Water supply

ABSTRACT

Ecosystem production functions for water supply, climate regulation, and water purification were estimated for 568 headwater streams and their catchments. Results are reported for nine USA ecoregions. Headwater streams represented 74–80% of total catchment stream length. Water supply per unit catchment area was highest in the Northern Appalachian Mountains ecoregion and lowest in the Northern Plains. C, N, and P sequestered in trees were highest in Northern and Southern Appalachian and Western Mountain catchments, but C, N, and P sequestered in soils were highest in the Upper Midwest ecoregion. Catchment denitrification was highest in the Western Mountains. In-stream denitrification was highest in the Temperate Plains. Ecological production functions paired with published economic values for theses services revealed the importance of mountain catchments for water supply, climate regulation, and water purification per unit catchment area. The larger catchment sizes of the plains ecoregions resulted in their higher economic value compared to the other ecoregions. The combined potential economic value across headwater catchments was INT \$14,000 ha^{-1} yr^{-1}, or INT \$30 million yr^{-1} per catchment. The economic importance of headwater catchments is even greater considering that our study catchments statistically represent more than 2 million headwater catchments in the continental United States.

Published by Elsevier B.V.

1. Introduction

Headwater streams and their catchments have received much attention in recent years, with issues ranging from their contribution to, and connection with, larger downstream ecosystems (Nadeau and Rains, 2007), to the loss of headwater streams to burial and routing through underground pipes (Roy et al., 2009; Kaushal and Belt, 2012). An emerging concern is the underestimation of the extent of headwater stream channels, even when mapped at scales finer than 1:100,000 scale (Roy et al., 2009). Headwater streams are defined as the terminal branchings of a stream drainage network, the point where water flowing in a catchment first coalesces into defined stream channels (Gomi et al., 2002). Nadeau and Rains (2007) extend the definition of headwater streams to first- and second-order streams (Strahler, 1957) on 1:100,000 scale maps, even though researchers have demonstrated the underestimation of headwater streams at this larger (coarser) map scale (Meyer and Wallace, 2001; Roy et al., 2009). Because of stream network scaling properties (Dodds and Rothman, 2004), the proportion of total basin-wide headwater stream length is approximately 70% of total stream length on both 1:100,000 and 1:24,000 scale maps (Leopold et al., 1964; Nadeau and Rains, 2007; Lassaletta et al., 2010).

In addition to their dominance in terms of numbers and cumulative length, headwater streams also exert controls on stream runoff and downstream fluxes of dissolved and particulate matter organic matter and nutrients (Alexander et al., 2007; Dodds and Oakes, 2008; Lassaletta et al., 2010). Using spatial regression models, Alexander et al. (2007) estimated that headwater streams deliver 60% of the runoff and 45% of the nitrogen load in downstream reaches in northeastern US streams and rivers. They attribute this result to the high density of headwater streams and the frequency of their connections to higher-order stream channels. In a review of the influence of headwater streams on downstream reaches, MacDonald and Coe (2007) reported an even greater proportion of runoff and nutrient loading is directly attributable to headwater streams. Similarly, Dodds and Oakes (2008) reported that nutrient chemistry in fourth-order Kansas streams was best predicted by riparian land cover adjacent to

upstream first-order streams. These results are similar to those reported for European streams (Lassaletta et al., 2010).

This downstream influence by headwater streams indicates a hydrologic connectivity that links headwater catchments, their soil, and groundwater resources, with larger-order streams (Gomi et al., 2002; Wipfli et al., 2007; Freeman et al., 2007). Headwater streams are not specifically protected by the Clean Water Act (CWA), but until recently they were included as necessary for the maintenance of healthy, productive, and navigable streams and rivers. Their protection under the CWA has recently been limited by the Supreme Court (Rapanos v. United States 547 US 715, 2006) to only those headwater streams that are directly connected to, or have demonstrated a significant influence on, navigable waters (Nadeau and Rains, 2007). Even with CWA protections, headwater streams have been lost from the landscape, primarily by human-driven changes in catchment land use including agriculture, urbanization, and mining (Meyer and Wallace, 2001; Roy et al., 2009; Kaushal and Belt, 2012). An analysis of 106 catchments from around the world revealed that nearly one-third of them experienced extensive conversions ($>$ 50% of the catchment) of forests to agriculture or urban development (Postel and Thompson, 2005).

Ecosystem services are the result of direct and indirect contributions of ecosystems to human well-being (Burkhard et al., 2012). The Millennium Ecosystem Assessment (2003) classified ecosystem services into four categories: provisioning services which provide goods for direct human use (food, freshwater, timber); regulating services to maintain biophysical properties for living beings (climate stability, water purification); cultural services including aesthetic and spiritual benefits; and supporting services which are necessary for the maintenance of functioning ecosystems (nutrient cycling, primary production, soil formation). Catchments represent a discrete unit for accounting for the delivery of ecosystem goods and services to society (Postel and Thompson, 2005). Catchment ecosystem services are many, including biodiversity, climate regulation, recreation, timber and crop production, and water supply and purification. Timber markets are globally well established, carbon exchange markets are developing (Intercontinental Exchange, 2012), and water supply is easily valued as a commodity (Krieger, 2001; Postel and Thompson, 2005; Nunez et al., 2006; de Groot et al., 2012; Townsend et al., 2012); but the value of water purification via nitrogen and phosphorus sequestration in biomass and soils, and through denitrification, are only beginning to receive economic consideration (Dodds et al., 2009; Turpie et al., 2010, Compton et al., 2011). Some of these catchment ecosystem services co-vary while others compete, and understanding the interplay and relationships among ecosystem services under varied management of these resources is critical to the sustainable delivery of catchment ecosystem goods and services (Bennett et al., 2009; de Groot et al., 2010; Deal et al., 2012; Townsend et al., 2012).

Our objectives in this paper are to highlight the importance of headwater catchments by focusing on the quantity and value of a few ecosystem services derived from them, and to extrapolate that importance from regional to national scales within the continental United States. We focus on headwaters because that is a particular category of streams that is of interest in the US regulatory community. As an under-protected resource, we wanted to highlight their particular value. We combine data collected from headwater streams as a part of the US Environmental Protection Agency's (USEPA) National Rivers and Streams Assessment (NRSA) with catchment attributes related to water supply, the sequestration of C, N, and P, and the removal of N via denitrification. We use these data to develop ecological production functions related to the delivery of ecosystem services from headwater catchments, and combine these services with published valuations to estimate potential cumulative benefits derived from headwater catchments in the United States.

2. Materials and methods

2.1. Study sites

Catchments included in this study were those drained by the 568 first- and second-order (Strahler, 1957) streams that were sampled during the NRSA (Fig. 1). The sampling design was spatially-balanced and employed an unequal probability survey with the unequal selection based on stream order. The design selected a single point along the center line of each stream as depicted by the National Hydrography Dataset (NHDPlus, Version 1; http://horizon-systems.com/nhdplus; based on 1:100,000 scale maps). All sample sites were selected using NHDPlus as the sample frame. Each site included in the survey represented a known stream or river length based on the population of streams included in the survey design, the probability of that site being selected for sampling, and the number of sites actually sampled. These stream and river lengths were summed to estimate the cumulative extent of streams sampled (Olsen and Peck, 2008).

The NRSA design allows the assessment of ecological conditions of streams at three hierarchical spatial scales: national, regional, and ecoregional (Olsen and Peck, 2008). Here we report results nationally and for nine ecoregions: Northern Appalachian Mountains, Southern Appalachian Mountains, Coastal Plains, Northern Plains, Southern Plains, Temperate Plains, Upper Midwest, Western Mountains, and Xeric ecoregions (Fig. 1).

2.2. Catchment attributes

Total catchment area (*A*, ha) for each site was calculated by summing the areas of all NHDPlus catchments intersected while navigating upstream from each sampling site. Cumulative catchment area (Cum *A*, ha) within an ecoregion was calculated as the product of mean *A* and the total number of catchments (n) in that ecoregion (Table 1; Fig. 2). Percent of the catchment in forests (% forest), grasslands (% grassland), row crops (% agriculture), and wetlands (% wetland) were extracted from the National Land Cover Database (NLCD, USGS, 2006; Fig. 2). The NLCD, derived from multi-temporal and terrain-corrected satellite imagery, provides consistent land cover estimates for the United States. Targeted assessments found accuracy of land cover estimates ranged from 78 to 89% (Xian et al., 2009).

Catchment stream lengths (*L*, km) were estimated using NHDPlus flow line and stream order data layers (Fig. 2). NHDPlus codes flow lines as connectors, canals and ditches, underground pipes, intermittent and perennial streams, artificial paths, and coastlines. We excluded underground pipes and coastlines from our analyses, and the remaining types of water conveyances are collectively treated as streams. Each stream segment of a given order was included in the estimate of *L* by stream order, and cumulative catchment stream length (Cum *L*, km) was calculated as the product of *L* and *n*.

Catchment-scale estimates of soil organic carbon (SOC) and % sand were derived from US Department of Agriculture soil survey data (SSURGO and STATSGO2; http://soildatamart.nrcs.usda.gov/; Fig. 2) and associated with each headwater catchment as the mean of the 30-m pixels included in each catchment. Soil drainage index (DI), previously called the natural soil wetness index, is a measure of the long-term wetness of a soil (Schaetzl et al., 2009). Catchment-scale estimates of DI were estimated from area-weighted STATSGO2 map units (http://www.drainageindex.msu.edu; Fig. 2) that intersected our study catchments.

Data on the wet deposition of atmospheric N were available from the National Atmospheric Deposition Program (NADP, http://nadp.sws.uiuc.edu). We used annual (2005–2009) precipitation-weighted mean TN concentrations in precipitation. Estimates of

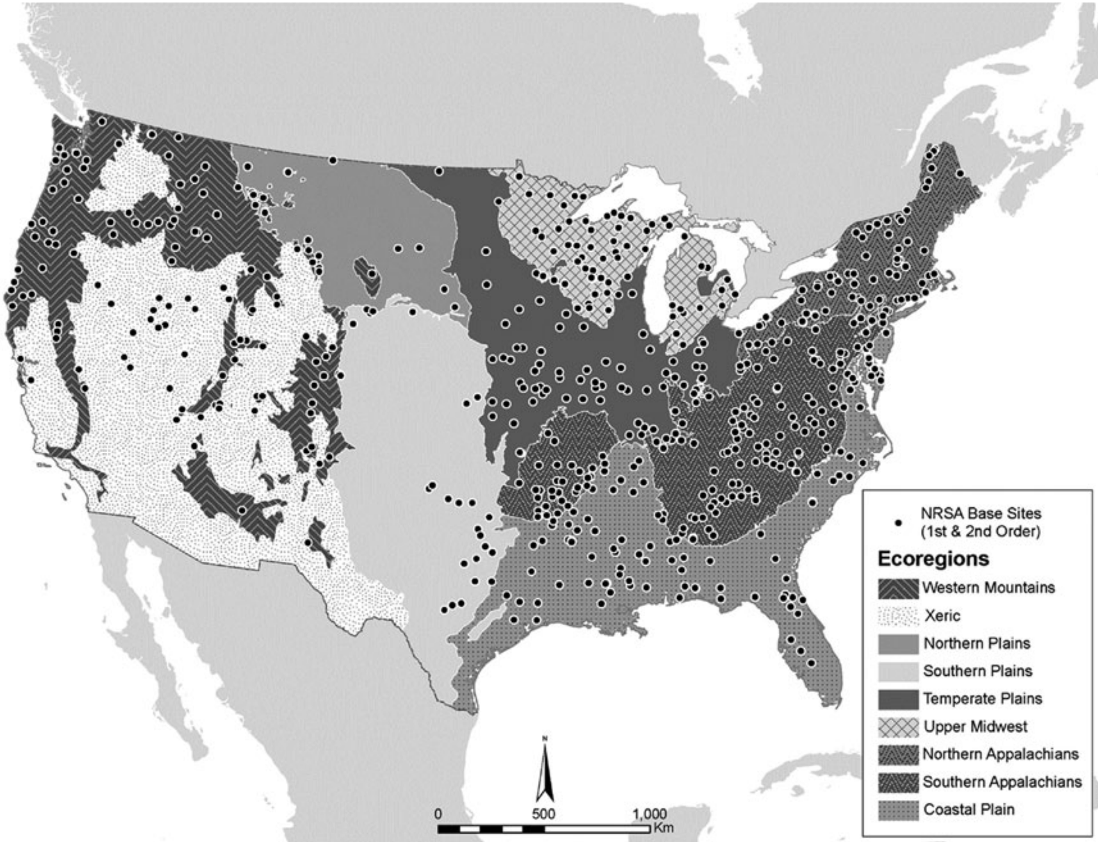

Fig. 1. Locations of headwater streams sampled during the National Rivers and Streams Assessment. The nine ecoregions for NRSA reporting are delineated.

wet TN deposition on each of our study catchments were based on NADP station data that were intersected with spatially-interpolated national grids (http://nadp.sws.uiuc.edu/isopleths). These interpolated data were averaged across the years of our study.

2.3. Carbon, nitrogen and phosphorus sequestration

Carbon sequestered in woody vegetation was estimated by multiplying catchment area by the proportion of the catchment covered by forests, and then by mean above and below ground C standing stocks for living tree biomass in the Eastern Highlands (Northern and Southern Appalachian Mountains ecoregions; 18,400 Mg km^{-2}), Plains and Lowlands (Coastal, Northern, Southern and Temperate Plains, Upper Midwest, and Xeric ecoregions: 20, 700 Mg km^{-2}), or Western Mountains (18,900 Mg km^{-2}; US Department of Agriculture, 2008; Heath et al., 2011; US Environmental Protection Agency (USEPA), 2011; Fig. 2). Nitrogen and phosphorus sequestered in tree biomass were estimated from global measures of tree C, N, and P stoichiometry (Schade et al., 2005). These C, N, and P standing stock estimates were divided by median forest stand age (Smith et al., 2009) to estimate annual C, N, and P sequestration by trees in US headwater catchments. It was assumed that non-woody catchment vegetation contributed negligibly to overall catchment C, N, and P sequestration. Sequestration of C, N, and P in agricultural crops was estimated by multiplying catchment area by the proportion of the catchment covered by row crop agriculture, and then by mean C, N, and P standing stocks (Vitousek et al., 2009).

Soil C content was estimated from US Department of Agriculture soil survey data (SSURGO and STATSGO2; http://soildatamart.nrcs.usda.gov/; Fig. 2) applied at the catchment scale (Bliss, 2003). Soil N and P content were based on average soil C, N, and P stoichiometry (Cleveland and Liptzin, 2007). Annual increments of soil C, N, and P sequestration were based on a 500 yr average age for soil organic matter, and assuming a linear increase in C, N, and P sequestration through time (Trumbore, 2000; Six and Jastrow, 2007).

2.4. Catchment and in-stream denitrification

Catchment-scale denitrification (Catch DN) was estimated from a regression model employing average % sand and DI for the 30-m pixels of each catchment (Groffman et al., 1992; Table 1; Fig. 2). Cumulative catchment DN was estimated as the product of Catch DN and Cum *A*. Mulholland et al. (2008) developed a model for predicting in-stream denitrification based on stream NO_3^- concentrations (Table 1; Fig. 2). We applied their DN model to measured NO_3^- concentrations from the NRSA streams to predict in-stream DN (Stream DN). Catchment-wide Stream DN was estimated as the product of Stream DN and Cum *L*.

2.5. Hydrology and water supply

Mean annual precipitation (PPT, mm yr^{-1}) was acquired as an NHDPlus data layer for each of our study catchments. NHDPlus uses a spatial interpolation model based on 30 yr of precipitation data (1981–2010) from the National Weather Service precipitation gauge network (http://water.weather.gov/ahps/). Mean annual discharge (Q, m^3 s^{-1}) from each catchment was also available as an NHDPlus data layer. NHDPlus uses a spatial interpolation model of unit runoff based on 30 yr of US Geological Survey stream gage data (http://waterdata.usgs.gov/nwis). Streamflow data were converted from volumetric rates (m^3 s^{-1}) to the more commonly

reported runoff (RO, mm yr^{-1}) to facilitate the calculation of actual evapotranspiration (ET = PPT-RO; mm yr^{-1}), evaporative index (ET Index = ET/PPT), and runoff ratio (RO Ratio = RO/PPT; Jones et al., 2012; Table 1; Fig. 2).

2.6. Economic value of ecosystem services

As a relative comparison among ecosystem services and between ecoregions, we estimated the potential economic value of ecosystem services provided by headwater catchments as the product of units of production (production function) and published economic values for those units of production. Economic values are reported in International $, where 1INT $ = 1 US $ (de Groot et al., 2012). We restrict our comparisons to considerations three ecosystem services, (1) water supply; (2) climate regulation (C sequestration), and (3) water purification (N and P sequestration and denitrification). The economic value of water supply was estimated as INT \$0.35 m^{-3} (INT \$40 acre - ft^{-1}; Sedell et al., 2000; Krieger, 2001; Nunez et al., 2006; Brauman et al., 2007). The value of the C sequestered in catchment biomass and soil was INT \$0.12 Mg^{-1} (Mg = 1000 t; Intercontinental Exchange, 2012). The value of N sequestered in catchment biomass and soil, and removal via DN was INT \$160 Mg^{-1} (US Environmental Protection Agency (USEPA), 2007; Dodds et al., 2009; Compton et al., 2011). P sequestered in catchment biomass and soils were conservatively valued at INT \$1600 Mg^{-1} (Sano et al., 2005; US Environmental Protection Agency (USEPA), 2007; Stanton et al., 2010).

2.7. Statistical analyses

We calculated mean values for catchment attributes; annual precipitation and runoff; C, N, and P sequestration; and N removal; and their economic values. Catchment means among ecoregions were compared using a non-parametric one-way analysis of variance on ranked scores (Wilcoxon) with the Kruskal–Wallis test. All analyses were done using SAS for Windows, release 9.2 (SAS Institute, Inc., Cary, NC, USA).

3. Results

3.1. Catchment attributes and ecosystem services production functions

The average size of the headwater catchments in our study ranged from < 2000 ha for catchments in the Eastern US (Northern and Southern Appalachian Mountains and Coastal Plains) to > 8000 ha in the Northern and Southern Plains ecoregions (Table 2). Headwater stream length was shorter in the Eastern US and longer in the Northern and Southern Plains and Xeric ecoregions. Overall, headwater streams represented 74–80% of total catchment stream length (Table 2). Percent of the catchment in forest land cover was greatest in the Northern and Southern Appalachian and Western Mountains; grasslands were greatest in the Northern and Southern Plains; wetlands were more prevalent in the Coastal Plains and in the Upper Midwest; and the Temperate

[d] Northern Plains.
[e] Southern Plains.
[f] Temperate Plains.
[g] Upper Midwest.
[h] Western Mountains.
[i] Xeric ecoregions.

Plains were dominated by row crop agriculture (Table 2). Precipitation (PPT) was higher in the East (Northern and Southern Appalachian Mountains, and Coastal Plains) and lower in the Northern Plains and Xeric ecoregions; evapotranspiration (ET) was greater in the Coastal, Southern and Temperate Plains ecoregions, and lower in the Northern Plains and Xeric ecoregions

(Table 2).The combination of high PPT and low ET resulted in higher runoff (RO) from the Appalachian and Western Mountain catchments, while low PPT and high ET resulted in lower RO from Northern and Southern Plains catchments. The resulting runoff coefficients, the proportion of PPT that leaves the catchment via runoff, ranged from 0.99 in the Northern Appalachian Mountains to 0.17 in the Southern Plains (Table 2). Annual runoff (or water supply, $m^3\ ha^{-1}\ yr^{-1}$) was 2–5 times higher in the Northern and Southern Appalachian Mountains, the Coastal Plains, and the Western Mountains than in the other ecoregions (Table 4). The sand content of catchment soil profiles ranged from 21% (Temperate Plains) to 51% (Upper Midwest), and the soil drainage index, a measure of relative soil moisture retention, ranged from 26 in the Xeric region to >50 in the Coastal and Temperate Plains and the Upper Midwest ecoregions. Neither of these soil properties exhibited statistical ecoregional differences (Table 2).

Carbon stocks sequestered in trees were highest in the Northern and Southern Appalachian and Western Mountains ecoregions and lowest in the Northern, Southern, and Temperate Plains (Table 3). This pattern was repeated for tree N and P stocks, because of the stoichiometric assumptions (Schade et al., 2005; Table 3). C stock sequestered in catchment soils was highest in the Upper Midwest ecoregion, but few other discernible patterns were noted. This relationship among ecoregions was also applicable to soil N and P, due to our stoichiometric assumptions (Cleveland and Liptzin, 2007; Table 3). C, N, and P sequestered in harvested agricultural crops were highest in the Temperate Plains and lowest in the Western Mountains and Xeric ecoregions (Table 3).

C, N, and P stocks sequestered in trees were annualized by dividing the cumulative catchment values by median stand age (Smith et al., 2009) to yield an annual sequestration increment ($Mg\ yr^{-1}$). Similarly, soil C, N, and P stocks were annualized on a

Table 3
Mean amounts of C, N, and P stocks ($kg\ ha^{-1}$) in forest and crop biomass and soil and removed through catchment and in-stream denitrification (DN, $kg\ N\ ha^{-1}\ yr^{-1}$) for headwater catchments in the nine NRSA ecoregions. Results of comparisons among ecoregions were based on Wilcoxon Rank sum scores and the Kruskal–Wallis test (χ^2 and $P<\chi^2$).

Table 4
Stand age (yr) and mean annual ecosystems goods and services (water supply, $m^3\ ha^{-1}\ yr^{-1}$; climate regulation, C-sequestered in trees [a] and soil [b], $kg\ ha^{-1}\ yr^{-1}$; and water purification, N and P sequestered in trees [a] and soil [b], $kg\ ha^{-1}\ yr^{-1}$; N removal by catchment and in-stream denitrification, $kg\ ha^{-1}\ yr^{-1}$) derived from headwater catchments of the nine ecoregions. C, N, and P sequestration trees, crops, and soil was estimated as the product of sequestration ($kg\ ha^{-1}$) and catchment area, divided by stand or soil OM age. Stream denitrification was calculated as the product of denitrification and cumulative stream length.

presumed 500 yr median soil organic matter age (Trumbore, 2000; Six and Jastrow, 2007). The combined tree and soil C, N, and P sequestration at the catchment scale indicated that the highest sequestration increments (Mg yr^{-1}) were in the Southern Plains and Southern Appalachian Mountains, with all the remaining ecoregions being lower (Table 4).

There was a marked longitudinal trend in N deposition with highest deposition in the industrial Eastern (Northern and Southern Appalachian Mountains and Coastal Plains) and Midwestern (Temperate Plains and Upper Midwest) ecoregions and lower in the Western Mountains and Xeric ecoregions (Table 2). Lower % sand and a higher DI of catchment soils contribute to higher Catch DN, and these conditions led to Catch DN values in the Western Mountains ecoregion significantly higher than in any other ecoregion (Table 3). In-stream DN was highest in the Temperate Plains ecoregion and lowest in the Northern Appalachian Mountains ecoregion (Table 3), but when extrapolated to Cum *L*, Stream DN was highest in the Southern Appalachian and Western Mountains ecoregions, and lowest in the Xeric ecoregion. The combined annual Catch DN and Stream DN were highest in the Temperate Plains ecoregion and lowest in the Xeric ecoregion (Table 4).

3.2. Economic value of ecosystem services

We used published economic value estimates based on commodity price (water supply), market value (climate regulation), or damage cost avoidance (water purification) to assess the potential economic value of ecosystem services provided by headwater catchments. The economic value of water supply per unit catchment area (INT \$ ha^{-1} yr^{-1}) was higher in the Northern Appalachian and Western Mountains, and lower in the Northern and Southern Plains, than in the other ecoregions. The weighted average water supply value for headwater catchments in the United States was INT \$ 245 ha^{-1} yr^{-1} (Table 5). Extrapolation of these values to the entire catchment (INT \$ yr^{-1}) resulted in more similar water supply value among the ecoregions, with the exception of the Western Mountains ecoregions which was twice as high as the other ecoregions. The weighted average for headwater catchments was INT \$ 470,000 yr^{-1} (Table 5).

The economic value of climate regulation per unit catchment area was higher in the Southern Appalachian Mountains and Coastal Plains ecoregions than in the remaining ecoregions. The average economic value of climate regulation for headwater catchments was INT \$ 278 ha^{-1} yr^{-1} (Table 5). The Northern and Southern Plains ecoregions, with their larger catchment areas, sequester more than twice as much C as do the other ecoregions. Average climate regulation value for headwater catchments in the United States was INT \$ 553,000 yr^{-1} (Table 5).

We considered three metrics related to the economic value of water purification, N and P sequestration in catchment trees, crops, and soil, and catchment and in-stream denitrification. The value of N sequestration per unit catchment area was greatest in the Southern Appalachian Mountains ecoregion, followed by the Coastal Plains and Upper Midwest ecoregions. All other ecoregions had similarly lower economic value. The average value of N sequestration was INT \$ 7456 ha^{-1} yr^{-1}. The greatest sequestration of P per unit catchment area was in the Upper Midwest ecoregion, with lowest sequestration occurring in the Northern Plains and Xeric ecoregions. The weighted average economic value of P sequestration by headwater catchments was INT \$ 2977 ha^{-1} yr^{-1}. Denitrification per unit catchment area was highest in the Temperate Plains ecoregion and lowest in the Xeric ecoregion. The average economic value of denitrification by headwater catchments was INT \$ 2981 ha^{-1} yr^{-1} (Table 5). As was the case with climate regulation, the larger sizes on the Northern and Southern Plains catchments increased their potential economic value as sinks for N and P, or pathways for N removal via denitrification (Table 5).

Table 5
Mean annual catchment economic value of ecosystem services per unit catchment area (INT \$ ha^{-1} yr^{-1}) and cumulative catchment value (\$1000 yr) for water supply[a]; climate regulation [b], and water purification [c] provided by headwater catchments of the nine ecoregions. Values (\$ ha^{-1} yr^{-1}) are derived as the product of marginal unit value and annual ecosystem goods and services from Table 4; those values were multiplied by catchment area to derive the cumulative catchment values (\$ yr^{-1}). Bundled services are the sum of all the measured service catchments for a given ecoregion. Weighted average is the average value, adjusted for unequal sample sizes, of a given service across the ecoregions, i.e. a national average.

	Unit Value		NAP[d]	SAP[e]	CPL[f]	NPL[g]	SPL[h]	TPL[i]	UMW[j]	WMT[k]	XER[l]	*Weighted Average*

The total potential economic value of these bundled ecosystem services ranged from INT \$7454 $ha^{-1} yr^{-1}$ in the Xeric ecoregion to INT \$ 17,311 $ha^{-1} yr^{-1}$ in the Southern Appalachian Mountains ecoregion. The weighted average economic value of these bundled ecosystem services was INT \$ 13,938 $ha^{-1} yr^{-1}$ (Table 5). Potential economic value extrapolated to the whole catchment ranged from INT \$ 16 million yr^{-1} for catchments in the Northern Appalachian Mountain ecoregion to INT \$ 90 million yr^{-1} for catchments in the Southern Plains ecoregion. The weighted average economic value for headwater catchments in the United States was INT \$ 31 million yr^{-1} per catchment (Table 5).

4. Discussion

Studies of catchment ecosystem services have focused more often on those services that have established markets, such as water supply, forest products, and climate regulation (Creedy and Wurzbacher, 2001; Postel and Thompson, 2005; Nunez et al., 2006; Brauman et al., 2007; Woodbury et al., 2007; Watanabe and Ortega, 2011). Fewer studies have considered the interactions and trade-offs related to multiple ecosystem services (Stenger et al., 2009; Deal et al., 2012; Watanabe and Ortega, 2011; Kline and Mazzotta, 2012; Townsend et al., 2012). Our focus is on the importance of headwater catchments and the ecosystem services they provide. As such, we limited our considerations to catchment-scale services that do not limit the future provision of these ecosystem goods and services. Within this construct, land cover is a major driver of the kinds and potential amounts of ecosystem services that can be acquired from headwater catchments, and this construct allows us to compare these services across a national scale, without the constraint of identified local markets and users of the services (Wainger and Mazzotta, 2011).

While not the largest or most valuable ecosystem services, water supply and climate regulation benefit from having established markets for their sale and trading. As such, these services are among the best studied (Creedy and Wurzbacher, 2001; Watanabe and Ortega, 2011; de Groot et al., 2012; Townsend et al., 2012). Our estimates of the economic value of water supply are similar to climate protection regulation services. However, we believe our water supply values underestimate the true value of catchment water dynamics by ignoring the amount of water necessary to support the maintenance and growth of catchment biomass, and by not accounting for the climatological effects of ET (Jansson et al., 1999; Jackson et al., 2005).

Private and public forests in the United States sequester 162 Tg C yr^{-1}, of which trees and soils were the two largest pools (Woodbury et al., 2007). Catchment C sequestration is related to forest cover (Creedy and Wurzbacher, 2001; Jackson et al., 2005; Boix-Fayos et al., 2009). Our estimates of forest C sequestration, both per unit catchment area and extrapolate to the whole catchment, are similar to those reported by previous researchers (Creedy and Wurzbacher, 2001; Jackson et al., 2005; Woodbury et al., 2007). And, given that headwater catchments represent the majority of forest lands in the United States, our estimates provide a unique view of the importance of headwater forest for climate protection.

Forest C sequestration, largely as trees, has been increasing over the past several decades (McKinley et al., 2011). Stoichiometric theory suggests that increases in C sequestration by trees and soil must be accompanied by increased N and P sequestration (Sterner and Elser, 2002; Hesson et al., 2004). Sequestration of elements other than C is infrequently represented in the published literature (McGroddy et al., 2004; Schade et al., 2005; Cleveland and Liptzin, 2007). Our research uses established C:N:P stoichiometries to extend the discussion of sequestration to N and P, and the importance of headwater catchments for sequestering N and P with subsequent economic savings from reduced costs for nutrient removal from surface waters (Keplinger et al., 2003; Sano et al., 2005; Dodds et al., 2009; Turpie et al., 2010; Compton et al., 2011; Watanabe and Ortega, 2011). Our results suggest that headwater forests are significant N and P sinks. From a standing stock perspective, C sequestered in soils is similar to that stored in trees, but because of their different stoichiometric ratios, soils sequester significantly more N and P than do trees. However, on an annual basis trees, because of their younger median age, sequester C, N, and P at rates that are several times greater than those for soil. A significant amount of C, N, and P sequestration is also attributed to agricultural crops (Vitousek et al., 2009; Post et al., 2012).

Denitrification is a special case of N removal not accounted for in our sequestration estimates. Seitzinger et al. (2006) reported that terrestrial catchments accounted for 22% of the global N removal via denitrification, second only to marine continental shelf ecosystems. Hofstra and Bouwman (2005), using the same denitrification model, suggested that agricultural soils may account more than half of all terrestrial denitrification. By comparison, streams and rivers accounted for 6% of global denitrification. Our estimates for headwater streams suggest even greater differences between streams and their catchments. From an N-budget perspective, the sum of Catch DN and Stream DN in our study catchments exceeds that of N input via wet deposition of atmospheric N. We report wet deposition because these are regularly collected as a part of the NADP network, while dry deposition of N is difficult to measure and is often modeled to estimate its contribution to the N budget. Because of these uncertainties, we rely on the empirical NADP wet deposition data, recognizing that it is likely only half of total (wet+dry) N deposition (US Environmental Protection Agency (USEPA), 2001; Anderson and Downing, 2006). Our N accounting also ignores significant sources of N that could support denitrification, including fertilizer N applied to row crop agriculture and commercial timber production, and biological N fixation. Together, these N inputs to catchments average about 40 kg N $ha^{-1} yr^{-1}$ across the conterminous United States (Sobota et al., 2013).

It is widely recognized that ecosystems provide multiple ecosystem services and there are several studies that demonstrate the integration of these multiple services (Bennett et al., 2009; de Groot et al., 2010, 2012; Deal et al., 2012; Kline and Mazzotta, 2012). One of the commonly observed trade-offs related to water supply is the inverse relationship between catchment water yield and forest land cover. Forests tend to increase water retention on the catchment due to a slowing of runoff and increased water lost through ET (Stednick, 1996; Creedy and Wurzbacher, 2001; Swank et al., 2001; Brown et al., 2005). Reducing the proportion of the catchment covered by forests is a one management strategy to increase runoff for downstream users (Stednick, 1996; Brown et al., 2005). This increase in water supply is often accompanied by increased export of base cations, anions, and sediment (Creedy and Wurzbacher, 2001; Swank et al., 2001). The opposite is true for afforestation of grasslands and agricultural lands, and the reforestation of harvested timber lands (Jackson et al., 2005; Townsend et al., 2012). This increased forest development comes with an additional demand for water and nutrients. Jackson et al. (2005) referred to this as “trading water for carbon.” Similarly, N and P sequestered in trees and soils will lead to better water quality of catchment runoff (Creedy and Wurzbacher, 2001; Swank et al., 2001; Postel and Thompson, 2005; Deal et al., 2012; Townsend et al., 2012). Our results demonstrate the complementary and contradictory relationships among a limited suite of ecosystem services. These results suggest that management of multiple ecosystem services may not yield win–win scenarios where more than one ecosystem service is maximized. More likely, management of multiple ecosystem services will result in an effective balance to optimize ecosystem services (Bennett et al., 2009; Deal et al., 2012).

We restricted our considerations of ecosystem services to a limited list of services provided by functioning headwater ecosystems. We would be remiss if we failed to at least mention some of the other commonly reported ecosystem services. For example, we considered only the climate regulation and water purification value of trees, but must also acknowledge the economic value of trees and forest products, which is reported to be in excess of INT \$250 billion yr^{-1} for all harvested catchments in the United States (US Energy Information Administration, 2001). Similarly, we have not reported on cultural ecosystem services and their economic value. Krieger (2001) reported that forested ecosystems provide recreational opportunities that are supported by services and suppliers for hunting (INT \$2 billion yr^{-1}), fishing (INT \$3 billion yr^{-1}), and other recreation (INT \$6 billion yr^{-1}). He places the aesthetics and spiritual value of forests in the United States at INT \$1.5 billion yr^{-1}. By comparison, the average economic value of the bundled ecosystem services we're reporting for our 568 headwater catchments, based on benefit transfer to estimate price and marginal changes in goods and services produced (water supply and climate regulation) or damages avoided (water purification), is about INT \$ 31 million yr^{-1} per catchment (INT \$ 14,000 $ha^{-1}\ yr^{-1}$). Extending these average values to our 568 study catchments yields a cumulative potential economic value of INT \$ 17.5 billion yr^{-1}. The national importance of headwater catchments, in terms of ecosystem services and their potential economic value, is even greater when one considers that our study catchments are a statistical representation of more than 2 million headwater catchments in the continental United States.

Acknowledgements

The USEPA Office of Water sponsored the National Rivers and Streams Assessment. AR Olsen supervised the creation of the survey design. We are indebted to the numerous state, federal, and contractor field crews and laboratory staff who collected and analyzed the NRSA samples. Benefit-Cost Analysis Tools for Drought, Ecosystem Services, and Post-Wildfire Mitigation for Hazard Mitigation Assistance

May 27, 2016

Purpose: The purpose of this policy clarification is to advise of and explain newly developed benefit-cost analysis tools to calculate benefits for climate resilient mitigation activities, including drought mitigation, ecosystem service, and pre-calculated benefits for cost effectiveness evaluation of soil stabilization, flood diversion, and reforestation projects in wildfire impacted areas to support expedient implementation of post-wildfire mitigation actions. On May 12, 2016, FEMA issued a memorandum titled *Benefit Cost Analysis Tools for Drought, Ecosystem Services, and Post-Wildfire Mitigation for Hazard Mitigation Assistance* releasing the new BCA Toolkit documents.

Background: In June 2013, FEMA released the *Considerations of Environmental Benefits in the Evaluation of Acquisition Projects under the Hazard Mitigation Assistance Programs*. This policy introduced the allowance of ecosystem services in the BCA of acquisition/open space projects. Ecosystem services are benefits provided to people by nature such as aesthetic value, air quality, recreation space, and water filtration.

In September 2015, FEMA released three new activities eligible for the Hazard Mitigation Assistance (HMA) programs: Aquifer Storage and Recovery, Floodplain and Stream Restoration, and Flood Diversion and Storage, known as the Climate Resilient Mitigation Activities (CRMA). These activities can be used for any hazard when appropriate and leverage traditional risk reduction benefits and applicable ecosystem services. Additionally, in 2015, FEMA developed pre-calculated benefits for cost effectiveness evaluation of soil stabilization, flood diversion, and reforestation projects in wildfire impacted areas to support expedient implementation of post-wildfire mitigation actions.

As stipulated by the May 12, 2016 memorandum, FEMA released the following additions to the Benefit-Cost Analysis (BCA) Toolkit and resources to support evaluating the cost-effectiveness of these mitigation activities:

- Aquifer Storage and Recovery BCA Tool
- Ecosystem Service Benefits Calculator
- Supplemental BCA Guidance for Floodwater Diversion and Storage Projects
- Supplemental BCA Guidance for Floodplain and Stream Restoration Projects
- Pre-calculated benefits for post-wildfire mitigation actions

These additional BCA Tools are available for Hazard Mitigation Grant Program (HMGP), Pre-Disaster Mitigation (PDM), and the Flood Mitigation Assistance (FMA) for which the application period is open on or after the date of the May 12, 2016 memorandum. Please note that not all mitigation activities are eligible under all three programs (e.g., wildfire mitigation is eligible under HMGP and PDM but not FMA).

Policy Clarifications: FEMA is committed to providing tools and resources to support communities in implementing drought mitigation actions. As part of CRMA, FEMA announced the eligibility of Aquifer Storage and Recovery projects to support community interest in increasing available water supply. FEMA has developed a tool to support cost-effectiveness evaluation for Aquifer Storage and Recovery projects.

The inclusion of ecosystem services in the BCA is no longer limited to only acquisition/open space mitigation activities; and may now be used for all eligible HMA activities that demonstrate the creation or enhancement of the environment including, but not limited to, CRMA projects or methods such as green infrastructure or nature-based design. The expanded offering of ecosystem services also supports the Office of Management and Budget (OMB) *Incorporating Ecosystem Services into Federal Decision Making* memorandum, dated October 7, 2015, that directed federal agencies to develop policies to promote consideration of ecosystem services in the decision making.

FEMA developed pre-calculated benefits to streamline implementation of mitigation actions in wildfire impacted areas to reduce risk from related hazards such as flood. Soil stabilization, flood diversion, and reforestation projects under the cost of $5,250 per acre are determined cost effective and no further BCA is required.

Benefit-Cost Analysis (BCA): FEMA has developed a tool to support cost-effectiveness evaluation for Aquifer Storage and Recovery projects, and BCA supplemental guidance documents for Floodwater Diversion and Storage and Floodplain and Stream Restoration projects. These BCA tools were developed to provide expedient interim tools to calculate benefits for drought mitigation and/or ecosystem services for mitigation activities. These tools and methods will be incorporated into a future update of the BCA Toolkit software.

FEMA has developed a methodology to calculate the ecosystem service benefits. The methodology is included in a spreadsheet tool (Ecosystem Service Benefits Calculator) and is a stand-alone tool that will be incorporated into a future update of the BCA Toolkit software. The primary purpose of the HMA programs is to protect lives and reduce or eliminate future damage to property. Therefore, the BCA will include ecosystem services only if an activity is calculated to have a benefit-cost ratio (BCR) of 0.75 or greater using traditional risk reduction benefits. This condition applies for all types of activities that are eligible under the HMA programs. Please note that pre-calculated benefits cannot be combined with benefits from a traditional BCR calculated using the BCA software.

To use the post-wildfire pre-calculated benefits, the applicant would multiply the number of acres being mitigated by the total benefits per acre. For example, if the project is to provide ground cover, soil stabilization and replanting for 1,000 acres, 1,000 x 5,250 = $5,250,000 in project benefits. These pre-calculated benefits are based on the risk reduction and ecosystem service benefits that are provided by forest and other vegetation with primary emphasis on the reduced flood risk these systems provide. The BCA Toolkit can be utilized to perform the benefit cost analysis for projects where the pre-calculated benefits are not enough to cover the mitigation activity. Post wildfire mitigation projects that demonstrate they are cost effective using the pre-calculated benefits do not need to submit a separate BCR.

The BCA Toolkit and the interim tools are available for download at https://www.fema.gov/media-library/assets/documents/110202 Please note that HMA Job Aids and Supplemental resources are forthcoming. All CRMA materials and HMA program resources can be found at https://www.fema.gov/climate-resilient-mitigation-activities-hazard-mitigation-assistance.

Contact Us: If you have any questions on details of the BCA, contact the BCA Technical Assistance Helpline at 1-855-540-6744 or bchelpline@fema.dhs.gov. For policy-related questions, contact the HMA Helpline at 1-866-222-3580 or hmagrantshelpline@fema.dhs.gov.

WATER RESOURCES RESEARCH, VOL. 28, NO. 3, PAGES 657–663, MARCH 1992

Benefit Transfer Studies: Myths, Pragmatism, and Idealism

KEVIN J. BOYLE

Department of Agricultural and Resource Economics, University of Maine, Orono

JOHN C. BERGSTROM

Department of Agricultural Economics, University of Georgia, Athens

Benefit transfer has been an ongoing, practical analysis for years in legal proceedings and government policy analyses where timely benefit estimates are critically dependent on the use of existing data. Most benefit transfer studies to date have been conducted behind closed doors and have not been open to scholarly review, and no systematic research agenda has been established to determine whether benefit transfer estimates are valid for public policy analyses. In this paper we propose a systematic, conceptual foundation for conducting benefit transfer studies, and suggest a research agenda to identify conditions under which valid benefit transfer estimates can be derived. We conclude, however, that this research agenda must be accompanied by improved conduct and reporting of original valuation studies before benefit transfer can become a widely used tool in public policy analyses.

INTRODUCTION

For purposes of this paper, benefit transfer is defined as the transfer of existing estimates of nonmarket values to a new study which is different from the study for which the values were originally estimated. In essence, this is simply the application of secondary data to a new policy issue, and one is tempted to ask "so what?" Benefit transfer, in fact, has been ongoing for years in legal proceedings and government policy analyses where timely benefits estimates are critically dependent on the use of existing data, i.e., there is not sufficient time or funds available to develop original benefit estimates using primary data specific to the issue at hand.

A well-known application of benefit transfer is the *U.S. Forest Services* [1987] development of RPA (Resource Planning Act) values for individual national forests to use in their long-range planning processes to meet the requirements of the National Forest Management Act. At a recent resource economics conference, a U.S. Army Corps of Engineers representative described current efforts by the Corps to develop a regional demand model which will be used to transfer recreation benefits from one Corps reservoir to another [*Henderson*, 1991].

We expect the demand for benefit transfer applications by resource management agencies will increase in the future due to three interrelated reasons. First, primary data collection on a site-by-site basis is expensive. Second, agencies face considerable uncertainty regarding continued budget support for primary data collection, particularly in the face of austere budget allocations resulting from large state and federal budget deficits. Third, primary data collection is time consuming, often taking one or more years to complete a study from start to finish. For certain policy and management decisions, agencies require inexpensive benefit estimates in a timely manner. Benefit transfer offers an opportunity to meet this need. Thus, we suspect that the demand for benefit transfer studies is likely to expand in the future in terms of the number and diversity of applications.

To our knowledge, prior benefit transfer studies have been conducted behind closed doors and have not been open to scholarly review. This obscurity is more the result of institutional processes than of deliberate attempts to avoid peer review. Consulting studies developed for legal proceedings, for example, may never become available for public review, and these studies must pass a test of relevance as to whether they meet the legal needs of the client. Government policy analyses, although often open to public review, are not typically documented in a medium that is readily available to members of the public. The test of relevance is whether the benefit transfer analysis provides the needed information for the policy issue being examined. It seems to us that these practical tests of relevance do not guarantee valid and reliable benefit transfer estimates.

In light of the potential use and misuse of benefit transfers, we feel that a "so what" attitude toward this issue is inappropriate. There is a definite need to critically examine benefit transfer studies. Given the opportunity for scholarly review of the concept and process of benefit transfer, there are two basic questions that we would like to pose: (1) Can benefit transfer studies yield valid and reliable estimates? (2) If the answer to the first question is yes, is it possible to improve the process of accomplishing benefit transfer? In attempting to answer these questions, we will discuss several benefit transfer philosophies. We will also discuss a generated protocol for conducting benefit transfer studies, and will use a real-world example to highlight some of the difficulties encountered in meeting this protocol. Our overall intent is to facilitate the development of a systematic procedure for conducting benefit transfer studies, which may also be used by decision makers to evaluate the credibility of benefit transfer estimates.

PHILOSOPHICAL ORIENTATIONS TOWARD BENEFIT TRANSFER

Pragmatism

The pragmatist that we allude to in the title of our paper may argue that the answers to both of the above questions is yes, perhaps an emphatic yes. Given the cost and time involved with the collection of primary data, the pragmatist would argue that the practical solution is to expand the number and diversity of benefit transfer studies. Such an expansion is facilitated by the rapid increse in the number of nonmarket valuation studies being conducted, particularly related to natural resource and environmental issues. Furthermore, as basic research continues to build the foundations of the various methods for estimating nonmarket values, the quality of data available for benefit transfer studies is improving.

Myth

Another benefit transfer philosophy, according to our somewhat arbitrary categorization, is the "impossibility myth." This myth states that benefit transfer is impossible. Consider the transfer of a value estimate at site A to a similar issue at site B. Those who adhere to the impossibility myth might point out that the levels of common technical attributes of sites A and B are different, and some attributes might occur at one site and not at the other. Of course, the preferences of individuals affected by the policy at site A may also be different from the preferences of individuals affected by the corresponding issue at site B. Given these differences, proponents of the myth would argue that these differences obviously result in different values at each of the sites so benefit transfer is impossible. The retort of the pragmatist might be that we simply need to learn whether these differences actually affect values, and if they do, are the differences large and how might one statistically control for these differing effects.

David Brookshire (personal communication, 1990) has stated that the impossibility myth reminds him of the early days of contingent valuation when opponents of contingent valuation argued that it is impossible to develop unbiased value estimates. Economists, and perhaps more frequently noneconomists, sometimes focus on whether differences in individual values can be adequately represented by one statistic (e.g., a mean), and whether the worth of an item can be adequately reduced to dollars. *Scott* [1965, p. 37] succinctly summed up the skepticism of economists when he stated "ask a hypothetical question and you will get a hypothetical response." Some of the concerns have been laid to rest [*Dickie et al.*, 1987; *Heberlein and Bishop*, 1986; *Mitchell and Carson*, 1989], but many questions remain [*Phillips and Zeckhauser*, 1989]. The pragmatist might ask whether a similar research agenda might be developed to establish conditions under which benefit transfer can accomplished with a reasonable degree of confidence.

Idealism

The idealist would acknowledge that benefit transfer is a reasonable concept to entertain, but sets strict standards for conducting benefit transfer studies. Transfer estimates must be unbiased (valid) and repetition of transfer estimates for a specific site must result in a small variance of replicated transfer estimates (reliability). To the pragmatist, these conditions may be too strict and may not appear to be functionally different from the impossibility myth. Moreover, the pragmatist may ask whether some error and a little larger variability may be acceptable as a trade-off to reduce the time and monetary costs involved in primary data collection.

The benefit transfer protocol discussed in this paper addresses the ideal. Our use of an example is an attempt to identify the difficulty of meeting this protocol and to begin to develop bounds for practically conducting benefit transfer. The impossibility myth, perhaps, will only be supported or refuted by future studies designed to validate transfer estimates. In our discussion of a benefit transfer protocol, we allude to the thought that benefit transfer, in practice, may require finding a "common ground" between the various philosophical orientations toward benefit transfer.

CONCEPTUAL FRAMEWORK FOR BENEFIT TRANSFER

To add relevance to the development of our conceptual framework we will use the valuation of various flow levels in the Kennebec River in Maine as an example. This example was selected because we thought that it would be of interest to *Water Resources Research* readers. Furthermore, this is a timely issue as all of the dams on the main stem of the Kennebec River, which control the river's flow, are required to file for relicensing by the Federal Energy Regulation Commission in the next decade. Finally, we have recently conducted studies examining Colorado River flows (K. J. Boyle, et al., University of Maine, unpublished manuscript, 1990) and reservoir levels in North Carolina [*Cordell et al.*, 1990], and in turn, we can apply our expertise in developing the Kennebec River example. Following nomenclature used by *Desvousges et al.* [this issue], the Kennebec River will be referred to as the "policy site." Existing studies identified as offering potential for benefit transfer will be termed "study sites."

Policy Site Value to Be Estimated

The first step in conducting a benefit transfer study is to specify the theoretical definition of the value(s) to be estimated at the policy site. For the Kennebec River we need to evaluate the effects of various river flows, measured in cubic feet per second (cfs) (1 cfs = 2.83×10^{-2} m^3/s) on white water rafter values. To begin, we specify an indirect utility function $V(\ )$ of the form

$$V(P_W, P, Y|A, S) = \max_{T,X} U(T, X|A, S) \quad \text{subject to } P_W T + PX = Y, \qquad (1)$$

where P_W is the cost of a white water trip, P is a vector of prices of other goods and services, Y is income, A is a vector of exogenous attributes of a white water trip which includes the flow experienced, S is a vector of socioeconomic characteristics, T is the quantity of white water trips taken and X is the quantity of all other goods consumed.

Following *Randall and Stoll* [1980], we can use the indirect utility function specified in (1) to define a Hicksian compensating willingness-to-pay measure for white water rafting as

TABLE 1. Potential Study Sites

Source	Study Area	Year	Valuation Method
K. J. Boyle et al.[a]	Colorado River from Glen Canyon Dam to Lake Mead	1985	contingent valuation
Daubert and Young [1981]	Poudre River, Colorado	1978	contingent valuation
W. B. O'Neil et al.[b]	Saco River and West Branch of Penobscot River, Maine	1984	contingent valuation
Walsh et al. [1980]	various rivers in western Colorado	1978	contingent valuation
Ward [1987]	Rio Chama, New Mexico	1982	travel cost

[a]Contingent valuation of unexperienced environmental conditions (unpublished manuscript, Department of Agricultural and Resource Economics, University of Maine, Orono, 1990).
[b]Estimating the value of river-related recreational activities: A comparison of two approaches based on case studies of the West Branch of the Penobscot River and the Saco River (unpublished Manuscript, Department of Economics, Colby College, Waterville, Maine, 1985).

$$V(P_W,\ P,\ Y - WTP_{\bar{f}};\ A_{\bar{f}},\ S) = V(P_W^\infty,\ P,\ Y;\ A_{\bar{f}};\ S) \tag{2}$$

where $WTP_{\bar{f}}$ is the value to be estimated for the fixed water flow represented by $\bar{f}(f \in A)$, and P_W^∞ is a choke price at which a person would choose to not take any white water trips.

The attribute and socioeconomic vectors represent key aspects of the policy site that must be considered when determining the transferability of values from a study site. The attribute vector may include elements such as flow, degree of crowding by other rafters, length of trip (single versus multiple day), etc. Socioeconomic characteristics may include age, sex, and rafting experience. This information allows the investigator to learn whether the object of valuation, and the user group, are the same, or at least similar, at both the policy site and the study site(s). If differences do exist, knowledge of these variables may allow for systematic manipulation of study site values so that they will be applicable at the policy site.

Identification of Study Sites

This step involves conducting a thorough literature search. Reviewing journal articles and citations is a practical first step, and electronic literature searches can help. Recent books by *Cummings et al.* [1986] and by *Mitchell and Carson* [1989], although focused on contingent valuation, provide extensive lists of references that can be quite helpful. However, this step is more difficult than it may first appear. As the number and diversity of valuation studies increases, many relevant study sites may not be identified via traditional search procedures (e.g., journal citations). This "hard to obtain" literature, often termed "gray" literature, includes research reports of well-done studies that do not contain a new twist that enables further publication, recently completed studies that have yet to be published, and various special publications that are not widely circulated (e.g., experiment station reports and bulletins from state land grant universities).

Accepting that the quality of study site values is critical to the quality of a benefit transfer, an obvious preference may exist for using recent studies employing state of the art data collection and value estimation procedures. One way to address potential oversights in the "gray" literature is to contact researchers investigating the issue of interest at identified study sites and ask them if they know of other studies that may be relevant. Government agencies involved in nonmarket valuation may also compile and maintain lists of nonmarket valuation studies. Published survey articles are also useful sources of references [e.g., *Sorg and Loomis*, 1984; *Walsh et al.*, 1988].

For our example we searched for study sites where values have been estimated for white water rafting under various flow regimes. Our search was facilitated by a review article by *Loomis* [1987], and the fact that we selected a valuation application we are familiar with. We identified five potential study sites (Table 1). This number of potential transfer sits is consistent with what we might expect to find for most benefit transfer applications. Although a large number of nonmarket valuation studies have been conducted, especially in the 1980s, the number of study sites is likely to be relatively small for any specific issue. Applications like deer hunting, and trout or bass fishing, represent exceptions where a large number of studies can be identified. A question still remains, though, as to whether these studies estimated a value that will be relevant for the policy site. For example, a study that simply estimated the total value of a deer hunt may not be applicable for benefit transfer when the issue at the policy site is whether hunters should be allowed to take an extra deer. This transferability of study site values will be addressed next.

Transferability of Study Site Values

Potential study site values must be examined to determine whether they are transferable. As with the deer hunting example above, the fact that values were estimated for white water boating at a study site does not mean that these values will be applicable to the issue being evaluated at the policy site. Transferability needs to be evaluated using objective criteria. For benefit transfer, we propose the following idealistic technical criteria: (1) the nonmarket commodity valued at the study site must be identical to the nonmarket commodity to be valued at the policy site; (2) the populations affected by the nonmarket commodity at the study site and the policy site have identical characteristics; and (3) the assignment of property rights at both sites must lead to the same theoretically appropriate welfare measure (e.g., willingness to pay versus willingness to accept compensation).

Following our technical criteria, we can exclude the *Walsh et al.* [1980] value estimates for transfer to the Kennebec River because participants in this study evaluated rivers at

20 to 80% of their bank-full levels. At the policy site we want to evaluate white water rafting as specific flows measured in cubic feet per second (cfs). With the available data, we cannot make a direct link between bank-full capacity and a specific flow in cubic feet per second.

Two other studies can be excluded because the flow levels evaluated do not correspond to the flows in the Kennebec River. Flows experienced by white water rafters on the Kennebec River are directly influenced by releases from Harris Dam. According to dam managers, the minimum release is about 150 cfs (3.25 m^3/s) and a typical maximum is 8000 cfs (226 m^3/s); the largest flow ever recorded at Harris Dam was 21,000 cfs (600 m^3/s) on June 1, 1984. Average flows for a typical day are in the range of 3500–4000 cfs (100–113 m^3/s) with a flow of 5000–6500 cfs (142–184 m^3/s) for peak power generation. The section of the river below Harris Dam requires 2500–3000 cfs (71–85 m^3/s) for rafting to occur, and informal reports indicate an optimal flow for rafting between 4800 and 5000 cfs (136–142 m^3/s). Thus, for policy evaluation purposes the relevant range of flows is 2500–6500 cfs (71–184 m^3/s).

The K. J. Boyle et al. (University of Maine, unpublished manuscript, 1990) study can be excluded because the lowest Colorado River flow evaluated was 10,000 cfs (283 m^3/s), which exceeds the capacity of Harris Dam and would only occur under flood conditions (see also *Bishop et al.* [1987]). A similar conclusion is reached when we consider the study by *Daubert and Young* [1981] (see also *Daubert et al.* [1979]). All flows evaluated for the Poudre River are below 1000 cfs (28 m^3/s), and the Kennebec River is not raftable at these low flows.

Of our original five studies two are left. The O'Neil et al. study (W. B. O'Neil et al., Colby College, unpublished manuscript, 1985) may seem the most likely study site for benefit transfer because values were estimated for rivers in Maine. However, these authors simply estimated an average value for a white water trip and no systematic relationship was developed between river flows and value. This single value was appropriate for the policy issue they investigated where the question was whether to build a dam on the West Branch of the Penobscot River, which would remove the raftable section of this river. The policy we are investigating in our example policy site is trade-offs between hydropower generation at an existing dam and flows for white water rafting.

The final study by *Ward* [1987] estimated only one flow-specific value, 4000 cfs (113 m^3/s), in the range being investigated at the policy site, 2500–6500 cfs (71–184 m^3/s; see also *Ward* [1985]). Furthermore, the optimal flow in the Ward study was 2000 cfs (57 m^3/s), which is below the raftable threshold on the Kennebec River. A single value at 4000 cfs (113 m^3/s) used for benefit transfer at the policy site would be insufficient for trade-off analyses. Furthermore, the fact that the optimum flow on the Rio Chama is below the raftable threshold on the Kennebec River indicates differences between the two rivers that make benefit transfer questionable. At this point we have excluded all potential study sites. We believe that this is likely to be the case for many specific investigations; a small number of potential study sites are available, and the value(s) estimated at these study sites may not be applicable to the issue at the policy site.

For may issues, like the effect of river flows on white water rafting values, a small library of study sites is gradually being built, and as the number and diversity of these original investigations expand, the potential for benefit transfer will expand. It would seem that a useful purpose would be served by a national clearinghouse of nonmarket valuation studies to which investigators could submit publications and perhaps data sets. For market data, many federal and state agencies maintain extensive data sets which are published in summary form at periodic intervals. Nonmarket valuation studies are generally conducted at a local or regional level and do not have a national focus like the data sets referred to above. Thus, a nonmarket valuation library might need joint support by several federal agencies, including agencies beyond those involved in managing natural resources and the environment as applications of nonmarket valuation spread to health services and other publicly provided services.

Quality of Benefit Transfer Estimates: Intersite

Assuming that one or more study sites have been identified as meeting the technical criteria for benefit transfer, the next step is to evaluate the quality of these estimates in terms of their original quality. This is a question of whether

$$E(V_{ss}) = \mu_{ss} \tag{3}$$

where $E(\ )$ is the expectation operator, V_{ss} is the estimated value at the study site and μ_{ss} is the true mean at the study site. Precisely, we hope that the estimate at the study site is unbiased. This means that the study site value must be investigated in terms of value specification (theoretical construct), data collection procedures, statistical methods and the nonmarket valuation application itself. For this investigation to be successful, it is incumbent on the investigators at the study site to have done a top-notch job of reporting their study results.

Useful contributions to the literature that may help in this evaluation are the recent books on contingent-valuation by *Cummings et al.* [1986] and by *Mitchell and Carson* [1989]. In addition, survey articles on valuation have been published by *Anderson and Bishop* [1989], by *Durden and Shogren* [1988], and by *Forster* [1989]. Both the *Anderson and Bishop* [1989] and the *Forster* [1989] pieces discuss contingent valuation, travel cost and hedonic price estimation. The *Durden and Shogren* [1988] article focuses on contingent valuation and travel cost. Finally, *Ward and Loomis* [1986] have written a survey article on travel cost that can also be useful.

At this step we do not intend to infer that biased estimates should not be considered for benefit transfer, but biased estimates at a study site certainly present serious questions about the transferability of these estimates. Rather, we hope for unbiased estimates, and if estimates are biased, we ask whether the bias is large or small. A small bias may, in fact, be acceptable in benefit transfer. A study with serious problems resulting in large biases probably should be excluded from further consideration. Furthermore, any nonmarket valuation study is likely to have some margin of error, and this error must be taken into consideration as benefit transfer proceeds.

Quality of Benefit Transfer Estimates: Intrasite

Considering that even statistically unbiased estimates of nonmarket values at the study site are measured with some degree of statistical error, and that nonmarket commodities, affected populations, and property right structures at the study site and policy site will rarely (if ever) match up exactly, we need to find a somewhat more pragmatic way of implementing our technical benefit transfer criteria than was suggested by our Kennebec River example. One possibility is to assume that the technical benefit transfer criteria are met if the nonmarket values at the study site and policy site are statistically identical. This is a question of whether

$$E(V_{ss}) = \mu_{ps} \tag{4}$$

where μ_{ps} is the true mean at the policy site. If it is determined that (4) holds (that is, the study site value provides a statistically unbiased estimate of the policy site value), then the study site value can be taken directly off the "library shelf" and used for the policy site.

The more likely outcome is that the study site value will not be a statistically unbiased estimate of the value to be estimated at the policy site. Three avenues are open to accomplishing benefit transfer here. The first avenue, which follows the idealistic benefit transfer philosophy, is to reject the study site for benefit transfer, ultimately confirming the impossibility myth. The second avenue, which is more in line with the pragmatic benefit transfer philosophy, is to ask whether the bias is small and within an acceptable range of error for the investigation at the policy site. The third, and perhaps most desirable, avenue is to determine whether the study site value can be systematically adjusted to remove or reduce the bias at the study site, thereby pushing us toward the practical ideal of satisfying identity (4).

Accomplishing a systematic adjustment of study site values requires proceeding with caution. We propose that the key to this procedure is knowing something about the attribute and socioeconomic vectors of the study site, and the effects of the variables in these vectors on the value(s) estimated at the study site. In the early days of nonmarket valuation, considerable descriptive statistics, diagnostic statistics, and estimation procedures might be reported in valuation studies. In recent years, however, the tendency has been to simply report mean values and, perhaps, median values. This seems to be a direct result of imposing theoretical consistency on value estimation, and in turn, simple models are easier to apply.

In addition, researchers may be reluctant to report all of the estimation steps and descriptive and diagnostic statistics used to arrive at final valuation results for fear of being accused of "data massaging." We certainly hold that empirical valuation models should be strongly based on economic theory. We do not presume, however, that investigators always know and use an appropriate economic model of preferences. Also, as hard as we may try to specify conceptually appropriate and complete economic models of preferences, these models will fall short of completely explaining valuation behavior. Thus, from a basic research perspective, examining statistical relationships between estimated values and attributes of the item being evaluated and characteristics of the individuals whose values are being investigated can serve to enhance future empirical modeling efforts. Better empirical modeling, and resulting enhancement of value estimates, can enhance the potential for benefit transfer. More importantly, the investigation and reporting of variables that affect estimated values at study sites enhance the potential for systematic adjustment of these values so that they provide more accurate value estimates at a policy site. Recent investigations into this area of research have been conducted by *Walsh et al.* [1989], and by *Smith and Kaoru* [1990].

Supplemental Data Needs

Benefit transfer may require, or at least be improved by, simultaneous collection of primary data. This may include conducting what *Naughton and Desvousges* [1986] refer to as a "key informants" survey to learn more detail about technical aspects of potential study sites and the policy site. In addition, a formal survey of principal investigators who estimated benefits at each study site might be warranted to insure consistency in reporting across study sites. This step attempts to identify details of the study site application that are not reported in available publications. One may also want to request the study site data set to see if recent contributions to the literature may be used to improve the study site value estimates, and may allow for statistical adjustment of study site values to make them suitable for the policy site. Finally, some primary data collection may be necessary at the policy site to get a handle on key variables characterizing individuals affected by the issue under investigation. Such information might be obtained in a short survey with a relatively small sample size. These data might be useful for determining the suitability for transfer of study site values and for enhancing the possible adjustment of study site values to corresond to the needs at the policy site.

PROPOSED RESEARCH AGENDA

If benefit transfer is going to become accepted by skeptics as a reasonable means of developing nonmarket values in the face of budget and time constraints, a careful research agenda must be developed to examine the validity of benefit transfer estimates. We see this research as having two primary areas of investigation.

One line of investigation involves concurrent estimation of nonmarket values at the study site and the policy site using primary data collected at both sites. We could then attempt to transfer benefits from the study site to the policy site using valuation models developed for the study site. We could then compare the benefit transfer values for the policy site (based on the study site valuation models) with the values estimated for the policy site from primary data. This research will determine whether $E(V_{ss}) = \mu_{ps}$.

If benefit transfer estimates are not statistically different from the primary data value estimates developed at the policy site, convergent validity is established. When benefit transfer estimates are biased, these concurrent evaluations can examine the size of the bias, direction of the bias and adjustments that might be made in study site estimates to mitigate the bias. Validity investigations ultimately will identify conditions where benefit transfer works and procedures necessary to make benefit transfer operational. To our knowledge, this type of investigation has not been conducted.

The second line of investigation involves examining original value estimates based on primary data to identify the magnitude and directional effect of variables that significantly affect estimated values. This would involve investigations across studies as done by *Smith and Kaoru* [1990] and by *Walsh et al.* [1989]. In addition, further investigations of original studies based on primary data and reporting of these results would also be extremely helpful, including reporting of insignificant as well as significant variable relationships.

Research using primary data is the basis of benefit transfer via the provision of data and models needed to extend study site values to one or more policy sites. Thus, original investigations using primary data must not simply focus on the end result of estimating a value for the policy issue at hand. Original analyses using primary data, and reporting of these analyses, must reflect their future use as data for benefit transfer studies. These investigations of statistical relationships will help identify key variables and relationships for determining the suitability of a study site value for transfer, and perhaps, for adjusting study site values at the policy site to reduce potential biases in transfer estimates.

Issues in Benefit Transfer

In the introduction of our paper we posed two questions. In response to the first question, we must conclude that little research has been conducted to either establish or refute the validity of benefit transfer estimates. Given this conclusion we feel that the process of accomplishing benefit transfer can be improved, and improvement is necessary to establish conditions under which benefit transfer estimates can be deemed to be credible.

A number of specific issues must be addressed over time to enhance the potential for successful benefit transfer applications.

1. For many specific issues, a small number of study sites exist. This issue can only be addressed through time as more original investigations based on primary data are conducted.

2. A systematic process of accomplishing benefit transfer should be established to avoid ad hoc decisions in the selection of study sites and the transfer of study site value estimates. This can be accomplished by undertaking the research agenda we propose. This agenda involves conceptual and empirical analysis of what may cause a divergence between study site and policy site nonmarket values, and how such divergences can be reduced or eliminated.

3. Improvements are needed in analysis and reporting of original valuation studies. This requires investigators to view their studies as providing data, as well as value estimates for the issue they are investigating.

4. Existing studies should be made more accessible to individuals conducting benefit transfer studies. This could be accomplished by establishing a national system of collecting valuation publications and data sets.

Accomplishing each of the above steps will take time and money. Given the potential gains of being able to successfully conduct benefit transfer studies, it seems that funding should be provided to begin the formative steps of attempting to establish the validity of benefit transfer estimates.

Conclusions

Consistently developing original value estimates based on primary data collection for every new policy issue is an expensive and time-consuming venture. Furthermore, a substantial investment has been made in existing valuation studies, and will continue to be made, and it seems reasonable to expect an additional return by using these data sets in benefit transfer studies. The reality of accomplishing these potential cost reductions and realizing additional returns to existing data sets is rather bleak in the near future due to the difficulties, only some of which we have cited, in accomplishing benefit transfers.

We do feel that investigations designed to establish and advance the conditions under which credible benefit transfers can be accomplished is an important and worthy research agenda. The primary focus of these studies should be to examine the validity of benefit transfers. Convergent validity would be established if the transfer estimates are statistically similar to the original estimates developed for the policy site. In cases where statistical differences are identified, the margin of error might be established to weigh against the potential cost savings of employing benefit transfer.

These validity investigations might also be instrumental in identifying key variables for determining the suitability of potential study sites, or for adapting study site values to the policy site. The focus of benefit transfer, therefore, should not be on simply pulling existing evaluation estimates off the shelf and using the value estimates directly. Rather, existing valuation studies should be viewed as secondary data sets that may require supplementation with some primary data collection at the policy site and possibly some reestimation.

Until a research agenda is developed and undertaken to establish the credibility of benefit transfer studies we are left with proponents of the pragmatism philosophy arguing without basis in fact that benefit transfer estimates "look and feel good" and are therefore "close enough" for off-the-shelf application. Proponents of the impossibility myth can continue to flatly reject benefit transfer estimates as "back room hocus pocus and ad hockery" designed to accomplish a predetermined policy agenda. Neither of these positions is tenable and we must move forward with benefit transfer, including validation studies that are adequately funded and meet conditions for publication in scholarly journals. Most importantly, conducting credible benefit transfer studies will ultimately require the same level of skill and care that currently goes into high quality, original value estimation based on primary data. We propose striving for an ideal set of benefit transfer criteria, although we recognize that establishing such criteria in the real world may require a moderate dose of pragmatism leading to acceptance of some "practical ideal."

Notation

$V(\ )$	indirect utility function.
P_W	cost of a white water trip.
P_W^∞	price high enough to choke off all use.
P	vector of prices of other goods and services.
Y	income.
$V_{\bar{f}}$	value to be estimated for flow $\bar{f}$.
A	vector of exogenous attributes of a white water trip.
$\bar{f}$	flow to be evaluated ($f \in A$).
S	vector of socioeconomic characteristics.
$U(\ )$	direct utility function.
T	white water trips.
X	vector of other goods and services.

$E(\ )$ expected value operator.
V_{ss} estimated value at the study site.
μ_{ss} true mean at the study site.
μ_{ps} true mean at the policy site.

The research reported in this paper was supported by the USDA Forest Service through Cooperative Research Agreement 04-CA-11330144-149 entitled "Assessment and Management of Natural Capital Benefits: Phase III" Between The University of Georgia Department of Agricultural & Applied Economics and The USDA Forest Service, Southern Research Station. Support was also provided by the Georgia Agricultural Experiment Station through the W-2133 Regional Research Project entitled "Benefits and Costs of Natural Resources Policies Affecting Public and Private Lands." Support and technical assistance from J. Ross Arnold, USDA Forest Service, Research and Development Staff, Washington, D.C. Office, is gratefully acknowledged.

I. INTRODUCTION

The USDA Forest Service (FS) manages 193 million acres of public land in the United States. These public resources include vast quantities of natural resources including timber, wildlife, watersheds, air sheds, and ecosystems. The Forest Service was established in 1905, and the FS has been directed by Congress to manage the National Forests and Grasslands for the benefit of the American people. Initially, this guiding principle was to maximize the sustainable yield of timber products from forest lands. Beginning in the 1960's, the FS was directed to manage these lands for multiple uses and benefits, as well as for the sustained yield of renewable resources such as water, forage, wildlife, wood, and recreation.[1]

In 1974 Congress passed the Forest and Rangeland Renewable Resources Act (RPA), and in 1976 passed the National Forest Management Act (NMFA). The RPA calls for planning at both the national and forest level. Two key documents produced at the national level are the RPA Assessment and the RPA Program. The Assessment describes the current state of forest and rangeland situation and trends likely to affect the resource situation over a 50 year planning horizon. Based upon the findings of the Assessment, a 50-year Program is recommended to the FS. The recommended Program is a strategic plan that establishes long-term resource management goals (McCollum et al., 1990).

By 1995, the RPA Program had been replaced by the Government Performance and Results Act (GPRA) Strategic Plan, which is on a 3-year cycle, and only looks 5 years into the future. The RPA Program is basically defunct, having been replaced by the GPRA Strategic Plan. The need for resource values stems from the need to have a common dollar-based metric with which to compare recreation related resources with more traditional resources such as grazing and timber. Forest managers and others find these values beneficial in the planning process under both the RPA Program and the newer GPRA.[2]

The goal of this study is to provide research into the Net Economic Value (NEV) of FS lands in support of the work conducted by the FS Strategic Planning and Resource Assessment (SPRA) staff in their strategic planning efforts. Our primary focus is to assess the net economic value (NEV) of recreation on National Forests. More specifically, we measure net willingness to pay for access (WTPA) to recreation opportunities on the National Forests.

To address our main objective of measuring net willingness to pay for recreation access on National Forest lands, we approach the problem as follows. First, we develop a national aggregate (multi-site) level recreation demand model for visitors to all National Forests, this model, using on-site survey data and a revealed preference estimation method (travel cost) is designed to be sufficiently flexible to allow estimating demand nationally for fourteen different recreation activity aggregates. Based on the parameters of the demand model, we are able to estimate WTPA for each of the fourteen recreation activities, on per-visit and per-activity day levels. Next, we develop four regional models which allow estimation of WTPA for the same fourteen activities at the RPA macro-region level. Related to the development and estimation of these models, we explore and report the sensitivity of WTPA estimates to a number of empirical judgments that are necessary to implement our modeling approach. Finally, we address the efficacy of using the National Visitor Use Monitoring (NVUM) database as the foundation for developing our models and WTPA estimates.

This report is comprised of six sections and a number of appendices. There is also a CD supplement to this report available upon request from the authors containing EXCEL spreadsheets with Table 1-9. The organization of the report is as follows: Section II provides a background discussion of previous valuation work for the FS and a brief review of the related literature; Section III describes the data used in the analysis; Section IV develops the models and methods used in estimation; Section V presents preliminary models and results; and Section VI provides some concluding remarks and areas for continuing research.

The appendices are arranged as follows: Appendix A contains technical information describing data preparation; the on-site sampling procedure and the resulting choice-based sample weights used in the empirical methods are discussed in Appendix B; Appendix C describes the model development process and presents some of the econometric issues considered during modeling. Appendices A-C are included as part of this Word document. Appendix D describes the data and provides descriptive statistics; Appendix E contains a full set of results for different recreation activities, spatial scales, and model specifications. Appendices D and E are in Microsoft Excel format and are available as electronic supplements to this document. Appendix F provides the SAS input files used to compile and generate the estimation data set, and is provided as electronic SAS files. Appendix G provides the LIMDEP files used in regression and value calculation, and is provided as electronic LIMDEP files. All tables listed in the text are provided in Appendices D and E, and are numbered as they appear in those appendices.

II. BACKGROUND

II.A. History of Forest Service Recreation Values

The passage of NMFA and RPA provided the impetus for significant research into the economic value of recreation and of nonmarket public resources held in trust by the FS. The valuation work done for the RPA Program has focused on providing values to planners and forest managers, with little emphasis on generating comprehensive values for FS resources as a whole.

Previous RPA Program analyses provided recreation values using a variety of data sources and methods. Sorg and Loomis (1984) provided an early literature review of recreation values which was later updated by Walsh, Johnson and McKean (1988). Values published in 1990 by McCollum et al. provide an extensive series of values based upon FS region and primary activity using a subset of the 1985-1986 Public Area Recreation Visitor Survey (PARVS) data. They used a reverse-gravity zonal travel cost method to estimate net economic value or consumer surplus for forest recreation. A more recent set of values is provided by Rosenberger and Loomis (2001) using a meta-analysis benefit transfer technique.

The Rosenberger and Loomis (2001) recreation value estimates are based on a detailed meta-analysis of previously published recreation valuation studies. An in-depth literature review was used to construct a database where the characteristics and values of each study were coded into numeric variables. Reported values were derived from 163 separate studies containing 760 different recreation valuation estimates. This information was then used to generate tables containing average per person per activity day net economic values, as well as regression models that allowed for the estimation of average WTPA per person per activity day for 21 different activities. Their methodology provides a comprehensive statistical summary of the literature that can be used for benefit transfer and to investigate the effects of a variety of factors on recreation values. Limitations of the study for National Forest policy and planning include reliance on secondary data estimates of recreation value and inclusion of recreation resources not in the National Forest inventory meaning that the reported values are not strictly National Forest recreation values.

The recreation value estimates presented in this report are based on a unique recreation use dataset containing only observations from National Forest visitors across the U.S. based on a scientifically designed and implemented sampling frame. To date, recreation value estimates for the National Forest system as a whole and by RPA regions based on primary data collected solely at National Forests have not been available.

II.B. Recreation Demand Modeling Background

For many of the goods and services provided by National Forests, valuing the costs and benefits of utilization are relatively straightforward through the use of market information. However, valuing recreation related benefits poses difficulties because traditional markets comparable to those for extractible goods like timber do not exist.

In a utilitarian framework, the net economic value (NEV) of a good or service is derived from the relationship between an individual's demand function for the good or service and the equilibrium price and quantity consumed. The net economic value per unit is the difference between the individual's maximum willingness to pay (WTP) as defined by the individual's underlying demand for the good or service and the price actually paid. The NEV is also commonly called consumer surplus (CS). While an individual's demand is not observed, prices and quantities are readily observable for goods and services traded in private markets. These observed prices and quantities can be combined with standard econometric methods to derive estimates of NEV for typical individuals or for market aggregates. Since access to National Forests for recreation is not typically traded in private markets, NEV must be estimated using nonmarket valuation techniques.

Several methods have been developed to estimate NEV for recreation opportunities. These same methods are also commonly used to estimate the economic value associated with a change in quality for a recreation resource. Stated preference (or attitude-based) methods involve directly asking individuals about their willingness to pay for a good or service or, in some cases, how their consumption of the good would be affected by a price or quality change. NEV is then estimated from the willingness to pay responses. Contingent valuation and contingent behavior methods are the most popular examples of stated preference methods.

Revealed preference methods for nonmarket valuation are based on actual behavior rather than stated intentions. Two of the most popular revealed preference methods used for valuing recreation opportunities are the hedonic method and travel cost method (Freeman 1999). The travel cost method (TCM) is by far the most commonly used revealed preference technique when valuing access to public lands for recreation activities. In its different variants (e.g., zonal and individual models) it has regularly been used since the 1960's to estimate the net economic value of recreation access (Clawson and Knetsch 1966; Freeman 1999; Loomis and Walsh, 1997).

In order to estimate demand and net economic value for recreation access on National Forests using the TCM, a crucial assumption is made that the cost of travel to the site (including associated fees) is a proxy, or shadow price, for recreation. Thus, the price-quantity relationship described by a demand model is captured as the relationship between travel cost and the number of visits to the site. Formally, the assumption is referred to as weak complementarity (Haab and McConnell 2002, p.15). The underlying insight is attributed to Harold Hotelling in a 1947 letter to the National Park Service, and later popularized by Clawson and Knetsch (1966).

The literature on recreation demand and TCM is expansive. The history of recreation demand begins with the first zonal travel cost methods (ZTCM) applied by Clawson and Knetsch (1966) which used aggregate data to estimate demand. These methods were later replaced, to a great extent, with individual travel cost methods (ITCM) using household or individual microlevel data. The next major advancement in recreation demand came from Hanemann (1984) in describing the Random Utility Model (RUM) that better captures the site/trip choice discrete modeling process. RUM models are particularly well-suited for modeling recreation demand in areas offering numerous substitute sites. A comprehensive review of the development of recreation demand models and the current state of TCM can be found in Phaneuf and Smith (2004). Additional detail concerning recreation demand modeling and the TCM can be found in, Bockstael and McConnell (1983); Bockstael, Strand, and Hanemann (1987); Bockstael and Strand (1987); Kling (1992), Freeman (1999), Haab and McConnell (2002) and Loomis and Walsh (1997). A critique of the travel cost methods can be found in Randall (1994).

The research presented here uses the ITCM to value public recreation on National Forests and Grasslands. As noted by Phaneuf and Smith (2004), despite more than fifty years of research into valuing the benefits of recreation using travel cost demand models, serious issues in the theoretical and empirical application of these methods remain. We acknowledge and discuss our approach to these issues as they apply to the modeling and results reported herein. Nevertheless, as long as recreation opportunities are provided on publicly owned lands and are not traded strictly in private markets, travel cost recreation demand models will provide a viable alternative to estimate the net economic value of recreation because the relationship between travel costs and visits (travel distance is costly) has proven empirical support.

III. DATA

In 2000, the FS began a comprehensive effort to scientifically estimate recreation visitation levels on National Forest lands on a continuous basis. The National Visitor Use Monitoring Program (NVUM), in its first 4-year cycle, collected data from 120 National Forests and Grasslands (hereafter referred to as National Forests or NFs) using a stratified random sampling procedure (English et al. 2002). In addition to providing a scientific basis from which to estimate visitation to the NF system and to individual NFs, an on-site survey was administered to obtain visitor information on the number of annual visits, primary activity, local area expenditures, satisfaction with facilities, and limited demographic information.[3,4] The preliminary or master dataset for the first cycle of on-site surveying (2000-2003 inclusive) contains 90,542 individual recreation visitor observations from 7,532 different sites aggregated from 120 National Forests and includes more than 200 variables per observation (English et al., 2002).[5]

For both theoretical and empirical reasons, a number of adjustments were performed on the preliminary dataset. Table 3 provides a detailed accounting of the adjustments made to yield the final sample used for travel cost model estimation. The data set was transformed as follows. Observations from Alaska were deleted from the master sample because the nature of recreation on the Alaska National Forests is significantly different from recreation on National Forests in the contiguous U.S. Alaska visitation is characterized by large numbers of tour groups including cruise liners and buses, as well as large numbers of locals who take numerous daily visits to the National Forests, particularly the Tongass. In addition, the physical characteristics of the National Forests in Alaska are dissimilar from other National Forests and the majority of nonresidents are not typically visiting the state solely to visit either of the two National Forests. Likewise, observations from Puerto Rico were deleted from the master sample due to the significantly dissimilar patterns of recreation relative to the rest of the NFs.

Visitors for whom the NF was not the primary purpose of their trip to the area (PRIME=0) were also deleted from the master sample. This action was necessitated because travel cost modeling assumes that all visits to a given recreation site are for the primary purpose of visiting that site. Incidental visits are not included in the estimation sample because adequate methods have not been developed to apportion the costs of the total trip to the incidental (non-primary purpose) visit. Foreign observations were also deleted from the master sample because of the high likelihood of being on a multi-purpose trip and also because of the intractability of accurately measuring travel costs.

Observations with missing values for the following relevant variables were also deleted from the master sample: annual number of visits to a National Forest (NFV12MO), distance traveled (PRACTD1S), gender (GENDER1) and whether or not the visit involved an overnight stay on the National Forest (ONITE). With respect to suspected outliers, observations were deleted from the master sample if annual visits were greater than 52 and distance traveled was greater than 720 miles as this translates into visiting at least once per week and traveling more than 12 hours each way.[6] Finally, observations where the number of people traveling in the vehicle was reported as more than 10 were deleted from the master sample.

After deleting observations from the master sample as described above, an adjusted sample consisting of 68,669 observations remained, this is referred to as the 'ALL' sample. Additionally, during estimation an additional dataset was created where the largest 5% of distances were trimmed from the adjusted sample, leaving 64,894 observations. This data is referred to as the 'trimmed' or 'TOP5' dataset. For key variables including age (AGE), people traveling in the vehicle (PEOPVEH), and income (INCES), missing values were replaced with the weighted sample mean for the variable.[7] The mean used to replace missing observations is based upon the adjusted samples.

The NVUM survey did not collect any income or substitute site information from respondents. Economic theory suggests that income and substitute prices should be included in travel cost demand models. To provide a proxy for income, U.S. Internal Revenue Service (IRS) data on adjusted gross income, tax returns, and Zip Code for Tax Year 2002 were used. Thus, income (INCES) is represented by the average after tax income as reported by the IRS for the Zip Code in which the individual resides. A substitute distance/price variable was constructed using the Geographic Names Information Service (GNIS) latitude-longitude for each National Forest in the NVUM sample. This information was used to construct a substitute distance (SUBDISTZ) variable that provides a one way distance from the individual's home Zip Code to the next nearest NF not visited. The substitute variable construction assumed that for each NF visitor, the relevant substitute site would be the nearest NF to the visitors origin exclusive of the NF visited on the current trip.[8]

Table 4 displays descriptive statistics for the untrimmed adjusted dataset (ALL) and Table 5 provides the descriptive statistics for the trimmed adjusted dataset (TOP5). As reported in Table 4 (ALL, National Sample), the weighted average number of annual visits per individual to a National Forest was 3.708 with a standard deviation of 10.272.[9] The average weighted one-way travel distance per individual visitor in our sample was 486.441 miles. Using a conversion factor of $0.12 per mile, the average travel cost (including necessary fees) with no opportunity cost for travel time included was $120.37 with a standard deviation of $169.58; the average travel cost with an income based opportunity cost included was $214.09; and the mean travel cost with a fixed wage rate opportunity cost included was $211.85. The travel cost constructions are discussed in more detail in Section IV.[10] The average after tax per person income in the sample was $29,100 per year. The average number of people per vehicle was 2.724. Females comprised 33.1% of our sample, and the average age for respondents was 43.44 years.[11] The most frequently listed primary activity per individual respondent was hiking (15.0%), followed by skiing (14.6%), camping (8.5%), fishing (7.4%), and hunting (6.6%). Further information about the dataset used in this study and adjustments thereto is detailed in Appendix A (Data Documentation) and Appendix D (Descriptive Statistics).

IV. MODELING

To estimate the net economic value of recreation access to National Forests with NVUM data, many theoretical and empirical issues must be addressed. This section describes our modeling efforts. It is divided into two subsections, one describing the economic theory on which our models are based, and the other detailing issues and consequent judgments used to develop our empirical models.

IV.A. Theoretical Considerations

The primary focus of this study is to estimate the net economic value (NEV) of recreation on National Forest lands. In this study, NEV is measured in terms of willingness-to-pay for access (WTPA) to National Forests for recreation. As Haab and McConnell (2002, p.158) point out, there are two types of welfare or value measures associated with valuing recreation – the value of access to the site and the value of a change in quality at the site. We are concerned primarily with the value of access to the National Forest site rather than the value associated with quality changes. WTPA is interpreted as a visitor's willingness-to-pay above current expenditures to participate in recreation at a National Forest site rather than not recreate at that site. Hence, WTPA is a visitor's maximum net willingness-to-pay (consumer surplus or CS) associated with continued use of the site for recreation (Haab and McConnell 2002).

The process of estimating WTPA involves estimating the parameters of an individual or household demand function and then calculating the welfare measure (termed NEV, WTPA, or CS) given the estimated parameters (Haab and McConnell 2002, p.159). This process necessitates the use of demand theory, which in turn is underpinned by utility theory. The essential result of utility theory is the link between the unobservable utility function of the individual and observable prices and quantities. The constructs provided by utility theory allow economists to model what motivates the consumer, and retrieve demand estimates that are guided by behavioral characteristics of the consumer.

An ideal recreation demand model would be rigorously derived from the underlying utility theory and implemented in a manner consistent with that theory. However, when modeling recreation behavior, the recreation commodity or service being valued can be ambiguously defined and subject to different constructions and interpretations. The cost of recreation is not observable in the market, indeed the cost of recreation is only truly known to the individual engaged in the visit. Therefore, the number of recreation visits (the quantity consumed) is not related to external, objectively observable prices, and thus must be constructed by the analyst (Randall, 1994).

Thus, in modeling demand for National Forest visits, we begin with the utility framework represented by the household production approach (Deaton and Muellbauer, 1980; Bockstael and McConnell 1983) as described by Freeman (1999, p.445-447). Utility is a function of market goods, X , the number of visits to the site, R , environmental quality of the site, Q , subject to the dual constraints of money, M and time, T^*. The price of time is valued at P_w, with T_w representing the quantity of time worked, which is equal to the amount of the numeraire good purchased (where X is valued at a price of $1 per unit) plus the product of recreation visits to the site, R, and the monetary cost per visit, C. Total discretionary time is given by summing the amount of time spent recreating on-site t_1, and round-trip travel time t_2 times the number of visits made plus the amount of time spent working T_w. Thus, the utility maximization process for the household can be represented by,

$$
\begin{aligned}
&Max \\
&U(X,R,Q) \\
&s.t. \\
&M + P_w * T_w = X + C \cdot R \\
&and \\
&T^* = T_w + (t_1 + t_2) * R
\end{aligned}
\qquad [1]
$$

From this utility maximization problem we can detail the relevant characteristics of recreation consumption. For the household, utility is derived from consuming market goods, recreation, and environmental quality. Environmental quality is assumed to be complementary to recreation, so that increases in environmental quality increase recreation that then increases utility. As shown by the constraints, it takes time to recreate and recreation is traded for time spent working for wages that can be used in the consumption of X; thus, there is an opportunity cost of time associated with recreation. Other critical assumptions of this model include: each visit to the site is for the sole purpose of recreating at the site so that non-primary purpose visits are not included in the model; each visit entails the same amount of time spent on-site; travel time is considered utility neutral; and the wage rate is the appropriate opportunity cost of time (Freeman 1999, p.445-447).[12] The utility maximization problem above can be solved for the general recreation demand function:

$$R = \left(P_R, P_S, M, T, H, Q\right) \qquad [2]$$

where, R is the number of visits demanded, P_R is the per visit recreation price, P_S is the price of substitutes, M is annual income, T is a measure of time on-site, H is a vector of individual specific socio-demographic measures, and Q is a measure of site quality[13] In the current study, we do not address quality changes because of lack of adequate data and therefore drop this vector from the general recreation demand function.

When estimating a recreation demand model, it is critical to base the model in utility theory, since theory is what guides the interpretation of the results and provides economic meaning to the statistical results. Much of the debate in the TCM literature is centered on the assumptions embodied by this type of utility function/demand model and the restrictions it places on estimating and interpreting results. A significant portion of recent research discusses how applications of this theory often violate many of the underlying theoretical constructs, and thus make strict interpretations of the models problematic. This theme is re-iterated strongly by Phaneuf and Smith (2004).[14]

Our empirical models are based on pooling the available NVUM observations across sites and across all four years of sampling to form a single data set that can be segmented into regions, and activity groupings. By pooling observations across sites (within and among NFs) and estimating them as a single equation model with dummy variables and dummy interaction terms, we are basically following a varying parameters approach (Vaughan and Russell 1982; Bowker and Leeworthy 1998). The data were collected from more than 7,500 different sites measuring visits to more than 120 National Forests. We could estimate TCM models for each forest separately; however, this would produce a smaller number of observations per equation and limit our ability to estimate values for activities. Moreover, separate models by forest and activity would require estimation of 1,680 equations $(120 \text{ forests} \times 14 \text{ activity aggregates})$, yielding a cumbersome strategic planning tool. Because the primary purpose of this study is to generate values for recreation to all the National Forests corresponding to RPA regions and activities, the multi-site pooled model is more tractable and practical for application to policy and management.

IV.B. Empirical Considerations

To apply the general theoretical framework described above, several empirical modeling issues must be addressed. These issues can be classified under two general headings. The first pertains to the type of estimator best suited for the NVUM sampling scheme, while the second pertains to variable selection and construction. Regarding the latter, we discuss the logic behind our variable selection and construction in the Application section below. Regarding the former, the type of estimator selected must be capable of mitigating the effects of four potential problems: (1) choice based sampling frame and sample weights; (2) over-dispersed non-negative count data; (3) high frequency visitors and endogenous stratification; and (4) spatial scale and aggregation. We detail our approach in addressing each of these issues below. Appendix C contains additional discussions concerning the modeling issues related to the NVUM data.

IV.B.1. Choice Based Sampling Frame and Sample Weights

The primary goal of NVUM is to accurately estimate visitation to all National Forests. This goal was achieved with a stratified on-site sampling methodology developed by English et al. 2002. The objective of the stratification was to achieve minimum variance in the estimate of visits up to the National Forest level. The sampling used a two stage method. The first sampling stage selected a stratified random sample of times and locations where recreation visitors can be counted as they exited the sites, creating a set of potential sites and times at which to survey. The survey sites were then classified by site type and use level. The site types were: day use developed sites (DUDS), overnite use developed sites (OUDS), wilderness sites (WILDERNESS), and general forest areas (GFA). The exit volume use-level strata were: low, medium, and high. Finding all the combinations of site-types and use levels then forms the total number of sampling strata. From within these strata and from across the forests to be sampled, random draws were selected from the available sampling days. For each sampling time and location, traffic counts were conducted concurrently with interviews of visitors to calibrate traffic counts to the number of unique visits. Thus, site visit estimates were obtained for each sample day, averaged by strata, and then expanded according to classical random sampling methodology (Cochran 1977).[15] Appendix B contains a further discussion of the NVUM weighting. English et al. (2002) provide detailed documentation concerning the NVUM sampling methodology.

The NVUM visit expansion weights (NVEXPAND) were developed in order to describe the characteristics of the estimate of total number of annual visits to the National Forest. These weights can be used to expand each sampled observation up to the number of visits it represents in a given stratum. Specifically, in NVUM the unit of measure is a National Forest visit, which is defined as, “one person entering and exiting a National Forest or National Grassland for recreation” (English et al. 2002). The weight, which is calculated for every individual interviewed, $i = 1 \ldots N$, is then defined as:

$$\text{NVEXPAND}_i = \left(\frac{\begin{array}{c}(\text{exiting traffic}) \times (\text{proportion last exiting}) \\ \times (\text{persons in } j^{\text{th}} \text{ vehicle})\end{array}}{(\text{number of sites visited}_i)} \right) \cdot N \qquad [3]$$

Where:

- (Exiting traffic) is the average exiting traffic count per day for the stratum;
- (Proportion last exiting) is the ratio of last exiting vehicles to total count of vehicles;
- (Persons in j^{th} vehicle) is defined as the average people per vehicle for recreating vehicles sampled in the stratum;

- (N) is defined as the number of site days in the stratum; and
- (Number of sites visited_i) is the total number of sites visited by the individual during the current NF visit.

This weight essentially replicates each observation up to the number of visits to the specific National Forest that it represents based upon the total proportion of last exiting vehicles.

The strata weights were designed to estimate visits with minimum variance. Applying these weights to other variables and in a recreation demand context may distort the distribution of data rather than create a representative sample.[16] Appendix B contains a numerical example of these choice based sample weights and some additional discussion concerning their use.

IV.B.2. On-site Count Data

Modeling on-site count data poses several challenges. As described by Shaw (1988, p. 211-212) on-site data are characterized by the following:

1. Non-negative integers: the number of visits taken to the site by the individual during a given time period is a count of non-negative integer values;
2. Truncation: only those individuals who participate in recreation and who have taken at least one visit are sampled, thus the sample is truncated at zero and contains only positive observations;
3. Endogenous Stratification: the probability of being included in the sample increases as the number of visits taken by the individual increases.

A key result of Shaw (1988) was defining endogenous stratification, or avidity bias, as being proportional to the number of visits taken. If the density function for the i^{th} person in the population is $f(y_i^* \mid X_i)$, given $y_i = y_i^*$ if $y_i^* > 0$, then the probability of being included in the sample for the i^{th} observation, given $y = t$ and $X = X^0$, is

$$\frac{yF(y)}{\sum_{y=t} f(y=t \mid x_i)} \quad [4]$$

Using this information Shaw (1988, p. 215-216, Equations 6, 9, 10-12) derives a Truncated Stratified Poisson (TSP) estimator that accounts for the non-negative count data and the avidity bias related to visit frequency. The model is given by

Let $y_i^* = X_i\beta + u_i$
Where $i = 1,...,N$
and
$y_i = y_i^*$ for
$y_i^* > 0$ [5]
Then the probability density function is given by
$$h(y \mid X_i) = \frac{\exp(-\lambda_i)\lambda_i^{y_i-1}}{(y_i-1)!}$$
With expected value $E(y_i \mid X_i) = \lambda_i + 1 = \exp(X_i\beta) + 1$
and variance $(y_i \mid X_i) = \lambda_i$

The avidity bias correction shown in Equation [4] can be applied to any family of discrete distributions.[17] The model in Equation [5] is based on a Poisson process, where the mean and variance are restricted to equality. Applications of the TSP can be found in the literature, including Ovaskainen et al. (2001). However, the TSP (or Poisson estimators in general) can yield inconsistent and inefficient parameter estimates if the mean and variance are not equal (Englin and Shonkwiler 1995; Cameron and Trivedi 1998; Greene 2000).

Recreation visit data often displays significant dispersion around the mean, i.e., the visits variable has a large variance, typically exceeding the mean. This could result from a segmented user population comprised of high frequency and low frequency visitors. This over-dispersion of visits can lead to unexplained heterogeneity and a form of heteroskedasticity in the demand model (Cameron and Trivedi 1998).

To accommodate this variance in the dependent variable, the Poisson assumption of equal mean and variance is relaxed and a parameter (α) is introduced that captures the unexplained heterogeneity. Different parameterizations of (α) can be used, but the most common is Cameron and Trivedi's NEGBINII (Cameron and Trivedi 1998, p.71, Equation 3.26). The variance function for visits can be parameterized as ($\mu + \alpha\mu^2$), and a probability density function

$$f(t \mid \mu, \alpha) = \frac{\Gamma(y+\alpha^{-1})}{\Gamma(y+1)\Gamma(\alpha^{-1})}\left(\frac{\alpha^{-1}}{\alpha^{-1}+\mu}\right)^{\alpha^{-1}}\left(\frac{\mu}{\alpha^{-1}+\mu}\right)$$

where

$\alpha \geq 0$ and $y = 0,1,2,...N$ [6]

and

Γ is the gamma function

The NEGBINII allows for over-dispersion and is frequently used outside economic applications (Gourieroux, Monfort, and Trognon 1984). Numerous variants that allow for complex modeling have been developed and appear as pre-programmed estimators in many econometric packages (Greene 2002), including truncated versions of Equation [6]. So, while this estimator improves upon the Poisson count data estimators popularized by Hellerstein (1991); and Hellerstein and Mendelsohn (1993), it does not contain an adjustment for the sampling process (endogenous stratification) as discussed above.

To overcome the inconsistency of the Poisson in the presence of over-dispersion while correcting for the non-negative integer nature of on-site data, Englin and Shonkwiler (1995) use Shaw's (1988) result presented in Equation [4] to derive a model that corrects for the non-negative integer nature of the data, the avidity bias from on-site sampling, and the tendency for recreation data to be over-dispersed. Using Shaw's (1988) results and Cameron and Trivedi's (1998) NEGBINII, they derive the following Truncated Stratified Negative Binomial (TSNB) estimator where,

$$f(t \mid \lambda, \alpha) = \frac{\Gamma(y + \frac{1}{\alpha})(\alpha)^y (\lambda)^y (1 + \alpha\lambda)^{-(y + \frac{1}{\alpha})}}{1 - (1 + \alpha\lambda)^{-\frac{1}{\alpha}} \Gamma(y + 1)\Gamma(\frac{1}{\alpha})} \quad [7]$$

The TSNB has not been incorporated as an estimator in any current econometric packages, and only a few applications of it can be found in the literature. Applications of the estimator can be found in Ovaskainen et al. (2001); Englin and Shonkwiler (1995); and Curtis (2002). For a discussion of some of the econometric issues related to count data models, readers are referred to: Cameron and Trivedi (1986); Shaw (1988); Cameron and Trivedi (1998); Gourieroux (2000); Englin and Shonkwiler (1995); Gourieroux, Monfort, and Trognon (1984); Grogger and Carson (1991); Ovaskainen et al. (2001); Ozuna and Gomez (1995); Waldman (2000); and Winklemann and Zimmerman (1995).

IV.B.3. Spatial Scale and Aggregation

The NVUM data were collected from more than 7,500 sites across 120 aggregated forest units. Each observation was collected from a single site. Individuals were asked to report the number of visits taken to the NF in which the site was located during the previous 12 months. Thus, the individual observations are aggregated up to the forest level and each forest then represents a 'site'. There are 120 forest units, or 'sites', that occur within 8 Forest Service regions, omitting Puerto Rico and Alaska.[18] Additionally, there are 29 different reported primary activities across all forests, which we aggregate into 14 activities because most individual forests typically have only a few observations for many of the activities. The nature of the data necessitates aggregation in order to avoid a proliferation of models and generating samples with too few observations. Table 1 provides a detailed description of the activities and the aggregated activities.

IV.B.4. High Frequency Visitors, Over-Dispersion, and Endogenous Stratification

The estimators developed by Shaw (1988) and Englin and Shonkwiler (1995) correct for the non-random sampling created by using on-site surveys, for the discrete nature of recreation demand data, and for the unobserved heterogeneity often observed in recreation data. The consensus in the TCM literature has been the need for an estimator that uses a count data generating process combined with an adjustment for the on-site nature of the data.

Shaw (1988) observed that the probability of being included in the sample is proportional to the number of visits taken, thus the TSP essentially weights the observation by the number of visits. By applying this insight to the NVUM choice based sampling scheme, we can generate the following weight that brings each NVUM observation up to its representative value and accounts for the endogenous stratification. Thus, the choice-based sample weight for NVUM can be defined as

$$
\begin{aligned}
&NVY_i = \left(\frac{NVEXPAND_i}{NFV12MO1_i} \right) \\
&\qquad\qquad \text{where} \\
&NVEXPAND_i = \text{expansion weight for } i \\
&NFV12MO1_i = \text{number of annual visits for } i
\end{aligned}
\qquad [8]
$$

Dividing NVEXPAND by NFV12MO1 adjusts the observation by the probability of being included in the sample, which is proportional to the number of visits taken. This provides a correction for the endogenous stratification, or avidity bias, found in choice based recreation samples. For example, if observation 1 has an NVEXPAND weight of 903.03 and annual visits of 5, then $NVY_1 = {}^{903.03}\!/_{5} = 180.606$. If observation 2 has an NVEXPAND weight of 301.01 and visits 40 times, then $NVY_2 = {}^{301.01}\!/_{40} = 4.5752$.

The avidity bias is also related to the unobserved heterogeneity in the count of visits. High frequency visitors take numerous short visits during the year, and these visits typically involve lower costs as these individuals tend to live close to the site and incur lower visit costs. Combining these observations with recreationists who take a few planned visits where large recreation costs are incurred is problematic and leads to the observed over-dispersion in the visits variable. The differences in these individuals are not captured in the data, and thus while we can identify the source of the over-dispersion (high-frequency, local visitors); the selection mechanism by which high-frequency and low-frequency visitors are determined is still unobserved.[19] Thus, the data contains unobserved heterogeneity in the dependent variable. To accommodate this over-dispersion, the choice based sampling frame, and the non-negative count nature of the data, we use a Truncated Negative Binomial (TNB) estimator weighted by NVY. The form of the estimator we use is given by

$$prob(Y = y \mid Y > 0) = \left[\Gamma\left(\frac{y+1}{\alpha}\right) \Big/ \Gamma(y+1)\Gamma\left(\frac{1}{\alpha}\right) \right] (\alpha\lambda)^{y} (1+\alpha\lambda)^{-\left(y+\frac{1}{\alpha}\right)} \left[1 - F_{NB}(0)\right]^{-1}$$

with conditional mean

[9]

$$\text{E(Y|X, Y>0)}=\lambda[1\text{-F}_{\text{NB}}(0)]^{-1} = \left(\frac{e^{\lambda}}{1-e^{-\lambda}}\right)$$

where λ is paramterized as $e^{X'\beta}$

Equation[9] is weighted by NVY during the estimation procedure. The NVY weight adjusts the observation so that it is representative of the target population, thereby correcting for the avidity bias and the stratified random sampling frame. This TNB estimator accounts for the truncation and over-dispersion in the dependent variable. Thus, this estimator addresses the key data issues related to the NVUM sampling process.

IV.C. Empirical Estimation

We use the general demand function presented in Equation[2] and the estimator as described by Equation[9] to specify an empirical TCM demand model as follows:

$$\text{Visits}_r = \text{R}\begin{pmatrix} \text{ONE}, \text{TC}_{r,m}, \text{TC}_{r,m} \cdot \text{ACT}^i_{r,k}, \text{ACT}^i_{r,k}, \text{PEOPVEH}_r, \\ \text{HF}_r, \text{ONITE}_r, \text{INCES}_r, \text{GENDER1}_r, \text{AGE}_r \end{pmatrix} \qquad [10]$$

Where:

- $r = 0...4$ the National pooled model and each of the 4 RPA regions;
- $m = 1...3$ for the three travel cost variants;
- And $k = 1...14$ for the aggregated activities.

The dependent variable in Equation[10] is the number of annual recreation visits to a National Forest per individual/group; this corresponds to the (Y) in Equation[9]. Demand for visits is a function of: own price (TC_m), travel cost-activity interaction terms ($\text{TC}_m \cdot \text{ACT}^i_k$) for each of the 14 RPA activity groupings, primary activity indicator ACT^i_k, number of people in the vehicle (PEOPVEH), annual income (INCES), gender (GENDER1), age (AGE), and an indicator for staying overnight (ONITE). An additional term has been incorporated to capture the differences between high and low frequency users (HF), where HF=1 if number of annual visits was greater than 15, else zero. The activity variables and price interaction terms are included to generate demand estimates for different activities and are designed to capture any differences in demand resulting from the different primary activity type. This structure allows us to estimate WTPA nationally and regionally by activity aggregates. Overall, we develop 30 models (3 travel cost constructions for the national model, and 3 travel cost constructions for each of the 4 RPA regions, by the ALL and TOP5 datasets). The regression results are presented in Tables 8 and 9. Below we expand on our travel cost constructions, including a discussion of the opportunity cost of time, and our treatment of substitutes.

The distance used in the travel cost variable (TC_m) was calculated using the respondent's Zip Code and the latitude and longitude for the *site* or *forest centroid* where they were surveyed.[20] The three travel cost variables were constructed as

$$
\begin{aligned}
TCH &= 2\left(.12 \cdot PRACTD1S\right) + RECFEES \\
TCWH &= 2\left(.12 \cdot PRACTD1S\right) + 2\left[.33\left(\frac{INCE}{2000}\right) \cdot PRACTIME\right] + RECFEES \\
TCFWH &= 2\left(.12 \cdot PRACTD1S\right) + 2\left[5.75 \cdot PRACTIME\right] + RECFEES
\end{aligned}
\qquad [11]
$$

Where PRACTD1S is the one-way distance described above, and RECFEES are the self-reported *on-site* recreation fees. A per mile cost of \$0.12 was used. This is the current (2004) value listed in AAA travel services and by the IRS for charity and personal vehicle use.[21] It is important to include an estimate for the opportunity cost of recreation time in the demand model since the use of travel cost as a shadow price of recreation is predicated upon the assumption of weak complementarity between time on-site and visits to the site (Freeman 1999). Additionally, using the household production approach that incorporates a time budget into the constraint implies a trade off between hours spent earning income and hours spent in leisure, including recreation. This trade off implies that the opportunity cost of time is the income foregone during time spent recreating (Bockstael, Strand, and Hanemann 1987).

There is no general consensus in the literature about treatment of time cost. Standard practice is to assume individuals can freely trade labor and leisure at the margin and that the opportunity cost of time is a fraction of the hourly income earned by the individual. We use two different methods to incorporate an opportunity cost of time in the travel cost variable. One variant uses 1/3 of the 'wage' rate, where the individual wage rate was calculated as the annual income (INCE) proxy divided by 2,000 hours. The second variant used the federal minimum wage of $5.25/hour as a proxy for the opportunity cost of time. Phaneuf and Smith (2004) note that many studies that have estimated an opportunity cost of time have found it to be roughly 1/3 the wage rate, which is often the standard estimate used in the TCM literature (the range is usually 0.25 to 0.50). Given that the total average private hourly wage rate in the U.S. for August 2004 was $15.77, our use of $5.25 is roughly 1/3 the average U.S. wage rate.[22]

Bowker and Leeworthy (1998) found that approximately 85% of their sample indicated that wages were not given up for their recreational visit to the Florida Keys. Similarly, Leeworthy (personal communication 2005) noted that in an ongoing study of marine fishing in Southern California, 92% percent of respondents indicated that they could not trade work time for leisure time. The Bowker and Leeworthy (1998) result indicates that including the opportunity cost of time in a travel cost model when information regarding the labor-leisure trade is unavailable may over-estimate the cost of the visit. Given the different methods present in the literature, we present results with these three constructions of travel cost to provide a range of values that incorporate different assumptions about the opportunity cost of time. Other recent papers regarding the opportunity cost of time include: Alvarez-Farizo, Hanley, and Barberan (2001); Casey, Vukina, and Danielson (1995); Common, Bull, and Stoeckl (1999); and Larson (1993); Shaw and Feather (1999).

Related to the issue of valuing the opportunity cost of time is the issue of time spent on-site. The travel cost model assumes the length of time spent on-site for each visit and by each individual is equal and that the good being valued is a recreation unit defined for a fixed measure of time, i.e., a recreation visitor day, an 8-hour recreation day, or a 4-hour recreation day (McConnell 1992; Freeman 1999; Rosenberger and Loomis 2001). This is assumed in order to avoid the issue of endogenous on-site time. If time on-site is not fixed but chosen as the number of visits are chosen, then time on-site cannot be included as a covariate and must be jointly determined with the visit frequency choice. Different treatments have been used to model time on-site. Some models use the fixed length visit specification; and other models assume it to be exogenous and include it as a covariate; others analyze total time spent on-site instead of number of visits (Bell and Leeworthy 1990); and yet other models estimate it separately in a two-stage estimation procedure (McConnell 1992). Other papers examining this and related issues are Berman and Hong (1999); Fix, Loomis, and Eichhorn (2000); Kerkvliet and Nowell (1999); and Smith and Kopp (1980).

Among the observations in the NVUM raw data set, time on-site ranges from 0.020 hours to more than 1,584 hours per National Forest visit, with a mean of 27.9 hours spent on-site. Thus, assuming equal visit lengths across the sample is not supported by the data. There are several approaches to modeling time on-site using NVUM. The first approach is to use it as a covariate and assume it to be exogenous to the choice of visits, and a second approach is to assume it is endogenous and use a two-stage or FIML estimation method (McConnell 1992). A third approach would be to segment the data into equal-visit lengths and estimate separate models for each segment.[23] We assume time on-site is exogenous and include a proxy (ONITE=1 if the individual stayed overnight, else=0) for time spent on the National Forest. The dummy variable ONITE differentiates the visitors into those who take day visits and those who stay longer.

As discussed above, demand for a good or service is theoretically considered to be a function of own price, prices of substitutes, income, and other variables related to tastes and preferences. In the case of recreation demand, defining substitutes is difficult because the choice of a substitute is known only to the individual and may include a different site within the same forest, a different forest, a non-forest area for the same activity, a different activity altogether, or the individual may choose not to participate at all if the 'price' of the current site/activity changed.[24] The analyst must therefore adopt a heuristic rule that captures some substitution behavior, albeit imperfectly. Excluding substitute prices from the demand equation is likely to cause the estimated demand to be more inelastic than the true demand relationship, and imply a higher willingness to pay for access; however, the effect of the collinearity between own-price and substitute prices is to reduce the precision of the estimated price coefficients which makes hypothesis testing more difficult (Haab and McConnell 2002, p. 173). Additional discussions regarding the effects of omitting substitute prices can be found in Kling (1989) and Rosenthal (1987). Caulkins, Bishop, and Bouwes (1986) provide examples of incorporating substitution effects into recreation demand models.

Because the main NVUM modules did not collect any information on substitute sites or substitute behavior, we developed a substitute price proxy based on the heuristic rule that the nearest National Forest to their Zip Code of origin that they did not visit would be the most likely alternative recreation destination. We attempted to estimate models based on this substitute price variable; however the own-price and substitute-price variable had a correlation factor greater than 0.95. Additionally, in the models where the substitute variable was included, it was not significant at the 0.10 or better level and did not have the expected sign. Given that our only available substitute price and own-price are correlated at the 0.95 level we opted to omit substitute price and acknowledge the potential bias in the estimated coefficient in order to gain increased reliability in the estimated parameters.

IV.D. Net Economic Value Measures

Using the estimated models described by Equation[9] and Equation[10], we can estimate the per visit per individual and the per activity day per individual net economic (WTPA) value for National Forest recreation. We provide WTPA estimates for each of the 15 model specifications. In addition, we examine the effect on estimated WTPA of removing observations where the one-way travel distance was greater than 1,250 miles (the top 5% of PRACTD1S).

As discussed in detail previously, we seek to calculate the value of access to the site as the net willingness to pay to visit the site (WTPA). This is calculated as the area under the utility and income constant demand curve for the site, where the area under the demand curve provides an estimate of willingness to pay for access to the site (Haab and McConnell 2002, p. 159). In general terms we calculate

$$WTPA = \int_{C_i^0}^{C^*} f(P_R, M, T, H)\,dp \qquad [12]$$

Where $C_i^0 = TC$, the cost of visiting the site, and C^* is the relevant choke price at which demand goes to zero (Haab and McConnell 2002, p. 159). Under an exponential distribution the relevant choke price is infinite. As given in Haab and McConnell (2002, p.167), for any finite travel cost, the seasonal or annual, WTPA can be defined as

$$WTPA = \int_{C^0}^{\infty} e^{\beta_0 + \beta_{TC} \cdot C} dC = \left[\frac{e^{\beta_0 + \beta_{TC} \cdot C}}{\beta_{TC}} \right]_{C=C^0}^{C \to \infty} = -\frac{\lambda}{\beta_{TC}} \qquad [13]$$

For the per visit WTPA we divide the result of Equation[13] by λ, the predicted number of trips, which simplifies to

$$WTPA = -\frac{1}{\beta_{TC}} \qquad [14]$$

Equation[14] is the essential per visit consumer surplus calculation under an exponential distribution. We calculate the following for each of the five spatial scales and ($k = 1 \ldots 14$) activities. This results in the following calculation for each individual i,

$$CS_k^i = \left(\frac{-1}{\left(TC + TC \cdot ACT \right)} \right) \Big/ PEOPVEH_i \qquad [15]$$

After calculating the individual values we adjust the results to incorporate the sampling structure of NVUM. To do this we calculate the following weighted consumer surplus CS_k^w,

$$CS_k^w = \left(\frac{\sum_{i=1}^{N} CS_k^i \cdot NVEXPAND_i}{\sum_{i=1}^{N+D} NVEXPAND_i} \right) \qquad [16]$$

The term in the denominator is the sum of the expansion weights for the given region, including the non-primary purpose and foreign visitors (N+D). The numerator is the sum of the consumer surplus values times its expansion weight, and summed over the sample (for the region-activity combination, excluding non-primary and foreign visitors whose net economic value is conservatively assumed to be zero[25]. This method allows us to derive the average WTPA per individual accounting for the stratified on-site sampling methodology of NVUM. Using the same methods as described in Equations [15] and [16] we adjust the WTPA values for the average days per visit for each activity. The activity days are based on the average time on-site for each activity and are counted in day integers

V. RESULTS

As discussed above, we used a weighted truncated negative binomial travel cost model to describe recreation demand to National Forests and to calculate the net economic value or WTPA associated with recreation access. Our demand models are estimated at the national level and for each of the four RPA regions and for each of fourteen primary activities, using three different travel cost constructions on the ALL and TOP5 datasets. The parameter estimates for the demand models are reported in Tables 8 and 9, respectively.[26] The total numbers of observations for each of these estimated models for the ALL dataset are: 68,669 for the National; 24,202 for Region 1 (Pacific); 31,209 for Region 2 (Rocky Mountain); 7,058 for Region 3 (Northern); and 6,187 observations for Region 4 (Southern). For the TOP5 dataset the total numbers of observations are: 64,894 for the National; 22,968 for Region 1 (Pacific); 28,860 for Region 2 (Rocky Mountain); 6,939 for Region 3 (Northern); and 6,126 observations for Region 4 (Southern). All the models reach stable convergence values, and the likelihood ratio indices, or pseudo r-squares, range from 0.126 to 0.158.

The number of predicted visits per individual is stable across the different travel cost constructions (no opportunity cost of time, 1/3 of the wage rate, and a minimum wage of $5.25 opportunity cost of time value). The overall predicted mean visits for the ALL data vary between the national and regional samples; ranging from 1.9 per year for Region 1 (Pacific), to 3.7 per year for Region 3 (Northern), and 2.3 visits per year for the pooled National; for the TOP5 sample average predicted visits vary from 2.4 per year for Region 1 (Pacific) to 3.7 for Region 4 (Southern), and 2.7 for the national pooled sample. It should be noted that these average predicted trip values include both the high-frequency and low-frequency visitors.

In all of the models, the estimated coefficient on travel cost is negative and significant at the 0.01 or better significance level, with estimated coefficients ranging from -0.007 to -0.013 for the ALL data, and -0.002 to -0.010 for the TOP5 data. In most of the models ONITE is negative, indicating that overnight visitors to National Forests are likely to make fewer visits annually. The number of persons traveling in the vehicle (PEOPVEH) is negative and significant at the 0.10 level in all but Region 4 (Southern) across all the travel cost variants and across both data sets, so that as the number of people traveling in the group increases the number of annual visits on average decreases.

Results for the constructed income proxy, (INCES) are mixed. Income is negative in the specifications with either no opportunity cost of time or a flat $5.25 per hour, but positive where travel cost includes an income based opportunity cost of time specification. The income proxy is significant at the 0.10 level in 25 of the 30 models. If recreational access to the National Forest is a normal good then we would expect income to be positive, as increasing income corresponds to an increasing number of recreational visits. The positive sign on the income variable when using the 1/3 wage rate is consistent with the normal good assumption and supports the use of the income-based opportunity cost of time construction. However, it is possible that certain activities may have a negative income effect as increasing incomes may decrease the tendency to take recreational visits to the forest. It is important to remember, however, that NVUM did not collect information on income or the opportunity cost of time and it may be difficult to extrapolate our results to general findings on the opportunity cost of time in travel cost studies. Moreover, in numerous published travel cost studies, income is often found to be statistically insignificant.

Being female (GENDER1) is negative and significant at the 0.01 level for most of the models (except for Region 3, Northern) where it is insignificant across all travel cost specifications); this indicates that, with the exception of the Northern region, females typically take fewer annual visits to the National Forests. Age (AGE) is positive and significant at the 0.10 or better level in 27 of the models indicating older people make more visits to the NFs. However, it should be reiterated that the age variable is for the respondent, and only those over 16 are interviewed.

The binary variable (HF) for high-frequency visitors (those who take more than 15 visits per year) is statistically significant at the 0.01 or better level and the estimated coefficient ranges from 2.789 to 3.174. Results suggest the HF binary variable helps to capture the unspecified heterogeneity present in the count of visits related to the two groups of users, and allows the models to converge more readily. When HF is removed from the models the (α) parameter becomes very large (some models had (α) values of more than 2,000), the models fail to converge, and the consumer surplus values are outside the range of range of values reported within the relevant body of literature, as the estimated coefficient is attenuated to near zero. In conjunction with the HF variable, the estimated coefficient on the over-dispersion parameter (α) for the truncated negative binomial model is significant at the .01 level or better in all 30 of the models and ranges from 1.210 to 2.409 for the ALL data, and 1.126 to 1.823 for the TOP5 sample. These results indicate strongly that the variance and mean of visits are unequal and that the truncated negative binomial estimator is statistically superior to the truncated Poisson in the current study.

The estimated travel cost coefficient (TC) is negative and significant at the 0.01 or better level across all 30 models suggesting an inverse relationship between travel cost and the number of recreation visits. In this study, hiking was selected as the base case activity for our estimates because it is the most frequently reported main activity. The estimated travel cost coefficient combined with equations [15] and [16] above, generates base case (hiking) WTPA values which range from $58.01 in Region 4 (Southern) to a high of $215.83 for Region 3 (Northern) for the ALL dataset; and from $34.45 for Region 1 (Pacific) to $121.96 per person per visit for the TOP5 dataset. The base case WTPAs, appropriately indexed for units and inflation (2004 U.S. dollars per visit per person, or per person per activity day), are within the range of values in the literature for forest recreation (Rosenberger and Loomis 2001). The base case (hiking) values can be found at the bottom of Tables 8 and 9 and also include the own-price elasticity measures for the base case (hiking).

The base case (hiking) elasticity for Region 3 (Northern) using the income-based wage rate for opportunity cost was -0.313296 (ALL data); Region 4 (Southern) had a base elasticity of -0.674462 using a flat wage (ALL data); Region 3 (Northern) had an elasticity of -0.507108 using no opportunity cost (TOP5 data); and Region 1 (Pacific) had an estimated elasticity of -0.750633 using the flat wage (TOP5 data). This indicates that recreational access is relatively price inelastic suggesting that increasing the cost of recreational access will have a much less than proportional effect on the number of base case visits to National Forests. For example, using the -0.313296 elasticity estimate above, a $10 increase to an average travel cost of $100 would result in a 3-percent decrease in hiking visits for Region 3.

Tables 8 and 9 report the regression results and provide the base case WTPA and elasticity measures. Overall, our modeling results are consistent with a priori expectations, economic theory, and previous recreation demand studies. Across all 30 models the estimated coefficient on the travel cost variable is significant at the 0.01 level and has the expected negative sign. Thus, in all 30 of our models price and quantity are inversely related, and we find the primary demand relationship predicted by theory is robust to a large variety of modeling specifications. The socio-demographic characteristics of gender (GENDER1) and age (AGE) are generally consistent with prior expectations based on previous studies.

The estimated coefficient on the income proxy (INCES) indicates that as income increases the number of visits per individual on average declines. This may indicate that as income rises there is less leisure time available for forest recreation, and that individuals in our sample do trade labor (wages) for leisure (forest recreation) as postulated by recreation demand theory. It is interesting to note that in the models using the income-based opportunity cost of time construction, the estimated coefficient on income becomes positive. It could be that using the income variable in the construction of the travel cost variable and including income as a variable in the vector of regressors creates collinearity problems, however other studies use this construction and we therefore include it in our set of results.

Consistent with previous literature, the models that include opportunity cost of time in the travel cost have higher consumer surplus values. We present the three different constructions to allow users of these values to determine the cost construction most appropriate for the policy/research setting of interest.

The effect of trimming the largest 5% of distance values (one-way distances greater than 1,250 miles) was surprisingly large. While we trimmed only 3,775 observations, the consumer surplus (WTPA) for the base case (hiking) where no opportunity cost of time is included for the National model drops from $111.48 for the untrimmed (ALL) data to only $55.28 for the trimmed (TOP5) data. Thus, trimming 5% of the distance values reduces the WTPA per visit by $56.20 (about 50 percent). This indicates that a small portion of the visitors who take few trips and travel great distances significantly influence the average WTPA values. This finding is consistent with others in the literature who examined recreation demand for sites with regional or national market areas. Hence, it is important to examine the sensitivity of the WTPA estimates to changes in the underlying distance distribution of visitors. Nevertheless, because the researcher can never know whether the given visit is truly single purpose, decisions to identify and exclude potential outliers will remain somewhat arbitrary and subject to professional judgment

One of the main goals of using NVUM data for assessing the value forest recreation was to attempt to estimate region-activity specific values. Using the travel cost varying parameter models and methods described in the previous sections we calculate a total of 840 region-activity based WTPA values and 420 own-price elasticity measures. The fourteen activities we examine are: camping (CAMP), scenic driving (DRIVE), fishing (FISH), general recreation (GEN), hiking (HIKE), hunting (HUNT), nature viewing (NAT), off-highway vehicle use (OHV), primitive camping and backpacking (PCAMP), picnicking (PICNIC), cross country and downhill skiing (SKI), snowmobile use (SNOWMB), trail use (TRAIL), and scenic viewing (VIEW). A complete description of activities and their aggregation can be found in Table 1.

For each of the five spatial scales (National, Pacific, Rocky Mountain, Northern, and Southern) we calculate the per person per visit consumer surplus and the per person per activity day consumer surplus measure across each of the three travel cost constructions (no opportunity cost, income based opportunity cost, and flat wage based opportunity costs) for each of the two datasets (ALL, and TOP5) for each of the fourteen activities. Table 10 presents the per person per visit and per person per activity day WTPA values for the untrimmed (ALL) data, and Table 11 provides the values for the trimmed (TOP5) data.

At the national scale using the untrimmed data, per person per visit values for camping (CAMP) were estimated across the three travel cost constructions at: $52.13 (no opportunity cost of time included); $75.85 (one-third income based wage opportunity cost of time); and $85.89 ($5.25 flat wage rate opportunity cost of time). The same camping (CAMP) values for the trimmed (TOP5) data are: $24.98, $40.02, and $40.45 respectively. Thus, the influence of different assumptions regarding the opportunity cost of time and the treatment of outliers on WTPA estimates is apparent. While the literature has no clear consensus regarding the best method for valuing the opportunity cost of time, theory suggests a positive rate at which individuals trade labor for leisure and thus suggests a measure of opportunity cost of time should be included in the demand model. The models that do not include an opportunity cost of time represent a lower-bound value and the flat wage based values provide upper bound values. The effect of long-distance travelers (those whose one-way distance from the forest is in the top 5% of the travel distance distribution) on per person per visit WTPA values are marked. The values for camping drop from $52.13 to $24.98, a reduction of 47.9%. As discussed above we believe those long-distance travelers may be outliers within the context of estimating average WTPA values because it is highly likely that their trip includes multiple sites and/or multiple purposes.

We also examine the effect of the spatial scale on the WTPA values. Continuing with camping (CAMP) values, the per person per visit estimates for the TOP5 data and a no opportunity cost of time assumption are: $24.98 (National); $25.25 Region 1(Pacific); $21.44 Region 2 (Rocky Mountain); and $58.67 Region 3 (Northern). We find the Northern U.S. to have the highest estimated values for camping, while the Pacific region has the lowest per person per visit WTPA values.

Off-highway vehicle use has become increasingly controversial on public lands as conflicts between different forest users become more frequent. We estimate the per person per visit value of off-highway use (OHV) activity under the no opportunity cost of time assumption for the TOP5 data at: $58.86 (National); $41.62 Region 1 (Pacific); and $71.57 Region 2 (Rocky Mountain). We note that the Rocky Mountain region has the highest OHV values while the Pacific has the lowest values. The forests of the Rocky Mountain region (including forests in Wyoming, New Mexico, Arizona, and Montana) tend to have large numbers of OHV users and substantial areas of land available for OHV use. Our WTPA estimates reflect these regional forest differences.

If we examine the Rocky Mountain region and look across the different activities we see the highest value per person per visit WTPA (for the TOP5 data with no opportunity cost of time) is for non-motorized trail use (TRAIL) at $143.35. TRAIL use includes biking, horseback riding, and non-motorized water uses such as canoeing. The lowest per visit values for the Rocky Mountain are for $21.35 for general recreation (GEN). General recreation includes hanging out, swimming, and non-specific forest recreation. Overall, we see that per person per visit values vary significantly by region and by activity as well as vary by activity within and between regions. These differences in WTPA values reflect the differing quantity, quality, and accessibility of recreation resources across the NF system, as well as the regional and activity specific differences in demand for recreation.

Previous RPA recreation valuation efforts have focused on the per person per activity day WTPA values, and our analysis includes 420 such values. These values take the estimated consumer surplus values and adjust them for the amount of time spent on-site for an average visit of the specified activity. These activity day calculations then allow our estimates to be compared with the Rosenberger and Loomis (2001) meta-analysis values. If we examine the camping (CAMP) values for the TOP5 data on the models that do not include any opportunity cost of time, for the National model, we estimate the per person per activity values of $10.37. This compares with the Rosenberger and Loomis (2001, Table 1 p.4) mean value of $30.36 per activity day per person. Rosenberger and Loomis (2001, Table 3, p.13) report an average per person per activity day value of $25.87 ($28.38 in 2004 dollars) for the Rocky Mountain (Intermountain) region compared with our value of $21.44 (2004 dollars) with no opportunity cost of time (TOP5 data) or $34.56 per person per activity day for the 1/3 income based wage rate opportunity cost of time WTPA value. For hunting (HUNT) use, we estimate $29.08 (no opportunity cost) and $42.90 (income based opportunity cost) for the Rocky Mountain region (TOP5) data, compared with the Rosenberger and Loomis (2001, Table 3, p. 13) mean value of $43.56 ($47.78 in 2004 dollars).

In addition to the two types of WTPA values (per visit and per activity day) we also present the own-price elasticity measures for the region-activity combinations. These values appear in Table 10 for the untrimmed (ALL) values, and in Table 11 for the trimmed (TOP5) estimates. Examining the trimmed (TOP5) National estimates (no opportunity cost of time) we estimate the activity specific own-price elasticities as: -0.6045 (CAMP), -0.6039 (DRIVE), -0.4699 (FISH), -0.6228 (GEN), -0.5976 (HIKE), -0.6306 (HUNT), -0.8688 (NAT), -0.6292 (OHV), -0.5824 (PCAMP), -0.4373 (PICNIC), -0.6156 (SKI), -0.6067 (SNOWMOB), -0.3489 (TRAIL), and -0.8175 (VIEW). These estimates indicate that NF recreation has relatively inelastic demand, with non-motorized trail use (TRAIL) having the most inelastic demand (visits taken changes the least as the price of visiting increases) and nature viewing (NAT) has the most elastic demand (visits taken decreases the most as the price of visiting increases). For trail use (TRAIL) if the cost of visiting increases by 10% the number of visits taken annually will decrease by 3.489%, and for nature viewing (NAT) if prices rise by 10% visits will decrease by 8.688%.

Comparing the National estimates to the Rocky Mountain region we find that TRAIL has an elasticity of -0.4160 (versus -0.3489 for the National); and NAT has an elasticity of -0.8844 (versus -0.8688 for the National). Thus, for the Rocky Mountain region demand for trail use on National Forests is more elastic (more responsive to price) than the National model, while nature viewing has a very similar price response between the two spatial scales. It is important to remember that all the values and elasticities reported herein are only for recreation that occurs on National Forests, whereas other comparative values (e.g., the Rosenberger and Loomis, 2001) meta-analysis) include a much broader base of areas and whose values may diverge from FS-only values.

In addition to the WTPA values presented in Tables 10 and 11, we provide 90% confidence intervals around the point CS estimates in Table 12 (for the untrimmed ALL data) and Table 13 (the trimmed TOP5 data) using the method of differentials (Kmenta, p. 444). The CS values presented in Tables 10 and 11 will vary from the values presented in Tables 12 and 13 due to the different methods used to calculate the point-estimate interval versus the mean of the expected individual CS values. In Table 13 for the National model, the per person per visit value for CAMP (no opportunity cost of time) was \$36.55 with a 90% confidence interval lower bound value of \$35.12 and an upper bound of \$37.98. For the Rocky Mountain region the per person per visit value was \$42.54 with a lower bound of \$40.04 and an upper bound of \$45.03. The per person per visit value for CAMP (Rocky Mountain, ALL data) when the opportunity cost of time was valued at one-third the income based wage was \$78.99 with a lower bound of \$74.23 and an upper bound \$83.75.[27]

In Table 14 and Table 15 we provide additional information regarding the WTPA values presented in Table 10 and Table 11. In the WTPA tables we replace any region-activity value where the estimated coefficient on the travel cost activity interaction term was not statistically significant at the 0.10 or better level with the base case (HIKE) for that region. In such cases, the estimates would not be statistically different. For the trimmed (TOP5) data, 18.1% of the region-activity models were not statistically significant at the 0.10 or better level. Additionally, if the estimated travel cost activity interaction term was significant but the WTPA value was less than $1.00 or greater than $500.00 the value was replaced with the base case for that region. For the TOP5 data 9 of the 210 models (4.29%) were less than $1.00, while no values were negative. Additionally, only three values in this set were greater than $500 (1.43%). Table 14 provides the 'raw' values for the untrimmed (ALL) data and Table 15 for the trimmed (TOP5) data and a series of codes that indicate the significance of the estimated coefficient on the travel cost activity interaction term and if it fell within the bounds considered reasonable for these types of recreation values as based upon the literature.

In general, we find significant variation across the spatial scales (regions) and the activities, indicating that demand for National Forest recreation varies among different activities and different regions, both within and among the sets of strata. Additionally, the method of travel cost construction and the treatment of outliers significantly affects the estimated WTPA values. Our estimated price elasticities confirm the significant variation in the different region-activity segments, and our confidence intervals suggest that for most of our results, the range of estimates falls within the bounds of previous studies and within the values found in the Rosenberger and Loomis (2001) meta-analysis.

VI. CONCLUSIONS

The primary focus of this study is to assess the net economic value (NEV) of recreation on National Forests using the National Visitor Use Monitoring data (NVUM). This study explores the suitability of NVUM data for the generation of willingness to pay for access values on the National Forests. Using this unique dataset we develop a series of models that allow us to estimate willingness to pay for access (WTPA) values for five different spatial scales and fourteen different primary activities. The data contain some unique features not present in other datasets including the large scale, the diversity of sampled sites, and the careful year-long scientifically based sampling frame with resulting sampling weights. A key element not heretofore attempted in previous FS recreation valuation studies is using the same National Forest visitation dataset to generate WTPA measures for recreation visits solely to National Forests.

Examining our WTPA results, we see differences across regions as well as across activities. Our results support the hypothesis that different regions of the U.S., with their different climates, natural amenities, tastes and preferences, and perhaps availability of substitutes, have different values for recreation access to National Forests. Additionally, our analysis indicates different activities have significantly different WTPA estimates.

Using a truncated negative binomial estimator weighted by a compound weight that adjusts for the sampling frame and for endogenous stratification we estimate a series of net economic values (average consumer surplus per person per activity and per person per activity day) for five different spatial scales (National, Pacific, Rocky Mountain, Northern, Southern) for each of fourteen activity groupings. We present each set of region-activity models for three different travel constructions and two different sets of data – one that includes all available observations (ALL) and one where the top 5% of one-way distance values (TOP5) have been removed from the estimating sample. This results in a total of 30 models and 840 consumer surplus values and 420 own-price elasticity estimates.

This research contributes a comprehensive analysis of forest recreation valuation using NVUM data and contributes a large set of net economic values and price elasticity estimates using the current best-practice approach to modeling and estimation. The choices made during the data construction, model development, and estimation emphasized conservative choices and methods that would best represent aggregate forest recreation values for the regions and activities for which we were deriving values. In many cases we explicitly chose lower-bound values or methods. Thus, we feel our estimates represent a conservative set of recreation values. Both the net economic value and price elasticity estimates are useful for National Forest policy and planning at the national, regional and National Forest levels. However, given the nature of the sample, and modeling assumptions, the results should be interpreted as being representative of the given spatial scale (national or region) and activity combination; not for a particular activity on a particular national forest.

Some of the more significant limitations of the NVUM data and the methods used to estimate net economic value and price elasticity estimates should be noted. For use in recreation demand modeling, the most significant limitations of the NVUM data were: (1) the lack of information on household/individual income; (2) individual site-characteristics; (3) the lack of substitute behavior information (if the individual chose not to go to the site where they were surveyed what would they have done or where would they have gone); and (4) the aggregation up to the forest-level visit. These limitations: (1) required us to use an IRS Zip Code based income level for the individual; (2) precluded any modeling that would include using site-characteristics to explain variation in visits; (3) introduced potential bias in the WTPA values by excluding any substitution behavior; and (4) meant we had to assume that the visit on which the individual was surveyed is typical of all visits taken by the individual to that NF, implying that the group size and activity would be the same for all reported visits (it should be noted, however, that this is a common assumption in ITCM). Other modeling/data limitations included: (1) the pooling of the eight available FS regions (Alaska, Region 10 is excluded) into four RPA macro-regions to ensure enough density of observations and to simplify the output; (2) forests in some states (e.g., North Carolina, Florida, Nebraska, and others) were pooled so that all National Forests and National Grasslands in that state were combined into an aggregate forest that covered that entire state; and (3) the aggregation of activities in order to increase the number of observations of each activity type, e.g., TRAIL was the aggregation of bicycling, horseback riding, and canoeing.

The sensitivity of the results to the treatment of potential outliers is important to note, but not unusual in empirical research, e.g., the rejection of individuals who traveled more than 1,250 miles each way and visited more than 52 times in a year reduced many of the estimated WTPA by nearly 48%. While NUVM provides a large sample size and broad-based view of National Forest recreation, the restrictions described above did limit our ability to utilize models that require better income, site-characteristics, or substitute behavior information.

In summary, the current generation of NVUM data provides a rich and unique set of information regarding National Forest recreation and visitation. Future years of NVUM and future recreation demand estimation could be improved by collecting information on household/individual incomes, substitute behavior, and information on site characteristics. Additionally, future research into better methods for handling the diverse nature of visitors and econometric methods to handle the structural nature of recreation data will further improve and refine the estimates of the value of recreation.

APPENDIX A: DETAILED DATA DESCRIPTION

The NVUM Recreation Demand data set was created using four years of NVUM project data combined with several other data sources. The recreation demand data set is named NACQ1, and contains: all four currently available NVUM data series, census data, IRS income data, and NORSIS quality data. This data set was created using SAS Version 8. The details of construction are provided in this appendix, and the input files used to generate the dataset are available upon request from the authors. The input files below are referenced by their original directory and filename specification.

The information that follows is in outline format to aid in documenting the steps taken to create the NACQ1 dataset. Below you will also find the internet resources and links (valid at the time of data set construction) and file specifications. Please see Appendix F for the complete input files discussed here.

Data Documentation of Dataset: NVUM ALL CENSUS QUALITY (NACQ1)

1. **Input File: 04STARBUCK/SAS/NACENS/geolocation creation.sas**
    a. Generates a combined file that contains ZIPCODE, state, county, state FIPS, county FIPS, region, forest name, forest code, latitude and longitude of forest centroid as defined by the USGS Geographic Names Information System (GNIS).
    b. GNIS Source: http://geonames.usgs.gov/stategaz/us_concise.
        i. This is an .XLS file containing all place names in the US with a latitude and longitude affixed. The last update to their US_CONCISE file was 4/23/2003. File contents are as follows (Column Width=Contents):
            1. 1-50=Feature Name
            2. 52-60=Feature Type
            3. 62-92=County Name
            4. 94-109=State Name
            5. 111-126=Latitude and Longitude (Geographic Coordinates)
            6. 128-132=Elevation.

ii. This file was used to provide a Lat/Long for each Forest (based on the GNIS location – these appear to be a "centroid" for each forest in the US. This allowed the creation of a 'geolocation' file for each forest.

iii. Final output file contains: state FIP, FIPS place, state abbreviation (state PO), place name, county FIPS, county name, ZIPCODE, state name, forest name.

iv. Final output file: nacens.forestgeolocation.

v. Note: DO NOT DELETE nacens.geolocation – this file was created as a fixed format/schema file and there is no input file to re-run to correctly import the data from the raw download state. The nacens.geolocation file contains all the GNIS information (105,791) observations.

1. ALL_FIPS55 used in creating the geolocation file are derived from the US GNIS database under the download file name FIPS55. This is a fixed schema file. The data and schema can be found at: http://geonames.usgs.gov/fips55 and http://geonames.usgs.gov/layout.

2. **Input File: 04STARBUCK/census projections/by5 creation.sas**

a. This is the SAS input file that generates the census projections by race and age for all 50 states by five year increments from 2000-2025. The input data are in files transferred using STATTRANSFER and in the 04STARBUCK/census projections/by5/ folder.

b. In SAS this in the folder called PROJECT. The base data set created is, "project. Statepopby5".

c. The output files are "project.by5columns00…project.by5columns25".

d. The data are derived and downloaded from the US Census Bureau at http://www.census.gov/population/www/projections/st_yrby5 for the data files. Each state has eight files in total. By going to the "Every Fifth Year" link 50 compressed folders are found where each state file containing 1204 rows x 20 columns containing all the race, gender, age, population projections are located. These are ASCII files.

e. For use in NVUM (for all states) the files were set together to generate a file containing the (1204*50) x (20) observations for the National set.

f. The "by5 creation" input file merges, and then separates by five year increments this larger data set.

g. NOTE: for PROJECTIONS the finest detail level is the STATE, but if county population estimates by race, age, and gender for 2000-2003 are wanted the data is available, cleaned, and one version of an NVUM set with this data exists. ***County level estimates are available*** – but not for projections. The files are available at: http://eire.census.gov/popest/data/counties/coarso_detail.php. Or go to the following census menus: population estimates, counties, characteristics. Each state has its own separate comma delimited file. These were downloaded, transferred using STATTRANSFER, and set together and formatted and incorporated into NVUM using the following input file(s): 04STARBUCK/1990 Census by county demo/SAS county1900-1990/ growthratesbycounty.sas. This was also incorporated with income data by county in the files: 04STARBUCK/census_population/ "incpopgrowthdemoginp".

i. *NOTE: THIS IS NOT HOW THE INCOME PROJECTIONS OR POPULATION PORJECTIONS WERE CREATED. BUT THE DATA AND FILES MIGHT BE USEFUL IN SOME ANALYSIS SO ARE NOTED HERE.*

ii. *NOTE: Bureau of Economic Analysis has county level income data for 2000-2002. This was found at: http://bea.doc.gov/bea/regiona/reis, under Local Area Personal Income. Provides one line of data for each county in the US. Again – this is not the income used in the final output (071604) but may be a useful data set.*

3. Input File: 04STARBUCK/SAS/census_population/deltainccpi_071604.sas

a. This is the file that generates the income growth projections. The "deltainccpi_071604" file contains the formulas for calculating the average growth rate from 1980-2000 and the average change in prices from 1980-2000. This is then used in the NACENS_1_CREATION file to generate the income growth rates by 5 year intervals from 2000-2025.

b. To generate values in terms of real values, and not nominal, the US Census Bureau's Consumer Price Index tables using the Bureau of Labor Statistics information were used. The CPI information can be found at:

i. http://www.bls.gov/cpi/cpirsdc.html. Information on these values can also be located at: http://www.bls.gov.cpi/cpifaq. The table used in this file comes from a Census Bureau's compilation, available at http://www.census.gov/hhes/income/income02/cpiurs.html. This table provides the CPI-U-RS 1 values from 1947 to 2002. To calculate the percentage change in prices between any two years divide the year of interest by the base year (CPIt/CPIt-1).

c. Using the output table nacens.adjincfrb in the NACENS_1_CREATION file to generate the income growth *(NOTE: Those calculations are presented in the NACENS_1_CREATION file section)*.

d. To generate the income projections three sources of data/information were utilized.

i. Using the IRS Statistical service website, an .XLS file was downloaded containing adjusted gross income, number of returns, and ZIPCODE for all ZIPCODES in the US for 1990. (www.irs.gov/taxstats/article/0,,id=96947,00.html – available through the IRS Statistics of Income (SOI). Going to the TAXSTATS link will get you the downloadable data files in .XLS v4).

ii. A data series downloaded from the BEA (Bureau of Economic Analysis): Regional Economic Accounts provides a per capita income series for 1969-2002 by county for the entire US. A subset of 1980-2000 for each county was used. This file was downloaded from http://www.bea.doc.gov/bea/regional/reis/defalult.cfm, Under the Regional Economic Accounts Local Area Personal Income section click on the "single line of data for all counties" radio button, then "CA05 – Personal Income by Major Source and Earnings by Industry (SIC), then 030- Per capita personal income (dollars) for whatever years the data user wishes to analyze. This file was saved as: C:\04STARBUCK\SAS\census_population\ "percapincbycounty0080". Transferred into SAS (same directory) is "percapincbycounty0080a.sasdb7". The raw SAS file was then saved as "census.deltainc1".

iii. A third data source from the Bureau of Labor Statistics (BLS) as found and used by the Federal Reserve Bank (FRB) Minneapolis. Their website is http://minneapolisfed.org/research/data/us/calc, click on the link "Consumer Price Index and Inflation Rates, 1913" to find the CPI and inflation rate from 1913 to 2004. The FRB uses the BLS CPI-U series and provides the following method for computing real dollars for any two years of examination:

$$\text{RealDollars}_t = \text{Value}_t$$

$$\text{REALDOLLARS}_t = \frac{\text{VALUE}_{t-1} * \text{CPI}_t}{\text{CPI}_{t-1}}$$

iv. for example if (t=2004)

and (t -1=1980)

then

$$\text{Real Dollars}_{2004} = \text{Dollars}_{1980} * \text{CPI}_{2004} / \text{CPI}_{1980}$$

v. This was used to convert the BEA series from nominal dollars to real dollars, then the change between each year from 1980-2000 was calculated then averaged over the 20 year time period. Then the average inflation rate over the 20 year period was calculated from the CPI table and added to the growth rate using the method described above, and then used as the growth factor (incgrowa) in the following formula:

$$\text{incag}_t = \text{zinc00} * (1 + \text{incgrowa})^t,$$

vi. where

$$t = (2005,\ 2010,\ 2015,\ 2020, 2025)$$

vii. and zinc00 is the IRS income for 1990 adjusted for 2000 real dollars. This method should provide for a projected income in real terms for each of the time periods in each question – based on a county level historical income growth rate and national average inflation rates for zipcode level income data.

viii. These calculations are found in: C:\04STARBUCK\SAS\census_population/ "deltainccpi_071604" and in C:\04STARBUCK\SAS\ "nacens_1_creation".

4. **Substitute Distance Creation: C:\04STARBUCK\SAS\census_population\ substitute distance creation.sas**

   a. This file calculates a substitute distance variable using the following steps and data sources:

   b. Using the same USCONCISE (which contains the lat/longs) file described above the forest names were reformatted to conform exactly to NVUM saved as "census.forlat". Then a base NVUMALL file was used and sorted by zipcode.

   c. Then an SQL procedure was used:

      i. The SQL took the lat/long from forlat and the zipcode from NVUM and constructed a file with all possible combinations of zipcode/latlong. That is – EACH zipcode in NVUM was paired with the lat/long for EACH forest, so each of the 40k or so unique zip codes found in NVUM was paired with EACH of the 100 or so forest names/latlongs in USCONCISE (GNIS lat/long centroid). This generated a file with 2.4 million observations labeled: "census.odpairsub" ***WARNING – DO NOT DELETE THIS FILE!*** This file was then formatted so that the lat/long was conformable to PCMILER needs and an "odpairsub" file was created that contains an origin destination pair for all 2.4 million zipcode/latlong combinations. This was then exported to a plain text file and used in PCMILER BATCHPRO to calculate a distance for each origin destination pair. This was then imported back into SAS as "census.odpairsubsas" ***WARNING – DO NOT DELETE THIS FILE!!!***

      ii. The odpairsubsas file was then merged back into the odpairsub file to generate a file with calculated distances, latlong, and formatted forest names.

      iii. This file is then sorted by zipcode and the calculated substitute distance. The SAS "rank" procedure is then used and the file then sorted by descending order by zipcode and rank, the "lag" procedure is used to generate 3 lags of the distance.

      iv. Then NVUM is sorted by zipcode and forest name as is the substitute distance file. The files are then merged by zipcode and forest name. Then cleaned up and saved as census.subdistnvum, with the substitute distance file "subdistz" (which is the 2nd lagged, ranked variable).

         1. Note: DO NOT DELETE census.subdist – critical intermediate file.

      v. Using the SQL and ranking/lagging procedures described above, the substitute distance file generates a distance variable that provides a distance value from the zip code of origin to the next forest (from zip code) not visited.

vi. The rationale for NOT using the rank/lag procedure on the existing set of zip code/forest destinations is as follows:

1. In examining NM – using the NVUM data the substitute sites for three of the Albuquerque area zip codes were Rio Grande (in Colorado) and Coconino (Arizona) and a forest in Montana. Substitutes should be Santa Fe, Carson, Lincoln, and Gila (if visited Cibola from Albuquerque).
2. The set of observations on zip code/forest in NVUM cannot provide sufficient coverage of all possible combinations in order to construct a distance from each observed zip code to the next nearest forest from origin.

5. NACENS_1_Creation: C:\04STARBUCK\NACENS\ nacens_1_creation.sas

a. This input file generates the actual NACENS file constructed from the above sections. It also generates the VISMOD subsets.

b. Essentially, the above sub-files are merged into the base NVUMALL file using what ever variable is present in both files, the geolocation files simplifies this since it contains all the relevant identify/merge information.

c. This file uses the NVUMALL8 or 7 (NVUMALL CREATION) base file that contains Don English's transformations and the setting of the different years of NVUM into one file.

d. Any of the NACENSMASTER files will contain all the different variable/subsets described above.

e. Note: NORSIS was added to NVUM using the county as the merge variable. Since the USCONCISE data contains the county in which the forest centroid sits the NORSIS quality data is available for at least a portion of the forest.

APPENDIX B: NVUM SAMPLING AND WEIGHTING ISSUES

There are two components to the weight used in this analysis. The first weight expands the observations to the stratum total and is given by

$$SV_h = N_h \sum_{i=1}^{Nh} \frac{C_{hi} P_{hi} V_{hij}}{n_h} \qquad \text{[B.1]}$$

where $i = 1, 2, 3, ..., n_h$ is the sampled site-day; $h = 1, 2, 3, ...H$ is the stratum; C_{hi} is the total traffic count; V_{hij} is the number of persons in the j^{th} sampled vehicle on site-day i;

$$P_{hi} = \sum_{j=1}^{J} \frac{LR_{hij}}{J} \qquad \text{[B.2]}$$

is the proportion of vehicles on-site day i that were last exiting, with LR_{hij} an indicator variable that equals 1 if the j^{th} vehicle sampled on site-day is a last exiting recreation vehicle and zero else; J is the mean persons per recreation vehicle for last-exiting recreation vehicles; and N_h is the total number of site days in stratum h. The second weight is

$$NV = \frac{\left(\frac{SV_h}{M_h}\right)}{SF_i} \qquad \text{[B.3]}$$

where the weight for each site stratum is SV_h, M_h is the number of visitors, and SF_i is the number of sites the individual visited (English et al. 2002).

For example, in the Cibola National Forest some of which sits adjacent to Albuquerque, New Mexico three surveyed sites were Sandia Crest Observatory, the Crest Trail, and the La Luz trail. The Crest Observatory draws many visits from individuals visiting New Mexico. The view from the 10,600 foot peak over Albuquerque is a popular attraction and most visits to the site are of short duration and usually involve walking and viewing as the primary activity. The Crest Trail which is near the observatory is a wilderness trail that attracts a wide variety of hikers and nature viewing. Trip duration is usually longer than at the observatory and the site draws both locals and non-locals. The La Luz trail is a very popular attraction for Albuquerque residents as the main trailhead sits adjacent to the city and provides locals easy access to a world class hiking trail. The La Luz rises from 5,280 feet at its base to more than 10,600 feet at the Crest all within a few short miles. Many of the visitors hike this trail several times a week as part of their fitness routine and many live within walking or biking distance of the trailhead. Additionally, the trailhead connects to Sandia Tram allowing hikers to complete the trail and take the tram down the mountain. Most of the visitors to this site are local and have very high visit counts.

Table B.1 Effect of Expansion Weights

Site	Strata	NV**	Trips*	Weighted Trips*	Distance*	Weighted Distance*
Sandia Observation	DUDSH	903.02	4.719	3.570	468.067	720.374
Crest Trail	DUDSL	17,674.03	4.094	4.143	476.019	483.140
La Luz	WILDH	471.27	33.553	33.473	148.056	148.664

**Means of the trimmed data, using the 5,000 observation random sample from the master NACQ1 dataset. NV=NVEXPAND.*

The NVUM visit expansion weights (NVEXPAND) were developed in order to describe the characteristics of the estimate of the total number of annual visits to the forest. These weights can be used to expand each sampled observation up to the number of visits it represents in a given stratum. Specifically, in NVUM the unit of measure is a National Forest visit, which is defined as, “one person entering and exiting a National Forest or National Grassland for recreation" (English et al. 2002). The weight, which is calculated for every individual $i = 1 \ldots N$, is then defined as:

$$\mathrm{NVEXPAND}_i = \left(\frac{\begin{array}{c}\text{(exiting traffic)} \times \text{(proportion last exiting)} \\ \times \text{(persons in } j^{\text{th}} \text{ vehicle)}\end{array}}{\text{(number of sites visited}_i\text{)}} \right) \cdot N \qquad \text{[B.4]}$$

Where:

- (N) is the number of site days in the stratum;
- (Exiting traffic) is the average exiting traffic count per day for the stratum;
- (Proportion last exiting) is the ratio of last exiting recreation vehicles to total count of vehicles;
- (Average persons) is defined as the average number of people per vehicle for recreating vehicles sampled in the stratum;
- (Number sampled in stratum) is the number of people sampled in the stratum;
- (Number of sites visited by *i*) is the total number of sites visited by the individual during the current NF visit.

For illustration, assume that a surveyed forest has three sites with the following observations for NFV12MO, PEOPVEH, and NVEXPAND weights.

Table B.2 Illustrating Weights

OBS	NVEXPAND	NFV12MO	NVEXPAND *NFV12MO	PEOPVEH	PEOPVEH* NFV12MO	NVEXPAND *NFV12MO* PEOPVEH
1	903.03	5	4515.13	1	5	4515.13
2	301.01	40	12040.33	5	200	60201.67
3	903.03	20	18060.50	1	20	18060.50
4	451.51	6	2709.08	1	6	2709.08
5	150.50	0	0.00	1	0	0.00
6	225.76	1	225.76	1	1	225.76
7	301.01	1	301.01	7	7	2107.06
8	225.76	36	8127.23	9	324	73145.03
9	225.76	3	677.27	3	9	2031.81
10	180.61	0	0.00	1	0	0.00
Average	**386.80**	**11.2**	**12.06**	**3**	**57.2**	**42.14**

In Table B.2 the effect of the weights on the means of visits and distance are illustrated. Since NVUM is drawn from a stratified sample, the strata must be incorporated in the estimation, and thus the NVEXPAND weight is used in the estimators, descriptive statistics, and calculations according to standard sampling theory (English et al. 2002). For each observation in our sample there is a corresponding NVEXPAND value which is used to weight the moments and the variance-covariance matrices.

Each observation is expanded up to its representative value according to the sampling information. For example, for observation 1 the weight is 903.03 thus the 5 visits sampled in NVUM represents 4,515 visits based on the proportion of total cars to last exiting vehicles.

In the NVUM framework a visit is defined as one person entering and last-exiting a National Forest area. The NVEXPAND weight then expands the observations up to the visit level by taking the proportion of last exiting vehicles to the total count of vehicles and multiplying by the number of people in the j^{th} sampled vehicle to generate the representative number of PERSON TRIPS (i.e. total visits). In modeling demand using NVUM we are assuming that the reported visit value is for the household, then include the number of people in vehicle as a regressor then divide the consumer surplus by the number of people in the vehicle to retrieve a per person per visit consumer surplus value.

An additional set of issues in applying the current NVEXPAND weight to the estimation of a demand model was raised by Stynes et al. (2003) in his work estimating expenditure profiles using the NVUM data. Stynes et al. (2003) has found that the large variance in the weights has a tendency to distort the means of the expenditures and can be traced to a few observations with very large weights dominating the expenditures. The same issue may arise in the demand data as a few observations with very large weights will dominate the travel cost and visits values and if those values are significantly different from the means, the demand estimates and resulting welfare values could be biased.

APPENDIX C: DETAILED MODELING DESCRIPTION

In using the NVUM data to generate forest recreation values, it is important to generate estimates that are theoretically correct in methodology since the potential uses of the estimates include benefits transfer and benefit cost analyses. Thus, it is necessary to select an estimator that models the stratified, on-site nature of the data and incorporates the latest advances in econometric modeling.[28] This appendix presents the exploratory econometric models we used in developing the recreation demand models presented in this research.[29, 30]

1. Log-Linear (M1):

The modeling begins with the simplest functional form. This is a linear model where OLS is used. The form is (Adamowicz et al. 1989):

$$\ln Trips = \alpha_1 + \beta' X \qquad [C.1]$$

This model relies on a continuous LHS variable that is normally distributed. It is known to be inconsistent if the distribution violates the assumption of a normal distribution. This model is the least 'best fit' to the NVUM data, and represents a naïve model.

2. Truncated Log-Linear (M2):

This is a limited dependant variable (LDV) model, where the distribution is truncated at zero and the probabilities adjusted for the limit on the dependant variable. This is a linear model using the log of the dependant variable. As in the case with the log-linear model, the effect of using a semi-continuous distribution for a count distribution may yield inconsistent results.

However, since this a more linear model it is likely to be more stable and more robust relative to the non-linear models. The form is (Greene 2002, E21-19 and E22-1):

$$\log L = \sum_{y_i = L_i} \log \Phi\left(\frac{L_i - x_i'\beta}{\sigma}\right) + \sum_{y_i = y_i*} \log\left[\frac{1}{\sigma}\phi\left(\frac{y_i - x_i'\beta}{\sigma}\right)\right] \quad \text{[C.2]}$$

$$E\left[y_i \mid x_i, L_i \le y_i \le U_i\right] = \beta' x_i + \sigma \frac{\phi_L - \phi_U}{\Phi_U - \Phi_L} \quad \text{[C.3]}$$

3. Truncated Poisson (M3):

This is the most basic form of count data estimator applied to travel cost models. It is a robust, stable estimator, but known to provide inefficient and potentially inconsistent estimates when over-dispersion in the dependant variable is significant. The inefficient standard errors can be corrected using a robust covariance matrix, but if the dependant variable is over-dispersed then the estimates are to be considered inconsistent. The form is (Greene 2000, 2002; Ovaskainen et al. 2001:

$$\Pr[y_i = j \mid y_i > C] = \frac{\exp(-\lambda_i)\lambda_i^{y_i} / y_i!}{1 - \sum_{j=0}^{C} \exp(-\lambda_i)\lambda_i^{j} / j!}$$

$$\textit{where} \quad \text{[C.4]}$$

$$C > 0$$

$$\log L_i = \log \Pr ob[Y_i = y_i] - \log\left(1 - \sum_{j=0}^{C} P_j\right) \quad \text{[C.5]}$$

Alternatively,

$$\Pr[y_i = j \mid y_i > C] = \frac{\exp(-\lambda_i)\lambda_i^{y_i} / y_i!}{1 - \sum_{j=0}^{C} \exp(-\lambda_i)\lambda_i^{j} / j!}$$

with conditional mean [C.6]

$$\text{E(Y|X, Y>0)} = \lambda[1\text{-F}_\text{P}(0)]^{-1} = \left(\frac{e^{X'\beta}}{1 - e^{-e^{X'\beta}}}\right)$$

5. Truncated Negative Binomial (M4):

This is an extension of the Poisson [truncated] where an additional parameter α is estimated that allows for dispersion in the dependant variable. As given in Ovaskainen (2001, 129):

$$prob(Y = y \mid Y > 0) = \left[\Gamma\left(\frac{y+1}{\alpha}\right) \Big/ \Gamma(y+1)\Gamma\left(\frac{1}{\alpha}\right) \right] (\alpha\lambda)^{y} (1+\alpha\lambda)^{-\left(y+\frac{1}{\alpha}\right)} \left[1 - F_{NB}(0)\right]^{-1}$$

with conditional mean [C.7]

$$\text{E(Y|X, Y>0)}=\lambda[1\text{-F}_{\text{NB}}(0)]^{-1} = \left(\frac{e^{X'\beta}}{1-e^{-e^{X'\beta}}} \right)$$

6. Truncated Stratified Poisson (M5):

As derived in Shaw (1988) the truncated, endogenously stratified, Poisson model is given by the following

$$y_i^* = X_i\beta + u_i$$

For $i = 1,...,N,$ where $y_i = y_i^*$ when $y_i^* > 0$, then

$$h(y \mid X_i) = \frac{\exp(-\lambda_i)\lambda_i^{y_i - 1}}{(y_i - 1)!} \qquad \text{[C.8]}$$

with conditional mean and variance

$$E(y_i \mid X_i) = \lambda_i + 1 = \exp(X_i\beta) + 1$$

$$\text{var}(y_i \mid X_i) = \lambda_i$$

These correspond to equations 10-12 in Shaw (1988, 216). This is the theoretically preferred model when the variance and mean of the trips data are equal. However, as noted in Englin and Shonkwiler (1995), Cameron and Trivedi (1998), and Greene (2000) the Poisson yields inconsistent and inefficient parameter estimates in the presence of over or under dispersion in the dependant variable. The reader is referred to Cameron and Trivedi (1998), Englin and Shonkwiler (1995), and Shaw (1988) for a more complete discussion of the issues of choice based samples and count data estimation.

7. Truncated Stratified Negative Binomial (M6):

This is found in Englin and Shonkwiler (1995) and Ovaskainen et al. (2001). The probability is derived by applying the following probabilistic structure to the negative binomial distribution,

$$\frac{yF(y)}{\sum_{y=t} f(y=t \mid x_i)} \qquad \text{[C.9]}$$

Note: this is the same formula provided by Shaw (1988) for the truncated stratified Poisson. This yields the truncated stratified negative binomial (TSNB) model

$$\frac{\Gamma(y+\frac{1}{\alpha})(\alpha)^y(\lambda)^y(1+\alpha\lambda)^{-(y+\frac{1}{\alpha})}}{1-(1+\alpha\lambda)^{-\frac{1}{\alpha}}\Gamma(y+1)\Gamma(\frac{1}{\alpha})} \qquad \text{[C.10]}$$

Where $\lambda = e^{X'B}$ and α is the dispersion or nuisance parameter. This model is found twice in the literature, as cited above.

8. Finite Mixture Truncated Stratified Negative Binomial (M7):

This initial application is found in Cameron and Trivedi (1998) on pages 128-133. No applications to the recreation demand literature have been found. Two articles appear by Trivedi that use a finite mixture negative binomial (FMNB) that are cited and discussed in Cameron and Trivedi (1998). The finite mixture allows a series of classes to be defined into which subpopulations of the data belong. The general probabilistic structure is then derived that allows for different classes within the master population C. In the NVUM data this corresponds to the 'high frequency' and 'low frequency' users. Modifying Cameron and Trivedi's (1998) FMNB model to two separate TSNB estimators results in the following functional form

$$f(y_i \mid \Theta) = \sum_{j=1}^{C-1} \pi_j f_j(y_i \mid \theta_j) + \pi_c f_c(y_i \mid \theta_c)$$

where π is further parameterized as

$$\pi_j = \frac{e^{x'\varepsilon}}{1+e^{x'\varepsilon}} \text{ and estimated along with the other parameters.} \qquad [C.11]$$

The log-likelihood is $\ln L(\pi, \Theta \mid y) = d_{ij}[\ln f_j(y_{ij}; \theta_j) + \ln \pi_j]$

Using the Englin and Shonkwiler (1995) TSNB as $f(y_j; \theta_j) \sim TSNB$ yields the FMTSNB distribution.

Modeling Summary

In developing the truncated, negative binomial model weighted by NVY we explored the above specifications. The linear family of models performed poorly with few significant coefficient estimates, low R^2 values, and often negative consumer surplus estimates. While the linear models are typically more robust than the exponential families, and represent well developed econometric methods, they are theoretically inconsistent with our data generating process. The Poisson models and the Negative Binomial variants are the appropriate class of distributions for the modeling NVUM data. We estimated a series of models using the truncated and stratified variants of both the Poisson and the Negative Binomial, as well as the finite mixture model. These models were run using NVEXPAND, NVY, and no weighting variable. The results of our modeling led us to the truncated, negative binomial using the NVY weight.

Further work using the finite mixture models and continued exploration of the endogenous stratification and effects of the sampling frame on estimation, as well as omitted variable bias, and measurement error in the dependant variable and travel cost variables are important areas in recreation demand research that NVUM could be used to explore.

ENDNOTES

[1] This information is available from the USDA Forest Service website, http://www.fs.fed.us/aboutus/meetfs.html. This site was accessed on 04/21/2005.

[2] It should be noted that RPA Assessments are the responsibility of the Strategic Planning and Resource Assessment staff and the Research and Development staff provides assistance, while the Forest Plans are completed and administered by FS National Forest Systems. The resource values are expected to provide a consistent set of values to be used in these forest plans and in planning forest projects. The values are developed by researchers and peer reviewed in order to provide a set of values which can be used by FS personnel and others in National Forest management and research.

[3] This represents most of the FS system. Some aggregation of the forest data were done such that in states such as Florida, North Carolina, Mississippi, and others were aggregated into a single forest entity. Thus, while there are 155 listed National Forests these are represented by the 120 forests described herein.

[4] These expenditures are limited to within a 50 mile radius of the forest visited.

[5] The "Economics Addendum" and "Satisfaction Addendum" are only available for a portion of the data, as the primary focus of this iteration of NVUM sampling was to generate visitation estimates.

[6] We suspect that some high frequency visitors were surveyed at a site on a National Forest that was far from home relative to a location on the same forest that is very close to their residence. This would give some high frequency users distance values that appear to be erroneous. Additionally, if someone spends several weeks on-site or near the forest making multiple visits

over the course of their stay but live far away and report their home Zip Code instead of their local Zip Code, the visit-distance combination will also appear erroneous. Note: for the way we have constructed the dependent variable, trimming these observations may introduce some bias if sampling is random within strata.

[7] For INCES we replaced 361 observations (.53%); PEOPVEH was missing 267 (.39%); and we replaced 1,307 missing AGE observations (1.90%).

[8] It should be noted that the distances used to construct this are not the distances for the own-price variable construction. The latitude-longitude from the GNIS uses the location identified by the USGS as the *National Forest*, whereas the own-price (PRACTD1) variable uses the latitude-longitude for the specific *site* where the individual was interviewed. SAS was used to generate a dataset that contained all the possible combinations of forest and Zip Code, which resulted in more than 2.1 million observations for which PCMILER software was used to construct a distance from the Forest center to the Zip Code, SAS was then used to find the next nearest forest from their home.

[9] All estimations, calculations, and descriptive statistics reported here are based upon the stratification weights developed by English et al. (2002), and described in Section IV Modeling, Subsection IV.B.1 Choice Based Sampling Frame and Sample Weights. The descriptive statistics provided here come from Table 4 (ALL) National Sample.

[10] We used the IRS 2004 standard mileage rate for charitable use of private vehicles.

[11] NVUM was conducted only on individuals over the age 16. Any visitors under 16 are not included in the NVUM sample.

[12] This makes it possible to measure site usage by the number of visits or by viewing time on-site as endogenous to the choice of visits.

