70 percent slopes, extremely stony	LeF	High
Layland-Dekalb-Rock outcrop complex, 55 to 80 percent slopes, extremely stony	LgG	High

Name	Symbol	Soil Slip Potential
Layland-Rock outcrop complex, 35 to 70 percent slopes, very rubbly	LkF	High
Lithic Udorthents-Rock outcrop complex, cut land, 5 to 100 percent slopes	LxG	High
Udorthents, graded, 15 to 55 percent slopes	UgF	High

GILMER		
Name	**Symbol**	**Soil Slip Potential**
Vandalia silt loam, 15 to 25 percent slopes	VaD	High
Vandalia silt loam, 15 to 35 percent slopes, very stony	VsE	High

HARRISON		
Name	**Symbol**	**Soil Slip Potential**
Clarksburg silt loam, 15 to 25 percent slopes	ClD	HIGH
Clarksburg silt loam, 15 to 25 percent slopes, severely eroded	ClD3	HIGH
Culleoka silt loam, 25 to 35 percent slopes	CuE	HIGH
Culleoka silt loam, 25 to 35 percent slopes, severely eroded	CuE3	HIGH
Culleoka silt loam, 35 to 60 percent slopes, severely eroded	CuF3	HIGH
Dekalb extremely stony sandy loam, very steep	DSF	HIGH
Ernest silt loam, 15 to 25 percent slopes	EnD	HIGH
Ernest very stony silt loam, 15 to 35 percent slopes	EsD	HIGH
Faywood silty clay loam, 15 to 25 percent slopes	FaD	HIGH
Faywood silty clay loam, 25 to 35 percent slopes	FaE	HIGH
Faywood silty clay loam, 35 to 60 percent slopes	FaF	HIGH
Gilpin silt loam, 25 to 35 percent slopes	GlE	HIGH
Gilpin silt loam, 35 to 70 percent slopes	GlF	HIGH
Gilpin very stony silt loam, 15 to 35 percent slopes	GsE	HIGH
Gilpin very stony silt loam, very steep	GTF	HIGH
Gilpin-Upshur complex, 15 to 25 percent slopes	GuD	HIGH
Gilpin-Upshur complex, 15 to 25 percent slopes, severely eroded	GuD3	HIGH
Gilpin-Upshur complex, 25 to 35 percent slopes	GuE	HIGH
Gilpin-Upshur complex, 25 to 35 percent slopes, severely eroded	GuE3	HIGH
Gilpin-Upshur complex, 35 to 70 percent slopes, severely eroded	GuF3	HIGH
Guernsey silt loam, 8 to 15 percent slopes	GyC	HIGH

Name	Symbol	Soil Slip Potential
Guernsey silt loam, 15 to 25 percent slopes	GyD	HIGH
Guernsey silt loam, 15 to 25 percent slopes, severely eroded	GyD3	HIGH
Upshur silty clay, 15 to 25 percent slopes, severely eroded	UhD3	HIGH
Vandalia silty clay loam, 15 to 25 percent slopes	VaD	HIGH
Vandalia silty clay loam, 15 to 25 percent slopes, severely eroded	VaD3	HIGH
Westmoreland silt loam, 25 to 35 percent slopes	WmE	HIGH
Westmoreland silt loam, 25 to 35 percent slopes, severely eroded	WmE3	HIGH
Westmoreland silt loam, 35 to 60 percent slopes	WmF	HIGH

HANCOCK		
Name	**Symbol**	**Soil Slip Potential**
Berks channery silt loam, 25 to 35 percent slopes, severely eroded	BeE3	High
Berks soils, 35 to 65 percent slopes	BkF	High
Brooke silty clay loam, 15 to 25 percent slopes	BoD	High
Brookside silt loam, 15 to 25 percent slopes	BrD	High