[13] The socio-demographic variables (H) are sometimes termed "human capital" as they represent the household skills, talents, and other individual or household specific characteristics that are essential inputs to the production of the recreation visit. In the fundamental household production framework, human capital is combined with physical/recreation capital and time to produce a recreation visit. Deaton and Muellbauer (1980, 245-253) present a good discussion of the household production approach and the concept of human capital. Bockstael and McConnell (1983) and Bockstael, Strand, and Hanemann (1987) develop the household production approach in a recreation demand setting.

[14] As shown by Bockstael and McConnell (1983) the standard household production approach based on a commodity space approach yields non-unique Marshallian demand curves due to the jointness in production. The implicit commodity prices of household goods become endogenous. Thus, they argue, because prices are endogenous, Roy's identity cannot be used to identify Marshallian demands. However, the household production approach can be used to derive the compensated Hicksian demands. Subsequent work by Bockstael and Strand (1987) and Kling (1992) show that the Marshallian approximations to the compensated demands can be used and that in most cases Willig's bounds apply. Theoretical and empirical analysis suggests that the errors in the specification of demand cause greater bias in the welfare estimates than the failure to use an exact measure of welfare.

[15] In addition to physical counts of vehicles, some sites had sufficient information on visitation to allow the use of 'proxy' counts of visitors. For example, ski areas with lift tickets, fee demonstration areas (fee envelopes); use permits that accurately and completely count the number of visitors are valid proxy sources. The use of proxy information resulted in smaller samples being drawn at these sites since only enough information to convert proxy information

into visit information was required. The proxy and non-proxy weights are constructed in the same manner. For more information refer to English et al. (2002).

[16] Stynes et al. (2003) provides a discussion of applying the strata weights to the expenditure information collected in NVUM.

[17] Shaw (1988) also derives the correction for continuous data.

[18] It is important to note that some of the forests were aggregated. For example, all forests in Florida were grouped as National Forests in Florida, and all North Carolina forests were grouped into one unit. Additionally, some forests that the FS has classified as separate units were grouped in NVUM. This results in the 120 units used here, which differs from the current FS defined units.

[19] Other examples of count data that displays this type of 'grouped' dependant variables can be found in Dobbs (1993); Deb and Trivedi (1997); Deb, Ming, and Trivedi (1998); and Kerkvleit and Nowell (1999).

[20] The distances were calculated using PCMILER software to generate a one-way distance from home Zip Code to forest sample point latitude-longitude using road distances; for the 2004 data series the self-reported one-way distance was used instead of the PCMILER distance; for observations where the FS generated latitude-longitude was missing the GNIS forest geolocation information was used to calculate the distances/times; if the PRACTIME value was missing it was replaced with the weighted mean.

[21] The choice of per mile cost can significantly impact the estimated travel cost and resulting consumer surplus values. Larger per mile values yield larger travel cost values and generally larger consumer surplus values.

[22] Table B-3 Average hourly and weekly earnings of production or non-supervisory workers on private non-farm payrolls by industry sector and selected industry detail. Available at: http://www.bls.gov/news.release/empsit.t16.htm. Accessed 9/24/2004.

[23] Because of the large sample size afforded by NVUM this last approach may be feasible. To define the visit lengths, cluster analysis could be used to identify the visit groupings with the greatest between grouping variance and minimum within grouping variance. These could be estimated as separate equations, as there should be no correlation between the time on-site groupings.

[24]The Random Utility Model (RUM) developed by Hanemann captures the participation modeling better than the ITCM but does not capture total choice of visits. While we could combine RUM with ITCM or use a nested RUM structure, the NVUM data is not well suited to this type of analysis.

[25] The value is assumed to be zero since it is problematic to parse out the portion of travel costs relevant to the visit to the National Forest and it is unlikely that all, or even a substantial portion, of the costs are attributable to the visit to the National Forest.

[26] As noted previously, all tables are in EXCEL spreadsheet form and are available from the authors upon request.

[27] Please see Creel and Loomis (1991) for an example of confidence intervals and truncated counts.

[28] Note the use of the term stratified, on-site sample. This is to indicate that the NVUM data is, by sampling design, stratified – and the data is truncated, endogenously stratified, and count data in nature.

[29] Two additional specifications were examined based upon the Tobit model. The grouped dependant limited dependent variable model and the Tobit. These are censored linear regression models. However, due to their difficulty in convergence and poor performance, they are not presented here. Numerous articles have explored the inconsistency of the Tobit under non-normal disturbances, Greene provides a test and in the NVUM data the null hypothesis of normal disturbances is strongly rejected. Some variants of the Tobit allow for heteroskedastic data, grouped dependant variables, and the following disturbance structures: Weibull, Logistic, and Exponential. The additional flexibility of the Tobit model may allow its use even under the non-normal errors in the NVUM data. The form as given in Greene (2002, E21-10):
$L_i\Phi_L + U_i(1-\Phi_U) + (\Phi_U - \Phi_L)\beta' x_i + \sigma_i(\phi_L - \phi_U)$ and $CS = -1/(2\beta_1)$.

[30] This is an extension of the Tobit (censored linear regression) model. This model is not yet well developed, and an example of the estimator applied to recreation values has not yet been found. This differs from the ordered probit is that the threshold values are known, and it is unnecessary to scale normalize σ to 1 and an estimate is produced. This gives rise to the inclusion [potentially] of an ordered probit for high-frequency observations. The conditional function is the same as for the Tobit above. As given in Greene (2002, E21-54 to 55):
$y^* = \beta' X + \varepsilon \sim N[0, \sigma^2]$ unobserved, and $y = j, A_{j-1} \le y^* < A_j, j = 1 \ldots J, A_0 = -\infty, A_J = +\infty$

$CS = -1/(2\beta_1)$

DSTATWTS	A table that compares provides descriptive statistics for selected variables using three different weights: unweighted, weighted by the simple NVEXPAND, and weighted by NVY=NVEXPAND/Y.	Table 7 Comparing Weighted and Unweighted Means for Selected Variables
CORALL	Correlation between variables for the full (NAC4 ALL) set of observations.	Table 8 Correlation ALL Data
TOP5CORR	Correlation between variables for the trimmed dataset (NAC4 TOP5) set	Table 9 Correlation TOP5 Data
ALLRESULTS	Complete regression results for the region-activities analyzed based on the full set of observations. Values in parentheses are t-statistics.	Table 10 Regression Results ALL data
TOP5RESULTS	Complete set of regression results for the region-activities analyzed based on the trimmed dataset. Value in parentheses are t-stats.	Table 11 Regression Results TOP5 Data
NOTCINTALLRESULTS	Complete set of regression results for the region-activities analyzed based on the untrimmed dataset. These models exclude all the travel cost interaction terms. Value in parentheses are t-stats.	Table 12 Regression Results ALL data: No Travel Cost Interactions
NOTCINTTOP5RESULTS	Complete set of regression results for the region-activities analyzed based on the trimmed dataset. These models exclude the travel cost interaction terms. Value in parentheses are t-stats.	Table 13 Regression Results TOP5 Data: No Travel Cost Interactions
ALLCSACTS	Consumer surplus results for each region-activity set based on the full set of observations.	Table 14 Consumer Surplus Values ALL Data
TOP5CSACTS	Consumer surplus results for each region-activity set based on the trimmed dataset.	Table 15 Consumer Surplus Results TOP5 Data
CIALL	90% confidence intervals around the reported consumer surplus values for each region-activity set based on the full set of observations.	Table 16 90% Confidence Intervals for Consumer Surplus ALL Data
CITOP5	90% confidence intervals around the reported consumer surplus values for each region-activity set based on the trimmed dataset.	Table 17 90% Confidence Interval around Consumer Surplus TOP5 Data

Notes

1	These models are based on the "NAC4" data set. Use 'nac4limu' or 'nac4limt' during estimation. This version incoporporates D.B.K. English's Activity Days coding and the latest grouping of RPA activities (14 total). The substitute distance variable has been dropped from the vector of regressors. Since the PCMILER calculated distances between zipcode and forest center (as defined by GNIS) are not being used in the regression (the substitute distance variable was correlated more than 95% with own distance) it can be used to fill in some of the missing distances (where the latitude and longitude were not available). ALL the travel cost variables are based on this combination distance variable.
2	The models use a dummy variable approach for the activities, and are run for each of the 4 RPA macro regions (Pacific, Rocky Mountain, North, South).
3	The models use a truncated negative binomial estimator weighted by NVY=NVEXPAND/NFV12MO1. ALL descriptive statistics and regressions use this weight.
4	The consumer surplus values are given for per individual per visit and for per individual per activity day, where calendar days are counted in whole integers. The calculation and construction of these and the RPA activity groupings were provided by D.B.K. English.
5	The consumer surplus values are calculated using the NVEXPAND weight and values non-primary purpose visitors and foreign visitors with a zero consumer surplus value.
6	Three different travel cost variables were used: TCH uses on opportunity cost of time value; TCWH uses the IRS income data to value travel time (computed by PCMILER) at 1/3 the 'wage' rate; TCFW uses a flat wage rate of $5.25 times the PCMILER calculated travel time.
7	The sheet labeled ACTIVITY DESCRIPTION provides a detailed description of the activities used in this analysis as drawn from RPA research.
8	The ALLRESULTS tab contains all three travel cost models for each of the four regions presented side by side for comparision. The base elasticity measures are provided at the bottom of the table. The values in the table are of the form (coefficient/tstat), so that the t-statistic is in parantheses underneath the coefficient estimate. YHAT is the predicted trips based on the truncated negative binomial model weighted by NVY. This is calculated for each individual and the weighted mean taken. LRI is the likelihood ratio calculation comparing the restricted and unrestricted log likelihoods.
9	The CSACTS tabs provides the Activity Based CS values both on a per individual per visit and per individual per day value. These are calculated for each individual and the weighted mean for the sample reported.
10	If a cell=1 it is a replacement value and means the observation is missing.
11	ALL endings are models run on the full 68,669 observations. TOP5 endings are models run on the data where the largest 5% of distance values were removed from the dataset, leaving 64,894 observations.
12	The two sheets labeled CIALL and CITOP5 provide 90% confidence intervals around the consumer surplus estimates. These are provided for all reported values. Please note that in the CS results tables, the CS values were replaced by the base case consumer surplus value (no travel cost interaction) if the travel cost interaction term was insignificant, if the value was less than $0, or if the value was greater than $500. In the CI table, the values were not replaced. So, for the activity CS values where the value was repalced, the CI table will show the non-replacement CS value.

Table 1 Description of Activities		
Activity	**Aggregation/Coding**	**Description**
CAMP	IF CAMPING7=1 OR RESORT7=1 THEN CAMP=1; ELSE CAMP =0;	Camping or resort stay on the forest
DRIVE	IF DRIVING7=1 OR H2OMOTR7=1 OR OTHMOTR7=1 OR SITESEE7=1 THEN DRIVE=1; ELSE DRIVE=0;	Motorized recreation, including: driving, motor-boating, site seeing, and other motorized activities (excluding off-highway vehicle use)
FISH	IF FISHING7=1 THEN FISH=1; ELSE FISH=0;	Fishing.
GENERAL	IF GENERAL7=1 THEN GENERAL=1; ELSE GENERAL=0;	Generalized recreation, including: hanging out, swimming, and non-specific forest recreation
HIKE	IF HIKE7=1 THEN HIKE=1; ELSE HIKE=0;	Hiking
HUNT	IF HUNTING7=1 THEN HUNT=1; ELSE HUNT=0;	Hunting
NATURE	IF GATHER7=1 OR HISTORY7=1 OR NATCENT7=1 OR NATSTUD7=1 THEN NATURE=1; ELSE NATURE=0;	Nature based activities, including: special forest product gathering, historical site visit, nature center visit, and nature study
OHVUSE	IF OHVUSE7=1 THEN OHVUSE=1; ELSE OHVUSE=0;	Off-Highway Vehicle (OHV) activities, including: three/four wheelers, and motorcycles
PCAMP	IF PCAMP7=1 OR BPACK7=1 THEN PCAMP=1; ELSE PCAMP =0;	Primitive Camping, including: primitive camping (undeveloped sites), and backpacking (typicALLy with overnight stays, backcountry activities)
PICNIC	IF PICNIC7=1 THEN PICNIC=1; ELSE PICNIC=0;	Picnicking
SKI	IF DOWNSKI7=1 OR XCSKI7=1 THEN SKI=1; ELSE SKI =0;	Skiing, including downhill and cross country
SNOWMOB	IF SNOWMOB7=1 THEN SNOWMOB=1; ELSE SNOWMOB=0;	Snowmobiling
TRAIL	IF BIKING7=1 OR HORSE7=1 OR H2ONMOT7=1 THEN TRAIL=1; ELSE TRAIL=0;	Trail use, including: bicycling, horseback riding, and non-motorized water activities such as canoeing
VIEW	IF VIEWNAT7=1 OR VIEWWLD7=1 OR VIEWOFF7=1 THEN VIEW =1; ELSE VIEW=0;	Viewing activities, including: nature viewing, and off-site viewing, wildlife viewing

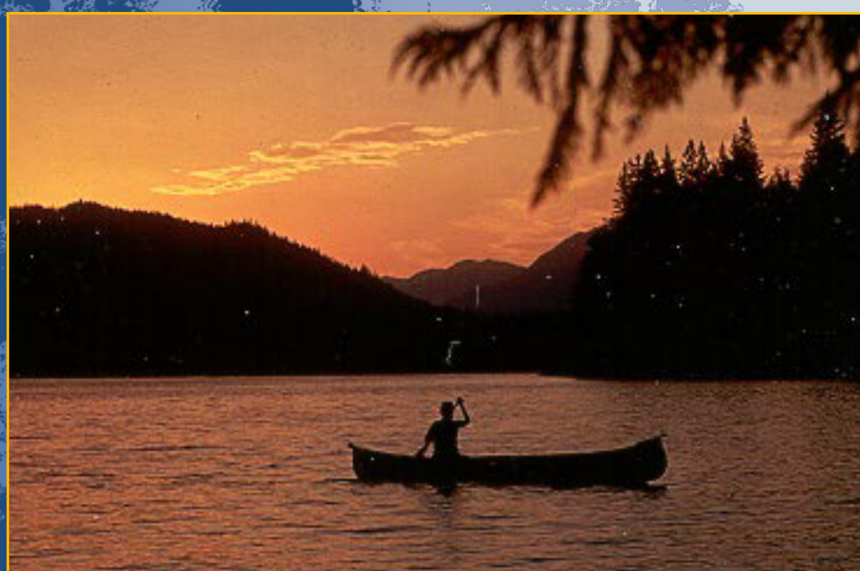
Benefit Transfer of Outdoor Recreation Use Values

Randall S. Rosenberger and John B. Loomis



A Technical Document Supporting the Forest Service Strategic Plan (2000 Revision)

U.S. Department of Agriculture Forest Service

Abstract

Rosenberger, Randall S.; Loomis, John B. 2001. **Benefit transfer of outdoor recreation use values: A technical document supporting the Forest Service Strategic Plan (2000 revision).** Gen. Tech. Rep. RMRS-GTR-72. Fort Collins, CO: U.S. Department of Agriculture, Forest Service, Rocky Mountain Research Station. 59 p.

We present an annotated bibliography that provides information on and reference to the literature on outdoor recreation use valuation studies. This information is presented by study source, benefit measures, recreation activity, valuation methodology, and USDA Forest Service region. Tables are provided that reference the bibliography for each activity, enabling easy location of studies. The literature review spans 1967 to 1998 and covers 21 recreation activities plus a category for wilderness recreation. There are 163 individual studies referenced, providing 760 benefit measures. Guidelines are provided for applying the various benefit transfer methods. Benefit transfer is the use of past empirical benefit estimates to assess and analyze current management and policy actions. Several theoretical and empirical issues to applying benefit transfers are identified for use in judging the relevance and credibility of transferring specific measures. Four benefit transfer models are discussed, including value transfers (single point estimates, average values) and function transfers (demand and benefit functions and meta analysis benefit function). A simple example application is followed throughout the discussion of the various benefit transfer methods. A decision tree is provided as a framework for determining how to obtain benefit measures for recreation activities.

Keywords: Benefit transfer, meta-analysis, outdoor recreation use values

Authors

Randall S. Rosenberger is Assistant Professor, Regional Research Institute and Division of Resource Management, West Virginia University, Morgantown, WV 26506.

John B. Loomis is Professor, Department of Agricultural and Resource Economics, Colorado State University, Fort Collins, CO 80523.

Final Report for the USDA Forest Service under Research Joint Venture Agreement #RMRS-98132-RJVA, "Theories and methods for measuring environmental values and modeling consumer and policy decision processes": Objective #4, "Benefit transfer."

Benefit Transfer of Outdoor Recreation Use Values: A Technical Document Supporting the Forest Service Strategic Plan (2000 Revision)

Randall S. Rosenberger
John B. Loomis

Contents

Executive Summary

This document serves four purposes: (1) it provides access to the literature on recreation use values; (2) it provides guidelines for conducting benefit transfers; (3) it provides a review of benefit transfer approaches; and (4) it provides a meta analysis of the recreation use value literature for use in benefit transfers. Benefit transfer is the application of data from a study site to a policy site. A study site is a place for which we have recreation value data collected through primary research. Primary research provides content- and context-specific estimates of recreation value for a site. A policy site is a place for which there is little or no data available on the economic value of recreation. When circumstances such as insufficient funding or time make primary research infeasible, benefit transfer provides a means by which the value of recreation at an unstudied site can be estimated using information about recreation values at other sites. Benefit transfer provides content- and context-relevant estimates of recreation value for policy sites.

Access to the outdoor recreation use value literature is provided via an annotated bibliography and cross-referencing of studies by recreation activity. The literature reviewed is comprised of outdoor recreation use value studies conducted from 1967 to 1998 in the United States and Canada. This includes 760 value measures estimated from 163 separate empirical research efforts covering 21 recreation activities.

Guidance is provided by identifying necessary conditions for and limitations to effective benefit transfers. Necessary conditions include issues concerning policy site needs, the quality of study site data, and the correspondence between the study site and the policy site. Several factors can affect benefit transfers and limit the accuracy of value estimation. These factors are categorized as data issues, methodological issues, site correspondence issues, temporal issues, and spatial issues. A decision tree is developed that guides field personnel and resource managers through a framework on how to obtain measures of recreation use value.

Four benefit transfer approaches are reviewed. An example application of each of the approaches is provided. Value transfers focus on measures of value. The use of single point measures and measures of central tendency for recreation values are discussed. Function transfers focus on statistical models estimated in primary research. These models relate value measures with measures of study site characteristics such as demographics of the user population, attributes of the recreation site or area, among others. The functions are adapted to characteristics of the policy site in order to estimate recreation values for the policy site. Demand or willingness to pay functions and meta analysis functions are discussed.

A meta analysis of the recreation use valuation literature is provided. Meta analysis is the statistical summarization of research outcomes. A meta analysis model is developed that can be applied to benefit transfers. It is based on 701 use value estimates from 131 separate primary research studies. A backward elimination procedure was used to optimize the meta analysis benefit transfer function by retaining only those 34 variables significant at the 80 percent level or better. The variables in the model include methodological factors, Forest Service regions, physical and political characteristics, and several recreation activities. The meta analysis benefit transfer function is used to estimate use values for 21 recreation activities for each of the Forest Service assessment regions and for the United States. This meta analysis benefit transfer function provides field personnel and resource managers with another tool for estimating use values for outdoor recreation activities.

Acknowledgments

This project was supported by funds provided by the Washington Office/Strategic Planning and Resource Assessment and the Rocky Mountain Research Station, Forest Service, U.S. Department of Agriculture. The authors acknowledge the assistance of Dennis Black in the literature search process, Shauna Page in the coding of the studies, Ram Shrestha for maintenance of the database, and Ross Arnold, George Peterson, and Dan McCollum for their valuable feedback and useful suggestions in analyzing the data. This report has benefited from a peer review by Linda Langner, Earl Ekstrand, and Jonathan Platt, and the USDA Forest Service General Technical Report review process, all of whom provided insightful comments. Any shortcoming of this report is the sole responsibility of the authors.

Introduction

The Renewable Resources Planning Act of 1974 has an assessment component and a program analysis component (SPRA 2000). First, the act requires an assessment of the supply of and demand for renewable resources on the nation's forests and rangelands. Second, it requires an analysis of the costs and benefits associated with the USDA Forest Service's programs including the National Forest System (superceded by the Government Performance and Results Act [GPRA] of 1993). These requirements create the need for credible measures of benefits. In this case, we are interested in developing credible measures of benefits for outdoor recreation. To this end, Strategic Planning and Resource Assessment (SPRS) staff (formerly RPA staff) supported the use of average values for various outdoor recreation activities based primarily on empirical estimates reported in past studies.

This report serves two functions. First, it provides information from a literature review of economic studies spanning 1967 to 1998 in the United States and Canada. These studies estimated outdoor recreation use values. A guide to this literature is provided through reference to the original studies in an annotated bibliography (appendix A). Second, this report provides guidelines on performing benefit transfers in the context of recreation use valuation. The review of the literature and benefit transfer methods in this report should increase the defensibility of benefit estimates transfers when management and policy impacts on outdoor recreation are evaluated.

We begin by discussing the source and coding of the data collected in the literature review. Issues and concerns surrounding benefit transfers are presented. The obstacles to performing critical benefit transfers highlight the need for a pragmatic approach to benefit transfer. Later we discuss theoretical aspects of the benefit estimates in the literature, including what the numbers mean and how they were estimated. We give a full account of the data collected from the literature review while examining different benefit transfer methods.

This report is not intended to be a cookbook for performing benefit transfers, but as a guide to the empirical estimates available. Along the way, various methods of benefit transfer will be discussed. An example transfer will be followed across all of the different methods. However, the many nuances of an actual benefit transfer cannot be illustrated with a simple example. Therefore, any plausible benefit transfer must involve the practicioner's use of judgment and insight when transferring values.

Data

Literature Review Efforts, Past and Present

We provide data on outdoor recreation use values based on empirical research conducted from 1967 to 1998 in the United States and Canada. This data is the compilation of four literature reviews conducted at the bequest and under the direction of the USDA Forest Service. The first review covered the literature on outdoor recreation and forest amenity use value estimation from the mid-1960s to 1982, collecting 93 benefit estimates in all (Sorg and Loomis 1984). The second review covered outdoor recreation use valuation studies from 1968 to 1988, building on the first review, but focusing primarily on the 1983 to 1988 period (Walsh and others 1988). This second review increased the number of benefit estimates to 287 estimates.

A third literature review on the subject covered the period 1968 to 1993 (MacNair 1993). This review formally coded information on the composition of the studies. While the database developed by MacNair (1993) includes 706 different benefit estimates, many of the studies in the previous reviews were not included in this effort. For example, only 64 out of the 120 studies included in the second review are included in the third review. However, the total number of benefit estimates has significantly increased. For example, 491 estimates from the lesser 64 studies included in this third review is larger than the total 287 estimates from all 120 studies as reported in the second review. This is due to the use of different criteria for including benefit estimates.

We conducted a fourth literature review on outdoor recreation use valuation, focusing on studies reported from 1988 to 1998 (Loomis and others 1999). We then merged the results of the fourth review with the MacNair (1993) database. Our main emphasis was to improve on coding procedures used in the past review efforts and to focus on obtaining use value estimates for all recreation activity categories identified by USDA Forest Service documents. We did not emphasize fishing benefit studies since this is the effort of a separate review sponsored by the U.S. Fish and Wildlife Service, which should be available by year 2001 (Markowski and others 1997). We did, however, include those fishing studies coded in the MacNair (1993) database that were from the Walsh and others (1988) review, as generally these were sufficient in number and coverage of fishing studies for statistical purposes. Therefore, our database includes 163 studies providing 760 benefit estimates, covering all recreation activity categories.

Data Sources and Coding Procedures

The focus of our literature review effort was for outdoor recreation use valuation studies conducted since 1988 in the United States and Canada. We concerted our efforts to locate studies on activities that were not previously investigated, such as rock climbing, snowmobiling, and mountain biking. Computerized databases, such as American Economic Association's ECONLIT, were searched for published literature along with the University of Michigan's Dissertation and Master's Thesis Abstracts. Gray literature was located by using conference proceedings, bibliographies on valuation studies (Carson and others 1994), and access to working papers. Details of studies conducted from 1967 to 1988 were obtained primarily from MacNair's (1993) database that coded the Walsh and others (1988) literature review. A few study details were obtained directly from the Walsh and others (1988) review that were not included in the MacNair (1993) database.

A master coding sheet was developed that contains 126 fields. The main coding categories include reference citation to the research, benefit measure(s) reported, methodology used, recreation activity investigated, recreation site characteristics, and user or sample population characteristics. Study reference citation details include, in part, author identification, year of study, and source of study results. Benefit measure(s) details include, in part, the monetary estimate provided by the study (converted to activity day units using information provided by the study), the units in which the estimate is reported (e.g., day, trip, season, or year), and temporally adjusted benefit measures for inflationary trends to fourth-quarter 1996 dollars using the implicit price deflator. An activity day is the typical amount of time pursuing an activity within a 24-hour period. This unit was chosen because of its ease in being converted to other visitation/participation units (e.g., recreation visitor days, trips, seasons). Table 1 provides summary statistics for the 21 recreation activities included in the database. All of the benefit measures reported in table 1 are adjusted to activity day units and fourth-quarter 1996 dollars.

Methodology details include survey mode (e.g., mail, telephone, in-person, use of secondary data), response rate for primary data collection studies, and sample frame (e.g., onsite users, general population). Methodology details are further divided between the application of revealed preference (RP) and stated preference (SP) modeling when appropriate. Details of RP modeling include, in part, identifying the model type (e.g., individual travel cost, zonal travel cost, random utility models), use of travel time or substitute sites in the model specification, and functional form (double log, linear, semi-log, log-linear). Details of SP modeling include, in part, identifying the model type (e.g., conjoint analysis, contingent valuation models), the elicitation technique for contingent valuation models (e.g., open ended, dichotomous choice, iterative bidding, payment card), and functional form.

Details of the recreation site include, in part, its geographic location, whether it was on public or private land, the type of public land (e.g., National Park, National Forest, State Park, State Forest), the state, the USDA Forest Service Region, and land type (e.g., lake, forest, wetland, grassland, river). In many cases, specific details about the recreation site were not provided either because of incomplete reporting or the activity was not linked with a specific site. Details of the user population characteristics include, in part, average age, average income, average education, and proportion female.

The details of each study were coded to the extent that they could be gleaned from the research-reporting venue. However, not every study could be fully coded according to the coding sheet. This was either because information was not reported or was not collected for a study. For example, coding each study for user characteristics was severely restricted in that very few of the studies in the literature review reported any details about the user population. This and other factors are indicative of the lack of consistent and complete data reporting, which further limits the ability to perform critical benefit transfers.

Benefit Transfer: Issues

What Is a Benefit Transfer?

Benefit transfer is a colloquial term referring to the use of existing information and knowledge to new contexts. For our present purposes, benefit transfer

Table 1—Summary statistics on average consumer surplus values per activity day per person from recreation demand studies—1967 to 1998 (fourth-quarter, 1996 dollars).

Activity	Number of studies	Number of estimates	Mean of estimates	Median of estimates	Std. error of mean	Range of estimates
Camping	22	40	$30.36	$24.09	5.50	$1.69 – 187.11
Picnicking	7	12	35.26	24.21	9.66	7.45 – 118.95

General recreation	12	31	24.26	10.03	7.48	1.18 – 214.59
Other recreation	11	16	40.58	33.78	9.64	4.76 – 172.34

[a]*Fishing includes all types of fishing such as cold water, warm water, and salt water fishing. The number of estimates for fishing is under-representative of the entire body of knowledge since fishing studies were not a primary focus of the literature review.*

is the adaptation and use of economic information derived from a specific site(s) under certain resource and policy conditions to a site with similar resources and conditions. The site with data is typically called the "study" site, while the site to which data are transferred is called the "policy" site. Benefit transfer is a practical way to evaluate management and policy impacts when primary research is not possible or justified because of:

1. budget constraints,
2. time limitations, or
3. resource impacts that are expected to be low or insignificant.

Primary research is the "first-best" strategy in which information is gathered that is specific to the action being evaluated, including the spatial and temporal dimensions, expected impacts, and the extent and inclusion of affected human populations and environmental resources. However, when primary research is not possible or plausible, then benefit transfer, as a "second-best" strategy, is important to evaluating management and policy impacts. The "worst-best" strategy in economic evaluation is to not account for recreation values, thus implying recreation has zero value in an evaluation or assessment model.

Conditions for Performing Benefit Transfers

Several necessary conditions should be met to perform effective and efficient benefit transfers (Desvousges and others 1992). First, the policy context should be thoroughly defined, including:

1. Identifying the extent, magnitude, and quantification of expected site or resource impacts from the proposed action.
2. Identifying the extent and magnitude of the population that will be affected by the expected site or resource impacts.
3. Identifying the data needs of an assessment or analysis, including the type of measure (unit, average, marginal value), the kind of value (use, nonuse, or total value), and the degree of certainty surrounding the transferred data (i.e., the accuracy and precision of the transferred data).

Second, the study site data should meet certain conditions for critical benefit transfers:

1. Studies transferred must be based on adequate data, sound economic method, and correct empirical technique (Freeman 1984).
2. The study contains information on the statistical relationship between benefits (costs) and socioeconomic characteristics of the affected population.
3. The study contains information on the statistical relationship between the benefits (costs) and physical/environmental characteristics of the study site.
4. An adequate number of individual studies on a recreation activity for similar sites have been conducted in order to enable credible statistical inferences concerning the applicability of the transferred value(s) to the policy site.

And third, the correspondence between the study site and the policy site should exhibit the following characteristics:

1. The environmental resource and the change in the quality (quantity) of the resource at the study site and the resource and expected change in the resource at the policy site should be similar. This similarity includes the quantifiability of the change and possibly the source of that change.
2. The markets for the study site and the policy site are similar, unless there is enough usable information provided by the study on own and substitute prices. Other characteristics should be considered, including similarity of demographic profiles between the two populations and their cultural aspects.
3. The conditions and quality of the recreation activity experiences (e.g., intensity, duration, and skill requirements) are similar between the study site and the policy site.

Most primary research was not conducted for future benefit transfer applications. The information requirements expressed in the above conditions are not always met in the reporting of data and results from primary research. In addition to weighing the benefits of more information from expensive primary research, the implicit cost of performing benefit transfers under conditions of incomplete information should be accounted for. Therefore, benefit transfer practitioners are required to be pragmatic in their applications of the method when considering the many limitations imposed upon them by primary research.

Potential Limitations of Benefit Transfers

Several factors can be identified that affect the reliability and validity of benefit transfers. A parallel effect that interacts with the following factors is the benefit transfer practitioner's judgment concerning empirical studies, including how to code the data reported by each study. One group of factors affect benefit transfers generally:

1. The quality of the original study greatly affects the quality of the benefit transfer process. This is the garbage-in, garbage-out factor.
2. Some recreation activities have a limited number of studies investigating their economic value, thus restricting the pool of estimates and studies from which to draw information.
3. Another data limitation is the documentation of data collected and reported. This increases the difficulty of demand estimation and benefit transfer.
4. As we have already noted, most primary research is not designed for benefit transfer purposes.

A second group of factors is related to methodological issues:

1. Different research methods may have been used across study sites for a specific recreation activity, including what question(s) was asked, how it was asked, what was affected by the management or policy action, how the environmental impacts were measured, and how these impacts affect recreation use.
2. Different statistical methods for estimating models can lead to large differences in values estimated. This also includes issues such as the overall impact of model mis-specification and choice of functional form (Adamowicz and others 1989).
3. Substitution in recreation demand is an important element when determining the potential impacts of resource changes. However, there is often a lack of data collection and or reporting on the availability of substitute sites, substitute site prices, and the substitution relationship across sites and among activities.
4. There are different types of values that may have been measured in primary research, including use values and/or passive- or non-use values. While this report focuses on use values, the benefit transfer practitioner should be aware of what is being measured in original research.

A third group of factors affecting benefit transfers is the correspondence between the study site and the policy site:

1. Some of the existing studies may be based on valuing recreation activities at unique sites and under unique conditions.
2. Characteristics of the study site and the policy site may be substantially different, leading to quite distinct values. This can include differences in quality changes, site quality, and site location.

A fourth factor is the issue of temporality or stability of data over time. The existing studies occurred at different points in time. The relevant differences between then and now may not be identifiable nor measurable based on the available data. A fifth factor is the spatial dimension between the study site and the policy site. This includes the extent of the implied market, both for the extent and comparability of the affected populations and the resources impacted between the study site and the policy site.

The above listed factors can lead to bias or error in and restrict the robustness of the benefit transfer process. An overriding objective of the benefit transfer process is to minimize mean square error between the "true" value and the "tailored" or transferred value of impacts at the policy site. However, the original or true values are themselves approximations and are therefore subject to error. As such, any information transferred from a study site to a policy site is accomplished with varying degrees of confidence in the applicability and precision of the information. Therefore, National Forest decisionmaking involving tradeoffs of recreation, commodity production, and nature preservation can often be improved by inclusion of even approximate estimates of nonmarket recreation values. Complete omission of recreation value estimates in economic analytic aids to decisionmaking implies a zero value for recreation, in which case the error of omission can be greater than the error of commission in benefit transfers procedures.

Validity and Reliability of Benefit Transfers

Several recent studies have tested the convergent validity and reliability of different benefit transfer methods (Loomis and others 1995; Downing and Ozuna 1996; Kirchhoff and others 1997; Desvousges and others 1998; Rosenberger and Loomis 2000). The methods tested, which we will presently discuss, include single point estimate, average value, demand function, and meta regression analysis transfers. While the above studies show that some of the methods are relatively more valid and reliable than other methods, the general indication is that benefit transfer cannot replace original research, especially when the costs of being wrong are high. In some tests of the benefit transfer methods, several cases produced tailored values very similar to the true values (as low as a few percentage points difference). In other cases, the disparity between the true value and the tailored value was quite large (in excess of 800% difference). Therefore, the policy context and process will most often dictate the acceptability of transferred data.

Benefit Transfer Methods

There are two broad approaches to benefit transfer: (1) value transfer and (2) function transfer (figure 1). Value transfers encompass the transfer of a single (point) benefit estimate from a study site, or a measure of central tendency for several benefit estimates from a study site or sites (such as an average value), or administratively approved estimates. Administratively approved value estimates will be discussed in conjunction with the measure of central tendency discussion. Function transfers encompass the transfer of a benefit or demand function from a study site, or a meta regression analysis function derived from several study sites. Function transfers then adapt the function to fit the specifics of the policy site such as socioeconomic characteristics, extent of market and environmental

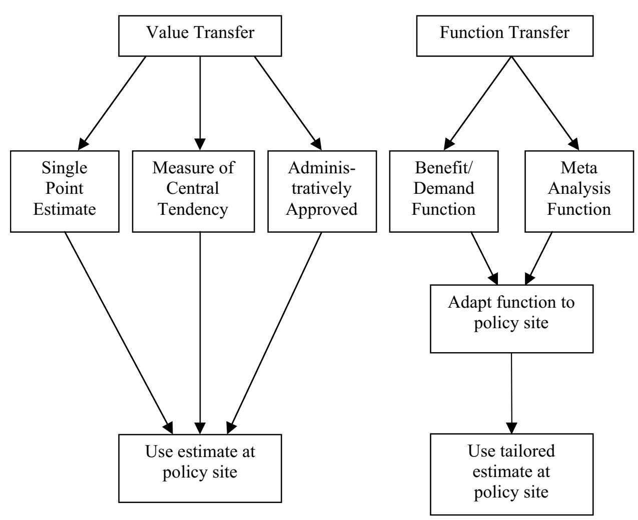

Figure 1. Benefit transfer approaches.

impact, and other measurable characteristics that systematically differ between the study site(s) and the policy site. The adapted function is then used to forecast a benefit measure for the policy site.

We will discuss each of these methods in the following sections, including a simple example application for each. However, we will first define and identify what the benefit measures are, what they mean, and how they were estimated.

Benefit Estimates

What Are They and What Do They Mean?

All of the benefit estimates provided by this report, either recorded from the literature review or forecasted by adapting benefit functions, are average consumer surplus per person per activity day. In the case of a single study, the estimate is the average consumer surplus for the average individual in the study. In the case of several studies, the estimate is the average of the study samples' average consumer surpluses from all included studies.

Consumer surplus is the value of a recreation activity beyond what must be paid to enjoy it.[1] Figure 2 illustrates the concept of consumer surplus. Looking just at current conditions when demand is D_0, consumer surplus is the area below the demand function (D_0) and above the expenditure line (E), or area CFH. Consumer surplus is also referred to as net willingness to pay, or willingness to pay in excess of the cost of the good. Total economic use value is consumer surplus plus the costs of participation, or area 0HFA in figure 2 when demand is D_0 and A is the number of days of participation.

When the change in recreation supply or days is small and localized, consumer surplus is equivalent to a virtual market price for a recreation activity (Rosenthal and Brown 1985). A general assumption when applying the benefit estimates is that the estimates are constant across all levels of resource impacts and perceived changes for an individual. This assumption may be plausible for small changes in visitation, but it may be unrealistic for large changes (Morey 1994). However, this assumption is necessary for the practical application of benefit transfers.

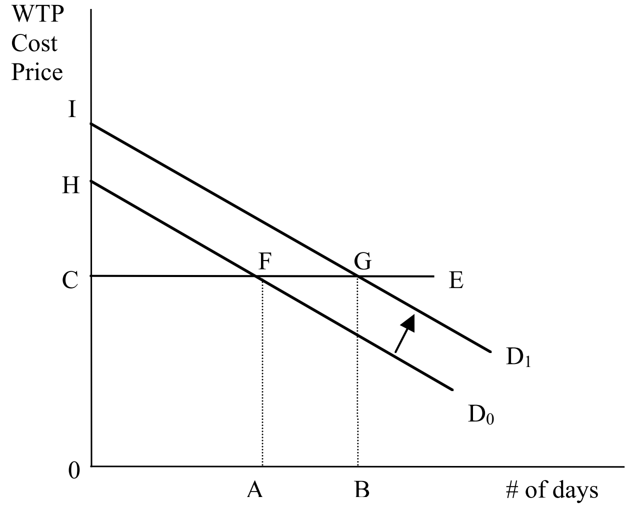

Figure 2. Consumer surplus measures for a quality-induced change in demand.

The valuation of management and policy impacts on recreation can be formally described as equation (1), following Smith and others (1999) nomenclature:

$$CS_P = \frac{CS_S}{\Delta d_S}(d_1 \cdot N_1 - d_0 \cdot N_0), \tag{1}$$

where CS_P = consumer surplus estimate for evaluating management or policy impacts on recreation;

CS_S = consumer surplus gain measure reported in the literature;

d_i = the amount of recreation use in activity days before (i = 0) and after (i = 1) the management or policy action;

N_i = the number of people participating in the recreation activity before (i = 0) and after (i = 1) the management or policy action; and

Δd_S = measured change in recreation participation or affected resource in the literature providing CS_S.

Simply stated, the benefit transfer estimate of a management- or policy-induced change in recreation is the average consumer surplus estimate for the average

[1]There are two prominent types of consumer surplus estimated using slightly different definitions of the demand function: Marshallian consumer surplus based on an ordinary demand function, and Hicksian consumer surplus based on either a compensated demand function or elicited directly using hypothetical market techniques. The difference between these measures is due to the income effect (Willig 1976). Since outdoor recreation expenditures are a relatively small percentage of total expenditures (income), differences between the two measures are expected to be negligible.

individual from the literature aggregated to the change in use of the natural resource. The change in recreational use of a resource may be induced either through a price change in participating in an activity (e.g., fee change or location of the site) or through a quality change in the recreation site.

The benefit estimates in the literature can vary according to many factors such as differences in recreation site and user population characteristics, extent of the market, temporal and spatial differences, and methodologically induced differences. Returning to figure 2, the potential range in benefit estimates provided in the literature can be illustrated. If the demand shift from D_0 to D_1 is due to a measurable increase in the quality of a recreation site, then three consumer surplus areas are identifiable: (1) CFH (existing level), (2) CGI (improved level), and (3) IHFG (net gain). Thus, another potential source for variability in benefit estimates provided is the context of the benefit estimate reported. For example, study A may provide a value for the creation of a new recreation site (area 1 or 3, depending upon expected demand level). Study B, by contrast, may provide an estimate of the current value of an activity with no implied change (area 1 or 3, depending on implied demand). Study C may provide an estimate of the value of a change in demand due to a management- or policy-induced change in implied cost or resource quality (area 2). Therefore, benefit estimates for the same activity reported in the literature can range from area 1 to area 3. All estimates provided in this report are of the first two types (studies A and B) above (we are not providing incremental or marginal values).

In any case, the benefit estimate provided in the literature will be treated as a constant per unit value applicable to all possible levels of resource use, with no accounting made for congestion. For example, the same benefit measure will be used whether recreation is affected by an increase (decrease) of 2 percent or 98 percent, measured as total activity days. Critical transfers would use estimates from a study site that best matches the policy site context as identified in the last section. However, because primary research is not typically conducted for the purpose of future benefit transfers and because of the limitations of study site data reporting listed above (especially incomplete and inconsistent reporting), the best match may not be a very good match at all. This is why benefit transfers must be pragmatic in application (some value may be better than no value at all). By being aware of the challenges to performing critical benefit transfers and what the estimates in the literature represent, practitioners of benefit transfer can better defend their transferred measures. There may be times when values or functions in the literature are used to arrive at a base value. These base values can then be adjusted up or down based on professional judgment to account for factors (like congestion) not accounted for in the benefit transfer. Such adjustments, if made, should be documented by the analyst.

How Are the Study Site Values Estimated?

There is an array of techniques used to estimate the economic use value of outdoor recreation.[2] These approaches are traditionally called nonmarket valuation, basically because not all of the resources important to the quantity and quality of recreation experiences are traded in markets. When market prices are not available, economic techniques may be employed that indirectly or directly estimate virtual market prices (as average consumer surplus or marginal willingness to pay). Revealed preference techniques are indirect methods for estimating consumer surplus and rely on the weak complementary between recreation participation and market-purchased goods necessary to recreation participation. Stated preference techniques are direct methods to estimating consumer surplus via constructed hypothetical markets through which people express their willingness to pay for environmental resources or recreation opportunities. Depending on the structure of a stated preference survey, it can also elicit information for use in indirectly estimating consumer surplus.

The most frequently used revealed preference technique is the travel cost method. Other methods included under the revealed preference technique heading are hedonic property and random utility methods. The travel cost method uses the variable costs of recreation participation (travel, lodging, entrance fees, equipment rentals, travel time) as a proxy for the price of recreating in deriving a demand function. The benefit of recreation is then the consumer surplus estimated from the demand function as shown in figure 2.

The most frequently used stated preference technique is the contingent valuation method. Another

[2] There are several accessible sources to issues in nonmarket valuation. For example, see Freeman (1993), Loomis and Walsh (1997), Champ and others (in preparation), and the website http://www.ecosystemvaluation.org (prepared under a cooperative agreement between U.S. Department of Agriculture, Natural Resource Conservation Service, U.S. Department of Commerce, NOAA-Sea Grant Office, and University of Maryland, Center for Environmental Science).

SINGLE POINT ESTIMATE TRANSFER

1. Identify the resources affected by a proposed action.
2. Translate resource impacts to changes in recreational use.
3. Measure recreation use changes.
4. Search the literature for relevant study sites.
5. Assess relevance and applicability of study site data.
6. Select a benefit measure from a single relevant study or a range of benefit measures if more than one study is relevant.
7. Multiply benefit measure by total change in recreation use.

Figure 3. Steps to performing a single point estimate transfer.

stated preference approach is conjoint analysis—a multi-attribute, multi-objective based method. The contingent valuation method directly solicits information from people by asking them their maximum willingness to pay or minimum compensation demanded for a recreation opportunity or change in a recreation experience, all within the confines of a hypothetical market.

While revealed preference approaches have typically resulted in slightly larger benefit measures than stated preference approaches, the approaches yield measures that are highly correlated (Carson and others 1996). Several studies comparing revealed and stated preference techniques for the same good have found the two measures not to be statistically different, providing evidence that the two techniques to nonmarket valuation exhibit convergent validity.

Benefit Transfer: Methods and Application

This section will discuss four different benefit transfer methods—single point estimate, average value, demand and benefit function, and meta regression analysis function. A simple example of each transfer will be presented. Specific information about the literature on outdoor recreation benefit measures will be provided.

Value Transfers

Single point estimate transfer

A single point estimate benefit transfer is based on using an estimate from a single relevant primary research study (or range of point estimates if more than one study is relevant). The primary steps to performing a single point estimate transfer include identifying and quantifying the management- or policy-induced changes on recreation use, and locating and transferring a "unit" consumer surplus measure. The text box (figure 3) provides a more detailed list of the steps involved in single point estimate transfers.

We provide information in this report that aids in identifying study site benefit measures from the literature.[3] An annotated bibliography of outdoor recreation use valuation studies is provided as appendix A, with additional information on some studies in appendix B. The bibliography includes studies conducted from 1967 through 1998 in the United States and Canada. There are 163 studies and 760 benefit measures identified (there is a total of 786 benefit measures provided, however, 26 of these are for wilderness recreation, some of which are a subset of other various activities). The bibliography includes information on:

1. reference to each study,
2. identification of the recreation activity investigated,
3. geographic location of the study (Forest Service region and RPA region),
4. original benefit measure(s) reported (adjusted to activity day units),
5. time adjusted benefit measure (to fourth-quarter 1996 dollars), and
6. valuation methodology used to measure benefits.

[3] *Another database that contains recreation use values in addition to other values for the environment is the Environmental Valuation Reference Inventory™ (EVRI™). This is a subscription database and can be found at http://www.evri.ec.gc.ca/evri/.*

Appendix C provides reference codes by recreation activity to the annotated bibliography (appendix A) for ease in locating potentially relevant studies.

It is important to note that all unit benefit measures provided in this report are in consumer surplus per activity day per person. Therefore, when translating resource impacts into recreation use changes, these impacts should be expressed in a comparable index as changes measured in activity days or convert the activity day measures into the relevant units.

The simplicity with which the steps to performing a single point estimate transfer are presented may be misleading. The steps involved in finding a valid and reliable benefit measure can be complex if taken to their theoretical extreme. This should become apparent when the information on the conditions for and limitations to benefit transfers are taken into account as previously identified. See Boyle and Bergstrom (1992) for an example of critically filtering existing research for applicability to a policy site context. In their example, they located five studies that measured the benefit of white water rafting. They then filtered the studies by three idealized technical considerations:

> (1) the nonmarket commodity of the site must be identical to the nonmarket commodity to be valued at the policy site; (2) the populations affected by the nonmarket commodity at the study site and the policy site have identical characteristics; and (3) the assignment of property rights at both sites must lead to the same theoretically appropriate welfare measure (e.g., willingness to pay versus willingness to accept compensation) (p. 659).

Their filtering of each study based on these considerations left them with no ideal benefit measures to transfer to their policy site. They state that this is likely to be the case for many transfer scenarios in which "a small number of potential study sites are available and the value(s) estimate at these study sites may not be applicable to the issue at the policy site" (p. 660). Therefore, when performing critical single point estimate benefit transfers, the original reporting of the study results must be obtained in order to determine its applicability to the evaluation issue at hand.

Another potentially critical aspect of benefit transfer is the defensibility of transferred values. Defensibility can be defined on two feasibility dimensions—technical and political. Technical feasibility is inversely related to the degree of technical and theoretical consistency between the study site context and the policy site context. Political feasibility is highly context- and scale-dependent, accounting for an array of social and cultural factors. The context surrounding each benefit transfer can be unique, meaning there is no single set of protocols that can be objectively followed. Benefit transfer is as much an art as it is a science. However, quite often information can be transferred with varying levels of confidence. A confidence interval for transferred point estimates can be calculated if the original study reports the standard error of the estimate. This confidence interval provides the statistical range in which we would expect the estimate to be some large percentage of the time (e.g., a 95% confidence interval means the estimate would be within the calculated range 95% of the time).

Example application: Background. The example that we will follow throughout the remainder of this report is hypothetical. We will be using this example to illustrate some of the issues when performing benefit transfers using the various approaches as they are discussed. Since this report is not intended to be a short course in nonmarket valuation, judgments concerning the validity, applicability, and quality of the valuation methodology used in each of the empirical studies are left to the benefit transfer practitioner.

The example application we will use to illustrate each of the transfer methods is to provide a per person activity day use value estimate for mountain biking in the Allegheny National Forest in north central Pennsylvania. The estimate can be used to either value current use on an existing trail or to value predicted use for a proposed trail. The total value of mountain biking in the forest can then enter into a resource allocation decision, assessment of a proposed forest plan, or accounting of the value of forest outputs. We will assume that this use of the national forest is important, but due to budgetary restrictions primary research is precluded. Therefore, we will attempt to use benefit transfer to provide a credible measure of the net benefits of an activity day of mountain biking in the forest. All measures will be reported in fourth-quarter 1996 dollars. Inflationary indexing such as the implicit price deflator can be used to adjust benefit measures to current dollars.

Example of a single point estimate transfer. We assume that the information requirements for steps 1 through 3 of figure 3 have been fulfilled. We will therefore begin with step 4, which is "search the literature for relevant study sites." Using appendix C, table C9, we find three biking studies referenced. Based on cross-referencing with the annotated bibliography, these three studies are Bergstrom and Cordell (1991), Fix and Loomis (1998), and Siderelis and Moore (1995).

Bergstrom and Cordell (1991) provide national zonal travel cost models for several recreation activities.

Their models were primarily developed using PARVS (Public Area Recreation Visitors Study) data. The authors identify several limitations of their models based on assumptions they have made in developing these models from the data. In particular, they have provided a benefit measure for biking. However, biking within the context of their study is a conglomerate of touring, leisure riding, and mountain biking, among others. Therefore, the benefit measure they provide is not specific to mountain biking, but to bicycling in general.

Siderelis and Moore (1995) investigate the net benefits of bicycling and walking on abandoned railroad beds that have been recycled to a rail-trail for recreation and transportation purposes. Their investigation used an onsite interview with followup mail questionnaire. Their research sites included the Heritage Trail that traverses a rural area in Iowa, the St. Marks Historic Railroad Trail that traverses a rural area with small towns in Florida, and the Lafayette/Moraga Trail that traverses a dense urban to suburban area in California. Bicycling on these trails was the dominant use of the trail for the Iowa and Florida trails, while walking was the dominant use of the California trail. Therefore, the reported values for the first two trails are primarily measures of biking value. Biking in this study was for leisure and transportation, not specifically mountain biking.

Fix and Loomis (1998) provide us with two estimates specifically for mountain biking. They use the individual travel cost and the contingent valuation methods to provide benefit estimates for mountain biking at the famed Slickrock Trail in Moab, Utah. Their data was collected using onsite surveys.

Each of the above studies should be assessed for relevance and applicability to the policy site issue. Several factors that can be assessed have been listed previously. For instance, the Bergstrom and Cordell (1991) study provides a general benefit measure for a generic bicycling day anywhere in the nation. Siderelis and Moore (1995) provide benefit measures for bicycling rail-trails for a specific region of the United States. And Fix and Loomis (1998) provide benefit measures for mountain biking, but in a high-profile, world-class site in Moab, Utah. Each study has positive and negative context-dependent aspects affecting their perceived relevance and applicability. However, for this example, we will assume each study is relevant, providing us with credible benefit measures.

Therefore, according to the annotated bibliography (appendix A), the three studies provide five estimates we could use for benefit transfer (table 2). We may conclude that the benefit of mountain biking on the proposed trail ranges from \$18 to \$63 per activity day. We do not know where in this range, if at all, the actual benefit of the proposed trail would be without conducting primary research. However, we may be able to use expert judgment concerning where in this range we believe a defensible measure would be given the context of the policy site and proposed action. For example, the Allegheny National Forest site is probably closer in composition to the Iowa trail than to the sandstone Slickrock Trail in Moab. Thus, the best single point estimate would be in the \$34 range. Whether it would be slightly more or less than this estimate depends on the similarity of characteristics of the trail in the Allegheny National Forest and the confidence interval surrounding this estimate (which is not recorded in the study report, but may be available from the authors).

Average value transfer

An average value transfer is based on using a measure of central tendency of all or subsets of relevant and applicable studies as the transfer measure for a policy site issue. The primary steps to performing an average value transfer include identifying and quantifying the management- or policy-induced changes on recreation use, and locating and transferring a "unit" average consumer surplus measure. The text box (figure 4) provides a more detailed list of the steps involved in average value transfers.

It is a common practice for federal public land agencies to use administratively approved average values in assessing management and policy actions. The USDA

Table 2. Single point estimates from the literature for the hypothetical mountain biking transfer.

Measure	95% Confidence Interval	Source
\$17.61	Not available	Bergstrom and Cordell
\$34.11	Not available	Siderelis and Moore (Iowa trail)
\$56.27	Not available	Siderelis and Moore (Florida trail)
\$54.90	\$33–\$161	Fix and Loomis (Travel cost method)
\$62.88	\$54–\$77	Fix and Loomis (Contingent valuation method)

AVERAGE VALUE TRANSFER

1. Identify the resources affected by a proposed action.
2. Translate resource impacts to changes in recreational use.
3. Measure recreation use changes.
4. Search the literature for relevant study sites.
5. Assess relevance and applicability of study site data.
6. Use average value provided in table 3 for that region or use an average of a subset of study measures.
7. Multiply benefit measure by total change in recreation use.

Figure 4. Steps to performing an average value transfer.

Forest Service has used RPA (Resources Planning Act) values since 1980 (USDA Forest Service 1989)[4]. These RPA values have been provided for groups of activities and Forest Service regions of the country. Along a similar vein, the U.S. Bureau of Reclamation and the U.S. Army Corps of Engineers have relied upon the U.S. Water Resources Council's "unit day values" for decades (U.S. Water Resources Council 1973, 1979, 1983). While some of the unit day values may not have been based directly on the emerging literature on outdoor recreation use values and measures, they have all been influenced to a certain degree by this literature. Past RPA average values were provided for each USDA Forest Service Region. However, this segregation results in two problems: (1) very small sample sizes per activity/region cell, and (2) numerous activity/region cells with no average value (because of the lack of primary research). To address both of these problems, the Forest Service regions are aggregated into RPA assessment regions with the Pacific Coast Area and Alaska being separately reported.

Table 3 provides measures of central tendency (mean, median, and 95% confidence intervals) of consumer surplus per activity day per person for 21 primary recreation activities, plus values for wilderness recreation, as defined by the USDA Forest Service (1989). These activity day values are provided for various regions of the United States and Canada. We report both mean and median values for all regional estimates, and confidence intervals for recreation activity estimates based on all activity-specific data. Under conditions of a normal distribution, mean and median estimates will be equal. Large divergences between these two measures indicate that the distribution of the estimates is skewed. That is, the average value is affected by large or small estimates. The effect of "outlier" estimates can be large when the total number of estimates is small. In addition, it is evident that margin of error is related to sample size.

In addition to the average values provided in table 3, subset average values can be calculated. For example, upon reviewing the literature behind the average values in table 3 the benefit transfer practitioner may determine that one or more of the inclusive studies is not applicable or may be influenced by atypically large values. The practitioner can then recalculate an average value based on the individual estimates that are judged applicable or use a rigorous statistical test to identify potential outlier values (Barnett and Lewis 1994).

Example of an average value transfer. To continue with our example transfer for mountain biking benefits of a trail in Allegheny National Forest, let us assume that none of the point estimates previously gathered match perfectly. Instead, maybe a benefit measure that is based on all three studies would be preferable. Using table 3, we search the northeast for an average value for biking. The average value is $34.11; however, it is based on a single estimate—the Siderelis and Moore (1995) estimate for Iowa. A measure that is based on all three studies would be the total U.S. studies column of table 3. The average of all five studies is $45.15. Alternatively, an average of the most closely matching studies ($34.11 for Iowa, $56.27 for Florida, and $17.61 for the nation) would be $36.00. Professional judgment determines which average value is most appropriate for the Allegheny National Forest site.

[4]The Resources Planning Act office of the USDA Forest Service is now the Strategic Planning and Resource Assessment office. However, reference to published value estimates and objectives of this group will be located under RPA. We will use RPA when referring to its history.

[a]Forest Service Regions per area are: Northeast Area = R9; Southeast Area = R8; Intermountain Area = R1, R2, R3, R4; Pacific Coast Area = R5, R6; and Alaskan Area = R10.

[b]Fishing values include different species, different bodies of water, and different angling techniques. The majority of the fishing benefit measures are from studies conducted between 1979 and 1988. Fishing was not a primary target of the literature review since it is the focus of a different project. Updated fishing values will be provided at the completion of the other project.

[c]General recreation is defined as a composite of recreation opportunities at a site with measure for site, not a specific activity.

[d]Other recreation is defined as sites with recreation opportunities that are undefined or obscure, such as cliff diving and mountain running.

[e]Total number of cases excludes Wilderness recreation as some of these estimates are a subset of other various recreation activities (see bibliography for identification of sources).

[f]Margin of error is calculated at the 95% confidence limit based on standard error of mean estimates (table 1). Confidence range illustrates magnitude of the range based on the data in which a mean estimate would lie with 95% confidence.

Average value estimates, however, are no better than the data they are based on. All of the issues that could be raised concerning the credibility of any single measure are also relevant for an average value based in part on that measure.

Benefit Function Transfers

Benefit function transfers entail the use of a model that statistically relates benefit measures with study factors such as characteristics of the user population and the resource being evaluated. Benefit function transfers usually come from two sources. First, a benefit function or demand function has been estimated and reported for a recreation activity in a geographic location through primary research. Second, meta regression analysis functions can be estimated from several independent primary research projects. In either case, the transfer process entails adapting the function to the characteristics and conditions of the policy site, forecasting a tailored benefit measure based on this adaptation of the function, and use of the forecast measure for evaluating the policy site.

Demand function transfer

The transfer of an entire demand function is conceptually sounder than value transfers. This is because the benefit estimates and use rates in recreation are a complex function of site characteristics, user characteristics, and different spatial and temporal dimensions of recreation site quality and site choice. When transferring a point estimate from a study site to a policy site, it is assumed or is implied that the two sites are identical across the various factors that determine the level of benefits derived in recreational use of the two sites. In the case of an average value transfer, it is assumed that the benefits of the policy site are around the mid-level of benefits measured for the study sites incorporated into the average value calculation. However, based on different validity and reliability assessments of point estimate and average value transfers, this is not always the case. The invariance surrounding the transfer of benefit measures alone makes these transfers insensitive or less robust to significant differences between the study site(s) and the policy site. Therefore, the main advantage of transferring an entire demand function to a policy site is the increased precision of tailoring a benefit measure to fit the characteristics of the policy site. It is in the adaptation stage of forecasting a benefit measure from a study site demand function that the additional value of the transfer method is realized (figure 5).

Disadvantages of the method are primarily due to data collection and model specification in the original research effort. Factors in the demand function may be relevant to the study site but not to the policy site. Also, factors that are important to demand at the policy site may not have been collected at the study site or were not significant in determining demand at the study site. These factors can have distinct effects on the tailored benefit measures at a policy site. This is evident in validity tests of benefit function transfers in which error in the tailored value ranged from as low as a few percentage points to as high as 800% (Loomis and others 1995; Downing and Ozuna 1996; Kirchhoff and others 1997). In comparative validity tests, demand function transfers were found to outperform (lower error) point estimate transfers. Therefore, demand function transfers may be an improvement over point estimate transfers but are still a second-best strategy to recreation valuation.

DEMAND AND BENEFIT FUNCTION TRANSFER

1. Identify the resources affected by a proposed action.
2. Translate resource impacts to changes in recreational use.
3. Measure recreation use changes.
4. Search the literature for relevant study sites.
5. Assess relevance and applicability of study site data and whether demand or benefit function is specified.
6. Adapt demand or benefit function to policy site characteristics and forecast benefit measure.
7. Multiply tailored benefit measure by total change in recreation use.

Figure 5. Steps to performing a demand function transfer.

We have not identified those studies in the literature review that reported demand or benefit equations (functions). The applicability of demand functions to policy site transfers requires an intimate knowledge of the policy site. In addition, the specification of individual demand functions can have significant effects on the reliability of their use under varying circumstances. If a demand function transfer is sought, then the transfer practitioner will have to use insight and expert judgment concerning the applicability of potentially transferable demand functions, the details of which are well beyond the scope of this report. Good illustrative examples of benefit function transfers are provided by Loomis and others (1995), Downing and Ozuna (1996), and Kirchhoff and others (1997).

Example of a demand function transfer. The adaptation of a demand function from a study site to a policy site can be complex and lead to a large error. This error can be influenced by dissimilarities between site and user population characteristics of the study site and policy site. Critical demand/benefit function transfer requires strong knowledge of economic methodology and estimation of consumer surplus. Therefore, it is highly recommended that when attempting to perform a demand function transfer you either have the requisite knowledge or solicit the aid of someone who does.

A demand function relates the number of occasions of an activity (typically as trips or days) to the price paid (travel costs including direct variable costs and travel time costs) (TC), characteristics of a site (SC), socioeconomic characteristics of the user population (SEC), and substitute site information (SubTC). This demand function would look something like:

$$\text{\# of Occasions} = \beta_0 + \beta_1{*}\text{TC} + \beta_2{*}\text{SubTC} + \beta_k{*}\text{SC} + \beta_m{*}\text{SEC}. \qquad (2)$$

The adaptation entails substituting equivalently measured information relevant to the policy site for the variables in the demand function. This adaptation then forecasts the lefthand side of the demand equation or number of occasions. Based on this adapted demand function, consumer surplus per day can be calculated. In some cases, this estimation of consumer surplus and conversion to per activity day is difficult.

For direct methods to estimating consumer surplus via stated preference, a bid or willingness to pay function is typically defined. The bid function relates consumer surplus or willingness to pay to quantity and/or quality of the activity or environmental resource (Q), characteristics of a site (SC), and socioeconomic characteristics of the user population (SEC). This function would look something like:

$$\text{WTP} = b_0 + b_1{*}\text{Q} + b_k{*}\text{SC} + b_m{*}\text{SEC}. \qquad (3)$$

Returning to our mountain biking example, we have several demand functions that could be transferred to our policy site. It can be argued that Siderelis and Moore's (1995) Iowa trail demand function is the best for our purposes. This is because the Fix and Loomis (1998) mountain biking study, although activity-specific, has noncomparable site characteristics between their site and our policy site. Siderelis and Moore's (1995) Florida trail model is neither activity-specific nor of comparable site characteristics. And Bergstrom and Cordell's (1991) national model for biking is not activity specific or site specific. Therefore, Siderelis and Moore's (1995) Iowa model is the closest to matching the issue for our hypothetical policy site—dirt-trail biking.

Siderelis and Moore (1995) estimate an individual travel cost model of the form:

$$\ln Trips = 3.62 + 1.511 - 0.033TC + 0.70W - 0.16A1 \qquad (4)$$

where the dependent variable ($\ln Trips$) is the natural logarithm of the number of trips, TC is the virtual price or travel costs (including direct variable costs of travel and wage rate value of travel time), W is whether the individual was using the Iowa trail for walking (versus bicycling), and $A1$ is the percentage of a group who is 26 years of age or less.[5] Average consumer surplus per trip is the area below the demand function and above the average price line (figure 2). For a semi-log function form, an approximation of average per trip consumer surplus is $-(1/\beta_{TC})$, where β_{TC} is the travel cost parameter (Adamowicz and others 1989). Thus, average consumer surplus per trip is $34.25 (adjusted to 1996 dollars).[6] We are not provided with information necessary to calculate a 95% confidence interval for this measure.

[5]Siderelis and Moore (1995) estimate six different models for the Iowa trail. They use this model to estimate consumer surplus per trip, which is subsequently the estimate recorded throughout this document and the database. Therefore, we will restrict our transfer exercise to this model.

The model estimated is a count data model using a negative binomial regression technique. Count data models are suggested for trip data in which the dependent variable is reported in integers (no partial trips) and restricted to be nonnegative (no negative trips). Negative binomial specifications automatically take the natural log of the dependent variable. For more information on count data travel cost models, see the discussion by Siderelis and Moore (1995) or Creel and Loomis (1990).

[6]The difference between this estimate and Siderelis and Moore's (1995) estimate of $34.11 (in comparable dollars) is that the authors of the original research used Simpson's rule for approximating integrals for calculating consumer surplus.

One of the disadvantages to transferring a demand function of the semi-log functional form is that consumer surplus is invariant in (or exogenous to) the demand model. That is, changes in the levels of the explanatory variables in the model are captured in the predicted use levels, but not in the estimate of average consumer surplus per trip. Adamowicz and others (1989) identify demand specifications in which quantity and price measures endogenously determine consumer surplus measures. Applying a benefit function with endogenously determined consumer surplus is similar to the application of the meta analysis benefit function discussed in the next section. However, one use of the Iowa trail model would be to predict the market area and use levels for the Pennsylvania trail.

Meta regression analysis benefit function transfer

Meta regression analysis is the statistical summarizing of relationships between benefit measures and quantifiable characteristics of studies. The data for a meta analysis is typically summary statistics from study site reports and includes quantified characteristics of the user population, study site's environmental resources, and valuation methodology used. Coding of the studies included in the literature review (as previously described) lends itself directly to the estimation of a meta analysis benefit function. However, interpretation of original study results can be a source of error in meta analysis databases.

Advantages and disadvantages

Meta analysis has been traditionally concerned with understanding the influence of methodological and study-specific factors on research outcomes and providing summaries and syntheses of past research. A more recent use of meta analysis is the systematic utilization of the existing value estimates from the literature for the purpose of benefit transfer. Essentially, meta analysis regression models can be used to forecast benefits at policy sites. Meta analysis has several conceptual advantages over other benefit transfer methods such as point estimate and demand function transfers:

- Meta analysis utilizes information from a greater number of studies, thus providing more rigorous measures of central tendency that are sensitive to the underlying distribution of the study site measures.
- Methodological differences can be controlled when calculating a value from the meta analysis function.
- By setting the independent variables (adapting the function) at levels specific to the policy site, the transfer practitioner is potentially accounting for differences between the study sites and the policy site.
- Multi-activity, multi-site meta analyses can provide estimates for regions in which no studies were conducted for an activity. That is, meta analysis can forecast estimates for new or unstudied sites.

Many of the same limitations to performing benefit transfers in general are applicable to meta analysis (Desvousges and others 1998):

- There should be enough original studies conducted so that statistical inferences can be made and relationships modeled.
- A meta analysis can only be as good as the quality of past research efforts. This quality includes the scientific soundness of the original research and the reporting of results and summary statistics on original data samples that are rich in detail.
- The studies should be similar enough in content and context that they can be combined and statistically analyzed.

Similar to demand function transfers, the main advantage of forecasting measures for a policy site via a meta analysis benefit function is the increased sensitivity of the tailored benefit measure to characteristics of the policy site. It is in the adaptation stage of forecasting a benefit measure from meta analysis benefit function that the additional value of the transfer method is realized (figure 6). An additional advantage of the meta analysis approach over a demand function approach is its ability to discern the effect of different factors on the level of benefit estimates provided in the literature.

An outdoor recreation meta analysis benefit function

As stated previously, a master coding sheet was developed that contains 126 fields. The main coding categories include study reference, benefit measure(s), methodology used, recreation activity investigated, recreation site characteristics, and user population characteristics. Table 4 lists and defines the variables

META ANALYSIS FUNCTION TRANSFER

1. Identify the resources affected by a proposed action.
2. Translate resource impacts to changes in recreational use.
3. Measure recreation use changes.
4. Adapt meta regression analysis benefit function (table 5) to policy site characteristics and forecast benefit measure or select appropriate forecast measure from meta forecasted measures (table 6)
5. Multiply tailored benefit measure by total change in recreation use.

Figure 6. Steps to performing a meta regression analysis function transfer.

Table 4. Description of variables tested in the meta analysis.

Variable	Description
Dependent variable	
CS	Consumer surplus (CS) per person per activity day (1996 dollars)
Method variables	
METHOD	Qualitative variable: 1 if stated preference (SP) valuation approach used; 0 if revealed preference (RP) approach used
DCCVM	Qualitative variable: 1 if SP and dichotomous choice elicitation technique was used; 0 if otherwise
OE	Qualitative variable: 1 if SP and open-ended elicitation technique was used; 0 if otherwise
ITBID	Qualitative variable: 1 if SP and iterative bidding elicitation technique was used; 0 if otherwise
PAYCARD	Qualitative variable: 1 if SP and payment card elicitation technique was used; 0 if otherwise
CONJOINT	Qualitative variable: 1 if SP and conjoint analysis technique was used; 0 if otherwise
SPRP	Qualitative variable: 1 if SP and RP used in combination; 0 if otherwise
ZONAL	Qualitative variable: 1 if RP and a zonal travel cost model was used; 0 if otherwise
INDIVID	Qualitative variable: 1 if RP and an individual travel cost model was used; 0 if otherwise
RUM	Qualitative variable: 1 if RP and a random utility model was used; 0 if otherwise
HEDONIC	Qualitative variable: 1 if RP and a hedonic travel cost model was used; 0 if otherwise (omitted category for METHOD) [0.024, 0.15][a]
TTIME	Qualitative variable: 1 if RP model included travel time; 0 if otherwise
SUBS	Qualitative variable: 1 if RP model included substitute sites; 0 if otherwise
ONSITE	Qualitative variable: 1 if sample frame was on-site; 0 if otherwise
MAIL	Qualitative variable: 1 if primary data collection used mail survey type; 0 if otherwise
PHONE	Qualitative variable: 1 if primary data collection used phone survey type; 0 if otherwise
INPERSON	Qualitative variable: 1 if primary data collection used in-person survey type; 0 if otherwise
SECOND	Qualitative variable: 1 if secondary data was used (omitted category for data collection) [0.063, 0.24][a]
LINLIN	Qualitative variable: 1 if functional form was linear on both dependent (d.v.) and independent variables (i.v.); 0 if otherwise
LOGLIN	Qualitative variable: 1 if functional form was log d.v. and linear i.v.; 0 if otherwise
LOGLOG	Qualitative variable: 1 if functional form was log on both d.v. and i.v.; 0 if otherwise
LINLOG	Qualitative variable: 1 if functional form was linear on d.v. and log on i.v.; 0 if otherwise (omitted category for functional form) [0.003, 0.05][a]
VALUNIT	Qualitative variable: 1 if CS was originally estimated as per day; 0 if otherwise (e.g., trip, season, or year)
TREND	Qualitative variable: year when data was collected, coded as 1967 = 1, 1968 = 2,…, 1996 = 30

(cont.'d)

Table 4 (Cont.'d)

Variable	Description
Site variables	
RECQUAL	Qualitative variable: site quality variable coded as 1 if the author stated site was of high quality or the site was either a National Park, National Recreation Area, or Wilderness Area; 0 if otherwise
FSADMIN	Qualitative variable: 1 if the study site(s) were National Forests (i.e., administered by the U.S. Forest Service [FS]); 0 if otherwise
R1	Qualitative variable: 1 if study sites were in FS Region 1 (Montana, No. Idaho); 0 if otherwise
R2	Qualitative variable: 1 if study sites were in FS Region 2 (Wyoming, Colorado); 0 if otherwise
R3	Qualitative variable: 1 if study sites were in FS Region 3 (Arizona, New Mexico); 0 if otherwise
R4	Qualitative variable: 1 if study sites were in FS Region 4 (Nevada, Utah, So. Idaho); 0 if otherwise
R5	Qualitative variable: 1 if study sites were in FS Region 5 (California); 0 if otherwise
R6	Qualitative variable: 1 if study sites were in FS Region 6 (Oregon, Washington); 0 if otherwise
R8	Qualitative variable: 1 if study sites were in FS Region 8 (Southern United States east of Rocky Mountains); 0 if otherwise
R9	Qualitative variable: 1 if study sites were in FS Region 9 (Northern United States east of Rocky Mountains); 0 if otherwise
R10	Qualitative variable: 1 if study sites were in FS Region 10 (Alaska); 0 if otherwise
NATL	Qualitative variable: 1 if study sites were the entire United States; 0 if otherwise
CANADA	Qualitative variable: 1 if study sites were in Canada; 0 if otherwise (omitted category for geographic location of study site) [0.015, 0.12][a]
LAKE	Qualitative variable: 1 if the recreation site was a lake; 0 if otherwise
RIVER	Qualitative variable: 1 if the recreation site was a river; 0 if otherwise
FOREST	Qualitative variable: 1 if the recreation site was a forest; 0 if otherwise
OCEAN	Qualitative variable: 1 if the recreation site was an estuary or bay of an ocean; 0 if otherwise (omitted category for site type) [0.169, 0.37][a]
PUBLIC	Qualitative variable; 1 if ownership of the recreation site was public; 0 if otherwise.
DEVELOP	Qualitative variable: 1 if the recreation site had developed facilities, such as picnic tables, campgrounds, restrooms, boat ramps, ski lifts, etc.; 0 if otherwise.
NUMACT	Quantitative variable: the number of different recreation activities the site offers.
Recreation activity variables	
CAMP . . . OTHERREC	Qualitative variables: 1 if the relevant recreation activity was studied; 0 if otherwise. Where CAMP is camping, PICNIC is picnicking, SWIM is swimming, SISEE is sightseeing, OFFRD is off-road driving, NOMTRBT is float boating, MTRBOAT is motor boating, HIKE is hiking backpacking, BIKE is biking, DHSKI is downhill skiing, XSKI is cross-country skiing, SNOWMOB is snowmobiling, BGHUNT is big game hunting, SMHUNT is small game hunting, WATFOWL is waterfowl hunting, FISH is fishing, WLVIEW is wildlife viewing, HORSE is horseback riding, ROCKCL is rock climbing, GENREC is general recreation (defined as a composite of recreation activity opportunities at a site), and OTHERREC is other recreation (for sites with recreation opportunities undefined or obscure—omitted category for recreation activity) [0.015, 0.12][a]

[a]Mean and standard deviation for omitted categories reported in square brackets; N = 701.

tested in developing a meta regression analysis benefit transfer function. The majority of the variables are qualitative dummy variables coded as 0 or 1, where 0 means the study does not have a characteristic and 1 means that it does. For example, if a study was conducted on a lake in New York, then R9 and LAKE would be coded as 1 while all other FS regions, FOREST, and RIVER would be coded as 0. The variables are grouped in table 4 according to whether they are methodological, site, or activity specific variables.

The user population characteristics were rarely reported with the results of a study. Other means for obtaining data on user population characteristics, such as contacting the researchers of the study, were not feasible given the financial and time constraints of the project. We did attempt to proxy user population characteristics by using 1990 U.S. Census average values for income, gender, education, age, and race, for the state in which the study was conducted, but found in preliminary analysis that these proxies were broadly insensitive to differences in benefit measures provided. Using U.S. Census average values at the county level and for the period in which the original study data was collected may be a viable alternative for future investigations. However, the lack of user population characteristics will be an additional limitation on the validity and reliability of the meta analysis function.

The meta analysis model is of the basic form:

$$y_i = \alpha + \beta' x_i + \varepsilon_i, \tag{5}$$

where i indexes each observation, y is the dependent variable (consumer surplus per person per activity day adjusted to 1996 dollars), α and β are parameters to be estimated and are respectively the intercept and slope coefficients for the model, x is a matrix of explanatory variables including methodology, site, and activity characteristics, and e is the classical error term with mean zero and variance σ^2_ε.

Some of the studies are not included in the meta analysis because of the lack of reporting of key information that would enable their full coding. Therefore, the meta analysis database consists of 701 estimates from 131 separate studies. The number of estimates per study ranged from 1 to 134. As identified in previous meta-analyses, the panel nature of the data can lead to econometric problems. If there is correlation among these multiple observations for each study, then a classical ordinary least-squares regression will be inefficient and inconsistent in estimated parameters. We tested for panel effects using various forms of stratifying the data (including the most obvious stratification by study) (Rosenberger and Loomis 2000). However, panel effects were not discernible with these tests. Therefore, we use classical ordinary least-squares with the robust Newey-West version of White's consistent covariance estimator to estimate the model (Smith and Kaoru 1990; Driscoll and Kraay 1998).

There is no precedent for choice of functional form when conducting meta-analyses. The functional form of the meta analysis models are linear in the dependent variable and the quantitatively defined variables, with the majority of the variables being qualitative dummy variables as previously noted. We tested and rejected logarithmic transformations of the quantitatively defined variables, finding the linear specification to be most efficient.

The meta analysis benefit transfer model (table 5) was optimized by retaining only those variables that were significant at an 80% level of confidence or better based on t-statistics. This optimization is necessary in order to reduce over-specification of the model when retaining variables whose coefficients are not significantly different than zero. A backward elimination procedure was used to optimize the benefit transfer model. The procedure began with the full specification of the model using all coded variables and sequentially eliminated the least significant variable until all remaining variables are significant at the 80% confidence level or better ($p = 0.20$).

The meta analysis benefit transfer model (table 5) has an adjusted R^2 of 0.27, meaning that 27% of the variance in the benefit measures is explained by the model. This is consistent with other meta analyses of recreation valuation studies (Walsh and others 1992; Smith and Kaoru 1990). A full meta regression analysis of the data investigating methodological, site, and activity factor effects and other nuances of the data can be found in Rosenberger and others (unpublished paper). Both models (the full and optimized meta regression models) have a standard error of 1.22, which means that at a 95% confidence limit they have a 7% margin of error in prediction.

For the most part, the signs of the methodology variables are consistent with past scientific results. *METHOD* is negative, meaning that stated preference (SP) methods yield lower benefit estimates than revealed preference (RP) methods, which is consistent with previous meta analysis results (Walsh and others 1992) and the bulk of travel cost / contingent valuation comparison studies (Carson and others 1996). Open-ended (*OE*), iterative bidding (*ITBID*), combined stated and revealed preference (*SPRP*), payment card (*PAYCARD*), and conjoint analysis (*CONJOINT*) contingent valuation elicitation techniques tend to further increase the difference between SP and RP value estimates, which is consistent with comparison studies (Brown and others 1996). For RP estimates, individual and zonal travel cost methods (*INDIVID* and *ZONAL*, respectively) and random utility models (*RUM*) produce relatively lower benefit estimates than hedonic property and travel cost methods (*HEDONIC*). The inclusion of substitute sites in a demand model (*SUBS*) lowers the benefit estimate (Rosenthal 1987). The use of phone surveys (*PHONE*) yields lower benefit estimates than either in-person or mail surveys. *VALUNIT* is negative, suggesting that if the original study estimated benefits in units such as per trip or per season, then this tended to yield higher per day estimates than those already reported in activity day units. Therefore, either (1) there may be a recall bias introduced when requesting values per trip, season, or year as compared to per day estimates, (2) per day estimates understate the total trip or season value when aggregated, or (3) our estimate of number of days per trip or season are understated. The *TREND* variable shows that benefit estimates generally have been increasing at a greater

**Variable is statistically significant at the $p < 0.05$ level or better. Overall margin of error is ±7% based on a standard error of 1.22 and 95% confidence limits.*

[a]Standard errors are corrected for heteroskedasticity and serial correlation using the robust Newey-West version of White's covariance consistent estimator and 11 periods (Smith and Karou 1990; Driscoll and Kraay 1998).

rate than inflation over time, or annually about one dollar per activity day per person.

USDA Forest Service administered sites (*FSADMIN*) yield lower benefit estimates. These sites, however, are juxtaposed to sites designated to be of higher quality (e.g., National Parks, State Parks, and National Wildlife Refuges). Therefore, it is plausible that USDA Forest Service sites would have somewhat lower recreation value than these other sites. Relatively speaking, estimates for recreation activities for Forest Service regions 1 and 4 are higher, while estimates for Forest Service regions 6 and 8 are lower than the composite base of the remaining estimates for other regions, the nation, and Canada.

LAKE has a negative sign, meaning that lake recreation has lower values than recreation activities in bays/oceans. This makes more sense when we consider that reservoirs were coded as lakes in this analysis. River recreation (*RIVER*) yields higher values than bay/ocean recreation. Estimates for recreation activities on forested lands (*FOREST*) are lower than bay/ocean recreation estimates, which is consistent with the *FSADMIN* variable. *PUBLIC* lands provide higher valued recreation than private areas, in general. One possible explanation is that private areas charge substantially more for access and onsite facilities and services than public areas. Therefore, private areas extract some of the consumer surplus from visitors, while visitors to public areas are charged much lower prices, retaining most of their consumer surplus (figure 2).

The recreation activities significant in the model are self-explanatory. Some activities (*SWIM, OFFRD, BIKE, XSKI, SNOWMOB*) provide relatively lower benefits than the composite recreation activity (composed of all omitted or insignificant activity variables), while other activities (*NOMTRBT, BGHUNT, WATFOWL, FISH, ROCKCL*) yield relatively higher values.

Variables that were tested but not found significant in the national meta analysis benefit transfer model are listed in figure 7. Any variables definitive of the user populations are necessarily left out of the model due to the lack of data.

Convergent validity of meta analysis benefit transfer model

We tested the meta analysis benefit function model for in-sample convergent validity. That is, we tested the accuracy of the benefit function model in forecasting the raw average values for each activity in all regions where data existed. We found the model performed well. While the forecast values ranged from 73% to 319% of the raw average values, the median difference was only 1%. The model forecasted within 50% of the raw average values primarily for those activities with a relatively large amount of data (*BGHUNT, FISH, WLVIEW*). Conversely, the model forecasted in excess of 100% difference from the raw average values for activities with relatively little data (*SWIM, NOMTRBT, MTRBOAT, XSKI, GENREC*).

We also tested regional models based on assessment region aggregation of the data and use of national mean values versus RPA assessment region mean values for adaptation of the models when forecasting regional average values (Rosenberger and Loomis 2000). The national model we are presenting is more robust to different adaptations of the model than all other models tested.

Example of a meta analysis benefit function transfer. The meta regression analysis benefit function is derived from information on all studies in the database. Theoretically, if a factor is significant in explaining the variation in outdoor recreation benefit measures, then the variable reflecting this factor will be significant in the model (table 5). As stated earlier, the overall model performance results in a grand mean ±7% margin of error. Thus, the meta regression

VARIABLES INSIGNIFICANT IN META ANALYSIS MODEL

analysis model provides more robust estimates than an average value transfer (table 3 confidence range).

The application of the meta analysis benefit function can provide three different measures of the benefit of mountain biking (forecast national and regional average values—table 6; and policy site specific forecast average value). However, it should be noted that the data behind the meta analysis is mostly not specific to mountain biking. Therefore, each of the values forecast is really an estimate for a generic biking activity. Many of the estimates that are provided in table 6 are the same. This is due to the lack of any statistically discovered variability across these activities (i.e., the activity-specific variable was not significant in the optimized national model [figure 7]).

Each of the three benefit measures forecast from the meta analysis function differ by degree of specificity to the policy site. The adaptation of the meta analysis function is essentially to substitute relevant values for the independent variables in the regression model, which then forecasts a benefit measure based on the specificity of these variable values. The specificity of each benefit measure will be identified as each of the measures is presented.

The first measure forecasted from the meta analysis function is the national average value. In table 6, this is the measure reported for the United States in the last column. For biking, this forecast value is $15.27 with a 95% confidence range of $14.20 to $16.34. The meta analysis function was adapted by holding all independent or explanatory variables constant at their national mean values (last column, table 5), with the exception of the activity variables. This means that each coefficient is multiplied by the relevant national mean value for each variable, providing the incremental consumer surplus due to that variable. In the case of biking, the variable BIKE was set at 1, while all other activity variables were set to 0. This adapts the function to

Table 6. Forecasted average values using meta analysis benefit function[a].

Activity	Northeast Area[b]	Southeast Area[b]	Intermountain Area[b]	Pacific Coast Area[b]	Alaska[b]	United States

Rock climbing	91.98	86.85	96.21	86.56	91.98	91.60
General recreation[d]	29.95	24.82	34.18	24.53	29.95	29.57
Other recreation[e]	29.95	24.82	34.18	24.53	29.95	29.57

[a]Benefit estimates are calculated from the meta analysis benefit function by holding each variable constant at its mean value except for regional and activity specific variables, which are either turned on (1) or off (0) where relevant. For the United States average value forecast, all variables are held at their national mean value except for activity variables.

[b]Forest Service Regions per area are: Northeast Area = R9; Southeast Area = R8; Intermountain Area = R1, R2, R3, R4; Pacific Coast Area = R5, R6; and Alaskan Area = R10.

[c]Fishing values include different species, different bodies of water, and different angling techniques. The majority of the fishing benefit measures are from studies conducted between 1979 and 1988. Fishing was not a primary target of the literature review since it is the focus of a different project.

[d]General recreation is defined as a composite of recreation opportunities at a site with measure for site, not a specific activity.

[e]Other recreation is defined as sites with recreation opportunities that are undefined or obscure, such as cliff diving and mountain running.

specifically reflect biking at the national level. All incremental consumer surplus values are then summed to provide the estimated consumer surplus for the activity of interest.

The second measure forecasted from the meta analysis function is the regional average value. In table 6, this is the measure reported for the Northeast Area. For biking, this forecast value is $15.64 with a 95% confidence range of $14.55 to $16.73. The meta analysis function was adapted by holding all independent variables at their national mean values (last column, table 5), with the exception of the activity and region variables. In the case of biking, the variable BIKE was set to 1, while all other activity and region variables were set to 0. This adapts the function to specifically reflect biking at the regional level.

The third measure forecasted from the meta analysis function is the average value that is most specific to the policy site. Table 7 shows the adaptation of the function to the policy site. All methodological variables were held at their national mean values (last column, table 5). These variables include *METHOD, DCCVM, OE, ITBID, SPRP, PAYCARD, CONJOINT, PHONE, INDIVID, ZONAL, RUM, SUBS, PHONE*, and *VALUNIT*. *TREND* is set to 30 to reflect 1996 dollars. All Forest Service region variables are set to 0. *FSADMIN* is set to 1 to reflect National Forest land. *LAKE* and *RIVER* are each set to 0, reflecting that the activity and/or policy site does not include a lake or a river, while *FOREST* is set to 1 to reflect a forested setting. *PUBLIC* is set to 1 to reflect that the policy site is on public land. *BIKE* is set to 1 to specify biking as the target activity, while all other activity variables are set to 0. After adapting the model specifically to the policy site, a benefit measure of $4.77 per activity day is forecasted, with a 95% confidence range of $4.44 to $5.10.

Estimates forecast from adapting the meta analysis benefit function at the national, regional, and site-specific levels ranged from about $6 to $16. This range in estimates is based on information from the entire database, including methodological, study site, and activity factors. However, the estimated measures are for a generic bicycling activity. Consumer surplus, or net willingness to pay, from mountain biking at exceptional sites may be significantly larger than this generic value, as evidenced by the measures reported in Fix and Loomis (1998). In addition, not all relevant information about a recreation site is available in the recreation database and therefore is not reflected in the meta analysis benefit function. Because of these two factors, we may conclude that meta analysis forecast values for biking are conservative measures.

Table 7. Example adaptation of meta analysis benefit function for mountain biking.

Variable	Coefficient	Adaptation value	Incremental consumer surplus
Constant	81.273	1	81.27
METHOD	–21.586	0.636	–13.73
DCCVM	–36.981	0.177	–6.54

BGHUNT	15.387	0	0
WATFOWL	9.894	0	0
FISH	7.057	0	0
ROCKCL	62.027	0	0
Total consumer surplus			$4.77

Example application: Summary. Figure 8 provides the different benefit measures derived from applying the various benefit transfer methods. The different measures are relatively consistent, being within a factor or two of each other. This is not surprising given that all of the benefit measures are essentially based on the same data or subsets of data.

Which estimate is best, if any, depends on a number of factors identified earlier. In addition to the factors built into the stock of knowledge concerning recreation use values (e.g., data collection, reporting, study site, methodology), judgments of the benefit transfer

Single point estimate transfer	$17.61 to $62.88
Average value transfer	
National	$45.15
Regional	$34.11
Demand function transfer	$34.25
Meta analysis transfer	
National	$15.27
Regional	$15.64
Site	$4.77

Figure 8. Summary of example benefit transfers.

practitioner can affect overall transfer results. All judgments regarding a benefit transfer framework affect the outcome of the process. Judgments about the policy context frame the entire evaluation process, including what is affected and by how much. Judgments concerning the quality and extent of the scientific body of knowledge can affect the availability of data. Judgments concerning the gathering, coding, and interpretation of data can affect its applicability and relevance to the policy context. And judgments concerning which benefit transfer approach should be used can affect confidence in and credibility of transferred data and policy evaluations. Smith (1992) compares the Luken et al. (1992) and Desvousges et al. (1992) uses of benefit transfer to assess the pulp and paper industry, illustrating the affect researcher judgment can have on policy recommendations.

Recommendations and Guidance to Field Users

We have discussed several different methods to using existing information for benefit transfers when primary research is prohibitive. First, single point estimates or an average of a subset of available point estimates are available through their listing in the annotated bibliography (appendix A). Second, measures of central tendency for recreation activity values provided in table 3 can be transferred to a policy site. Third, a demand or benefit function for a study site can be adapted to the policy site. Fourth, the national values (last column of table 3) can be transferred to a policy site, providing a measure of central tendency for an activity based on all empirical research. However, locational factors are greatly ignored with this approach. Fifth, the meta regression analysis forecasted average values (table 6) can be transferred to a policy site. And sixth, the meta regression analysis benefit transfer function (table 5) can be adapted to specific characteristics of a policy site in order to forecast a site-specific benefit measure for use in evaluating a policy site. Regardless of which method is chosen, the measure(s) transferred have a certain level of confidence surrounding them.

Figure 9 provides a flow chart of the decision process to aid in deriving a benefit measure for recreation. We do not intend to imply that any path in the flow chart is preferred to any other. Instead, the flow chart illustrates possible pathways to determining if and how recreation benefit measures are to be obtained. Depending on the context of the choice among the different methods, one method may be preferable to another. As Desvousges and others (1998) remind us, an important component in any benefit transfer is the involvement and judgment of the transfer practitioner.

The conceptual framework provided in figure 9 shows potential paths to choosing a method for obtaining recreation values when assessing management and policy actions. The first decision to make is whether recreation is affected by the proposed action (figure 9, step I). If recreation is affected, then the second decision is whether the impact on recreation is expected to be major (figure 9, step II). If the impact on recreation is expected to be major, then path A may be followed. If the impact on recreation is expected to be minor, then path B may be preferred. A preliminary benefit transfer could be conducted at this stage to determine the expected magnitude of recreation impacts. A major impact on recreation probably warrants consideration

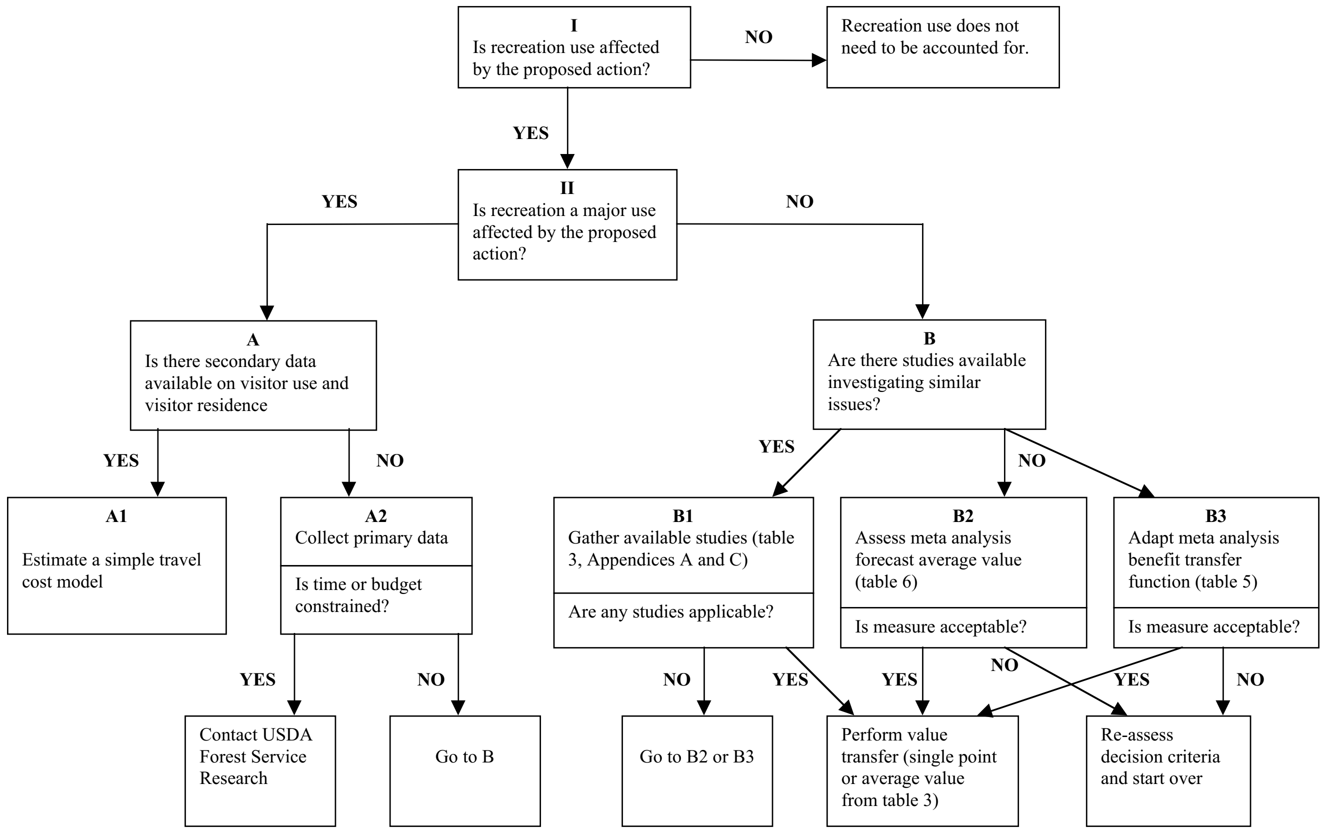

Figure 9. Framework for obtaining benefit measures for recreation.

of doing primary research either through analysis of secondary data (figure 9, step A1) or the collection of original data through survey research (figure 9, step A2). Step A1 is placed prior to step A2 because it typically requires lower budget and time inputs.

Path B would be followed if either of the following conditions exist: (1) the impact on recreation is major, but there is no good secondary data available or budget and time constraints are prohibitive to doing primary research, or (2) the impact on recreation is minor, thus not warranting the expense of primary analysis. Also note, however, that benefit transfers can be as tedious and time consuming as some primary research. A decision criterion for all benefit transfer derived measures is their degree of defensibility in light of political and theoretical feasibility. We cannot determine this feasibility *a priori* since feasibility criteria are specific to the context of the decision.

Following path B in figure 9, the first step is to determine if there are any studies available that resemble the recreation issue at hand. If there are, then these studies should be gathered and filtered for applicability and acceptability of benefit transfer measures (figure 9, step B1; studies can be located through table 3 and appendices A and C). If there are available studies that are applicable and acceptable, then the value transfer can be performed either as a single point estimate or average value transfer (table 3). If there are no studies available or the available studies are not applicable or acceptable, then steps B2 or B3 can be pursued.

In step B2 of figure 9, the forecast average values from the meta regression analysis model (table 6) can be used. If the forecast measure is acceptable, then use this measure for benefit transfer. However, if these values are not acceptable, then step B3 of figure 9 may be pursued. Step B3 adapts the meta regression analysis benefit transfer model (table 5) to a policy site via characteristics specific to that site. One then will have to determine if this tailored benefit measure is acceptable. If the tailored measure is acceptable, then use this measure for benefit transfer. If the measure is not acceptable, we have then exhausted the various sources of benefit measures based on the recreation valuation literature. At this point, one should go back to the beginning and reassess the criteria used in making decisions about the different methods of obtaining benefit measures. This is definitely a judgment call and it may seem that defensibility of an accepted benefit measure will be decreased. However, recall that benefit transfer should be pragmatic in the sense that when benefit measures are sought, tradeoffs are necessary in choosing the best in a "second best" world. A rough estimate of the dollar value of recreation in economic analysis or assessment of planning and policy objectives is better than implying a zero value for recreation by leaving recreation out of the economic model.

RMRS
ROCKY MOUNTAIN RESEARCH STATION

The Rocky Mountain Research Station develops scientific information and technology to improve management, protection, and use of the forests and rangelands. Research is designed to meet the needs of National Forest managers, Federal and State agencies, public and private organizations, academic institutions, industry, and individuals.

Studies accelerate solutions to problems involving ecosystems, range, forests, water, recreation, fire, resource inventory, land reclamation, community sustainability, forest engineering technology, multiple use economics, wildlife and fish habitat, and forest insects and diseases. Studies are conducted cooperatively, and applications may be found worldwide.

About Island Press

Island Press is the only nonprofit organization in the United States whose principal purpose is the publication of books on environmental issues and natural resource management. We provide solutions-oriented information to professionals, public officials, business and community leaders, and concerned citizens who are shaping responses to environmental problems.

In 2005, Island Press celebrates its twenty-first anniversary as the leading provider of timely and practical books that take a multidisciplinary approach to critical environmental concerns. Our growing list of titles reflects our commitment to bringing the best of an expanding body of literature to the environmental community throughout North America and the world.

Support for Island Press is provided by the Agua Fund, The Geraldine R. Dodge Foundation, Doris Duke Charitable Foundation, Ford Foundation, The George Gund Foundation, The William and Flora Hewlett Foundation, Kendeda Sustainability Fund of the Tides Foundation, The Henry Luce Foundation, The John D. and Catherine T. MacArthur Foundation, The Andrew W. Mellon Foundation, The Curtis and Edith Munson Foundation, The New-Land Foundation, The New York Community Trust, Oak Foundation, The Overbrook Foundation, The David and Lucile Packard Foundation, The Winslow Foundation, and other generous donors.

The opinions expressed in this book are those of the authors and do not necessarily reflect the views of these foundations.

Millennium Ecosystem Assessment: Objectives, Focus, and Approach

The Millennium Ecosystem Assessment was carried out between 2001 and 2005 to assess the consequences of ecosystem change for human well-being and to establish the scientific basis for actions needed to enhance the conservation and sustainable use of ecosystems and their contributions to human well-being. The MA responds to government requests for information received through four international conventions—the Convention on Biological Diversity, the United Nations Convention to Combat Desertification, the Ramsar Convention on Wetlands, and the Convention on Migratory Species—and is designed to also meet needs of other stakeholders, including the business community, the health sector, nongovernmental organizations, and indigenous peoples. The sub-global assessments also aimed to meet the needs of users in the regions where they were undertaken.

The assessment focuses on the linkages between ecosystems and human well-being and, in particular, on "ecosystem services." An ecosystem is a dynamic complex of plant, animal, and microorganism communities and the nonliving environment interacting as a functional unit. The MA deals with the full range of ecosystems—from those relatively undisturbed, such as natural forests, to landscapes with mixed patterns of human use and to ecosystems intensively managed and modified by humans, such as agricultural land and urban areas. Ecosystem services are the benefits people obtain from ecosystems. These include *provisioning services* such as food, water, timber, and fiber; *regulating services* that affect climate, floods, disease, wastes, and water quality; *cultural services* that provide recreational, aesthetic, and spiritual benefits; and *supporting services* such as soil formation, photosynthesis, and nutrient cycling. The human species, while buffered against environmental changes by culture and technology, is fundamentally dependent on the flow of ecosystem services.

The MA examines how changes in ecosystem services influence human well-being. Human well-being is assumed to have multiple constituents, including the *basic material for a good life*, such as secure and adequate livelihoods, enough food at all times, shelter, clothing, and access to goods; *health,* including feeling well and having a healthy physical environment, such as clean air and access to clean water; *good social relations,* including social cohesion, mutual respect, and the ability to help others and provide for children; *security,* including secure access to natural and other resources, personal safety, and security from natural and human-made disasters; and *freedom of choice and action,* including the opportunity to achieve what an individual values doing and being. Freedom of choice and action is influenced by other constituents of well-being (as well as by other factors, notably education) and is also a precondition for achieving other components of well-being, particularly with respect to equity and fairness.

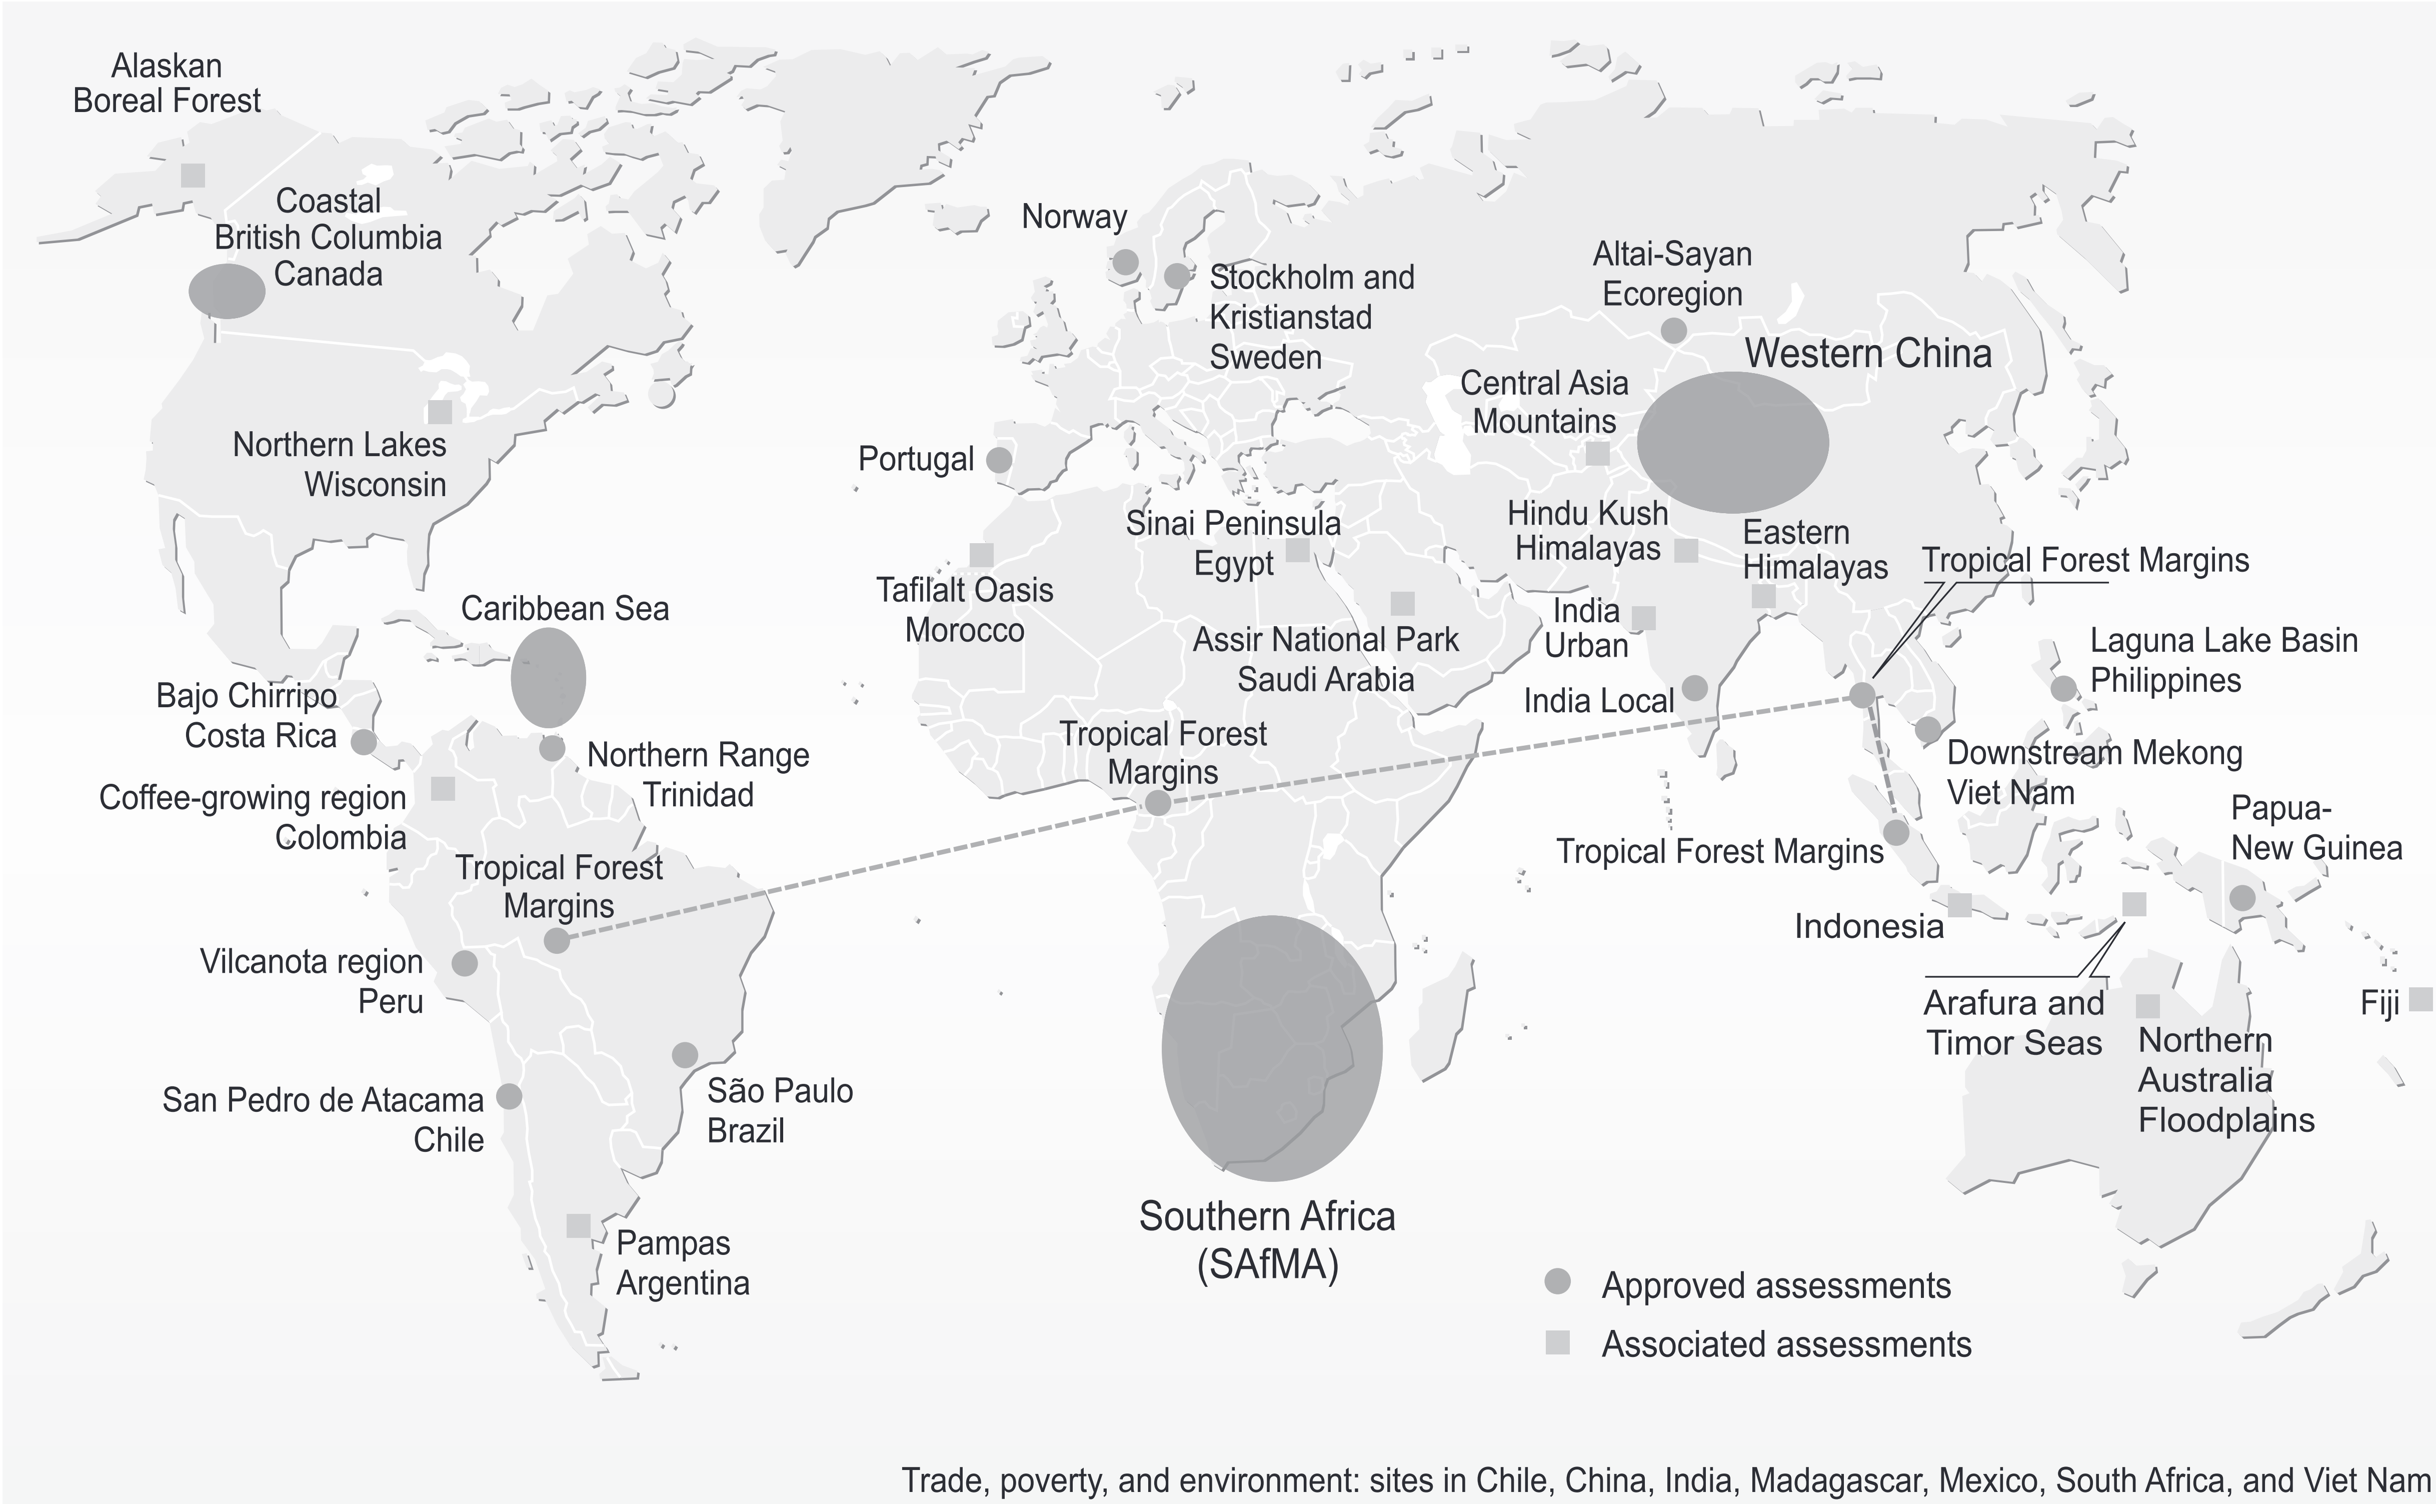
The conceptual framework for the MA posits that people are integral parts of ecosystems and that a dynamic interaction exists between them and other parts of ecosystems, with the changing human condition driving, both directly and indirectly, changes in ecosystems and thereby causing changes in human well-being. At the same time, social, economic, and cultural factors unrelated to ecosystems alter the human condition, and many natural forces influence ecosystems. Although the MA emphasizes the linkages between ecosystems and human well-being, it recognizes that the actions people take that influence ecosystems result not just from concern about human well-being but also from considerations of the intrinsic value of species and ecosystems. Intrinsic value is the value of something in and for itself, irrespective of its utility for someone else.

The Millennium Ecosystem Assessment synthesizes information from the scientific literature and relevant peer-reviewed datasets and models. It incorporates knowledge held by the private sector, practitioners, local communities, and indigenous peoples. The MA did not aim to generate new primary knowledge but instead sought to add value to existing information by collating, evaluating, summarizing, interpreting, and communicating it in a useful form. Assessments like this one apply the judgment of experts to existing knowledge to provide scientifically credible answers to policy-relevant questions. The focus on policy-relevant questions and the explicit use of expert judgment distinguish this type of assessment from a scientific review.

Five overarching questions, along with more detailed lists of user needs developed through discussions with stakeholders or provided by governments through international conventions, guided the issues that were assessed:

- What are the current condition and trends of ecosystems, ecosystem services, and human well-being?
- What are plausible future changes in ecosystems and their ecosystem services and the consequent changes in human well-being?
- What can be done to enhance well-being and conserve ecosystems? What are the strengths and weaknesses of response options that can be considered to realize or avoid specific futures?
- What are the key uncertainties that hinder effective decision-making concerning ecosystems?
- What tools and methodologies developed and used in the MA can strengthen capacity to assess ecosystems, the services they provide, their impacts on human well-being, and the strengths and weaknesses of response options?

The MA was conducted as a multiscale assessment, with interlinked assessments undertaken at local, watershed, national, regional, and global scales. A global ecosystem assessment cannot easily meet all the needs of decision-makers at national and sub-national scales because the management of any



Eighteen assessments were approved as components of the MA. Any institution or country was able to undertake an assessment as part of the MA if it agreed to use the MA conceptual framework, to centrally involve the intended users as stakeholders and partners, and to meet a set of procedural requirements related to peer review, metadata, transparency, and intellectual property rights. The MA assessments were largely self-funded, although planning grants and some core grants were provided to support some assessments. The MA also drew on information from 16 other sub-global assessments affiliated with the MA that met a subset of these criteria or were at earlier stages in development.

particular ecosystem must be tailored to the particular characteristics of that ecosystem and to the demands placed on it. However, an assessment focused only on a particular ecosystem or particular nation is insufficient because some processes are global and because local goods, services, matter, and energy are often transferred across regions. Each of the component assessments was guided by the MA conceptual framework and benefited from the presence of assessments undertaken at larger and smaller scales. The sub-global assessments were not intended to serve as representative samples of all ecosystems; rather, they were to meet the needs of decision-makers at the scales at which they were undertaken. The sub-global assessments involved in the MA process are shown in the Figure and the ecosystems and ecosystem services examined in these assessments are shown in the Table.

The work of the MA was conducted through four working groups, each of which prepared a report of its findings. At the global scale, the Condition and Trends Working Group assessed the state of knowledge on ecosystems, drivers of ecosystem change, ecosystem services, and associated human well-being around the year 2000. The assessment aimed to be comprehensive with regard to ecosystem services, but its coverage is not exhaustive. The Scenarios Working Group considered the possible evolution of ecosystem services during the twenty-first century by developing four global scenarios exploring plausible future changes in drivers, ecosystems, ecosystem services, and human well-being. The Responses Working Group examined the strengths and weaknesses of various response options that have been used to manage ecosystem services and identified promising opportunities for improving human well-being while conserving ecosystems. The report of the Sub-global Assessments Working Group contains lessons learned from the MA sub-global assessments. The first product of the MA—*Ecosystems and Human Well-being: A Framework for Assessment,* published in 2003—outlined the focus, conceptual basis, and methods used in the MA. The executive summary of this publication appears as Chapter 1 of this volume.

Approximately 1,360 experts from 95 countries were involved as authors of the assessment reports, as participants in the sub-global assessments, or as members of the Board of Review Editors. The latter group, which involved 80 experts, oversaw the scientific review of the MA reports by governments and experts and ensured that all review comments were appropriately addressed by the authors. All MA findings underwent two rounds of expert and governmental review. Review comments were received from approximately 850 individuals (of which roughly 250 were submitted by authors of other chapters in the MA), although in a number of cases (particularly in the case of governments and MA-affiliated scientific organizations), people submitted collated comments that had been prepared by a number of reviewers in their governments or institutions.

The MA was guided by a Board that included representatives of five international conventions, five U.N. agencies, international scientific organizations, governments, and leaders from the private sector, nongovernmental organizations, and indigenous groups. A 15-member Assessment Panel of leading social and natural scientists oversaw the technical work of the assessment, supported by a secretariat with offices in Europe, North America, South America, Asia, and Africa and coordinated by the United Nations Environment Programme.

The MA is intended to be used:

- to identify priorities for action;
- as a benchmark for future assessments;
- as a framework and source of tools for assessment, planning, and management;
- to gain foresight concerning the consequences of decisions affecting ecosystems;
- to identify response options to achieve human development and sustainability goals;
- to help build individual and institutional capacity to undertake integrated ecosystem assessments and act on the findings; and
- to guide future research.

Because of the broad scope of the MA and the complexity of the interactions between social and natural systems, it proved to be difficult to provide definitive information for some of the issues addressed in the MA. Relatively few ecosystem services have been the focus of research and monitoring and, as a consequence, research findings and data are often inadequate for a detailed global assessment. Moreover, the data and information that are available are generally related to either the characteristics of the ecological system or the characteristics of the social system, not to the all-important interactions between these systems. Finally, the scientific and assessment tools and models available to undertake a cross-scale integrated assessment and to project future changes in ecosystem services are only now being developed. Despite these challenges, the MA was able to provide considerable information relevant to most of the focal questions. And by identifying gaps in data and information that prevent policy-relevant questions from being answered, the assessment can help to guide research and monitoring that may allow those questions to be answered in future assessments.

Contents

Foreword

The Millennium Ecosystem Assessment was called for by United Nations Secretary-General Kofi Annan in 2000 in his report to the UN General Assembly, *We the Peoples: The Role of the United Nations in the 21st Century.* Governments subsequently supported the establishment of the assessment through decisions taken by three international conventions, and the MA was initiated in 2001. The MA was conducted under the auspices of the United Nations, with the secretariat coordinated by the United Nations Environment Programme, and it was governed by a multistakeholder board that included representatives of international institutions, governments, business, NGOs, and indigenous peoples. The objective of the MA was to assess the consequences of ecosystem change for human well-being and to establish the scientific basis for actions needed to enhance the conservation and sustainable use of ecosystems and their contributions to human well-being.

This volume has been produced by the MA Condition and Trends Working Group and assesses the state of knowledge on ecosystems and their services, the drivers of ecosystem change, and the consequences of ecosystem change for human well-being. The material in this report has undergone two extensive rounds of peer review by experts and governments, overseen by an independent Board of Review Editors.

This is one of four volumes (*Current State and Trends, Scenarios, Policy Responses,* and *Multiscale Assessments*) that present the technical findings of the Assessment. Six synthesis reports have also been published: one for a general audience and others focused on issues of biodiversity, wetlands and water, desertification, health, and business and ecosystems. These synthesis reports were prepared for decision-makers in these different sectors, and they synthesize and integrate findings from across all of the Working Groups for ease of use by those audiences.

This report and the other three technical volumes provide a unique foundation of knowledge concerning human dependence on ecosystems as we enter the twenty-first century. Never before has such a holistic assessment been conducted that addresses multiple environmental changes, multiple drivers, and multiple linkages to human well-being. Collectively, these reports reveal both the extraordinary success that humanity has achieved in shaping ecosystems to meet the needs of growing populations and economies and the growing costs associated with many of these changes. They show us that these costs could grow substantially in the future, but also that there are actions within reach that could dramatically enhance both human well-being and the conservation of ecosystems.

A more exhaustive set of acknowledgments appears later in this volume but we want to express our gratitude to the members of the MA Board, Board Alternates, Exploratory Steering Committee, Assessment Panel, Coordinating Lead Authors, Lead Authors, Contributing Authors, Board of Review Editors, and Expert Reviewers for their extraordinary contributions to this process. (The list of reviewers is available at www.MAweb.org.) We also would like to thank the MA Secretariat and in particular the staff of the Condition and Trends Working Group Technical Support Unit for their dedication in coordinating the production of this volume, as well as the World Conservation Monitoring Centre, which housed this TSU.

We would particularly like to thank the Co-chairs of the Condition and Trends Working Group, Dr. Rashid Hassan and Dr. Robert Scholes, and the TSU Coordinator, Neville Ash, for their skillful leadership of this Working Group and their contributions to the overall assessment.

Preface

The *Current State and Trends* assessment presents the findings of the Condition and Trends Working Group of the Millennium Ecosystem Assessment. This volume documents the current condition and recent trends of the world's ecosystems, the services they provide, and associated human well-being around the year 2000. Its primary goal is to provide decision-makers, ecosystem managers, and other potential users with objective information and analyses of historical trends and dynamics of the interaction between ecosystem change and human well-being. This assessment establishes a baseline for the current condition of ecosystems at the turn of the millennium. It also assesses how changes in ecosystems have affected the underlying capacity of ecosystems to continue to provide these services in the near future, providing a link to the Scenarios Working Group's report. Finally, it considers recent trends in ecosystem conditions that have been the result of historical responses to ecosystem service problems, providing a link to the Responses Working Group's report.

Although centered on the year 2000, the temporal scope of this assessment includes the ''relevant past'' to the ''foreseeable future.'' In practice, this means analyzing trends during the latter decades of the twentieth century and extrapolating them forward for a decade or two into the twenty-first century. At the point where the projections become too uncertain to be sustained, the Scenarios Working Group takes over the exploration of alternate futures.

The Condition and Trends assessment aims to synthesize and add to information already available from other sources, whether in the primary scientific literature or already in assessment form. In many instances this information is not reproduced in this volume but is built upon to report additional findings here. So this volume does not, for example, provide an assessment of the science of climate change per se, as that is reported in the findings of the Intergovernmental Panel on Climate Change, but the findings of the IPCC are used here as a basis to present information on the consequences of climate change for ecosystem services.

A summary of the process leading to this document is provided in Figure A.

The document has three main parts plus a synthesis chapter and supporting material. (See Figure B.) After the introductory material in Part I, the findings from the technical assessments are presented in two orthogonal ways: Part II deals with individual categories of ecosystem services, viewed across all the ecosystem types from which they are derived, while Part III analyses the various systems from which bundles of services are derived. Such organization allows the chapters to be read as standalone documents and assists readers with thematic interests. In Part IV, the synthesis chapter pulls out the key threads of findings from the earlier parts to construct an integrated narrative of the key issues relating ecosystem change (through changes in ecosystem services) to impacts on human well-being.

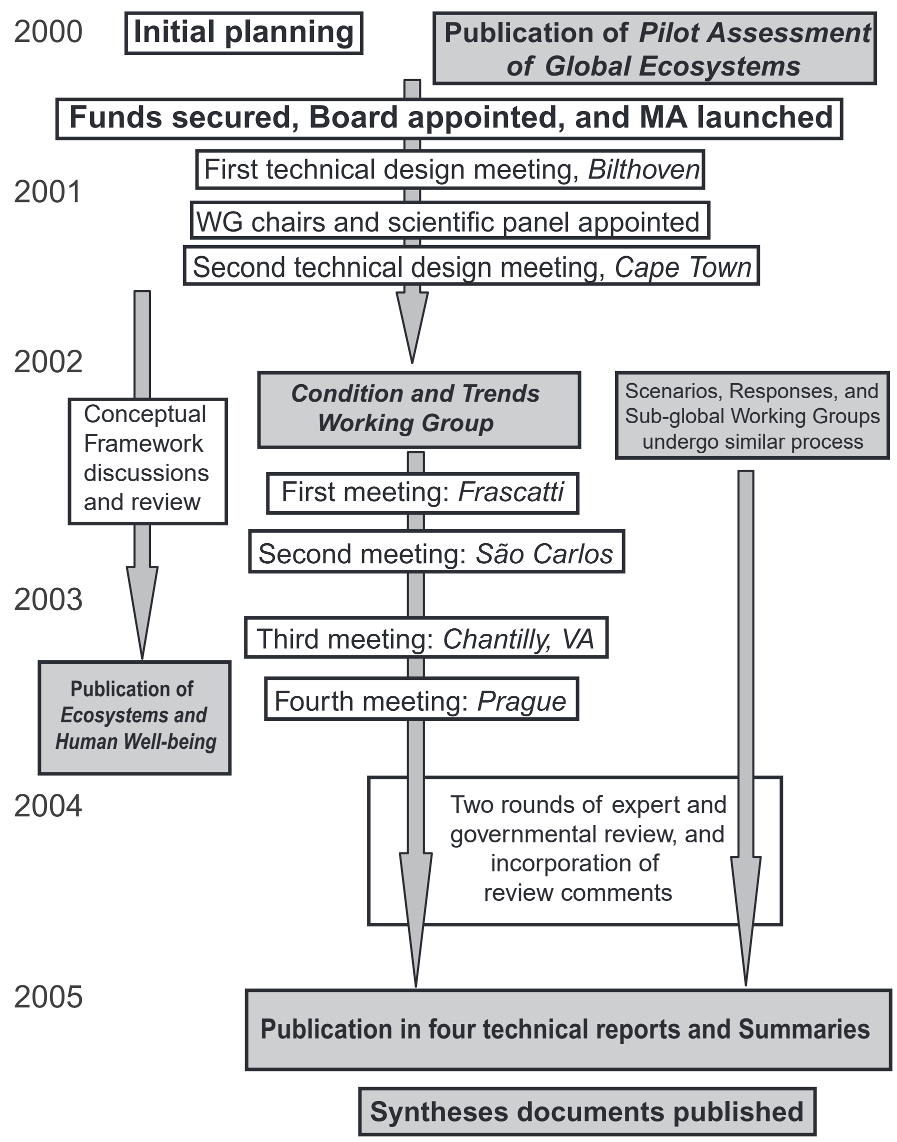

Figure A. Schedule of the Condition and Trends Working Group Assessment

Appendices provide an extensive glossary of terms, abbreviations, and acronyms; information on authors; and color graphics.

Part I: General Concepts and Analytical Approaches

The first part of this report introduces the overarching conceptual, methodological, and crosscutting themes of the MA integrated approach, and for this reason it precedes the technical assessment parts. Following the executive summary of the MA conceptual framework volume (*Ecosystems and Human Well-being: A Framework for Assessment*), which is **Chapter 1,** the analytical approaches to a global assessment of ecosystems and ecosystem services are outlined in **Chapter 2. Chapter 3** provides a summary assessment of the most important changes in key indirect and direct drivers of ecosystem change over the last part of the

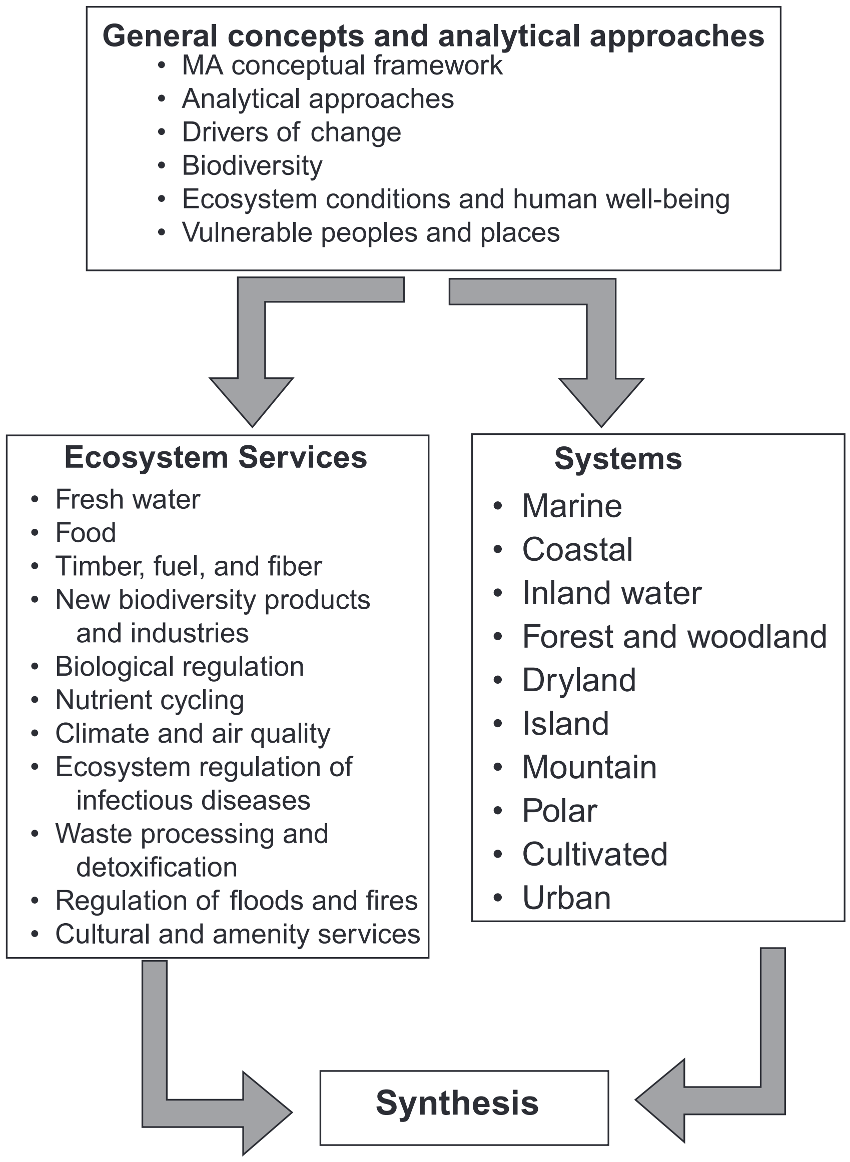

Figure B. Structure of the Condition and Trends Working Group Assessment Report

twentieth century, and considers some of the key interactions between these drivers (the full assessment of drivers, of which this chapter is a summary, can be found in the *Scenarios* volume, Chapter 7). The remaining chapters in Part I—on biodiversity (**Chapter 4**), human well-being (**Chapter 5**), and vulnerability (**Chapter 6**)—introduce issues at a global scale but also contain a synthesis of material drawn from chapters in Parts II and III.

Each of these introductory overarching chapters aims to deal with the general issues related to its topic, leaving the specifics embedded in later chapters. This is intended to enhance readability and to help reduce redundancy across the volume. For example, **Chapter 2** seeks to give an overview of the types of analytical approaches and methods used in the assessment, but not provide a recipe for conducting specific assessments, and **Chapter 3** aims to provide the background to the various drivers that would otherwise need to be discussed in multiple subsequent chapters.

Biodiversity provides composition, structure, and function to ecosystems. The amount and diversity of life is an underlying necessity for the provision of all ecosystem services, and for this reason **Chapter 4** is included in the introductory section rather than as a chapter in the part on ecosystem services. It outlines the key global trends in biodiversity, our state of knowledge on biodiversity in terms of abundance and distribution, and the role of biodiversity in the functioning of ecosystems. Later chapters consider more fully the role of biodiversity in the provision of ecosystem services.

The consequences of ecosystem change for human well-being are the core subject of the MA. **Chapter 5** presents our state of knowledge on the links between ecosystems and human well-being and outlines the broad patterns in well-being around the world.

Neither the distribution of ecosystem services nor the change in these services is evenly distributed across places and societies. Certain ecosystems, locations, and people are more at risk from changes in the supply of services than others. **Chapter 6,** on vulnerable peoples and places, identifies these locations and groups and examines why they are particularly vulnerable to changes in ecosystems and ecosystem services.

Part II: An Assessment of Ecosystem Services

The Condition and Trends assessment sets out to be comprehensive in its treatment of ecosystem services but not exhaustive. The list of "benefits that people derive from ecosystems" grows continuously with further investigation. The 11 groups of services covered by this assessment deal with issues that are of vital importance almost everywhere in the world and represent, in the opinion of the Working Group, the main services that are most important for human well-being and are most affected by changes in ecosystem conditions. The MA only considers ecosystem services that have a nexus with life on Earth (biodiversity). For example, while gemstones and tidal energy can both provide benefits to people, and both are found within ecosystems, they are not addressed in this report since their generation does not depend on the presence of living organisms. The ecosystem services assessed and the chapter titles in this part are:

Provisioning services:
- Fresh Water
- Food
- Timber, Fiber, and Fuel
- New Products and Industries from Biodiversity

Regulating and supporting services:
- Biological Regulation of Ecosystem Services
- Nutrient Cycling
- Climate and Air Quality
- Human Health: Ecosystem Regulation of Infectious Diseases
- Waste Processing and Detoxification
- Regulation of Natural Hazards: Floods and Fires

Cultural services:
- Cultural and Amenity Services

Each of the chapters in this section in fact deals with a cluster of several related ecosystem services. For instance, the chapter on food covers the provision of numerous cereal crops, vegetables and fruits, beverages, livestock, fish, and other edible products; the chapter on nutrient cycling addresses the benefits derived from a range of nutrient cycles, but with a focus on nitrogen; and the chapter on cultural and amenity services covers a range of such services, including recreation, aesthetic, and spiritual services. The length of the treatment afforded to each service reflects several factors: our assessment of its relative importance to human well-being; the scope and complexity of the topic; the degree to which it has been treated in other assessments (thus reducing the need for a comprehensive treatment here); and the amount of information that is available to be assessed.

Part II considers services from each of the four MA categories: provisioning, regulating, cultural, and supporting services. Each service chapter has been developed to cover the same types of information. First the service is defined. Then, for each service, the spatial distribution of supply and demand is quantified, along with recent trends. The direct and indirect drivers of change in the service are analyzed. And finally the consequences of the changes in the service for human well-being are examined and quantified to the degree possible.

Examples are given of the responses by decision-makers at various levels (from the individual to the international) to issues relating to change in service supply. Both successful and unsuccessful interventions are described, as supportive material for the *Policy Responses* volume.

Part III: An Assessment of Systems from which Ecosystem Services Are Derived

The Condition and Trends Working Group uses the term ''systems'' in describing these chapters rather than the term ''ecosystems.'' This is for several reasons. First, the ''systems'' used are essentially reporting units, defined for pragmatic reasons. They represent easily recognizable broad categories of landscape or seascape, with their included human systems, and typically represent units or themes of management or intervention interest. Ecosystems, on the other hand, are theoretically defined by the interactions of their components.

The 10 selected systems assessed here cover much larger areas than most ecosystems in the strict sense and include areas of system type that are far apart (even isolated) and that thus interact only weakly. In fact, there may be stronger local interactions with embedded fragments of ecosystems of a different type rather than within the nominal type of the system. The ''cultivated system,'' for instance, considers a landscape where crop farming is a primary activity but that probably includes, as an integral part of that system, patches of rangeland, forest, water, and human settlements.

Second, while it is recognized that humans are always part of ecosystems, the definitions of the systems used in this report take special note of the main patterns of human use. The systems are defined around the main bundles of services they typically supply and the nature of the impacts that human use has on those services.

Information within the systems chapters is frequently presented by subsystems where appropriate. For example, the forest chapter deals separately with tropical, temperate, and boreal forests because they deliver different services; likewise, the coastal chapter deals explicitly with various coastal subsystems, such as mangroves, corals, and seagrasses.

The 10 system categories and the chapter titles in this part are:

- Marine Fisheries Systems
- Coastal Systems
- Inland Water Systems
- Forest and Woodland Systems
- Dryland Systems
- Island Systems
- Mountain Systems
- Polar Systems
- Cultivated Systems
- Urban Systems

Definitions for these system categories can be found in Box 1.3 in Chapter 1. These system categories are not mutually exclusive, and some overlap spatially. For instance, mountain systems contain areas of forest systems, dryland systems, inland water systems, cultivated systems, and urban systems, while coastal systems include components of all of the above, including mountain systems. Due to this overlap, simple summations of services across systems for global totals should be avoided (an exercise that the MA has avoided in general): some may be double-counted, while others may be underrepresented. Notwithstanding these caveats, the systems have been defined to cover most of the Earth's surface and not to overlap unnecessarily. In many instances the boundaries between systems are diffuse, but not arbitrary. For instance, the coastal system blends seamlessly into the marine system on the one hand and the land systems on the other. The 50-meter depth distinction between coastal and marine separates the systems strongly influenced by actions on the land from those overwhelmingly influenced by fishing. There is significant variation in the area of coverage of each system.

The system definitions are also not exhaustive, and no attempt has been made to cover every part of the global surface. Although ~99% of global surface area has been covered in this assessment, there are just over 5 million square kilometers of terrestrial land surface not included spatially within any of the MA system boundaries. These areas are generally found within grassland, savanna, and forest biomes, and they contain a mix of land cover classes—generally grasslands, degraded forests, and marginal agricultural lands—that are not picked up within the mapping definitions for the system boundaries. However, while these excluded areas may not appear in the various statistics produced along system boundaries, the issues occurring in these areas relating to ecosystem services are well covered in the various services chapters, which do not exclude areas of provision outside MA system boundaries.

The main motivation for dealing with ''systems'' as well as ''services'' is that the former perspective allows us to examine interactions between the services delivered from a single location. These interactions can take the form of trade-offs (that is, where promoting one service reduces the supply of another service), win-win situations (where a single management package enhances the supply of several services), or synergies, where the simultaneous use of services raises or depresses both more than if they were independently used.

The chapters in Part III all present information in a broadly similar manner: system description, including a map and descriptive statistics for the system and its subsystems; quantification of the services it delivers and their contribution to well-being; recent trends in the condition of the system and its capacity to provide services; processes leading to changes in the system; the choices and resultant trade-offs between systems and between services within the system; and the contributions of the system to human well-being.

Part IV: Synthesis

Chapter 28 does not intend to be a summary. That task is left to the summaries or Main Messages of each chapter and to the Summary at the start of this volume. Instead, the synthesis chapter constructs an integrated narrative, tracing the principal causes of ecosystem change, the consequences for ecosystems and ecosystem services, and the resultant main impacts on human well-being. The chapter considers the key intellectual issues arising from the Condition and Trends assessment and presents an assessment of our underlying knowledge on the consequences of ecosystem change for people.

Supporting material for many of the chapters, and further details of the Millennium Ecosystem Assessment, including of the various sub-global assessments, plus a full list of reviewers, can be found at the MA Web site at www.MAweb.org.

Acknowledgments

First and foremost, we would like to thank the MA Condition and Trends Working Group for their hard work, and for all the stimulating discussions we had over the course of the project. Special thanks are also due to the MA Secretariat staff who worked tirelessly on this project:

Walter V. Reid—Director

Administration
Nicole Khi—Program Coordinator
Chan Wai Leng—Program Coordinator
Belinda Lim—Administrative Officer
Tasha Merican—Program Coordinator

Sub-Global
Marcus J. Lee—Technical Support Unit Coordinator and MA Deputy Director
Ciara Raudsepp-Hearne—TSU Coordinator

Condition and Trends
Neville J. Ash—TSU Coordinator
Dalène du Plessis—Program Assistant
Mampiti Matete—TSU Coordinator

Scenarios
Elena Bennett—TSU Coordinator
Veronique Plocq-Fichelet—Program Administrator
Monika B. Zurek—TSU Coordinator

Responses
Pushpam Kumar—TSU Coordinator
Meenakshi Rathore—Program Coordinator
Henk Simons—TSU Coordinator

Engagement and Outreach
Christine Jalleh—Communications Officer
Nicolas Lucas—Engagement and Outreach Director
Valerie Thompson—Associate

Other Staff
John Ehrmann—Lead Facilitator
Keisha-Maria Garcia—Research Assistant
Lori Han—Publications Manager
Sara Suriani—Conference Manager
Jillian Thonell—Data Coordinator

Interns
Emily Cooper, Elizabeth Wilson, Lina Cimarrusti

We would like to acknowledge the contributions of all of the authors of this book, and the support provided by their institutions that enabled their participation. We would like to thank the host organizations of the MA Technical Support Units—WorldFish Center (Malaysia); UNEP-World Conservation Monitoring Centre (United Kingdom); Institute of Economic Growth (India); National Institute of Public Health and the Environment (Netherlands); University of Pretoria (South Africa), U.N. Food and Agriculture Organization; World Resources Institute, Meridian Institute, and Center for Limnology of the University of Wisconsin-Madison (all in the United States); Scientific Committee on Problems of the Environment (France); and International Maize and Wheat Improvement Center (Mexico)—for the support they provided to the process.

We thank several individuals who played particularly critical roles: Linda Starke, Nigel Varty, and Lynn Newton for editing the report; Hyacinth Billings and Caroline Taylor for providing invaluable advice on the publication process; Maggie Powell for preparing the page design and all the Figures and Tables; Elizabeth Wilson for helping to proof the Figures and Tables; Carol Inskipp and Gill Bunting for checking chapter citations and references; and Ian May, Corinna Ravilious, and Simon Blythe for the preparation of numerous graphics and GIS-derived statistics. And we thank the other MA volunteers, the administrative staff of the host organizations, and colleagues in other organizations who were instrumental in facilitating the process: Mariana Sanchez Abregu, Isabelle Alegre, Adlai Amor, Emmanuelle Bournay, Herbert Caudill, Habiba Gitay, Helen Gray, Sherry Heileman, Norbert Henninger, Toshi Honda, Francisco Ingouville, Timothy Johnson, Humphrey Kagunda, Brygida Kubiak, Nicolas Lapham, Liz Levitt, Elaine Marshall, Christian Marx, Stephanie Moore, John Mukoza, Arivudai Nambi, Laurie Neville, Adrian Newton, Carolina Katz Reid, Liana Reilly, Philippe Rekacewicz, Carol Rosen, Anne Schram, Jeanne Sedgwick, Tang Siang Nee, Darrell Taylor, Tutti Tischler, Dan Tunstall, Woody Turner, Mark Valentine, Gillian Warltier, Elsie Vélez Whited, Kaveh Zahedi, and Mark Zimsky.

For technical assistance with figures and references in Chapter 13, we thank Natalia Ungelenk and Silvana Schott, and for their work in developing, applying, and constructing tables from the Gridded Rural-Urban Mapping Project, which was used not only in Chapter 27 but in several others as well, we would like to thank Francesca Pozzi, Greg Booma, Adam Storeygard, Bridget Anderson, Greg Yetman, and Lisa Lukang. Kai Lee, Terry McGee, and Priscilla Connolly deserve special mention for their review of Chapter 27, as does Maria Furhacker for her review of Chapter 15.

We thank the members of the MA Board and its chairs, Robert Watson and A.H. Zakri, the members of the MA Assessment Panel and its chairs, Angela Cropper and Harold Mooney, and the members of the MA Review Board and its chairs, José Sarukhán and Anne Whyte, for their guidance and support for this Working Group. We also thank the current and previous Board Alternates: Ivar Baste, Jeroen Bordewijk, David Cooper, Carlos Corvalan, Nick Davidson, Lyle Glowka, Guo Risheng, Ju Hongbo, Ju Jin, Kagumaho (Bob) Kakuyo, Melinda Kimble, Kanta Kumari, Stephen Lonergan, Charles Ian McNeill, Joseph Kalemani Mulongoy, Ndegwa Ndiang'ui, and Mohamed Maged Younes. We thank the past members of the MA Board whose contributions were instrumental in shaping the MA focus and process, including Philbert Brown, Gisbert Glaser, He Changchui, Richard Helmer, Yolanda Kakabadse, Yoriko Kawaguchi, Ann Kern, Roberto Lenton, Corinne Lepage, Hubert Markl, Arnulf Müller-Helbrecht, Seema Paul, Susan Pineda Mercado, Jan Plesnik, Peter Raven, Cristián Samper, Ola Smith, Dennis Tirpak, Alvaro Umaña, and Meryl Williams. We wish to also thank the members of the Exploratory Steering Committee that designed the MA project in 1999–2000. This group included a number of the current and past Board members, as well as Edward Ayensu, Daniel Claasen, Mark Collins, Andrew Dearing, Louise Fresco, Madhav Gadgil, Habiba Gitay, Zuzana Guziova, Calestous Juma, John Krebs, Jane Lubchenco, Jeffrey McNeely, Ndegwa Ndiang'ui, Janos Pasztor, Prabhu L. Pingali, Per Pinstrup-Andersen, and José Sarukhán. We thank Ian Noble and Mingsarn Kaosa-ard for their contributions as members of the Assessment Panel during 2002.

We would particularly like to acknowledge the input of the hundreds of individuals, institutions, and governments (see list at www.MAweb.org) who reviewed drafts of the MA technical and synthesis reports. We also thank the thousands of researchers whose work is synthesized in this report. And we would like to acknowledge the support and guidance provided by the secretariats and the scientific and technical bodies of the Convention on Biological Diversity, the Ramsar Convention on Wetlands, the Convention to Combat Desertification, and the Convention on Migratory Species, which have helped to define the focus of the MA and of this report.

We also want to acknowledge the support of a large number of nongovernmental organizations and networks around the world that have assisted in outreach efforts: Alexandria University, Argentine Business Council for Sustainable Development, Asociación Ixacavaa (Costa Rica), Arab Media Forum for Environment and Development, Brazilian Business Council on Sustainable Development, Charles University (Czech Republic), Cambridge Conservation Forum, Chinese Academy of Sciences, European Environmental Agency, European Union of Science Journalists' Associations, EIS-Africa (Burkina Faso), Forest Institute of the State of São Paulo, Foro Ecológico (Peru), Fridtjof Nansen Institute (Norway), Fundación Natura (Ecuador), Global Development Learning Network, Indonesian Biodiversity Foundation, Institute for Biodiversity Conservation and Research–Academy of Sciences of Bolivia, International Alliance of Indigenous Peoples of the Tropical Forests, IUCN office in Uzbekistan, IUCN Regional Offices for West Africa and South America, Permanent Inter-States Committee for Drought Control in the Sahel, Peruvian Society of Environmental Law, Probioandes (Peru), Professional Council of Environmental Analysts of Argentina, Regional Center AGRHYMET (Niger), Regional Environmental Centre for Central Asia, Resources and Research for Sustainable Development (Chile), Royal Society (United Kingdom), Stockholm University, Suez Canal University, Terra Nuova (Nicaragua), The Nature Conservancy (United States), United Nations University, University of Chile, University of the Philippines, World Assembly of Youth, World Business Council for Sustainable Development, WWF-Brazil, WWF-Italy, and WWF-US.

We are extremely grateful to the donors that provided major financial support for the MA and the MA Sub-global Assessments: Global Environment Facility; United Nations Foundation; David and Lucile Packard Foundation; World Bank; Consultative Group on International Agricultural Research; United Nations Environment Programme; Government of China; Ministry of Foreign Affairs of the Government of Norway; Kingdom of Saudi Arabia; and the Swedish International Biodiversity Programme. We also thank other organizations that provided financial support: Asia Pacific Network for Global Change Research; Association of Caribbean States; British High Commission, Trinidad & Tobago; Caixa Geral de Depósitos, Portugal; Canadian International Development Agency; Christensen Fund; Cropper Foundation, Environmental Management Authority of Trinidad and Tobago; Ford Foundation; Government of India; International Council for Science; International Development Research Centre; Island Resources Foundation; Japan Ministry of Environment; Laguna Lake Development Authority; Philippine Department of Environment and Natural Resources; Rockefeller Foundation; U.N. Educational, Scientific and Cultural Organization; UNEP Division of Early Warning and Assessment; United Kingdom Department for Environment, Food and Rural Affairs; United States National Aeronautic and Space Administration; and Universidade de Coimbra, Portugal. Generous in-kind support has been provided by many other institutions (a full list is available at www.MAweb.org). The work to establish and design the MA was supported by grants from The Avina Group, The David and Lucile Packard Foundation, Global Environment Facility, Directorate for Nature Management of Norway, Swedish International Development Cooperation Authority, Summit Foundation, UNDP, UNEP, United Nations Foundation, United States Agency for International Development, Wallace Global Fund, and World Bank.

Reader's Guide

The four technical reports present the findings of each of the MA Working Groups: Condition and Trends, Scenarios, Responses, and Sub-global Assessments. A separate volume, *Our Human Planet*, presents the summaries of all four reports in order to offer a concise account of the technical reports for decision-makers. In addition, six synthesis reports were prepared for ease of use by specific audiences: Synthesis (general audience), CBD (biodiversity), UNCCD (desertification), Ramsar Convention (wetlands), business and industry, and the health sector. Each MA sub-global assessment will also produce additional reports to meet the needs of its own audiences.

All printed materials of the assessment, along with core data and a list of reviewers, are available at www.MAweb.org. In this volume, Appendix A contains color maps and figures. Appendix B lists all the authors who contributed to this volume. Appendix C lists the acronyms and abbreviations used in this report and Appendix D is a glossary of terminology used in the technical reports. Throughout this report, dollar signs indicate U.S. dollars and ton means tonne (metric ton). Bracketed references within the Summary are to chapters within this volume.

In this report, the following words have been used where appropriate to indicate judgmental estimates of certainty, based on the collective judgment of the authors, using the observational evidence, modeling results, and theory that they have examined: very certain (98% or greater probability), high certainty (85–98% probability), medium certainty (65%–58% probability), low certainty (52–65% probability), and very uncertain (50–52% probability). In other instances, a qualitative scale to gauge the level of scientific understanding is used: well established, established but incomplete, competing explanations, and speculative. Each time these terms are used they appear in italics.

Ecosystems and Human Well-being: Current State and Trends, Volume 1

Summary: Ecosystems and Their Services around the Year 2000

Core Writing Team: Robert Scholes, Rashid Hassan, Neville J. Ash
Extended Writing Team: Condition and Trends Working Group

CONTENTS

Human Well-being and Life on Earth

- **Human well-being depends, among other things, on the continued supply of services obtained from ecosystems.**
- **Human actions during the last 50 years have altered ecosystems to an extent and degree unprecedented in human history. The consequences for human well-being have been mixed. Health and wealth have, on average, improved, but the benefits are unevenly distributed and further improvement may be limited by an insufficient supply of key ecosystem services.**
- **Biological diversity is a necessary condition for the delivery of all ecosystem services. In most cases, greater biodiversity is associated with a larger or more dependable supply of ecosystem services. Diversity of genes and populations is currently declining in most places in the world, along with the area of near-natural ecosystems.**

Inescapable Link between Ecosystem Condition and Human Well-being

All people depend on the services supplied by ecosystems, either directly or indirectly. Services are delivered both by "near-natural" ecosystems, such as rangelands, oceans, and forests, and by highly managed ecosystems such as cultivated or urban landscapes.

Human well-being, by several measures and on average across and within many societies, has improved substantially over the past two centuries and continues to do so. The human population in general is becoming better nourished. People live longer, and incomes have risen. Political institutions have become more participatory. In part these gains in well-being have been made possible by exploiting certain ecosystem services (the provisioning services, such as timber, grazing, and crop production), sometimes to the detriment of the ecosystem and its underlying capacity to continue to provide these and other services. Some gains have been made possible by the unsustainable use of other resources. For example, the increases in food production have been partly enabled by drawing on the finite supply of fossil fuels, an ecosystem service laid down millions of years ago.

The gains in human well-being are not distributed evenly among individuals or social groups, nor among the countries they live in or the ecosystems of the world. The gap between the advantaged and the disadvantaged is increasing. For example, a child born in sub-Saharan Africa is 20 times more likely to die before age five than a child born in an industrial country, and this ratio is higher than it was a decade ago. People living in urban areas, near coasts, and in systems with high ecosystem productivity in general have above-average well-being. **People living in drylands and mountainous areas, both characterized by lower ecosystem productivity, tend to have below-average, and more variable, well-being.**

Populations are growing faster in ecosystems characterized by low well-being and low ecosystem productivity than in high well-being, high productivity areas. Figure C1, which uses GDP as a proxy for human well-being, illustrates this situation. Trends are similar for other measures of human well-being, such as infant mortality rate. [5, 6, 16, 22]

Many human and ecological systems are under multiple severe and mutually reinforcing stresses. The causes include the direct and indirect impacts of extraction of services themselves, as well as the unintended side effects of other human activities. Certain linked ecological-human systems, by virtue of their structure or location, are more sensitive to stress than others. Examples include freshwater, coastal, mountain, island, and dryland systems.

Some groups of people are disproportionately likely to experience loss of well-being associated with declining levels of ecosystem services. The billion people poorest people in the world mostly live in rural areas where they are directly dependent on croplands, rangelands, rivers, seas, and forests for their livelihoods. For them especially, mismanagement of ecosystems threatens survival. Among better-off and urban populations, ecosystem changes affect well-being in less direct ways, but they remain important. They are partly buffered by technology and the ability to substitute some resources with others, but they also remain ultimately dependent on ecosystems for the basic necessities of life. Impacts are experienced differentially as a function of adaptive capacity, which can be manifested at the individual, household, community, national, or regional level. The groups ultimately responsible for the loss or decline of ecosystem services are often not the ones that bear the immediate impacts of their decline.

A large and growing number of people are at high risk of adverse ecosystem changes. The world is experiencing a worsening trend of human suffering and economic losses from natural disasters. Over the past four decades, for example, the number of weather-related disasters affecting at least a million people has increased fourfold, while economic losses have increased tenfold. The greatest loss of life has been concentrated in developing countries. Ecosystem transformation has played a significant, but not exclusive, role in increasing the vulnerability of people to such disasters. Examples are the increased susceptibility of coastal populations to tropical storms when mangrove forests are cleared and the increase in downstream flooding that followed land use changes in the upper Yangtze River. [16]

Special Role of Biodiversity in Supplying Ecosystem Services

In some cases, biodiversity can be treated as an ecosystem service in its own right, such as when it is the basis of nature-based tourism or the regulation of diseases. In other respects, it is a necessary condition underpinning the long-term provision of other services, such as food and clean fresh water. **Variation among genes, populations, and species and the variety of structure, function, and composition of ecosystems are necessary to maintain an acceptable and resilient level of ecosystem services in the long term.** [1]

For ecosystem functions such as productivity and nutrient cycling, the level, constancy of the service over time, and resilience to shocks all decline over the long term if biodiversity declines (*established but incomplete*). In general, there is no sudden biodiversity threshold below which ecosystem services fail. Quantifying the relationship between biodiversity and levels of ecosystem function has only been achieved in a few experimental situations and remains an area of active research. The amount and type of biodiversity required varies from service to service. **Regulatory services generally need higher levels of biodiversity than provisioning services do.** [11]

Changes in species composition can alter ecosystem processes even if the number of species present remains unchanged or increases. Thus, conserving the composition of communities rather than simply maximizing species numbers is more likely to maintain higher levels of ecosystem services. Reduction of the number of species, especially if the species lost are locally rare, may have a hardly detectable effect on ecosystem services in the short term. However, there is evidence from terres-

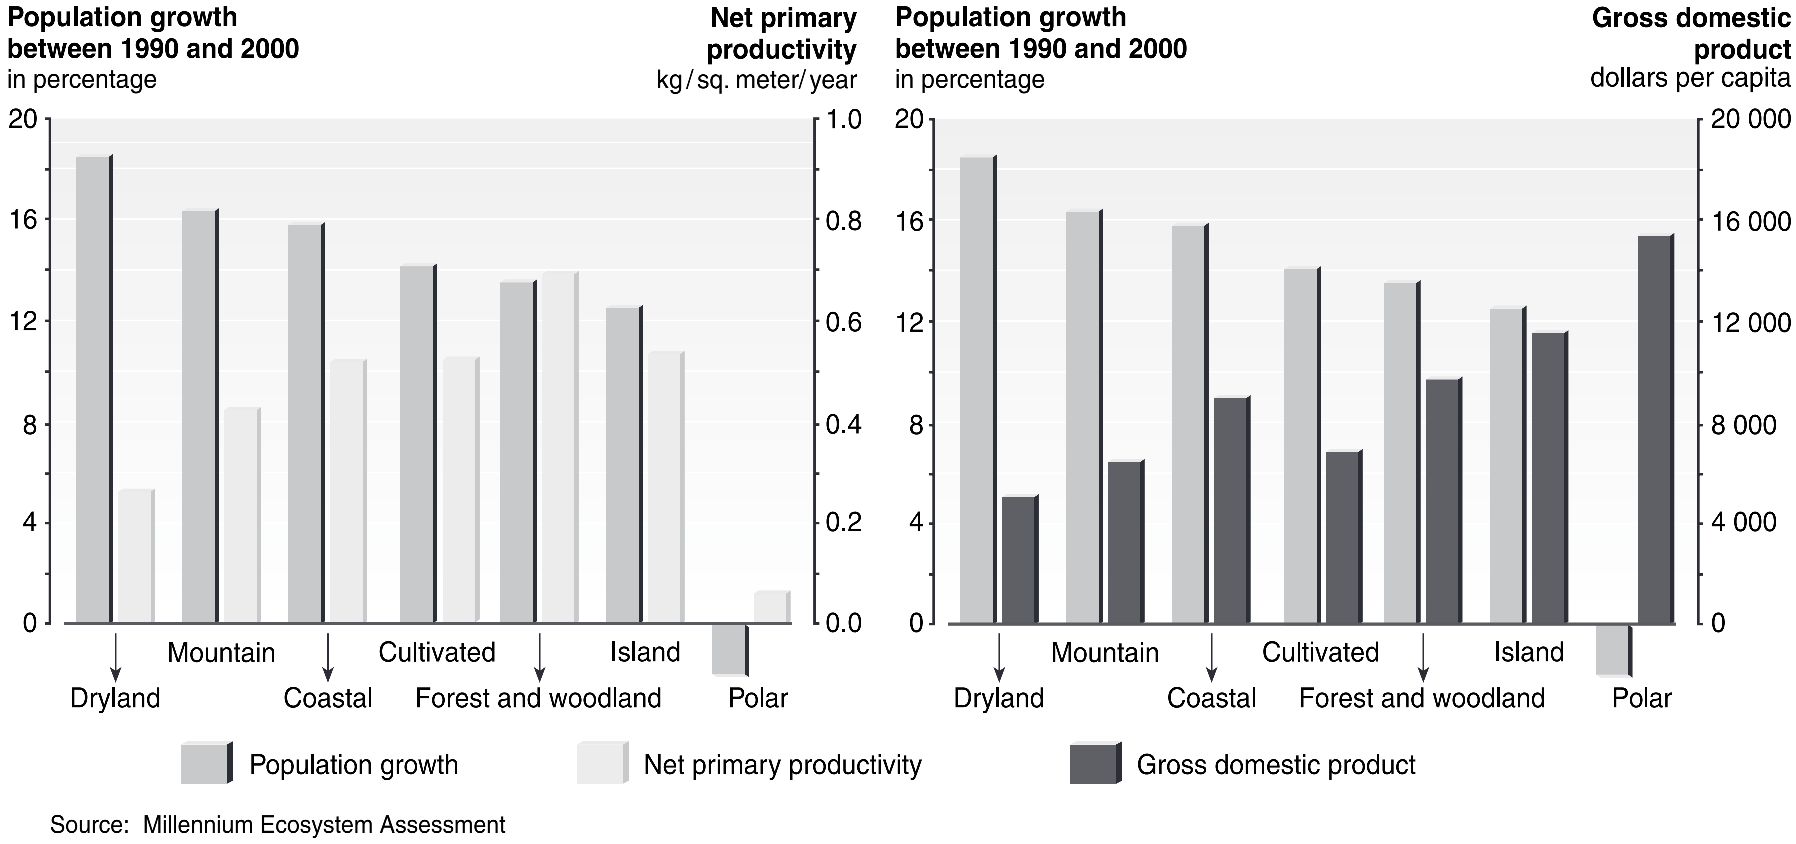

Figure C1. Population Growth Rates in 1990–2000, Per Capita GDP, and Ecosystem Productivity in 2000 in MA Ecological Systems

trial and aquatic systems that a rich regional species pool is needed to maintain ecosystem stability in the face of a changing environment in the long term. [11]

The integrity of the interactions between species is critical for the long-term preservation of human food production on land and in the sea. For example, pollination is an essential link in the production of food and fiber. Plant-eating insects and pathogens control the populations of many potentially harmful organisms. The services provided by coral reefs, such as habitat and nurseries for fish, sediment stabilization, nutrient cycling, and carbon fixing in nutrient-poor environments, can only be maintained if the interaction between corals and their obligate symbiotic algae is preserved. [11]

The preservation of genetic variation among crop species and their wild relatives and spatial heterogeneity in agricultural landscapes are considered necessary for the long-term viability of agriculture. Genetic variability is the raw material on which plant breeding for increased production and greater resilience depends. In general practice, agriculture undermines biodiversity and the regulating and supporting ecosystem services it provides in two ways: through transforming ecosystems by converting them to cultivated lands (extensification) and through the unintended negative impacts of increased levels of agricultural inputs, such as fertilizers, biocides, irrigation, and mechanical tillage (intensification). Agroforestry systems, crop rotations, intercropping, and conservation tillage are some of the agricultural techniques that maintain yields and protect crops and animals from pests without heavy investment in chemical inputs. [11]

A large proportion of the world's terrestrial species are concentrated in a small fraction of the land area, mostly in the tropics, and especially in forests and on mountains. Marine species are similarly concentrated, with the limited area of coral reefs, for example, having exceptionally high biodiversity. Most terrestrial species have small geographical ranges, and the ranges are often clustered, leading to diagnosable "hotspots" of both richness and endemism. These are frequently, but not exclusively, concentrated in isolated or topographically variable regions such as islands, peninsulas, and mountains. The African and American tropics have the highest recorded species numbers in both absolute terms and per unit of area. Endemism is also highest there and, as a consequence of its isolation, in Australasia. Locations of species richness hotspots broadly correspond with centers of evolutionary diversity. Available evidence suggests that across the major taxa, tropical humid forests are especially important for both overall diversity and their unique evolutionary history. [4]

Among plants and vertebrates, the great majority of species are declining in distribution, abundance, or both, while a small number are expanding. Studies of African mammals, birds in cultivated landscapes, and commercially important fish all show the majority of species to be declining in range or number. Exceptions can be attributed to management interventions such as protection in reserves and elimination of threats such as overexploitation, or they are species that thrive in human-dominated landscapes. In some regions there may be an increase in local biodiversity as a result of species introductions, the long-term consequences of which are hard to foresee. [4]

The observed rates of species extinction in modern times are 100 to 1,000 times higher than the average rates for comparable groups estimated from the fossil record (*medium certainty*). (See Figure C2.) The losses have occurred in all taxa, regions, and ecosystems but are particularly high in some—for instance, among primates, in the tropics, and in freshwater habitats. Of the approximately 1,000 recorded historical extinctions, most have been on islands. Currently and in the future, the most threatened species are found on the mainland, particularly in locations of habitat change and degradation. **The current rate of biodiversity loss, in aggregate and at a global scale, gives no indication of slowing, although there have been local successes in some groups of species. The momentum of the underlying drivers of biodiversity loss, and the consequences of this loss, will extend many millennia into the future.** [4]

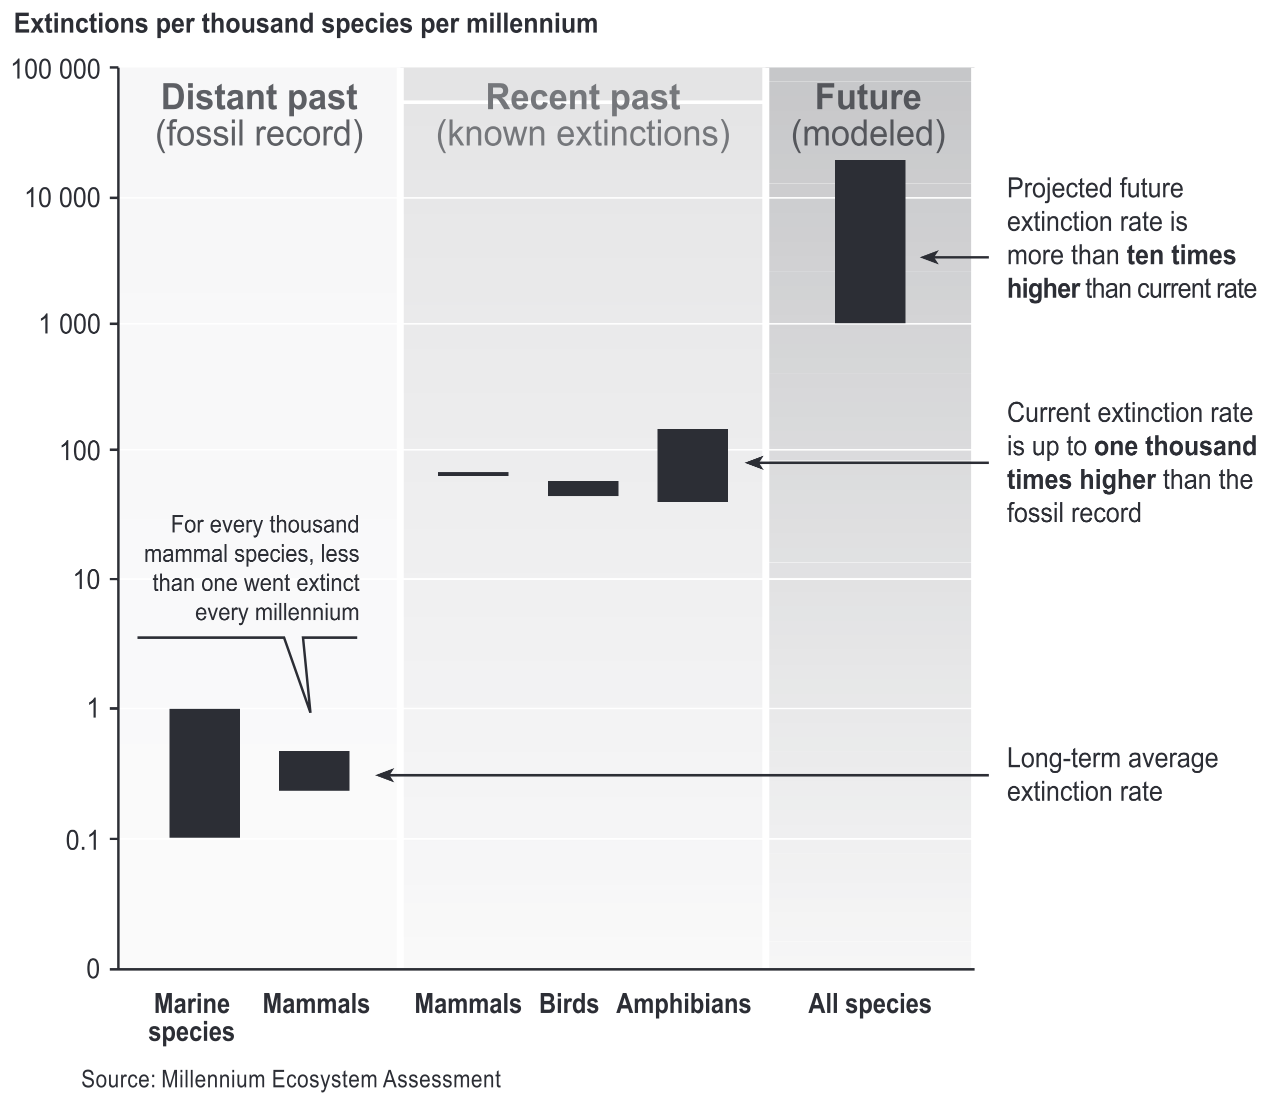

Figure C2. Species Extinction Rates Determined from the Fossil Record, from Observation, and from Estimation of Projected Rates

Less than a tenth of known plant and vertebrate species have been assessed in terms of their vulnerability to extinction (''conservation status''). Birds have the lowest proportion (12%) threatened with global extinction (defined as a high certainty of loss from throughout its range) in the near-to-medium term (*high certainty*). Among mammal species, 23% are threatened with extinction (*high certainty*). Of the amphibia for which sufficient information is available to make an assessment, 32% are threatened (*medium certainty*). For cycads (an ancient group of plants), 52% of the species are threatened, as are 25% of conifer species (*high certainty*). [4]

The taxonomic groups with the highest proportion of threatened species tend to be those that rely on freshwater habitats. Extinction rates, based on the frequency of threatened species, are broadly similar across terrestrial biomes (broad ecosystem types). Most terrestrial extinctions during the coming century are predicted to occur in tropical forests, because of their high species richness. [4]

Factors Causing Changes in Ecosystems

Increasing Demand for Ecosystem Services

Increasing consumption per person, multiplied by a growing human population, are the root causes of the increasing demand for ecosystem services. The global human population continues to rise, but at a progressively slower rate. The population increased from 3 billion to 6 billion between 1960 and 2000 and is likely to peak at 8.2–9.7 billion around the middle of the twenty-first century. Migration to cities and population growth within cities continue to be major demographic trends. The world's urban population increased from about 200 million to 2.9 billion over the past century, and the number of cities with populations in excess of 1 million increased from 17 to 388. (See Figure C3.) [3]

Overall demand for food, fiber, and water continue to rise. Improvements in human well-being, enabled by economic growth, almost invariably lead to an increase in the per capita demand for provisioning ecosystem services such as food, fiber, and water and in the consumption of energy and minerals and the production of waste. **In general, the increase in demand for provisioning services is satisfied at the expense of supporting, regulating, and cultural ecosystem services.** Efficiency gains permitted by new technology reduce per capita consumption levels below what they would have been without technological and behavioral adaptation, but they have tended not to keep pace with growth in demand for provisioning services. [3]

Increasing Pollution and Waste

Ecosystem problems associated with contaminants and wastes are in general growing. Some wastes are produced in nearly direct proportion to population size (such as sewage). Others, such as domestic trash and home-use chemicals, reflect the affluence of society. Where there is significant economic development, waste loadings tend to increase faster than population growth. In some cases the per capita waste production subsequently decreases, but seldom to the pre-growth level. The generation of industrial wastes does not necessarily increase with population or development state, and it may often be reduced by adopting alternate manufacturing processes. The neglect of waste management leads to impairment of human health and well-being, economic losses, aesthetic value losses, and damages to biodiversity and ecosystem function. [3, 15]

The oversupply of nutrients (eutrophication) is an increasingly widespread cause of undesirable ecosystem

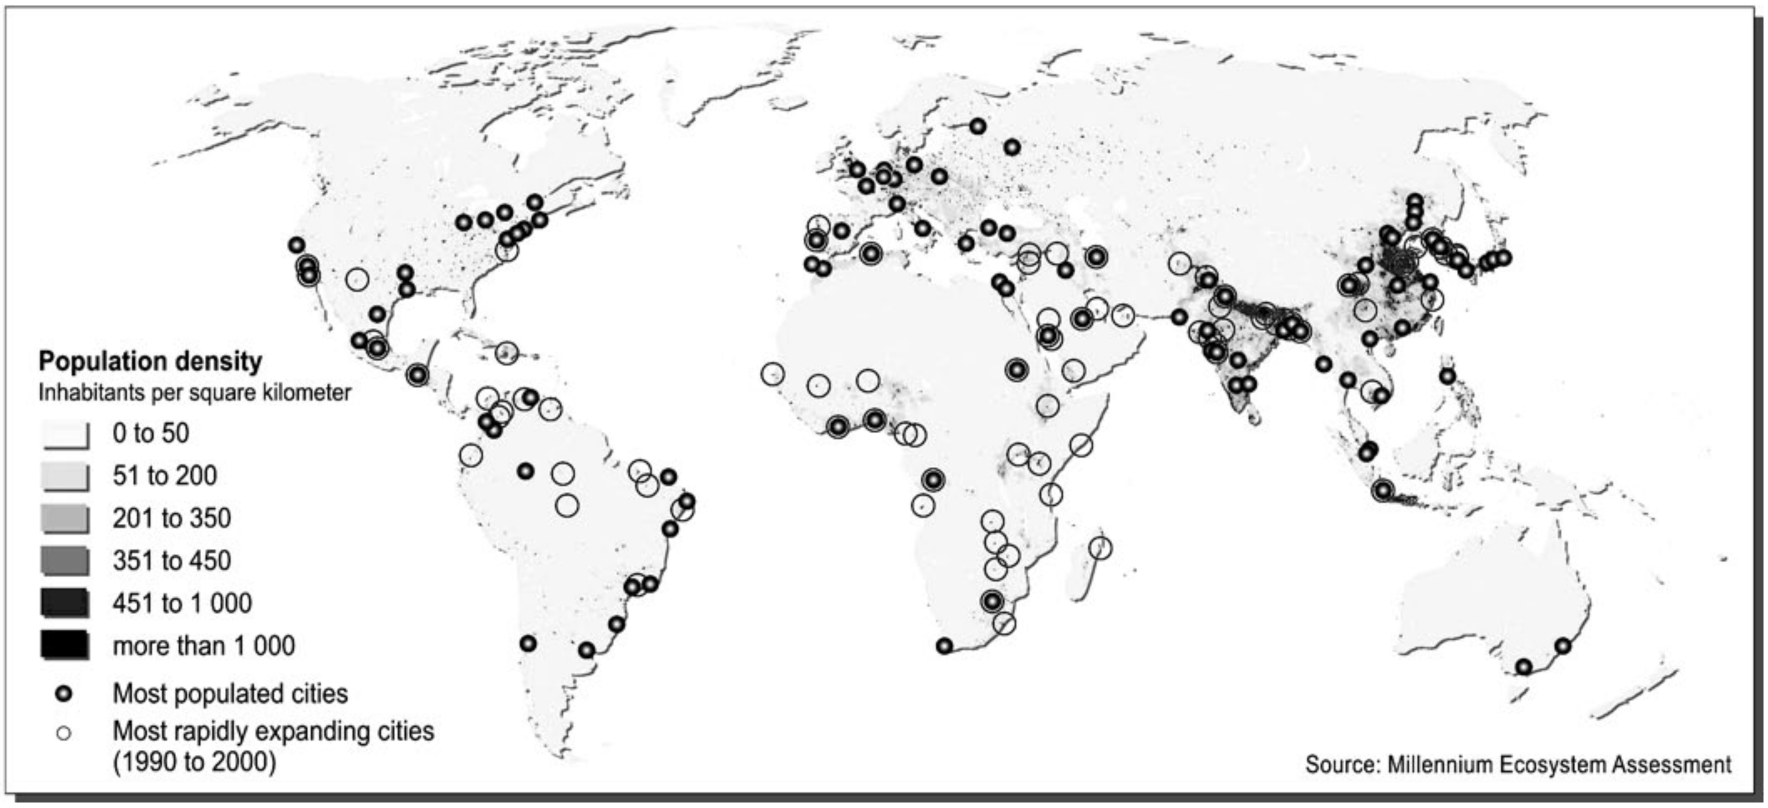

Figure C3. Human Population Density in 1995 and the Most Populated and Rapidly Changing Cities in 1990-2000

change, particularly in rivers, lakes, and coastal systems. Nutrient additions on the land, including synthetic fertilizers, animal manures, the enhancement of N-fixation by planted legumes, and the deposition of airborne pollutants, have resulted in approximately a doubling of the natural inputs for reactive nitrogen in terrestrial ecosystems and an almost fivefold increase in phosphorus accumulation. The reduction of biodiversity at the species and landscape levels has permitted nutrients to leak from the soil into rivers, the oceans, and the atmosphere. Emissions to the atmosphere are a significant driver of regional air pollution and the buildup of the greenhouse gas nitrous oxide (and, to a small extent, methane). [3, 12, 19, 20]

Global Trade

The increasing volume of goods and services that are traded internationally, the distance that they are moved, the mobility of people, and the connectivity of local and global economies have all increased the spatial separation between cause and effect in ecosystem change. **Without appropriate regulation, global trade can be a key driver of overharvesting of resources such as high-value timber and marine resources.** Trade pressures and opportunities underlie patterns of land use change in many parts of the world. The movement of people and goods is an important vector in the spread of diseases and non-native invasive organisms. [3]

Changing Climate

The effects of climate change on ecosystems are becoming apparent, especially in polar regions, where on average temperatures are now warmer than at any time in the last 400 years and the Antarctic peninsular is one of the most rapidly warming regions on the planet; in mountains, where there has been widespread glacier retreat and loss of snowpack; and in coastal systems, where coral reefs in particular have been affected by sea temperature warming and increased carbon dioxide concentrations. Although many of the potential effects of climate change on ecosystem service provision to date have not been clearly distinguishable from short-term variations, **climate change over the next century is projected to affect, directly and indirectly, all aspects of ecosystem service provision.** [3, 13, 19, 24, 25]

Overexploitation of Natural Resources

If a renewable natural resource is used at a faster rate than it is replenished, the result is a decline in the stock and eventually a decrease in the quantity of the resource that is available for human use. Overfishing, overgrazing, and overlogging are widespread examples of overexploitation. In the process of fishing, logging, mining, cultivation, and many other human activities, unintended collateral damage is done to ecosystems, affecting the supply of both the target resource and other services as well. When the net supply of ecosystem services is so damaged that it fails to recover spontaneously within a reasonable period after the level of the action causing the damage is reduced, the ecosystem is degraded. **Significant areas of forest, cultivated land, dryland rangelands, and coastal and marine systems are now degraded, and the degraded area continues to expand.** [4]

Changing Land Use and Land Cover

Current rates of land cover change are greatest for tropical moist forests and for temperate, tropical, and flooded grasslands, with $>$14% of each of these lost between 1950 and 1990. Temperate broadleaf forests, Mediterranean forests, and grasslands had already lost more than 70% of their original extent by 1950. The rates of loss in these forest types have now slowed, and in some cases the forest area has expanded. Deforestation and forest degradation are currently focused in the tropics. Data on changes in boreal forests are especially limited. [4, 21]

Habitat loss is the fastest-growing threat to species and populations on land and will continue to be the dominant factor for the next few decades. Fishing is the dominant factor reducing populations and fragmenting the habitats of marine species and is predicted to lead to local extinctions, especially among large, long-lived, slow-growing species and endemic species. [4]

Habitat fragmentation (the reduction of natural cover into smaller and more disconnected patches) compounds the effects of habitat loss. The disruptive effects of fragmentation extend hundreds of meters inwards from the edges of the patches, making small patches highly vulnerable to loss of species and functions. [11]

Invasion by Alien Species

In a wide range of terrestrial, marine, and freshwater ecosystems, accidental or voluntary introduction of non-native species by humans has altered local biological community interactions, triggering dramatic and often unexpected changes in ecosystem processes and causing large monetary and cultural losses. [3, 4, 23]

Trends in Ecosystem Services

- **The supply of certain ecosystem services has increased at the expense of others. Significant gains in the provision of food and fiber have been achieved through habitat conversion, increased abstraction and degradation of inland waters, and reduced biodiversity.**
- **Fish cannot continue to be harvested from wild populations at the present rate. Deep-ocean and coastal fish stocks have changed substantially in most parts of the world and the harvests have begun to decline and will continue to do so.**
- **The supply of fresh water to people is already inadequate to meet human and ecosystem needs in large areas of the world, and the gap between supply and demand will continue to widen if current patterns of water use will continue.**
- **Declining trends in the capacity of ecosystems to render pollutants harmless, keep nutrient levels in balance, give protection from natural disasters, and control the outbreaks of pests, diseases, and invasive organisms are apparent in many places.**

The main trends in key ecosystem services over the last 50 years are summarized in Table C1. Individual ecosystem services are discussed below in further detail.

Provisioning Services

Food

Major inequalities exist in access to food despite the more than doubling of global production over the past 40 years. An estimated 852 million people were undernourished in 2000–02, up 37 million from 1997–99. [8] There are important differences in the regional trends: the number of undernourished people in China is declining, while the number in Africa continues to increase. Of the global undernourished, 1% live in industrial countries, 4% live in countries in transition, and the remaining 95% are found in developing countries.

Figure C4 demonstrates that the economic value of food production is also not evenly distributed around the world, both because of the uneven distribution of natural factors such as climate and nutrient supply and because the prices obtained for food products vary according to demand and wealth. The impacts of activities associated with food production on other ecosystem services are unevenly distributed as well.

New cultivars of wheat, maize, and rice, coupled with increased inputs of fertilizers, irrigation, and an expansion of the cultivated area, were the main factors underlying the 250% increase in total cereal production since 1960. **The rate of increase of cereal production has slowed over the last decade,** for reasons that are uncertain but that include a long-term decline in the real price of cereals, a saturation in the per capita cereal consumption in many countries, a temporary decline in the use of cereals as livestock feed in the 1970s and 1980s, the declining quality of land in agricultural production, and diminishing returns to efforts aimed at improving yields of maize, wheat, and rice.

Adequate nutrition requires a diverse diet, containing sufficient micronutrients and protein as well as calories. The world's poorest people continue to rely on starchy staples, which leads to protein, vitamin, and mineral deficiencies. **Demand for high-value, protein-rich products such as livestock and fish has increased** with rising incomes in East and Southeast Asia (7% annual growth in livestock production over past 30 years). **The accelerating demand for animal protein is increasingly met by intensive (''industrial'' or ''landless'') production systems,** especially for chicken and pigs. While these systems have contributed to large increases in production, they create serious waste problems and put increased pressure on cultivated systems and fisheries to provide feed inputs (and are thus not truly ''landless'').

The dietary changes that accompany increasing income can improve health; however, overconsumption, leading to obesity and heart disease, is also a growing health problem (65% of Americans and more than 17 million children in developing countries are overweight). Calorie intake is only 20% higher per capita in industrial countries than in developing countries on average, but protein intake is 50% higher and fat intake is almost twice as high.

Harvest pressure has exceeded maximum sustainable levels of exploitation in one quarter of all wild fisheries and is likely to exceed this limit in most other wild fisheries in the near future. In every ocean in the world, one or more important targeted stocks have been classified as collapsed, overfished, or fished to their maximum sustainable levels, and at least one quarter of important commercial fish stocks are overharvested (*high certainty*). Although fish consumption has doubled in developing countries in the last three decades, the per capita annual consumption has declined by 200 grams since 1985, to 9.2 kilograms per person (excluding China). Fish products are heavily traded, and approximately 50% of fish exports are from developing countries. Exports from developing countries and the Southern Hemisphere presently offset much of the demand shortfall in European, North American, and East Asian markets.

The growth in demand for fish protein is being met in part by aquaculture, which now accounts for 22% of total fish production and 40% of fish consumed as food. **Marine aquaculture has not to date relieved pressure on wild fisheries, because the food provided to captive fish is partly based on wild-harvested fish products.**

Government policies are significant drivers of food production and consumption patterns, both locally and globally. Investments in rural roads, irrigation, credit systems, and agricultural research and extension serve to stimulate food production. Improved access to input and export markets boosts productivity. Opportunities to gain access to international markets are conditioned by international trade and food safety regulations and by a variety of tariff and non-tariff barriers. Selective production and export subsidies stimulate overproduction of many food crops. This translates into relatively cheap food exports that benefit international consumers at the expense of domestic taxpayers and that undermine the welfare of food producers in poorer countries.

Wild terrestrial foods are locally important in many developing countries, often bridging the hunger gap created by stresses such as droughts and floods and social unrest. Wild foods are important sources of diversity in some diets, in

Table C1. Trends in the Human Use of Ecosystem Services and Enhancement or Degradation of the Service around the Year 2000

Service	Sub-category	Human Use[a]	Enhanced or Degraded[b]	Notes	MA Chapter
Provisioning Services					
Food	Crops	↑	↑	Food provision has grown faster than overall population growth. Primary source of growth from increase in production per unit area but also significant expansion in cropland. Still persistent areas of low productivity and more rapid area expansion, e.g., sub-Saharan Africa and parts of Latin America.	C8.2
	Livestock	↑	↑	Significant increase in area devoted to livestock in some regions, but major source of growth has been more intensive, confined production of chicken, pigs, and cattle.	C8.2
	Capture Fisheries	↓	↓	Marine fish harvest increased until the late 1980s and has been declining since then. Currently, one quarter of marine fish stocks are overexploited or significantly depleted. Freshwater capture fisheries have also declined. Human use of capture fisheries has declined because of the reduced supply, not because of reduced demand.	C18 C8.2.2 C19
	Aquaculture	↑	↑	Aquaculture has become a globally significant source of food in the last 50 years and, in 2000, contributed 27% of total fish production. Use of fish feed for carnivorous aquaculture species places an additional burden on capture fisheries.	C8 Table 8.4
	Wild plant and animal food products	NA	↓	Provision of these food sources is generally declining as natural habitats worldwide are under increasing pressure and as wild populations are exploited for food, particularly by the poor, at unsustainable levels.	C8.3.1
Fiber	Timber	↑	+/−	Global timber production has increased by 60% in the last four decades. Plantations provide an increasing volume of harvested roundwood, amounting to 35% of the global harvest in 2000. Roughly 40% of forest area has been lost during the industrial era, and forests continue to be lost in many regions (thus the service is degraded in those regions), although forest is now recovering in some temperate countries and thus this service has been enhanced (from this lower baseline) in these regions in recent decades.	C9.ES C21.1
	Cotton, hemp, silk	+/−	+/−	Cotton and silk production have doubled and tripled respectively in the last four decades. Production of other agricultural fibers has declined.	C9.ES
	Wood fuel	+/−	↓	Global consumption of fuelwood appears to have peaked in the 1990s and is now believed to be slowly declining buts remains the dominant source of domestic fuel in some regions.	C9.ES
Genetic resources		↑	↓	Traditional crop breeding has relied on a relatively narrow range of germplasm for the major crop species, although molecular genetics and biotechnology provide new tools to quantify and expand genetic diversity in these crops. Use of genetic resources also is growing in connection with new industries base on biotechnology. Genetic resources have been lost through the loss of traditional cultivars of crop species (due in part to the adoption of modern farming practices and varieties) and through species extinctions.	C26.2.1

Table C1. continued

Service	Sub-category	Human Use[a]	Enhanced or Degraded[b]	Notes	MA Chapter
Biochemicals, natural medicines, and pharmaceuticals		⬆	⬇	Demand for biochemicals and new pharmaceuticals is growing, but new synthetic technologies compete with natural products to meet the demand. For many other natural products (cosmetics, personal care, bioremediation, biomonitoring, ecological restoration), use is growing. Species extinction and overharvesting of medicinal plants is diminishing the availability of these resources.	C10
Fresh water		⬆	⬇	Human modification to ecosystems (e.g., reservoir creation) has stabilized a substantial fraction of continental river flow, making more fresh water available to people but in dry regions reducing river flows through open water evaporation and support to irrigation that also loses substantial quantities of water. Watershed management and vegetation changes have also had an impact on seasonal river flows. From 5% to possible 25% of global freshwater use exceeds long-term accessible supplied and require supplied either through engineered water transfers of overdraft of groundwater supplies. Between 15% and 35% of irrigation withdrawals exceed supply rates. Fresh water flowing in rivers also provides a service in the form of energy that is exploited through hydropower. The construction of dams has not changed the amount of energy, but it has made the energy more available to people. The installed hydroelectric capacity doubled between 1960 and 2000. Pollution and biodiversity loss are defining features of modern inland water systems in many populated parts of the world.	C7
Regulating Services					
Air quality regulation		⬆	⬇	The ability of the atmosphere to cleanse itself of pollutants has declined slightly since preindustrial times but likely not by more than 10%. Then net contribution of ecosystems to this change is not known. Ecosystems are also a sink for tropospheric ozone, ammonia, NO_x, SO_2, particulates, and CH_4, but changes in these sinks were not assessed.	C13.ES
Climate regulation	Global	⬆	⬆	Terrestrial ecosystems were on average a net source of CO_2 during the nineteenth and early twentieth century and became a net sink sometime around the middle of the last century. The biophysical effect of historical land cover changes (1750 to present) is net cooling on a global scale due to increased albedo, partially offsetting the warming effect of associated carbon emissions from land cover change over much of that period.	C13.ES
	Regional and local	⬆	⬇	Changes in land cover have affected regional and local climates both positively and negatively, but there is a preponderance of negative impacts. For example, tropical deforestation and desertification have tended to reduce local rainfall.	C13.3 C11.3
Water regulation		⬆	+/–	The effect of ecosystem change on the timing and magnitude of runoff, flooding, and aquifer recharge depends on the ecosystem involved and on the specific modifications made to the ecosystem.	C7.4.4

Erosion regulation		↑	↓	Land use and crop/soil management practices have exacerbated soil degradation and erosion, although appropriate soil conservation practices that reduce erosion, such as minimum tillage, are increasingly being adopted by farmers in North America and Latin America.	C26
Water purification and waste treatment		↑	↓	Globally, water quality is declining, although in most industrial countries pathogen and organic pollution of surface waters has decreased over the last 20 years. Nitrate concentration has grown rapidly in the last 30 years. The capacity of ecosystems to purify such wastes in limited, as evidenced by widespread reports of inland waterway pollution. Loss of wetlands has further decreased the ability of ecosystems to filter and decompose wastes.	C7.2.5 C19
Disease regulation		↑	+/−	Ecosystem modifications associated with development have often increased the local incidence of infectious diseases, although major changes in habitats can both increase or decrease the risk of particular infectious diseases.	C14
Pest regulation		↑	↓	In many agricultural areas, pest control provided by natural enemies has been replaced by the use of pesticides. Such pesticide use has itself degraded the capacity of agroecosystems to provide pest control. In other systems, pest control provided by natural enemies is being used and enhanced through integrated pest management. Crops containing pest-resistant genes can also reduce the need for application of toxic synthetic pesticides.	C11.3
Pollination		↑	↓[c]	There is *established but incomplete* evidence of a global decline in the abundance of pollinators. Pollinator declines have been reported in at least one region or country on every continent except for Antarctica, which has no pollinators. Declines in abundance of pollinators have rarely resulted in complete failure to produce seed or fruit, but more frequently resulted in fewer seeds or in fruit of reduced viability or quantity. Losses in populations of specialized pollinators have directly affected the reproductive ability of some rare plants.	C11 Box 11.2
Natural hazard regulation		↑	↓	People are increasingly occupying regions and localities that are exposed to extreme events, thereby exacerbating human vulnerability to natural hazards. This trend, along with the decline in the capacity of ecosystems to buffer from extreme events, has led to continuing high loss of life globally and rapidly rising economic losses from natural disasters.	C16 C19
Cultural Services					
Cultural diversity		**NA**	**NA**		
Spiritual and religious values		↑	↑	There has been a decline in the numbers of sacred groves and other such protected areas. The loss of particular ecosystem attributes (sacred species or sacred forests), combined with social and economic changes, can sometimes weaken the spiritual benefits people obtain from ecosystems. On the other hand, under some circumstances (e.g., where ecosystem attributes are causing significant threats to people), the loss of some attributes may enhance spiritual appreciation for what remains.	C17.2.3

(continues)

Table C1. continued

Service	Sub-category	Human Use[a]	Enhanced or Degraded[b]	Notes	MA Chapter
Knowledge systems		**NA**	**NA**		
Educational values		**NA**	**NA**		
Inspiration		**NA**	**NA**		
Aesthetic values		⬆	⬇	The demand for aesthetically pleasing natural landscapes has increased in accordance with increased urbanization. There has been a decline in quantity and quality of areas to meet this demand. A reduction in the availability of and access to natural areas for urban residents may have important detrimental effects on public health and economies.	C17.2.5
Social relations		**NA**	**NA**		
Sense of place		**NA**	**NA**		
Cultural heritage values		**NA**	**NA**		
Recreation and ecotourism		⬆	+/−	The demand for recreational use of landscapes is increasing, and areas are increasingly being managed to cater for this use, to reflect changing cultural values and perceptions. However, many naturally occurring features of the landscape (e.g., coral reefs) have been degraded as resources for recreation.	C17.2.6 C19
Supporting Services					
Soil formation		†	†		
Photosynthesis		†	†		
Primary production		†	†	Several global MA systems, including drylands, forest, and cultivated systems, show a trend of NPP increase for the period 1981 to 2000. However, high seasonal and inter-annual variations associated with climate variability occur within this trend on the global scale	C22.2.1
Nutrient cycling		†	†	There have been large-scale changes in nutrient cycles in recent decades, mainly due to additional inputs from fertilizers, livestock waste, human wastes, and biomass burning. Inland water and coastal systems have been increasingly affected by eutrophication due to transfer of nutrients from terrestrial to aquatic systems as biological buffers that limit these transfers have been significantly impaired.	C12
Water cycling		†	†	Humans have made major changes to water cycles through structural changes to rivers, extraction of water from rivers, and, more recently, climate change.	C7

[a] For provisioning services, human use increases if the human consumption of the service increases (e.g., greater food consumption); for regulating and cultural services, human use increases if the number of people affected by the service increases. The time frame is in general the past 50 years, although if the trend has changed within that time frame, the indicator shows the most recent trend.

[b] For provisioning services, we define enhancement to mean increased production of the service through changes in area over which the service is provided (e.g., spread of agriculture) or increased production per unit area. We judge the production to be degraded if the current use exceeds sustainable levels. For regulating and supporting services, enhancement refers to a change in the service that leads to greater benefits for people (e.g., the service of disease regulation could be improved by eradication of a vector known to transmit a disease to people). Degradation of a regulating and supporting service means a reduction in the benefits obtained from the service, either through a change in the service (e.g., mangrove loss reducing the storm protection benefits of an ecosystem) or through human pressures on the service exceeding its limits (e.g., excessive pollution exceeding the capability of ecosystems to maintain water quality). For cultural services, degradation refers to a change in the ecosystem features that decreases the cultural (recreational, aesthetic, spiritual, etc.) benefits provided by the ecosystem. The time frame is in general the past 50 years, although if the trend has changed within that time frame the indicator shows the most recent trend.

[c] *Low to medium certainty.* All other trends are *medium to high certainty.*

Legend

⬆ = Increasing (for human use column) or enhanced (for enhanced or degraded column)

⬇ = Decreasing (for human use column) or degraded (for enhanced or degraded column)

+/− = Mixed (trend increases and decreases over past 50 years or some components/regions increase while others decrease)

NA = Not assessed within the MA. In some cases, the service was not addressed at all in the MA (such as ornamental resources), while in other cases the service was included but the information and data available did not allow an assessment of the pattern of human use of the service or the status of the service.

† = The categories of "human use" and "enhanced or degraded" do not apply for supporting services since, by definition, these services are not directly used by people. (Their costs or benefits would be double-counted if the indirect effects were included). Changes in supporting services influence the supply of provisioning, cultural, or regulating services that are then used by people and may be enhanced or degraded.

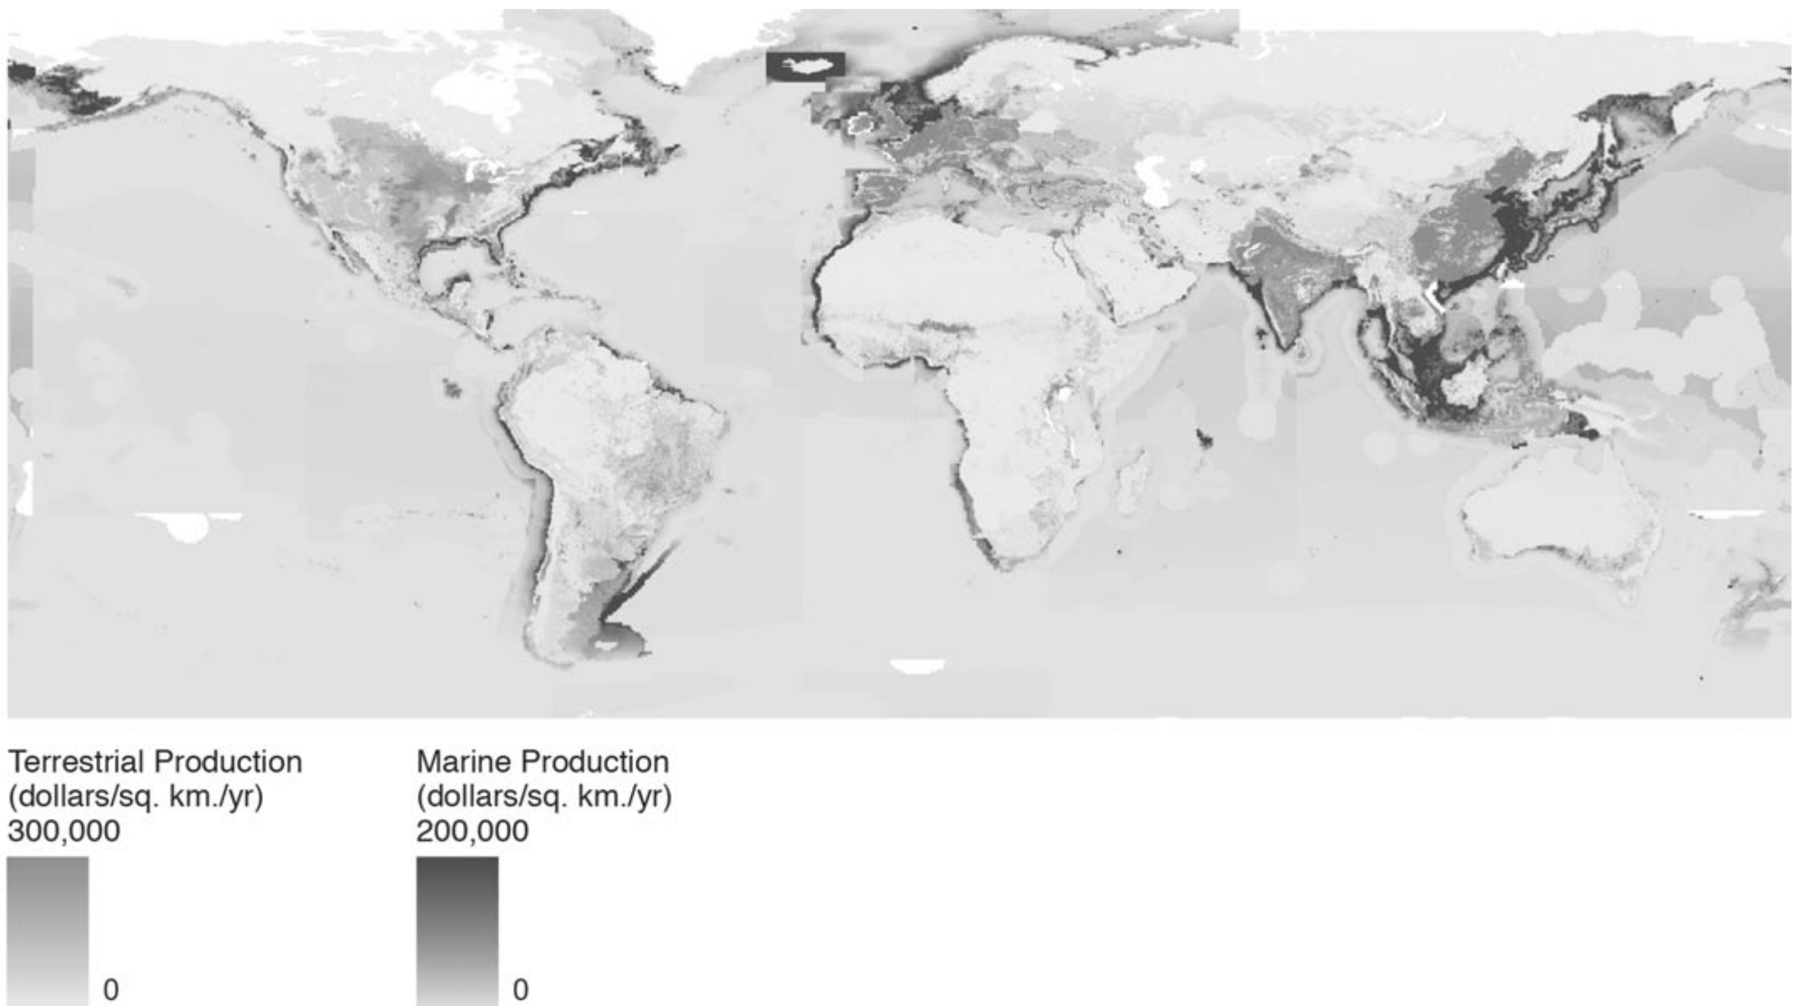

Figure C4. Spatial Distribution of Value of Food Production for Crops, Livestock, and Fisheries, 2000. This Figure was constructed by multiplying the harvest derived from all regions of the world by the average product price obtained in that region. (Data for Iceland were only available aggregated to the rectangular area shown.) A color version of this map appears in Appendix A (see Figure 8.2).

that they are highly nutritious and are often not labor-intensive to collect or prepare. Although they have significant economic value, in most cases wild foods are excluded from economic analysis of natural resource systems as well as official statistics, so the full extent of their importance is poorly quantified.

Wood for Timber and Pulp

The absolute harvest of timber is projected, with *medium certainty*, to increase in the future, albeit at a slower rate than over the past four decades. [9] The high growth in timber harvests since 1960 (60% and 300% for sawlogs and pulpwood respectively) has slowed in recent years. Total forest biomass in temperate and boreal regions increased over this period but decreased in mid-latitude and tropical forests. Demand for hardwoods is a factor in tropical deforestation, but is typically not the main driver. Conversion to agricultural land, a trend often underlain by policy decisions, is overall the major cause. **A third of timber is harvested from plantations rather than naturally regenerating forests, and this fraction is projected to grow.** Plantations currently constitute 5% of the global forest area. In general, plantations provide a less diverse set of ecosystem services than natural forests do.

Most trade in forest products is within-country, with only about 25% of global timber production entering international trade. However, international trade in forest products has increased three times faster in value than in harvested volume. The global value of timber harvested in 2000 was around $400 billion, about one quarter of which entered in world trade, representing some 3% of total merchandise traded. Much of this trade is among industrial countries: the United States, Germany, Japan, the United Kingdom, and Italy were the destination of more than half of the imports in 2000, while Canada, the United States, Sweden, Finland, and Germany account for more than half of the exports.

The global forestry sector annually provides subsistence and wage employment of 60 million work years, with 80% in the developing world. There is a trend in increasing employment in sub-tropical and tropical regions and declining employment in temperate and boreal regions.

Biomass Energy

Wood and charcoal remain the primary source of energy for heating and cooking for 2.6 billion people. [9] Global consumption appears to have peaked in the 1990s and is now believed to be slowly declining as a result of switching to alternate fuels and, to a lesser degree, more-efficient biomass energy technologies. Accurate data on fuelwood production and consumption are difficult to collect, since much is produced and consumed locally by households. The global aggregate value of fuelwood production per capita has declined in recent years, easing concerns about a widespread wood energy crisis, although local and regional shortages persist.

Serious human health damages are caused by indoor pollution associated with the use of traditional biomass fuels in homes of billions of the rural and urban poor that lack adequate smoke venting. In 2000, 1.6 million deaths and the equivalent of 39 million person-years of ill health (disability-adjusted life years) were attributed to the burning of traditional biomass fuels, with women and children most affected. Health hazards increase where wood shortages lead to poor families using dung or agricultural residues for heating and cooking. Where adequate fuels are not available, the consumption of cooked foods declines, with adverse effects on nutrition and health. Local fuelwood shortages contribute to deforestation and result in lengthy and arduous travel to collect wood in rural villages, largely by women.

While examples of full commercial exploitation of modern biomass-based energy technologies are still fairly modest, their production and use is likely to expand over the next decades.

Agricultural Fibers

Global cotton production has doubled and silk production has tripled since 1961, with major shifts in the production regions. [9] The total land area devoted to cotton production has stayed virtually constant; area expansion in India and the United States was offset by large declines in Pakistan and the former Soviet Union. These shifts have impacts on land available for food crops and on water resources, since much of the cotton crop is irrigated. Silk production shifted from Japan to China. Production of wool, flax, hemp, jute, and sisal has declined.

Fresh Water

Water scarcity has become globally significant over the last four decades and is an accelerating condition for roughly 1–2 billion people worldwide, leading to problems with food production, human health, and economic development. Rates of increase in a key water scarcity measure (water use relative to accessible supply) from 1960 to the present averaged nearly 20% per decade globally, with values of 15% to more than 30% per decade for individual continents. Although a slowing in the global rate of increase in use is projected between 2000 and 2010, to 10% per decade, the relative use ratio for some regions is likely to remain high, with the Middle East and North Africa at 14% per decade, Latin America at 16%, and sub-Saharan Africa at 20%. [7]

Contemporary water withdrawal is approximately 10% of global continental runoff, although this amounts to between 40% and 50% of the continental runoff to which the majority of the global population has access during the year.

Population growth and economic development have driven per capita levels of water availability down from 11,300 to about 5,600 cubic meters per person per year between 1960 and 2000. Global per capita water availability is projected (based on a 10% per decade rate of growth of water use, which is slower than the past decades) to drop below 5,000 cubic meters per person per year by 2010 (*high certainty*).

Terrestrial ecosystems are the major global source of accessible, renewable fresh water. Forest and mountain ecosystems are associated with the largest amounts of fresh water—57% and 28% of the total runoff, respectively. These systems each provide renewable water supplies to at least 4 billion people, or two thirds of the global population. Cultivated and urban systems generate only 16% and 0.2%, respectively, of global runoff, but due to their close proximity to humans they serve from 4.5–5 billion people. Such proximity is associated with nutrient and industrial water pollution.

More than 800 million people currently live in locations so dry that there is no appreciable recharge of groundwater or year-round contribution by the landscape to runoff in rivers. They are able to survive there by drawing on "fossil" groundwater, by having access to piped water, or by living along rivers that have their source of water elsewhere. From 5% to possibly 25% of global freshwater use exceeds long-term accessible supplies and is now met either through engineered water transfers or overdraft of groundwater supplies (*medium certainty*). In North Africa and the Middle East, nonsustainable use (use in excess of the long-term accessible renewable supply) represents 43% of all water use, and the current rate of use is 40% above that of the sustainable supply (*medium certainty*).

Growing competition for water is sharpening policy attention on the need to allocate and use water more efficiently. **Irrigation accounts for 70% of global water withdrawals (over 90% in developing countries),** but chronic inefficiencies in irrigated systems result in less than half of that water being used by crops.

The burden of disease from inadequate water, sanitation, and hygiene totals 1.7 million deaths and the loss of up to 54 million healthy life years per year. Some 1.1 billion people lack access to improved water supply and more than 2.6 billion lack access to improved sanitation. It is *well established* that investments in clean drinking water and sanitation show a close correspondence with improvement in human health and economic productivity. Half of the urban population in Africa, Asia, and Latin America and the Caribbean suffer from one or more diseases associated with inadequate water and sanitation.

The management of fresh water through dams, levees, canals, and other infrastructure has had predominantly negative impacts on the biodiversity of inland waters and coastal ecosystems, including fragmentation and destruction of habitat, loss of species, and reduction of sediments destined for the coastal zone. The 45,000 existing large dams (more than 15 meters high) generate both positive and negative effects on human well-being. Positive effects include flow stabilization for irrigation, flood control, and hydroelectricity. Negative effects include health issues associated with stagnant water and the loss of services derived from land that has become inundated. A significant economic consequence of soil erosion is the reduction of the useful life of dams lower in the drainage basin due to siltation.

Genetic Resources

The exploration of biodiversity for new products and industries has yielded major benefits for humanity and has the potential for even larger future benefits. [10] The diversity of living things, at the level of the gene, is the fundamental resource for such "bioprospecting." While species-rich environments such as the tropics are in the long term expected to supply the majority of pharmaceutical products derived from ecosystems, bioprospecting to date has yielded valuable products from a wide variety of environments, including temperate forests and grasslands, arid and semiarid lands, freshwater ecosystems, mountain and polar regions, and cold and warm oceans.

The continued improvements of agricultural yields through plant breeding and the adaptation of crops to new and changing environments, such as increased temperatures, droughts, and emerging pests and diseases, requires the conservation of genetic diversity in the wild relatives of domestic species and in productive agricultural landscapes themselves.

Regulating Services

The Regulation of Infectious Diseases

Ecosystem changes have played a significant role in the emergence or resurgence of several infectious diseases of humans. [14] The most important drivers are logging, dam building, road building, expansion of agriculture (especially irrigated agriculture), urban sprawl, and pollution of coastal zones. There is evidence that ecosystems that maintain a higher diversity of species reduce the risks of infectious diseases in humans living within them; the pattern of Lyme disease in North America is one example. **Natural systems with preserved structure and characteristics are not receptive to the introduction of invasive human and animal pathogens brought by human migration and settlement.** This is indicated for cholera, kala-azar, and schistosomiasis (*medium certainty*).

Increased human contact with ecosystems containing foci of infections raises the risk of human infections. Examples occur where urban systems are in close contact with forest systems (associated with malaria and yellow fever) and where cultivated lands are opened in forest systems (hemorrhagic fevers or hantavirus). Major changes in habitats can both increase or decrease the risk of a particular infectious disease, depending on the type of land use, the characteristics of the cycle of disease, and the characteristics of the human populations. Although disease emergence and re-emergence due to ecosystem alteration can occur anywhere, people in the tropics are more likely to be affected in the future due to their greater exposure to reservoirs of potential disease and their greater vulnerability due to poverty and poorer health infrastructure.

Regulation of Climate, Atmospheric Composition, and Air Quality

Ecosystems are both strongly affected by and exert a strong influence on climate and air quality. [13] **Ecosystem management has significantly modified current greenhouse gas concentrations.** Changes in land use and land cover, especially deforestation and agricultural practices such as paddy rice cultivation and fertilizer use, but also rangeland degradation and dryland agriculture, made a contribution of 15–25% to the radiative forcing of global climate change from 1750 to present.

Ecosystems are currently a net sink for CO_2 and tropospheric ozone, while they remain a net source of methane and nitrous oxide. About 20% of CO_2 emissions in the 1990s originated from changes in land use and land management, primarily deforestation.

Terrestrial ecosystems were on average a net source of CO_2 during the nineteenth and early twentieth centuries; they became a net sink sometime around the middle of the last century (*high certainty*) and were a sink for about a third of total emissions in the 1990s (energy plus land use). The sink may be explained partially by afforestation, reforestation, and forest management in North America, Europe, China, and other regions and partially by the fertilizing effects of nitrogen deposition and increasing atmospheric CO_2. The net impact of ocean biology changes on global CO_2 fluxes is unknown.

The potential of terrestrial ecosystem management to alter future greenhouse gas concentrations is significant through, for instance, afforestation, reduced deforestation, and conservation agriculture. However, the potential reductions in greenhouse gases remain much smaller than the projected fossil fuel emissions over the next century (*high certainty*). The management of ecosystems for climate mitigation can yield other benefits as well, such as biodiversity conservation.

Ecosystems also modify climate through alteration of the physical properties of Earth's surface. For instance, deforestation in snowy regions leads to regional cooling of land surface during the snow season due to increase in surface albedo and to warming during summer due to reduction in transpiration (water recycled by plants to atmosphere). Positive feedbacks involving sea surface temperature and sea ice propagate this cooling to the global scale. The net physically mediated effect of conversion of high-latitude forests to more open landscapes is to cool the atmosphere (*medium certainty*). Observations and models indicate, with *medium certainty*, that **large-scale tropical and sub-tropical deforestation and desertification decrease the precipitation in the affected regions.** The mechanism involves reduction in within-region moisture recycling and an increase in surface albedo. [14]

Tropospheric ozone is both a greenhouse gas and an important pollutant. It is both produced and destroyed by chemical reactions in the atmosphere, and about a third of the additional tropospheric ozone produced as a result of human activities is destroyed by surface absorption in ecosystems. The capacity of the atmosphere to convert pollutants harmful to humans and other life forms into less harmful chemicals is largely controlled by the availability of hydroxyl radicals. The global concentration of these is believed to have declined by about 10% over the past centuries.

Detoxification of Wastes

Depending on the properties of the contaminant and its location in the environment, wastes can be rendered harmless by natural processes at relatively fast or extremely slow rates. The more slowly a contaminant is detoxified, the greater the possibility that harmful levels of the contaminant will occur. Some wastes, such as nutrients and organic matter, are normal components of natural ecosystem processes, but the anthropogenic loading rates are often so much higher than the natural throughput that they significantly modify the ecosystem and impair its ability to provide a range of services, such as recreation and appropriate-quality fresh water and air. **The costs of reversing damages to waste-degraded ecosystems are typically large, and the time scale for remediation is long. In some cases, rehabilitation is effectively impossible.** [15]

Protection from Floods

The impact of extreme weather events is increasing in many regions around the world. [7, 16, 19] For example, flood damage recorded in Europe in 2002 was higher than in any previous year. Increasing human vulnerability, rather than increasing physical magnitude or frequency of the events themselves, is overall the primary factor underlying the rising impact. People are increasingly occupying regions and locations that are exposed to flooding—settling on coasts and floodplains, for instance—thus exacerbating their vulnerability to extreme events. **Ecosystem changes have in some cases increased the severity of floods,** however, for example as a result of deforestation in upland areas and the loss of mangroves. Local case studies have shown that appropriate management of ecosystems contributes to reduction of vulnerability to extreme events.

Cultural Services

Human societies have developed in close interaction with the natural environment, which has shaped their cultural identity, their value systems, and indeed their economic well-being. Human cultures, knowledge systems, religions, heritage values, social interactions, and the linked amenity services (such as aesthetic enjoyment, recreation, artistic and spiritual fulfillment, and intellectual development) have always been influenced and shaped by the nature of the ecosystem and ecosystem conditions in which culture is based. **Rapid loss of culturally valued ecosystems and landscapes has led to social disruptions and societal marginalization in many parts of the world.** [17]

The world is losing languages and cultures. At present, the greatest losses are occurring in situations where languages are not officially recognized or populations are marginalized by rapid industrialization, globalization, low literacy, or considerable ecosystem degradation. Especially threatened are the languages of 350 million indigenous peoples, representing over 5,000 linguistic groups in 70 countries, which contain most of humankind's traditional knowledge. Much of the traditional knowledge that existed in Europe (such as knowledge on medicinal plants) has also gradually eroded due to rapid industrialization in the last century. [17]

The complex relationships that exist between ecological and cultural systems can best be understood through both "formal knowledge" and "traditional knowledge." Traditional knowledge is a key element of sustainable development, particularly in relation to plant medicine and agriculture, and the understanding of tangible benefits derived from traditional ecological knowledge such as medicinal plants and local species of food is relatively well developed. However, understanding of the linkages between ecological processes and social processes and their intangible benefits (such as spiritual and religious values), as well as the influence on sustainable natural resource management at the landscape level, remains relatively weak. [17]

Many cultural and amenity services are not only of direct and indirect importance to human well-being, they also represent a considerable economic resource. (For example, nature- and culture-based tourism employs approximately 60 million people and generates approximately 3% of global GDP.) Due to changing cultural values and perceptions, there is an increasing tendency to manage landscapes for high amenity values (such as recreational use) at the expense of traditional landscapes with high cultural and spiritual values. [17]

Supporting Services

There are numerous examples of both overabundance and insufficiency of nutrient supply. Crop yields and nutritional value in parts of Africa, Latin America, and Asia are strongly limited by poor soils, which have become even more depleted by farming with low levels of nutrient replenishment. On the other hand, overfertilization is a major contributor to environmental pollution through excess nutrients in many areas of commercial farming in both industrial and developing countries.

The capacity of terrestrial ecosystems to absorb and retain the nutrients supplied to them either as fertilizers or from the deposition of airborne nitrogen and sulfur has been undermined by the radical simplification of ecosystems into large-scale, low-diversity agricultural landscapes. Excess nutrients leak into the groundwater, rivers, and lakes and are transported to the coast. Treated and untreated sewage released from urban areas adds to the load. The consequence of the excessive and imbalanced nutrient load in aquatic ecosystems is an explosion of growth of certain plants (particularly algae) and a loss of many other forms of life, a syndrome known as eutrophication. The decomposing residues of the plants (often compounded by organic pollutants) deplete the water of oxygen, creating anaerobic "dead zones" devoid of life forms that depend on oxygen. Such dead zones have been discovered in many lakes and estuaries and off the mouths of several large rivers, and they are expanding.

How Are Key Ecological Systems Doing?

The systems where multiple problems are occurring at the same time, seriously affecting the well-being of hundreds of millions of people, are:

- **wetlands, including rivers, lakes, and salt and saltwater marshes, where water abstraction, habitat loss and fragmentation, and pollution by nutrients, sediments, salts, and toxins have significantly impaired ecosystem function and biodiversity in most major drainage basins;**
- **the arid parts of the world, where a large, growing, and poor population often coincides with water scarcity, cultivation on marginal lands, overgrazing, and overharvesting of trees;**
- **particular coastal systems, notably coral reefs, estuaries, mangroves, and urbanized coasts, where habitat loss and fragmentation, overharvesting, pollution, and climate change are the key issues; and**
- **tropical forests, where unsustainable harvesting and clearing for agriculture threatens biodiversity and the global climate.**

The majority of ecosystems have been greatly modified by humans. Within 9 of the 14 broad terrestrial ecosystem types (biomes), one fifth to one half of the area has been transformed to croplands, mostly over the past two centuries. Tropical dry forests are the most affected by cultivation, with almost half of the biome's native habitats replaced with cultivated lands. Temperate grasslands, temperate broadleaf forests, and Mediterranean forests have each experienced more than 35% conversion. Only the biomes unsuited to crop plants (deserts, boreal forests, and tundra) are relatively intact. (See Table C2.) [4]

Freshwater Systems: Wetlands, Rivers, and Lakes

It is *established but incomplete* that **inland water ecosystems are in worse condition overall than any other broad ecosystem type,** and it is *speculated* that about half of all freshwater wetlands have been lost since 1900 (excluding lakes, rivers, and reservoirs). The degradation and loss of inland water habitats and species is driven by water abstraction, infrastructure development (dams, dikes, levees, diversions, and so on), land conversion in the catchment, overharvesting and exploitation, introduction of exotic species, eutrophication and pollution, and global climate change. [20]

Clearing or drainage for agricultural development is the principal cause of wetland loss worldwide. It is estimated that by 1985, 56–65% of available wetland had been drained for intensive agriculture in Europe and North America, 27% in Asia, 6% in South America, and 2% in Africa. **The construction of dams and other structures along rivers has resulted in fragmentation of almost 40% of the large river systems in the world.** This

Table C2. Comparative Table of Systems as Reported by the Millennium Ecosystem Assessment. Note that these are linked human and ecological systems and often are spatially overlapping. They can therefore be compared but they should not be added up. Figure C1 presents data on human well-being by system type graphically.

[a] Area estimates based on GLC2000 dataset for the year 2000 except for cultivated systems where area is based on GLCCD v2 dataset for the years 1992–93 (C26 Box 1).

[b] Deaths of children less than one year old per 1,000 live births.

[c] Includes only natural protected areas in IUCN categories I to VI.

[d] For all systems except forest/woodland, area transformed is calculated from land depicted as cultivated or urban areas by GLC2000 land cover dataset. The area transformed for forest/woodland systems is calculated as the percentage change in area between potential vegetation (forest biomes of the WWF ecoregions) and current forest/woodland areas in GLC2000. Note: 22% of the forest/woodland system falls outside forest biomes and is therefore not included in this analysis.

[e] Percent of total surface of Earth.

[f] Population density, growth rate, GDP per capita, and growth rate for the inland water system have been calculated with an area buffer of 10 kilometers.

[g] Excluding Antarctica.

is particularly the case in river systems with parts of their basins in arid and semiarid areas. [20]

The water requirements of aquatic ecosystems are in competition with human water demands. Changes in flow regime, transport of sediments and chemical pollutants, modification of habitat, and disruption of the migration routes of aquatic biota are some of the major consequences of this competition. Through consumptive use and interbasin transfers, **several of the world's largest rivers no longer run all the way to the sea for all or part of the year** (such as the Nile, the Yellow, and the Colorado). [7]

The declining condition of inland waters is putting the services derived from these ecosystems at risk. The increase in pollution to waterways, combined with the degradation of wetlands, has reduced the capacity of inland waters to filter and assimilate waste. Water quality degradation is most severe in areas where water is scarce—arid, semiarid, and dry subhumid regions. Toxic substances and chemicals novel to the ecosystem are reaching waterways in increasing amounts with highly uncertain long-term effects on ecosystems and humans. [20]

Estimates are that between 1.5 billion and 3 billion people depend on groundwater supplies for drinking. Groundwater is the source of water for 40% of industrial use and 20% of irrigation globally. In arid countries this dependency is even greater; for example, Saudi Arabia supplies nearly 100% of its irrigation requirement through groundwater. Overuse and contamination of groundwater aquifers are known to be widespread and growing problems in many parts of the world, although many pollution and contamination problems that affect groundwater supplies have been more difficult to detect and have only recently been discovered. [7]

Inland waters have high aesthetic, artistic, educational, cultural, and spiritual values in virtually all cultures and are a focus of growing demand for recreation and tourism. [20]

Dryland Systems: Deserts, Semiarid, and Dry Subhumid Rangelands

Drylands cover 41% of Earth's land surface and are inhabited by more than 2 billion people, about one third of the human population. **Semiarid drylands are the most vulnerable to loss of ecosystem services** (*medium certainty*), because they have a relatively high population in relation to the productive capacity of the system. [22].

Desertification is the process of degradation in drylands, where degradation is defined as a persistent net loss of capacity to yield provisioning, regulating, and supporting ecosystem services. **Worldwide, about 10–20% of drylands are judged to be degraded** (*medium certainty*). The main causes of dryland degradation are grazing with domestic livestock and cutting of trees at rates exceeding the regrowth capacity of the ecosystem, inappropriate cultivation practices that lead to erosion and salinization of the soil, and climate change, which is affecting rates of evapotranspiration and precipitation.

Where the limits to sustainable cultivation and pastoralism have been reached, the promotion of alternative livelihoods such as production of crafts, tourism-related activities, and even aquaculture (such as aquatic organisms of high market value, cultured in often abundant drylands' low-quality water, within evaporation-proof containers) can take some pressure off dryland ecosystems and their services. [22]

Wetlands in drylands, such as oases, rivers, and marshes, are disproportionately important in terms of the biodiversity that they support and the ecosystem services they provide. [20, 22]

It is *well established* that desertification has adverse impacts in non-dryland areas, often many thousands of kilometers away. For example, dust storms resulting from reduced vegetative cover lead to air quality problems, both locally and far away. Drought and loss of land productivity are dominant factors that cause people to migrate from drylands to better-serviced areas. [22]

Forests, Including Woodlands and Tree Plantations

The global area of naturally regenerating forest has declined throughout human history and has halved over the past three centuries. **Forests have effectively disappeared in 25 countries, and more 90% of the former forest cover has been lost in a further 29 countries.** [21]

Following severe deforestation in past centuries, forest cover and biomass in North America, Europe, and North Asia are currently increasing due to the expansion of forest plantations and regeneration of natural forests. From 1990 to 2000, the global area of temperate forest increased by almost 3 million hectares per year, of which approximately 1.2 million hectares were was planted forest. The main location of deforestation is now in the tropics, where it has occurred at an average rate exceeding 12 million hectares per year over the past two decades. (See Figure C5.) **Taken as a whole, the world's forests are not managed in a sustainable way, and there is a total net decrease in global forest area, estimated at 9.4 million hectares per year.** In absolute terms, the rate and extent of woodland loss exceeds that of forests.

The decline in forest condition is caused, among other factors, by the low political power of human communities in forest areas in many countries; deforestation due to competitive land use and poor management; slow change of traditional, wood-oriented forest management paradigms; the lack of forest management on landscape-ecosystem basis; acceleration of natural and human-induced disturbance regimes during the last decade (possibly linked to climate change); and illegal harvest in many developing countries and countries with economies in transition, often linked to corruption. [21]

In addition to the 3.3 billion cubic meters of wood delivered by forests annually, numerous non-wood forest products are important in the lives of hundreds of millions people. Several studies show that the combined economic value of "nonmarket" (social and ecological) services often exceeds the economic value of direct use of the timber, but the nonmarket values are usually not considered in the determination of forest use. Wooded landscapes are home to about 1.2 billion people, and **350 million of the world's people, mostly the poor, depend substantially for their subsistence and survival on local forests.** Forests and woodlands constitute the natural environment and almost sole source of livelihood for 60 million indigenous people and are important in the cultural, spiritual, and recreational life of communities worldwide. [21]

Terrestrial ecosystems, and wooded lands in particular, are taking up about a fifth of the global anthropogenic emissions of carbon dioxide, and they will continue to play a significant role in limiting global climate change over the first decades of this century. Tree biomass constitutes about of 80% of terrestrial biomass, and **forests and woodlands contain about half of the world's terrestrial organic carbon stocks.** Forests and woodlands provide habitat for half or more of the world's known terrestrial plant and animal species, particularly in the tropics. [21]

Marine and Coastal Systems

All the oceans of the world, no matter how remote, are now affected by human activities. Ecosystem degradation associated with fishing activities is the most widespread and dominant impact, with pollution as an additional factor on coastal shelves, and habitat loss a factor in populated coastal areas. [18, 19]

Global fish landings peaked in the late 1980s and are now declining (*medium certainty*). There is little likelihood of this declining trend reversing under current practices. Fishing pressure is so strong in some marine systems that the biomass of targeted species, especially larger fishes as well as those caught incidentally, has been reduced by 10 times or more relative to levels prior to the onset of industrial fishing. **In addition to declining landings, the average trophic level of global landings is declining** (in other words, the high-value top-predator fish are being replaced in catches by smaller, less preferred species), and the mean size of caught fish is diminishing in many species, including yellowfin and bigeye tuna. [18]

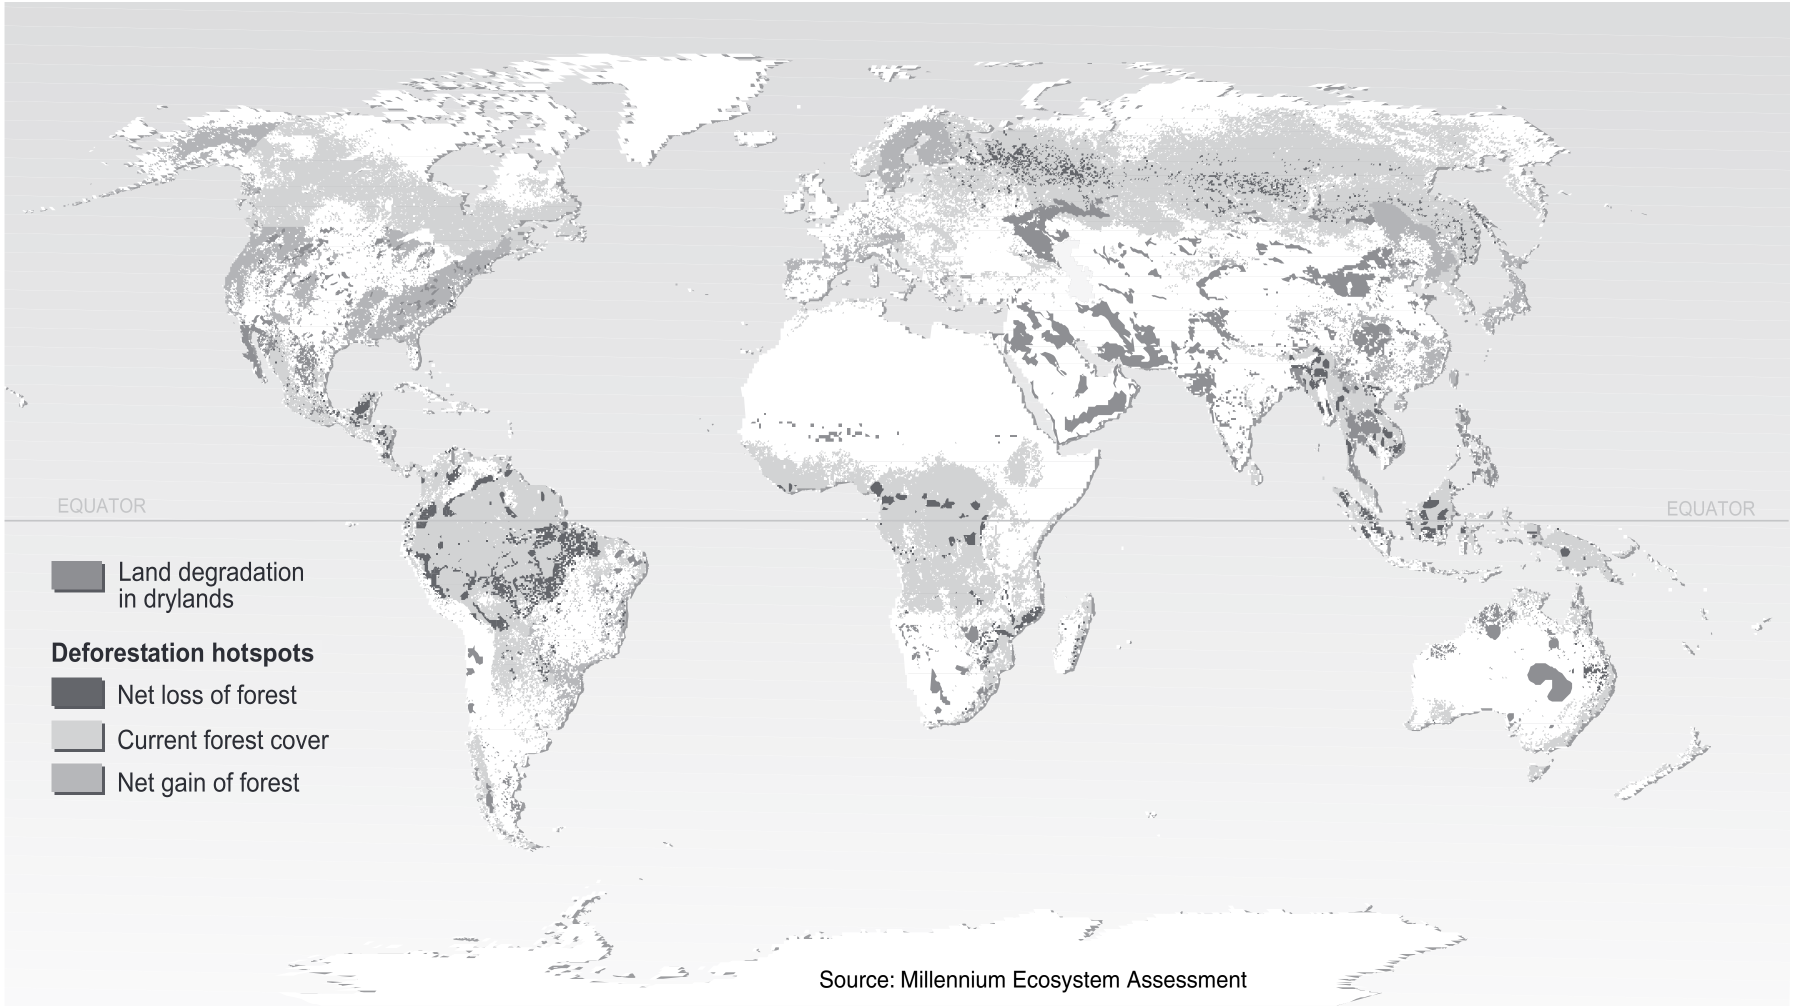

Figure C5. Locations Reported by Various Studies as Undergoing High Rates of Land Cover Change in the Past Few Decades. In the case of forest cover change, the studies refer to the period 1980–2000 and are based on national statistics, remote sensing, and to a limited degree expert opinion. In the case of land cover change resulting from degradation in drylands (desertification), the period is unspecified but inferred to be within the last half-century, and the major study was entirely based on expert opinion, with associated high levels of uncertainty. Change in cultivated area is not shown. Note that areas showing little current change are often locations that have already undergone major change.

Industrial fleets are fishing further offshore and deeper to meet the global demand for fish. Until a few decades ago, depth and distance from coasts protected much of the deep-ocean fauna from the effect of fishing. Massive investments in the development of fishing capacity has led to fleets that now operate in all parts of the world's oceans, including polar areas, at great depths, and in low-productivity tropical zones. These trawl catches are extracted from easily depleted accumulations of long-lived species. The biomass of large pelagic fishes exploited by long liners, purse seiners, and drift netters have also plummeted. **Some fisheries that collapsed in recent decades show no signs of recovering**, such as Newfoundland cod stocks in the northwest Atlantic and orange roughy in New Zealand. [18]

Oil spills, depletions of marine mammals and seabirds, and ocean dumping also contribute to degradation in marine systems, especially at local and regional scales. Although major oils spills are infrequent, their impacts are severe when they do occur. Overfishing and pollution affect marine mammals and seabirds through declining food availability. An estimated 313,000 containers of low-intermediate radioactive waste dumped in the Atlantic and Pacific Oceans since 1970 pose a significant threat to deep-sea ecosystems should the containers leak. [18]

Coastal ecosystems are among the most productive yet highly threatened systems in the world. Approximately 35% of mangroves for which data are available and 20% of coral reefs are estimated to have been destroyed, and a further 20% of corals degraded globally since 1960. Degradation is also a severe problem, both from pressures originating within the coastal zones and from the negative impacts of upstream land uses. Upstream freshwater diversion has meant a 30% decrease worldwide in water and sediment delivery to estuaries, which are key nursery areas and fishing grounds. [19] Knowledge of cold-water corals is limited, and new large reefs are still being discovered. Cold-water coral reefs are estimated to have high species diversity, the biggest threat to which comes from fishery trawling activities.

The main indirect drivers of coastal ecosystem change are related to development activities on the land, particularly in areas adjacent to the coast. Approximately 17% of the world lives within the boundaries of the MA coastal system (up to an elevation of 50 meters above sea level and no further than 100 kilometers from a coast), and approximately 40% live in the full area within 100 kilometers of a coast. The absolute number is increasing through a combination of in-migration, high reproduction rates, and tourism. Physical demand on coastal space is increasing through urban sprawl, resort and port development, and aquaculture, the impacts of which extend beyond the direct footprints due to pollution, sedimentation, and changes in coastal dynamics. Destructive fishing practices, overharvesting, climate change, and associated sea level rise are also important threats to coastal habitats, including forests, wetlands, and coral reefs.

Nearly half of the coastal population has no access to improved sanitation and thus faces increasing risks of disease as well as decreasing ecosystem services as a result of pollution by human wastes. Harmful algal blooms and other pathogens affecting the health of both humans and marine organisms are on the rise. [19] Nitrogen loading to the coastal zone has doubled worldwide and has driven coral reef community shifts. Alien species invasions have also altered coastal ecosystems and threaten both marine species and human well-being. [18]

Island Systems

The ability of island systems to meet the rising demands of local populations for services has declined considerably, such that some islands are now unable to meet such demands without importing significant services from elsewhere. **Biodiversity loss and habitat destruction on islands can have more immediate and serious repercussions than on continental systems,** as a consequence of the relatively restricted genetic diversity, small population sizes and narrow distribution ranges of plants and animals on islands. Many studies show that specialization, coupled with isolation and endemism, make island ecosystems especially sensitive to disturbances. Island species have become extinct at rates that have exceeded those observed on continents, and the most important driver of wild population declines and species extinction on islands has been the introduction of invasive alien species. Although the idea that islands are more susceptible to biological invasion is poorly supported by current information, the impacts of invasive species once they are established are usually more rapid and more pronounced on islands. [23]

In recent years tourism, especially nature-based tourism, has been the largest area of economic diversification for inhabited islands. However, unplanned and unregulated development has resulted in ecosystem degradation, including pollution, and loss of coral reefs, which is undermining the very resource on which the tourism sector is based. Alternative, more environmentally and culturally sensitive forms of tourism ("ecotourism") have developed in some areas. [23]

Cultivated Systems: Croplands, Planted Pastures, and Agroforestry

Cultivated lands are ecosystems highly transformed and managed by humans for the purpose of providing food and fiber, often at the expense of other ecosystem services. **More land was converted to cropland in the 30 years after 1950 than in the 150 years between 1700 and 1850, and one quarter of Earth's terrestrial surface is now occupied by cultivated systems.** (See Figure C6.) Within this area, one fifth is irrigated. [26]

As the demand for food, feed, and fiber has increased, farmers have responded both by expanding the area under cultivation (extensification) and by raising yields per unit land and per unit time (intensification). **Over the past 40 years, in global aggregate, intensification has been the primary source of increased output,** and in many regions (including in the European Union, North America, Australia, and recently China) the extent of land under cultivation has stabilized or even contracted. However, countries with low productivity and high population pressure—conditions that apply in much of sub-Saharan Africa—continue to rely mainly on expansion of cultivated areas for increasing food productivity. In Asia (outside of China), almost no high-productivity land remains available for the expansion of agriculture. Area expansion usually brings more marginal land (steeper slopes, poorer soils, and harsher climates) into production, often with unwelcome social and environmental consequences. Urban expansion is a growing cause of displacement of cultivation, but the area involved remains small in global terms. [26]

Increases in the yields of crop production systems due to increased use of inputs over the past 40 years have reduced the pressure to convert other ecosystems into cropland. Twenty million square kilometers of natural ecosystem have been protected from conversion to farmland since 1950 due to more intensive production. On the other hand, intensification has increased pressure on inland water ecosystems due to increased water withdrawals for irrigation and to nutrient and pesticide leakage from cultivated lands, with negative consequences for freshwater and coastal systems, such as eutrophication. Intensification also generally reduces biodiversity within agricultural landscapes and requires higher energy inputs in the form of mechanization and the production of chemical fertilizers. Especially in systems that are already highly intensified, the marginal value of further increased production must be weighed against the additional environmental impacts. [26]

The intrinsic capacity of cultivated systems to support crop production is being undermined by soil erosion and salinization and by loss of agricultural biodiversity, but their effect on food production is masked by increasing use of fertilizer, water, and other agricultural inputs. (See Figure C7.) [8, 22, 26]

National policies, international agreements, and market forces play a significant role in determining the fate of ecosystems services as a consequence of cultivation. They all influence farmer choices about the scale and type of cultivation as well as the level and mix of production inputs that, in turn, influence trade-offs among the mix and level of ecosystem services that cultivated systems can deliver. [26]

Urban Systems

Urban areas currently cover less than 3% of the total land area of Earth, but they contain an increasing fraction of the world's population. Currently about half of the world's people live in urban areas. The urban requirements for ecosystem services are high, but it could be just as stressful if the same number of people, with similar consumption and production patterns, were dispersed over the rural landscape. In general, **the well-being of urban dwellers is higher than that of their rural neighbors,** as measured by wealth, health, and education indicators. Urban centers facilitate human access to and management of certain ecosystem services through, for example, the scale economies of piped water systems. [27]

Nevertheless, urban developments pose significant challenges with respect to ecosystem services and human well-being. The problems include inadequate and inequitable access to ecosystem services within urban areas, degradation of ecosystems adjoining urban areas, and pressures on distant ecosystems resulting from production, consumption, and trade originating in urban areas. [27]

In affluent countries, the negative impacts of urban settlements on ecosystem services and human well-being have been delayed and passed on to future generations or displaced onto locations away from the urban area. While urban developments in other parts of the world have been quite different, this trend and its political implication remain significant. [27]

Interrelated problems involving local water, sanitation, waste, and pests contribute a large share of the urban burden of disease, especially in low-income settlements. The consumption and production activities driving long-term, global ecosystem change are concentrated in urban centers, especially upper-income settlements. [27]

Urbanization is not inherently bad for ecosystems: ecosystems in and around urban areas can provide a high level of biodiversity, food production, water services, comfort, amenities, cultural values, and so on if well managed. When the loss of ecosystem services due to urban activities is systematically addressed,

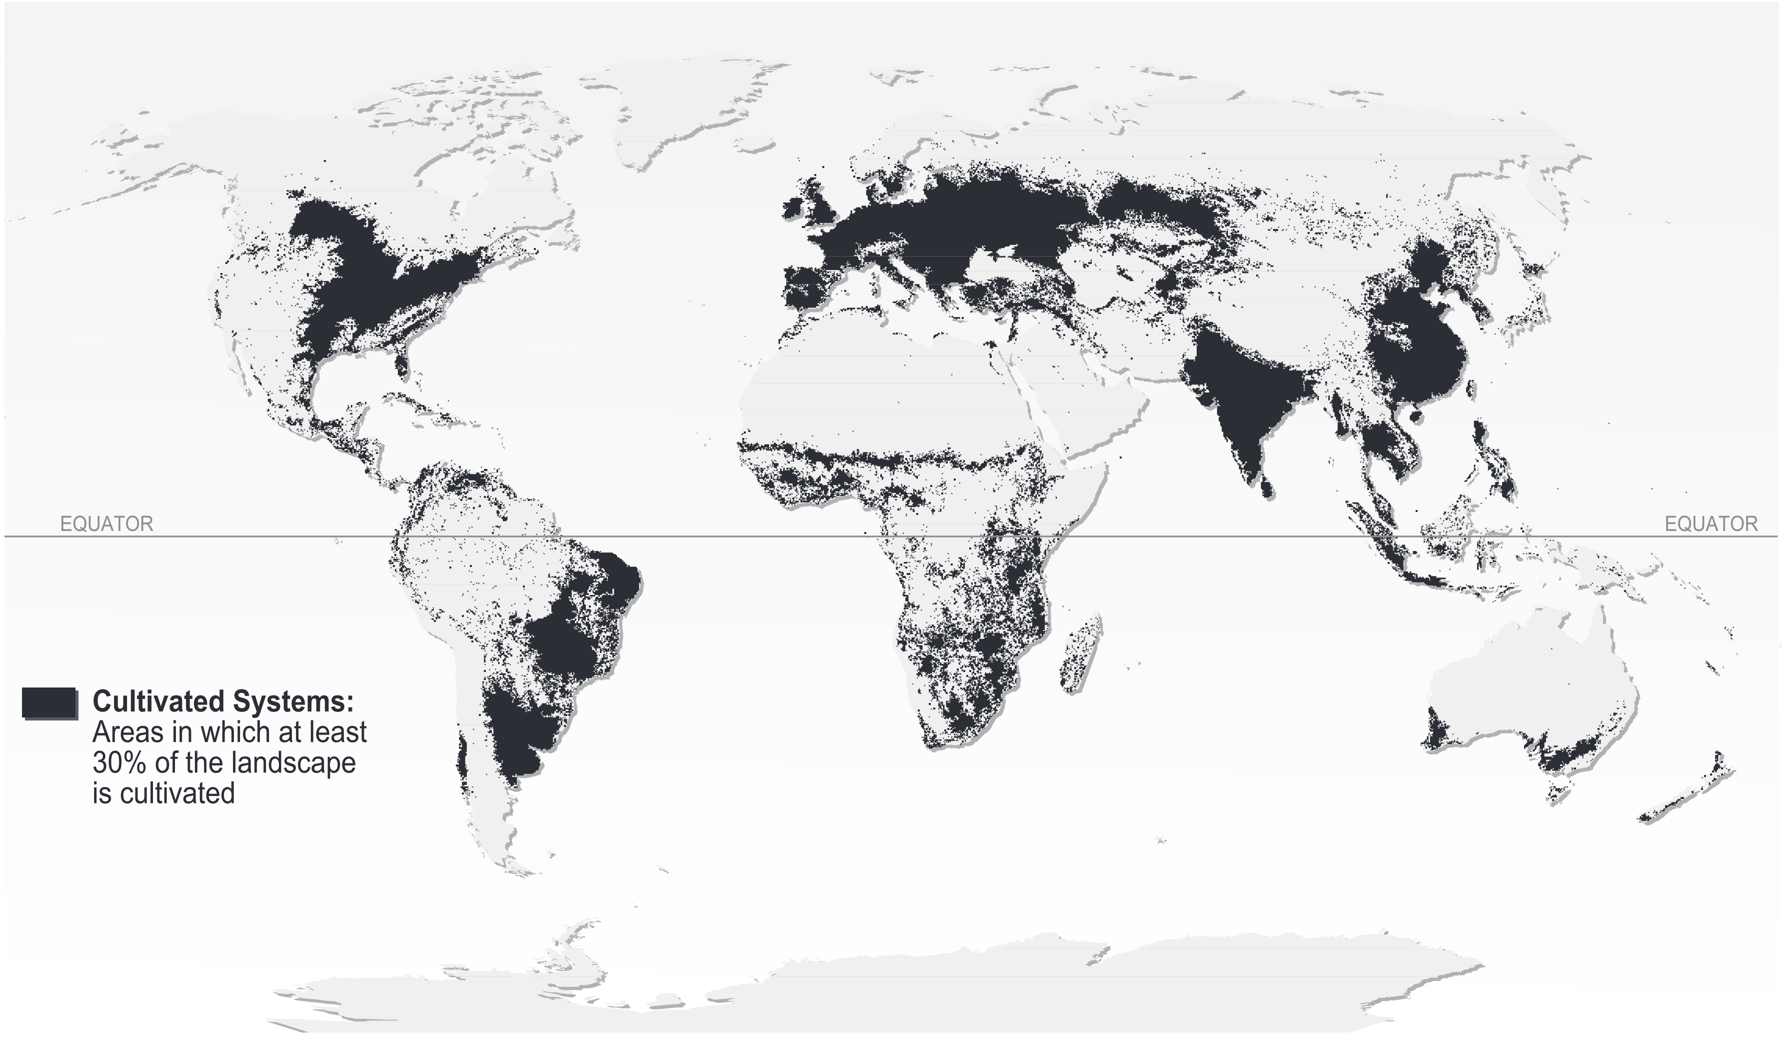

Figure C6. Extent of Cultivated Systems in 2000. Cultivated systems (defined in the MA to be areas in which at least 30% of the landscape comes under cultivation in any particular year) cover 24% of the terrestrial surface.

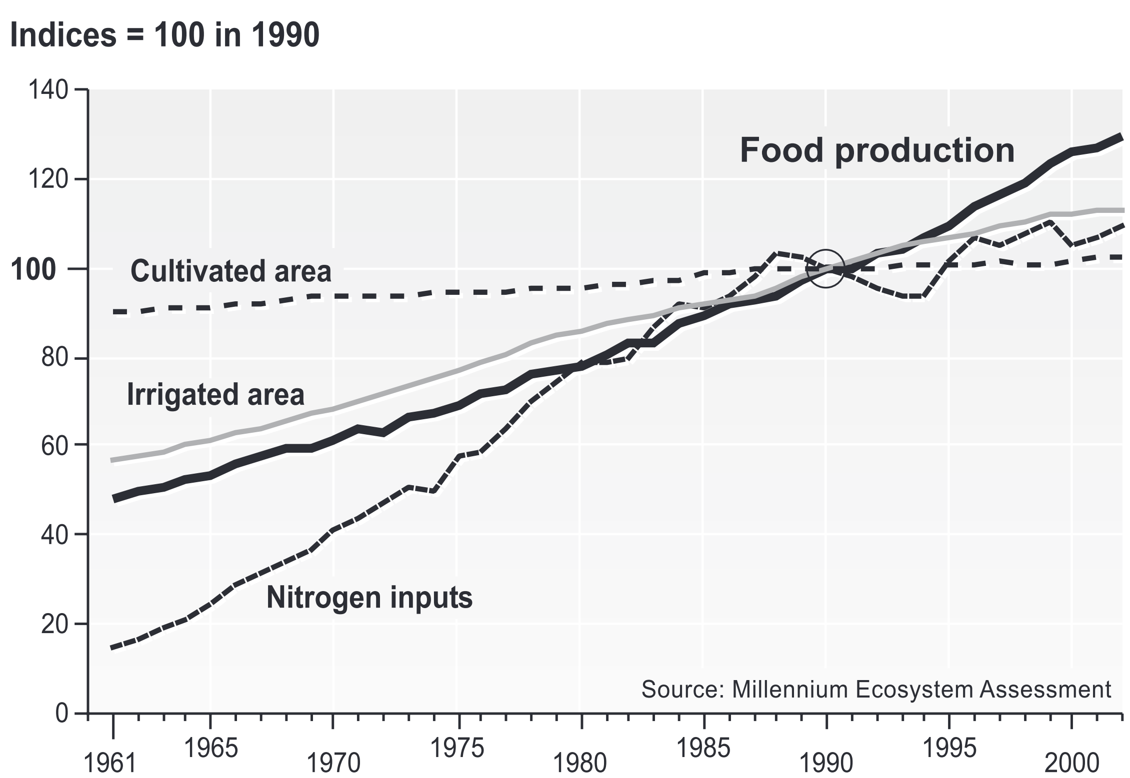

Figure C7. Trends in the Factors Related to Global Food Production since 1961. There have been significant trade-offs in cultivated systems between food production and water availability for other uses (due to irrigation), as well as water quality (due to increased nutrient loading). The role of improved crop varieties has also been extremely significant since 1961.

these losses can be greatly reduced. With a few exceptions, however, there is little evidence of cities taking significant steps to reduce their global ecosystem burdens. A city may be sustained by ecosystem services derived from an area up to 100 times larger than the city itself. [27]

Polar Systems

Direct, locally caused impacts of human activities on polar regions have been modest, and the most significant causes of change mainly originate outside the polar region. These global drivers must be addressed if loss of polar ecosystem services and human well-being is to be avoided, but in the immediate term, mitigation of impacts is the most feasible and urgent strategy. Polar regions have a high potential to continue providing key ecosystem services, particularly in wetlands, where biodiversity and use of subsistence resources are concentrated. [25]

The climate has warmed more quickly in portions of the Arctic (particularly in the western North American Arctic and central Siberia) and Antarctic (especially the Antarctic peninsula) than in any other region on Earth. **As a consequence of regional warming, ecosystem services and human well-being in polar regions have been substantially affected** (*high certainty*). Warming-induced thaw of permafrost is widespread in Arctic wetlands, causing threshold changes in ecosystem services, including subsistence resources and climate feedbacks (energy and trace gas fluxes) and support for industrial and residential infrastructure.

Regional warming interacts with socioeconomic change to reduce the subsistence activities of indigenous and other rural people, the segment of society with greatest cultural and economic dependence on these resources. Warming has reduced access to marine mammals due to there being less sea ice and has made both the physical and the biotic environment less predictable. Industrial development has further reduced the capacity of ecosystems to support subsistence activities in some locations. The net effect is generally to increase the economic disparity between rural subsistence users and urban residents in polar regions. [25]

Changes in polar biodiversity are affecting the resources on which Arctic people depend for their livelihoods. Important changes include increased shrub dominance in Arctic wetlands, which contributes to summer warming trends and alters forage available to caribou; changes in insect abundance that alter food availability to wetland birds and energy budgets of reindeer and caribou; increased abundance of snow geese that are degrading Arctic wetlands; and overgrazing by domestic reindeer in parts of Fennoscandia and Russia. There has also been a reduction of top predators in Antarctic food webs, altering marine food resources in the Southern Ocean. [25]

Increases in persistent organic pollutants and radionuclides in subsistence foods have increased health risks in some regions of the Arctic, but diet changes associated with the decline in harvest of these foods are usually a greater health risk. [25]

Mountain Systems

Mountain systems straddle all geographical zones and contain many different ecosystem types. Ninety percent of the 720 million people in the global mountain population live in developing and transition countries, with one third of them in China. **Almost all of the people living above 2,500 meters (about 70 million people) live in poverty and are especially vulnerable to food insecurity.**

Human well-being in lowland areas often depends on resources originating in mountain areas, such as timber, hydroelectricity, and water. Indeed, river basins from mountain systems supply nearly half of the human population with water, including in some regions far from the mountains themselves, and **loss of ecosystem functions in mountains increases environmental risks in both mountains and adjacent lowland areas.** However, there is rarely a systematic reinvestment of benefits derived from mountain systems in the conservation of upland resources. Mountains often represent political borders, narrow key transport corridors, or refuges for minorities and political opposition, and as such they are often focal areas of armed conflicts. [24]

The compression of climatic zones along an elevation gradient in mountains results in large habitat diversity and species richness in mountains, which commonly exceeds that found in lowlands. Rates of endemism are also relatively high in mountains due to topographic isolation. Mountains occupy about one fifth of the terrestrial surface but host a quarter of terrestrial biodiversity, nearly half of the world's biodiversity "hotspots," and 32% of the global area designated for biodiversity protection. Mountains also have high ethnocultural diversity. Scenic landscapes and clean air make mountains target regions for recreation and tourism. [24]

Mountain ecosystems are unusually exposed and sensitive to a variety of stresses, specifically climate-induced vegetative changes, volcanic and seismic events, flooding, loss of soil and vegetation caused by extractive industries, and inappropriate agricultural practices. On average, glaciers have lost 6–7 meters of depth (thickness) over the last 20 years, and this reduction in glacier volume is expected to have a strong impact on dry-season river flows in rivers fed largely by ice melt. **The specialized nature of mountain biota and low temperatures in mountain systems make recovery from disturbances typically very slow.** [24]

Limits, Trade-offs, and Knowledge

- **The growing demand for provisioning services, such as water, food, and fiber, has largely been met at the expense of supporting, regulating, and cultural ecosystem services.**
- **For some provisioning services, notably fresh water and wild-harvested fish, demand exceeds the available supply in large and expanding parts of the world.**
- **Some ongoing, large-scale human-induced ecosystem changes, such as those involving loss of biodiversity, climate change, excessive nutrient supply, and desertification, are effectively irreversible. Urgent mitigation action is needed to limit the degree of change and its negative impacts on human well-being.**
- **Enough is known to begin to make wiser decisions regarding protection and use of ecosystem services. Making this information available to decision-makers is the purpose of the Millennium Ecosystem Assessment.**

Limits and Thresholds in Coupled Human-Ecological Systems

The current demand for many ecosystems services is unsustainable. If current trends in ecosystem services are projected, unchanged, to the middle of the twenty-first century, there is a high likelihood that widespread constraints on human well-being will result. This highlights the need for globally coordinated adaptive responses, a topic further explored in the MA *Scenarios* and *Policy Responses* volumes.

Some limits to the degree of acceptable ecosystem change represent the level of tolerance by society, reflecting the trade-offs that people are willing (or forced) to make between different aspects of well-being. They are "soft limits," since they are socially determined and thus move as social circumstances change. Many such limits are currently under international negotiation, indicating that some key ecosystem services are approaching levels of concern. Examples are the amounts of fresh water allocated to different countries in shared basins, regional air quality norms, and the acceptable level of global climate change.

Other limits are a property of the ecological system itself and can be considered "hard limits." Two types of hard limit are of concern. The first is nonlinearity, which represents a point beyond which the loss of ecosystem services accelerates, sometimes abruptly. An example is the nitrogen saturation of watersheds: once the absorptive capacity of the ecosystem is exceeded, there is a sudden increase in the amount of nitrogen leaking into the aquatic environment. The second type is a true system threshold that, if crossed, leads to a new regime from which return is difficult, expensive, or even impossible. An example is the minimum habitat area required to sustain a viable population of a given species. If the area falls below this, eventual extinction is inevitable. We have fallen below this limit for many thousands of species (*medium certainty*).

Abrupt and possibly irreversible change may not be widely apparent until it is too late to do much about it. The dynamics of both ecological and human systems have intrinsic inertia—the tendency to continue changing even when the forces causing the change are relieved. The complexity of coupled human–ecological systems, together with our state of partial knowledge, make it hard to predict precisely at what point such thresholds lie. The overexploitation of wild fisheries is an example of a threshold that has already been crossed in many regions. [6, 13, 18, 25]

Thresholds of abrupt and effectively irreversible change are known to exist in the climate-ocean-land system (*high certainty*), although their location is only known with *low to medium certainty*. For example, it is *well established* that a decrease in the vegetation cover in the Sahara several thousand years ago was linked to a decrease in rainfall, promoting further loss of cover, leading to the current dry Sahara. It is *speculated* that a similar mechanism may have been involved in the abrupt decrease in rainfall in the Sahel in the mid-1970s. There are potential thresholds associated with climate feedbacks on the global carbon cycle, but large uncertainties remain regarding the strength of the feedback processes involved (such as the extent of warming-induced increases in soil respiration, the risk of large-scale dieback of tropical forests, and the effects of CO_2, nitrogen, and dust fertilization on carbon uptake by terrestrial and marine ecosystems). [12, 13, 22, 25]

Current human-induced greenhouse gas emissions to the atmosphere are greater than the capacity of global ecosystems to absorb them (*high certainty*). The oceans and terrestrial ecosystems are currently absorbing only about half of the carbon emissions resulting from fossil fuel combustion. As a result, the atmospheric concentration of CO_2 is rising, along with other greenhouse gases, leading to climate change. Although land use management can have a significant impact on CO_2 concentrations in the short term, future trends in atmospheric CO_2 are likely to depend more on fossil fuel emissions than on ecosystem change. [13]

Nitrogen additions to the environment are approaching critical limits in many regions. The increasing extent of oxygen-poor "dead zones" in freshwater or coastal ecosystems that have received elevated inputs of nutrients—nitrogen and phosphorus, in particular—over long periods of time is a symptom of the degree to which the nutrient retention capacity of terrestrial and freshwater systems has been overloaded. [12]

The capacity of Earth as a whole to render other waste products of human activities relatively harmless is unknown. It is *well established* that at high loading rates of wastes such as persistent organic pollutants, heavy metals, and radionuclides, the local ecosystem capacity can be overwhelmed, allowing waste accumulation to the detriment of human well-being and the loss of ecosystem biodiversity [15]. A potential nonlinear response, currently the subject of intensive scientific research, is the atmospheric capacity to cleanse itself of air pollution (in particular, hydrocarbons and reactive nitrogen compounds). This capacity depends on chemical reactions involving the hydroxyl radical, the atmospheric concentration of which has declined by about 10% (*medium certainty*) since preindustrial times. [13]

Understanding the Trade-offs Associated with Our Actions

The growth in human well-being over the last several decades has come in large part through increases in provisioning services, usually at the expense of other services. In particular:

- The substantial increase in the production of food and fiber has expanded the area of cultivated systems (including plantation forests) at the expense of semi-natural ecosystems such as forests, rangelands, and wetlands. It has largely been achieved as a result of large inputs of nutrients, water, energy, and pesticides, with deleterious consequences for other ecosystems and the global climate.
- Clearing and transformation of previously forested land for agricultural and timber production, especially in tropical and sub-tropical forests, has reduced the land's capacity to regulate flows of water, store carbon, and support biological diversity and the livelihoods of forest-dwelling people.
- Harvesting of fish and other resources from coastal and marine systems (which are simultaneously under pressure from elevated flows of nutrients, sediments, and pollutants from the land) has impaired these systems' capacity to continue to deliver food in the future.

This assessment has shown that although we have many of the conceptual and analytical tools to illustrate the existence of trade-offs, the detailed information required to quantify adequately even the main trade-offs in economic terms is generally either lacking or inaccessible. An example of a tool useful for trade-off analysis is the valuation of ecosystem services, but such valuations have only been done for a few services and in a few places. The MA has also shown that failure to fully comprehend the trade-offs associated with particular actions has, in many instances, resulted either in a net decrease in human well-being or in an increase that is substantially less than it could have been. Examples of this include the loss of non-wood products and watershed services from overlogged forests, the loss of timber and the declines in offshore fisheries and storm protection from conversion of mangroves to aquaculture, and the loss of wetland products from conversion to intensive agriculture. (See Figure C8.) The continued tendency to make decisions on a sectoral basis prevents trade-offs from being fully considered.

Several independently derived international goals and commitments are interconnected via the ecosystems they affect. Thoughtful and informed consideration of trade-offs and synergies would be best achieved by coordinated implementation. An example of the importance of ecosystem service trade-offs in the pursuit of human well-being is provided by the Millennium Development Goals. In meeting the goal of reducing hunger, for instance, progress toward the goal of environmental sustainability could be compromised, and vice versa. A narrowly sectoral approach often simply displaces problems to other sectors. Ecosystem approaches, as adopted by the Convention on Biological Diversity, the Ramsar Convention on Wetlands, the Food and Agriculture Organization, and others, show promise for improving the future condition of services and human

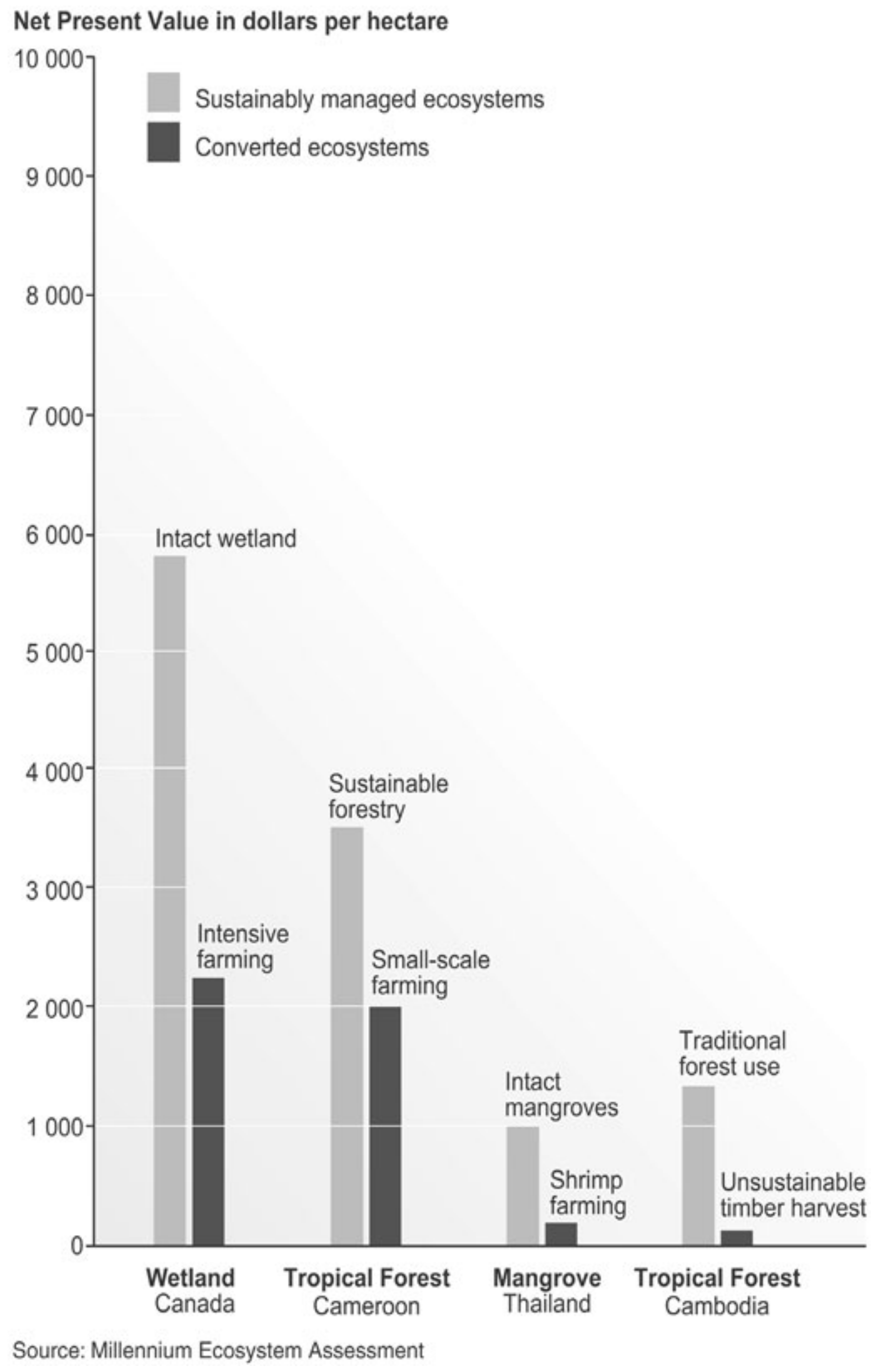

Figure C8. Economic Benefits under Alternate Management Practices. In each case, the net benefits from the more sustainably managed ecosystem are greater than those from the converted ecosystem even though the private (market) benefits would be greater from the converted ecosystem. (Where ranges of values are given in the original source, lower estimates are plotted here.)

well-being as a whole, specifically by balancing the objectives of economic development and ecosystem integrity. In managing ecosystems, a balance needs to be found between provisioning services on the one hand and supporting, regulating, cultural and amenity services on the other hand. [7, 28]

Knowledge and Uncertainty

The experience of this assessment has been that it is hard to demonstrate, quantitatively and unequivocally, the widely accepted and intuitive link between ecosystem changes and changes in human well-being. There are several reasons for this. First, the impacts of ecosystem change on well-being are often subtle, which is not to say unimportant; impacts need not be blatant to be significant. Second, human well-being is affected by many factors in addition to the effects of ecosystem services. Health outcomes, for example, are the combined result of ecosystem condition, access to health care, economic status, and myriad other factors. Unequivocally linking ecosystem changes to changes in well-being, and vice versa, is especially difficult when the data are patchy in both cases, as they usually are. Analyses linking well-being and ecosystem condition are most easily carried out at a local scale, where the linkages can be most clearly identified, but information on ecosystems and human well-being is often only available in highly aggregated form, for instance at the national level. Spatially explicit data with sub-national resolution would greatly facilitate future assessments. [2]

The availability and accuracy of data sources and methods for this assessment were greatest for provisioning services, such as crop yield and timber production. Direct data on regulating, supporting, and cultural services such as nutrient cycling, climate regulation, or aesthetic value are difficult to obtain, making it necessary to use proxies, modeled results, or extrapolations from case studies. Data on biodiversity have strong biases toward the species level, large organisms, temperate systems, and species used directly by people. [2, 4, 28]

Knowledge for quantifying ecosystem responses to stress is equally uneven. Methods to estimate crop yield responses to fertilizer application, for example, are well developed, but methods to quantify relationships between ecosystem services and human well-being, such as the effects of altered levels of biodiversity on the incidence of diseases in humans, are at an earlier stage of development. Thousands of novel chemicals, including long-lived synthetic pharmaceuticals, are currently entering the biosphere, but there are few systematic studies to understand their impact on ecosystems and human well-being. [2, 28]

Observation systems relating to ecosystem services are generally inadequate to support informed decision-making. Some previously more-extensive observation systems have declined in recent decades. For example, substantial deterioration of hydrographic networks is occurring throughout the world. The same is true for standard water quality monitoring and the recording of biological indicators. [7]

Both "traditional" and "formal" knowledge systems have considerable value for achieving the conservation and sustainable use of ecosystems. The loss of traditional knowledge has significantly weakened the linkages between ecosystems and cultural diversity and cultural identity. This loss has also had a direct negative effect on biodiversity and the degradation of ecosystems, for instance by exceeding traditionally established norms for resource use. This knowledge is largely oral. As significant is the loss of languages, which are the vehicle by which cultures are communicated and reproduced. [17]

A Call for Action

Despite the gaps in knowledge, **enough is known to indicate the need for urgent collective action, building on existing activities, to mitigate the further loss of ecosystem services.** It is *well established* that inadequate access to ecosystem services currently is an important factor in the low well-being of a large fraction of the global population and is likely to constrain improvements in well-being in the future.

Urgency is indicated because in situations where the probability of effectively irreversible, negative impacts is high, where the human and natural systems involved have high inertia, and where knowledge of the consequences is incomplete, early action to reduce the rate of change is more rational than waiting until conditions become globally intolerable and potentially irreversible. **Collective action is required** because uncoordinated individual action is necessary but insufficient to mitigate the many issues that have large-scale underlying causes, mechanisms, or consequences. Coordinated action at all levels of social organization—from local to global—is called for if the many islands of local failure are not to coalesce into expanding regions of degradation and if problems with global reach are to be managed. Coordinated action is also required to enable islands of local success to be expanded and propagated in distant locations.

The history of human civilization has many examples of social upheaval associated with ecosystem service failure at the local or regional scale. There are many current examples where the demands on ecosystems are exceeding the limits of the system to supply ecosystem services. Global-scale examples are given in this report, and local and regional examples are found in the *Multiscale Assessments* volume. **Two things are different now compared with any other time in history: human impacts are now ubiquitous and of greater intensity than at any time in the past, and in most cases we can no longer plead ignorance of the consequences.** Whereas in the past, natural disasters, pollution, or resource depletion led to local hardships, realignment of power, and the regional migration of people to better-serviced areas, in the present era the impacts are global in reach. Displacement of the problem to other places and future generations, or starting afresh in a new place, are no longer viable options.

A turning point in the growth of the human population on Earth is likely by mid-century. As the *Scenarios* and *Policy Responses* volumes show, the opportunity and technical means exist to provide food, water, shelter, a less-hazardous environment, and a better life to the existing population, and even to the additional 3 billion people likely to inhabit Earth by the middle of the twenty-first century, but we are currently failing to achieve this. We are also undermining our capacity to do so in the future by failing to take actions that will reduce the risk of adverse changes in Earth's ecological systems that will be difficult and costly to reverse.

Reducing the pressure on critical systems and services will be neither easy nor cost-free, but it is certain that net human well-being is better served by maintaining ecosystems in a condition that is capable of providing adequate levels of essential services than by trying to restore such functions at some future time.

Chapter 1

MA Conceptual Framework

BOXES

FIGURES

This chapter provides the summary of Millennium Ecosystem Assessment, *Ecosystems and Human Well-being: A Framework for Assessment* (Island Press, 2003), pp. 1–25, which was prepared by an extended conceptual framework writing team of 51 authors and 10 contributing authors.

Main Messages

Human well-being and progress toward sustainable development are vitally dependent upon improving the management of Earth's ecosystems to ensure their conservation and sustainable use. But while demands for ecosystem services such as food and clean water are growing, human actions are at the same time diminishing the capability of many ecosystems to meet these demands.

Sound policy and management interventions can often reverse ecosystem degradation and enhance the contributions of ecosystems to human well-being, but knowing when and how to intervene requires substantial understanding of both the ecological and the social systems involved. Better information cannot guarantee improved decisions, but it is a prerequisite for sound decision-making.

The Millennium Ecosystem Assessment was established to help provide the knowledge base for improved decisions and to build capacity for analyzing and supplying this information.

This chapter presents the conceptual and methodological approach that the MA used to assess options that can enhance the contribution of ecosystems to human well-being. This same approach should provide a suitable basis for governments, the private sector, and civil society to factor considerations of ecosystems and ecosystem services into their own planning and actions.

1.1 Introduction

Humanity has always depended on the services provided by the biosphere and its ecosystems. Further, the biosphere is itself the product of life on Earth. The composition of the atmosphere and soil, the cycling of elements through air and waterways, and many other ecological assets are all the result of living processes—and all are maintained and replenished by living ecosystems. The human species, while buffered against environmental immediacies by culture and technology, is ultimately fully dependent on the flow of ecosystem services.

In his April 2000 Millennium Report to the United Nations General Assembly, in recognition of the growing burden that degraded ecosystems are placing on human well-being and economic development and the opportunity that better managed ecosystems provide for meeting the goals of poverty eradication and sustainable development, United Nations Secretary-General Kofi Annan stated that:

> *It is impossible to devise effective environmental policy unless it is based on sound scientific information. While major advances in data collection have been made in many areas, large gaps in our knowledge remain. In particular, there has never been a comprehensive global assessment of the world's major ecosystems. The planned Millennium Ecosystem Assessment, a major international collaborative effort to map the health of our planet, is a response to this need.*

The Millennium Ecosystem Assessment was established with the involvement of governments, the private sector, nongovernmental organizations, and scientists to provide an integrated assessment of the consequences of ecosystem change for human well-being and to analyze options available to enhance the conservation of ecosystems and their contributions to meeting human needs. The Convention on Biological Diversity, the Convention to Combat Desertification, the Convention on Migratory Species, and the Ramsar Convention on Wetlands plan to use the findings of the MA, which will also help meet the needs of others in government, the private sector, and civil society. The MA should help to achieve the United Nations Millennium Development Goals and to carry out the Plan of Implementation of the 2002 World Summit on Sustainable Development. It has mobilized hundreds of scientists from countries around the world to provide information and clarify science concerning issues of greatest relevance to decision-makers. The MA has identified areas of broad scientific agreement and also pointed to areas of continuing scientific debate.

The assessment framework developed for the MA offers decision-makers a mechanism to:

- ***Identify options that can better achieve core human development and sustainability goals. All countries and communities are grappling with the challenge of meeting growing demands for food, clean water, health, and employment.*** And decision-makers in the private and public sectors must also balance economic growth and social development with the need for environmental conservation. All of these concerns are linked directly or indirectly to the world's ecosystems. The MA process, at all scales, was designed to bring the best science to bear on the needs of decision-makers concerning these links between ecosystems, human development, and sustainability.
- ***Better understand the trade-offs involved—across sectors and stakeholders—in decisions concerning the environment.*** Ecosystem-related problems have historically been approached issue by issue, but rarely by pursuing multisectoral objectives. This approach has not withstood the test of time. Progress toward one objective such as increasing food production has often been at the cost of progress toward other objectives such as conserving biological diversity or improving water quality. The MA framework complements sectoral assessments with information on the full impact of potential policy choices across sectors and stakeholders.
- ***Align response options with the level of governance where they can be most effective.*** Effective management of ecosystems will require actions at all scales, from the local to the global. Human actions now directly or inadvertently affect virtually all of the world's ecosystems; actions required for the management of ecosystems refer to the steps that humans can take to modify their direct or indirect influences on ecosystems. The management and policy options available and the concerns of stakeholders differ greatly across these scales. The priority areas for biodiversity conservation in a country as defined based on ''global'' value, for example, would be very different from those as defined based on the value to local communities. The multiscale assessment framework developed for the MA provides a new approach for analyzing policy options at all scales—from local communities to international conventions.

1.2 What Is the Problem?

Ecosystem services are the benefits people obtain from ecosystems, which the MA describes as provisioning, regulating, supporting, and cultural services. (See Box 1.1.) Ecosystem services include products such as food, fuel, and fiber; regulating services such as climate regulation and disease control; and nonmaterial benefits such as spiritual or aesthetic benefits. Changes in these services affect human well-being in many ways. (See Figure 1.1.)

The demand for ecosystem services is now so great that trade-offs among services have become the rule. A country can increase food supply by converting a forest to agriculture, for example, but

BOX 1.1
Key Definitions

Ecosystem. An ecosystem is a dynamic complex of plant, animal, and microorganism communities and the nonliving environment interacting as a functional unit. Humans are an integral part of ecosystems. Ecosystems vary enormously in size; a temporary pond in a tree hollow and an ocean basin can both be ecosystems.

Ecosystem services. Ecosystem services are the benefits people obtain from ecosystems. These include provisioning services such as food and water; regulating services such as regulation of floods, drought, land degradation, and disease; supporting services such as soil formation and nutrient cycling; and cultural services such as recreational, spiritual, religious and other nonmaterial benefits.

Well-being. Human well-being has multiple constituents, including basic material for a good life, freedom of choice and action, health, good social relations, and security. Well-being is at the opposite end of a continuum from poverty, which has been defined as a "pronounced deprivation in well-being." The constituents of well-being, as experienced and perceived by people, are situation-dependent, reflecting local geography, culture, and ecological circumstances.

in so doing it decreases the supply of services that may be of equal or greater importance, such as clean water, timber, ecotourism destinations, or flood regulation and drought control. There are many indications that human demands on ecosystems will grow still greater in the coming decades. Current estimates of 3 billion more people and a quadrupling of the world economy by 2050 imply a formidable increase in demand for and consumption of biological and physical resources, as well as escalating impacts on ecosystems and the services they provide.

The problem posed by the growing demand for ecosystem services is compounded by increasingly serious degradation in the capability of ecosystems to provide these services. World fisheries are now declining due to overfishing, for instance, and a significant amount of agricultural land has been degraded in the past half-century by erosion, salinization, compaction, nutrient depletion, pollution, and urbanization. Other human-induced impacts on ecosystems include alteration of the nitrogen, phosphorous, sulfur, and carbon cycles, causing acid rain, algal blooms, and fish kills in rivers and coastal waters, along with contributions to climate change. In many parts of the world, this degradation of ecosystem services is exacerbated by the associated loss of the knowledge and understanding held by local communities—knowledge that sometimes could help to ensure the sustainable use of the ecosystem.

This combination of ever-growing demands being placed on increasingly degraded ecosystems seriously diminishes the prospects for sustainable development. Human well-being is affected not just by gaps between ecosystem service supply and demand but also by the increased vulnerability of individuals, communities, and nations. Productive ecosystems, with their array of services, provide people and communities with resources and options they can use as insurance in the face of natural catastrophes or social upheaval. While well-managed ecosystems reduce risks and vulnerability, poorly managed systems can exacerbate them by increasing risks of flood, drought, crop failure, or disease.

Ecosystem degradation tends to harm rural populations more directly than urban populations and has its most direct and severe impact on poor people. The wealthy control access to a greater share of ecosystem services, consume those services at a higher per capita rate, and are buffered from changes in their availability (often at a substantial cost) through their ability to purchase scarce ecosystem services or substitutes. For example, even though a number of marine fisheries have been depleted in the past century, the supply of fish to wealthy consumers has not been disrupted since fishing fleets have been able to shift to previously underexploited stocks. In contrast, poor people often lack access to alternate services and are highly vulnerable to ecosystem changes that result in famine, drought, or floods. They frequently live in locations particularly sensitive to environmental threats, and they lack financial and institutional buffers against these dangers. Degradation of coastal fishery resources, for instance, results in a decline in protein consumed by the local community since fishers may not have access to alternate sources of fish and community members may not have enough income to purchase fish. Degradation affects their very survival.

Changes in ecosystems affect not just humans but countless other species as well. The management objectives that people set for ecosystems and the actions that they take are influenced not just by the consequences of ecosystem changes for humans but also by the importance people place on considerations of the intrinsic value of species and ecosystems. Intrinsic value is the value of something in and for itself, irrespective of its utility for someone else. For example, villages in India protect "spirit sanctuaries" in relatively natural states, even though a strict cost-benefit calculation might favor their conversion to agriculture. Similarly, many countries have passed laws protecting endangered species based on the view that these species have a right to exist, even if their protection results in net economic costs. Sound ecosystem management thus involves steps to address the utilitarian links of people to ecosystems as well as processes that allow considerations of the intrinsic value of ecosystems to be factored into decision-making.

The degradation of ecosystem services has many causes, including excessive demand for ecosystem services stemming from economic growth, demographic changes, and individual choices. Market mechanisms do not always ensure the conservation of ecosystem services either because markets do not exist for services such as cultural or regulatory services or, where they do exist, because policies and institutions do not enable people living within the ecosystem to benefit from services it may provide to others who are far away. For example, institutions are now only beginning to be developed to enable those benefiting from carbon sequestration to provide local managers with an economic incentive to leave a forest uncut, while strong economic incentives often exist for managers to harvest the forest. Also, even if a market exists for an ecosystem service, the results obtained through the market may be socially or ecologically undesirable. Properly managed, the creation of ecotourism opportunities in a country can create strong economic incentives for the maintenance of the cultural services provided by ecosystems, but poorly managed ecotourism activities can degrade the very resource on which they depend. Finally, markets are often unable to address important intra- and intergenerational equity issues associated with managing ecosystems for this and future generations, given that some changes in ecosystem services are irreversible.

The world has witnessed in recent decades not just dramatic changes to ecosystems but equally profound changes to social systems that shape both the pressures on ecosystems and the opportunities to respond. The relative influence of individual nation-states has diminished with the growth of power and influence of a far more complex array of institutions, including regional

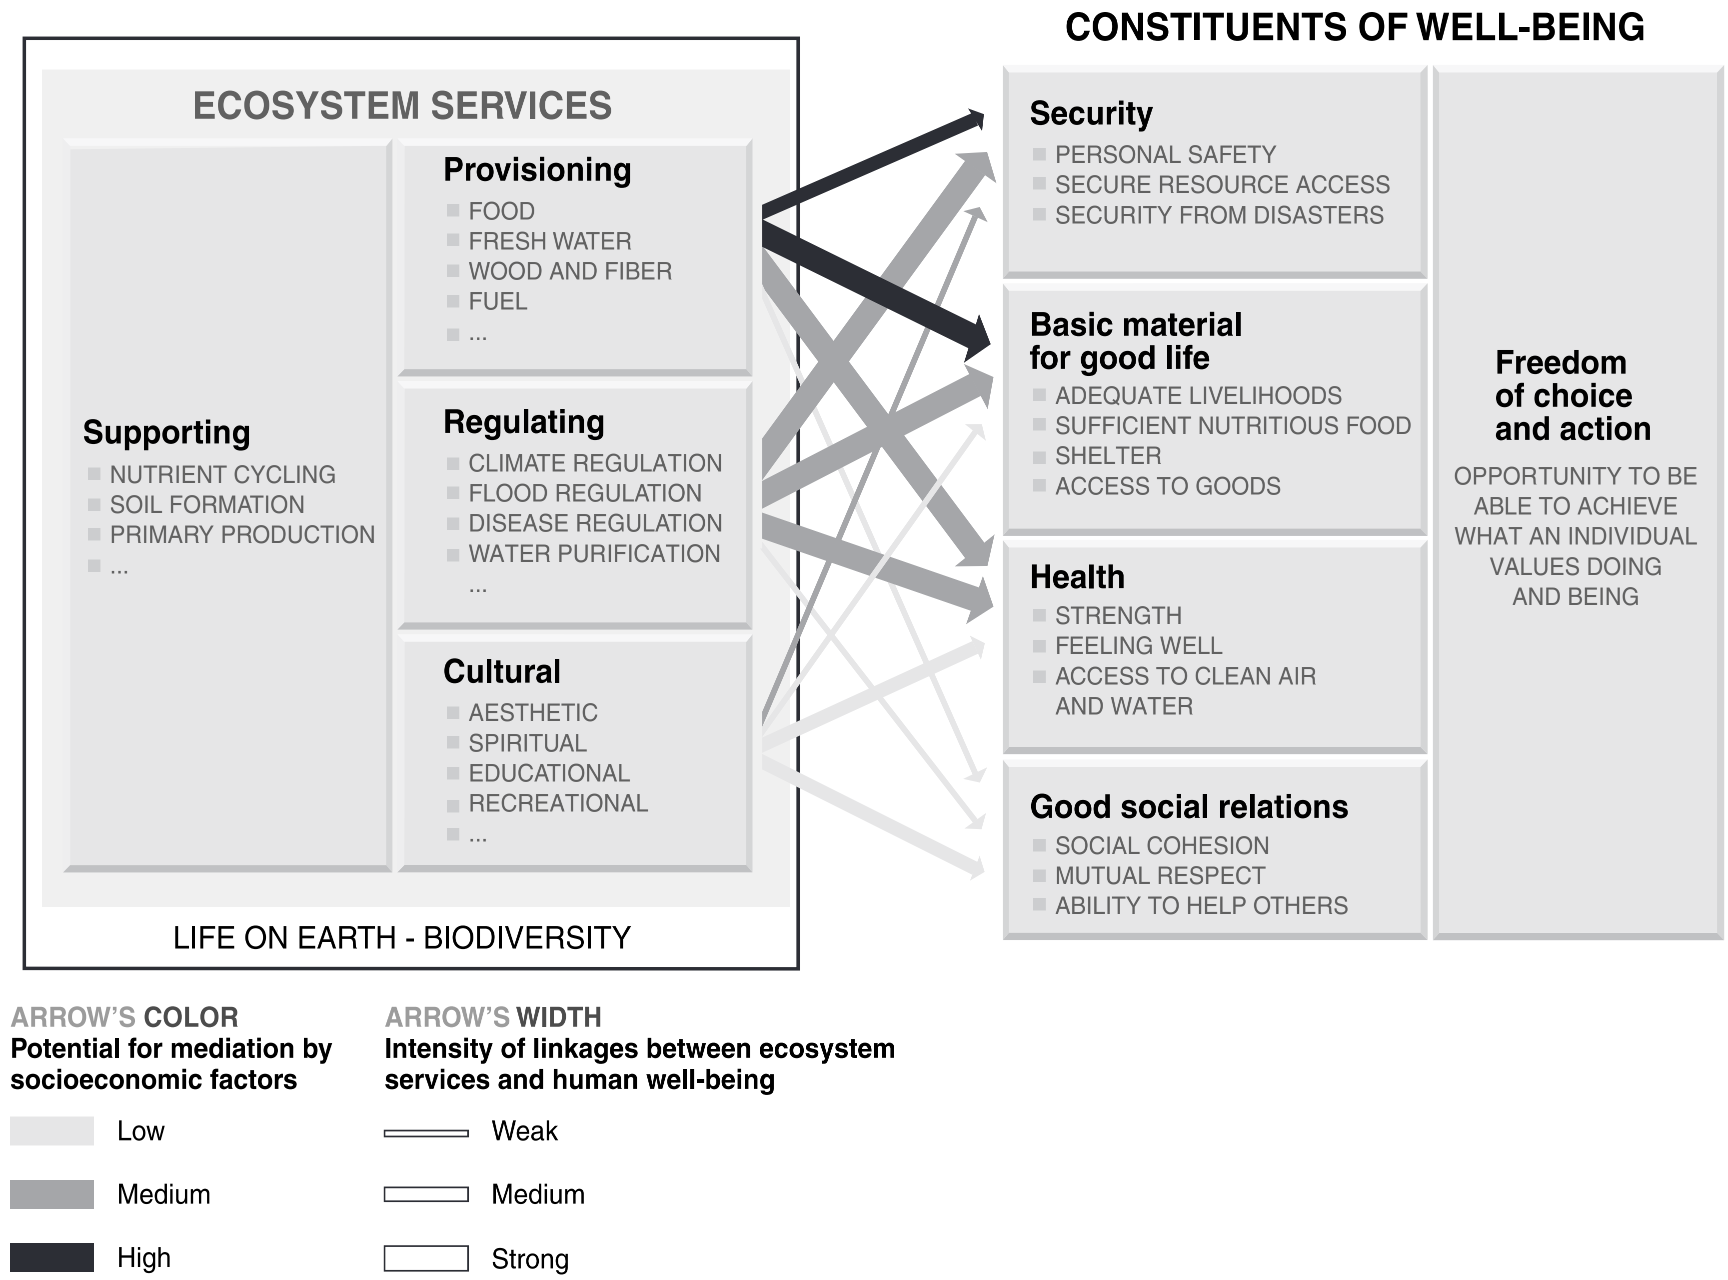

Figure 1.1. Linkages between Ecosystem Services and Human Well-being. This Figure depicts the strength of linkages between categories of ecosystem services and components of human well-being that are commonly encountered and includes indications of the extent to which it is possible for socioeconomic factors to mediate the linkage. (For example, if it is possible to purchase a substitute for a degraded ecosystem service, then there is a high potential for mediation.) The strength of the linkages and the potential for mediation differ in different ecosystems and regions. In addition to the influence of ecosystem services on human well-being depicted here, other factors—including other environmental factors as well as economic, social, technological, and cultural factors—influence human well-being, and ecosystems are in turn affected by changes in human well-being. (Millennium Ecosystem Assessment)

governments, multinational companies, the United Nations, and civil society organizations. Stakeholders have become more involved in decision-making. Given the multiple actors whose decisions now strongly influence ecosystems, the challenge of providing information to decision-makers has grown. At the same time, the new institutional landscape may provide an unprecedented opportunity for information concerning ecosystems to make a major difference. Improvements in ecosystem management to enhance human well-being will require new institutional and policy arrangements and changes in rights and access to resources that may be more possible today under these conditions of rapid social change than they have ever been before.

Like the benefits of increased education or improved governance, the protection, restoration, and enhancement of ecosystem services tends to have multiple and synergistic benefits. Already, many governments are beginning to recognize the need for more effective management of these basic life-support systems. Examples of significant progress toward sustainable management of biological resources can also be found in civil society, in indigenous and local communities, and in the private sector.

1.3 Conceptual Framework

The conceptual framework for the MA places human well-being as the central focus for assessment, while recognizing that biodiversity and ecosystems also have intrinsic value and that people take decisions concerning ecosystems based on considerations of well-being as well as intrinsic value. (See Box 1.2.) The MA conceptual framework assumes that a dynamic interaction exists between people and other parts of ecosystems, with the changing human condition serving to both directly and indirectly drive change in ecosystems and with changes in ecosystems causing changes in human well-being. At the same time, many other factors independent of the environment change the human condition, and many natural forces are influencing ecosystems.

The MA focuses particular attention on the linkages between ecosystem services and human well-being. The assessment deals with the full range of ecosystems—from those relatively undisturbed, such as natural forests, to landscapes with mixed patterns of human use and ecosystems intensively managed and modified by humans, such as agricultural land and urban areas.

A full assessment of the interactions between people and ecosystems requires a multiscale approach because it better reflects the multiscale nature of decision-making, allows the examination of driving forces that may be exogenous to particular regions, and provides a means of examining the differential impact of ecosystem changes and policy responses on different regions and groups within regions.

This section explains in greater detail the characteristics of each of the components of the MA conceptual framework, moving clockwise from the lower left corner of the Figure in Box 1.2.

1.3.1 Ecosystems and Their Services

An ecosystem is a dynamic complex of plant, animal, and microorganism communities and the nonliving environment interacting as a functional unit. Humans are an integral part of ecosystems. Ecosystems provide a variety of benefits to people, including provisioning, regulating, cultural, and supporting services. Provisioning services are the products people obtain from ecosystems, such as food, fuel, fiber, fresh water, and genetic resources. Regulating services are the benefits people obtain from the regulation of ecosystem processes, including air quality maintenance, climate regulation, erosion control, regulation of human diseases, and water purification. Cultural services are the nonmaterial benefits people obtain from ecosystems through spiritual enrichment, cognitive development, reflection, recreation, and aesthetic experiences. Supporting services are those that are necessary for the production of all other ecosystem services, such as primary production, production of oxygen, and soil formation.

Biodiversity and ecosystems are closely related concepts. Biodiversity is the variability among living organisms from all sources, including terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are part. It includes diversity within and between species and diversity of ecosystems. Diversity is a structural feature of ecosystems, and the variability among ecosystems is an element of biodiversity. Products of biodiversity include many of the services produced by ecosystems (such as food and genetic resources), and changes in biodiversity can influence all the other services they provide. In addition to the important role of biodiversity in providing ecosystem services, the diversity of living species has intrinsic value independent of any human concern.

The concept of an ecosystem provides a valuable framework for analyzing and acting on the linkages between people and the environment. For that reason, the ‘‘ecosystem approach’’ has been endorsed by the Convention on Biological Diversity, and the MA conceptual framework is entirely consistent with this approach. The CBD states that the ecosystem approach is a strategy for the integrated management of land, water, and living resources that promotes conservation and sustainable use in an equitable way. This approach recognizes that humans, with their cultural diversity, are an integral component of many ecosystems.

In order to implement the ecosystem approach, decision-makers need to understand the multiple effects on an ecosystem of any management or policy change. By way of analogy, decision-makers would not make a decision about financial policy in a country without examining the condition of the economic system, since information on the economy of a single sector such as manufacturing would be insufficient. The same need to examine the consequences of changes for multiple sectors applies to ecosystems. For instance, subsidies for fertilizer use may increase food production, but sound decisions also require information on whether the potential reduction in the harvests of downstream fisheries as a result of water quality degradation from the fertilizer runoff might outweigh those benefits.

For the purpose of analysis and assessment, a pragmatic view of ecosystem boundaries must be adopted, depending on the questions being asked. A well-defined ecosystem has strong interactions among its components and weak interactions across its boundaries. A useful choice of ecosystem boundary is one where a number of discontinuities coincide, such as in the distribution of organisms, soil types, drainage basins, and depth in a waterbody. At a larger scale, regional and even globally distributed ecosystems can be evaluated based on a commonality of basic structural units. The global assessment being undertaken by the MA reports on marine, coastal, inland water, forest, dryland, island, mountain, polar, cultivated, and urban regions. These regions are not ecosystems themselves, but each contains a number of ecosystems. (See Box 1.3.)

People seek multiple services from ecosystems and thus perceive the condition of given ecosystems in relation to their ability to provide the services desired. Various methods can be used to assess the ability of ecosystems to deliver particular services. With those answers in hand, stakeholders have the information they need to decide on a mix of services best meeting their needs. The MA considers criteria and methods to provide an integrated view of the condition of ecosystems. The condition of each category of ecosystem services is evaluated in somewhat different ways, although in general a full assessment of any service requires considerations of stocks, flows, and resilience of the service.

1.3.2 Human Well-being and Poverty Reduction

Human well-being has multiple constituents, including the basic material for a good life, freedom of choice and action, health, good social relations, and security. Poverty is also multidimensional and has been defined as the pronounced deprivation of well-being. How well-being, ill-being, or poverty are experienced and expressed depends on context and situation, reflecting local physical, social, and personal factors such as geography, environment, age, gender, and culture. In all contexts, however, ecosystems are essential for human well-being through their provisioning, regulating, cultural, and supporting services.

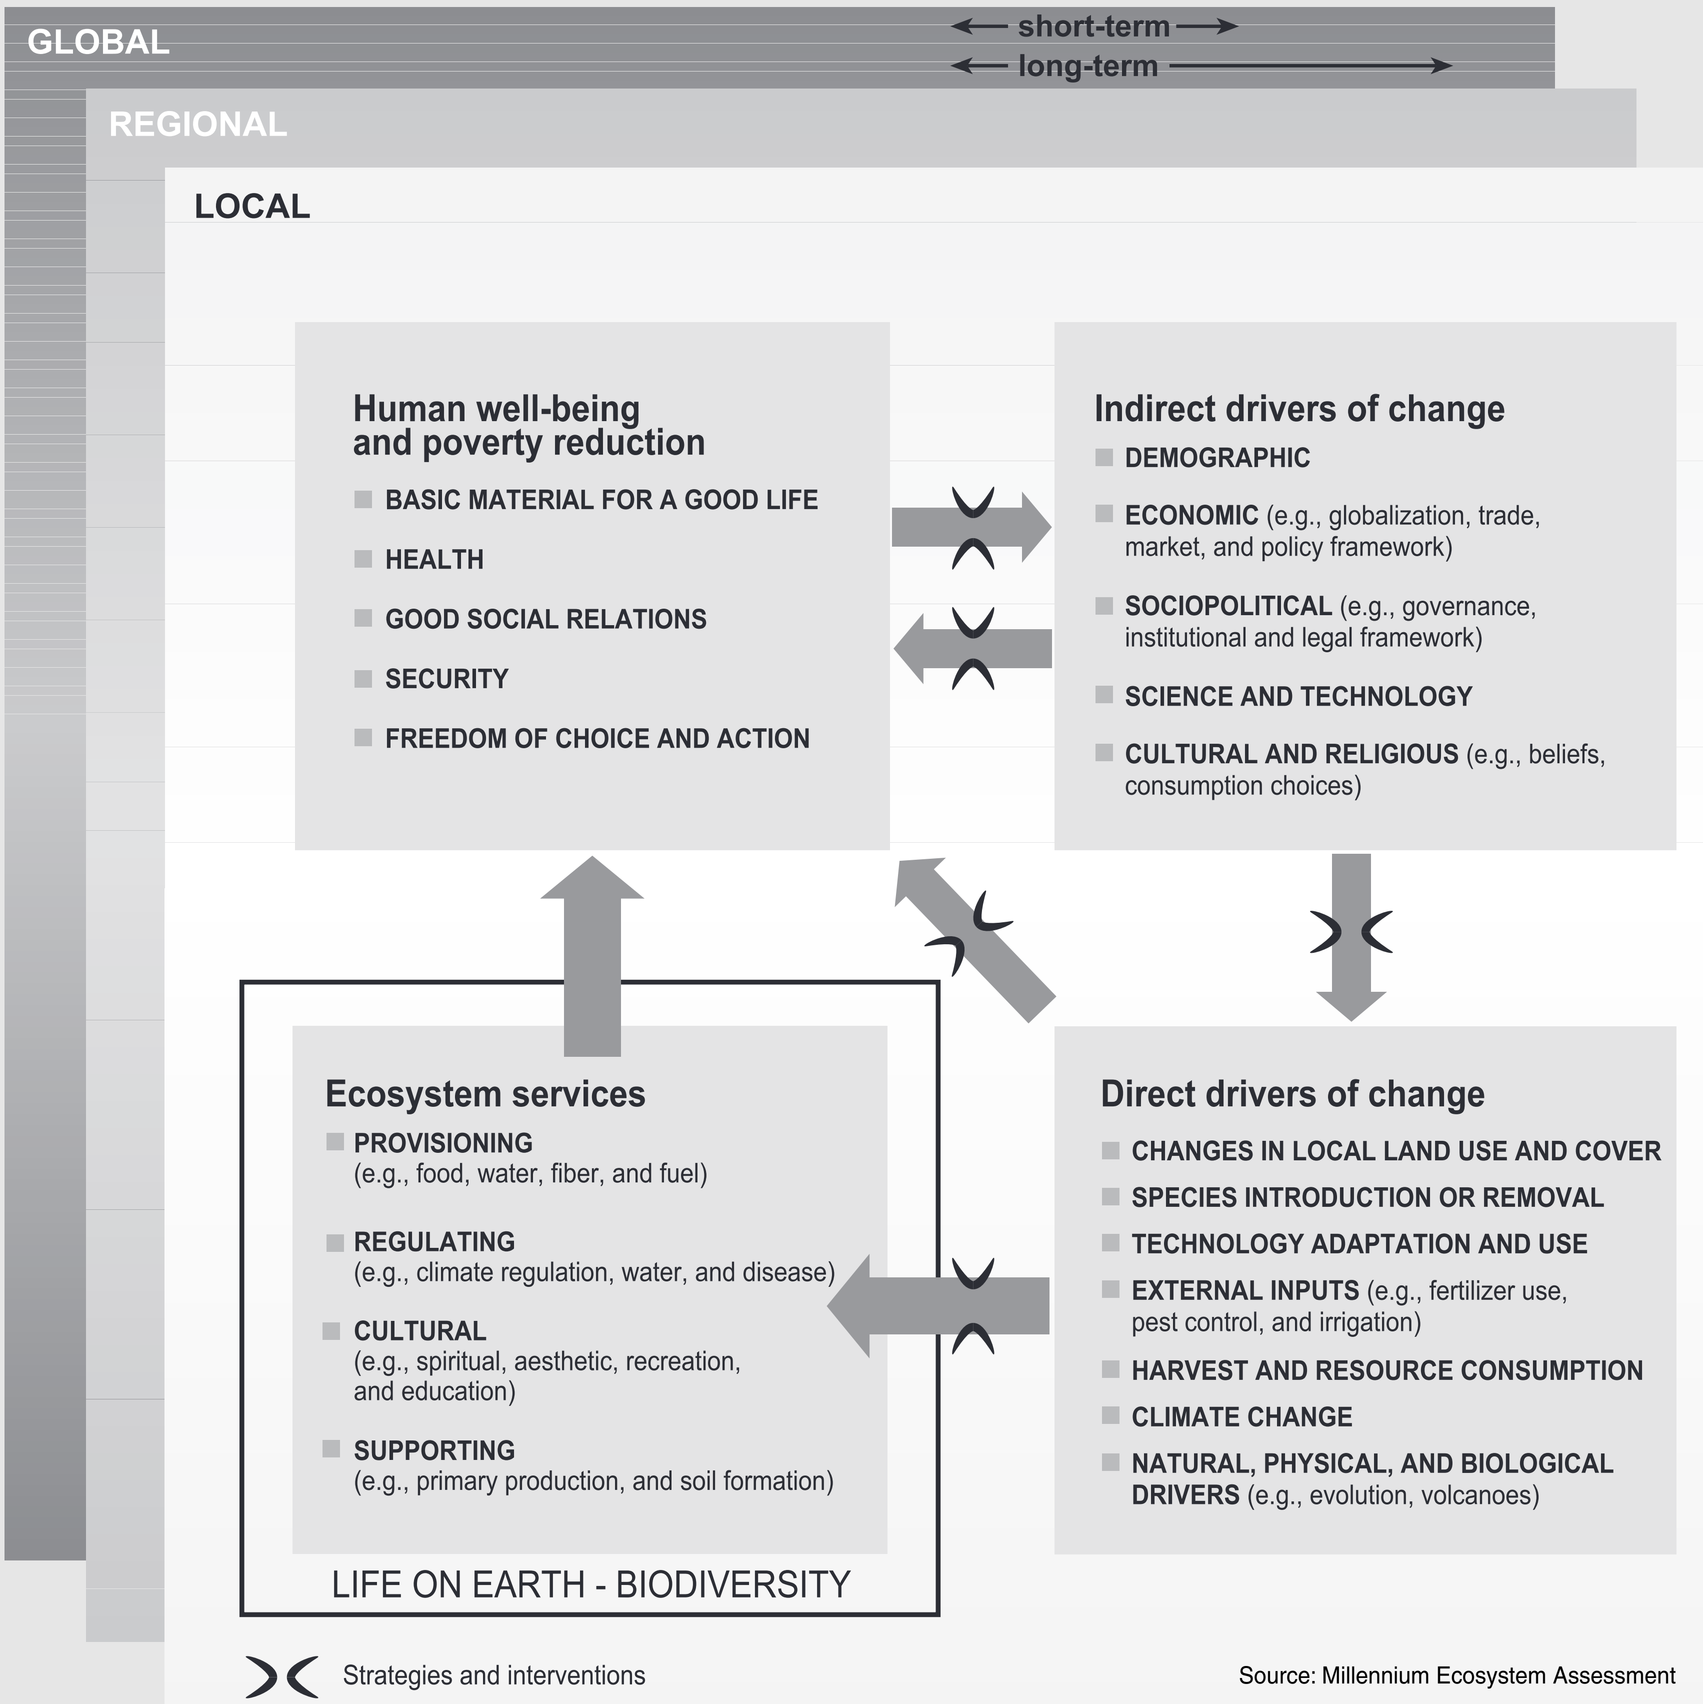
Human intervention in ecosystems can amplify the benefits to human society. However, evidence in recent decades of escalating human impacts on ecological systems worldwide raises concerns about the spatial and temporal consequences of ecosystem changes detrimental to human well-being. Ecosystem changes affect human well-being in the following ways:

- ***Security*** is affected both by changes in provisioning services, which affect supplies of food and other goods and the likelihood of conflict over declining resources, and by changes in regulating services, which could influence the frequency and magnitude of floods, droughts, landslides, or other catastrophes. It can also be affected by changes in cultural services as, for example, when the loss of important ceremonial or spiritual attributes of ecosystems contributes to the weakening of social relations in a community. These changes in turn affect material well-being, health, freedom and choice, security, and good social relations.
- ***Access to basic material for a good life*** is strongly linked to both provisioning services such as food and fiber production and regulating services, including water purification.
- ***Health*** is strongly linked to both provisioning services such as food production and regulating services, including those that influence the distribution of disease-transmitting insects and of irritants and pathogens in water and air. Health can also be

BOX 1.2

Millennium Ecosystem Assessment Conceptual Framework

Changes in factors that indirectly affect ecosystems, such as population, technology, and lifestyle (upper right corner of figure), can lead to changes in factors directly affecting ecosystems, such as the catch of fisheries or the application of fertilizers to increase food production (lower right corner). The resulting changes in the ecosystem (lower left corner) cause the ecosystem services to change and thereby affect human well-being. These interactions can take place at more than one scale and can cross scales. For example, a global market may lead to regional loss of forest cover, which increases flood magnitude along a local stretch of a river. Similarly, the interactions can take place across different time scales. Actions can be taken either to respond to negative changes or to enhance positive changes at almost all points in this framework (black cross bars).



linked to cultural services through recreational and spiritual benefits.

- ***Social relations*** are affected by changes to cultural services, which affect the quality of human experience.
- ***Freedom of choice and action*** is largely predicated on the existence of the other components of well-being and are thus influenced by changes in provisioning, regulating, or cultural services from ecosystems.

Human well-being can be enhanced through sustainable human interactions with ecosystems supported by necessary instruments, institutions, organizations, and technology. Creation of these through participation and transparency may contribute to

BOX 1.3

Reporting Categories Used in the Millennium Ecosystem Assessment

The MA used 10 categories of systems to report its global findings. (See Table.) These categories are not ecosystems themselves; each contains a number of ecosystems. The MA reporting categories are not mutually exclusive: their areas can and do overlap. Ecosystems within each category share a suite of biological, climatic, and social factors that tend to differ across categories. Because these reporting categories overlap, any place on Earth may fall into more than one category. Thus, for example, a wetland ecosystem in a coastal region may be examined both in the MA analysis of "coastal systems" as well as in its analysis of "inland water systems."

Millennium Ecosystem Assessment Reporting Categories

Category	Central Concept	Boundary Limits for Mapping
Marine	Ocean, with fishing typically a major driver of change	Marine areas where the sea is deeper than 50 meters.
Coastal	Interface between ocean and land, extending seawards to about the middle of the continental shelf and inland to include all areas strongly influenced by the proximity to the ocean	Area between 50 meters below mean sea level and 50 meters above the high tide level or extending landward to a distance 100 kilometers from shore. Includes coral reefs, intertidal zones, estuaries, coastal aquaculture, and seagrass communities.
Inland water	Permanent water bodies inland from the coastal zone, and areas whose ecology and use are dominated by the permanent, seasonal, or intermittent occurrence of flooded conditions	Rivers, lakes, floodplains, reservoirs, and wetlands; includes inland saline systems. Note that the Ramsar Convention considers "wetlands" to include both inland water and coastal categories.
Forest	Lands dominated by trees; often used for timber, fuelwood, and non-timber forest products	A canopy cover of at least 40% by woody plants taller than 5 meters. The existence of many other definitions is acknowledged, and other limits (such as crown cover greater than 10%, as used by the Food and Agriculture Organization of the United Nations) are also reported. Includes temporarily cut-over forests and plantations; excludes orchards and agroforests where the main products are food crops.
Dryland	Lands where plant production is limited by water availability; the dominant uses are large mammal herbivory, including livestock grazing, and cultivation	Drylands as defined by the Convention to Combat Desertification, namely lands where annual precipitation is less than two thirds of potential evaporation, from dry subhumid areas (ratio ranges 0.50–0.65), through semiarid, arid, and hyper-arid (ratio $<$0.05), but excluding polar areas; drylands include cultivated lands, scrublands, shrublands, grasslands, semi-deserts, and true deserts.
Island	Lands isolated by surrounding water, with a high proportion of coast to hinterland	Islands of at least 1.5 hectares included in the ESRI ArcWorld Country Boundary dataset.
Mountain	Steep and high lands	As defined by Mountain Watch using criteria based on elevation alone, and at lower elevation, on a combination of elevation, slope, and local elevation range. Specifically, elevation $>$2,500 meters, elevation 1,500–2,500 meters and slope $>$2 degrees, elevation 1,000–1,500 meters and slope $>$5 degrees or local elevation range (7 kilometers radius) $>$300 meters, elevation 300–1,000 meters and local elevation range (7 kilometers radius) $>$300 meters, isolated inner basins and plateaus less than 25 square kilometers extent that are surrounded by mountains.
Polar	High-latitude systems frozen for most of the year	Includes ice caps, areas underlain by permafrost, tundra, polar deserts, and polar coastal areas. Excludes high-altitude cold systems in low latitudes.
Cultivated	Lands dominated by domesticated plant species, used for and substantially changed by crop, agroforestry, or aquaculture production	Areas in which at least 30% of the landscape comes under cultivation in any particular year. Includes orchards, agroforestry, and integrated agriculture-aquaculture systems.
Urban	Built environments with a high human density	Known human settlements with a population of 5,000 or more, with boundaries delineated by observing persistent night-time lights or by inferring areal extent in the cases where such observations are absent.

freedoms and choice as well as to increased economic, social, and ecological security. By ecological security, we mean the minimum level of ecological stock needed to ensure a sustainable flow of ecosystem services.

Yet the benefits conferred by institutions and technology are neither automatic nor equally shared. In particular, such opportunities are more readily grasped by richer than poorer countries and people; some institutions and technologies mask or exacerbate environmental problems; responsible governance, while essential, is not easily achieved; participation in decision-making, an essential element of responsible governance, is expensive in time and resources to maintain. Unequal access to ecosystem services has often elevated the well-being of small segments of the population at the expense of others.

Sometimes the consequences of the depletion and degradation of ecosystem services can be mitigated by the substitution of knowledge and of manufactured or human capital. For example, the addition of fertilizer in agricultural systems has been able to offset declining soil fertility in many regions of the world where people have sufficient economic resources to purchase these inputs, and water treatment facilities can sometimes substitute for the role of watersheds and wetlands in water purification. But ecosystems are complex and dynamic systems and there are limits to substitution possibilities, especially with regulating, cultural, and supporting services. No substitution is possible for the extinction of culturally important species such as tigers or whales, for instance, and substitutions may be economically impractical for the loss of services such as erosion control or climate regulation. Moreover, the scope for substitutions varies by social, economic, and cultural conditions. For some people, especially the poorest, substitutes and choices are very limited. For those who are better off, substitution may be possible through trade, investment, and technology.

Because of the inertia in both ecological and human systems, the consequences of ecosystem changes made today may not be felt for decades. Thus, sustaining ecosystem services, and thereby human well-being, requires a full understanding and wise management of the relationships between human activities, ecosystem change, and well-being over the short, medium, and long term. Excessive current use of ecosystem services compromises their future availability. This can be prevented by ensuring that the use is sustainable.

Achieving sustainable use requires effective and efficient institutions that can provide the mechanisms through which concepts of freedom, justice, fairness, basic capabilities, and equity govern the access to and use of ecosystem services. Such institutions may also need to mediate conflicts between individual and social interests that arise.

The best way to manage ecosystems to enhance human well-being will differ if the focus is on meeting needs of the poor and weak or the rich and powerful. For both groups, ensuring the long-term supply of ecosystem services is essential. But for the poor, an equally critical need is to provide more equitable and secure access to ecosystem services.

1.3.3 Drivers of Change

Understanding the factors that cause changes in ecosystems and ecosystem services is essential to designing interventions that capture positive impacts and minimize negative ones. In the MA, a "driver" is any factor that changes an aspect of an ecosystem. A direct driver unequivocally influences ecosystem processes and can therefore be identified and measured to differing degrees of accuracy. An indirect driver operates more diffusely, often by altering one or more direct drivers, and its influence is established by understanding its effect on a direct driver. Both indirect and direct drivers often operate synergistically. Changes in land cover, for example, can increase the likelihood of introduction of alien invasive species. Similarly, technological advances can increase rates of economic growth.

The MA explicitly recognizes the role of decision-makers who affect ecosystems, ecosystem services, and human well-being. Decisions are made at three organizational levels, although the distinction between those levels is often diffuse and difficult to define:

- by individuals and small groups at the local level (such as a field or forest stand) who directly alter some part of the ecosystem;
- by public and private decision-makers at the municipal, provincial, and national levels; and
- by public and private decision-makers at the international level, such as through international conventions and multilateral agreements.

The decision-making process is complex and multidimensional. We refer to a driver that can be influenced by a decision-maker as an endogenous driver and one over which the decision-maker does not have control as an exogenous driver. The amount of fertilizer applied on a farm is an endogenous driver from the standpoint of the farmer, for example, while the price of the fertilizer is an exogenous driver, since the farmer's decisions have little direct influence on price. The specific temporal, spatial, and organizational scale dependencies of endogenous and exogenous drivers and the specific linkages and interactions among drivers are assessed in the MA.

Whether a driver is exogenous or endogenous to a decision-maker is dependent upon the spatial and temporal scale. For example, a local decision-maker can directly influence the choice of technology, changes in land use, and external inputs (such as fertilizers or irrigation), but has little control over prices and markets, property rights, technology development, or the local climate. In contrast, a national or regional decision-maker has more control over many factors, such as macroeconomic policy, technology development, property rights, trade barriers, prices, and markets. But on the short time scale, that individual has little control over the climate or global population. On the longer time scale, drivers that are exogenous to a decision-maker in the short run, such as population, become endogenous since the decision-maker can influence them through, for instance, education, the advancement of women, and migration policies.

The indirect drivers of change are primarily:

- demographic (such as population size, age and gender structure, and spatial distribution);
- economic (such as national and per capita income, macroeconomic policies, international trade, and capital flows);
- sociopolitical (such as democratization, the roles of women, of civil society, and of the private sector, and international dispute mechanisms);
- scientific and technological (such as rates of investments in research and development and the rates of adoption of new technologies, including biotechnologies and information technologies); and
- cultural and religious (such as choices individuals make about what and how much to consume and what they value).

The interaction of several of these drivers, in turn, affects levels of resource consumption and differences in consumption both within and between countries. Clearly these drivers are changing—population and the world economy are growing, for instance, there are major advances in information technology and biotechnology, and the world is becoming more interconnected. Changes in these drivers are projected to increase the demand for and consumption of food, fiber, clean water, and energy, which will in turn affect the direct drivers. The direct drivers are primarily physical, chemical, and biological—such as land cover change, climate change, air and water pollution, irrigation, use of fertilizers, harvesting, and the introduction of alien invasive species. Change is apparent here too: the climate is changing, species ranges are shifting, alien species are spreading, and land degradation continues.

An important point is that any decision can have consequences external to the decision framework. These consequences are called externalities because they are not part of the decision-making calculus. Externalities can have positive or negative effects. For example, a decision to subsidize fertilizers to increase crop production might result in substantial degradation of water quality from the added nutrients and degradation of downstream fisheries. But it is also possible to have positive externalities. A beekeeper might be motivated by the profits to be made from selling honey, for instance, but neighboring orchards could produce more apples because of enhanced pollination arising from the presence of the bees.

Multiple interacting drivers cause changes in ecosystem services. There are functional interdependencies between and among the indirect and direct drivers of change, and, in turn, changes in ecological services lead to feedbacks on the drivers of changes in ecological services. Synergetic driver combinations are common. The many processes of globalization lead to new forms of interactions between drivers of changes in ecosystem services.

1.3.4 Cross-scale Interactions and Assessment

An effective assessment of ecosystems and human well-being cannot be conducted at a single temporal or spatial scale. Thus the MA conceptual framework includes both of these dimensions. Ecosystem changes that may have little impact on human well-being over days or weeks (soil erosion, for instance) may have pronounced impacts over years or decades (declining agricultural productivity). Similarly, changes at a local scale may have little impact on some services at that scale (as in the local impact of forest loss on water availability) but major impacts at large scales (forest loss in a river basin changing the timing and magnitude of downstream flooding).

Ecosystem processes and services are typically most strongly expressed, are most easily observed, or have their dominant controls or consequences at particular spatial and temporal scales. They often exhibit a characteristic scale—the typical extent or duration over which processes have their impact. Spatial and temporal scales are often closely related. For instance, food production is a localized service of an ecosystem and changes on a weekly basis, water regulation is regional and changes on a monthly or seasonal basis, and climate regulation may take place at a global scale over decades.

Assessments need to be conducted at spatial and temporal scales appropriate to the process or phenomenon being examined. Those done over large areas generally use data at coarse resolutions, which may not detect fine-resolution processes. Even if data are collected at a fine level of detail, the process of averaging in order to present findings at the larger scale causes local patterns or anomalies to disappear. This is particularly problematic for processes exhibiting thresholds and nonlinearities. For example, even though a number of fish stocks exploited in a particular area might have collapsed due to overfishing, average catches across all stocks (including healthier stocks) would not reveal the extent of the problem. Assessors, if they are aware of such thresholds and have access to high-resolution data, can incorporate such information even in a large-scale assessment. Yet an assessment done at smaller spatial scales can help identify important dynamics of the system that might otherwise be overlooked. Likewise, phenomena and processes that occur at much larger scales, although expressed locally, may go unnoticed in purely local-scale assessments. Increased carbon dioxide concentrations or decreased stratospheric ozone concentrations have local effects, for instance, but it would be difficult to trace the causality of the effects without an examination of the overall global process.

Time scale is also very important in conducting assessments. Humans tend not to think beyond one or two generations. If an assessment covers a shorter time period than the characteristic temporal scale, it may not adequately capture variability associated with long-term cycles, such as glaciation. Slow changes are often harder to measure, as is the case with the impact of climate change on the geographic distribution of species or populations. Moreover, both ecological and human systems have substantial inertia, and the impact of changes occurring today may not be seen for years or decades. For example, some fisheries' catches may increase for several years even after they have reached unsustainable levels because of the large number of juvenile fish produced before that level was reached.

Social, political, and economic processes also have characteristic scales, which may vary widely in duration and extent. Those of ecological and sociopolitical processes often do not match. Many environmental problems originate from this mismatch between the scale at which the ecological process occurs, the scale at which decisions are made, and the scale of institutions for decision-making. A purely local-scale assessment, for instance, may discover that the most effective societal response requires action that can occur only at a national scale (such as the removal of a subsidy or the establishment of a regulation). Moreover, it may lack the relevance and credibility necessary to stimulate and inform national or regional changes. On the other hand, a purely global assessment may lack both the relevance and the credibility necessary to lead to changes in ecosystem management at the local scale where action is needed. Outcomes at a given scale are often heavily influenced by interactions of ecological, socioeconomic, and political factors emanating from other scales. Thus focusing solely on a single scale is likely to miss interactions with other scales that are critically important in understanding ecosystem determinants and their implications for human well-being.

The choice of the spatial or temporal scale for an assessment is politically laden, since it may intentionally or unintentionally privilege certain groups. The selection of assessment scale with its associated level of detail implicitly favors particular systems of knowledge, types of information, and modes of expression over others. For example, non-codified information or knowledge systems of minority populations are often missed when assessments are undertaken at larger spatial scales or higher levels of aggregation. Reflecting on the political consequences of scale and boundary choices is an important prerequisite to exploring what multi- and cross-scale analysis in the MA might contribute to decision-making and public policy processes at various scales.

1.4 Values Associated with Ecosystems

Current decision-making processes often ignore or underestimate the value of ecosystem services. Decision-making concerning ecosystems and their services can be particularly challenging because different disciplines, philosophical views, and schools of thought assess the value of ecosystems differently. One paradigm of value, known as the utilitarian (anthropocentric) concept, is based on the principle of humans' preference satisfaction (welfare). In this case, ecosystems and the services they provide have value to human societies because people derive utility from their use, either directly or indirectly (use values). Within this utilitarian concept of value, people also give value to ecosystem services that they are not currently using (non-use values). Non-use values, usually known as existence values, involve the case where humans ascribe value to knowing that a resource exists even if they never use that resource directly. These often involve the deeply held historical, national, ethical, religious, and spiritual values people ascribe to ecosystems—the values that the MA recognizes as cultural services of ecosystems.

A different, non-utilitarian value paradigm holds that something can have intrinsic value—that is, it can be of value in and for itself—irrespective of its utility for someone else. From the perspective of many ethical, religious, and cultural points of view, ecosystems may have intrinsic value, independent of their contribution to human well-being.

The utilitarian and non-utilitarian value paradigms overlap and interact in many ways, but they use different metrics, with no common denominator, and cannot usually be aggregated, although both paradigms of value are used in decision-making processes.

Under the utilitarian approach, a wide range of methodologies has been developed to attempt to quantify the benefits of different ecosystem services. These methods are particularly well developed for provisioning services, but recent work has also improved the ability to value regulating and other services. The choice of valuation technique in any given instance is dictated by the characteristics of the case and by data availability. (See Box 1.4.)

Non-utilitarian value proceeds from a variety of ethical, cultural, religious, and philosophical bases. These differ in the specific entities that are deemed to have intrinsic value and in the interpretation of what having intrinsic value means. Intrinsic value may complement or counterbalance considerations of utilitarian value. For example, if the aggregate utility of the services provided by an ecosystem (as measured by its utilitarian value) outweighs the value of converting it to another use, its intrinsic value may then be complementary and provide an additional impetus for conserving the ecosystem. If, however, economic valuation indicates that the value of converting the ecosystem outweighs the aggregate value of its services, its ascribed intrinsic value may be deemed great enough to warrant a social decision to conserve it anyway. Such decisions are essentially political, not economic. In contemporary democracies these decisions are made by parliaments or legislatures or by regulatory agencies mandated to do so by law. The sanctions for violating laws recognizing an entity's intrinsic value may be regarded as a measure of the degree of intrinsic value ascribed to them. The decisions taken by businesses, local communities, and individuals also can involve considerations of both utilitarian and non-utilitarian values.

The mere act of quantifying the value of ecosystem services cannot by itself change the incentives affecting their use or misuse. Several changes in current practice may be required to take better account of these values. The MA assesses the use of information on ecosystem service values in decision-making. The goal is to improve decision-making processes and tools and to provide feedback regarding the kinds of information that can have the most influence.

BOX 1.4

Valuation of Ecosystem Services

Valuation can be used in many ways: to assess the total contribution that ecosystems make to human well-being, to understand the incentives that individual decision-makers face in managing ecosystems in different ways, and to evaluate the consequences of alternative courses of action. The MA uses valuation primarily in the latter sense: as a tool that enhances the ability of decision-makers to evaluate trade-offs between alternative ecosystem management regimes and courses of social actions that alter the use of ecosystems and the multiple services they provide. This usually requires assessing the change in the mix (the value) of services provided by an ecosystem resulting from a given change in its management.

Most of the work involved in estimating the change in the value of the flow of benefits provided by an ecosystem involves estimating the change in the physical flow of benefits (quantifying biophysical relations) and tracing through and quantifying a chain of causality between changes in ecosystem condition and human welfare. A common problem in valuation is that information is only available on some of the links in the chain and often in incompatible units. The MA can make a major contribution by making various disciplines better aware of what is needed to ensure that their work can be combined with that of others to allow a full assessment of the consequences of altering ecosystem state and function.

The ecosystem values in this sense are only one of the bases on which decisions on ecosystem management are and should be made. Many other factors, including notions of intrinsic value and other objectives that society might have (such as equity among different groups or generations), will also feed into the decision framework. Even when decisions are made on other bases, however, estimates of changes in utilitarian value provide invaluable information.

1.5 Assessment Tools

The information base exists in any country to undertake an assessment within the framework of the MA. That said, although new data sets (for example, from remote sensing) providing globally consistent information make a global assessment like the MA more rigorous, there are still many challenges that must be dealt with in using these data at global or local scales. Among these challenges are biases in the geographic and temporal coverage of the data and in the types of data collected. Data availability for industrial countries is greater than that for developing ones, and data for certain resources such as crop production are more readily available than data for fisheries, fuelwood, or biodiversity. The MA makes extensive use of both biophysical and socioeconomic indicators, which combine data into policy-relevant measures that provide the basis for assessment and decision-making.

Models can be used to illuminate interactions among systems and drivers, as well as to make up for data deficiencies—for instance, by providing estimates where observations are lacking. The MA makes use of environmental system models that can be used, for example, to measure the consequences of land cover change for river flow or the consequences of climate change for the distribution of species. It also uses human system models that can examine, for instance, the impact of changes in ecosystems on production, consumption, and investment decisions by households or that allow the economy-wide impacts of a change in production in a particular sector like agriculture to be evaluated. Finally, integrated models, combining both the environmental and human systems linkages, can increasingly be used at both global and sub-global scales.

The MA incorporates both formal scientific information and traditional or local knowledge. Traditional societies have nurtured and refined systems of knowledge of direct value to those societies but also of considerable value to assessments undertaken at regional and global scales. This information often is unknown to science and can be an expression of other relationships between society and nature in general and of sustainable ways of managing natural resources in particular. To be credible and useful to decision-makers, all sources of information, whether scientific, traditional, or practitioner knowledge, must be critically assessed and validated as part of the assessment process through procedures relevant to the form of knowledge.

Since policies for dealing with the deterioration of ecosystem services are concerned with the future consequences of current actions, the development of scenarios of medium- to long-term changes in ecosystems, services, and drivers can be particularly helpful for decision-makers. Scenarios are typically developed through the joint involvement of decision-makers and scientific experts, and they represent a promising mechanism for linking scientific information to decision-making processes. They do not attempt to predict the future but instead are designed to indicate what science can and cannot say about the future consequences of alternative plausible choices that might be taken in the coming years.

The MA uses scenarios to summarize and communicate the diverse trajectories that the world's ecosystems may take in future decades. Scenarios are plausible alternative futures, each an example of what might happen under particular assumptions. They can be used as a systematic method for thinking creatively about complex, uncertain futures. In this way, they help us understand the upcoming choices that need to be made and highlight developments in the present. The MA developed scenarios that connect possible changes in drivers (which may be unpredictable or uncontrollable) with human demands for ecosystem services. The scenarios link these demands, in turn, to the futures of the services themselves and the aspects of human welfare that depend on them. The scenario building exercise breaks new ground in several areas:

- development of scenarios for global futures linked explicitly to ecosystem services and the human consequences of ecosystem change,
- consideration of trade-offs among individual ecosystem services within the ''bundle'' of benefits that any particular ecosystem potentially provides to society,
- assessment of modeling capabilities for linking socioeconomic drivers and ecosystem services, and
- consideration of ambiguous futures as well as quantifiable uncertainties.

The credibility of assessments is closely linked to how they address what is not known in addition to what is known. The consistent treatment of uncertainty is therefore essential for the clarity and utility of assessment reports. As part of any assessment process, it is crucial to estimate the uncertainty of findings even if a detailed quantitative appraisal of uncertainty is unavailable.

1.6 Strategies and Interventions

The MA assesses the use and effectiveness of a wide range of options for responding to the need to sustainably use, conserve, and restore ecosystems and the services they provide. These options include incorporating the value of ecosystems in decisions, channeling diffuse ecosystem benefits to decision-makers with focused local interests, creating markets and property rights, educating and dispersing knowledge, and investing to improve ecosystems and the services they provide. As seen in Box 1.2 on the MA conceptual framework, different types of response options can affect the relationships of indirect to direct drivers, the influence of direct drivers on ecosystems, the human demand for ecosystem services, or the impact of changes in human well-being on indirect drivers. An effective strategy for managing ecosystems will involve a mix of interventions at all points in this conceptual framework.

Mechanisms for accomplishing these interventions include laws, regulations, and enforcement schemes; partnerships and collaborations; the sharing of information and knowledge; and public and private action. The choice of options to be considered will be greatly influenced by both the temporal and the physical scale influenced by decisions, the uncertainty of outcomes, cultural context, and the implications for equity and trade-offs. Institutions at different levels have different response options available to them, and special care is required to ensure policy coherence.

Decision-making processes are value-based and combine political and technical elements to varying degrees. Where technical input can play a role, a range of tools is available to help decision-makers choose among strategies and interventions, including cost-benefit analysis, game theory, and policy exercises. The selection of analytical tools should be determined by the context of the decision, key characteristics of the decision problem, and the criteria considered to be important by the decision-makers. Information from these analytical frameworks is always combined with the intuition, experience, and interests of the decision-maker in shaping the final decisions.

Risk assessment, including ecological risk assessment, is an established discipline and has a significant potential for informing the decision process. Finding thresholds and identifying the potential for irreversible change are important for the decision-making process. Similarly, environmental impact assessments designed to evaluate the impact of particular projects and strategic environmental assessments designed to evaluate the impact of policies both represent important mechanisms for incorporating the findings of an ecosystem assessment into decision-making processes.

Changes also may be required in decision-making processes themselves. Experience to date suggests that a number of mechanisms can improve the process of making decisions about ecosystem services. Broadly accepted norms for decision-making process include the following characteristics. Did the process:

- bring the best available information to bear?
- function transparently, use locally grounded knowledge, and involve all those with an interest in a decision?
- pay special attention to equity and to the most vulnerable populations?
- use decision analytical frameworks that take account of the strengths and limits of individual, group, and organizational information processing and action?
- consider whether an intervention or its outcome is irreversible and incorporate procedures to evaluate the outcomes of actions and learn from them?
- ensure that those making the decisions are accountable?
- strive for efficiency in choosing among interventions?
- take account of thresholds, irreversibility, and cumulative, cross-scale, and marginal effects and of local, regional, and global costs, risk, and benefits?

The policy or management changes made to address problems and opportunities related to ecosystems and their services, whether at local scales or national or international scales, need to be adaptive and flexible in order to benefit from past experience, to hedge against risk, and to consider uncertainty. The understanding of ecosystem dynamics will always be limited, socioeconomic systems will continue to change, and outside determinants can never be fully anticipated. Decision-makers should consider whether a course of action is reversible and should incorporate, whenever possible, procedures to evaluate the outcomes of actions and learn from them. Debate about exactly how to do this continues in discussions of adaptive management, social learning, safe minimum standards, and the precautionary principle. But the core message of all approaches is the same: acknowledge the limits of human understanding, give special consideration to irreversible changes, and evaluate the impacts of decisions as they unfold.

Main Messages

Many tools are available to assess ecosystem condition and support policy decisions that involve trade-offs among ecosystem services. Clearing forested land, for example, affects multiple ecosystem services (such as food production, biodiversity, carbon sequestration, and watershed protection), each of which affects human well-being (such as increased income from crops, reduced tourism value of biodiversity, and damage from downstream flooding). Assessing these trade-offs in the decision-making process requires scientifically based analysis to quantify the responses to different management alternatives. Scientific advances over the past few decades, particularly in computer modeling, remote sensing, and environmental economics, make it possible to assess these linkages.

The availability and accuracy of data sources and methods for this assessment are unevenly distributed for different ecosystem services and geographic regions. Data on provisioning services, such as crop yield and timber production, are usually available. On the other hand, data on regulating, supporting, and cultural services such as nutrient cycling, climate regulation, or aesthetic value are seldom available, making it necessary to use indicators, model results, or extrapolations from case studies as proxies. Systematic data collection for carefully selected indicators reflecting trends in ecosystem condition and their services would provide an improved basis for future assessments. Methods for quantifying ecosystem responses are also uneven. Methods to estimate crop yield responses to fertilizer application, for example, are well developed. But methods to quantify relationships between ecosystem services and human well-being, such as the effects of deteriorating biodiversity on human disease, are at an earlier stage of development.

Ecosystems respond to management changes on a range of time and space scales, and careful definition of the scales included in analyses is critical. Soil nutrient depletion, for example, occurs over decades and would not be captured in an analysis based on a shorter time period. Some of the impact of deforestation is felt in reduced water quality far downstream; an analysis that only considers the forest area itself would miss this impact. Ideally, analysis at varying scales would be carried out to assess trade-offs properly. In particular, it is essential to consider nonlinear responses of ecosystems to perturbations in analysis of trade-offs, such as loss of resilience to climate variability below a threshold number of plant species.

Ecosystem condition is only one of many factors that affect human well-being, making it challenging to assess linkages between them. Health outcomes, for example, are the combined result of ecosystem condition, access to health care, economic status, and myriad other factors. Interpretations of trends in indicators of well-being must appropriately account for the full range of factors involved. The impacts of ecosystem change on well-being are often subtle, which is not to say unimportant; impacts need not be drastic to be significant. A small increase in food prices resulting from lower yields will affect many people, even if none starve as a result. Tracing these impacts is often difficult, particularly in aggregate analyses where the signal of the effect of ecosystem change is often hidden by multiple confounding factors. Analyses linking well-being and ecosystem condition are most easily carried out at a local scale, where the linkages can be most clearly identified.

Ultimately, decisions about trade-offs in ecosystem services require balancing societal objectives, including utilitarian and non-utilitarian objectives, short- and long-term objectives, and local- and global-scale objectives. The analytical approach for this report aims to quantify, to the degree possible, the most important trade-offs within different ecosystems and among ecosystem services as input to weigh societal objectives based on comprehensive analysis of the full suite of ecosystem services.

2.1 Introduction

This report systematically assesses the current state of and recent trends in the world's ecosystems and their services and the significance of these changes for human livelihoods, health, and well-being. The individual chapters draw on a wide variety of data sources and analytical methods from both the natural and social sciences. This chapter provides an overview of many of these data and methods, their basis in the scientific literature, and the limitations and possibilities for application to the assessment of ecosystem condition, trends, and implications for human well-being. (See Figure 2.1.)

The Millennium Ecosystem Assessment's approach is premised on the notion that management decisions generally involve trade-offs among ecosystem services and that quantitative and scientifically based assessment of the trade-offs is a necessary ingredient for sound decision-making. For example, decisions to clear land for agriculture involve trade-offs between food production and protection of biological resources; decisions to extract timber involve trade-offs between income from timber sales and watershed protection; and decisions to designate marine protected areas involve trade-offs between preserving fish stocks and the availability of fish or jobs for local populations. Accounting for these trade-offs involves quantifying the effects of the management decision on ecosystem services and human-well being in comparable units over varying spatial and temporal scales.

The next section of this chapter discusses data and methods for assessing conditions and trends in ecosystems and their services. Individual chapters of this report apply these methods to identify the implications of changes in ecosystem condition (such as forest conversion to cropland) for ecosystem services (such as flood protection). Rigorous analyses of these linkages are a key prerequisite to quantifying the effects on human well-being (such as damage from downstream flooding).

The third section discusses data and methods for quantifying the effects of changes in ecosystem services on human well-being, including human health, economic costs and benefits, and poverty and other measures of well-being, and on the intrinsic value of ecosystems. These methods provide a framework for assessing management decisions or policies that alter ecosystems, based on comprehensive information about the repercussions for human well-being from intentional or unintentional alteration of ecosystem services.

The final section of this chapter discusses approaches for assessing trade-offs from management decisions. These approaches aim to quantify, in comparable units, the repercussions of a decision for the full range of ecosystem services. The approaches must also account for the varying spatial and temporal scale over which management decisions alter ecosystem services. Decisions to clear forests, for example, provide immediate economic benefits for local interests but contribute to an increase of greenhouse gases in the atmosphere, with longer-term implications at the global scale.

While this chapter provides a general overview of the available methods and data sources and their applicability to the assessment, individual chapters provide detailed descriptions of data sources used in reference to a particular ecosystem or service. Core data sets used by all chapters to ensure consistency and comparability among the different ecosystems are described in Appendix 2.1.

The data sources and methods used in this report were generally not developed explicitly for this assessment. Yet the combination of approaches—including computer modeling, natural resource and biodiversity inventories, remote sensing and geographic information systems, traditional knowledge, case studies,

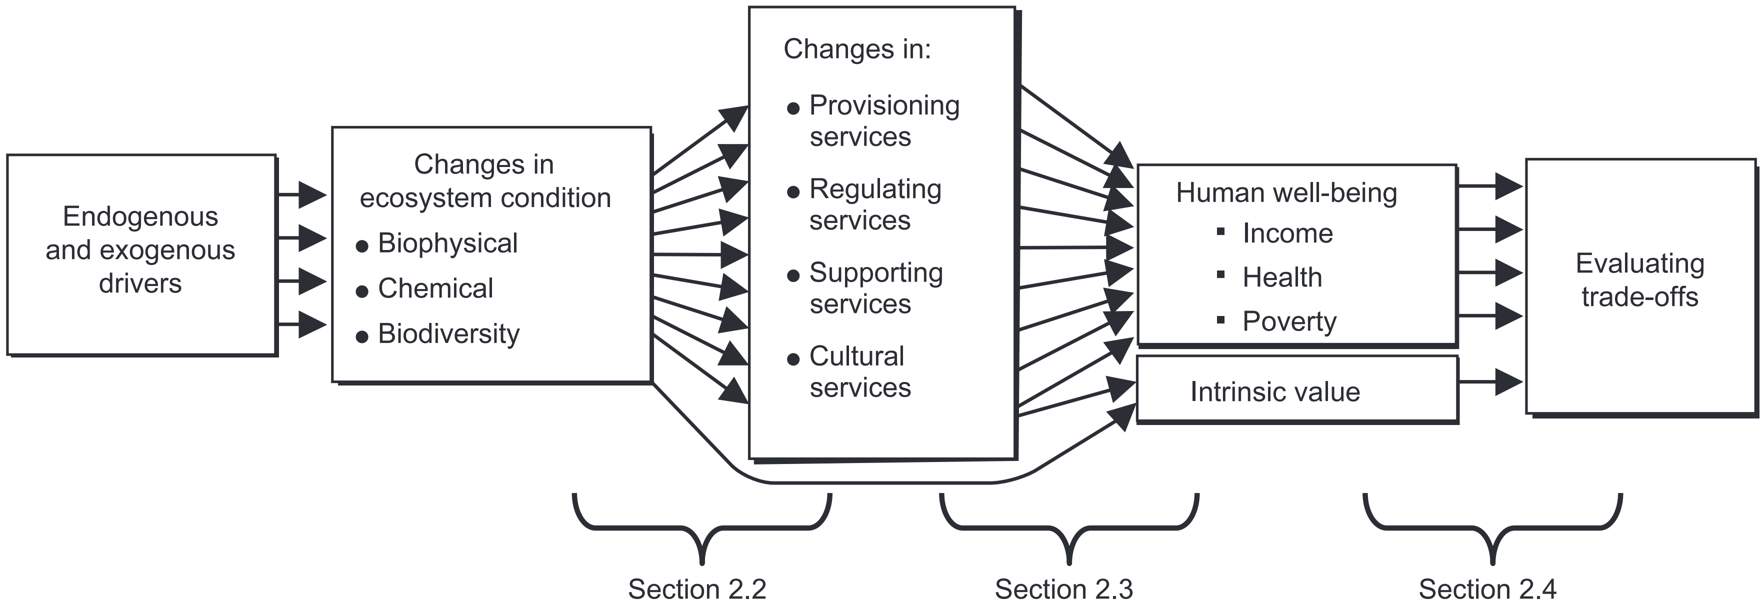

Figure 2.1. Linking Ecosystem Condition to Well-being Requires Assessing Ecosystem Condition and Its Effect on Services, the Impact on Human Well-being and Other Forms of Value, and Trade-offs among Objectives

indicators of ecosystem conditions and human well-being, and economic valuation techniques—provides a strong scientific foundation for the assessment. Systematic data collection for carefully selected indicators reflecting trends in ecosystem condition and their services would provide a basis for future assessments.

2.2 Assessing Ecosystem Condition and Trends

The foundation for analysis is basic information about each ecosystem service (Chapters 7–17) and spatially defined ecosystem (Chapters 18–27). Deriving conclusions about the important trends in ecosystem condition and trade-offs among ecosystem services requires the following basic information:

- What are the current spatial extent and condition of ecosystems?
- What are the quality, quantity, and spatial distributions of services provided by the systems?
- Who lives in the ecosystem and what ecosystem services do they use?
- What are the trends in ecosystem condition and their services in the recent (decades) and more distant past (centuries)?
- How does ecosystem condition, and in turn ecosystem services, respond to the drivers of change for each system?

The availability of data and applicability of methods to derive this basic information (see Table 2.1) vary from ecosystem to ecosystem, service to service, and even region to region within an ecosystem type. For example, the U.N. Food and Agriculture Organization reports data on agricultural products, timber, and fisheries at the national level (e.g., FAO 2000a). Although data reliability is sometimes questionable due to known problems such as definitions that vary between data-submitting countries, data on provisioning ecosystem services with value as commodities are generally available. On the other hand, data on the spatial distribution, quantity, and quality of regulating, supporting, and cultural services such as nutrient cycling, climate regulation, or aesthetic value have generally not been collected, and it is necessary to use indicators, modeled results, or extrapolations from case studies as proxy data. Within a given ecosystem service or geographic system, resource inventories and census data are generally more readily available and reliable in industrial than developing countries.

The following sections provide overviews of each of these data sources and analytical approaches used throughout the report.

2.2.1 Remote Sensing and Geographic Information Systems

The availability of data to monitor ecosystems on a global scale is the underpinning for the MA. Advances in remote sensing technologies over the past few decades now enable repeated observations of Earth's surface. The potential to apply these data for assessing trends in ecosystem condition is only beginning to be realized. Moreover, advances in analytical tools such as geographic information systems allow data on the physical, biological, and socioeconomic characteristics of ecosystems to be assembled and interpreted in a spatial framework, making it feasible to establish linkages between drivers of change and trends in ecosystem services.

2.2.1.1 Remote Sensing

Ground-based surveys for mapping vegetation and other biophysical characteristics can be carried out over limited areas, but it would be an enormous undertaking to carry out globally comprehensive ground-based surveys over the entire surface of Earth. Remote sensing—broadly defined as the science of obtaining information about an object without being in direct physical contact (Colwell 1983)—is the primary data source for mapping the extent and condition of ecosystems over large areas. Moreover, remote sensing provides measurements that are consistent over the entire area being observed and are not subject to varying data collection methods in different locations, unlike ground-based measurements. Repeated observations using the same remote sensing instrument also provide measurements that are consistent through time as well as through space.

Most remote sensing data useful to assess ecosystem conditions and trends are obtained from sensors on satellites. (See Table 2.2.) Satellite data are generally digital and consequently amenable to computer-based analysis for classifying land cover types and assessing trends. There are several types of digital remotely sensed data (Jensen 2000). Optical remote sensing provides digital images of the amount of electromagnetic energy reflected or emitted from Earth's surface at various wavelengths. Active remote sensing of long-wavelengths microwaves (radar), short-wavelength laser light (lidar), or sound waves (sonar) measures the amount of backscatter from electromagnetic energy emitted from the sensor itself.

The spatial resolution (area of ground observed in a picture element or pixel), temporal resolution (how often the sensor re-

Human populations residing in and deriving livelihoods from system			X			X	X
Trends in ecosystem conditions and services	X	X		X	X	X	X
Response of ecosystem condition and services to drivers				X	X	X	X

cords imagery from a particular area), spectral resolution (number of specific wavelength intervals in the electromagnetic spectrum to which the sensor is sensitive), and radiometric resolution (precision in the detected signal) determine the utility of the data for a specific application. For example, data with very high spatial resolution can be used to map habitats over local areas, but low temporal resolution limits the ability to map changes over time.

A key element in the interpretation of remote sensing data is calibration and validation with in situ data. Ground-based data aids the interpretation of satellite data by identifying locations of specific features in the land surface. These locations can then be pinpointed on the satellite image to obtain the spectral signatures of different features. Ground-based data are also critical to test the accuracy and reliability of the interpretation of satellite data. Linking ground-based with satellite data poses logistical challenges if the locations required are inaccessible. Moreover, the land surface is often heterogeneous so that a single pixel observed by the satellite contains multiple vegetation types. The ground observations then need to be scaled to the spatial resolution of the sensor. Despite these challenges, ground-based data for calibration and validation are central to the effective use of satellite data for ecosystem assessment.

Analyses of satellite data are a major contribution to assessments of ecosystem conditions and trends, especially over large areas where it is not feasible to perform ground surveys. Technological challenges such as sensor drift and sensor degradation over time, lack of data continuity, and persistent cloud cover, particularly in humid tropics, are challenges to routine application of satellite data to monitor ecosystem condition. Ground observations and local expertise are critical to accurate interpretation of satellite data.

Satellite data contribute to several types of information needs for assessments of ecosystem condition, including land cover and land cover change mapping, habitat mapping for biodiversity, wetland mapping, land degradation assessments, and measurements of land surface attributes as input to ecosystem models.

2.2.1.1.1 Mapping of land cover and land cover change

Over the last few decades, satellite data have increasingly been used to map land cover at national, regional, continental, and global scales. During the 1980s, pioneering research was conducted to map vegetation at continental scales, primarily with data acquired by the U.S. National Oceanographic and Atmospheric Administration's meteorological satellite, the Advanced Very High Resolution Radiometer. Multitemporal data describing seasonal variations in photosynthetic activity were used to map vegetation types in Africa (Tucker 1985) and South America (Townshend 1987). In the 1990s, AVHRR data were used to map land cover globally at increasingly higher spatial resolution, with the first global land cover classification at 1x1 degree resolution (approximately 110x110 kilometers) (DeFries and Townshend 1994), followed by 8x8 kilometer resolution (DeFries 1998) and finally 1x1 kilometer resolution (Loveland and Belward 1997; Hansen 2000).

Global satellite data also have enabled mapping of fractional tree cover to further characterize the distributions of forests over Earth's surface (DeFries 2000). At pantropical scales, AVHRR data have been used to map the distribution of humid forests (Malingreau 1995; Mayaux 1998), and radar data provide useful information for mapping land cover types where frequent cloud cover presents difficulties for optical data (DeGrandi 2000; Saatchi 2000; Mayaux et al. 2002). A suite of recently launched sensors, including MODIS, SPOT Vegetation, and GLI, provide globally comprehensive data to map vegetation types with greater accuracy due to improved spectral, spatial, and radiometric resolutions of these sensors (Friedl 2002). The GLC2000 land cover map derived from SPOT Vegetation data provides the basis for the MA's geographic designation of ecosystems (Bartholome and Belward 2004; Fritz et al. 2004). (See Appendix 2.1.)

One of the most significant contributions to be gained from satellite data is the identification and monitoring of land cover change, an important driver of changes in ecosystem services.

Table 2.2. Satellite Sensors for Monitoring Land Cover, Land Surface Properties, and Land and Marine Productivity

Platform	Sensor	Spatial Resolution at Nadir	Date of Observations
Coarse Resolution Satellite Sensors (> 1 km)			
NOAA–TIROS (National Oceanic and Atmospheric Administration–Television and Infrared Observation Satellite)	AVHRR (Advanced Very High Resolution Radiometer)	1.1km (local area coverage) 8km (global area coverage)	1978–present
SPOT (Systéme Probatoire pour la Observation de la Terre)	VEGETATION	1.15km	1998–present
ADEOS-II (Advanced Earth Observing Satellite)	POLDER (Polarization and Directionality of the Earth's Reflectances)	7km x 6km	2002–present
SeaStar	SeaWIFS (Sea viewing Wide Field of View)	1km (local coverage); 4km (global coverage)	1997–present
Moderate Resolution Satellite Sensors (250 m–1 km)			
ADEOS-II (Advanced Earth Observing Satellite)	GLI (Global Imager)	250m–1km	2002–present
EOS AM and PM (Earth Observing System)	MODIS (Moderate Resolution Spectroradiometer)	250–1,000m	1999–present
EOS AM and PM (Earth Observing System)	MISR (Multi-angle Imaging Spectroradiometer)	275m	1999–present
Envisat	MERIS (Medium Resolution Imaging Spectroradiometer)	350–1,200m	2002–present
Envisat	ASAR (Advanced Synthetic Aperature Radar)	150–1,000m	2002–present
High Resolution Satellite Sensors (20 m–250 m)[a]			
SPOT (Systéme Probatoire pour la Observation de la Terre)	HRV (High Resolution Visible Imaging System)	20m; 10m (panchromatic)	1986–present
ERS (European Remote Sensing Satellite)	SAR (Synthetic Aperture Radar)	30m	1995–present
Radarsat		10–100m	1995–present
Landsat (Land Satellite)	MSS (Multispectral Scanner)	83m	1972–97
Landsat (Land Satellite)	TM (Thematic Mapper)	30m (120m thermal-infrared band)	1984–present
Landsat (Land Satellite)	ETM+ (Enhanced Thematic Mapper)	30m	1999–present
EOS AM and PM (Earth Observing System)	ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer)	15–90m	1999–present
IRS (Indian Remote Sensing)	LISS 3 (Linear Imaging Self-scanner)	23m; 5.8m (panchromatic)	1995–present
Very High Resolution Satellite Sensors (< 20 m)[a]			
JERS (Japanese Earth Resources Satellite)	SAR (Synthetic Aperature Radar)	18m	1992–98
JERS (Japanese Earth Resources Satellite)	OPS	18mx24m	1992–98
IKONOS		1m panchromatic; 4m multispectral	1999–present
QuickBird		0.61m panchromatic; 2.44m multispectral	2001–present
SPOT–5	HRG–HRS	10m; 2.5m (panchromatic)	2002–present

Note: The list is not intended to be comprehensive.

[a] Data were not acquired continuously within the time period.

Data acquired by Landsat and SPOT HRV have been the primary sources for identifying land cover change in particular locations. Incomplete spatial coverage, infrequent temporal coverage, and large data volumes have precluded global analysis of land cover change. With the launch of Landsat 7 in April 1999, data are obtained every 16 days for most parts of Earth, yielding more comprehensive coverage than previous Landsat sensors. Time series of Landsat and SPOT imagery have been applied to identify and measure deforestation and regrowth mainly in the humid tropics (Skole and Tucker 1993; FAO 2000a; Achard 2002). Deforestation is the most measured process of land cover change at the regional scale, although major uncertainties exist about absolute area and rates of change (Lepers et al. 2005).

Data continuity is a key requirement for effectively identifying land cover change. With the exception of the coarse resolution AVHRR Global Area Coverage observations over the past 20 years, continuous global coverage has not been possible. DeFries et al. (2002) and Hansen and DeFries (2004) have applied the AVHRR time series to identify changes in forest cover over the last two decades, illustrating the feasibility of using satellite data to detect these changes on a routine basis. Continuity of observations in the future is an essential component for monitoring land cover change and identifying locations with rapid change. For long-term data sets that cover time periods longer than the lifetime of a single sensor, cross calibration for a period of overlap is necessary. Moreover, classification schemes used to interpret the satellite data need to be clearly defined and flexible enough to allow comparisons over time.

2.2.1.1.2 Applications for biodiversity

There are two approaches for applying remote sensing to biodiversity assessments: direct observations of organisms and communities and indirect observations of environmental proxies of biodiversity (Turner et al. 2003). Direct observations of individual organisms, species assemblages, or ecological communities are possible only with hyperspatial, very high resolution (~1m) data. Such data can be applied to identify large organisms over small areas. Airborne observations have been used for censuses of large mammal abundances spanning several decades, for example in Kenya (Broten and Said 1995).

Indirect remote sensing of biodiversity relies on environmental parameters as proxies, such as discrete habitats (for example, woodland, wetland, grassland, or seabed grasses) or primary productivity. This approach has been employed in the US GAP analysis program (Scott and Csuti 1997). Another important indirect use of remote sensing is the detection of habitat loss and fragmentation to estimate the implications for biodiversity based on species-area relationships or other model approaches. (See Chapter 4.)

2.2.1.1.3 Wetland mapping

A wide range of remotely sensed data has been used to map wetland distribution and condition (Darras et al. 1998; Finlayson et al. 1999; Phinn et al. 1999). The utility of such data is a function of spatial and spectral resolutions, and careful choices need to be made when choosing such data (Lowry and Finlayson in press). The NOAA AVHRR, for example, observes at a relatively coarse nominal spatial resolution of 1.1 kilometer and allows only the broad distribution of wetlands to be mapped. More detailed observations of the extent of wetlands can be obtained using finer resolution Landsat TM (30 meters) and SPOT HRV (20 meters) data. As with all optical sensors, the data are frequently affected by atmospheric conditions, especially in tropical coastal areas where humidity is high and the presence of water beneath the vegetation canopy cannot be observed.

Remotely sensed data from newer spaceborne hyperspectral sensors, Synthetic Aperture Radar, and laser altimeters provide more comprehensive data on wetlands. Although useful for providing present-day baselines, however, the historical archive is limited, in contrast to the optical Landsat, AVHRR, and SPOT sensors, which date back to 1972, 1981, and 1986 respectively.

Aerial photographs have been acquired in many years for over half a century at fine spatial resolutions and when cloud cover is minimal. Photographs are available in a range of formats, including panchromatic black and white, near-infrared black and white, true color, and color infrared. Stereo pairs of photographs can be used to assess the vertical structure of vegetation and detect, for example, changes in the extent and height of mangroves (Lucas et al. 2002).

The European Space Agency's project Treaty Enforcement Services using Earth Observation has assessed the use of remote sensing for wetland inventory, assessment, and monitoring using combinations of sensors in support of wetland management. The approach has been extended through the GlobWetland project and its Global Wetland Information Service project to provide remotely sensed products for over 50 wetlands across 21 countries in Africa, Europe, and North and Central America. The project is designed to support on-the-ground implementation of the Ramsar Convention on Wetlands.

2.2.1.1.4 Assessing land degradation in drylands

Interpretation of remotely sensed data to identify land degradation in drylands is difficult because of large variations in vegetation productivity from year-to-year variations in climate. This variability makes it problematic to distinguish trends in land productivity attributable to human factors such as overgrazing, soil salinization, or burning from variations in productivity due to inter-annual climate variability or cyclical drought events (Reynolds and Smith 2002). Land degradation is defined by the Convention to Combat Desertification as "reduction or loss, in arid, semi-arid and dry sub-humid areas, of the biological or economic productivity of rainfed cropland, irrigated cropland, or ranges, pastures, forests, and woodlands resulting from land uses or from a process or combination of processes, including processes arising from human activities and habitation patterns." Quantifying changes in productivity involves an established baseline of land productivity against which changes can be assessed. Such a baseline is often not available. Furthermore, the inherent variability in year-to-year and even decade-to-decade fluctuations complicates the definition of a baseline.

One approach to assess land productivity is through rain-use efficiency, which quantifies net primary production (in units of biomass per unit time per unit area) normalized to the rainfall for that time period (Prince et al. 1990). Rain-use efficiency makes it possible to assess spatial and temporal differences in land productivity without the confounding factor of climate variability. Several models are available to estimate net primary production, as described later, with some using remotely sensed vegetation indices such as the Normalized Difference Vegetation Index (ratio of red to infrared reflectance indicating vegetative activity) as input data for the models. Studies have examined patterns in NDVI, rain-use efficiency, climate, and land use practices to investigate possible trends in land productivity and causal factors (e.g., Prince et al. 1990; Tucker et al. 1991; Nicholson et al. 1998).

The European Space Agency's TESEO project has examined the utility of remote sensing for mapping and monitoring desertification and land degradation in support of the Convention to Combat Desertification (TESEO 2003). Geostationary satellites such as Meteosat operationally provide basic climatological data, which are necessary to estimate rain-use efficiency and distinguish climatic from land use drivers of land degradation. Operational meteorological satellites, most notably the Advanced Very High Resolution Radiometer, have provided the longest continuous record for NDVI from the 1980s to the present. More recently launched sensors such as VEGETATION on-board SPOT and MODIS on-board the Earth Observation System have been designed specifically to monitor vegetation. Satellite data also identify locations of fire events and burn scars to provide information on changes in dryland condition related to changes in fire regime (Giglio et al. 1999). Applications of microwave sensors such as ERS are emerging as possible approaches to map and monitor primary production. Microwave sensors are sensitive to the amount of living aboveground vegetation and moisture content of the upper soil profile and are appropriate for identifying changes in semiarid and arid conditions.

Advancements in the application of remote sensing for mapping and monitoring land degradation involve not just technical issues but institutional issues as well (TESEO 2003). National capacities to use information and technology transfer currently limit the possible applications.

2.2.1.1.5 Measurements of land surface and marine attributes as input to ecosystem models

Satellite data, applied in conjunction with ecosystem models, provide spatially comprehensive estimates of parameters such as evapotranspiration, primary productivity, fraction of solar radiation absorbed by photosynthetic activity, leaf area index, percentage of solar radiation reflected by the surface (albedo) (Myneni 1992; Sellers 1996), ocean chlorophyll (Doney et al. 2003), and species distributions (Raxworthy et al. 2003). These parameters are related to several ecosystem services. For example, a decrease in evapotranspiration from the conversion of part of a forest to an urban system alters the ability of the forest system to regulate climate. A change in primary production relates to the food available for humans and other species. The satellite-derived parameters provide an important means for linking changes in ecosystem condition with implications for their services—for example, linking changes in climate regulation with changes in land and marine surface properties. (See Chapter 13.)

2.2.1.2 Geographic Information Systems

To organize and analyze remote sensing and other types of information in a spatial framework, many chapters in this report rely on geographic information systems. A GIS is a computer system consisting of computer hardware and software for entering, storing, retrieving, transforming, measuring, combining, subsetting, and displaying spatial data that have been digitized and registered to a common coordinate system (Heywood 1998; Johnston 1998). GIS allows disparate data sources to be analyzed spatially. For example, human population density can be overlain with data on net primary productivity or species endemism to identify locations within ecosystems where human demand for ecosystem services may be correlated with changes in ecosystem condition. Locations of roads can be entered into a GIS along with areas of deforestation to examine possible relationships between the two variables. The combination of remote sensing, GIS, and Global Positioning Systems for field validation is powerful for assessing trends in ecosystem condition (Hoffer 1994; ICSU 2002a).

GIS can be used in conjunction with remote sensing to identify land cover change. A common approach is to compare recent and historical high-resolution satellite images (such as Landsat Thematic Mapper). For example, Figure 2.2 illustrates the changes in forest cover between 1992 and 2001 in Mato Grosso, Brazil. Achard et al. (2002) have used this approach in 100 sample sites located in the humid tropical forests to estimate tropical deforestation.

GIS has also been applied in wilderness mapping, also known as ''mapping human impact.'' These exercises estimate human influence through geographic proxies such as human population density, settlements, roads, land use, and other human-made features. All factors are integrated within the GIS and either summed up with equal weights (Sanderson 2002) or weighted according to perceptions of impact (Carver 2002). This exercise has been carried out at regional scales (for example Lesslie and Maslen 1995; Aplet 2000; Fritz 2001) as well as on a global scale (for example, UNEP 2001; Sanderson 2002). Sanderson et al. (2002) used the approach to estimate the 10% wildest areas in each biome of the world. The U.N. Environment Programme's Global Biodiversity (GLOBIO) project uses a similar methodology and examines human influence in relation to indicators of biodiversity (UNEP 2001).

A further application of GIS and remote sensing is to test hypotheses and responses of ecosystem services to future scenarios (Cleland 1994; Wadsworth and Treweek 1999). For example, GIS is used in the MA's sub-global assessment of Southern Africa to predict the degree of fuelwood shortages for the different districts of Northern Sofala Province, Mozambique, in 2030. This is done by using the GIS database showing available fuelwood per district in 1995 and projecting availability in 2030, assuming that the current trend of forest degradation of 0.05 hectares per person per year will continue. This allows identification of districts where fuelwood would be most affected.

GIS is also applicable for assessing relationships between health outcomes and environmental conditions (see Chapter 14) and for mapping risks of vulnerable populations to environmental stressors (see Chapter 6). The spatial displays aim to delineate the places, human groups, and ecosystems that have the highest risk associated with them. Examples include the ''red data'' maps depicting critical environmental situations (Mather and Sdasyuk 1991), maps of ''environmentally endangered areas'' (National Geographic Society 1989), and locations under risk from infrastructure expansion (Laurance et al. 2001), biodiversity loss (Myers et al. 2000), natural hazards, impacts from armed conflicts (Gleditsch et al. 2002), and rapid land cover change (Lepers et al. 2005). The analytical and display capabilities can draw attention to priority areas that require further analysis or urgent attention. Interactive Internet mapping is a promising approach for risk mapping but is currently in its infancy.

2.2.2 Inventories of Ecosystem Components

Inventories provide data on various ecosystem components relevant to this assessment. The most common and thorough types of inventories relate to the amount and distribution of provisioning services such as timber and agricultural products. Species inventories also provide information useful for assessing biodiversity, and demographic data provide essential information on human populations living within the systems.

2.2.2.1 Natural Resource Inventories

Many countries routinely conduct inventories of their natural resources. These generally assess the locations and amounts of

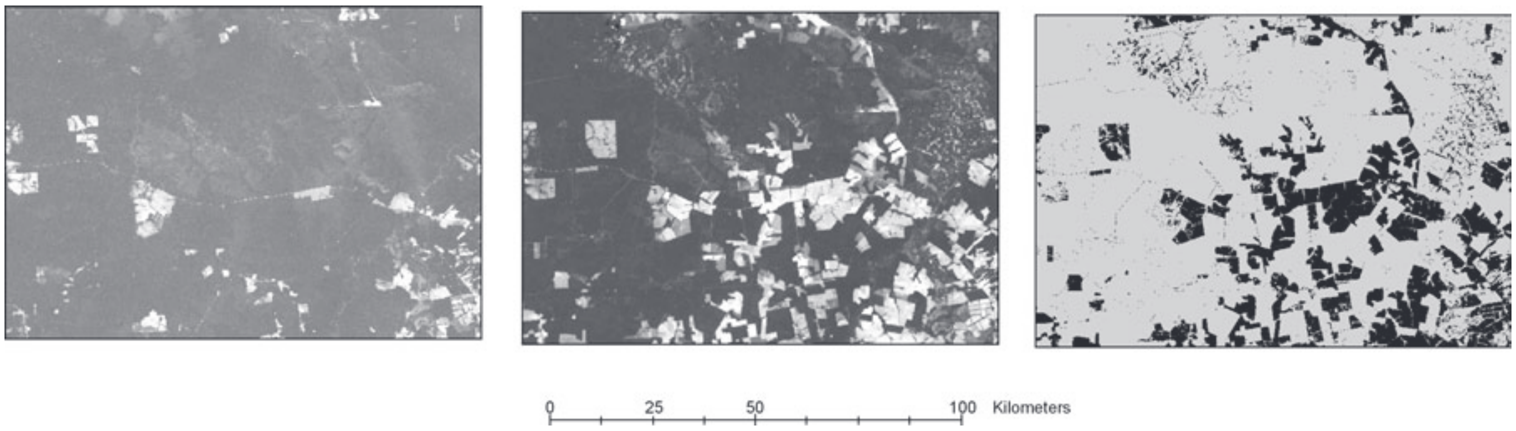

Figure 2.2. Subset of Landsat ETM+ Scenes for an Area in the State of Mato Grosso, Brazil Acquired August 6, 1992 (left) and July 30, 2001 (middle). Light to dark shades represent radiance in band 3 (.63–.62). The difference between the dates indicates deforestation in black (right). The area includes approximately 5534'25"W, 1154'20"S (bottom right corner).

economically important ecosystem services such as timber, agricultural products, and fisheries. FAO periodically publishes compilations of the national-level statistics in forest resources, agricultural production, fisheries production, and water resources. (See Table 2.3.) These statistics are widely used throughout this report. They are in many cases the only source of globally comprehensive data on these ecosystem services. Meta-analyses of local natural resource inventories also provide information on ecosystem condition and trends (Gardner et al. 2003), although they are not spatially comprehensive.

Although the assessment of ecosystem conditions and trends relies heavily on data from resource inventories, there are a number of limitations. First, questions remain about varying methods and definitions used by different countries for data collection (Matthews 2001). For example, several studies based on analysis of satellite data indicate that the FAO Forest Resource Assessment overestimates the rate of deforestation in some countries (Steininger 2001; Achard 2002; DeFries 2002). For fisheries, there are no globally consistent inventories of fisheries and fishery resources. Efforts to develop them are only starting, with the implementation of the FAO Strategy for Improving Information on Status and Trends of Capture Fisheries, which was adopted in 2003 in response to concerns about the reliability of fishery data (FAO 2000b).

Second, resource inventories are often aggregated to the national level or by sub-national administrative units. This level of aggregation does not match the ecosystem boundaries used as the reporting unit for the MA. Third, data quality is highly uneven, with greater reliability in industrial than developing countries. In many countries, deforestation ''data'' are actually projections based on models rather than empirical observations (Kaimowitz and Angelsen 1998). Fourth, statistics on the production of an ecosystem service do not necessarily provide information about the capacity of the ecosystem to continue to provide the service. For example, fisheries catches can increase for years through ''mining'' of the stocks even though the underlying biological capability of producing fish is declining, eventually resulting in a collapse. Finally, inventories for noncommodity ecosystem services, particularly the regulating, supporting, and cultural services, have not been systematically carried out.

2.2.2.2 Biodiversity Inventories

Inventories of the biodiversity of ecosystems are far less extensive than those of individual natural resources with value as commodities. Only a small fraction of biodiversity is currently monitored and assessed. This is probably because there are few perceived economic incentives to inventory biodiversity per se and because biodiversity is a complex phenomenon that is difficult to quantify and measure. (See Chapter 4.) Nonetheless, biodiversity inventories can provide a general sense of the relative biodiversity importance (such as richness, endemism) of ecosystems; they can illuminate the impacts of different human activities and management policies on biodiversity; and, when targeted at service-providing taxa or functional groups (pollinators, for instance), they can link changes in biodiversity within these groups directly to changes in the service provided.

Biodiversity inventories are conducted at a range of spatial scales, which are chosen to best address the issue or question at hand. Most, however, can be usefully grouped into three distinct categories: global inventories, regional inventories, and local inventories. Because biodiversity is complex, inventories typically focus on one aspect of biodiversity at a time, such as species richness or habitat diversity. A few examples of inventories at each of these scales illustrate their relative strengths, limitations, and utilities for the MA.

At the global scale, only a handful of biodiversity inventories exist. These typically provide species lists for relatively well-known taxa, based on relatively large spatial units. For example, the World Conservation Monitoring Centre (1992) compiled species inventories of mammals, birds, and swallowtail butterflies for all nations in the world. The World Wild Fund for Nature is conducting an inventory of all vertebrates and plants in each of the world's 867 terrestrial ecoregions (defined by WWF as relatively large units of land or water containing a distinct assemblage of natural communities and species, with boundaries that approximate the original extent of natural communities prior to major land use change).

These inventories are useful for documenting overall patterns of biodiversity on Earth, in order to indicate global priorities for biodiversity conservation or areas of high-expected threat (Sisk et al. 1994; Ceballos and Brown 1995; Dinerstein 1995). Their utility for focused analyses is limited, however, by the coarse units on which they are based and their restriction to mostly vertebrate taxa (which are not often the most important for the provision of ecosystem services).

In addition, the World Conservation Union–IUCN has been producing Red Data Books and Red Lists of Threatened Species since the 1960s. Currently, the IUCN Red List is updated annually (see www.redlist.org). The criteria for listing are transparent and quantitative. The IUCN Red List is global in coverage and is the most comprehensive list of threatened species, with almost all known bird, mammal, and amphibian species evaluated; there are plans for complete coverage of reptiles in the next few years. Data on fish species include FISHBASE (Frose and Pauly 2000), Ceph-

Table 2.3. Examples of Resource Inventories Applicable to Assessing Ecosystem Condition and Trends

Type	Source	Description
Forest Resources		
Forest area and change	FAO, *Global Forest Resources Assessment*	Published every 10 years (1980, 1990, 2000). Provides national and global estimates of total forest area and net changes during the preceding decade, as well as information on plantations, forest ownership, management, and environmental parameters such as forest fires and biomass volumes.
Forest products	FAO, *State of the World's Forests*	Published every two years. Provide summary tables of national and regional production statistics for major categories of industrial roundwood, pulp, and paper.
	ITTO, *Annual Review and Assessment of the World Timber Situation*	Published annually. Tabular databases on volume and value of production, consumption, and trade among ITTO producer and consumer countries. Time series for five years prior to publication.
Wood energy	IEA, *Energy Statistics and Balances of OECD and Non-OECD Countries* (four reports)	Published every two years. IEA data since 1994–95 have covered combustible renewables and waste in national energy balances, including disaggregated data for production and consumption of wood, charcoal, black liquor, and other biomass. Data provided at national and various regional aggregate levels.
Agricultural Resources		
Agricultural land, products, and yields	*FAOSTAT-Agriculture* (data available on-line)	Time series data since 1961 on extent of agricultural land use by country and region, production of primary and processed crops, live animals, primary and processed animal products, imports and exports, food balance sheets, agricultural inputs, and nutritional yield of many agricultural products.
Specific products	Member organizations of the Consultative Group on International Agricultural Research	Issue-specific datasets on crops, animals, animal products, agricultural inputs, and genetic resources. Variety of spatial and temporal scales.
Fish Resources		
Fish stocks	FAO, *Review of the State of World Fishery Resources: Marine Fisheries*	Tabular information on the state of exploitation, total production, and nominal catches by selected species groups for major world fisheries.
Marine and inland fisheries	FAO, *FISHSTAT* (data available on-line at www.fao.org/fi/statist/statist.asp)	Databases on fishery production from marine capture and aquaculture, fish commodity production, and trade. Global, regional, and national data. Time series range from 20 to 50 years.
	FAO, *The State of World Fisheries and Aquaculture*	Published every two years. Data on five-year trends in fisheries production, utilization, and trade for the world and for geographic and economic regions. National data for major fishing countries. Also provides extensive analysis of fishery issues.
	FAO, *Yearbook of Fishery Statistics*	Updated annually. Includes aquaculture production and capture production by country, fishing area, principal producers, and principal species. Also trade data in fishery products.
	FAO, *Fisheries Global Information System,* at www.fao.org/fi/figis	Information on aquatic species, marine fisheries, fisheries issues, and, under development in collaboration with regional fishery bodies, the state of marine resources and inventories of fisheries and fishery resources.
	International Center for Living Aquatic Management, *FishBase 2000*	Database on more than 27,000 fish species and references. Many datasets incomplete.
Freshwater/Inland Water Resources		
Water resources	FAO, *AQUASTAT*	Global data on water resources and irrigation by country and region. Information on average precipitation, total internal water resources, renewable groundwater and surface water, total renewable water resources, and total exploitable water resources.
	State Hydrological Institute (Russia) and UNESCO, *World Water Resources and Their Use,* 1999	Global database on surface water resources and sectoral use. Includes water use forecasts to 2025.

BASE (Wood et al. 2000), ReefBase (Oliver et al.), and the Census of Marine Life (O'Dor 2004). Freshwater fish species are also being evaluated on a region basis for inclusion in the IUCN Red Lists.

Inventories at regional or continental scales are generally of higher overall quality and are more common than global data. Many of these data sets are based on grids of varying resolution. Examples include data on vertebrates in sub-Saharan Africa (grid size 1 degree or approximately 110 square kilometers) (Balmford et al. 2001), birds in the Americas (grid size 611,000 square kilometers) (Blackburn and Gaston 1996), several taxa of plants and animals in Britain (grid size 10 square kilometers) (Prendergast et al. 1993), and terrestrial vertebrates and butterflies in Australia (grid size 1 degree) (Luck et al. 2004). These grid-based inventories, as well as others based on political boundaries (countries, states) are based on arbitrary units that rarely reflect ecosystem boundaries. As a result, their utility is limited in assessing the biodiversity of a particular ecosystem. Some regional-scale inventories are based on ecological units, including a study on vertebrates, butterflies, tiger beetles, and plants for 116 WWF ecoregions in North America (Ricketts et al. 1999).

All these regional inventories can be used to understand patterns of biodiversity and endangerment (e.g., Ceballos and Brown 1995) and to link these patterns to threats and drivers operating at regional scales (e.g., Balmford et al. 2001; Ricketts in press). As is often the case, these data sets are most complete and dependable in the industrial world, although data are improving in many developing regions.

Because many ecosystem services (such as pollination and water purification) are provided locally, local-scale biodiversity inventories are often the most directly valuable for assessing those services. There are thousands of local inventories in the literature, comparing biodiversity between ecosystem types, among land use intensities, and along various environmental gradients. This literature has not been systematically compiled, and it is not possible to list all the studies here.

We illustrate the types of available data here with biodiversity studies in agricultural landscapes dominated by coffee cultivation. Local inventories in these landscapes have quantified the decline in both bird (Greenberg et al. 1997) and arthropod (Perfecto et al. 1997) diversity with increasing intensification of coffee production. Other studies have shown a decline in moth (Ricketts et al. 2001) and bird (Luck and Daily 2003) diversity with increasing distance from remnant patches of forest. Most relevant to ecosystem services supporting coffee production, the diversity and abundance of coffee-visiting bees declines with increasing distance from forest (Ricketts in press) and with increasing intensification (Klein et al. 2002).

Local inventories offer data that can directly inform land use policies and illuminate trade-offs among ecosystem services for decision-makers. Unfortunately, they are often time- and resource-intensive. In addition, the results are only relevant to the specific taxon and location under study, so general lessons are often difficult to glean. However, the collective results of many such studies can lead to useful general guidelines and principles.

Another method of compiling results from many biodiversity inventories is to examine the collections of museums and herbaria (Ponder et al. 2001). These house enormous amounts of information, accumulated sometimes over centuries of study. Furthermore, museums are beginning to use information technologies and the Internet to pool their information into aggregate databases, such that records from any museum can be searched (e.g., Edwards et al. 2000). These aggregate databases are an invaluable resource for studying the distribution of biodiversity. Museum and herbaria records, however, often contain a variety of spatial, temporal, and taxonomic biases and gaps due to the ad hoc and varying interests of collecting scientists (Ponder et al. 2001). These biases must be carefully considered when using museum data to assess biodiversity status and trends.

Ideally, data for characterizing biodiversity in the individual systems and its response to changes in ecosystem condition would be collected routinely according to an appropriate sampling strategy that meets the needs of the specified measures. Most often this is not the case, however, and data assimilated for other purposes are used, such as routine or sporadic surveys and observations made by naturalists. Generally such observations relate only to the most obvious and common species, especially birds and sometimes mammals, butterflies, and so on.

2.2.2.3 Demographic and Socioeconomic Data on Human Populations

Because the MA considers human populations as integral components of ecosystems, data on the populations living within the systems are one of the foundations for this analysis. Demographic and socioeconomic data provide information on the distributions of human populations within ecosystems, a prerequisite to analyzing the dependence of human well-being on ecosystem services.

Most information on the distribution and characteristics of human population is collected through population censuses and surveys. Nearly all countries of the world conduct periodic censuses (see www.census.gov/ipc/www/cendates/cenall.pdf); most countries conduct them once per decade. Census data are collected and reported by administrative or political units, such as counties, provinces, or states. These administrative boundaries generally do not correspond to the geographic boundaries of ecosystems.

To address this mismatch, the most recent version of the Gridded Population of the World (version 3) (CIESIN et al. 2004; CIESIN and CIAT 2004) contains population estimates for over 350,000 administrative units converted to a grid of latitude-longitude quadrilateral cells at a nominal spatial resolution of 5 square kilometers at the equator (Deichmann et al. 2001). The accuracy depends on the quality and year of the input census data and the resolution of the administrative units. Other data sets show how population is distributed relative to urban areas, roads, and other likely population centers, such as LandScan, which uses many types of ancillary data, including land cover, roads, night-time lights, elevation and slope, to reallocate populations within administrative areas to more specific locations (Dobson 2000).

There are large data gaps on poverty distribution and access to ecosystem services such as fresh water (UNDP 2003). Some census data include resource use such as fuelwood and water source (Government of India 2001), but inventories on the use of ecosystems services are not generally available to establish trends. Increasingly, however, censuses and large-scale surveys are beginning to include questions on resource use. The World Bank's Living Standards Measurement Survey, for example, is introducing modules on resource use (Grosh and Glewwe 1995). As most nationally representative socioeconomic and demographic surveys are not georeferenced beyond administrative units, they must be used with care when making inferences at the moderate and high resolutions often used in ecological data analysis.

By combining census information about human settlements with geographic information, such as city night-time lights from satellite data, a new global database indicates urban areas from rural ones (CIESIN et al. 2004). These can be applied to distinguish urban and rural land areas in different ecosystems and to infer implications for resource use. (See Chapter 27.)

2.2.3 Numerical Simulation Models

Numerical models are mathematical expressions of processes operating in the real world. The ecological and human interactions within and among ecosystems are complex, and they involve physical, biological, and socioeconomic processes occurring over a range of temporal and spatial scales. Models are designed as simplified representations to examine assumptions and responses to driving forces.

Models span a wide range in complexity with regard to processes and spatial and temporal scales. Simple correlative models use statistical associations established where data are adequate in order to predict responses where data are lacking. For example, the CLIMEX model (Sutherst 1995) predicts the performance of an insect species in a given location and year in response to climate change based on previously established correlations from comparable locations and previous years. Dynamic, process-based models, on the other hand, are sets of mathematical expressions describing the interactions among components of a system at a specified time step. For example, the CENTURY model simulates fluxes of carbon, water, and nitrogen among plant and soil pools within a grassland ecosystem (Parton 1988). An emerging class of models, such as IBIS (Foley 1996) and LPJ (Sitch et al. 2003), incorporate dynamic processes but also simulate the dynamics of interacting species or plant functional types. Such models have been applied at the site, regional, and global scales to investigate ecosystem responses to climate change scenarios and increasing atmospheric carbon dioxide concentrations (e.g., Cramer et al. 2004).

Table 2.4 lists categories of models useful for the assessment of ecosystem condition and services. These models address various aspects of ecosystem condition. For example, hydrologic models can be used to investigate the effects of land cover changes on flood protection, population models can assess the effects of habitat loss on biodiversity, and integrated assessment models can synthesize this information for assessing effects of policy alternatives on ecosystem condition. Assessments rely on models to:

- **Fill data gaps.** As noted, data to assess trends in ecosystem condition and their services are often inadequate, particularly for regulating, supporting, and cultural services. Models are used to address these deficiencies. For example, Chapter 13 uses results from four ecosystem models (McGuire 2001) to estimate the impacts of changes in land use, climate, and atmospheric composition on carbon dioxide emissions from ecosystems.
- **Quantify responses of ecosystem services to management decisions.** One of the major tasks for the MA is to assess how changes in ecosystem condition alter services. Does removal of forest cover within a watershed alter flood protection? Does conversion to cropland alter climate regulation? Models can be used to simulate changes in the ecosystem condition (such as land cover) and estimate the response (in stream flow, for instance). A hydrologic model (e.g., Liang 1996) can quantify the change in stream flow in response to removal of forest cover. A land surface model linked to a climate model (e.g., Sellers 1986) can quantify the change in water and energy fluxes to the atmosphere from a specified change in land cover and the resulting effect on surface temperature. To the extent that models are adequate representations of reality, they provide an important tool for quantifying the effects of alternative management decisions on ecosystem services.
- **Predict long-term ecological consequences of altered ecosystem condition.** Many human activities affect ecosystem condition only after a time lag. As a consequence, some effects of ecosystem management are not observed for many years. In such cases, models can be used to predict long-term ecological consequences. For example, the effect of timber harvest on the persistence of threatened species such as the spotted owl can be assessed using habitat-based metapopulation models (Akçakaya and Raphael 1998).

  The reliability of long-term model predictions depends on the level of understanding of the system, the amount and quality of available data, the time horizon, and the incorporation of uncertainty. Predictions about simpler systems (such as single-species dynamics) are more reliable than those about complex systems (such as community composition and dynamics), because of the higher level of understanding ecologists have for simpler systems. The amount and quality of the data determine the uncertainty in input parameters, which in turn affect the reliability of the output. Longer-term predictions are less reliable because these uncertainties are compounded over time. Even uncertain predictions can be useful, however, if the level of uncertainty can be objectively quantified. Complex models can also identify shifts in ecosystem regime, such as the sudden loss of submerged vegetation in shallow lakes subject to eutrophication (Scheffer et al. 2001), and nonlinear responses to drivers.
- **Test sensitivities of ecosystem condition to individual drivers or future scenarios.** Observed changes in ecosystem condition result from the combined responses to multiple drivers. Changes in soil fertility in a rangeland, for example, reflect the combined response to grazing pressure, climate variations, and changes in plant species. Direct observations of soil fertility do not enable understanding of which driver is causing the response or how the drivers interact. A series of model simulations, changing one or more drivers for each model run, facilitates understanding of the response of soil fertility to each of the drivers. To the extent that models represent processes realistically, model simulations can identify nonlinear and threshold responses of ecosystems to multiple drivers. For example, neither overfishing nor pollution alone may lead to precipitous declines in fish stocks, but the combined response could have unanticipated effects on fish stocks.
- **Assess future viability of species.** Quantitative methods and models for assessing the chances of persistence of species in the future are collectively called population viability analysis. Models used in PVAs range from unstructured single-population models to metapopulation models with explicit spatial structure based on the distribution of suitable habitat (Boyce 1992; Burgman 1993). PVA provides a rigorous methodology that can use different types of data, incorporate uncertainties and natural variabilities, and make predictions that are relevant to conservation goals. PVA is most useful when its level of detail is consistent with the available data and when it focuses on relative (comparative) rather than absolute results and on risks of decline rather than extinction (Akçakaya and Sjogren-Gulve 2000). An important advantage of PVA is its rigor. In a comprehensive validation study, Brook et al. (2000) found the risk of population decline predicted by PVA closely matched observed outcomes, there was no significant bias, and population size projections did not differ significantly from reality. Further, the predictions of five PVA software packages they tested were highly concordant. PVA results can also be

Table 2.4. Examples of Numerical Models for Assessing Condition and Trends in Ecosystems and Their Services

Type of Model	Description	Examples of Models
Climate and land-atmosphere models	Land surface models of exchanges of water, energy, and momentum between land surface and atmosphere.	Sellers et al. 1986; Liang et al. 1996
Watershed and hydrologic models	Large basin models of hydrologic processes and biogeochemical exchanges in watersheds.	Fekete et al. 2002; Green et al. in press; Seitzinger and Kroeze 1998
Population and metapopulation models	Models of dynamics of single populations predicting future abundance and trends, risk of decline or extinction, and chance of growth. They can be scalar, structured (e.g., age-, stage-, and/or sex-based), or individual-based and incorporate variability, density dependence, and genetics. Metapopulation models focus on the dynamics of and interactions among multiple populations, incorporating spatial structure and dispersal and internal dynamics of each population. Their spatial structure can be based on the distribution and suitability of habitat, and they can be used to assess species extinction risks and recovery chances.	Akçakaya 2002; Lacy 1993
Community or food-web models	Models focusing on the interactions among different trophic levels (producers, herbivores, carnivores) or different species (e.g., predator-prey models).	Park 1998; USDA 1999
Ecosystem process models	Models that include both biotic and abiotic components and that represent physical, chemical, and biological processes in coastal, freshwater, marine, or terrestrial systems. They can predict, for example, vegetation dynamics, including temporal changes in forest species and age structure.	Pastorok et al. 2002
Global terrestrial ecosystem models	Models of biogeochemical cycling of carbon, nitrogen, and other elements between the atmosphere and biosphere at the global scale, including vegetation dynamics, productivity, and response to climate variability.	Field et al. 1995; Foley et al. 1996; McGuire et al. 2001; Sitch et al. 2003
Multi-agent models	Agents are represented by rules for behavior based on interactions with other actors or physical processes.	Moss et al. 2001
Integrated assessment models	Models that assemble, summarize, and interpret information to communicate to decision-makers.	Alcamo et al. 1994

tested for single models by comparing predicted values with those observed or measured in the field (McCarthy 2001).

- **Understand the dynamics of social environmental interactions.** Individually based methods such as multiagent modeling are increasingly used to understand social and environmental interactions. Multiagent behavioral systems seek to model social-environment interactions as dynamic processes (see Moss et al. 2001). Human actors are represented as software agents with rules for their own behavior, interactions with other social agents, and responses to the environment. Physical processes (such as soil erosion) and institutions or organizations (such as an environmental regulator) may also be represented as agents. A multiagent system could represent multiple scales of vulnerability and produce indicators of multiple dimensions of vulnerability for different populations. Multiagent behavioral systems have an intuitive appeal in participatory integrated assessment. Stakeholders may identify with particular agents and be able to validate a model in qualitative ways that is difficult to do for econometric or complex dynamic simulation models. However, such systems require significant computational resources (proportional to the number of agents), and a paucity of data for validation of individual behavior is a constraint.

Models are useful tools for ecosystem assessments if the selection of models, input data, and validation are considered carefully for particular applications. A model developed with data from one location is not directly applicable to other locations. Moreover, data to calibrate and validate models are often difficult to obtain. The appropriateness of a model for an assessment task also depends as much on the capacity of the model variables to capture the values and interests of the decision-making and stakeholding communities as on the accuracy of the underlying scientific data.

2.2.4 Indicators of Ecosystem Condition and Services

An indicator is a scientific construct that uses quantitative data to measure ecosystem condition and services, drivers of changes, and human well-being. Properly constituted, an indicator can convey relevant information to policymakers. In this assessment, indicators serve many purposes, for example:

- as easily measured quantities to serve as surrogates for more difficult to measure characteristics of ecosystem condition—for example, the presence of fecal coliform in a stream is relatively easy to measure and serves a surrogate for poor sanitation in the watershed, which is more difficult to measure.
- as a means to incorporate several measured quantities into a single attribute as an indicator of overall condition—for example, the widely used Index of Biotic Integrity is an indicator of aquatic ecosystem condition (Karr et al. 1986). The IBI is an additive index combining measures of abundances of different taxa. The individual measures can be weighted according to the importance of each taxa for aquatic health.
- as a means to communicate effectively with policy-makers regarding trends in ecosystem conditions and services—for example, information on trends in disease incidence reflects trends in disease control as a ''regulating'' ecosystem service. The former can be readily communicated to a policymaker.
- as a means to measure the effectiveness of policy implementation.

Identifying and quantifying the appropriate indicators is one of the most important aspects of the chapters in this report because it is simply not possible to measure and report all aspects of ecosystems and their relation to human well-being. It is also important to identify appropriate indicators to establish a baseline against which future ecosystem assessments can be compared.

Indicators are designed to communicate information quickly and easily to policy-makers. Economic indicators, such as GDP, are highly influential and well understood by decision-makers. Measures of poverty, life expectancy, and infant mortality directly convey information about human well-being. Some environmental indicators, such as global mean temperature and atmospheric carbon dioxide concentrations, are becoming widely accepted as measures of anthropogenic effects on global climate. Measures of ecosystem condition are far less developed, although some biophysical measures such as spatial extent of an ecosystem and agricultural output are relatively easy to quantify. There are at this time no widely accepted indicators to measure trends in supporting, regulating, or cultural ecosystem services, much less indicators that measure the effect of changes in these services on human well-being. Effective indicators meet a number of criteria (NRC 2000). (See Box 2.1.)

The U.S. National Research Council (NRC 2000) identifies three categories of ecological indicators. First, the extent and status of ecosystems (such as land cover and land use) indicate the coverage of ecosystems and their ecological attributes. Second, ecological capital, further divided into biotic raw material (such as total species diversity) and abiotic raw materials (such as soil nutrients), indicates the amount of resources available for providing services. Finally, indicators of ecological functioning (such as lake trophic status) measure the performance of ecosystems.

Table 2.5 provides examples of three major types of indicators used in this report. (Indicators of human well-being and their utility for measuring how well-being responds to changes in ecosystem services are described later in this chapter.)

- **Indicators of direct drivers of change.** No single indicator represents the totality of the various drivers. Some direct drivers of change (see MA 2003 and Chapter 3) have relatively straightforward indicators, such as fertilizer usage, water consumption, irrigation, and harvests. Indicators for other drivers, including invasion by non-native species, climate change, land cover conversion, and landscape fragmentation, are not as well developed, and data to measure them are not as readily available. Measures such as the per capita "ecological footprint," defined as the area of arable land and aquatic ecosystems required to produce the resources used and assimilate wastes produced per person (Rees 1992), attempt to quantify the demand on ecosystem services into a single indicator. (See Chapter 27.)
- **Indicators of ecosystem condition.** Indicators of biophysical condition of ecosystems do not directly reflect the cause and effect of the drivers but nevertheless can contribute to policy formulation by directing attention to changes of importance. To determine causal relationships, models of interactions among variables must be used. As an analogy with human health, an increase in body temperature indicates infection that warrants further examination. As an example in the biophysical realm, declining trends in fish stocks can trigger investigations of possible causal mechanisms and policy alternatives. Indicators of ecosystem condition include many dimensions, ranging from the extent of the ecosystem to demographic characteristics of human populations to amounts of chemical contaminants (The H. John Heinz III Center for Science, Economics, and the Environment 2002).
- **Indicators of ecosystem services.** Indicators for the provisioning services discussed in Chapters 7–17 generally relate to commodity outputs from the system (such as crop yields or fish) and are readily communicable to policy-makers. Indicators related to the underlying biological capability of the system to maintain the production through supporting and regulating services are a greater challenge. For example, indicators measuring the capability of a system to regulate climate, such as evapotranspiration or albedo, are not as readily interpretable for a policy-maker.

Indicators are essential, but they need to be used with caution (Bossel 1999). Over-reliance on indicators can mask important changes in ecosystem condition. Second, while it is important that indicators are based on measurable quantities, the selection of indicators can be biased toward attributes that are easily quantifiable rather than truly reflective of ecosystem condition. Third, comparing indicators and indices from different temporal and spatial scales is challenging because units of measurement are often inconsistent. Adding up and combining factors has to be done very carefully and it is crucial that the method for combining individual indicators is well understood.

Indicators of biodiversity are particularly important for this assessment. Indicators of the amount and variability of species within a defined area can take many forms. The most common measures are species richness—the number of species—and species diversity, which is the number of species weighted by their relative abundance, biomass, or other characteristic, as in Shannon-Weiner or other similar indices (Rosenzweig 1995).

These two simple measures do not capture many aspects of biodiversity, however. They do not differentiate between native and invasive or introduced species, do not differentiate among species in terms of sensitivity or resilience to change, and do not focus on species that fulfill significant roles in the ecosystem (such as pollinators and decomposers). Moreover, the result depends on the definition of the area and may be scale-dependent. The measures also may not always reflect biodiversity trends accurately. For example, ecosystem degradation by human activities may temporarily increase species richness in the limited area of the impact. Thus refinements of these simple measures provide more insights into the amount of biodiversity. (See Box 2.2.)

Aggregate indicators of trends in species populations such as the Index of Biotic Integrity for aquatic systems (Karr and Dudley 1981) and the Living Planet Index (Loh 2002) use existing data sets to identify overall trends in species abundance and, by implication, the condition of the ecosystems in which they occur. The

Criteria for Effective Ecological Indicators (NRC 2000)

- Does the indicator provide information about changes in important processes?
- Is the indicator sensitive enough to detect important changes but not so sensitive that signals are masked by natural variability?
- Can the indicator detect changes at the appropriate temporal and spatial scale without being overwhelmed by variability?
- Is the indicator based on well-understood and generally accepted conceptual models of the system to which it is applied?
- Are reliable data available to assess trends and is data collection a relatively straightforward process?
- Are monitoring systems in place for the underlying data needed to calculate the indicator?
- Can policymakers easily understand the indicator?

Table 2.5. Examples of Indicators to Assess Ecosystem Condition and Trends

Characteristic Described by Indicator	Example of Indicator	Category of Indicator	Availability of Data for Indicator	Units
Direct drivers of change				
Land cover conversion	area undergoing urbanization	ecological state	high	hectares
Invasive species	native vs. non-native species	ecological capital	medium	percent of plant species
Climate change	annual rainfall	ecological state	high	millimeters per year
Irrigation	water usage	ecological functioning	high	cubic meters per year
Ecosystem condition				
Condition of vegetation	landscape fragmentation	ecological state	medium	mean patch size
Condition of soil	soil nutrients	ecological capital	medium	nutrient concentration
	soil salinization	ecological state	low	salt concentration
Condition of biodiversity	species richness	ecological capital	low	number of species/unit area
	threatened species	ecological functioning	medium	percent of species at risk
	visibility of indicator species	ecological functioning	low-medium	probability of extinction
Condition of fresh water	presence of contaminants	ecological state	high	concentration of pollutants index of biotic integrity
Ecosystem service				
Production service	food production	ecological functioning	high	yield (kilograms per hectare per year)
Capacity to mitigate floods	change in stream flow per unit precipitation	ecological capital	low	discharge (cubic meters per second)
Capacity for cultural services	spiritual value	ecological capital	low	?
Capacity to provide biological products	biological products of potential value	ecological capital	low	number of products or economic value

Note: See section 2.3.4 for indicators of human well-being.

BOX 2.2

Indicators of Biodiversity

The following is a sample of the types of indicators that can be used to monitor status and trends in biodiversity. The list is not exhaustive, and specific choice of indicators will depend on particular scale and goals of the monitoring program.

- **Threatened species:** the number of species that are in decline or otherwise classified as under threat of local or global extinction.
- **Indicator species:** species that can be shown to represent the status or diversity of other species in the same ecosystem. Indicator species have been explored as proxies for everything from whole ecosystem restoration (e.g., Carignan and Villard 2002) to overall species richness (e.g., MacNally and Fleishman 2002). The phrase "indicator species" is also used broadly to include several of the other categories listed here.
- **Umbrella species:** species whose conservation is expected to confer protection of other species in the same ecosystem (for example, species with large area requirements). If these species persist, it is assumed that others persist as well (Roberge and Angelstam 2004).
- **Taxonomic diversity:** the number of species weighted by their evolutionary distinctiveness (Mace et al. 2003). This indicator is increased with both high species richness and high levels of taxonomic diversity among species. Care is needed that the indicator of taxonomic diversity represents lineage in evolutionary history.
- **Endemism:** the number of species found only in the specific area (e.g., Ricketts in press). Note that this is a scale-dependent measure: as the area assessed increases, higher levels of endemism will result.
- **Ecological role:** species with particular ecological roles, such as pollinators and top predators (e.g., Kremen et al. 2002).
- **Sensitive or sentinel species:** trends in species that react to changes in the environment before other species, especially changes due to human activities (e.g., de Freitas Rebelo et al. 2003). Similar to the famous "canary in the coal mine," monitoring these sensitive species is thought to provide early warning of ecosystem disruption.
- **Aggregate indicators:** indices that combine information about trends in multiple species, such as the Living Planet Index, which aggregates trends in species abundances in forest, fresh water, and marine species (Loh 2002), and the Index of Biotic Integrity, which combines measures of abundances of different taxa in aquatic systems (Karr and Dudley 1981).

Living Planet Index is an aggregation of three separate indices, each the average of trends in species abundances in forest, freshwater, and marine biomes. It can be applied at national, regional, and global levels. The effectiveness of such an aggregate indicator depends on availability and access to data sets on a representative number of species, which is particularly problematic in many developing countries.

The number of species threatened with extinction is an important indicator of biodiversity trends. Using this indicator requires that a number of conditions to be met, however. First, the criteria used to categorize species into threat classes must be objective and transparent and have a scientific basis. Second, the changes in the status of species must reflect genuine changes in the conservation status of the species (rather than changes in knowledge or taxonomy, for example). Third, the pool of species evaluated in two different time periods must be comparable (if more threatened species are evaluated first, the proportion of threatened species may show a spurious decline).

The IUCN Red List of Threatened Species mentioned earlier meets these conditions. The criteria used in assigning species to threat categories (IUCN 2001) is quantitative and transparent yet allows for flexibility and can incorporate data uncertainties (Akçakaya 2000). The IUCN Red List database also records whether or not a species has been evaluated for the first time. For species evaluated previously, the assessment includes reasons for any change in status, such as genuine change in the status of the species, new or better information available, incorrect information used previously, taxonomic change affecting the species, and previous incorrect application of the Red List criteria. Finally, the complete coverage of some taxonomic groups helps make evaluations comparable, although the fact that new species are being evaluated for other groups must be considered when calculating measures such as the proportion of threatened species in those groups.

2.2.5 Indigenous, Traditional, and Local Knowledge

Traditional knowledge broadly represents information from a variety of sources including indigenous peoples, local residents, and traditions. The term indigenous knowledge is also widely used referring to the knowledge held by ethnic minorities from the approximately 300 million indigenous people worldwide (Emery 2000). The International Council for Science defines TK as "a cumulative body of knowledge, know-how, practices and representation maintained and developed by peoples with extended histories of interaction with the natural environment. These sophisticated sets of understandings, interpretations and meanings are part and parcel of a cultural complex that encompasses language, naming and classification systems, resource use practices, ritual, spirituality and worldview" (ICSU 2002b).

TK and IK are receiving increased interest as valuable sources of information (Martello 2001) about ecosystem condition, sustainable resource management (Johannes 1998; Berkes 1999; 2002), soil classification (Sandor and Furbee 1996), land use investigations (Zurayk et al. 2001), and the protection of biodiversity (Gadgil et al. 1993). Traditional ecological knowledge is a subset of TK that deals specifically with environmental issues.

Pharmaceutical companies, agribusiness, and environmental biologists have all found TEK to be a rich source of information (Cox 2000; Kimmerer 2000). TEK provides empirical insight into crop domestication, breeding, and management. It is particularly important in the field of conservation biology for developing conservation strategies appropriate to local conditions. TEK is also useful for assessing trends in ecosystem condition (Mauro and Hardinson 2000) and for restoration design (Kimmerer 2000), as it tends to have qualitative information of a single local record over a long time period.

Oral histories can play an important role in the field of vulnerability assessment, as they are especially effective at gathering information on local vulnerabilities over past decades. Qualitative information derived from oral histories can be further developed as storylines for further trends and can lead into role playing simulations of new vulnerabilities or adaptations (Downing et al. 2001).

However, TK has for a long time not been treated equally to knowledge derived from formal science. Although Article 27 of the Universal Declaration of Human Rights of 1948 protects Intellectual Property, the intellectual property rights of indigenous people have often been violated (Cox 2000). The Convention on Biological Diversity of 1992 for the first time established international protocols on the protection and sharing of national biological resources and specifically addressed issues of traditional knowledge. In particular, the parties to the convention agree to respect and preserve TK and to promote wide applications and equitable sharing of its benefits (Antweiler 1998; Cox 2000; Singhal 2000).

The integration of TEK with formal science can provide a number of benefits, particularly in sustainable resource management (Johannes 1998; Berkes 2002). However, integrating TEK with formal science is sometimes problematic (Antweiler 1998; Fabricus et al. 2004). Johnson (1992) cites the following as reasons why integrating TEK is difficult:

- Traditional environmental knowledge is disappearing and there are few resources to document it before it is lost.
- Translating concepts and ideas from cultures based on TEK (mainly oral-based knowledge systems) into the concepts and ideas of formal science is difficult.
- Appropriate methods to document and integrate TEK are lacking, and natural scientists often criticize the lack of rigor of the traditional anthropological methods for interviewing and participant observation
- Integrating TEK and formal science is linked to political power, and TEK is often seen as subordinate.

Moreover, existing practices of TEK, such as forest management, are not necessarily sustainable (Antweiler 1998).

It has been repeatedly pointed out that if TEK is integrated it needs to be understood within its historical, socioeconomic, political, environmental, and cultural location (Berkes 2002). This implies that the ratio of local to scientific knowledge will vary depending on the case and situation (Antweiler 1998). The limitations and shortcomings of integrating TEK and formal science must be addressed, and the methods chosen to collect this knowledge should take the location-specific environments in which they operate into account (Singhal 2000). Integration can also be hindered by different representations of cross-scale interactions, nonlinear feedbacks, and uncertainty in TEK and formal science (Gunderson and Holling 2002). Due to this high degree of uncertainty, it is essential to validate and compare both formal and informal knowledge (Fabricus et al. 2004).

There have been general concerns about scaling up TEK to broader spatial scales, as this traditional knowledge is seldom relevant outside the local context (Forsyth 1999; Lovell et al. 2002). Moreover, analysts warn of a downplaying of environmental problems when TEK is overemphasized. On the other hand, researchers have also warned that efforts to integrate or bridge different knowledge systems will lead inevitably to the compartmentalization and distillation of traditional knowledge into a form that is understandable and usable by scientists and resource managers alone (Nadasdy 1999).

Despite these limitations, TEK—if interpreted carefully and assessed appropriately—can provide important data on ecosystem conditions and trends. The most promising methods of data collection are participatory approaches, in particular Participatory Rural Appraisal (Catley 1996). PRA is an alternative to unstructured visits to communities, which may be biased toward more accessible areas, and to costly, time-consuming questionnaire surveys (Chambers 1994). PRA was developed during the early 1990s from Rapid Rural Appraisal, a cost-effective and rapid way of gathering information. RRA was criticized as being too ''quick and dirty'' and not sufficiently involved with local people. PRA tries to overcome the criticisms of RRA by allowing recipients more control of problem definition and solution design and by carrying out research over a longer period (Zarafshani 2002; Scoones 1995). Activities such as interviewing, transects, mapping, measuring, analysis, and planning are done jointly with local people (Cornwall and Pratt 2003).

Participatory methods have their limitations: First, they only produce certain types of information, which can be brief and superficial. Second, the information collected may reflect peoples' own priorities and interests. Third, there might be an unequal power relation among participants and between participants and researchers (Cooke and Kothari 2001). Glenn (2003) warns that a rush to obtain traditional knowledge can be biased toward preexisting stereotypes and attention to vocal individuals who do not necessarily reflect consensus.

The MA sub-global assessments used a wide range of participatory research techniques to collect and integrate TEK and local knowledge into the assessment process. In addition to PRA (Pereira 2004), techniques such as focus group workshops (Borrini-Feyerabend 1997), semi-structured interviews with key informants (Pretty 1995), forum theater, free hand and GIS mapping, pie charts, trend lines, timelines, ranking, Venn diagrams, problem trees, pyramids, role playing, and seasonal calendars were used (Borrini-Feyerabend 1997; Jordan and Shrestha 1998; Motteux 2001).

2.2.6 Case Studies of Ecosystem Responses to Drivers

Case studies provide in-depth analyses of responses of ecosystem conditions and services to drivers in particular locations. For example, the study of the Yaqui Valley in Mexico illustrates the response of birds, marine mammals, and fisheries to upland runoff generated by increasing fertilizer use in the heavily irrigated valley (Turner II et al. 2003). Evidence generated from a sufficient number of case studies allows general principles to emerge about ecosystem responses to drivers. Case studies, which can analyze relationships in more detail than would be possible with nationally aggregated statistics or coarse resolution data, also illustrate the range of ecosystem responses to drivers in different locations or under different biophysical conditions.

Few studies have been undertaken to synthesize information from case studies. One such effort analyzed 152 sub-national case studies investigating the response of tropical deforestation to economic, institutional, technological, cultural, and demographic drivers (Geist and Lambin 2001, 2002). The analysis revealed complex relationships between drivers and deforestation in different regions of the tropics, indicating challenges for generic and widely applicable land-use policies to control deforestation. The MA does not carry out such extensive meta-analyses, but rather uses their results where available as well as results from individual case studies from the scientific literature.

Drawing conclusions from case studies must be done with caution. First, individual studies do not generally use standard protocols for data collection and analysis, so comparisons across case studies are difficult. Second, researchers make decisions about where to carry out a case study on an individual basis, so biases might be introduced from inadequate representation from different locations. Third, unless a sufficient number of case studies are available it is not prudent to draw general conclusions and extrapolate results from one location to another. In spite of these limitations, case studies can illustrate possible linkages between ecosystem response and drivers and can fill gaps generated by lack of more comprehensive data when necessary.

2.3 Assessing the Value of Ecosystem Services for Human Well-being

This section addresses the data and methods for assessing the linkages between ecosystem services and human well-being.

2.3.1 Linking Ecosystem Condition and Trends to Well-being

Ecosystem condition is only one of many factors that affect human well-being, making it challenging to assess linkages between them. Health outcomes, for example, are the combined result of ecosystem condition, access to health care, economic status, and myriad other factors. Interpretations of trends in indicators of well-being must appropriately account for the full range of factors involved.

The impacts of ecosystem change on well-being are often subtle, which is not to say unimportant; impacts need not be drastic to be significant. A small increase in food prices resulting from lower yields as a result of land degradation will affect the well-being of many people, even if none starve as a result.

Two basic approaches can be used to trace the linkages between ecosystem condition and trends and human well-being. The first attempts to correlate trends in ecosystem condition to changes in human well-being directly, while the second attempts to trace the impact to the groups affected through biophysical and socioeconomic processes. For example, the impact of water contamination on the incidence of human disease could be estimated by correlating measures of contaminants in water supplies with measures of the incidence of gastrointestinal illnesses in the general population, controlling for other factors that might affect the relationship. Alternatively, the impact could be estimated by using a dose-response function that relates the incidence of illness to the concentration of contaminants to estimate the increase in the probability of illness, then combining that with estimates of the population served by the contaminated water to arrive at a predicted total number of illnesses.

Both approaches face considerable problems. Efforts to correlate ecosystem condition with human well-being directly are difficult because of the presence of multiple confounding factors. Thus the incidence of respiratory illness depends not only on the concentration of airborne contaminants but also on predisposition to illness through factors such as nutritional status or the prevalence of smoking, exposure factors such as the proportion of time spent outdoors, and so on. Analyses linking well-being and ecosystem condition are most easily carried out at a local scale, where the linkages can be most clearly identified.

2.3.2 Measuring Well-being

Human well-being has several key components: the basic material needs for a good life, freedom and choice, health, good social relations, and personal security. Well-being exists on a continuum with poverty, which has been defined as ''pronounced deprivation in well-being.'' One of the key objectives of the MA is to identify the direct and indirect pathways by which ecosystem change can affect human well-being, whether positively or negatively.

Well-being is multidimensional, and so very hard to measure. All available measures have problems, both conceptual (are they measuring the right thing, in the right way?) and practical (how do we actually implement them?). Moreover, most available measures are extremely difficult to relate to ecosystem services.

Economic valuation offers a way both to value a wide range of individual impacts (some quite accurately and reliably, others less so) and, potentially but controversially, to assess well-being as a whole by expressing the disparate components of well-being in a single unit (typically a monetary unit). It has the advantage that impacts denominated in monetary units are readily intelligible and comparable to other benefits or to the costs of intervention. It can also be used to provide information to examine distributional, equity, and intergenerational aspects. Economic valuation techniques are described in the next section.

Health indicators address a key subset of impacts of ecosystem services on well-being. They are an important complement to economic valuation because they concern impacts that are very difficult and controversial to value. Some health indicators address specific types of health impacts; others attempt to aggregate a number of health impacts. Likewise, poverty indicators measure a dimension of well-being that is often of particular interest. These, too, are described later in the chapter.

Numerous other well-being indicators (such as the Human Development Index) have been developed in an effort to capture the multidimensionality of well-being into a single number, with varying degrees of success. Although these indicators are arguably better measures of well-being, they tend not to be very useful for assessing the impact of ecosystems, as many of the dimensions they add (literacy, for instance) tend not to be sensitive to ecosystem condition. These aggregate indicators and the limitations they face are described near the end of this chapter.

2.3.3 Economic Valuation

One of the main reasons we worry about the loss of ecosystems is that they provide valuable services—services that may be lost or diminished as ecosystems degrade. The question then immediately arises: how valuable are these services? Or, put another way, how much worse off would we be if we had less of these services? We need to be able to answer these questions to inform the choices we make in how to manage ecosystems.

Economic valuation attempts to answer these questions. It is based on the fact that human beings derive benefit (or ''utility'') from the use of ecosystem services either directly or indirectly, whether currently or in the future, and that they are willing to ''trade'' or exchange something for maintaining these services. As utility cannot be measured directly, economic valuation techniques are based on observation of market and nonmarket exchange processes. Economic valuation usually attempts to measure all services in monetary terms, in order to provide a common metric in which to express the benefits of the diverse variety of services provided by ecosystems. This explicitly does not mean that only services that generate monetary benefits are taken into consideration in the valuation process. On the contrary, the essence of most work on valuation of environmental and natural resources has been to find ways to measure benefits that do not enter markets and so have no directly observable monetary benefits. The concept of Total Economic Value is a framework widely used to disaggregate the utilitarian value of ecosystems into components (Pearce 1993). (See Box 2.3.)

Valuation can be used in many different ways (Pagiola et al. 2004). The MA uses valuation primarily to evaluate trade-offs between alternative ecosystem management regimes that alter the use of ecosystems and the multiple services they provide. This approach focuses on assessing the value of changes in ecosystem services resulting from management decisions or other human ac-

BOX 2.3

Total Economic Value

The concept of total economic value is widely used by economists (Pearce and Warford 1993). This framework typically disaggregates the utilitarian value of ecosystems into direct and indirect use values and non-use values:

- **Direct use values** are derived from ecosystem services that are used directly by humans. They include the value of *consumptive uses,* such as harvesting of food products, timber for fuel or construction, medicinal products, and hunting of animals for consumption, and of *non-consumptive uses,* such as the enjoyment of recreational and cultural amenities like wildlife and bird watching, water sports, and spiritual and social utilities that do not require harvesting of products. Direct use values correspond broadly to the MA notion of provisioning and cultural services. They are typically enjoyed by people located in the ecosystem itself.
- **Indirect use values** are derived from ecosystem services that provide benefits outside the ecosystem itself. Examples include the natural water filtration function of wetlands, which often benefits people far downstream; the storm protection function of coastal mangrove forests, which benefits coastal properties and infrastructure; and carbon sequestration, which benefits the entire global community by abating climate change. This category of benefits corresponds broadly to the MA notion of regulating and supporting services.
- **Option values** are derived from preserving the option to use in the future services that may not be used at present, either by oneself (*option value*) or by others or heirs (*bequest value*). Provisioning, regulating, and cultural services may all form part of option value to the extent that they are not used now but may be used in the future.
- **Non-use values** refer to the value people may have for knowing that a resource exists even if they never use that resource directly. This kind of value is usually known as *existence value* (or, sometimes, *passive use value*). This is one area of partial overlap with non-utilitarian sources of value (see the section on intrinsic value).

The TEV framework does not have any direct analog to the MA notion of supporting services of ecosystems. Rather, these services are valued indirectly, through their role in enabling the ecosystem to provide provisioning and enriching services.

Valuation is usually relatively simple in the case of direct use value, and then increasingly difficult as one moves on to indirect use value, option value, and non-use value.

About Island Press

Island Press is the only nonprofit organization in the United States whose principal purpose is the publication of books on environmental issues and natural resource management. We provide solutions-oriented information to professionals, public officials, business and community leaders, and concerned citizens who are shaping responses to environmental problems.

In 2005, Island Press celebrates its twenty-first anniversary as the leading provider of timely and practical books that take a multidisciplinary approach to critical environmental concerns. Our growing list of titles reflects our commitment to bringing the best of an expanding body of literature to the environmental community throughout North America and the world.

Support for Island Press is provided by the Agua Fund, The Geraldine R. Dodge Foundation, Doris Duke Charitable Foundation, Ford Foundation, The George Gund Foundation, The William and Flora Hewlett Foundation, Kendeda Sustainability Fund of the Tides Foundation, The Henry Luce Foundation, The John D. and Catherine T. MacArthur Foundation, The Andrew W. Mellon Foundation, The Curtis and Edith Munson Foundation, The New-Land Foundation, The New York Community Trust, Oak Foundation, The Overbrook Foundation, The David and Lucile Packard Foundation, The Winslow Foundation, and other generous donors.

The opinions expressed in this book are those of the authors and do not necessarily reflect the views of these foundations.

Millennium Ecosystem Assessment: Objectives, Focus, and Approach

The Millennium Ecosystem Assessment was carried out between 2001 and 2005 to assess the consequences of ecosystem change for human well-being and to establish the scientific basis for actions needed to enhance the conservation and sustainable use of ecosystems and their contributions to human well-being. The MA responds to government requests for information received through four international conventions—the Convention on Biological Diversity, the United Nations Convention to Combat Desertification, the Ramsar Convention on Wetlands, and the Convention on Migratory Species—and is designed to also meet needs of other stakeholders, including the business community, the health sector, nongovernmental organizations, and indigenous peoples. The sub-global assessments also aimed to meet the needs of users in the regions where they were undertaken.

The assessment focuses on the linkages between ecosystems and human well-being and, in particular, on "ecosystem services." An ecosystem is a dynamic complex of plant, animal, and microorganism communities and the nonliving environment interacting as a functional unit. The MA deals with the full range of ecosystems—from those relatively undisturbed, such as natural forests, to landscapes with mixed patterns of human use and to ecosystems intensively managed and modified by humans, such as agricultural land and urban areas. Ecosystem services are the benefits people obtain from ecosystems. These include *provisioning services* such as food, water, timber, and fiber; *regulating services* that affect climate, floods, disease, wastes, and water quality; *cultural services* that provide recreational, aesthetic, and spiritual benefits; and *supporting services* such as soil formation, photosynthesis, and nutrient cycling. The human species, while buffered against environmental changes by culture and technology, is fundamentally dependent on the flow of ecosystem services.

The MA examines how changes in ecosystem services influence human well-being. Human well-being is assumed to have multiple constituents, including the *basic material for a good life*, such as secure and adequate livelihoods, enough food at all times, shelter, clothing, and access to goods; *health,* including feeling well and having a healthy physical environment, such as clean air and access to clean water; *good social relations,* including social cohesion, mutual respect, and the ability to help others and provide for children; *security,* including secure access to natural and other resources, personal safety, and security from natural and human-made disasters; and *freedom of choice and action,* including the opportunity to achieve what an individual values doing and being. Freedom of choice and action is influenced by other constituents of well-being (as well as by other factors, notably education) and is also a precondition for achieving other components of well-being, particularly with respect to equity and fairness.

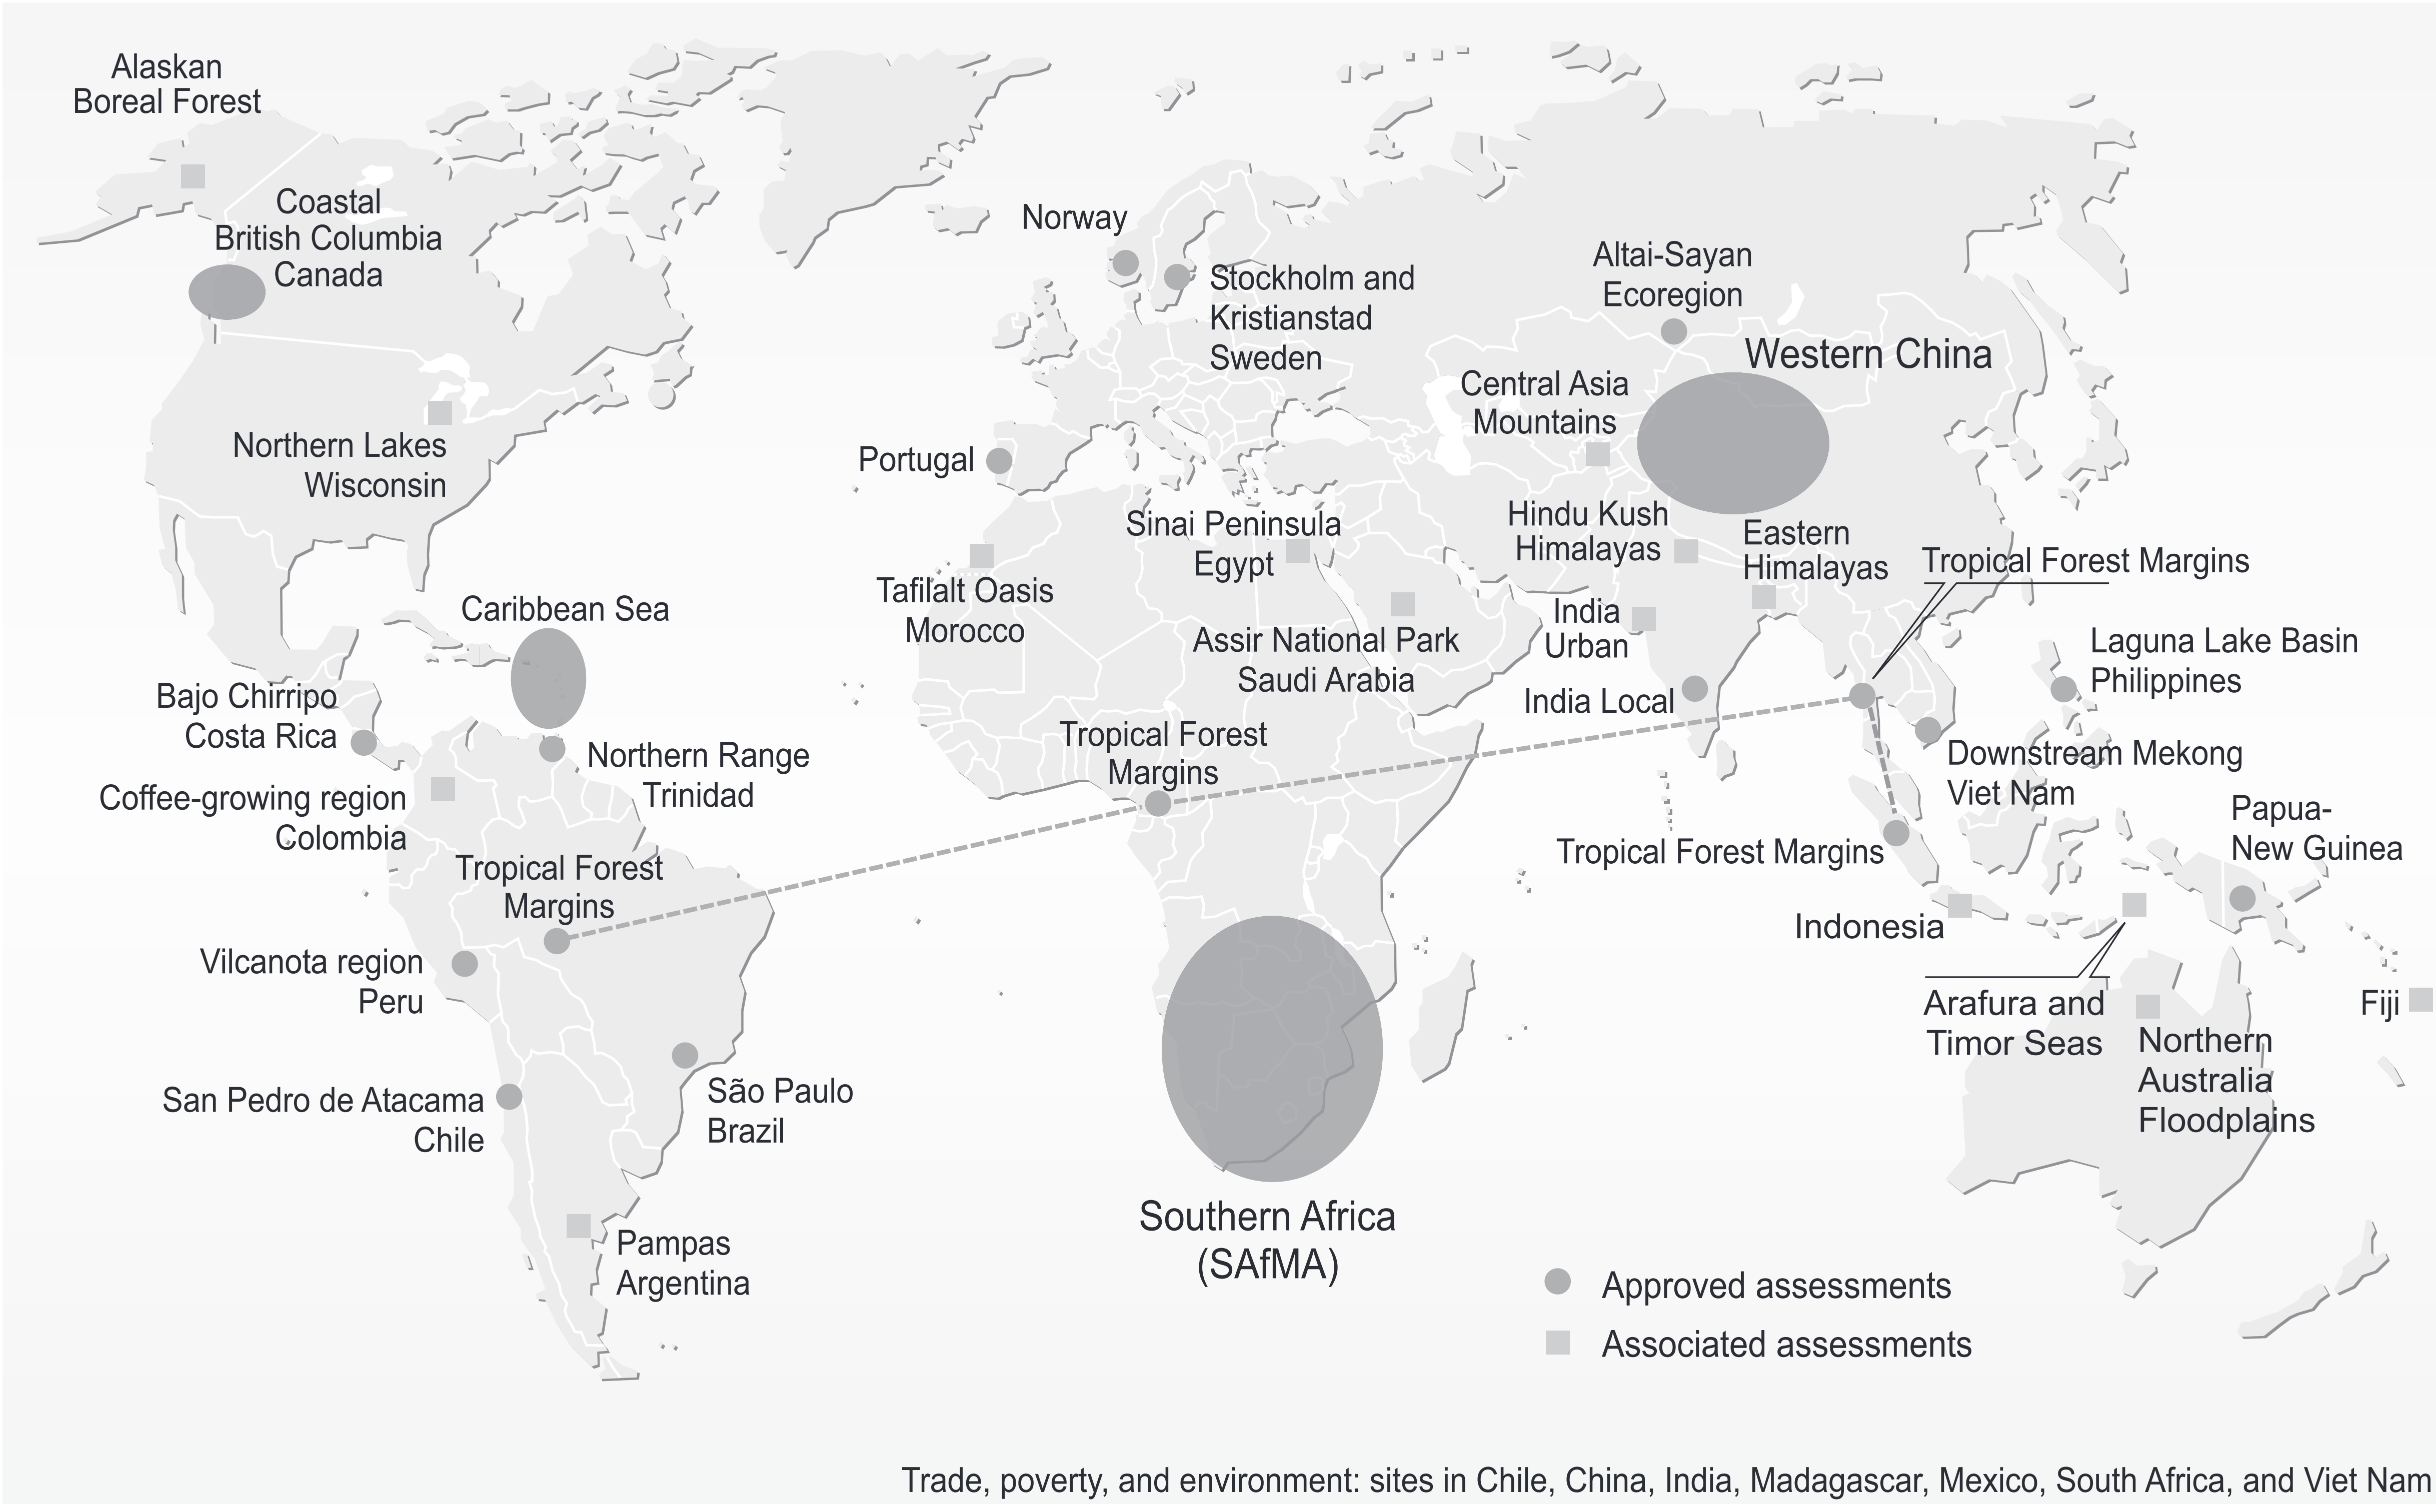
The conceptual framework for the MA posits that people are integral parts of ecosystems and that a dynamic interaction exists between them and other parts of ecosystems, with the changing human condition driving, both directly and indirectly, changes in ecosystems and thereby causing changes in human well-being. At the same time, social, economic, and cultural factors unrelated to ecosystems alter the human condition, and many natural forces influence ecosystems. Although the MA emphasizes the linkages between ecosystems and human well-being, it recognizes that the actions people take that influence ecosystems result not just from concern about human well-being but also from considerations of the intrinsic value of species and ecosystems. Intrinsic value is the value of something in and for itself, irrespective of its utility for someone else.

The Millennium Ecosystem Assessment synthesizes information from the scientific literature and relevant peer-reviewed datasets and models. It incorporates knowledge held by the private sector, practitioners, local communities, and indigenous peoples. The MA did not aim to generate new primary knowledge but instead sought to add value to existing information by collating, evaluating, summarizing, interpreting, and communicating it in a useful form. Assessments like this one apply the judgment of experts to existing knowledge to provide scientifically credible answers to policy-relevant questions. The focus on policy-relevant questions and the explicit use of expert judgment distinguish this type of assessment from a scientific review.

Five overarching questions, along with more detailed lists of user needs developed through discussions with stakeholders or provided by governments through international conventions, guided the issues that were assessed:

- What are the current condition and trends of ecosystems, ecosystem services, and human well-being?
- What are plausible future changes in ecosystems and their ecosystem services and the consequent changes in human well-being?
- What can be done to enhance well-being and conserve ecosystems? What are the strengths and weaknesses of response options that can be considered to realize or avoid specific futures?
- What are the key uncertainties that hinder effective decision-making concerning ecosystems?
- What tools and methodologies developed and used in the MA can strengthen capacity to assess ecosystems, the services they provide, their impacts on human well-being, and the strengths and weaknesses of response options?

The MA was conducted as a multiscale assessment, with interlinked assessments undertaken at local, watershed, national, regional, and global scales. A global ecosystem assessment cannot easily meet all the needs of decision-makers at national and sub-national scales because the management of any



Eighteen assessments were approved as components of the MA. Any institution or country was able to undertake an assessment as part of the MA if it agreed to use the MA conceptual framework, to centrally involve the intended users as stakeholders and partners, and to meet a set of procedural requirements related to peer review, metadata, transparency, and intellectual property rights. The MA assessments were largely self-funded, although planning grants and some core grants were provided to support some assessments. The MA also drew on information from 16 other sub-global assessments affiliated with the MA that met a subset of these criteria or were at earlier stages in development.

particular ecosystem must be tailored to the particular characteristics of that ecosystem and to the demands placed on it. However, an assessment focused only on a particular ecosystem or particular nation is insufficient because some processes are global and because local goods, services, matter, and energy are often transferred across regions. Each of the component assessments was guided by the MA conceptual framework and benefited from the presence of assessments undertaken at larger and smaller scales. The sub-global assessments were not intended to serve as representative samples of all ecosystems; rather, they were to meet the needs of decision-makers at the scales at which they were undertaken. The sub-global assessments involved in the MA process are shown in the Figure and the ecosystems and ecosystem services examined in these assessments are shown in the Table.

The work of the MA was conducted through four working groups, each of which prepared a report of its findings. At the global scale, the Condition and Trends Working Group assessed the state of knowledge on ecosystems, drivers of ecosystem change, ecosystem services, and associated human well-being around the year 2000. The assessment aimed to be comprehensive with regard to ecosystem services, but its coverage is not exhaustive. The Scenarios Working Group considered the possible evolution of ecosystem services during the twenty-first century by developing four global scenarios exploring plausible future changes in drivers, ecosystems, ecosystem services, and human well-being. The Responses Working Group examined the strengths and weaknesses of various response options that have been used to manage ecosystem services and identified promising opportunities for improving human well-being while conserving ecosystems. The report of the Sub-global Assessments Working Group contains lessons learned from the MA sub-global assessments. The first product of the MA—*Ecosystems and Human Well-being: A Framework for Assessment,* published in 2003—outlined the focus, conceptual basis, and methods used in the MA. The executive summary of this publication appears as Chapter 1 of this volume.

Approximately 1,360 experts from 95 countries were involved as authors of the assessment reports, as participants in the sub-global assessments, or as members of the Board of Review Editors. The latter group, which involved 80 experts, oversaw the scientific review of the MA reports by governments and experts and ensured that all review comments were appropriately addressed by the authors. All MA findings underwent two rounds of expert and governmental review. Review comments were received from approximately 850 individuals (of which roughly 250 were submitted by authors of other chapters in the MA), although in a number of cases (particularly in the case of governments and MA-affiliated scientific organizations), people submitted collated comments that had been prepared by a number of reviewers in their governments or institutions.

The MA was guided by a Board that included representatives of five international conventions, five U.N. agencies, international scientific organizations, governments, and leaders from the private sector, nongovernmental organizations, and indigenous groups. A 15-member Assessment Panel of leading social and natural scientists oversaw the technical work of the assessment, supported by a secretariat with offices in Europe, North America, South America, Asia, and Africa and coordinated by the United Nations Environment Programme.

The MA is intended to be used:

- to identify priorities for action;
- as a benchmark for future assessments;
- as a framework and source of tools for assessment, planning, and management;
- to gain foresight concerning the consequences of decisions affecting ecosystems;
- to identify response options to achieve human development and sustainability goals;
- to help build individual and institutional capacity to undertake integrated ecosystem assessments and act on the findings; and
- to guide future research.

Because of the broad scope of the MA and the complexity of the interactions between social and natural systems, it proved to be difficult to provide definitive information for some of the issues addressed in the MA. Relatively few ecosystem services have been the focus of research and monitoring and, as a consequence, research findings and data are often inadequate for a detailed global assessment. Moreover, the data and information that are available are generally related to either the characteristics of the ecological system or the characteristics of the social system, not to the all-important interactions between these systems. Finally, the scientific and assessment tools and models available to undertake a cross-scale integrated assessment and to project future changes in ecosystem services are only now being developed. Despite these challenges, the MA was able to provide considerable information relevant to most of the focal questions. And by identifying gaps in data and information that prevent policy-relevant questions from being answered, the assessment can help to guide research and monitoring that may allow those questions to be answered in future assessments.

Contents

Foreword

The Millennium Ecosystem Assessment was called for by United Nations Secretary-General Kofi Annan in 2000 in his report to the UN General Assembly, *We the Peoples: The Role of the United Nations in the 21st Century.* Governments subsequently supported the establishment of the assessment through decisions taken by three international conventions, and the MA was initiated in 2001. The MA was conducted under the auspices of the United Nations, with the secretariat coordinated by the United Nations Environment Programme, and it was governed by a multistakeholder board that included representatives of international institutions, governments, business, NGOs, and indigenous peoples. The objective of the MA was to assess the consequences of ecosystem change for human well-being and to establish the scientific basis for actions needed to enhance the conservation and sustainable use of ecosystems and their contributions to human well-being.

This volume has been produced by the MA Condition and Trends Working Group and assesses the state of knowledge on ecosystems and their services, the drivers of ecosystem change, and the consequences of ecosystem change for human well-being. The material in this report has undergone two extensive rounds of peer review by experts and governments, overseen by an independent Board of Review Editors.

This is one of four volumes (*Current State and Trends, Scenarios, Policy Responses,* and *Multiscale Assessments*) that present the technical findings of the Assessment. Six synthesis reports have also been published: one for a general audience and others focused on issues of biodiversity, wetlands and water, desertification, health, and business and ecosystems. These synthesis reports were prepared for decision-makers in these different sectors, and they synthesize and integrate findings from across all of the Working Groups for ease of use by those audiences.

This report and the other three technical volumes provide a unique foundation of knowledge concerning human dependence on ecosystems as we enter the twenty-first century. Never before has such a holistic assessment been conducted that addresses multiple environmental changes, multiple drivers, and multiple linkages to human well-being. Collectively, these reports reveal both the extraordinary success that humanity has achieved in shaping ecosystems to meet the needs of growing populations and economies and the growing costs associated with many of these changes. They show us that these costs could grow substantially in the future, but also that there are actions within reach that could dramatically enhance both human well-being and the conservation of ecosystems.

A more exhaustive set of acknowledgments appears later in this volume but we want to express our gratitude to the members of the MA Board, Board Alternates, Exploratory Steering Committee, Assessment Panel, Coordinating Lead Authors, Lead Authors, Contributing Authors, Board of Review Editors, and Expert Reviewers for their extraordinary contributions to this process. (The list of reviewers is available at www.MAweb.org.) We also would like to thank the MA Secretariat and in particular the staff of the Condition and Trends Working Group Technical Support Unit for their dedication in coordinating the production of this volume, as well as the World Conservation Monitoring Centre, which housed this TSU.

We would particularly like to thank the Co-chairs of the Condition and Trends Working Group, Dr. Rashid Hassan and Dr. Robert Scholes, and the TSU Coordinator, Neville Ash, for their skillful leadership of this Working Group and their contributions to the overall assessment.

Preface

The *Current State and Trends* assessment presents the findings of the Condition and Trends Working Group of the Millennium Ecosystem Assessment. This volume documents the current condition and recent trends of the world's ecosystems, the services they provide, and associated human well-being around the year 2000. Its primary goal is to provide decision-makers, ecosystem managers, and other potential users with objective information and analyses of historical trends and dynamics of the interaction between ecosystem change and human well-being. This assessment establishes a baseline for the current condition of ecosystems at the turn of the millennium. It also assesses how changes in ecosystems have affected the underlying capacity of ecosystems to continue to provide these services in the near future, providing a link to the Scenarios Working Group's report. Finally, it considers recent trends in ecosystem conditions that have been the result of historical responses to ecosystem service problems, providing a link to the Responses Working Group's report.

Although centered on the year 2000, the temporal scope of this assessment includes the ''relevant past'' to the ''foreseeable future.'' In practice, this means analyzing trends during the latter decades of the twentieth century and extrapolating them forward for a decade or two into the twenty-first century. At the point where the projections become too uncertain to be sustained, the Scenarios Working Group takes over the exploration of alternate futures.

The Condition and Trends assessment aims to synthesize and add to information already available from other sources, whether in the primary scientific literature or already in assessment form. In many instances this information is not reproduced in this volume but is built upon to report additional findings here. So this volume does not, for example, provide an assessment of the science of climate change per se, as that is reported in the findings of the Intergovernmental Panel on Climate Change, but the findings of the IPCC are used here as a basis to present information on the consequences of climate change for ecosystem services.

A summary of the process leading to this document is provided in Figure A.

The document has three main parts plus a synthesis chapter and supporting material. (See Figure B.) After the introductory material in Part I, the findings from the technical assessments are presented in two orthogonal ways: Part II deals with individual categories of ecosystem services, viewed across all the ecosystem types from which they are derived, while Part III analyses the various systems from which bundles of services are derived. Such organization allows the chapters to be read as standalone documents and assists readers with thematic interests. In Part IV, the synthesis chapter pulls out the key threads of findings from the earlier parts to construct an integrated narrative of the key issues relating ecosystem change (through changes in ecosystem services) to impacts on human well-being.

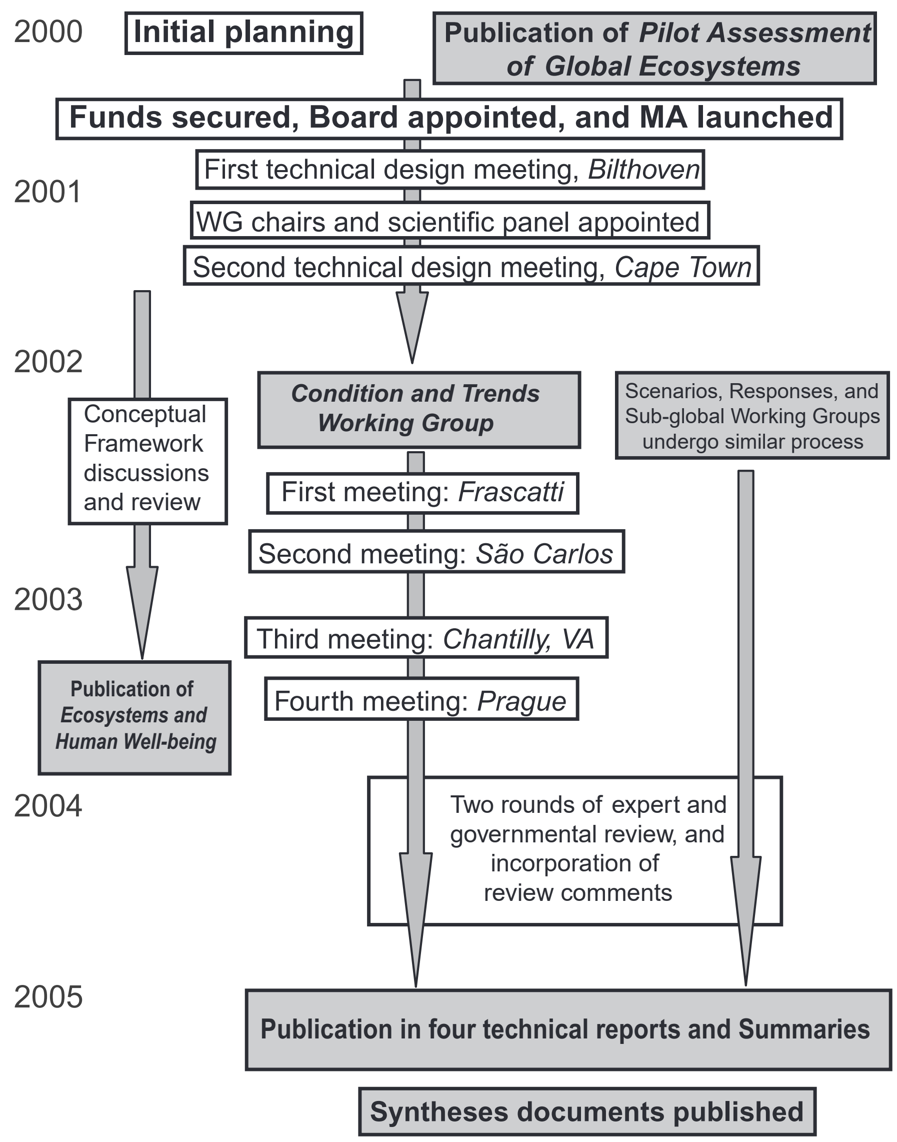

Figure A. Schedule of the Condition and Trends Working Group Assessment

Appendices provide an extensive glossary of terms, abbreviations, and acronyms; information on authors; and color graphics.

Part I: General Concepts and Analytical Approaches

The first part of this report introduces the overarching conceptual, methodological, and crosscutting themes of the MA integrated approach, and for this reason it precedes the technical assessment parts. Following the executive summary of the MA conceptual framework volume (*Ecosystems and Human Well-being: A Framework for Assessment*), which is **Chapter 1,** the analytical approaches to a global assessment of ecosystems and ecosystem services are outlined in **Chapter 2. Chapter 3** provides a summary assessment of the most important changes in key indirect and direct drivers of ecosystem change over the last part of the

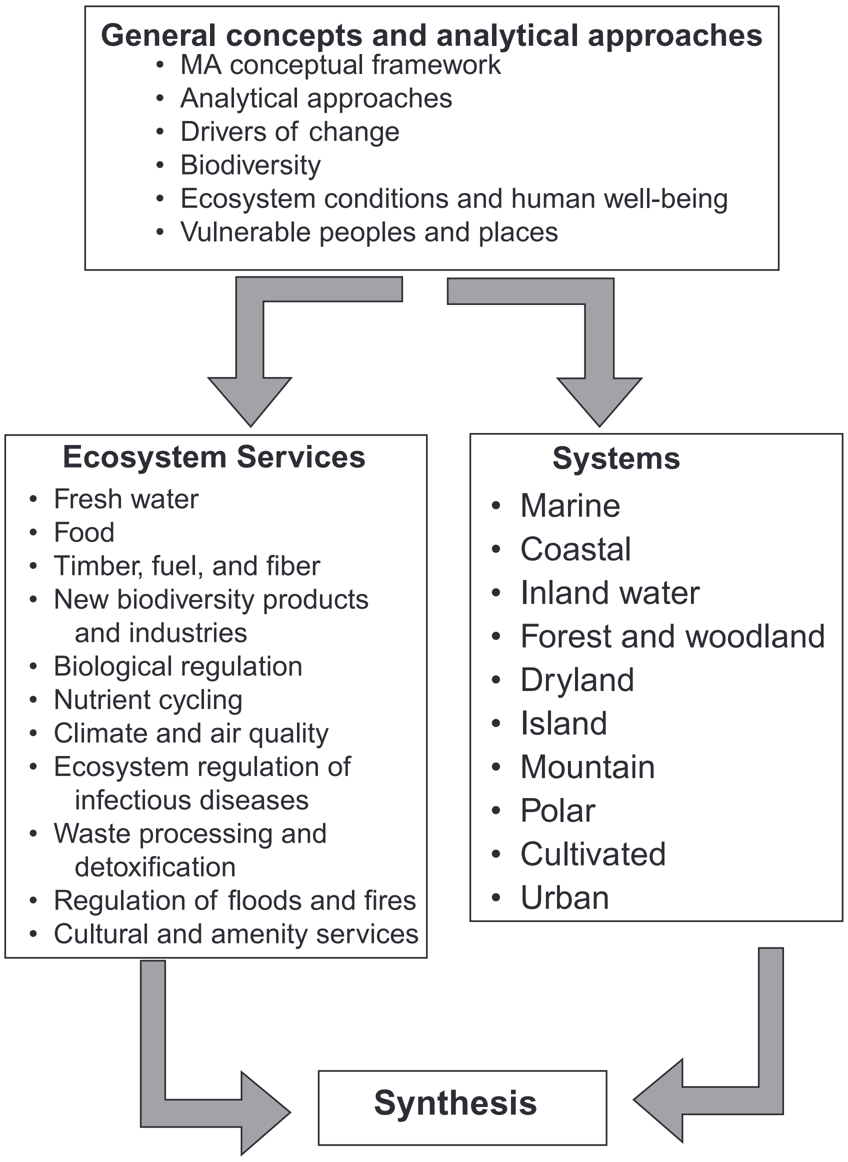

Figure B. Structure of the Condition and Trends Working Group Assessment Report

twentieth century, and considers some of the key interactions between these drivers (the full assessment of drivers, of which this chapter is a summary, can be found in the *Scenarios* volume, Chapter 7). The remaining chapters in Part I—on biodiversity (**Chapter 4**), human well-being (**Chapter 5**), and vulnerability (**Chapter 6**)—introduce issues at a global scale but also contain a synthesis of material drawn from chapters in Parts II and III.

Each of these introductory overarching chapters aims to deal with the general issues related to its topic, leaving the specifics embedded in later chapters. This is intended to enhance readability and to help reduce redundancy across the volume. For example, **Chapter 2** seeks to give an overview of the types of analytical approaches and methods used in the assessment, but not provide a recipe for conducting specific assessments, and **Chapter 3** aims to provide the background to the various drivers that would otherwise need to be discussed in multiple subsequent chapters.

Biodiversity provides composition, structure, and function to ecosystems. The amount and diversity of life is an underlying necessity for the provision of all ecosystem services, and for this reason **Chapter 4** is included in the introductory section rather than as a chapter in the part on ecosystem services. It outlines the key global trends in biodiversity, our state of knowledge on biodiversity in terms of abundance and distribution, and the role of biodiversity in the functioning of ecosystems. Later chapters consider more fully the role of biodiversity in the provision of ecosystem services.

The consequences of ecosystem change for human well-being are the core subject of the MA. **Chapter 5** presents our state of knowledge on the links between ecosystems and human well-being and outlines the broad patterns in well-being around the world.

Neither the distribution of ecosystem services nor the change in these services is evenly distributed across places and societies. Certain ecosystems, locations, and people are more at risk from changes in the supply of services than others. **Chapter 6,** on vulnerable peoples and places, identifies these locations and groups and examines why they are particularly vulnerable to changes in ecosystems and ecosystem services.

Part II: An Assessment of Ecosystem Services

The Condition and Trends assessment sets out to be comprehensive in its treatment of ecosystem services but not exhaustive. The list of ''benefits that people derive from ecosystems'' grows continuously with further investigation. The 11 groups of services covered by this assessment deal with issues that are of vital importance almost everywhere in the world and represent, in the opinion of the Working Group, the main services that are most important for human well-being and are most affected by changes in ecosystem conditions. The MA only considers ecosystem services that have a nexus with life on Earth (biodiversity). For example, while gemstones and tidal energy can both provide benefits to people, and both are found within ecosystems, they are not addressed in this report since their generation does not depend on the presence of living organisms. The ecosystem services assessed and the chapter titles in this part are:

Provisioning services:
- Fresh Water
- Food
- Timber, Fiber, and Fuel
- New Products and Industries from Biodiversity

Regulating and supporting services:
- Biological Regulation of Ecosystem Services
- Nutrient Cycling
- Climate and Air Quality
- Human Health: Ecosystem Regulation of Infectious Diseases
- Waste Processing and Detoxification
- Regulation of Natural Hazards: Floods and Fires

Cultural services:
- Cultural and Amenity Services

Each of the chapters in this section in fact deals with a cluster of several related ecosystem services. For instance, the chapter on food covers the provision of numerous cereal crops, vegetables and fruits, beverages, livestock, fish, and other edible products; the chapter on nutrient cycling addresses the benefits derived from a range of nutrient cycles, but with a focus on nitrogen; and the chapter on cultural and amenity services covers a range of such services, including recreation, aesthetic, and spiritual services. The length of the treatment afforded to each service reflects several factors: our assessment of its relative importance to human well-being; the scope and complexity of the topic; the degree to which it has been treated in other assessments (thus reducing the need for a comprehensive treatment here); and the amount of information that is available to be assessed.

Part II considers services from each of the four MA categories: provisioning, regulating, cultural, and supporting services. Each service chapter has been developed to cover the same types of information. First the service is defined. Then, for each service, the spatial distribution of supply and demand is quantified, along with recent trends. The direct and indirect drivers of change in the service are analyzed. And finally the consequences of the changes in the service for human well-being are examined and quantified to the degree possible.

Examples are given of the responses by decision-makers at various levels (from the individual to the international) to issues relating to change in service supply. Both successful and unsuccessful interventions are described, as supportive material for the *Policy Responses* volume.

Part III: An Assessment of Systems from which Ecosystem Services Are Derived

The Condition and Trends Working Group uses the term ''systems'' in describing these chapters rather than the term ''ecosystems.'' This is for several reasons. First, the ''systems'' used are essentially reporting units, defined for pragmatic reasons. They represent easily recognizable broad categories of landscape or seascape, with their included human systems, and typically represent units or themes of management or intervention interest. Ecosystems, on the other hand, are theoretically defined by the interactions of their components.

The 10 selected systems assessed here cover much larger areas than most ecosystems in the strict sense and include areas of system type that are far apart (even isolated) and that thus interact only weakly. In fact, there may be stronger local interactions with embedded fragments of ecosystems of a different type rather than within the nominal type of the system. The ''cultivated system,'' for instance, considers a landscape where crop farming is a primary activity but that probably includes, as an integral part of that system, patches of rangeland, forest, water, and human settlements.

Second, while it is recognized that humans are always part of ecosystems, the definitions of the systems used in this report take special note of the main patterns of human use. The systems are defined around the main bundles of services they typically supply and the nature of the impacts that human use has on those services.

Information within the systems chapters is frequently presented by subsystems where appropriate. For example, the forest chapter deals separately with tropical, temperate, and boreal forests because they deliver different services; likewise, the coastal chapter deals explicitly with various coastal subsystems, such as mangroves, corals, and seagrasses.

The 10 system categories and the chapter titles in this part are:

- Marine Fisheries Systems
- Coastal Systems
- Inland Water Systems
- Forest and Woodland Systems
- Dryland Systems
- Island Systems
- Mountain Systems
- Polar Systems
- Cultivated Systems
- Urban Systems

Definitions for these system categories can be found in Box 1.3 in Chapter 1. These system categories are not mutually exclusive, and some overlap spatially. For instance, mountain systems contain areas of forest systems, dryland systems, inland water systems, cultivated systems, and urban systems, while coastal systems include components of all of the above, including mountain systems. Due to this overlap, simple summations of services across systems for global totals should be avoided (an exercise that the MA has avoided in general): some may be double-counted, while others may be underrepresented. Notwithstanding these caveats, the systems have been defined to cover most of the Earth's surface and not to overlap unnecessarily. In many instances the boundaries between systems are diffuse, but not arbitrary. For instance, the coastal system blends seamlessly into the marine system on the one hand and the land systems on the other. The 50-meter depth distinction between coastal and marine separates the systems strongly influenced by actions on the land from those overwhelmingly influenced by fishing. There is significant variation in the area of coverage of each system.

The system definitions are also not exhaustive, and no attempt has been made to cover every part of the global surface. Although ~99% of global surface area has been covered in this assessment, there are just over 5 million square kilometers of terrestrial land surface not included spatially within any of the MA system boundaries. These areas are generally found within grassland, savanna, and forest biomes, and they contain a mix of land cover classes—generally grasslands, degraded forests, and marginal agricultural lands—that are not picked up within the mapping definitions for the system boundaries. However, while these excluded areas may not appear in the various statistics produced along system boundaries, the issues occurring in these areas relating to ecosystem services are well covered in the various services chapters, which do not exclude areas of provision outside MA system boundaries.

The main motivation for dealing with ''systems'' as well as ''services'' is that the former perspective allows us to examine interactions between the services delivered from a single location. These interactions can take the form of trade-offs (that is, where promoting one service reduces the supply of another service), win-win situations (where a single management package enhances the supply of several services), or synergies, where the simultaneous use of services raises or depresses both more than if they were independently used.

The chapters in Part III all present information in a broadly similar manner: system description, including a map and descriptive statistics for the system and its subsystems; quantification of the services it delivers and their contribution to well-being; recent trends in the condition of the system and its capacity to provide services; processes leading to changes in the system; the choices and resultant trade-offs between systems and between services within the system; and the contributions of the system to human well-being.

Part IV: Synthesis

Chapter 28 does not intend to be a summary. That task is left to the summaries or Main Messages of each chapter and to the Summary at the start of this volume. Instead, the synthesis chapter constructs an integrated narrative, tracing the principal causes of ecosystem change, the consequences for ecosystems and ecosystem services, and the resultant main impacts on human well-being. The chapter considers the key intellectual issues arising from the Condition and Trends assessment and presents an assessment of our underlying knowledge on the consequences of ecosystem change for people.

Supporting material for many of the chapters, and further details of the Millennium Ecosystem Assessment, including of the various sub-global assessments, plus a full list of reviewers, can be found at the MA Web site at www.MAweb.org.

Acknowledgments

First and foremost, we would like to thank the MA Condition and Trends Working Group for their hard work, and for all the stimulating discussions we had over the course of the project. Special thanks are also due to the MA Secretariat staff who worked tirelessly on this project:

Walter V. Reid—Director

Administration
Nicole Khi—Program Coordinator
Chan Wai Leng—Program Coordinator
Belinda Lim—Administrative Officer
Tasha Merican—Program Coordinator

Sub-Global
Marcus J. Lee—Technical Support Unit Coordinator and MA Deputy Director
Ciara Raudsepp-Hearne—TSU Coordinator

Condition and Trends
Neville J. Ash—TSU Coordinator
Dalène du Plessis—Program Assistant
Mampiti Matete—TSU Coordinator

Scenarios
Elena Bennett—TSU Coordinator
Veronique Plocq-Fichelet—Program Administrator
Monika B. Zurek—TSU Coordinator

Responses
Pushpam Kumar—TSU Coordinator
Meenakshi Rathore—Program Coordinator
Henk Simons—TSU Coordinator

Engagement and Outreach
Christine Jalleh—Communications Officer

Jillian Thonell—Data Coordinator

Interns
Emily Cooper, Elizabeth Wilson, Lina Cimarrusti

We would like to acknowledge the contributions of all of the authors of this book, and the support provided by their institutions that enabled their participation. We would like to thank the host organizations of the MA Technical Support Units—WorldFish Center (Malaysia); UNEP-World Conservation Monitoring Centre (United Kingdom); Institute of Economic Growth (India); National Institute of Public Health and the Environment (Netherlands); University of Pretoria (South Africa), U.N. Food and Agriculture Organization; World Resources Institute, Meridian Institute, and Center for Limnology of the University of Wisconsin-Madison (all in the United States); Scientific Committee on Problems of the Environment (France); and International Maize and Wheat Improvement Center (Mexico)—for the support they provided to the process.

We thank several individuals who played particularly critical roles: Linda Starke, Nigel Varty, and Lynn Newton for editing the report; Hyacinth Billings and Caroline Taylor for providing invaluable advice on the publication process; Maggie Powell for preparing the page design and all the Figures and Tables; Elizabeth Wilson for helping to proof the Figures and Tables; Carol Inskipp and Gill Bunting for checking chapter citations and references; and Ian May, Corinna Ravilious, and Simon Blythe for the preparation of numerous graphics and GIS-derived statistics. And we thank the other MA volunteers, the administrative staff of the host organizations, and colleagues in other organizations who were instrumental in facilitating the process: Mariana Sanchez Abregu, Isabelle Alegre, Adlai Amor, Emmanuelle Bournay, Herbert Caudill, Habiba Gitay, Helen Gray, Sherry Heileman, Norbert Henninger, Toshi Honda, Francisco Ingouville, Timothy Johnson, Humphrey Kagunda, Brygida Kubiak, Nicolas Lapham, Liz Levitt, Elaine Marshall, Christian Marx, Stephanie Moore, John Mukoza, Arivudai Nambi, Laurie Neville, Adrian Newton, Carolina Katz Reid, Liana Reilly, Philippe Rekacewicz, Carol Rosen, Anne Schram, Jeanne Sedgwick, Tang Siang Nee, Darrell Taylor, Tutti Tischler, Dan Tunstall, Woody Turner, Mark Valentine, Gillian Warltier, Elsie Vélez Whited, Kaveh Zahedi, and Mark Zimsky.

For technical assistance with figures and references in Chapter 13, we thank Natalia Ungelenk and Silvana Schott, and for their work in developing, applying, and constructing tables from the Gridded Rural-Urban Mapping Project, which was used not only in Chapter 27 but in several others as well, we would like to thank Francesca Pozzi, Greg Booma, Adam Storeygard, Bridget Anderson, Greg Yetman, and Lisa Lukang. Kai Lee, Terry McGee, and Priscilla Connolly deserve special mention for their review of Chapter 27, as does Maria Furhacker for her review of Chapter 15.

We thank the members of the MA Board and its chairs, Robert Watson and A.H. Zakri, the members of the MA Assessment Panel and its chairs, Angela Cropper and Harold Mooney, and the members of the MA Review Board and its chairs, José Sarukhán and Anne Whyte, for their guidance and support for this Working Group. We also thank the current and previous Board Alternates: Ivar Baste, Jeroen Bordewijk, David Cooper, Carlos Corvalan, Nick Davidson, Lyle Glowka, Guo Risheng, Ju Hongbo, Ju Jin, Kagumaho (Bob) Kakuyo, Melinda Kimble, Kanta Kumari, Stephen Lonergan, Charles Ian McNeill, Joseph Kalemani Mulongoy, Ndegwa Ndiang'ui, and Mohamed Maged Younes. We thank the past members of the MA Board whose contributions were instrumental in shaping the MA focus and process, including Philbert Brown, Gisbert Glaser, He Changchui, Richard Helmer, Yolanda Kakabadse, Yoriko Kawaguchi, Ann Kern, Roberto Lenton, Corinne Lepage, Hubert Markl, Arnulf Müller-Helbrecht, Seema Paul, Susan Pineda Mercado, Jan Plesnik, Peter Raven, Cristián Samper, Ola Smith, Dennis Tirpak, Alvaro Umaña, and Meryl Williams. We wish to also thank the members of the Exploratory Steering Committee that designed the MA project in 1999–2000. This group included a number of the current and past Board members, as well as Edward Ayensu, Daniel Claasen, Mark Collins, Andrew Dearing, Louise Fresco, Madhav Gadgil, Habiba Gitay, Zuzana Guziova, Calestous Juma, John Krebs, Jane Lubchenco, Jeffrey McNeely, Ndegwa Ndiang'ui, Janos Pasztor, Prabhu L. Pingali, Per Pinstrup-Andersen, and José Sarukhán. We thank Ian Noble and Mingsarn Kaosa-ard for their contributions as members of the Assessment Panel during 2002.

We would particularly like to acknowledge the input of the hundreds of individuals, institutions, and governments (see list at www.MAweb.org) who reviewed drafts of the MA technical and synthesis reports. We also thank the thousands of researchers whose work is synthesized in this report. And we would like to acknowledge the support and guidance provided by the secretariats and the scientific and technical bodies of the Convention on Biological Diversity, the Ramsar Convention on Wetlands, the Convention to Combat Desertification, and the Convention on Migratory Species, which have helped to define the focus of the MA and of this report.

We also want to acknowledge the support of a large number of nongovernmental organizations and networks around the world that have assisted in outreach efforts: Alexandria University, Argentine Business Council for Sustainable Development, Asociación Ixacavaa (Costa Rica), Arab Media Forum for Environment and Development, Brazilian Business Council on Sustainable Development, Charles University (Czech Republic), Cambridge Conservation Forum, Chinese Academy of Sciences, European Environmental Agency, European Union of Science Journalists' Associations, EIS-Africa (Burkina Faso), Forest Institute of the State of São Paulo, Foro Ecológico (Peru), Fridtjof Nansen Institute (Norway), Fundación Natura (Ecuador), Global Development Learning Network, Indonesian Biodiversity Foundation, Institute for Biodiversity Conservation and Research–Academy of Sciences of Bolivia, International Alliance of Indigenous Peoples of the Tropical Forests, IUCN office in Uzbekistan, IUCN Regional Offices for West Africa and South America, Permanent Inter-States Committee for Drought Control in the Sahel, Peruvian Society of Environmental Law, Probioandes (Peru), Professional Council of Environmental Analysts of Argentina, Regional Center AGRHYMET (Niger), Regional Environmental Centre for Central Asia, Resources and Research for Sustainable Development (Chile), Royal Society (United Kingdom), Stockholm University, Suez Canal University, Terra Nuova (Nicaragua), The Nature Conservancy (United States), United Nations University, University of Chile, University of the Philippines, World Assembly of Youth, World Business Council for Sustainable Development, WWF-Brazil, WWF-Italy, and WWF-US.

We are extremely grateful to the donors that provided major financial support for the MA and the MA Sub-global Assessments: Global Environment Facility; United Nations Foundation; David and Lucile Packard Foundation; World Bank; Consultative Group on International Agricultural Research; United Nations Environment Programme; Government of China; Ministry of Foreign Affairs of the Government of Norway; Kingdom of Saudi Arabia; and the Swedish International Biodiversity Programme. We also thank other organizations that provided financial support: Asia Pacific Network for Global Change Research; Association of Caribbean States; British High Commission, Trinidad & Tobago; Caixa Geral de Depósitos, Portugal; Canadian International Development Agency; Christensen Fund; Cropper Foundation, Environmental Management Authority of Trinidad and Tobago; Ford Foundation; Government of India; International Council for Science; International Development Research Centre; Island Resources Foundation; Japan Ministry of Environment; Laguna Lake Development Authority; Philippine Department of Environment and Natural Resources; Rockefeller Foundation; U.N. Educational, Scientific and Cultural Organization; UNEP Division of Early Warning and Assessment; United Kingdom Department for Environment, Food and Rural Affairs; United States National Aeronautic and Space Administration; and Universidade de Coimbra, Portugal. Generous in-kind support has been provided by many other institutions (a full list is available at www.MAweb.org). The work to establish and design the MA was supported by grants from The Avina Group, The David and Lucile Packard Foundation, Global Environment Facility, Directorate for Nature Management of Norway, Swedish International Development Cooperation Authority, Summit Foundation, UNDP, UNEP, United Nations Foundation, United States Agency for International Development, Wallace Global Fund, and World Bank.

Reader's Guide

The four technical reports present the findings of each of the MA Working Groups: Condition and Trends, Scenarios, Responses, and Sub-global Assessments. A separate volume, *Our Human Planet*, presents the summaries of all four reports in order to offer a concise account of the technical reports for decision-makers. In addition, six synthesis reports were prepared for ease of use by specific audiences: Synthesis (general audience), CBD (biodiversity), UNCCD (desertification), Ramsar Convention (wetlands), business and industry, and the health sector. Each MA sub-global assessment will also produce additional reports to meet the needs of its own audiences.

All printed materials of the assessment, along with core data and a list of reviewers, are available at www.MAweb.org. In this volume, Appendix A contains color maps and figures. Appendix B lists all the authors who contributed to this volume. Appendix C lists the acronyms and abbreviations used in this report and Appendix D is a glossary of terminology used in the technical reports. Throughout this report, dollar signs indicate U.S. dollars and ton means tonne (metric ton). Bracketed references within the Summary are to chapters within this volume.

In this report, the following words have been used where appropriate to indicate judgmental estimates of certainty, based on the collective judgment of the authors, using the observational evidence, modeling results, and theory that they have examined: very certain (98% or greater probability), high certainty (85–98% probability), medium certainty (65%–58% probability), low certainty (52–65% probability), and very uncertain (50–52% probability). In other instances, a qualitative scale to gauge the level of scientific understanding is used: well established, established but incomplete, competing explanations, and speculative. Each time these terms are used they appear in italics.

Main Messages

Biodiversity—the diversity of genes, populations, species, communities, and ecosystems—underlies all ecosystem processes. Ecological processes interacting with the atmosphere, geosphere, and hydrosphere determine the environment on which organisms, including people, depend. Direct benefits such as food crops, clean water, clean air, and aesthetic pleasures all depend on biodiversity, as does the persistence, stability, and productivity of natural systems.

For many ecosystem services, local population extinctions are more significant than global extinctions—human communities depend for their well-being on populations of species that are accessible to them. The most appropriate measures and indicators of biodiversity depend on the value or service being assessed and involve a consideration of the components of biodiversity that are involved (from genes, individuals, populations, species, and communities to ecosystems) and the service that is being delivered.

Knowledge of biodiversity is uneven, with strong biases toward the species level, large animals, temperate systems, and components of biodiversity used by people. This results in gaps in knowledge, especially regarding the status of tropical systems, marine and freshwater biota, plants, invertebrates, microorganisms, and subterranean biota.

Most estimates of the total number of species on Earth lie between 5 million and 30 million. Of this total, roughly 2 million species have been formally described; the remainder are unknown or unnamed. The overall total could be higher than 30 million if poorly known groups such as deep-sea organisms, fungi, and microorganisms including parasites have more species than currently estimated.

Most macroscopic organisms have small, often clustered, geographical ranges, leading to diagnosable centers of both diversity and endemism, which are frequently concentrated in isolated or topographically variable regions (islands, mountains, peninsulas). A large proportion of the world's terrestrial biodiversity at the species level is concentrated in a small area of the world, mostly in the tropics. The Neotropics and Afrotropics have the highest species richness. Endemism is also high in these regions and, as a consequence of its isolation, in Australasia. Even among the larger and more mobile species such as the terrestrial vertebrates, more than one third of all species have ranges less than 1,000 square kilometers. In contrast, local and regional diversity of microorganisms appears to be more similar to large-scale and global diversity, indicating greater dispersal, larger range sizes, and lower levels of regional species clustering.

Across a range of measures, tropical forests are outstanding in their levels of biodiversity at and above the species level. Regions of high species richness broadly correspond with centers of evolutionary diversity, and available evidence suggests that across major taxa, tropical moist forests are especially important for both overall variability and unique evolutionary history. Species richness, family richness, and species endemism are all highest for this biome, even after accounting for area and productivity.

Over the past few hundred years humans may have increased the species extinction rate by as much as three orders of magnitude. This estimate is uncertain because the extent of extinctions in undescribed taxa is unknown, because the status of many described species is poorly known, because it is difficult to document the final disappearance of very rare species, and because there are extinction lags between the impact of a threatening process and the resulting extinction. However, the most definite information, based on recorded extinctions of known species over the past 100 years, indicates extinction rates are around 100 times greater than rates characteristic of species in the fossil record. Other less direct estimates, some of which refer to extinctions hundreds of years into the future, estimate extinction rates 1,000 to 10,000 times higher than rates recorded among fossil lineages.

Between 12% and 52% of species within well-studied higher taxa are threatened with extinction, according to the *IUCN Red List.* Less than 10% of named species have been assessed in terms of their conservation status. Of those that have, birds have the lowest percentage of threatened species at 12%. The patterns of threat are broadly similar for mammals and conifers, which have 23% and 25% of species threatened, respectively. The situation with amphibians looks similar, with 32% threatened, but information is more limited. so this may be an underestimate. Cycads have a much higher proportion of threatened species, with 52% globally threatened. In regional assessments, taxonomic groups with the highest proportion of threatened species tended to be those that rely on freshwater habitats. Threatened species show continuing declines in conservation status, and species threat rates tend to be highest in the realms with highest species richness.

The main causes of species extinction are changing from a historical trend of introductions and overexploitation affecting island species to present-day habitat loss and degradation affecting continental species. While the vast majority of recorded extinctions since 1500 have occurred on oceanic islands, continental extinctions are now as common as island extinctions. Approximately 50% of extinctions over the past 20 years occurred on continents. This trend is consistent with the observation that most terrestrial species threatened with extinction are continental. Despite the growing importance of habitat loss and degradation, species introductions and overexploitation also remain significant threats to biodiversity on continents and islands.

Climate change, which contributes to habitat change, is becoming the dominant driver, particularly in vulnerable habitats. Under climate change, endemic montane, island, and peninsula species are especially vulnerable, and coastal habitats such as mangroves, coral reefs, and coastal wetlands are especially at risk from resulting sea level rises. Both recent empirical evidence and predictive modeling studies suggest that climate change will increase population losses. In some regions there may be an increase in local biodiversity—usually as a result of species introductions, the long-term consequences of which are hard to foresee.

Among a range of higher taxa, the majority of species are currently in decline. Studies of amphibians globally, African mammals, birds in intensively managed agricultural lands, British butterflies, Caribbean corals, waterbirds, and fishery species show the majority of species to be declining in range or number. Those species that are increasing have benefited from management interventions such as protection in reserves or elimination of threats such as overexploitation or are species that tend to thrive in human-dominated landscapes.

The majority of biomes have been greatly modified by humans. Between 20% and 50% of 9 of the 14 biomes have been transformed to croplands. Tropical dry forests are the most reduced by cultivation, with almost half of the biome's native habitats replaced with cultivated lands. Three other biomes—temperate grasslands, temperate broadleaf forests, and Mediterranean forests—have experienced 35% or more conversion. Biomes least reduced by cultivation include deserts, boreal forests, and tundra. While cultivated lands provide many provisioning services, such as grains, fruits, and meat, habitat conversion to agriculture typically leads to reductions in native biodiversity.

Homogenization, the process whereby species assemblages become increasingly dominated by a small number of widespread, human-adapted

species, represents further losses in biodiversity that are often missed when only considering changes in absolute numbers of species. The many species that are declining as a result of human activities tend to be replaced by a much smaller number of expanding species that thrive in human-altered environments.

We lack comprehensive global-scale measures to assess whether the internationally agreed target of significantly reducing the rate of loss of biodiversity by 2010 will be met. However, our understanding of the dynamics of drivers, and particularly of lag times from changes in drivers to eventual impacts on biodiversity, suggest it is most unlikely to be achievable. The 2010 target, as agreed at WSSD in 2002 and adopted by the parties to the Convention on Biological Diversity, is an important goal for biodiversity management. It is probably too late to reverse the near-term trends in biodiversity loss given the lag times in ecosystem responses. Until critical drivers are mitigated, most declines seem likely to continue at the same or increased rates, although there is evidence that biodiversity loss is slowing or even recovering for some habitats (such as temperate woodlands) and species (temperate birds, for example).

4.1 Introduction

Biodiversity is fundamental to ecosystem functioning. Extrinsic or abiotic factors, such as climate and geophysical conditions, help to determine the boundaries of ecosystems (Colwell and Lees 2000; Gaston 2000). But within these boundaries, intrinsic or biotic factors such as the abundance, distribution, dynamics, and functional variation among biodiversity components of ecosystems regulate the magnitude and variability of ecosystem processes, such as production or decomposition. (See Chapter 11.) Together, these extrinsic and intrinsic factors determine the specific properties of an ecosystem, such as its stability, its fertility, or its susceptibility to invasion. They also determine the type of ecosystem found, such as drylands, forest or woodland, or inland waters.

The benefits that humans derive from ecosystems are known as ecosystem services (see Chapter 1) and include breathable air, fertile soils, and productive forests and fisheries, as well as many cultural benefits such as recreational hunting or inspirational values. Such ecosystem services are obtained only if ecosystems include the biodiversity that guarantees the functional processes necessary to deliver them.

This chapter focuses on the fundamental aspects of biodiversity that underpin all ecosystem processes and that are valued in their own right. Biodiversity relevant to particular services is documented in the Chapters 7 to 17 of this volume, while biodiversity as one element in the management of particular ecosystems for the delivery of services is discussed in Chapters 18 to 27. This chapter describes what is known about biodiversity globally, the nature of biodiversity variation and its measurement, the main drivers of change, and the observed trends in distribution, variation, and abundance of biodiversity.

4.1.1 Biodiversity and Its Assessment

Biodiversity is the diversity among living organisms in terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are part. It includes diversity within and between species and the diversity of ecosystems. In addition to the important role of biodiversity in providing ecosystem services, it also has intrinsic value, independent of any human concern.

In addition to its intrinsic value, the roles of biodiversity in the provision of ecosystem services can be summarized under the following headings:

- *supporting roles* include the underpinning of ecosystems through structural, compositional, and functional diversity;
- *regulatory roles* through the influence of biodiversity on the production, stability, and resilience of ecosystems;
- *cultural roles* from the nonmaterial benefits people derive from the aesthetic, spiritual, and recreational elements of biodiversity; and
- *provisioning roles* from the direct and indirect supply of food, fresh water, fiber, and so on.

All these roles are strongly interrelated, and it is rarely possible to separate them in practice. Yet defining roles is an essential step in assessing biodiversity: any measures should be relevant to the role being examined and to the purpose of the assessment (The Royal Society 2003). For example, a biologist wishing to assess the changing status of biodiversity in a wetland before and after land use changes in the watershed might turn to the most widely available information—trends in bird population sizes. People interested in birds would regard this as important, but if the observer were concerned about overall species richness, the bird data could be insufficient or even misleading. Due to their unusual dispersal ability, birds might be relatively well buffered from the effects of habitat change. The consequences of the land use change on less vagile species, such as plants, invertebrates, or below-ground biota could be very different. Similarly, if the effect on ecosystem services were of most interest, then other species and measures other than population size will be more informative. If provisioning services were under examination, then the assessment would be better focused on the abundance and distribution of the ecosystem components essential for food or fiber production. Thus, given the complexity of biodiversity, the most readily available measures rarely reflect the real attribute of interest for any particular role (The Royal Society 2003).

Biodiversity is commonly measured at the levels of genes, species or ecosystems. At each of these, measures may represent one or many of the following:

- *Variety,* reflecting the number of different types. For example, this could refer to different species or genes, such as how many bird species live in a particular place or how many varieties of a genetic crop strain are in production.
- *Quantity and quality,* reflecting how much there is of any one type. Variation on its own will only rarely meet people's needs. For example, for many provisioning services (food, fresh water, fiber) the quantity or the quality matter more than the presence of a particular genetic variety, species, or ecosystem.
- *Distribution,* reflecting where that attribute of biodiversity is located. For example, having all the world's pollinators present but only in a single location will not meet the needs of the plants that depend on them. Many ecosystem services are location-specific. For instance, human and natural communities need to be close to wetlands to benefit from their regulatory roles.

In practice, the relevant measure and attribute depends on the role being assessed. For example, many benefits of biodiversity depend on the functional and structural variability in species, whereas most provisioning services and many regulatory services depend more on the quantity and distribution of populations and ecosystems. Long-term sustainability of many services depends on the maintenance of genetic variability. Ultimately, maintaining variability in any biodiversity component provides options for the future, even if not all variants have an obvious role to play. Thus, variability plays a special role, which probably explains why it is generally emphasized in discussions of biodiversity value.

Table 4.1 summarizes the importance of quantity versus variability among different biodiversity components in relation to ecosystem services. Broadly speaking, and according to our present level of understanding, variability is more significant at the genetic and species levels, whereas quantity and distribution are more significant at the population and ecosystem levels. For most ecosystem services, local loss of biodiversity (population reduction or local extinction) is most significant; but for future option values and for certain services such as genetic variability and bioprospecting, global loss is the primary consideration.

4.1.2 The Diversity and Evolution of Life

Living organisms were originally divided into two kingdoms: animal and vegetable (the Animalia and the Plantae), but more recently it has become clear that this simple division does not reflect the true diversity of life. The five Kingdom scheme that followed divided all living organisms into Monera (bacteria), Protista (single-celled organisms), Fungi, Plants, and Animals. In terms of either numerical diversity or phylogenetic diversity (measuring the degree of independent evolutionary history), however, it is now clear that this too misrepresents the diversity of life.

Most organisms are very small (microscopic), and DNA and RNA studies reveal that the living world is more appropriately divided into three groups: the Bacteria, the Archaea (a group once included with the bacteria but now shown to be as different from them as they both are from the rest), and the rest—the Eukaryotae. Bacteria and Archaea have no well-defined nucleus and are referred to as Prokaryotae (or prokaryotes). The Eukaryotae (or eukaryotes) have a well-defined nucleus and comprise the animals, plants, fungi, and protists. A fourth group of biological entities, the viruses, are not organisms in the same sense that eukaryotes, archaeans, and bacteria are, and so they are not included. However, they are of considerable biological importance.

Life arose on Earth 3.5–4.5 billion years ago, and for probably the first 1–2 billion years there were only prokaryotes. The first definitive fossils of eukaryotes are found about 2 billion years ago, but they started to proliferate quite rapidly and the multicellular eukaryotes appear about 1.5 billion years ago. The first animals appeared much later, around 700 million years ago for many soft-bodied marine invertebrates, such as the sponges, jellyfish, soft corals, and worms. By about 500 million years ago an abundant fossil record includes marine invertebrates with exoskeletons, vertebrates, and plants. All phyla existing today appear shortly after. Today's diverse assemblage of mammals, birds, and flowering plants appeared within the past 70 million years, but it is not until about 7 million years ago that humans in their most primitive form appeared, and not until 100,000–200,000 years ago that modern humans appeared.

Evolutionary biologists believe that all existing life is derived from a single, common ancestral form. The fact that millions of species live on Earth today is a consequence of processes leading to speciation. Speciation involves the splitting of a single species lineage. It occurs in three different ways: allopatric, parapatric, and sympatric. Allopatric speciation is speciation by geographic isolation and requires the imposition of a barrier that prevents individuals in the two lineages from interbreeding with one another. For most animals, geographical isolation has been the most important barrier, and the larger and more vagile the animal, the wider the barrier must be. As a result, allopatric speciation in most animals can take place only in large geographic areas where substantial barriers, such as wide water gaps or isolated mountains exist. In parapatric speciation there is no complete geographic isolation, but lineages diverge across environmental gradients. Sympatric speciation is speciation without geographic isolation. Plants, for example, commonly speciate via a duplication of their chromosomes, a process that can be accomplished in a single generation. The different process and conditions required for speciation results in a great variation in the rate of speciation. However, in general the process is slow, usually taking millions of years.

The short and clustered branches on the molecular tree of life (see Figure 4.1) illustrate the relatively close and recent relationships among the organisms with which we are most familiar and that dominate most biodiversity assessments (Plants, Animals, Fungi). However, the microorganisms that dominate the branches of the evolutionary tree are extremely important in any assessment of biodiversity. These groups include most of the forms that are the main providers of most regulating and supporting services and that are key to many provisioning services (Nee 2004).

Table 4.1. Measures of Biodiversity at Different Levels. The measures reflect different service benefits. In practice, some kinds of measures are more significant than others. The bold text reflects the most significant measures for ecosystem services.

Level	Importance of Variability	Importance of Quantity and Distribution
Genes	**adaptive variability for production and resilience to environmental change, pathogens, etc.**	local resistance and resilience
Populations	different populations retain local adaptation	**local provisioning and regulating services, food, fresh water**
Species	**the ultimate reservoir of adaptive variability, representing option values**	**community and ecosystem interactions are enabled through the co-occurrence of species**
Ecosystems	different ecosystems deliver a diversity of roles	**the quantity and quality of service delivery depends on distribution and location**

4.1.3 Practical Issues for Ecosystem Assessment

The term ecosystem can be applied to any functioning unit with biotic and abiotic elements, ranging from tiny pockets of life to the entire planet. Hence there are some practical issues to address in determining units for analysis and assessment. The Millennium Ecosystem Assessment uses ecosystems as a unit for assessment based on the definition adopted by the Convention on Biological Diversity: "a dynamic complex of plant, animal and microorganism communities and their nonliving environment interacting as a functional unit" (UN 1992). As such, ecosystems do not have clearly definable boundaries, and any classification, no matter how many categories it has, can become somewhat arbitrary. A practical approach to this problem is to build up a series of map overlays of significant factors, mapping the location of discontinuities, such as in the distribution of organisms, the biophysical environment (soil types, drainage basins, depth in a water body), and spatial interactions (home ranges, migration patterns, fluxes of matter). A useful ecosystem boundary for analysis is then the place where a number of these discontinuities coincide.

Based on this general methodology, different systems for classifying terrestrial ecosystem classifications have been developed.

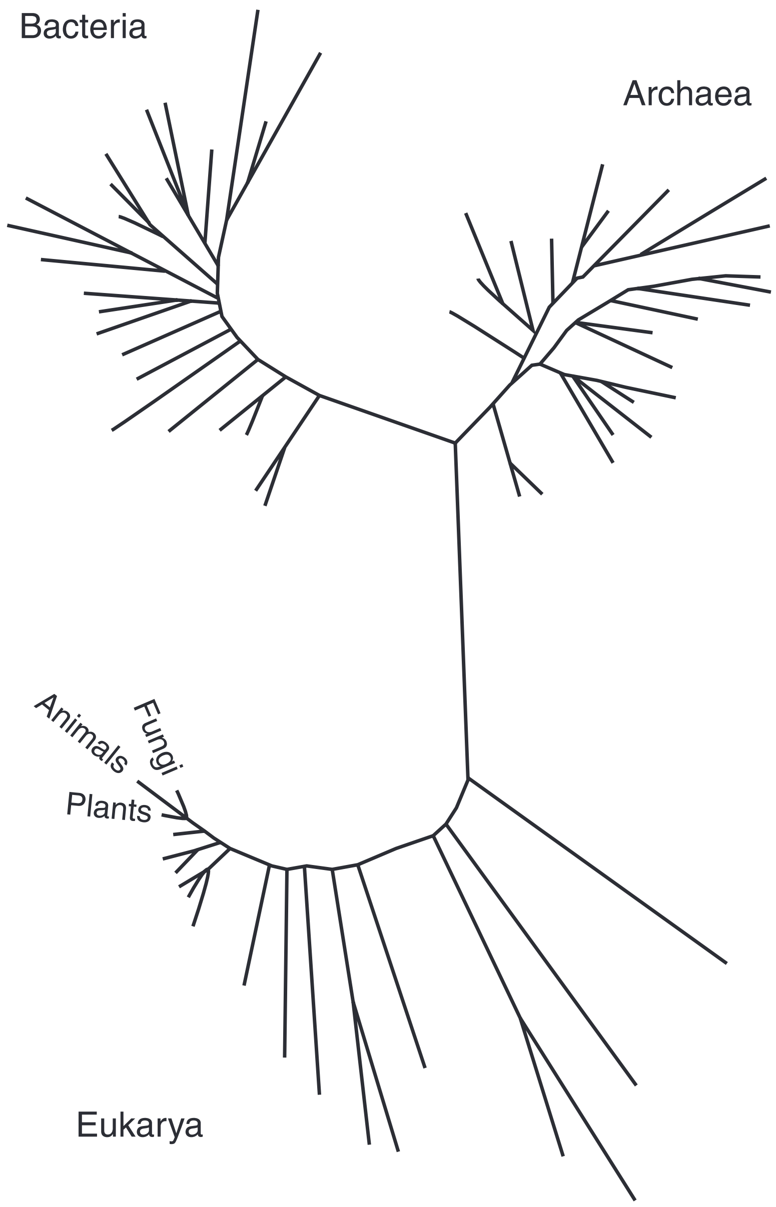

Figure 4.1. Tree of Life: Biodiversity through a Molecular Lens. This scheme is based on ssRNA gene-sequence data and shows the relationships of organisms in the three main domains of life—Bacteria, Archaea, and Eukarya (creatures with cells like our own). Visible organisms are found among the plants, animals, and fungi. Not only are these groups just twigs on the tree of life, many of their members are invisible as well. (Nee 2004)

(See Table 4.2.) Generally, ecosystems can be characterized by either community structure and functioning or species composition or by a combination of the two. Spatially, ecosystem maps have been derived through various techniques, such as modeling (using climatic parameters for example), mapping (from remotely sensed images or delineation of species extents), or a combination of both.

Different classifications serve different purposes and may yield different results. For example, the result of an analysis between five broad global biomes and six global terrestrial ecosystem classifications is shown in Figure 4.2. The ecosystem classifications were chosen to capture a range of the varying techniques that have been used to map ecosystem boundaries. The five broad biomes include desert (both hot and cold deserts), forest and woodland, grassland (includes grassland, savanna, steppe, and shrub), mixed, and tundra. The mixed class comprises the mixed mountain classes of FAO, the mixed mountain and island systems of Udvardy (1975), and the Mediterranean forests, woodland, and scrub class of WWF. It is difficult to divide mixed classes accurately between the remaining broad biome classes, so they were classified as a separate class.

There is reasonable agreement in area between some of the biomes and less agreement among others. The biomes that are reasonably consistent across ecosystem maps are forest and woodland, desert, and tundra. Delineation of grasslands is less consistent, and the reported grassland area differs across ecosystem maps by as much as 30%. Forest and woodland, the most predominant biome, is represented at between 42% and 53% of the terrestrial land surface (approximately 55 million to 73 million square kilometers). These results illustrate the implications of different choices of global ecosystem classifications for assessment, particularly as relates to the grassland biome.

Table 4.2 illustrates the methods used to define the ecosystem boundaries, the purpose for which they were classified, and the scale at which they were mapped. These are variables that should be considered in order to determine the appropriateness of a classification for a particular assessment.

In this chapter and elsewhere in this assessment, the WWF terrestrial biomes, built up from the classification of terrestrial ecoregions, were chosen to assess magnitude, distribution, condition, and trend of terrestrial biodiversity. (See Figure 4.3 in Appendix A.) Currently there is no equivalent classification for marine ecosystems. A separate set of freshwater biomes, used to classify freshwater ecoregions, is in preparation by WWF and The Nature Conservancy.

4.2 Current Status of Biodiversity

This section presents information on the global status of biodiversity, measured at the scale of biogeographic realms, biomes, species, populations, and genes. Under each heading, the significance of that level is introduced, followed by information on what is known about its current condition

4.2.1 Biogeographic Realms

Biogeographic realms are large spatial regions within which ecosystems share a broadly similar biota. Eight terrestrial biogeographic realms are typically recognized, corresponding roughly to continents (for example, the Afrotropical realm). Terrestrial biogeographic realms reflect freshwater biodiversity patterns reasonably well, but marine biogeographic realms are poorly defined.

4.2.1.1 Definition and Measurement

Similar ecosystems (tropical moist forests, for instance) share processes and major vegetation types worldwide, but their species composition varies markedly among the world's eight biogeographic realms (Olson et al. 2001). For example, the major tree species in tropical moist forests in Southeast Asia differ from those dominating tropical moist forests in South America. There is substantial variation in the extent of change and degradation to biodiversity among the biogeographic realms, and they face different combinations of drivers of change. In addition, the options for mitigating or managing drivers vary among realms. Although realms map roughly onto continents, they differ from continents in important ways as a result of biogeographic history.

4.2.1.2 Current Status of Biogeograpical Realms

Biogeographic realms vary widely in size. The largest is the Palearctic, followed by the Afrotropical and Nearctic realms; the smallest is Oceania. (See Table 4.3.) These area estimates are based on terrestrial area only, although the realm boundaries can be applied to inland water ecosystems with slight modifications of the boundaries to ensure that they do not cut across freshwater ecoregions or biomes (habitat types). Among terrestrial realms, net primary productivity (Imhoff et al. 2004) and biomass (Olson et al. 1980) values are highest in the Neotropics, followed closely by

Table 4.2. Description of Six Common Global Ecosystem Classifications

Ecosystem Classification	Description	Use	Spatial Resolution
Bailey Ecoregions (Bailey and Hogg 1986)	Bailey and Hogg developed a hierarchical classification including domains, divisions, and provinces that incorporates bioclimatic elements (rainfall and temperature)—based largely on the Koppen-Trewartha climatic system, altitude, and landscape features (soil type and drainage). Macroclimate defines the highest classification level and increasing numbers of variables are used to describe more detailed regional classifications.	Intended to demarcate ecologically similar areas to predict the impact of management and global change (Bisby 1995).	1: 30,000,000 scale (Bailey 1989)
FRA Global Ecological Zones (FAO 2001)	FAO's classification is based on the Koppen-Trewartha climate system and combined with natural vegetation characteristics that are obtained from regional ecological or potential vegetation maps.	Developed for the "Global Forest Resources Assessment 2000" as a way to aggregate information on forest resources.	useful at 1: 40,000,000 scale (FAO 2001)
Holdridge Life Zones (Holdridge 1967)	Holdridge's life zones are derived using three climatic indicators: biotemperature (based on the growing season length and temperature); mean annual precipitation; and a potential evapotranspiration ratio, linking biotemperature with annual precipitation to define humidity provinces. R. Leemans, then at IIASA, prepared the digital spatial data.	Initially derived to incorporate into models of global climate change.	0.5° geographic latitude/ longitude
Ramankutty Global Potential Vegetation (Ramankutty and Foley 1999)	Derived from a combination of satellite data and the Haxeltine and Prentice potential natural vegetation data. In places that are not dominated by humans, satellite-derived land cover (mainly the DISCover dataset) is used as a measure of potential vegetation. In places dominated by anthropogenic land cover, the Haxeltine and Prentice data set was used to fill in the gaps.	Initially derived to facilitate the analysis of cultivation land use practices and global natural or "potential" vegetation. Potential vegetation is regarded as the vegetation most likely to currently exist without the impact of human activities.	5 minute geographic latitude/ longitude
Udvardy's Biogeographical Realms and Provinces (Udvardy 1975)	This system combines physiognomic and biogeographical approaches. The physical structure of the dominant vegetation in combination with distinctive flora and fauna compositions defines the boundaries.	The classification has been used for biogeographical and conservation purposes. IUCN, for example, has used this map as a basis for assessing the representativness of global projected areas.	usable at 1: 30,000,000 scale
WWF Terrestrial Ecoregions of the World (Olson et al. 2001)	WWF ecoregions have been delineated through the combination of existing global ecoregion maps, global and regional maps of the distribution of selected groups of plants and animals, and vegetation types and through consultation with regional experts. Ecoregions identify relatively large units of land containing a distinct assemblage of natural communities and species, with boundaries that approximate the original extent of natural communities prior to major land use change.	A tool to identify areas of outstanding biodiversity and representative communities for the conservation of biodiversity.	variable, based on global or regional source (1:1 million to 1:7.5 million); useful at scales of 1:1 million or higher

the Afrotropical and Indo-Malayan realms. The least productive is the Antarctic realm.

Land cover composition also varies widely between realms. Because realms are defined biogeographically, and not by dominant habitat type, each realm typically contains a mix of land cover types as mapped by GLC2000 (USGS-EDC 2003). (See Figure 4.4 in Appendix A.) Some biogeographic realms, however, are dominated by a single land cover type. For example, more than 40% of the Australasian realm consists of herbaceous cover and more than 40% of the Neotropics consist of broadleaf forests. In each biogeographic realm, significant areas have been converted from native habitats to agriculture and urban land uses. All realms have experienced at least 10% habitat conversion, and the Indo-Malayan realm has by far the largest percentage of agricultural and urban lands (54%).

Partly in response to this land conversion, nations in all biogeographic realms have designated formal protected areas to conserve native ecosystems. Protection (IUCN classes I–IV) (WCMC 2003) of terrestrial biogeographic realms ranges between 4.0 and 9.5%. The realms with the greatest proportion of protected land area are Oceania (9.5%) and the Nearctic (7.8%). The Indo-Malayan (4.8%) and Palearctic (4.0%) realms contain the lowest proportion of protected land area. The Palearctic is the largest, and although only 4.0% is protected, it contains the largest total protected land area. The vast majority of protected areas have been designed to protect terrestrial ecosystems and biodiversity features, which has led to relative under-protection of inland water and marine biodiversity. (See Chapters 18, 19, and 20.)

The extent of inland water systems is greatest in the Nearctic and Palearctic realms (for example, lakes and peatlands). The

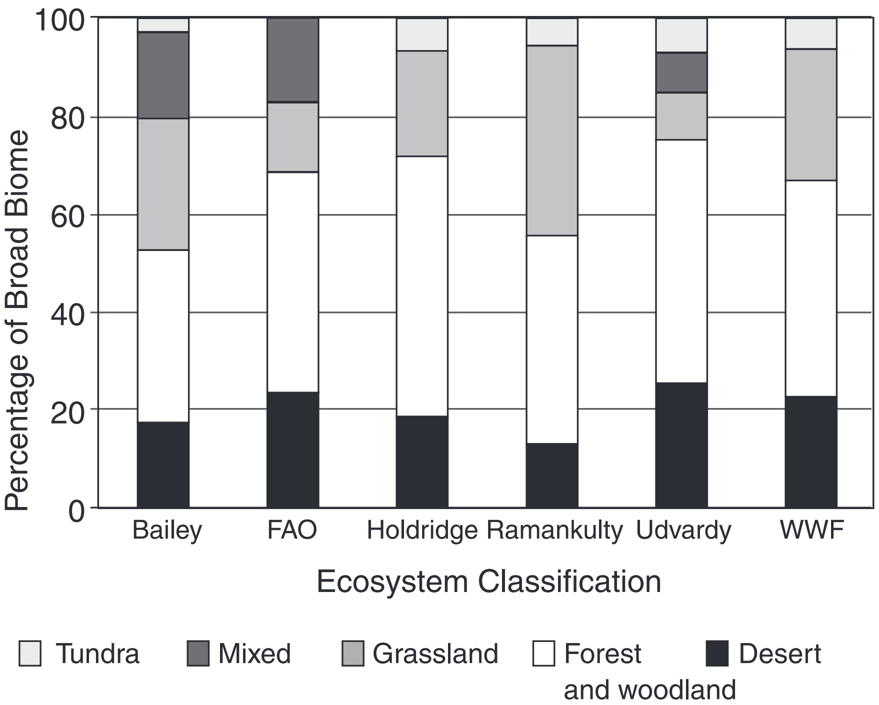

Figure 4.2. Area of Broad Biomes as Estimated by Six Ecosystem Classifications

Nearctic realm has by far the largest proportion of the world's lakes (Revenga and Kura 2003). In terms of water volume, however, the Neotropic and the Indo-Malayan realms contribute the most discharge into the oceans. Australasia contributes the least, with only 2% of the world's freshwater discharge (Fekete et al. 1999). The extent and distribution of inland water ecosystems has not been exhaustively documented at the global or regional scale. And while the biogeographic and ecological classification of inland water ecosystems is less well developed than for terrestrial ecosystems, more than 50 classifications are in use (see, e.g., Asian wetland classification system: Finlayson 2002; Darwall and Revenga in prep).

Each biogeographic realm contains a range of major habitat types or biomes. The Indo-Malayan, Oceanic, and Neotropical realms are dominated by tropical forest and grassland biomes, while the polar realms (Palearctic, Nearctic) contain higher proportions of tundra and boreal forest. The Afrotropics are dominated by tropical grasslands. Although dominated by different biomes, most realms contain similar biome richness. All but Oceania include 9–11 of the 14 terrestrial biomes. Oceania is composed mostly of low, tropical islands and is dominated by tropical forest and tropical grassland biomes.

In part due to differences in biome richness and composition, biogeographic realms differ markedly in species and family richness, at least for the four vertebrate classes for which data exist. Figure 4.5 shows species richness among realms based on presence or absence records of terrestrial vertebrates (birds, mammals, and reptiles) in each of the 825 WWF terrestrial ecoregions (WWF 2004). This is supplemented by an analysis of extent of occurrence polygon data for amphibians and threatened birds (Baillie et al. 2004; BirdLife 2004b). The Neotropics are by far the most species-rich realm, both overall for terrestrial vertebrates and for each of the four taxa. (See Figure 4.5a.) Other realms containing high proportions of tropical forests (such as Indo-Malayan) also show high species richness in terrestrial vertebrates. With the exception of Antarctica, Oceania is the least species-rich realm due to its small overall land area and the relatively species-poor faunas typical of islands.

Biodiversity at the level of families is more similar among biogeographic realms (see Figure 4.5b) except for Oceania and Antarctica. These patterns differ somewhat among some inland water

Table 4.3. Magnitude and Biodiversity of the World's Eight Terrestrial Biogeographic Realms. Realms are mapped in Figure 4.3.

	Size, Productivity, and Protection				Richness				Endemism				Family Richness				Family Endemism

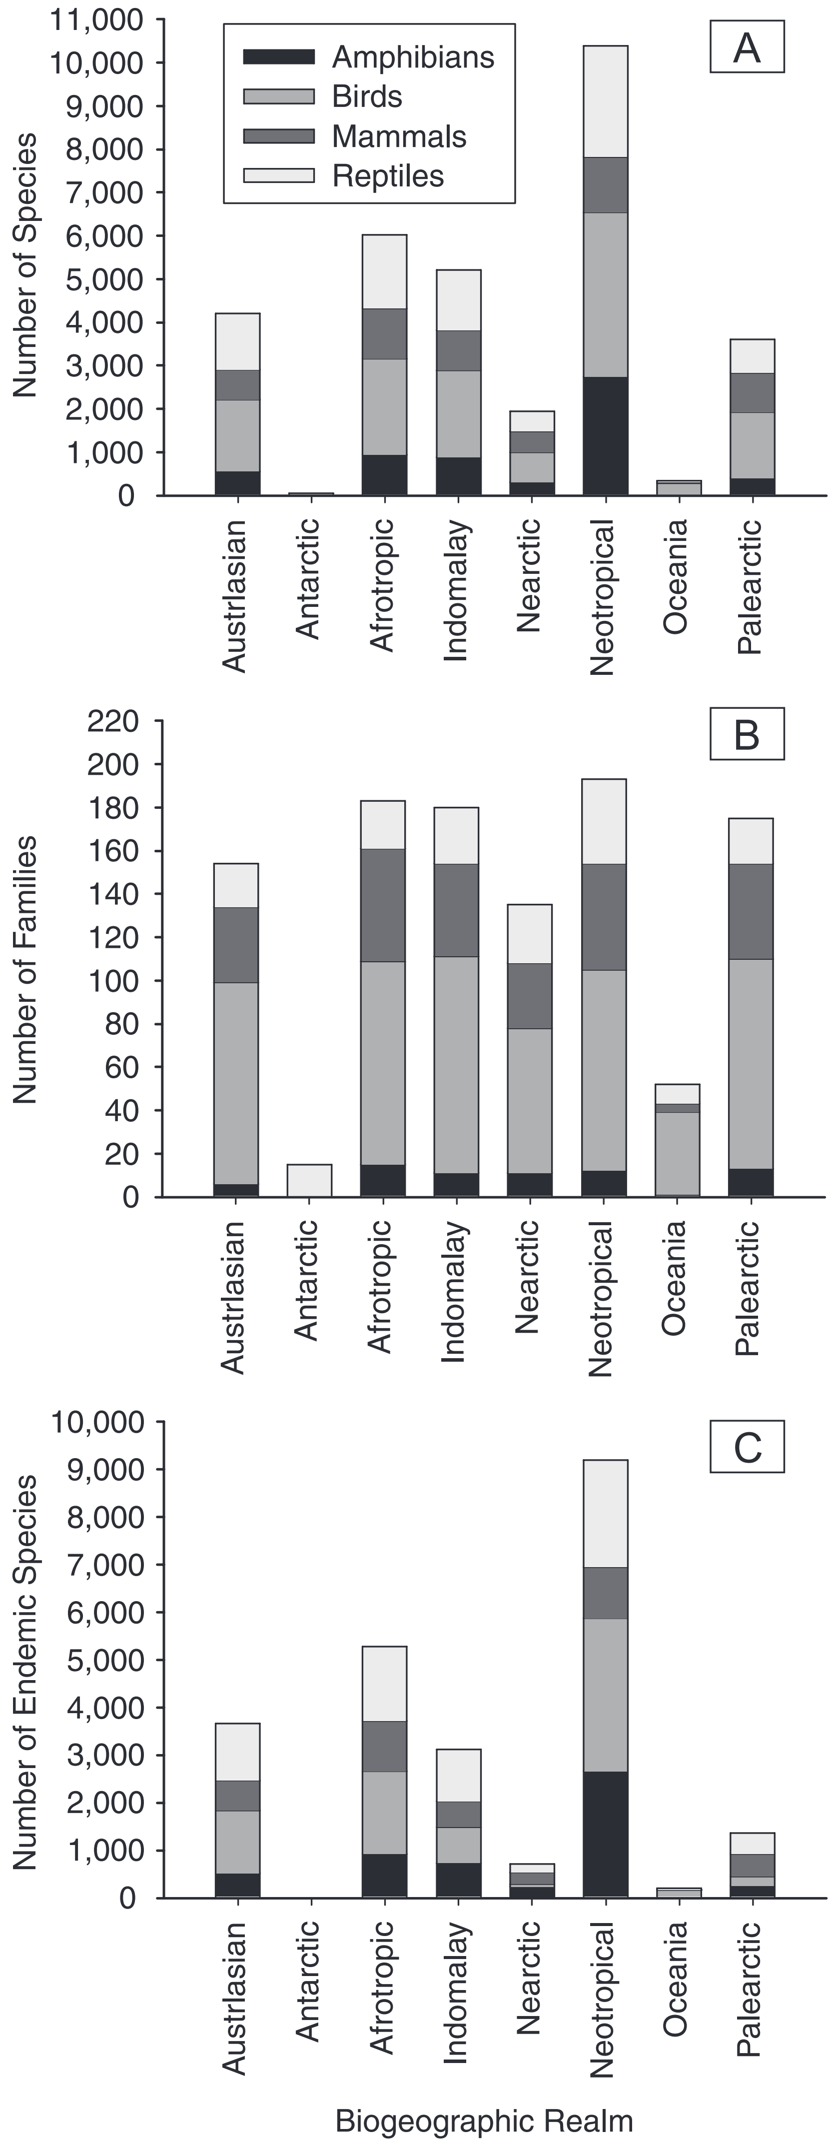

Figure 4.5. Diversity Comparisons for Eight Terrestrial Biogeographic Realms. The comparisons shown are for species richness (A), family richness (B), and endemism (C).

groups. The Neotropics have more than twice as many freshwater fish families as the Nearctic and Palearctic, and the Afrotropic and Indo-Malayan realms are only slightly behind the Neotropics (Berra 2001).

The number of species restricted to single realms (realm endemics) closely mirrors species richness patterns, at least for the four vertebrate classes assessed here. (See Figure 4.5c.) The Neotropics contain not only the greatest number of terrestrial vertebrate species but also the greatest number that occur only there. In all realms, however, the percentage of endemic species compared with total species richness is substantial (34–88%). Oceans, deserts, and other barriers to dispersal have resulted in vertebrate terrestrial faunas that are largely unique to each continent. We do not know how this pattern compares to patterns of realm endemism in nonvertebrates.

4.2.2 Biomes

4.2.2.1 Definition and Measurement

Biomes represent broad habitat and vegetation types and span across biogeographic realms (for example, the tundra biome is found in both Palearctic and Nearctic realms). Biomes are useful units for assessing global biodiversity and ecosystem services because they stratify the globe into ecologically meaningful and contrasting classes.

Throughout this chapter, and elsewhere in the MA, the 14 biomes of the WWF terrestrial biome classification are used, based on WWF terrestrial ecoregions (Olson et al. 2001). The nested structure of this classification, with finer-scale ecoregions nested into both biomes and biogeographic realms, allows assessments to be scaled up or down depending on the objectives. Furthermore, several datasets are already available and others continue to be associated with the WWF classification (such as vertebrate and plant species distribution data, threatened species, area-based estimates of net primary productivity, and land cover). The biome-level boundaries have very good resolution and accuracy, as they are based on the finer-scale ecoregions and are of an appropriate scale and number for global reporting.

These boundaries are based on the original or potential extent of these ecosystems or biomes, and do not take human-induced land cover changes into account. The extent of the ecosystems or biomes before the extensive changes brought about with the rise of the human population and industrialization in the modern era will probably never be known. We refer to this earlier, less altered state as ''original,'' while recognizing that climatic and environmental changes have always caused change and movements in Earth's ecosystems. Therefore the global classifications can only be an approximation of the original boundaries of these ecosystems. The difference between original and current extent can be significant and forms an important component of the assessment of biodiversity loss.

There is no comparable global classification of freshwater biomes, but WWF and The Nature Conservancy are developing a major new biome classification for fresh water, to be completed in 2005. Terrestrial biomes tell us little by themselves about the size or type of freshwater habitat, which in turn has an enormous influence on the kind and number of species occurring there. For instance, a major river system can be adjacent to a very small basin, and both may fall within the same terrestrial biome, but they can contain vastly different assemblages of aquatic species. Freshwater biomes in the forthcoming classifications will be based largely on a combination of system size and type (such as large rivers versus small lakes), connectivity to coastal zones (such as total connectivity for islands), and overarching climatic conditions (such as temperate versus tropical or dry versus moist).

Like freshwater biomes, marine biome classification is less developed than that for terrestrial systems. The dynamic nature and the relative lack of natural boundaries in oceanic ecosystems make biogeographic divisions problematic, and there is no standard classification scheme. Nonetheless, several classifications of the marine realm exist, some based on biogeography (such as Briggs 1974), others on oceanographic and hydrological properties, and still others on ecological features, such as using the distribution of species assemblages in relation to seasonal characteristics of local and regional water masses (Ford 1999). Longhurst (1995) classified the world's oceans into four ecological domains and 56 biogeochemical provinces, largely on the basis of estimates of primary production rates and their changes over time. (See chapter 18.) Hayden et al. (1984) subdivided Dietrich's (1963) 12 marine realms into oceanic realms and coastal regions on the basis of physical and chemical properties including salinity, temperature, and seasonal movement of water and air masses.

Two marine classification systems have been used more widely. First, Bailey (also based on Dietrich 1963, 1998) includes oceanic ecoregions in his global classifications, mapping 14 marine divisions spread between the three domains. Continental shelves (less than 200 meters water depth) are distinguished; other divisions are delineated on the ocean surface based on four main factors: latitude and major wind systems (determining thermal zones) and precipitation and evaporation (determining salinity).

Second, Sherman and Alexander's (1986) system of large marine ecosystems delineates 62 regions of ocean encompassing near-coastal areas from river estuaries to the seaward boundary of continental shelves and the seaward margins of coastal current systems. They are relatively large regions (greater than 200,000 square kilometers), characterized by distinct bathymetry, hydrography, biological productivity, and trophically dependent populations. This approach aims to facilitate regional ecosystem research, monitoring, and management of marine resources and focuses on the products of marine ecosystems (such as the fish harvest). In general, no marine biome classification scheme has successfully covered the wide range of oceanic depths and addressed the lack of regional uniformity, thus complicating a global assessment of marine biodiversity.

Table 4.4. Magnitude and Biodiversity of the World's 14 Terrestrial Biomes. Key to biome abbreviations can be found in Figure 4.3 in Appendix A.

	Size, Productivity, and Protection			
Biome	**Area** *($x10^5 km^2$)*	**Mean NPP** *(10^{10}gC/yr/cell)[a]*	**Biomass** *(kgC/m^2)*	**Percent Protected** *(IUCN I-IV)*
TMF	231.6	74.2	8.41	5.5

4.2.2.2 Current Status of Major Terrestrial Biomes

The world's 14 terrestrial biomes vary in total area by two orders of magnitude, from nearly 35 million square kilometers (deserts and dry shrublands) to 350,000 square kilometers (mangroves). (See Table 4.4.)

Biomes also vary widely in per-area measures of plant biomass (Olson et al. 1980) and net primary productivity (Imhoff et al. 2004). Net primary productivity is the net amount of carbon fixed by plants through photosynthesis (after subtracting respiration) and represents the primary energy source for the world's ecosystems (Vitousek et al. 1986). Tropical moist forests show high levels of both standing biomass and annual productivity, while other biomes, such as temperate coniferous forests and boreal forests, have high biomass despite low annual (and more seasonal) productivity.

Each biome mapped in Figure 4.3, while typically dominated by the expected vegetation cover, actually comprises a complex mosaic of different land cover types as mapped by GLC2000. (See Figure 4.6 in Appendix A.) This heterogeneity is due in part to fine-scale mixture of ecosystems within these broadly defined biomes. For example, boreal forests are composed primarily of coniferous forest land cover but contain a substantial proportion of shrublands and grasslands.

Another cause of land cover heterogeneity within biomes is conversion of native habitats to agriculture, pastures, and other human land uses. Indeed, in over half the biomes, 20–50% of land area has been converted to human use. Tropical dry forests are the most affected by cultivation, with almost half of the biome's native habitats replaced by cultivated lands. Three additional biomes—temperate grasslands, temperate broadleaf forests, and Mediterranean forests—have experienced 35% or more conversion. Biomes least affected by cultivation include deserts, boreal forests, and tundra. While cultivated lands provide many provisioning services (such as grains, fruits, and meat), habitat conversion to intensive agriculture leads to reductions in native biodiversity.

Biomes differ widely in the percentage of the total area under protection. Table 4.4 shows the total area under protection, including only lands classified in the four highest IUCN Protected Area categories (IUCN 1994). Flooded grasslands, tundra, temperate coniferous forests, mangroves, and boreal forests have the highest percentage area under protection—perhaps because these biomes are among the least useful for competing land uses, such as agriculture. Conversely, temperate grasslands, Mediterranean forests, and tropical coniferous forests are the least protected biomes.

To compare species richness among biomes, a similar methodology used to determine species richness at the level of realms has been applied. Tropical biomes have the highest levels of overall species richness, as well as the highest richness for each of the four taxa analyzed. (See Figure 4.7.) This is true of tropical moist forest, but also, perhaps surprisingly, of tropical grasslands and savannas and tropical dry forests, the second and fourth richest biomes

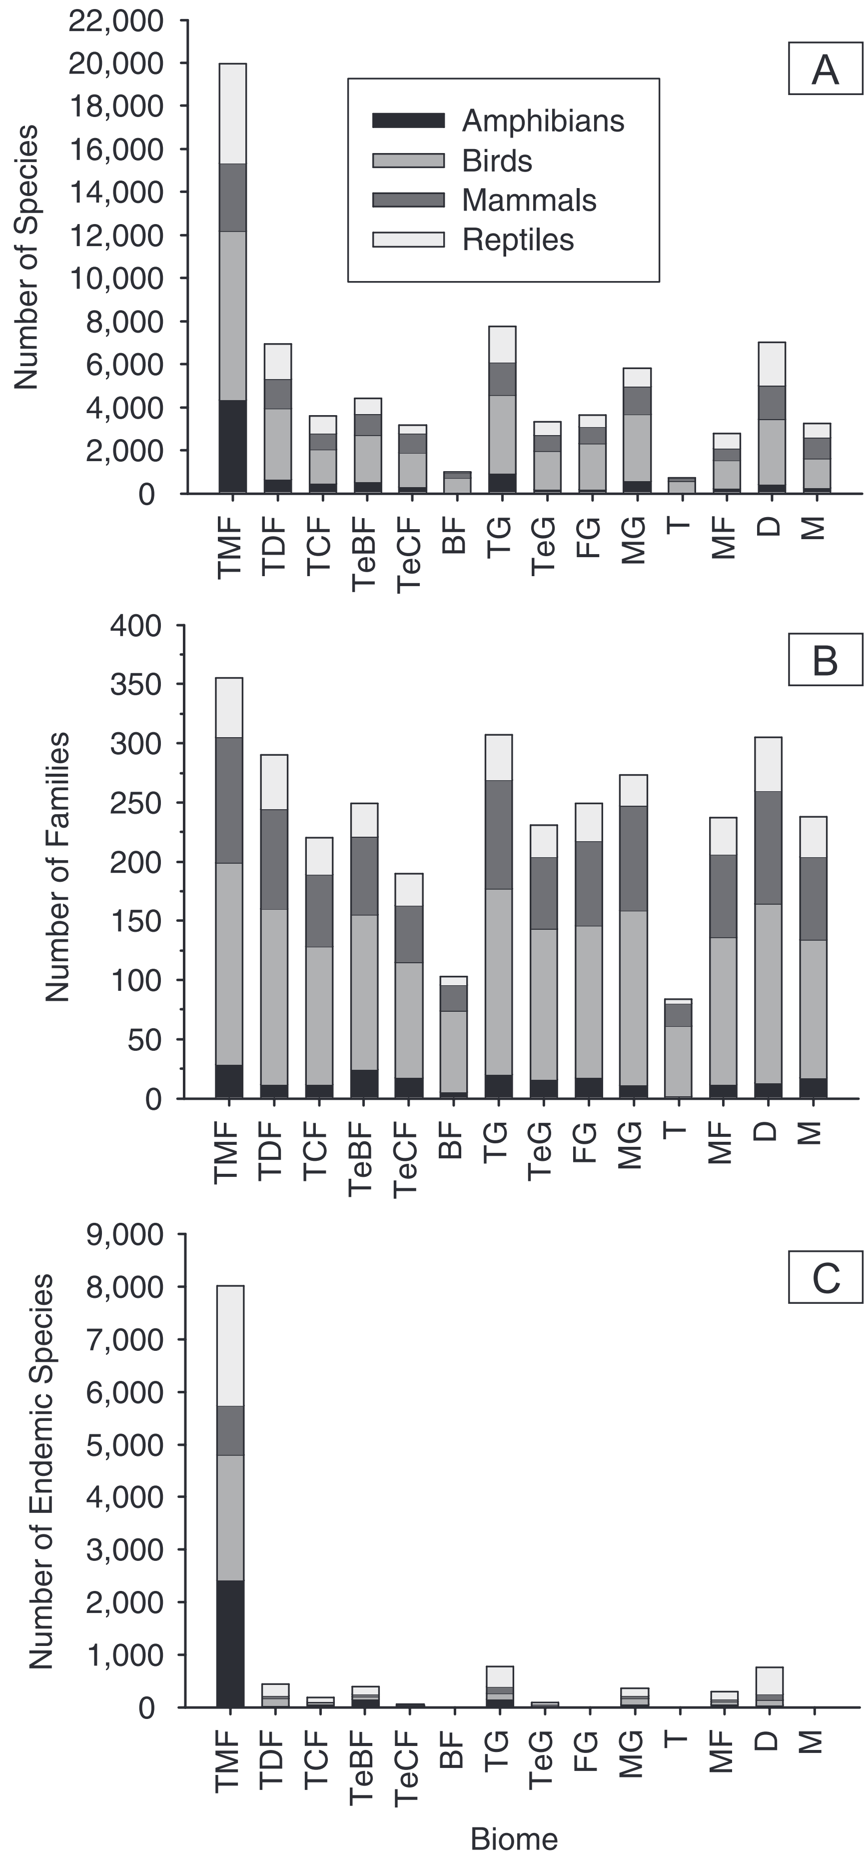

Figure 4.7. Diversity Comparisons for 14 Terrestrial Biomes. The comparisons shown are for species richness (A), family richness (B), and endemism (C). Biome codes as in Figure 4.3 (in Appendix A).

overall. Deserts and Mediterranean grasslands are also relatively rich biomes for terrestrial vertebrate species.

Tropical moist forests also contain the greatest diversity of higher taxa and therefore represent the greatest store of Earth's evolutionary history. The five biomes richest in terrestrial vertebrate species are also the five richest in families, although differences among biomes are not as pronounced. Tropical moist forests, therefore, contain many more species per family on average, suggesting that this biome has experienced higher rates of species diversification within families.

The number of biome-endemic species—that is, species found in a certain biome and nowhere else—varies widely among biomes. Tropical moist forests contain by far the highest number of endemic species, an order of magnitude more than any other biome. This pattern again may be the result of high speciation rates in this biome, as well as relatively smaller range sizes in lower latitudes (Rosenzweig 1995; Gaston 2000).

The relative richness of the world's biomes, however, may be influenced by their relative sizes as well. Biomes vary enormously in area, as noted earlier, and species richness is well known to increase with the area sampled (Rosenzweig 1995). Therefore, although both tropical moist forests and tropical grasslands contain high total richness, this may be due in part to the fact that they represent two of the largest biomes. Figure 4.8 plots species richness against area for the 14 biomes. In fact, the two are not statistically related ($p > 0.75$).

4.2.3 Species

The classification of living organisms into manageable groups greatly facilitates their study. The hierarchical system of classification used today is largely based on evolutionary relationships. The major categories, from the most inclusive to the smallest groups Kingdom-Phylum-Class-Order-Family-Genus-Species. It is at the level of species that living organisms are most widely known, both by common and scientific names.

4.2.3.1 Definition and Measurement

Although natural historians have been classifying living organisms into species since at least classical times, there is still no consensus on how this is best done (Hey 2001). Since the middle of the twentieth century, the dominant idea of how to define the term "species" has been the biological species concept (Mayr 1963), which defines species as groups of interbreeding natural populations whose members are unable to successfully reproduce with members of other such groups. Gene flow within a species leads to cohesion, whereas the lack of gene flow between different species means they are independent evolutionary lineages. Species therefore have natural and objective boundaries under this view, and so are natural units for biodiversity assessment.

Another hierarchy to which species belong is the evolutionary "family tree," or phylogeny, that links them all. In some well-studied groups (such as angiosperms (APG 1998) and birds (Sibley and Monroe 1990)), current taxonomic classification largely (and increasingly) reflects evolutionary relationships, such that species in a given taxon are all thought to share a more recent common

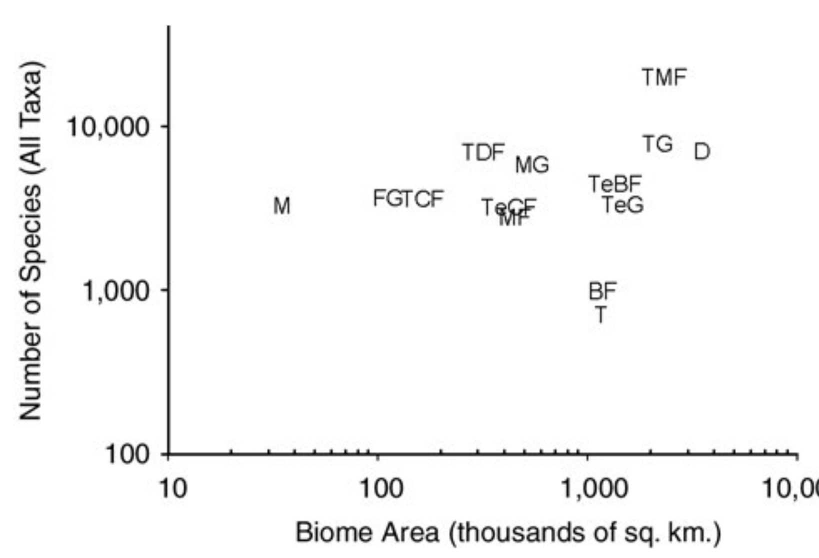

Figure 4.8. Species Richness of 14 Terrestrial Biomes in Relation to Biome Area. Biome codes as in Figure 4.3 (in Appendix A).

ancestor with each other than with species in other taxa. Higher taxonomic groupings then represent increasing levels of independent evolutionary history. In less well known groups, by contrast, classifications may not (and may not even attempt to) reflect phylogeny.

Regardless of how phylogenetic groups are recognized and named, decisions about the taxonomic rank (genus, family, and so on) of the various groups are arbitrary (Avise and Johns 1999). Many genera of insects, for instance, originated earlier than most avian families. Unlike biological species, higher taxonomic categories and lower taxonomic categories, like subspecies or races, have no natural boundaries.

Therefore species have advantages over other levels in the classificatory hierarchy and are useful units for biodiversity assessment. Some problems with using species as a unit for biodiversity assessment remain—both theoretical and practical; they can often be overcome or ameliorated with care, but they should never be overlooked (Isaac et al. 2004; Mace 2004). (See Box 4.1.)

4.2.3.2 How Many Species Are There?

Estimates of the total number of eukaryotic species vary greatly, most commonly falling between 5 million and 30 million (May 1992). The uncertainty stems from the fact that most taxonomic work is concentrated away from the most species-rich taxa (Gaston and May 1992) and regions (Gaston 1994a). In addition, the intensity of taxonomic work is actually declining (Godfray 2002). The discussion here is restricted to eukaryotic species. In the prokaryotes, different methods for recognizing and naming species, as well as severe problems with incomplete knowledge, make assessments and comparisons of species richness unreliable (Ward 2002; Curtis et al. 2002; Nee 2003).

Many methods of estimating total species numbers are based in some way on numbers of known, named species. Uncertainties around these estimates themselves pull in opposing directions. On the one hand, the lack of comprehensive systematic databases results in underestimates of known species numbers (Sugden and Pennisi 2000). On the other hand, the extent of synonomy between named taxa results in overestimates (May and Nee 1995). Several ongoing initiatives, such as Species 2000, the Integrated Taxonomic Information System, and the Global Biodiversity Information Facility, aim to eliminate these problems by providing up-to-date, electronic catalogues of known species (Bisby et al. 2002).

In total, summing across taxa suggests that the number of known species on the planet lies at around 1.75 million (Heywood and Watson 1995; Groombridge and Jenkins 2002). (See Figure 4.9.) It has, however been shown that some of these figures are underestimates; for example, mollusks are now believed to number 100,000 known species (Peeters and Van Goethem 2003). Further, current rates of species description average 15,000 species per year (Stork 1993), less than 1% of the known total, and hence at least another 135,000 species are likely to have been described over the decade since 1995, bringing the total of known species toward 2 million (Peeters et al. 2003).

A range of techniques exist for estimating the total species richness of the planet (May 1988). These can be grouped into two main classes (Stork 1997)—methods based on ratios of known to unknown species and those based on the extrapolation of samples (see Table 4.5)—with more speculative techniques based on scaling rules between species and body size (May 1990a), specialist opinion (Gaston 1991), and community pattern (Godfray et al. 1999).

Methods based on ratios between known and unknown species have a long history but were first brought to high profile by Raven (1983). Specifically, he extrapolated the known 2:1 ratio of tropical to temperate vertebrate species to the existing 2 million known species—most of which are temperate insects—to estimate that there should be two as-yet-undescribed tropical insects for each temperate species, for a total of 3–5 million species. Stork and Gaston (1990) used similar logic (based on the percentage of British insects that are butterflies) to estimate the total numbers of insects at 4.9–6.6 million. Hodkinson and Casson (1991) extrapolated the percentage of undescribed Hemiptera in samples from Sulawesi to all insects, suggesting a total of 1.84–2.57 million species, while Hodkinson (1992) generalized this argument to suggest the number of species could be estimated at approximately 5 million, based on percentages of undescribed species in studies from the tropics.

The development of the second method—extrapolation of samples—is much more recent and was first developed by Erwin (1982). In studies of beetle species inhabiting tropical trees on Panama, he recorded high levels of both richness and local endemism. Extrapolating these figures globally, he estimated the total number of species at 30 million. His assumptions and methods have been tested and refined (Stork 1988; Hammond 1994; Ødegaard 2000; Sørensen 2003; Novotny et al 2002), and this method now suggests a lower global species richness of 4–6 million.

In general, there continues to be much debate in the literature regarding estimates of species richness, even among well-studied groups such as the extant seed plants. Lower estimates for seed plants range from 223,000 (Scotland and Wortley 2003) to 270,000 and 320,000 (May 1992; Prance et al. 2000), while higher estimates range up to 422,000 (Govaerts 2001; Bramwell 2002), although the higher figure is somewhat controversial (Thorne 2002; Scotland and Wortley 2003).

Several other particularly poorly known groups of organisms present additional problems for the estimation of global species richness (May 1995). Based on extrapolations of box-core samples from the seafloor, Grassle and Maciolek (1992) suggested a total of 10 million marine macrofaunal species; this may be rather high, but clearly enormous deep-sea species richness remains undiscovered. Likewise, the known global total of 72,000 fungi is certainly a large underestimate; based on the ratio of fungi to plants in Britain, Hawksworth (1991) estimated the global number to be closer to 1.5 million. Maybe most important, parasitic richness remains largely unknown: if the possibility that there is at least one host-specific parasite for all metazoan or vascular plant species is borne out (Toft 1986), the number of estimated species could double.

4.2.3.3 Variation in Species Richness in Time and Space

While the number of species on the planet is hard to estimate, its variability across space and time is much harder. Nearly all patterns of species richness are known with greater confidence for terrestrial than for either marine or freshwater systems. Species are unevenly distributed over Earth's surface (Rosenzweig 1995) and across phylogenetic space: species' ages and histories vary widely (May 1990b). Considerable data have recently been compiled that allow the identification of numerous patterns of variation, but these remain restricted to tiny subsets of all species, and so their general applicability remains unknown. Nevertheless, for lack of any truly comprehensive datasets, these data form the basis for the rest of this section.

For many purposes, species are not all equal—in particular those species with long independent evolutionary histories and

BOX 4.1

Species in Theory and Practice

Species concepts based on gene flow and its limits, such as the biological species concept, are not applicable to asexual taxa. They are also inadequate for "pansexual" taxa, such as some bacteria, where gene flow can be common between even very dissimilar types. However serious these concerns are in theory, they rarely matter for biodiversity assessment because the data collected on such groups are usually insufficient for the problems to emerge.

These and other issues have, however, led to a proliferation of species concepts: there are dozens in current use (Claridge et al. 1997; Mayden 1997), though most share the feature that species are independent evolutionary lineages. Most of the concepts—whether based on gene flow, ecological separation, or morphological distinctiveness—tend to give similar answers in most cases, for two reasons. First, most species have a considerable history of independent evolution—maybe millions of years—and have evolved morphological, ecological, and reproductive characters that set them apart from other species. Second, most populations within species share common ancestors with other populations in the very recent past, so they are barely differentiated at all. Borderline cases, where different criteria disagree, are relatively rare (Turner 1999).

Application of the phylogenetic species concept, however, may lead to the recognition of very many more species than when other concepts are used. A phylogenetic species is "the smallest group of organisms that is diagnosably distinct from other such clusters and within which there is a parental pattern of ancestry and descent" (Cracraft 1983); any diagnosable difference, however small, is deemed a sufficient basis for describing a new species. Taxonomic revisions that apply this concept to a taxon for the first time typically roughly double the number of species recognized (Agapow et al. 2004).

Most theoretical species concepts, like the biological one, are not very operational: they define the sort of entity a species should be but do not provide a method for delimiting them (Mayden 1997). In practice, simpler, perhaps informal decision rules are typically used to determine how many species to describe (Quicke 1993), with these rules differing among major taxa (Claridge et al. 1997). Even within a group, taxonomists lie on a continuum from "lumpers" (who recognize few species, which will consequently tend to be widespread) to "splitters" (who recognize many species, which often have restricted distributions), with obvious consequences for biodiversity assessment (Hull 1997).

The recognition that a full catalogue of the world's species is hundreds of years away, at current rates of description, has prompted initiatives to simplify the jobs of describing and defining animal and plant species (Godfray et al. 1999; Hebert et al. 2003; Tautz et al. 2003) and calls for a program to sequence DNA from all the world's biota (Wilson 2003). These initiatives are controversial and are currently only at the trial stage.

Species are the major taxonomic unit for counting biodiversity: species lists are important for both monitoring and broad-scale priority setting (Mace et al. 2003). However, species may differ in the weighting they receive, to reflect differences in their perceived biodiversity value. In addition to species of recognized economic importance, four other categories of species that might receive more weight are keystones (whose loss from a system would lead to large-scale changes in it), indicators (whose sensitive requirements mean that their abundance reflects overall system health), flagships (charismatic species whose plight attracts publicity), and umbrellas (flagships whose conservation in situ would automatically help conserve many other species) (Meffe and Carroll 1994). More weight might also be assigned to species that are at risk of extinction, or rare, or have restricted distributions (e.g., Myers et al. 2000).

There is no consensus about exactly how any of these weights should be determined nor their relative importance. Phylogenetic information can also be considered, by weighting species or locations according to the amount of unique evolutionary history they embody (Vane-Wright et al. 1991; Faith 1992).

These ways of augmenting information in species lists may be of little use when species lists are very incomplete (Mace et al. 2003), which they can be for even well-known taxa. Then, any comparisons between regions, systems, or taxa that do not control for variation in sampling effort run the risk of serious error. The picture is even cloudier when sampling effort differences are compounded with differences in species concept. Counts of higher taxa (such as genera or families) might be more robust than species counts to sampling differences among regions, and so they may be pragmatic choices despite the loss of precision incurred (Balmford et al. 1996). Some very broad-scale comparisons among groups (bacteria versus mammals, for example) are practically meaningless because the differences in taxonomic practice are so great (Minelli 1993). Comparisons over time are hampered by the taxonomic instability that results from discovery of new species and changes in species concepts and by changing information about previously known species (Mace et al. 2003).

Because of these considerations, the interpretation of biodiversity measures based on species numbers is not always straightforward. Such measures are most likely to be useful when the taxonomy of the group is apparently almost complete (that is, few species remain to be discovered), when the sampling and taxonomic effort has been equal among the units being compared, or when sampling and effort have at least been measured in a way permitting correction for sampling biases. In addition, it is clearly important that taxonomic practice, including the choice of species concept, be reasonably consistent.

These requirements mean that species-based approaches are much more useful when applied to unusually well known taxa or well-known parts of the world (such as birds and mammals or Northern temperate regions) rather than to other taxonomic groups or less well documented systems (such as nematodes or freshwater and marine systems). The wealth of data available for the best-known groups permits very useful comparisons to be made between places in, for example, how many species there are, how many are threatened with extinction, or how many are threatened by overexploitation. However, patterns seen in a single group may be specific to that group (Prendergast et al. 1993).

Different lineages have different ecological requirements and biogeographical histories, so they naturally may have different patterns of diversity and trends: consequently, no single taxon is sure to be a good surrogate for biodiversity as a whole. If comparisons are intended to reflect overall biodiversity, they should therefore be replicated using multiple taxa wherever possible.

few surviving relatives contain irreplaceable genetic diversity. Measures of phylogenetic diversity reflect this and can sometimes be approximated by higher taxon diversity.

Global species richness maps exist for mammals (terrestrial species only) (see Figure 4.10 in Appendix A), amphibians (see Figure 4.11 in Appendix A), sceleractinian corals (Veron 2000), the 239 bumblebee species of the genus *Bombus* (Williams 1998), marine finfish species across FAO region and freshwater finfish by continent (Froese and Pauly 2003) (see Figure 4.12 in Appendix A), plants (see Figure 4.13 in Appendix A) (Barthlott et al. 1999),

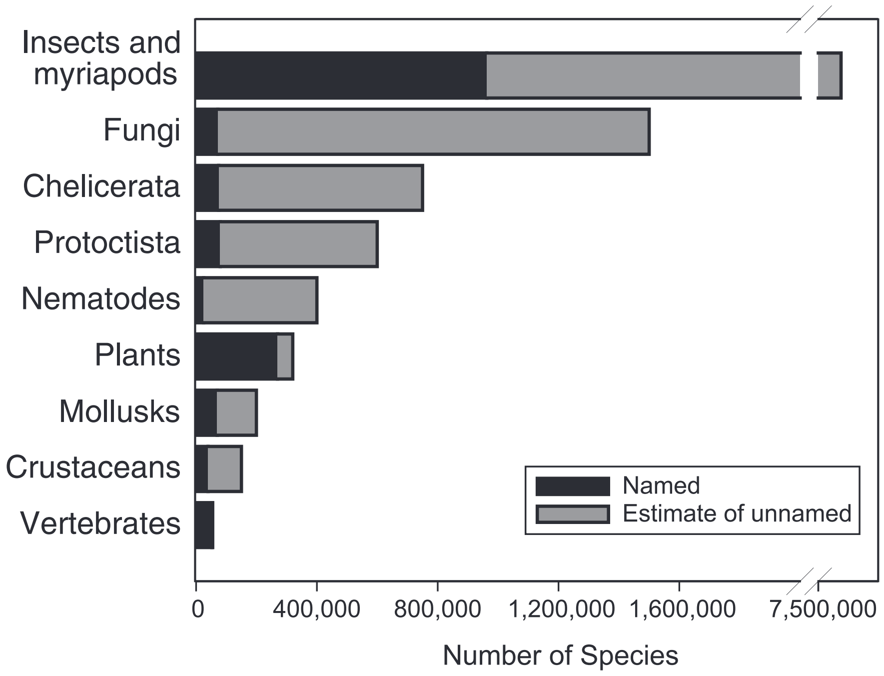

Figure 4.9. Estimates of Proportions and Numbers of Named Species and Total Numbers in Groups of Eukaryote Species (following Groombridge and Jenkins 2002)

Table 4.5. Estimates of Number of Species Worldwide

Estimate	Reference	Method
30 million	Erwin 1982	extrapolation from samples
3–5 million	Raven 1983	ratios known:unknown species
10–80 million	Stork 1988	extrapolation from samples
4.9–6.6 million	Stork and Gaston 1990	ratios known:unknown species
1.84–2.57 million	Hodkinson and Casson 1991	ratios known:unknown species
5 million	Hodkinson 1992	ratios known:unknown species
4–6 million	Novotny et al. 2002	extrapolation from samples

and freshwater fish by river basin (multimedia.wri.org/watersheds_2003/gm2.html). The lack of distributional data for invertebrates generally (in particular, for aquatic species) is clearly a major limitation on inference from these data; some regional data sets exist, but these are so heavily skewed toward north temperate regions as to have limited value in a global assessment. Another limitation of these data is their static nature: they reflect current extent of occurrence, not historical range, which can often be very different (Channell and Lomolino 2000), and they fail to reflect temporal variation within species' ranges—for example, for migratory species (Gómez de Silva Garza 1996). Further limitations come from wholesale sampling artifacts: for instance, the Congo Basin and New Guinea are particularly poorly sampled for all taxa, likely leading to an underrepresentation of species richness in these areas.

The most obvious pattern emerging from these data is that for most taxa the tropics hold much higher species richness than do the temperate, boreal, and polar regions. Figure 4.14 demonstrates this by plotting the number of species in each 5-degree latitudinal band for all terrestrial mammals, threatened birds (as global bird data are not yet available), and amphibians. As expected from the species-area relationship (Rosenzweig 1995), some of this pattern is explained by variation in landmass across latitudinal bands. However, species richness is much higher in the tropics than would be expected based on area alone, peaking around the equator for all taxa (rather than in northern high latitudes, as would be predicted based on area alone).

The other pattern apparent from Figures 4.10–4.13 is the broadly similar distribution of diversity between taxa. Thus, for example, species richness per grid cell is tightly correlated between mammals and amphibians. Differences seem likely to be driven by particular biological traits. Birds, for example, have the ability to disperse over water more than most of the taxa mapped here, and so occur in larger numbers on islands, while ectothermic reptiles flourish in desert regions generally impoverished in other taxa. Other differences are less easily explained, such as the high richness of mammal species in East Africa and of amphibians in the Atlantic forest. In general, these differences will increase with increasing evolutionary distance (and hence often corresponding ecological differences) between taxa (Reid 1998): less correlation is expected between mammal and coral distributions, for instance, than between mammal and bird distributions.

Macroecological patterns of freshwater and marine species richness are less well understood. Diversity of pelagic predators seems to peak at intermediate latitudes (20–30° N and S), where tropical and temperate species ranges overlap (Worm et al. 2003). Several studies have documented a latitudinal gradient in the shallow-water benthos, with decreasing richness toward the poles, but data on nematodes suggest that no latitudinal trend exists (see Snelgrove 1999, and references therein). A recent global assessment of local stream insect richness found peaks in generic richness near 30–40° N latitude, though the study compared individual stream surveys rather than summing values across all latitudinal bands (Vinson and Hawkins 2003).

4.2.3.4 Geographic Centers of Endemism and Evolutionary Distinctiveness

Interacting with geographic variation in species richness is variation among species in range size. Most species have small range sizes (Gaston 1996), although there is variation within this general pattern. Among the vertebrates, the more mobile species, such as birds, tend to have large ranges, while those of less mobile species, such as amphibians, generally have much smaller ranges. (See Figure 4.15.) Nevertheless, the shape of frequency distributions of species' range sizes appears to be similar across all taxa examined to date (with the median range size consistently an order of magnitude smaller than the mean), probably because shared processes are shaping these distributions (Gaston 1998). The small range size of most species has important consequences for the conservation of biological diversity, given the widespread inverse correlation between species' range size and extinction risk (Purvis et al. 2000b).

Not only do most species have small ranges, but these narrowly distributed species tend to co-occur in ''centers of endemism'' (Anderson 1994). Such centers have traditionally been identified through the overlap of restricted-range species, found using threshold approaches that consider only species with distributions smaller than a given percentile or area (Hall and Moreau 1962). Among vertebrates, almost all such centers of endemism lie in isolated or topographically varied regions. This is true for both geographical isolates, such as mountains and peninsulas, and real land isolates—islands (Baillie et al. 2004). Maybe as a consequence of this, they also tend to be near the coast.

The degree to which this pattern is found for other taxa, and in particular in the aquatic realm, is unclear, but evidence from analysis of scleractinian corals and selected fish, mollusks, and lob-

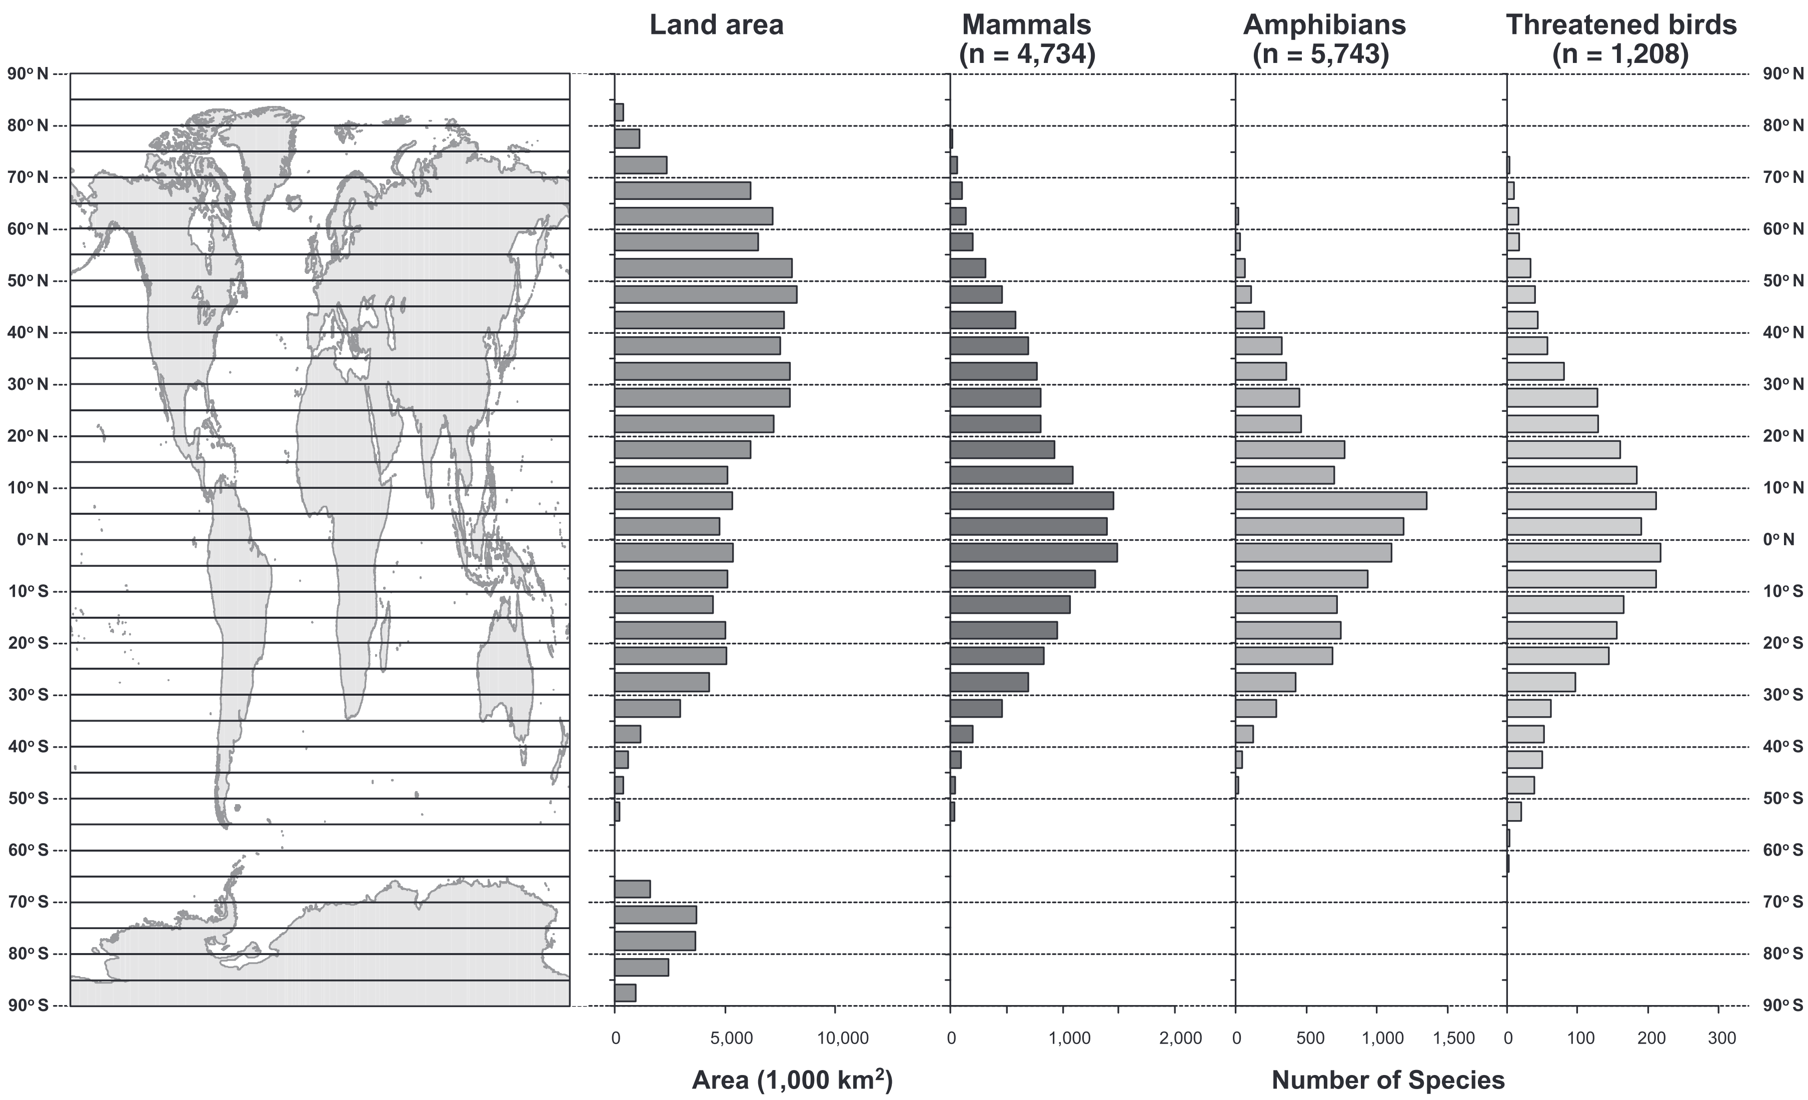

Figure 4.14. Variation in Species Richness across 5-degree Latitudinal Bands for All Mammal (Terrestrial Only), Amphibian, and Threatened Bird Species, Shown in Relation to Total Land Area per Latitudinal Band

sters suggests that coral reef centers of endemism also tend to be isolated, either by distance or by current flow (Roberts et al. 2002).

Centers of endemism are also concentrated in the tropics. Centers of endemism across birds, mammals, and amphibians tend to overlap (Baillie et al. 2004), and a broadly similar pattern is expected for plant endemism as well (WWF and IUCN 1994, 1995, 1997; Myers et al. 2000), although Mediterranean regions are more important as centers of endemism for plants than for vertebrates.

The range area and endemism patterns characteristic of the vertebrates (as well as of the plants, possibly) do not appear to represent the situation for invertebrates or microorganisms. Despite the fact that the data are extremely sparse and species have rarely been comprehensively identified locally, let alone mapped, various lines of evidence suggest that patterns of spatial turnover for these groups may be very different. While it is known that local endemism can be very high for some invertebrates in certain areas, this measure—calculated as the ratio of local to regional richness—varies widely. In Amazonia, for example, these ratios varied from about 80% for some moth species (indicating low endemism) to less than a few percent for earthworms (indicating very high endemism and spatial turnover) (Lavelle and Lapied 2003).

Species richness in soils is important for many ecosystem processes, but this habitat has been relatively poorly studied compared with aboveground systems (Fitter 2005). Microbial diversity is known to be high, though quantification at both local and global scales is limited by the technical issues of standardizing methods for defining microbial species. Richness of larger soil organism varies: some groups appear to be locally very diverse relative to global or regional diversity. This seems to be especially the case for smaller organisms and those with high dispersal abilities (through wind and water, for instance). Currently poorly understood, species richness in soils may be best explained through a better understanding of the temporal and spatial variability of the physical properties of soil as a habitat (Fitter 2005).

More generally, it has been suggested that the extent of local endemism correlates negatively with the dispersal capabilities of the taxon. Interpreting this pattern more broadly, and using extensive inventories of free-living protists and other microbial eukaryotes in a freshwater pond and a shallow marine bay, Finlay and Fenchel (2004) suggested that most organisms smaller than 1 millimeter occur worldwide wherever their required habitats are found. This can result from almost unrestricted dispersal driven by huge population sizes and very small body size, with the consequently low probability of local extinction. Organisms larger than 10 millimeters are much less abundant and rarely cosmopolitan. In Finlay and Fenchel's data, the 1–10 millimeter size range accommodates a transition from a more-or-less cosmopolitan to a regionally restricted distribution.

More detailed studies can reveal different spatial richness patterns within taxa and in different major biomes. For example, in one study of Neotropical mammals, dryland habitats were shown to be more diverse in endemic mammalian species than were the tropical forests (Mares 1992). Marine biota reveal a similar overall decline in diversity with increasing latitude to that observed in terrestrial realms, but the strength and slope of the gradient are subject to regional, habitat, and organismal features (Hillebrand 2004). Detailed studies of the species richness of fish and inverte-

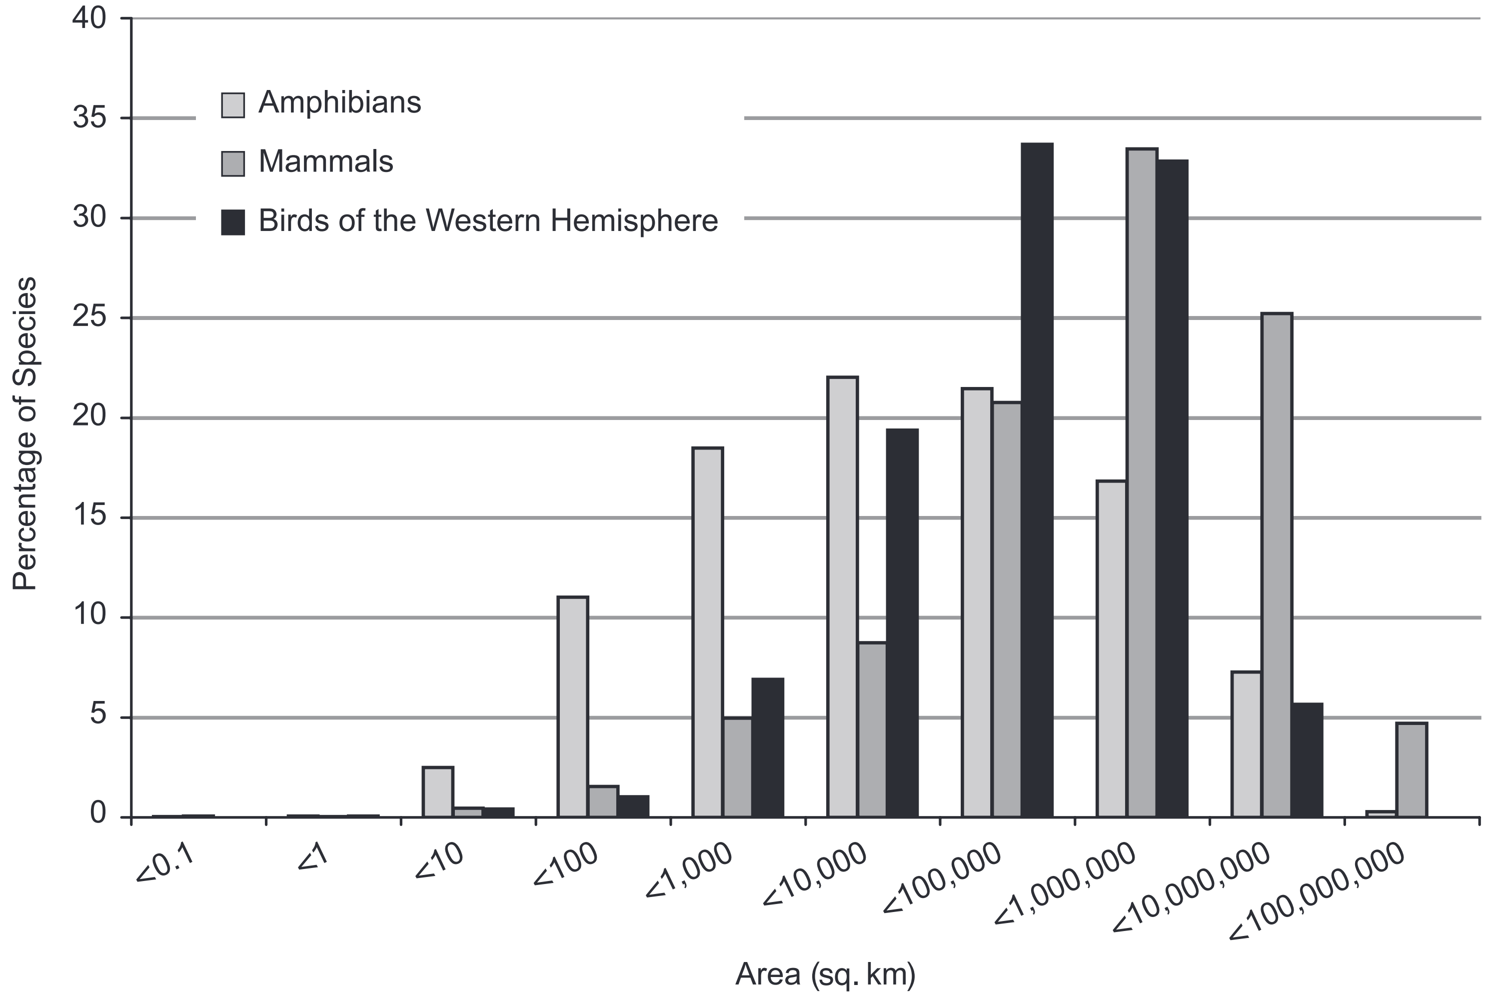

Figure 4.15. Frequency Distribution of Log10 Transformed Range Sizes for Mammal, Bird, and Amphibian Species. Mammal, terrestrial species only: n = 4,734, mean = 1.7×10^6 sq. km.; median = 2.5×10^5 sq. km.; bird, species endemic to the Western Hemisphere only: n = 3,980, mean = 2.1×10^6 sq. km., median = 4.0×10^5 sq. km.; amphibians: n = 4,141, mean = 3.2×10^5 sq. km., median = 1.3×10^4 sq. km. Data-deficient species are excluded. The log10 transformation makes the distribution look slightly left-skewed, but in fact the untransformed distribution is strongly right-skewed—that is, most species have very small range sizes.

brates in the Atlantic showed no clear trends but seemed to be related to sea-surface temperature or nitrate concentrations (Macpherson 2002).

In addition to the variability of species richness across geographic space, species richness varies over time. There is enormous variation between species in terms of their evolutionary age or the time since divergence from their closest relative (Faith 1992). Comprehensive phylogenetic data allowing evolutionary relationships to be drawn across entire species groups remain sparse. However, it is possible to use taxonomic relationships to approximate evolutionary relationships (Vane-Wright et al. 1991) in order to measure evolutionary distinctiveness among species. As with species richness, the few data that exist for terrestrial taxa indicate that tropical rainforests are regions with the greatest number of taxa with lengthy independent evolutionary history—for example, for plant families (Williams et al. 1994) and primates and carnivores (Sechrest et al. 2002). The applicability of this variation in higher taxon diversity in aquatic systems remains largely untested, however, and the massive phylum diversity in the sea (32 of 33 phyla occur in the sea, compared with just 12 on land) suggests some important differences here (May 1994).

Based on the notion that conserving global biodiversity requires preserving these spatial and temporal patterns, one recent analysis investigated the extent to which species diversity is covered by the current network of protected areas (Rodrigues et al. 2004). The analyses were based on distribution maps of 11,633 species of terrestrial vertebrates and found that at least 12% of all species analyzed do not occur in protected areas. This rises to 20% of threatened species, the loss of which would result in the disappearance of at least 38 threatened genera. (See Table 4.6.) Most species not found in protected areas are concentrated in tropical regions, and within these in centers of endemism: mainly islands and tropical mountain areas (Rodrigues et al. 2004).

Equivalent analyses are not possible yet for hyper-rich taxa such as plants or insects. However, the results for vertebrates indicate that taxa with higher levels of endemism (smaller range sizes) are proportionally less covered by protected areas; if so, the number of plant and insect species not found in any protected areas may be higher than for terrestrial vertebrates (Rodrigues et al. 2004). Freshwater species are also likely to be poorly covered, as most currently existing protected areas were not created focusing on freshwater habitats; even when species-rich freshwater systems occur in protected areas, they are not necessarily protected. The coverage of marine richness is surely tiny, with only about 0.5% of the world's oceans covered by protected areas (Chape et al. 2003).

4.2.4 Populations

4.2.4.1 Definition and Measurement

The term population is used in many different fields and at many scales, resulting in a number of different definitions (Wells and Richmond 1995). Most definitions identify a population as a geographical entity within a species that is distinguished either ecologically or genetically (Hughes et al. 1997). The genetically based definition (''Mendelian population'') is a reproductive community of sexual and cross-fertilizing individuals that share a common gene pool (Dobzhansky 1950). This is measured by assessing gene flow and genetic variation. The demographically based definition identifies populations based on groups of individuals

Table 4.6. Numbers of Gap Species and Genera of Mammals, Birds, Amphibians, and Freshwater Turtles and Tortoises in the Current Global Protected Area Network. (Adapted from Rodrigues et al. 2004) Values in parentheses are percentage of all taxa/threatened taxa analyzed within a given group. A threatened genus is one in which all species are threatened. For birds, it was only possible to evaluate gaps for threatened species and genera. Data for mammals (terrestrial species only) and threatened birds are as in Figure 4.25, and for amphibians, as in chapter 20; data for turtles based on the EMYSystem World Turtle Database 2003 (Iverson et al. 2003).

Group	Median Species Range Size	Number of Species	Numbers of Gap Species	Number of Genera	Numbers of Gap Genera
	(square kilometers)				
Threatened and non-threatened					
Mammals	247,341	4,735	258 (5.5%)	1,091	14 (1.3%)
Birds	n.a.	9,917	n.a.	2,085	n.a.
Turtles	309,172	273	21 (7.7%)	84	2 (2.4%)
Amphibians	7,944	5,454	913 (16.7%)	445	9 (2.0%)
Threatened					
Mammals	22,902	1,063	149 (14.0%)	194	14 (7.2%)
Birds	4,015	1,171	232 (19.8%)	128	15 (11.7%)
Turtles	167,611	119	12 (10.1%)	21	0 (0%)
Amphibians	896	1,543	411 (26.6%)	65	9 (13.9%)
All taxa analyzed	38,229	11,633	1,424 (12.2%)	n.a.	n.a.

that are sufficiently isolated to have independent population dynamics (Luck et al. 2003).

For some purposes, it is useful to categorize groups of organisms that may not correspond to a Mendelian or demographic population. For example, a group of bees in a field might be a population worthy of study. A population can also be defined as a unit that is important for conservation (conservation unit), such as evolutionary significant units, (Moritz 1994; Crandall et al. 2000) or for management (management units), such as fish stocks. Populations may also be defined in relation to the services that they provide. Thus, a service-providing unit would be that section of a population that is essential for providing a specific ecosystem service (Luck et al. 2003).

The definition of population used in the MA is more general and could lead to a number of different interpretations of a population's boundary. It is ''a group of individuals of the same species, occupying a defined area and usually isolated to some degree from other similar groups.'' Specification of the way in which the term population is being used is clearly important, given the great diversity of uses of the term.

4.2.4.2 Current Status of Population-Level Biodiversity

Populations are an important aspect of biodiversity as they are widely understandable units and are the ones most often monitored, exploited, and managed by people. Change in the status of populations provides insight into the status of genetic diversity, as the extinction of a population may represent the loss of unique genetic material. Populations are also the level at which we can best observe the relationship between biodiversity and ecosystem functioning. Most of the services provided by ecosystems require a large number of local populations (Hughes et al. 1997). For example, erosion control requires a number of different local plant populations. The loss of these local populations may have profound effects on erosion but limited impact on the overall status of the species involved. Thus it is important to focus on the condition of local populations if we are concerned with the maintenance of ecosystem processes and the provision of ecosystem services.

There are a number of ways that the condition of populations can be measured: the total number of populations in a given area, the total number of individuals within each population, the geographic distribution of populations, and the genetic diversity within a population or across populations (Luck et al. 2003). The most common measures are assessments of the distribution and abundance.

Populations are dynamic and are continually changing due to variation in births and deaths, immigration, and emigration. At any one time a species will likely have some populations that are increasing while others are decreasing, and it may be going extinct. A species can have many different structures, ranging from one continuous population of individuals, to disjunct populations of individuals with some exchange of individuals among them (known as a metapopulation) (Wells and Richmond 1995) and to disjunct populations that are completely isolated. Although there is great variation in abundance and distribution, the majority of species have small distributions (see Hughes et al. 1997) and therefore small populations. Small numbers of individuals or limited distributions result in such populations being more susceptible to extinction due to stochastic events (Gilpin and Soulé 1986; Lande 1993) such as a hurricane or fire, random demographic effects (Richter-Dyn and Goel 1972; Goodman 1987), the potential negative effects of limited genetic variability (Soulé 1980); or simply because a threat process such as habitat loss, exploitation, or introduced species is more likely to drive to extinction a species that is restricted in distribution or composed of few individuals.

Given the magnitude of populations, it is little surprise that there are few comprehensive global datasets. One example is the global inventory of population estimates and trends for waterbirds maintained since 1996 by Wetlands International. The most recent (third) edition (Wetlands International 2002) listed 2,271 biogeographic populations of 868 species of waterbirds. Other organizations, such as IUCN–the World Conservation Union, BirdLife International, NatureServe, UNEP World Conservation Monitoring Centre, FAO, and the European Nature Information System, collect data on species distributions and in some cases populations.

But the quality of the population data remains poor, and where data do exist the species tend to be either commercially important (such as fish stocks), charismatic (such as tigers and elephants), or threatened with extinction. There is also a significant regional bias, with the least data available in regions such as the tropics, where population numbers are likely the highest. Another useful source of data for trends on populations is the Global Population Dynamics Database (NERC 1999), with 5,000 separate time series available, ranging from annual counts of mammals or birds at individual sampling sites to weekly counts of zooplankton and other marine fauna.

Despite these limitations, population-level information is extremely useful for a range of applications for assessments of biodiversity and ecosystem services.

4.2.5 Genes and Genomes

Genes are sequences of nucleotides in a particular segment (locus) of a DNA molecule. Slightly different sequences (alleles) at a locus may result in protein variants differing in amino acid sequence, which may have different biochemical properties and thus cause phenotypic differences in morphology, physiology or the behavior of individuals. The allele that causes sickle-cell anemia in humans, for example, is the result of a single nucleotide substitution (adenine replaced by guanine) in the second position of the sixth codon of the beta-globin gene.

The complete genetic material of a species constitutes its genome. Eukaryotic genomes are organized into discrete longitudinal bodies in the nucleus, called chromosomes. The number, size, and shape of chromosomes within species are usually constant, but often differ between species. The human genome has 46 chromosomes and about 3.2 billion nucleotides, containing about 30,000 to 40,000 genes.

Biodiversity at the within-species level is usually measured by genetic diversity, which refers to the variety of alleles and allele combinations (genotypes) present in a species. Genetic diversity is reflected in the differences among individuals for many characters, from DNA sequences and proteins to behavioral and morphological traits such as eye, skin, and hair color in humans. This diversity allows populations to evolve by means of changing relative frequency of different alleles to cope with environmental changes, including new diseases, pests, parasites, competitors and predators, pollution, and global change. Naturally outbreeding species with large populations usually possess large stores of genetic diversity that confer differences among individuals in their responses to any environmental change.

Numerous species have been observed to evolve in response to environmental change as a result of genetic diversity. For example, industrial melanism has evolved in about 200 species of moths in areas subject to industrial pollution (Majerus 1998), and resistance to insecticides, herbicides, antibiotics, and other biocontrol agents has evolved in numerous ''pest'' species (McKenzie 1996).

The plentiful genetic diversity in many plant and animal species has been exploited extensively by humans through artificial selection to generate numerous breeds specialized in providing various service products such as meat, milk, eggs, fiber, guidance, hunting, companion, and aesthetics. (See also Chapter 10 for a discussion of genetic bioprospecting.) In contrast, species lacking genetic diversity usually have difficulty adapting to environmental changes and face increased risk of extinction because any environmental change that harms one individual is likely to harm other individuals to a similar extent. It has been demonstrated that inbred populations lacking genetic diversity have lower fitness and are less adaptable to new environmental challenges than the outbred populations they are derived from (Reed et al. 2003).

Genetic diversity is also important in maintaining the reproductive and survival ability (reproductive fitness) of individuals in outbreeding species even in a stable environment. In naturally outbreeding species, loss of genetic diversity usually leads to the homogeneity within individuals and thus reduced reproductive fitness (inbreeding depression) and increased risk of extinction. The U.S. endangered Florida panther, a subspecies restricted to a small relic population of approximately 60–70 individuals in southern Florida, has very low levels of genetic diversity revealed by different genetic markers. As a result, Florida panthers suffer from inbreeding depression evidenced by an extraordinarily high frequency of morphological abnormalities (''cow lick'' patterns in their fur and kinked tails), cardiac defects, undescended testis, and poor semen quality (Roelke et al. 1993).

Inbreeding depression, interacting with environmental and demographic stochasticity, is believed to contribute to the extinction of populations (Saccheri et al. 1998). In many inbred species and populations, the effects of inbreeding cease to be a problem, probably because most mutations deleterious under inbreeding become selectively removed, and the populations that survive are those that no longer possess such alleles. However, usually numerous populations become extinct and only a very small fraction survive this inbreeding and selection process (Frankham 1995).

A variety of methods can be used to measure genetic diversity. (See Box 4.2.)

Generally, plenty of genetic variation can be found within an outbreeding species at various organization levels, within individuals, between individuals within a population, and between populations. From a functional point of view, genetic variation can be classified as neutral and adaptive. The rich neutral genetic diversity is (arguably) revealed by using various molecular markers. In a typical large outbreeding species, about 80% of microsatellite loci are polymorphic, which have on average 5~10 distinctive alleles and heterozygosities of 0.6~0.8 (Frankham et al. 2002). The adaptive variation is also abundant within various species, although more difficult to identify and quantify than neutral variation. A study on the plant of white clover (*Trifolium repens*), a stoloniferous perennial species, provides a good example (Dirzo and Raven 2003). Individual plants taken from a population growing in a 1-hectare field in North Wales were screened for those genes associated with different characters of known adaptive importance. Among 50 clones selected from the field, all but a few differed in the combinations of genes affecting their fitness in nature.

The current magnitude and distribution of genetic diversity within a species depends on the effects and interactions of several evolutionary forces (such as mutation, selection, migration, and genetic drift) over the long evolutionary history of the species. Mutations are sudden changes in the nucleotide sequence of genes or the organization of genes in a genome and are the ultimate source of new genetic variation. Migration is the exchange of genes between populations. It changes the distribution of genetic variation directly and its magnitude indirectly when interacting with other evolutionary forces. Selection is the nonrandom transmission of alleles or allele combinations between generations, depending on their adaptive values in a given environment. It acts to either maintain or deplete genetic variation, depending on the way it operates. Genetic drift refers to the random changes in allele frequency over time due to sampling (reproduction and survival) in a genetically small population. It usually reduces genetic variation.

BOX 4.2

Measuring Genetic Diversity

Like biodiversity at other levels, genetic diversity within a species can be measured in many different ways. A simple measurement is the proportion of polymorphic loci among all loci sampled. A locus is regarded as polymorphic if two or more alleles coexist in the population and the most frequent allele has a frequency smaller than 99%. The proportions of polymorphic loci for proteins revealed by electrophoresis are about 30% in mammalian species.

Genetic diversity is measured more appropriately by allelic diversity (the average number of alleles per locus) and gene diversity (average heterozygosity across loci). These measures are not suitable for DNA sequences, however, because the extent of genetic variation at the DNA level is generally quite extensive. When long DNA sequences are considered, each sequence in the sample may be different from the other sequences. In such cases, these measures cannot discriminate among different loci or populations and are therefore no longer informative about genetic diversity. More appropriate measures of genetic diversity for DNA sequences are the average number of nucleotide differences between two homologous sequences randomly chosen from a population and the number of segregating nucleotide sites in a sample of sequences.

In practice, the genetic diversity of a population is assessed by sampling a number of individuals, genotyping them at some marker loci, and calculating one or more of the diversity measurements. Various markers, including enzymes and other proteins, microsatellites (simple sequence repeats or short tandom repeats), RAPD (random amplified polymorphic DNA), AFLP (amplified fragment length polymorphism), RFLP (restriction fragment length polymorphism), SNP (single nucleotide polymorphism), and DNA sequences, can be assayed to assess the genetic diversity of a population.

However, caution should be exercised in measuring and comparing the genetic diversity between different populations. First, any measurement of genetic diversity suffers from sampling errors. To obtain a reliable estimate, a large number of individuals should be sampled and genotyped at a large number of marker loci. Second, different measures of genetic diversity cannot be compared directly. Gene diversity, for example, is determined by not only allelic diversity but also allele frequencies. Third, different kinds of markers usually show different degrees of diversity in a population. Genetic diversity detected by microsatellites is typically much greater than that by proteins. In large outbreeding species, the number of alleles and heterozygosity per polymorphic locus is typically 5–10 and 0.6–0.8, respectively, for microsatellites but around 2 and 0.3, respectively, for proteins. When comparing the genetic diversity among populations, the same diversity measurement should be calculated for the same set of markers assayed from large samples.

A species is usually not homogenous genetically, and the genetic diversity within it can be partitioned at different hierarchic levels, between populations, between individuals within a population, and within individuals (for nonhaploids). Usually Wright's F statistics (Wright 1969) are used to describe the hierarchical genetic structure of a species. When the observed and expected heterozygosity averaged across populations of a species are denoted by H_I and H_S, respectively, and the expected heterozygosity for the entire species is denoted by H_T, the F statistics can be expressed as $F_{IS} = 1 - (H_I / H_S)$, $F_{ST} = 1 - (H_S / H_T)$, and $F_{IT} = 1 - (H_I / H_T)$ for a diallelic locus (Nei 1987). The heterozygosity (H_I, H_S, and H_T) and thus F statistics can be determined from various genetic markers. F_{IS} indicates the reduction of within-individual diversity relative to within-population diversity, and is determined mainly by the mating system (such as selfing, random mating) of the species. F_{ST} measures the between-population diversity as a proportion of the total diversity of the entire species. It is determined by the balance between the homogenizing force of migration among populations and the opposing force of local drift within populations. Habitat fragmentation may lead to excessive inbreeding within and differentiation between populations in the short term, and to extinction or speciation in the long term. F_{IT} indicates the reduction of within-individual diversity relative to the total diversity of the species, and is determined by both the mating system and the subdivision (isolation) of the species. The relationship of the three measures is $(1 - F_{IT}) = (1 - F_{IS})(1 - F_{ST})$.

Despite the well-established theory concerning the genetic structure of populations, empirical data are mostly limited to a relatively restricted set of species and situations, most commonly related to agriculture. Even less common are continuing assessments over time and space that would allow inferences about the large-scale and long-term trends in genetic diversity.

The genetic diversity harbored within a population or species varies greatly among loci, depending on the mutation and selection forces acting on them. Proteins, for example, generally have much less genetic variation due to their functional (selective) constraints and low mutation rate than molecular markers (such as microsatellites). For protein variation as assessed by electrophoresis, only about 28% loci are polymorphic and 7% loci are heterozygous in an average individual, both being much smaller than those for microsatellites (Frankham et al. 2002).

Genetic diversity is reduced at loci subject to directional selection and increased at loci under balancing selection, compared with that of neutral loci. For example, the major histocompatibility complex loci are involved in fighting disease, combating cancer, and controlling transplant acceptance or rejection and are thus believed to be under balancing selection. The MHC contains over 100 loci falling into three main groups, termed class I, II, and III. In vertebrates, MHC loci exhibit the highest polymorphism of all known functional loci. The human MHC (called HLA), for example, have 67, 149, and 35 alleles at the class I HLA-A, HLA-B, and HLA-C loci and 69, 29, and 179 at the class II DPB, DQB, and DRB loci, respectively (Hedrick and Kim 2000).

The amount of diversity also depends on the effective size (*Ne*) of a population, defined as the size of the idealized Wright-Fisher population (a diploid monoecious species with random mating including self-fertilization, with constant size and discrete generations and with an equal probability of reproduction and survival among individuals) that would give rise to the variance of change in gene frequency or the rate of inbreeding observed in the actual population under consideration. In populations with small to intermediate values of *Ne,* most loci are effectively neutral and their genetic diversity is predominantly determined by genetic drift and is lost at a rate of $1/2$ *Ne* per generation. Therefore large populations tend to have higher genetic diversity than small populations.

Reductions in the size of large populations will have major consequences for their diversity, even if the reduction is only for a short period. Hence, populations fluctuating in sizes tend to have less diversity than might be expected from their average size. Most endangered species and populations are found to possess lower genetic diversity than related, nonendangered species with large population sizes. Of 38 endangered mammals, birds, fish, insects, and plants, 32 had lower genetic diversity than related nonendangered species (Frankham 1995). A survey of allozyme genetic diversity in major taxa showed that the average heterozygosity within species is lower in vertebrates (6.4%) than in invertebrates (11.2%) or plants (23%), possibly due to the usually smaller population sizes in the former (Ward et al. 1992).

Local adaptation shapes the distribution of genetic diversity at selected loci among populations and geographic regions. A good example is the human sickle cell anemia allele, whose distribution (in Africa, the Mediterranean, and Asia) coincides with that of malaria. More variation is found between populations for loci that confer adaptations to local conditions. The distribution of diversity also depends on population structure and mating system. Species capable of long-range migration (such as flying birds and insects) tend to have small geographic intraspecific variation.

4.3 Anthropogenic Drivers

In the past, major changes to the world's biota appear to have been driven largely by processes extrinsic to life itself, such as climate change, tectonic movements leading to continental interchange, and even extra-terrestrial events in the case of the late Tertiary changes. (See Chapter 3.) While these processes remain important, current changes in biodiversity result primarily from processes intrinsic to life on Earth, and almost exclusively from human activities—rapid climate change, land use change, exploitation, pollution, pathogens, the introduction of alien species, and so on. These processes are known as anthropogenic direct drivers.

Having provided an overview of the current status of global diversity in the preceding sections, the current processes leading to change are considered here. Although the interactions are complex and often synergistic, it is important to distinguish among the main causes of biodiversity loss in order to identify, propose, and implement effective response strategies. The most important direct impacts on biodiversity are habitat destruction (Bawa and Dayanandan 1997; Laurance et al. 2001; Tilman et al. 2001), the introduction of alien species (Everett 2000; Levine 2000), overexploitation (Pauly et al. 2002; Hutchings and Reynolds 2004), disease (Daszak et al. 2001), pollution (Baillie et al. 2004), and climate change (Parmesan et al. 1999; McLaughlin et al. 2002; Walther et al. 2002; Thomas et al. 2004a, 2004b).

In order to provide information on existing linkages between anthropogenic drivers of change in species richness patterns and the rate and nature of such changes, indices for such linkages based on the most prominent anthropogenic drivers have been calculated based on expert knowledge. (See Figure 4.16 in Appendix A.) Although subjective, these indices are the best information currently available. Their aim is not to provide exact information on the existing trends between anthropogenic drivers and biodiversity patterns but rather to provide a general overview of such trends.

The figure indicates that habitat change is presently the most pervasive anthropogenic driver, with habitat fragmentation, introduced alien species, and exploitation being the next most common drivers. Threats such as disease, pollution, and climate change are identified as having slightly less impact, but it should be noted that these estimates are based on a projection until 2010. Threats such as disease (Baillie et al. 2004) and climate change will likely play a much greater role in the near future (Thomas et al. 2004a, 2004b). Where trend estimates have been made, all the main direct drivers are expected to increase in intensity. The various drivers have also been rated by the extent to which the process is believed to be reversible. Climate change and the introduction of invasive alien species are highlighted as the two drivers that are most difficult to reverse. Certainty of these estimates is highest for the most common drivers and interactions at the species, population, and biome level and lowest at the genetic level.

4.3.1 Habitat Change, Loss, and Degradation

The land use requirements of a large and growing human population have led to very high levels of conversion of natural habitat. Loss of habitat area through clearing or degradation is currently the primary cause of range declines in species and populations. When areas of high human activity and significant human land transformation (Easterling et al. 2001; Harcourt et al. 2001) are spatially congruent with areas of high species richness or endemism (Balmford and Long 1994; Fjeldså and Rahbek 1998; Freitag et al. 1998; Ceballos and Ehrlich 2002), the negative implications for biodiversity are greatly exacerbated.

Agricultural land is expanding in about 70% of countries, declining in 25%, and roughly static in 5% (FAO 2003). Forest cover alone is estimated to have been reduced by approximately 40% in historical times (FAO 1997). This decline continues, with about 14.6 million hectares of forest destroyed each year in the 1990s, resulting in a 4.2% loss of natural forest during this time period (FAO 2000b). Other habitats types have experienced even greater change in historical times, such as tropical, sub-tropical, and temperate grasslands, savannas, and shrublands as well as flooded grasslands. (Habitat change is described further later in this chapter.)

A major issue in habitat and land use change is habitat fragmentation, which has severe consequences for many species. Fragmentation is caused by natural disturbance (fires or wind, for instance) or by human-driven land use change and habitat loss, such as the clearing of natural vegetation for agriculture or road construction, which leads previously continuous habitats to become divided. Larger remnants, and remnants that are close to other remnants, are less affected by fragmentation. Small fragments of habitat can only support small species populations, which therefore tend to be vulnerable to extinction. Moreover, small fragments of habitat may have altered interior habitat. Habitat along the edge of a fragment has a different climate and favors different species to the interior. Small fragments are therefore unfavorable for species that require interior habitat. Fragmentation affects all biomes, including, in particular, forests. Globally, over half of the temperate broadleaf and mixed forest biome and nearly one quarter of the tropical rain forest biome have been fragmented or removed by humans, as opposed to only 4% of the boreal forest. Overall, Europe has faced the most human-caused fragmentation and South America has the least (Wade et al. 2003).

Species that disappear most quickly from fragmented terrestrial landscapes often have large area requirements and are primary-habitat specialists that avoid the modified habitats (Tilman et al. 1994; Laurance et al. 2001). Some species are also particularly vulnerable to so-called edge effects, where the area of land at the edge of the habitat patch is altered and less suitable for the species (Woodroffe and Ginsberg 1998). Species that are specialized to particular habitats and those with poor dispersal ability suffer from fragmentation more than generalist species with good dispersal ability. Species with naturally unstable populations may also be intrinsically vulnerable to fragmentation, presumably because their fluctuating populations are likely to fall below some critical threshold. Likewise, organisms with low rates of population growth may be less likely to recover from population declines and suffer a greater loss of genetic diversity (via genetic drift and inbreeding) during population bottlenecks.

River fragmentation, which is the interruption of a river's natural flow by dams, inter-basin transfers, or water withdrawal, is an indicator of the degree that rivers have been modified by humans (Ward and Stanford 1989). An analysis of river fragmentation and flow regulation (Revenga et al. 2000) assessing 227 large river systems around the world, with the exception of South Asia and Australia, shows that 60% of the world's large rivers are highly or moderately fragmented. Waterfalls, rapids, riparian vegetation, and wetlands are some of the habitats that disappear when rivers are regulated or impounded (Dynesius 1994).

Fragmentation has also affected 90% of the water volume in these rivers. All river systems with parts of their basins in arid areas or that have internal drainage systems are highly fragmented. The only remaining large free-flowing rivers in the world are found in the tundra regions of North America and Russia and in smaller coastal basins in Africa and Latin America. (See Chapter 20.)

Even though dam construction has greatly slowed in many industrial countries (and some countries, such as the United States, are even decommissioning a few dams), the demand and untapped potential for dams is still high in many parts of the world, particularly in Asia, Latin America, and Turkey. As of 2003, around 1,500 dams over 60 meters are planned or under construction around the world (WWF and WRI 2004). The basins with the largest number of dams planned or under construction include the Yangtze River in China with 46 dams, La Plata basin in Argentina with 27 dams, and the Tigris and Euphrates basin with 26 (WWF and WRI 2004).

While many species disappear or decline in fragmented habitats, others can increase dramatically. Species that favor habitat edges or disturbed habitats, that readily tolerate the surrounding matrix, or whose predators or competitors have declined often become more abundant after fragmentation (Laurance et al. 2001). For instance, common species that adapt well to standing water habitats often replace stream-adapted species in river systems with many dams. In addition, the matrix commonly supports abundant populations of exotic weeds or generalist animals that can invade habitat fragments.

4.3.2 Invasive Alien Species

Humans have been responsible for introducing animals and plants to new areas for thousands of years (Milberg and Tyrberg 1993). With improvements in transportation and the globalization of trade, however, the introduction of non-native species to new habitats or ecosystems has greatly increased (e.g., Gaston et al. 2003). Most introductions fail (Mack et al. 2000), but when they are successful and become established as invasive alien species—defined as those species introduced outside their normal area of distribution whose establishment and spread modify ecosystems, habitats, or species, with or without economic or environmental harm—they can have a major impact on native biodiversity. Invasive alien species may threaten native species as direct predators or competitors, as vectors of disease, or by modifying the habitat (for example, the impact of herbivores on plant communities) or altering native species dynamics.

The causes of introductions are many. Some are intentional (a species released for hunting or introduced as a biological control, for example), but more commonly they are unintentional (introduced with traded goods such as lumber, for instance, or in the ballast water of ships or through the pet trade). Although species that have recently extended their native range or have experienced major changes in species dynamics within their native range are not considered as alien invasive species, the negative impact on other aspects of biodiversity can be just as serious.

Homogenization is partially a consequence of invasive alien species, along with the extirpation of native endemic species and habitat alterations (Rahel 2002). For example, European settlers introduced fish into North America for sport and for food, and fish faunas across the continental United States have become more similar through time. On average, pairs of states have 15.4 more species in common now than before European settlement of North America. The 89 pairs of states that formerly had no species in common now share an average of 25.2 species. Introductions have played a larger role than extirpations of local endemic species in homogenizing fish faunas (Rahel 2000). At the same time, North American fish species (such as the rainbow trout) have become established in Europe, leading to further homogenization of fish faunas between Europe and North America.

Invasive alien species have been a major cause of extinction, especially on islands and in freshwater habitat. In the latter, the introduction of alien species is the second leading cause of species extinction (Hill et al. 1997; Harrison and Stiassny 1999), and on islands it compares with habitat destruction as the lead cause of extinction over the past 20 years (Baillie et al. 2004). Islands such as Guam (Fritts and Rodda 1998; Wiles et al. 2003), Hawaii (Atkinson et al. 2000), New Zealand (Atkinson and Cameron 1993), and the Mascarenes (Cheke 1987) provide clear examples of the devastating influence invasive alien species continue to have on native biodiversity. Awareness about the importance of stemming the tide of invasive alien species is increasing, but effective implementation of preventative measures is lacking (Simberloff 2000). The rate of introductions continues to be extremely high; for example, in New Zealand plant introductions alone have occurred at a rate of 11 species per year since European settlement in 1840 (Atkinson and Cameron 1993).

The water hyacinth (*Eichhorina crassipes)* and the European zebra mussel (*Dreissena polymorpha*) are just two examples of the many alien species that have significantly altered the ecosystems in which they have successfully invaded, with major implications for native biodiversity as well as economic ramifications.

The water hyacinth has had negative effects on fisheries, hydroelectric production, agriculture, human health, and economies across the tropics. A native to the Amazon basin, it has invaded more than 50 countries on five continents, sometimes taking over entire river and lake systems (Barrett 1989). It was introduced both intentionally and unintentionally, specifically to help purify water from waste treatment facilities and for use as an ornamental aquarium plant. Lake Victoria, which borders Uganda, Tanzania, and Kenya, is the most dramatic example of the havoc water hyacinth can wreak on an ecosystem. First sighted in 1989, water hyacinth now covers 90% of Lake Victoria's shoreline. This thick mat of water hyacinth competes with the native plants, fish, and frogs for oxygen, often causing asphyxiation and massive die-offs (see www.state.gov/g/oes/ocns/inv/cs/2299.htm) and costing local economies millions of dollars (McNeely 1996).

In 1988 the European zebra mussel was transported to Lake St. Clair (in the United States and Canada) in the ballast water of a transatlantic freighter. Within 10 years the mussel had spread to all five neighboring great lakes (USGS 2000). The mussels form massive colonies and tend to clog underwater structures, such as intake pipes for power plants and other industrial infrastructure. Their efficiency at filtering the water and removing alga and microorganisms has greatly increased clarity and also resulted in reduced food availability for larval fish and many invertebrates, which could cause a shift in fish species composition (Griffiths 1993). The mussel has also greatly reduced the population of native mussels (Masteller and Schloesser 1991). The economic costs of these alien mussels for U.S. and Canadian water users has been estimated by the U.S. Fish and Wildlife Services at about $5 billion over the next 10 years (USGS 2000).

4.3.3 Introduced Pathogens

As with alien species, the process of globalization, with increased international travel and commerce, has greatly facilitated the spread of pathogens. This process has been further assisted by an increase in the conditions under which pathogens thrive, such as very high population densities in domestic plants or animals, or species living in suboptimal conditions due to rapid environmental change. As these processes intensify, newly emerging diseases may become an even greater threat to species (Daszak et al. 2001). When diseases become established in a population, initial declines may be followed by chronic population depression, which in turn increases the population's vulnerability to extinction. In some cases pathogens can cause catastrophic depopulation of the naïve host species and even extinction (Daszak et al. 2000).

Parallels between human and wildlife emerging infectious diseases extend to early human colonization of the globe and the dissemination of exotic pathogens. For instance, the impacts within Africa of rinderpest were severe. Transmitted by a highly pathogenic morbillivirus, enzootic to Asia, the disease was introduced into Africa in 1889. It wiped out more than 90% of the Kenya's buffalo population and had secondary effects on predator populations and local extinctions of the tsetse fly (Daszak et al. 2000). It also had serious consequences for the human population, leading to famine and subsequently the spread of tsetse. (See Chapter 14 for more on human infectious disease agents.)

Over the last decade, a number of pathogens introduced directly or indirectly by human activities have caused large-scale declines in several wildlife species (Dobson and Foufopoulos 2001). One example is the 20% decline of the lion population in the Serengeti, Tanzania (Roelke-Parker et al. 1996). The epidemic was caused by the canine distemper virus, transmitted to the wild carnivores from domestic dogs introduced by the local communities surrounding the park. African wild dogs are also believed to have been affected by this virus. Their local extinction from the Serengeti in 1991 was concurrent with epizootic canine distemper in sympatric domestic dogs (Roelke-Parker et al. 1996). More surprisingly, canine distemper has also spread from the terrestrial to aquatic habitats. A canine distemper virus infection has caused mortality in seals on a number of occasions in the former Soviet Republics (Stone 2000).

Infectious disease is currently a serious problem in aquaculture, not only to the fish being farmed but to wild populations as well. When infected farmed fish escape from aquaculture facilities, they can transmit these diseases and parasites to wild stocks, creating further pressure on them. For instance, infectious salmon anemia, a deadly disease affecting Atlantic salmon, poses a serious threat to the salmon farming industry. It was first detected in Norwegian salmon farms in 1984, from which it is believed to have spread to other areas, being detected in Canadian salmon (1996), in Scotland (1999), and in U.S. farms (2001) (Doubleday 2001; Goldburg et al. 2001). Norwegian field studies observed that wild salmon often become heavily infected with sea lice (parasites that eat salmon flesh) while migrating through coastal waters, with the highest infection levels occurring in salmon-farming areas (Goldburg et al. 2001).

Introduced diseases have been implicated in the local extinction of a number of species and the global (species) extinction of seven amphibians, three birds, and one plant over the past 20 years (Baillie et al. 2004). However, the first proven example of extinction by infection occurred when a microsporidian parasite killed the captive remnant population of the Polynesian tree snail, *Partula turgida* (Daszak et al. 2000). The actual number of amphibians that have gone extinct due to disease is almost certainly much higher than seven species, as 122 species have been identified as "possibly extinct" (not formally "extinct" until extensive surveys to establish their disappearance have been completed), with 113 having disappeared since 1980. The explanation for this rapid decline is not well understood, but disease and climate change are the most commonly cited reasons (Stuart et al. 2004). In 1998, a previously unknown chytrid fungus named *Batrachochytrium dendrobatidis* was discovered and is believed to be a major cause of amphibian decline (Berger et al. 1998; Longcore et al. 1999).

4.3.4 Overexploitation

People have exploited wildlife throughout history, and even in ancient times the extinction of some species was caused through unsustainable harvesting levels. However, exploitation pressures have increased with the growing human population. Although sustainable exploitation of many species is theoretically achievable, many factors conspire to make it hard to achieve in practice, and overexploitation remains a serious threat to many species and populations. Among the most commonly overexploited species or groups of species are marine fish and invertebrates (FAO 2000a, see section 5.5.1.5), trees, animals hunted for bushmeat, and plants and animals harvested for the medicinal and pet trade (IIED and Traffic 2002; TRAFFIC 2002).

Most industrial fisheries are either fully or overexploited (FAO 2000a), as documented later in this chapter. An increasing number of studies are highlighting the inherent vulnerability of marine species to overexploitation (Hoenig and Gruber 1990; Griffiths 1993; Huntsman et al. 1999; Reynolds et al. 2001; Dulvy et al. 2003). Particularly susceptible species tend to be both valuable and relatively easy to catch as well as having relatively "slow" life history strategies (Reynolds et al. 2002). Thus species such as large groupers, croakers, sharks, and skates are particularly vulnerable (Baillie et al. 2004). Although the response of species and ecosystems to severe depletions is extremely complex (Jackson et al. 2001; Hutchings and Reynolds 2004), there is increasing evidence that many marine populations do not recover from severe depletion, even when fishing has stopped (Hutchings 2000; Baillie et al. 2004; Hutchings and Reynolds 2004). (See Chapter 18 for more on exploitation of marine fisheries.)

Many of the current concerns with overexploitation of bushmeat—wild meat taken from the forests by local people for income or subsistence—are similar to those of fisheries, where sustainable levels of exploitation remain poorly understood and where the offtake is difficult to effectively manage. Although the true extent of exploitations is poorly known, it is clear that rates of offtake are extremely high in the tropical forest throughout the world (Anstey 1991; Robinson and Redford 1991; Bennett et al. 2000; FitzGibbon et al. 2000). Unsustainable levels of hunting are believed to be of great concern for a large number of target species, many of which are extremely high profile, such as gorillas, chimpanzees, and elephants. The loss of species or populations due to exploitation will not only have ecological implications, it will greatly affect the food security and livelihoods of the communities that depend on these resources.

The trade in wild plants and animals and their derivatives is poorly documented but is estimated at nearly $160 billion (IIED and Traffic 2002). It ranges from live animals for the food and pet trade (such as parrots, tropical fish, and turtles) to ornamental plants and timber (such as rattan, orchids, and mahogany). An array of wildlife products and derivatives, such as food, exotic leather goods, musical instruments, and even medicines, can be found in markets around the world.

Because the trade in wild animals and plants crosses borders between countries, the effort to regulate it requires international cooperation to safeguard certain species from overexploitation. The Convention on International Trade in Endangered Species of Wild Fauna and Flora is an international governmental agreement aimed at ensuring that international commercial trade in species of wild animals and plants does not threaten their survival. Today CITES provides varying degrees of protection to more than 30,000 species of animals and plants, whether they are traded as live specimens, fur coats, or dried herbs. CITES only applies to international trade, leaving most of the national trade in wild species poorly regulated and monitored in many countries.

In freshwater systems, trade in wild plants and animals is seriously threatening some species. Three quarters of Asia's freshwater turtles, for instance, are listed as threatened, many due to increase in trade. For example, on average there are over 30 tons per year of all imported turtle shells into Taiwan alone. The total trade may add up to several times this amount (TRAFFIC 2002).

4.3.5 Climate Change

The detectable impact of human actions on the rate and direction of global environmental change is already being felt on global biodiversity. Modern climate change may have been a contributing factor in the extinction of at least one species, the golden toad (*Bufo periglenes*) (Pounds et al. 1999), and present evidence suggests strong and persistent effects of such change on both plants and animals, evidenced by substantial changes to the phenology and distribution of many taxa (Parmesan and Yohe 2003; Root et al. 2003). For example, there have been substantial advances in the dates of bird nesting, budburst, and migrant arrivals across the Holarctic, and in the same region both birds and butterflies have shown considerable northward range expansions (Parmesan et al. 1999; Walther et al. 2002). Climate change is not likely to affect all species similarly. Certain species or communities will be more prone to extinction than others due to the direct or underlying effects of such change, and risk of extinction will increase especially for those species that are already vulnerable. Vulnerable species often have one or more of the following features: limited climatic ranges, restricted habitat requirements, reduced mobility, or isolated or small populations.

Best estimates suggest that present climate change trends will continue (Watson 2002) and that these changes will have substantial impacts on biodiversity, with some scenarios indicating that as many as 30% of species will be lost as a consequence of such change (Thomas et al. 2004a). Although past climate variation may not have caused many extinctions (Huntley and Webb 1989; Roy et al. 1996), modern change is likely to have a considerably greater effect owing to interactions between rapid climate change and substantial anthropogenic habitat destruction and alteration (Hill et al. 1999; Sala et al. 2000; Warren et al. 2001; Walther et al. 2002). See Chapter 3 of this volume and Chapter 7 of the *Scenarios* volume for more information on climate change and other drivers.

4.3.6 Changing Threat Processes over Time

An examination of bird extinctions over the past 500 years identifies introduced species as the main cause of bird extinction, followed by exploitation and then habitat loss (Baillie et al. 2004). However, dominant drivers attributed to currently threatened birds highlight habitat loss as the greatest threat, followed by exploitation and, last, introduced species (Baillie et al. 2004; BirdLife 2004b). This shift in dominant drivers of bird extinction can be explained by the rapid increase in habitat destruction over the last century. This, combined with other threat processes, has resulted in a greater number of mainland bird species becoming threatened with extinction (see BirdLife 2004b).

Just as habitat change has replaced introduced species as the dominant cause of extinction for birds, the dominant driver could easily change again in the near future. For example, climate change could become the dominant cause of extinction (Thomas et al. 2004a). However, as the main drivers of extinction continue to intensify, it will be increasingly difficult to disentangle the main cause of extinction, as the interactions between them will become increasingly complex.

4.4 Recent Trends in Biodiversity

The beginning of this chapter presented an overview of the status of different components of biodiversity. This section presents information about rates and patterns of change in each of these components. Because of the lack of data, genetic diversity is omitted from consideration here. Although genetic diversity is lost from declining and fragmented populations at rates that can be estimated and measured, hardly any data exist to estimate this or its impact in most places and species. As more complete information is available regarding genetic diversity of cultivated species, a further description of agricultural genetic diversity can be found in Chapter 26.

Even for better-studied taxa and for the data-rich parts of the world, monitoring schemes that allow for a quantification of biodiversity trends have been operating for a few decades at most. The initial ecological conditions at the time such schemes were implemented are used as baselines against which subsequent changes are assessed. However, in most cases these are not "pristine" conditions, and in fact may correspond to ecosystems that have already suffered significant change in their biodiversity levels. The "shifting baseline syndrome" was first described for fisheries science (Pauly 1995; Sheppard 1995; Jackson 2001; Jackson et al. 2001), with the observation that every new generation of scientists accepts as a baseline the stock size and species composition that occurred at the beginning of their careers, using this to evaluate changes and propose management recommendations. The implication of the shifting baseline syndrome not only for fisheries but also for conservation science in general is that as biodiversity erodes, so do our targets for its conservation (Balmford 1999).

Our ignorance on the characteristics of pristine ecosystems often makes it difficult to understand whether observed short-term changes in biodiversity correspond to true trends or to noise created by natural fluctuations. This reinforces the need for long-term monitoring programs, as well as making the best use of existing historical evidence, even if only as anecdotal records (Pauly 1995). Some of the more important datasets collected on trends in the amount of biodiversity are presented here, although it is very difficult to extrapolate from any of these to infer a trend in the amount of species-level biodiversity, either globally or regionally.

4.4.1 Populations

Species are generally composed of a number of populations. Therefore, assessing all populations within a species is the same thing as a species-level assessment. In some cases, a species comprises only one population. Thus there is natural overlap when assessing trends in populations and species. The distinction between the two is further blurred by the fact that many studies monitor the status of all populations that make up a species distribution, as well as taxa where only a subset of populations are represented. Here we focus on large-scale analyses that provide insight into trends in either the distribution or abundance of populations, and in many cases the examples contain species-level assessments. We first discuss population trends on a global scale and then highlight trends in specific taxonomic groups. Where possible, we focus on long-term studies, as for these there is greater certainty that observed trends are not the result of short-term fluctuations (Ranta et al. 1997).

Little is known about the rate of loss of populations on a global scale. Hughes et al. (1997) present an extremely rough estimate of the global loss of populations by first estimating the total number of populations in the world (their intermediate estimate is about 3 billion populations). They then estimate a rate of habitat loss in the tropics of 0.08%, and conclude that roughly 16 million populations are being lost per year in tropical forests alone.

The best available estimate of global trends in populations is WWF's Living Planet Index. Time-series population data has been collected from a number of sources over the past 30 years. The LPI is calculated by averaging three ecosystem-based population indices, including 555 terrestrial species, 323 freshwater species, and 267 marine species (Loh 2002; Loh and Wackermagel 2004). Between 1970 and 2000, the LPI dropped by approximately 40%. During this time there were declines of approximately 30% in the terrestrial species population index, 30% in the marine species population index, and 50% in the freshwater species population index. The dependence of the index on relatively long-term datasets available in the published literature results in a strong taxonomic and regional bias. It also means many small, remote, and often threatened populations being overlooked. Such populations are difficult to monitor, and thus measures of their abundance are rarely consistently reported (Gaston 1994). However, it does clearly demonstrate that for well-known taxa and regions, the trends are consistently downward.

4.4.1.1 Birds

Although birds are one of the best-studied groups, we lack data on population trends for the majority of species. However, important studies of specific regions or groups of birds provide insight into overall trends. Here the findings are presented from a few examples of the large-scale bird population studies, including a global study of waterbird populations, a large-scale study of bird populations in Europe, and a study of range decline in Central and South America.

Waterbirds—bird species that are ecologically dependent on wetlands and other freshwater habitats—and particularly migratory waterbirds are probably one of the best-studied groups of animals on Earth (Rose and Scott 1997). Global-level information on the status and trends of waterbirds by biogeographic population is compiled and regularly updated by Wetlands International through its International Waterbird Census and published as *Waterbird Population Estimates* (Wetlands International, 2002). More detailed information is also available for waterbird species in North America, compiled by the U.S. Geological Service, and for the Western Palaearctic and Southwest Asia, prepared by Wetlands International (e.g., Delany et al. 1999). For African-Eurasian waterbird populations, comprehensive analyses have been compiled for ducks, geese, and swans (Anatidae) (e.g., Scott and Rose 1996) and waders (Charadrii) (Stroud et al. 2004). Although distributional data are available for other regions, comprehensive information on status and trends of waterbirds is generally lacking (Revenga and Kura 2003).

Despite the variations in availability of information, trend data show that in every region the proportion of populations of waterbirds in decline exceeds those that are increasing. At the global level, 41 % of known populations are decreasing, 36 % are stable, and 19 % are increasing (Wetlands International 2002). (See Table 4.7.) Asia and Oceania are the regions of highest concern for the conservation of waterbirds. In Africa and the Neotropics, more than twice as many known populations are decreasing than increasing. In Europe and North America, waterbird population numbers seem to be more equally distributed among the three categories (stable, increasing, and decreasing). It is important to note, however, that these data are more readily available for smaller populations, which are more likely to be in decline.

Trends in bird populations more generally have been best documented in Europe, North America, and Australia. In Europe, trend data are available from the Pan-European Common Bird Monitoring Scheme, currently implemented in 18 countries (Gregory et al. 2003). The data show trends in common in widespread farmland and woodland birds since 1980. (See Figure 4.17.) On average, populations of woodland birds in Europe have remained stable over the last 20 years, although their numbers have fluctuated in response to winter conditions (trend 1980–2002 = −2%). Populations of common and widespread farmland birds, in contrast, have declined sharply, especially in the 1980s, and the downward trend continues at a slower rate (trend 1980–2002 = −29%). This rapid decrease is believed to reflect a severe deterioration in the quality of farmland habitats in Europe, affecting both birds and other elements of biodiversity.

In Central and South America, where population-level data on bird species are scarce, BirdLife International has devised a different approach to measuring the decline in species richness. In Figure 4.18 (in Appendix A), a density map depicts the areas where threatened bird species used to occur but now no longer do so (mapped at a resolution of 1/4 degree grid cell) (BirdLife 2004b). This measures a decline in occupancy (measured as a decline in extent of occurrence), a variable typically correlated to abundance (Brown 1984; He and Gaston 2000). In the Neotropics, some 230 globally threatened birds—approximately 50% of threatened species that occur in the region—have become extinct across significant parts of their range. (This high proportion is not surprising, as many threatened species are classified as so based on declining trends in their ranges/populations (IUCN 2001)). On average, approximately 30% of their total ranges has been lost, varying from tiny areas of less than 100 square kilometers (approximately 40 species) to considerable areas of greater than 20,000 square kilometers (approximately 70 species).

This analysis is based on a review of areas or sites where species were recorded historically but not recently, or where habitat loss or other threats seem certain to have resulted in their disappearance. In some areas, up to 20 species have disappeared—the highest recorded density of local extirpations of globally threatened bird species in the world. Losses of range are inevitably associated with a reduction in the total numbers of individuals and hence, an increasing risk of extinction.

4.4.1.2 Mammals

Global estimates of changes in populations exist for many mammals. Ceballos and Ehrlich (2002) used a dataset consisting of all ranges of terrestrial mammals of Australia and subsets of ranges for terrestrial mammals of Africa, South East Asia, Europe, and North and South America, consisting of roughly 4% of about 4,650

Table 4.7. Waterbird Population Trends (Revenga and Kura 2003, based on Wetlands International 2002)

Geographic Region	Population Trend				Number of Populations		
	Stable	Increasing	Decreasing	Extinct	With Known Trend	Lacking Trend	Total Number
Africa	141	62	172	18[a]	384	227	611
Europe	83	81	100	0	257	89	346
Asia	65	44	164	6	279	418	697
Oceania	51	11	42	28	138	241	379
Neotropics	100	39	88	6	234	306	540
North America	88	62	68	2	220	124	344
Global total[b]	**404**	**216**	**461**	**60**	**1,138**	**1,133**	**2,271**

[a] Most extinctions in Africa have been on small islands.

[b] Global totals do not equal the sum of the column because a population is often distributed in more than one Ramsar region.

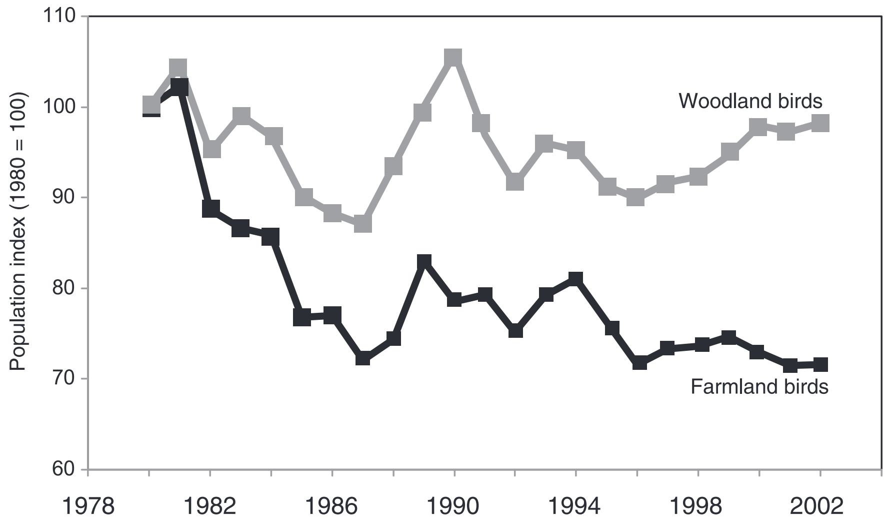

Figure 4.17. Trends in Common Farmland and Woodland Birds in Europe since 1980 (data courtesy of the Pan-European Common Bird Monitoring Scheme)

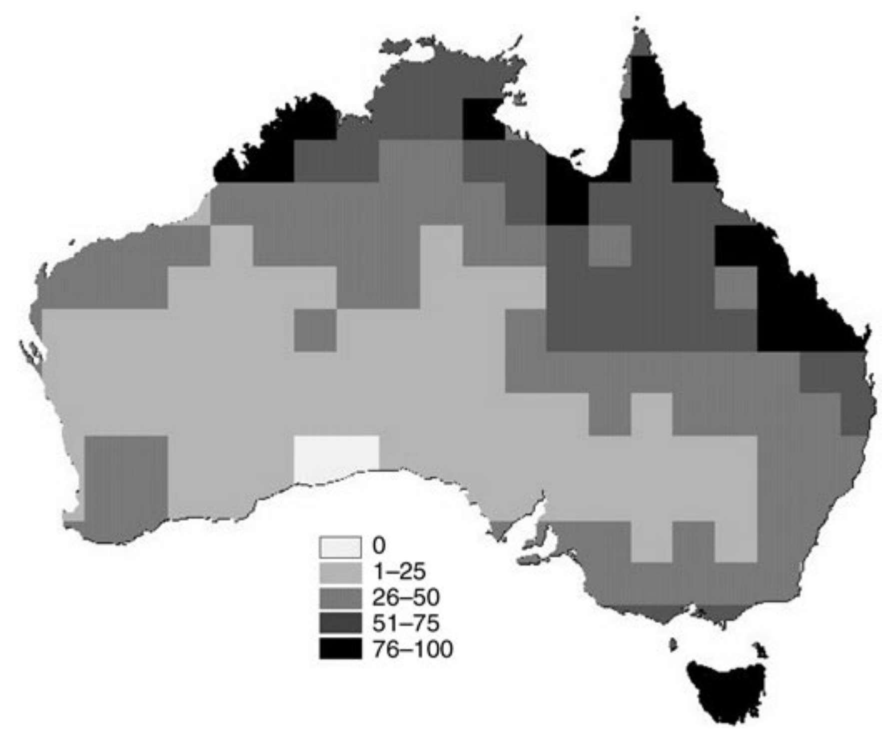

Figure 4.19. Percentage of Mammals That Have Disappeared from Each 2 Degree by 2 Degree Quadrant in Australia during Historic Times (Ceballos and Ehrlich 2002)

known mammal species to compare historic and present ranges. In their sample, declining mammal species had collectively lost 50% of their continental populations as judged by loss in area. In Australia, where the data were most comprehensive, the proportion of declining species was 22%. The greatest population declines occurred in northeastern Australia and Tazmania. (See Figure 4.19.) If this were representative of all regions, it would suggest a greater than 10% loss of mammal populations. However, this may not be indicative of other areas, as Australian mammals have been among the most prone to extinction (Hilton-Taylor 2000).

There are a few important datasets on population trends in large mammals. For example, the IUCN Species Survival Commission has monitored trends in rhinoceros populations in Africa and Asia for over 20 years (Khan 1989; Cumming et al. 1990; Foose and van Strien 1997; Emslie and Brooks 1999). This dataset reveals highly divergent trends between the different rhinoceros species. Two species, the southern white rhinoceros (*Ceratotherium simum simum*) and the Indian rhinoceros (*Rhinoceros unicornis*), have experienced long-term increases for the last century under very strict conservation and management regimes, whereas the black rhinoceros (*Diceros bicornis*), northern white rhinoceros (*C. simum cottoni*), and the Sumatran rhinoceros (*Dicerorhinus sumatrensis*) have suffered from catastrophic declines, mainly due to illegal hunting. In the case of the black rhinoceros, intensive conservation measures have stabilized the situation since the early 1990s. For the northern white rhinoceros and the Javan rhinoceros (*R. sondaicus*), the trends are uncertain (both have perilously small populations).

Whale populations are monitored by the Scientific Committee of the International Whaling Commission. Their data indicate significantly increasing population trends for four whale stocks involving three species: gray whale *Eschrichtius robustus* eastern north Pacific; bowhead whale *Balaena mysticetus* Bering-Chukchi-Beaufort Seas stock; humpback whale *Megaptera novaeangliae* western north Atlantic; and humpback whale *M. novaeangliae* Southern Hemisphere south of 60° S in summer. These increasing trends reflect population recoveries following a period of very heavy harvesting pressure; at present, the datasets are not available to compare current whale population levels with historical estimates (although recalculation of the whaling commission's catch data might make this possible in the future). So although these data indicate some recovery in certain whale populations, it is in the context of major overall declines since the onset of commercial whaling. Recent analyses based on genetic markers indicate that these declines may have been even more dramatic than previously thought (Roman and Palumbi 2003).

While there are few strictly freshwater mammal species, some are considered freshwater system–dependent or semi-aquatic mammals, given that they spend a considerable amount of time in fresh water. Unfortunately, population trend data on most of these species are lacking, but information does exist for some well-studied species (such as the pygmy hippopotamus and some otter populations in Europe) (Revenga and Kura 2003). A group for which there is more information on population trends, given their precarious conservation status, is the freshwater cetaceans or river dolphins. There are five species of river dolphins and one species of freshwater porpoise living in large rivers in Asia and South America. Populations of river cetaceans have declined rapidly in recent years, driven by habitat loss and degradation (Reeves et al. 2000).

While trends in populations of single species or small taxonomic groups provide useful information, multispecies datasets are more useful for identifying general overall trends. In Figure 4.20, trend data from various IUCN/SSC sources have been assembled into trend categories (reflecting changes over the last 20 years) in order to provide an overall picture of population or abundance trends among 101 large mammal species in Africa (data provided courtesy of the IUCN/SSC, with particular reference to Oliver 1993; Nowell and Jackson 1996; Oates 1996; Sillero-Zubiri and Macdonald 1997; Woodroffe et al. 1997; Mills and Hofer 1998; Barnes et al. 1999; East 1999; Emslie and Brooks 1999; Moehlman 2002). From this figure, it can be seen that over 60% of the species are clearly decreasing, and another almost 20% are in the "stable or decreasing" category. Only 4% of the species are clearly increasing. The Figure also shows that a larger fraction of the species with smaller populations is declining than those with larger populations. This overall heavily negative trend is likely to be indicative of a deteriorating environmental situation over much of the African continent.

4.4.1.3 Amphibians

Populations of many amphibians are declining in several parts of the globe. Different possible causes have been suggested, including habitat change (mainly affecting small-scale freshwater habitats such as ponds and streams), disease, climate change, acid precipitation, habitat loss, and increased UV-B irradiation. Houlahan et al. (2000) used data from 936 populations to examine global trends in amphibian populations. The studies that were analyzed ranged from 2 to 31 years in duration. Their findings suggest a relatively rapid decline from the late 1950s peaking in the 1960s, followed by a reduced decline to the present. Alford et al. (2001) later reanalyze the same data and suggested that the global decline may have begun in the 1990s.

Regardless of the exact timeframe, it is commonly accepted that amphibian populations have recently declined on a global scale. This is supported by the recent IUCN-SSC/CI-CABS/NatureServe Global Amphibian Assessment (Stuart et al. 2004). Out of the 4,048 amphibian species (70.9%) for which trends have been recorded, 61.0% (2,468 species) are estimated to be declining, 38.3% (1,552 species) are stable, and 0.69% (28 species) are increasing (Baillie et al. 2004). The report estimated that there are presently 435 more amphibians listed in the IUCN higher categories of threat then would have been in 1980 and that between 9 and 122 species have gone extinct during this time period (Stuart et al. 2004).

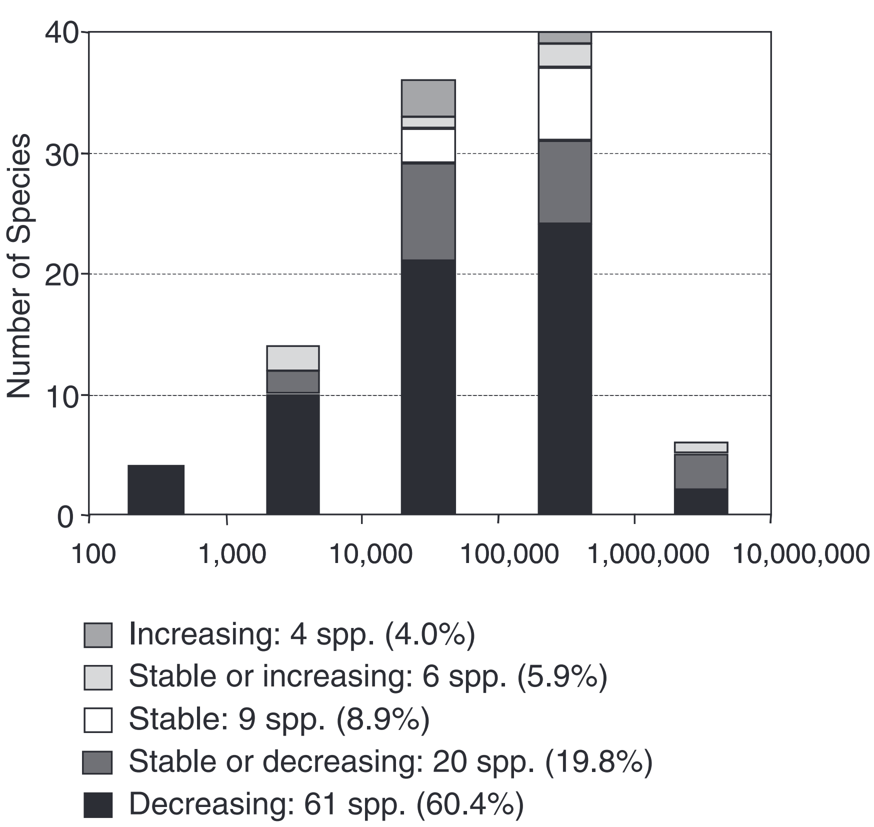

Figure 4.20. Trends in 101 African Large Mammal Species

4.4.1.4 Reptiles

Global trends in reptiles have not been synthesized to the same extent as they have for amphibians. The fact that IUCN has only assessed the conservation status of 6% of the 8,163 described reptiles indicates how little is known about their global status and trends (Baillie et al. 2004). Reptiles share many of the same environments and are susceptible to many of the same threats as amphibians, and it has therefore been suggested that they may be experiencing similar or greater declines (Gibbins et al. 2000), but this remains to be rigorously tested.

Turtles and tortoises are among the best-studied reptiles. Within this group, large declines have been identified in the marine turtles, with six of the seven species listed as threatened by IUCN (Baillie et al. 2004). Overall rates of decline are unknown for turtles and tortoises, but reports on the trade of Southeast Asian freshwater turtles indicate that many of these species are rapidly declining. TRAFFIC Southeast Asia estimates trade volumes at a minimum of 13,000 tons of live turtles in 1999 (TRAFFIC Southeast Asia 2001, see section 5.4.5) and that this trade is increasing. IUCN is now conducting a Global Reptile Assessment that will soon help clarify the status and trends of this group.

4.4.1.5 Fish

Little is known about the majority of fish populations, but the global decline of commercially important fish stocks or populations is relatively well documented (e.g., Jackson et al. 2001; Myers and Worm 2003; Hutchings and Reynolds 2004).

Data on trends of some 600 fish populations covering more than 100 species can be found at fish.dal.ca/ to myers/data.html, usually in terms of trends in spawning stock biomass. Summarized data on the overall status of fish stocks, based on catch statistics in their SOFIA report, are available from FAO in *The State of the World's Fisheries and Aquaculture* reports produced every two years (see FAO 2000a).

The data available to FAO at the end of 1999 identified 590 "stock" items. For 441 (75%) of these, there is some information on the state of the stocks and, although not all of this is recent, it is the best that is available. The stock items are classified as underexploited (U), moderately exploited (M), fully exploited (F), overexploited (O), depleted (D), or recovering (R), depending on how far they are, in terms of biomass and fishing pressure, from the levels corresponding to full exploitation. Full exploitation is taken as being loosely equivalent to maximum sustainable yield (equivalent to being harvested at the biological limit). The overall state of the fish stocks being monitored according to these classifications is shown in Figure 4.21.

Figure 4.21 indicates that 28% (R + D + O) of the fish stocks being assessed have declined to levels below which a maximum sustainable yield can be taken and that a further 47% (F) require stringent management (which may or may not already be in place) to prevent decline into a similar situation. In total, 75% of these stocks (R + D + O + F) need management to prevent further declines or to bring about recovery in spawning stock biomass. Conversely, 72% (F + M + U) of the stocks are still capable of producing a maximum sustainable yield. These data have also been broken down regionally and are available in FAO (2002).

The State of the World's Fisheries and Aquaculture report (FAO 2000a) identifies trends since 1974 in each stock classification, as a percentage of the total number of fish stocks being assessed by FAO. The percentage of underexploited stocks (U + M) has declined steadily, while the proportion of stocks exploited beyond maximum sustainable yield levels (O + D + R) has increased steadily over this time period. If these data are representative of fisheries as a whole, they indicate an overall declining trend in spawning stock biomass for commercially important fish species over the last 30 years.

The FAO data (FAO 2000a) demonstrate that there is significant increase in the exploitation of deep-sea fish stocks, such as populations of orange roughy (*Hoplostethus atlanticus),* alfonsinos (*Berycidae*), and dories (*Zeidae*). Many of these species have slow growth rates, and it is not yet clear that the methods established to fish them sustainably will be successful.

Little is known about the status of most shark populations (Castro et al. 1999). Baum et al. (2003) used the largest shark dataset covering the north Atlantic to assess declines of coastal and oceanic shark populations. Shark declines are believed to be occurring as a result of increased bycatch from pelagic long-line fisheries and direct exploitation for shark fins. Baum et al. (2003) found that all recorded shark species within the study area, with the exception of makos, have experienced a decline of more than 50% in the past 8–15 years. Sharks grow and reproduce slowly, so even if exploitation were stopped, their recovery would be slow.

The use of catch statistics to assess freshwater stocks, which is common practice with marine species, is difficult because much of the inland catch is underreported by a factor of three or four, according to FAO (FAO 1999; FAO 2000a). Nevertheless, FAO's last major assessment of inland fisheries (FAO 1999) reported that most inland capture fisheries that rely on natural reproduction of the stocks are overfished or are being fished at their biological limit.

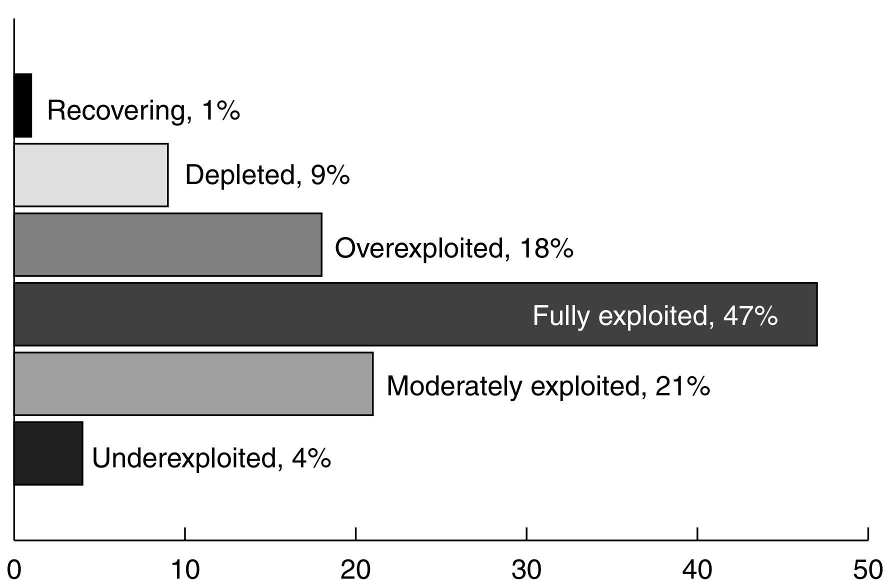

Figure 4.21. The State of Fish Stocks, 1999 (FAO 2000)

Some large lakes have been systematically studied because of their importance as a fishery resource. The North American Great Lakes are a case in point. Annual fish stock assessments are conducted for commercially important salmonoid species, such as lake trout and Pacific salmon, and for their prey species (such as alewife, rainbow smelt, bloater, sculpin, and lake herring) (USGS Great Lakes Science Center 2003). The prey population assessments for the five lakes show that with the exception of Lake Superior, whose status is mixed but improving, populations of prey species in the other four lakes are all decreasing (USGS Great Lakes Science Center 2003). With respect to predator species in the lakes, many native species, such as lake trout and sturgeon, are found in vastly reduced numbers and have been replaced by introduced species (Environment Canada and U.S. EPA 2003).

Other regularly assessed lakes include Lake Victoria and Lake Tanganyika in Africa. These also show a decline in native fisheries and replacement with exotic species. The most widely known and frequently cited is the disappearance of over 300 haplochromine cichlids in Lake Victoria and the decline or disappearance of most of the riverine fauna in the east and northeastern forests of Madagascar (Stiassny 1996). There is also documented evidence of the threatened fish fauna of crater lakes in western Cameroon and the South African fish fauna, which has 63 % of its species endangered, threatened, or "of special concern" (Moyle 1992; Lévêque 1997).

The few examples of riverine fish assessments show that many inland fisheries of traditional importance have also declined precipitously. The European eel fishery, for example, has steadily declined over the last 30 years (Kura et al. 2004). By the mid-1980s, the number of new glass eels (eel juveniles) entering European rivers had declined by 90%. Recent figures show that this has now dropped to 1% of former levels (Dekker 2003).

Other fish stocks for which there is longer-term catch and status information include Pacific and Atlantic salmon in North America, fisheries of the Rhine and Danube Rivers in Europe, and fisheries of the Pearl River in China. All of these have declined to just a small fraction of their former levels due to overexploitation, river alteration, and habitat loss, putting some of these species at serious risk of extinction (Balcalbaca-Dobrovici 1989; Lelek 1989; Liao et al. 1989; WDFW and ODFW 1999).

Finally, even fisheries that until recently were reasonably well managed, such as the caviar-producing sturgeons in the Caspian Sea, and fisheries from relatively intact rivers such as the Mekong in Southeast Asia are rapidly declining (Kura et al. 2004.). For example, while almost all 25 species of sturgeon in the world have been affected to some degree by habitat loss, fragmentation of rivers by dams, pollution, and overexploitation, much of the recent decline in the catch of caviar-producing sturgeon is a direct result of overfishing and illegal trade (De Meulenaer and Raymakers 1996; WWF 2002). Major sturgeon populations have already declined by up to 70% (WWF 2002).

4.4.1.6 Corals

A meta-analysis of trends in Caribbean corals reveals that there has been a significant decline over the past three decades and although the decline has slowed, the trend persists. The average hard coral cover on reefs has been reduced by 80%, from around 50% to 10% cover, in three decades (Gardner et al. 2003). This significant trend supports the notion that coral reefs are globally threatened (Hodgson and Liebeler 2002; Hughes et al. 2003). (See Chapter 19.)

4.4.1.7 Invertebrates

Invertebrates represent the greatest proportion of eukaryotic biodiversity, but we know virtually nothing about their distributions, populations, or associated trends. However, especially among the insects a few well-studied groups such as butterflies, moths, and dragonflies (Hilton-Taylor 2000) may provide some insight. One example—a regional study of butterflies in the Netherlands (van Swaay 1990)—identifies decline as the most common trend over the past century. Of the 63 species assessed, 29 (46%) decreased or became extinct, 17 (27%) experienced little change, and 7 (11%) appeared to have increased their range. The remaining 10 species (16%) tended to fluctuate in range. Butterflies have also been relatively well monitored in the UK. Although many common and widespread species are believed to have increased in range and abundance (Pollard et al. 1995), the overall trend appears to be one of decline. A recent study examining population and regional extinctions indicates that British butterfly distributions have decreased by 71% over the past 20 years (Thomas et al. 2004b). This was found to be much higher than both birds and plants.

Although trends of well-studied insects indicate that this group shows similar trends of decline to other taxonomic groups, some studies indicate that insects in specific habitat types may be relatively resistant (Karg and Ryszkowski 1996). Understanding the general trends associated with insects is extremely important as it will provide much greater insight into global trends in biodiversity.

Two other groups of invertebrates that have been studied in more detail are freshwater mollusks and crustaceans. There are many lists on freshwater mollusks at national and regional levels, a number of which are available on the Internet (e.g. species.enviroweb.org/omull.html and www.worldwideconchology.com/DatabaseWindow.html). These databases, however, are not standardized or comparable; therefore an assessment of the current status and trends of freshwater mollusks at the global level is difficult. Existing lists are also biased toward terrestrial and marine groups.

The United States is one of the few countries in which the conservation status of freshwater mollusks and crustaceans has been widely assessed. Half of the known U.S. crayfish species and two thirds of U.S. freshwater mollusks are at risk of extinction (Master et al. 1998), with severe declines in their populations in recent years. Furthermore, at least 1 in 10 of the freshwater mollusks is likely to have already gone extinct (Master et al. 1998). The alarming rate of extinction of freshwater mollusks in eastern North America is even more pronounced. According to the U.S. Federal Register, less than 25% of the present freshwater bivalves appear to have stable populations. The status of gastropods is much less known. Of 42 species of extinct gastropods in the United States, 38 were reported from the Mobile Bay Basin in Southern North America (Bogan 1997).

4.4.1.8 Plants

Information on global trends in the status of plants is lacking, but overall population declines are likely given the high rates of habitat modification and deforestation described earlier, along with other threats, such as overexploitation, alien invasive species, pollution, and climate change. In addition, 12 of the 27 documented global extinctions over the past 20 years have been plants (Baillie et al. 2004).

The sixth meeting of the Conference of the Parties of the Convention on Biological Diversity adopted the Global Strategy for Plant Conservation. This strategy highlights monitoring the status and trends of global plant diversity as one of the objectives (UNEP 2002b), which it is hoped will lead to greater insight into global trends.

Cycads are one of the few groups where the conservation status of all species has been assessed and trend data exist. Population trends are available for 260 species of cycads (Cycadopsida, 288 species in total). Of these, 79.6% (207 species) are declining, 20.4% (53 species) are stable, and none are considered to be increasing (Baillie et al. 2004).

Another important dataset is available for trends in wood volume and biomass. FAO's *Forest Resources Assessment 2000* indicates opposing trends between the tropics and nontropics in terms of both volume and above-ground woody biomass over the period 1990–2000. There has been a decreasing trend in the tropics, compared with an increasing trend in the nontropics. These data should be interpreted with caution, due in part to problems of data compatibility between countries (see FAO 2001b and Chapter 21 for more details). Note also that no distinction is made here between undisturbed forest, secondary forests, and plantations.

4.4.1.9 Conclusion on Population

Measuring change in populations is important for understanding the link between biodiversity and ecosystem function, as significant changes in populations can have important implications for the function of ecosystems long before any species actually goes extinct (e.g., Jackson et al. 2001; Springer et al. 2003).

The data presented in this section represent a brief assessment of the types of data that are available on the trends in populations. Although the datasets described are not easily comparable with each other and are certainly not collectively representative of biodiversity as a whole, a few basic conclusions can be drawn.

Both declining and increasing trends can be documented from available studies; in most cases, declining trends appear to outweigh increasing trends, often by a considerable margin, and some increasing trends can be related to very specific situations (for example, population recovery following periods of intensive harvesting or successful reintroduction programs). Overall, the emerging evidence suggests that for macroorganisms, especially those with small areas of distribution, most populations are declining as a result of human activities and are being replaced by individuals from a much smaller number of expanding species that thrive in human-altered environments. The result will be a more homogenized biosphere with lower diversity at regional and global scales (McKinney and Lockwood 1999).

4.4.2 Species

4.4.2.1 Current Extinction Rates

The evolution of new species and the extinction of others is a natural process. Species present today represent only 2–4% of all species that have ever lived (May et al. 1995). Over geological time there has been a net excess of speciation over extinction that has resulted in the diversity of life experienced today. However, the high number of recent extinctions suggests that the world might now be facing a rapid net loss of biodiversity. This can be tested by comparing recent extinction rates to average extinction rates over geological time.

The fossil record appears to be punctuated by five major mass extinctions (Jablonski 1986), the most recent of which occurred 65 million years ago. However, the majority of extinctions have been spread relatively evenly over geological time (Raup 1986), enabling estimates of the average length of species' lifetimes through the fossil record. Studies of the marine fossil record indicate that individual species persisted for periods ranging from 1 million to 10 million years (May et al. 1995). These data probably underestimate background extinction rates, because they are necessarily largely derived from taxa that are abundant and widespread in the fossil record.

Using a conservative estimate of 5 million as the total number of species on the planet, we would therefore expect anywhere between five extinctions per year to roughly one extinction every two years (for all 5 million species on the planet). As noted earlier, recent extinctions have been best studied for birds, mammals, and amphibians, and in these groups over the past 100 years roughly 100 species have become extinct. This is in itself similar to background extinction rates, but these groups represent only 1% of described species.

Assuming for the moment that the susceptibility to extinction of birds, mammals, and amphibians is similar to species as a whole, then 100 times this number of species (10,000 species) were lost over the past 100 years. But this assumption of equivalent extinction risk is very uncertain, and given the additional uncertainty over the total number of species on the planet, it is preferable to convert these data into a relative extinction rate, measured as the number of extinctions per million species per year (Pimm et al. 1995). A background extinction rate of 0.1–1 E/MSY then corresponds to the average marine fossil species lifetimes. Mammalian background extinction rates are also believed to be within these limits, falling within a range of 0.21 E/MSY (strictly for lineages rather than species, but provides a conservative estimate (Alroy 1998; Regan et al. 2001) and 0.46 E/MSY (Foote 1997).

Measuring recent extinction rates is difficult, not only because our knowledge of biodiversity is limited, but also because even for the best studied taxa there is a time lag between the decline toward extinction and the actual loss of species. In the case of extinctions caused by habitat loss, in particular, it may take thousands of years before a restricted remnant population is finally driven to extinction (Diamond 1972).

With this in mind, it is possible to use recent documented extinctions to make a very conservative estimate of current extinction rates, though this is limited because only a few taxonomic groups have been reasonably well analyzed for extinctions. There are approximately 21,000 described species of birds, mammals, and amphibians. The roughly 100 documented extinctions for these groups during the past century yields an E/MSY of 48, which is 48 to 476 times greater than the background extinction rate of 0.1 to 1. If "possibly extinct" species are included in this analysis, the total number of extinctions and possible extinctions over the past 100 years for these groups is 215 species, which results in an E/MSY that is 102 to 1,024 higher than background rates. Broken down by taxonomic group, mammals have the highest E/MSY (64) followed by birds (at 45) and finally amphibians (40). If possibly extinct species are considered, however, then amphibians have the highest E/MSY at 167 followed by mammals with 68 and finally birds with 59. (It should be noted that mammals have not been completely assessed for possibly extinct species (see Baillie et al. 2004).)

A broad range of techniques have been used to estimate contemporary extinction rates, including estimates based on both direct drivers (such as habitat destruction) and indirect drivers (such as human energy consumption) of extinction (Myers 1979; Myers 1988; Reid 1992; Smith et al. 1993; Ehrlich 1994; Mace and Kunin 1994; Pimm and Brooks 1999; Regan et al. 2001; Baillie et al. 2004; also see MA *Scenarios,* Chapter 10). Many of these studies give rise to estimates of E/MSY that are 1,000 to 10,000 higher than background rates (Pimm and Brooks 1999), generally higher than the conservative estimate for birds, mammals, and amphibians based on documented extinctions. (See Figure 4.22 in Appendix A.) Estimates based on documented extinctions are likely to be underestimates because the *IUCN Red List* is very conservative in recording species as actually extinct and because many extinctions have probably been missed due to limited survey effort for most taxonomic groups.

The trend in species extinction rates can be deduced by putting together extinction rates characteristic of well-recorded lineages in the fossil record, recorded extinctions from recent times, and estimated future extinction rates based on the approaches just described. All these estimates are uncertain because the extent of extinctions of undescribed species is unknown, because the status of many described species is poorly known, because it is difficult to document the final disappearance of very rare species, and because there are extinction lags between the impact of a threatening process and the resulting extinction (which particularly affects some modeling techniques). However, the most definite information, based on recorded extinctions of known species over the past 100 years, indicates extinction rates are around 100 times greater than rates characteristic of comparable species in the fossil record. Other less direct estimates, some of which refer to extinctions hundreds of years into the future, estimate extinction rates 1000 to 10,000 times higher than rates recorded among fossil lineages.

Current anthropogenically caused extinction is not solely a characteristic of contemporary societies. Since the initial revelations that humanity greatly inflated extinction rates with stone-age technology (Martin and Wright 1967; Martin and Klein 1984), large quantities of new data have demonstrated significant extinction episodes occurred with, for example, the arrival of people in Australia 46,000 years ago (Roberts et al. 2002), in the Americas 12,000 years ago (Alroy 2001), in Madagascar (Goodman and Patterson 1997) and the Pacific 2,000 years ago (Steadman 1995), and elsewhere (MacPhee 1999).

4.4.2.2 Current Levels of Threat to Species

At a global level, nearly 850 species have been recorded as becoming extinct or at least extinct in the wild since 1500 (Baillie et al. 2004). Species extinctions represent the final point in a series of population extinctions; in fact, distinct populations may be being lost at a rate much faster than species overall, with serious negative consequences for local ecosystem function (Hughes et al. 1997).

The most extensive global dataset on trends in species richness is the *IUCN Red List of Threatened Species* (see www.redlist.org and Baillie et al. 2004). The *IUCN Red List* is formalized through the application of categories and criteria (IUCN 2001) that are based on assessments of extinction risk (Mace and Lande 1991). These criteria are now broadly used in many parts of the world and have been adapted for use at multiple scales.

The *2004 IUCN Red List of Threatened Species* is based on assessments of 38,047 species. Of these, 7,266 animal species and 8,321 plant species (15,547 species in total) have been placed in one of the IUCN Categories of Threat (vulnerable, endangered, or critically endangered). However, the *IUCN Red List* needs to be interpreted with caution, because for most taxonomic groups the assessments are very incomplete and heavily biased toward the inclusion of the most threatened species. As of 2004, assessments of almost every species have been completed for three animal groups (mammals, birds, and amphibians) and two plant groups (conifers and cycads). The number of species in each IUCN Red List Category for all five of these groups is given in Table 4.8. Reptiles have not yet been completely assessed.

In all five of these groups, the proportions of species in categories of high extinction risk are much greater than would be expected if species were becoming extinct at rates typically observed over geological time. The levels of threat are lowest among

Table 4.8. Number of Species in IUCN Red List Categories for Comprehensively Assessed Taxonomic Groups (Baillie et al. 2004)

Class	EX	EW	Subtotal	CR	EN	VU	Subtotal	LR/cd	NT	DD	LC	Total

EW extinct in the wild	VU vulnerable		DD data deficient
CR critically endangered			LC least concern

birds, where 12% of species are threatened (vulnerable + endangered + critically endangered). There has been a trend of increasing threat between 1988 and 2004, as measured by the movement of species into more threatened Red List Categories (BirdLife 2004b). The relatively low level of threat in birds is possibly related to their tendency to be highly mobile, resulting in their generally wide geographic distributions.

The pattern of distribution of threat categories among species is broadly similar for mammals and conifers, with 23% (1,101) and 25% (153) respectively of the species being globally threatened. Based on the evidence from comprehensive regional assessments (e.g., Stein et al. 2000), it is more than possible that future studies will show this very high level of threat to be typical of the current global situation among most groups of terrestrial species.

The situation with amphibians is broadly similar: 32% (1,856) globally threatened. However, the true level of threat among amphibians is probably masked by the fact that 23% of the species are classified as data-deficient (compared with 8% for mammals and 10% for conifers). The overall conservation situation of amphibians will probably eventually prove to be much worse than the mammal and conifer situations and might be typical of the higher levels of threat associated with freshwater (or freshwater-dependent) species (Master et al. 2000). Amphibian extinction risk has been retrospectively analyzed back to the early 1980s, and shows a similar rate of decline to that of birds (BirdLife 2004b), but with a greater number of the more seriously threatened species declining (Baillie et al. 2004).

The cycad situation is much worse, with 52% (151) of species globally threatened. This is possibly reflective of the relict nature of these ancient species, with most species now surviving only in very small populations.

Species are not all equal: some represent much more evolutionary history than others (Vane-Wright et al. 1991). If extinctions were randomly distributed across the tree of life, surprisingly little evolutionary history would be lost (Nee and May 1997). However, extinctions are far from phylogenetically random: there is strong taxonomic selectivity in the current extinction crisis, with the result that the loss of evolutionary history is much more than that expected were species to be lost randomly with respect to their taxonomic affiliation (Purvis et al. 2000a).

There is a clear trend for higher levels of threat among the larger species. Of the mammals, for example, 38% (81) of the Artiodactyla (antelopes, cattle, sheep, and so on), 82% (14) of the Perissodactyla (horses, rhinos, and tapirs), 39% (114) of the Primates, 100% (2) of the Proboscidea (elephants), and 100% (5) of Sirenia (dugongs and manatees) are globally threatened (Baillie et al. 2004). Among the birds, high levels of threat are particularly apparent among orders such as Apterygiformes (kiwis) with 100% (4) threatened, Sphenisciformes (penguins) 57% (10), Pelecaniformes (cormorants, pelicans, and so on) 26% (17), Procellariiformes (albatrosses and petrels) 47% (62), Ciconiiformes (storks, ibises, and spoonbills) 21% (28), Galliformes (pheasants, partridges, quails, and so on) 27% (78), Gruiformes (cranes, bustards, rails, and so on) 33% (76), Columbiformes (doves and pigeons) 22% (75), and Psittaciformes (parrots) 29% (109) (Baillie et al. 2004). These orders include species that are flightless, ground-dwelling, particularly vulnerable to alien predators, and edible or economically valuable. The most noteworthy result from the threat analysis of amphibians is the particularly large proportion of globally threatened salamanders—46% (234) of the total number of threatened amphibians. Salamanders are often long-lived, slow-breeding species, with limited ability to disperse over significant distances.

The *IUCN Red List* does not yet include comprehensive datasets for taxonomic groups confined to freshwater ecosystems. Nor have there been any complete assessments of any invertebrate groups. Some important regional datasets are becoming available, however, for example for North America, compiled by NatureServe. A summary and analysis of these data for the United States are presented in Stein et al. (2000). NatureServe uses a different system for categorizing levels of threat, and their categories are not strictly comparable with those of IUCN. Nevertheless, for the purposes of this assessment their system does broadly indicate levels of extinction risk and is therefore useful in determining trends.

Based on an assessment of 20,439 species, NatureServe determined that one third of the U.S. flora and fauna appears to be of conservation concern. NatureServe has comprehensively assessed the status of every U.S. species in 13 taxonomic groups, and the percentage of each of these species that is at risk is shown in Figure 4.23. The most noteworthy finding of this study is that the species groups relying on freshwater habitats—mussels, crayfishes, stoneflies, fishes, and amphibians—exhibit the highest levels of risk. Sixty-nine percent of freshwater mussels are at risk. Dragon-

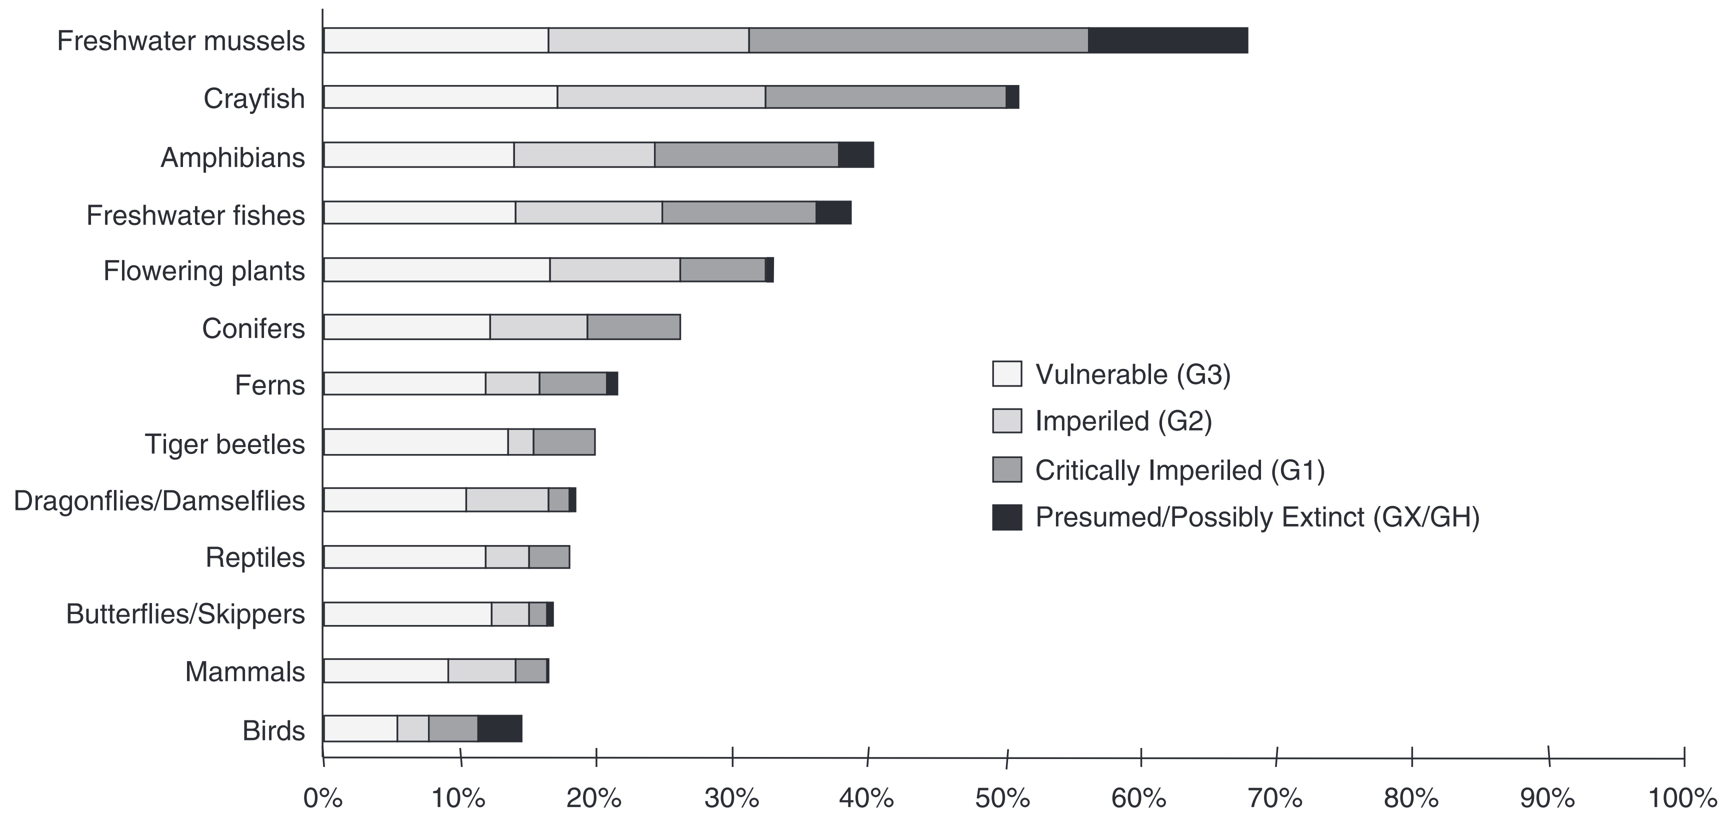

Figure 4.23. Percentage of Species at Risk in the United States, by Plant and Animal Groups (Stein et al. 2000, reproduced with permission of NatureServe)

flies and damselflies seem to be an exception to this pattern since, despite being freshwater-dependent, their threat level is relatively low. The threat levels are also very high in the United States for flowering plants (33%).

No comprehensive assessment has yet been carried out on the threat levels for any marine group. However, work is progressing fast to assess the status of all the chondrichthyan fishes (sharks, rays, and chimaeras). To date, the IUCN/SSC Shark Specialist Group has assessed one third (373 species) of the world's chondrichthyans (out of a total of approximately 1,100 species), and 17.7% are listed as threatened (critically endangered, endangered, or vulnerable), 18.8% near-threatened, 37.5% data-deficient, and 25.7% of least concern (Baillie et al. 2004). However, it is not at all clear that sharks and rays are good indicators of overall biodiversity trends in marine ecosystems. In view of the life history strategies for these species (slow-breeding, long-lived), it is likely that they are more threatened than some other marine groups.

4.4.2.3 Traits Associated with Threat and Extinction

The patterns of threat and extinction are not randomly distributed among species (Bennett and Owens 1997; Gaston and Blackburn 1997b; Owens and Bennett 2000). Ecological traits demonstrated to be associated with high extinction risk (even after controlling for phylogeny) include high trophic level, low population density, slow life history or low fecundity, and small geographical range size (Bennett and Owens 1997; Purvis et al. 2000b). For primates and carnivores, these traits together explain nearly 50% of the total between-species variation in extinction risk, and much of the remaining variation can be accounted for by external anthropogenic factors that affect species irrespective of their biology (Purvis et al. 2000b).

However, different taxa are threatened by different mechanisms, which interact with different biological traits to affect extinction risk. For bird species, extinction risk incurred through persecution and introduced predators is associated with large body size and long generation time but is not associated with degree of specialization, whereas extinction risk incurred through habitat loss is associated with habitat specialization and small body size but not with generation time Owens and Bennett (2000). For Australian marsupials, the risk of extinction has been found to be better predicted by geographical range overlap with sheep (Fisher et al. 2003).

Extinction risk is not independent of phylogeny, presumably because many of the biological traits associated with higher extinction risk tend to co-occur among related species. Among birds, for example, families that contain significantly more threatened species than average are the parrots (Psittacidae), pheasants and allies (Phasianidae), albatrosses and allies (Procellariidae), rails (Rallidae), cranes (Gruidae), cracids (Cracidae), megapodes (Megapodidae), and pigeons (Columbidae) (Bennet and Owens 1997). There is also a positive relationship between the proportion of species in a taxon that are considered to be threatened and the evolutionary age of that taxon, both for the global avifauna and the avifauna of the New World (Gaston and Blackburn 1997b).

The majority of recorded species extinctions since 1500 have occurred on islands. A total of 72% of recorded extinctions in five animal groups (mammals, birds, amphibians, reptiles, and mollusks) were of island species (Baillie et al. 2004). Island flora and fauna were especially vulnerable to the human-assisted introduction of predators, competitors, and diseases, whereas species on continents were not so ecologically naive. However, predictions of future extinctions stem from the ongoing loss of continental, tropical forests; hence 452 of a total of 1,111 threatened bird species are continental (Manne et al. 1999). A shift from island to mainland extinctions is consistent with a recent examination of extinctions over the past 20 years, where island and mainland extinctions were roughly equal (Baillie et al. 2004).

4.4.2.4 Geographical Patterns of Threat and Extinction

The geography of threat and extinction is far from even, with the majority of threatened species concentrated in tropical and warm temperate endemic-rich ''hotspots'' (Myers et al. 2000). Figure 4.24 shows the locations of known mammal, bird, and amphibian extinctions since 1500. The different patterns between these three groups are striking. Mammal extinctions are concentrated in the Caribbean and Australia. In both cases, these are thought to be

Figure 4.24. Locations of Extinct and Extinct in the Wild Mammal, Bird, and Amphibian Species since 1500 (Baillie et al. 2004)

second waves of human-induced extinction, following the overexploitation of the Pleistocene (MacPhee 1999); in any case, the current mammalian fauna in these regions is but a modest sample of the native fauna prior to human arrival, particularly in terms of medium- and large-sized mammals (Woods and Sergile 2001; Brook and Bowman 2004). The remainder of the recorded mammalian extinctions are widely scattered, most being on oceanic islands.

Avian extinctions are overwhelmingly concentrated on oceanic islands, especially on Hawaii and New Zealand (Steadman 1995), with very few elsewhere. With few exceptions, oceanic island avifaunas have lost most of their endemic species over the last 1,000 years.

The highest number of recorded amphibian extinctions is on Sri Lanka. However, the current wave of amphibian extinction, which appears to be accelerating, is concentrated in montane areas from Honduras south to northern Peru, in the Caribbean islands, in eastern Australia, and perhaps in the Atlantic Forest of southern Brazil.

Maps of species richness of threatened mammals and birds are presented in Figure 4.25 (in Appendix A). (For a species richness map of threatened amphibians, see Chapter 20.) The maps show interesting similarities and differences. They all show concentrations of threatened species in hotspots (Myers et al. 2000), in particular in the Andes, southern Brazil, West Africa, Cameroon, the Albertine Rift of Central Africa, the Eastern Arc Mountains of Tanzania, eastern Madagascar, Sri Lanka, the Western Ghats of India, the eastern Himalayas, central China, mainland Southeast Asia, and Borneo.

The mammal map is noteworthy in that there is at least one threatened mammal species in most parts of the world. In addition to the geographic regions just listed, important concentrations of threatened mammals also occur in the eastern Amazon basin, southern Europe, Kenya, Sumatra, Java, the Philippines, and New Guinea. Interestingly, MesoAmerica, Australia, and the Caribbean islands appear to have relatively low numbers of threatened mammals. However, it should be noted that patterns of threat will appear low in areas where the vulnerable species have already gone extinct (which may be the case in the Caribbean and Australia) and that threatened mammals with extremely small distributions will not be easily viewed on the map (such as many restricted-range montane species in MesoAmerica).

The bird map differs in that the importance of oceanic islands is emphasized. Other areas that are of great importance for threatened birds but not listed earlier include the Caribbean islands, the Cerrado woodlands of Brazil, the highlands of South Africa, the plains of northern India and Pakistan, Sumatra, the Philippines, the steppes of central Asia, eastern Russia, Japan, southeastern China, and New Zealand. As with mammals, MesoAmerica and Australia are relatively unimportant for threatened birds. But so are the Amazon basin, Europe, Java, and New Guinea.

Amphibians generally have much more restricted ranges than birds and mammals (see Chapter 20), and threatened amphibian species therefore occupy a much smaller global area, a very different picture to mammals. In the small areas where they are concentrated, however, threatened amphibians occur more densely than either mammals or birds (up to 44 species per half-degree grid square, compared with 24 for both mammals and birds) (Baillie et al. 2004). The majority of the world's known threatened amphibians occur from Mexico south to northern Peru and on the Caribbean islands. Most of the other important concentrations of globally threatened amphibians mirror the patterns of threat for mammals and birds, although eastern Australia and the southwestern Cape region of South Africa are also centers of threatened amphibians. The paucity of data from certain parts of the world probably results in serious underestimation of the concentrations of threatened amphibians, especially in the Albertine Rift, Eastern Himalayas, much of mainland Southeast Asia, Sumatra, Sulawesi, the Philippines, and Peru.

Lack of comprehensive geographic and threat assessment for other species groups precludes the presentation of maps for other taxa. Given the similarity between patterns of threatened species for mammals, birds, and amphibians, many other taxonomic groups such as reptiles, fish, invertebrates, and plants may demonstrate broadly similar patterns. However, there are also likely to be many differences. For example, distribution patterns of threatened reptiles (in particular, lizards) are likely to highlight the importance of many arid ecosystems. It is already known that some distribution patterns of threatened plants do not match those of most animal groups, the most notable examples being the Cape Floral Region and Succulent Karoo of South Africa and the deserts of the southwestern United States and northern Mexico. Patterns of threat in marine ecosystems will of course be completely different, and data on these patterns are still largely unavailable.

One potentially useful device for understanding variation in threat intensity across areas is the concept of extinction filters, whereby prior exposure to a threat selectively removes those organisms that are most vulnerable to it, leaving behind a community that is more resilient to similar threats in the future (Balmford 1996). This idea can explain temporal and spatial variation in species' vulnerability to repeated natural changes in the past (such as glaciation events). It may also shed light on the contemporary and future impact of anthropogenic threats. For example, the impact of introduced rats on island-nesting seabirds appears less marked on islands with native rats or land crabs, which have selected for resilience to predators (Atkinson 1985). In a similar fashion, corals may be less likely to bleach in response to rising sea temperatures in areas where they have been repeatedly exposed to temperature stresses in the past (Brown et al. 2000; Podesta and Glynn 2001; West and Salm 2003).

One consequence of the global patterns of extinction and invasion is biotic homogenization. This is the process whereby species assemblages become increasingly dominated by a small number of widespread, human-adapted species. It represents further losses in biodiversity that are often missed when only considering local changes in absolute numbers of species. The many species that are declining as a result of human activities tend to be replaced by a much smaller number of expanding species that thrive in human-altered environments. The outcome is a more homogenized biota with lower diversity at regional and global scales. One effect is that in some regions where diversity has been low because of isolation, the biotic diversity may actually increase—a result of invasions of non-native forms (for example, some continental areas such as the Netherlands as well as oceanic islands). Recent data also indicate that the many losers and few winners tend to be nonrandomly distributed among higher taxa and ecological groups, enhancing homogenization.

4.4.2.5 Conclusion on Species

The rate of species extinction is several orders of magnitude higher than the natural or background rate, even in birds, where the level of threat is the lowest among the assessed taxa. And the great majority of threatened species continue to decline. The geography of declines and extinctions is very uneven and concentrated in particular areas, especially in the humid tropics. Past geographic extinction patterns vary markedly between mammals, birds, and amphibians, but future patterns (as indicated by patterns of currently threatened species) are likely to be more closely correlated. The limited data that exist suggest that biodiversity is more severely threatened in freshwater ecosystems than in terrestrial ecosystems. Studies suggest that ancient taxonomic lineages are particularly prone to extinction (Gaston and Blackburn 1997b; Purvis et al. 2000a). Biodiversity trends in marine ecosystems are yet to emerge, although from the limited data available, it appears that the general trends are not fundamentally different from those in terrestrial ecosystems.

4.4.3 Biomes

Rates of loss of natural land cover for the world's biomes can be measured using a unique dataset on land use change, the HYDE dataset (Klein Goldewijk 2001). This dataset uses information on historical population patterns and agriculture statistics to estimate habitat conversion between 1950 and 1990, based on maps of 0.5-degree resolution. These data indicate that by 1950 all but two biomes (boreal forests and tundra) had lost substantial natural land cover to croplands and pasture. (See Figure 4.26.) Mediterranean forests and temperate grassland biomes had experienced the most extensive conversion, with roughly only 30% of native vegetation cover remaining in 1950.

Loss of native habitat cover has continued, with most biomes experiencing substantial additional percentages of native land cover between 1950 and 1990. The tropical dry broadleaf forests biome has lost the highest percentage of additional habitat (16.1%); only tundra has lost very little if anything to agricultural conversion in those 40 years.

The percentage of remaining habitat in 1950 is highly correlated with rates of additional loss since then. This result indicates that, in general, patterns of human conversion among biomes have remained similar over at least the last century. For example, boreal forests had lost very little native habitat cover through until 1950 and have lost only a small additional percentage since then. In contrast, the temperate grasslands biome had lost nearly 70% of its native cover by 1950 and has lost an additional 15.4% since then. Two biomes appear to be exceptions to this pattern: Mediterranean forests and temperate broadleaf forests. Both of these biomes had lost the majority of their native habitats by 1950 but since then have lost less than 2.5% further habitat. These biomes contain many of the world's most established cities and most extensive surrounding agricultural development (Europe, the

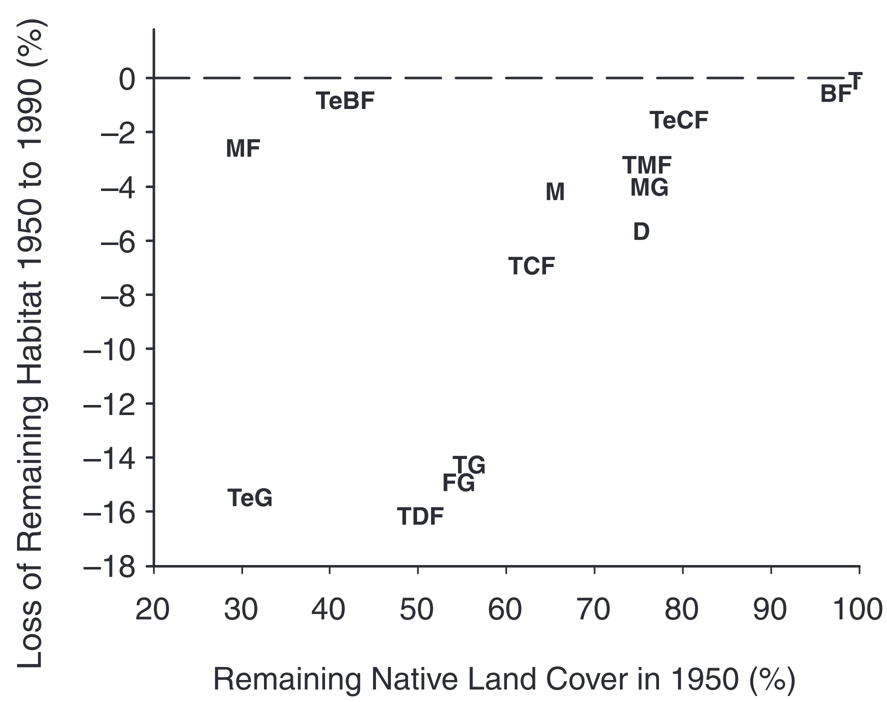

Figure 4.26. Relationship between Native Habitat Loss by 1950 and Additional Losses between 1950 and 1990. Biome codes as in Figure 4.3 (in Appendix A).

United States, the Mediterranean basin, and China). It is possible that in these biomes the most suitable land for agriculture had already been converted by 1950.

In addition to the total amount of habitat loss, the spatial configuration of loss can strongly affect biodiversity. Habitat fragmentation typically accompanies land use change, leaving a complex landscape mosaic of native and human-dominated habitat types. Quantitative data on habitat fragmentation are difficult to compile on the scale of biomes or realms, but habitat fragmentation typically endangers species by isolating populations in small patches of remaining habitat, rendering them more susceptible to genetic and demographic risks as well as natural disasters (Laurance et al. 1997; Boulinier et al. 2001).

Changes in the biodiversity contained within the world's biomes are generally assessed in terms of the species they contain. Changes in species, however, are difficult to measure. Species abundances can fluctuate widely in nature, making it difficult at times to detect a true decline in abundance. And, as described earlier, species extinctions are difficult to count, as the vast majority of species on Earth have yet to be described, extinctions are still relatively rare among known species, and establishing an extinction with confidence is difficult.

Given these difficulties, a reasonable indicator of current and likely future change in biodiversity within a biome is the number of species facing significant extinction risk. The threatened species identified by IUCN are used in this analysis. As such, the analysis is limited to terrestrial vertebrates, which represent less than 1% of the total species on Earth and may not fully represent patterns in other taxa.

Biomes differ markedly in the number of threatened species they contain (see Figure 4.27), with tropical moist forests housing by far the largest number. The percentage of total species that are endangered, however, is more similar among biomes with temperate coniferous forests approaching a similar percentage as tropical moist forests. Comparing these two patterns of threat suggests that higher absolute losses of species in tropical moist forests may be expected, with more similar rates of extinction in other biomes.

4.4.4 Biogeographic Realms

Like biomes, biogeographic realms differ markedly in the amounts of habitat conversion to agriculture before and since 1950. (Klein Goldewijk 2001). (See Figure 4.28.) By 1950, for example, the Indo-Malayan realm had already lost almost half its natural habitat cover. In all realms, at least a quarter of the area had been converted to other land uses by 1950. (These findings exclude Oceania and Antarctica due to lack of data.)

In the 40 years from 1950 to 1990, habitat conversion continued in nearly all biogeographic realms. More than 10% of the land area of the temperate northern realms of the Nearctic and Palearctic as well as the Neotropical realm has been converted to cultivation. Although these realms are currently extensively cultivated and urbanized, the amount of land under cultivation and pasture seems to have stabilized in the Nearctic, with only small increases in the Palearctic in the last 40 years. Within the tropics, rates of conversion to agriculture range from very high in the Indo-

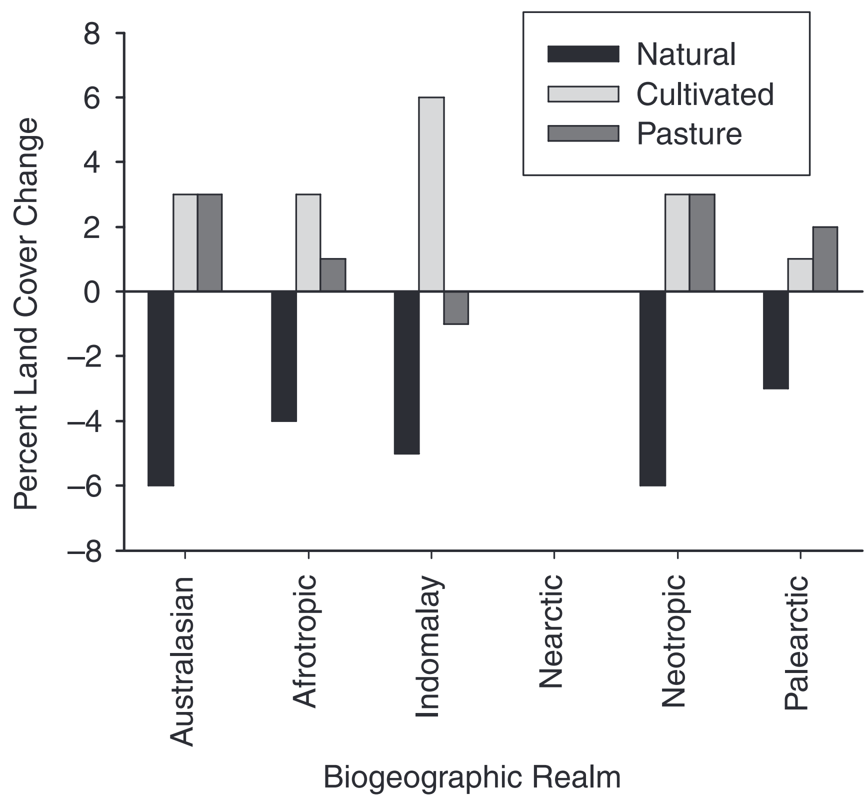

Figure 4.28. Percentage Change (1950–90) in Land Area of Biogeographic Realms Remaining in Natural Condition or under Cultivation and Pasture. Two biogeographic realms are omitted due to lack of data: Oceania and Antarctica.

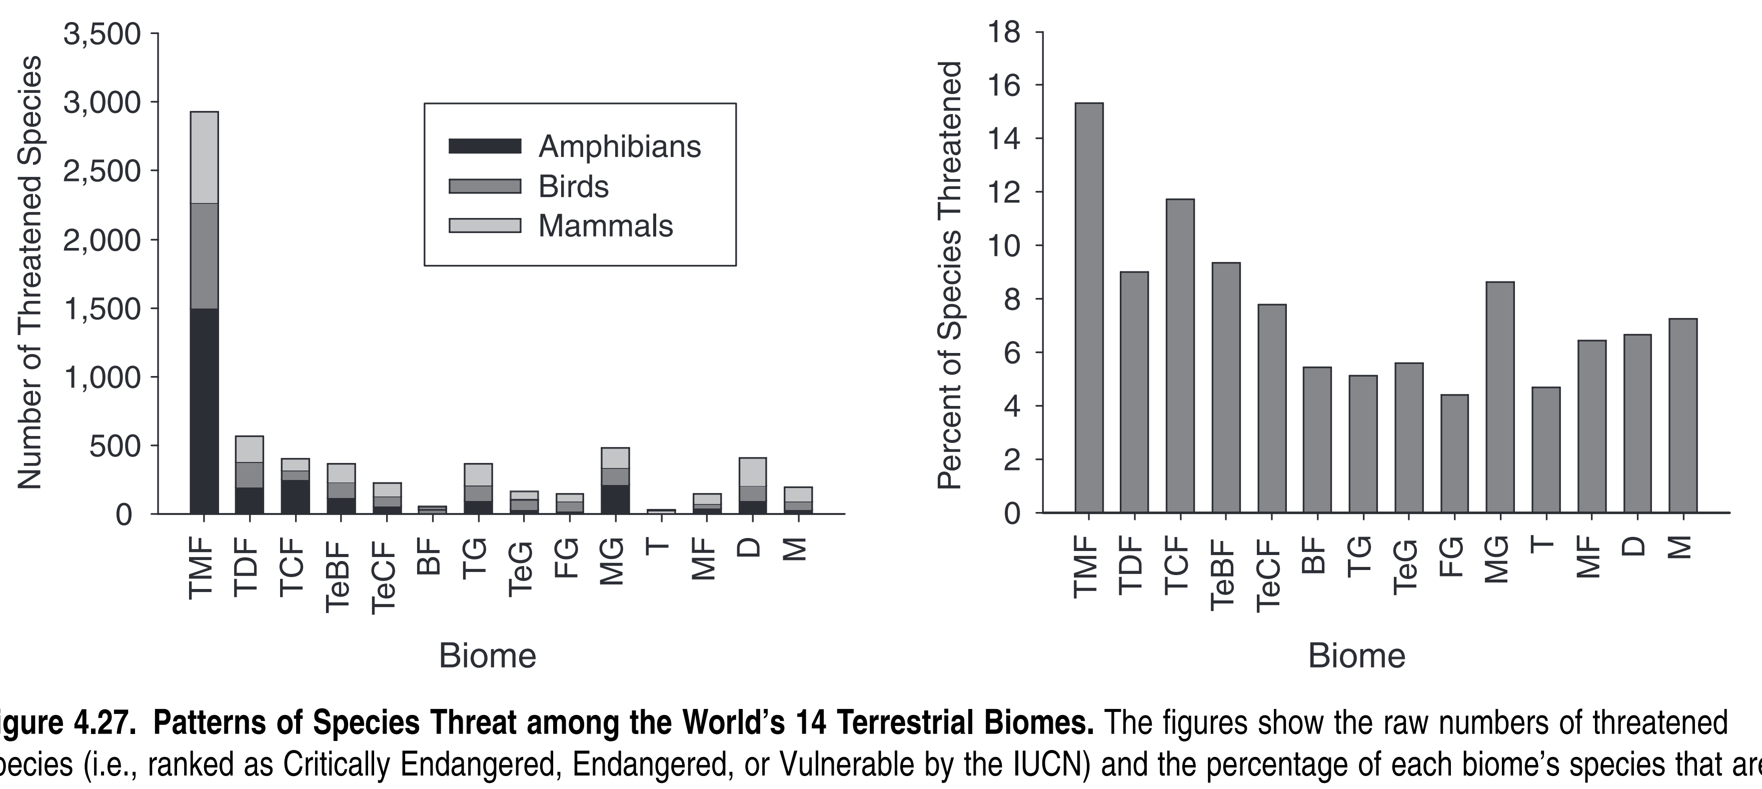

Figure 4.27. Patterns of Species Threat among the World's 14 Terrestrial Biomes. The figures show the raw numbers of threatened species (i.e., ranked as Critically Endangered, Endangered, or Vulnerable by the IUCN) and the percentage of each biome's species that are threatened. Reptiles have not been completely assessed. Biome codes as in Figure 4.3 (in Appendix A).

Malayan realm to moderate in the Neotropics and the Afrotropics, although land cover change has not yet stabilized and shows large increases, especially in cropland area since the 1950s. Australasia has relatively low levels of cultivation and urbanization, but these have also increased in the last 40 years.

As with biomes, the number of threatened vertebrate species differs widely among biogeographic realms (Baillie et al. 2004). (See Figure 4.29.) The largest numbers are found in tropical realms (Neotropic, Indo-Malay, and Afrotropic), while the Nearctic, Oceania, and Antarctica realms hold the least. The percentage of total species that are endangered, however, shows a very different pattern. Most strikingly, over 25% of species in Oceania are threatened, more than twice the percentage of any other realm. The high rates of species threat in Oceania are likely due to well-known factors that endanger island faunas, including high rates of endemism, severe range restriction, and vulnerability to introduced predators and competitors (Manne et al. 1999). Although the Neotropics contain many threatened species, the extraordinary richness of this realm results in a lower percentage of threatened species than Oceania. Therefore, based on species threat levels, we can expect a larger absolute change in biodiversity (measured as expected species extinctions) in the tropical continents, but the highest rates of extinction on tropical islands.

4.5 Improving Our Knowledge of Biodiversity Status and Trends

Biodiversity is a complex concept and so, therefore, is its measurement. Ideally, for any particular assessment, measures of biodiversity would reflect those aspects particularly relevant to the context (Royal Society 2003). For an assessment of ecosystem services for example, biodiversity assessment should be based on measures that are relevant to the provision of services and to human well-being. Unfortunately, the information currently available on global biodiversity is limited, and the data presented in this chapter are therefore rather general. As our understanding of the role of biodiversity improves, so does the potential for better and more relevant measures to be developed. This section considers the need for better indicators of biodiversity status and the specific context of indicators to measure progress against the 2010 biodiversity target, and some clear gaps that will have to be filled if we are to make progress in understanding trends in biodiversity and their consequences are highlighted.

4.5.1 Indicators of Global Biodiversity Status

Documenting trends in biodiversity and the actions and activities that affect it requires suitable indicators. Indicators in this sense are a scientific construct that uses quantitative data to measure biodiversity, ecosystem condition and services, or drivers of change. A useful indicator will provide information about changes in important processes, be sensitive enough to detect important changes but not so sensitive that signals are masked by natural variability, detect changes at the appropriate temporal and spatial scale without being overwhelmed by variability, be based on well-understood and generally accepted conceptual models of the system to which it is applied, be based on reliable data to assess trends and have a relatively straightforward data collection process, have monitoring systems in place for the underlying data needed to calculate the indicator, and be easily understood by policy-makers (NRC 2000 and see also Chapter 2).

Unfortunately, as noted earlier, most existing biological measures, especially those reflecting species richness or various aspects of species diversity, do not reflect many important aspects of biodiversity, especially those that are significant for the delivery of ecosystem services. In addition, few measures have been repeated to allow for a fair assessment of trends over time. Care also needs to be taken in the interpretation of these measures and their use as indicators. For example, these simple measures of species richness may not differentiate between native and invasive or introduced species, differentiate among species in terms of sensitivity or resilience to change, or focus on species that fulfill significant roles in the ecosystem (such as pollinators or decomposers). Moreover, many measures depend on the definition of the area and may be scale-dependent, and they may not always reflect biodiversity trends accurately.

Aggregate indicators of trends in species populations such as the Index of Biotic Integrity for aquatic systems (Karr and Dudley 1981) and the Living Planet Index (Loh and Wackermagel 2004; Loh et al. 2005) use published data on trends in populations of a variety of wild species to identify overall trends in species abundance and, by implication, the condition of the ecosystems in

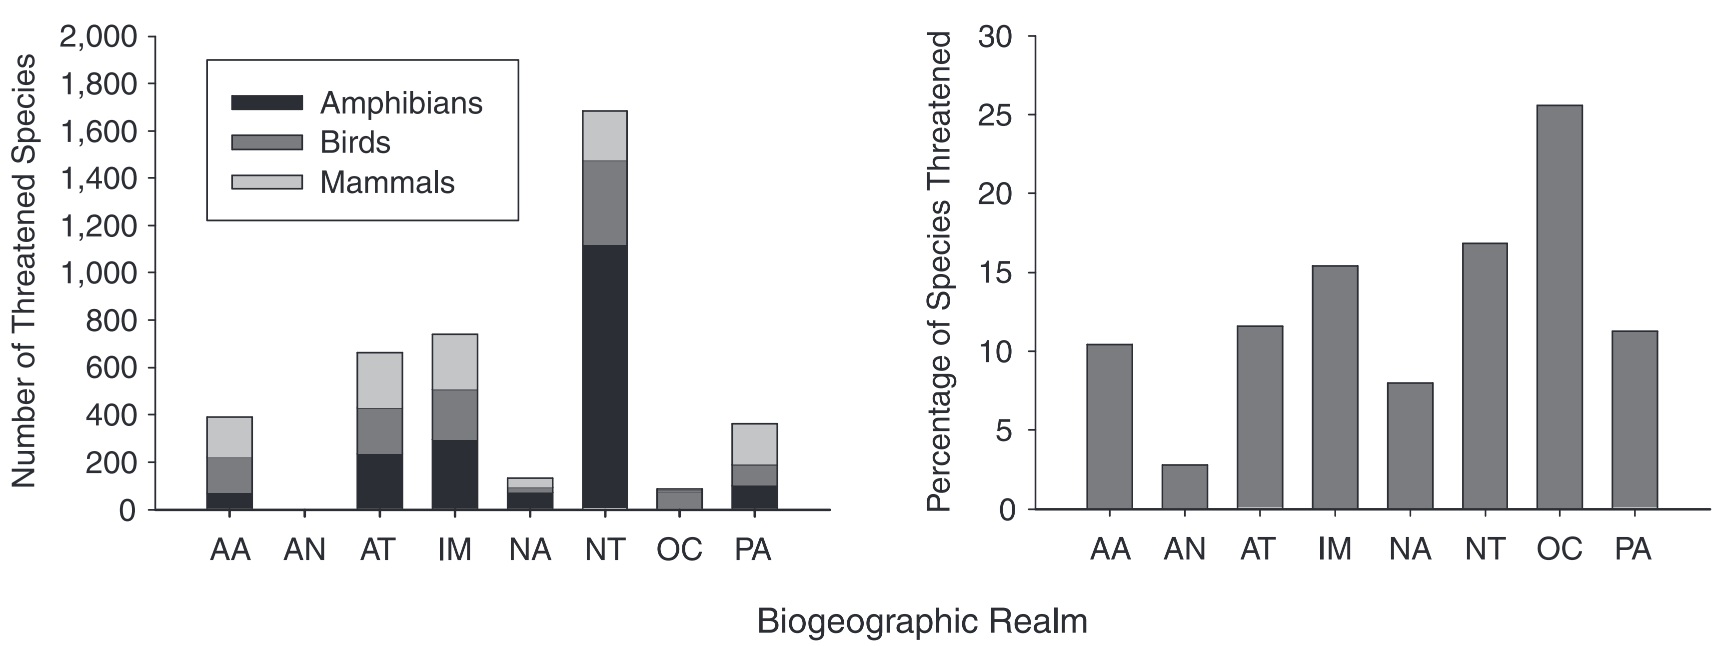

Figure 4.29. Patterns of Species Threat among the World's Eight Terrestrial Biogeographic Realms. The figures show the raw numbers of threatened species (i.e., ranked as Critically Endangered, Endangered, or Vulnerable by the IUCN) and the percentage of each realm's species that are threatened. Reptiles have not been completely assessed. Realm codes as in Table 4.3.

which they occur. The LPI can be applied at national, regional, and global levels, as described earlier. Although it is based on a large number of population trends, various sampling biases affect the index, though with care these biases can be addressed (Loh et al. 2005). Being based on local population abundances, the LPI may be an appropriate biodiversity indicator for ecosystem services, especially with careful sampling of the populations included in its calculation. A complementary index is the Red List Index derived from the *IUCN Red List* of threatened species (Butchart et al. 2004). Red List Indices illustrate the relative rate at which a particular set of species changes in overall threat status (that is, projected relative extinction-risk), based on population and range size and trends as quantified by Red List categories. RLIs can be calculated for any representative set of species that has been fully assessed at least twice. The RLI for the world's birds shows that that their overall threat status has deteriorated steadily during 1988–2004 in all biogeographic realms and ecosystems. A preliminary RLI for amphibians for 1980–2004 shows similar rates of decline (Butchart et al 2005). Both these indexes (LPI and RLI) synthesize much detailed information into a few compelling data points and are being used for assessing progress against the Convention on Biological Diversity's 2010 target.

Currently there has been much less attention paid to the development of indicators for aspects of biodiversity other than species and populations. One recent attempt to collate and synthesize all up-to-date estimates of global trends in population size or habitat extent could find global estimates of habitat change (spanning at least five years since 1992) for only four major biomes (tropical forest, temperate and boreal forest, seagrass, and mangroves) (Balmford et al. 2003a). Neither has there been a focused process to measure the intensity and trends in the key drivers of biodiversity change or the implementation and effectiveness of response options. (See Chapter 5 of the *Policy Responses* volume.) It is clear that a broader set of biodiversity indicators is required, with indicators that are aligned against valued aspects of biodiversity. The adoption of the 2010 biodiversity target makes this task still more urgent (Balmford et al. 2005; Green et al. 2005).

4.5.2 The CBD 2010 Biodiversity Target

In April 2002, at the Sixth Conference of the Parties of the Convention on Biological Diversity, 123 Ministers described a desire to halt biodiversity loss and further committed themselves to actions to "achieve, by 2010, a significant reduction of the current rate of biodiversity loss at the global, regional and national levels as a contribution to poverty alleviation and to the benefit of all life on earth" (Decision VI/26; CBD Strategic Plan). Carrying this message forward, the world's leaders, at the World Summit on Sustainable Development, set a target for "a significant reduction in the current rate of loss of biological diversity" by 2010. This target has now been adopted formally by the parties to the CBD as well as by all participants in the WSSD. The same or a similar target is being adopted at regional levels. For example, the European Union Council adopted a more ambitious target and agreed in 2001 "that biodiversity decline should be halted . . . by 2010" (European Council 2001).

Apart from the data gathering needed to assess progress against the target, its formulation poses some technical challenges, especially for its implementation at a global level. First, the measures of biodiversity to be used as indicators need to be available over a sufficient time period, need to have been measured or estimated consistently, and need to be relevant to the goals. At global level, consistent and repeated measures of biodiversity are rather few, although there are better options at national and regional scales.

Second, because the target is "a significant reduction in the current rate of loss of biological diversity," it requires that the rate of loss has declined, not that there is no more biodiversity loss, or even recovery. In this sense, especially given the time scale, this makes achieving the target more realistic. To demonstrate any change in rate, however, at least three estimates of the measure need to be available for a period of time prior to 2010. Two measures at different points in time can only give information about absolute change, not changes in the rate.

Third, consideration needs to be given to timelines against which progress will be measured. In highly degraded systems, the target may be achieved simply because the system is so reduced that further loss has to be at a slower rate. The choice of baseline against which changes are measured will affect the decision about whether or not the target has been met. A slight increase from a recent low biodiversity score might more readily be perceived as a reduction in rate than the same increase compared with a historically longer and greater decline.

4.5.2.1 The Development of Indicators for the 2010 Target

Efforts to develop indicators for the 2010 target have progressed on a number of fronts, most notably through the work of the CBD. The WSSD was followed by the Open-Ended Intersessional Meeting on the Multi-Year Programme of Work, which recommended that CBD COP7 "establish specific targets and timeframes on progress toward the 2010 target" and "develop a framework for evaluation and progress, including indicators" (UNEP 2003a, 2003b, 2003c).

At the Ninth Meeting of the Subsidiary Body on Scientific, Technical and Technological Advice, it was recommended that development and adoption of indicators of biodiversity loss might be accomplished through a pilot phase between the Seventh and Eighth Conference of the Parties to test a limited set of indicators for their suitability and feasibility, to be implemented by national institutes of the Parties and international organizations with relevant data and expertise (Recommendation IX/13). The recommendations from SBSTTA 9 were carried forward at COP 7 in February 2004 via Decision VII/30, in which the Parties agreed to the following seven focal areas for indicator development:

- reducing the rate of loss of the components of biodiversity, including: (i) biomes, habitats and ecosystems; (ii) species and populations; and (iii) genetic diversity;
- promoting sustainable use of biodiversity;
- addressing the major threats to biodiversity, including those arising from invasive alien species, climate change, pollution, and habitat change;
- maintaining ecosystem integrity, and the provision of goods and services provided by biodiversity in ecosystems, in support of human well-being;
- protecting traditional knowledge, innovations and practices;
- ensuring the fair and equitable sharing of benefits arising out of the use of genetic resources; and
- mobilizing financial and technical resources, especially for developing countries, in particular least developed countries and small island developing States among them, and countries with economies in transition, for implementing the Convention and the Strategic Plan.

It was further agreed that goals and sub-targets would be established, and indicators identified, for each of the focal areas. At the time of writing, eight indicators had been identified for immediate testing and a further 13 were under development. (See Table 4.9.)

Table 4.9. Focal Areas, Indicators for Immediate Testing, and Indicators for Future Development, Agreed to by SBSTTA 10, February 2005

Focal Area	Indicator for Immediate Testing	Possible Indicators for Development by SBSTTA or Working Groups
Status and trends of the components of biological diversity	trends in extent of selected biomes, ecosystems, and habitats	
	trends in abundance and distribution of selected species	
	coverage of protected areas	
	change in status of threatened species (Red List indicator under development)	
	trends in genetic diversity of domesticated animals, cultivated plants, and fish species of major socioeconomic importance	
Sustainable use	area of forest, agricultural, and aquaculture ecosystems under sustainable management	proportion of products derived from sustainable sources
Threats to biodiversity	nitrogen deposition	
	numbers and cost of alien invasions	
Ecosystem integrity and ecosystem goods and services	marine trophic index	application to freshwater and possibly other ecosystems
	water quality in aquatic ecosystems	incidence of human-induced ecosystem failure
	connectivity/fragmentation of ecosystems	health and well-being of people living in biodiversity-based, resource-dependent communities
		biodiversity used in food and medicine
Status of traditional knowledge, innovations, and practices	status and trends of linguistic diversity and numbers of speakers of indigenous languages	further indicators to be identified by a Working Group
Status of access and benefit-sharing		indicator to be identified by a Working Group
Status of resource transfers	official development assistance provided in support of the Convention (OECD-DAC-Statistics Committee)	indicator for technology transfer

The first measures to move from the indicators for development to indicators for immediate testing seem likely to be the Red List Index (Butchart et al. 2004) and possibly also new measures of the extent and quality of key habitats. Coral reef extent may be assessed using established methods (Gardner et al. 2003), and there are likely to be other potential habitats whose extent can be assessed, using remote sensing techniques (such as mangroves).

4.5.2.2 Prospects for Meeting the 2010 Target

Despite the fact that at the time of writing there is no agreement on a complete set of indicators to be used for the 2010 target, various lines of evidence indicate that it is unlikely to be met. First, as evident from information in the preceding section, trends are still downwards for most species and populations, and the rate of decline is generally not slowing. The same is true also for data presented in aggregate indices such as the Living Planet Index (Loh and Wackermagel 2004), the Red List Index (Baillie et al. 2004), and the Pan-European Common Bird Monitoring Scheme (Gregory et al. 2003).

In the case of both the simple and aggregate measures, there are a few exceptions of species and ecosystems where declines are slowing or have been reversed. For example, the reduction in decline rates for some temperate woodland bird species and the recovery of some large mammals in Africa are testament to the potential success of effective management. These cases, however, generally result from management interventions that have been in place for many years and in some cases decades and they are in the minority.

For the species and habitats that showed continuing decline in 2004, prospects for meeting the 2010 target will depend on sources of inertia and the time lag between a management intervention and the response. Natural sources of inertia correspond to the time scales inherent to natural systems; for example, all external factors being equal, population numbers grow or decline at a rate corresponding to the average turnover time or generation time. Even though meeting the 2010 target does not require recovery, many natural populations have generation times that limit the long-lasting improvements that can be realistically expected between now and 2010. On top of this is anthropogenic inertia resulting from the time scales inherent in human institutions for decision-making and implementation (MA 2003). For most systems these two sources of inertia will lead to delays of years, and more often decades, in slowing and reversing a declining biodiversity trend. This analysis assumes that the drivers of change could indeed be halted or reversed in the near term, although there is currently little evidence that any of the direct or indirect drivers are slowing or that any are well controlled at large to global scale.

The delay between a driver affecting a system and its consequences for biodiversity change can be highly variable. In the case of species extinctions this process has been well studied, and habitat loss appears to be one direct driver for which lag times will be long . In studies of African tropical forest bird species, the time from habitat fragmentation to species extinction has been estimated to have a half-life of approximately 50 years for fragments of roughly 1,000 hectares (Brooks et al. 1999). In Amazonian forest fragments of less than 100 hectares, half of the bird species were lost in less than 15 years, whereas fragments larger than 100 hectares lost species over time scales of a few decades to perhaps a century (Ferraz et al. 2003).

On the one hand, these time lags mean that estimates of current extinction rates may be underestimates of the ultimate legacy of habitat loss. For example, for African primate populations it is estimated that over 30% of species that will ultimately be lost as a result of historical deforestation still exist in local populations (Cowlishaw 1999). On the other hand, the time lags offer opportunities for interventions to be put in place to slow or reverse the trends, so long as in this case the period to habitat recovery is shorter than the time to extinction.

4.5.3 Key Gaps in Knowledge and Data

Certain gaps in knowledge and data relating to biodiversity are almost certain to prove critical over coming years, and efforts are urgently needed to gather this information, particularly if biodiversity indicators are to become more reliable and informative.

- Data are sparse for certain key taxa—especially invertebrates, plants, fungi, and significant groups of microorganisms, including those in the soil. These groups are especially important for ecosystem services, yet global syntheses and trend information on even significant subsets are entirely missing. It seems likely that both extinction rates and local diversity and endemism may be lower among microorganisms than in the well-studied groups, suggesting that intense monitoring may not be so important. However this remains to be validated. Taxonomy as a discipline underpins much of this work yet is in decline worldwide.
- Conservation assessment has proceeded at increased intensity over recent decades. However, knowledge of biodiversity trends falls far behind knowledge of status. Too often assessments are undertaken using new methods, new measures, or new places. Trends, which are critical to current questions, rely on a time series of comparable measures.
- Local and regional datasets are generally of higher quality and cover longer time periods than global data. A better understanding of the relationship of local to global processes and the development of techniques to allow local dynamics to inform large-scale assessments would allow rapid progress to be made in large to global-scale assessments.
- There are far fewer studies at the genetic level than for populations, species, and ecosystems, yet these are significant components of biodiversity for assessing present and future adaptability to changing environments.
- Marine and freshwater areas are less well known than terrestrial areas. Among terrestrial habitats, biodiversity trends in biomes such as drylands and grasslands are less well known than trends in forests.
- The impacts of biodiversity change on ecosystems services are still poorly understood. Even where knowledge is better, there are almost no studies documenting the trends over time.

Alongside new data, approaches to long-term, large-scale continuous monitoring of biodiversity and attitudes to data sharing will need to be developed, as well as the infra-structure and technical and human resources that such an effort will require.

4.6 A Summary of Biodiversity Trends

The evidence presented in this chapter supports three broad conclusions about recent and impending changes in the amount and variability of biodiversity: there have been and will continue to be substantial changes that are largely negative and largely driven by people; these changes are varied—taxonomically, spatially, and temporally; and the changes are complex, in several respects.

First, changes are substantial and predominantly negative. Although there are very real limitations in the extent and quality of our knowledge of the changing state of nature, we already have overwhelming evidence that humans have caused the loss of a great deal of biodiversity over the past 50,000 years and that rates of loss have accelerated sharply over the past century. Current rates of species extinction are at least two orders of magnitude above background rates and are expected to rise to at least three orders above background rates.

Among extant species, 20% of all species in those groups that have been comprehensively assessed (mammals, birds, amphibians, conifers, and cycads) are believed to be threatened with extinction in the near future. For birds (the only taxon for which enough data are available), this proportion has increased since 1988 (BirdLife 2004a). Even among species not threatened with extinction, the past 20–40 years have seen substantial declines in population size or the extent of range in most groups monitored. These include European and North American farmland birds, large African mammals, nearly 700 vertebrate populations worldwide (Loh 2002), British birds, waders worldwide (IWSG et al. 2002), British butterflies and plants (Thomas et al. 2004a), amphibians worldwide (Houlahan et al. 2000; Alford and Pechmann 2001; Stuart et al. 2004), and most commercially exploited fish. These declines in populations are broadly mirrored by declines in the extent and condition of natural habitats (Jenkins et al. 2003).

Second, changes are varied. Rates of biodiversity decline, although very largely negative, vary widely on at least three dimensions. Taxonomically, certain groups appear more vulnerable to change than others: thus amphibians, and freshwater organisms in general, exhibit higher levels of threat and steeper rates of population decline than do better-known groups such as birds or mammals (Houlahan et al. 2000; Alford and Pechmann 2001; Loh 2002). Within groups, phylogenetically distinct, ancient, and species-poor lineages seem consistently to be faring disproportionately badly. Some generalist species are expanding their ranges, either naturally or as invasive aliens, whereas many ecological specialists are in decline.

Spatially, most species losses to date have been concentrated on islands. Disproportionately high rates of contemporary habitat conversion in endemic-rich areas of the tropics, where areas of dense human settlement and high species richness tend to coincide, mean that impending extinctions are particularly concentrated in tropical island and montane systems. In temperate regions, in contrast, substantial historical reductions in habitat extent have led to relatively few global extinctions (due in part to species having larger ranges at higher latitudes). Currently, populations and habitats are expanding in some temperate regions, such as temperate forests (Jenkins et al. 2003). Freshwater and marine patterns are less well documented.

Temporally, two patterns stand out. The first is that the scale of loss is in general increasing (although it is important to note that, both on land and at sea, preindustrial human-caused losses were also very substantial (Jackson 1994; Jackson et al. 2001)). The second pattern is that the anthropogenic drivers of loss are also changing; for example, invasive species and overexploitation were the predominant causes of bird extinctions in historic times, while habitat conversion, especially to agriculture, is the most significant driver currently facing threatened species (Baillie et al. 2004; BirdLife 2004a), with climate change predicted to emerge as another major threat in the near future (Thomas et al. 2004a).

Third, changes are complex. Besides variety, the overriding feature of biodiversity is its complexity. Patterns of biodiversity loss are in turn correspondingly complex, in several respects. Species, populations, and ecosystems differ not just in their exposure but also in their vulnerability to anthropogenic drivers of change. In addition, complex interactions within communities mean that changes in the abundance of one species will often have broad-ranging effects through a system. (See also Chapter 12.) One well-documented example is the recent switch by Aleutian island killer whales to hunting sea otters instead of pinnipeds (likely triggered by fishing-related declines in pinnipeds); this has greatly reduced sea otter numbers, allowing the population and grazing pressure of sea urchins to increase, in turn leading to a dramatic decline in kelp density (Estes et al. 1998). In Australia, the deliberate introduction of African grasses (such as gamba grass, *Andropogon gayanus*) to native woody savannas has also increased the intensity of frequent, very intense fires due to the highly flammable nature of the introduced grasses (Rossiter et al. 2003); as elsewhere (D'Antonio and Vitousek 1992), changes in the fire regime in turn reduced native tree and shrub cover, thereby accelerating the invasion of fire-tolerant aliens and resulting in a wholesale ecosystem shift from woody vegetation to open grassland.

Another aspect of the complexity is that community dynamics mean threats themselves rarely operate in isolation (Myers 1995). The impact of climate change, for example, is predicted to be far more marked where habitat transformation and fragmentation blocks the movement of species in response to shifting climate (Thomas et al. 2004a), a hypothesis recently supported by data on U.K. butterflies (Warren et al. 2001). Similarly, there is now growing evidence of synergistic effects of increased UV-B exposure, acidification, and pathogens on declining amphibian populations (Kiesecker and Blaustein 1995; Long et al. 1995) and of synergistic effects between logging, forest fragmentation, and fire in tropical forests (Cochrane et al. 1999; Cochrane 2003).

It is also becoming clear that often ecosystems respond not linearly to external changes but in a stepwise manner (Myers 1995). Thus cumulative biotic or abiotic pressures that at first appear to have little effect may lead to quite sudden and unpredictable changes once thresholds are crossed (Scheffer et al. 2001). Moreover, such thresholds may become lower as anthropogenic impacts simplify systems and reduce their intrinsic resilience to change. (See also Chapter 12.) One well-studied example is the sudden switch in 1983 from coral to algal domination of Jamaican reef systems. This followed several centuries of overfishing of herbivores, which left the control of algal cover almost entirely dependent on a single species of sea urchin, whose populations collapsed when exposed to a species-specific pathogen (Hughes 1994; Jackson 1997). As a result, Jamaica's reefs shifted (apparently irreversibly) to a new low diversity, algal-dominated state with very limited capacity to support fisheries (McManus et al. 2000). Given their potential importance, much more work is needed on whether threshold effects such as this are typical, how reversible they are, and where thresholds lie.

Extrapolation from current trends suggests that both the amount and variability of nature will continue to decline over much of Earth (UNEP 2002a; Jenkins et al. 2003). The exception is likely to be in some industrial countries, where forest cover may continue to increase and, with it, the population sizes of many forest-dependent species. In contrast, clearance of natural habitats, reductions of populations, and the associated loss of populations and indeed species look set to persist and even accelerate across much of the tropics and across many if not most aquatic systems. Particularly vulnerable areas include cloud forests, coral reefs, mangroves (threatened by the synergistic effects of climate change and habitat clearance), all but the very largest blocks of tropical forest, and most freshwater habitats. Particularly vulnerable taxa include large marine species, large-bodied tropical vertebrates, and many freshwater groups (Jenkins et al. 2003).

Main Messages

Over historical time frames, human well-being has on aggregate improved by several orders of magnitude. Incomes have increased, populations have grown, life expectancies have risen, and political institutions have become more participatory. In the global aggregate, human well-being continues to expand, although there are variations across geographical regions.

Well-being is not distributed evenly among individuals, countries, or social groups. Inequality is high, and gaps between the well-off and the disadvantaged are increasing. A child born in sub-Saharan Africa is 20 times more likely to die before age five than a child born in an OECD country, and this ratio is higher than it was a decade ago.

The ecosystems as classified by the Millennium Ecosystem Assessment vary in the degree to which they harbor high values of human well-being. For example, cultivated systems and coastal ecosystems tend to be characterized by high human well-being, while drylands are characterized by low human well-being.

The degree to which well-being varies across ecosystems is not the same everywhere. Variance in human well-being is highest in Asia and sub-Saharan Africa and lowest in the OECD. For example, per capita incomes in Asia are 40% higher in the coastal zones than they are in the drylands, while in OECD countries there is no significant difference between incomes in the two systems.

Populations are increasing in ecosystems characterized currently by low well-being. Whereas historically populations have tended to shift from low-productivity ecosystems to high-productivity ecosystems or to urban areas, today there are signs that the relative concentration of people in less productive ecosystems is going up. The concentration of poor in less-favored lands of Asia and sub-Saharan Africa is an example.

These trends signify that there are a large number of people at risk of adverse ecosystem changes. Approximately 1.1 billion people survive on less than $1 per day of income, most of them in rural areas where they are highly dependent on agriculture, grazing, and hunting for subsistence. For these people, degradation and declining productivity of ecosystems threatens their survival.

Ecosystem changes affect human well-being in a variety of different ways. Often the impacts of ecosystem changes are shifted from the groups responsible for them onto other groups. Sometimes ecosystem change is embedded in distributional conflicts over resources, with one group improving at another group's expense. Often impacts are experienced differentially as a function of levels of coping capacity—such differences can manifest themselves at the individual, household, regional, or national level.

Among less poor populations, ecosystem changes affect well-being in more subtle but not necessarily less important ways. Declines in incomes, loss of culturally important natural resources, and increases in threats to health can be expected to accompany declining ecosystem health.

5.1 Introduction

This chapter provides an overview of the primary patterns and trends in human well-being and summarizes what is known broadly about the connections between human well-being and ecosystems. It does not substitute for the more detailed findings found in the other chapters of this volume, but rather provides an overarching empirical foundation for assessing human well-being and ecosystem change side by side.

5.2 Dimensions of Human Well-being

This section reviews how the different dimensions of human well-being are measured, the extent of our knowledge about them, and the primary measurement gaps. (See also Chapter 2 for further description of the measurement of human well-being.) The benefits of qualitative data and new approaches for assessing human well-being are acknowledged, but the use of this information is limited in this global assessment because of difficulties comparing data across countries and aggregating information within units of ecosystems. Five dimensions of human well-being are recognized in the MA: basic material for a good life, freedom and choice, health, good social relations, and security (MA 2003).

5.2.1 Basic Material for a Good Life

The basic materials for a good life include adequate income, household assets, food, water, and shelter. Considerable effort goes into measuring and monitoring these dimensions of well-being. Systems of national accounts generate regular estimates of gross national income and GNP; these estimates are made roughly comparable through calculation of purchasing power parity, estimates that correct for price differences across countries. Food production is measured by central governments and by international organizations such as the Food and Agriculture Organization. FAO also measures national per capita dietary energy supply for most countries. (See Chapter 8 for further information.) Micronutrient information on vitamin A, iodine, and iron is collected at the community level but is not as widely available as DES. National-level water estimates are available, though these tend to be less precise than income and food measures. Of all these measures, shelter is probably the most poorly measured. The distribution of the quality of substandard housing is not known with any confidence.

Increasingly, measures of these basic material dimensions of well-being are being carried out through detailed household surveys (Deaton 1997). Living standard measurement surveys began collecting standardized measures of well-being at the household level in 1985. Approximately 100 developing countries have carried out such surveys. Other large-scale household survey efforts include demographic and health surveys and national-level multiple indicator cluster surveys. Surveys such as these provide information about nutrition, housing type, household assets, and access to water, health care, and sanitation.

Although great effort goes into these measurement efforts, they do not provide a complete enough picture to support a full understanding of the distribution of well-being and its relationship to ecosystem services. Comparable measures of water and sanitation access, for example, are scarce, because terminologies, methodologies, and measurement priorities differ from place to place (Millennium Project 2004). Even the measurements that receive the greatest level of effort, the national income measures, are inadequate for many purposes. They imperfectly capture economic activity outside the formal sector and the value from subsistence activities, for example, which is often highly important among populations vulnerable to decline in ecosystem services.

Especially problematic is the concept of poverty. Although poverty is the focus of many local, national, and international policies, and although many countries measure it, there is little congruence of measurement efforts and, as a result, little ability to portray clear patterns and trends (Deaton 2003; Reddy and Pogge

2002). Some efforts to measure poverty do so strictly in terms of income. For example, the World Bank relies heavily on household survey data to estimate the number of people living on less than $1 per day, and this measure is a prominent component of the Millennium Development Goal targets.

However, measures of income poverty have been criticized because of problems of comparability and relevance. Comparability is difficult because of the challenges involved in comparing prices, which is quite important at such low thresholds of income. Relevance is a problem where human well-being is often heavily dependent on non-income factors such as household assets (stoves, bicycles, toilets, housing materials, and so on) and output from subsistence activities (cultivation, hunting, and fishing). In spite of such measurement and comparability difficulties, an attempt is made here to provide an overview of trends in selected human well-being indicators and ecosystems.

5.2.2 Freedom and Choice

Freedom is defined as the range of options a person has in deciding on and realizing the kind of life to lead. At a broad scale, only a few of the many specific phenomena that are relevant to this dimension of well-being are measured at all, and many of those that are measured are problematic.

The degree to which political institutions are participatory is not measured by any intergovernmental agency, chiefly because of disputes over what are appropriate measures. The most widely used measure in the scientific literature is the polity database, which provides annual measures of democratic institutions for 160 countries (Jaggers and Gurr 1995). The polity data, and similar efforts such as the Heritage Foundation's index of civil liberties, provide comparable, clear measures of national political institutions that emphasize electoral institutions and constraints on chief executives. There are no comparable data that measure citizen participation in decision-making at regional or local levels, although this dimension of freedom and choice has been well connected to ecosystem management and human well-being (Ostrom 1990; Ostrom et al. 2002).

Education is a clear aspect of well-being that enhances life prospects. Comparable international measures are poor. A frequently used measure is literacy, which is a component of the Human Development Index. Literacy is hard to measure accurately and comparably (Bruns et al. 2003). Moreover, it represents only a small aspect of education. Some countries collect comparable data on the percent of the population (often broken down by gender) enrolled in school, but this too is incomplete. More relevant for life prospects is the school completion rate, but this is not well measured.

5.2.3 Health

Human health is measured in a variety of ways, and knowledge about broad trends and patterns concerning health is good. Life expectancy, infant mortality, and child mortality are measured fairly intensively. Most central governments collect these vital statistics and publish them; international organizations such as the World Health Organization and World Bank collate and harmonize these measures. As a result, high-quality country-level time series on these measures are available. Some scholars have been able to construct time series going back several centuries by relying on a range of vital statistics collections (Maddison 2001).

Knowledge of health aspects of human well-being is more limited when it comes to more precise dimensions such as sub-national patterns or specific disease prevalences. There are no consistent monitoring or measurement efforts that measure health outcomes at a sub-national level. Infant mortality and child mortality are measured through a set of coordinated household survey efforts, including the DHS and MICS, and these can be used to generate estimates for sub-national regions, on the order of about 10 regions per country. Such surveys are not carried out in every country, however, and no more than about once per decade. As a result, it is difficult to portray the distribution of human health at a level of resolution more precise than national boundaries.

When it comes to measuring health outcomes in terms of specific diseases, monitoring and surveillance are also less complete than for vital statistics. Few disease incidence statistics are collected across a significant number of countries in a comparable enough fashion to permit robust tracking of patterns. The World Health Organization collects disease-specific data by country, but reports primarily at the level of six world regions because of limitations in comparability (WHO 2004).

5.2.4 Good Social Relations

Humans enjoy a state of good social relations when they are able to realize aesthetic and recreational values, express cultural and spiritual values, develop institutional linkages that create social capital, show mutual respect, have good gender and family relations, and have the ability to help others and provide for their children (MA 2003; Dasgupta and Serageldin 1999). This aspect of human well-being is not well measured, largely because it is more difficult to observe directly. Partly as a result of recent scholarship identifying the importance of social relations and social capital in explaining a range of important public policy outcomes (e.g., Putnam et al. 1993; OECD 2001), interest in measuring this dimension has increased considerably in the past decade. Although comparable quantitative measurements remain very primitive, there are case studies that illustrate the sensitivity of ecosystem changes on good social relations. (See Box 20.12 in Chapter 20, on North America's Great Lakes and Invasive Species.) Some research has noted that high levels of economic development are sometimes associated with poor social relations (Jungeilges and Kirchgässner 2002). Problems such as suicide and divorce are observed consequences of such dynamics.

5.2.5 Security

Humans can be said to live in a state of security when they do not suffer abrupt threats to their well-being. Chapter 6 indicates that people within the geographical region of a threat are differently susceptible to its negative effects. Those who are poor, sick, or malnourished generally have fewer assets and coping strategies and are more likely to be more severely affected.

Some of the most salient threats are organized violence, economic crises, and natural disasters. Comparable measures of organized violence are available for international warfare and civil war, but generally not for banditry and other forms of crime. One prominent collection of data on war is the Uppsala conflict database, which attempts to document all political conflicts resulting in 25 or more deaths for the period 1946–2003 (Gleditsch et al. 2002). It provides measures of the frequency of war as well as estimates of the magnitude of war, and rough information on geographical extent. Political violence is not evenly distributed across the world; it is especially concentrated in the poor countries of the world, though not all poor countries experience violence and not all violence takes place among the poor. Figure 5.1, showing the distribution of political conflict, maps the combined incidence of low-intensity (25 deaths or fewer), middle-intensity, and high-intensity (1,000 deaths or more) conflicts for the period 1975–2003. If a region had all three types of conflicts during each of

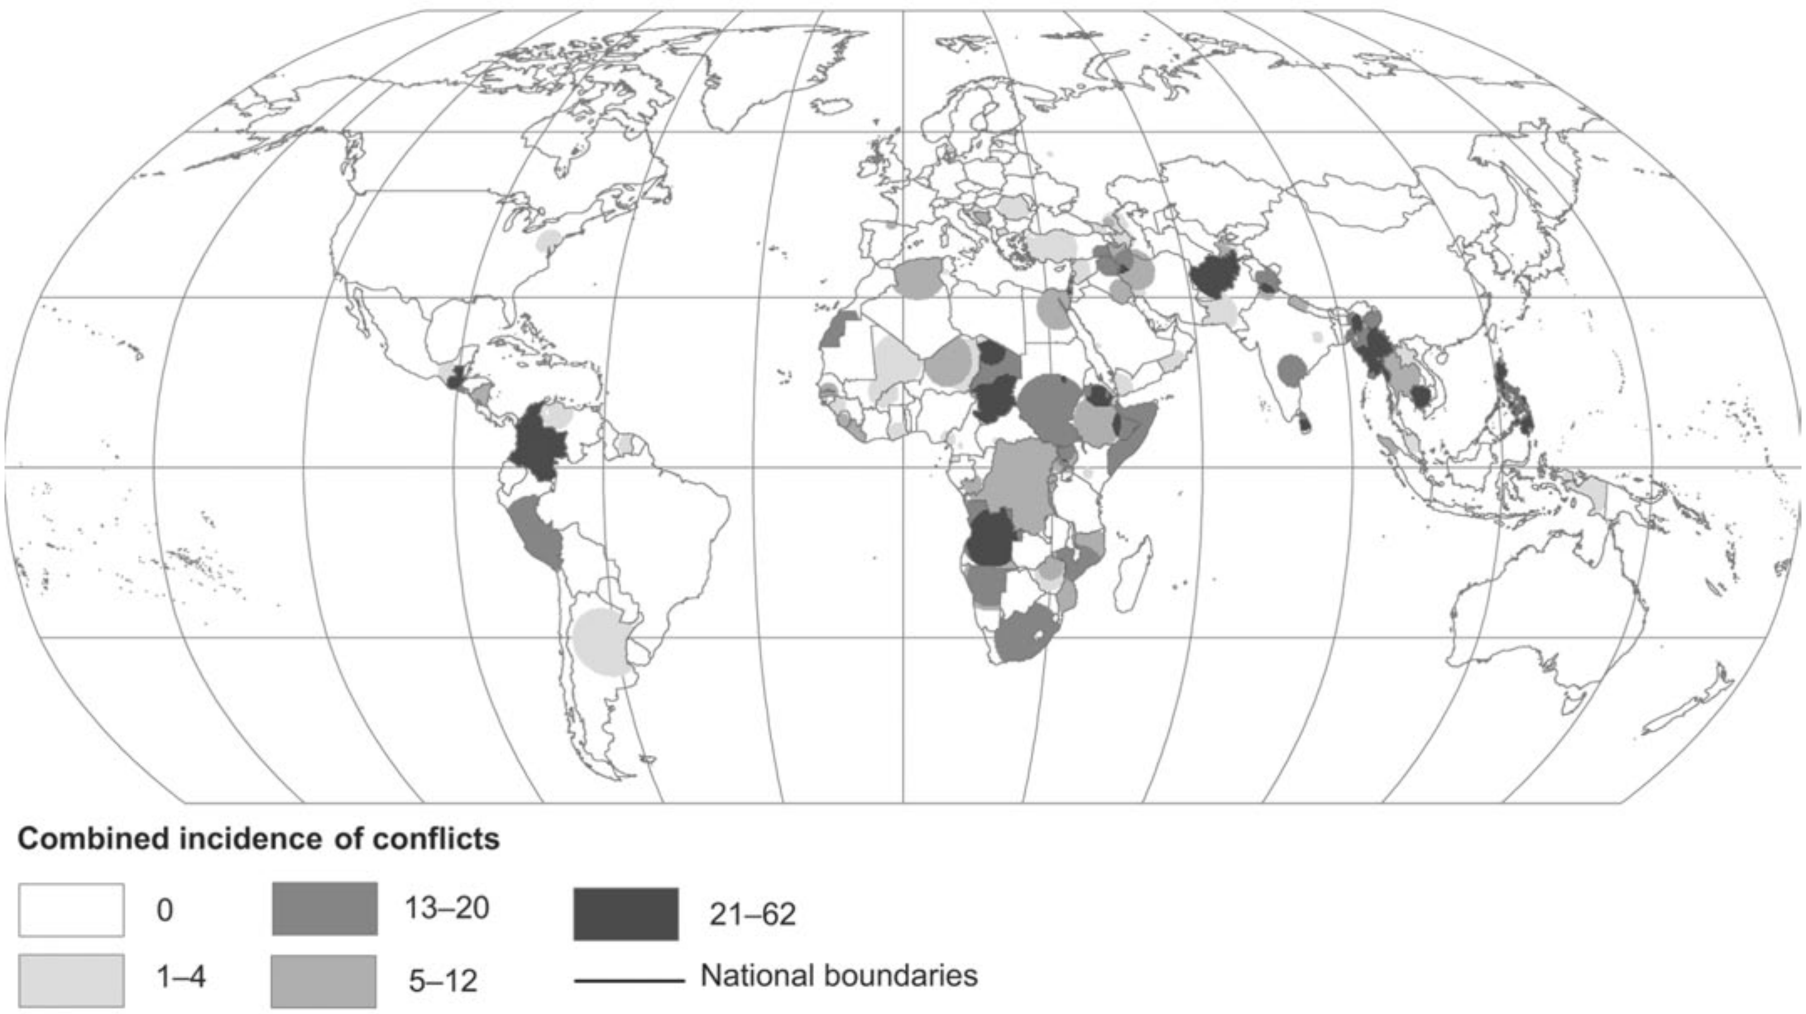

Figure 5.1. Distribution of Internal Political Conflict, 1975–2003 (Robinson Projection)

these 29 years, it would have a value of 87; the observed range is 0–62.

Economic crises—hyperinflation, depressions, exchange-rate shocks, and so on—are well measured by international financial institutions such as the International Monetary Fund, the World Bank, and various regional and national financial authorities. Yet the direct impact of such shocks on ecosystems have not been studied or documented adequately.

Natural disasters are not measured well, though various international organizations and research centers are seeking to improve measurement (Guha-Sapir and Below 2002). The most glaring deficiency in efforts to measure natural disasters is in the area of human impacts. Although some insurance companies undertake considerable efforts to quantify insured economic losses due to natural disasters, many of the grossest effects on human well-being are not insured economic losses, but rather loss of life and shelter in poor communities. (Further information on natural disasters can be found in Chapters 6 and 16.)

5.2.6 Aggregations

A wide variety of efforts to aggregate the multiple dimensions of human well-being have been attempted, the most prominent of which is the Human Development Index. The HDI is endorsed by the intergovernmental community through the U.N. General Assembly and widely used in policy assessments and the scholarly literature. A large number of countries now calculate their own HDIs, typically reporting at sub-national levels. (Other aggregations enjoy less support and are used less widely; see Chapter 2.) The HDI aggregates measures of economic well-being (per capita income), health (life expectancy), and education (literacy and enrollment). It does not take into account cultural or social aspects of well-being, and it considers security dimensions only insofar as they are reflected in economic and health outcomes. It is not meant to be an all-encompassing measure of well-being but rather a useful indicator of development consistent with the development-as-freedom approach pioneered by Sen (1999).

It is acknowledged that human well-being is not equally distributed among different social groups, including among men and women. In response, the U.N. Development Programme in 1995 began calculating the Gender-related Development Index (Prescott-Allen 2001).

Beyond measuring current well-being, there is the important question of sustaining well-being in the future. Asset accounting (an outgrowth of ''green'' national accounting) provides the necessary framework for assessing sustainability. As Hamilton and Clemens (1999) and Dasgupta and Mäler (2000) show, the change in real wealth—genuine savings—is equal to the change in the discounted future flows of well-being measured in dollars. The World Bank publishes figures on ''adjusted net saving'' that account for depreciation of assets; investment in human capital; depletion of minerals, energy and forests; and selected pollution damages (World Bank 2004). While ecosystem services are not directly valued in the published figures, the framework is robust enough to incorporate the economic value of the degradation of ecosystem ''assets'' where these values have been estimated.

5.3 Patterns and Trends in the Distribution of Human Well-being

5.3.1 Global Trends

In the aggregate, human well-being has improved dramatically since the advent of agriculture first made possible the accumulation of wealth. Incomes have risen, life expectancy has gone up, food supplies have risen, culture has become enriched, and political institutions have become more participatory. Two exceptions to this generalization have been the trends in warfare and hunger. Battle deaths (both combatant and civilian) peaked in the middle of the twentieth century, as a consequence of the intensity of the two world wars. Since 1945 they have declined. The second exception is the number of hungry people, which is now increasing. Although the size of world population is not a direct measure of well-being, it constitutes a fundamental background measure and is therefore included in this summary.

Of these trends, population growth shows clear signs of leveling off. (See Chapter 3.) Per capita incomes, life expectancy, and democratization do not yet show signs of leveling off, although they have increased historically at different rates. The absolute number of hungry people began to rise in 1995/97 (FAO 2003), as described in Chapter 8. Warfare patterns are not stable enough to identify clear trends, although the past 50 years have been comparatively peaceful in historical terms. Cultural trends are not susceptible to simple generalizations. Some observers have argued that the global reach of a relatively homogenous mass media threatens local cultural institutions, while others have argued that knowledge of cultural traditions has been able to spread globally; placing values on recent changes such as these is difficult.

Many dimensions of human well-being that can be measured on a large scale, then, have increased considerably over the past 10 centuries and in the aggregate shows signs of continued expansion. Figure 5.2 shows estimates of human life expectancy and per capita income over the past 2,000 years, demonstrating the enormous improvements in basic material aspects of well-being over this long time frame. Figure 5.3 shows trends in the level of democracy and warfare since 1800 in 25-year increments; signs of progress are also visible in these more social dimensions of well-being. As Modelski and Perry (2002) demonstrate, the percentage of the world's population living under democratic institutions has increased steadily for several centuries and crossed the 50% mark in the 1990s. War deaths are lower today than they were in the first half of the twentieth century, but not low in longer historical comparison.

5.3.2 Distributional Patterns

Human well-being is not evenly distributed across individuals, social groups, or nations. Inequality across national boundaries is

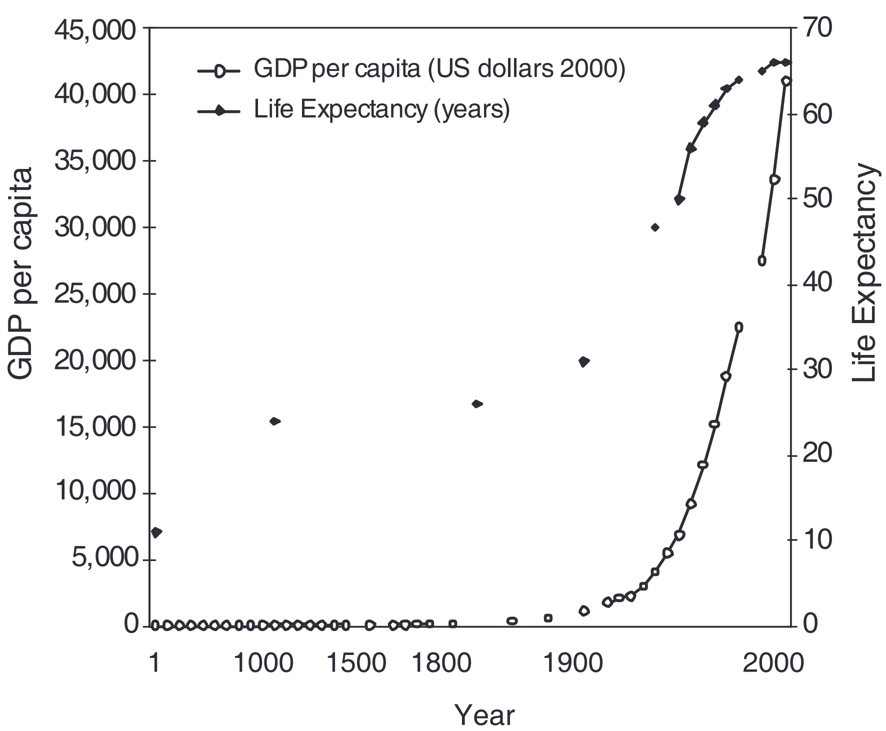

Figure 5.2. Trends for Life Expectancy and Per Capita Income, Past 2,000 Years (Maddison 2001; World Bank 2004; Kremer 1993; Haub 1995; United Nations 1953)

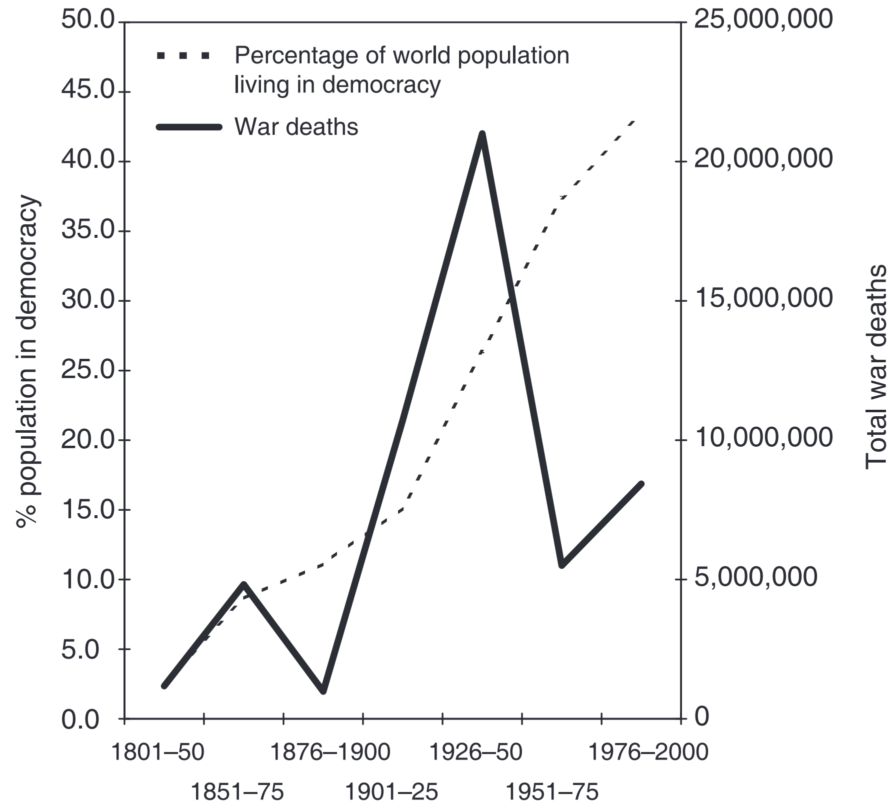

Figure 5.3. Trends in the Level of Democracy and Warfare since 1800 (Modelski and Perry III 1991 and 2002; Sarkees 2000)

high by historical standards. Prior to the industrial revolution in the nineteenth century, national differences in economic output per capita were relatively low; as countries and regions accelerated at different rates of industrialization, they generated dramatic differences in economic growth rates (Maddison 2001; Baudrillard 1998). Cross-national income inequality has increased over the past decade (World Bank 2003). National inequality is apparent in other measures of well-being as well. A child born in sub-Saharan Africa is 20 times more likely to die before age five than a child born in an OECD country, and this ratio is higher than it was a decade ago.

At the individual level, the gap between the world's poorest and the world's richest individuals has increased over the past two decades, though whether this signifies a general increase in inequality among the world's population is the subject of debate (UNDP 2003).

Recent increases in human well-being have been most pronounced in East Asia, where income-poverty levels have been reduced by approximately half since 1990. However, there have been systematic decreases in human well-being in many countries over the last decade. Although differences in growth rates are common, absolute declines in well-being on this scale have been rare. During the 1980s only four countries experienced declines in their rankings in the Human Development Index; during the 1990s, 21 countries registered declines, 14 of which were in sub-Saharan Africa (UNDP 2003). Hundreds of millions of people are living in countries with economic growth rates too low to permit significant poverty reductions (UN Millennium Project 2004).

The overall global pattern of human well-being, therefore, is one in which aggregate levels are continuing to increase at historical rates, although a large number of individuals appear to be stuck at very low levels of well-being.

5.3.3 Spatial Patterns

Human well-being is not evenly distributed with respect to the world's ecosystems. At a global level, there are a limited number of measures of human well-being available through which to assess patterns across ecosystem boundaries. Population totals and densities, infant mortality rates, GDP, and GDP per capita can be calculated using spatial data derived from sub-national sources.

The primary indicators for the MA systems and subsystems are reported in Tables 5.1 to 5.4 and shown graphically in Figure 5.4. (These aggregations do not take into account the urban system; a separate set of aggregations is reported in Chapter 27.) Of these indicators, infant mortality is the most spatially representative measure of human well-being because it is available for most countries at a sub-national level. The global distribution of infant mortality rates is provided in Figure 5.5 (in Appendix A).

At the broadest level of generalization, it is clear that infant mortality rates are highest within drylands and that most of the world's population and GDP is located within cultivated systems. One way to assess well-being across ecosystems more precisely is to compare the fraction of the world's population found within each ecosystem to the fraction of the world's GDP within each ecosystem. If well-being were distributed randomly with respect to ecosystem boundaries, these two numbers would be approximately equal in each ecosystem. Where the ratio of population fraction to GDP fraction is much higher than one, people are less well off in relative terms; where it is much lower than one, people are better off.

Table 5.1. Human Well-being Indicators, by MA System

System	GDP	Infant Mortality Rate	Area	Population	Population Density
	(billion dollars)	*(deaths per thousand live births)*	*(million sq. km.)*	*(billion)*	*(people per sq. km.)*
Coastal	9,148	41.5	6.0	1.0	169.7
Cultivated	27,941	54.3	35.3	4.1	116.2
Drylands	10,395	66.6	59.9	2.1	35.2
Forest	11,406	57.7	41.9	1.2	28.4
Inland Water	10,215	57.6	29.1	1.4	48.1
Island	7,029	30.4	7.1	0.6	85.5
Mountain	7,890	57.9	31.9	1.2	38.2
Polar (Arctic)	96	12.8	8.1	0.0	0.7

Table 5.2. Population Growth within MA Systems, 1990–2000

System	Change in Population	Net Change in Population	Change in Population per Square Kilometer
	(million)	*(percent)*	
Cultivated	505.7	14.1	14.3
Dryland	329.6	18.5	5.5
Inland Water	203.5	17.0	7.0
Mountain	171.0	16.3	5.4
Forest	142.1	13.5	3.4
Coastal	140.3	15.9	23.3
Island	67.0	12.3	9.5
Polar	–117.9	–6.5	0.0

Table 5.3. Distribution of Dryland Population Growth, 1990–2000

Region	Increase in Dryland Population	Share of World Population Increase
	(million)	*(percent)*
Asia	180	54.5
Former Soviet Union	5	1.4
Latin America	21	6.4
Northern Africa	65	19.6
OECD	10	3.2
Sub-Saharan Africa	49	14.9
World	**330**	**100.0**

As seen in Figure 5.6, this ratio varies considerably across the MA systems, and this variation is correlated with differences in measured infant mortality rates. The drylands emerge as clearly an ecosystem characterized by low levels of human well-being. (See Box 5.1.) In each region, the dryland ecosystem shows higher infant mortality rates than the forest ecosystems, though the ratio of the two varies across regions. The ratio is highest in the former Soviet Union and lowest in Latin America. (See Table 5.5.)

The same comparisons can be performed for the MA subsystems. The results reveal even greater variation in patterns of human well-being than at the system level. As Figure 5.7 shows, infant mortality ranges from over 100 to under 10 in the MA subsystems, and some subsystems have a share of the world's population that is almost three times as large as their share of the world's GDP. At this level of resolution, the drylands do not emerge as clearly disadvantaged as they do in the system comparison. This is likely to be because the 56 MA subsystems are not distributed as evenly across geopolitical regions as the systems are, and therefore the strong effects of these geopolitical regions become more prominent in the subsystem analysis. For example, the MA subsystem with the highest infant mortality rate and the highest ratio of world population fraction to world GDP fraction is a forest subsystem: broadleaf, deciduous, open tree cover. Three quarters of this subsystem type are found within sub-Saharan Africa, where poverty rates in general are quite high, irrespective of ecosystem type.

It must be emphasized that none of these generalizations implies anything about causality. If infant mortality is high within a particular ecosystem, this does not mean that the ecosystem explains the high infant mortality. Rather, it indicates that the ecosystem is home to populations experiencing comparatively low levels of well-being and that these populations are therefore, other things being equal, potentially vulnerable to declines in ecosystem services.

Table 5.4. Human Well-being Indicators, by MA Subsystems. GDP and infant mortality rate estimates were not calculated for polar subsystems due to lack of appropriate resolution data.

MA System	Subsystem	Area	Population	Population Density	GDP	GDP Per Capita	Infant Mortality Rate
		(thousand sq. km.)	*(million)*	*(people/ sq. km.)*	*(bill. 2000 dollars)*	*(2000 dollars)*	*(deaths per thousand live births)*
Coastal	coastal	6,020	1,022	170	9,148	8,956	41.5
Cultivated	agriculture/ two other land cover types	630	91	145	932	10,202	49.6
	agriculture/forest mosaic	4,459	294	66	3,017	10,272	48.2
	agriculture/other mosaic	5,922	508	86	3,001	5,903	62.2
	agriculture with forest	2,170	247	114	3,003	12,154	38.2
	agriculture with other vegetation	2,884	288	100	2,160	7,492	47.7
	cropland	8,270	3,013	243	8,924	4,433	55.3
	cropland/pasture	2,612	152	58	2,515	16,528	45.1
	forest with agriculture	1,601	97	61	1,969	20,235	15.9

	semiarid	22,270	855	38	4,773	5,580	72.4
	arid	15,325	243	16	1,135	4,677	74.2
	hyper-arid	9,635	101	11	601	5,928	41.3
Forest	mosaic: tree cover/ other natural vegetation	2,409	53	22	217	4,137	59.3
	tree cover, broadleaved, deciduous, closed	6,526	348	53	3,312	9,503	58.9
	tree cover, broadleaved, deciduous, open	3,776	88	23	232	2,645	103.7
	tree cover, broadleaved, evergreen	12,210	266	22	1,436	5,394	60.3
	tree cover, burnt	298	0.3	1.0	2.4	8,238	15.9
	tree cover, mixed leaf type	3,182	51	16	953	18,843	12.4
	tree cover, needle-leaved, deciduous	3,804	3.5	0.9	28	8,127	27.2
	tree cover, needle-leaved, evergreen	9,032	370	41	5,184	14,013	28.5
	tree cover, regularly flooded, fresh	562	3.6	6.3	20	5,531	73.4
	tree cover, regularly flooded, saline (daily variation)	89	7.9	89	22	2,794	90.0

If the geopolitical regions are brought into the analysis explicitly, additional detail can be seen. Figure 5.8 (in Appendix A) shows that the differences across geopolitical regions are by and large more significant than the differences across ecosystem boundaries. Sub-Saharan Africa is less well off within each ecosystem than all other world regions, for example. There is also significant deviation from global averages within Asia: the Asian cultivated system contains 44% of the world's population, for example, but only 20% of the world's GDP.

By looking simultaneously at world geopolitical regions and the MA subsystems, the world is divided into 274 overlapping units. The basic patterns are seen in Figure 5.9 (in Appendix A). Well-being disparities across ecosystem types are lowest in the OECD countries and highest in Asia and sub-Saharan Africa. The very low variation within the OECD countries probably reflects the fact that high incomes and advanced infrastructures eliminate the kind of gross sensitivity to ecosystem effects that would influence infant mortality. This figure also shows the fundamentally

Table 5.4. *continued*

different situation that sub-Saharan Africa is in with respect to well-being patterns. Almost all of its IMR values are higher than those found in any other region. Significant exceptions are the Asian dry boreal/subalpine subsystem and the Asian arid subsystem, where IMR values are much higher than the Asian average and well within the sub-Saharan African range.

5.3.4 Temporal Patterns

Most global socioeconomic indicators that are available in spatially disaggregated (sub-national) formats are not available in time series, and therefore it is difficult to say much about broad trends within the MA system boundaries. The exception to this generalization is

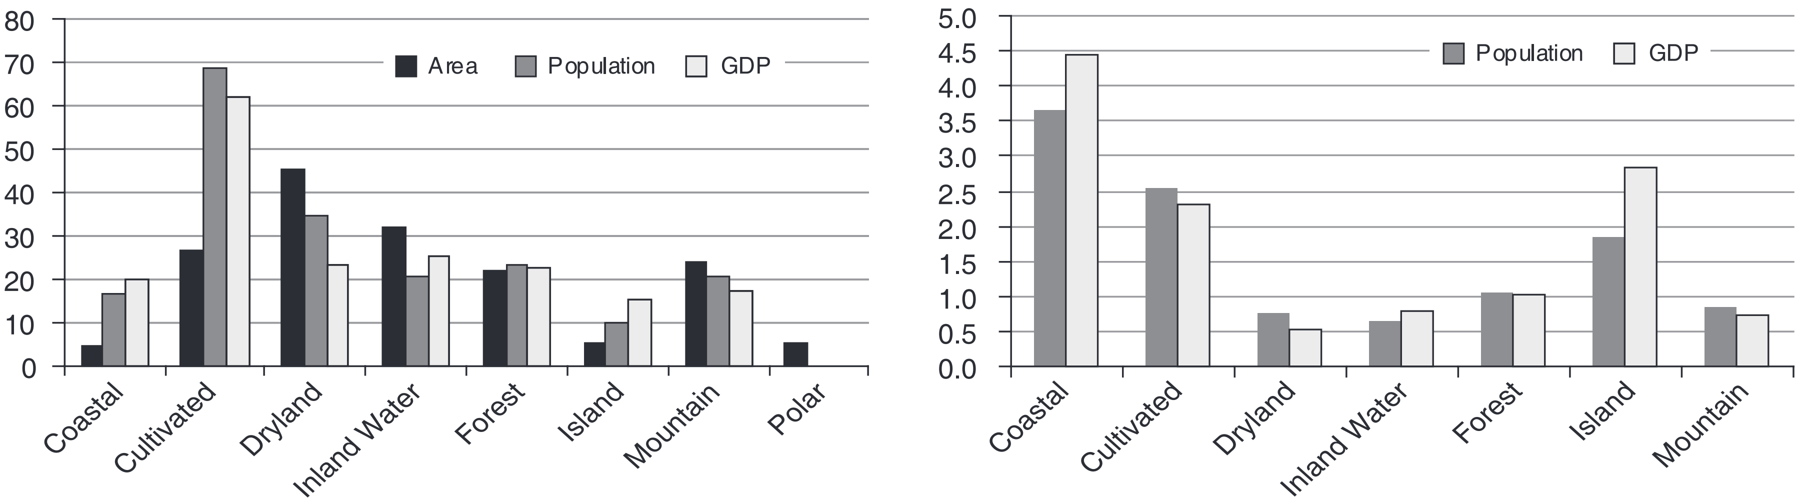

Figure 5.4. MA System Attributes as Percentage of World Total and Share of World Population and GDP as Ratio of Share of World Area (CIESIN 2004)

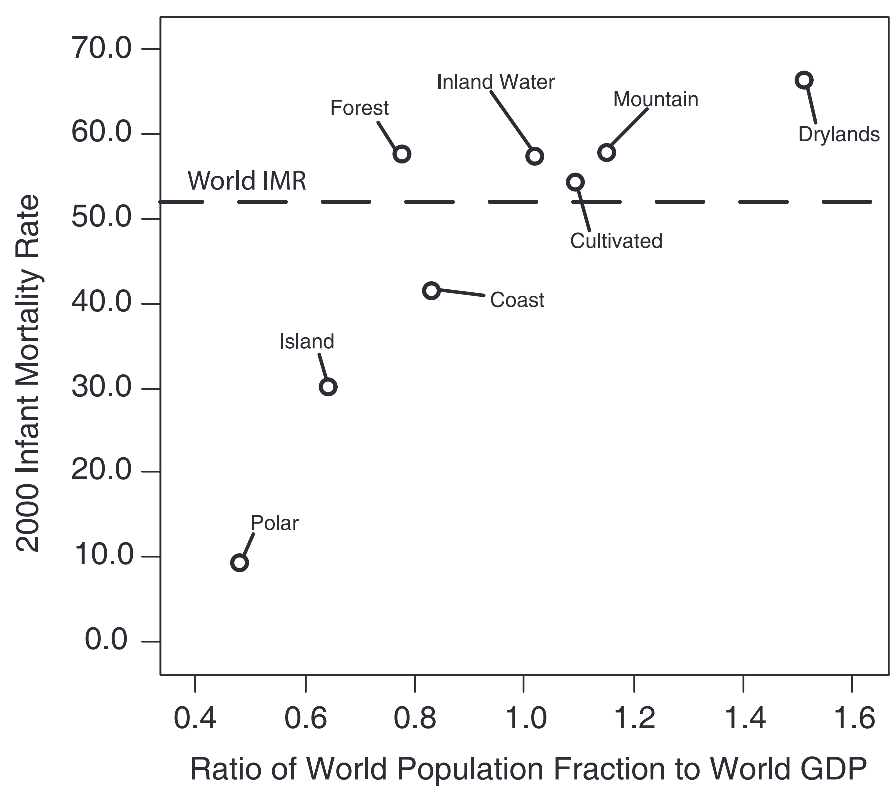

Figure 5.6. MA Systems and Relative Measures of Well-being

population. Because most countries carried out censuses both around 1990 and around 2000, and since these have been geo-referenced and integrated into a consistent grid, it is possible to estimate changes over the 1990–2000 period within the MA systems, as in Table 5.2.

Considering the global MA systems, the fastest growth rate during the 1990s occurred in the drylands, where population increased by 18.5%. The MA system with the greatest increase in total population is the cultivated system, where population increased by 506 million. If population growth is divided by land area, the highest value is observed in the coastal zone, where over the 1990s population grew by 23.3 people per square kilometer.

The fact that the highest growth rates are in an especially vulnerable ecosystem is significant. As the World Bank (2003) has pointed out, historically populations have migrated out of marginal lands to cities or to agriculturally productive regions; today the opportunities for such migration are limited due to poor economic growth in many African cities and much tighter immigration restrictions in wealthy countries.

Table 5.3 showed how the increased population in the drylands is distributed across world regions. More than half the people are located in Asia, but significant portions are also in Africa.

5.4 Sensitivity to Ecosystem Change

This section briefly reviews the state of knowledge about the degree to which the various dimensions of human well-being are sensitive to ecosystem change. In assessing the level of sensitivity, several issues arise that make an isolated understanding of the exact effect of a change in ecosystems on human well-being difficult. The affects of appropriating an ecosystem service today may have a different effect in the future on the appropriating social group. For example, the consumption of water today for irrigation will raise current crop productivity for the consuming population, but the impact on the future population is unknown, and so the net effect cannot be determined. Another difficulty in isolating the human well-being impact of ecosystem change is the distribution of ecosystem services. These may be derived from one geographical location but consumed in another one. Devising the net impact needs to take into account the costs and benefits to groups in all affected geographical locations.

5.4.1 Basic Material for a Good Life

The assessment of changes in the ecosystems on access to the basic needs for a good life has been one of the two dimensions of

BOX 5.1

Drylands and Human Well-being

Dryland ecosystems are characterized by extreme rainfall variability, recurrent but unpredictable droughts, high temperatures, low soil fertility, high salinity, grazing pressure, and fires. They reflect and absorb solar radiation, maintain balance in the functioning of the atmosphere, and sustain biomass and biodiversity. (This section is derived from World Bank 2003.)

Of the 500 million rural people who live on arid and dry semiarid land (see Table), most live in Asia and Africa, but there are also large pockets in Mexico and Northeastern Brazil. The low volume and extreme variability of precipitation limit the productive potential of this land for settled farming and nomadic pastoralism. Many ways of expanding agricultural production in the drylands—shifting cultivation from other areas, reducing fallow periods, switching farming practices, overgrazing pasture areas, cutting trees for fuelwood—result in greater environmental degradation.

Rural Population Living on Arid Lands (World Bank 2003)

Land Characteristics	Number of People *(million)*
Aridity only	350
Arid, slope	36
Arid, poor soil	107
Arid, slope, poor soil, forest	25
Total	518

The Southern Plains of North America, Africa's Sahel, and the inner Asian grasslands face similar climatic and soil characteristics but different political, financial, and institutional constraints. The result is differing patterns of resource management, with different impacts on human well-being.

The Southern Plains of North America

The European settlers in the Great Plains converted prime grazing land into intensive agricultural uses (monocropping, usually wheat). This pattern was badly suited to the lighter soils of the Southern Plains. Deep plowing dislodged soils, and monocropping mined soil nutrients. Large-scale farming in the 1920s pushed the expansion of wheat cultivation further onto native grasslands. By the next decade overgrazing, overplowing, and monocropping were exacerbated by the worst drought in U.S. history. An area of about 50 million hectares was affected each year in the Dust Bowl of the 1930s. (This section is based on Worster 1979.)

The response to the Dust Bowl included zoning laws for the most fragile areas, repurchases of submarginal private land, cash payments for leaving land fallow, and farm loans tied to approved land practices. In addition, there was planting of shelterbelts, adoption of soil and water conservation techniques such as the introduction of contour plowing, small dam and pond construction, mixed cropping, replanting of grasses, and state and federal protection of the remaining open grasslands.

Beginning in 1940, normal rainfall patterns resumed, while outmigration reduced the farm population and increased farm sizes (about 1 million people left the area between 1930 and 1970). But in the 1950s Dust Bowl II hit, followed in the 1970s by Dust Bowl III. Conservation practices had helped, but to achieve reliable production the United States needed to achieve a "climate-free" agriculture on the plains. In response, a striking feature has been the reliance on fossil fuel–intensive agricultural production with deep pumping of underground aquifers (up to 600 feet), and heavy reliance on chemical fertilizers and mechanization. In the Texas High Plains Region, irrigated land area shrunk by 34% between 1974 and 1989 because the cost of overpumping the Ogallala aquifer exceeds the value of crops grown there. This vast aquifer is now being pumped faster than replenishment rates, with a net depletion rate of 3.62 million acre-feet (4.5 billion cubic meters) a year (Postel 1993).

The African Sahel

Throughout much of Africa the plowing and monocropping on fragile soils adopted in colonial times continued after independence (Swearingen and Bencherifa 1996). Inappropriate land use can rapidly lower soil quality, and intensive cultivation can deplete soil nutrients. Deforestation can cause erosion, washing away the layers of soil most suitable for farming. Two patterns are typical in Africa (note, however, that population growth in low density areas can be positive for resource management; see Tiffen et al. 1994):

- Growing populations convert high quality pastureland to grow cash crops. Herders lose the better grazing land, their security against drought. Migratory movements for herders are reduced, lower-quality land is more intensively grazed, and overgrazing leads to degradation.
- Poor subsistence farmers reduce fallow periods in order to grow more food to feed growing families. The reduction in fallow increases vulnerability to drought and without sufficient inputs, depletes soil nutrients. Degradation and soil erosion get worse.

In the Sahel, favorable rainfall from the 1950s to the mid-1960s attracted more people to the region. However, rainfall reverted to normal low levels after 1970, and by the mid-1970s many people and their livestock had died. The possibility that the Sahel could enter another period of favorable rainfall poses the risk of repeating the same tragedy as poor people are drawn back to the land. The Intergovernmental Panel on Climate Change (IPCC 2002) reports that Africa is highly vulnerable to climate change. Although the equatorial region and coastal areas are humid, the rest of the continent is dry subhumid to arid. Global warming scenarios suggest that soil moisture and runoff will be reduced in subhumid zones. Already, water storage has been reduced to critical levels in some lakes and major dams, with adverse repercussions for industrial activity and agricultural irrigation.

The poor quality of soils in the Sahel is another constraining environmental factor. Phosphorus deficiency, low organic content, and low water infiltration and retention capacity on much of African soil have been limiting factors in agriculture. Unlike climate variability, this problem can be addressed: soil quality can be augmented through careful management and soil nutrient supplementation. More difficult to address are the recurrent droughts.

The Asian Drylands

Population pressure on arable land in Asia is considerable and growing. Severe land degradation affects some 35% of productive land. The result has been to put more population pressure on the Inner Asian drylands. Most affected are Afghanistan, China, India, and Pakistan (FAO et al. 1994; ESCAP 1993), as well as Inner Asia's high steppe, the largest

BOX 5.1
continued

remaining pastureland in the world, which includes Mongolia, northwestern China, and parts of Siberia. Over thousands of years, these grasslands have been home to nomadic herders of horses, camels, goats, sheep, and cattle who practice elaborate systems of seasonal pasture rotation across wide stretches of land in response to climate fluctuations. Herd rotation has helped sustain the fertility and resilience of grassland ecosystems and improve the health of livestock (Ojima 2001).

Over the past decade, population pressures and competing uses on these fragile lands have made it hard to find the right balance between traditional land management and demand for higher agricultural productivity. Government policies that discouraged a nomadic lifestyle, herd movement, and temporary use of patchy grasses led to dependence on agricultural livelihoods and sedentary herds, which created greater pressure on local ecosystems and degraded fragile grasslands. The contrasting experiences of Mongolia and northwestern China illustrate some of the problems.

Mongolia has retained many traditional herding customs and customary tenure with land management as a commons. (This section is drawn from WRI 2000 and from Mearns 2001, 2002.) Herders rely on local breeds (which are stronger and more resilient) that graze year-round on native grasses. These customary practices were effectively supported by collective agriculture between the 1950s and 1980s. Policies allowed people and herds to move over large areas and provided the possibility of sustainable grasslands management under controlled-access conditions.

The economic transition since 1990 has not been conducive to sustainable management. Livestock mobility declined significantly. Many public enterprises closed. Having few alternatives, people turned to herding—often for the first time. The numbers of herders more than doubled from 400,000 in 1989 (17% of Mongolia's population) to 800,000 in the mid-1990s (representing 35%). Poverty also increased to 36% of the population by 1995 from a very low base in the 1980s. Herd size grew from the traditional 25 million head to about 30 million. Today, an estimated 10% of pastureland is believed to be degraded, causing noticeable increases in the frequency and intensity of dust storms.

This problem is considered manageable in Mongolia because population pressures are not very high. Rural population increased by about 50% from 1950 to 2000 (compared with a 700% increase in neighboring northwestern China).

As in Mongolia, the grasslands in China are state-owned. (This section is drawn from Mearns 2001, 2002.) But settled pastoralism and the conversion of grasslands to arable cultivation were more common in northwestern China than in Mongolia, beginning in the 1950s, when state-owned pastureland was allocated to "people's communes." The concentration of people in villages meant declining pasture rotation and expanding agriculture. Policies encouraged conversion of prime pasturelands into arable cropland, leading to salinization and wind erosion in some areas.

Common policies were applied to highly diverse circumstances, resulting in perverse outcomes and higher degradation in some places. Subsidies encouraged mixed farming systems, which put more pressure on fragile land than the traditional mobile pastoralism. Economic reforms in the early 1990s granted households nominal shares in the collective land pool. Shared areas were fenced off, making herd mobility more difficult. Subsidized inputs, income transfers, and deep pumping of underground aquifers encouraged a rapid increase in farming. From an estimated 3 million indigenous pastoralists in the 1950s in the Inner Mongolian part of northwestern China, farmers and livestock producers today number 20 million, and cattle doubled from 17 million head in 1957 to 32 million today.

China's western development plan shares two characteristics with the policies followed in the Southern Plains of the United States: intensification of agricultural production and creation of "climate-free" agriculture in the grasslands through irrigation from underground aquifers. The objective is to make the area a bread-and-meat basket to meet China's growing demands for protein-rich diets. But unlike the Southern Plains—where about 1 million farmers left between the 1930s and the 1970s, enabling reconsolidation of landholdings and conversion of vast grassland areas to protected areas—population pressures have continued to increase in China's grasslands. Poverty rates in these degraded and ecologically sensitive areas are well above the national average (25% in some provinces, compared with the national average of 6.3%). The frequency and intensity of dust storms are increasing. Estimates of areas degraded are 50–75%, compared with 10–15% in the grasslands of Mongolia.

Improving Prospects for Well-being in the Drylands

Agricultural research in China and India shows diminishing returns to investments in many high-potential areas, but investments in drylands can produce large returns in reducing poverty, even if yields are modest (Hazell 1998; Hazell and Fan 2000; Fan et al. 2000; Wood et al. 1999). Governments, researchers, and donor organizations are beginning to pay some attention to research and development on crop breeding varieties for people on marginal lands, but much more needs to be done by the public sector to replace antiquated crop varieties (UNEP 1992, 1997). In partnership with South African institutions, the International Maize and Wheat Improvement Center (a research center of the Consultative Group on International Agricultural Research) has developed two maize varieties for small farmers in South Africa's drought-prone, acidic, nutrient-depleted soils. Both varieties are drought-resistant, and one matures early, when farm food supplies are at their lowest. Trials from Ethiopia to South Africa have shown yields that are 34–50% higher than currently grown varieties (Ter-Minassian 1997; Rodden et al. 2002; Bardham and Mookherjee 2000). There are opportunities to achieve sustainable livelihoods in quite a few areas. But development decision-makers must recognize that the drylands are not homogeneous and cannot be made to function sustainably as non-drylands.

Some arid areas can take advantage of solar energy potential; others may have scenic value worthy of ecotourism development. The Mozambique Transfrontier Conservation Area Program and Burkina Faso's wildlife reserve development are two attempts in the direction of ecotourism that combine local and international cooperation. Research and innovations for appropriate service delivery—combined with policies that link human activities (farming, herding, and settlements) with natural processes (vegetation distribution, seasonal growing cycles, and watersheds)—can help sustain vulnerable dryland ecosystems while enhancing productivity to support growing populations.

Northern Africa	1.2
OECD	1.4
Sub-Saharan Africa	1.1

human well-being that has been most thoroughly investigated, and there are numerous well-documented examples demonstrating that declining ecosystem services are capable of having serious negative consequences on incomes, food security, and water availability. Some studies have also suggested that the decline and in some cases even the collapses of several ancient civilizations—including the Mesopotamians, the ancient Greeks, the Mayans, the Maori, and the Rapanui of Easter Island—were associated with the overexploitation of biological resources (Deevey et al. 1979; Flenley and King 1984; van Andel et al. 1990; Ponting 1991; Flannery 1994; Diamond 1997; Redman 1999).

Economic theory shows clearly how continued improvements in income depend on growing levels of assets to be sustainable. If assets, or wealth, do not grow, incomes will eventually fall (Sachs et al. 2004). Some economists have attempted to quantify the natural resource components to assets, including such resource stocks as forests and minerals (Repetto et al. 1989; Vincent et al. 1997; Lange et al. 2003), and have sought to estimate the net social benefits of habitat conversion, taking into account both the narrow economic gains associated with conversion and the decline of broader social benefits. These studies support the generalization that private gains achieved by conversion are typically outweighed by the loss of public benefits, so that in overall societal terms, conversion of remaining intact habitat rarely makes net economic sense (Balmford 2002; Turner et al. 2003). For example, the early 1990s collapse of the Newfoundland cod fishery has cost tens of thousands of jobs, as well as at least $2 billion in income support and retraining (Beaudin 2001).

Recent reviews of such dynamics have concluded that many countries appear to be experiencing declines in net per capita assets when such resource components are taken into account (Dasgupta and Mäler 2004; Hamilton and Clements 1999). (See Box 5.2.) These findings suggest that some of the declines in well-being in sub-Saharan Africa may be in part attributable to declines in natural resource assets, and that other regions currently experiencing increases in well-being may be doing so at the expense of a declining resource base, which will create problems in the future.

5.4.2 Freedom and Choice

There are some direct connections between ecosystem services and the freedom and choice dimensions of well-being that are partly understood. The declining provision of fuelwood and drinking water as the result of deteriorating ecosystems, for example, has been shown to increase the amount of time needed to collect such basic necessities, which in turn reduces the amount of time available for education, employment, and care of family members. Such impacts are typically thought to be disproportionately experienced by women. However, the empirical foundation for this understanding is limited to a handful of isolated studies (e.g., Awumbila and Momsen 1995); little work based on comparative, cross-national data has been done.

The findings in the literature on common pool or common property resources is that when a resource is abundant relative to demand, there tend to be few rules about its use. If a resource is valuable and limited, however, then common property institutions develop (Ostrom 1990). Such institutions evolve according to the importance of the resource in question, the technology used to exploit it, and various social or political changes in that society. For many kinds of commons, such as forests, water, and grazing lands, resources may be controlled under government

BOX 5.2

Economic Values Associated with Ecosystem Services

Many ecosystem services, such as the purification of water, regulation of floods, or provision of esthetic benefits, do not pass through markets. The benefits they provide to society, therefore, are largely unrecorded: only a portion of the total benefits provided by an ecosystem make their way into statistics, and many of these are misattributed (the water regulation benefits of wetlands, for example, do not appear as benefits of wetlands but as higher profits in water-using sectors). Moreover, for ecosystem services that do not pass through markets there is often insufficient incentive for individuals to invest in their maintenance (although in some cases common property management systems provide such incentives). Typically, even if individuals are aware of the services provided by an ecosystem, they are neither compensated for providing these services nor penalized for reducing them.

Nonmarketed ecosystem services do have economic value, and a number of techniques can be used to measure the economic benefits of the services and the costs of their degradation. (See Chapter 2.) A growing literature exists concerning measurements of the value of the nonmarketed ecosystem services, in order to provide better estimates of the total economic value of ecosystems (Pearce and Warford 1993). Some of the methods used to value nonmarketed services are still controversial, and in some cases estimates of the same services may differ by as much as several orders of magnitude. Moreover, even in the cases where the economic valuation methods are well established, the physical and ecological information necessary to value marginal changes in ecosystems may not be available. (For example, the calculation of the marginal cost of deforestation in terms of reduced water services requires accurate information on the relationship between forest cover loss and change in the timing and magnitude of river flows, and that biophysical information may not be available.)

Despite these challenges, even imperfect estimates of the economic costs and benefits of changes in ecosystem services can be useful for decision-making. Well-designed valuation studies tell us not only how much ecosystem services are worth, but inform resource management decisions with information about the economic benefits of alternative management options. Moreover, valuation studies help to identify who benefits from different ecosystem services and how various factors, including institutional ones, influence values. Information on beneficiaries and their willingness-to-pay under different institutional arrangements can help in the design of payment mechanisms or of mechanisms to turn economic values into actual financial flows.

The marketed portion of ecosystem services is often only a small portion of the total economic value of an ecosystem. In the case of forest ecosystems, for example, marketed services can include some provisioning services, such as timber production, and some cultural services, such as recreation. Even these services are only partially marketed: informal collections of fuelwood and non-timber products such as fruit and mushrooms, for example, are often not marketed (although local systems of rights or management may serve to maintain sustainable harvests). Regulating and supporting services have rarely been marketed, although some markets—such as for carbon sequestration—have recently been established to ameliorate the rate of change in climate services.

Figure A in Appendix A shows the results of one of the few comprehensive efforts to estimate the TEV of ecosystems on a significant scale, in this case forests in selected Mediterranean and nearby countries. Timber and fuelwood generally account for less than a third of estimated TEV, on average, and even this share is likely overestimated as it is easier to measure such provisioning services than other services. Recreation and hunting benefits were imperfectly measured, but in European countries these benefits rival and sometimes exceed timber values. Watershed protection is an important benefit in Italy, Syria, Tunisia, Algeria, and Morocco and would likely have played an important role in several other countries as well had it been possible to better estimate its value. If forests were to be considered only for their timber, as is all too often the case, they would appear much less valuable than they actually are and would tend to be managed only for their extractive uses, such as timber harvest.

The estimated values of individual non-marketed ecosystem services are often substantial but are rarely included in resource management decisions, although incorporation of these values is now beginning to become somewhat more common. For example:

- *Recreational benefits of protected areas:* The annual recreational value of the coral reefs of each of six marine protected areas in the Hawaiian Islands in 2003 ranged from $300,000 to $35 million (van Beukering and Cesar 2004).
- *Water quality:* The net present value in 1998 of protecting water quality in the 360-kilometer Catawba River in the United States for a five-year period was estimated to be $346 million (Kramer and Eisen-Hecht 1999).
- *Nursery habitat for fisheries:* Deforestation of an 860-square-kilometer mangrove habitat in the state of Campeche, Mexico, at an average rate of 2 square kilometers a year in 1980–90 resulted in a loss in shrimp harvest each year of about 28.8 tons, amounting to a loss of approximately $279,000 in revenue (Barbier and Strand 1998). In contrast, a 1981 study of the marginal value of wetlands on the Gulf Coast of Florida for production of blue crab estimated the present value of only $7.40 per hectare (Lynne et al. 1981).
- *Water purification service of wetlands:* Approximately half of the total economic value of the Danube River floodplain in 1992—which included values associated with timber, cattle, fisheries, recreation, hunting, and the filtering of nutrients—could be accounted for in its role as a nutrient sink (Gren et al. 1995).
- *Native pollinators:* A study in Costa Rica found that forest-based pollinators increased coffee yields by 20% within 1 kilometer of forest (as well as increasing the quality of the coffee). During 2000–03, pollination services from two forest fragments (of 46 and 111 hectares) increased the income of a 1,100-hectare farm by $60,000 per year, a value commensurate with expected revenues from competing land uses (Ricketts et al. 2004).
- *Flood control:* Muthurajawela Marsh, a 3,100-hectare coastal peat bog in Sri Lanka, provides an estimated $5 million in annual benefits ($1,750 per hectare) through its role in local flood control (Emerton and Bos 2004).
- *Open space protection:* In an ex-urban area of Maryland in the United States, the marginal economic benefits per household of preserving neighboring open space range from $994 to $3,307 per acre of farmland preserved (Irwin 2002). And in Grand Rapids, Michigan, lots for residential homes that border forest preserves were found to sell at premiums of about $5,800–8,400 during the 1990s (19–35% of lot price) (Thorsnes 2002).
- *Biochemical resources:* Estimates of the economic value of species-rich ecosystems (such as neotropical forests) for bioprospecting for new pharmaceutical products range from $20 to $9,000 per hectare, depending on assumptions used in the economic models (Simpson et al. 1996; Rausser and Small 2000).

Relatively few studies have compared the TEV of ecosystems under alternate management regimes. The results of several that attempted to do so are shown in the Table. In each case where the TEV of sustainable management practices was compared to management regimes involving conversion of the ecosystem or unsustainable practices, the benefit of managing the ecosystem more sustainably exceeded that of the converted ecosystem, although the private benefits—that is, the actual monetary benefits captured from the services entering the market—would favor conversion or unsustainable management.

These studies are consistent with the understanding that market failures associated with ecosystem services lead to greater conversion of ecosystems than is economically justified. However, this finding would not hold at all locations. For example, the value of conversion of an ecosystem in areas of prime agricultural land or in urban regions often exceeds the total economic value of the intact ecosystem (although even in dense urban areas, the TEV of maintaining some "greenspace" can be greater than development of these sites). Similarly, in a study of the economic benefits of forest protection for maintaining water flows as "drought mitigation" for farmers in Eastern Indonesia, Pattanayak and Kramer (2001) found that where increased watershed protection mitigates droughts, the economic benefits can be sizable (as much as 10% of annual agricultural profits), but they found that forest cover did not necessarily increase baseflow for all households in a watershed or in all watersheds.

Comparisons of Economic Benefits of Retaining and Converting Ecosystems. (Values in dollars, rounded to two significant digits.) Each of the examples selected includes estimates of one or more regulating or cultural services in addition to provisioning services.

Ecosystem	Alternatives Compared	Services Included in TEV Calculations	Private Benefits	Total Economic Value	Source
Comparison of benefits of sustainably managed ecosystem to converted ecosystem					
Tropical forest, Cameroon	comparison of low-impact logging to small-scale farming or conversion to oil palm and rubber plantation	benefits from agricultural or plantation output, sedimentation control, flood prevention, carbon storage, and option, bequest and existence values; 10% discount rate over 32 years	Small-scale agriculture had greatest private benefits	across five study sites, average TEV of sustainable forestry was approximately $3,400 per hectare and that of small-scale farming $2,000 per hectare; across four of the sites, average TEV of conversion to oil palm plantation was $-1000 per hectare	Yaron 2001
Mangrove, Thailand	comparison of existing uses of mangrove system to conversion to shrimp farming	benefits from shrimp farming, timber, charcoal, NTFPs, offshore fisheries, and storm protection. 10% discount rate over 20 years	conversion to aquaculture had greatest private benefits	TEV value of intact mangroves was a minimum of $1,000 and possibly as high as $36,000 per hectare; TEV of shrimp farming was about $200 per hectare	Sathirathai and Barbier 2001
Wetland, Canada	comparison of intact wetlands to conversion to intensive farming	benefits of agriculture, hunting, angling, trapping; 4% discount rate over 50 years	conversion to agriculture had highest private benefits (in part due to substantial drainage subsidies)	TEV was highest for intact wetlands (average for three wetland types of approximately $5,800 per hectare) versus TEV of converted wetlands of $2,400 per hectare	Van Vuuren and Roy 1993
Tropical forest, Cambodia	comparison of traditional forest uses to benefits associated with commercial timber extraction	examined benefits associated with swidden agriculture and extraction of non-timber forest products (including fuelwood, rattan and bamboo, wildlife, malva nuts, and medicine) and ecological and environmental functions such as watershed, biodiversity, and carbon storage; 6% discount rate over 90 years	private benefits associated with unsustainable harvest practices exceeded private benefits of NTFP collection	total benefits were greatest for traditional uses, ranging from $1,300 to $4,500 per hectare (environmental services accounted for $590 per hectare while NTFPs provided between $700 and $3,900); private benefits for timber harvest ranged from $400 to $1,700 per hectare but after accounting for lost services the total benefits were $150 to $1,100 per hectare	Bann 1997
Comparison of benefits of establishing protected area to current use					
Coastal habitat, Jamaica	comparison of current management (includes destructive fishing, loss of mangroves, pollution) to establishment of Portland Bight Protected Area	benefits of fisheries, forestry, tourism, carbon sequestration, biodiversity, costal protection; 10% discount rate over 25 years	current overfishing has resulted in a decline of profits effectively to zero	total incremental benefits of establishment of protected area estimated to be $53 million ($28 per hectare) in the optimistic tourism scenario and $41 million ($22 per hectare) in the pessimistic tourism case; cost of protected area establishment and management would total $19 million ($10 per hectare) over the next 25 years, resulting in net benefits of $11 to $18 per hectare	Cesar et al. 2000
Marine protected areas, Hawaii	comparison of net benefits of protection of six existing MPAs with the costs associated with their protection	benefits associated with tourism, contribution to fisheries in adjacent areas, biodiversity, and amenity values; discount rate of 3%, period of 25 years		benefits for individual MPAs ranged from $15 million (Diamond Head) to $84 million (Hanauma), with management costs for these two MPAs of $1.1 million and $22 million respectively; the net benefit per hectare (benefits minus management costs) ranged from $144,000 (Diamond Head) to $17 million (Kahalu'u)	van Beukering and Cesar 2004

(continues over)

BOX 5.2
continued

The economic costs associated with damage to ecosystem services can be substantial:

- The early 1990s collapse of the Newfoundland cod fishery due to overfishing resulted in the loss of tens of thousands of jobs and has cost at least $2 billion (CAN$2.66 billion) in income support and retraining (Commission for Economic Cooperation 2001).
- In 1996, the external cost of U.K. agriculture associated with damage to water (pollution, eutrophication), air (emissions of greenhouse gases), soil (off-site erosion damage, carbon dioxide loss), and biodiversity was $2.6 billion (£1.566 billion at 1996 exchange rates)—9% of average yearly gross farm receipts for the 1990s (Pretty et al. 2000). Similarly, the cost of freshwater eutrophication in England and Wales was estimated to be $105–160 million per year in the 1990s, with an additional $77 million per year being spent to address those damages (Pretty et al. 2003).
- The largely deliberate burning in 1997 of approximately 50,000 square kilometers of Indonesian vegetation (about 60% of the total area burned from 1997 to 1998) affected around 70 million people (Schweithelm and Glover 1999). Some 12 million people required health care; overall economic costs—through lost timber and non-wood forest products, lost agriculture, reduced health, increased CO_2 emissions, lost industrial production, and lost tourism revenues—have been conservatively estimated at $4.5 billion (Ruitenbeek 1999; Schweithelm et al. 1999).
- The total damages for the Indian Ocean region over a 20-year time period (with a 10% discount rate) resulting from the long-term impacts of a massive 1998 coral bleaching episode are estimated to be between $608 million (if there is only a slight decrease in tourism-generated income and employment results) and $8 billion (if tourism income and employment and fish productivity drop significantly and reefs cease to function as a protective barrier) (Cesar and Chong 2004).
- The net annual loss of economic value associated with invasive species in the fynbos vegetation of the Cape Floral region of South Africa in 1997 was estimated to be $93.5 million (R455 million), equivalent to a reduction of the potential economic value without the invasive species of more than 40%. The invasive species have caused losses of biodiversity, water, soil, and scenic beauty, although they also provide some benefits, such as provision of firewood (Turpie and Heydenrych 2000).

Significant investments are often needed to restore or maintain nonmarketed ecosystem services. Examples include:

- In South Africa, invasive tree species threaten both native species and water flows by encroaching into natural habitats, with serious impacts for economic growth and human well-being. In response, the South African government established the Working for Water Programme. Between 1995 and 2001 the program invested $131 million (R1.59 billion at 2001 exchange rates) in clearing programs to control invasive species (van Wilgen 2004).
- The state of Louisiana in the United States has put in place a $14-billion wetland restoration plan to protect 10,000 square kilometers of marsh, swamp, and barrier islands in part to reduce storm surges generated by hurricanes (Bourne 2000).
- A plan to restore semi-natural water flows in the Everglades wetlands in the United States in part through the removal of 400 kilometers of dikes and levees is expected to cost $7.8 billion over 20 years (Kloor 2000).

In addition to efforts to measure the value of nonmarketed ecosystem services, recent years have also seen increasing efforts to devise mechanisms to bring these services into the market, thus improving incentives to conserve ecosystems (Pagiola et al. 2002). Examples include:

- *Markets for carbon sequestration:* Approximately 64 million tons of carbon dioxide equivalent were exchanged through projects from January to May 2004, nearly as much as during all of 2003 (78 million tons) (World Bank 2004). (See Figure B in Appendix A.) The value of carbon trades in 2003 was approximately $300 million. Some 25 percent of the trades (by volume of CO_2 equivalents) involve investment in ecosystem services (hydropower or biomass) (World Bank 2004). The World Bank has established a fund with a capital of $33.3 million (as of January 2005) to invest in afforestation and reforestation projects that sequester or conserve carbon in forests and agroecosystems while promoting biodiversity conservation and poverty alleviation. It is speculated that the value of the global carbon emissions trading markets could reach $44 billion in 2010 and involve trades totaling 4.5 billion tons of carbon dioxide or equivalent (http://www.pointcarbon.com/).
- *Markets for forest environmental services.* In 1997, Costa Rica established a nationwide system of payments for environmental services (Pago de Servicios Ambientales). Under this program, Costa Rica pays land users who conserve forests, thus helping to maintain environmental services such as downstream water flows, biodiversity conservation, carbon sequestration, and scenic beauty. Funds for the program come partly from earmarked taxes and partly from environmental service buyers, including the Global Environment Facility (biodiversity), Costa Rica's Office of Joint Implementation (carbon), and water users such as hydroelectric producers, municipal water utilities, and bottlers (watershed services). By 2001, over 280,000 hectares of forest had been incorporated into the program at a cost of about $30 million, with pending applications covering an additional 800,000 hectares. Typical payments have ranged from $35 to $45 a hectare per year for forest conservation (MA *Policy Responses,* Box 5.3; Pagiola 2002). Payments under Costa Rica's program do not reflect the values attached to the services provided so much as the costs associated with their provision. As a result, while this market mechanism provides for the cost-effective imposition of quantitative targets, it is not a typical market in the sense of private parties undertaking voluntary transactions in environmental services. Worldwide, the number of initiatives involving payments for ecosystem services is growing rapidly.

regulations, market mechanisms, or community-based institutions that develop among the users themselves. Even with these community institutions, in some cases ecosystem services have declined, although in other cases the development of effective partnerships or of participatory management institutions—with power-sharing between governments, local communities, or corporate resource owners—has reduced the further decline and even brought about improvement of ecosystem services.

In South Africa, for instance, data gathered over decades showed that invasive forestry trees not only threaten native species by encroaching into natural habitats, but also severely reduce stream flows, with serious impacts for economic growth and human well-being (van Wilgen et al. 1998). In response to this evidence, the South African government established its Working for Water Programme. With an annual budget now over $60 million, this simultaneously increases water availability, employs 20,000 skilled and semi-skilled workers, and addresses a major driver of biodiversity change (van Wilgen et al. 2002; Working for Water 2004). Similarly, in Madagascar continued upland deforestation by an estimated 50,000 slash-and-burn farmers has led to increased siltation and reduced water flows to 250,000 downstream rice farmers (Carret and Loyer 2003), and this played an important role in the Malagasy government's 2003 decision to triple the size of Madagascar's network of protected forests (J. Carret, personal communication).

5.4.3 Health

Connections between declining ecosystem services and human health are well documented and may be the best understood of the well-being impacts. As shown in Chapter 14, infectious disease impacts are rising as a consequence of land use change such as deforestation, dam construction, road building, agricultural conversion, and urbanization. Such effects can be observed in all regions of the world. The World Health Organization has attempted to quantify the environmental burden of disease through a modeling of the percentage of disability-adjusted life years lost as a consequence of such environmental drivers as unsafe water, air pollution, indoor smoke, and climate change. (See also Chapter 2.) Such analysis provides strong evidence that deteriorating water and air quality account for a large percentage of poor health outcomes in many locations, especially in developing countries (WHO 2002 Chapter 4).

The environmental impact on health, according to WHO analysis, is dependent on levels of poverty. Such impacts are highest in poor countries with high mortality rates, where unsafe water and indoor smoke from solid fuel use account for 9–10% of DALYs (WHO 2002:86).

5.4.4 Good Social Relations

There are clear examples of declining ecosystem services disrupting social relations. Indigenous societies whose cultural identities are tied closely to particular habitats or wildlife suffer if habitats are destroyed or wildlife populations decline. Such impacts have been observed in coastal fishing communities (see Chapter 19), in Arctic populations (see Chapter 25), in traditional forest societies, and among pastoral nomads (e.g., Mather 1999; Parkinson 1999). The 95% decline in the *Gyps* vulture populations of the Indian subcontinent since the mid-1990s (Cunningham et al. 2003) has led to divisions in the Parsi religion about how to dispose of their dead now that the traditional laying out of corpses in Towers of Silence is no longer practicable (Triveldi 2001).

Deterioration in ecosystems can also provide an opportunity for social relations when communities join together to form community-based institutions in response to degraded ecosystem services (Ostrom et al. 2002).

5.4.5 Security

The impact of declining ecosystem services on natural disasters is well understood and well documented, and this is further explored in Chapter 16. Although there has been much speculation about the relationship between ecosystem conditions and political violence (Myers 1994; Homer-Dixon 1999), scholars have been unable to demonstrate causal connections robustly (Gleditsch 1998).

5.5 Multiple Causal Mechanisms Link Ecosystem Change to Human Well-being

The causal connections between ecosystem change and changes in human well-being are not uniform. A variety of mechanisms link the two. This section delineates some distinct mechanisms and illustrates them with specific examples, in order to demonstrate the variety of pathways linking ecosystem change and human well-being. The presentation is not meant to imply that ecosystem changes are linked to human well-being in simple orderly mechanisms. Socioecological systems are dynamic and nonlinear, and their response to stress may not be predictable. They typically combine in complicated ways; yet drivers of behavior may be identified, and behavior may be bounded by political, social, technological, or economic limitations. Decision-making behavior about the use of different ecosystem services needs to consider trade-offs in human well-being.

The benefits and costs of declining ecosystem services are seldom evenly distributed. There are typically winners and losers, and this can lead to an improvement in well-being for one group at the expense of another. If mountain communities convert forests to agricultural lands, for example, that may reduce downstream ecosystem services to low-lying areas in the form of increased siltation and declining water quality. (See Chapter 24.) If wetlands are converted to human settlements in one area of a watershed, other communities in the watershed may experience diminished flood buffering capacities. (See Chapters 16 and 20.) When ecosystem change is linked to well-being change through this mechanism, some groups of people improve and other groups decline.

Another example is the growth of shrimp farming and the consequent damage of such aquaculture on mangroves. (See Chapter 19.) Stonich et al. (1997) have shown how, in Honduras, social conflict has increased between shrimp farm concession holders and those who are not concession holders but believe that shrimp farms are intruding on government-reserved natural resources.

The often-cited example of the Aral Sea provides a vivid illustration of how a government policy aimed at improving the national economy can generate large negative impacts on human well-being by focusing on the benefits of a single ecosystem service. Under Soviet rule, the small-scale independent irrigation systems were transformed into unsustainable large-scale collective irrigation systems for cotton production. With the Soviet Union's attention focused on cotton self-sufficiency, the long-term adverse effects of a rapid, large-scale expansion of inefficient irrigation systems, sole reliance on high-water demanding production systems, poor water distribution and drainage, and non-dose-related uses of fertilizers and pesticides around the Aral Sea were not considered high priority.

During the second half of the 1900s, these inefficient systems decreased water inflow into the sea to a mere trickle, shrunk the size of the sea by half, reduced the water level by 16 meters, and tripled its salinity (Micklin 1993). The government and the cotton producers were the initial winners. The Soviet Union met its need to be self-sufficient in cotton. However, there were many losers who suffered. Thirty-five million people have lost access to the lake for its water, fish, reed beds, and transport functions. The fishing industry around the Aral Sea has collapsed, with fishing ceasing in the 1980s.

More far-reaching environmental and ecological problems, such as dust storms, erosion, and poor water quality for drinking and other purposes have contributed to decreased human health in the area around the Aral Sea. Rates of anemia, tuberculosis, kidney and liver diseases, respiratory infections, allergies, and cancer have increased, and now far exceed the rest of the former Soviet Union and present-day Russia (Ataniyazova et al. 2001). High levels of reproductive pathologies (infertility, miscarriages, and complications during pregnancy and childbirth) have been observed in this region for more than 20 years. The rate of birth abnormalities, another serious consequence of pollution, is also increasing. One in every 20 babies is born with abnormalities, a figure approximately five times the rate in European countries (Ataniyazova et al. 2001; Ataniyazova 2003). (For more information about the Aral Sea and ecosystems, see Chapters 20 and 24.)

China has also witnessed the effects of ecosystem trade-offs, especially in connection with economic development and land use change in the north and west. Excessive collection of fuelwood, blind mining, harvesting of medicinal herbs, construction projects, rising populations, and farming have all contributed to China's desertification through deforestation, water mismanagement, and overgrazing. Excessive cutting of fuelwood has reduced the sand fixing vegetation in Qaidam Basin by one third. Illegal cultivation, harvesting, and exploitation have degraded 12 million hectares of rangeland, steppe, and grasslands from 1993 to 1996. The large-scale diversion of water from the upper reach of some rivers has caused the reduction and even the drying off of the water flow in lower reaches. Desertification has silted up rivers, raised riverbeds, and retreated lake surfaces (Asian Regional Network for Desertification Monitoring and Assessment, n.d.).

The spread of desertification in northern China is threatening villages and towns, thousands of kilometers of railway, highway, and irrigation canal, and a large number of reservoirs, dams, and hydraulic power stations due to sandstorms and dune movement. Since the early 1950s, there have been more than 70 heavy sandstorms and dust devils that have caused huge losses. In the sandstorm of May 1993 in northwest China, more than 12 million people were directly affected, 116 people were killed or missing, and more than 120,000 heads of livestock were lost. The direct economic loss was approximately $66 million (Asian Regional Network for Desertification Monitoring and Assessment, n.d.).

Finally, the Chesapeake Bay in the United States provides an example of major deterioration of an ecosystem through urbanization. Land use has changed considerably in the area. The population in the bay's watershed increased 34% between 1970 and 2000 (Chesapeake Bay Program 2003b), while the number of households grew by 67% (Chesapeake Bay Foundation Report, 2004). The low-density, single-use development pattern was accompanied by infrastructure such as roads, parking lots, and shopping malls, which had a negative impact on water quality. Agriculture also expanded, and nitrogen runoff from agricultural land has been the largest contributor to pollution to the bay (Horton 2003). Chemical runoff from urban centers has also gone up (Chesapeake Bay Program 2003a, 2003b). Increased levels of air pollution have contributed to increased toxic pollution in the Chesapeake Bay.

Nitrogen pollution has depleted the oxygen levels of the waters (Cestti et al. 2003), which has resulted in increased dead zones, leading to a decline in the numbers of fish, crabs, and other aquatic life. The Chesapeake Bay has seen significant reductions in the water quality during the last decade. Declines in species like oysters and underwater grass have also accentuated the bay's capacity to naturally purify the water. Sustained high levels of pollution may result in groundwater contamination, which is the source of potable water for most people in the region.

The high pollution levels affect both income and health. The Chesapeake has been a major source of seafood, but declines in biodiversity in the bay have led to loss of income for the fishing communities who depended on it for their livelihoods (Horton 2003). The Water Quality Improvement Act requires all farms with sales of at least $2,500 to develop nutrient management plans (Joint Legislative Audit and Review Commission of the Virginia General Assembly 2003). Traditionally, farmers would rely on animal manure generated in poultry and dairy farms in the area. Since manure contains more phosphorus than nitrogen, the government advises farmers to add commercial nitrogen fertilizer. This has increased costs for farms. The animal farms, on the other hand, must now dispose of their manure as required by the Maryland Water Quality Improvement Act.

Main Messages

Some of the people and places affected by changes in ecosystems and ecosystem services are highly vulnerable to the effects and are particularly likely to experience much of the damage to well-being and loss of life that such changes will entail. Indeed, many of these people and places are already under severe stress from environmental, health, and socioeconomic pressures, as well as new forces involved in globalization. Further threats arising from changes in ecosystems and ecosystem services will interact with these other on-going stresses to threaten the well-being of these groups while many others throughout the world benefit and prosper from human interactions with ecosystems.

The patterns and dynamics of vulnerability in coupled socioenvironmental systems are shaped by drivers operating at scales from the international to the local, all interacting with the specifics of places. The dominant drivers and patterns of vulnerability differ, depending on the threat or perturbation addressed, the scale of analysis selected, and not least the conceptual framework employed. While our existing knowledge of the sources and patterns of vulnerability is still incomplete, substantial progress is being made in this relatively new area of analysis, and vulnerability assessment is proving useful in addressing environmental management and sustainable development.

At a global level, various efforts over the past several decades have defined vulnerability indictors and indexes and have mapped relevant global patterns. Because they use different conceptual frameworks and consider vulnerability to different types of threats, these efforts largely identify different national-scale patterns of vulnerability. Examples in the chapter introduce major efforts to address vulnerability to environmental change broadly defined, as a dimension of environmental sustainability, in respect to climate change and natural hazards. Improvements in the state of knowledge and methodology development are needed generally to deepen understanding of these global patterns and their causes, although the topics of natural hazards, desertification, and food security have received more attention than others, due to the level of societal concern on these issues.

Trends in natural hazards reveal several patterns that are known with high confidence at the national level. The world is experiencing a worsening trend of human suffering and economic losses from natural disasters over the past several decades. In the last 40 years, the number of "great" disasters has increased by a factor of 4 while economic losses have increased by a factor of 10. The significance of these events to the social vulnerability of exposed human populations is of special concern. Even before the December 2004 tsunami, Asia was disproportionately affected, with more than 43% of all natural disasters and 70% of deaths occurring there over the last decade of the twentieth century. The greatest loss of life continues to be highly concentrated in developing countries as a group.

Desertification is another phenomenon that has received extensive attention. Vulnerability to desertification has multiple causes that are highly intermingled; like all vulnerability, it is the product of the interaction between environmental change and social and political systems. The driving forces of environmental change generally have a high patchiness, and effects vary widely with differences in social and geographic scales.

Food insecurity is a third primary area of concern in changes in ecosystem services. Multiple domains of vulnerability exist in food security regimes and livelihood systems. Production, economic exchanges, and nutrition are key elements, along with more-structural issues associated with the political economy. At this point in time, the more generalized, major contributions to knowledge are emerging in the realms of better understanding of driving forces, interactions across biophysical scales and social levels, connections between ecosystems services and human well-being, and differential vulnerability at local levels. While many challenges remain in aggregating diverse case study findings, consistency is emerging around a number of themes:

- Socioeconomic and institutional differences are major factors shaping differential vulnerability. The linkages among environmental change, development, and livelihoods are receiving increasing attention in efforts to identify sources of resilience and increase adaptive capacity, but knowledge in this area is uneven in its coverage of environmental threats and perturbations as they act in relation to different ecosystems and livelihoods.

- Poverty and hazard vulnerability are often closely related, as the poor often lack assets and entitlements that allow them some buffer from environmental degradation and variability.

- The interactions of multiple forms of stress—economic, social, political, and physical—with environmental change can amplify and attenuate vulnerability abruptly or gradually, creating dynamic situations for assessment that have still to be fully captured in research methodologies. Major worldwide trends of population growth, urbanization, the spread of HIV/AIDS, economic development, and globalization are acting to shape patterns of vulnerability at national and local scales. The implications of these processes for climate change are still poorly understood.

The limitations of existing understanding point to the need for a variety of efforts to improve assessment and identify measures to reduce vulnerability. These include the need for a robust and consensual conceptual framework for vulnerability analysis, improved analysis of the human driving forces of vulnerability as well as stresses, clarification of the overlaps and interactions between poverty and vulnerability, the tracking of sequences of stresses and perturbations that produce cumulative vulnerability, the role of institutions in creating and mitigating vulnerability, the need to fill gaps in the knowledge base of global patterns of vulnerability, improved assessment methods and tools, and the need for interventions aimed at reducing vulnerability.

6.1 Introduction

The Third Assessment of the Intergovernmental Panel on Climate Change noted that over the past century average surface temperatures across the globe have increased by 0.6° Celsius and evidence is growing that human activities are responsible for most of this warming (IPCC 2001b). Human activities are also altering ecosystems and ecosystem services in myriad ways, as assessed in other chapters. While both positive and negative effects on human societies are involved, it is unrealistic to expect that they will balance out.

Many of the regions and peoples who will be affected are highly vulnerable and poorly equipped to cope with the major changes in ecosystems that may occur. Further, many people and places are already under severe stress arising from a panoply of environmental and socioeconomic forces, including those emanating from globalization processes. Involved are such diverse drivers of change as population growth, increasing concentrations of populations in megacities, poverty and poor nutrition, accumulating contamination of the atmosphere as well as of land and water, a growing dependence on distant global markets, growing gender and class inequalities, the ravages of wars, the AIDS epidemic, and politically corrupt governments. (See Chapter 3 for further discussion on drivers of change.) Environmental change will produce varied effects that will interact with these other stresses and multiple vulnerabilities, and they will take their toll particularly among the most exposed and poorest people of the world.

The most vulnerable human and ecological systems are not difficult to find. One third to one half of the world's population already lacks adequate clean water, and climate change—involving increased temperature and droughts in many areas—will add to the severity of these issues. As other chapters in this volume establish, environmental degradation affects all ecosystems and ecosystem services to varying degrees. Many developing countries (especially in Africa) are already suffering declines in agricultural production and food security, particularly among small farmers and isolated rural populations. Mountain locations are often fragile or marginal environments for human uses such as agriculture (Jodha 1997, 2002). Increased flooding from sea level rise threatens low-lying coastal areas in many parts of the globe, in both rich and poor countries, with a loss of life and infrastructure damages from more severe storms as well as a loss of wetlands and mangroves. (See Chapters 19 and 23.)

The poor, elderly, and sick in the burgeoning megacities of the world face increased risk of death and illness from growing contamination from toxic materials. Dense populations in developing countries face increased threats from riverine flooding and its associated impacts on nutrition and disease. These threats are only suggestive, of course, of the panoply of pressures that confront the most vulnerable regions of the world. It is the rates and patterns of environmental change and their interaction with place-specific vulnerabilities that are driving local realities in terms of the eventual severities of effects and the potential effectiveness of human coping mitigation and adaptation.

Research on global environmental change and on-going assessments in many locales throughout the world have greatly enriched our understanding of the structure and processes of the biosphere and human interactions with it. At the same time, our knowledge is growing of the effects that changes in ecosystems and ecosystem services have upon human communities. Nonetheless, the knowledge base concerning the vulnerabilities of coupled socioecological systems is uneven and not yet sufficient for systematic quantitative appraisal or validated models of cause-and-effect relationships of emerging vulnerability. Yet what we need to understand is apparent in the questions that researchers are addressing (Turner et al. 2003a): Who and what are vulnerable to the multiple environmental and human changes under way, and where? How are these changes and their consequences attenuated or amplified by interactions with different human and environmental conditions? What can be done to reduce vulnerability to change? How may more resilient and adaptive communities and societies be built?

In this chapter key definitions and concepts used in vulnerability analysis are first considered. Included in this is a clarification of what is meant by the terms "vulnerability" and "resilience." Several of the principal methods and tools used in identifying and assessing vulnerability to environmental change are then examined (but see also Chapter 2). Efforts to identify and map vulnerable places at the global scale are described, followed by three arenas—natural disasters, desertification, and food security—that have received substantial past analyses in vulnerability research and assessment. Several specific case studies that illustrate different key issues that pervade vulnerability assessments are presented and, finally, implications of our current knowledge for efforts to assess and reduce vulnerability and to build greater resilience in coupled socioecological systems are assessed.

6.2 Definitions and Conceptual Framework

The term vulnerability derives from the Latin root *vulnerare,* meaning to wound. Accordingly, vulnerability in simple terms means the capacity to be wounded (Kates 1985). Chambers (1989) elaborated this notion by describing vulnerability as "exposure to contingencies and stress, and the difficulty in coping with them." It is apparent from relating the notion of vulnerability to the broader framework of risk that three major dimensions are involved:

- exposure to stresses, perturbations, and shocks;
- the sensitivity of people, places, and ecosystems to stress or perturbation, including their capacity to anticipate and cope with the stress; and
- the resilience of exposed people, places, and ecosystems in terms of their capacity to absorb shocks and perturbations while maintaining function.

6.2.1 Conceptual Framework for Analyzing Vulnerability

A wide variety of conceptual frameworks have arisen to address the vulnerability of human and ecological systems to perturbations, shocks, and stresses. Here we draw on a recent effort of the Sustainability Science Program to frame vulnerability within the context of coupled socioecological systems (Turner et al. 2003a, 2003b). The framework seeks to capture as much as possible of the totality of the different elements that have been demonstrated in risk, hazards, and vulnerability studies and to frame them in regard to their complex linkages. (See Figure 6.1.)

The framework recognizes that the components and linkages in question vary by the scale of analysis undertaken and that the scale of the assessment may change the specific components but not the overall structure. It identifies two basic parts to the vulnerability problem and assessment: perturbation-stresses and the coupled socioecological system.

Perturbations and stresses can be both human and environmental and are affected by processes often operating at scales larger than the event in question (such as local drought). For example, globally induced climate change triggers increased variation in precipitation in a tropical forest frontier, while political strife elsewhere drives large numbers of immigrants to the frontier. The coupled socioecological system maintains some level of vulnerability to these perturbations and stresses, related to the manner in which they are experienced. This experience is registered first in terms of the nature of the exposure—its intensity, frequency, and duration, for instance—and involves measures that the human and environment subsystems may take to reduce the exposure. The coupled system experiences a degree of harm to exposure (risk and impacts), determined by its sensitivity. The linkage between exposure and impact is not necessarily direct, however, because the coupled system maintains coping mechanisms that permit immediate or near-term adjustments that reduce the harm experienced and, in some cases, changes the sensitivity of the system itself.

If perturbations and stresses persist over time, the types and quality of system resilience change. These changes are potentially irreversible, as the case of ozone depletion illustrates. Change may lead to adaptation (fundamental change) in the coupled system. The role of perception and the social and cultural evaluation of stresses and perturbations is important to both the recognition of stresses and the decisions regarding coping, adaptation, and adjustment. These decisions reflect local and regional differences in perceptions and evaluations. The social subsystem must be altered, or

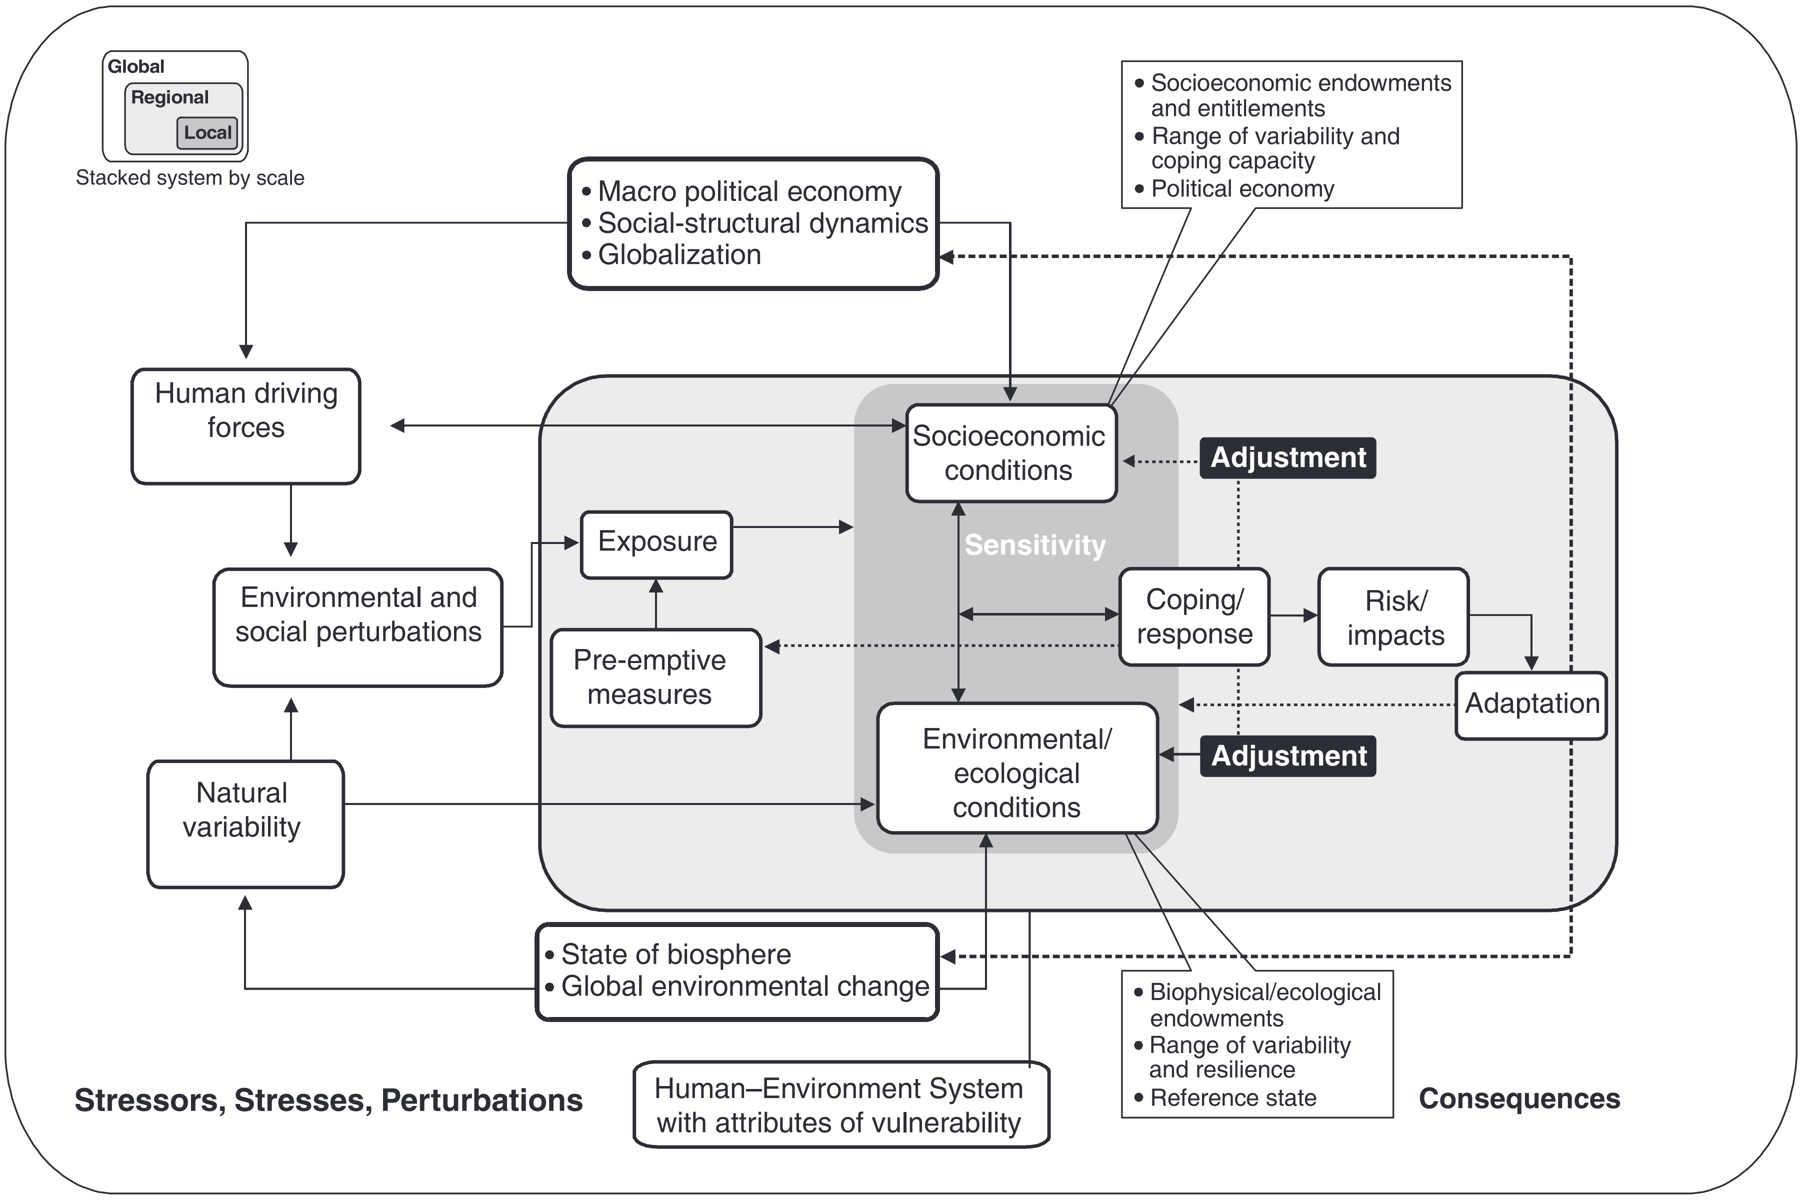

Figure 6.1. A Framework for Analyzing Vulnerability

it ceases to function (a place or region is abandoned, for example); the ecological subsystem changes in climate and vegetation. This process of more fundamental change, sometimes also referred to as ''reorganization,'' may move the coupled socioecological system in a direction of greater sustainability, but perhaps at a cost to those depending on current patterns of ecosystem services. The MA *Policy Responses* volume addresses adjustments and adaptation in ecosystems and with respect to human well-being in greater detail. By definition, no part of a system in this vulnerability framework is unimportant.

6.2.2 The Concept of Resilience

The concept of resilience as applied to integrated socioecological systems may be defined as the amount of disturbance a system can absorb and still remain within the same state or domain of attraction, the degree to which the system is capable of self-organization (versus lack of organization or organization forced by external factors), and the degree to which the system can build and increase its capacity for learning and adaptation (Carpenter et al. 2001). Socioecological systems are complex adaptive systems that are constantly changing, and the resilience of such systems represents the capacity to absorb shocks while maintaining function (Holling 1995, 2001; Gunderson and Holling 2002; Berkes et al. 2002). When a human or ecological system loses resilience, it becomes vulnerable to change that previously could be absorbed (Kasperson and Kasperson 2001).

New insights have been gained during the last 10 years about the essential role of resilience for a prosperous development of human society (Gunderson and Holling 2002). A growing number of case studies have revealed the tight connection between resilience, diversity, and the sustainability of socioecological systems (Berkes and Folke 1998; Adger et al. 2001).

Ecosystems with low resilience may still maintain function and generate resources and ecosystem services—that is, they may seem to be in good shape—but when subject to disturbances and stochastic events, they may reach a critical threshold and slide into a less desirable state. Such shifts may significantly constrain options for social and economic development, reduce options for livelihoods, and create environmental migrants as a consequence of the impact on ecosystem life-support.

In ecological systems, Lawton (2000) and Loreau et al. (2001) synthesized the evidence from many experiments and affirmed that the diversity of functionally different kinds of species affected the rates of stability and increased the reliability of ecosystem processes locally. Furthermore, a number of observations suggest that biodiversity at larger spatial scales, such as landscapes and regions, ensures that appropriate key species for ecosystem functioning are recruited to local systems after disturbance or when environmental conditions change (Peterson et al. 1998; Bengtsson et al. 2003). In this sense, biological diversity provides insurance, flexibility, and risk spreading across scales in the face of uncertainty and thereby contributes to ecosystem resilience (Folke et al. 1996). (See also Chapter 11.)

Ecological resilience typically depends on slowly changing variables such as land use, nutrient stocks, soil properties, and biomass of long-lived organisms (Gunderson and Pritchard 2002), which are in turn altered by human activities and socioeconomic driving forces (Lambin et al. 2001). The increase in social and economic vulnerability as a consequence of reduced resilience through land degradation and drought may cause losses of livelihood and trigger tension and conflict over critical resources such as fresh water or food (Homer-Dixon and Blitt 1998).

Increased vulnerability and fragility places a region on a trajectory of greater risk to the panoply of stresses and shocks that occur over time. Stressed ecosystems are often characterized by a "distress syndrome" that is indicated not only by reduced biodiversity and altered primary and secondary productivity but also by increased disease prevalence, reduced efficiency of nutrient cycling, increased dominance of exotic species, and increased dominance by smaller, shorter-lived opportunistic species (Rapport and Whitford 1999). The process is a cumulative one, in which sequences of shocks and stresses punctuate the trends, and the inability to replenish coping resources propels a region and its people to increasing vulnerability (Kasperson et al. 1995).

Key attributes of resilience in ecosystems, flexibility in economic systems, and adaptive capacity in institutions used in assessments include the following:

- Ecological resilience can be assessed by the amount of variability that can be absorbed without patterns changing and controls shifting to another set of keystone processes.
- Key sources of resilience lie in the requisite variety of functional groups; the accumulated financial, physical, human, and natural capital that provides sources for reorganization following disturbances; and the social networks and institutions that provide entitlements to assets as well as coping resources and social capital (Adger 2003).
- In an ecosystem, these key processes can be recognized as the processes that interact and are robust in an overlapping, redundant manner.
- When a system is disrupted, resilience is reestablished through regeneration and renewal that connect that system's present to its past.

Management can destroy or build resilience, depending on how the socioecological system organizes itself in response to management actions (Carpenter et al. 2001; Holling 2001; MA *Policy Responses*). There are many examples of management suppressing natural disturbance regimes or altering slowly changing ecological variables, leading to disastrous changes in soils, waters, landscape configurations, or biodiversity that did not appear until long after the ecosystems were first managed (Holling and Meffe 1996). Similarly, governance can disrupt social memory or remove mechanisms for creative, adaptive response by people in ways that lead to the breakdown of socioecological systems (McIntosh et al. 2000; Redman 1999). By contrast, management that builds resilience can sustain socioecological systems in the face of surprise, unpredictability, and complexity. Successful ecosystem management for human well-being requires monitoring and institutional and organizational capacity to respond to environmental feedback and surprises (Berkes and Folke 1998; Danter et al. 2000), a subject treated at the conclusion of this chapter.

6.3 Methods and Tools for Vulnerability Analysis

Many tools and methods exist for undertaking vulnerability analysis, as described in Chapter 2. This section describes several tools more specific to assessing vulnerability issues and outcomes. The vulnerability toolkit described here and in Chapter 2 is considerable, ranging from qualitative to quantitative methods, with various levels of integration among disciplines, and it is suitable for participation of stakeholders. Matching the types of analytical approaches in a toolkit to the characteristics of a specific assessment is a necessary step in scoping projects.

6.3.1 The Syndromes Approach

The syndromes approach aims to "assess and monitor a multitude of coupled processes taking place on different (spatial and temporal) scales with different specificities" (Petschel-Held 2002). The goal of the syndromes approach is to identify where intervention can help contribute to sustainable development pathways. In order to achieve this, similarities between regions are found by looking for functional patterns that are called "syndromes" (Schellnhuber et al. 1997). An assessment of these patterns of relationships is achieved by combining qualitative and quantitative approaches. Some 16 syndromes of global change are grouped according to the dominant logic: utilization of resources, economic development, and environmental sinks. The results enable critical regions to be identified for different syndromes, so that future development can set priorities for key areas necessary for establishing more-sustainable systems.

The syndromes approach recognizes the need to examine human-environment interactions, as global change is a function of how society responds to natural changes and vice versa. It is therefore important that the socioecological system is seen as a whole. Within this context, archetypal patterns are most relevant to representing the process of global change. For example, the Sahel syndrome (Lüdeke et al. 1999), characterizes a set of processes that result in the overuse of agriculturally marginal land. (Note that the names of syndromes represent an archetype rather than a specific location, event, or situation; for more detailed analysis of environmental change in the Sahel itself, see Chapter 22.)

The Sahel syndrome can be located in certain parts of the world and characterized by a number of factors. Its driving forces or core mechanisms include impoverishment, intensification of agriculture, and soil erosion, which in turn lead to productivity loss. Various factors might contribute to the disposition toward this syndrome, including socioeconomic dimensions, such as high dependence on fuelwood, and natural dimensions, such as aridity and poor soils. The core mechanisms can be quantitatively assessed to determine which areas of the world experience the syndrome most extensively and intensively. The syndromes approach is a transdisciplinary tool, drawing on both quantitative and qualitative assessments of dynamic patterns at a variety of scales, and by identifying patterns of unsustainable development, it can be used to target future development priorities aimed at enabling sustainable development.

6.3.2 Multiagent Modeling

Multiagent behavioral systems seek to model socioecological interactions as dynamic processes (Moss et al. 2001). Human actors are represented as software agents with rules for their own behavior, interactions with other social agents, and responses to the environment. Physical processes (such as soil erosion) and institutions or organizations (such as an environmental regulator) may also be represented as agents. A multiagent system could represent multiple scales of vulnerability and produce indicators of multiple dimensions of vulnerability for different populations.

Multiagent behavioral systems have an intuitive appeal in participatory integrated assessment. Stakeholders may identify with "their" agents and be able to validate a model in qualitative ways that is difficult to do for econometric or complex dynamic simulation models. However, such systems require significant computational resources (proportional to the number of agents), and a paucity of data for validation of individual behavior is a constraint.

6.3.3 Vulnerability and Risk Maps

The development of indicators and indices of vulnerability and the production of global maps are prominent vulnerability assessments techniques at the global level, although these approaches are still being developed to better capture the full concept of vulnerability. Global assessments using these techniques are described later in this chapter.

In order to bring conceptual understanding of vulnerability closer to their cartographic representations, vulnerability and risk mapping efforts are working to resolve several methodological challenges. Generally, risk maps are explicitly concerned with the human dimensions of vulnerability, such as the risks to human health and well-being associated with the impacts from natural hazards.

Given the common focus on human well-being at an aggregate level, vulnerability is quantified in terms of either single or multiple outcomes, such as water scarcity and hunger. Two exceptions are the hotspots of biodiversity (Myers et al. 2000) and the GLOBIO analysis (Nellemann et al. 2001), which are concerned with the vulnerability of biodiversity. For example, the hotspots of biodiversity identify areas featuring exceptional concentrations of endemic species and experiencing exceptional loss of habitat. The GLOBIO analysis relates infrastructure density and predicted expansion of infrastructure to human pressure on ecosystems in terms of the reduced abundance of wildlife. Limited progress, however, has been made as yet in integrating analyses of the vulnerability of human and ecological systems.

Many of the risk maps have been generated from remotely sensed data or information held in national data libraries. The maps are generally developed and displayed using a geographic information system. The analytical and display capabilities of GIS can draw attention to priority areas that require further analysis or urgent attention. Interactive risk mapping is presently in its infancy. The PreView project (UNEP-GRID 2003) is an interactive Internet map server presently under development that aims to illustrate the risk associated with natural disasters at the global level.

For the most part, risk maps have tended to be scale-specific snapshots at a particular time, rarely depicting cumulative and long-term risk. A challenge is linking global and local scales in order to relate indirect drivers (which operate at global, national, and other broad levels and which originate from societal, economic, demographic, technological, political, and cultural factors) to direct drivers (the physical expressions of indirect drivers that affect human and natural systems at regional or local scales). Temporally, risk maps generally depict short-term assessments of risk. The accuracy of these maps is rarely assessed, and risk maps are usually not validated empirically. Two exceptions are the fire maps and the maps of the risk of land cover change. The uncertainty that surrounds the input risk data needs to be explicit and should also be mapped.

A challenging problem for the effective mapping of risk is to move from solely identifying areas of stress or likely increased stress to mapping the resistance or sensitivity of the receptor system. This would highlight regions where the ability to resist is low or declining and the sensitivity of the receptor systems is high. The difficulty here lies in quantifying the ability to resist external pressures. Quantifying resistance, at least in ecological systems, is presently largely intractable as it requires information on the effects of different levels of severity of threats, which is usually species-specific, as well as ways of integrating this information across assemblages of species or areas of interest.

A further challenge to risk mapping is the analysis of multiple and sequential stressors. Generally, single threats or stressors are analyzed and multiple stressors are rarely treated. The ProVention Consortium (2003) aims to assess risk, exposure, and vulnerability to multiple natural hazards. Possible limitations to undertaking a multiple hazard assessment of this kind include accounting for the different ways of measuring hazards (for example, in terms of frequency, intensity, duration, spatial extent), different currencies of measurement, varied data quality, and differences in uncertainty between varying hazard assessments.

Scale and how to represent significant variation within populations of regions are common challenges for global mapping exercises, with broad implications for vulnerability assessment (German Advisory Council on Global Change 1997). Political and social marginalization, gendered relationships, and physiological differences are commonly identified variables influencing vulnerability, but incorporating this conceptual understanding in global mapping remains a challenge. Global-scale maps may consider vulnerability of the total population, or they may consider the situation of specific groups believed to be particularly vulnerable. Because many indigenous peoples are less integrated into political and social support systems and rely more directly on ecosystem services, they are likely to be more sensitive to the consequences of environmental change and have less access to support from wider social levels.

Women and children are also often reported to be more vulnerable than men to environmental changes and hazards (Cutter 1995). Because the gendered division of labor within many societies places responsibility for routine care of the household with women, degradation of ecosystem services—such as water quality or quantity, fuelwood, agricultural or rangeland productivity—often results in increased labor demands on women. These increased demands on women's time to cope with loss of ecosystem services can affect the larger household by diverting time from food preparation, child care, and other beneficial activities. While women's contributions are critical to the resilience of households, women are sometimes the focus of vulnerability studies because during pregnancy or lactation their physiology is more sensitive and their ill health bears on the well-being of children in their care. Children and elderly people are also often identified as particularly vulnerable primarily because of their physiological status.

Measures of human well-being and their relationship to ecosystems services also often incorporate data on the sensitivity and resilience dimensions of vulnerability, expressed as assets, capabilities, or security. These measures are discussed in greater detail in Chapter 5.

6.4 Assessing Vulnerability

The causes and consequences of human-induced change in ecosystems and ecosystem services are not evenly distributed throughout the world but converge in certain regions and places. For some time, for example, Russian geographers prepared "red data maps" to show the locations of what they regarded as "critical environmental situations" (Mather and Sdasyuk 1991). The National Geographical Society (1989) created a map of "environmentally endangered areas" depicting areas of natural hazards, pollution sources, and other environmental stresses. Nonetheless, it is only in recent years that concerted efforts have been made to develop indices and generate maps that depict the global distribution of people and places highly vulnerable to environmental stresses.

As noted earlier, several challenges remain in developing indicators, indices, and maps that capture all the dimensions of vulnerability, but this section reviews major notable efforts that address vulnerability in the context of human security, as an aspect of environmental sustainability, and natural disasters and that point to environmental health issues addressed further in Chapter 14.

Although modest progress has occurred in identifying and mapping vulnerable places and peoples, the state of knowledge and methodology are still significantly limited. Few of the analyses presented here integrate ecological and human systems. They rarely treat multiple stresses, interacting events, or cumulative change. Indicators continue to be chosen without an adequate underlying conceptual framework and are typically not validated against empirical cases. For the most part, they are scale-specific and snapshots in time. Disaggregated data are lacking, and much remains to be done before a robust knowledge base at the global scale will exist.

In a demonstration project, the Global Environmental Change and Human Security Project of the International Human Dimensions Programme on Global Environmental Change (Lonergan 1998) mapped regions of ecological stress and human vulnerability, using an ''index of vulnerability'' composed from 12 indicators:

- food import dependency ratio,
- water scarcity,
- energy imports as percentage of consumption,
- access to safe water,
- expenditures on defense versus health and education,
- human freedoms,
- urban population growth,
- child mortality,
- maternal mortality,
- income per capita,
- degree of democratization, and
- fertility rates.

The criteria used in selecting indicators were that data were readily available, that the resulting ''index'' consisted of a small number of indictors, and that the indicators covered six major categories—ecological and resource indicators, economic indicators, health indicators, social and demographic indicators, political/social indicators, and food security indicators. Through cluster analysis, a vulnerability ''index'' was derived and then used to map estimated vulnerability patterns, such as one for Africa. (See Figure 6.2.)

The work of the Intergovernmental Panel on Climate Change (IPCC 2001a) has made clear that ongoing and future climate changes will alter nature's life-support systems for human societies in many parts of the globe. Significant threats to human populations, as well as some potential benefits, are involved. (See Box 6.1.) As the example on the Arctic region illustrates, changes that benefit some may harm others in the same area. (See also Chapter 25.)

But it is unrealistic to assume that positive and negative effects will balance out, particularly in certain regions and places. Many of the regions and human groups, the IPCC makes clear, will be highly vulnerable and poorly equipped to cope with the major changes in climate that may occur. Many people and places are already under severe stresses arising from other environmental degradation and human driving forces, including population growth, urbanization, poverty and poor nutrition, accumulating environmental contamination, growing class and gender inequalities, the ravages of war, AIDS/HIV, and politically corrupt governments. The IPCC points to the most vulnerable socioecological systems: one third to one half of the world's population lack adequate clean water; many developing countries are likely to suffer future declines in agricultural production and food security; sea level rise is likely to greatly affect low-lying coastal areas; small-island states face potential abandonment of island homes and relocation; and the poor and sick in growing megacities face increased risk for death and illness associated with severe heat and humidity.

In preparation for the World Summit on Sustainable Development in 2002, the Global Leaders for Tomorrow Environment Task Force (2002) of the World Economic Forum to created a global Environmental Sustainability Index. It has five major components developed from globally available national data, including one on reducing human vulnerability. (See Table 6.1.) While it would be desirable to display regional differences within countries, finer-scale information is not consistently available for many types of data.

Human vulnerability seeks to measure the interaction between humans and their environment, with a focus on how environmental change affects livelihoods. Two major issues are included in the vulnerability component (one of the five components in the overall index): basic human sustenance and environmental health. The index is based on five indicators: proportion undernourished in the total population, percentage of population with access to improved drinking water supply, child death rate from respiratory diseases, death rate from intestinal infectious diseases, and the under-five mortality rate. The standardized values for each indicator were calculated and converted to a standard percentile indicator for ease of interpretation. The indicators were unweighted. Country scores were then derived to demarcate global patterns, as shown in Table 6.2.

The United Nations Environment Programme (UNEP 2003) has also assessed definitions, concepts, and dimensions of vulnerability to environmental change in different areas of the world. In particular, it calls attention to the importance of environmental health in the vulnerability of different regions and places. It notes, for example, that every year thousands of people die from a range of disasters, but the fate of many of these people is never reported. The International Red Cross Federation (IFRC 2000) has shown that the death toll from infectious diseases (such as HIV/AIDS, malaria, respiratory diseases, and diarrhea) was 160 times the number of people killed in natural disasters in 1999. And this situation is becoming worse rapidly. It is estimated, for example, that over the next decade HIV/AIDS will kill more people in sub-Saharan Africa than died in all wars of the twentieth century.

The United Nations Development Programme, in *Reducing Disaster Risk: A Challenge for Development* (UNDP 2004), undertakes the formulation of a ''disaster risk index,'' which it then uses to assess global patterns of natural disasters and their relationship to development. The Disaster Risk Index calculates the relative vulnerability of a country to a given hazard (such as earthquakes or floods) by dividing the number of people killed by the number of people exposed to the hazard. The analysts then compared the risk of the hazard (the number of people actually killed by the hazard in a country) with 26 indicators of vulnerability, selected through expert opinion. Analyzing a series of statistical analyses, a number of findings concerning the impact of development on disaster risk emerge:

- The growth of informal settlements and inner city slums has led to the growth of unstable living environments, often located in ravines, on steep slopes, along floodplains, or adjacent to noxious industrial and transport facilities.

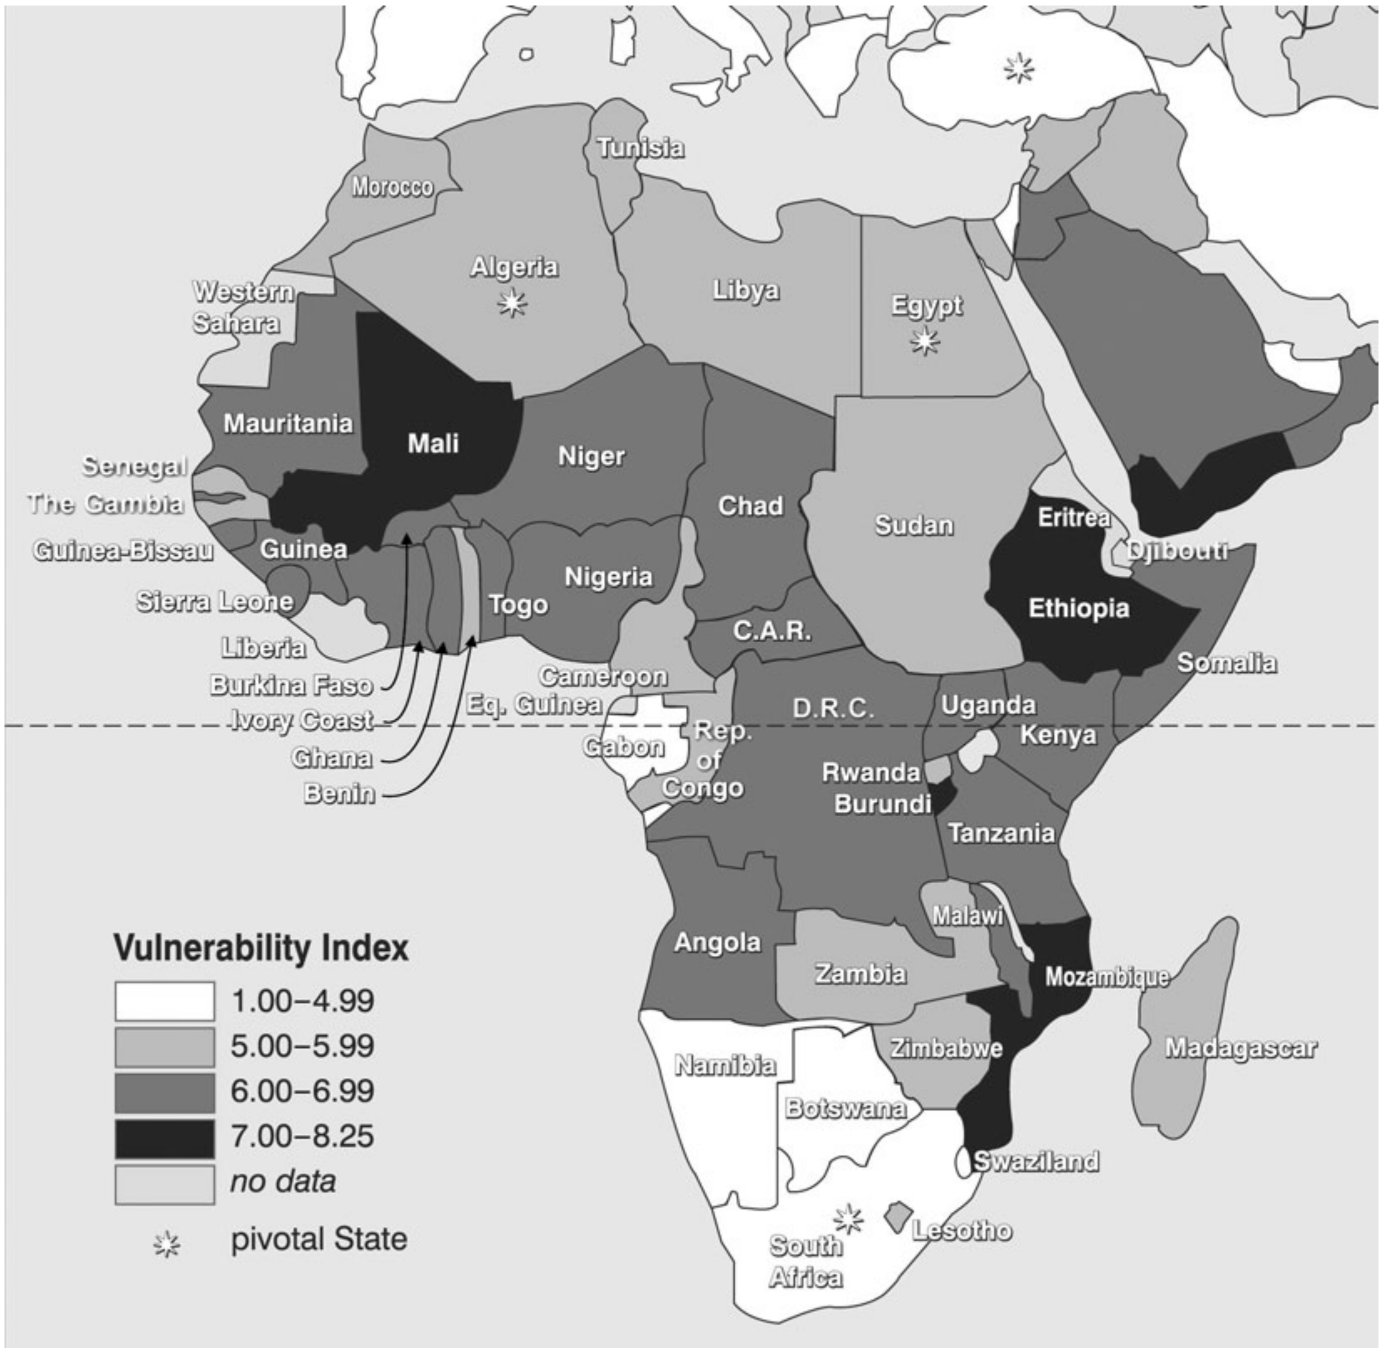

Figure 6.2. Vulnerability Index for African Countries (Lonergan 1998)

- Rural livelihoods are put at risk by the local impacts of global climate change or environmental degradation.
- Coping capacities for some people have been undermined by the need to compete in a globalizing economy, which presently rewards productive specialization and intensification over diversity and sustainability (UNDP 2004, p. 2).

6.5 Natural Hazards and Vulnerability

Natural hazards and disasters are products of both natural variability and human-environment interactions, and vulnerability to them has received substantial past attention. (See also Chapter 16.) The extremes of environmental variability are defined as hazards when they represent threats to people and what they value and defined as disasters when an event overwhelms local capacity to cope. Natural hazards offer a particularly dramatic view of the role of vulnerability in explaining patterns of losses among people and places. Indeed, research on this topic was the first realm to document the vast differences in the magnitude of losses among people and places experiencing the same types of events (White 1974). Since the 1970s, researchers have consistently reported greater loss of life among poorer populations and countries than in industrial countries, along with the inverse relationship for economic damage.

Natural hazards and disasters have always been a part of human history. Yet human relationships to hazards have evolved as the power of humans to shape natural landscapes and their biogeochemical processes has grown. Over the centuries, humans have changed from relatively powerless victims in the face of natural hazards and disasters to active participants shaping natural hazards and our vulnerability to them. Only recently has policy recognized that natural hazards are not "Acts of God" and begun to shift hazard management from a model of response and relief to an active engagement with mitigation, prevention, and integration of hazard management into development planning (ISDR 2002).

It is well established that the impacts of natural disasters continue to create uneven patterns of loss in populations around the world. The rising economic costs, the relative significance of those costs to the budgets of developing countries, the increasing numbers of people affected, and the decreasing loss of life demonstrate the dynamics of vulnerability across scales and experienced in local places.

6.5.1 Trends in Natural Hazards and Vulnerability

The best available data on a global scale (e.g., Swiss Re 2000; Munich Re 2003; CRED 2002) indicate that the world is witnessing a worsening trend of human suffering and economic loss

BOX 6.1

Threats and Potential Benefits of Climate Change to Human Societies (IPCC 2001a)

Threats

- Reduced potential crop yields in some tropical and sub-tropical regions and many mid-latitude regions
- Decreased water availability for populations in many water-scarce regions, particularly those with inadequate management systems
- An increase in the number of people exposed to vector-borne diseases (such as malaria) and waterborne diseases (such as cholera)
- Increases in the number of people dying from heat stress, particularly in large cities in developing countries
- A widespread increase in the risk of flooding for many human settlements throughout the world
- Severe threats to millions of people living on low-lying islands and atolls
- Threats to aboriginals living in Arctic and high mountains (for example, through the breakup of ice fields preventing people from reaching their traditional hunting and fishing grounds)

Potential Benefits

- Increased potential crop yields in some mid-latitude regions
- A potential increase in global timber supply from appropriately managed forests
- Increased water availability for populations in some water scarce regions (such as parts of South East Asia)
- Reduced winter mortality in mid- and high latitudes
- Improved marine transportation in the Arctic

Table 6.1. Components of Environmental Sustainability (Global Leaders for Tomorrow Environmental Task Force 2002)

Component	Logic
Environmental systems	A country is environmentally sustainable to the extent that its vital environmental systems are maintained at healthy levels and to the extent to which levels are improving rather than deteriorating.
Reducing environmental stresses	A country is environmentally sustainable if the levels of anthropogenic stress are low enough to engender no demonstrable harm to its environmental systems.
Reducing human vulnerability	A country is environmentally sustainable to the extent that people and social systems are not vulnerable (in the way of basic needs such as health and nutrition) to environmental disturbances; becoming less vulnerable is a sign that a society is on a track to greater sustainability.
Social and institutional capacity	A country is environmentally sustainable to the extent that it has in place institutions and underlying social patterns of skills, attitudes, and networks that foster effective responses to environmental challenges.
Global stewardship	A country is environmentally sustainable if it cooperates with other countries to manage common environmental problems, and if it reduces negative transboundary environmental impacts on other countries to levels that cause no serious harm.

to natural disasters over recent decades.(Data available at the time this chapter was written do not include losses caused by the 2004 tsunami.) While the general trend is clear, the precise estimates vary somewhat, due to improvements in reporting over time, data gathering practices, and definitional differences across organizations. (See Chapter 16 for more detailed description of the limitations and variations among data sets.)

During the past four decades, the number of ''great'' catastrophes—when the ability of a region to help itself is distinctly overtaxed, making interregional or international assistance necessary—has increased about four times, while economic losses have increased over 10 times. (Munich Re 2000) (See Table 6.3.) This trend reflects the increasing economic costs of disasters, lives lost, and the unequal ability of nations to cope with the impacts. Natural disasters affected twice as many people in the 1990s as in the 1980s (CRED 2003). The annual average losses for all disasters over the 1990s were 62,000 deaths, 200 million affected, and $69 billion in economic losses (IFRC 2001). Although comprehensive global databases do not exist for smaller-scale natural hazard events, the significance of these more common events to the social vulnerability of exposed human populations is also a major concern (ISDR 2002; Wisner et al. 2004).

Throughout the twentieth century, three general observations can be drawn from global trends: the number of disasters has increased, economic losses from disasters have increased (primarily in industrial countries), and the ratio of loss of life to total population affected has decreased, although this decline has also been heavily concentrated in industrial societies. (See Figure 6.3 in Appendix A.)

The global trends in natural disaster occurrences and impacts suggest several important patterns of vulnerability among people and places at the same time that they mask considerable geographic variation. Asia is disproportionately affected, with more than 43% of all natural disasters in the last decade of the twentieth century. During the same period, Asia accounted for almost 70% of all lives lost due to natural hazards. In China alone, floods affected more than 100 million people on average each year (IFRC 2002).

Variation among types of natural hazards is also significant. Over the decade 1991–2000, the number of hydro-meteorological disasters doubled, accounting for approximately 70% of lives lost from natural disasters (IFRC 2001). Floods and windstorms were the most common disaster events globally, but not consistently the cause of greatest losses. Disasters causing the greatest number of deaths varied among regions, with floods causing the most deaths in the Americas and Africa, drought or famine the most in Asia, earthquakes the most in Europe, and avalanches or landslides narrowly exceeded windstorms or cyclones in Oceania. Chapter 16 provides a more comprehensive description of flood and fire hazards.

While the economic loss per event is much larger in industrial countries, the greatest losses still occur in developing nations in absolute numbers of lives as well as in relative impact as measured by percentage of GDP represented by disaster losses. (See Figure 6.4.)

Considering lack of resources and capacity to prevent or cope with the impacts, it is clear that the poor are the most vulnerable to natural disasters. Among the poorest countries, 24 of 49 face a

142.	Angola	1.9

high level of disaster risk; at least 6 countries have been affected by two to eight major disasters per year in the past 15 years, with long-term consequences for human development (UNEP 2002). Ninety percent of natural disaster–related loss of life occurs in the developing world. When countries are grouped according to the UNDP Human Development Index, socioeconomic differences are strongly reflected in disaster losses (IFRC 2001). For the 1990s, countries of low human development experienced about 20% of the hazard events and reported over 50% of the deaths and just 5% of economic losses. High human development countries accounted for over 50% of the total economic losses and less than 2% of the deaths.

In assessing the distribution of vulnerability, several limitations to existing research need to be considered. First, economic valuations do not reflect the difference in relative value of losses among wealthier and poorer populations or the reversibility of environmental damages incurred. Similarly, land degradation due to landslides, flooding, or saline inundation from coastal events can diminish the natural capital resources of livelihoods, further compounding recovery challenges. The meaning of the economic value of these losses of ecosystem services is also difficult to capture and is seldom included in conventional economic assessments.

Second, because of the definitions of disaster used, local-scale disasters of significance to the affected community are often not reflected in these disaster statistics. If those losses were included, the figures on damages could easily be much higher.

Finally, there is the tendency to treat natural hazards in separate categories and to treat disasters as discrete, individual events.

Table 6.3. Great Natural Catastrophes and Economic Losses: Comparison of Decades, 1950–99 (Munich Re 2000)

Catastrophes and Losses	1950–59	1960–69	1970–79	1980–89	1990–99
Number	20	27	47	63	82
Economic losses (bill. 1998 dollars)	38.5	69.0	124.2	192.9	535.8
Insured losses (bill. 1998 dollars)	unknown	6.6	11.3	23.9	98.9

Note: Natural catastrophes are classified as "great" if the ability of the region to help itself is distinctly overtaxed, making interregional or international assistance necessary.

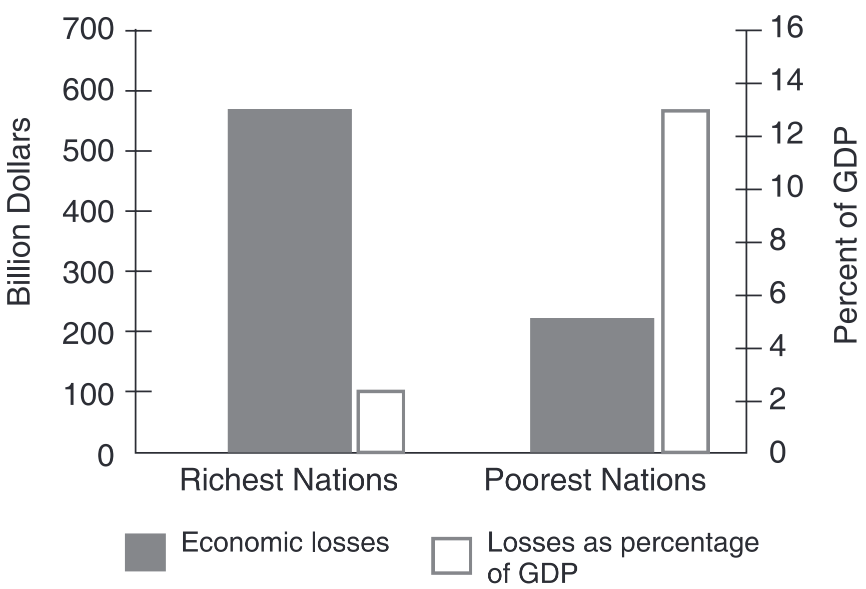

Figure 6.4. Disaster Losses, Total and as Share of GDP, in 10 Richest and Poorest Nations, 1985–99 (Abramovitz 2002)

This accounting practice limits insights into the consequences of threats from multiple hazards in one place and of sequences of disasters following upon one another. Over time, multiple and recurring hazards exacerbate vulnerability, and across scales, vulnerability is generally greater during the recovery period, when systems are already damaged. These patterns of differential impact affect efforts to cope with the impacts of environmental variability and degradation, as described earlier.

6.5.2 Explaining Vulnerability to Natural Hazards

Human-driven transformation of hydrological systems, population growth (especially in developing countries), and movements of people and capital into harm's way are major driving forces underlying the increasing numbers of disasters (Mitchell 2003). Conflict among people contributes further to vulnerability (Hewitt 1997). The causal reasons relate to basic characteristics of economy and political system but also to the perceptions, knowledge, and behavior of local managers and institutions (Hewitt 1997).

In some regions, significant environmental changes have resulted in the degradation of ecological services that mediated the effects of hydro-climatological events. Two common forms of ecological change—desertification and deforestation—can exacerbate the impacts of drought in some areas by reducing the moisture-holding capacity of the soil and contribute to increased flooding through reducing infiltration. (See Chapter 16.) In Honduras, deforestation contributed losses through increasing flooding as well as landslides following Hurricane Mitch in 1998. In other areas, efforts at river or flood control have reduced vulnerability to smaller hazard events, but increased losses when larger events overwhelmed dams, dykes, or levees and damaged the usually protected area.

The growth in numbers of people affected is a particularly important measure, as it provides an indication of the potential increase of exposure and sensitivity of people to environmental variability. The global annual average number of people affected has increased over the last decade, although the number of deaths due to disasters has declined. This shift highlights the potential for changes in pattern of vulnerability though adaptations. (See also MA *Policy Responses,* Chapter 11.) The greatest proportion of people affected resides in countries of medium human development, which include the large-population countries of Brazil, China, India, and Indonesia (IFRC 2001).

In addition to changing exposure, socioeconomic changes are shaping the overall patterns of vulnerability. First, while poverty is not synonymous with vulnerability, it is a strong indicator of sensitivity, indicating a lack of capability to reduce threats and recover from harm. The number of people living in poverty is increasing (UNDP 2002a). The greater number of people affected in medium human development countries may also reflect their experience with the additional challenges of transition, a situation somewhat akin to recovery, in which infrastructure and support systems, both physical and social, may be disrupted by the processes of change and be unable to contribute to reducing vulnerability.

Urbanization creates particular problems in disaster vulnerability. Due to the concentrations of people and complex infrastructure systems involved, the repercussions of an event in cities can spread quickly and widely, and the scale of resources needed for effective response is often challenging for national or international coordination. In many cases, these cities also draw in vast numbers of people seeking better lives, but they are often unable to keep up with the demand for planning, housing, infrastructure, and jobs. The informal housing that immigrants create is often located in marginal areas, such as hill slopes and floodplains, and accessible construction options cannot address the site limitations (Wisner et al. 2004). In 1950, just under 30% of the world's population (of 2.5 billion) lived in cities; by 2025 it is projected to be over 60% (of an estimated 8.3 billion) (UNDP 2002b). This rapid urbanization trend is particularly pronounced in countries with low per capita income. (See also Chapter 27.)

Globalization is contributing to natural hazard vulnerability as it is changing the sensitivity and coping options available (Adger and Brooks 1003; Pelling 2003). On an international scale, increasing connectedness is causing societies to become more dependent on services and infrastructure ''lifelines.'' In such a connected world, the consequences of natural disaster reach far beyond the area physically damaged. It has been estimated that the possible extent of damage caused by a extreme natural catastrophe in one of the megacities or industrial centers of the world has already attained a level that could result in the collapse of the economic system of entire countries and may even be capable of affecting financial markets worldwide (Munich Re 2000, 2002). Globalization has also increased the risks faced by marginalized indigenous peoples; many of these are developmental effects that will become apparent over only the long term. Traditional coping mechanisms have come under severe pressure, and adaptation strategies, at one time effective, can no longer cope (Pelling 2003).

Data on global trends do not report on the social differentiation among victims, but case study evidence and other synthesis efforts indicate some social groups are continually disproportionately represented among those harmed the most (Wisner et al. 2004). These are often people who are marginalized within society, due to combinations of prejudice, lack of or ignored rights, and lack of access to social supports or personal resources or due to distance from concentrations of services and power. Indigenous peoples, such as the Inuit, Sami, and others from northern regions, represent the vulnerability of this type of situation well. (See Chapter 25 for further details). These circumstances often apply to poor people, women, children, elderly individuals, and ethnic minorities in affected areas. In addition, the elderly, children, women, and handicapped people are more likely to have physical limitations or special needs that reduce their ability to cope with disaster.

6.6 Desertification: Lessons for Vulnerability Assessment

Desertification—land degradation in drylands—has been a subject of interest for over 30 years, with numerous technical assessments and policy analyses, and it is a good example of changes in a coupled socioecological system that threaten livelihoods across large swaths of Earth. It is also a good example of understanding vulnerability. (See Downing and Lüdeke (2002) and Chapter 22 for more on drylands and desertification and a useful set of maps.)

Local to global studies of social vulnerability to desertification suggest at least three lessons for vulnerability from past experience:

- *Vulnerability is dynamic.* Desertification arises from the interactions of the environment and social, political, and economic systems—through the actions of stakeholders and the vulnerable themselves (Downing and Lüdeke 2002).
- *Vulnerability takes different forms at different scales.* Similar constellations of institutions have diverse effects at different social or geographic scales. The patchiness of driving forces, often represented in global scenarios, precludes developing a simple hierarchy from local vulnerability to global maps of desertification risks.
- *Vulnerability cannot be differentiated into different causes.* At the level of human livelihoods and systems, exposure to desertification is entangled with poverty, drought, water, food and other threats and stresses.

One example of the close coupling of social and environmental systems related to desertification is apparent in the syndromes approach developed by the Potsdam Institute for Climate Impact Research, which depicts the close linkages and components involved in the coupling. The basic idea behind syndromes is "not to describe Global Change by regions or sectors, but by archetypical, dynamic, co-evolutionary patterns of civilization–nature interactions" (Petschel-Held et al. 1999, p. 296). Syndromes are charted in dynamic process models that link state variables that change over time and between states. The scale is intermediate, reflecting processes that occur between household and national/macro scales. The typology of syndromes reflects expert opinion, modified over time based on modeling. Local case examples are used to generalize to mechanisms in the modeling and also to validate the syndrome results. Desertification is a case of several syndromes operating independently, reflecting the internal dynamics of places, resources, economies, and populations.

The syndrome approach illustrates how concepts of dynamic vulnerability might be implemented to understand multiple stresses arising from the human use of ecosystem services. It takes the analysis one stage beyond purely biophysical explanations to examine linkages with human systems. The next steps might be integrated analysis at the level of different users of ecosystem services, and how they interact with each other in markets and in governance.

6.7 Food Insecurity

The arena of food security has been a third primary focus of vulnerability analysis. The severe famines in the 1980s in Africa saw the launch of dozens of famine early warning schemes. These implemented various designs, but all expanded beyond the simple monitoring of agricultural production. By the mid-1980s, Amartya Sen's entitlement theory (Sen 1981), which emphasized factors influencing the distribution of food as well as the absolute levels of available food, was widely circulated and implemented in food security monitoring. Attention to the socioeconomic failures that limit access to global food supplies became a substantial component of these efforts. More recently, more holistic approaches have sought to focus on livelihood security, to include food security, thereby widening the conceptual framing of vulnerability still further.

Much of the literature on food security focuses on human vulnerability; ecosystem services are limited to crop production, grazing for livestock, and to a lesser extent wild foods. While vulnerability assessment is maturing as an analytical tool, the need exists for assessments that are more dynamic and actor-oriented. An essential way forward in vulnerability analysis is to adopt a more precise terminology and nomenclature (see, e.g., the papers in Smith et al., 2003).

6.7.1 Methodology

Methodological lessons learned in vulnerability assessment over the past several decades reinforce the general messages of this chapter: food security is a relative measure that can be captured in various quantitative and semi-quantitative ways, but it is not an absolute condition that can be measured objectively. Food security is multidimensional and it integrates exposure to stresses beyond more narrow treatment of the production or availability of food. (See Chapters 8 and 18 for a further description of food provisioning services.) It is also clear that indicators of food security need to represent an explicit conceptual framework, such as that offered earlier in this chapter. The collation of indicators into profiles and aggregated indexes needs also to reflect the causal structure of food insecurity, going beyond the indiscriminate adding up of available indicators into a single index (see Downing et al. 2001).

A common feature of almost all food security (and livelihood) analyses is the recognition of multiple domains of vulnerability. Operational assessments commonly treat production, economic exchanges, and nutrition, while longer-term and more structural analyses include some measure of the political economy that underlies the more immediate dimensions of food security. Examples of operational assessments include India (MSSRF 2001) and Kenya (Haan et al. 2001). Figure 6.5 charts three domains of rural food insecurity for states in India.

A more heuristic illustration of the multiple dimensions of food security, related to climate change, is shown in Figure 6.6 (in Appendix A). The Figure is speculative, based on a subjective assessment of food security and climatic risks. Nevertheless, it clearly shows that global food production is of less concern than

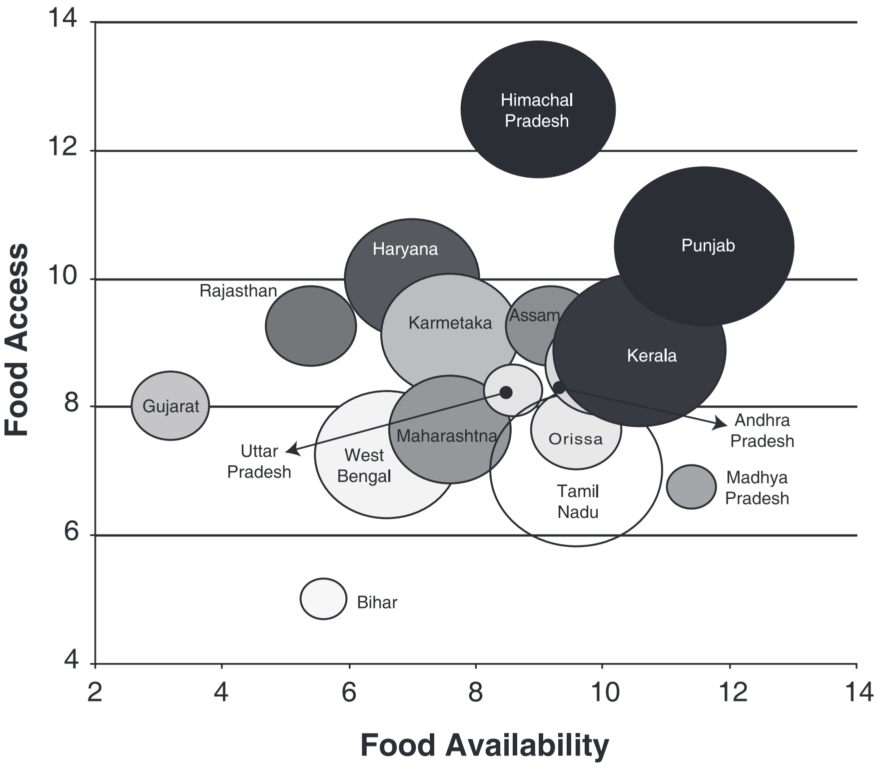

Figure 6.5. Food Insecurity Indicators of Rural India. Compiled at the state level, the MS Swaminathan Research Foundation aggregated food insecurity into three dimensions—food availability and production (x-axis), economic access (y-axis), and nutritional utilization (size of the circles, where larger is better-off). (MS Swaminathan Research Foundation 2001)

the impacts of droughts, which are already economically and socially significant for some livelihoods.

6.7.2 Wild Foods at the Local Scale

While a myriad of propositions regarding food security are possible, relating to different elements of causal structure, from the nature of the hungry themselves to the global political economy of food trade, here the case of wild foods and their role in food security is examined. (See also Chapters 5, 8, and 18 for food production and hunger issues.)

The most common approaches to food security are designed to balance consumption and production at the household level—including such indicators as expected yields of major foods (related to rainfall, soil quality, and pests, for instance), economic exchanges (such as terms of trade for agricultural sales or access to off-farm employment), hunting of wild foods, and some measures of entitlement through remittances from kin, official food relief, and relief work schemes. Set against the total of available food is the expected consumption, from meeting the FAO calorie standards to various levels of deprivation and starvation resulting in measurable effects on health. Aggregating to a regional or national level, such food balances guide policies for imports and exports, for targeted relief, and for declaration of a food crisis.

Notably absent from such food balances is the role of off-farm food collection—the gathering of wild foods either for consumption or sales. (See Chapter 8 for a more detailed description of the role of wild foods, including game, fish, and plants, in diets and for the underestimation in accounting in food balances.) In forest regions, these are called non-wood forest products and can be a major livelihood activity. Equally, few monitoring schemes include direct measures of ecosystem services such as charcoal sales, increased burdens of water shortages, or even effects of vegetation and land cover on livestock and pests. Nevertheless, for some marginal communities, such ecosystem services are essential and particularly important for surviving food shortages (Ericksen 2003).

Investigations of two dryland sites in Kenya and Tanzania found that indigenous plants were an important source of raw material in the majority of coping mechanisms when alternative sources of food or income were required, such as when the harvest failed or sudden expenses had to be met. Such coping mechanisms included making use of trees for making and hanging beehives (flowering trees are also a source of nectar); of fuelwood for sale, burning bricks, or producing charcoal; of reeds, fibers, and wood for handicrafts such as mats or tools; and of fruit, vegetables, and tubers for food and sale. Indigenous plant-based coping mechanisms are particularly important for the most vulnerable, who have little access to formal employment or market opportunities, thus providing a crucial safety net in times of hardship. Wild fruits provide important nutrients to children during times when meals are reduced at home in many parts of Africa and South Asia (Brown et al. 1999), for example.

Such raw materials can often be acquired from communal land or from neighbors without cash transactions, and they are available at critical times of the year due to the climatic resilience of indigenous plants. In addition, the sale of livestock and poultry and engaging in casual labor, which are critical sources of cash during crises, often depend on ecosystem services, such as grazing land and fodder or forest products for fencing, construction, and other typical casual labor tasks. Table 6.4 shows the high percentage of households that depended on indigenous plant-based coping mechanisms in the Kenya and Tanzania site (Eriksen 2000), and Figure 6.7 illustrates the relative importance of indigenous foods. While the findings refer to a particular point in time (the 1996 drought), the widespread use of forest products as a source of food and income figures is consistent with findings from numerous other studies (Arnold 1995; Brown et al. 1999).

6.7.3 Global Influence on Local Food Balance

The literature on food security has a long tradition recognizing that local food balances are embedded in national economies and global flows of food trade and aid (for one representation, see Kates et al. 1988). A fictitious illustration captures the notion of global exposure:

During a drought, a farm household suffers a loss of yields in one of its fields of maize and beans. The field is primarily used for domestic consumption, cultivated by the women. Rainfall shortages are apparent with the delay in the onset of the rains—although the field is planted and later weeded by the women, the family does not apply expensive pesticides and fertilizers, expecting low returns during a poor season. Another field has a different problem. The head of the household acquired it as part of a community-based irrigation scheme

Table 6.4. Households That Depended on Indigenous Plant-based Coping Mechanisms in Kenya and Tanzania (Eriksen 2000)

Activities that Involve Use of Indigenous Plants	Share of Households, Kenya site	Share of Households, Tanzania site
	(percent)	
All use	94	94
Food use	69	54
Non-food use	40	42

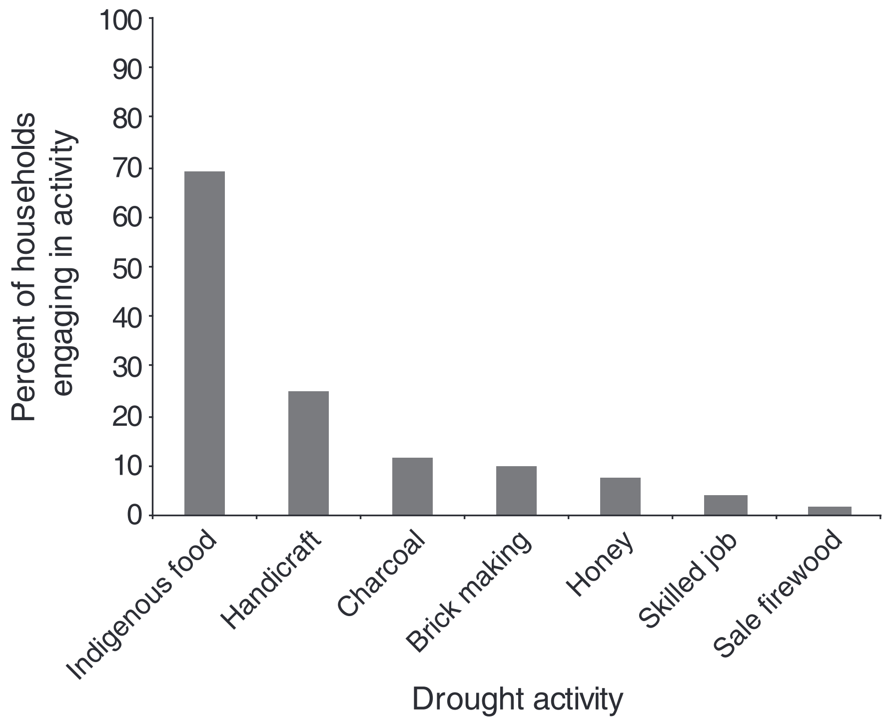

Figure 6.7. Use of Indigenous Plants in Mbitini, Kenya, by Activity during the 1996 Drought. "Skilled job" entailed tailoring, stone masonry/construction of houses, and woodcarving. Total number of households is 52. (Eriksen 2000)

that he joined a few years ago. He plants it this year with a cash crop of tomatoes and invests in fertilizer and pesticide. Halfway through the season, however, the drought restricts the availability of irrigation water. As a "junior" member of the scheme, his supply is reduced earlier than expected and his yields and quality are poor. When he tries to sell his crop to the local factory for processing into tomato juice, he discovers that there is a glut in the market due to a relaxation of import controls. Good conditions in a nearby country and export subsidies have produced a surplus, and the factory cannot afford to purchase local produce.

The fictitious example is not unrealistic—farmers have to contend with local conditions, with social, economic, and environmental relations in their community, and with the global and national food system. This global nature of vulnerability makes it impossible to clearly "bound" exposure, and it is often misleading to adopt a single spatial scale, as is often attempted in mapping vulnerability (as noted earlier regarding tools and methods).

6.7.4 Reporting Vulnerability

An essential way forward in food security analysis is to use at least a more precise terminology and nomenclature. A fairly simple scheme is proposed here, which makes clear four fundamental considerations that are not consistently reported: who is exposed, what the stresses are, what time frame is considered, and what consequences evaluated (see Downing et al. 2004). The notation below calls for reporting vulnerability (V) as specific to time frame (t); the sector, such as agriculture (s); the group, such as small-scale farmers, women farmers, or residents of peri-urban areas (g); and the consequences evaluated, such as food production, change in food purchasing power, nutritional levels or hunger (c).

$$^{t}V_{s,g}^{\;c}$$

(where s = sector, g = group, c = consequence, t = time frame and V = vulnerability)

For instance, an examination of climate change vulnerability in agriculture could offer greater utility to future comparisons and policy by specifying differences as follows:

- Climate change vulnerability (T = climate change, no other terms specified)
- Drought (T) vulnerability for food systems (s)
- Drought (T) vulnerability for smallholder (g) agriculturalists (s)
- Drought (T) vulnerability for smallholder (g) agriculturalists (s) at risk of starvation (c = health effects of reduced food consumption)

These four different statements about climate change vulnerability suggest the range of potential differences in assessment findings. The process of conducting a vulnerability assessment can be labeled VA. If the indicators are mapped, this is extended to a vulnerability assessment map, a VAM. A database of vulnerability indictors used in a VA (or VAM) can be labeled VI. Greater precision and analytical comparability could be gained by assigning a nomenclature to individual indicators (VI_x), such as:

t = time period (historical, present or specific projection)
g = group of people if specific to a vulnerable population
r = region (or geographic pixel)
$*$ = transformed indictors, as in standard scores

This basic set of relationships can be extended into a variety of assessment tools and facilitate comparison of case studies.

6.8 Exploring Vulnerability Concepts: Three Case Studies

The broad patterns of vulnerability apparent in the patterns and trends of natural disasters, the assessment of desertification, and the lessons from food security studies all demarcate important aspects of the sources and outcomes of stresses and perturbations on coupled socioecological systems. But it is well known that these interactions are highly place-specific. Thus it is useful to turn to particular cases to explore these issues in greater depth.

This section considers three specific examples. First, the situation of two types of resource-poor farmers in northeastern Argentina is examined, illustrating how vulnerability can take different forms with different types of farming systems. Second, we look at how shifting the scale of analysis or vulnerability and resilience yields quite different insights on the sources of vulnerability and the potential effectiveness of resilience-building strategies, using a case study from Southern Africa. Finally, efforts to reduce vulnerability and the challenges involved in assessing the benefits of different types of interventions are examined through a case study from the one of the poorest areas of India.

6.8.1 Resource-poor Farmers in Northeastern Argentina

The Misiones region, in a hilly area of northeastern Argentina, has a sub-tropical wet climate where about 60% of the original vegetation (sub-tropical forest) has now been replaced by agriculture, despite the fact that soils are fragile, ill-suited for continuous cropping, and subject to nutrient depletion and erosion (Rosenfeld 1998).

Subsistence farming is common in the region, and two major types of farmers can be distinguished. Both have a similar farm structure in terms of land, capital, and labor; both are very poor; and both types often cannot meet their basic needs (Cáceres 2003). But they have designed very different farming systems and developed contrasting strategies to interact with the wider context within which they operate. On the one hand, agroecological farmers have developed farming systems of very high diversity, use few external inputs, rely mostly on local markets, and are part of representative peasant farmer organizations. Tobacco growers, by contrast, manage less diverse agroecosystems, rely on external inputs provided by the tobacco industry, have a weak participation in local organizations, and are closely linked to external markets. (See Table 6.5.)

6.8.1.1 Agrobiodiversity

The number of domesticated animals and cultivated plants (agrobiodiversity) maintained by the two types of farmers is strikingly different. On average, agroecological farmers grow or raise three times as many species within a single farm as tobacco growers do. The total number of species in all surveyed farms is also very different: 97 species in the case of agroecological farmers and 41 species for tobacco growers. This indicates that agrecological farmers maintain a higher degree of heterogeneity among farms and a higher agrobiodiversity at the landscape-to-region level. Horticultural, aromatic, and medicinal crops and fruit trees are the most diverse categories both within and among farms.

Agrobiodiversity has a direct impact on food security (Altieri 1995). The more diverse farms are, the more likely they are to meet subsistence food needs. The opposite occurs in the case of farmers specialized in the production of commodities (such as tobacco), since most of the farm resources are allocated to a goal that does not strengthen local food security (Dewey 1979; Fleuret and Fleuret 1980). This situation is clearly observed in this case, where agroecological farmers grow more than three times as many species for food as tobacco growers do.

6.8.1.2 Technology

Agroecological farmers and tobacco growers also differ strongly in terms of farm technology. Although both draw on the same technological matrix (draft power and the use of fire to clear up land), the "final" technologies used in their farms are very different (Cáceres 2003). In order to produce their cash crop, tobacco growers rely on modern technology and a conventional approach to farming. This involves the use of high external input technology (chemical pesticides and fertilizers and high-yield seeds) and monocropping. Nearly all the inputs needed for tobacco production come from the market. Because tobacco growers have an extremely limited financial capacity, they rely on the credit provided by tobacco companies, which in turn buy the tobacco leaves from them, in a typical contract-farming relationship.

In contrast, the technology used by agroecological farmers rests mostly on the understanding and management of natural processes and cycles. Rather than relying on external inputs, they maximize the use of both local and agroecological knowledge and resources that are locally available. As a consequence of both their traditions and the extension work of development agencies, the use of raised beds, composting practices, intercropping, biological pest control, and crop rotation is common among the agroecological farmers (Rosenfeld 1998). In order to gain access to this technology, these farmers do not need to develop a heavy reliance on the market, nor do they require the financial support of the agroindustry.

6.8.1.3 Scale Interactions

The socioeconomic and institutional context, in particular of markets and organization, is another key element shaping the vulnerability of rural societies. Tobacco growers in the Misiones have a less diversified relationship with the markets, since the tobacco companies are the main social actor with whom they interact. This is the highly asymmetrical relationship that typically develops in contract farming (Watts 1990). Tobacco growers are unable to make the most important farming decisions (such as how many tobacco plants to have, or which varieties), negotiate the quality and price of their tobacco with the agroindustry, or even decide which company to sell their product to.

The contacts of agroecological farmers with the agroindustry, on the other hand, are weak, and they are mostly linked to NGOs and governmental programs fostering rural sustainable development. Agroecological farmers have substantial control over the productive decisions concerning their farms and have developed a more diversified relationship with the market. They sell their production through different channels, of which the organic farmers' markets is the main one. In these markets, farmers and consumers meet once a week, when they set the price and other aspects of the commercial transactions. The wider range of products that agroecological farmers bring to the market also allows more spreading of commercial risks and thereby has a favorable impact on the stability of their cash flow.

The differences among these two types of farmers are even more noteworthy in terms of their participation in local organizations. Agroecological farmers not only relate with a higher number of organizations, they are also part of a larger number of grassroots representative organizations committed to peasant interests and civil rights. In contrast, tobacco growers are almost exclusively related to the Tobacco Growers' Association of Misiones, a highly bureaucratized organization that primarily represents tobacco company-interests (Schiavoni 2001). Yet the participation of tobacco growers in this organization is compulsory in order to be able to sell their tobacco to the agroindustry.

6.8.1.4 Synthesis: Differential Vulnerability

Agroecological farmers and tobacco growers share many key social and productive features. Both types of farmers and the envi-

Table 6.5. Differences between Agroecological Farmers and Tobacco Growers in Terms of Agrobiodiversity, Food Safety, Links with Markets, and Representative Organizations ($P < 0.001$, Mann-Witney U test for independent samples) (Cáceres 2003)

	Agroecological Farmers			Tobacco Growers		
Variable	Median	Minimum	Maximum	Median	Minimum	222
Total number of plant and animal species grown or raised on the farm	40	21	54	14	7	82
Number of species grown or raised for family consumption	28	18	42	10	4	11
Number of species sold in the market	5	3	10	2	1	1
Participation in organizations (number)	2	1	5	1	1	1

ronment in which they develop their farming strategies may be regarded as "vulnerable." However, as this case illustrates, factors shaping vulnerability can come together in a variety of ways that result in substantial variations in the magnitude and types of vulnerability, even among a group such as small-scale farmers, who are often assumed to be homogeneous.

Given these differences in vulnerability, the agroecological farmers appear less vulnerable overall than tobacco growers. Differences in agrobiodiversity, technology, and articulation to the wider context are the main factors underpinning this contrast. On the one hand, agroecological farmers appear to have developed more autonomous and resilient livelihood strategies. They manage more diverse and stable agroecosystems, produce more food, and show a stronger negotiating capacity within the political process. The strategy of tobacco growers, in contrast, depends far more on the agroindustry. They produce less food, have very limited negotiation power, and are more exposed to the control of tobacco companies and the fluctuations of tobacco prices and industry.

All this suggests that livelihood strategies used by different groups can dramatically increase or decrease their level of vulnerability. Since the articulation to the wider context is a key aspect in determining the vulnerability of poor farmers, the latter can change drastically due to external factors, no matter how "sensible" the within-farm decisions. This suggests that vulnerability involves the amplification and attenuation of a variety of conditions that depend on both internal and external circumstances, and that vulnerability changes over time with changing stresses or needs in households or with wider socioeconomic and political changes that increase or decrease access to various assets and opportunities.

6.8.2 Vulnerability and Resilience in Southern Africa: Perspectives from Three Spatial Scales

The southern African region is currently facing a suite of complex emergencies driven by a mix of factors, including HIV/AIDS, conflict, land tenure, governance, and lack of access to resources, coupled with climate risks—not least of which is the emergence of floods as a serious hazard (Mano et al. 2003; Vogel and Smith 2002; IPCC 2001a). Existing adaptive capacity is also, arguably, being increasingly eroded and undermined by such factors. The World Food Programme has recently estimated that around 14 million people in the region are in a heightened food insecurity situation (Morris 2002). Contributing factors emerging from this situation include, among others, low opening stocks of cereals from previous years, low grain reserves in some countries, low levels of preparedness for such food insecurity, and inappropriate and constraining policies that contributed to market failures (Mano et al. 2003).

This case examines the multiple roles of global environmental change as part of a complex suite of stressors (such as climate, governance, and health) and adaptation to such stressors in South Africa, using the 2002/03 famine situation in the Southern African Development Community as a backdrop. The theme of resilience and adaptation in the face of global change (Adger 2000) is analyzed at three spatial scales, moving from the regional (SADC) level to the district and community levels, focusing particularly on the role of information as a potential input into building sustainability. The greatest priority in such an investigation is less one of describing the problem than it is interactively crafting appropriate sustainable interventions. (No suitable "sustainable" interventions can be designed in isolation of the institutions and stakeholders involved.)

6.8.2.1 The SADC Region 2002/03 Season: Coping with Complex Environmental Stress

The contributions of various socioeconomic and political factors, often generated outside the region, have long been acknowledged to contribute to the complexities associated with climate stress and food insecurity facing Southern Africa (Benson and Clay 1998). Several of these myriad of factors usually become particularly important during a severe dry spell, flood, or other climate-driven event.

In response to the droughts of the 1970s, 1980s, and 1990s, international organizations, bilateral donors, African governments and NGOs established numerous early warning systems and enlarged institutional capacity to manage food security and risks (Moseley and Logan 2001). These entities have been actively undertaking efforts to reduce vulnerability to a number of risk factors in the region. A clear activity has been to examine current risks and threats primarily relating to drought-induced production deficits and to provide improved climate information to serve the agricultural sector (see, e.g., Archer 2003).

Another priority has been not only to increase the understanding of food provision and production but also to improve assessments of food procurement and access to food by households in the region (e.g., see Devereux 2000; Vogel and Smith 2002) and the factors (such as institutions, governance, and policy issues) that enhance or constrain access to food. The contributions of adverse synergies, including natural triggers (such as drought) and politics (such as civil stress) that have precipitated famines (Devereux 2000), have in some cases become more prevalent and endemic in sub-Saharan Africa.

A number of interesting adaptive measures have emerged from assessments undertaken of the 2002/03 famine in the region (see www.fews.net). Vulnerability assessments show, for example, that cereal production is sometimes not a key activity in procuring food in risk-prone households. Rather, it is food purchases and other inputs (remittances, gifts, and so on) that enable households to obtain food. Such insight on adaptation practices has only emerged from detailed food economy investigations. Such studies reveal and question the role of "food relief" as an intervention strategy in reducing the impacts of the crisis. Furthermore, the role of HIV/AIDS in aggravating the situation in several households is also emerging as a strong and negative factor (SADC FANR Vulnerability Assessment Committee 2003).

With the background of this regional scale, vulnerabilities to a similar suite of risks (including climate, management, and other factors) can be understood at the scale of South Africa and Limpopo Province. These case studies clearly show that, similar to the regional examples described earlier, a well-intentioned focus on early warning can do little to enhance resilience to risks if it is not coupled with a careful examination of the wider socioeconomic environment in which such activities operate (such as the policy environment, or institutional strengths and weaknesses), consistent with the northern Argentina case.

6.8.2.2 South Africa, 2002/03 Season—The National Scale

An unusually dry 2002/03 summer rainfall season caused widespread livestock mortality and water scarcity for growing crops in Limpopo, Mpumalanga, and North West Provinces in South Africa. In Limpopo, the provincial government requested 40 million rand in drought relief from the National Department of Agriculture, in addition to 6 million rand of provincial emergency funding that was made available (largely for subsidized fodder). Official estimates were that drought-related cattle mortalities exceeded 18,000.

A range of potentially valuable mechanisms to promote drought mitigation and risk reduction was, however, in place. Institutions and mechanisms included the Agricultural Risk Management Directorate, whose Early Warning Subdirectorate was substantively involved in improving awareness of early warning in the agricultural sector. The Early Warning Subdirectorate was established to improve forecast dissemination to smallholder farmers after forecasters and decision-makers realized that the information did not reach any further than provincial departments of agriculture (Archer and Easterling 2004). In addition, the National Agrometeorological Committee was established as a forum for reviewing updated seasonal outlook and provincial reports regularly throughout the season.

Essentially, the seasonal warning advisory was developed and disseminated at least to the provincial level in South Africa for the 2002/03 season. In spite of this, the adverse effects of climatic risk were substantial. Accepting that further investigation is required (and is planned), some preliminary observations on the 2002/03 season at the national scale in South Africa are possible.

As is well documented in a variety of case studies, forecasts, warnings, and information were in themselves insufficient to ensure action to improve resilience to environmental stress. In this case study, failures may have occurred in dissemination (for example, forecast information may not have been disseminated to extension officers or farmers). There may also have been failures in response capacity—even had farmers heard the seasonal warning, they may, for a variety of reasons, have been constrained in their ability to take anticipatory action (such as destocking). Last, there may have been weaknesses in institutional capability as well as weaknesses of ''fit'' and ''interplay'' between what institutions are providing and what is required (see, e.g., Folke et al. 1998; Berkes and Folke 1998; Orlove and Tosteson 1999; Raskin et al. 2002). Even with effective information dissemination, provincial, municipal, and local institutions may themselves be constrained in their ability to either recommend or support appropriate actions to improve resilience.

6.8.2.3 Vhembe District, Limpopo Province, 2002/03 Season

Results from research at the district and local level in Vhembe district of Limpopo Province show where gaps and weaknesses existed with regard to improved resilience to climatic risk in the 2002/03 season. It appears that this was the first season that the surveyed community (first surveyed in 2000/01) had exposure to seasonal forecast information. The Vhembe District Department of Agriculture and the District Department of Water Affairs and Forestry also received the forecast. Yet both at the community level and at the district institutional level, little response was apparent. Identifying the reasons for the lack of action is key to understanding the adverse drought effects at the national and provincial level described earlier.

First, it is clear that the forecast alone was insufficient, both for the needs of farmers and for district institutions. Both farmers and institutions explicitly asked for more guidance in terms of what actions might be appropriate in the light of the forecast or warning information. Farmers requested, for example, that when the seasonal forecast (or severe weather warning) was broadcast over the radio, the announcement needed to be coupled with an advisory. Such an advisory could include a wide range of general advice at various scales—at the district level, for instance, information on planting dates; at the farm level, very specific information on cultivars and planting. The District Department of Agriculture asked that the existing agricultural advisory be further developed and refined for local district conditions. The District Department of Water Affairs and Forestry requested that the agricultural advisory be adapted for the water sector (and for other climate-sensitive sectors as well, such as health).

Second, farmers themselves may have been constrained in their ability to respond to information about climatic stress. The most commonly documented constraint on response capacity was resource limitation, including lack of access to credit, supplemental irrigation, land, and markets as well as lack of decision-making power (particularly in the case of women farmers) (Archer 2003). Further research in the area is seeking to understand the precise role of resource limitations and misdirected inputs (such as inappropriate irrigation infrastructure) in constraining both the ability to respond to forecasts and warnings and, more important, the ability to increase resilience and adaptive capacity.

There are also, however, encouraging signs in Vhembe district and at the national scale in South Africa of building adaptive capacity under conditions of climatic (and environmental) stress. Progress has been made in the dissemination of the forecast to district institutions and to the community level. And intermediary mechanisms described at the national scale (such as the programs under the Directorate of Agricultural Risk Management) show promise. There are signs that research on ways to improve adaptive capacity in South Africa is becoming increasingly well positioned to produce generalized recommendations that may inform policy.

6.8.2.4 Synthesis: Cross-scale Interactions and Multiple Stressors

The results from this case suggest that although gaps and weaknesses were evident in the ability of entities at different scales to decrease vulnerability to the emergence of multiple stressors, success stories were also apparent. In this example it is clear that the spatial scale is a valuable unit of analysis. The level of interplay, however, between scales of ''intervention'' is equally important (e.g., Orlove and Tosteson 1999).

This example illustrates the ''misfit'' between scales of research and intervention, between what is investigated and what is required. This example points to a greater understanding of these complex issues, particularly in a region undergoing complex shocks and stressors, and the deeper interrogation that is required of the range of institutional responses that may be needed to manage these systems effectively. The South African Weather Service, as the official national forecast producer, works with other forecast producers at the international and national levels to derive a multiple-sourced seasonal outlook, containing three-month rainfall and temperature forecasts. The forecast, looking specifically at the agricultural sector, is disseminated to the National Department of Agriculture and from there to provincial, district, ward extension, and finally farm level.

The process of sub-provincial dissemination of the forecast is still in progress. There are three areas of on-going activity to improve the system: the process of combining multiple source forecasts, the role of the National Disaster Management Centre in receiving forecasts and coordinating response in appropriate areas and sectors, and the sub-provincial receipt of, and response to, the forecasts.

At present, however, there remains a misfit between what is currently being provided by the forecast producers and the suggested requirements from the agricultural sector within the provincial levels. From the province down to ward level extension, suggested forecast information differs from the three-month temperature and rainfall forecasts provided from the national and international levels. Finer levels suggest information be provided on seasonal quality (such as information on intra-seasonal variability), advisories coupled to forecasts, retroactive forecast applications, and impact-specific interpretation of forecasts (Orlove and Toste-son 1999). To reiterate, the system is highly dynamic and should be seen as evolving. The key question remains how to best intervene to aid a system in building resilience to sustain socioecological systems under conditions of environmental stress and surprise.

6.8.3 The Benefits of Reducing Vulnerability in Bundelkhand, India

The Bundelkhand region in the central highlands of India consists of semiarid plateau land. Rising population, subsequent agricultural expansion, and increased demand for wood has led to rapid deforestation in the region, which together with poor land management practices and government-approved commercial logging has aggravated soil erosion and ecological degradation. Erratic rainfall coupled with soil erosion has further reduced soil productivity and contributed to crop failure, and the area is now highly degraded (EcoTech Services 1997). (This paper draws on EcoTech Services 1999; the study was carried out to support the Uttar Pradesh state government initiatives in the area, under a grant from the Government of the Netherlands.)

The region has some of the lowest levels of per capita income and human development in India. Illiteracy and infant mortality rates were high, and local inhabitants depended on rain-fed single-crop agriculture and small-scale livestock production. The forests that were the traditional source of livelihood have largely disappeared.

Lalitpur district lies at the heart of the Bundelkhand region. The main monsoon crops grown in the district are maize, gram, and groundnut, while the main winter crops are wheat, peas, and gram. Most people collect green fodder from their own land during kharif and feed harvest remains to the animals in rabi and summer. Harvest is sold as dry fodder. Most households use the same well through the year, and it takes approximately two hours per household to collect water each day. Nonavailability of potable water is a major problem across the district (EcoTech Services 1997).

6.8.3.1 Watershed Management

A technical plan for the Donda Nala watershed in Lalitpur district was drawn up, aimed at land treatment and drainage line treatment measures (EcoTech Services 1997). Land treatment measures sought to reduce the loss of topsoil and to augment rainwater retention and biomass production. Measures such as embankments, earthen gully (channel) plugs, and agroforestry were deemed applicable to cultivated land, while silvipasture was deemed applicable to uncultivated lands. Drainage treatments suggested by the plan included mechanical measures such as the construction of dams and surface water storage tanks. Long-term benefits envisioned from these measures were retention of topsoil and an increase in the moisture-retaining capacity of soil. The technical plan estimated that the high-grade lands in the watershed would show increased crop yields by about 50% in the first five years as a result of such improvements.

6.8.3.2 Quantifying Benefits

Benefits projected from the watershed management activities included increased productivity of land, improvement in the health of animals due to increased fodder availability, better access to drinking water, increased employment, lower rates of soil erosion, and stabilizing environmental degradation. For the economic analysis in the plan, the benefits were summarized as irrigation benefits, benefits from vegetative treatments, drinking water benefits, and employment benefits. (The assessment did not attempt to evaluate environmental and health benefits, which are more complex to quantify.)

Farmers realized benefits from cultivation in the form of increased profits. The incremental net profit was computed as the difference between current profits and potential future profits from cultivation. Assuming that prices would remain constant, profits in the future were estimated on the present value of future cultivation. It was estimated that the average annual incremental profit would be 3,910,700 rupees (or 1,450 rupees per acre) as a result of additional water on existing farmlands. It was estimated that there would be additional benefits due to cultivation on marginal lands due to a further 257 hectares coming under cultivation during monsoon and 90 hectares in winter. This value was estimated as 1,681,000 rupees.

Vegetative treatments led to increased biomass in the form of fodder, firewood, and timber. Locally accepted species were identified for long-term community-managed common land. The estimates from increased fodder availability were based on fodder collection amounts. The incremental production of dry fodder or crop residues was valued at the existing market rate and estimated at 777,800 rupees for the watershed as a whole. A detailed cost-benefit estimation of silvipastural treatments planned in the wastelands for a period of 30 years was also assessed to compute the net present value of the future stream of benefits. Some 420 hectares of land were to be covered under the afforestation plan.

The potential benefits from better access to drinking water were valued by using the opportunity cost of time saved in water collection for women. Three open wells were proposed in the villages of Agar, Dhurwara, and Ghisoli. These sought to enhance women's participation in the project and to benefit families who lacked easy access to drinking water. The new wells were typically located near a cluster so that these families would not have to go more than a quarter of a kilometer. The estimated cost of digging wells in the watershed was 304,065 rupees, and the total value of time savings was 45,090 rupees for the year. The value of this is projected to rise over time as daily wages increase.

Given the labor requirements for each type of project activity, the market and opportunity costs for labor were determined. The benefits were calculated from activity-specific labor components of the technical work plan. Total incremental benefits from employment were valued at the prevailing wage rate. The employment benefits disbursed in the first two years of project activities were estimated at 5,480,000 rupees.

The projected present value of the future stream of the total annual benefits from each of the estimated components provides the overall value for the stream of benefits accruing from the project. The average projected present value of benefits per hectare was 47,461 rupees as opposed to an average project activity cost of 7,500 rupees per hectare. (See Table 6.6.) Assuming a 30-year horizon, the present projected value of the estimated benefits were computed using a 12% discount rate. The net present value of total benefits worked out to be over 100 million rupees for the entire watershed.

6.8.3.3 Synthesis: Distributional Issues

Most of the village community of Lalitpur district consists of small farmers and landless people. While the benefits from additional employment and access to drinking water are projected to directly enhance their quality of life, benefits from irrigation and green fodder production (which are the major source of benefits) are

Table 6.6. Total Benefits for Donda Nala Watershed (EcoTech Services 1997)

Project Activity	Total Undiscounted Benefits	Total Discounted Benefits
	(Rs crores)	
Irrigation	16.5620	3.5799
Digging wells	0.1300	0.0281
Employment	0.5476	0.4132
Silvipasture	24.4177	6.0871
Forestry	5.5876	0.3949
Total benefits	**47.2449**	**10.5320**

likely to accrue to those with land or cattle. The benefits will reach poorer households only if the access to treated wastelands and to harvest can be assured.

6.9 Implications for Assessment and Policy

The discussion and cases in this chapter emphasize that the patterns and dynamics that shape the vulnerability of coupled socio-ecological systems are composed of a multitude of linkages and processes. As such, assessments of vulnerability need to be comprehensive, sensitive to driving forces at different scales, but also appreciative of the differences among places.

A number of observations relevant to attempts to assess and reduce vulnerability and to build resilience may be offered. First, conceptual frameworks of vulnerability have improved, representing human and biophysical vulnerabilities as a coupled socio-ecological system. However, the relationships across scales and the role of specific actors (as drivers of systems) are poorly represented in most frameworks, and the existing state of knowledge is still weak. Different components of the coupled socioecological system may have quite different vulnerabilities and may experience exposure to stresses and perturbations quite differently. Diverse impacts are likely as a result; broad frameworks should not be taken as reliable guides to local conditions. The term vulnerability is still used in disparate ways in many assessments; a clear nomenclature is required to make assessments more consistent and coherent.

Second, the driving conditions of vulnerability have been well characterized at least at a general level. Human alterations of ecosystems and ecosystem services shape both the threats to which people and places are exposed and their vulnerabilities to the threats. The same alterations of environment can have very different consequences, depending on the differential vulnerability of the receptor systems.

Third, poverty and hazard vulnerability are linked and often mutually reinforcing by creating circumstances in which the poor and those with limited assets have few options but to exploit environmental resources for survival. At the same time, poverty and vulnerability are overlapping but distinct conditions, and they require analysis to determine overlaps and interactions.

Fourth, vulnerability can also be increased by the interaction of stresses over time. In particular, sequences of stresses that erode coping capacity or lengthen recovery periods can have long-term impacts that still often are not adequately treated in many assessments. Capturing these dynamics of vulnerability in assessment is an ongoing challenge.

Fifth, socioeconomic and institutional differences are major contributors to patterns of differential vulnerability. The linkages among environmental change, development, and livelihood are attracting increasing attention as a nexus in building resilient communities and strengthening adaptive capacity, but existing knowledge is still uneven and not well developed.

Sixth, despite this general level of explanation, it is still difficult to document adequately the effects of different changes upon different human groups with precision. While environmental changes and natural disasters are affecting increasing numbers of people, the existing knowledge base of vulnerability and resilience is highly uneven, with much known about some situations and very little about others. Some of the most vulnerable peoples and places are those about which the least is known. New vulnerabilities may be realized in the future, as in the dramatic increase of flooding damages in Africa or the effects of HIV/AIDS as a compounding factor in livelihood security. Filling the major gaps is a high priority in improving current assessments.

Seventh, assessment methods are improving. Entering vulnerability assessments at different scales of analysis, and particularly the local scales of place-based assessments, holds potential for greater depth and understanding of the complexity and dynamics of changing vulnerability.

Finally, despite the limitations of theory, data, and methods, sufficient knowledge exists in most regions to apply vulnerability analysis to contemporary problems of ecosystem management and sustainable development in order to provide useful information to decision-makers and practitioners.

Main Messages

Some of the people and places affected by changes in ecosystems and ecosystem services are highly vulnerable to the effects and are particularly likely to experience much of the damage to well-being and loss of life that such changes will entail. Indeed, many of these people and places are already under severe stress from environmental, health, and socioeconomic pressures, as well as new forces involved in globalization. Further threats arising from changes in ecosystems and ecosystem services will interact with these other on-going stresses to threaten the well-being of these groups while many others throughout the world benefit and prosper from human interactions with ecosystems.

The patterns and dynamics of vulnerability in coupled socioenvironmental systems are shaped by drivers operating at scales from the international to the local, all interacting with the specifics of places. The dominant drivers and patterns of vulnerability differ, depending on the threat or perturbation addressed, the scale of analysis selected, and not least the conceptual framework employed. While our existing knowledge of the sources and patterns of vulnerability is still incomplete, substantial progress is being made in this relatively new area of analysis, and vulnerability assessment is proving useful in addressing environmental management and sustainable development.

At a global level, various efforts over the past several decades have defined vulnerability indictors and indexes and have mapped relevant global patterns. Because they use different conceptual frameworks and consider vulnerability to different types of threats, these efforts largely identify different national-scale patterns of vulnerability. Examples in the chapter introduce major efforts to address vulnerability to environmental change broadly defined, as a dimension of environmental sustainability, in respect to climate change and natural hazards. Improvements in the state of knowledge and methodology development are needed generally to deepen understanding of these global patterns and their causes, although the topics of natural hazards, desertification, and food security have received more attention than others, due to the level of societal concern on these issues.

Trends in natural hazards reveal several patterns that are known with high confidence at the national level. The world is experiencing a worsening trend of human suffering and economic losses from natural disasters over the past several decades. In the last 40 years, the number of "great" disasters has increased by a factor of 4 while economic losses have increased by a factor of 10. The significance of these events to the social vulnerability of exposed human populations is of special concern. Even before the December 2004 tsunami, Asia was disproportionately affected, with more than 43% of all natural disasters and 70% of deaths occurring there over the last decade of the twentieth century. The greatest loss of life continues to be highly concentrated in developing countries as a group.

Desertification is another phenomenon that has received extensive attention. Vulnerability to desertification has multiple causes that are highly intermingled; like all vulnerability, it is the product of the interaction between environmental change and social and political systems. The driving forces of environmental change generally have a high patchiness, and effects vary widely with differences in social and geographic scales.

Food insecurity is a third primary area of concern in changes in ecosystem services. Multiple domains of vulnerability exist in food security regimes and livelihood systems. Production, economic exchanges, and nutrition are key elements, along with more-structural issues associated with the political economy. At this point in time, the more generalized, major contributions to knowledge are emerging in the realms of better understanding of driving forces, interactions across biophysical scales and social levels, connections between ecosystems services and human well-being, and differential vulnerability at local levels. While many challenges remain in aggregating diverse case study findings, consistency is emerging around a number of themes:

- Socioeconomic and institutional differences are major factors shaping differential vulnerability. The linkages among environmental change, development, and livelihoods are receiving increasing attention in efforts to identify sources of resilience and increase adaptive capacity, but knowledge in this area is uneven in its coverage of environmental threats and perturbations as they act in relation to different ecosystems and livelihoods.

- Poverty and hazard vulnerability are often closely related, as the poor often lack assets and entitlements that allow them some buffer from environmental degradation and variability.

- The interactions of multiple forms of stress—economic, social, political, and physical—with environmental change can amplify and attenuate vulnerability abruptly or gradually, creating dynamic situations for assessment that have still to be fully captured in research methodologies. Major worldwide trends of population growth, urbanization, the spread of HIV/AIDS, economic development, and globalization are acting to shape patterns of vulnerability at national and local scales. The implications of these processes for climate change are still poorly understood.

The limitations of existing understanding point to the need for a variety of efforts to improve assessment and identify measures to reduce vulnerability. These include the need for a robust and consensual conceptual framework for vulnerability analysis, improved analysis of the human driving forces of vulnerability as well as stresses, clarification of the overlaps and interactions between poverty and vulnerability, the tracking of sequences of stresses and perturbations that produce cumulative vulnerability, the role of institutions in creating and mitigating vulnerability, the need to fill gaps in the knowledge base of global patterns of vulnerability, improved assessment methods and tools, and the need for interventions aimed at reducing vulnerability.

6.1 Introduction

The Third Assessment of the Intergovernmental Panel on Climate Change noted that over the past century average surface temperatures across the globe have increased by 0.6° Celsius and evidence is growing that human activities are responsible for most of this warming (IPCC 2001b). Human activities are also altering ecosystems and ecosystem services in myriad ways, as assessed in other chapters. While both positive and negative effects on human societies are involved, it is unrealistic to expect that they will balance out.

Many of the regions and peoples who will be affected are highly vulnerable and poorly equipped to cope with the major changes in ecosystems that may occur. Further, many people and places are already under severe stress arising from a panoply of environmental and socioeconomic forces, including those emanating from globalization processes. Involved are such diverse drivers of change as population growth, increasing concentrations of populations in megacities, poverty and poor nutrition, accumulating contamination of the atmosphere as well as of land and water, a growing dependence on distant global markets, growing gender and class inequalities, the ravages of wars, the AIDS epidemic, and politically corrupt governments. (See Chapter 3 for further discussion on drivers of change.) Environmental change will produce varied effects that will interact with these other stresses and multiple vulnerabilities, and they will take their toll particularly among the most exposed and poorest people of the world.

The most vulnerable human and ecological systems are not difficult to find. One third to one half of the world's population already lacks adequate clean water, and climate change—involving increased temperature and droughts in many areas—will add to the severity of these issues. As other chapters in this volume establish, environmental degradation affects all ecosystems and ecosystem services to varying degrees. Many developing countries (especially in Africa) are already suffering declines in agricultural production and food security, particularly among small farmers and isolated rural populations. Mountain locations are often fragile or marginal environments for human uses such as agriculture (Jodha 1997, 2002). Increased flooding from sea level rise threatens low-lying coastal areas in many parts of the globe, in both rich and poor countries, with a loss of life and infrastructure damages from more severe storms as well as a loss of wetlands and mangroves. (See Chapters 19 and 23.)

The poor, elderly, and sick in the burgeoning megacities of the world face increased risk of death and illness from growing contamination from toxic materials. Dense populations in developing countries face increased threats from riverine flooding and its associated impacts on nutrition and disease. These threats are only suggestive, of course, of the panoply of pressures that confront the most vulnerable regions of the world. It is the rates and patterns of environmental change and their interaction with place-specific vulnerabilities that are driving local realities in terms of the eventual severities of effects and the potential effectiveness of human coping mitigation and adaptation.

Research on global environmental change and on-going assessments in many locales throughout the world have greatly enriched our understanding of the structure and processes of the biosphere and human interactions with it. At the same time, our knowledge is growing of the effects that changes in ecosystems and ecosystem services have upon human communities. Nonetheless, the knowledge base concerning the vulnerabilities of coupled socioecological systems is uneven and not yet sufficient for systematic quantitative appraisal or validated models of cause-and-effect relationships of emerging vulnerability. Yet what we need to understand is apparent in the questions that researchers are addressing (Turner et al. 2003a): Who and what are vulnerable to the multiple environmental and human changes under way, and where? How are these changes and their consequences attenuated or amplified by interactions with different human and environmental conditions? What can be done to reduce vulnerability to change? How may more resilient and adaptive communities and societies be built?

In this chapter key definitions and concepts used in vulnerability analysis are first considered. Included in this is a clarification of what is meant by the terms "vulnerability" and "resilience." Several of the principal methods and tools used in identifying and assessing vulnerability to environmental change are then examined (but see also Chapter 2). Efforts to identify and map vulnerable places at the global scale are described, followed by three arenas—natural disasters, desertification, and food security—that have received substantial past analyses in vulnerability research and assessment. Several specific case studies that illustrate different key issues that pervade vulnerability assessments are presented and, finally, implications of our current knowledge for efforts to assess and reduce vulnerability and to build greater resilience in coupled socioecological systems are assessed.

6.2 Definitions and Conceptual Framework

The term vulnerability derives from the Latin root *vulnerare,* meaning to wound. Accordingly, vulnerability in simple terms means the capacity to be wounded (Kates 1985). Chambers (1989) elaborated this notion by describing vulnerability as "exposure to contingencies and stress, and the difficulty in coping with them." It is apparent from relating the notion of vulnerability to the broader framework of risk that three major dimensions are involved:

- exposure to stresses, perturbations, and shocks;
- the sensitivity of people, places, and ecosystems to stress or perturbation, including their capacity to anticipate and cope with the stress; and
- the resilience of exposed people, places, and ecosystems in terms of their capacity to absorb shocks and perturbations while maintaining function.

6.2.1 Conceptual Framework for Analyzing Vulnerability

A wide variety of conceptual frameworks have arisen to address the vulnerability of human and ecological systems to perturbations, shocks, and stresses. Here we draw on a recent effort of the Sustainability Science Program to frame vulnerability within the context of coupled socioecological systems (Turner et al. 2003a, 2003b). The framework seeks to capture as much as possible of the totality of the different elements that have been demonstrated in risk, hazards, and vulnerability studies and to frame them in regard to their complex linkages. (See Figure 6.1.)

The framework recognizes that the components and linkages in question vary by the scale of analysis undertaken and that the scale of the assessment may change the specific components but not the overall structure. It identifies two basic parts to the vulnerability problem and assessment: perturbation-stresses and the coupled socioecological system.

Perturbations and stresses can be both human and environmental and are affected by processes often operating at scales larger than the event in question (such as local drought). For example, globally induced climate change triggers increased variation in precipitation in a tropical forest frontier, while political strife elsewhere drives large numbers of immigrants to the frontier. The coupled socioecological system maintains some level of vulnerability to these perturbations and stresses, related to the manner in which they are experienced. This experience is registered first in terms of the nature of the exposure—its intensity, frequency, and duration, for instance—and involves measures that the human and environment subsystems may take to reduce the exposure. The coupled system experiences a degree of harm to exposure (risk and impacts), determined by its sensitivity. The linkage between exposure and impact is not necessarily direct, however, because the coupled system maintains coping mechanisms that permit immediate or near-term adjustments that reduce the harm experienced and, in some cases, changes the sensitivity of the system itself.

If perturbations and stresses persist over time, the types and quality of system resilience change. These changes are potentially irreversible, as the case of ozone depletion illustrates. Change may lead to adaptation (fundamental change) in the coupled system. The role of perception and the social and cultural evaluation of stresses and perturbations is important to both the recognition of stresses and the decisions regarding coping, adaptation, and adjustment. These decisions reflect local and regional differences in perceptions and evaluations. The social subsystem must be altered, or

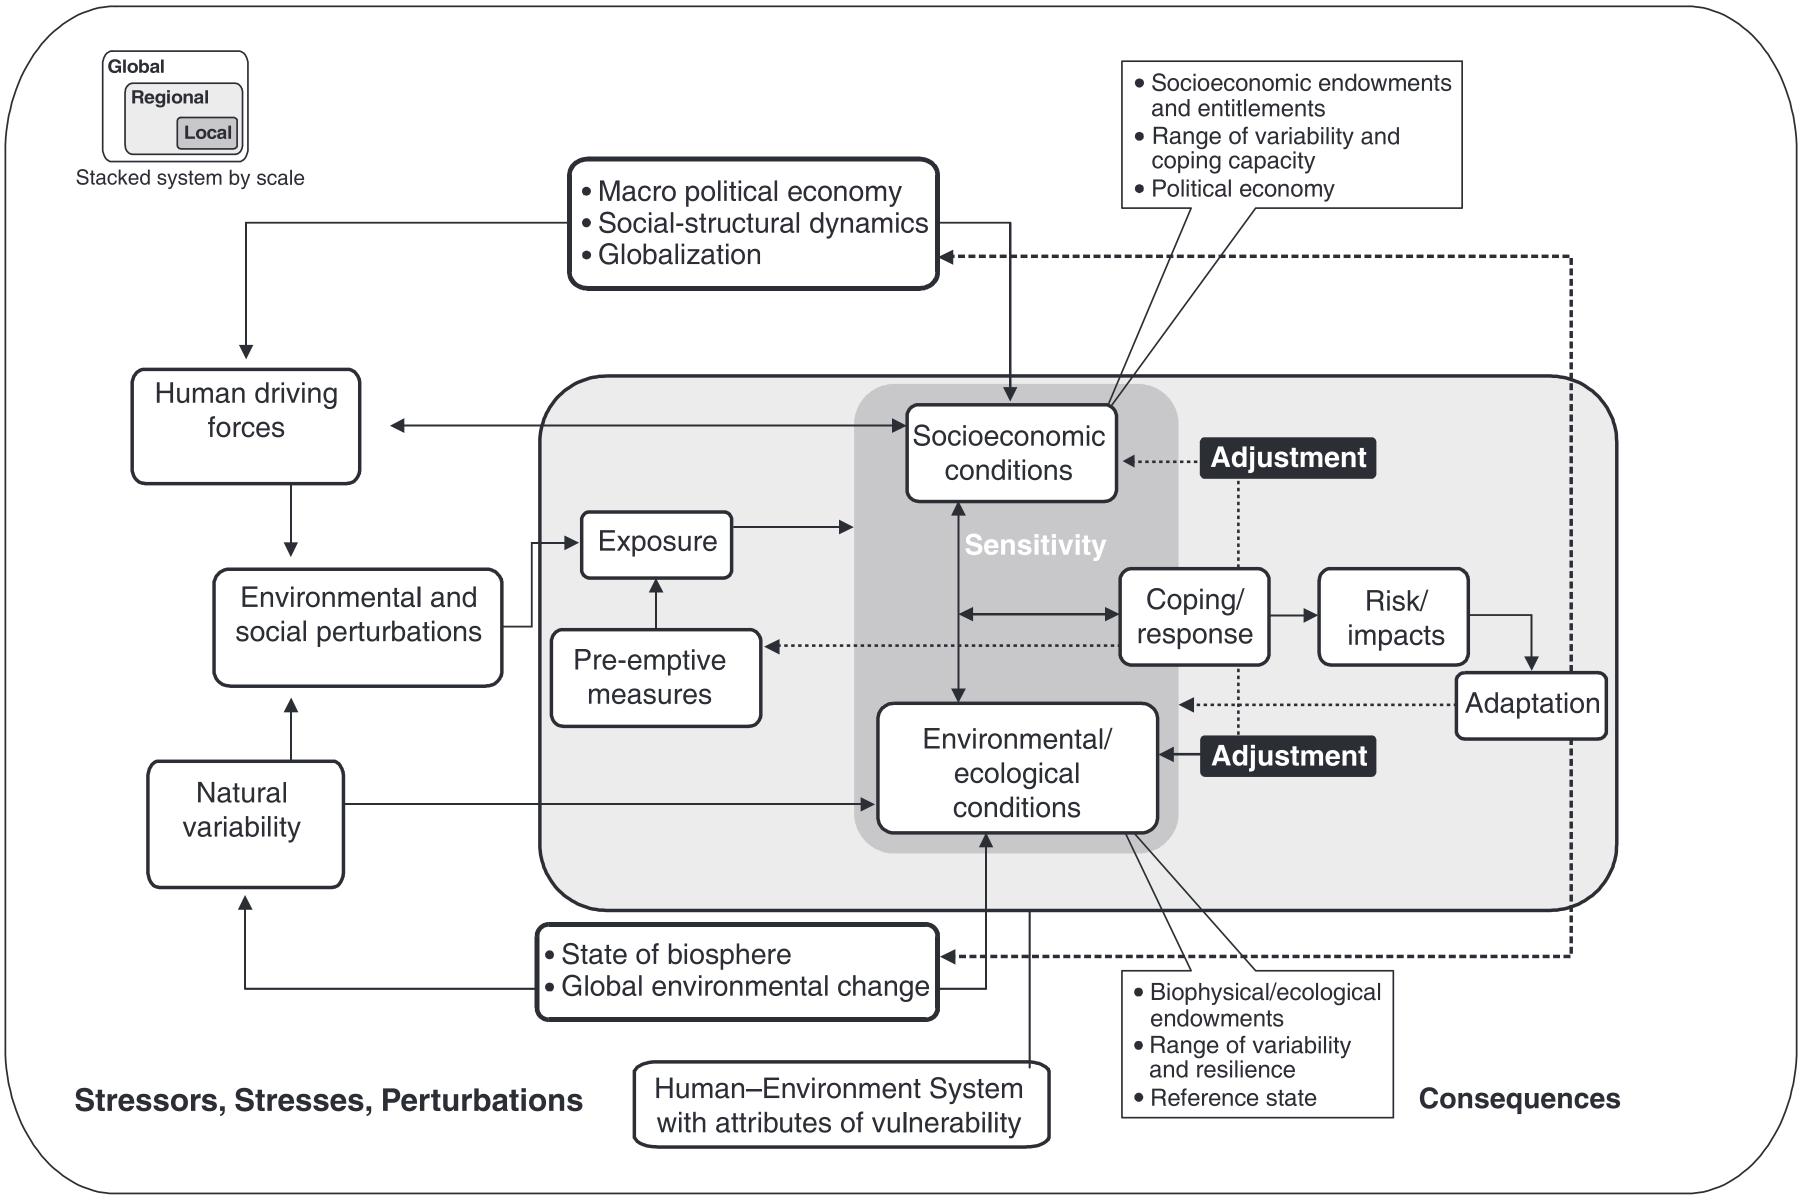

Figure 6.1. A Framework for Analyzing Vulnerability

it ceases to function (a place or region is abandoned, for example); the ecological subsystem changes in climate and vegetation. This process of more fundamental change, sometimes also referred to as ''reorganization,'' may move the coupled socioecological system in a direction of greater sustainability, but perhaps at a cost to those depending on current patterns of ecosystem services. The MA *Policy Responses* volume addresses adjustments and adaptation in ecosystems and with respect to human well-being in greater detail. By definition, no part of a system in this vulnerability framework is unimportant.

6.2.2 The Concept of Resilience

The concept of resilience as applied to integrated socioecological systems may be defined as the amount of disturbance a system can absorb and still remain within the same state or domain of attraction, the degree to which the system is capable of self-organization (versus lack of organization or organization forced by external factors), and the degree to which the system can build and increase its capacity for learning and adaptation (Carpenter et al. 2001). Socioecological systems are complex adaptive systems that are constantly changing, and the resilience of such systems represents the capacity to absorb shocks while maintaining function (Holling 1995, 2001; Gunderson and Holling 2002; Berkes et al. 2002). When a human or ecological system loses resilience, it becomes vulnerable to change that previously could be absorbed (Kasperson and Kasperson 2001).

New insights have been gained during the last 10 years about the essential role of resilience for a prosperous development of human society (Gunderson and Holling 2002). A growing number of case studies have revealed the tight connection between resilience, diversity, and the sustainability of socioecological systems (Berkes and Folke 1998; Adger et al. 2001).

Ecosystems with low resilience may still maintain function and generate resources and ecosystem services—that is, they may seem to be in good shape—but when subject to disturbances and stochastic events, they may reach a critical threshold and slide into a less desirable state. Such shifts may significantly constrain options for social and economic development, reduce options for livelihoods, and create environmental migrants as a consequence of the impact on ecosystem life-support.

In ecological systems, Lawton (2000) and Loreau et al. (2001) synthesized the evidence from many experiments and affirmed that the diversity of functionally different kinds of species affected the rates of stability and increased the reliability of ecosystem processes locally. Furthermore, a number of observations suggest that biodiversity at larger spatial scales, such as landscapes and regions, ensures that appropriate key species for ecosystem functioning are recruited to local systems after disturbance or when environmental conditions change (Peterson et al. 1998; Bengtsson et al. 2003). In this sense, biological diversity provides insurance, flexibility, and risk spreading across scales in the face of uncertainty and thereby contributes to ecosystem resilience (Folke et al. 1996). (See also Chapter 11.)

Ecological resilience typically depends on slowly changing variables such as land use, nutrient stocks, soil properties, and biomass of long-lived organisms (Gunderson and Pritchard 2002), which are in turn altered by human activities and socioeconomic driving forces (Lambin et al. 2001). The increase in social and economic vulnerability as a consequence of reduced resilience through land degradation and drought may cause losses of livelihood and trigger tension and conflict over critical resources such as fresh water or food (Homer-Dixon and Blitt 1998).

Increased vulnerability and fragility places a region on a trajectory of greater risk to the panoply of stresses and shocks that occur over time. Stressed ecosystems are often characterized by a ''distress syndrome'' that is indicated not only by reduced biodiversity and altered primary and secondary productivity but also by increased disease prevalence, reduced efficiency of nutrient cycling, increased dominance of exotic species, and increased dominance by smaller, shorter-lived opportunistic species (Rapport and Whitford 1999). The process is a cumulative one, in which sequences of shocks and stresses punctuate the trends, and the inability to replenish coping resources propels a region and its people to increasing vulnerability (Kasperson et al. 1995).

Key attributes of resilience in ecosystems, flexibility in economic systems, and adaptive capacity in institutions used in assessments include the following:

- Ecological resilience can be assessed by the amount of variability that can be absorbed without patterns changing and controls shifting to another set of keystone processes.
- Key sources of resilience lie in the requisite variety of functional groups; the accumulated financial, physical, human, and natural capital that provides sources for reorganization following disturbances; and the social networks and institutions that provide entitlements to assets as well as coping resources and social capital (Adger 2003).
- In an ecosystem, these key processes can be recognized as the processes that interact and are robust in an overlapping, redundant manner.
- When a system is disrupted, resilience is reestablished through regeneration and renewal that connect that system's present to its past.

Management can destroy or build resilience, depending on how the socioecological system organizes itself in response to management actions (Carpenter et al. 2001; Holling 2001; MA *Policy Responses*). There are many examples of management suppressing natural disturbance regimes or altering slowly changing ecological variables, leading to disastrous changes in soils, waters, landscape configurations, or biodiversity that did not appear until long after the ecosystems were first managed (Holling and Meffe 1996). Similarly, governance can disrupt social memory or remove mechanisms for creative, adaptive response by people in ways that lead to the breakdown of socioecological systems (McIntosh et al. 2000; Redman 1999). By contrast, management that builds resilience can sustain socioecological systems in the face of surprise, unpredictability, and complexity. Successful ecosystem management for human well-being requires monitoring and institutional and organizational capacity to respond to environmental feedback and surprises (Berkes and Folke 1998; Danter et al. 2000), a subject treated at the conclusion of this chapter.

6.3 Methods and Tools for Vulnerability Analysis

Many tools and methods exist for undertaking vulnerability analysis, as described in Chapter 2. This section describes several tools more specific to assessing vulnerability issues and outcomes. The vulnerability toolkit described here and in Chapter 2 is considerable, ranging from qualitative to quantitative methods, with various levels of integration among disciplines, and it is suitable for participation of stakeholders. Matching the types of analytical approaches in a toolkit to the characteristics of a specific assessment is a necessary step in scoping projects.

6.3.1 The Syndromes Approach

The syndromes approach aims to ''assess and monitor a multitude of coupled processes taking place on different (spatial and temporal) scales with different specificities'' (Petschel-Held 2002). The goal of the syndromes approach is to identify where intervention can help contribute to sustainable development pathways. In order to achieve this, similarities between regions are found by looking for functional patterns that are called ''syndromes'' (Schellnhuber et al. 1997). An assessment of these patterns of relationships is achieved by combining qualitative and quantitative approaches. Some 16 syndromes of global change are grouped according to the dominant logic: utilization of resources, economic development, and environmental sinks. The results enable critical regions to be identified for different syndromes, so that future development can set priorities for key areas necessary for establishing more-sustainable systems.

The syndromes approach recognizes the need to examine human-environment interactions, as global change is a function of how society responds to natural changes and vice versa. It is therefore important that the socioecological system is seen as a whole. Within this context, archetypal patterns are most relevant to representing the process of global change. For example, the Sahel syndrome (Lüdeke et al. 1999), characterizes a set of processes that result in the overuse of agriculturally marginal land. (Note that the names of syndromes represent an archetype rather than a specific location, event, or situation; for more detailed analysis of environmental change in the Sahel itself, see Chapter 22.)

The Sahel syndrome can be located in certain parts of the world and characterized by a number of factors. Its driving forces or core mechanisms include impoverishment, intensification of agriculture, and soil erosion, which in turn lead to productivity loss. Various factors might contribute to the disposition toward this syndrome, including socioeconomic dimensions, such as high dependence on fuelwood, and natural dimensions, such as aridity and poor soils. The core mechanisms can be quantitatively assessed to determine which areas of the world experience the syndrome most extensively and intensively. The syndromes approach is a transdisciplinary tool, drawing on both quantitative and qualitative assessments of dynamic patterns at a variety of scales, and by identifying patterns of unsustainable development, it can be used to target future development priorities aimed at enabling sustainable development.

6.3.2 Multiagent Modeling

Multiagent behavioral systems seek to model socioecological interactions as dynamic processes (Moss et al. 2001). Human actors are represented as software agents with rules for their own behavior, interactions with other social agents, and responses to the environment. Physical processes (such as soil erosion) and institutions or organizations (such as an environmental regulator) may also be represented as agents. A multiagent system could represent multiple scales of vulnerability and produce indicators of multiple dimensions of vulnerability for different populations.

Multiagent behavioral systems have an intuitive appeal in participatory integrated assessment. Stakeholders may identify with ''their'' agents and be able to validate a model in qualitative ways that is difficult to do for econometric or complex dynamic simulation models. However, such systems require significant computational resources (proportional to the number of agents), and a paucity of data for validation of individual behavior is a constraint.

6.3.3 Vulnerability and Risk Maps

The development of indicators and indices of vulnerability and the production of global maps are prominent vulnerability assessments techniques at the global level, although these approaches are still being developed to better capture the full concept of vulnerability. Global assessments using these techniques are described later in this chapter.

In order to bring conceptual understanding of vulnerability closer to their cartographic representations, vulnerability and risk mapping efforts are working to resolve several methodological challenges. Generally, risk maps are explicitly concerned with the human dimensions of vulnerability, such as the risks to human health and well-being associated with the impacts from natural hazards.

Given the common focus on human well-being at an aggregate level, vulnerability is quantified in terms of either single or multiple outcomes, such as water scarcity and hunger. Two exceptions are the hotspots of biodiversity (Myers et al. 2000) and the GLOBIO analysis (Nellemann et al. 2001), which are concerned with the vulnerability of biodiversity. For example, the hotspots of biodiversity identify areas featuring exceptional concentrations of endemic species and experiencing exceptional loss of habitat. The GLOBIO analysis relates infrastructure density and predicted expansion of infrastructure to human pressure on ecosystems in terms of the reduced abundance of wildlife. Limited progress, however, has been made as yet in integrating analyses of the vulnerability of human and ecological systems.

Many of the risk maps have been generated from remotely sensed data or information held in national data libraries. The maps are generally developed and displayed using a geographic information system. The analytical and display capabilities of GIS can draw attention to priority areas that require further analysis or urgent attention. Interactive risk mapping is presently in its infancy. The PreView project (UNEP-GRID 2003) is an interactive Internet map server presently under development that aims to illustrate the risk associated with natural disasters at the global level.

For the most part, risk maps have tended to be scale-specific snapshots at a particular time, rarely depicting cumulative and long-term risk. A challenge is linking global and local scales in order to relate indirect drivers (which operate at global, national, and other broad levels and which originate from societal, economic, demographic, technological, political, and cultural factors) to direct drivers (the physical expressions of indirect drivers that affect human and natural systems at regional or local scales). Temporally, risk maps generally depict short-term assessments of risk. The accuracy of these maps is rarely assessed, and risk maps are usually not validated empirically. Two exceptions are the fire maps and the maps of the risk of land cover change. The uncertainty that surrounds the input risk data needs to be explicit and should also be mapped.

A challenging problem for the effective mapping of risk is to move from solely identifying areas of stress or likely increased stress to mapping the resistance or sensitivity of the receptor system. This would highlight regions where the ability to resist is low or declining and the sensitivity of the receptor systems is high. The difficulty here lies in quantifying the ability to resist external pressures. Quantifying resistance, at least in ecological systems, is presently largely intractable as it requires information on the effects of different levels of severity of threats, which is usually species-specific, as well as ways of integrating this information across assemblages of species or areas of interest.

A further challenge to risk mapping is the analysis of multiple and sequential stressors. Generally, single threats or stressors are analyzed and multiple stressors are rarely treated. The ProVention Consortium (2003) aims to assess risk, exposure, and vulnerability to multiple natural hazards. Possible limitations to undertaking a multiple hazard assessment of this kind include accounting for the different ways of measuring hazards (for example, in terms of frequency, intensity, duration, spatial extent), different currencies of measurement, varied data quality, and differences in uncertainty between varying hazard assessments.

Scale and how to represent significant variation within populations of regions are common challenges for global mapping exercises, with broad implications for vulnerability assessment (German Advisory Council on Global Change 1997). Political and social marginalization, gendered relationships, and physiological differences are commonly identified variables influencing vulnerability, but incorporating this conceptual understanding in global mapping remains a challenge. Global-scale maps may consider vulnerability of the total population, or they may consider the situation of specific groups believed to be particularly vulnerable. Because many indigenous peoples are less integrated into political and social support systems and rely more directly on ecosystem services, they are likely to be more sensitive to the consequences of environmental change and have less access to support from wider social levels.

Women and children are also often reported to be more vulnerable than men to environmental changes and hazards (Cutter 1995). Because the gendered division of labor within many societies places responsibility for routine care of the household with women, degradation of ecosystem services—such as water quality or quantity, fuelwood, agricultural or rangeland productivity—often results in increased labor demands on women. These increased demands on women's time to cope with loss of ecosystem services can affect the larger household by diverting time from food preparation, child care, and other beneficial activities. While women's contributions are critical to the resilience of households, women are sometimes the focus of vulnerability studies because during pregnancy or lactation their physiology is more sensitive and their ill health bears on the well-being of children in their care. Children and elderly people are also often identified as particularly vulnerable primarily because of their physiological status.

Measures of human well-being and their relationship to ecosystems services also often incorporate data on the sensitivity and resilience dimensions of vulnerability, expressed as assets, capabilities, or security. These measures are discussed in greater detail in Chapter 5.

6.4 Assessing Vulnerability

The causes and consequences of human-induced change in ecosystems and ecosystem services are not evenly distributed throughout the world but converge in certain regions and places. For some time, for example, Russian geographers prepared "red data maps" to show the locations of what they regarded as "critical environmental situations" (Mather and Sdasyuk 1991). The National Geographical Society (1989) created a map of "environmentally endangered areas" depicting areas of natural hazards, pollution sources, and other environmental stresses. Nonetheless, it is only in recent years that concerted efforts have been made to develop indices and generate maps that depict the global distribution of people and places highly vulnerable to environmental stresses.

As noted earlier, several challenges remain in developing indicators, indices, and maps that capture all the dimensions of vulnerability, but this section reviews major notable efforts that address vulnerability in the context of human security, as an aspect of environmental sustainability, and natural disasters and that point to environmental health issues addressed further in Chapter 14.

Although modest progress has occurred in identifying and mapping vulnerable places and peoples, the state of knowledge and methodology are still significantly limited. Few of the analyses presented here integrate ecological and human systems. They rarely treat multiple stresses, interacting events, or cumulative change. Indicators continue to be chosen without an adequate underlying conceptual framework and are typically not validated against empirical cases. For the most part, they are scale-specific and snapshots in time. Disaggregated data are lacking, and much remains to be done before a robust knowledge base at the global scale will exist.

In a demonstration project, the Global Environmental Change and Human Security Project of the International Human Dimensions Programme on Global Environmental Change (Lonergan 1998) mapped regions of ecological stress and human vulnerability, using an ''index of vulnerability'' composed from 12 indicators:

- food import dependency ratio,
- water scarcity,
- energy imports as percentage of consumption,
- access to safe water,
- expenditures on defense versus health and education,
- human freedoms,
- urban population growth,
- child mortality,
- maternal mortality,
- income per capita,
- degree of democratization, and
- fertility rates.

The criteria used in selecting indicators were that data were readily available, that the resulting ''index'' consisted of a small number of indictors, and that the indicators covered six major categories—ecological and resource indicators, economic indicators, health indicators, social and demographic indicators, political/social indicators, and food security indicators. Through cluster analysis, a vulnerability ''index'' was derived and then used to map estimated vulnerability patterns, such as one for Africa. (See Figure 6.2.)

The work of the Intergovernmental Panel on Climate Change (IPCC 2001a) has made clear that ongoing and future climate changes will alter nature's life-support systems for human societies in many parts of the globe. Significant threats to human populations, as well as some potential benefits, are involved. (See Box 6.1.) As the example on the Arctic region illustrates, changes that benefit some may harm others in the same area. (See also Chapter 25.)

But it is unrealistic to assume that positive and negative effects will balance out, particularly in certain regions and places. Many of the regions and human groups, the IPCC makes clear, will be highly vulnerable and poorly equipped to cope with the major changes in climate that may occur. Many people and places are already under severe stresses arising from other environmental degradation and human driving forces, including population growth, urbanization, poverty and poor nutrition, accumulating environmental contamination, growing class and gender inequalities, the ravages of war, AIDS/HIV, and politically corrupt governments. The IPCC points to the most vulnerable socioecological systems: one third to one half of the world's population lack adequate clean water; many developing countries are likely to suffer future declines in agricultural production and food security; sea level rise is likely to greatly affect low-lying coastal areas; small-island states face potential abandonment of island homes and relocation; and the poor and sick in growing megacities face increased risk for death and illness associated with severe heat and humidity.

In preparation for the World Summit on Sustainable Development in 2002, the Global Leaders for Tomorrow Environment Task Force (2002) of the World Economic Forum to created a global Environmental Sustainability Index. It has five major components developed from globally available national data, including one on reducing human vulnerability. (See Table 6.1.) While it would be desirable to display regional differences within countries, finer-scale information is not consistently available for many types of data.

Human vulnerability seeks to measure the interaction between humans and their environment, with a focus on how environmental change affects livelihoods. Two major issues are included in the vulnerability component (one of the five components in the overall index): basic human sustenance and environmental health. The index is based on five indicators: proportion undernourished in the total population, percentage of population with access to improved drinking water supply, child death rate from respiratory diseases, death rate from intestinal infectious diseases, and the under-five mortality rate. The standardized values for each indicator were calculated and converted to a standard percentile indicator for ease of interpretation. The indicators were unweighted. Country scores were then derived to demarcate global patterns, as shown in Table 6.2.

The United Nations Environment Programme (UNEP 2003) has also assessed definitions, concepts, and dimensions of vulnerability to environmental change in different areas of the world. In particular, it calls attention to the importance of environmental health in the vulnerability of different regions and places. It notes, for example, that every year thousands of people die from a range of disasters, but the fate of many of these people is never reported. The International Red Cross Federation (IFRC 2000) has shown that the death toll from infectious diseases (such as HIV/AIDS, malaria, respiratory diseases, and diarrhea) was 160 times the number of people killed in natural disasters in 1999. And this situation is becoming worse rapidly. It is estimated, for example, that over the next decade HIV/AIDS will kill more people in sub-Saharan Africa than died in all wars of the twentieth century.

The United Nations Development Programme, in *Reducing Disaster Risk: A Challenge for Development* (UNDP 2004), undertakes the formulation of a ''disaster risk index,'' which it then uses to assess global patterns of natural disasters and their relationship to development. The Disaster Risk Index calculates the relative vulnerability of a country to a given hazard (such as earthquakes or floods) by dividing the number of people killed by the number of people exposed to the hazard. The analysts then compared the risk of the hazard (the number of people actually killed by the hazard in a country) with 26 indicators of vulnerability, selected through expert opinion. Analyzing a series of statistical analyses, a number of findings concerning the impact of development on disaster risk emerge:

- The growth of informal settlements and inner city slums has led to the growth of unstable living environments, often located in ravines, on steep slopes, along floodplains, or adjacent to noxious industrial and transport facilities.

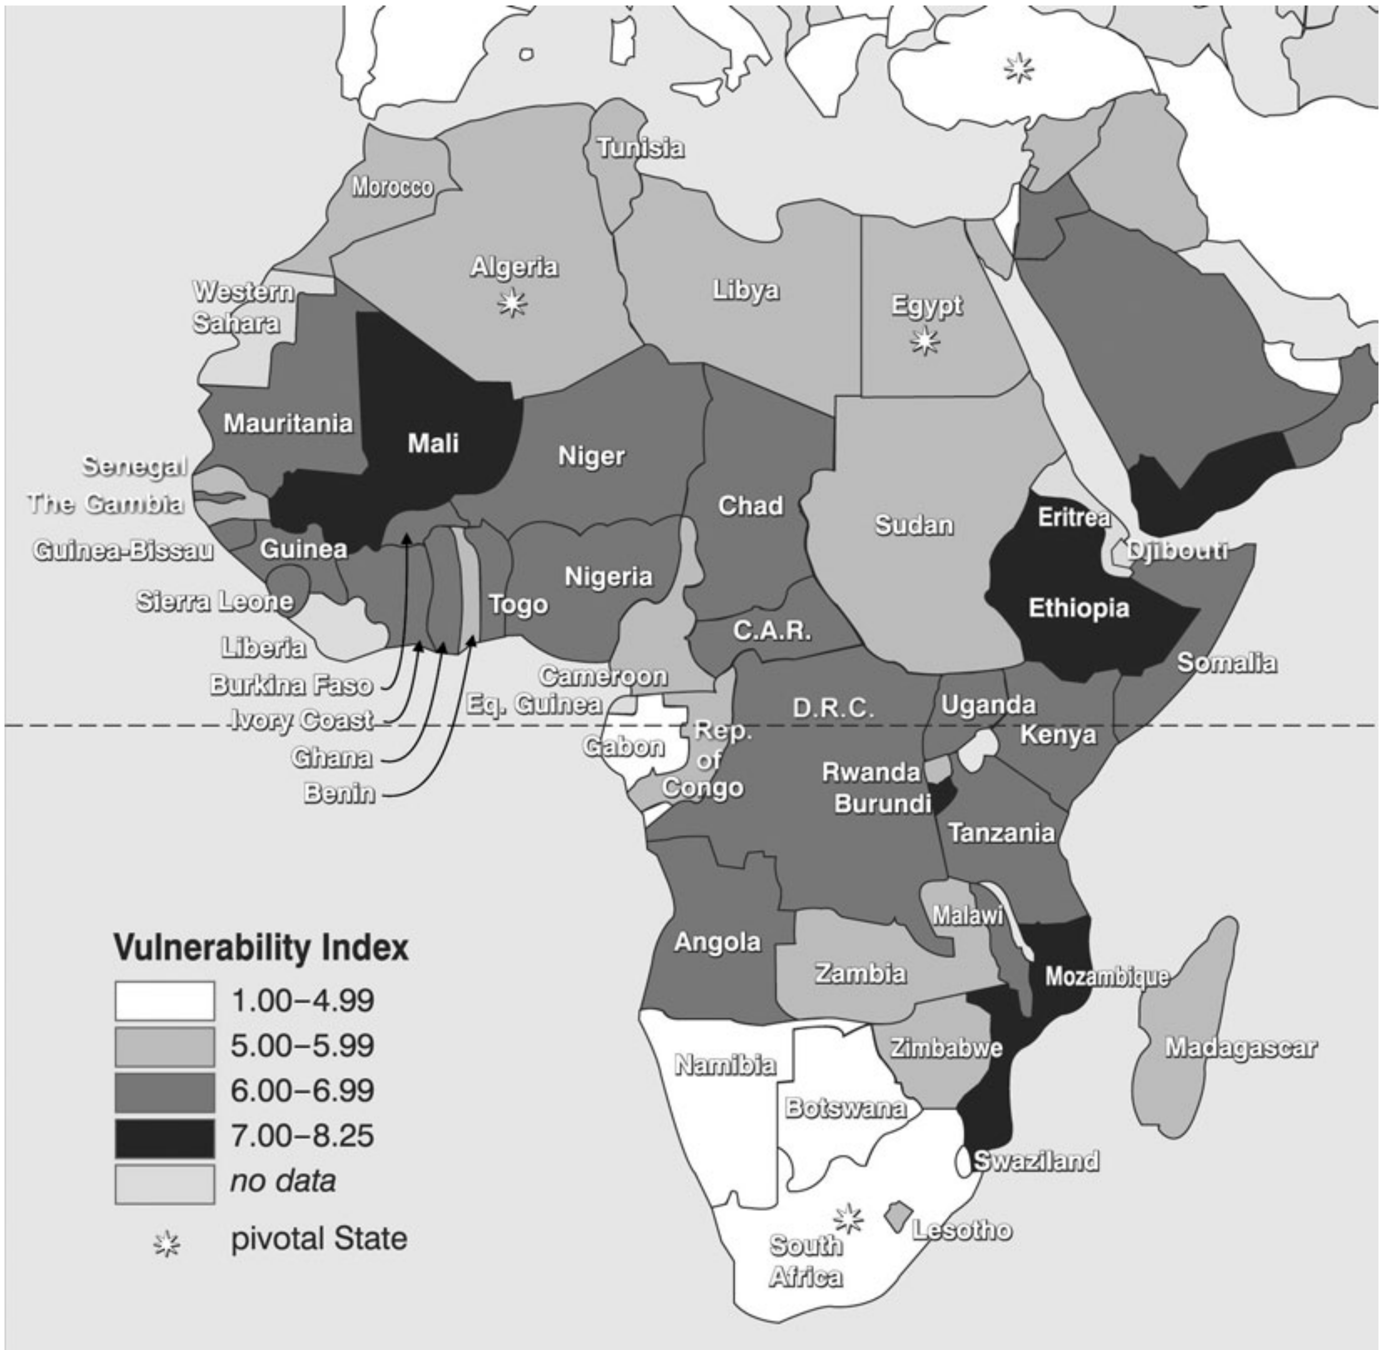

Figure 6.2. Vulnerability Index for African Countries (Lonergan 1998)

- Rural livelihoods are put at risk by the local impacts of global climate change or environmental degradation.
- Coping capacities for some people have been undermined by the need to compete in a globalizing economy, which presently rewards productive specialization and intensification over diversity and sustainability (UNDP 2004, p. 2).

6.5 Natural Hazards and Vulnerability

Natural hazards and disasters are products of both natural variability and human-environment interactions, and vulnerability to them has received substantial past attention. (See also Chapter 16.) The extremes of environmental variability are defined as hazards when they represent threats to people and what they value and defined as disasters when an event overwhelms local capacity to cope. Natural hazards offer a particularly dramatic view of the role of vulnerability in explaining patterns of losses among people and places. Indeed, research on this topic was the first realm to document the vast differences in the magnitude of losses among people and places experiencing the same types of events (White 1974). Since the 1970s, researchers have consistently reported greater loss of life among poorer populations and countries than in industrial countries, along with the inverse relationship for economic damage.

Natural hazards and disasters have always been a part of human history. Yet human relationships to hazards have evolved as the power of humans to shape natural landscapes and their biogeochemical processes has grown. Over the centuries, humans have changed from relatively powerless victims in the face of natural hazards and disasters to active participants shaping natural hazards and our vulnerability to them. Only recently has policy recognized that natural hazards are not "Acts of God" and begun to shift hazard management from a model of response and relief to an active engagement with mitigation, prevention, and integration of hazard management into development planning (ISDR 2002).

It is well established that the impacts of natural disasters continue to create uneven patterns of loss in populations around the world. The rising economic costs, the relative significance of those costs to the budgets of developing countries, the increasing numbers of people affected, and the decreasing loss of life demonstrate the dynamics of vulnerability across scales and experienced in local places.

6.5.1 Trends in Natural Hazards and Vulnerability

The best available data on a global scale (e.g., Swiss Re 2000; Munich Re 2003; CRED 2002) indicate that the world is witnessing a worsening trend of human suffering and economic loss

BOX 6.1

Threats and Potential Benefits of Climate Change to Human Societies (IPCC 2001a)

Threats

- Reduced potential crop yields in some tropical and sub-tropical regions and many mid-latitude regions
- Decreased water availability for populations in many water-scarce regions, particularly those with inadequate management systems
- An increase in the number of people exposed to vector-borne diseases (such as malaria) and waterborne diseases (such as cholera)
- Increases in the number of people dying from heat stress, particularly in large cities in developing countries
- A widespread increase in the risk of flooding for many human settlements throughout the world
- Severe threats to millions of people living on low-lying islands and atolls
- Threats to aboriginals living in Arctic and high mountains (for example, through the breakup of ice fields preventing people from reaching their traditional hunting and fishing grounds)

Potential Benefits

- Increased potential crop yields in some mid-latitude regions
- A potential increase in global timber supply from appropriately managed forests
- Increased water availability for populations in some water scarce regions (such as parts of South East Asia)
- Reduced winter mortality in mid- and high latitudes
- Improved marine transportation in the Arctic

Table 6.1. Components of Environmental Sustainability (Global Leaders for Tomorrow Environmental Task Force 2002)

Component	Logic
Environmental systems	A country is environmentally sustainable to the extent that its vital environmental systems are maintained at healthy levels and to the extent to which levels are improving rather than deteriorating.
Reducing environmental stresses	A country is environmentally sustainable if the levels of anthropogenic stress are low enough to engender no demonstrable harm to its environmental systems.
Reducing human vulnerability	A country is environmentally sustainable to the extent that people and social systems are not vulnerable (in the way of basic needs such as health and nutrition) to environmental disturbances; becoming less vulnerable is a sign that a society is on a track to greater sustainability.
Social and institutional capacity	A country is environmentally sustainable to the extent that it has in place institutions and underlying social patterns of skills, attitudes, and networks that foster effective responses to environmental challenges.
Global stewardship	A country is environmentally sustainable if it cooperates with other countries to manage common environmental problems, and if it reduces negative transboundary environmental impacts on other countries to levels that cause no serious harm.

to natural disasters over recent decades.(Data available at the time this chapter was written do not include losses caused by the 2004 tsunami.) While the general trend is clear, the precise estimates vary somewhat, due to improvements in reporting over time, data gathering practices, and definitional differences across organizations. (See Chapter 16 for more detailed description of the limitations and variations among data sets.)

During the past four decades, the number of ''great'' catastrophes—when the ability of a region to help itself is distinctly overtaxed, making interregional or international assistance necessary—has increased about four times, while economic losses have increased over 10 times. (Munich Re 2000) (See Table 6.3.) This trend reflects the increasing economic costs of disasters, lives lost, and the unequal ability of nations to cope with the impacts. Natural disasters affected twice as many people in the 1990s as in the 1980s (CRED 2003). The annual average losses for all disasters over the 1990s were 62,000 deaths, 200 million affected, and $69 billion in economic losses (IFRC 2001). Although comprehensive global databases do not exist for smaller-scale natural hazard events, the significance of these more common events to the social vulnerability of exposed human populations is also a major concern (ISDR 2002; Wisner et al. 2004).

Throughout the twentieth century, three general observations can be drawn from global trends: the number of disasters has increased, economic losses from disasters have increased (primarily in industrial countries), and the ratio of loss of life to total population affected has decreased, although this decline has also been heavily concentrated in industrial societies. (See Figure 6.3 in Appendix A.)

The global trends in natural disaster occurrences and impacts suggest several important patterns of vulnerability among people and places at the same time that they mask considerable geographic variation. Asia is disproportionately affected, with more than 43% of all natural disasters in the last decade of the twentieth century. During the same period, Asia accounted for almost 70% of all lives lost due to natural hazards. In China alone, floods affected more than 100 million people on average each year (IFRC 2002).

Variation among types of natural hazards is also significant. Over the decade 1991–2000, the number of hydro-meteorological disasters doubled, accounting for approximately 70% of lives lost from natural disasters (IFRC 2001). Floods and windstorms were the most common disaster events globally, but not consistently the cause of greatest losses. Disasters causing the greatest number of deaths varied among regions, with floods causing the most deaths in the Americas and Africa, drought or famine the most in Asia, earthquakes the most in Europe, and avalanches or landslides narrowly exceeded windstorms or cyclones in Oceania. Chapter 16 provides a more comprehensive description of flood and fire hazards.

While the economic loss per event is much larger in industrial countries, the greatest losses still occur in developing nations in absolute numbers of lives as well as in relative impact as measured by percentage of GDP represented by disaster losses. (See Figure 6.4.)

Considering lack of resources and capacity to prevent or cope with the impacts, it is clear that the poor are the most vulnerable to natural disasters. Among the poorest countries, 24 of 49 face a

high level of disaster risk; at least 6 countries have been affected by two to eight major disasters per year in the past 15 years, with long-term consequences for human development (UNEP 2002). Ninety percent of natural disaster–related loss of life occurs in the developing world. When countries are grouped according to the UNDP Human Development Index, socioeconomic differences are strongly reflected in disaster losses (IFRC 2001). For the 1990s, countries of low human development experienced about 20% of the hazard events and reported over 50% of the deaths and just 5% of economic losses. High human development countries accounted for over 50% of the total economic losses and less than 2% of the deaths.

In assessing the distribution of vulnerability, several limitations to existing research need to be considered. First, economic valuations do not reflect the difference in relative value of losses among wealthier and poorer populations or the reversibility of environmental damages incurred. Similarly, land degradation due to landslides, flooding, or saline inundation from coastal events can diminish the natural capital resources of livelihoods, further compounding recovery challenges. The meaning of the economic value of these losses of ecosystem services is also difficult to capture and is seldom included in conventional economic assessments.

Second, because of the definitions of disaster used, local-scale disasters of significance to the affected community are often not reflected in these disaster statistics. If those losses were included, the figures on damages could easily be much higher.

Finally, there is the tendency to treat natural hazards in separate categories and to treat disasters as discrete, individual events.

Table 6.3. Great Natural Catastrophes and Economic Losses: Comparison of Decades, 1950–99 (Munich Re 2000)

Catastrophes and Losses	1950–59	1960–69	1970–79	1980–89	1990–99
Number	20	27	47	63	82
Economic losses (bill. 1998 dollars)	38.5	69.0	124.2	192.9	535.8
Insured losses (bill. 1998 dollars)	unknown	6.6	11.3	23.9	98.9

Note: Natural catastrophes are classified as "great" if the ability of the region to help itself is distinctly overtaxed, making interregional or international assistance necessary.

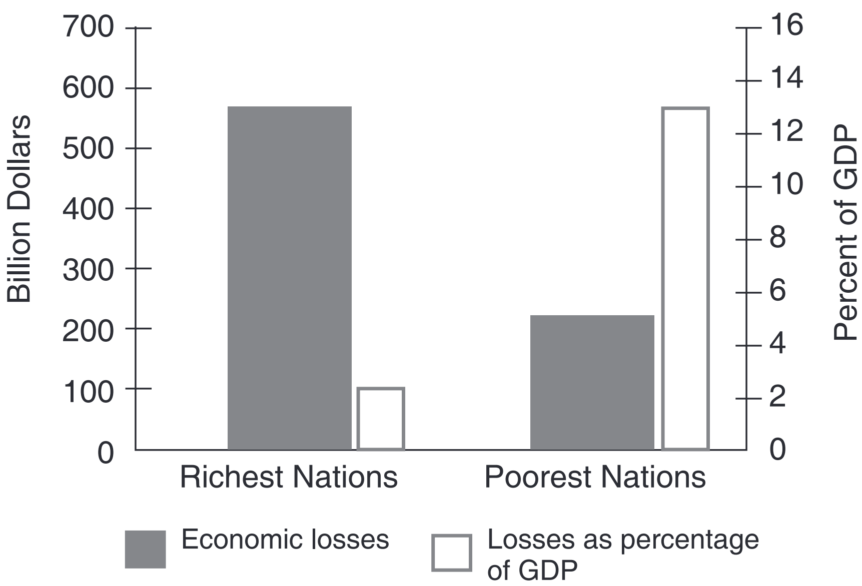

Figure 6.4. Disaster Losses, Total and as Share of GDP, in 10 Richest and Poorest Nations, 1985–99 (Abramovitz 2002)

This accounting practice limits insights into the consequences of threats from multiple hazards in one place and of sequences of disasters following upon one another. Over time, multiple and recurring hazards exacerbate vulnerability, and across scales, vulnerability is generally greater during the recovery period, when systems are already damaged. These patterns of differential impact affect efforts to cope with the impacts of environmental variability and degradation, as described earlier.

6.5.2 Explaining Vulnerability to Natural Hazards

Human-driven transformation of hydrological systems, population growth (especially in developing countries), and movements of people and capital into harm's way are major driving forces underlying the increasing numbers of disasters (Mitchell 2003). Conflict among people contributes further to vulnerability (Hewitt 1997). The causal reasons relate to basic characteristics of economy and political system but also to the perceptions, knowledge, and behavior of local managers and institutions (Hewitt 1997).

In some regions, significant environmental changes have resulted in the degradation of ecological services that mediated the effects of hydro-climatological events. Two common forms of ecological change—desertification and deforestation—can exacerbate the impacts of drought in some areas by reducing the moisture-holding capacity of the soil and contribute to increased flooding through reducing infiltration. (See Chapter 16.) In Honduras, deforestation contributed losses through increasing flooding as well as landslides following Hurricane Mitch in 1998. In other areas, efforts at river or flood control have reduced vulnerability to smaller hazard events, but increased losses when larger events overwhelmed dams, dykes, or levees and damaged the usually protected area.

The growth in numbers of people affected is a particularly important measure, as it provides an indication of the potential increase of exposure and sensitivity of people to environmental variability. The global annual average number of people affected has increased over the last decade, although the number of deaths due to disasters has declined. This shift highlights the potential for changes in pattern of vulnerability though adaptations. (See also MA *Policy Responses,* Chapter 11.) The greatest proportion of people affected resides in countries of medium human development, which include the large-population countries of Brazil, China, India, and Indonesia (IFRC 2001).

In addition to changing exposure, socioeconomic changes are shaping the overall patterns of vulnerability. First, while poverty is not synonymous with vulnerability, it is a strong indicator of sensitivity, indicating a lack of capability to reduce threats and recover from harm. The number of people living in poverty is increasing (UNDP 2002a). The greater number of people affected in medium human development countries may also reflect their experience with the additional challenges of transition, a situation somewhat akin to recovery, in which infrastructure and support systems, both physical and social, may be disrupted by the processes of change and be unable to contribute to reducing vulnerability.

Urbanization creates particular problems in disaster vulnerability. Due to the concentrations of people and complex infrastructure systems involved, the repercussions of an event in cities can spread quickly and widely, and the scale of resources needed for effective response is often challenging for national or international coordination. In many cases, these cities also draw in vast numbers of people seeking better lives, but they are often unable to keep up with the demand for planning, housing, infrastructure, and jobs. The informal housing that immigrants create is often located in marginal areas, such as hill slopes and floodplains, and accessible construction options cannot address the site limitations (Wisner et al. 2004). In 1950, just under 30% of the world's population (of 2.5 billion) lived in cities; by 2025 it is projected to be over 60% (of an estimated 8.3 billion) (UNDP 2002b). This rapid urbanization trend is particularly pronounced in countries with low per capita income. (See also Chapter 27.)

Globalization is contributing to natural hazard vulnerability as it is changing the sensitivity and coping options available (Adger and Brooks 1003; Pelling 2003). On an international scale, increasing connectedness is causing societies to become more dependent on services and infrastructure ''lifelines.'' In such a connected world, the consequences of natural disaster reach far beyond the area physically damaged. It has been estimated that the possible extent of damage caused by a extreme natural catastrophe in one of the megacities or industrial centers of the world has already attained a level that could result in the collapse of the economic system of entire countries and may even be capable of affecting financial markets worldwide (Munich Re 2000, 2002). Globalization has also increased the risks faced by marginalized indigenous peoples; many of these are developmental effects that will become apparent over only the long term. Traditional coping mechanisms have come under severe pressure, and adaptation strategies, at one time effective, can no longer cope (Pelling 2003).

Data on global trends do not report on the social differentiation among victims, but case study evidence and other synthesis efforts indicate some social groups are continually disproportionately represented among those harmed the most (Wisner et al. 2004). These are often people who are marginalized within society, due to combinations of prejudice, lack of or ignored rights, and lack of access to social supports or personal resources or due to distance from concentrations of services and power. Indigenous peoples, such as the Inuit, Sami, and others from northern regions, represent the vulnerability of this type of situation well. (See Chapter 25 for further details). These circumstances often apply to poor people, women, children, elderly individuals, and ethnic minorities in affected areas. In addition, the elderly, children, women, and handicapped people are more likely to have physical limitations or special needs that reduce their ability to cope with disaster.

6.6 Desertification: Lessons for Vulnerability Assessment

Desertification—land degradation in drylands—has been a subject of interest for over 30 years, with numerous technical assessments and policy analyses, and it is a good example of changes in a coupled socioecological system that threaten livelihoods across large swaths of Earth. It is also a good example of understanding vulnerability. (See Downing and Lüdeke (2002) and Chapter 22 for more on drylands and desertification and a useful set of maps.)

Local to global studies of social vulnerability to desertification suggest at least three lessons for vulnerability from past experience:

- *Vulnerability is dynamic.* Desertification arises from the interactions of the environment and social, political, and economic systems—through the actions of stakeholders and the vulnerable themselves (Downing and Lüdeke 2002).
- *Vulnerability takes different forms at different scales.* Similar constellations of institutions have diverse effects at different social or geographic scales. The patchiness of driving forces, often represented in global scenarios, precludes developing a simple hierarchy from local vulnerability to global maps of desertification risks.
- *Vulnerability cannot be differentiated into different causes.* At the level of human livelihoods and systems, exposure to desertification is entangled with poverty, drought, water, food and other threats and stresses.

One example of the close coupling of social and environmental systems related to desertification is apparent in the syndromes approach developed by the Potsdam Institute for Climate Impact Research, which depicts the close linkages and components involved in the coupling. The basic idea behind syndromes is "not to describe Global Change by regions or sectors, but by archetypical, dynamic, co-evolutionary patterns of civilization–nature interactions" (Petschel-Held et al. 1999, p. 296). Syndromes are charted in dynamic process models that link state variables that change over time and between states. The scale is intermediate, reflecting processes that occur between household and national/macro scales. The typology of syndromes reflects expert opinion, modified over time based on modeling. Local case examples are used to generalize to mechanisms in the modeling and also to validate the syndrome results. Desertification is a case of several syndromes operating independently, reflecting the internal dynamics of places, resources, economies, and populations.

The syndrome approach illustrates how concepts of dynamic vulnerability might be implemented to understand multiple stresses arising from the human use of ecosystem services. It takes the analysis one stage beyond purely biophysical explanations to examine linkages with human systems. The next steps might be integrated analysis at the level of different users of ecosystem services, and how they interact with each other in markets and in governance.

6.7 Food Insecurity

The arena of food security has been a third primary focus of vulnerability analysis. The severe famines in the 1980s in Africa saw the launch of dozens of famine early warning schemes. These implemented various designs, but all expanded beyond the simple monitoring of agricultural production. By the mid-1980s, Amartya Sen's entitlement theory (Sen 1981), which emphasized factors influencing the distribution of food as well as the absolute levels of available food, was widely circulated and implemented in food security monitoring. Attention to the socioeconomic failures that limit access to global food supplies became a substantial component of these efforts. More recently, more holistic approaches have sought to focus on livelihood security, to include food security, thereby widening the conceptual framing of vulnerability still further.

Much of the literature on food security focuses on human vulnerability; ecosystem services are limited to crop production, grazing for livestock, and to a lesser extent wild foods. While vulnerability assessment is maturing as an analytical tool, the need exists for assessments that are more dynamic and actor-oriented. An essential way forward in vulnerability analysis is to adopt a more precise terminology and nomenclature (see, e.g., the papers in Smith et al., 2003).

6.7.1 Methodology

Methodological lessons learned in vulnerability assessment over the past several decades reinforce the general messages of this chapter: food security is a relative measure that can be captured in various quantitative and semi-quantitative ways, but it is not an absolute condition that can be measured objectively. Food security is multidimensional and it integrates exposure to stresses beyond more narrow treatment of the production or availability of food. (See Chapters 8 and 18 for a further description of food provisioning services.) It is also clear that indicators of food security need to represent an explicit conceptual framework, such as that offered earlier in this chapter. The collation of indicators into profiles and aggregated indexes needs also to reflect the causal structure of food insecurity, going beyond the indiscriminate adding up of available indicators into a single index (see Downing et al. 2001).

A common feature of almost all food security (and livelihood) analyses is the recognition of multiple domains of vulnerability. Operational assessments commonly treat production, economic exchanges, and nutrition, while longer-term and more structural analyses include some measure of the political economy that underlies the more immediate dimensions of food security. Examples of operational assessments include India (MSSRF 2001) and Kenya (Haan et al. 2001). Figure 6.5 charts three domains of rural food insecurity for states in India.

A more heuristic illustration of the multiple dimensions of food security, related to climate change, is shown in Figure 6.6 (in Appendix A). The Figure is speculative, based on a subjective assessment of food security and climatic risks. Nevertheless, it clearly shows that global food production is of less concern than

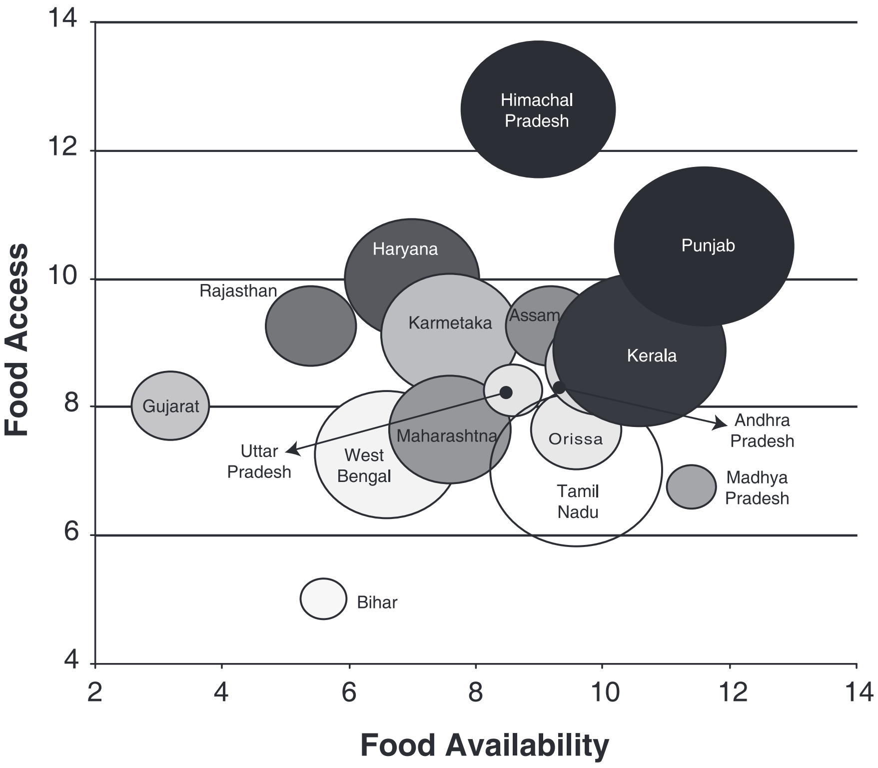

Figure 6.5. Food Insecurity Indicators of Rural India. Compiled at the state level, the MS Swaminathan Research Foundation aggregated food insecurity into three dimensions—food availability and production (x-axis), economic access (y-axis), and nutritional utilization (size of the circles, where larger is better-off). (MS Swaminathan Research Foundation 2001)

the impacts of droughts, which are already economically and socially significant for some livelihoods.

6.7.2 Wild Foods at the Local Scale

While a myriad of propositions regarding food security are possible, relating to different elements of causal structure, from the nature of the hungry themselves to the global political economy of food trade, here the case of wild foods and their role in food security is examined. (See also Chapters 5, 8, and 18 for food production and hunger issues.)

The most common approaches to food security are designed to balance consumption and production at the household level—including such indicators as expected yields of major foods (related to rainfall, soil quality, and pests, for instance), economic exchanges (such as terms of trade for agricultural sales or access to off-farm employment), hunting of wild foods, and some measures of entitlement through remittances from kin, official food relief, and relief work schemes. Set against the total of available food is the expected consumption, from meeting the FAO calorie standards to various levels of deprivation and starvation resulting in measurable effects on health. Aggregating to a regional or national level, such food balances guide policies for imports and exports, for targeted relief, and for declaration of a food crisis.

Notably absent from such food balances is the role of off-farm food collection—the gathering of wild foods either for consumption or sales. (See Chapter 8 for a more detailed description of the role of wild foods, including game, fish, and plants, in diets and for the underestimation in accounting in food balances.) In forest regions, these are called non-wood forest products and can be a major livelihood activity. Equally, few monitoring schemes include direct measures of ecosystem services such as charcoal sales, increased burdens of water shortages, or even effects of vegetation and land cover on livestock and pests. Nevertheless, for some marginal communities, such ecosystem services are essential and particularly important for surviving food shortages (Ericksen 2003).

Investigations of two dryland sites in Kenya and Tanzania found that indigenous plants were an important source of raw material in the majority of coping mechanisms when alternative sources of food or income were required, such as when the harvest failed or sudden expenses had to be met. Such coping mechanisms included making use of trees for making and hanging beehives (flowering trees are also a source of nectar); of fuelwood for sale, burning bricks, or producing charcoal; of reeds, fibers, and wood for handicrafts such as mats or tools; and of fruit, vegetables, and tubers for food and sale. Indigenous plant-based coping mechanisms are particularly important for the most vulnerable, who have little access to formal employment or market opportunities, thus providing a crucial safety net in times of hardship. Wild fruits provide important nutrients to children during times when meals are reduced at home in many parts of Africa and South Asia (Brown et al. 1999), for example.

Such raw materials can often be acquired from communal land or from neighbors without cash transactions, and they are available at critical times of the year due to the climatic resilience of indigenous plants. In addition, the sale of livestock and poultry and engaging in casual labor, which are critical sources of cash during crises, often depend on ecosystem services, such as grazing land and fodder or forest products for fencing, construction, and other typical casual labor tasks. Table 6.4 shows the high percentage of households that depended on indigenous plant-based coping mechanisms in the Kenya and Tanzania site (Eriksen 2000), and Figure 6.7 illustrates the relative importance of indigenous foods. While the findings refer to a particular point in time (the 1996 drought), the widespread use of forest products as a source of food and income figures is consistent with findings from numerous other studies (Arnold 1995; Brown et al. 1999).

6.7.3 Global Influence on Local Food Balance

The literature on food security has a long tradition recognizing that local food balances are embedded in national economies and global flows of food trade and aid (for one representation, see Kates et al. 1988). A fictitious illustration captures the notion of global exposure:

> *During a drought, a farm household suffers a loss of yields in one of its fields of maize and beans. The field is primarily used for domestic consumption, cultivated by the women. Rainfall shortages are apparent with the delay in the onset of the rains—although the field is planted and later weeded by the women, the family does not apply expensive pesticides and fertilizers, expecting low returns during a poor season. Another field has a different problem. The head of the household acquired it as part of a community-based irrigation scheme*

Table 6.4. Households That Depended on Indigenous Plant-based Coping Mechanisms in Kenya and Tanzania (Eriksen 2000)

Activities that Involve Use of Indigenous Plants	Share of Households, Kenya site	Share of Households, Tanzania site
	(percent)	
All use	94	94
Food use	69	54
Non-food use	40	42

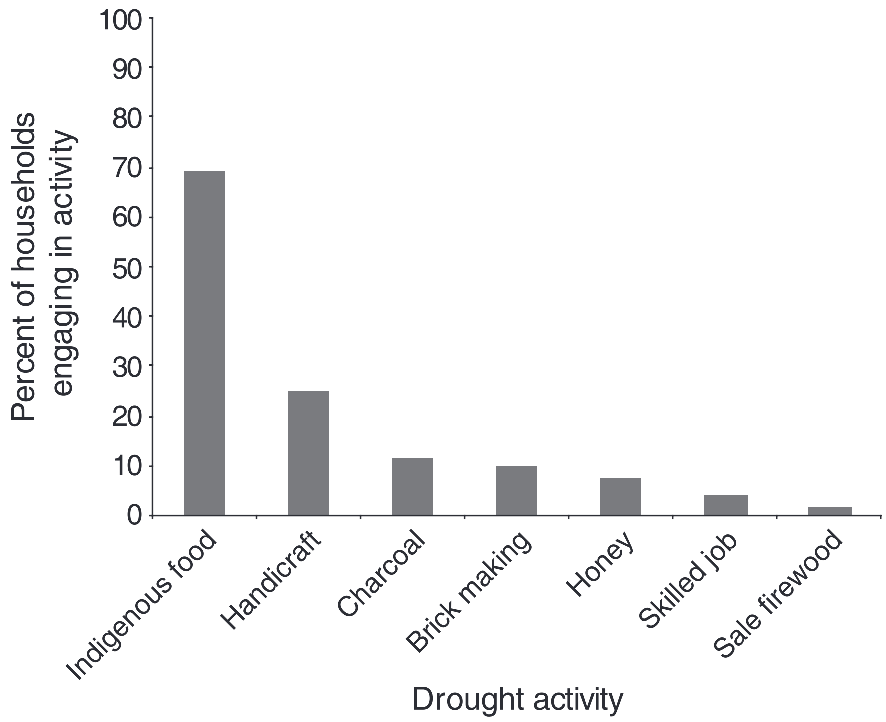

Figure 6.7. Use of Indigenous Plants in Mbitini, Kenya, by Activity during the 1996 Drought. "Skilled job" entailed tailoring, stone masonry/construction of houses, and woodcarving. Total number of households is 52. (Eriksen 2000)

that he joined a few years ago. He plants it this year with a cash crop of tomatoes and invests in fertilizer and pesticide. Halfway through the season, however, the drought restricts the availability of irrigation water. As a "junior" member of the scheme, his supply is reduced earlier than expected and his yields and quality are poor. When he tries to sell his crop to the local factory for processing into tomato juice, he discovers that there is a glut in the market due to a relaxation of import controls. Good conditions in a nearby country and export subsidies have produced a surplus, and the factory cannot afford to purchase local produce.

The fictitious example is not unrealistic—farmers have to contend with local conditions, with social, economic, and environmental relations in their community, and with the global and national food system. This global nature of vulnerability makes it impossible to clearly "bound" exposure, and it is often misleading to adopt a single spatial scale, as is often attempted in mapping vulnerability (as noted earlier regarding tools and methods).

6.7.4 Reporting Vulnerability

An essential way forward in food security analysis is to use at least a more precise terminology and nomenclature. A fairly simple scheme is proposed here, which makes clear four fundamental considerations that are not consistently reported: who is exposed, what the stresses are, what time frame is considered, and what consequences evaluated (see Downing et al. 2004). The notation below calls for reporting vulnerability (V) as specific to time frame (t); the sector, such as agriculture (s); the group, such as small-scale farmers, women farmers, or residents of peri-urban areas (g); and the consequences evaluated, such as food production, change in food purchasing power, nutritional levels or hunger (c).

$${}^{t}V_{s,g}^{\,c}$$

(where s = sector, g = group, c = consequence, t = time frame and V = vulnerability)

For instance, an examination of climate change vulnerability in agriculture could offer greater utility to future comparisons and policy by specifying differences as follows:

- Climate change vulnerability (T = climate change, no other terms specified)
- Drought (T) vulnerability for food systems (s)
- Drought (T) vulnerability for smallholder (g) agriculturalists (s)
- Drought (T) vulnerability for smallholder (g) agriculturalists (s) at risk of starvation (c = health effects of reduced food consumption)

These four different statements about climate change vulnerability suggest the range of potential differences in assessment findings. The process of conducting a vulnerability assessment can be labeled VA. If the indicators are mapped, this is extended to a vulnerability assessment map, a VAM. A database of vulnerability indictors used in a VA (or VAM) can be labeled VI. Greater precision and analytical comparability could be gained by assigning a nomenclature to individual indicators (VI_x), such as:

t = time period (historical, present or specific projection)
g = group of people if specific to a vulnerable population
r = region (or geographic pixel)
$*$ = transformed indictors, as in standard scores

This basic set of relationships can be extended into a variety of assessment tools and facilitate comparison of case studies.

6.8 Exploring Vulnerability Concepts: Three Case Studies

The broad patterns of vulnerability apparent in the patterns and trends of natural disasters, the assessment of desertification, and the lessons from food security studies all demarcate important aspects of the sources and outcomes of stresses and perturbations on coupled socioecological systems. But it is well known that these interactions are highly place-specific. Thus it is useful to turn to particular cases to explore these issues in greater depth.

This section considers three specific examples. First, the situation of two types of resource-poor farmers in northeastern Argentina is examined, illustrating how vulnerability can take different forms with different types of farming systems. Second, we look at how shifting the scale of analysis or vulnerability and resilience yields quite different insights on the sources of vulnerability and the potential effectiveness of resilience-building strategies, using a case study from Southern Africa. Finally, efforts to reduce vulnerability and the challenges involved in assessing the benefits of different types of interventions are examined through a case study from the one of the poorest areas of India.

6.8.1 Resource-poor Farmers in Northeastern Argentina

The Misiones region, in a hilly area of northeastern Argentina, has a sub-tropical wet climate where about 60% of the original vegetation (sub-tropical forest) has now been replaced by agriculture, despite the fact that soils are fragile, ill-suited for continuous cropping, and subject to nutrient depletion and erosion (Rosenfeld 1998).

Subsistence farming is common in the region, and two major types of farmers can be distinguished. Both have a similar farm structure in terms of land, capital, and labor; both are very poor; and both types often cannot meet their basic needs (Cáceres 2003). But they have designed very different farming systems and developed contrasting strategies to interact with the wider context within which they operate. On the one hand, agroecological farmers have developed farming systems of very high diversity, use few external inputs, rely mostly on local markets, and are part of representative peasant farmer organizations. Tobacco growers, by contrast, manage less diverse agroecosystems, rely on external inputs provided by the tobacco industry, have a weak participation in local organizations, and are closely linked to external markets. (See Table 6.5.)

6.8.1.1 Agrobiodiversity

The number of domesticated animals and cultivated plants (agrobiodiversity) maintained by the two types of farmers is strikingly different. On average, agroecological farmers grow or raise three times as many species within a single farm as tobacco growers do. The total number of species in all surveyed farms is also very different: 97 species in the case of agroecological farmers and 41 species for tobacco growers. This indicates that agrecological farmers maintain a higher degree of heterogeneity among farms and a higher agrobiodiversity at the landscape-to-region level. Horticultural, aromatic, and medicinal crops and fruit trees are the most diverse categories both within and among farms.

Agrobiodiversity has a direct impact on food security (Altieri 1995). The more diverse farms are, the more likely they are to meet subsistence food needs. The opposite occurs in the case of farmers specialized in the production of commodities (such as tobacco), since most of the farm resources are allocated to a goal that does not strengthen local food security (Dewey 1979; Fleuret and Fleuret 1980). This situation is clearly observed in this case, where agroecological farmers grow more than three times as many species for food as tobacco growers do.

6.8.1.2 Technology

Agroecological farmers and tobacco growers also differ strongly in terms of farm technology. Although both draw on the same technological matrix (draft power and the use of fire to clear up land), the "final" technologies used in their farms are very different (Cáceres 2003). In order to produce their cash crop, tobacco growers rely on modern technology and a conventional approach to farming. This involves the use of high external input technology (chemical pesticides and fertilizers and high-yield seeds) and monocropping. Nearly all the inputs needed for tobacco production come from the market. Because tobacco growers have an extremely limited financial capacity, they rely on the credit provided by tobacco companies, which in turn buy the tobacco leaves from them, in a typical contract-farming relationship.

In contrast, the technology used by agroecological farmers rests mostly on the understanding and management of natural processes and cycles. Rather than relying on external inputs, they maximize the use of both local and agroecological knowledge and resources that are locally available. As a consequence of both their traditions and the extension work of development agencies, the use of raised beds, composting practices, intercropping, biological pest control, and crop rotation is common among the agroecological farmers (Rosenfeld 1998). In order to gain access to this technology, these farmers do not need to develop a heavy reliance on the market, nor do they require the financial support of the agroindustry.

6.8.1.3 Scale Interactions

The socioeconomic and institutional context, in particular of markets and organization, is another key element shaping the vulnerability of rural societies. Tobacco growers in the Misiones have a less diversified relationship with the markets, since the tobacco companies are the main social actor with whom they interact. This is the highly asymmetrical relationship that typically develops in contract farming (Watts 1990). Tobacco growers are unable to make the most important farming decisions (such as how many tobacco plants to have, or which varieties), negotiate the quality and price of their tobacco with the agroindustry, or even decide which company to sell their product to.

The contacts of agroecological farmers with the agroindustry, on the other hand, are weak, and they are mostly linked to NGOs and governmental programs fostering rural sustainable development. Agroecological farmers have substantial control over the productive decisions concerning their farms and have developed a more diversified relationship with the market. They sell their production through different channels, of which the organic farmers' markets is the main one. In these markets, farmers and consumers meet once a week, when they set the price and other aspects of the commercial transactions. The wider range of products that agroecological farmers bring to the market also allows more spreading of commercial risks and thereby has a favorable impact on the stability of their cash flow.

The differences among these two types of farmers are even more noteworthy in terms of their participation in local organizations. Agroecological farmers not only relate with a higher number of organizations, they are also part of a larger number of grassroots representative organizations committed to peasant interests and civil rights. In contrast, tobacco growers are almost exclusively related to the Tobacco Growers' Association of Misiones, a highly bureaucratized organization that primarily represents tobacco company-interests (Schiavoni 2001). Yet the participation of tobacco growers in this organization is compulsory in order to be able to sell their tobacco to the agroindustry.

6.8.1.4 Synthesis: Differential Vulnerability

Agroecological farmers and tobacco growers share many key social and productive features. Both types of farmers and the envi-

Table 6.5. Differences between Agroecological Farmers and Tobacco Growers in Terms of Agrobiodiversity, Food Safety, Links with Markets, and Representative Organizations (P< 0.001, Mann-Witney U test for independent samples) (Cáceres 2003)

	Agroecological Farmers			Tobacco Growers		
Variable	Median	Minimum	Maximum	Median	Minimum	222
Total number of plant and animal species grown or raised on the farm	40	21	54	14	7	82
Number of species grown or raised for family consumption	28	18	42	10	4	11
Number of species sold in the market	5	3	10	2	1	1
Participation in organizations (number)	2	1	5	1	1	1

ronment in which they develop their farming strategies may be regarded as "vulnerable." However, as this case illustrates, factors shaping vulnerability can come together in a variety of ways that result in substantial variations in the magnitude and types of vulnerability, even among a group such as small-scale farmers, who are often assumed to be homogeneous.

Given these differences in vulnerability, the agroecological farmers appear less vulnerable overall than tobacco growers. Differences in agrobiodiversity, technology, and articulation to the wider context are the main factors underpinning this contrast. On the one hand, agroecological farmers appear to have developed more autonomous and resilient livelihood strategies. They manage more diverse and stable agroecosystems, produce more food, and show a stronger negotiating capacity within the political process. The strategy of tobacco growers, in contrast, depends far more on the agroindustry. They produce less food, have very limited negotiation power, and are more exposed to the control of tobacco companies and the fluctuations of tobacco prices and industry.

All this suggests that livelihood strategies used by different groups can dramatically increase or decrease their level of vulnerability. Since the articulation to the wider context is a key aspect in determining the vulnerability of poor farmers, the latter can change drastically due to external factors, no matter how "sensible" the within-farm decisions. This suggests that vulnerability involves the amplification and attenuation of a variety of conditions that depend on both internal and external circumstances, and that vulnerability changes over time with changing stresses or needs in households or with wider socioeconomic and political changes that increase or decrease access to various assets and opportunities.

6.8.2 Vulnerability and Resilience in Southern Africa: Perspectives from Three Spatial Scales

The southern African region is currently facing a suite of complex emergencies driven by a mix of factors, including HIV/AIDS, conflict, land tenure, governance, and lack of access to resources, coupled with climate risks—not least of which is the emergence of floods as a serious hazard (Mano et al. 2003; Vogel and Smith 2002; IPCC 2001a). Existing adaptive capacity is also, arguably, being increasingly eroded and undermined by such factors. The World Food Programme has recently estimated that around 14 million people in the region are in a heightened food insecurity situation (Morris 2002). Contributing factors emerging from this situation include, among others, low opening stocks of cereals from previous years, low grain reserves in some countries, low levels of preparedness for such food insecurity, and inappropriate and constraining policies that contributed to market failures (Mano et al. 2003).

This case examines the multiple roles of global environmental change as part of a complex suite of stressors (such as climate, governance, and health) and adaptation to such stressors in South Africa, using the 2002/03 famine situation in the Southern African Development Community as a backdrop. The theme of resilience and adaptation in the face of global change (Adger 2000) is analyzed at three spatial scales, moving from the regional (SADC) level to the district and community levels, focusing particularly on the role of information as a potential input into building sustainability. The greatest priority in such an investigation is less one of describing the problem than it is interactively crafting appropriate sustainable interventions. (No suitable "sustainable" interventions can be designed in isolation of the institutions and stakeholders involved.)

6.8.2.1 The SADC Region 2002/03 Season: Coping with Complex Environmental Stress

The contributions of various socioeconomic and political factors, often generated outside the region, have long been acknowledged to contribute to the complexities associated with climate stress and food insecurity facing Southern Africa (Benson and Clay 1998). Several of these myriad of factors usually become particularly important during a severe dry spell, flood, or other climate-driven event.

In response to the droughts of the 1970s, 1980s, and 1990s, international organizations, bilateral donors, African governments and NGOs established numerous early warning systems and enlarged institutional capacity to manage food security and risks (Moseley and Logan 2001). These entities have been actively undertaking efforts to reduce vulnerability to a number of risk factors in the region. A clear activity has been to examine current risks and threats primarily relating to drought-induced production deficits and to provide improved climate information to serve the agricultural sector (see, e.g., Archer 2003).

Another priority has been not only to increase the understanding of food provision and production but also to improve assessments of food procurement and access to food by households in the region (e.g., see Devereux 2000; Vogel and Smith 2002) and the factors (such as institutions, governance, and policy issues) that enhance or constrain access to food. The contributions of adverse synergies, including natural triggers (such as drought) and politics (such as civil stress) that have precipitated famines (Devereux 2000), have in some cases become more prevalent and endemic in sub-Saharan Africa.

A number of interesting adaptive measures have emerged from assessments undertaken of the 2002/03 famine in the region (see www.fews.net). Vulnerability assessments show, for example, that cereal production is sometimes not a key activity in procuring food in risk-prone households. Rather, it is food purchases and other inputs (remittances, gifts, and so on) that enable households to obtain food. Such insight on adaptation practices has only emerged from detailed food economy investigations. Such studies reveal and question the role of "food relief" as an intervention strategy in reducing the impacts of the crisis. Furthermore, the role of HIV/AIDS in aggravating the situation in several households is also emerging as a strong and negative factor (SADC FANR Vulnerability Assessment Committee 2003).

With the background of this regional scale, vulnerabilities to a similar suite of risks (including climate, management, and other factors) can be understood at the scale of South Africa and Limpopo Province. These case studies clearly show that, similar to the regional examples described earlier, a well-intentioned focus on early warning can do little to enhance resilience to risks if it is not coupled with a careful examination of the wider socioeconomic environment in which such activities operate (such as the policy environment, or institutional strengths and weaknesses), consistent with the northern Argentina case.

6.8.2.2 South Africa, 2002/03 Season—The National Scale

An unusually dry 2002/03 summer rainfall season caused widespread livestock mortality and water scarcity for growing crops in Limpopo, Mpumalanga, and North West Provinces in South Africa. In Limpopo, the provincial government requested 40 million rand in drought relief from the National Department of Agriculture, in addition to 6 million rand of provincial emergency funding that was made available (largely for subsidized fodder). Official estimates were that drought-related cattle mortalities exceeded 18,000.

A range of potentially valuable mechanisms to promote drought mitigation and risk reduction was, however, in place. Institutions and mechanisms included the Agricultural Risk Management Directorate, whose Early Warning Subdirectorate was substantively involved in improving awareness of early warning in the agricultural sector. The Early Warning Subdirectorate was established to improve forecast dissemination to smallholder farmers after forecasters and decision-makers realized that the information did not reach any further than provincial departments of agriculture (Archer and Easterling 2004). In addition, the National Agrometeorological Committee was established as a forum for reviewing updated seasonal outlook and provincial reports regularly throughout the season.

Essentially, the seasonal warning advisory was developed and disseminated at least to the provincial level in South Africa for the 2002/03 season. In spite of this, the adverse effects of climatic risk were substantial. Accepting that further investigation is required (and is planned), some preliminary observations on the 2002/03 season at the national scale in South Africa are possible.

As is well documented in a variety of case studies, forecasts, warnings, and information were in themselves insufficient to ensure action to improve resilience to environmental stress. In this case study, failures may have occurred in dissemination (for example, forecast information may not have been disseminated to extension officers or farmers). There may also have been failures in response capacity—even had farmers heard the seasonal warning, they may, for a variety of reasons, have been constrained in their ability to take anticipatory action (such as destocking). Last, there may have been weaknesses in institutional capability as well as weaknesses of ''fit'' and ''interplay'' between what institutions are providing and what is required (see, e.g., Folke et al. 1998; Berkes and Folke 1998; Orlove and Tosteson 1999; Raskin et al. 2002). Even with effective information dissemination, provincial, municipal, and local institutions may themselves be constrained in their ability to either recommend or support appropriate actions to improve resilience.

6.8.2.3 Vhembe District, Limpopo Province, 2002/03 Season

Results from research at the district and local level in Vhembe district of Limpopo Province show where gaps and weaknesses existed with regard to improved resilience to climatic risk in the 2002/03 season. It appears that this was the first season that the surveyed community (first surveyed in 2000/01) had exposure to seasonal forecast information. The Vhembe District Department of Agriculture and the District Department of Water Affairs and Forestry also received the forecast. Yet both at the community level and at the district institutional level, little response was apparent. Identifying the reasons for the lack of action is key to understanding the adverse drought effects at the national and provincial level described earlier.

First, it is clear that the forecast alone was insufficient, both for the needs of farmers and for district institutions. Both farmers and institutions explicitly asked for more guidance in terms of what actions might be appropriate in the light of the forecast or warning information. Farmers requested, for example, that when the seasonal forecast (or severe weather warning) was broadcast over the radio, the announcement needed to be coupled with an advisory. Such an advisory could include a wide range of general advice at various scales—at the district level, for instance, information on planting dates; at the farm level, very specific information on cultivars and planting. The District Department of Agriculture asked that the existing agricultural advisory be further developed and refined for local district conditions. The District Department of Water Affairs and Forestry requested that the agricultural advisory be adapted for the water sector (and for other climate-sensitive sectors as well, such as health).

Second, farmers themselves may have been constrained in their ability to respond to information about climatic stress. The most commonly documented constraint on response capacity was resource limitation, including lack of access to credit, supplemental irrigation, land, and markets as well as lack of decision-making power (particularly in the case of women farmers) (Archer 2003). Further research in the area is seeking to understand the precise role of resource limitations and misdirected inputs (such as inappropriate irrigation infrastructure) in constraining both the ability to respond to forecasts and warnings and, more important, the ability to increase resilience and adaptive capacity.

There are also, however, encouraging signs in Vhembe district and at the national scale in South Africa of building adaptive capacity under conditions of climatic (and environmental) stress. Progress has been made in the dissemination of the forecast to district institutions and to the community level. And intermediary mechanisms described at the national scale (such as the programs under the Directorate of Agricultural Risk Management) show promise. There are signs that research on ways to improve adaptive capacity in South Africa is becoming increasingly well positioned to produce generalized recommendations that may inform policy.

6.8.2.4 Synthesis: Cross-scale Interactions and Multiple Stressors

The results from this case suggest that although gaps and weaknesses were evident in the ability of entities at different scales to decrease vulnerability to the emergence of multiple stressors, success stories were also apparent. In this example it is clear that the spatial scale is a valuable unit of analysis. The level of interplay, however, between scales of ''intervention'' is equally important (e.g., Orlove and Tosteson 1999).

This example illustrates the ''misfit'' between scales of research and intervention, between what is investigated and what is required. This example points to a greater understanding of these complex issues, particularly in a region undergoing complex shocks and stressors, and the deeper interrogation that is required of the range of institutional responses that may be needed to manage these systems effectively. The South African Weather Service, as the official national forecast producer, works with other forecast producers at the international and national levels to derive a multiple-sourced seasonal outlook, containing three-month rainfall and temperature forecasts. The forecast, looking specifically at the agricultural sector, is disseminated to the National Department of Agriculture and from there to provincial, district, ward extension, and finally farm level.

The process of sub-provincial dissemination of the forecast is still in progress. There are three areas of on-going activity to improve the system: the process of combining multiple source forecasts, the role of the National Disaster Management Centre in receiving forecasts and coordinating response in appropriate areas and sectors, and the sub-provincial receipt of, and response to, the forecasts.

At present, however, there remains a misfit between what is currently being provided by the forecast producers and the suggested requirements from the agricultural sector within the provincial levels. From the province down to ward level extension, suggested forecast information differs from the three-month temperature and rainfall forecasts provided from the national and international levels. Finer levels suggest information be provided on seasonal quality (such as information on intra-seasonal variability), advisories coupled to forecasts, retroactive forecast applications, and impact-specific interpretation of forecasts (Orlove and Tosteson 1999). To reiterate, the system is highly dynamic and should be seen as evolving. The key question remains how to best intervene to aid a system in building resilience to sustain socioecological systems under conditions of environmental stress and surprise.

6.8.3 The Benefits of Reducing Vulnerability in Bundelkhand, India

The Bundelkhand region in the central highlands of India consists of semiarid plateau land. Rising population, subsequent agricultural expansion, and increased demand for wood has led to rapid deforestation in the region, which together with poor land management practices and government-approved commercial logging has aggravated soil erosion and ecological degradation. Erratic rainfall coupled with soil erosion has further reduced soil productivity and contributed to crop failure, and the area is now highly degraded (EcoTech Services 1997). (This paper draws on EcoTech Services 1999; the study was carried out to support the Uttar Pradesh state government initiatives in the area, under a grant from the Government of the Netherlands.)

The region has some of the lowest levels of per capita income and human development in India. Illiteracy and infant mortality rates were high, and local inhabitants depended on rain-fed single-crop agriculture and small-scale livestock production. The forests that were the traditional source of livelihood have largely disappeared.

Lalitpur district lies at the heart of the Bundelkhand region. The main monsoon crops grown in the district are maize, gram, and groundnut, while the main winter crops are wheat, peas, and gram. Most people collect green fodder from their own land during kharif and feed harvest remains to the animals in rabi and summer. Harvest is sold as dry fodder. Most households use the same well through the year, and it takes approximately two hours per household to collect water each day. Nonavailability of potable water is a major problem across the district (EcoTech Services 1997).

6.8.3.1 Watershed Management

A technical plan for the Donda Nala watershed in Lalitpur district was drawn up, aimed at land treatment and drainage line treatment measures (EcoTech Services 1997). Land treatment measures sought to reduce the loss of topsoil and to augment rainwater retention and biomass production. Measures such as embankments, earthen gully (channel) plugs, and agroforestry were deemed applicable to cultivated land, while silvipasture was deemed applicable to uncultivated lands. Drainage treatments suggested by the plan included mechanical measures such as the construction of dams and surface water storage tanks. Long-term benefits envisioned from these measures were retention of topsoil and an increase in the moisture-retaining capacity of soil. The technical plan estimated that the high-grade lands in the watershed would show increased crop yields by about 50% in the first five years as a result of such improvements.

6.8.3.2 Quantifying Benefits

Benefits projected from the watershed management activities included increased productivity of land, improvement in the health of animals due to increased fodder availability, better access to drinking water, increased employment, lower rates of soil erosion, and stabilizing environmental degradation. For the economic analysis in the plan, the benefits were summarized as irrigation benefits, benefits from vegetative treatments, drinking water benefits, and employment benefits. (The assessment did not attempt to evaluate environmental and health benefits, which are more complex to quantify.)

Farmers realized benefits from cultivation in the form of increased profits. The incremental net profit was computed as the difference between current profits and potential future profits from cultivation. Assuming that prices would remain constant, profits in the future were estimated on the present value of future cultivation. It was estimated that the average annual incremental profit would be 3,910,700 rupees (or 1,450 rupees per acre) as a result of additional water on existing farmlands. It was estimated that there would be additional benefits due to cultivation on marginal lands due to a further 257 hectares coming under cultivation during monsoon and 90 hectares in winter. This value was estimated as 1,681,000 rupees.

Vegetative treatments led to increased biomass in the form of fodder, firewood, and timber. Locally accepted species were identified for long-term community-managed common land. The estimates from increased fodder availability were based on fodder collection amounts. The incremental production of dry fodder or crop residues was valued at the existing market rate and estimated at 777,800 rupees for the watershed as a whole. A detailed cost-benefit estimation of silvipastural treatments planned in the wastelands for a period of 30 years was also assessed to compute the net present value of the future stream of benefits. Some 420 hectares of land were to be covered under the afforestation plan.

The potential benefits from better access to drinking water were valued by using the opportunity cost of time saved in water collection for women. Three open wells were proposed in the villages of Agar, Dhurwara, and Ghisoli. These sought to enhance women's participation in the project and to benefit families who lacked easy access to drinking water. The new wells were typically located near a cluster so that these families would not have to go more than a quarter of a kilometer. The estimated cost of digging wells in the watershed was 304,065 rupees, and the total value of time savings was 45,090 rupees for the year. The value of this is projected to rise over time as daily wages increase.

Given the labor requirements for each type of project activity, the market and opportunity costs for labor were determined. The benefits were calculated from activity-specific labor components of the technical work plan. Total incremental benefits from employment were valued at the prevailing wage rate. The employment benefits disbursed in the first two years of project activities were estimated at 5,480,000 rupees.

The projected present value of the future stream of the total annual benefits from each of the estimated components provides the overall value for the stream of benefits accruing from the project. The average projected present value of benefits per hectare was 47,461 rupees as opposed to an average project activity cost of 7,500 rupees per hectare. (See Table 6.6.) Assuming a 30-year horizon, the present projected value of the estimated benefits were computed using a 12% discount rate. The net present value of total benefits worked out to be over 100 million rupees for the entire watershed.

6.8.3.3 Synthesis: Distributional Issues

Most of the village community of Lalitpur district consists of small farmers and landless people. While the benefits from additional employment and access to drinking water are projected to directly enhance their quality of life, benefits from irrigation and green fodder production (which are the major source of benefits) are

Table 6.6. Total Benefits for Donda Nala Watershed (EcoTech Services 1997)

Project Activity	Total Undiscounted Benefits	Total Discounted Benefits
	(Rs crores)	
Irrigation	16.5620	3.5799
Digging wells	0.1300	0.0281
Employment	0.5476	0.4132
Silvipasture	24.4177	6.0871
Forestry	5.5876	0.3949
Total benefits	**47.2449**	**10.5320**

likely to accrue to those with land or cattle. The benefits will reach poorer households only if the access to treated wastelands and to harvest can be assured.

6.9 Implications for Assessment and Policy

The discussion and cases in this chapter emphasize that the patterns and dynamics that shape the vulnerability of coupled socioecological systems are composed of a multitude of linkages and processes. As such, assessments of vulnerability need to be comprehensive, sensitive to driving forces at different scales, but also appreciative of the differences among places.

A number of observations relevant to attempts to assess and reduce vulnerability and to build resilience may be offered. First, conceptual frameworks of vulnerability have improved, representing human and biophysical vulnerabilities as a coupled socioecological system. However, the relationships across scales and the role of specific actors (as drivers of systems) are poorly represented in most frameworks, and the existing state of knowledge is still weak. Different components of the coupled socioecological system may have quite different vulnerabilities and may experience exposure to stresses and perturbations quite differently. Diverse impacts are likely as a result; broad frameworks should not be taken as reliable guides to local conditions. The term vulnerability is still used in disparate ways in many assessments; a clear nomenclature is required to make assessments more consistent and coherent.

Second, the driving conditions of vulnerability have been well characterized at least at a general level. Human alterations of ecosystems and ecosystem services shape both the threats to which people and places are exposed and their vulnerabilities to the threats. The same alterations of environment can have very different consequences, depending on the differential vulnerability of the receptor systems.

Third, poverty and hazard vulnerability are linked and often mutually reinforcing by creating circumstances in which the poor and those with limited assets have few options but to exploit environmental resources for survival. At the same time, poverty and vulnerability are overlapping but distinct conditions, and they require analysis to determine overlaps and interactions.

Fourth, vulnerability can also be increased by the interaction of stresses over time. In particular, sequences of stresses that erode coping capacity or lengthen recovery periods can have long-term impacts that still often are not adequately treated in many assessments. Capturing these dynamics of vulnerability in assessment is an ongoing challenge.

Fifth, socioeconomic and institutional differences are major contributors to patterns of differential vulnerability. The linkages among environmental change, development, and livelihood are attracting increasing attention as a nexus in building resilient communities and strengthening adaptive capacity, but existing knowledge is still uneven and not well developed.

Sixth, despite this general level of explanation, it is still difficult to document adequately the effects of different changes upon different human groups with precision. While environmental changes and natural disasters are affecting increasing numbers of people, the existing knowledge base of vulnerability and resilience is highly uneven, with much known about some situations and very little about others. Some of the most vulnerable peoples and places are those about which the least is known. New vulnerabilities may be realized in the future, as in the dramatic increase of flooding damages in Africa or the effects of HIV/AIDS as a compounding factor in livelihood security. Filling the major gaps is a high priority in improving current assessments.

Seventh, assessment methods are improving. Entering vulnerability assessments at different scales of analysis, and particularly the local scales of place-based assessments, holds potential for greater depth and understanding of the complexity and dynamics of changing vulnerability.

Finally, despite the limitations of theory, data, and methods, sufficient knowledge exists in most regions to apply vulnerability analysis to contemporary problems of ecosystem management and sustainable development in order to provide useful information to decision-makers and practitioners.

Main Messages

Global freshwater use is estimated to expand 10% from 2000 to 2010, down from a per decade rate of about 20% between 1960 and 2000. These rates reflect population growth, economic development, and changes in water use efficiency. Projections that this trend will continue have a high degree of certainty. Contemporary water withdrawal is approximately 3,600 cubic kilometers per year globally or 25% of the continental runoff to which the majority of the population has access during the year. If dedicated instream uses for navigation, waste processing, and habitat management are considered, humans then use and regulate over 40% of renewable accessible supplies. Regional variations from differential development pressures and efficiency changes during 1960–2000 produced increases in water use of 15–32% per decade.

Four out of every five people live downstream of, and are served by, renewable freshwater services, representing 75% of the total supply. Because the distribution of fresh water is uneven in space and time, more than 1 billion people live under hydrologic conditions that generate no appreciable supply of renewable fresh water. An additional 4 billion (65% of world population) is served by only 50% of total annual renewable runoff that is positioned in dry to only moderately wet conditions, with concomitant pressure on that resource base. Only about 15% live with relative water abundance.

Forest and mountain ecosystems serve as source areas for the largest amounts of renewable freshwater supply—57% and 28% of total runoff, respectively. These ecosystems each provide renewable water supplies to at least 4 billion people, or two thirds of the global population. Cultivated and urban ecosystems generate only 16% and 0.2%, respectively, of global runoff, but because of their close proximity to human settlements, they serve 4–5 billion people. Such proximity is also associated with nutrient and industrial water pollution.

From 5% to possibly 25% of global freshwater use exceeds long-term accessible supply. Overuse implies delivery of freshwater services through engineered water transfers or nonrenewable groundwater supplies that are currently being depleted. Much of this water is used for irrigation with irretrievable losses in water-scarce regions. All continents record overuse. In the relatively dry Middle East and North Africa, non-sustainable use is exacerbated, with current rates of freshwater use equivalent to 115% of total renewable runoff. In addition, possibly one third of all withdrawals come from nonrenewable sources, a condition driven mainly by irrigation demand. Crop production requires enormous quantities of fresh water; consequently, many countries that aim at self-sufficiency in food production have entrenched patterns of water scarcity. Alternatively, crops can be traded on global food markets, with some countries accruing substantial benefits from importing "virtual water" that would otherwise be required domestically to irrigate crops.

The water requirements of aquatic ecosystems in the context of expanding human freshwater use results in competition for the same resources. Changes in flow regime, transport of sediments and chemical pollutants, modification of habitat, and disruption of migration routes of aquatic biota are some of the key consequences of this competition. In many parts of the world, competition for fresh water has produced impacts that fully extend to the coastal zone, with effects including oxygen depletion, coastal erosion, and harmful algal blooms. Through consumptive use and interbasin transfers, several of the world's largest rivers (the Nile, the Yellow, and the Colorado in the United States) have been transformed into highly stabilized and in some cases seasonally nondischarging river channels.

The supply of fresh water continues to be reduced by severe pollution from anthropogenic sources in many parts of the world. Over the past half-century, there has been an accelerated release of artificial chemicals into the environment. Inorganic nitrogen pollution of inland waterways, for example, has increased substantially, with nitrogen loads transported by the global system of rivers rising more than twofold over the preindustrial state. Increases of more than tenfold are recorded across many industrialized regions of the world. Many anthropogenic chemicals are long-lived and transformed into by-products whose behaviors, synergies, and impacts are for the most part unknown as yet. As a consequence of pollution, the ability of ecosystems to provide clean and reliable sources of fresh water is impaired. Severe deterioration in the quality of fresh water is magnified in cultivated and urban systems (high use, high pollution sources) and dryland systems (high demand for flow regulation, absence of dilution potential).

The demand for reliable sources of fresh water and flood control has encouraged engineering practices that have compromised the sustainability of inland water systems and their provision of freshwater services. Prolific dam-building (45,000 large dams and possibly 800,000 smaller ones) has generated both positive and negative effects. Positive effects on human well-being have included flow stabilization for irrigation, flood control, drinking water, and hydroelectricity. Negative effects have included fragmentation and destruction of habitat, loss of species, health issues associated with stagnant water, and loss of sediments and nutrients destined to support coastal ecosystems and fisheries.

Water scarcity is a globally significant and accelerating condition for 1–2 billion people worldwide, leading to problems with food production, human health, and economic development. A high degree of uncertainty surrounds these estimates, and defining water scarcity merits substantial further analysis in order to support sound water policy formulation and management. Rates of increase in a key water scarcity measure—water use relative to accessible supply—from 1960 to present averaged nearly 20% per decade globally, with values of 15% to more than 30% per decade for individual continents. Inequalities in level of economic development, education, and governance result in differences in coping capacity for water scarcity.

The annual burden of disease from inadequate water, sanitation, and hygiene totals 1.7 million deaths and the loss of at least 50 million healthy life years. Some 1.1 billion people lack access to safe drinking water and 2.6 billion lack access to basic sanitation. Investments in drinking water supply and sanitation show a close correspondence with improvement in human health and economic productivity. Each person needs only 20 to 50 liters of water free of harmful contaminants each day for drinking and personal hygiene to survive, yet there remain substantial challenges to providing this basic service to large segments of the human population. Half of the urban population in Africa, Asia, and Latin America and the Caribbean suffers from one or more diseases associated with inadequate water and sanitation.

The state of freshwater resources is inadequately monitored, hindering the development of indicators needed by decision-makers to assess progress toward national and international development commitments. Substantial deterioration of hydrographic networks is occurring throughout the world, increasing the difficulty of making an accurate assessment of global freshwater resources. The same is true for groundwater monitoring, standard water quality monitoring, and freshwater biological indicators. New techniques make it possible to identify literally thousands of chemicals, including long-lived synthetic pharmaceuticals, in freshwater resources. But universal application of these techniques is lacking, and there are no systematic epidemiological studies to understand their impact on long-term human well-being.

Trade-offs in meeting the Millennium Development Goals and other international commitments are inevitable. It is *very certain* that the condition of inland waters and coastal ecosystems has been compromised by the conventional sectoral approach to water management, which, if continued, will jeopardize human well-being. In contrast, the implementation of the established ecosystem-based approaches adopted by the Convention on Biological Diversity, the Convention on Wetlands, the Food and Agriculture Organization, and others could substantially improve the future condition of water-provisioning services by balancing economic development, ecosystem conservation, and human well-being objectives.

7.1 Introduction to Fresh Water as a Provisioning Service

This chapter provides a picture of the recent history and contemporary state of global freshwater provisioning services. It documents a growing dependence of human populations on these services, which has resulted in a variety of activities aimed at stabilizing and delivering water supplies. So effective has been the ability of water management to influence the state of this resource, in terms of both its physical availability and chemical character, that anthropogenic signatures are now evident across the global water cycle. Much of this influence is negative due to overuse and poor management. The capacity of ecosystems to sustain freshwater provisioning services is thus strongly compromised throughout much of the world and may continue to remain so if historic patterns of managed use persist.

7.1.1 Fresh Water in the MA Context

Within the MA conceptual framework (see Chapter 1), water is treated as a service provided by ecosystems as well as a system (inland waters). Because the water cycle plays so many roles in the climate, chemistry, and biology of Earth, it is difficult to define it as a distinctly supporting, regulating, or provisioning service. Precipitation falling as rain or snow is the ultimate source of water supporting ecosystems. Ecosystems, in turn, control the character of renewable freshwater resources for human well-being by regulating how precipitation is partitioned into evaporative, recharge, and runoff processes. Together with energy and nutrients, water is arguably the centerpiece for the delivery of ecosystem services to humankind (Falkenmark and Folke 2003).

While recognizing the role of water in supporting and regulating services, the placement of this chapter among other provisioning services is done from a practical point of view, in part because water resources are the most tangible and well-documented aspect of this broader spectrum of freshwater services. This chapter assesses the condition and recent trends in global freshwater resources, examining the amount and condition of renewable and nonrenewable surface and groundwater supplies, changes in these supplies over time and into the near future, and the impacts on human well-being of changes in the service. Chapter 20 examines the role of inland water ecosystems that provide a multitude of services, including water, fish, habitat, cultural and aesthetic values, and flood prevention. Because fresh water is so essential to life on Earth, its assessment overlaps with services and ecosystem chapters across the MA.

Throughout this chapter reference is made to summary statistics on the fresh water associated with specific ecosystems. While ecosystems are strongly dependent on the water cycle for their very existence, at the same time these systems represent domains over which precipitation is processed and transferred back to the atmosphere as ''green water'' (through evapotranspiration drawn from soils and plant canopies in natural ecosystems and rain-fed agriculture). The remainder runs off as ''blue water'' which constitutes the renewable water supply that can pass to downstream users—both aquatic ecosystems and humans such as farmers who irrigate. These water flows can be tabulated across ecosystems to identify areas that are critical to human well-being as well as those that require particular attention in designing strategies for environmental protection. Box 7.1 defines key terms used in this analysis.

7.1.2 Setting the Stage

Prior to the twentieth century, global demand for fresh water was small compared with natural flows in the hydrologic cycle. With population growth, industrialization, and the expansion of irrigated agriculture, however, demand for all water-related goods and services has increased dramatically, putting the ecosystems that sustain this service, as well as the humans who depend on it, at risk. While demand increases, supplies of clean water are diminishing due to mounting pollution of inland waterways and aquifers. Increasing water use and depletion of fossil groundwater adds to the problem. These trends are leading to an escalating competition over water in both rural and urban areas. Particularly important will be the challenge of simultaneously meeting the food demands of a growing human population and expectations for an improved standard of living that require clean water to support domestic and industrial uses.

Meeting even the most basic of needs for safe drinking water and sanitation continues to be an international development priority. Some 1.1 billion people lack access to clean water supplies and more than 2.6 billion lack access to basic sanitation (WHO/UNICEF 2004). Reducing these numbers is a key development priority. By adopting the initial targets of the Millennium Development Goals, governments around the world have made a commitment to reduce by half the proportion of people lacking access to clean water supply and basic sanitation between 1990 and 2015.

The ministerial declaration from the 2nd World Water Forum in The Hague in 2000 captured the essence of the goals and challenges faced (see Box 7.2), including articulation of the importance of ecosystems in sustaining freshwater services. Water continues to rise in importance in major policy circles, with 2003 declared the International Year of Fresh Water, release of the first World Water Development Report (UN/WWAP 2003) by a collaboration of 24 U.N. agencies through the World Water Assessment Programme, and proclamation by the UN General Assembly of the International Decade of Action ''Water for Life'' in 2005–15.

Societies have benefited enormously through their use of fresh water. However, due to the central role of water in the Earth system, the effects of modern water use often reverberate throughout the water cycle. Key examples of human-induced changes include alteration of the natural flow regimes in rivers and waterways, fragmentation and loss of aquatic habitat, species extinction, water pollution, depletion of groundwater aquifers, and ''dead zones'' (aquatic systems deprived of oxygen) found in many inland and coastal waters. Thus, trade-offs have been made—both explicitly and inadvertently—between human and natural system requirements for freshwater services.

The challenge for the twenty-first century will be to manage fresh water to balance the needs of both people and ecosystems, so that ecosystems can continue to provide other services essential for human well-being. Human impacts on the capacity of ecosystems to continue delivering freshwater services are assessed in

BOX 7.1

Operational Definitions of Key Terms on Fresh Water

The global water cycle involves major transports that link Earth's atmosphere, land mass, and oceans, though the emphasis in this chapter is on the continental hydrologic cycle. The Figure here outlines the major fluxes of fresh water, which help to define the renewable supplies on which humans and ecosystems depend. The water cycle can be divided into a portion that is accessible to humans and that which is not. The portion of the global water cycle that is accessible to humans is shown in the diagram. The following nomenclature is used throughout this chapter.

Total Precipitation (P_t). This term is equivalent to the total sustainable water supply falling as rain and snow over the terrestrial portion of Earth. P_t represents the ultimate source of fresh water for recharge into soils, evaporation, and transpiration by plants in natural and cropped ecosystems, recharge into groundwaters, and, eventually, runoff and discharge through river corridors. For the purposes of this study, P_t represents climatic means, unless otherwise noted. P_t can be divided into precipitation that is accessible (P_a) or inaccessible (P_i) to humans on the land mass. Ocean precipitation is denoted as P_o.

Total Blue Water Flow (B_t). This term represents the global renewable water supply computed as surface and sub-surface runoff. "Total" here refers to "blue water" that is both accessible and inaccessible to humans. It is a subcomponent of P_t, representing the net fresh water remaining after accounting for evapotranspiration (ET) losses to the atmosphere from the soils and vegetation of natural ecosystems and rain-fed agriculture, known as "green water" (G_t). Blue water represents the sustainable supply of fresh water that emanates from ecosystems and is then transferred through rivers, lakes, and other inland aquatic systems. These downstream ecosystems evaporate and consume water (C_{iws}) and reduce blue water flows. In basins occupied by humans, accessible blue water (B_a) is further reduced (B_a') through consumptive losses (C_a) from water resource management, such as irrigation.

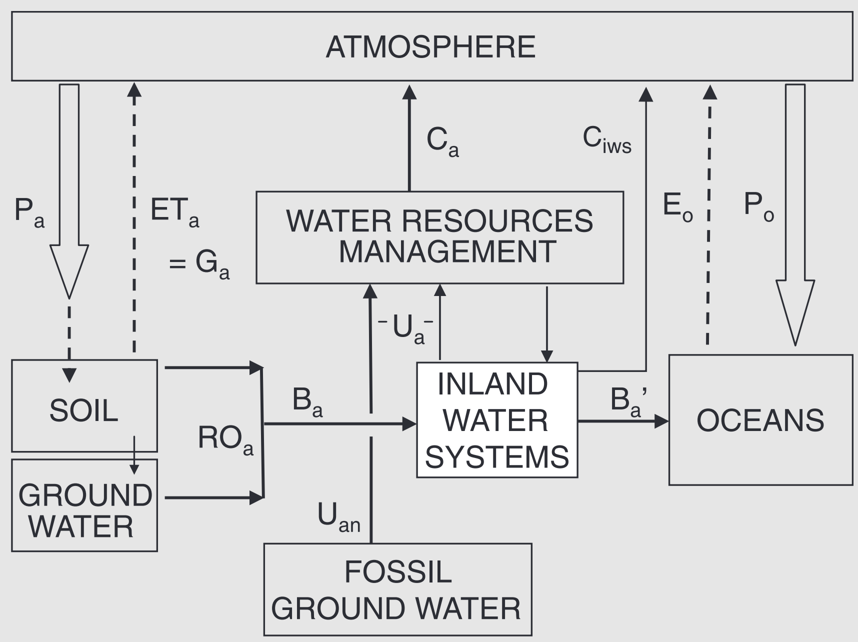
Water Use (U_a). This represents water withdrawn or used by humans. U_a is derived from either accessible blue water flows (B_a) or nonrenewable sources, predominantly fossil groundwater mining, which constitutes a non-sustainable water use. Use is divided into domestic (D_a), industrial (I_a), and agricultural (A_a) applications, a part of which can be returned to inland water systems, though sometimes degraded in its quality in such return flows.

Water Consumption (C_a). The portion of water that is lost as net evapotranspiration after being withdrawn from an accessible supply source (U_a). Such losses are associated predominantly with irrigation, and emerge from both renewable and nonrenewable freshwater supplies. C_a is also referred to as irretrievable losses. While humans "consume" water directly for drinking, this is not termed water consumption but simply a component of domestic water use tabulated under U_a.

Non-sustainable Water Use (U_{an}). This is computed by comparing total water demand or withdrawals for human use (U_a) to the available renewable water supply (B_a). Where U_a exceeds B_a at the point of extraction, non-sustainable use is tabulated. For most parts of the planet, this will refer to the "mining" of groundwaters, especially in arid and semiarid areas, where recharge rates to the underground aquifer are limited. U_{an} can also embody the interbasin transport of fresh water from water rich to water poor areas.

Environmental Flows. These are the water requirements needed to sustain freshwater ecosystems.

Water Abundance and Scarcity. The conjunction of renewable freshwater supply, withdrawals, consumptive losses, and level of development can be used to define quantitative measures of water abundance or scarcity. The number of people supported on a unit of renewable freshwater flows (the "water crowding" index) will define thresholds of chronic water scarcity, as will use-to-supply ratios (U_a /B_t or U_a / B_a).



Chapter 20. Some options on balancing human and ecosystem water requirements are discussed in Chapter 7 of the MA *Policy Responses* volume.

Before describing the details of this chapter's assessment, a word is in order on the quality of information on which it is based. Monitoring the continental water cycle in a timely manner at the global scale using traditional discharge gauging stations—the mainstay of water resource assessment—continues to challenge the water sciences (IAHS 2001; NRC 1999; Kanciruk 1997). Data collection is now highly project-oriented, yielding often poorly integrated time series of short duration, restricted spatial coverage, and limited availability. In addition, there has been a legal assault on the open access to basic hydrometeorological data sets, aided in large measure by commercialization and fears surrounding piracy of intellectual property. Delays in data reduction and release (up to several years in some places) are also prevalent. Much information has yet to be digitized, and exists in difficult-to-use book and report formats.

Based on available global archives at the WMO Global Runoff Data Center, to which member states contribute voluntarily, there was arguably a better knowledge of the state of renewable surface water supplies in 1980 than today. Such statements apply to many parts of the world, including otherwise well monitored countries like the United States and Canada (IAHS 2001; Shiklomanov et al. 2002), though most marked declines are in the developing world. Our understanding of groundwater resources is even more limited, since well-log, groundwater discharge/recharge, and aquifer property data for global applications are only beginning to be synthesized (Foster and Chilton 2003; UNESCO-IHP 2004). Information on water use and operation of infrastructure has never been assembled for global analysis (IAHS 2001; Vörösmarty and Sahagian 2000).

While remote sensing and models of the water cycle can be used to fill some data gaps, these approaches themselves produce a range of outputs arising from differences in their input data streams and detailed calculation procedures (e.g., Fekete et al.

BOX 7.2

Ministerial Declaration from the 2nd World Water Forum

The ongoing series of World Water Forums (Marrakech 1997, Hague 2000, Kyoto 2003, Mexico 2006), organized by the World Water Council and its partners, brings together a broad array of thousands of stakeholders to discuss strategies for sustainable development with respect to water. While there have been three such gatherings to date, outputs from the affiliated Ministerial Conference of the 2nd Forum are most relevant to the MA. This Ministerial Declaration captures the interconnections among ecosystem integrity, human actions affecting water supply, and human well-being. It is precisely these interactions that define the contemporary conditions and trends and that are suggestive of responses that foster water stewardship, sustainable water use, and progress toward development. These fundamental goals highlight the need for well-functioning ecosystems. They also reflect strongly the Millennium Development Goals:

- meeting basic human needs—that is, access to safe and sufficient water and sanitation, which are essential to health and human well-being;
- securing the food supply to enhance food security through a more efficient mobilization and use of water for food production;
- protecting ecosystems and ensuring their integrity through sustainable water resources management;
- sharing water resources to promote peaceful cooperation and develop synergies between the different uses of water within and between the states concerned;
- managing risks to provide security from floods, droughts, pollution, and other water-related hazards;
- valuing water to manage it in a way that reflects economic, social, environmental, and cultural values for all its uses; and
- governing water wisely to ensure good governance, including public participation.

2004). Without a sustained international commitment to baseline monitoring, global water assessments will be difficult to make and fraught with uncertainty. Box 7.3 gives the range of current estimates used in global water resource models, an uncertainty that in part arises from these data problems.

7.2 Distribution, Magnitude, and Trends in the Provision of Fresh Water

While it is true that there is an abundance of water across blue planet Earth, only a small portion of it exists as fresh water, and even a smaller fraction is accessible to humans. Nearly all water on Earth is contained in the oceans, leaving only 2.5% as fresh water. (See Table 7.1.) Of this small percentage, nearly three quarters is frozen, and most of the remainder is present as soil moisture or lies deep in the ground. The principal sources of fresh water that are available to society reside in lakes, rivers, wetlands, and shallow groundwater aquifers—all of which make up but a tiny fraction (tenths of 1%) of all water on Earth. This amount is regularly renewed by rainfall and snowfall and is therefore available on a sustainable basis.

Global averages fail to portray a complete picture of the world's water resource base, however. The basic climatology of the planet dictates that fresh water will be distributed unevenly around the globe, with abundant supplies across zones like the wet tropics and absolute water scarcity across the desert belts and in the rain shadow of mountains. For this assessment, both locally available runoff and water transported though river networks is considered (Vörösmarty et al. 2005). River corridor flows convey essential water resources to those living on the banks of large rivers, such as along the lower Nile. Figure 7.1 (in Appendix A) shows the broad range of sustainable water resources (blue water flows), which varies from essentially zero in many arid and semiarid regions to hundreds and thousands of cubic kilometers per year as major river corridor flow. Such regional differences in the quantity of available fresh water establish the diverse patterns of water supply across the globe.

The supply of fresh water is conditioned by several additional factors, which amplify the patterns of abundance and scarcity. These factors include the distribution of humans relative to the supply of water (that is, access to water), patterns of demand, presence of water engineering to stabilize flows, seasonal and interannual climate variations, and water quality. The following sections assess the state of global freshwater supplies, demands (withdrawals or use), and water quality. The time domain covered here is the last several decades and into the near future of 2010–15.

7.2.1 Available Water Supplies for Humans

Estimates of global water supply are imprecise and complicated by several factors, including differences in data and methodologies used, loss of hydrographic monitoring capacity, alternative time frames considered, and distortions from land cover, climate, and hydraulic engineering that are increasingly a part of the water cycle. The renewable resource base expressed as long-term mean runoff has been estimated to fall between 33,500 and 47,000 cubic kilometers per year (Korzoun et al. 1978; L'vovich and White 1990; Gleick 1993; Shiklomanov and Rodda 2003; Fekete et al. 2002; Nijssen et al. 2001; Döll et al. 2002). Within-year variations also define the basic nature of water supply. At the continental scale, maximum-to-minimum runoff ratios vary between 2:1 and 10:1 (Shiklomanov and Rodda 2003), with individual rivers experiencing ratios far higher, such as in snowmelt-dominated basins or episodically flooded arid and semiarid river systems. These variations necessitate flow stabilization through hydraulic engineering for either protection (for example, from floods) or seasonal supply augmentation (for example, for dry-season agriculture or hydroelectricity).

Water supply can also be assessed from the standpoint of societal access to renewable runoff and river flow, from which humans can secure provisioning services. By one estimate (Postel et al. 1996), one third of global renewable water supply is accessible to humans, when taking into account both its physical proximity to population and its variation over time, such as when flood waves pass uncaptured on their way to the ocean. Such accessibility is considered as part of this assessment later in this chapter.

Groundwater plays an important role in water supply. It has been estimated that between 1.5 billion (UNEP 1996) and 3 billion people (UN/WWAP 2003) depend on groundwater supplies for drinking. It also serves as the source water for 40% of self-supplied industrial uses and 20% of irrigation (UN/WWAP 2003). For certain countries this dependency is even greater; for example, Saudi Arabia meets nearly 100% of its irrigation requirements through groundwater (Foster et al. 2000). Two important classes of groundwater can be identified. The first is renewable groundwater resources, closely linked to the cycling of fresh water, through which the ground is periodically replenished when sufficient precipitation is available to recharge soils or when floodplains become inundated. The second, fossil groundwater, is

BOX 7.3

Uncertainties in Estimates of Contemporary Freshwater Services, Use, and Scarcity

All entries are ranges in the units indicated and represent near-contemporary conditions.

Geographic Region	Renewable Water Supply[a]	Total Withdrawals	Mean Water Crowding	Mean Use-to-Supply (U_a/B_t) Ratio	Population with U_a/B_t Ratio Greater than 40%
	(cu. km. per year)		(people/mill. m³/yr)	(percent)	(million)
Asia	7,850–9,700	1,520–1,790	320–384	16–22	712–1,200
Former Soviet Union	3,900–5,900	270–380	48–74	6–8	56–110
Latin America	11,160–18,900	200–260	25–42	1–2	84–160
North Africa/Middle East	300–367	270–370	920–1,300	74–108	91–240
Sub-Saharan Africa	3,500–4,815	60–90	115–160	2–2	16–140
OECD	7,900–12,100	920–980	114–129	8–12	164–370
World Total	**38,600–42,600**	**3,420–3610**	**133–150**	**8–9**	**1,123–2,100**

[a] For the purpose of this intercomparison, supply is total supply (B_t). See also Box 7.1 and Table 7.2.

The ranges reported here are from three global-scale water resource models, two of which were used directly in the MA: University of New Hampshire (Vörösmarty et al. 1998a; Fekete et al. 2002; Federer et al. 2003) for the Condition and Trends Working Group assessment and Kassel University (Alcamo et al. 2003; Döll et al. 2003) used in the Scenarios Working Group. A third model from the University of Tokyo and Global Soil Wetness Project (Oki et al. 2001, 2003b; Dirmeyer et al. 2002) was also compared.

The global-scale correspondence for total supply, withdrawals, water crowding, and demand-to-supply ratio is high, but masks continental-scale differences. Such disparities can be large, as for water supply in Latin America, where large remote tropical river systems have proved difficult to monitor systematically. Substantial differences at the continental scale are noted for population living under severe water scarcity (use-to-supply >40%). The order-of-magnitude range apparent for sub-Saharan Africa can be linked in part to the distribution of sharp climatic gradients that are difficult to analyze geographically. The result is also a function of the assumptions made regarding access to water. Because of such uncertainties, the current state-of-the-art in global models put 1–2 billion people at risk worldwide arising from high levels of water use. The MA models predict a much smaller range, from 2.0–2.1 billion.

Large uncertainties surround current estimates of water consumption by the largest user of water, agriculture. Recent estimates vary from 900 (Postel 1998) up to 2000 cubic kilometers per year (Shiklomanov and Rodda 2003). A value of 1200 cubic kilometers per year is reported in this assessment (Table 7.4).

Table 7.1. Major Storages Associated with the Contemporary Global Water System (Shiklomanov and Rodda 2003)

Type	Volume	Fraction of Total Volume	Fraction of Fresh Water

Total hydrosphere	1,386,000	100	–
Total fresh water	**35,029**	**2.53**	**100**

typically locked in deep aquifers that often have little if any long-term net recharge. Whenever this is extracted, it is functionally "mined," a particularly acute problem in arid regions, where replenishment times can be on the order of thousands of years (Margat 1990a, 1990b).

Establishing the contribution of groundwater to the global supply of freshwater inserts a substantial element of uncertainty into the overall assessment. Problems of poor data harmonization, incomplete and fragmentary inventories, and methodological difficulties are well documented (Revenga et al. 2000; UN/WWAP 2003; Morris et al. 2003). As a result, there is large uncertainty in estimates of fresh groundwater resources, ranging from 7 million to 23 million cubic kilometers (UN/WWAP 2003; Morris et al. 2003). While abundant, their use can be severely restricted by pollution (Foster and Chilton 2003) or by the cost of extracting water from aquifers, which rises progressively in the face of extraction rates exceeding recharge (Dennehy et al. 2002).

Another important water supply is represented by the widespread construction of artificial impoundments that stabilize river flow. Today, approximately 45,000 large dams (>15 meters high or between 5 and 15 meters high and a reservoir volume of more than 3 million cubic meters) (WCD 2000) and possibly 800,000 smaller dams (McCully 1996; Hoeg 2000) have been built for municipal, industrial, hydropower, agricultural, and recreational water supply and for flood control. Recent estimates place the volume of water trapped behind documented dams at 6,000–7,000 cubic kilometers (Shiklomanov and Rodda 2003; Avakyan and Iakovleva 1998; Vörösmarty et al. 2003). In drainage basins regulated by large reservoirs (>0.5 cubic kilometers) alone, one third of the mean annual flow of 20,000 cubic kilometers is stored (Vörösmarty et al. 2003). Assuming seasonal six-month low flows constitute roughly 40% of annual discharge (Shiklomanov and Rodda 2003), this impounded water represents a global potential to carry over an entire year's minimum flows.

Desalinization constitutes a renewable water supply using distillation and membrane techniques to withdraw salt from otherwise unusable water. While the technology continues to improve, desalinization remains the most costly means of supplying fresh water and is highly energy-intensive (Gleick 2000). Costs range between $1 and $4 per cubic meter, placing it well above the most expensive traditional sources (Gleick 2000). Despite this, in 2002 there were over 10,000 desalinization plants in 120 countries supplying more than 5 cubic kilometers per year, with a global market of $35 billion per year (UN/WWAP 2003). Collectively, these plants provide for much less than 1% of global freshwater use.

More than 70% of global installed desalinization capacity is in the oil-rich states of the Middle East and North Africa (UN/WWAP 2003). While its use may be difficult to justify for high-water-consumptive activities like irrigation, investments in desalinization technologies are likely to improve efficiency and bring down costs, creating a potentially important source at least for domestic drinking water (Gleick 2000), and the annual supply of desalinized water could double in 15 years (UN/WWAP 2003). The unresolved issue of adequately managing brine waste from the desalinization process to protect nearby coastal ecosystems requires special attention.

Finally, rainwater harvesting through traditional methods or modern technology is another way in which humans augment freshwater supply. Rainwater harvesting can directly increase the soil water content or be stored for later application as supplemental irrigation during dry periods. This is particularly important in places like India, which relies heavily on a short period of intense rainfall (WWC 2000). The groundwater authorities in India, for instance, have made it mandatory for multistoried buildings in New Delhi and several other states to have a rooftop rainwater harvesting system (Hindustan Times, Patna, September 2002). Rainwater harvesting can also be an appropriate technology for maintaining groundwater base flow and reducing flood peaks. (See MA *Policy Responses,* Chapter 7, for further discussion.)

7.2.1.1 Total Flows of Fresh Water

Ecosystems vary greatly in their exposure to precipitation and hence as source areas for renewable runoff that emerges as part of the hydrologic cycle. (See Table 7.2.) The proportional contribution of each ecosystem to global runoff is generally equivalent to the fraction of precipitation to which it is exposed. Forests therefore are associated with slightly more than half of global precipitation and yield about half of global runoff, while mountains represent one quarter of both global precipitation and runoff. Cultivated and island systems are the next most important source areas, each constituting about 15% of global runoff. All other systems contribute 10% or less. Paradoxically, dryland ecosystems, due to their large aerial extent, receive a nearly identical fraction of global precipitation as mountains do, yet because of substantial losses from the system due to evapotranspiration, they are a relatively minor contributor to global renewable water supply (<10%). Urban systems, because of their restricted extent (<<1% of land area), receive only 0.2% of global precipitation and provide the same very minor proportion of global runoff.

From a regional perspective, Latin America is most water-rich, with about one third of global runoff. Asia is next, with one quarter of global runoff, followed by OECD (20%), and sub-Saharan Africa and the former Soviet Union, each with 10%. The Middle East and North Africa is clearly driest and most water-limited, accounting for only 1% of global runoff.

7.2.1.2 Freshwater Flows Accessible to Humans

Ecosystems constitute the ultimate source areas for freshwater provisioning services. The accessibility of renewable water supply can be estimated through an index measuring the proportion of total annual renewable runoff generated locally that eventually flows through river corridors and encounters downstream human populations. The importance of upstream ecosystems as source areas for freshwater supply is demonstrated in Table 7.2. Cultivated, coastal, and urban systems, with sizable fractions of the global population, have from 90% to 100% of their renewable runoff accessible. Drylands also show high accessibility, likely reflecting the propensity of humans to settle near scarce freshwater resources. Mountains, forests, and inland waters each show 70–80% of total runoff as accessible to downstream populations. The exception is polar systems, which yield less than 20% of total runoff as accessible, reflecting their remote and generally uninhabited environment.

Populations served by accessible runoff emerging from individual ecosystems are typically in the billions. Cultivated systems, forests, inland waters, and mountains each serve at least 4 billion people. Four fifths of the world lives downstream of runoff from cultivated lands, followed by a nearly identical fraction downstream from forests. Inland waters and mountains provide water to two thirds of global population and drylands to one third. Remote islands and polar systems serve the fewest people. Runoff from urban systems, nearly all generated in close proximity to densely settled areas, serves nearly three quarters of the world's population.

The large fractions of total runoff expressed as accessible runoff indicate that, by and large, human society has positioned itself into areas with identifiable local sustainable water supplies or river corridor flows. A geographic distribution of human settlement thus is linked to the availability of fresh water (see also Meybeck et al. 2001). The global geography of accessible runoff, expressed in units of dependent population per unit of delivered flow, was shown in Figure 7.1. Mountains serve 3 times, forests 4 times, and inland waters 12 times as many people downstream through river corridors as they do through locally derived runoff. Urban areas nearly double the total service when tabulating downstream populations. Remaining ecosystems show more-limited importance in transferring precipitation as accessible runoff to downstream populations. For drylands, this is due to a lack of substantial quantities of runoff, while for coastal or island systems it is a consequence of short flow pathways to the ocean. Each of these systems still supplies 15–30% of global population with renewable and accessible runoff.

From a regional perspective, Latin America and Asia constitute the largest proportion (together nearly 60%) of global accessible runoff. And while the OECD, sub-Saharan Africa, and the former Soviet Union generate a large portion of the global runoff, substantial quantities are remote and inaccessible particularly in the former Soviet states (see also Postel et al. 1996). The Middle East and North Africa generates less than 1% of renewable accessible runoff.

Overall, the global fraction of total annual runoff that is accessible to humans is 75%, with slightly more than 80% of world

Table 7.2. Estimates of Renewable Water Supply, Access to Renewable Supplies, and Population Served by the Provision of Freshwater Services, Year 2000 Condition (computed based on methods in Vörösmarty et al. 2005; renewable water supply estimates from Fekete et al. 2002 from simulated water budgets using climatology data from 1950–96)

population (4.9 billion people) being served by these renewable and accessible water flows. However, while providing an estimate of long-term water supply, these figures overstate the effective availability of fresh water. Given that approximately 30% of annual runoff is uncaptured flood flow (Shiklomanov and Rodda 2003), the world's population has its access reduced from 75% to 53% of total runoff.

Globally, renewable freshwater services reflect the geographic distributions of both water supply and human populations. Four out of every five people live downstream of and are served by renewable freshwater services. (See Figure 7.2.) Thus, while the human population is generally well organized with respect to the availability of fresh water, 20% of humanity remains without any appreciable quantities of sustainable supply or must gain access to such resources through costly interbasin transfers from more water-rich areas. (See also Table 7.2.) These people are highly reliant on unsustainable water resources. For those with access to renewable supplies, a total of 65% of the world's population is served by the 50% of total annual renewable runoff that is positioned in dry to moderately wet conditions, with concomitant pressure on that resource base. Only 15% live with relative water abundance—that is, in conjunction with the remaining 50% of total runoff (represented by the high runoff-producing regions shown in the upper part of the curve in Figure 7.2). If uncaptured flood flow is incorporated into these calculations, for the 80% of

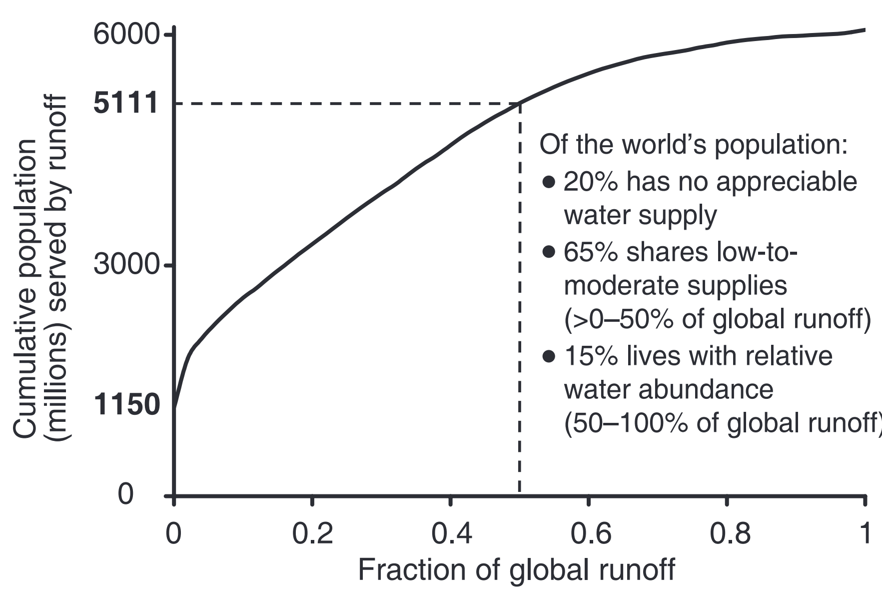

Figure 7.2. Cumulative Distribution of Population with Respect to Freshwater Services, 1995–2000. Fraction of runoff is ranked from low to high based on mean annual conditions. This distribution is also affected by seasonal variations in available runoff.

world population who reside in the lower half of the water availability spectrum in Figure 7.2 (65% plus 15% with no appreciable renewable freshwater flows), the effective supply is reduced from 50% to 35% of total runoff.

7.2.2 Water Use

Over the last few centuries, global water use has shown roughly an exponential growth and been linked closely to both population growth and economic development. There was a fifteenfold increase in global water withdrawals between 1800 and 1980 (L'vovich and White 1990), when population increased by a factor of four (Haub 1994). Since the 1900s, the overall increase has been sixfold (WMO 1997). Global consumptive water losses, primarily from evapotranspiration through irrigation, increased thirteenfold during this same period. A major, recent feature of human water use is the reduction in per capita use rates, dropping as of around 1980 from about 700 to 600 cubic meters per year, though the aggregate global withdrawal continues to increase (Gleick 1998; Shiklomanov and Rodda 2003).

While the general features of a historical rise in freshwater demands are clear, there are substantial uncertainties surrounding water use estimates, reflecting the current state of knowledge, assumptions (or lack thereof) on potential efficiency changes and reuse potential, number of years projected into the future, and interactions with market forces (Gleick 2000; Shiklomanov and Rodda 2003). The summary statistics from three global tabulations provided earlier, in Box 7.3, demonstrate the current degree of uncertainty.

Global water withdrawals today total about 3,600 cubic kilometers per year, with a wide range of use over individual continents. (See Table 7.3.) The largest user is Asia, accounting for nearly half of the world total, with OECD next, using about one third. The remaining continents each represent less than 10% of global use. Water use today is dominated by agricultural withdrawals (70% of all use), followed by industrial and then domestic applications. Withdrawals in agriculture are fundamentally defined by irrigation. In Asia, the Middle East and North Africa, and sub-Saharan Africa, agriculture accounts for 85–90% of all withdrawals. Driven by irrigation demand, overall withdrawals across MENA constitute 120% of renewable accessible supplies, meaning that this region relies on nonrenewable supplies for food production. Agricultural water use in the former Soviet Union and the OECD is proportionally much lower, reflecting the water needs of other sectors in these industrial economies. In contrast, industrial water use is only 4% in sub-Saharan Africa, reflecting a low level of economic development.

Table 7.3. Freshwater Services Tabulated as Withdrawals for Human Use over MA Regions and the World, 1995–2000 (WRI et al., 1998, updated using Shiklomanov and Rodda 2003, as in Vörösmarty et al. 2000; resampled to MA reporting units)

MA Geographic Region	Domestic Water Use D_a	Industrial Water Use I_a	Agricultural Water Use A_a	Total Use (Withdrawals) U_a
			(cu. km. per year)	
Asia	80	99	1,373	1,550
Former Soviet Union	34	115	188	337
Latin America	33	31	205	269
North Africa/ Middle East	22	15	247	284

OECD	149	489	384	1,020
Global Total	**328**	**753**	**2,480**	**3,560**

Water lost from groundwater and surface water sources to the atmosphere through net evaporation (such as from irrigation, cooling towers, or reservoirs) is termed water consumption or irretrievable losses, which today represent a substantial fraction of water use. Contemporary irretrievable losses through irrigation, computed as the evapotranspiration component of agricultural withdrawals, are assessed here. (See Table 7.4.) Irretrievable losses from irrigation represent one third of all water use globally. The efficiency computed for irrigated agriculture (the ratio of water withdrawn to water consumed or lost through evapotranspiration on irrigated cropland) is on average 50% globally and varies from 25% (in Latin America) to 60% (in Asia). Additional losses from evaporation from reservoirs, irrigation ditches, and so on are difficult to estimate accurately but could total over 500 cubic kilometers per year (Postel 1998), thus indicating the conservative nature of the consumption estimates in Table 7.4. (See Box 7.3 earlier in this chapter for the range in current estimates of consumptive loss from irrigation.)

Non-sustainable water use could be a substantial component of total withdrawals. Earlier work based on documentary evidence showed approximately 200 cubic kilometers per year of global aquifer overdraft (Postel 1999; WWC 2000), though the estimate is regarded as highly uncertain (Foster 2000). This assessment of water supply and use (based on Vörösmarty et al. 2000, 2005; Fekete et al. 2002) using a geospatial framework (about 50-kilometer resolution) enables calculations to be made of the degree to which water withdrawal exceeds locally accessible supplies—in other words, non-sustainable water use (U_{an}). Worldwide, non-sustainable withdrawals can be computed using two endpoints: crop evaporative demands or water use statistics, which include both consumption and transport losses, some unknown fraction of which reenters the surface-groundwater system for potential reuse (Molden 2003). These endpoints give a calculated non-sustainable use of about 400–800 cubic kilometers per year. In terms of total freshwater withdrawals, 10–25% could represent nonrenewable use. When the earlier estimate of 200 cubic kilometers per year is also included, a large degree of uncertainty results, and from 5% to 25% of freshwater withdrawals could represent nonrenewable use.

Nevertheless, each of these estimates reflects a high dependence on existing water services, especially in areas where induced, chronic water stress necessitates costly water engineering remedies, groundwater depletion, or curtailment of water-using activities. Each continent shows a heavy reliance on such nonrenewable extraction, ranging up to one third of total use based on the high estimates. Asia and MENA show the greatest level of such dependence; OECD, the least. In MENA, 30% of all water use is from non-sustainable sources, and this use is equivalent to over one third of accessible renewable supplies.

Figure 7.3 (in Appendix A) shows the contemporary geography of such non-sustainable use and demonstrates the much larger impacts that arise at subcontinental scales. The summary in Table 7.4 may thus understate the true degree of this overconsumption locally. The spatial pattern of overuse is broadly consistent with previously reported regions of use exceeding supply, major water transfer schemes, or groundwater overdraft: Australia, western Asia, northern China, India, North Africa, Pakistan, Spain, Turkey, and the western United States (Muller 2000; Shah et al. 2000;

Table 7.4. Consumptive and Non-sustainable Freshwater Use over MA Regions and the World, 1995–2000. Renewable supplies calculated as for Table 7.2. Irrigated water consumption was computed over irrigation-equipped land (Döll and Siebert 2000) within the cropland domain depicted by Ramankutty and Foley (1999). Evapotranspiration losses from irrigated cropland (Vörösmarty et al. 1998; Federer et al. 2003) relative to available local runoff or, when available, river corridor flows determine non-sustainable use. See Figure 7.3 for geography of non-sustainable use.

[a] Range represents crop demand alone (low estimate) versus reported withdrawals (high estimate, which includes delivery loss; Table 7.3). Recycling within river basins of irrigation withdrawals that are not consumed by crops reduces, to some unknown degree, the high estimate (see Molden 2003). Calculations assume a maximum 75-kilometer buffer around river corridors from which irrigation areas can secure fresh water.

Vörösmarty and Sahagian 2000; Dennehy et al.2002; EEA 2003; MDBC 2003; NLWRA 2004).

Non-sustainable use expressed as a proportion of irrigated agricultural withdrawals shows an even higher degree of dependency on nonrenewable supplies. Globally, about 15–35% of irrigation withdrawals are computed to be non-sustainable. Individual continental areas show percentages ranging from less than 10% to 40%, as in the case of Asia. Such high rates indicate an increasing degree of food insecurity. Given projections showing no major expansion in global cropland area (Bruinsma 2003), increasing pressure will be placed on irrigated cropland, which today provides nearly 40% of crop production (Shiklomanov and Rodda 2003; UN/WWAP 2003). By its very nature, this water use cannot persist indefinitely, and many regions of the world have well-documented cases of aquifer depletion and abandonment of irrigation, adding constraints to irrigated crop production arising from rising development costs, soil salinization, and competition for water required by sensitive ecosystems and commercial fisheries (Postel and Carpenter 1997; Postel 1998; Foster and Chilton 2003).

7.2.3 The Notion of Water Scarcity

The assessment thus far has shown a growing dependence of human society on accessible freshwater resources. To assess the state of these provisioning services more comprehensively, the supply of renewable water must be placed into the context of interactions with people and their use of water. A set of relative measures can be used in this regard.

One measure of dependence on fresh water is the population served per million cubic meters per year of accessible runoff (renewable supply). This is known as the "water crowding" index, with levels on the order of 600–1,000 people per million cubic meters per year (that is, 1,000–1,700 cubic meters per year supply per person) showing water stress, and above 1,000 people (that is, less than 1000 cubic meters per year per person) indicating extreme water scarcity (Falkenmark 1997). Another measure is the relative water use or water stress index (WMO 1997; UN/WWAP 2003), expressed as the ratio of water withdrawals to supply. More sophisticated indicators are available that incorporate social and economic dimensions of water use (Raskin 1997; Sullivan et al. 2003), and these will be described in the section on water and human well-being. A major water scarcity indicator effort is under way through the World Water Assessment Programme (UN/WWAP 2003).

Worldwide, a substantial quantity of renewable freshwater supply—nearly 30,000 cubic kilometers per year—is accessible to humans. Thus contemporary use represents slightly more than 10% of annual supply. However, there is a substantial range in the share of accessible runoff used by humans across different continents as well as a rapidly changing picture over the last few decades. Time series of use indicate increasing pressures on the freshwater resource base.

Between 1960 and 2000, world water use doubled from about 1,800 to 3,600 cubic kilometers per year, a rate of about 17% per decade, with a slower (10%) increase projected to 2010. (See Table 7.5.) Individual continents show increases over the 1960–2000 timeframe from 15% up to 32% per decade. MENA has historically shown a great dependence on its freshwater supply, using well over half as early as 1960 and exceeding all renewable supplies shortly after 1980. Today its withdrawals represent 120% of accessible sustainable supply, and these are projected to rise to >130% by 2010. Asia, the former Soviet Union, and OECD countries show intermediate levels of use relative to supply over this period. In sub-Saharan Africa, substantial contributions of fresh water from river basins in the wet tropics coupled with rela-

Table 7.5. Indicators of Freshwater Provisioning Services and Their Historical and Projected Trends, 1960–2010. Water use, "water crowding" (population supplied per unit accessible renewable supply), and use relative to accessible supply, by region, are shown. These figures are based on mean annual conditions. The values for the relative use statistics shown rise when the sub-regional spatial and temporal distributions of renewable water supply and use are considered. (Population from Vörösmarty et al. 2000; demand estimates from WRI et al. 1998, updated using Shiklomanov and Rodda 2003, as in Vörösmarty et al. 2000; resampled to MA reporting units)

MA Geographic Region	Population	Water Use U_a	Water Crowding on Accessible Renewable Supply[a]	Use Relative to Accessible Renewable Supply[1] (U_a/B_a)

[a] Renewable supply calculated as for Table 7.2, and refers to accessible blue water flows (B_a). Index uses full regional population.

tively poor water delivery infrastructure and restricted development mean that only 2% of renewable supply is tapped. In water-rich Latin America, relative use rates also remain low, at less than 5%.

The contemporary water crowding index is modest in almost all regions. Only MENA shows a value reflective of its well-known position as a highly water-scarce region. Over the last four decades there has been a sustained and substantial increase in the water crowding index with respect to accessible runoff, reflecting directly the impact of population growth. Worldwide, the number of people served per unit of supply has doubled during this period, at an average rate of 20% per decade. Several regions show even greater rates of increase—a tripling for MENA and sub-Saharan Africa and a more than doubling for Asia and Latin America. Globally, an additional 13% crowding in renewable supply is predicted between 2000 and 2010, with greatest regional increases expected in sub-Saharan Africa (30%) and MENA (20%). A slight slowing in rate of increase is noted globally, with near stability in the index for OECD and the former Soviet states.

Several cautionary notes are needed in interpreting these trends. The statistics are based on mean annual flows and access computed for 100% of individual continental and global populations. In the context of the 50% of continental runoff generated in dry to moderately wet climate zones (19,800 cubic kilometers per year) that serves the majority of global population, contemporary use represents nearly 20% of the mean annual supply. When seasonal variations in runoff are considered (reducing supplies to 13,900 cubic kilometers per year), withdrawals exceed 25% of the renewable resource. In addition, if dedicated instream uses of about 2,000 cubic kilometers per year for navigation, waste processing, and habitat management are considered (based on Postel et al. 1996), humans then use and regulate 40% or more of renewable accessible supplies.

Further, the crowding index does not take into account different countries' abilities to deal with water shortages. For example, high-income countries that are water-scarce may be able to cope to some degree with water shortages by investing in desalination or reclaimed wastewater. The study also discounts the use of fossil water sources because such use is unsustainable in the long term.

In addition, while the global numbers are well below the extreme scarcity threshold of 1,000 people per million cubic meters per year of renewable supply, they mask important local and regional differences and thus understate the true degree of stress (Vörösmarty et al. 2000, 2005). Prior assessments (Revenga et al. 2000) show that as of 1995 some 41% of the world's population, or 2.3 billion people, were living in river basins under water stress, with some 1.7 billion of these people residing in river basins under conditions of extreme water scarcity. From a river basin perspective, the Volta, Nile, Tigris and Euphrates, Narmada, and Colorado in the United States will show ongoing pressure through 2025 (Revenga et al. 2000). Another 29 basins will descend further into scarcity by 2025, including the Jubba, Godavari, Indus, Tapti, Syr Darya, Orange, Limpopo, Yellow, Seine, Balsas, and Rio Grande. Indicators based on mean annual conditions also mask important supply limits imposed by seasonal and inter-annual variability. For example, in India most of the annual water supply is generated as a result of the monsoons, which in many cases means both flooding downstream as well as seasonal drought.

Another measure of adequacy of the freshwater supply is the mean use-to-supply ratio. A set of thresholds for water stress was given by the United Nations in a recent global analysis that used this ratio based on mean annual conditions (WMO 1997): low (<10%), moderate (10–20%), medium/high (20–40%), and high (>40%). Using this classification and a grid-based approach necessary to capture the high degree of spatial heterogeneity (see Vörösmarty et al. 2000), the contemporary global-scale ratio is from low-to-moderate, as seen in Table 7.5, although entire continents are under a moderate (Asia, former Soviet Union, and OECD) to high (MENA) state of scarcity. This is in stark contrast to the situation in 1960, when uniformly low levels of scarcity were noted (with the exception of MENA). Globally, it has been shown that 2.5 billion people suffer from at least moderate levels of chronic water stress (Vörösmarty et al. 2000) and from 1–2 billion people suffer high levels of scarcity even when tabulations are made conservatively on total renewable supplies. Calculating the population at risk through a ratio based on accessible supplies would increase the overall exposure to stress.

Water scarcity as a globally significant problem is a relatively recent phenomenon, evolving only over the last four decades. Rates of increase in the relative use ratio from 1960 to the present averaged about 20% per decade globally, with values from 15% to more than 30% for individual regions. A slowing in the rate of increase in use is projected between 2000 and 2010, to 10% per decade globally. With anticipated population growth, economic development, and urbanization, a further increase in the relative use ratio for some continents is likely to remain high (MENA at 14% per decade, Latin America at 16%, and sub-Saharan Africa at 20%).

7.2.4 Environmental Flows for Ecosystems

In light of the expanding use of fresh water by humans and several indicators of growing water stress, an important issue emerges with respect to the sustainability of water provisioning services—that is, being able to continue providing water for human use while also meeting the water requirements of aquatic ecosystems so as to maintain their capacity to provide other services. ''Environmental flows'' refers to the water considered sufficient for protecting the structure and function of an ecosystem and its dependent species. These flow requirements are defined by both the long-term availability of water and its variability and are established through environmental, social, and economic assessment (King et al. 2000; IUCN 2003).

Determining how much water can be allocated to human uses or distorted through flow stabilization (such as dam construction) without loss of ecosystem integrity is central to an understanding of how freshwater ecosystems support human well-being through the range of provisioning, supporting and regulating services. Assessment of water availability, water use, and water stress at the global scale has been the subject of on-going research. However, water requirements of aquatic ecosystems are only now being estimated globally and considered explicitly in these assessments (Smakhtin et al. 2003). Flow requirements can range globally from 20% up to 80% of mean annual flow, depending on the river type, its species composition, and the river health condition objectives sought (for instance, pristine, moderate modification from natural conditions, minimum flows), indicating the high degree of potential conflict with river regulation and human uses should the environment be preserved.

If human systems are viewed as being embedded within natural systems, human water use can expand to a ''sustainability boundary'' beyond which a substantial degradation of ecosystem services results (King et al. 2000; Postel and Richter 2003). Determining the location of the sustainability boundary is critical to successful management and rests on clearly defining what constitutes a degraded ecosystem. Environmental flows should consider both the quantity and timing of flow to maintain ''naturally variable flow regimes'' (Poff et al. 1997), whereby seasonal flow patterns are maintained with the aim of retaining the benefits provided by low and high flows. (See Figure 7.4.) Naturally low flows, for example, help exclude invasive species while high flows, especially floods, shape channels and allow the delivery of nutrients, sediments, seeds, and aquatic animals to seasonally inundated floodplains. High flows may also provide suitable migration and spawning cues for fish (Poff et al. 1997; Baron et al. 2002).

7.2.4.1 Global Trends in Water Diversion and Flow Distortion

While global trends in altered water regime are difficult to assemble with certainty due to incomplete information, they reflect an overall increase in regulation of the world's inland river systems (Revenga et al. 2000; Vörösmarty and Sahagian 2000). Tables 7.4 and 7.5 provided an indication of the scope of such changes. Water withdrawals show a doubling between 1960 and 2000, by which time irretrievable losses from irrigation alone totaled 34% of all global use.

One third of all rivers for which contemporary and predisturbed discharges could be compared in a compendium (Meybeck and Ragu 1997) showed substantial declines in discharges to the ocean. Long-term trend analysis (more than 25 years) of 145 major world rivers indicated more than one fifth with declines in discharge (Walling and Fang 2003). From 1960 to 2000 there was a near quadrupling of reservoir storage capacity and more than a doubling of installed hydroelectric capacity (Revenga et al. 2000). Worldwide, large artificial impoundments (storing each 0.5 cubic kilometers or more) now hold two to three months of runoff, capable of significant hydrograph distortion, with several major basins showing storage potentials of greater than a year's runoff (Vörösmarty et al. 2003). Much of this regulation occurred over the last 40 years.

Through consumptive use and interbasin transfers, several of the world's largest rivers (Nile, Yellow, Colorado) have been transformed into highly stabilized and in some cases seasonally nondischarging river channels (Meybeck and Ragu 1997; Kowalewski et al. 2000). In the case of the Yellow River, improved water management since 2000 has helped to restore flows (MWR 2004).

7.2.4.2 Recent History of Governance and Management for Environmental Flows

Over the last decade, policy solutions to developing environmental flows have taken several forms, depending on social and historical context, degree of scientific knowledge, water infrastructure,

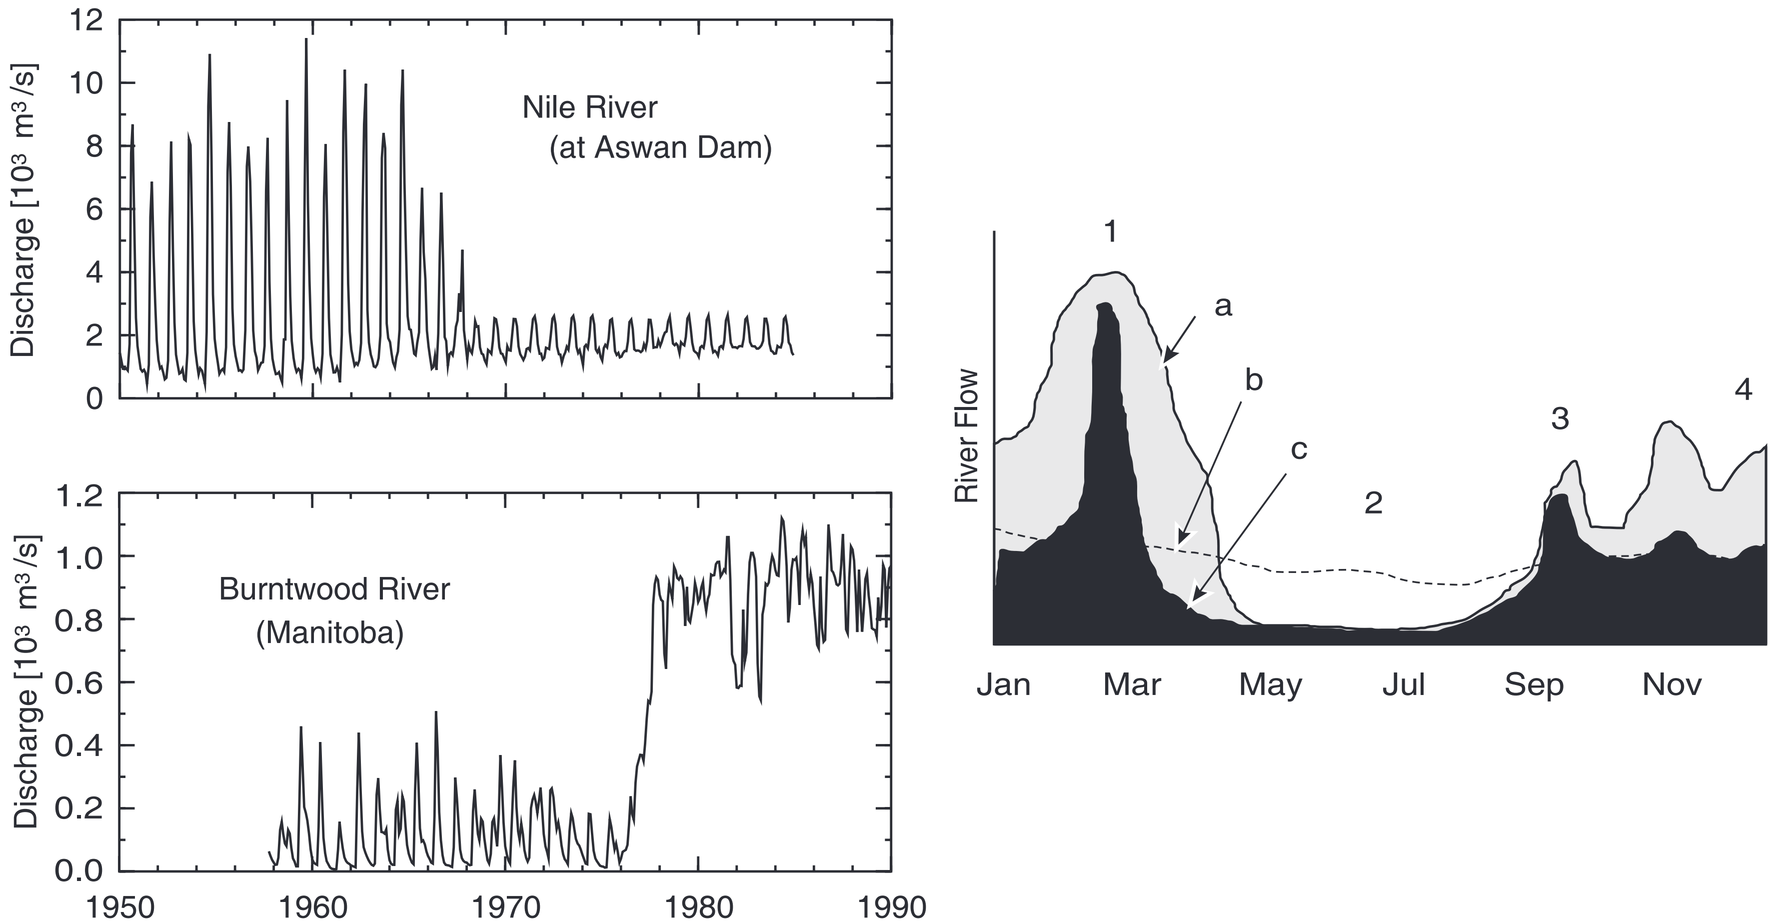

Figure 7.4. Managing for Environmental Flows: Contrasts among Natural, Reservoir-affected, and Reconstituted River Discharge Regimes. Observed alteration of natural flow regimes (left) arises from the provision of freshwater services, as through impoundment on the Nile River and interbasin transfer to optimize hydropower on the Burntwood River (Vörösmarty 2002). Environmental flow management attempts (right) to preserve key facets of the (a) natural flow regime in light of (b) typical 20th century flow distortion after damming. Condition (c) represents a partially "re-naturalized" flow regime, which retains important hydrologic characteristics: 1) peak wet season flood, 2) baseflow during the dry season, and 3) a "flushing" flow at the start of the wet season to cue life cycles, and 4) variable flows during the early wet season. Flow regime (b) shows many more negative effects than (c), even though both regulate similar volumes of water annually. (Right panel adapted from Tharme and King 1998)

and local ecosystem conditions. These approaches include managing the quantity and temporal pattern of water withdrawals or releases (Poff 2003; Postel and Richter 2003), developing water markets, and preemptively managing land use to protect watersheds.

Water allocation for environmental flows to sustain functioning freshwater ecosystems is practiced in parts of Australia, Europe, New Zealand, North America, and South Africa. However, there appears to be very little consideration of this matter anywhere in Asia, despite aggressive water extraction from many rivers during the dry season across the continent. But there is cause for cautious optimism. The calculation, adoption, and implementation of environmental flows are under consideration in other parts of the world. In addition, more than 2,000 river, lake, and floodplain restoration projects in at least 20 countries, particularly in Europe but also in Africa and Asia, are being carried out (DRRC 1998; UKRRC 2004; Richter et al. in prep.). Some key examples include the restoration of the Diawling delta in Mauritania (Hamerlynck and Duvail 2003), the Waza Logone floodplain in Cameroon (Loth 2004), the Danube and Rhine Rivers, and the South Florida Everglades—one of the largest ecosystem restoration projects ever attempted (Baron et al. 2002).

The shift toward management for natural flow regimes is also reflected by parallel shifts in public policy from laws favoring private interests and prior appropriations (as in much of the American West) to protecting water rights and environmental flows as part of the "public trust." In 1998, South Africa passed landmark legislation to aid decision-making on all or part of any significant water resource (National Water Act 1998). One of the most progressive aspects of this act was establishment of a Reserve to support both essential human needs (water for drinking, food preparation, personal hygiene) and aquatic ecosystem integrity. Notably, this two-part Reserve—with human and environmental components—takes priority over other uses such as irrigation and industrial withdrawal. In Burkina Faso, a new water framework law (Loi d'Orientation sur L'eau), adopted in 2001, establishes the legal and institutional framework for promoting integrated basin management, equitable access, water for nature, and international cooperation. The legislation recognizes that "infrastructures which are built on a water course must maintain a minimal flow that guaranties aquatic life" (MEE 2001).

For many highly regulated river systems in North America (e.g., Colorado, Columbia, Missouri, Savannah), recent changes in dam operations and adaptive management plans are now fostering conditions that improve fish habitat, river-floodplain connectivity, and estuarine ecosystems, often at the cost of hydroelectric generation or navigability to barges (Postel and Richter 2003; Richter et al. in prep.). In addition, the decommissioning and removal of some dams has begun in the United States (Hart et al. 2002). In Australia, water allocation reforms have led to limits on future withdrawal (that is, a "water cap") in the Murray-Darling River basin, subsequent development of a water market where allocations are traded, and creation of incentives to increase water productivity and efficiency (Blackmore 1999; MDBC 2004). Similarly, water markets developed in Mexico, Chile, and some western states in the United States have been used to secure flows for ecosystems (Thobani 1997).

Watershed management strategies that integrate ecological principles have been used to prevent water supply crises from developing. An often-cited example is the New York City water supply management strategy, which includes protection of riparian habitat in the nearby source area of the Catskills Mountains, thus eliminating the need to construct a water filtration plant at an estimated cost of $6 billion. The ~400,000-hectare Pinelands National Reserve in nearby New Jersey is regulated under a Comprehensive Management Plan developed at the local, state, and federal level in 1978–79 (Good and Good 1984). The plan permits a wide spectrum of land use development categories, ranging from intensive development to full protection, and it successfully redirected human activities to areas deemed appropriate while protecting a large core area, which is ecologically sensitive, drought-prone, and nutrient-poor and which harbors a unique community of wildlife with a large number of endemic species (Walker and Solecki 1999; Bunnell et al. 2003). The benefits of maintaining high water quality are recognized outside the reserve through the delivery of relatively high-quality fresh water to an estimated 9 million people in New York City for less than if a water filtration plant were built. In addition, water discharged into Delaware Bay helps to support populations of anadromous fish and spawning horseshoe crabs, which in turn support large numbers of migrating shorebirds and local industries.

7.2.5 Water Quality

Summarizing patterns and trends in water quality, particularly at a global scale, encompasses an array of challenges that include basic definitional problems, a lack of worldwide monitoring capacity, and an inherent complexity in the chemistry of both natural and anthropogenic pollutants. From a management perspective, water quality is defined by its desired end use. Water for recreation, fishing, drinking, and habitat for aquatic organisms thus require higher levels of purity, whereas for hydropower, quality standards are much less important. For this reason, water quality takes on a broad definition as the "physical, chemical, and biological characteristics of water necessary to sustain desired water uses" (UN/ECE 1995).

Natural water chemistry is inherently highly variable over space and time (Meybeck and Helmer 1989; Meybeck 2003), and aquatic biota are adapted to this variability. With added pressure from human activities, the biogeophysical state of inland waters plus their variability is altered, often to the detriment of aquatic species (see Chapter 20), thereby compromising the sustainability of aquatic ecosystems. Many chemical, physical, biological, and societal factors affect water quality: organic loading (such as sewage); pathogens, including viruses in waste streams from humans and domesticated animals; agricultural runoff and human wastes laden with nutrients (such as nitrates and phosphates) that give rise to eutrophication and oxygen stress in waterways; salinization from irrigation and water diversions; heavy metals; oil pollution; literally thousands of synthetic and persistent engineered chemicals, such as plastics and pesticides, medical drug residues, and hormone mimetics and their by-products; radioactive pollution; and even thermal pollution from industrial cooling and reservoir operations.

Furthermore, despite important improvements in analytical methodologies (UN/ECE 1995; Meybeck 2002), the capacity to operationally monitor contemporary trends in water quality is even more limited than monitoring the physical quantity of water. In terms of the spatial coverage, frequency, and duration of monitoring, data currently available for global and regional-scale assessments are patchy at best, leading to oversimplified and sometimes misleading information. (See Table 7.6.)

Data abundance is generally associated with level of economic development: industrial countries show a higher level of data availability, while water quality in developing countries is less well monitored. Even when data from monitoring stations are available, they only provide a fragmented view of water quality issues for very local sections of rivers, necessitating potentially unreliable extrapolation to the rest of the basin (Meybeck 2002). For this reason, water quality assessments or trajectories are usually river- or station-specific. Even for the best-represented regions of the globe, a coherent time series of data is available for only the last 30 years or less, constraining the ability to clearly quantify trends in water quality.

Data comparability problems are yet another constraint on the utility of water quality data. Standardized protocols, in terms of sampling frequency, spatial distribution of sampling networks, and chemical analyses, are still not in place to ensure the production of comparable data sets collected in disparate parts of the world. The monitoring of groundwater supplies is even more problematic (Meybeck 2003; Foster and Chilton 2003); because ground-

Table 7.6. Data Assessment of Existing Monitoring Programs Worldwide. The entries relate to the quantity of available data, indicated by the number of + symbols. For the purposes of this assessment, data quantity is an aggregate measure of station network density, spatial coverage, frequency of data collection, and duration of monitoring programs. (Updated from Vörösmarty et al. 1997b)

water is hidden from view, many pollution and contamination problems that affect supplies have been more difficult to detect and have only recently been discovered.

These many factors make it difficult to estimate the impact of changing water quality on global water supply. The following sections provide an overview assessment of trends in water quality that have bearing on the capacity of the contemporary water cycle to provide provisioning services for fresh water and on the sustainability of inland water systems. Other assessments specifically target water quality issues over selected regional-to-continental domains (e.g., AMAP 2002; Hamilton et al. 2004).

7.2.5.1 General Trends in Water Quality

The state of inland water quality illustrates the long-term and complex nature of human interactions with their environment. The earliest changes attributable to humans likely occurred in tandem with land use change in small to medium-sized catchments some 5,000 or 6,000 years ago in the Middle East and Asia, where water and sediment budgets were substantially altered (Wasson 1996; Vörösmarty et al. 1998b; Alverson et al. 2003; Meybeck et al. 2004). Water also has been considered since ancient times to be the preferred medium for cleaning, transporting, and disposing of wastes—establishing a tradition that today has substantially transformed the physical, biological, and chemical properties of global runoff.

A set of syndromes depicting riverine changes arising from anthropogenic pressures has been proposed (GACGC 2000; Meybeck 2003) through which society transforms inland fresh waters from a pristine state fully controlled by the natural Earth system to a modern condition in which humans provide many of the predominant controls. In most of the densely populated areas of the world, river engineering, waste production, and other human impacts have significantly changed the water and material transfers through river systems (Vörösmarty and Meybeck 1999, 2004) to the extent that this now likely exceeds the influence of natural drivers. This is true today in many parts of the Americas, Africa, Australasia, and Europe (Vörösmarty and Meybeck 1999, 2004).

The contrast between pristine and contemporary states can be dramatic and potentially global in scope. Changes to the global nitrogen cycle are emblematic of those in water quality more generally, through which high concentrations of people or major landscape disturbances (such as industrial agriculture) translate into a disruption of the basic character of natural water systems. In addition, modern changes often ''reverberate'' far downstream of the original point of origin. Compared with the preindustrial condition, loading of reactive nitrogen to the landmass has doubled from 111 million to 223 million tons per year (Green et al. 2004) or possibly 268 million tons (Galloway et al. 2004). (See also Chapter 12.) Model results show these accelerated loadings transformed into elevated freshwater transports through inland waterways to the coastal zone, doubling pre-disturbance rates from 21 million to 40 million tons per year (Green et al. 2004; Seitzinger et al. 2002). North America, continental Europe, and South, East and Southeast Asia show the greatest change. (See Figure 7.5 in Appendix A.)

Riverine transport of dissolved inorganic nitrogen (immediate precursors to nutrient pollution, algal blooms, and eutrophication) have increased substantially from about 2–3 million tons per year from the preindustrial level to 15 million tons today, with order-of-magnitude increases in drainage basins that are heavily populated or supporting extensive industrial agriculture. Rivers with high concentrations of inorganic nitrogen constitute a major global source for inorganic nitrogen, despite relatively modest contributions to aggregate water runoff. (See Figure 7.6.) While it is noteworthy that aquatic ecosystems ''cleanse'' on average 80% of their global incident nitrogen loading (Green et al. 2004; Howarth et al. 1996; Seitzinger et al. 2002; Galloway et al. 2004), the intrinsic self-purification capacity of aquatic ecosystems varies widely and is not unlimited (Alexander et al. 2000; Wollheim et al. 2001). As a result, sustained increases in loading from land-based activities are already reflected in the deterioration of water quality over much of the inhabited portions of the globe, they extend their impacts to major coastal receiving waters (e.g., Rabalais et al. 2002), and they are likely to continue well into the future (Seitzinger and Kroeze 1998).

While the stark contrast between pristine and contemporary states demonstrates the overall impact of anthropogenic influences on water quality, much of the contamination of fresh water has occurred over the last century. The main contamination problems 100 years ago were fecal and organic pollution from untreated human wastewater. Even though this type of pollution has decreased in the surface waters of many industrial countries over the last 20 years, it is still a problem in much of the developing world, especially in rapidly expanding cities (WMO 1997; UN/WWAP 2003). (See also Chapter 27.)

In developing countries, sewage treatment is still not commonplace, with 85–95% of sewage discharged directly into rivers, lakes, and coastal areas (UNFPA 2001; Bouwman et al. 2005), some of which are also used for water supply. Consequently, water-related diseases, such as cholera and amoebic dysentery, among others, claim millions of lives annually (WHO/UNICEF 2000). In Europe, organic pollution and contamination by toxic metals are probably now less than the levels observed between the 1950s and1980s, due to improved environmental regulation (Meybeck 2003). In the developing world, the riverine evolution is likely to be similar to that found in Europe, with a major lag corresponding to their different stages of industrialization, urbanization, and intensification of agriculture (Meybeck 2003).

New pollution problems from agricultural and industrial sources have emerged in industrial and developing countries and have become one of the biggest challenges facing water resources in many parts of the world (WMO 1997). In Western Europe and North America, on the one hand phosphorus contamination in waterways has been reduced considerably with the introduction

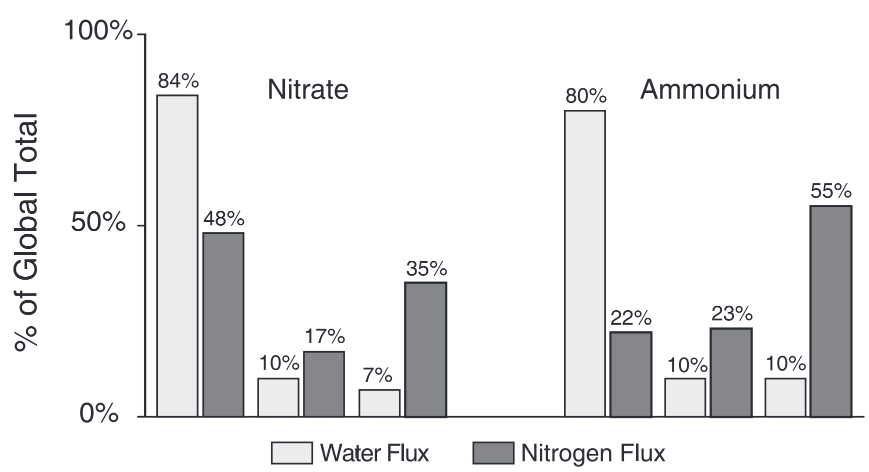

Figure 7.6. Global Summary of Inorganic Nitrogen Transport by Contemporary Rivers. Modern patterns of pollution from anthropogenic sources have created characteristically high-impact regions or ''hotspots'' that represent highly polluted river systems that today carry much greater quantities of nitrogen than their collective discharge would indicate. (Meybeck and Ragu 1997; Vörösmarty and Meybeck 2004)

of phosphate-free household detergents, investments in wastewater treatment plants, and to some degree modified agroecosystem management. On the other hand, residues of synthetic pharmaceuticals for humans and livestock are increasingly being discovered at low doses in rivers and lakes (Schiermeier 2003). There are indications that these residues can disturb the physiology of invertebrates, and it is still a matter of debate whether and, if so, to what degree these newly discovered pollutants may affect human physiology (Daughton and Ternes 1999; Jones et al. 2003).

Water contamination by pesticides has grown rapidly since the 1970s. In a medium-sized river basin like the Seine, over 100 different types of active molecules from pesticides can be found (Chevreuil et al 1998). Even if the use of xenobiotic substances is increasingly being regulated in Western Europe and North America, bans—when they exist—occur generally two to three decades after the first commercial use of the products. For example, DDT, atrazine (a common pesticide), and PCBs were in use for a long time before they were banned in parts of the industrial world. In general these bans take longer to implement in the developing world, so these products are still commercialized and used in some countries.

In the United States, PCB and DDT records in estuarine sedimentary archives peaked in the 1970s and are now markedly decreasing (Valette-Silver 1993). At the same time, persistent xenobiotics are widespread, with a recent study (Kolpin et al. 2002) finding traces of at least one drug, endocrine-disrupting compound, insecticide, or other synthetic chemical in 80% of samples from 139 streams in 30 states of the United States. The persistence of these products in continental aquatic systems can be high, and their degradation products can be more toxic than the parent molecules (Daughton and Ternes 1999). Because of the poor monitoring of the long-term effects of xenobiotics, the global and long-term implications of their use cannot be fully assessed.

7.2.5.2 Global Ranking of Water Quality Issues Based on Regional Assessment

A global water quality assessment, originally as part of the Dublin International Conference on Water and the Environment and in preparation for the Rio Summit (Meybeck et al. 1991) is summarized here. The original report determined a global ranking of key water quality issues based on U.N. Global Environmental Monitoring System data, the perceptions of local/regional scientists and managers, published reports and papers, and expert knowledge. Lakes, groundwater, and reservoir issues were considered, although as Siberia and northern Canada were not expressly covered in the 1991 report, these have been considered separately using the same approach (Meybeck 2003). Eleven variables were considered and ranked, the scoring of which ultimately reflects the aggregate impact of human pressures, natural rates of self-purification, and pollution control measures.

The results show that pathogens and organic matter pollution (from sewage outfalls, for example) are the two most pressing global issues (see Figure 7.7), reflecting the widespread lack of waste treatment. As water is often used and reused in a drainage basin context, a suite of attendant public health problems arises, thus directly affecting human well-being. At the other extreme, acidification is ranked #10 and fluoride pollution #11. The importance of the various issues varies between regions, however, and some of these globally low-ranked issues are particularly important in certain areas, such as acidification in Northern Europe, salinization in the Arabic peninsula, and fluoride in the Sahel and African Great Lakes (see maximum scores on Figure 7.7). Fluoride and salinization issues are mostly due to natural conditions (rock types and climate), but mining-related salinization can also be found (for instance, in Western Europe). All other concerns directly arise through human influences. An annotated continental summary is given in Table 7.7.

Although these updated results correspond well to the state of water quality in the 1980–90s (Meybeck 2003), since the 1990s the situation in most developing countries and countries in transition is likely worse in terms of overall water quality. In Eastern Europe, Central and South populated Americas, China, India, and populated Africa, it is probably worse for metals, pathogens, acidification, and organic matter, while for the same issues Western Europe, Japan, Australia, New Zealand, and North America have shown slight improvements. Nitrate is still generally increasing everywhere, as it has since the 1950s. In the former Soviet Union there has been a slight improvement in water quality due to the economic decline and associated decrease in industrial activities. Eastern Europe has also seen some improvements, such as those in the Danube and the Elbe basins. A few rivers, such as the Rhine, have seen a stabilization of nitrate loads after 1995.

7.3 Drivers of Change in the Provision of Fresh Water

The drivers of change in the global water cycle and the system's capacity to generate freshwater provisioning services act on a variety of spatial and time scales. Throughout history, humans have pursued a very direct and growing role in shaping the character of inland water systems, often applied at local scales, but sometimes reflecting provincial or national policies on water. The collective significance of human influences on the hydrologic cycle may today be of global significance, but this has only recently begun to be articulated (Vörösmarty and Meybeck 2004).

Humans today control and use a significant proportion of the runoff—from 40% to 50% (Postel et al. 1996)—to which the vast majority has access. Given high numbers of people dependent on water provisioning services derived from ecosystems and the growing degree of water crowding, urbanization, and industrialization, the global water cycle is and will continue to be affected strongly by humans.

Water engineering to facilitate use by humans has fragmented aquatic habitats, interfered with migration patterns of economically important fisheries, polluted receiving waters, and compromised the capacity of inland water ecosystems to provide reliable, high-quality sources of water. Land cover changes have also altered the patterns of runoff and created sources of pollution, negatively affecting human health, aquatic ecosystems, and biodiversity. (See Chapter 20.) Due to a growing reliance on irrigated agriculture for domestic food production and international trade, freshwater services—in decline in many parts of the world through non-sustainable resource use practices—are directly linked to the global food security issue. (See Chapters 8 and 26.) Finally, natural climate variability and anticipated changes associated with greenhouse warming convey additional, major constraints on the provision of renewable freshwater services.

7.3.1 Population Growth and Development

Population growth is a major indirect driver of change in the provision of fresh water. Although freshwater supplies are renewed through a more or less stable global water cycle that produces precipitation in excess of evapotranspiration over the continents, the mean quantity of water supply available per capita is ever-decreasing due to population growth and expanding con-

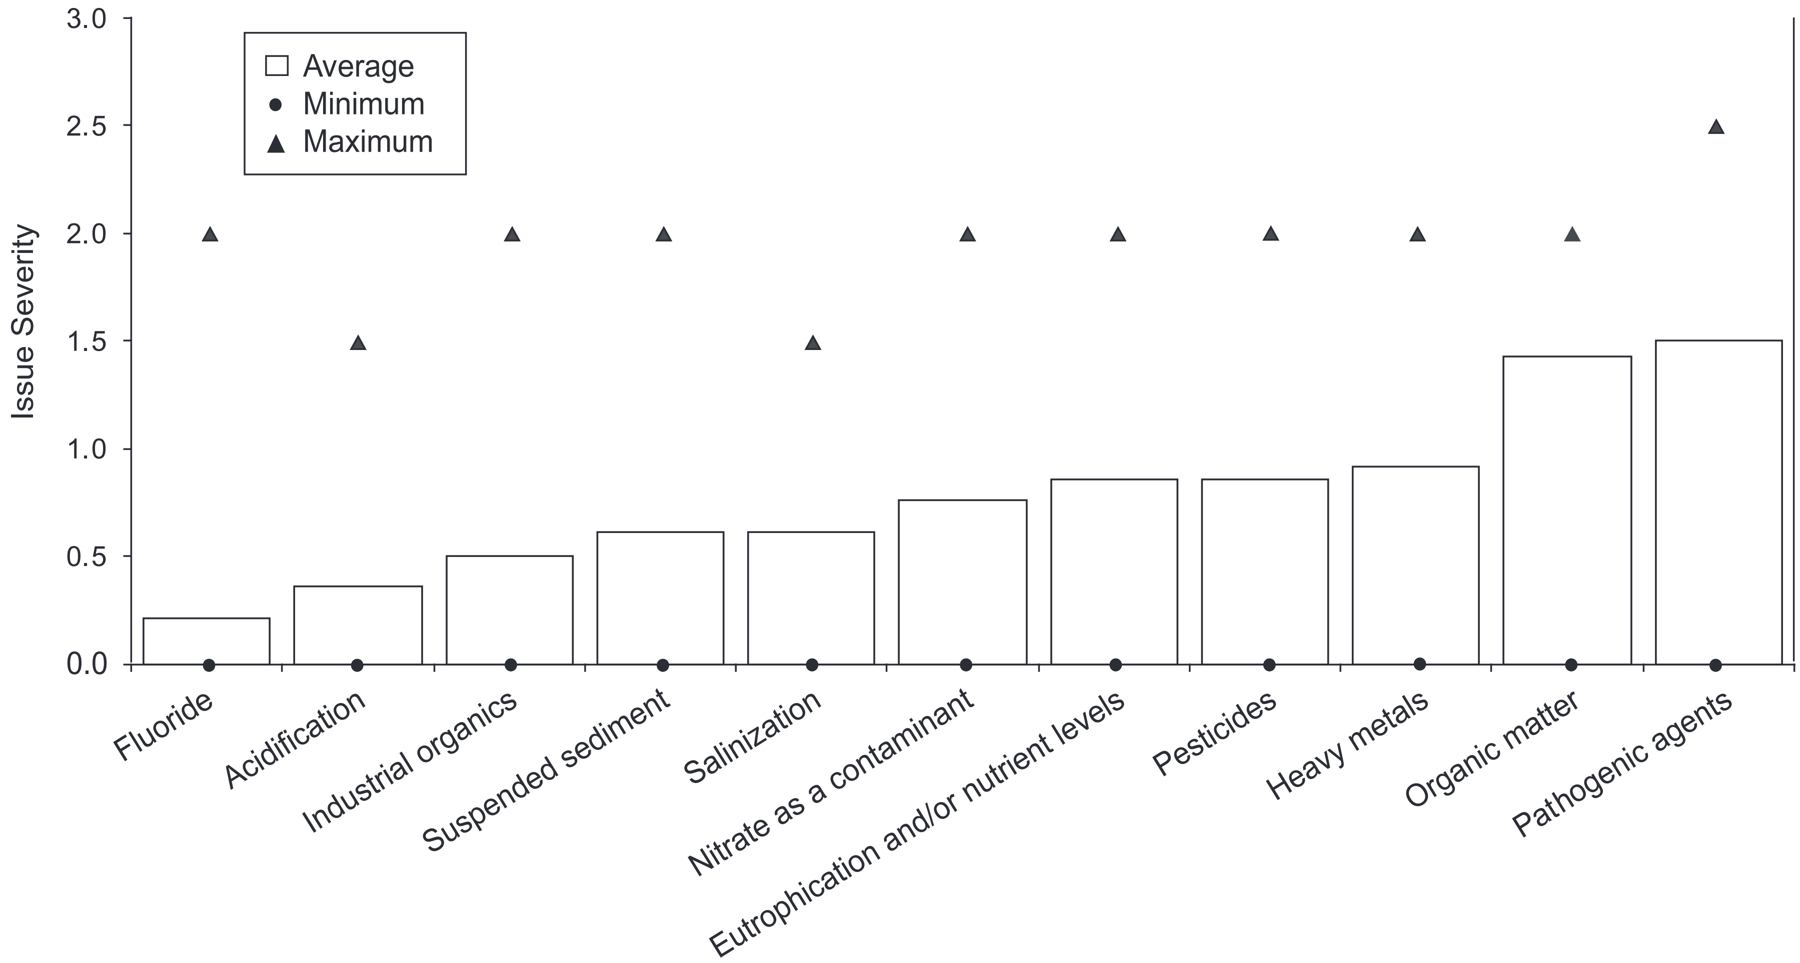

Figure 7.7. Ranking of Globally Significant Water Quality Issues Affecting the Provision of Freshwater Services for Water Resource End Uses. Averages show the general tendencies for specific pollutants, but a wide range is noted, with minima in all cases ranked zero and maxima often several times more severe than the mean condition. Although this ranking shows organic matter pollution and pathogens to be relatively more important at the global scale, information to quantify the degree to which water supplies are compromised by pollution is currently insufficient. Scores are as follows: 0: No problem or irrelevant; 1: Some pollution, water can be used if appropriate measures are taken; 2: Major pollution with impacts on human health and/or economic use, or aquatic biota; 3: Severe pollution—impacts are very high, losses involve human health and/or economy and/or biological integrity. (Based on expert opinion; Meybeck et al. 1991, updated by Meybeck 2003)

sumptive use (Shiklomanov and Rodda 2003). Human population doubled from 1960 until the present (Cohen 2003), and nearly 20 contemporary cities are home to 10 million people or more (Cohen 2003). Substantial flow stabilization and increased withdrawals have occurred across all regions, supporting an increase in the number of people sustained by the accessible, renewable water supply.

Continued growth in population will fuel increases in food production, which in the context of a stable cropland base (Bruinsma 2003) will require greater diversions of fresh water for irrigation or considerably more efficient use of water supplies. The same applies to industry and municipalities, amplifying current pressures on the global water supply. Economic development, technology, and lifestyle changes (such as increasing meat consumption) further define the functional availability of water in the context of declining per capita supplies. Over the twentieth century, water withdrawals increased by a factor greater than six—more than twice the rate of population growth (WMO 1997).

In addition to increased water demands, as mentioned in section 7.2.5, pollution from industry, urban centers, and agricultural runoff limits the amount of surface and groundwater available for domestic use and food production. Threats of water quality degradation are most severe in areas where water is scarce because the dilution effect is inversely related to the amount of water in circulation.

7.3.2 Managed Water Supplies

A broad array of water engineering schemes has enabled variability in the hydrologic cycle to be controlled and increasing amounts of water to be stored and withdrawn for human use. This technology refers to any sort of engineering used in the storage, management, and distribution of water, such as dams, canals, water transfers, irrigation ditches, levees, and so on. It also includes both traditional water harvesting techniques as well as modern production and treatment facilities like desalinization plants.

Global patterns of water management are not driven solely by investments in technology and large-scale engineering. Water is also managed through international trade, by way of the embodied or "virtual" water content of commodities exchanged. The agricultural sector, in particular, requires huge amounts of rainfall or irrigation water, much of which is lost to evapotranspiration, and in the case of irrigation there are also transit losses. Water input-to-crop output ratios, expressed on a weight-to-weight basis, vary from the hundreds to the thousands. Given enormous contrasts in local availability of fresh water, there is a potentially enormous comparative advantage in virtual water trade strategies that transport products from water-rich to water-poor areas.

This section first assesses the role of major engineering works in the provision of water and then considers the significance of virtual water trade of agricultural products in the global economy.

Table 7.7. Continental-scale Assessment of Major Water Quality Issues. The purpose of this table is to present a general overview. It does not capture fully large sub-regional differences that are known to occur. (Updated from Meybeck et al. 1991)

Continental Domain	Summary of Key Findings
Africa	Major sources of pollution in Africa, according to the 1992 assessment, are fecal contamination; toxic pollution downstream of major cities, industrial centers, and/or mining; and vector-borne diseases. The Nile Basin and Northern Africa show more contamination problems than other regions, but this also may be because of more information and monitoring stations in these regions, or more altered water flows that affect dilution potential in rivers.
Americas	In the United States and Canada, the major pollution problem is eutrophication from agricultural runoff and acidification from atmospheric deposition. Major problems also include persistent toxic water pollution from point and non-point sources. In South and Central America the major contaminant problems, except in the Amazon and Orinoco basins, where ecosystems are more intact and high flows foster dilution, are pathogens and organic matter, as well as industrial and mining discharges of heavy metals and pesticide and nutrient runoff.
Asia and the Pacific	Arid and semiarid regions tend to have different pollution problems than areas in the monsoon belt. In the Indian subcontinent the major problems are pathogens and contamination from organic matter. While these are prevalent in Southeast Asia as well, heavy metals, eutrophication, and sediment loads from deforestation are also critical in this sub-region. The Pacific Islands have higher levels of salinization than other regions in Asia, while still having problems with pathogens and organic matter, like much of the developing world. China has a combination of all pollution problems in its major watersheds. In the dry north, eutrophication, organic matter, and pathogens are major problems, while in the south in addition there is a large sedimentation problem. Finally, Japan, New Zealand, and Australia present similar pollution problems as other industrial nations, like the United States and Europe. Australia has particular problems with salinization due to agricultural practices, especially in the Murray-Darling Basin.
Europe	In the Nordic countries the major problem is acidification, while other contaminant levels are relatively low. In Western Europe eutrophication and nitrates pose the greatest challenge, while in Southern and Eastern Europe the major contaminants are organic matter and pathogens, nitrates, increasingly pesticides, and eutrophication.
Eastern Mediterranean and Middle East	Characterized by its arid climate, this area shows great demands and pressure on its scarce water resources. Industrial pollution and toxics are a problem in some locales, but overall salinization from overabstraction is the key concern in this region.

7.3.2.1 The Role of Engineering on Water Supply

7.3.2.1.1 Dams and reservoirs

Humans have altered waterways around the world since historical times to harness more water for irrigation, industry, and domestic and recreational use. Dams have been a particularly significant driver of change, buffering against both spatial and temporal scarcity of water supplies and increasing the security of water and food supply over the past half-century. However, large engineering works that impound and divert fresh water have caused damage to key habitats and migratory routes of important commercial and subsistence fisheries (Revenga et al. 2000), as well as serious societal disruptions, including public health problems (as described later; see also Chapter 14) and forced displacements (WCD 2000).

Large dams are today the fundamental feature of water management across the globe (FC/GWSP 2004). Approximately 45,000 large dams (>15 meters in height) (WCD 2000) and possibly 800,000 smaller dams (McCully 1996; Hoeg 2000) are in place and an estimated $2 trillion has been invested in them over the last century. These facilities have served as important instruments for development, with 80% of the global expenditure of $32–46 billion per year focused on the developing world (WCD 2000).

Major stabilization of global river runoff from major engineering works expanded greatly between 1950 and 1990. (See Figure 7.8.) Currently the largest reservoirs—those with more than 0.5 cubic kilometers of storage capacity—intercept locally 40% of the water that flows off the continents and into oceans or inland seas (Vörösmarty et al. 2003). The volumetric storage behind all large dams represents from three to six times the standing stock of water held by natural river channels (Vörösmarty et al. 1997a, 2003; Shiklomanov and Rodda 2003). In addition, large reservoir construction has doubled or tripled the residence time of river water—that is, the average time that a drop of water takes to reach the sea, with the mouths of several large rivers showing delays on the order of many months to years (Vörösmarty et al. 1997a).

Such regulation has enormous impacts on the water cycle and hence aquatic habitats, suspended sediment, carbon fluxes, and waste processing (Dynesius and Nilsson 1994; Vörösmarty et al. 2003; Stallard 1998; Syvitski et al. 2005). Large dams, in particular, have been a controversial component of the freshwater debate. While contributing to economic development and food security, they also produce environmental, social, and human health impacts. A World Bank review (1996a) of the impacts and economic benefits of 50 large dams concluded that these projects showed proven economic and development benefits but had a mixed record in terms of their treatment of displaced people and environmental impacts. A further review by the World Commission on Dams on the performance of large dams showed considerable shortfalls in their technical, financial, and economic performance relative to proposed expectations, particularly irrigation dams, which often have not met physical targets, failed to recover cost, and have been less profitable than expected (WCD 2000).

In Pakistan, for example, the direct benefits from irrigation made possible by the Tarbela and Mangla dams are estimated at about $260 million annually, with the farmers who own irrigated land clearly benefiting from increased incomes (World Bank 1996a). However, the increased use of irrigation water has led to waterlogging and increased soil salinity in the Punjab area, with a

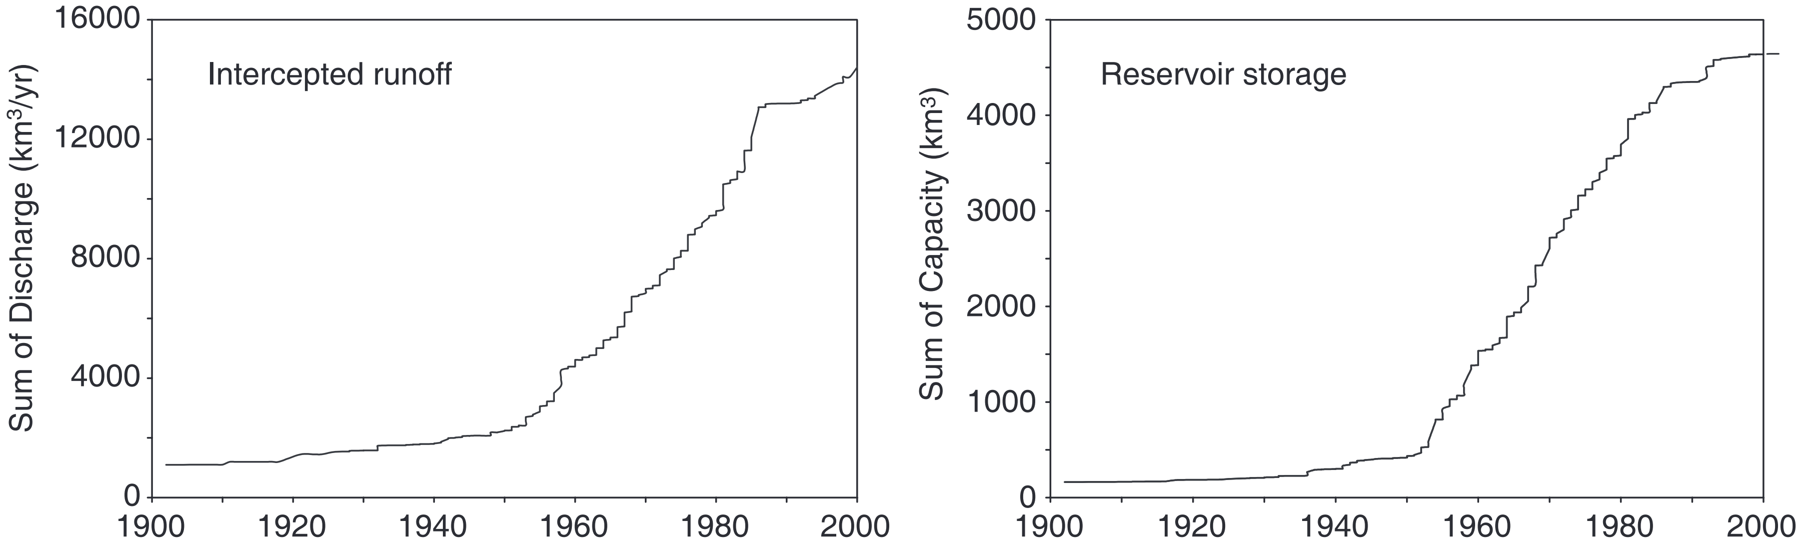

Figure 7.8. Time Series of Intercepted Continental Runoff and Large Reservoir Storage, 1900–2000. The series is taken from a subset of large reservoirs (>0.5 km^3 maximum storage each), geographically referenced to global river networks and discharge. The years 1960–2000 have shown a rapid move toward flow stabilization, which has slowed recently in some parts of the world, due to the changing social, economic, and environmental concerns surrounding large hydraulic engineering works. (Vörösmarty and Sahagian 2000)

direct link to a decline in crop productivity, and an increase in malaria transmission (World Bank 1996b).

Hydroelectricity is another important benefit from dams. Total production of hydropower reached 2,740 terawatt-hours in 2001 or 19% of global electrical production, and many industrial (such as Norway and Iceland) and developing countries (Democratic Republic of Congo, Mozambique, Brazil, Honduras, Tajikistan, and Laos) rely on dams for more than 90% of their power production (UN/WWAP 2003). As with irrigation dams, in many circumstances the effectiveness of large dams for hydroelectricity generation has not been sufficient to meet the predicted benefits (WCD 2000), and they have caused loss of habitats and species as well as the displacement of millions of people (WCD 2000).

Flood control continues to be another major objective for building large dams. In Japan, for example, 50% of the population lives in flood-prone areas, and in the last 10 years floods have affected 80% of municipalities in the country. Japan is one of the top five dam-building countries in the world. Matsubara and Shimouke Dams on the Chikugo River in the Kyushu District in southern Japan, for instance, were built for flood control after a flood in 1953 inundated one fifth of the entire catchment, killing 147 people and destroying 74,000 households. These two dams successfully reduced peak flows in the river years later during a 1982 flood, saving lives and property (Green et al. 2000).

However, the effectiveness of large dams to replace the role of natural wetlands for flood mitigation is not well supported by scientific evidence. Wetlands and floodplains act as natural sponges; they expand by absorbing excess water in time of heavy rain and they contract as they release water slowly throughout the dry season to maintain streamflow. (See Chapter 20.) The large-scale conversion of floodplains and wetlands (some of it through dams) has resulted in declines in the natural mechanism for flood regulation. And while a handful of dams are being decommissioned in some countries (268 out of 80,000 in the United States, for example), an estimated 1,500 dams are under construction worldwide and many more are planned, particularly in the developing world (WWF and WRI 2004). River basins with the largest number of dams over 60 meters high planned or under construction include the Yangtze Basin in China with 46 large dams, the La Plata Basin in South America with 27, and the Tigris and Euphrates River Basin in the Middle East with 26 (WWF and WRI 2004).

The debate on cost, benefits, and performance of large dams continues, but given recent reviews (see WCD 2000), the traditional reliance on constructing such large operations for water supply is being called into question on environmental, political, and socioeconomic grounds (Gleick 1998; WCD 2000).

7.3.2.1.2 Interbasin transfers

Interbasin water transfers represent yet another form of securing water supplies that can greatly alleviate water scarcity. They include any canals, ditches, tunnels or pipelines that divert water from one river or groundwater system to another, typically from dammed reservoirs, and often represent massive engineering works involving both ground and surface waters. Changes to natural surface water hydrographs can be enormous and virtually instantaneous. The Great Man-Made River Project in Libya, for example, transports over 2 cubic kilometers of fossil groundwater a year through 3,500 kilometers of desert to huge coastal storage reservoirs that support 135,000 hectares of irrigable cropland, one third of the country's total (UN/WWAP 2003).

Two of the world's largest interbasin transfers are the 93% loss of flow (27 cubic kilometers per year) from the Eastmain River and a 97% gain of flow (53 cubic kilometers per year) in the La Grande River (Dynesius and Nilsson 1994), both in Canada. In total, the flow being diverted without return to its stream of origin in Canada alone totaled 140 cubic kilometers a year in the 1980s (Day and Quinn 1987), more than the mean annual discharge of the Nile River and twice the mean annual flow of Europe's Rhine River. The Farraka Barrage alone diverts over 9% of the Ganges River's historical mean annual flow and over 5% of the flow for the entire Ganges-Brahmaputra basin (Nilsson et al. 2005).

A gigantic diversion project is also under way in China, which proposes to move 40 cubic kilometers per year (MWR 2004) of water from southern China to the parched parts of northern China, thus connecting the Yangtze River with the Hai, Huai and Yellow Rivers. Three channels, two of which are over 1,000 kilometers long, will be needed for this transfer, which corresponds to 4% of the average flow of the Yangtze River (U.S. Embassy in China 2003). Developers plan to bring enough water to replenish groundwater aquifers in the north. This withdrawal from the Yangtze, even though it represents only a small fraction of the river's annual flow, will likely still have some effect on downstream ecosystems: sediment loads needed to maintain riparian and coastal wetlands will be reduced, and pollutants will be marginally less diluted, raising their concentration in the Yangtze River's lower reaches (U.S. Embassy in China 2003). In addition, as water flows north from one basin to another, the introduction of non-native species and the transfer of contaminants could affect native fauna in the receiving basins (Snaddon and Davies 1998; Snaddon et al. 1998; U.S. Embassy in China 2003).

Social effects of interbasin water transfers are complex. Populations in the recipient basin of water transfers gain water for irrigation, industry, and human consumption, all leading to indisputable economic and social benefits. However, those living in the basin of origin (and particularly those downstream of the diversion point) often lose precisely those same benefits (Boyer 2001), and many times they are displaced to other parts of the country, losing their homes and cultural heritage. While sometimes economic compensation is offered to people displaced by dams, the amounts usually do not cover the potential losses in terms of livelihoods, economic productivity, and cultural and historical heritage (WCD 2000).

Resettlement is an issue for water transfers as well as for dams, with many resettled communities suffering from a marginalized status, and cultural and economic conflicts with the population into which they are resettled. The central route of the Yangtze-to-Yellow water transfer in China, for example, will require the resettlement of 320,000 people, each of whom is supposed to receive the equivalent of $5,000 in compensation (U.S. Embassy in China 2003).

The trade-offs involved in interbasin transfer schemes include both direct societal costs and benefits, as well as those involving ecosystems services and biodiversity. Yet given increasing demands for water in the future, such transfers are likely to remain an important mechanism for alleviating regional water shortages (Nilsson et al. 2005).

7.3.2.2 Virtual Water in Trade

Virtual water, or VW, refers to the amount of fresh water used during the production process and thus "embodied" in a good or service (Allan 1993). While tabulations could be made for any product, VW has been explored mainly from the perspective of crop and livestock production and trade, given the predominance of agriculture in water use globally.

Operationally, VW in agriculture can be defined as the quantity of water used to support evapotranspiration in crops, which are then consumed domestically (as human food or animal feeds) or traded internationally. Additional water to process food products and to care for livestock can also be tabulated (Oki et al. 2003a), but VW estimates are fundamentally determined by irretrievable water losses through crops. There is a vast mismatch between the weight of agricultural commodities produced and the VW embodied in their production. For example, 1 kilogram of grain requires 1,000–2,000 kilograms (liters) of water, even under the most favorable of climatic conditions (Hoekstra and Hung 2002), producing 1 kilogram of cheese requires >5,000 kilograms of water, and 1 kilogram of beef requires an average of 16,000 kilograms of water (Hoekstra 2003).

Water has been transported in internationally traded products for hundreds of years, but the concept of trading VW has only recently begun to be considered as a mechanism to alleviate regional or global water security by exploiting the comparative advantage of water-rich or water-efficient countries (Allan 1996; Jaeger 2001). However, VW does not take into account the nature of food production systems and other factors, such as soil erosion, biodiversity impacts, or pollution. Moreover, for political and social reasons, countries may elect to be self-sufficient and independent in food production. For example, India, which is food self-sufficient in aggregate, serves as a net exporter of food and virtual water despite being water-stressed.

A substantial volume of VW trade in food commodities has nonetheless been taking place. (See Figure 7.9.) Worldwide, international VW trade in crops has been estimated at between 500 and 900 cubic kilometers per year, depending on tabulations made from the exporting or importing country perspective and the number of commodities considered (Oki et al. 2003a; Hoekstra and Hung 2002; Hoekstra 2003). (See Table 7.8.) An additional 130–150 cubic kilometers per year is traded in livestock and livestock products. For comparison, current rates of water consumption for irrigation total 1,200 cubic kilometers per year, and taking into account the use of precipitation in rain-fed agriculture as well, the total water use by crops has been estimated to range from 3,200 to 7,500 cubic kilometers per year, depending on whether allied agroecosystem evapotranspiration is included (Postel 1998; Rockström and Gordon 2001). The most important exporters of crop-related VW are the OECD and Latin America, though individual sub-regions, such as Western Europe, are net importers of VW. Asia (Central and South) is the largest importer of VW.

Of the top 10 virtual water exporters, 7 countries are in water-rich regions, while of the 10 largest importers of VW, 7 are highly water-short, indicating a general redistribution of VW from relatively wet to dry regions. However, the notable absence of clear-cut relationships linking the degree of domestic water scarcity to dependence on external VW supplies (Hoekstra and Hung 2002) suggests that an optimal redistribution of water through crop production and trade is yet to emerge. The consequences of food self-sufficiency thus entrench present-day patterns of water scarcity, as can decisions to pursue an aggressive export marketing strategy in the face of unsustainable water use. Future increases in water stress over the coming decades (Vörösmarty et al. 2000; Alcamo et al. 2000) and further integration of a global economy are likely to be powerful forces in adopting the notion of VW into food production and trade policies. An analysis of international trade in VW for Africa is provided in Box 7.4.

7.3.3 Land Use and Land Cover Change

Among the major processes influencing water quantity and quality at the river basin scale are changes in land use intensity and land cover change. (See Table 7.9.) Land use changes affect evapotranspiration, infiltration rates, and runoff quantity and timing. Particularly important for human well-being are contrasting reductions in the overall quantity of available runoff with some types of land cover change versus concentrated peaks of runoff associated with flooding under other land cover changes that can often be translocated far downstream through river networks (Douglas et al. 2005).

For example, expanding impervious areas due to urban expansion greatly increases the volume and rate of stormflow into receiving streams. Such changes also affect the water quality and biodiversity of freshwater ecosystems (Jones et al. 1997). Land use changes that compact soils and reduce infiltration are associated with deficiencies in groundwater recharge and dry period baseflow, the long-term global consequences of which are yet to be documented. Reduced infiltration can also lead to longer lifespans of pools with stagnant water, thus providing increased breeding opportunities for mosquitoes and other vectors of human disease.

The impact on local water budgets of changes from forest cover to pasture, agricultural, or urban land cover are well docu-

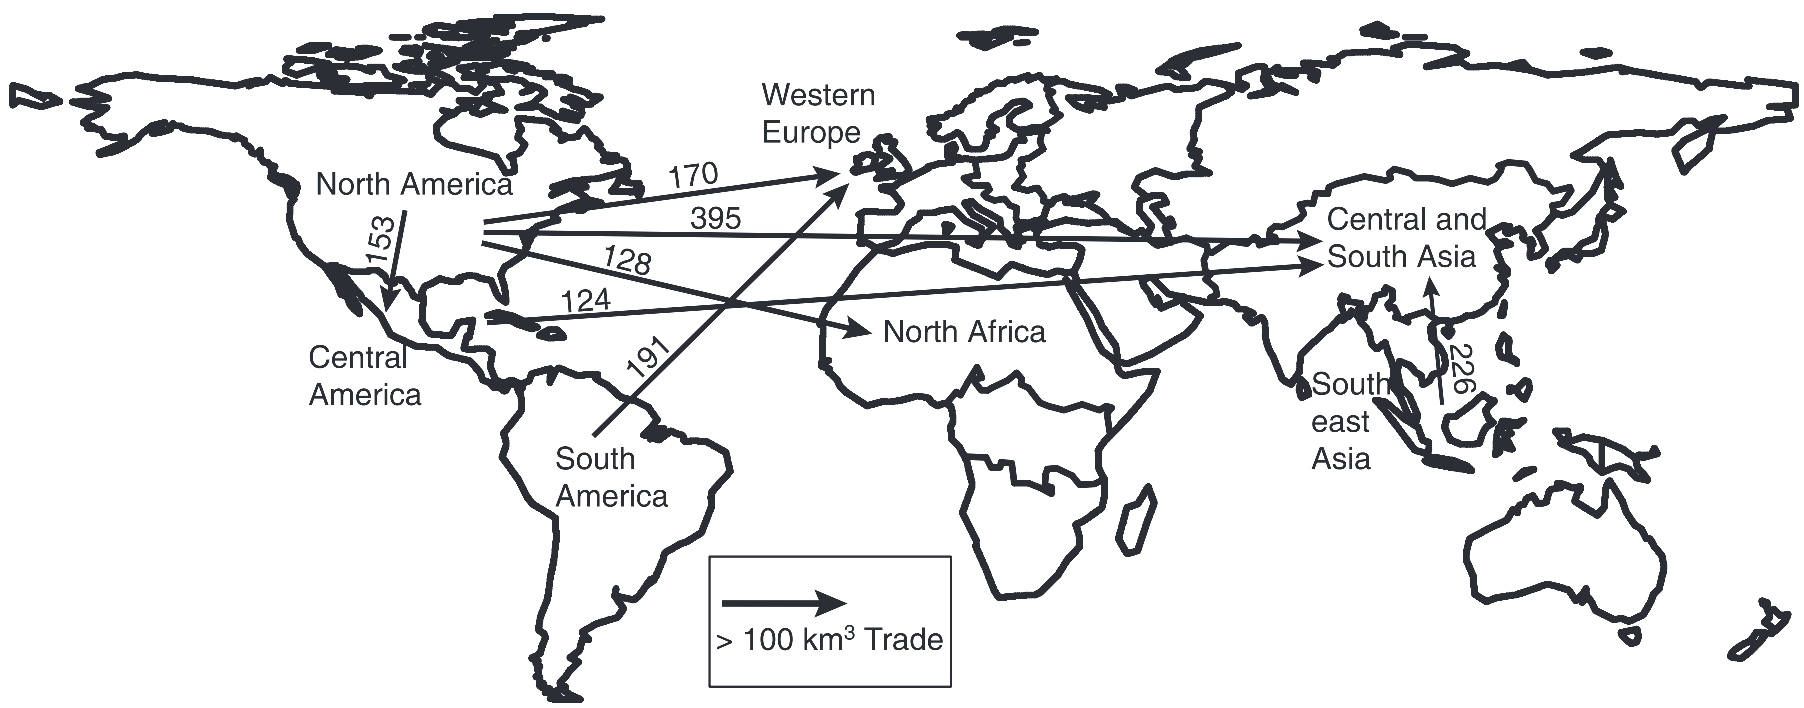

Figure 7.9. Net Inter-regional Trade in Major Crops Expressed as Embodied or "Virtual" Water Expended in Production of These Agricultural Commodities, 1995–99. The regions used differ from those used in the MA. Virtual water flows <100 km^3 for the full period are not shown. Rain-fed and irrigated agriculture are considered, although estimates do not include transfer and drainage losses during irrigation. (Hoekstra and Hung 2003)

Table 7.8. Annual Transfer of Virtual and Real Water through Global Trade of Cereal and Meat Commodities, 2000. "Virtual" water in this table is estimated as the fresh water required by the importing country to produce the commodity, while "real" water is the fresh water expended by the exporter to produce the same commodity. Water equivalents are vastly greater than the actual weights traded, from 1000:1 to 3000:1 for cereals and >20,000:1 for beef. Through such trade there is a water-saving equivalent to approximately 20% of agricultural water withdrawals. (Oki et al. 2003a)

Commodity	Virtual Water Trade	Real Water Trade	Water "Saved"
	(cubic kilometers per year)		
Maize	130	50	80
Wheat	460	270	190
Rice	190	110	80
Barley	92	38	54
Cereal total	870	470	400
Beef	86	82	4
Pork	28	20	8
Chicken	37	25	12
Meat total	150	130	24

mented in the hydrological and ecological literature. While historically a large portion of the available information was generated for temperate and boreal areas of North America and Europe (Swank and Crossley 1988; Buttle et al. 2000), information is becoming available for selected sites in Amazonia, South Africa, and Australia, among others (Bruijnzeel 1990; Le Maitre et al. 1999). The global impact of 110,000 square kilometers per year net deforestation (FAO 1999) on runoff, however, has yet to be fully quantified.

Impacts of land use change patterns of weather and climate at different scales are only starting to be understood. (See Chapter 13.) Fragmenting a landscape alone can generate changes in local weather patterns (Avissar and Liu 1996; Pielke et al. 1997). At the continental level, land use changes can reduce recycling rates of water leading to reduced precipitation and distortions in the atmospheric circulation patterns that link otherwise widely separated regions of the globe (Chase et al. 1996; Costa and Foley 2000; Pitman and Zhao 2000). There has also been continental-to-global-scale acceleration in the loading of pollutants, including nutrients, onto the land mass associated with industrial agriculture, urbanization, and grazing. (See Chapters 12 and 15.) These inputs are translated into greatly elevated fluxes to and transport through inland water systems (Chapter 20), the effects of which pass in many cases fully to the coastal zone (Chapter 19).

Intensive agricultural and urbanized areas have expanded rapidly in the last 50 years. The current extent of cultivated systems provides an indication of the location of freshwater ecosystems that are likely to experience water quality degradation from pesticide and nutrient runoff as well as increased sediment loading (Revenga et al. 2000). (See Figure 7.10 in Appendix A.) Figure 7.11 (in Appendix A) shows, from a drainage basin perspective, the distribution and pattern of urban areas, as judged by satellite images of nighttime lights for 1994–95 (NOAA-NGDC 1998). Because more urbanized river basins tend to have greater impervious area as well as higher quantities of sewage and industrial pollution, this figure suggests the contemporary geography of pressures on freshwater systems arising from these classes of contaminants (Revenga et al. 2000).

The two Figures show contrasting patterns of modified land use across the world. Intensively cropped lands are concentrated in five areas: Europe, India, eastern China, Southeast Asia, and the midwestern United States, with smaller concentrations in Argentina, Australia, and Central America. Africa is striking for its lack of intensively cropped land, with the exception of small patches along the Nile, on the Mediterranean coast, and in South Africa. This reflects the minimal use of chemical inputs and the low level of agricultural productivity in most African countries. Figure 7.11 shows that highly urbanized watersheds are concentrated along the east coast of the United States, Western Europe, and Japan, with smaller concentrations in coastal China, India,

BOX 7.4

Virtual Water Content Associated with African Food Supply

The interplay between water availability and irrigation is critical in defining whether a country (or regions within a country) can be self-sufficient in food production and do so in a sustainable manner. This is especially true in Africa, where the climate and hydrology are highly unpredictable and as much as 40% of irrigation withdrawals in the driest regions are estimated to be non-sustainable (Vörösmarty et al. 2005). Africa also represents a flashpoint for future water scarcity and food security, with a large and rapidly growing population, enormous expanses of dry landscapes, extensive poverty, lack of investment in water infrastructure, and a lingering human health crisis.

Virtual water is the fresh water needed to produce crops embodying all evapotranspiration on rain-fed or irrigated cropland, plus any transit losses for irrigation (Raskin et al. 1995; Allan 1996). There are enormous throughputs of water within agroecosystems to satisfy the evaporative demands of crops, with ratios of >1,000-to-1 by weight for cereal products and >15,000-to-1 for beef (Hoekstra 2003). Thus, while food trade can be highly beneficial in simply economic terms, it could also help compensate for local water scarcity by exploiting the comparative advantage of water-rich countries to produce food (Allan 1996; Jaeger 2000).

The map of Africa (see Box 7.4 Figure A in Appendix A) shows the spatial distribution of annual virtual water production on rain-fed and irrigated croplands, computed from long-term average (1950–95) water balance terms. VW embodied in meat (beef, pork, and chicken) production was also estimated as the sum of VW in feed and fodder plus a portion of evapotranspiration that occurs over grazing lands, where it is assumed that 30% of net primary production and hence evapotranspiration could be used sustainably.

In Africa, much of the sustainable (rain-fed) agriculture occurs within the more humid regions of the continent, while most irrigated agriculture occurs in the semiarid and arid regions in northern and southern Africa and along the Sahel. At the continental scale, about 18% of total African VW is used for meat production, although this number is probably much higher because it is doubtful that all grazing land is used sustainably. Food imports (both crops and meat) represent over 20% of Africa's total VW consumption, illustrating a reliance on external sources for meeting the food needs of today's population. This reliance will likely continue to increase in the future, though some unknown fraction is intra-continental.

Globally, VW from crop production is computed to co-opt 14,600 cubic kilometers (20%) of the 66,400 cubic kilometers annual evapotranspiration. For Africa, crop production co-opts only 9% of annual evapotranspiration, a reflection of the fact that three quarters of Africa's cropland is located in arid and semiarid climates characterized by highly limited soil moisture stocks (Vörösmarty et al. 2005). The bar chart (see Box 7.4 Figure B in Appendix A) illustrates that while sub-Saharan Africa relies heavily on rain-fed agriculture (60–75% for South, East, West) and very little on irrigated agriculture (3–7%) for food production, North Africa has very little rain-fed crop production and obtains more than 60% of its within-region VW from irrigated agriculture. Much of this irrigation water is withdrawn from highly exploited river corridors, such as the Nile, as well as groundwater. To satisfy overall food demand, North Africa nearly doubles its available VW through food trade.

Table 7.9. Brief Overview of Hydrologic Consequences Associated with Major Classes of Land Cover and Use Change (Bosch and Hewlett 1982; Swank et al. 1988; Bruijnzeel 1990; Hornbeck and Smith 1997; Jipp et al. 1998; Swanson 1998; Bonnell 1999; Le Maitre et al. 1999; Buttle et al. 2000; Le Maitre et al. 2000; Zavaleta 2000; Zhang et al. 2001; Paul and Meyer 2001; Sun et al. 2001; Zoppou 2001; Tollan 2002)

Type of Land Use Change	Consequences on Freshwater Provisioning Service	Confidence Level
Natural forest to managed forest	slight decrease in available freshwater flow and a decrease in temporal reliability (lower long-term groundwater recharge)	likely in most temperate and warm humid climates, but highly dependent on dominant tree species adequate management practices may reduce impacts to a minimum
Forest to pasture/agriculture	strong increase in amount of superficial runoff with associated increase in sediment and nutrient flux decrease in temporal reliability (floods, lower long-term groundwater recharge)	very likely at the global level; impact will depend on percentage of catchment area covered consequences are less severe if conversion is to pasture instead of agriculture most critical for areas with high precipitation during concentrated periods of time (e.g., monsoons)
Forest to urban	very strong increase in runoff with the associated increase in pollution loads strong decrease in temporal reliability (floods, lower long-term groundwater recharge)	very likely at the global level with impact dependent on percent of catchment area converted stronger effects when lower part of catchment is transformed most critical for areas with recurrent strong precipitation events
Invasion by species with higher evapotranspiration rates	strong decrease in runoff strong decrease in temporal reliability (low long-term groundwater recharge)	very likely, although highly dependent on the characteristics of dominant tree species scarcely documented except for South Africa, Australia, and the Colorado River in the United States

Central America, most of the United States, Western Europe, and the Persian Gulf (Revenga et al. 2000). While Figures 7.10 and 7.11 show the average composition of each large river basin in terms of intensively cultivated land or urban and industrial areas, they nonetheless hide within-basin differences that arise from highly localized patterns of crop production and urban point sources of pollution (Revenga et al. 2000).

The implications of these changes and the incomplete understanding of their consequences affect the manner in which humans interact with the water cycle. Integrated watershed management is the current paradigm for sustainable water use and conservation (Poff et al. 1997). It can yield important environmental and social benefits, as shown by a survey of 27 U.S. water suppliers that found the cost of water treatment in watersheds forested 60% or more was only half that of systems with 30% forest cover (Ernst 2004).

In practice, the integrated management approach is complex and difficult to implement because of limits to the understanding of interactions linking the physical and biotic processes that control water quantity and quality (Schulze 2004). Integrated management research typically has focused on local and short time scales and been limited to a very small portion of the world's watersheds. Most of the understanding of watershed dynamics and management principles comes from hydrological research on small watersheds and from studies at the local scale (Vörösmarty 2002). At present, the longest hydrological studies encompass only the last 20–40 years, but the recent application of GIS techniques facilitates reconstruction of past events to place the impact of contemporary land management into a longer-term perspective (Bhaduri et al. 2000).

One significant challenge to both scientific understanding and sound management is that multiple processes control water quantity, quality, and flow regime. The pattern and extent of cities, roads, agricultural land, and natural areas within a watershed influences infiltration properties, evapotranspiration rates, and runoff patterns, which in turn affect water quantity and quality. Additional challenges surround the fact that river basins extend across contrasting political, cultural, and economic domains (the Mekong River, for instance, flows through China, Laos, Thailand, Cambodia, and Viet Nam). Thus, there remains substantial uncertainty about the effects of management on different components of the hydrological cycle arising from the unique combinations of climatic, social, and ecological characteristics of the world's watersheds (Bruijnzeel 1990; Tollan 2002).

It is widely recognized that while much more information is needed to evaluate the impact of land use and cover change on freshwater provisioning services, integrated watershed management—despite its present degree of uncertainty—is both possible and would contribute significantly to improved management of water resources (Swanson 1998; Tollan 2002).

7.3.4 Climate Change and Variability

A major and natural characteristic of the land-based water cycle, and hence of water supply, is its variability over space and time. The large-scale patterns of atmospheric circulation dictate the world's climate zones and regional water availability. One particular concern arises from climate change, which in the past has shaped major shifts in the water cycle, such as changes in the Sahara from a much wetter region with abundant vegetation about 10,000 years ago to the desert of today (Sircoulon et al. 1999). A changing climate can modify all elements of the water cycle, including precipitation, evapotranspiration, soil moisture, groundwater recharge, and runoff. It can also change both the timing and intensity of precipitation, snowmelt, and runoff.

Two issues are critical for water supply: changes in the average runoff supply and changes in the frequency and severity of extreme events, including both flooding and drought. Both of these changes have been difficult to articulate due to complexities in the processes at work as well as a non-uniform and, in many parts of the world, deteriorating monitoring network, as discussed in section 7.1.2.

Shiklomanov and Rodda (2003) present a study of continental-scale variations in water supply as represented in the observational record spanning 1921–88. They used data from a total of approximately 2,500 stations, maximizing, to the degree possible, length of record, suitably large river basins, and hydrographs reflecting near-natural conditions. The stations represented <10% of all available records and reflect great disparities in maximum length of record (from 5 to 178 years). (Statistically, the optimal record length for trend analysis is on the order of 30 years (Lanfear and Hirsh 1999; Shiklomanov et al. 2002), but detectability of a trend also depends on the relative lengths of the "base" (pre-change) and changed periods of record (Radziejewski and Kundzewicz 2004).)

Year-to-year variations over five continents were 10% or less (see Figure 7.12) but rose to as high as 35% when examining 27 climate-based subdivisions. Relatively dry periods occurred in the 1940s, 1960s, and late 1970s, with global runoff declining by up to 3,000 cubic kilometers a year. This is in contrast to relatively wet conditions in the 1920s, late-1940s to early 1950s, and mid-1970s. Though there are limitations to making such global statements, the overall conclusion with respect to renewable supplies of runoff is that despite some recent continental-scale trends (an increase in South America and decrease in Africa), there was no substantial global trend in renewable supplies of runoff over the 67 years tested. Labat et al. (2004) did, however, compute an increasing global trend in runoff. This was correlated to increasing global surface air temperature, amounting to 4% per degree Celsius over the last century, though with regional increases (Asia, North and South America) and decreases (Africa) or stability (Europe) over the last few decades.

Care must be exercised in interpreting such long-term trends, which are anticipated to be associated with climate change. Maps of trends presented by the IPCC (Houghton et al. 2001) show large-scale and spatially coherent increases as well as decreases in precipitation over multi-decadal periods that start in 1910, although these patterns shift depending on the time frame observed. A similar time dependency is evident in interpreting changes in rain-to-snow ratios across Canada, with a time frame of 1948–96 indicating completely opposite results than with a time series starting at 1960 and ending in 1990 (Mekis and Hogg 1999; Lammers et al. 2001).

The clearest signatures require long time periods and sufficient spatial integration units (that is, large drainage basins). Peterson et al. (2002), for example, found it impossible to detect a coherent trend in runoff without first aggregating the flow records from six large Eurasian rivers and over 65 years. Insofar as northern Eurasia is among the regions historically to show the clearest trends in climate warming and the general absence of other confounding effects such as land cover change and water engineering, these results point to the difficulty in assessing recent runoff trends.

Nonetheless, there is evidence that climate change may already be causing long-term shifts in seasonal weather patterns and the runoff production that defines renewable freshwater supply. Shifts toward less severe winters and earlier thaw periods in cold temperate climates that depend on snowfall and snowmelt result

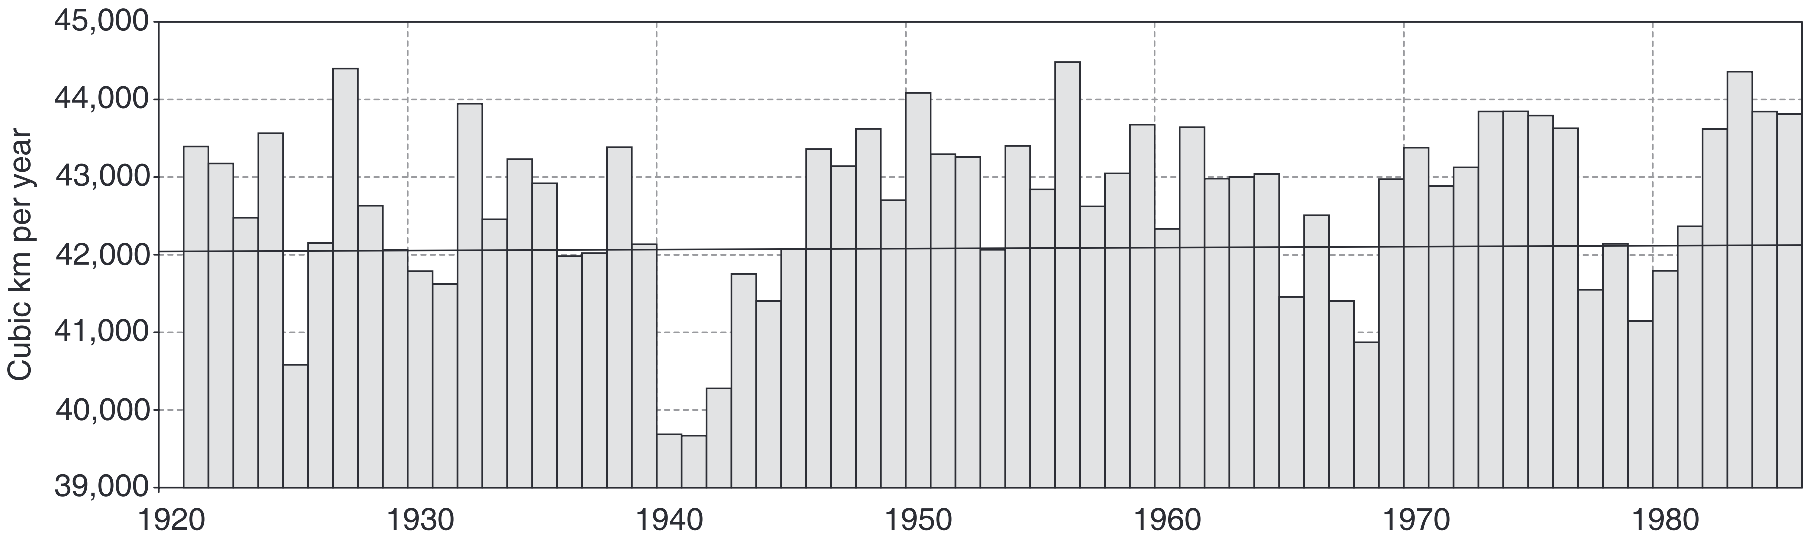

Figure 7.12. Time Series of Renewable Water Supply across the Global Landmass since 1920. The series is based on a subset of available discharge station records. (Shiklomanov and Rodda 2003)

in important changes in water availability (Dettinger and Cayan 1995; Hamlet and Lettenmaier 1999; WSAT 2000; Hodgkins et al. 2003). Multi-decade hydrological anomalies are apparent for Africa, with decreases on the order of 20% between 1951 and 1990 for both humid and arid zone basins that discharge into the Atlantic (Mahé 1993).

In the Sahel, persistent rainfall deficits could entrench desertification through a critical loss of water recycling between land and atmosphere, exacerbated by reduced soil infiltration when so-called hydrophobic soils are created in arid environments, and by soil compaction over poorly managed lands (Sircoulon et al. 1999). Such rainfall deficits also reduce replenishment of the groundwater resource, exacerbated by the decreased permeability of soils that favor storm runoff and flooding, even in the context of lower overall precipitation. In the transition zones between wet and dry regions across Africa, there is a highly uneven and erratic distribution of rainfall and river corridor flow (Vörösmarty et al. 2005). While this climate already produces chronic water stress, episodic droughts greatly increase the number of people at risk. Once each generation, the major sub-regions of the western Sahel, Horn of Africa, and SADCC region see a tripling in the number of people at risk from severe water stress (Vörösmarty et al. 2005).

An intensification of the water cycle, through more extreme precipitation in the United States (Karl et al. 1996; Karl and Knight 1998) and other parts of the world (Easterling et al. 2000; Houghton et al. 2001; Frich et al. 2002) has also been recorded. However, the effect of these increases on the rest of the hydrological cycle is only now being articulated.

In the United States, where sufficient records are available, Lins and Slack (1999) and Douglas et al. (2000) used stream gauging stations with 50 years of continuous records (from unregulated systems) to conclude that annual minimum and mean flows have increased. This was later confirmed by McCabe and Wollock (2002), who found statistically significant increases in annual moisture surplus (moisture that eventually becomes runoff) over the contiguous United States as a whole, but especially in the East. And while Yue et al. (2003) found similar increases in minimum and mean daily flows in northern Canada, they found the opposite to be true (significant decreases in minimum, mean, and maximum daily flows) in the southern part of the country.

Groisman et al. (2004) reported that warming in the northern half of the coterminous United States was related to a reduction in the extent of springtime snow cover and to the earlier onset of spring-like weather conditions and snow retreat. This has resulted in the increased frequency of cumulonimbus clouds and in a nationwide increase in very heavy precipitation. Warming in the southwest and northeast part of the country has led to greater summer dryness and increased fire danger. An interseasonal shift of precipitation from summer to fall in the Southeast was also noted.

The effect of increased precipitation extremes on floods is still debated (Douglas et al. 2000; Groisman et al. 2001; McCabe and Wolock 2002; Robson 2002; Milly et al. 2002) because flood response is influenced by many interacting factors, such as basin geology, terrain, and land cover as well as basin size and rainfall patterns. Also, the natural variability of flood flows can mask small changes in precipitation inputs.

Trends are also apparent in soil moisture distributed around the globe. Historical time series from more than 600 sites indicate a modest increase in growing period wetness for the majority of stations examined (Robock et al. 2000), contrary to the expectation (by general circulation models) of drier conditions in mid-continental areas due to climate change (e.g., Cubasch and Meehl 2000).

Taken together, these results indicate a high natural degree of variability and difficult-to-interpret shifts in runoff generation associated with historical climate change. The detection of such changes is complicated by the interactions among existing physical climate variations (that is, decadal and ENSO-type oscillations), land cover change, and water engineering, which for many parts of the world dominate the character of renewable water supplies.

7.3.5 Urbanization

During the twentieth century, the world's urban population increased almost fifteenfold, rising from less than 15% to close to half the total population (see Chapter 27), and by 2015 nearly 55% of the world will live in urban areas (UNPD 2003). In developing countries alone, the proportion of the population living in urban centers will rise from less than 20% in 1950 to 48% in 2015 (UNPD 1999, 2003). In fact, 60% of the fastest-growing cities with more than 750,000 people are located in the developing world, mostly in Asia (World Bank 2001). While 70% of the world's water use is for agriculture, the remaining withdrawals are for domestic household and other urban uses, including industry, and in many places these water resources are heavily polluted and limited by local shortages and distribution problems (UN-HABITAT 2003).

Urban residents bring with them a set of new challenges for water supply delivery, management, and waste treatment (WHO/UNICEF 2004; UN-HABITAT 2003). Because of the rapid rate of increase in cities around the world, water infrastructure is practically unable to keep apace, especially in the megacities with more than 10 million people. Large parts of these megacities lack the basic infrastructure for drinking water and sanitation, and most large cities in the developing world, and many in the industrial world, lack basic waste and storm water treatment plants (UN-HABITAT 2003).

The geographic location of many of these large and growing cities, such as close to coastal areas, and their rapid pace of growth has encouraged the overtapping of water resources that are not necessarily renewable, such as coastal aquifers. In Europe, for instance, nearly 60% of the cities with more than 100,000 people are located in areas where there is groundwater overabstraction (EEA 1995). Groundwater overexploitation is also evident in many Asian cities. Bangkok, Manila, Tianjin, Beijing, Chennai (formerly Madras), Shanghai, and Xian all have registered a decline in water table levels of 10–50 meters (Foster et al. 1998). These high levels of abstraction in many cases are accompanied by water quality degradation and land subsidence. For instance, the aquifer that supplies much of Mexico City had fallen by 10 meters as of 1992, with a consequent land subsidence of up to 9 meters (Foster et al. 1998).

Overabstraction is also an increasing problem with tourism-associated development, particularly in coastal areas. Groundwater overabstraction in such areas can reverse the natural flow of groundwater into the ocean, causing saltwater to intrude into inland aquifers. Because of the high marine salt content, even low concentrations of seawater in an aquifer are enough to make groundwater supplies unfit for human consumption (Scheidleder et al. 1999). Of 126 groundwater areas in Europe for which status was reported, 53 showed saltwater intrusion, mostly of aquifers used for public and industrial water supply (Scheidleder et al. 1999).

Unfortunately, the poor, mostly migrant workers from rural areas suffer most from reduced quality or quantity of water supply when they resettle to large cities. Poor residents of cities tend to concentrate in the outskirts, where safe drinking water and sanitation are less available, and they often depend on contaminated sources of water or intermediate water vendors who charge exorbitant prices.

In the context of these many problems, an emerging trend toward protecting water supplies for urban areas is noteworthy. A study of more than 100 of the world's largest cities, for example, found that more than 40% rely on runoff-producing areas that are fully or partially protected (Dudley and Stolton 2003). This reflects a growing recognition of the value of ecosystem services linked to sound watershed management approaches, as well as of the limits placed on urban water supply from polluted upstream source areas (UN-HABITAT 2003). The geography of downstream populations supported by upstream runoff-producing areas suggests the potential global importance of this management strategy. This is further demonstrated by Table 7.2, with data showing billions of people living downstream of particular MA ecosystems and their renewable freshwater flows.

7.3.6 Industrial Development

Industrial processes, which include withdrawals for manufacturing and thermoelectric cooling, today use about 20% of the total freshwater withdrawals, which has more than doubled between 1960 and 2000 (Shiklomanov and Rodda 2003). Even though this global use remains small in comparison to water used for agriculture, the current trend in shifting the manufacturing base from industrial to developing countries, due to globalization and international trade, is of concern for future water security. Much of the technology developed for industry is adapted to industrial nations, which are generally considerably more water-rich. When industrial plants are relocated to developing countries, many of which are water-poor or have limited water delivery services, these operations add pressure to the water resource base and increase conflict among water users. In addition, the environmental safeguards for effluent treatment are less well established or enforced in developing nations, adding to the scarcity problems by increasing pollution.

The most polluting industries, in terms of organic water pollutants, are those whose products are based on organic raw materials, such as food and beverage, paper and pulp, and textile plants (UN/WWAP 2003). Power station electric generation is the largest source of thermal water pollution. Estimates correlating water withdrawals for industrial use with population density by river basin show that many already water-stressed river basins are also centers for industrial production, such as in eastern China, India, and parts of Europe (UN/WWAP 2003).

Industrial emissions are released not only as thermal and chemical effluents into rivers and streams but also as gases and aerosols into the atmosphere. These can be transported for large distances and may end up deposited in other water bodies far from the emission source. Large areas of the continents show atmospheric deposition as the single most important source of nitrogen loading, with concomitant increases in pollutant transport through inland waterways (Green et al. 2004).

7.4 Consequences for Human Well-being of Changes in the Provision of Fresh Water

Water is essential for human well-being, but not all parts of the world receive the same amount or timing of available water supplies. Some areas contain abundant water throughout the year, others have seasonal floods and droughts, and still others have hardly any water at all. In river basins with high water demand relative to the available supply, water scarcity is a growing problem, as is water pollution. Water availability is already one of the major challenges facing human society, and the lack of water will be one of the key factors limiting development (WMO 1997; UN/WWAP 2003). The socioeconomic implications of delivering, using, managing, or buying water also have impacts on human well-being. This section begins with a brief overview of the benefits and required investments for water resource systems; examines the implications of freshwater scarcity, including treatment of pricing and equity issues; and concludes with descriptions of the consequences of too much water (flooding) and the connections between freshwater services and human health.

7.4.1 Freshwater Provision: Benefits and Investment Requirements

Over the long term, water use has generally increased geometrically, in line with population growth, increased food production, and economic development (L'vovich and White 1990), and during the last 40 years, there has been a doubling in the water used by society—from 1,800 to 3,600 cubic kilometers a year. In an aggregate sense, water is a required input generating value-added in all sectors of the economy, and trends in its use can be assessed from its ability to yield economic productivity. In the United States, for example, water productivity measured as GDP per cubic meter of freshwater use rose dramatically between 1960 and 2000 by about 25% per decade, to $18 per cubic meter (Postel and Vickers 2004), in response to shifts in regulation, technology, and restructuring of the economy.

Water provided for irrigation has a particularly important role, being responsible for 40% of global crop production (UN/WWAP 2003). And despite major challenges in conveying adequate drinking water and sanitation, more than 5 billion people are routinely provided with clean water and more than 3.5 billion have access to sanitation (WHO/UNICEF 2004). Further, with continued investments in water infrastructure, much of the world's population has benefited from allied improvements in public health, flood control, electrification, food security through irrigation, and associated economic development. From this standpoint, well-managed water resources have helped promote economic development, which is tied closely to improvements in many aspects of human well-being.

A good example is provided by a recent analysis (Hutton and Haller 2004) of the cost-effectiveness of different options to achieve MDG 7 (on access to safe water and basic sanitation). Of five scenarios tested, two considered Target 10—halving the proportion of people without sustainable access to safe water by 2015 and halving the proportion of people without sustainable access to improved sanitation. It was shown that for each dollar invested in both improved water supply and sanitation, a return of $3–34 can be expected. Among the health benefits of achieving the MDG drinking water target was a global reduction in diarrheal episodes of 10%. The economic benefits of simultaneously meeting the drinking water and sanitation MDG targets on households and the health sector amount to $84 billion per year, representing reduced health care costs, value of days gained from reduced illness, averted deaths, and time savings from proximity to drinking water and sanitation facilities for productive endeavor.

Because of the variability of the water cycle, economic benefits often accrue only after substantial investments in infrastructure and operations that stabilize and improve the reliability of water resources. Capital investments in water infrastructure totaled $400 billion in the United States over the last century (Rogers 1993). When the annual investment in water storage for irrigation globally during the 1990s of about $15 billion (WCD 2000) is tabulated, an important source of required capital can be seen, which can constitute a major fraction of agricultural investment for many developing countries (UN/WWAP 2003).

Worldwide, investments in dams have totaled $2 trillion (WCD 2000). World Bank lending for irrigation and drainage averaged about $1.5 billion per year from 1960 to 2000, although this continues to decrease from a peak of $2.5 billion in 1975 to its current rate of $500 million (Thompson 2001). Global costs for expanding irrigation facilities are estimated at $5 billion annually, but rehabilitation and modernization costs on existing irrigation works are estimated at an additional $10 billion or more per year (UN/WWAP 2003). Although projected funding for economic development and meeting the MDGs for the entire water sector is estimated to reach $111–180 billion a year, current investments in sanitation and water supply total from $10 billion to $30 billion annually (UN/WWAP 2003). Securing water resources is thus deeply embedded within development investment and planning but incompletely resolved. The private sector, with global revenues today standing at $300 billion annually (Gleick et al. 2002a), is a major player in providing potential investments, as described later.

7.4.2 Consequences of Water Scarcity

With population growth and the overexploitation and contamination of water resources, the gap between available water supply and water demand is increasing in many parts of the world. In areas where water supply is already limited, water scarcity is likely to be the most serious constraint on development, particularly in drought-prone areas. Earlier in this chapter we provided a quantification of water scarcity in physical terms. Here scarcity is mapped to issues relating directly to human well-being.

While decreased or variable water supply has sometimes presented itself as an opportunity to develop efficiency-enhancing responses (Wolff and Gleick 2002) and cooperation (Wolf et al. 1999; UN/WWAP 2003), more often it has spawned numerous development challenges, including increased levels of competition for water among people and between people and ecosystems; the use of non-sustainable supplies or development of costly alternatives; limits to economic growth, including curtailment of activities and required importation of food and other water-intensive commodities; pollution and public health problems; potential political and civil instability (Furlong and Gleditsch 2003; Miguel et al. 2004); and international disputes in transboundary river basins (Gleick 1998). These situations arise in part because society has typically managed ecosystems for one dominant service such as timber or hydropower without fully realizing the trade-offs being made in such management. This approach has led to the documented decline in freshwater ecosystem condition, with accompanying consequences for human well-being. The poor, whose livelihoods often depend most directly on ecosystem services, suffer most when ecosystems are degraded. (See Chapter 6.)

One of the problems thus far has been the difficulty of relating ecosystem condition to human well-being, particularly from the socioeconomic perspective. An emphasis on water supply, by developing more dams and reservoirs, coupled with weak enforcement of regulations, thus has limited the effectiveness of water resource management, particularly in developing regions of the world (Revenga and Cassar 2002).

As a consequence, policy-makers are now shifting from entirely supply-based solutions to demand management, highlighting the importance of using a combination of measures to ensure adequate supplies of water for different sectors, and slowly moving toward an integrated approach to water resources management (Schulze 2004) that is now linked directly to development initiatives (GWP 2000; UN-HABITAT 2003; Kakabadse-Navarro et al. 2004). Measures include improving water use efficiency, pricing policies, preservation of environmental flows, market incentives, privatization of water delivery, and public-private partnerships among others. (See MA *Policy Responses,* Chapter 7, for more on response measures in integrated water resource management.)

Human society has relied for decades on economic and social indicators for planning, but in virtually complete isolation of measures depicting the state and trends of ecosystem services. This section presents some of the latest findings relating water as an ecosystem service through social and economic indicators.

The need for integrated indicators or indices at the national or regional scale to help donors and decision-makers establish priorities in water resource management is widely acknowledged. Such metrics can also assist in monitoring progress toward sustainable development goals in a systematic manner. Many such tools have been proposed over the last several decades. For example, the Water Stress Index was developed in the 1970s to link population to water resources (Falkenmark 1997), and various other indices have been proposed, such as the Stockholm Environment Institute's Water Resources Vulnerability Index (Gleick et al. 2002b). New water scarcity indices capitalizing on geospatial data sets and high-resolution digital representations of river networks can define the climatic and hydrological sources of water-related stress (Vörösmarty et al. 2005).

One important indicator that combines physical, environmental, economic, and social information related to water availability and use is the Water Poverty Index. The WPI is similar to the Human Development Index but applicable to a more local scale, where the impacts of water scarcity are fundamentally expressed. It measures water stress at the household and community level and was designed to ''aid national decision makers, at community and central government level, as well as donor agencies, to determine priority needs for intervention in the water sector'' (Sullivan et al. 2003).

The WPI reflects an attempt to quantify inequities in water allocation and the inability of the poor to govern access to water. It has five key components, each based on a series of input variables that are weighed and aggregated into the overall index. When an element cannot be measured, proxy indicators are used in its place. The WPI relies in part on standardized data collected for other purposes, and thus can be used in comparative analysis of water stress across countries. For instance, to provide inputs on water management capacity the index uses Log GDP per capita, under-5 mortality rates, and a UNDP education index, all used previously in constructing the HDI. The five components of the WPI and some of its key variables are:

- *Water resources*: The physical characteristics of water availability and water quality. This component includes total water availability, its variability across time (seasonality), and its quality.
- *Access to water*: This includes not only the distance to water from dwellings but, more important, the time spent in collecting water, conflicts over water use, and access to sanitation.
- *Water use*: This represents withdrawals for domestic, agricultural, and industrial purposes. In many parts of the world, small-scale irrigation and livestock are key components of livelihood strategies and thus are tabulated as inputs.
- *Capacity to manage water*: This component is measured in terms of income, education level, membership in water users associations, and the burden of illness due to contaminated water.
- *Environmental integrity*: If the ecosystems that support water delivery are degraded, then provision of water per se plus the many services derived from freshwater systems will be jeopardized. This component evaluates the integrity of freshwater ecosystems based on the use of natural resources, crop losses reported in the previous five years, and household reports of land erosion. Overall, no variables of the actual condition of aquatic ecosystems are included, suggesting a component of the index that could benefit from revision.

The WPI has been tested internationally in 140 countries as well as at the local scale in South Africa, Tanzania, and Sri Lanka. Finland and Iceland were found to score the best, while Haiti and Ethiopia fared worst (Lawrence et al. 2003). The results of the local pilot analysis look promising, but the WPI would benefit from a better incorporation of ecosystem condition and capacity measures. Nevertheless, the WPI is a vehicle for understanding the complex relationship between water services and human well-being. Moreover, as the authors state, it constitutes ''a systematic approach that is open and transparent to all'' (Sullivan et al. 2003), allowing incremental improvements to the index to be made through community consensus.

There are also important gender-related issues associated with water poverty. Women and men usually have different roles in water and sanitation activities, and these differences are pronounced in rural areas across the developing world (Brismar 1997; UN/WWAP 2003). Women are most often the users, providers, and managers of water in rural households and the guardians of household hygiene. In many parts of the world, women and girls can spend several hours a day carrying heavy water containers, suffering acute physical problems as a result (WEDO 2004). The inordinate burden of acquiring water also inhibits women's and girls' opportunities to secure an education and contribute to family income (WEDO 2004).

7.4.3 The Cost and Pricing of Water Delivery

Water users in most countries are generally charged but a small fraction of the actual cost of water abstraction, delivery, disposal, and treatment (Briscoe 1999; WHO/UNICEF 2000; Walker et al. 2000), and in some countries implicit and explicit water subsidies can reach up to 93% (Pagiola et al. 2002). Moreover, externalities associated with freshwater use, such as salinization of soils, degradation of ecosystems, and pollution of waterways, have been almost universally ignored, promoting current inefficiencies in use and threats to freshwater ecosystems. In general, those with access to abundant or underpriced water use it in a wasteful manner, while many, usually the poor, still lack sufficient access to water resources.

When water is in short supply or when it is polluted or unsafe to drink, the expense of delivering water services can rise dramatically or force curtailment in use. As scarcity increases, the cost of developing new freshwater resources also reflects the need to secure water from sources sometimes at great distances from the eventual user, often involving complex hydrological engineering (Hirji 1998; Rosegrant et al. 2002). Until recently there were few incentives in most countries to use water efficiently. However, increasing costs of water supply, dwindling supplies, and losses of aquatic habitat and biodiversity are increasingly providing incentives to value water as an economic good. In most countries, governments bear the burden of water delivery to users, but maintaining necessary infrastructure and expanding it to reach unserved users or improve the efficiency of water delivery is the exception rather than the norm (Pagiola et al. 2002). Inadequate funding results in a lack of new connections and unreliable service, with serious consequences for the poor, who usually incur higher costs when forced to obtain water from alternative sources (Pagiola et al. 2002).

Water can be priced in a number of different ways, and the past decade has shown the increasing application of several common methods, including flat fees, fixed fees plus volumetric charges, decreasing block rates, and increasing block rates. Some of these measures discourage waste, while others lead to overuse. (See MA *Policy Responses,* Chapter 7). This section surveys recent trends in the price and cost of water, reviews cost-recovery strategies, and assesses the impact on human well-being of privatization and public-private partnerships that deliver freshwater services.

7.4.3.1 The Price of Water and Recent Trends

There are enormous disparities in the price of fresh water supplied to end-users, reflecting a complex interplay among several factors, including proximity to natural sources of sufficient quantity and quality, level of economic development, investments—both public and private—in water infrastructure, and governance. A survey of urban households across the developing world showed water costs from both public and private sources varying by a factor of 10,000, from $0.00001 per liter (for piped supply in Calcutta) to as high as $0.1 per liter (through private water vendors) (UN-HABITAT 2003). Even municipal supplies can constitute a substantial fraction of monthly family expenditure—for example, up to 20% in informal settlements in Namibia (UN-HABITAT 2003). An analysis of urban areas in Asia showed that prices charged by informal water vendors are more than 100 times that from domestic connections (ADB 2001). In Benin, Burkina Faso, Kenya, Mauritania, and Uganda, household connection fees to piped water supplies exceeded per capita GDP by factors of up to 5:1, rendering these unaffordable (Collignon and Vezina 2000).

Cities also have seen a marked increase in the cost of financing new water supplies. In Amman, Jordan, during the 1980s groundwater sources were used to meet water needs at an incremental cost of $0.41 per cubic meter. As groundwater supplies declined, the city began to rely on surface water pumped from a site 40 kilometers away at an average incremental cost of $1.33 per cubic meter (Rosegrant et al. 2002). In another example, the real cost of water supply for irrigation in Pakistan more than doubled between 1980 and 1990 (Dinar and Subramanian 1997).

In Algeria, drought during 2000–02 forced cuts in the provision of water supply from municipal networks (access restricted to several hours every two to four days), despite large investments in water supply networks by the Algerian government since 1962 (UN-HABITAT 2003). The situation was further exacerbated by lack of maintenance of the network, with water losses through leaking pipes and underpricing of the resource use. Today, price increases and a major facilities upgrade are under way. Many African cities have exhausted and polluted local groundwater supplies, necessitating expensive transport of fresh water from distant suppliers (200 kilometers in the case of Dakar, Senegal) (UN-HABITAT 2003) or the need to invest in desalination, which is among the costliest methods of supplying fresh water (Gleick 2000; UN/WWAP 2003).

In addition to direct prices paid, additional costs are incurred by the poor provision of water services. Time spent in traveling to supplies, queuing, and transporting water can be a significant burden on household incomes for the poor. Compared with the late 1960s, households without piped water supply in Kenya, Uganda, and Tanzania today spend triple the time each day securing water, an average of over 90 minutes (UN-HABITAT 2003). Public taps are often in short supply, as in many Asian cities, where several hundred people are served by a single source (McIntosh and Yñinguez 1997). Further, the true costs associated with water delivery services are amplified by significant health burdens incurred when supplies are insufficient to meet basic needs. In the case of Lima, Peru, a major portion of household income (27%) is represented by medical costs and lost wages from water-related disease (Alcazar et al. 2000), while in Khulna, Bangladesh, an average of 10 labor days per month are lost due illness from poor water provision (Pryer 1993).

7.4.3.2 Cost Recovery

The fourth guiding principle of the Dublin Statement on Development Issues for the 21st Century (ICWE 1992) articulated that ''water has an economic value'' and ''should be recognized as an economic good.'' At the same time, the statement argued that water should be available to all people at affordable prices. After much discussion and controversy, which continues to this day, the Ministerial Declaration from the 2nd World Water Forum (2002) established that ''the economic value of water should be recognized and fully reflected in national policies and strategies by 2005'' and that ''mechanisms should be established by 2015 to facilitate the full cost pricing for water services, while the needs of the poor are guaranteed.''

Supporters of full-cost water pricing argue that to improve efficiency, the set price of water needs to reflect the cost of supplying, distributing, and treating it. There is some evidence that this principle works. For instance, price increases for water in Bogor, Indonesia, reduced domestic consumption by 30% (Rosegrant et al. 1995). Proponents of full-cost water pricing also point out that most of the poor are not meeting their basic water needs today under current public management, usually because of lack of government capacity and resources. Consequently, poor communities are already paying higher prices through intermediate water vendors than if they were connected to a water delivery system.

But while pricing water to reflect its true cost is relatively simple in theory, the political and social obstacles are formidable. Opponents to the idea of full-cost water pricing claim that access to water is a fundamental human right. Water, like air, should therefore not be treated as an exchangeable, marketable commodity, because if market conditions rule, access to water becomes dependent on the ability to pay and not an inherent entitlement. In the eyes of many, establishing a price for water or privatizing its delivery puts many of the poorest, most marginalized people at risk of not getting enough water to meet basic needs.

The majority of OECD countries have adopted or are adopting, as an operating principle, the full-cost recovery concept in water management, although what should be covered under this ''full cost'' is still a matter of debate. Infrastructure costs, however, are not usually included (UN/WWAP 2003). As pricing was restructured and subsidies reduced during the 1990s and in the current decade in industrial countries to capture the full-cost recovery of water, the real price of water was increasing in 18 out of 19 countries surveyed (Australia being the only exception). In two thirds of OECD countries, over 90% of single-family homes are currently metered (OECD 1999).

The concept of full-cost water pricing in the developing world has been introduced with the support of local communities in situations where a more reliable service is assured. In Haiti, for example, shantytown residents with no connection to the water utility pay 10 times more for water from water vendors (water trucks) than those who are connected to the private water utility grid in nearby villages (Constance 1999). Residents connected to the grid have their water use metered and pay the corresponding fees.

7.4.3.3 Water Privatization

One of the most controversial trends in today's globalized economy is the increasing privatization of some water management and delivery services. In many countries, due to increasing costs of maintaining and expanding water networks and overstretched government budgets, private companies have been invited to take over some of the management and operations of public water systems. Private-sector investment in theory results in more financing for infrastructure as well as more-efficient operations and cost recovery, and the hope is that the public will benefit from a more stable and reliable water delivery system at a reasonable price.

Opponents to privatizing water services argue that putting private companies in charge of water will drive prices to the point that marginalized groups have no capacity to secure sufficient water even for their most basic of needs. In addition, because the profit motive fails to recognize environmental externalities, they argue that privatization will increase risk to the very ecosystems that help supply fresh water. The debate on public-private partnerships for water management was prominent on the agenda of the World Water Forum gatherings (in particular, at the 2nd Forum in The Hague and the 3rd Forum in Kyoto), as well as at the World Summit on Sustainable Development.

Despite trends toward privatization, at present over 80% of the world's investments in water, sanitation, and hydropower systems are by publicly owned bodies or international donors (Winpenny 2003). Therefore, the responsibility for providing water, over the short to medium term, will remain largely a public enterprise. Among industrial countries, there is much variation in the degree of privatization. In the United States in 2000, private companies provided only 15% of municipal water supply, although in the nineteenth century they provided nearly 95% (Gleick et al. 2002a). France, in contrast, shows more than half of all residents currently served by private companies (Gleick et al. 2002a).

In Latin America, Chile has been successful at delivering water through privatization, and nearly all houses in Santiago have access to clean water and sanitation. Despite exchange-rate fluctuations, a foreign company, Suez, has remained the water provider for Santiago and its region, investing over $1 billion in water infrastructure. Water in Chile has been priced at rates affordable by the middle classes, and stamps are given to poor people to guarantee near-universal access. Conversely, in Argentina, what looked like a positive trend did not withstand economic troubles. In 1993 privatization in Buenos Aires increased the share of residents served with water from 70% to 85%—an increase of 1.6 million people, with a concurrent drop in prices (Peet 2003). Exchange-rate fluctuations in many developing countries, such as the currency devaluation in Argentina in 2002, add challenges to successful implementation of privatization schemes. If the currency of a country devalues, the price paid for water will be worth much less, and the foreign firm could pull out of the market, leaving users without reliable service (Peet 2003).

South Africa is using a different pricing scheme to improve poor people's access to water and has made good progress in providing water to nearly two thirds of those who lacked access in 1994, when apartheid officially ended. Despite the relatively low cost of water, however, some rural residents opted to consume free—but contaminated—water from other sources. In February 2000, to improve public health for the poor, the government introduced a scheme to provide households with 6,000 free liters of water per month, enough to provide 25 liters per person per day, with charges for additional use.

Privatization can be executed in many ways, depending on the level of transfer from public to private hands. Full transfer of ownership and operations of water resource systems so far has been rare. The majority of cases embody the transfer of certain operational aspects, such as water delivery, but the ownership of the water resources usually remains with the state, thereby forming a public-private partnership.

These partnerships have been demonstrated over the last few years to capture the benefits of privatization without all of the risk (Blokland et al. 1999). They do not privatize all of the water assets, but they do give private actors control over some elements of the water rights, infrastructure, and distribution systems. Yet public entities typically maintain ownership over some or all of these systems. Public-private partnerships work best when strong regulatory controls exist. A typical arrangement in France, for example, delegates the operation, maintenance, and development of public potable water and sanitation to private companies, though public bodies retain ownership of the system (Barraque et al. 1994; Gleick et al. 2002c).

Experience has shown that a clear legal framework, where risks are decreased and the cost of capital decreases, would be necessary to enlist private-sector involvement (Winpenny 2003). More detailed analysis of privatization as a response option for the sustainable management of water resources and freshwater ecosystems is presented in Chapter 7 of the MA *Policy Responses* volume.

7.4.4 Consequences of Too Much Water: Floods

In addition to water scarcity, the accumulation of too much water in too little time in a specific area can be devastating to populations and national economies. (See Chapter 16.) According to the latest *World Disasters Report* (IFRC/RCS 2003), on average 140 million people are affected by floods each year, more than all other natural or technological disasters put together. Between 1990 and 1999, there were over 100,000 people reportedly killed by floods. The majority of these deaths were in Asia (56,000), followed by the Americas (35,000), Africa (9,000), and Europe (3,000) (IFRC/RCS 2000).

In addition to human lives, floods are a costly natural hazard in monetary terms, with more than $244 billion damage from 1990 to 1999, the most of any single class of natural hazard (IFRC/RCS 2000). Although this arises from potential changes in climate variability and extreme weather, humans also play an important role, settling and expanding into vulnerable areas (Kunkel et al. 1999; van der Wink et al. 1998).

While catastrophic flooding has negatively affected society for thousands of years, naturally occurring floods also provide benefits to humans through maintenance of ecosystem functioning such as sediment and nutrient inputs to renew soil fertility in floodplains, providing floodwaters to fish spawning and breeding sites and helping to define the dynamics to which coastal ecosystems are adapted. Although floods are primarily natural events, human activity influences their frequency and severity. By converting natural landscapes to urban centers, deforesting hillsides, and draining wetlands, humans reduce the capacity of ecosystems and soils to absorb excess water and to evaporate or transpire water back into the atmosphere, creating conditions that promote increased runoff and flooding.

There are, then, potentially costly consequences of upstream anthropogenic activities on hydrological function that place downstream populations at risk, sometimes affecting other nations, as in the case of more than 250 international river basins (Wolf et al. 1999). Douglas et al. (2005) reported on a simulation study suggesting that, in aggregate, a 32% conversion of forests to agriculture across the pan-tropics has led to a mean increase in annual basin yields of approximately 10%, with a concomitant rise in seasonal high flows. More than 800 million people live along floodplains in river basins containing some amount of tropical forest, and if the most threatened of the existing forests are converted to agriculture in the future, approximately 80 million of them could be at risk from the hydrologic impacts associated with these land conversions. Costa et al. (2003) present empirical evidence that large-scale savanna clearance in the Tocantins basin in Brazil (175,000 square kilometers) has been associated with increases of 24% in mean annual and 28% in wet season flows, independent of climate variations.

Nevertheless, there is some agreement that the most catastrophic floods in large basins result from storms so large and persistent that peak flows are unaffected by land cover (Calder 1999; Bruijnzeel 2004). Further, the proclivities of particular regions to landslides, soil erosion, and debris flows, as in the Himalayas, constitute the dominant source of risk (Gilmour et al. 1987; Hamilton 1987; Gardner 2002). Thus the costs and benefits of designing interventions to mitigate floods have their limits, and there may be little opportunity to escape potential vulnerabilities to flooding, given current patterns of human settlement in high-risk areas.

These findings should not suggest abandonment of good land stewardship, which yields fundamental benefits in sustaining ecosystem services. But they do argue for clearly identifying the source areas of hazard and designing response strategies to protect life and property. Even when specific and well-established policy goals for watershed protection are formulated, stakeholder interests and sustainable funding issues add to the challenge of designing effective upstream-downstream management strategies (Pagiola 2002).

Further information on the impact of natural hazards, including floods, on human well-being can be found in Chapter 16.

7.4.5 Consequences of Poor Water Quality on Human Health

Water is an essential resource for sustaining human health, and there is a basic per capita daily water requirement of 20 to 40 liters of water free from harmful contaminants and pathogens for the purposes of drinking and sanitation, which rises to 50 liters when bathing and kitchen needs are considered (Gleick 1996, 1998, 1999). Yet billions of people lack the services to meet this need, as documented earlier. Water-related diseases include four major classes: waterborne, water-washed, water-based, and water-related vector-borne infections (Bradley 1977). Threats to health also arise from chemical pollution.

7.4.5.1 Water-Related Diseases

As a whole, water-related diseases are a leading cause of morbidity and mortality in many parts of the developing world, with estimates ranging from 2 million to 12 million deaths per year (Gleick 2002), although monitoring and reporting remain poor in many countries. (See Table 7.10.) UN/WWAP (2003) reports 3.2 million deaths each year from water-related infectious disease, or about 6% of all deaths. The lack of access to safe water and to basic sanitary conditions also translates into the annual loss of 1.7 million lives and at least 50 million disability-adjusted life years. (The DALY is a summary measure of population health, calculated as the sum of years lost due to premature mortality and the healthy years lost due to disability for incident cases of the ill health condition. The DALY is not only an effectiveness indicator in the economic evaluation of different intervention options but also a reflection of the impact of ill health on the income-generating capacity of the poor.)

The first three categories of water-related diseases are most clearly associated with lack of access to improved sources of drinking water, and in turn to ecosystem condition. Improved sanitation through the safe disposal of human waste is a major development objective that improves the health of those served directly by separating drinking water from wastewater. In developing countries, however, 90–95% of all sewage and 70% of industrial wastes are dumped untreated into surface waters (UNFPA 2001), placing both downstream populations as well as ecosystem functions at risk. (See Chapter 15.) The fourth category of water-related disease is associated with ecological conditions that favor disease vector breeding. These may be natural (such as those supporting malaria transmission by *Anopheles gambiae* mosquito across large parts of Africa south of the Sahara) or anthropogenic, through improperly planned irrigation systems, dams, and urban water systems. (See Chapter 14.)

Waterborne diseases are caused by consumption of water contaminated by human or animal waste and containing pathogenic parasites, bacteria, or viruses. They include the diverse group of diarrheal diseases as well as cholera, typhoid, and amoebic dysentery. These diseases occur where there is a lack of access to safe drinking water for basic hygiene, and most could be prevented by treating water before use. The World Health Organization estimates that there are 4 billion cases of diarrhea each year in addition to millions of other cases of illness associated with lack of access to safe water (WHO/UNICEF 2000). This translates into 1.7 million deaths per year, mostly among children under the age of five (WHO 2004). Morbidity and mortality from microbial contamination are orders of magnitude greater in developing countries than in the industrial world.

Water-washed diseases are caused by poor personal hygiene and skin or eye contact with contaminated water; their incidence is associated with the lack of access to basic sanitation and suffi-

Table 7.10. Selected Water-Related Diseases. Approximate yearly number of cases, mortality, and disability-adjusted life years. The DALY is a summary measure of population health, calculated as the sum of years lost due to premature mortality and the healthy years lost due to disability for incident cases of the ill-health condition. (WHO 2001, 2004)

Disease	Number of Cases	Disability- Adjusted Life Years	Estimated Mortality	Relationship to Freshwater Services
		(thousand DALYs)	*(thousand)*	
Diarrhea	4 billion	55,000[a]	1,700[a]	water contaminated by human feces
Malaria	300–500 million	46,500	1,300	transmitted by *Anopheles* mosquitoes
Schistosomiasis	200 million	1,700	15	transmitted by aquatic mollusks
Dengue and dengue hemorrhagic fever	50–100 million dengue; 500,000 DHF	616	19	transmitted by *Aedes* mosquitoes
Onchocerciasis (river blindness)	18 million	484	0	transmitted by black fly
Typhoid and paratyphoid fevers	17 million			contaminated water, food; flooding
Trachoma	150 million, 6 million blind	2,300	0	lack of basic hygiene
Cholera	140,000–184,000[b]		5–28[b]	water and food contaminated by human feces
Dracunculiasis (Guinea worm disease)	96,000			contaminated water

[a] Specifically attributable to unsafe water, sanitation, and hygiene from WHO (2002).

[b] The upper part of the range refers specifically to 2001 as reported in UN/WWAP 2003.

cient water for effective hygiene (Bradley 1977; Gleick 2002; Jensen et al. 2004). These include scabies, trachoma, and flea, lice, and tick-borne diseases. Trachoma alone is estimated to cause blindness in 6 million people (WHO/UNICEF 2000). In addition, the transmission of intestinal helminths (*Ascaris, Trichuris,* and hookworm) is linked to a lack of sanitation facilities and is estimated to account for a global annual loss of over 2 million DALYs.

Water-based diseases are those caused by aquatic organisms that spend part of their life cycle in the water and another part as parasites of animals. As parasites, they usually take the form of worms, using intermediate animal vectors such as snails to thrive, and then directly infecting humans either by boring through the skin or by being swallowed. They include Guinea worm infection, schistosomiasis (bilharzia), and a few other helminths (certain liver flukes of local importance in Southeast Asia, for instance, such as *Opisthorchis viverrini*) that infect humans through either direct contact with contaminated water or the consumption of uncooked aquatic organisms.

Although these diseases are not usually fatal, they prevent people from living normal lives and impair their ability to work. For instance, 200 million people worldwide are infected with schistosomiasis, of which 20 million suffer severe consequences, with an estimated global annual burden of 1.7 million DALYs (WHO 2004). The prevalence of water-based diseases often increases where dams are constructed, because stagnant water is the preferred habitat for aquatic snails, their most important intermediary hosts. For instance, the Akosombo Dam in Ghana, the Aswan High Dam on the Nile in Egypt, and the Diamma Dam at the mouth of the Senegal river have resulted in huge increases of local schistosomiasis prevalence. (See also Chapter 14.)

Water-related vector-borne diseases are caused by parasites that require a vector (such as insects) to develop and transmit the disease to humans. For example, *Anopheles* mosquitoes are the vectors for a protozoan parasite (*Plasmodium*) that causes malaria. These diseases are strongly ecosystem-linked, in contrast to the other three categories of water-related diseases, where water quality (and to some extent quantity) is the key determinant. Their distribution reflects the distribution of ecosystems suited to the propagation of the vectors.

Vector species, moreover, are highly diverse, so that detailed ecological requirements differ over wide ranges. Anopheline mosquitoes—vectors of malaria (1.3 million deaths a year and an annual burden of over 46 million DALYs), for example—breed in different types of freshwater ecosystems and brackish water coastal lagoons. *Aedes,* vectors of dengue and yellow fever, originally breeding in leaf axils of bromeliads, are cosmopolitan in human settlement areas, where they breed in small water pools. Urban filariasis vectors (*Culex* ssp.) breed in organically polluted water. And the blackfly vectors of onchocerciasis breed in oxygenated waters of rapids.

These vector-borne diseases are not typically associated with lack of access to safe drinking water but rather with water management practices in tropical and sub-tropical regions of the world. Several parasitic diseases endemic of tropical regions, such as Rift Valley Fever and Japanese encephalitis, spread easily with the presence of reservoirs, irrigation ditches and canals, and rice fields (WCD 2000). (See Chapter 14.) In all, more than 30 diseases have been linked to irrigation and paddy agriculture (WRI et al. 1998). Consequently, improved water management, drainage, and storage practices can help reduce the transmission risk, particularly in areas where anthropogenic conditions have led to the introduction of these diseases.

7.4.5.2 Chemical Pollution

Another set of diseases affecting industrial and developing nations alike arises in response to chemical pollution of water by heavy metals, toxic substances, and long-lived synthetic compounds. While evidence of the long-term impacts of chemical pollution can be detected even in the remote Arctic (AMAP 2002), the impacts on poor populations in developing countries are difficult to identify, given the lack of reliable and comprehensive records. However, exposure to chemical agents in water has been related to a range of chronic diseases, including cancer, lung damage, and birth defects. Many such diseases develop over several years, making the links between cause and effect difficult to establish. On a global scale, the burden of disease from chemical pollution is much lower than from microbial contamination and parasitic diseases, but in some highly polluted regions these risks can be substantial (WRI et al. 1998). Exposure to chemical pollutants can also compromise the immune system, rendering people more susceptible to microbial and viral infections. The cumulative and synergetic effects of long-term exposure to a variety of chemicals, especially at low concentrations, cannot be well quantified at present.

Naturally occurring inorganic pollutants constitute a class of chemical pollution with serious long-term health effects. Arsenic, which occurs naturally in some soils, for example, can become toxic when exposed to the atmosphere, as seen in areas with high water abstraction from underground aquifers (WRI et al. 1998). Arsenicosis is the result of arsenic poisoning from drinking arsenic-rich water over long periods of time and is a great concern in many countries, including Argentina, Bangladesh, China, India, Mexico, Thailand, and the United States (Bonvallot 2003). WHO estimated in 2001 that in Bangladesh alone, 35–77 million people—close to half the population—were exposed to drinking water from deep wells contaminated with high levels of arsenic (5–50 times the limit of 0.01 milligrams per liter recommended by WHO) (Bonvallot 2003). Arsenic is a carcinogen linked to skin, lung, and kidney cancer, although these diseases can go undetected for decades (WRI et al. 1998). In other parts of the world, high fluoride concentrations in drinking water have resulted in long-term effects that weaken the skeleton.

Chronic effects also arise from anthropogenic pollutants such as discharge from mining operations, pesticide runoff, and industrial sources. Long-term lead poisoning from old water pipes, for example, can cause significant neurological impairment (WRI et al. 1998). Mercury contamination can also originate from industrial discharge and runoff from mining activities, accumulating in animal tissue, particularly fish (WCD 2000).

Nutrient runoff is another concern from the standpoint of human health, especially in light of pandemic increase in loadings to inland water ecosystems, for example, of nitrogen (described earlier; see also Chapters 12 and 20). Although there is no global assessment of how many water bodies exceed the WHO guidelines on nitrate levels, most countries report that nitrates are one of the most common contaminants found in drinking water (WRI et al. 1998). Coastal and inland waters in regions with high levels of eutrophication have been observed to often propagate toxic algal blooms (toxic cyanobacteria) that can cause chronic disease. (See Chapter 19.) In China, for instance, the presence of cyanobacterial toxins in drinking water has been associated with elevated levels of liver cancer (WCD 2000). Excess nitrate in drinking water has also been linked to methaemoglobin anemia in infants, the "blue baby" syndrome (WRI et al. 1998).

Discharge from aquaculture facilities can also be loaded with pollutants, including high levels of nutrients from uneaten fish feed and fish waste, antibiotic drugs, and other chemicals, including disinfectants such as chlorine and formaline, antifoulants such as tributyltin, and inorganic fertilizers such as ammonium phosphate and urea (GESAMP 1997). These chemicals can significantly degrade the surrounding environment, particularly local waterways (GLFC 1999). The use of antibiotics and other synthetic drugs in aquaculture can also have serious health effects on people and ecosystems more broadly. The antibiotic chloramphenicol, for example, can cause human aplastic anaemia, a serious blood disorder that is usually fatal. While many countries have banned the use of chloramphenicol in food production, the level of enforcement varies considerably (GESAMP 1997; Health Canada 2004). A further risk from antibiotic use is the spread of antibiotic resistance in both human and fish pathogens. The U.S. Center for Disease Control and Prevention reported that certain antibiotic resistance genes in *Salmonella* might have emerged following antibiotic use in Asian aquaculture (Angulo 1999 as cited in Goldburg et al. 2001).

There is also evidence from studies on wildlife that humans may be at risk from persistent organic pollutants and residual material that has the ability to mimic or block the natural functioning of hormones, interfering with natural physiological processes, including normal sexual development (WRI et al. 1998). Certain chemicals such as PCBs, DDT, dioxins, and at least 80 pesticides are regarded as ''endocrine disrupters,'' chemicals that may interfere with normal human physiology, undermining disease resistance and affecting reproductive health (WRI et al. 1998).

Finally, pharmaceutical products excreted by livestock or humans comprise a set of ''emerging contaminants,'' whose impacts on human well-being, ecosystems, and species are not yet understood. These contaminants are hard to detect with current technologies, but their impact on wildlife are already observed in some parts of the world. In the United States, the first nationwide survey conducted in 1999 and 2000 found hormones in 37% of the streams surveyed and caffeine in more than half (Kolpin et al. 2002). Just recently, 42% of the sampled male bass in a relatively pristine stretch of the Potomac River in the United States were found to be producing eggs. The exact cause is still unknown, but it is hypothesized that it could be caused by chicken estrogen left over in poultry manure or perhaps human hormones discharged into the river with processed sewage.

7.4.5.3 Sanitation and Provision of Clean Water: Challenges for the Twenty-first Century

Providing ''improved'' clean water supply and sanitation to large parts of the human population remains a challenge (WHO/UNICEF 2004; United Nations Statistics Division 2004). (See Box 7.5 for definitions of improvement.) The most recently completed and comprehensive assessment of improved water and sanitation (WHO/UNICEF 2004) concluded that 1.1 billion people around the world still lack access to improved water supply and more than 2.6 billion lack access to improved sanitation, with strong geographic variations. (See Table 7.11 and Figures 7.13 and 7.14 in Appendix A.) Asia contains two thirds of all people who lack access to improved drinking water and three quarters of those who lack access to improved sanitation. Africa is next most prominent in terms of numbers still awaiting improvements in supply and sanitation. Other continents show much smaller numbers but may have relatively low rates of service, as in Oceania, with less than 50% served for both supply and sanitation.

There has been progressive improvement in the provision of sanitation since 1990 (see Table 7.12), recently prompted by the ambitious target for sanitation of the MDG environmental sustainability goal—namely, to halve by 2015 the proportion of people lacking such service in 1990. Worldwide, the goal was set to move coverage from 49% to 75%, and progress is nearly on track with the interim target for 2002 of 62% nearly attained. Of the nine regions analyzed, however, only four are on track or nearly, while five are behind schedule. The greatest challenge remains sub-Saharan Africa, which met only 4% of a targeted 17% improvement by 2002. Western Asia and Eurasia are less off their targets but have not moved forward. Overall, improvements in sanitation in rural areas have been significantly less than in urban areas, and there has even been a decline in the provision of sanitation in rural areas of Oceania and the former Soviet Union (WHO/UNICEF 2004).

BOX 7.5

Defining Improved Water Supply and Sanitation

''Improved'' water supply includes household connections, public standpipes, boreholes, protected dug wells, protected springs, and rainwater harvesting systems, but it does not include protected rivers or ponds, unprotected wells or springs, and unmonitored vendor-provided water (bottled water is not considered improved due to quantity limits arising from its high expense).

''Improved'' sanitation technologies include connections to a public sewer, connections to a septic system, pour-flush latrines, simple pit latrines, and ventilated improved pit latrines. Excreta disposal systems are considered adequate if they are private or shared (but not public) and if they hygienically separate human excreta from human contact. ''Not improved'' sanitation systems are service or bucket latrines (where excreta are manually removed), public latrines, or open pit latrines.

The rapid and disorganized growth in cities and peri-urban areas in developing countries is likely to hinder progress toward improved water delivery and sanitation systems. In 2000 alone, 16 cities around the world became megacities, with more than 10 million inhabitants each, housing 4% of the world's population (United Nations 2002). Most of these megacities fall within regions already suffering from water stress (UN/WWAP 2003). In Africa, Asia, and Latin America, 25–50% of the population live in informal or illegal settlements around urban centers where no public services and no effective regulation of pollution and ecosystem degradation are available (UN-HABITAT 2003). Half of the urban population in Africa, Asia, and Latin America and the Caribbean suffers from one or more diseases associated with inadequate water and sanitation (UN/WWAP 2003).

Even if government or municipal authorities were inclined to expand water and sanitation services to informal urban settlements, the lack of formal land ownership, plot designation, and infrastructure make this very difficult and unlikely. In many countries, water and sanitation authorities are only allowed to provide services and connect households to the water grid if proof of landownership is provided (UN-HABITAT 2003). These problems are in addition to the basic inability of slum dwellers to pay for connection charges and monthly fees without subsidies. With urban populations expected to encompass 80% of the world's population by 2030 (UNPD 1999), the supply of water and sanitation to city dwellers is set to become one of the greatest challenges to development.

7.5 Trade-offs in the Contemporary Use of Freshwater Resources

This chapter has provided an assessment of the recent history and contemporary state of global freshwater provisioning services. It

has documented a growing dependence of human well-being on fresh water, which in turn has promoted a variety of engineering strategies aimed at delivering reliable freshwater supplies. So effective has been the ability of water management to influence the state of this resource that anthropogenic impacts are now evident across the global water cycle. Much of the human influence is negative due to overuse and poor management, which has resulted in human-induced water scarcity, widespread pollution, and habitat and biodiversity loss. The capacity of ecosystems to sustain freshwater provisioning services thus has been greatly compromised throughout much of the world and may continue to remain so if historic patterns of managed use persist.

Sector-specific decisions often drive the nature of human interactions with water, with often unintended or purposefully ignored externalities on ecosystems. There is no shortage of examples. Flow stabilization optimizing hydroelectricity can severely fragment and degrade aquatic habitats and lead to losses of economically important fisheries. Industrial development with poor effluent management can result in severe pollution, leading to the loss of aquatic ecosystem function and biodiversity. Connecting urban dwellers to water supply and sewerage systems without due attention to water treatment, as has been commonplace, results in the release of toxic compounds and waterborne diseases that affect downstream water users. In arid and semiarid regions, decisions to promote national food self-sufficiency can translate into great risk to downstream populations and costly infrastructure, as rivers that normally carry water and sediments nourishing coastal lands and floodplains are diverted onto croplands or stabilized behind dams.

Trade-offs are thus an unavoidable component of human-freshwater interactions. Trade-offs are also inevitable in meeting Millennium Development Goals and other international commitments. To demonstrate this, a heuristic analysis is presented here to explore how emphasis on a particular objective could influence the capacity to attain others. The analysis uses the contemporary setting as its starting point, which is then tracked with respect to the impact of five specific interventions. These correspond directly to major objectives embodied in the Kyoto Protocol (carbon mitigation), the MDGs (poverty alleviation, hunger reduction, improved water services), and the Conventions on Biological Diversity and Wetlands (pragmatic ecosystem maintenance applied to inland and coastal ecosystems).

A non-intervention case (current trends) is also considered, analyzing the implications of allowing contemporary trends to continue. A time frame of approximately 10–15 years is considered, allowing sufficient time for general patterns to emerge. This time frame also is associated with the first targets of the MDGs.

The interventions and their impacts are specifically viewed through the lens of freshwater services and ecosystem maintenance. Thus, for carbon mitigation the positive impacts of expanding hydropower to reduce carbon emissions are considered, together with the negative impacts of flow fragmentation that compromises the normal functions of inland freshwater and coastal ecosystems. To maximize relevancy to the international development agenda, the findings refer to poor countries alone. The interventions and key results are summarized in Table 7.13 and Figure 7.15. In each case the contemporary baseline is the starting point, given by the intermediate of three circles. Improvement is depicted by movement outward to the larger circle. Declining condition is represented by a move inward, and no appreciable change settles on the middle curve.

It is important to note that these experiments are not predictions but instead are thematic devices to demonstrate broad-scale effects that can be supported by findings in this chapter. Although the details could be argued legitimately one way or another, it is the basic character of the response that is sought. Furthermore, as will become apparent, it is the behavior of the full set of experiments rather than individual cases that becomes most instructive.

Current Trends in Figure 7.15 is the first case, representing no meaningful change in the pace at which human development is attained or interventions are made to reverse ongoing threats to ecosystem services. This scenario shows direct beneficiary effects on human well-being but also sustained and substantial declines in the condition of aquatic ecosystems. On the positive side, there is some alleviation of hunger through increased food production that relies on expanded irrigation and use of agrochemicals; continued improvement to health by way of drinking water and sanitation access; some progress toward reducing poverty; and an expansion of hydropower, which in some parts of the developing world (such as South America) is already an important source of energy, with some beneficiary effects on carbon mitigation.

At the same time, aquatic ecosystems and their biodiversity will be increasingly degraded in this scenario due to the combined forces of industrial, agricultural, and domestic sources of pollution, hydropower with associated flow fragmentation, and habitat destruction. Lack of environmental regulation and enforcement exacerbates the trend. Reduced and highly regulated water flows in rivers continue to decrease the transport of water and sediment to estuaries and coastal wetlands. Food provisioning services, in terms of natural inland and coastal fisheries, are in decline, and freshwater provisioning will continue to be placed in jeopardy by the dual threats of overuse and pollution.

Major supporting and regulating services also continue their decline due to loss of ecosystem function across both inland aquatic systems and their linked terrestrial ecosystems. Particularly relevant to fresh water are losses in flood control (from poor land management, erosion, loss of wetlands), in self-purification potential of waterways (from chronic and acute land-based sources of pollution), and in protection of human health (from inappropriate waste disposal). The links between ecosystem services and human well-being mean that these losses of natural services could ultimately compromise the attainment of important development goals.

While the value of controlling greenhouse gases or instituting the MDGs is almost universally accepted, results in Table 7.13 and Figure 7.15 suggest that pursuing each objective in isolation of other development goals or environmentally sound management principles will be counterproductive. Interventions in accordance with strategies being promoted through the Conventions on Biological Diversity and Wetlands, which stress protection and wise use of ecosystems and their services for sustainable development, yield several positive effects on human well-being. These improvements arise from a purposeful strategy of integrated environmental management, which links environmental stewardship directly to poverty alleviation, food security, and clean water targets (CBD 2004; Ramsar Convention 2004).

There is a growing recognition that maintaining biodiversity and ecosystem integrity will require compromise and trade-offs. A good example is the critical choice between providing water for crop production or for healthy rivers and wetlands. In areas where irrigation and storage reservoirs are upstream of sensitive ecosystems, both livelihoods and environmental integrity can be at stake. One possible strategy to accommodate potential losses in food production and income is by managing basin-wide improvements in water productivity for agriculture through new crop breeding, innovative technologies, and water reuse strategies (Molden 2003), all saving water and reducing the need for irrigation and flow stabilization.

While only qualitative in nature, these findings clearly demonstrate the consequences of optimizing one development goal or conservation objective over others. This assessment indicates that there would be substantial inconsistencies in the major development and sustainability strategies should they not become better integrated. The impacts of these conflicts on freshwater provisioning services and ecosystem functioning are likely to compromise the sought-after progress inherent in these same international commitments. The conjunction of several incongruous objectives will further exacerbate the deterioration of inland and coastal systems documented in Chapters 19 and 20.

It is very certain that the condition of inland waters and coastal ecosystems has been compromised by the conventional sectoral approach to water management, which, if continued, will constrain progress to enhance human well-being. In contrast, the ecosystem approach, as adopted by CBD, Ramsar, FAO, and others, shows promise for improving the future condition of water provisioning services, specifically by balancing the objectives of economic development, ecosystem needs, and human well-being.

Table 7.13. Major Objectives Optimized in Experiments to Discern the Compatibility of Development Goals and International Conventions. These objectives are considered in the context of freshwater provisioning services and protection of inland and coastal waters. General categories of responses are given, as depicted in Figure 7.13. Positive, intermediate, and negative effects are relative to contemporary condition. A time horizon of 10–15 years is considered.

Sectoral Intervention	Relevant International Commitment	Positive Effects	Intermediate or Small Effects	Negative Effects
Current trends (non-intervention)			some progress toward carbon mitigation, poverty reduction, hunger alleviation, and access to water services	persistent decline in health of inland and coastal ecosystems and their services (provisioning, regulating, supporting)
Carbon mitigation	Kyoto Protocol	reduced CO_2 emissions through increased reliance on hydropower assumed to override reservoir respiration and methane emission; progress on hunger reduction, water services, poverty reduction as under current trends	water storage for irrigation yields some reservoir fisheries for food; urban benefits of hydroelectricity; rural poverty alleviation effects small in relation to current trends	waterborne disease increases in tropical regions; dams fragment habitat and modify fluxes of constituents and water through inland waterways; loss of inland fisheries; erosion, nutrient imbalance in coastal systems due to upstream reservoir trapping
Hunger reduction	MDG 1, Target 2	major beneficial effects on nutrition	well-fed populations show increased health benefits and poverty reduction; consumptive losses from expanded irrigation mean less water for hydroelectricity; little effect on improved water/sanitation	expanded irrigation and impoundment storage means less available water for inland and coastal ecosystems
Improved water services (access to clean water and sanitation)	MDG 7, Target 10	improved health; increased productivity of labor reduces poverty	similar water quality as under current trends if waste treatment assumed (not the norm); no impact on carbon mitigation or hunger alleviation assumed	inland and coastal pollution from sewage, assuming no treatment
Poverty alleviation	MDG 1, Target 1	rising standards of living; increased availability of hydropower with benefits for carbon mitigation; increased food demands and availability	increased access to water services leads to improved health for those served; effect mitigated by increased pollution and water-related diseases for remaining poor	strong impacts on natural ecosystems from agricultural pollution; water diversions for crops and industrial production; river fragmentation from dams
Pragmatic ecosystem maintenance (inland and coastal wetlands)	Convention on Biological Diversity, Convention on Wetlands (Ramsar)	integrated management leads to protection of inland/coastal ecosystems with improved freshwater provision (quantity and quality)	land management improves carbon mitigation and crop productivity; food sources from aquatic systems; stable water supplies allow for some high-productivity irrigation and well-managed reservoirs (for C mitigation as well); improved water quality leads to better health; aggregate benefit from all factors reduces poverty	no single objective met fully; compromises among stakeholders inherent in such a multiobjective framework

Figure 7.15. Trade-off Analysis, Depicting Major Interventions and Consequences on Condition of Ecosystems and Development Goals. Note that in the absence of integrated sustainable development and environmental protection plans, current trends and development-related interventions may compromise ecosystem functioning. Better balanced effects are noted by instituting strategies guiding the Convention on Biological Diversity and Convention on Wetlands (Ramsar). An approach balancing ecosystem protection and economic development could yield an aggregate net benefit to the entire suite of objectives. The contemporary starting point is the middle circle. Movement toward the outside circle indicates improvement while movement inward depicts negative trends. See text and Table 7.13 for further interpretation.

Main Messages

Despite the fact that food production per capita has been increasing globally, major distributional inequalities exist. Global food production has increased by 168% over the past 42 years. The production of cereals has increased by about 130%, but that is now growing more slowly. Nevertheless, an estimated 852 million people were undernourished in 2000–02, up 37 million from the period 1997–99. Of this total, nearly 96% live in developing countries. Sub-Saharan Africa, the region with the largest share of undernourished people, is also the region where per capita food production has lagged the most.

Rising incomes, urbanization, and shifting consumption patterns have increased per capita food consumption in most areas of the world. Food preferences, including those arising from cultural differences, are important drivers of food provision. As incomes have increased in regions such as East and Southeast Asia, so has demand for high-value products such as livestock and fish, but cereals are likely to remain the major single component of global diets and to occupy the predominant share of cultivated land.

A diverse diet, with sufficient protein, oils and fats, micronutrients, and other dietary factors is as important for well-being as access to and consumption of sufficient calories. Average daily energy (calorific) intake has declined recently in the poorest countries. Inadequate energy intake is exacerbated by the fact that poor people tend to have low-quality diets. The world's poorest rely on starchy staples for energy, which leads to significant protein, vitamin, and mineral deficiencies. Overconsumption is also a health problem. Nutritional status and children's growth rates improve with consumption of greater food diversity, particularly of fruits and vegetables.

A global epidemic of diet-related obesity and noncommunicable disease is emerging as increasingly urbanized people adopt diets that are higher in energy and lower in diversity in fruits and vegetables than traditional diets (known as the nutrition transition). Many countries now face the double burden of diet-related disease: the simultaneous challenges of significant incidence of acute, communicable diseases in undernourished populations and increasing incidence of chronic diseases associated with the overweight and obese.

An increasing number of people everywhere suffer from diseases caused by contaminated food. As the world eats more perishable foods such as meat, milk, fish, and eggs, the risk of food-borne illnesses is increasing. The relative health risks from food vary by climate, diet, income, and public infrastructure. Food of animal origin poses health risks particularly when it is improperly prepared or inadequately refrigerated. Microbial contamination is of special concern in developing countries. Non-microbial contaminants include metals and persistent organic pollutants. Other growing health concerns related to food production are diseases passed from animals to humans (zoonoses), toxin-containing animal wastes, and overuse of antibiotics in livestock production that may cause allergies or render human antibiotics less effective.

Local food production is critical to eliminating hunger and promoting rural development in areas where the poor do not have the capacity to purchase food from elsewhere. The number of food-insecure people is growing fastest in developing regions, where underdeveloped market infrastructures and limited access to resources prevent food needs from being satisfied by international trade alone. In these areas, local food production is critical to eliminating hunger and providing insurance against rising food prices. In addition, rural households gain income and employment from engaging in food provision enterprises. In sub-Saharan Africa, two thirds of the population relies on agriculture or agriculture-related activities for their livelihoods.

Maintaining a focus on raising the productivity of food production systems continues to be a priority for both global food security and environmental sustainability. While major cereal staples are likely to continue as the foundation of the human food supply, some doubts are being raised about our ability to reproduce past yield growth in the future—especially with regard to sustaining rates of yield growth in high-productivity systems that are already producing near the yield potential threshold, as well as in terms of the availability of land that is suitable for sustaining expanded food output needs.

Government policies are significant drivers of food production and consumption patterns, both locally and globally. Investments in rural roads, irrigation, credit systems, and agricultural research and extension serve to stimulate food production. Improved access to input and export markets boosts productivity. Opportunities to gain access to international markets are conditioned by international trade and food safety regulations and by a variety of tariff and non-tariff barriers. Selective production and export subsidies, including those embodied in the European Union's Common Agricultural Policy and the U.S. Farm Bill, stimulate overproduction of many food crops. This in turn translates into relatively cheap food exports that benefit international consumers at the expense of domestic taxpayers and has often undermined the ability of food producers in many poorer countries to enter international food markets.

The accelerating demand for livestock products is increasingly being met by intensive (industrial or so-called landless) production systems, especially for chicken and pigs, and especially in Asia. These systems have contributed to large increases in production: over the last decade, bovine and ovine meat production increased by about 40%, pig meat production rose by nearly 60%, and poultry meat production doubled. However, intensified livestock production poses serious waste problems and puts increased pressure on cultivated systems to provide feed inputs, with consequent increased demand for water and nitrogen fertilizer.

Per capita consumption of fish is increasing, but this growth is unsustainable with current practices. Total fish consumption has declined somewhat in industrial countries, while it has doubled in the developing world since 1973. Demand has increased without corresponding increases in supply productivity, leading to increases in the real prices of most fresh and frozen fish products at the global level. Pressure on marine ecosystems is increasing to the point where a number of targeted stocks in all oceans are near or exceeding their maximum sustainable levels of exploitation, and world fish catches have been declining since the late 1980s due to overexploitation. Inland water fisheries in the developing world are expanding slowly and will remain an important source of high-quality food for many of the world's poor, particularly in Africa and Asia; however, habitat modifications and water abstraction threaten the continued supply of freshwater fish. For the world as a whole, increases in the volume of fish consumed are made possible by aquaculture, which in 2002 is estimated to have contributed 27% of all fish harvested and 40% of the total amount of fish products consumed as food. Future growth of aquaculture will be constrained by development costs and by fishmeal and oil supplies, which are increasingly scarce.

Wild foods are locally important in many developing countries, often bridging the hunger gap created by stresses such as droughts and civil unrest. In addition to fish, wild plants and animals are important sources of nutrition in some diets, and some wild foods have significant economic value. In most cases, however, wild foods are excluded from economic analysis of natural resource systems as well as official statistics, so the full extent of their importance is improperly understood. In some cases, plants and animals are under pressure from unsustainable levels of harvesting, and there is a local need for conservation of wild food resources to satisfy the nutritional needs of those who do not have access to agricultural land or resources.

8.1 Introduction

The initial use and subsequent transformation of ecosystems for the purpose of meeting human food needs has been a vital, longstanding, and, for the most part, fruitful dimension of the human experience. The provision, preparation, and consumption of food are daily activities that for most societies represent an important part of their identity and culture. But while human ingenuity has transformed the specter of global famine into an unparalleled abundance of food, there are still too many people in the world for whom an adequate, safe, nutritious diet remains an illusion.
